Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface to the Second Edition

We are delighted to present the updated and revised Second Edition of *Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application.* Like its predecessor, this new edition's primary aim is to bridge the gap between introductory texts and comprehensive reference books by providing an in-depth overview of pharmacology and physiology for anesthesiology, intensive care, and pain medicine specialists, whether in training or practicing. The topics are chosen to cover fundamentals included in training and recertification examinations by bridging scientific principles and clinical practice.

The Second Edition has been thoroughly updated. Each revised chapter includes the latest advances in clinical science along with relevant, novel basic science discoveries. Hundreds of new segments, figures, and references have been added to provide essential information for trainees and practicing anesthetists alike.

This thoroughly revised edition includes extensive new content. New chapters on special populations (e.g., anesthetic pharmacology in obesity, geriatrics, and pediatrics), oral and non-intravenous opioids, thermoregulation, physiology and pharmacology of obstetric anesthesia, chemotherapeutic and immunosuppressive drugs, and surgical infection and antimicrobial drugs were commissioned and written by recognized experts in these fields.

Two entirely new features have been incorporated into the Second Edition to provide essential basic information in relevant areas of physics, anatomy, and imaging. The Physics sections, edited by Dr. Kai Kuck, review essential physics and engineering concepts important in anesthesia practice. The Anatomy and Imaging sections, edited by Dr. Jeffrey D. Swenson, outline practical anatomic and imaging concepts that are now indispensable in modern anesthesia. Interspersed throughout the book, these new sections are beautifully and copiously illustrated.

The Second Edition also benefits from all the enhancements that are part of the "Expert Consult" platform at Elsevier, including the "eBook" feature that enables portability and searchability on most common electronic devices; the book's full text and all the other assets are available anywhere on your mobile device. Shareable social media features also augment the Second Edition's utility.

We are grateful to the authors for their contributions to the Second Edition; their high-level knowledge and expertise are evident throughout. We also express our appreciation to the dedicated professionals at Elsevier; special thanks are due to Sarah Barth, William Schmitt, Joan Ryan, and Sharon Corell for their collective experience and hard work. We are confident that the newly updated and expanded *Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application* will build your understanding of the fundamental concepts underpinning anesthesia practice and thereby improve your ability to deliver outstanding care to your patients.

Hugh C. Hemmings, Jr.
Talmage D. Egan

Excerpts from the Preface to the First Edition

The successful practice of the art of anesthesia, critical care, and pain medicine demands a sound understanding of core scientific concepts founded in physiology and pharmacology. The importance of physiology and pharmacology to anesthesiology is recognized in postgraduate anesthesia training programs and certification examinations worldwide because a thorough understanding of these disciplines is essential for graduation, certification, and successful clinical practice. Although this scientific foundation is available from a number of sources, the necessary level of detail is often insufficient in introductory texts and perhaps too esoteric in specialized monographs targeted to academics. The goal of *Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application* is to bridge this gap between introductory texts and comprehensive reference books by providing a detailed overview of these fundamental subject areas for anesthesiologists, intensivists, and pain practitioners, both in training and in practice.

Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application is intended to be a definitive source for in-depth coverage of these core basic and clinical sciences in a single text. Focusing on physiology, pharmacology, and molecular-cellular biology, the text's approach is integrated and systems oriented, avoiding the artificial boundaries between the basic and clinical sciences. The book is divided into eight sections: Basic Principles of Pharmacology; Nervous System; Cardiovascular System; Pulmonary System; Gastrointestinal and Endocrine Systems; Immunity and Infection; Fluid, Electrolyte, and Hematologic Homeostasis; and Blood and Hemostasis.

Recognizing that no single author possesses the necessary breadth and depth of understanding in all the core subject areas, each chapter is authored by an expert representing many of the finest institutions of North America, the United Kingdom, Europe, and Asia. This allows an international presentation of current anesthesia science presented by recognized experts at the cutting edge of anesthesia research and education.

A number of features significantly enhance the use of *Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application* as a tool for learning, teaching, and review. These include access to the online text via the Expert Consult platform, including a complete, downloadable image bank. Recognizing that graphics are often the most expressive and effective way of conveying concepts, full-color illustrations facilitate use of the book as a learning aid and make it enjoyable to read. The text is copiously illustrated; all figures having been drawn or redrawn by the superb artists at Elsevier.

Each chapter stresses the scientific principles necessary for the understanding and management of various situations encountered in anesthesia practice. Detailed explanations of clinical techniques are avoided because this information is available in many comprehensive and subspecialty clinical anesthesia texts and handbooks. This book is not intended to provide a detailed review of specialized research areas for the scientist. Rather, the fundamental information necessary to understand essential concepts and principles is stressed, and basic science concepts are related to relevant clinical anesthesia applications. Chapters are self-contained with minimal repetition and include a short list of key points for review and key references to stimulate further exploration of interesting topics. The expertise and hard work of the contributing authors is evident in the quality of each chapter. We are confident that *Pharmacology and Physiology for Anesthesia: Foundations and Clinical Application* will help solidify your understanding of core anesthesia topics and thereby improve the safety and effectiveness of the care you render to your patients.

Novel Antidotes

Understanding the basic principles of pharmacology is fundamental to the practice of medicine in general, but is perhaps most relevant to the practice of anesthesiology. It is now widely accepted that cells contain a host of specific receptors that mediate the medicinal properties of drugs. Although the use of plant-derived medicinal compounds dates back to antiquity, the mechanisms by which these drugs act to modify disease processes remained mysterious until relatively recently. As late as 1964, de Jong wrote, "To most of the modern pharmacologists the receptor is like a beautiful but remote lady. He has written her many a letter and quite often she has answered the letters. From these answers the pharmacologist has built himself an image of this fair lady. He cannot, however, truly, claim ever to have seen her, although one day he may do so."[1]

This chapter briefly reviews the history of the receptor concept from the abstract notion alluded to by de Jong to the modern view of receptors as specific, identifiable cellular macromolecules to which drugs must bind in order to initiate their effects. Also introduced and defined are basic concepts that describe drug-receptor interactions such as affinity, efficacy, specificity, agonism, antagonism, and the dose-response curve. Finally, the evolving discipline of molecular pharmacology is discussed as it relates to modern drug development. Mathematical representations of the concepts are included in the form of equations for the reader seeking quantitative understanding, although the explanations of key concepts in the text are intended to be understood without reliance on mathematics.

The Receptor Concept

Historical Beginnings

The specificity of drugs for a particular disease has been known since at least the 17th century. The best known example of this is the efficacy of Peruvian bark, the predecessor of quinine, in the treatment of malaria.[2] Sobernheim (1803–1846) first applied the concept of selective affinity to explain the apparent specificity of drugs. He believed, for example, that strychnine had an affinity for spinal cord while digitalis had affinity for the heart.[1] Blake (1814–1893) first demonstrated that inorganic compounds with similar macroscopic crystalline structures exert similar effects when administered intravenously.[3] This triggered a vigorous scientific debate at the turn of the 20th century regarding whether it was the chemical structure or physical properties of drugs that endow them with medicinal properties.[4] This debate was particularly relevant for the theories of actions of general anesthetics because it was believed until recently that their relatively simple and diverse chemical structures precluded the possibility of a specific drug-receptor interaction.[5]

The term *receptor* was first coined in 1900 by Ehrlich (1854–1915) as a replacement for his original term "side chain" *(Seitenkette)* that he used to explain the specificity of the antibacterial actions of antitoxins (antibodies).[6] Ehrlich did not originally believe that specific receptors existed for small molecules such as medicinal compounds because they could easily be washed out of the body by solvents. This belief was at odds with the remarkable experimental findings of Langley (1852–1925), who was investigating whether the origin of the automatic activity of the heart resided in the heart muscle itself or was imposed on the heart by the nervous system. He demonstrated that the effect of the plant-derived drug jabonardi—bradycardia—occurred even when innervation was blocked, and that this effect was reversed by applying atropine directly to the heart. He went on to show that the relative abundance of the agonist (jabonardi) over its antagonist (atropine) determined the overall physiologic effect. This observation led Langley to

Abstract

Understanding the basic principles of pharmacology is fundamental to the practice of medicine in general, but it is perhaps most relevant to the practice of anesthesiology. It is now widely accepted that cells contain a host of specific receptors that mediate the medicinal properties of drugs. Although the use of plant-derived medicinal compounds dates back to antiquity, the mechanisms by which these drugs act to modify disease processes remained mysterious until relatively recently. As late as 1964, de Jong wrote, "To most of the modern pharmacologists the receptor is like a beautiful but remote lady. He has written her many a letter and quite often she has answered the letters. From these answers the pharmacologist has built himself an image of this fair lady. He cannot, however, truly, claim ever to have seen her, although one day he may do so."[1] This chapter briefly reviews the history of the receptor concept from the abstract notion alluded to by de Jong to the modern view of receptors as specific, identifiable cellular macromolecules to which drugs must bind to initiate their effects. Also introduced and defined are basic concepts that describe drug-receptor interactions such as affinity, efficacy, specificity, agonism, antagonism, and the dose-response curve. Finally, the evolving discipline of molecular pharmacology is discussed as it relates to modern drug development. Mathematic representations of the concepts are included in the form of equations for the reader seeking quantitative understanding, although the explanations of key concepts in the text are intended to be understood without reliance on mathematics.

propose that competition of the two drugs for binding to the same substance explained their antagonistic effects on the heart rate. However, the key experiment that led Langley to formulate his receptor concept came 30 years later in 1905, when he showed that the contractile effect of nicotine on skeletal muscle can be antagonized by curare. From the observation that even after application of curare the relaxed muscle contracted following direct application of electric current, he concluded that neither curare nor nicotine acted directly on the contractile machinery. Instead, Langley argued that the drugs interacted with a "receptive substance" that was essential for the initiation of the physiologic actions of the drug.[7]

Modern Development

Langley's concept of "receptive substance" forms the basis of the modern concept of a receptor, but it was not accepted without debate. It took years of work by Clark (1885–1941) and Gaddum (1900–1965), among others, to solidify the receptor concept. Clark demonstrated that the relationship between drug concentration and the physiologic response formed a hyperbolic relationship (the familiar sigmoidal dose-response curve; see later). Clark concluded that the relationship arose from equilibration between the drug and its receptor and argued that the effect was directly proportional to the number of drug-receptor complexes.[8] Ariëns (1918–2002) elaborated on Clark's theory and showed that the *affinity* of the drug for the receptor is distinct from the ability of the drug-receptor complex to elicit a physiologic response.[9] This distinction was further elaborated by Stephenson (1925–2004), who mathematically defined and quantified *efficacy*—the propensity of a drug to elicit a response.[10] Through his investigation of sympathomimetic compounds, Ahlquist (1914–1983) found that responses in various tissues occurred with two distinct orders of potency. This led him to propose multiple types of receptors for the same drug (α- and β-adrenergic receptors in this case), and the concept of *specificity,* which was finally published in 1948 after multiple rejections.[11]

Ahlquist's work is the foundation of modern pharmacology, including the development of the first and still widely used receptor-specific drugs—β-blockers—by Black (1924–2010), who also developed H_2-histamine receptor blockers used to diminish stomach acid production in the treatment of peptic ulcer disease. Since Black's fundamental discovery, many receptors have been identified, structures of many drug-receptor complexes have been solved using x-ray crystallography and nuclear magnetic resonance (NMR), and the concept of drug-receptor interactions is now universally considered as the basis of the physiologic actions of drugs.

Pharmacodynamics

Drug Binding

Pharmacodynamics is broadly defined as the biochemical and physiologic effects of drugs. Proteins constitute the largest class of drug receptors, but other biomolecules can also be targeted. Proteins and other complex macromolecules can exist in a number of different conformational states. For simplicity, assume just two receptor conformations: physiologically active and inactive. In the case of an ion channel, for instance, the active conformation is an open conformation that allows ion permeation across the membrane, and the inactive conformation is the closed ion channel.

The following equation describes the relationship between the active and inactive states of the receptor (R):

[1]

$$R^I \underset{k_i}{\overset{k_a}{\rightleftharpoons}} R^A$$

R^I denotes the inactive (closed) ion channel and R^A denotes the active (open) ion channel, and k_a and k_i are rate constants for the forward and reverse conformational changes, respectively. In this example, rate k_i is higher than k_a (shown by arrow thickness) to illustrate a situation in which the channel is mostly closed in the absence of drug. The equilibrium relationship between the active and inactive conformations can be written as the ratio of the rate constants:

[2]

$$\frac{[R^A]}{[R^I]} = \frac{k_a}{k_i}$$

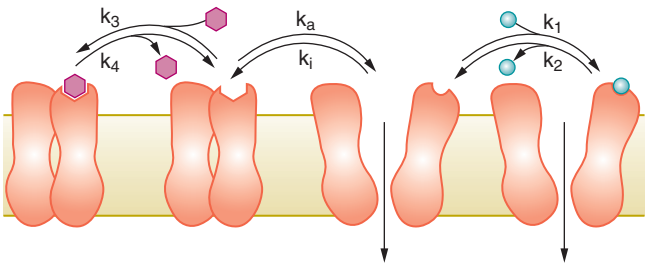
To initiate its pharmacologic action, a drug (D) first needs to bind its receptor"

[3]

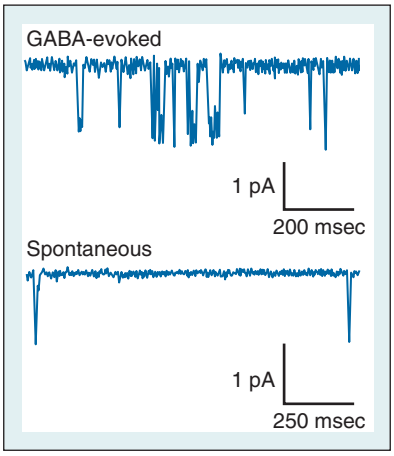
$$R^I \underset{k_i}{\overset{k_a}{\rightleftharpoons}} R^A + D \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^A * D$$

In this example, drug D binds an active form of the receptor (R^A) to form the complex R^A*D. As in the first example, this binding reaction has two rate constants, k_1 and k_2, that dictate the rates of drug-receptor complex formation and dissociation, respectively. The equilibrium constant for this binding reaction is therefore the ratio of the rate constants (k_1/k_2). The net effect of drug binding is an increase in active receptors as drug selectively binds the active conformation and thus prevents it from converting to the inactive conformation. This type of interaction of drug with a receptor is called *agonism* (discussed later). Fig. 1.1 shows a more general case, in which one drug (agonist) binds to an active (open) form of the ion channel while another drug (antagonist) selectively binds the closed form.

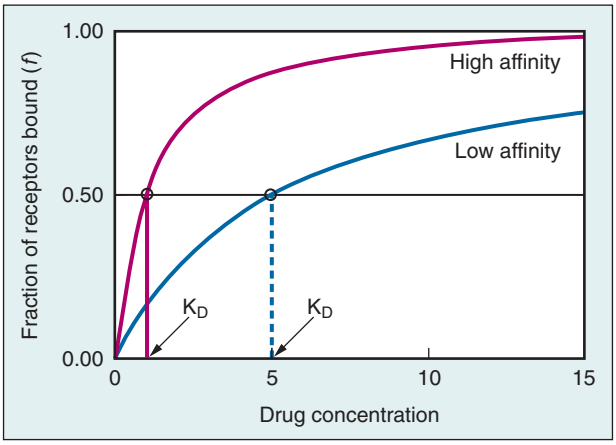
Although it might seem at first counterintuitive that even in the absence of agonist a receptor can be found in its active form, modern experimental methods such as single-channel patch clamp recordings can show this directly.[12] An example of such a recording is shown in Fig. 1.2.[13]



• **Fig. 1.1** Illustration of an ion channel in a lipid bilayer in equilibrium between two conformational states. The abundance of active (open) and inactive (closed) conformations is dictated by the rate constants k_a and k_i. An agonist *(aqua circle)* selectively binds to the open conformation of the ion channel, whereas an antagonist *(magenta hexagon)* selectively binds to the closed conformation. In both cases, drug binding stabilizes the receptor conformation: open in the case of an agonist and closed in the case of antagonist. The equilibrium for drug binding is dictated by the ratio of the rates k_1/k_2 and k_3/k_4 for the agonist and antagonist, respectively.



• **Fig. 1.2** An example of agonist elicited and spontaneous formation of the active form of a receptor. A single γ-aminobutyric acid $(GABA)_A$ receptor complex during a voltage clamp experiment. Active (open) $GABA_A$ receptors conduct chloride ions; inward flux is seen as downward deflections in the current trace, which reflect the times the channel is open. Even in the absence of GABA (the endogenous ligand at this receptor), the receptor can open spontaneously (trace labeled *Spontaneous*), but these openings occur more frequently and last longer when GABA is present. (Reproduced from Neelands TR, Fisher JL, Bianchi M, Macdonald RL. Spontaneous and gamma-aminobutyric acid (GABA)-activated GABA(A) receptor channels formed by epsilon subunit-containing isoforms. *Mol Pharmacol.* 1999;55:168-178.)



• **Fig. 1.3** Drug-receptor binding curves illustrating the importance of drug affinity for the receptor. As drug concentration increases, the fraction of receptor bound by drug *(f)* increases until all receptors are bound ($f = 1$). Curves are shown for two drugs with the dissociation constant (K_D) = 1 *(red)* and for $K_D = 5$ *(blue)*. It takes much higher concentrations of drug to occupy the same number of receptors when the K_D is higher (or affinity is lower). When the drug concentration equals K_D, exactly half of the receptors are bound by drug (shown by *circles*).

This model of drug stabilizing a receptor in its active conformation nicely explains the actions of gamma-aminobutyric acid (GABA) on $GABA_A$ receptors (see Fig. 1.2), but it is a very simplified view in several ways: (1) receptors can have more than two states (e.g., voltage-gated sodium ion [Na^+] channel). (2) Different conformational states can have different levels of activity rather than the all-or-none view presented here (e.g., nicotinic acetylcholine receptors). (3) Drugs can bind to more than one state of the receptor or at more than one site.[14–17] However, this model of drug-receptor interactions serves as a foundation for building more sophisticated models. This simplified description is used in the following discussion to derive the basic pharmacologic concepts.

Rearranging the equilibrium expression for drug binding to receptor yields the following expression in which the ratio of the two rate constants is defined as the dissociation constant K_D:

[4]

$$\frac{[R][D]}{[R*D]} \approx \frac{k_2}{k_1} \equiv K_D$$

Note that if K_D is small, then $k_1 \gg k_2$ and the complex of drug and its receptor is favored (as illustrated in Eq. 3). When the converse is true and K_D is large, the drug-receptor complex is not favored. Thus K_D reflects the propensity of the drug-receptor complex to break down. One can alternatively define *affinity* as the inverse of K_D, which reflects the propensity of the drug to form a complex with the receptor:

[5]

$$A \equiv \frac{1}{K_D} = \frac{k_1}{k_2}$$

To illustrate the importance of the dissociation constant K_D, the parameter f (fraction of receptor occupied by drug) is first defined as

[6]

$$f \equiv \frac{[R*D]}{[R]+[R*D]}$$

and then expressed f as a function of drug concentration and the K_D (or affinity) by substituting Eq. 4:

[7]

$$f = \frac{[D]}{[D]+K_D} = \frac{[D]}{[D]+1/A} = \frac{A[D]}{A[D]+1}$$

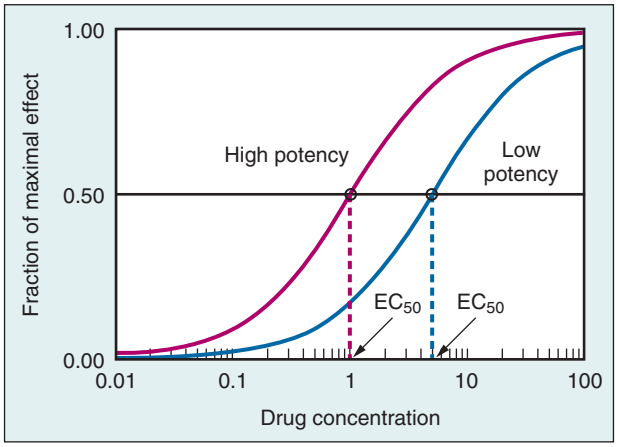
K_D is a fundamental property of the drug-receptor interaction (given constant conditions such as temperature, pH, and so on) but can be different for different drug-receptor pairs. To illustrate the effect of differences in K_D on the formation of drug-receptor complexes, Eq. 7 is plotted for two drugs characterized by different values of K_D (Fig. 1.3).

From Drug Binding to Physiologic Effect

Clark originally proposed that the number of drug-receptor complexes was directly proportional to the physiologic effect of the drug.[8] Although this is not entirely correct, for simplicity, first assume Clark's theory to derive the basic concentration (dose)-effect (response) curve and illustrate potency. Then Clark's assumption will be relaxed to arrive at the notion of efficacy.

If a physiologic response is directly proportional to the fraction of bound receptors, one should be able to derive the concentration-response relationship simply from the binding curve illustrated in Fig. 1.3. Indeed, the familiar sigmoid concentration-effect curve shown in Fig. 1.4 results from plotting the same equation as in Fig. 1.3. The only difference is that drug concentration is plotted on a logarithmic rather than linear scale and the *y*-axis is labeled as "Fraction of maximal effect."

Initially, as drug concentration increases, the increase in effect is rather small. In fact, until a certain concentration threshold is reached, no effect is apparent despite increasing drug concentrations. A further increase in drug concentration causes a steep increase in the effect until maximal effect is attained. This sigmoid relationship characterizes actions of many different drugs acting at different receptors. The circles in the plot denote drug concentrations at which half of the maximal effect is attained. This concentration is termed EC_{50} (effective concentration for 50% effect). Conceptually this is similar to K_D defined earlier. The major difference is that EC_{50} refers to the half maximal *effect, w*hereas K_D refers to half maximal *binding*. The smaller the EC_{50}, the less drug is required to produce the same effect. This is why EC_{50} is commonly used as a measure of drug *potency* or the ability of the drug to elicit a physiologic response.



• **Fig. 1.4** Concentration-effect curves illustrating the influence of potency *(EC_{50})* on curve position for two drugs of the same class. *EC_{50}* = 1 *(red)* and for *EC_{50}* = 5 *(blue)*. *EC_{50}*, Effective concentration for 50% effect.

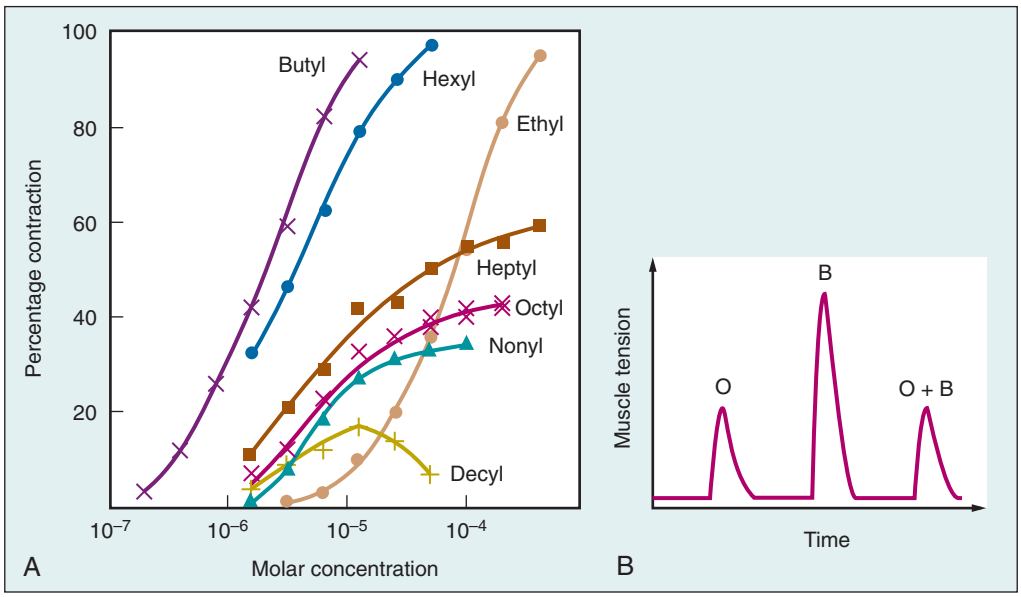
The curve in Fig. 1.4 is derived from an abstract notion of equilibrium between bound and free receptors. It is totally independent of the chemical identity of the drug or the receptor—it reflects the general property of drug-receptor interactions and is fundamental to the understanding of the action of any drug.

Efficacy

The concentration-effect curves in Fig. 1.4 depend on the important assumption that the effect of the drug is proportional to the amount of receptor bound by the drug. This hypothesis makes very strong predictions: (1) given high enough concentration, all drugs will give the same maximal effect; and (2) the slope of the curve should be similar for all drugs acting on the same receptor. Indeed, the only difference between the red and blue curves in Fig. 1.4 is that the blue curve is shifted to the right. However, this is not always true, as shown by Stephenson in 1956 in a landmark study (Fig. 1.5).[10]

While investigating the *pharmacodynamics* of tetramethylammonium (TMA) compounds known to elicit muscle contractions, Stephenson observed that different response curves were not simply shifted versions of each other. Specifically, it appeared that maximal contraction was not always attainable even at the highest concentration of a drug. For instance, even at the highest concentration, octyl-TMA elicited contraction was only 40% of the maximal attainable, whereas 100-fold smaller concentrations of butyl-TMA elicited near maximal contraction (see Fig. 1.5A). This observation alone does not invalidate Clark's theory. It is possible that octyl-TMA has really low affinity for the receptor and is therefore unable to elicit maximal response in the range of experimental concentrations.

The results in Fig. 1.5B definitively rule out this possibility. If the small contraction size elicited by octyl-TMA is due to its low affinity for the receptor, then some receptors will remain unoccupied even at maximal octyl-TMA concentration. If so, additional butyl-TMA should bind these available receptors and make the contraction



• **Fig. 1.5** Examples of differences in agonist potency and efficacy. A, Concentration-effect curves for various tetramethylammonium compounds illustrating that similar molecules can have different potencies (EC_{50s}) and different maximal effects (i.e., partial agonists). B, Muscle contractions elicited by octyl-TMA *(O)* and butyl-TMA *(B)* applied separately or together *(O + B)*. *EC_{50}*, Effective concentration for 50% effect. (Modified with permission from Stephenson RP. Modification of receptor theory. *Br J Pharmacol Chemother.* 1956;11:379–393.)

maximal. Yet, in contrast to this prediction, addition of butyl-TMA did very little to the contraction elicited by octyl-TMA alone. Thus weak affinity of octyl-TMA for the receptor cannot explain submaximal response and Clark's theory therefore must be incomplete.

To explain these observations, Stephenson generalized Clark's theory by proposing that the response R is not directly proportional to the fraction of receptor bound by drug, but instead is some function F of the variable he referred to as stimulus S:

[8]

$$R = F(S)$$

where S is a product of the efficacy (e) and the fraction of the receptors occupied f:

[9]

$$S = ef$$

In the case of muscle contraction, F can be conceptualized as excitation-contraction coupling and efficacy as the ability of the drug-receptor complex to produce excitation. By substituting Eq. 7 into Eq. 9, affinity A, drug concentration D, and efficacy e can be combined in the same equation:

[10]

$$S = e\left(\frac{A*[D]}{A*[D]+1}\right)$$

For conditions where the fraction of the occupied receptors is small, this simplifies to

[11]

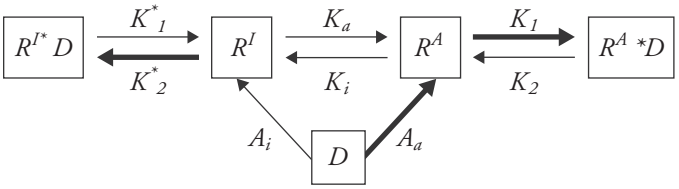
$$S = eAD$$

Accordingly, even when the fraction of the occupied receptors is small, the observed physiologic effect can be quite large if the efficacy is high. Conversely, even if affinity is high but the efficacy is low, the overall effect can be quite low. Therefore the overall drug *potency* for a given system is a function of two variables that characterize drug-receptor interactions: *affinity* and *efficacy*.

Full Agonists, Partial Agonists, and Inverse Agonists

Drugs can be classified based on the features of their concentration-effect relationships. This section focuses on different kinds of agonists and the following section discusses different forms of antagonism. First, features of drug-receptor interactions that make a particular drug an agonist are defined. In schema Eq. 3, it is assumed that drug binds only the active conformation of the receptor (see also Fig. 1.1). In a more general case (schema Eq. 12), drug can bind both active and inactive receptor conformations with different affinities.

[12]



The higher the affinity for the active conformation, the more equilibrium will be driven to the active receptor conformation until essentially all receptors are activated. This is called a *full agonist.* If the affinities for both active and inactive conformations of the receptor are comparable, the drug will be unable to convert a significant fraction of the receptor to the active conformation, even at high concentrations (reviewed for glutamate receptors).[18] This drug is called a *partial agonist.*

This is a microscopic level description of the basis of drug agonism, but in most cases, there is no detailed understanding of the molecular events. It is difficult to measure experimentally the differences in affinity for different conformational states of a receptor. Usually this problem is solved by performing molecular dynamics simulations.[19]

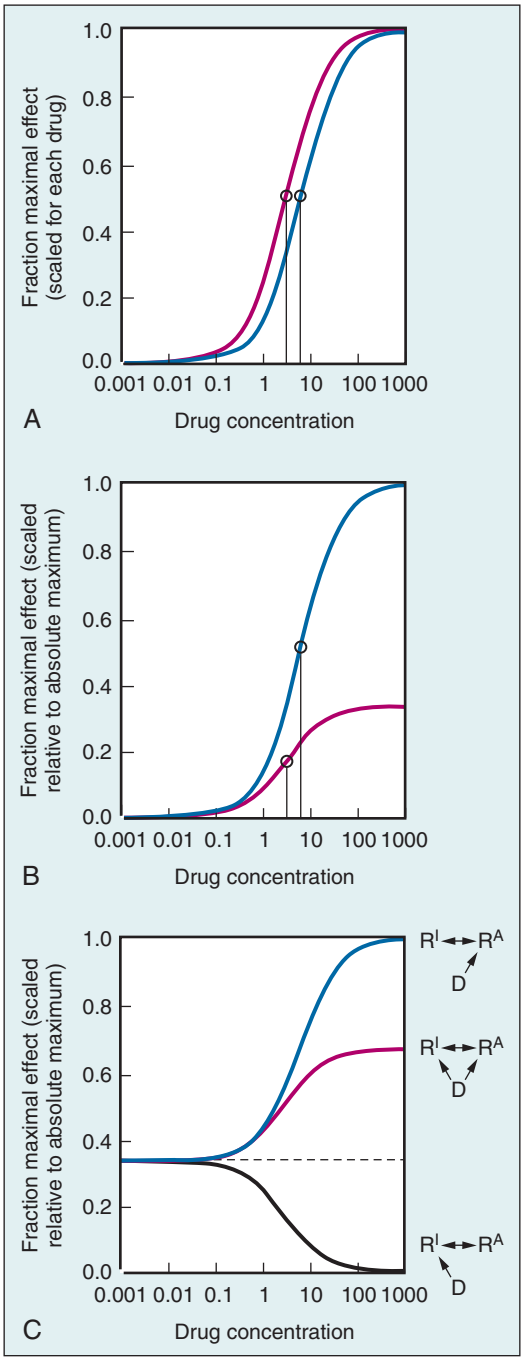
There is, however, a way to discover differences between agonists by characterizing their concentration-effect curves on a macroscopic level. Recall that the overall effect of a drug depends on two factors: affinity and efficacy. According to Eq. 10, efficacy determines the maximal effect attainable at the limit of high drug concentration, and affinity determines the range of drug concentrations at which the steep portion of the concentration-effect curve occurs. Therefore the effect of drug affinity can be isolated by scaling the y-axis of the concentration-response curve to the maximal effect attainable for that drug, and differences in efficacy can be characterized by comparing maximal attainable effects.

Fig. 1.6A shows two drugs that are distinguished by their affinity (higher for the red drug) scaled relative to the maximal effect attainable for each drug. When the effect of each drug is plotted relative to the absolute maximal effect (see Fig. 1.6B), it becomes evident that although the red drug has higher affinity, it has lower efficacy with a maximal response of one-third of that attainable by the blue drug. Therefore the red drug is a *partial agonist,* whereas the blue drug is a *full agonist.* Although the shapes of the plots in Figs. 1.6A and B appear quite different, in fact the relationship between their EC_{50} values stays exactly the same regardless of how the data are plotted.

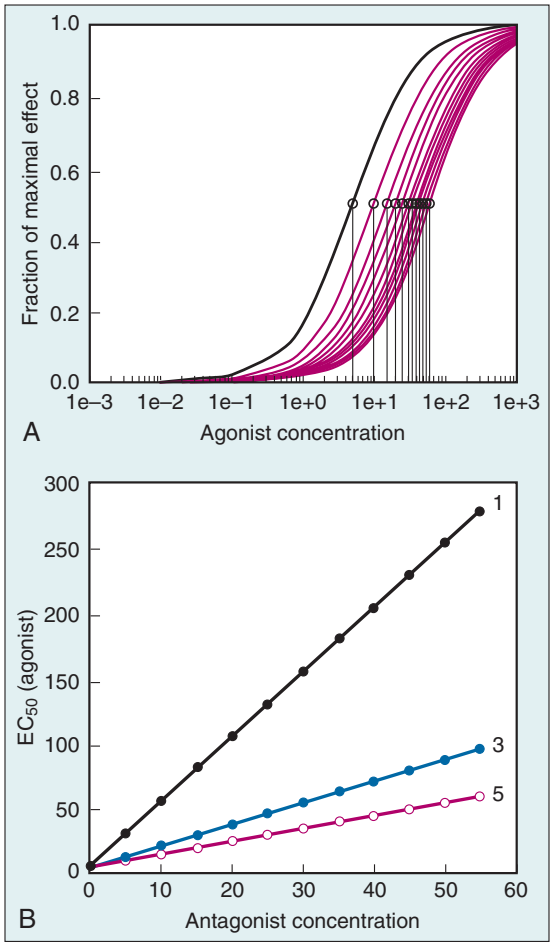
Up until this point we made an implicit assumption that concentration-response curves start at zero. In other words, in the absence of drug there is no effect. In Fig. 1.6C this assumption is relaxed. The plot in Fig. 1.6C shows the behavior of a system exhibiting intrinsic receptor activity, even in the absence of drug. This occurs in systems where even in the absence of drug a significant number of receptors exist in their active conformations. The blue curve shows a full agonist and the red curve shows a partial agonist. When the black drug is added, it appears that the intrinsic activity of the receptor is diminished. This can occur if the drug has a higher affinity for the inactive conformation of the receptor. This drug-receptor interaction is called *inverse agonism;* an inverse agonist is a drug that has a *negative efficacy*. If the inverse agonist was added after adding the full agonist, the overall effect would be diminished, suggesting that the inverse agonist is an antagonist (see later). In fact, the distinction between an antagonist and an inverse agonist can be subtle and is often evident only in genetically modified systems that express constitutively active receptors. For instance, the commonly used β-blockers such as propranolol are in fact inverse agonists at β-adrenergic receptors.[20]

Antagonism

The overall effect of a drug depends on both affinity and efficacy. All agonists have some nonzero value of efficacy and therefore



• **Fig. 1.6** Concentration-effect curves illustrating the concepts of EC_{50}, agonist, partial agonist, and inverse agonist. A, Concentration-effect curves of two drugs. The effect is scaled to the maximal response obtained for each drug. EC_{50} is 3 and 6 for the *red* and *blue* drugs, respectively. B, The same data as A, but the response is scaled to the absolute maximal possible physiologic response. *C,* Concentration-response curve for full agonist *(blue),* partial agonist *(red),* and inverse agonist *(black)* for a receptor with nonnegligible intrinsic activity. Affinity of the drug (D) for the active *(R^A)* and inactive *(R^I)* receptor conformations is indicated by the *single arrows*. *EC_{50},* Effective concentration for 50% effect.



• **Fig. 1.7** Competitive antagonism effect on the EC_{50}. A, Effects of increasing concentrations of a competitive antagonist on the concentration-response of a drug. The *black curve* shows curve in the absence of antagonist. EC_{50} for each curve is shown as a circle. B, Shift in EC_{50} plotted as a function of antagonist concentration derived using the $K_{D(B)}$ values shown. This plot allows calculation of the dissociation constant of the antagonist from the slope (see text). *EC_{50},* Effective concentration for 50% effect; *K_D,* dissociation constant.

produce an observable biologic effect. Conversely, drugs with some affinity for the receptor but no efficacy are defined as *antagonists*. Because antagonists do not produce an effect on their own, their actions can only be observed in the context of modification of the effects of an agonist.

The simplest way to conceptualize actions of an antagonist is to consider competition between an agonist and antagonist for binding to the same receptor. When the antagonist binds, no effect is elicited; when the agonist binds, it elicits an effect dictated by its efficacy. At a given concentration of antagonist, the effect elicited by the agonist will be diminished, but if the relative concentration of the agonist is increased, the same maximum effect will be eventually attained. Therefore the net effect of *competitive antagonism* is a shift in the agonist concentration-effect curve to the right (Fig. 1.7).

This can be expressed mathematically by modifying the previously derived equation for the fraction of receptors bound by agonist as follows:

[13]

$$f = \frac{[A]}{[A] + K_{D(A)}\left(1 + {}^{[B]}\!/\!_{K_{D(B)}}\right)}$$

where A is the agonist, $K_{D(A)}$ is its dissociation constant, B is the antagonist, and $K_{D(B)}$ is its dissociation constant.[21] The *EC_{50}* of the

agonist can now be expressed as a function of the antagonist concentration and its dissociation constant:

$$EC_{50} = EC_{50}^{0}\left(1+{}^{[B]}\!/\!_{K_{D(B)}}\right) \quad [14]$$

If the antagonist concentration is zero then the expression reduces to the EC_{50} of the drug in the absence of antagonist (EC_{50}^{0} in Eq. 14). The expression $\left(1+{}^{[B]}\!/\!_{K_{D(B)}}\right)$, known as the *dose ratio,* indicates the fold increase of the agonist needed to achieve the same response at a given concentration of antagonist. The effect of the dissociation constant of a competitive antagonist on the shift in EC_{50} is shown in Fig. 1.7B. The shift in EC_{50} is proportional to the antagonist concentration, and the proportionality constant (slope) is related to $1/K_{D(B)}$ (the affinity of antagonist for the receptor). The higher the affinity of the antagonist, the less antagonist it takes to shift the concentration-response curve of the agonist.

Another important class of antagonists is *noncompetitive antagonists.* The molecular mechanisms of noncompetitive antagonists are diverse. In the simplest case, irreversible binding of an antagonist takes the receptor out of the available pool to which agonists can bind. If the fraction of these unavailable receptors becomes sufficiently large, the maximal effect of the agonist will be partially reduced, even at very high agonist concentrations. Thus a noncompetitive antagonist makes the concentration-effect curve for a full agonist resemble that of a partial agonist.

Allosteric Drug Interactions

The discussion of antagonists in the previous section rests on an idea that both agonist and antagonist compete for binding to the same receptor site. The notion of what exactly a receptor is has been somewhat abstract, however. As mentioned earlier, most drug receptors are complex biologic macromolecules (example shown in Fig. 1.8), and to discuss allosteric drug interactions—the subject of this section—a few details about receptor structure are clarified.

Multiple Binding Sites on the Same Receptor Protein

Proteins constitute the largest class of receptor molecules. Although the amino acid sequence of proteins is encoded in the genetic code, the final three-dimensional structure of the protein is a result of complex interactions among the many amino acids that make up each subunit, interactions between subunits that make up the receptor, post-translational modifications, the cellular milieu, and so on. Only a small part of the resulting large and complex macromolecule is typically directly involved in binding the agonist. For instance, GABA binds the interface between the α and β subunits of the pentameric $GABA_A$ receptor.[22] The specific portion of a receptor molecule that is directly involved in binding drug is called a *binding site.* Identifying the actual binding site is no simple matter and usually requires a combination of experimental approaches. Indirect evidence for the identity of a binding site could be obtained through recombinant DNA techniques aimed at changing the identity of specific amino acids within the overall receptor-protein sequence by site-directed mutagenesis.[22] Direct evidence for the identity of a binding site can be obtained using x-ray crystallography, NMR spectroscopy, and chemical cross-linking, among other techniques.[23-26]

To determine the effect of changing the identity of a particular amino acid on drug binding, a reliable method for estimating drug binding is needed. Drug effect is not necessarily synonymous with drug binding (see earlier), so the concentration-effect curve cannot be directly used to infer the K_D. When a drug binds its receptor, heat is either absorbed (endothermic reaction) or released (exothermic reaction). These changes in heat can be recorded in solution maintained at constant temperature as a function of increasing drug concentration using a technique called *isothermal titration calorimetry* (ITC). In addition to measuring the binding constant, ITC experiments can also yield measurements of changes in entropy, enthalpy, and Gibbs free energy associated with drug binding, and thus provide a complete thermodynamic profile of the binding reaction that can then be used as a guide for molecular dynamic simulations.[27] Another technique that has gained popularity and was useful in identification of binding sites of anesthetic agents is photolabeling (Fig. 1.9) of drug binding sites using photoreactive drugs.[28] This technique involves an addition of a reactive chemical group such as a diazirine ring to the drug of interest When exposed to ultraviolet light, the diazirine ring forms a reactive carbene that rapidly reacts with amino acid residues in its vicinity, forming a covalent bond. This technique allows for stabilization of the normally transient drug receptor interactions. The binding site can then be identified by mass spectrometry and other structural techniques.[29,30]

The binding site itself typically consists of a very small fraction of the total amino acid sequence of the protein. Yet binding of drug to the binding site induces a set of complex conformational changes in the overall receptor protein. For instance, binding of GABA to its binding site leads to opening a pore, which allows flux of chloride ions (Cl^-) across the plasma membrane (see Fig. 1.2), a process called *gating*.[31]

Competitive antagonists tend to bind to the same binding site as the agonist (GABA in this case); competition for occupancy of the binding site is sufficient to account for the effects of the antagonist. However, other drugs that bind to the same receptor might do so at a site distinct from that occupied by the agonist. The interaction between drugs binding the same molecule at different sites is referred to as *allosteric* ("other site"). For instance, the noncompetitive $GABA_A$ receptor antagonist picrotoxin most likely binds the receptor within the ion pore.[32]

Allosteric Binding Sites

$GABA_A$ receptors contain a number of distinct binding sites, including those for benzodiazepines, volatile and intravenous anesthetics, and ethanol.[32] Binding of drugs to these allosteric sites can affect GABA affinity, efficacy, and number of spontaneously open ion channels, for example. These kinds of interactions cannot be adequately described as simple agonists and antagonists.

The classic model of allosteric drug interactions was proposed by Ehlert[33] (Fig. 1.10). The allosteric nature of drug interactions allows for many more transformations of the concentration-effect curves elicited by two or more drugs binding the same receptor. To quantify the nature of allosteric interactions, a technique called *response surface modeling* is typically applied. A response surface is a generalization of the concentration-effect curve to more than two dimensions. Experimentally this corresponds to determining the effect of different combinations of two or more drugs acting at the same receptor protein (see Fig. 1.10). This concept will be applied to drug interactions in Chapter 6.

GABA(A) receptors: structure and function in the basal ganglia. *Progr Brain Res.* 2007;160:21–41.)

Pharmacogenetics

Because most receptors are proteins whose amino acid sequence is encoded in the DNA, the binding sites can vary significantly between individuals. *Pharmacogenetics* refers to the study of how this genetic variability between individuals contributes to differences in drug effects (see Chapter 4). The effect of genetic variability on the pharmacology $GABA_A$ receptor is illustrated in Fig. 1.11. Because GABA and diazepam (a benzodiazepine) bind different sites on the $GABA_A$ receptor, it is possible to generate mutant receptor molecules that have different responses to one drug (diazepam), while the responses to the other drug (GABA) are preserved. In the wild-type receptor, diazepam acts as positive modulator of GABA, causing a left shift in the GABA concentration-effect curve. Yet after mutating a single amino acid, diazepam acts as a partial agonist.

The dependence of drug effects on the genotype has profound clinical implications. For instance, specific $GABA_A$ receptor α subunit polymorphisms can predict responses to alcohol such as susceptibility to delirium tremens and withdrawal symptoms; these polymorphisms might even predict a propensity for the development of alcohol addiction.[34] Other examples of genetic factors that

$$\rho = \frac{\alpha[A]/K_A[B]/K_B + [A]/K_A}{\alpha[A]/K_A[B]/K_B + [A]/K_A + [B]/K_B + 1}$$

• **Fig. 1.10** Illustration of allosteric drug-receptor interactions. Agonist *(green)* can bind the receptor *(purple)* with affinity K_a, which leads to a response dictated by the efficacy of the agonist. Alternatively, the receptor can bind an allosteric modulator *(yellow)* with affinity K_b. The receptor-modulator complex can then bind the agonist but not necessarily with the same affinity (thus K_a in this case is multiplied by some modulator-specific constant α). The resulting receptor-agonist-modulator complex can have a different efficacy (expressed as *"Filtered" response*). This complex can then decay by either dissociation of the agonist or the modulator. The overall fraction of receptor bound by the agonist ρ can be expressed in an equation shown at the bottom. (Reproduced from Kenakin T. Allosteric modulators: the new generation of receptor antagonist. *Mol Interv.* 2004;4:222–229.)

contribute to drug responses include genetic variability in enzymes that influence pharmacokinetics (see Chapter 4).[35]

Drug Discovery

Historically, medicines have been derived from plant extracts used without rigorous testing or validation. Most of these medicines were not single compounds but complex mixtures of compounds, only some of which had the desired physiologic actions. Opium, one of the oldest medicines, is a mixture of a number of alkaloids including morphine, which constitutes only ~12% of the total formulation. In the 19th century, major advances in chemistry allowed fractionation of crude plant extracts and isolation of individual compounds, which were then tested to determine which components of the extract were pharmacologically active and had desirable effects. This development was coupled with the purification and determination of the structure of naturally occurring hormones such as norepinephrine.

Structure-Activity Relationship

In the early to mid-20th century, many new drugs were synthesized as modifications of physiologically active plant and animal-derived compounds, yielding new drugs with desirable characteristics. The similarity between the structure of tyramine and epinephrine, for instance (Fig. 1.12), suggested the synthesis of many amine compounds that possessed sympathomimetic properties when tested in isolated organ systems such as the trachea and heart. One fundamental insight from this early work was that even small modifications in the chemical structure led to the profound changes in physiologic actions.

Identification of Drug Targets

Although many physiologically active compounds were synthesized during this early era of pharmacology, the mechanisms of action of these drugs remained mysterious as their receptors were not known. A fundamental insight was provided by Ahlquist,[11] who hypothesized that differences in drug effects might not only be due to differences in drug chemical structure but also to differences in the receptors expressed in different tissues. This led to the development of drugs acting in a tissue-specific manner by Black and colleagues.[36] They used a drug previously known as a bronchoconstrictor to develop the first novel, receptor-selective compounds, the β-blockers.[36]

Purification of Receptors

Advances in molecular biology have allowed rapid progress in the identification and molecular characterization of specific receptors

for drugs. In the 1980s, receptors were identified using high-affinity ligands, usually specific antagonists, that were used as bait in affinity chromatography to isolate the low-abundance receptor protein from detergent-solubilized tissue extracts.[37,38] Amino acid sequences of these purified receptors could then be determined, which allowed structural and functional analysis, as well as homology searching.

The advent of molecular cloning of cDNA from the cellular messenger RNA (mRNA) species allowed rapid identification of homologous receptors without tedious receptor purification techniques. In the past 20 years, the proteins encoding the receptors for many therapeutic drugs have been identified and most have been expressed at high levels (overexpressed) in other cell types (heterologous expression) to allow more detailed pharmacologic studies of receptors in isolation from other potentially confounding receptors and signaling molecules. It is now possible to express genes coding for a specific receptor protein in cell culture and simultaneously screen many different compounds for their ability to activate or inhibit the receptor using a variety of optical and other high-throughput drug screening methods.[39]

Drug Targets

Most drugs act by facilitating or blocking endogenous signaling molecules involved in intercellular and intracellular signaling, most commonly neurotransmitters or hormones. Most of these extracellular signaling molecules (ligands) are synthesized and released by one cell to affect another by interacting with a cognate receptor (e.g., endocrine signaling, synaptic transmission), although local effects on adjacent cells (paracrine) or the same cells (autocrine) are also common (Fig. 1.13).

Binding sites for hydrophilic extracellular signals typically exist as grooves or pockets on the surface of the extracellular protein domains. Lipophilic compounds (e.g., steroids, retinoids, and thyroxine), in contrast, can traverse membranes to interact with binding sites within the hydrophobic core or intracellular domains of the receptor. NO, HS, and CO are gaseous signaling molecules (gasotransmitters) that can also diffuse across membranes to affect intracellular targets.[40–42] Most transmembrane receptors consist of multiple membrane-spanning segments made up of amphipathic helices that fold to form a complex three-dimensional structure, usually consisting of multiple subunits. In ion channels, these membrane-spanning domains create a gate for ion permeation that is regulated by voltage or ligand binding. In other receptors, the intracellular domain contains protein signaling domains that either directly or indirectly affect signaling pathways. Receptor structures are highly dynamic and can exist in multiple conformations that differ in their activities. Ligands and modulators regulate

receptor function by selectively binding to specific conformers to alter these conformational equilibria.

Cell Signaling

Signal transduction refers to the process through which receptors act to mediate their physiologic actions (Fig. 1.14). In many cases this process involves molecules that are themselves not involved in binding the original ligand, but act as molecular relays. These molecules are referred to as *second messengers.* Important second messengers include cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), calcium ions, and inositol phosphates. Changes in concentration and subcellular localization of these molecules are coupled to activity of regulatory enzymes and effectors, including ion channels, cyclases, protein kinases, protein phosphatases, and phosphodiesterases. Many second messengers either directly or indirectly regulate protein kinases, which reversibly phosphorylate hydroxylated amino acid residues on key effector molecules in the cell, including receptors, to alter their function and localization.

The interactions between different second messengers form complex molecular signaling networks that allow greater flexibility in how ligand binding affects cellular function and for the coordination between different signals. *Signal amplification* occurs as a result of sequential activation of catalytically active enzymes, each of which can activate multiple downstream targets. *Specificity* is imparted by the receptor itself and its cell- and tissue-specific expression. *Signal integration* occurs as the downstream signaling pathways of different signals interact at multiple levels both positively and negatively (cross talk).[43] Signals can be graded (i.e., analog) or discrete and bistable.[44] *Feedback,* both positive and negative, can occur when downstream components interact with upstream components of the signaling cascade.[45,46] Many signaling pathways are compartmentalized by protein interaction domains on scaffolding proteins that bring together multiple components of the pathway, including receptors and their target effectors to increase their local concentrations.[47] These mechanisms of cell signaling and signal transduction are critical for intercellular communication in multicellular organisms and provide multiple sites susceptible to modulation by exogenous compounds including drugs and toxins.

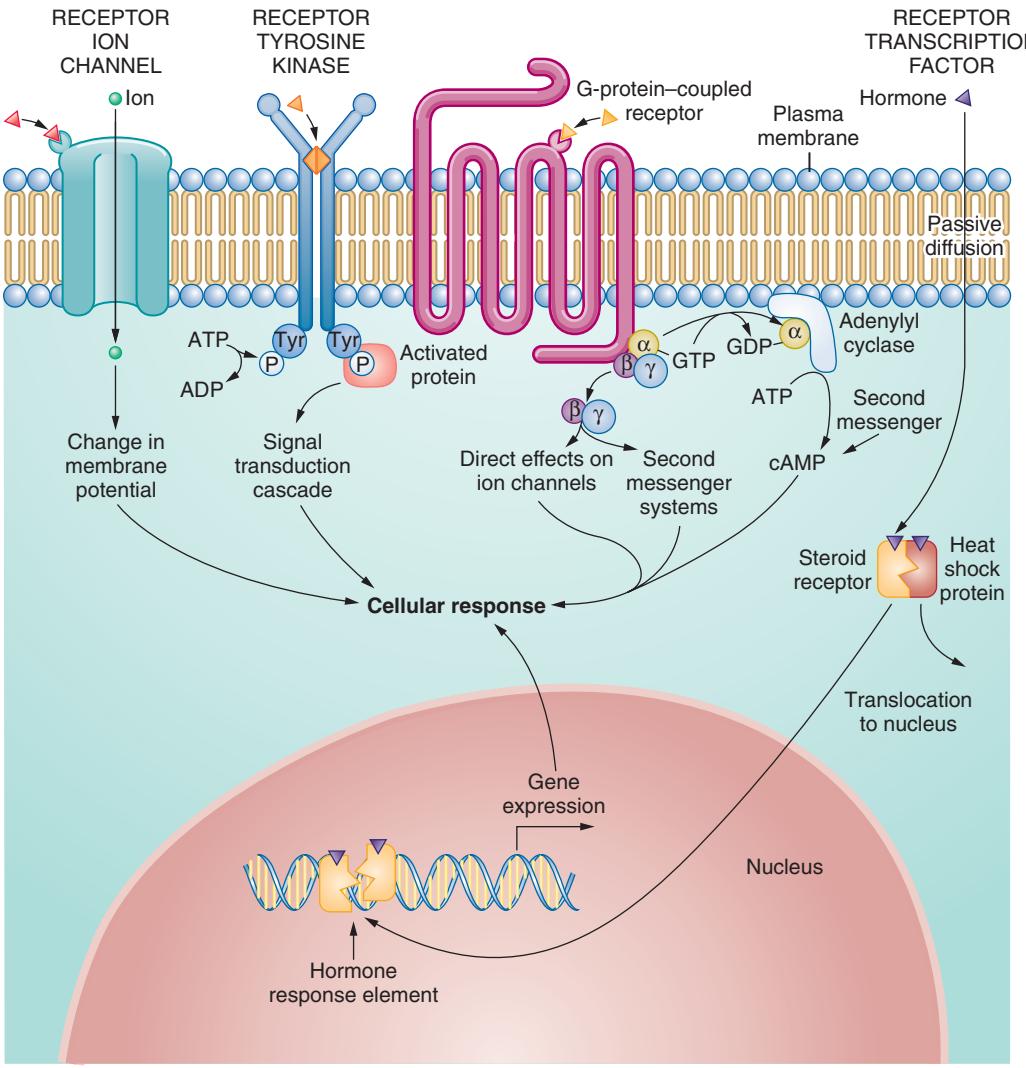
The most common types of drug target proteins involved in signal transduction are G protein-coupled receptors (GPCRs), ligand-gated ion channels (ionotropic receptors), which are major targets of general anesthetics, and voltage-gated ion channels, the major targets of local anesthetics and certain antihypertensive drugs.[16,48–50] There are also a number of enzyme-linked cell surface receptors, a heterogeneous group of receptors usually coupled to intracellular protein kinase or phosphatase activity. These proteins fall into different classes based on their amino acid sequences and biologic activities. The activation of many receptors leads to transient changes in intracellular second messengers.

GPCRs constitute the largest family of cell surface receptor proteins, and indeed comprise the largest family of membrane proteins in the human genome. They mediate the cellular responses to a diverse array of extracellular signals, including hormones and neurotransmitters. GPCRs contain seven transmembrane α helices and bind their ligands in the extracellular space, as demonstrated by the recent three-dimensional structure determined for several members of this class.[51–54] On the cytoplasmic surface, GPCRs transduce their signals into cells by coupling to intracellular heterotrimeric G proteins that are made up of three subunits (α, β, and γ). Although there are many GPCRs, the number of G proteins is much smaller (21 Gα subunits encoded by 16 genes, 6 Gβ subunits encoded by 5 genes, and 12 Gγ subunits in humans). In the inactive form, G proteins bind GDP. When ligand binds the receptor, GDP is exchanged for guanosine triphosphate (GTP), which causes dissociation of the G protein into the α subunit and the βγ dimer, each of which interacts with specific effectors.[55] This process is terminated once GTP is hydrolyzed to GDP (see Fig. 1.14) and the G protein subunits reassociate.

Some G proteins activate their effectors, whereas others inhibit them. Many endogenous signaling molecules exert their effects through multiple subtypes of GPCRs with distinct downstream targets and/or cellular expression. Examples include multiple receptor subtypes for epinephrine, dopamine, serotonin, and endogenous opioids.[25] Natural ligands for a large fraction of the many GPCRs present in the human genome have yet to be identified (orphan receptors) and represent potential future drug targets.[48]

Although the structure of the GPCR determines its ligand recognition, the overall effect is determined by which G protein associates with the receptor and which effectors are coexpressed in the same cell. Some of the well-known effectors of GPCRs are adenylyl cyclases, phospholipases, and various ion channels (Table 1.1). These effector proteins control the concentration of second-messenger molecules such as cAMP and phosphatidylinositol bisphosphate in the case of adenylyl cyclase and phospholipase, respectively. Thus GPCRs are capable of eliciting a diverse range of responses depending on the cellular context in which they are expressed. This feature of G proteins makes them attractive targets for drug development. Furthermore, the effector proteins such as adenylyl cyclases and phosphodiesterases (enzymes that degrade cAMP and cGMP) have themselves been targeted for drug discovery.[56]

In addition to activation of canonical G-protein–mediated signal transduction pathways, GPCR activation leads to feedback pathways that eventually terminate signaling. These feedback pathways fall into two general classes: heterologous and homologous. Although both pathways involve receptor phosphorylation, the former does not require that the GPCR is bound by agonist, while the latter specifically involves agonist-bound GPCRs. Heterologous receptor desensitization involves receptor phosphorylation by second-messenger–dependent kinases (e.g., cAMP-dependent kinase, PKC) that reduces receptor binding to bind G proteins and thus terminates canonical signaling. In contrast, homologous desensitization involves GPCK phosphorylation by G-protein–coupled receptor kinases



• **Fig. 1.14** Major modes of signal transduction and intracellular signaling. Binding of an agonist to a receptor ion channel (e.g., $GABA_A$ receptor or nicotinic acetylcholine receptor) leads to opening of a transmembrane pore that permits movement of ions across the plasma membrane. This leads to a change in membrane potential that results in the physiologic response (e.g., change in the firing characteristics of a neuron or muscle contraction). Binding of a ligand to a receptor tyrosine kinase results in receptor dimerization and phosphorylation of the intracellular kinase domain. The activated (phosphorylated) kinase domain is then specifically recognized by proteins such as Src and phospholipase C that in turn activate a network of downstream effectors. These signal transduction pathways ultimately lead to changes in physiologic functioning of the cell such as glucose utilization and cell growth. Binding of a ligand to a seven-transmembrane domain G-protein–coupled receptor results in the dissociation of the G protein into the membrane α subunit and the soluble βγ dimer. The α subunit then interacts with downstream effectors such as adenylyl cyclase, which converts adenosine triphosphate *(ATP)* into cyclic adenosine monophosphate *(cAMP)* (a second messenger) that then modifies a number of effector proteins. The βγ dimer can also exert direct cellular effects by modulating activity of a number of ion channels, for example. Effects of steroid hormones are mediated by intracellular receptors, which upon binding their ligand dissociate from a heat shock protein and translocate into the nucleus where they serve to modify gene expression by binding to hormone response elements in the promoter regions. *ADP,* Adenosine diphosphate; *GABA,* γ-aminobutyric acid; *GDP,* guanosine diphosphate; *GMP,* guanosine monophosphate; *P,* phophoryl group; *Tyr,* tyrosine.

on the third intracellular loop and carboxyl tail, leading to recruitment of β-arrestins, which targets the receptor for clathrin-mediated endocytosis. This mechanism plays a role in a variety of processes, most notably development of tolerance to opioids (as reviewed in Pierce and Lefkowitz[57]).

Ligand-gated ion channels are involved primarily in fast synaptic transmission between cells (e.g., the nicotinic acetylcholine receptor in neuromuscular transmission). $GABA_A$ receptors are ligand-gated Cl^- channels that open in response to binding their principal agonist, GABA (see Fig. 1.2), the major fast inhibitory

TABLE 1.1 Diversity of G-Protein–Coupled Receptor Signal Transduction Pathways

G-Protein α Subunit[a]	Representative Receptors	Effectors	Effect
$G\alpha_s$	β_1, β_2, β_3—adrenergic, D_1, D_5-dopamine	Adenylyl cyclase, Ca^{2+} channels	Increased cAMP, increased Ca^{2+} influx
$G\alpha_i$	α_2-adrenergic; D_2-dopamine; M_2, M_4 muscarinic; μ, δ,κκ opioid	Adenylyl cyclase, phospholipase A_2, K^+ channels	Decreased cAMP, eicosanoid release, hyperpolarization
$G\alpha_t$	Rhodopsin	cGMP phosphodiesterase	Decreased cGMP (vision)
$G\alpha_q$	M_1, M_3 muscarinic; α_1-adrenergic	Phospholipase Cββ	Increased IP_3, DG, Ca^{2+}
$G\alpha_{12/13}$	Angiotensin II (AT_1), endothelin (ET_A), thromboxane A_2 (TP), and thrombin (PAR_{1-4})	Rho guanine nucleotide exchange factor, others	Rho A activation

Ca^{2+}, Calcium ion; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *DG,* diacylglyceron; *IP_3,* inositrol triphosphate.
[a]G-protein α subunits are encoded by 16 genes classified into four families: $G\alpha_s$, $G\alpha_i$ ($G\alpha_i$, $G\alpha_o$, $G\alpha_t$), $G\alpha_q$, and $G\alpha_{12/13}$. *PAR1-4,* protease-activated receptor 1-4. See reference 67 for review.

neurotransmitter in the central nervous system. $GABA_A$ receptors belong to the cys-loop superfamily of ligand-gated ion channels that contains many other neurotransmitter receptors that all share certain structural motifs. Many of the members of this superfamily (Fig. 1.15) have been successfully targeted for drug development.

Another large group of drug targets are voltage-gated ion channels (Fig. 1.16). Like ligand-gated ion channels, these proteins also form pores that allow permeation of ions across the plasma membrane. However, rather than opening in response to ligand binding, pores within these proteins open when transmembrane electrical potential reaches a certain value. The voltage and time dependence of pore opening as well as ion selectivity differs widely between these proteins.[58] Many clinically useful drugs such as local anesthetics and several antiarrhythmic drugs target voltage-gated sodium (Na^+) channels (see Chapter 20).

Another prominent family of proteins that has been successfully targeted for drug discovery includes receptor proteins with enzymatic activity. These receptors typically contain a ligand-binding domain, a single transmembrane domain, and the catalytic domain. Of these, the most prominent are the receptor tyrosine kinases, important targets for novel anticancer drugs. Binding of ligand in the extracellular space activates the tyrosine kinase to add phosphate groups onto tyrosine moieties of other proteins. Some clinically significant signaling pathways that involve receptor tyrosine kinases are receptors for cytokines and insulin.[59] In some cases, both the ligand-binding domain of the receptor and the tyrosine kinase structural domains are a part of the same polypeptide chain, and in other cases these two domains are expressed in different proteins that oligomerize to form a functional receptor.[60] Other receptors with enzymatic activity include tyrosine phosphatases and guanylyl cyclases.[61]

The identity and abundance of proteins, including those that mediate drug actions, are not static. Expression of proteins is dynamically regulated through a network of signaling cascades depending on cell type, developmental stage, and environmental demands, for example. These regulatory cascades converge on proteins, known as *transcription factors,* that control transcription of mRNA. Thus transcription factors play an incredibly important role in controlling the function of the cell and present attractive targets for drug discovery. Various steroid compounds that modulate the endocrine system act on transcription factors to alter gene expression (see Fig. 1.14). Transcription factors consist of homologous domains that control the specificity of ligand binding and regulatory motifs that determine DNA sequences to which these transcription factors bind to modulate gene expression.

Emerging Developments

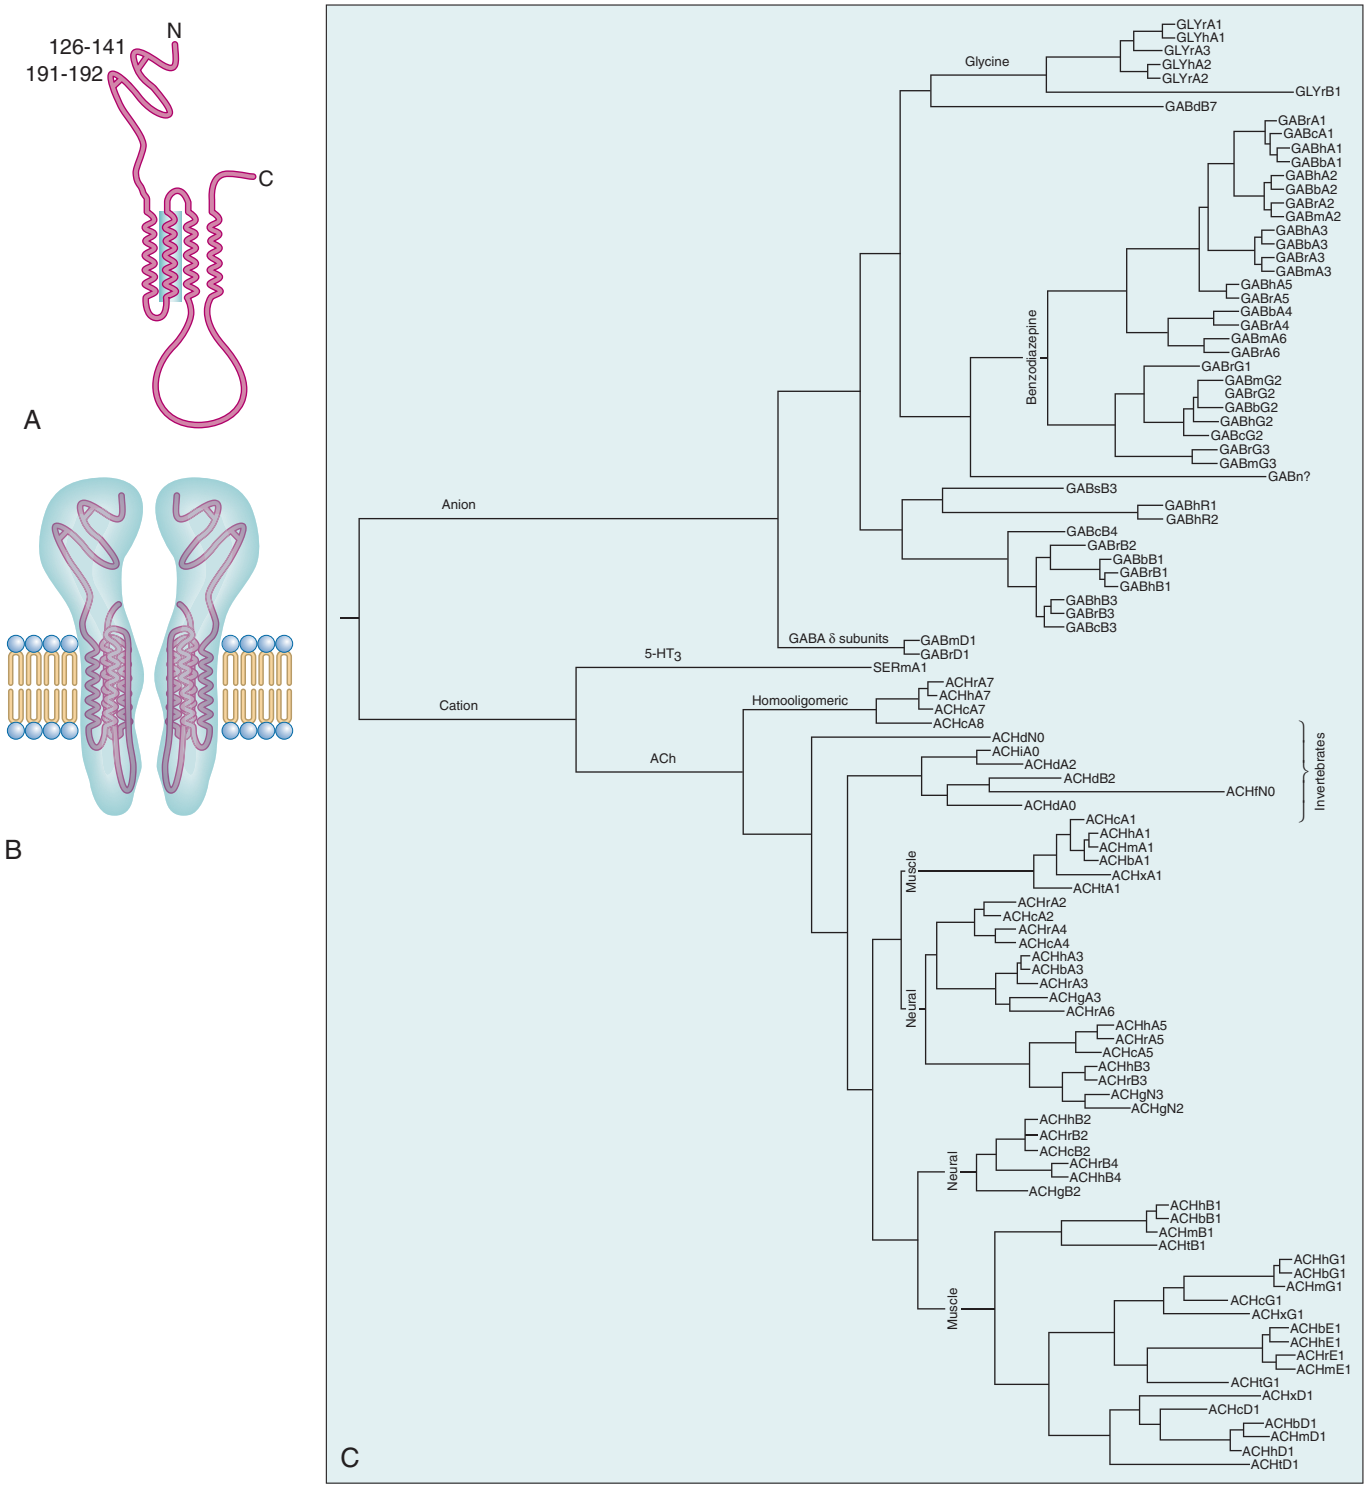
Pharmacophore Modeling

The realization that binding sites of many different proteins are homologous and the observation that chemically similar compounds tend to bind to the same binding site suggest that structure-activity relationships can be formalized. This could in principle significantly reduce the need to characterize experimentally the binding and efficacy of many different compounds and be able to predict which compounds should have the desirable binding characteristics. In practice, however, it is extremely difficult to develop because at the subatomic level, details of all the different forces that govern noncovalent interactions are extremely complex and analytic solutions exist for only the simplest molecules. Currently each potential drug-receptor pair must be numerically simulated, which is computationally expensive and impractical on a large number of drug candidates.

An exciting development in modern drug design—pharmacophore modeling—provides a way to describe qualitatively drug-receptor interactions to provide an albeit imprecise guide for selecting promising drug candidates. Pharmacophore is defined as "an ensemble of steric and electronic features that is necessary to ensure the optimal supramolecular interactions with a specific biologic target and to trigger (or block) its biologic response."[62] Pharmacophore models combine a large number of observations of active and inactive compounds and attempt to extract statistically significant motifs that predict drug activity (Fig. 1.17). Pharmacophore modeling has been successful in predicting binding characteristics of many candidate drugs.

Phenotype-Based Drug Discovery

Using methodologies such as pharmacophore modeling and high-throughput screening, it is now possible to readily synthesize new compounds with high specificity for the desired receptor. This, however, does not guarantee therapeutic efficacy. It has become clear that many of the most prevalent diseases, such as depression and obesity, are mediated by complex changes occurring



• **Fig. 1.15** Structure and evolutionary relationship of ligand-gated ion channels. A, Proposed structure of a single subunit of a pentameric ligand-gated ion channel. B, Structure of the whole pentamer viewed from the side (in plane). C, Evolutionary relationship between different members of the superfamily based on sequence homology. *GABA,* γ-aminobutyric acid. simultaneously in many biologic macromolecules. Furthermore, these changes are mediated through networks of molecular interactions involved in signal transduction in a cell type–specific manner. It is exceedingly unlikely therefore that specifically targeting a particular receptor, or second-messenger system, will guide these molecular networks toward "normal" function. Thus paradoxically it is commonly found that some of the most clinically efficacious compounds are not necessarily the most specific on the molecular level. For instance, tricyclic antidepressants act on adrenergic, cholinergic, serotonergic, histaminergic, and dopaminergic systems.

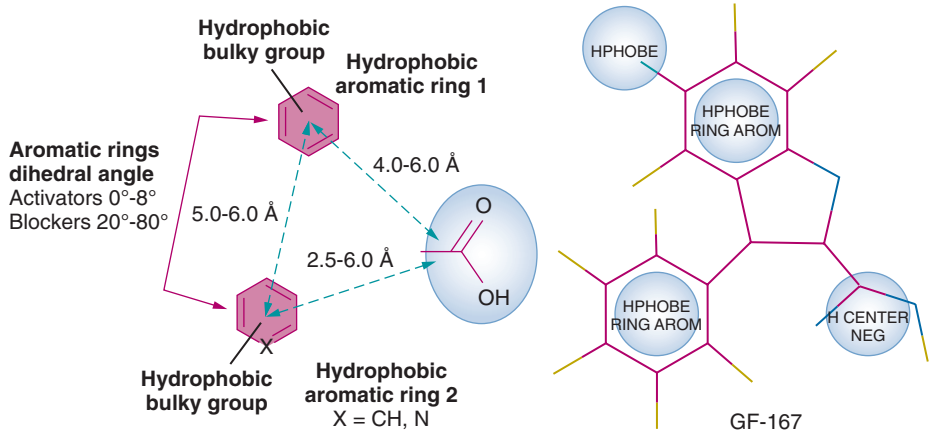
• **Fig. 1.16** Structure and evolutionary relationship between members of the voltage-gated ion channel superfamily. (Reproduced from Yu FH, Yarov-Yarovoy V, Gutman GA, et al. Overview of molecular relationships in the voltage-gated ion channel superfamily. *Pharmacol Rev.* 2005;57:387–395.)



• **Fig. 1.17** Representation of the pharmacophore model illustrating the essential requirements for drug action. For comparison, the stick model and the chemical function descriptors of the master compound GF-167 are shown. (Reproduced from Liantonio A, Picollo A, Carbonara G, et al. Molecular switch for CLC-K Cl^- channel block/activation: optimal pharmacophoric requirements towards high-affinity ligands. *Proc Natl Acad Sci USA.* 2008;105:1369–1373.)

A promising complementary strategy is *phenotype-based* drug discovery. Rather than discovering compounds with the most desirable binding characteristics to a particular receptor, phenotype-based approaches screen compounds based on their ability to produce a desired phenotype in the whole animal. For instance, the cholesterol-lowering medication ezetimibe (Zetia) was identified based on its ability to lower serum cholesterol level in an animal model, although it was not a successful inhibitor of acyl-coenzyme A cholesterol acetyltransferase (the original target for the target-based drug discovery approach).[63]

Novel Antidotes

Anesthesiologists are familiar with the use of antidotes, classically defined as a drug that counteracts the effects of a poison (Tables 1.2 and 1.3). Some classic examples include the anticholinesterases to antagonize neuromuscular blockers, naloxone to antagonize opioids, and protamine to antagonize heparin. The first two agents represent physiologic antidotes that work through receptor antagonism, while the latter represents complex formation to inactive the drug. A number of new antidotes take advantage of complex formation, or sequestration, to reverse the effects of a drug. For example, the newer neuromuscular blocker reversal agents sugammadex and calabadion work by encapsulating the neuromuscular blocker to sequester it from interacting with nicotinic receptors, leading to rapid and complete restoration of neuromuscular function without muscarinic side effects seen with cholinesterase inhibitors.[64] A second novel approach to reversing neuromuscular blockade involves using a chemical antidote is taking advantage of the thiol reactivity of the benzylisoquinolinium blockers to enhance blocker degradation by administering exogenous cysteine as a reversal agent.[65] Reversal of direct acting oral anticoagulants is now achievable with novel antidotes: a humanized monoclonal antibody specific for dabigatran (idarucizumab), and a mutated form of factor Xa that acts as a decoy to neutralize the factor Xa inhibitors rivaroxaban, apixaban, edoxaban, and fundaparinux.[66] A current goal in drug development is to create both specific and universal antidotes to specific drugs or drug classes.

TABLE 1.2 Classical Anesthesia Antidotes

Drug	Antidote
Acetaminophen/paracetamol	Acetylcysteine
Anticholinergic	Physostigmine
Anticholinesterase	Atropine/pralidoxime
Benzodiazepines	Flumazenil
Ca^{2+} Channel blockers	Calcium chloride
Digoxin	Anti-digoxin Fab
Heparin	Protamine sulfate
Malignant hyperthermia	Dantrolene
Neuromuscular Blocker	Anticholinesterase
Opioids	Naloxone
Warfarin	Vitamin K

Ca^{2+}, calcium ion.

DOAC, Direct oral anticoagulant; *DTI*, direct thrombin inhibitor.

Key Points

- A drug must first bind a receptor and form a complex to initiate its physiologic effect. The propensity of the drug-receptor complex to form is described by a constant called *affinity*, whereas its propensity to break down is described by the *dissociation constant*.
- Most drug receptors are proteins in the plasma membrane that are involved in cell signaling, such as G-protein–coupled receptors and ion channels.
- Drug binding is not equivalent to *drug effect*. The propensity of the drug-receptor complex to elicit *a physiologic* effect is governed by a characteristic constant called *efficacy*.
- Together, affinity and efficacy give rise to drug *potency*, typically measured as effective concentration for 50% of maximal effect (EC_{50}).
- Depending on their relative efficacies, drugs are characterized as *full, partial,* or *inverse agonists.* Drugs with receptor affinity but no efficacy are referred to as *antagonists*.
- Drugs often bind receptors at multiple distinct binding sites, which can influence receptor actions in complex ways. These interactions are called *allosteric*.
- *Signal transduction* is the process by which receptors transduce signals from extracellular messengers via *second messengers* to regular cellular functions.
- The ability of a drug to bind a particular binding site depends on interactions determined by the chemical structure of the drug and the structure of the binding site. The compatibility between a chemical compound and a binding site can be expressed in a *pharmacophore* model.

The science broadly referred to as clinical pharmacology is the foundation on which anesthesiologists base their therapeutic decisions, including the rational selection of anesthetics and the formulation of safe and effective dosage regimens. Focusing exclusively on intravenous anesthetics, this chapter reviews the fundamental theory and practical application of clinical pharmacology in anesthesia, including pharmacokinetics, pharmacodynamics, the "biophase" concept, compartmental models, and pharmacologic simulation. Although clinical pharmacology is grounded in complex mathematics, the chapter avoids excessive reliance on equations by emphasizing a conceptual understanding of the quantitative ideas, and highlights the intuitive understanding that comes from computer simulation of pharmacologic models. Understanding what a pharmacologic model is and how such a model is built and applied is therefore an important focus of the chapter.

The ultimate goal of the chapter is to provide the clinician with a solid understanding of the fundamental concepts of clinical pharmacology, thereby enabling practical clinical application of these concepts, primarily through the use of pharmacologic simulation. From a pharmacology perspective, there is perhaps nothing more relevant to day-to-day decision making in anesthesiology than the theories explained here. These concepts are the scientific foundation to answer a very important clinical question: "What are the right drug and the optimal dose for my patient?"

Historical Perspective

From the earliest days of modern anesthesia, anesthesiologists sought to understand the dose-response relationship. Using dose escalation study methods, clinician-scientists quantified the magnitude and duration of anesthetic effect over a spectrum of doses, thereby identifying a dosage range that would produce anesthesia without excessive toxicity. For many decades, modern anesthesia practice relied on such dose-response studies as the basis for rational drug administration schemes.

With advances in analytical chemistry and the widespread availability of computing technology, new approaches to understanding drug behavior emerged. By measuring blood anesthetic concentrations over time using techniques such as radioimmunoassay or gas chromatography, it became possible to characterize the relationship between drug dose and the time course of drug levels in the bloodstream, a field of study called pharmacokinetics (often

pharmacologic simulation

abbreviated as PKs[a]). A natural extension of this new discipline of pharmacokinetics was the characterization of the relationship between the concentration of the drug and the magnitude of effect, a branch of pharmacology called pharmacodynamics (abbreviated as PDs[b]). Coherent linkage of these two pharmacologic disciplines, pharmacokinetics and pharmacodynamics, necessitated creation of the biophase concept wherein plasma drug concentrations from PK studies are translated into apparent "effect site" concentrations, which are then related to drug effects measured in PD studies.

The underlying theory of pharmacokinetics was largely developed in therapeutic areas unrelated to anesthesiology.[1–3] However, because the clinical pharmacology of anesthesia is so unique[4,5] (e.g., the necessity to predict onset and offset of drug effect very accurately), some PK concepts have been developed by anesthesia investigators for specific application in anesthesia.[6–8] Moreover, because of the ease with which profound anesthetic effects can be noninvasively measured in real time (e.g., the peripheral nerve stimulator for neuromuscular blockers, the electroencephalogram [EEG] for hypnotics, among others), many important theoretical advances in pharmacodynamics applicable to other fields of medicine have originated from the study of anesthetics. An especially notable example is the conception of the biophase or effect site concept.[9]

Compared with old-fashioned dose-response methods, a major advantage of these more sophisticated PK-PD studies is that the analysis results in a quantitative model of drug behavior. Using nonlinear regression techniques, equations are fit to raw PK and PD data, yielding a set of PK-PD parameters estimates (i.e., distribution volumes, clearances, potencies) that constitute a quantitative model.[10] Unlike dose-response studies of the past, these quantitative PK-PD models can be applied to more diverse and clinically relevant circumstances through computer simulation.[11]

The application of modern PK-PD concepts into anesthesia practice has blossomed in unanticipated ways. Automated administration of intravenous anesthetics according to a PK model, a technology known as target-controlled infusion (TCI), is now commonplace.[12] The use of real-time PK-PD simulation to guide anesthetic administration, wherein a PK-PD prediction module is placed alongside a traditional physiologic monitor, is also an emerging technology with promising potential.[13]

Unique Aspects of Anesthetic Pharmacology

Anesthesiology Compared With Other Disciplines

The pharmacology of anesthesia is unique compared with other disciplines within medicine (Table 2.1). Perhaps the most obvious difference relates to the safety of anesthetic drugs. Many drugs within the anesthesia formulary produce profound physiologic alterations (e.g., unresponsiveness, paralysis, ventilatory and hemodynamic depression) and have a very low therapeutic index. There are few therapeutic areas in medicine where 2 to 3 times the typical therapeutic dose is often associated with severe adverse or even lethal effects (see Chapter 7). It is perhaps for this reason more than any other that the specialty of anesthesiology evolved. The consequences of "under" or "over" dosing anesthetics can be catastrophic.

[a]When used as an adjective in this chapter, "pharmacokinetic" is abbreviated as "PK."

[b]When used as an adjective in this chapter, "pharmacodynamic" is abbreviated as "PD."

TABLE 2.1 Unique Aspects of Anesthesia Clinical Pharmacology Related to Safety and Efficiency

Safety Issues
• Very low therapeutic index drugs
• Severe consequences to "under" or "over" dosing
• Necessity to adjust the level of drug effect frequently
Efficiency Issues
• Necessity to produce onset of drug effect quickly
• Necessity to produce offset of drug effect quickly

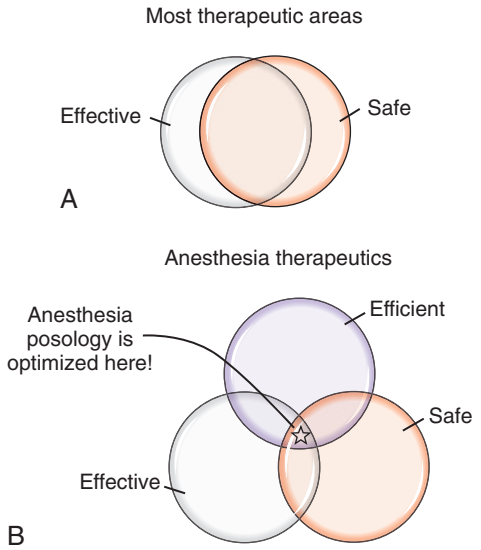
Another important difference between anesthesiology and other therapeutic areas relates to efficiency. Most settings in clinical medicine do not require immediate onset and rapid offset of pharmacologic effect. When an internist prescribes an antihypertensive, for example, the fact that a few days may be required for establishment of a steady-state therapeutic effect is of little consequence. Similarly, when terminating therapy, the necessity to wait a few days to achieve complete dissipation of drug effect is usually of no clinical importance.

Anesthesiologists, in contrast, must respond to the dynamic needs of patients under anesthesia during which the optimal degree of central nervous system depression can vary widely and frequently, requiring continuous adjustment of drug concentrations. In addition, the anesthesiologist must respond to the practical realities of modern medical practice in terms of operating room efficiency and the outpatient revolution; the anesthesiologist must rapidly anesthetize the patient and then quickly reanimate him or her when the surgeons have finished their work, enabling the patient to transition quickly through the recovery process in preparation for going home. Thus optimal anesthesia posology exists at the nexus of at least three domains: safety, effectiveness, and efficiency. Most other therapeutic areas in medical practice are not constrained by this efficiency imperative (Fig. 2.1).

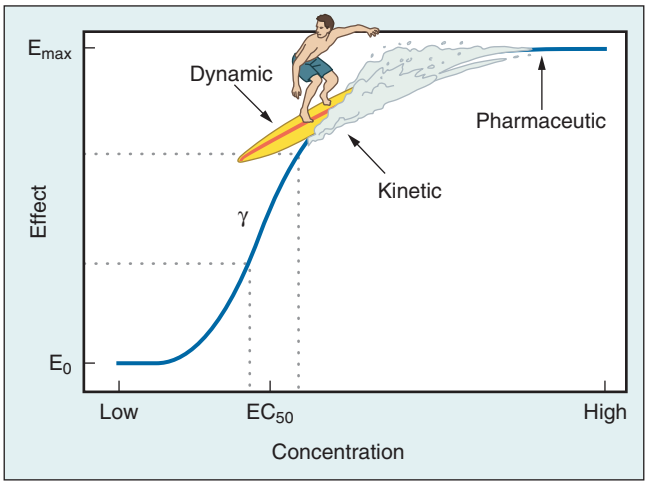
In summary, the profound physiologic alterations of the anesthetized state (and their reversal) must be produced on demand to ensure the rapid achievement and maintenance of the anesthetic state intraoperatively with return of responsiveness, spontaneous ventilation, and other vital functions at the appropriate time. To achieve this degree of pharmacologic control, anesthesiologists in the modern era increasingly rely on the application of advanced PK-PD concepts and technology to formulate and implement rational dosing schemes.[14,15] In addition, anesthesiologists take advantage of drugs that were specifically developed to address the unique concerns of anesthesia pharmacology (i.e., drugs with rapid onset and predictable offset of effect).[4]

A Surfing Analogy as a Simple Conceptual Framework

A surfing analogy is helpful in simply conceptualizing how PK-PD principles can be applied to the problem of rational drug administration in anesthesia.[16] The anesthesiologist typically targets the upper portion of the steep part of the concentration-effect relationship; that is, the concentration that produces considerable drug effect but from which drug effect will recover quickly once drug administration is terminated. This can be visualized as a surfer riding near the crest of a wave as in Fig. 2.2. Targeting ("surfing") the steep portion of the concentration-effect relationship makes it



• **Fig. 2.1** Venn diagrams comparing the posology of most therapeutic areas with anesthesia therapeutics. In most therapeutic areas (A), there is considerable overlap between safe doses and effective doses. In contrast, in anesthesia practice the overlap between safe doses and effective doses is much smaller (B). In addition, anesthesiologists must also adjust the dosage to achieve practical efficiency (see text for full explanation). (Adapted with permission from Kuck K, Egan TD. Getting the dose right: anaesthetic drug delivery and the posological sweet spot. *Br J Anaesth*. 2017 1;119(5):862-864.)



• **Fig. 2.2** A surfing analogy as a graphical explanation of how anesthesiologists use a combination of three approaches (i.e., pharmacokinetic, pharmacodynamic, and pharmaceutic) to administer anesthetics to maintain the anesthetic effect while making rapid recovery possible. See the accompanying text for a detailed explanation. E_0, Effect at zero drug concentration; E_{max}, maximal drug effect; EC_{50}, concentration that produces 50% of maximal drug effect; γ, steepness of the curve. (Reproduced with permission from Egan TD, Shafer SL. Target-controlled infusions for intravenous anesthetics: surfing USA not! *Anesthesiology*. 2003;99:1039–1041.)

possible to achieve large reductions in effect with relatively small decreases in concentration.

In clinical pharmacology terms, there are essentially three approaches to targeting this area of the concentration-effect relationship. Perhaps the most straightforward among them is the PD approach, wherein a drug effect measure is used as a feedback signal to guide drug administration irrespective of the drug concentration achieved. Propofol titrated to a specific processed EEG target or a neuromuscular blocker administered to maintain a specific degree of twitch depression as measured by a peripheral nerve stimulator are examples of this PD approach.

Another common approach in targeting the steep portion of the concentration-effect relationship is the PK approach. Drawing on knowledge about the concentration-effect relationship (i.e., therapeutic windows), the PK approach targets drug concentrations that are typically appropriate for a given anesthetic application. The use of an agent specific vaporizer to deliver some fraction or multiple of an inhaled agent's minimum alveolar concentration (MAC), and the use of a TCI device to infuse propofol to a specified concentration (e.g., the Diprifusor, AstraZeneca, Cambridge, England; and others) are sophisticated examples of this approach. Of course, even in situations when an advanced delivery technology is not used, standard dosage regimens for drugs in anesthesia are devised to achieve concentrations that are within the therapeutic window based on the drug's pharmacokinetics.

A third approach to targeting the steep portion of the concentration-effect relationship can be referred to as the "forgiving drug" or "pharmaceutic" approach. The pharmaceutic approach takes advantage of the responsive pharmacokinetic profiles of modern anesthetic agents. With this approach, within the constraints of acceptable adverse effects such as hemodynamic depression, it is unnecessary to hit the target with as much precision and accuracy as with the other approaches. Because short-acting agent concentrations can be manipulated up or down rapidly, adjustments can be made quickly as suggested by PD feedback. If the empirical dosage scheme is obviously too high or too low, the anesthetist can achieve a more appropriate level of drug effect in short order. Short-acting agents essentially make it unnecessary to hit the target perfectly.

As a practical matter, of course, anesthetists combine all three approaches (i.e., the PD, PK, and pharmaceutic approaches). Typically, pharmacokinetically responsive agents are administered by advanced, target-controlled delivery devices according to PD feedback. Adjusting the propofol TCI target based on feedback from a processed EEG brain function monitor is an example of this combined approach to anesthesia drug delivery. The pharmacologic science underpinning this three-pronged approach to rational drug selection and administration for intravenous anesthesia is the focus of this chapter.

Clinical Pharmacology

Posology

Although defining exactly what comprises the field of "clinical pharmacology" is challenging,[17] it consists of numerous branches, including pharmacokinetics, pharmacodynamics, toxicology, drug interactions, and clinical drug development. Defined in general terms, clinical pharmacology is the branch of pharmacology concerned with the safe and effective use of drugs. Articulated in a more practical way, the ultimate goal of clinical pharmacology is the translation of the relevant pharmacologic science into rational drug selection and dosing strategies.

Posology, although a little used term, is the science of drug dosage and is thus also a branch of clinical pharmacology (or perhaps a synonym). Combining the Greek words *posos* (how much) and *logos* (science), posology can be thought of more simply as "dosology." In the posology of anesthesia, the fundamental question "What is the optimal dose for my patient?" has numerous, clinically important permutations as shown in Table 2.2. All of these questions

have obvious clinical relevance in the day-to-day practice of anesthesia.

The accurate and precise prediction of the time course and magnitude of drug effect is the primary pharmacology-related task of anesthesia. Given the unique challenges of anesthesia pharmacology, one could argue that pharmacokinetics and pharmacodynamics are perhaps more relevant in anesthesia than in any other therapeutic area of medicine. Indeed, despite the conspicuous unpopularity of these mathematically oriented fields among anesthesia practitioners, perhaps without conscious acknowledgment, anesthesiologists are real-time clinical pharmacologists applying PK-PD principles to the optimization of anesthetic posology (and the myriad posologic questions suggested by Table 2.2).

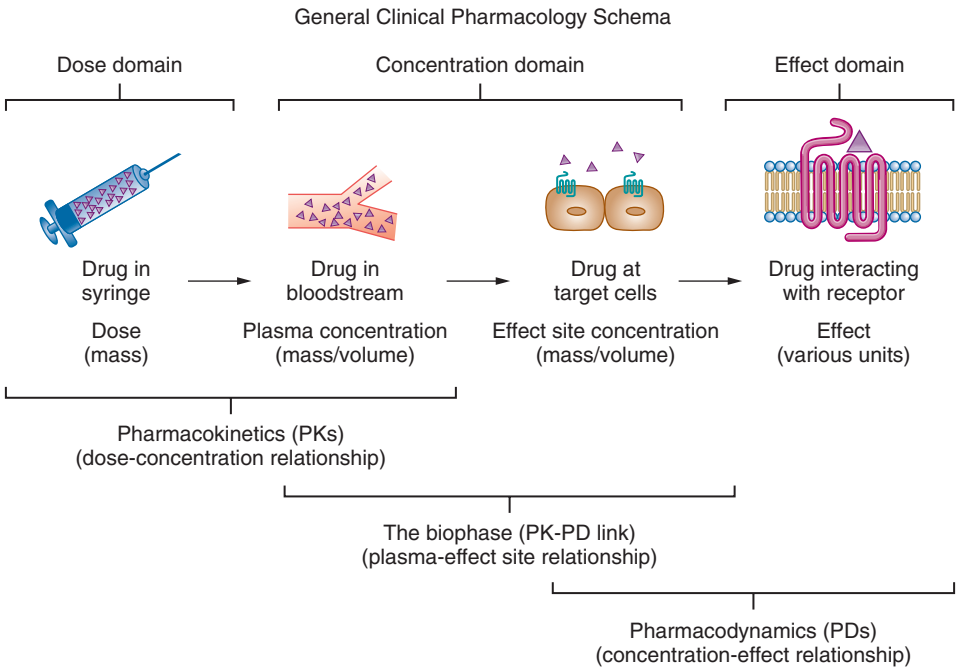
TABLE 2.2 Selected Clinically Important Questions in the Posology of Anesthesia

- What is an appropriate initial dose?
- How soon will the intended effect begin?
- When will the effect peak?
- How long will the effect last?
- Should the drug be given by bolus or infusion or both?
- When will repeat bolus doses or infusion rate changes be necessary?
- When should drug administration stop to promote timely emergence?
- What are the typical therapeutic target concentrations?
- What are the expected consequences of underdosing or overdosing?
- Will tolerance develop?
- What factors might alter the dosage requirement (e.g., demographic, pathologic, genomic)?
- What is the expected amount of variability in drug response?
- How will drug interactions influence outcome?

General Schema

A general schema summarizing a framework for understanding clinical pharmacology is presented in Fig. 2.3. The topic can be considered clinically from three domains: the dosage, concentration, and effect domains. Similarly, the underlying science can be divided into three areas of study: pharmacokinetics, the biophase, and pharmacodynamics. Before advances in clinical pharmacology the clinician could consider only the adequacy of intravenous anesthetic therapy in terms of dosage or effect (i.e., without the aid of a computer model, predicted concentrations in the plasma and effect site were not available and thus the concentration domain was unknowable). Likewise, before the development of modern pharmacologic modeling theory, the three distinct disciplines of clinical pharmacology (i.e., pharmacokinetics, the biophase, and pharmacodynamics) were naively lumped together in the study of the dose-response relationship.

From the practitioner's standpoint, the adequacy of therapy can be considered in any of the three clinical domains. Is the dosage adequate? Are the predicted concentrations adequate? Is the intended effect adequate? From the scientist's perspective, the answers to these clinically oriented questions are grounded in the principles of pharmacokinetics, pharmacodynamics, and the biophase. For some drugs (now mostly older drugs), because a suitable PK model does not exist, consideration of the concentration domain cannot contribute to therapeutic decisions. Similarly, because for some drugs the measurement of drug effect in real time is difficult (e.g., opioids in unresponsive, mechanically ventilated patients), consideration of the effect domain plays a lesser role in guiding therapy.



• **Fig. 2.3** A general schema of clinical pharmacology divided into dose, concentration, and effect domains. The science underpinning the field can be divided into the disciplines of pharmacokinetics, pharmacobiophasics, and pharmacodynamics. See the accompanying text for a detailed explanation. The *purple triangles* represent drug molecules. *PDs,* pharmacodynamics; *PKs,* pharmacokinetics.

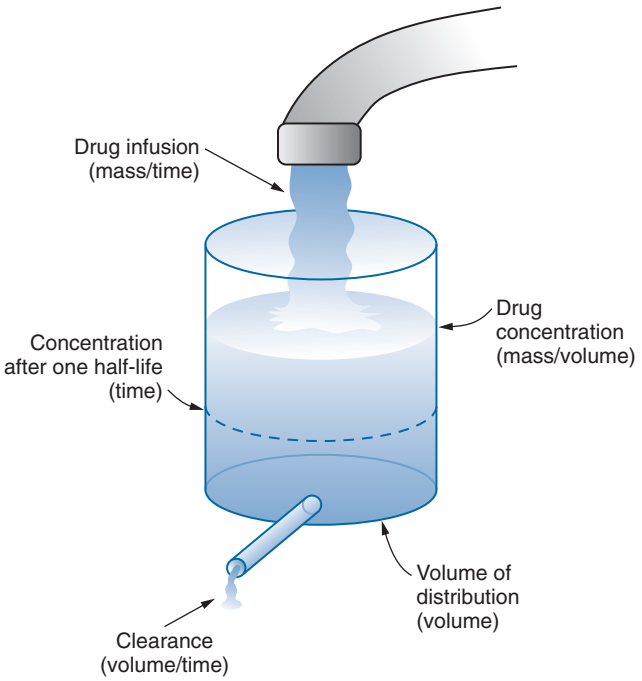
Consider the fate of drug molecules as summarized in Fig. 2.3. The anesthesiologist administers the desired dose intravenously using a handheld syringe or pump (the dose domain). The drug is then distributed via the circulation to body tissues and eventually eliminated through biotransformation and/or excretion according to the drug's pharmacokinetics. The predicted plasma (or blood) concentration versus time profile can be the basis of therapeutic decisions regarding subsequent doses (the concentration domain), although the plasma concentration is sometimes misleading because it might not be in equilibrium with the site of action. Meanwhile, some very small fraction of the administered drug is distributed from the blood to the target cells in the effect site or biophase according to the drug's biophase behavior. The predicted concentration in the effect site (also the concentration domain) is a more reliable indicator of the adequacy of therapy than is the blood concentration because the target receptors are always in equilibrium with this concentration. Finally, the drug molecules in the biophase interact with the relevant receptors, producing the intended effect (the effect domain). For drugs with easily measurable effects, the dose and concentration domain are obviously less relevant to successful therapy because drug effect is the ultimate goal of therapy; when there is a reliable, real-time effect measurement, the drug can be administered to the targeted level of effect irrespective of what the dose or predicted concentration may be.

Pharmacokinetics

Pharmacokinetics is typically defined in introductory pharmacology courses as "what the body does to the drug." A much better and clinically useful definition is the study of the relationship between the dose of a drug and the resulting concentrations in the body over time (the dose-concentration relationship; see Fig. 2.3). In simple terms, pharmacokinetics is the drug's disposition in the body.

Commonly considered PK parameters include distribution volumes, clearances, and half-lives; other, less intuitively meaningful PK parameters such as microrate constants are mathematical transformations of these more common parameters.[18] A simple hydraulic model representation of these fundamental parameters for a one-compartment model is presented in Fig. 2.4. The pharmacokinetics of most anesthetic drugs are described by more complex models with two or three compartments (see also "PK-PD Model Building Methods" in later text). When conceptualized in terms of an hydraulic model, of course, multicompartment models consist of additional containers (i.e., volumes) connected to the central volume by pipes of varying sizes.

Distribution volumes, expressed in units of volume such as liters or liters per kilogram, are "apparent" in that they are estimated based on the volume of water into which the drug appears to have distributed; they do not represent any actual volume or anatomic space within the body. Clearance parameters, expressed in units of flow such as liters per minute or liters per kilogram per minute, simply quantify the volume of plasma from which the drug is completely cleared per unit of time. For drugs with a very high hepatic extraction ratio (i.e., the liver biotransforms almost all the drug delivered to it), the central clearance is nearly equal to hepatic blood flow (e.g., about 1 L/min). Half-lives, perhaps the most commonly known PK parameter, are expressed in units of time and represent the time required for the concentration to decrease by 50% after drug administration has ceased. Half-life varies directly with volume of distribution and inversely with clearance; these relationships make intuitive sense given that a larger volume will take longer to clear and that a higher clearance will obviously speed the decline of drug levels.

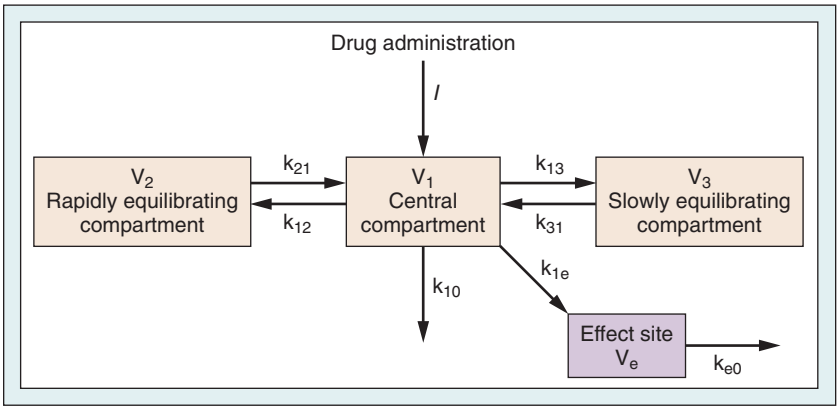


• **Fig. 2.4** A hydraulic representation of a one-compartment pharmacokinetic (PK) model simply illustrating various PK parameters. Water running from the faucet into the container represents an infusion of drug. The size of the container represents the volume into which the drug will distribute (i.e., the volume of distribution). The height of the water level is the drug concentration. The water flowing out of the pipe at the bottom of the container represents drug elimination (i.e., clearance). The half-life of the drug after the infusion is stopped is also shown.

Pharmacodynamics

Pharmacodynamics is typically defined as "what the drug does to the body." A better definition is the study of the relationship between the concentration of the drug in the body and its effects (i.e., the concentration-effect relationship; see Fig. 2.3). In straightforward terms, pharmacodynamics is a description of drug effects, both therapeutic and adverse.

Particularly important PD parameters include potency and the steepness of the concentration-effect relationship (see "PK-PD Model Building Methods" in later text). Expressed in units of mass per volume (e.g., micrograms per milliliter; nanograms per milliliter), potency is usually estimated as the concentration required to produce 50% of maximal effect, often abbreviated as the C_{50} (sometimes called the EC_{50}, the effective concentration producing 50% of maximal effect; see Fig. 2.2). Obviously, the lower the EC_{50}, the more potent is the drug. The EC_{50} is important in determining the range of target concentrations that will be necessary for effective therapy (i.e., the therapeutic window). The steepness of the concentration-effect relationship is typically quantified by a parameter called *"gamma,"* a unitless number that reflects the verticality of the concentration-effect relationship. A highly vertical concentration-effect relationship (i.e., large gamma) means that small changes in drug concentration are associated with large changes in drug effect; some groups of drugs (e.g., opioids) have steeper concentration-effect relationships than others.[19]



• **Fig. 2.5** A schematic representation of a three-compartment model with an effect compartment attached to the central compartment to account for the equilibration delay between concentration in the central compartment and drug effect. *I*, Drug input; k_{12}, k_{13}, and so on, rate constants characterizing drug movement between compartments and out of the system; k_{e0}, rate constant for drug elimination out of the effect compartment; V_1, V_2, and so on, compartment volumes. See the accompanying text for a detailed explanation.

The Biophase

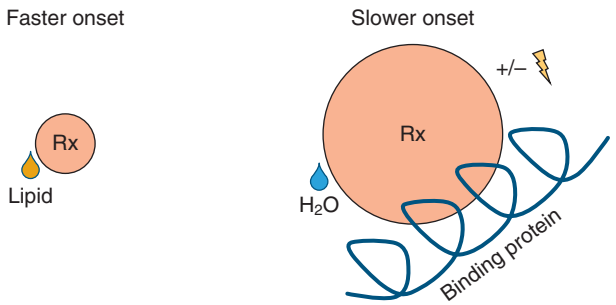
The biophase concept is a nuance of clinical pharmacology that is perhaps not as widely covered in pharmacology courses because its clinical application is most relevant to just a few acute care disciplines like anesthesiology. "Pharmacobiophasics," a neologism not in common usage (coined by author TDE), is the study of drug behavior in the biophase. The biophase is the site of drug action, often referred to as the *effect site* (e.g., target cells and receptors within the brain, the neuromuscular junction, the spinal cord).

The biophase concept is essential to clinical anesthetic pharmacology because during non–steady-state conditions (i.e., after a bolus injection or an infusion rate change) the concentration of drug in the blood does not correlate well with drug effect. After a bolus injection, compartmental models predict that peak plasma drug concentration occurs immediately (i.e., a key "well stirred" model assumption), and yet peak drug effect does not occur immediately. This is because most drugs do not exert their effect in the blood; rather, they must be delivered to the site of action (i.e., the biophase) before they can elicit the desired therapeutic effect. Thus predictions regarding the magnitude of drug effect based on plasma concentrations can be misleading, particularly when plasma drug concentrations are rapidly changing such as after a bolus injection.

As originally proposed by investigators working with d-tubocurarine and pancuronium,[9,20,21] the biophase (effect site) concept has revolutionized the ability to predict the time to maximal drug effect during non–steady-state conditions. As shown in Fig. 2.5, incorporating a theoretical "effect compartment" into a standard compartmental PK model enables characterization of the plasma-biophase equilibration process. It is the central compartment concentration (i.e., the concentration in the arterial blood) that drives the concentration in the effect site.

The key pharmacobiophasics parameter, expressed in units of inverse time, is a rate constant called k_{e0} (see "PK-PD Model Building Methods" in later text).[9,20,22] The k_{e0} characterizes the rate of equilibration between plasma and effect site concentrations. When k_{e0} is known for a drug, it is possible to predict the time course of "apparent" effect site concentrations based on the time course of plasma concentration. These effect site concentrations correlate directly with drug effect. Thus the biophase can be viewed as the link between drug disposition in the blood (pharmacokinetics) and drug effect at the site of action (pharmacodynamics).

The time required to achieve peak effect site concentration after bolus administration is a function of the drug's physicochemical properties in vivo. Small, lipid-soluble, un-ionized, unbound molecules (i.e., drugs with a high "diffusible fraction") reach peak effect site concentration more rapidly than larger, less lipid-soluble, charged, highly protein-bound drugs (Fig. 2.6). For drugs that achieve a peak effect site concentration more slowly, the onset of therapeutic effect can be hastened with higher doses (see Fig. 2.16).



• **Fig. 2.6** A schematic representation of the physicochemical properties that hasten or slow the achievement of peak effect site concentration. Small, lipid-soluble, un-ionized, unbound molecules reach peak effect site concentration more rapidly. Molecular weight, the octanol-water partition coefficient, pKa, and the percent protein bound are the parameters that quantify these physicochemical properties. *Rx* indicates a drug molecule. The lipid droplet indicates high lipid solubility. The *H_2O* droplet represents high water solubility. The *+/– lightning bolt* indicates a charged molecule. The *ribbon-like structure* represents a protein binding molecule such as albumin.

Drug Interactions

In anesthesiology, unlike most medical disciplines, PD drug interactions are frequently produced by design. Anesthesiologists take advantage of the PD synergy that results when two drugs with different mechanisms of action but similar therapeutic effects are combined.[23] These synergistic combinations can be advantageous because the therapeutic goals of the anesthetic can often be achieved with less toxicity and faster recovery than when individual drugs are used alone in higher doses. In fact, except for specific, limited clinical circumstances in which a volatile agent or propofol alone is an acceptable approach (e.g., a brief procedure in a pediatric patient such as tympanostomy tubes or radiation therapy), modern-day anesthesia involves at least a two-drug combination consisting of an analgesic (typically an opioid) and an hypnotic (e.g., an inhaled agent or propofol).[24] Therefore from a strictly pharmacologic perspective, anesthesiology can be thought of as the practice of PD synergism using central nervous system depressants.

Because anesthetics are rarely administered alone, understanding the interactions between drugs is critical to their safe and effective use.[25,26] Although PK interactions (i.e., where one drug alters the concentration of another) are sometimes observed in select clinical circumstances,[27] PD interactions are an important part of nearly every anesthetic. This topic is of such importance in anesthesia pharmacology that an entire chapter is devoted to it (see Chapter 6); a limited discussion is included here.

The study of drug interactions in anesthesiology has traditionally been approached using the "isobologram" method.[28,29] An isobologram is a curve defining the concentrations of two drugs that, when given together, produce the same effect (the isobole is an "iso" or "equal" effect curve). Perhaps the most common example of an isobole in anesthesiology is a plot showing the reduction in the MAC of an inhaled agent produced by an opioid.[30,31] The main limitation of an isobologram is that the curve applies to only one level of drug effect. This is a problem in anesthesiology because during anesthesia patients experience a spectrum of drug effect ranging from minimal sedation to profound central nervous system depression.

Response surface methods address this shortcoming of the isobologram. The response surface approach creates a three-dimensional plot of the two drug concentrations (e.g., propofol and fentanyl) versus drug effect (e.g., sedation), quantitatively describing the PD interaction of the two drugs (see Chapter 6). The response surface method is an advance because it describes the drug interaction over the entire range of drug effect and thereby enables simulation from one clinical state to another. This is critical in anesthesia pharmacology because anesthesiologists must take the patient from the awake to the anesthetized state, and then back to the awake state again on demand.[4,16] Response surface methods yield a set of parameters that indicate whether the interaction is additive, synergistic, or antagonistic.

Pharmacologic Modeling

PK-PD Models as Versions of Pharmacologic Reality

Scientific models seek to represent empirical objects, biologic phenomena, or physical processes in a coherent and logical way. Models are a way of thinking about and understanding the natural world; models are essentially a simplified version of reality intended to provide scientific insight.

By providing a framework for understanding the natural world, models can also be a means of creating new knowledge. Knowledge from models comes in many forms, each with certain advantages and limitations. In biomedical science, for example, models of physiologic processes conducted in test tube experiments provide in vitro knowledge wherein confounding variables can be carefully controlled. Experiments conducted in animal models of disease provide in vivo insight that reflects biologic reality at the whole animal level. Since the advent of computational scientific methods, models of natural phenomena are often represented as a mathematical system (an equation or set of equations); these mathematical models provide in silico understanding, meaning that experiments that might be practically impossible or too expensive in actual subjects can be conducted by computer simulation.

PK-PD models are examples of this kind of mathematical model applied to clinical pharmacology.[32] Various equations are used to represent the pharmacologic processes of interest.[2] Although a PK-PD model is a gross oversimplification of reality (e.g., the body is not a set of three containers connected by pipes as suggested in Fig. 2.5), considerable insight into drug behavior has come from the application of PK-PD models to important questions in anesthesia pharmacology. When applying PK-PD models through simulation, rather than conducting the experiment in a test tube (in vitro) or in an experimental animal (in vivo), the experiment is conducted in the computer (in silico) on a virtual subject or subjects.

It is axiomatic that the true utility of a pharmacologic model is a function of its performance in the real world. Clinically useful models adequately describe past observations and satisfactorily predict future observations. Among scientists involved in all kinds of modeling, it is often quipped that "all models are wrong, but some models are useful!"[33] There is no question that PK-PD models, despite their limitations, are very useful in refining the posology of anesthesia practice.[14,15]

PK-PD Model Building Methods

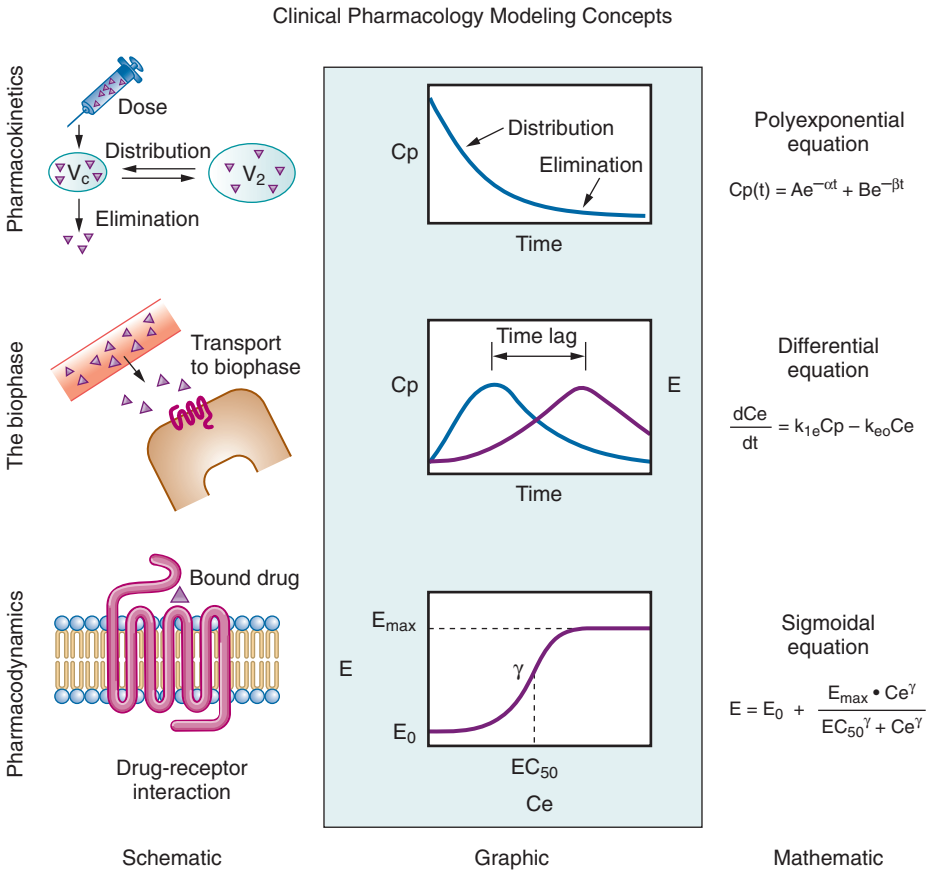
A summary of the PK-PD model building process is outlined in Fig. 2.7. The process, of course, begins with the gathering of the raw data in appropriately designed experiments.[34,35] Elements of a well-designed PK-PD modeling experiment for an intravenous anesthetic include careful attention to the administered dose by infusion[15]; frequent, prolonged sampling of arterial blood for concentration measurement[36,37];use of a quality-assured, validated drug assay; and administration of sufficient drug to elicit maximal or near-maximal effect (but not too rapidly).[20] Without quality raw data it is impossible to characterize the pharmacologic system using modeling techniques.

Because the mathematics involved in PK-PD modeling can be complex, it is perhaps best for the clinician to consider the modeling methods from other perspectives.[38] As shown in Fig. 2.7, approaching the modeling process from schematic and graphic perspectives makes the mathematics less intimidating for non-mathematicians. Ultimately the mathematical equations involved are simply quantitative expressions of the ideas and concepts represented by the schematic diagrams and plots.

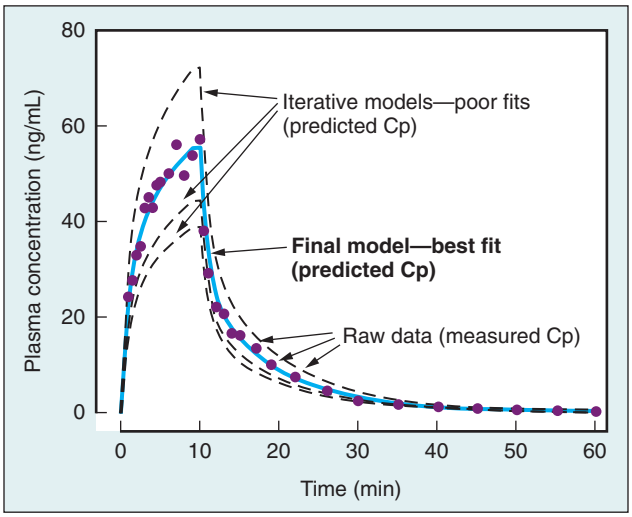
Schematically, basic PK processes are well represented by a compartmental model (see upper panel of Fig. 2.7). After injection into the central compartment, a drug is either distributed to other compartments or is eliminated from the central compartment altogether. Graphing these PK processes reveals the distinct distribution and elimination phases typically observed in plasma concentration decay curves. Curves of this general shape can be represented by polyexponential equations of the form shown in upper panel of Fig. 2.7.[39]

Fig. 2.8 summarizes how raw PK data from a single subject might be modeled in a typical PK model building experiment. Using nonlinear regression techniques, a polyexponential equation is fit to the raw concentration versus time data.[40] This is an iterative process in which the nonlinear regression software alters the parameters of the equation repeatedly until the "best model" is obtained, thereby estimating the PK parameters of the model (i.e., distribution volumes, clearances, microrate constants).[41] The best model is one that fits the data well (e.g., minimizes the difference between the measured concentration and the concentration predicted by the model).[42] The PK model enables prediction of the time course of drug concentrations in blood or plasma.

Biophase behavior and pharmacodynamics can be modeled in generally the same way. When the biophase is considered schematically, the delay between peak plasma concentration and peak drug effect is a function of the time required for drug delivery to the site of action (middle panel of Fig. 2.7).[10] This delay (or hysteresis



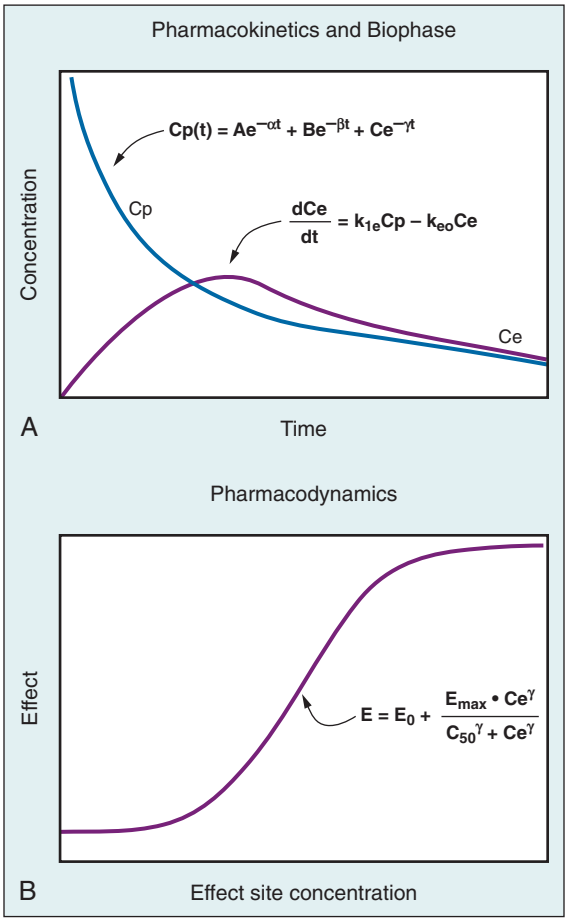
• **Fig. 2.7** A summary of clinical pharmacology modeling concepts for the disciplines of pharmacokinetics, the biophase, and pharmacodynamics. The modeling foundation for each area is presented schematically, graphically, and mathematically. The purple triangles represent a drug. See the accompanying text for a detailed explanation, including discussion of the equations. *Ce,* effect site concentration; *Cp*, plasma concentration; *E,* effect; E_0, effect at zero drug concentration; E_{max}, maximal drug effect; EC_{50}, concentration that produces 50% of maximal drug effect; γ, steepness of the curve.



• **Fig. 2.8** An example of fitting a model (a polyexponential equation in this case) to raw pharmacokinetic (PK) data from a single experimental subject. The measured plasma concentrations (i.e., the raw data) are represented by the *pink circles.* Preliminary models (i.e., poor fits) generated during the iterative, nonlinear regression process are shown as *dotted lines.* The final model (i.e., best fit) is shown as a *thick, blue line.* The thick, blue line thus represents the predicted concentrations according to the PK model. See the accompanying text for a detailed explanation.

in engineering terms) is represented by a simple plot showing a time lag between peak plasma concentration and peak effect, and can be characterized by a simple differential equation of the general form shown. Using nonlinear regression and other techniques, the biophase modeling process estimates the key biophase model parameter called k_{e0} (see previous text).[9,22] The biophase model enables prediction of effect site concentrations.

These effect site concentration predictions are essential for the PD modeling process. Considered schematically, the PD system is represented by a drug molecule interacting with a target receptor (bottom panel of Fig. 2.7). This drug-receptor interaction is represented graphically by a sigmoidal curve. In the absence of drug, the level of biologic effect is at baseline (E_0). As drug concentration in the effect site (predicted from the biophase model) increases, eventually some drug effect is produced. As the steep portion of the concentration-effect relationship is approached, more pronounced degrees of drug effect are observed. Further increases in drug concentration produce greater and greater effect, eventually reaching the biologic maximum (E_{max}). This sigmoidal curve is represented by equations of the general form shown in the bottom panel of Fig. 2.7. Using nonlinear regression techniques such as those illustrated in Fig. 2.8, the PD modeling process fits the sigmoidal equation to the raw PD data, thereby estimating the parameters of the equation. Combined with the PK and biophase model, the PD modeling process enables prediction of the time course of drug effect.



• **Fig. 2.9** Basic equations for modeling drug plasma concentration *(Cp)*, effect site concentration *(Ce)*, and effect. These equations (or various transformations of these equations) are the mathematical basis for pharmacokinetic-pharmacodynamic modeling. The equations represent curves of the appropriate shape to characterize the raw data. See text for complete explanation. *Ce,* effect site concentration; *Cp*, plasma concentration; E_0, effect at zero drug concentration; E_{max}, maximal drug effect; C_{50}, concentration that produces 50% of maximal drug effect;

In summary, PK-PD model building is an exercise in fitting appropriate equations to experimental data using nonlinear regression modeling software and other related techniques.[41] As summarized in Fig. 2.9, the mathematical equations simply represent the general shape of the relationships being modeled. A polyexponential equation is typically used to characterize the plasma concentration decay curve. A differential equation is the basis for modeling the delay between equilibration of plasma and effect site concentration. A sigmoidal equation is used to characterize the concentration-effect relationship. Fitting the equations to the raw data results in a set of PK-PD parameter estimates that constitute the quantitative model.[18] These parameters can then be used to conduct PK-PD simulations to explore the clinical implications of the models. It is important to emphasize that the iterative, nonlinear regression process yields only parameter "estimates;" the true values of the parameters are unknowable.[a]

It is of course possible to fit these equations to an individual subject's data and also to a group of subjects' data. Because a main thrust of PK-PD modeling is to characterize drug behavior in the population for which it is intended, a primary focus of modeling is to build a model that represents the entire population (not just an individual).[35] Special techniques such as "mixed-effects" modeling (e.g., the NONMEM program and others)[43,44] have been developed and refined to estimate typical PK-PD parameter values for an entire population (and also the intersubject variability of the parameters).[45] Sophisticated methods to quantify the influence of "covariate" effects (e.g., age, body weight, metabolic organ failure, among others) on the PK-PD system have also been described.[46]

Limitations in Building & Applying PK-PD Models

As simplified versions of reality, PK-PD models fail to account for certain biologic complexities. In selected situations, these complexities make it difficult or impossible to apply PK-PD models in a useful way. Thus intelligent construction and application of PK-PD models requires awareness of their limitations.

Early Model Misspecification

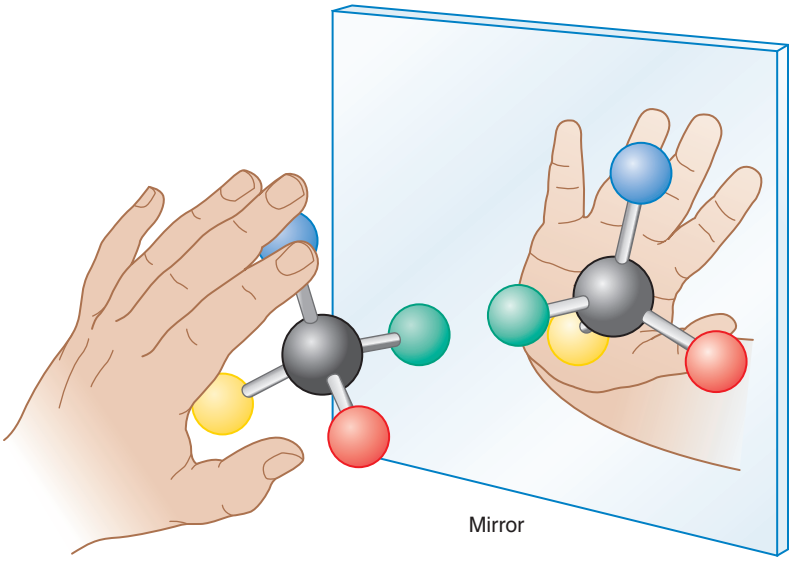
A major shortcoming of the standard compartmental PK model is a function of model misspecification during the early period after drug injection.[47] Standard compartmental models assume the central volume is well stirred and that peak plasma concentration occurs immediately after injection, an assumption that is obviously invalid. Similarly, standard compartmental models assume that plasma concentration declines monotonically after it reaches a peak; although perhaps less obvious, this assumption is also false.[48] Careful study of the early period after drug injection confirms that standard compartmental models sometimes do not reliably predict drug disposition in the first few minutes after injection.[47] Model misspecification is important because anesthetics are often intended to exert their most profound effects very soon after a bolus is administered.[49]

The reasons underpinning this model misspecification in the period shortly after bolus injection are numerous and include the influence of cardiac output on drug distribution, the appearance of a "recirculatory," second concentration peak (after the first circulation time), and pulmonary uptake of drug, among others.[48,50,51] These limitations of compartmental models can be addressed with more complex physiologic and recirculatory models,[52–55] although standard compartmental models are more commonly applied clinically despite their sometimes poor performance. These more physiologically based PK modeling approaches have identified factors that influence anesthesia induction doses, such as age, cardiac output, and concomitant use of drugs that alter cardiac function.[50,56,57]

Stereochemistry

Chirality in molecular structure introduces substantial complexity in characterizing drug behavior with PK-PD models if the chiral drug is studied as a racemate.[58] Taken from the Greek word *chier* (meaning hand), "chiral" is the term used to designate a molecule that has a center (or centers) of three-dimensional asymmetry. The appropriateness of the term's Greek origin is clear when considering that a pair of human hands are perhaps the most common example of chirality (Fig. 2.10). Although they are mirror images of each other, a pair of hands cannot be superimposed. Similarly, chirality in molecular structure results in a set of mirror image molecular twins (i.e., the two enantiomers of a racemic mixture) that cannot be superimposed. This kind of molecular handedness in biologic

[a]In this chapter, "parameter estimates" will sometimes be referred to as just "parameters."



• **Fig. 2.10** The concept of molecular chirality compared to the anatomic asymmetry of a pair of human hands. Like a pair of hands, chiral molecules are identical, mirror images of one another, but they cannot be superimposed. The molecular asymmetry of chirality is a function of the tetrahedral bonding characteristics of the carbon atom (carbon is represented in *black;* the *other colors* represent any four different groups of atoms). The two molecules shown are considered enantiomers; when combined, they constitute a racemic mixture. Chirality has important pharmacologic implications in terms of pharmacokinetic-pharmacodynamic behavior.

systems is ubiquitous in nature and is almost always a function of the unique, tetrahedral bonding characteristics of the carbon atom.[59]

Drug chirality is significant because the molecular interactions that are the mechanistic foundation of drug action and disposition occur in three dimensions and therefore can be altered by stereochemical asymmetry (see Chapter 1).[60] Thus, pharmacologically, not all enantiomers are created equal! The implications of chirality span the entire PK-PD spectrum. Enantiomers can exhibit differences in absorption and bioavailability, distribution and clearance, potency, and toxicology. When a pharmacologic process discriminates in a relative fashion between enantiomers (e.g., one enantiomer being metabolized more rapidly than the other), it is termed *stereoselective.* If the discrimination is absolute (e.g., one enantiomer being completely incapable of producing drug effect), the process is termed *stereospecific.*

The implications of chirality on PK-PD modeling are obvious. A PK-PD model of a racemic mixture is really a model of two drugs with presumably different PK and PD behavior and thus must be interpreted with caution. This "racemate" complexity applies to a surprisingly diverse array of anesthetic drugs, including thiopental, methohexital, ketamine, isoflurane, desflurane, mepivacaine, bupivacaine, ibuprofen, ketorolac, and methadone, among others.[61] It is for this reason that novel drug development in anesthesia over the past decade has avoided racemic mixtures (there is considerable pressure from regulatory bodies like the United States Food and Drug Administration to do so).[62,63] Single enantiomer formulations such as (S)-ketamine, ropivacaine, cisatracurium, and levobupivacaine are all cases in point; single enantiomer formulations often have some clinical advantage in terms of their PK and/or PD behavior, reflecting the PK-PD differences between enantiomers.[61]

Active Metabolites

When a drug has an active metabolite, applying a PK-PD model of the parent compound to predict overall drug effect is obviously problematic. Not only will the metabolite contribute to drug effect, but the metabolite will also have a different rate of concentration decay (i.e., different pharmacokinetics). The PK-PD model of the parent drug does not account for this complexity and thus the model must be applied with awareness of this shortcoming.[64] Therapeutic drug monitoring of parent drugs with active metabolites has long been known to be fraught with similar problems.[65]

This active metabolite issue applies to a number of anesthetic drugs, including diazepam, midazolam, codeine, morphine, and ketamine, among others. Particular interest in recent years has been focused on morphine's active metabolite, morphine-6-glucuronide (M6G). Because M6G accumulates in patients with altered renal clearance mechanisms (unlike the parent drug),[66,67] prolonged administration of morphine in patients with kidney failure can be complicated by severe ventilatory depression.[68] PK-PD models for morphine that also include the concentration time course and effect of the M6G metabolite provide a scientific explanation for these clinical observations.[69]

Variability

Another major shortcoming in applying PK-PD models clinically is that standard simulations using PK-PD model parameters do not typically include an expression of variability in the PK-PD predictions. As a result, from a statistical perspective, these standard simulations are being applied deterministically rather than probabilistically. Given the well-described and considerable variability in drug behavior in terms of both PK and PD relationships[70] (and that PK-PD model parameters are only estimates), this shortcoming of standard PK-PD model simulation is an important one. Applying advanced statistical methods such as Monte Carlo simulation to standard PK-PD analysis is a means of addressing this problem by providing the clinician with a sense of the expected variability in drug behavior.[71]

Pharmacologic Simulation

Unimportance of Individual PK-PD Model Parameters

In contrast to well-entrenched conventional wisdom, single PK-PD model parameter estimates considered in isolation are not very helpful in drawing clinically useful conclusions. PK-PD studies in the anesthesia literature traditionally include a table of values for PK-PD parameters such as in the left column of Table 2.3. In

the early days of PK-PD modeling, it was commonplace for investigators to make clinical inference by comparing a particular parameter value for one drug with the corresponding parameter of another drug. For example, certain clinical conclusions might have been drawn depending on how the half-lives or clearances for a pair of drugs compared.

The problem with this simplistic approach is that it fails to account for the complexity of the typical PK model. A standard three-compartment model as shown in Fig. 2.5, for example, has six fundamental parameters (i.e., three clearances and three distribution volumes); these fundamental parameters can be converted to a variety of other parameters (e.g., half-lives, microrate constants).[18] These multiple parameters interact in a complex way over time in determining the predicted drug concentration.[6,72] Thus comparing a single PK parameter value of one drug with that of another drug is of limited value and provides very little clinically relevant intuitive understanding.

TABLE 2.3 Selected Traditional Pharmacokinetic-Pharmacodynamic Model Parameters Versus Practical Model Predictions[a]

Traditional Parameters (From the Model)	Practical Model Predictions (From Model Simulation)
Pharmacokinetic	**Front-End and Back-End Bolus Behavior**
Distribution volumes	Time to peak effect after a bolus injection?
Clearances	Time to offset of effect after a bolus injection?
Half-lives	
Pharmacobiophasics	**Front-End and Back-End Infusion Behavior**
k_{e0}	Time to steady state after beginning an infusion?
Pharmacodynamic	Time to offset of effect after stopping an infusion?
E_0	**Dosage Domain Issues**
E_{max}	Dosage necessary to achieve a specified target concentration?
EC_{50}	Dosage reduction necessary when combining synergistic drugs?
Gamma (γ)	**Concentration Domain Issue**
	Concentration necessary to achieve specified effect?

E_0, Effect at zero drug concentration; *EC_{50}*, concentration that produces 50% of maximal drug effect; *E_{max}*, maximal drug effect; *gamma (γ)*, steepness of the curve; *k_{e0}*, rate constant for drug elimination out of the effect compartment.

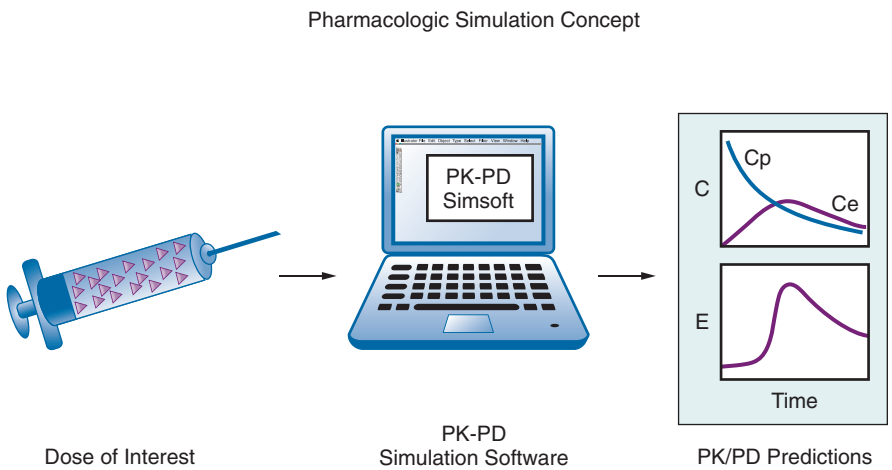
[a]Single PK-PD parameters considered in isolation are not clinically useful; predictions from model simulations are very useful (see text for complete explanation).

Importance of PK-PD Model Simulation

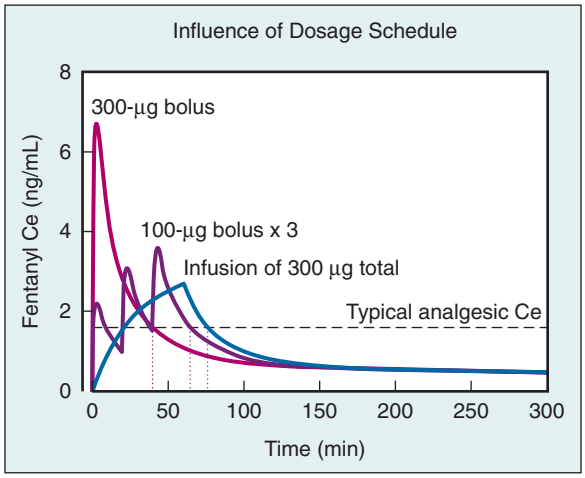
Understanding the clinical implications of a table of PK-PD parameters is best accomplished through in silico application of the associated model by computer simulation.[73] Through simulation, the practically oriented clinical questions shown on the right column of Table 2.3 (among many other questions) can be explored and answered. In contrast to a table of parameter values, PK-PD model simulation provides straightforward, clinically oriented information that the practitioner can apply in actual practice.[38]

The PK-PD model simulation process is summarized in Fig. 2.11. Using PK-PD model simulation software, the user inputs a dosing scheme of interest. The simulation software predicts the time course and magnitude of drug concentration and effect according to the model. An infinite number of such simulations can be performed in silico to gain insight into anesthesia posology. When presented graphically, the results of PK-PD simulations provide a picture of the time course of drug concentration and effect. Most commonly, drug effect site concentrations are simulated. Combined with knowledge about the concentration-effect relationship (i.e., pharmacodynamics), clinical insight into optimal dosing is gained.[74]

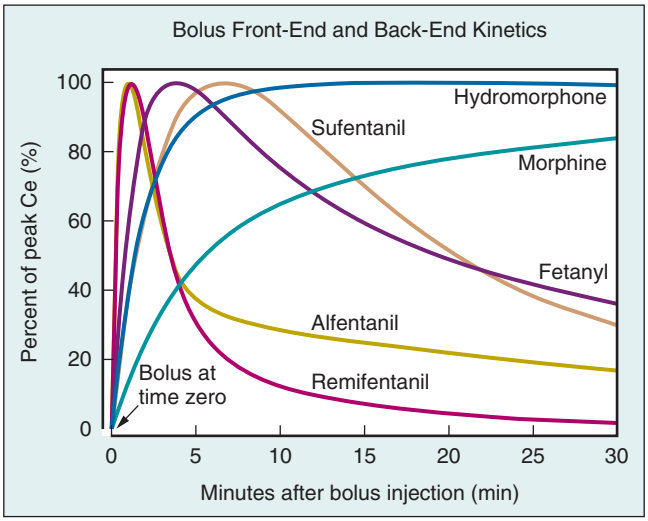
The simulation in Fig. 2.12 illustrates the power of PK-PD simulation in terms of intuitively understanding the implications of various dosing schemes. The simulation depicts the very different time courses of drug concentration in the biophase when identical total doses of fentanyl (i.e., 300 µg) are administered in three different ways. By providing a simple picture of how a specified dosing scheme translates into effect site concentrations over time (and how the resulting concentration versus time profile compares to therapeutic windows), PK-PD simulation constitutes a powerful tool to study and optimize anesthesia posology.



• **Fig. 2.11** A simple representation of the concept of a pharmacokinetic-pharmacodynamic (PK-PD) model simulation. Using PK-PD model simulation software (called "PK-PD Simsoft" in this figure just for illustration purposes; PK-PD Simsoft is not an actual product), the user inputs a dosing scheme of interest. The simulation software predicts plasma concentrations *(Cp)*, effect site concentrations *(Ce)*, and effect *(E)* according to the parameters of the PK-PD model. In this diagram, PK-PD Simsoft is a fictitious simulation software product. See the accompanying text for a detailed explanation.



• **Fig. 2.12** A pharmacokinetic simulation of predicted fentanyl effect site concentrations *(Ce)* resulting from three different regimens to administer 300 µg of fentanyl (a single 300-µg bolus, three 100-µg boluses every 20 minutes, an infusion of 300 µg at a constant rate over 1 hour). The *horizontal dotted line* indicates a typical analgesic fentanyl level. The *colored vertical dotted lines* represent the time at which the fentanyl concentration falls permanently below the typical analgesic level. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[107]



• **Fig. 2.13** A simulation exploring bolus injection front and back-end pharmacokinetic behavior for a variety of commonly used opioids. For comparison purposes, the effect site concentrations *(Ce)* are normalized to the percentage of the peak. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[69,107–113]

PK-PD Model Simulation and Anesthesia Posology

Exploring anesthesia posology through PK-PD simulation equips the practitioner with the knowledge necessary to formulate rational drug selection and administration schemes. Although the possibilities are endless in terms of the number and variety of PK-PD simulations that can be performed, a limited set of straightforward simulations form the foundation on which the answers to many routine anesthesia posology questions are based.

Among this fundamental set of simulations, perhaps the most important are those that address the front-end and back-end PK behavior of intravenous anesthetics. Because drug behavior is substantially different for bolus injections compared with infusions,[7] the two conditions must be considered separately. Other fundamental simulations include the influence of dose on the onset and offset of effect after bolus injection, the influence of dose on the front and back-end kinetics of infusions, the influence of special populations on drug behavior, and the influence of a second drug on PD effect.

Bolus Front-End and Back-End Kinetics

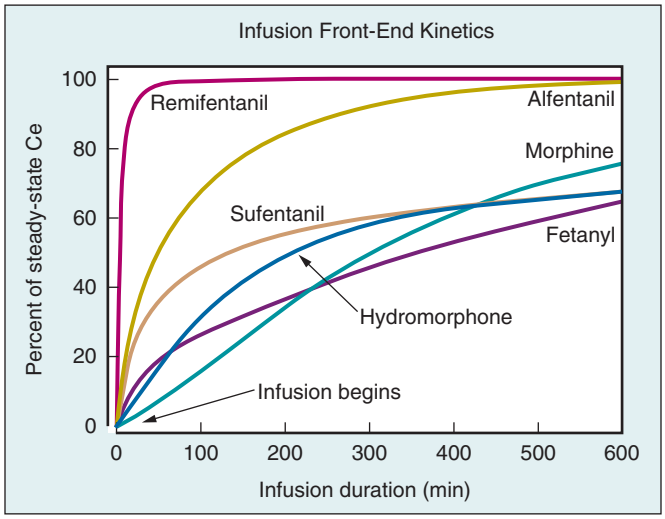
As noted in Table 2.2, important posologic questions regarding bolus injections include "How long will it take to reach peak effect and how long will it take for the effect to dissipate?" The simulations plotted in Fig. 2.13 explore these questions for a number of commonly used opioids. After bolus injection, remifentanil and alfentanil predicted effect site concentrations reach a peak quickly and then decline significantly before any of the other opioids have even begun to peak. This rapid achievement of peak effect site concentrations for these two highly lipid-soluble fentanyl congeners is likely a function of their high "diffusible fractions" (i.e., the proportion that is un-ionized and unbound — see Fig. 2.6). Interestingly, morphine's front-end kinetics are notably different. Morphine does not approach a substantial fraction of the ultimate peak until 20 to 30 minutes have elapsed.

The simulations depicted in Fig. 2.13 have obvious clinical implications. When a brief pulse of opioid effect followed by a quick offset is desirable (such as a brief period of intense analgesia before injection of local anesthetic during a regional block), remifentanil or alfentanil would be rational choices. In contrast, when the clinical situation calls for a slower onset followed by a more sustained period of opioid effect, one of the other opioids may be more appropriate. Given the lockout period of a typical patient-controlled analgesia (PCA) dosing regimen, it is surprising that morphine has been the mainstay of PCA therapy; fentanyl's latency to peak effect of 4 to 5 minutes is much more favorable for PCA, particularly in terms of avoiding a "dose stacking" problem wherein the patient requests additional doses before the prior doses have reached their peak effect.

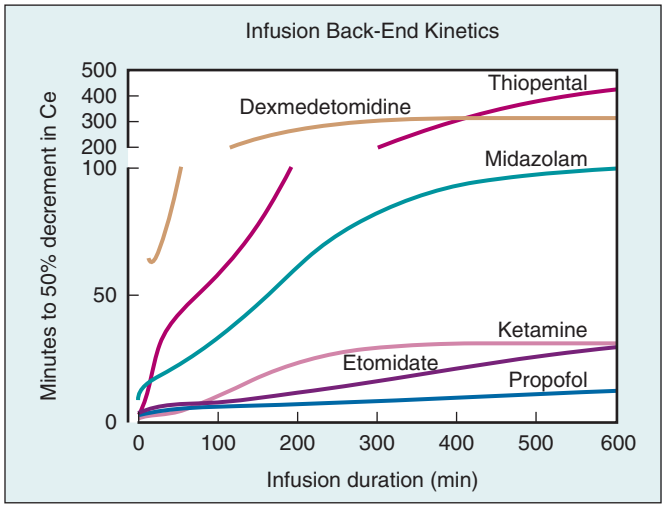
Infusion Front-End Kinetics

The relevant questions concerning the posology of anesthetic infusions are similar to those for bolus injections (see Table 2.2). The simulations plotted in Fig. 2.14 explore the front-end kinetic behavior of a number of opioids when administered by infusion. With the exception of remifentanil, no opioid comes anywhere near the ultimate steady-state level even after many hours of infusion. Remifentanil is the only opioid in common use that can be expected to reach steady state during the time course of typical anesthetic.

Several clinically important points are evident from inspection of the simulations presented in Fig. 2.14. Most obviously, although remifentanil is a notable exception, the practitioner must be aware that when an opioid infusion is ongoing, the concentrations will continue to rise for the duration of any conceivable anesthetic (this general rule applies less fully to alfentanil). An extension of



• **Fig. 2.14** Simulations exploring infusion front-end pharmacokinetic behavior for a variety of commonly used opioids. For comparison purposes, effect site concentrations *(Ce)* are normalized to a percentage of the eventual steady-state concentration. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[69,107–113]



• **Fig. 2.15** Simulations exploring the infusion back-end pharmacokinetic behavior for a variety of commonly used sedative-hypnotics. This simulation is usually referred to as the *context-sensitive half-time* (the context being the duration of a continuous, steady-state infusion) or the 50% decrement time (for effect site concentrations). The upper portion of the vertical axis is shown on a more compressed scale than the lower portion. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[114–120] *Ce,* Effect site concentration.

this observation is that if the level of opioid effect part way through a long anesthetic is appropriate, it would be necessary to decrease the infusion rate somewhat to maintain the existing therapeutic concentration (without the infusion rate decrease, the concentration will continue to rise).

That remifentanil reaches a steady state quickly is at least partially responsible for its popularity as part of a total intravenous anesthetic (TIVA) technique. However, even for remifentanil, it is best to precede an infusion with a bolus injection as a "loading dose" to speed achievement of a steady-state drug level (see later text). Because they take so long to reach steady state, the loading dose concept is even more important when using the other opioids in Fig. 2.14.

Infusion Back-End Kinetics

The simulations presented graphically in Fig. 2.15 summarize the back-end kinetic behavior for a number of commonly used intravenous sedative-hypnotics when administered by infusion. In terms of anesthesia posology, these simulations are valuable in explaining how various sedative-hypnotics exhibit different recovery profiles depending on the duration of the infusion. The simulation also helps guide therapeutic decision making in terms of the best time to turn off a continuous infusion to promote a timely emergence from anesthesia.

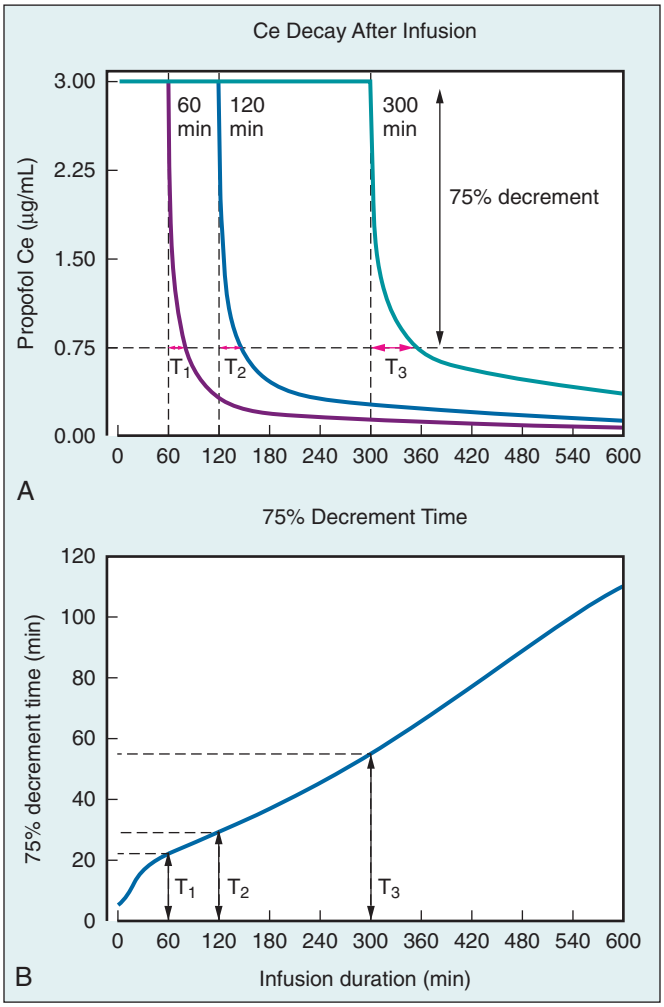
The simulations in Fig. 2.15 predict the time necessary to achieve a 50% decrease in drug concentration after termination of a variable length continuous infusion to a steady-state drug level. Using concepts originally developed for opioids,[7] these simulations are an attempt to provide *context-sensitive half times* (CSHTs).[6] In this case the context is the duration of a continuous infusion. The CSHT has also been referred to as the 50% decrement time (although the decrement time concept usually refers to simulations of effect site concentrations, not plasma).[8] These simulations illustrate how PK parameters interact in a complex way that can only readily be understood through model simulation.[7,72] The CSHT simulations also illustrate the utter irrelevance of using terminal half-lives to predict drug offset behavior for intravenous anesthetics described by three compartment models.[72]

Interpreted from a clinical perspective, CSHT simulations are very instructive. For example, they provide an explanation for why propofol has been so widely embraced as an intravenous anesthetic for TIVA; propofol has a relatively short, time-independent CSHT that is well suited for longer infusions. The CSHT simulations also explain at least one reason why thiopental and midazolam never emerged as popular anesthetics for infusion (and why "barbiturate coma" was sometimes complicated by extremely long recovery times). Another interesting clinical correlation from the CSHT simulations is that when infusion duration is very brief (i.e., <15 to 20 minutes), many of the sedative-hypnotics exhibit similar back-end kinetic behavior.

It is important to emphasize that the shapes of these back-end kinetic curves vary depending on the percentage decrease in concentration simulated; this is why the term *decrement time* was coined (e.g., the 20%, 50%, or 80% decrement times).[8] For most TIVA cases involving propofol, the relevant concentration decrease to promote recovery is closer to 75% rather than 50% (i.e., the biophase concentration must decline from a therapeutic target of approximately 3–4 μg/mL to 0.5–1 μg/mL for the patient to regain responsiveness). The simulations in Fig. 2.16 illustrate this important nuance. For propofol, as for most drugs, the time required for recovery lengthens as the duration of infusion lengthens; the drug input history is clinically important.

Influence of Dose on Bolus Onset and Offset of Effect

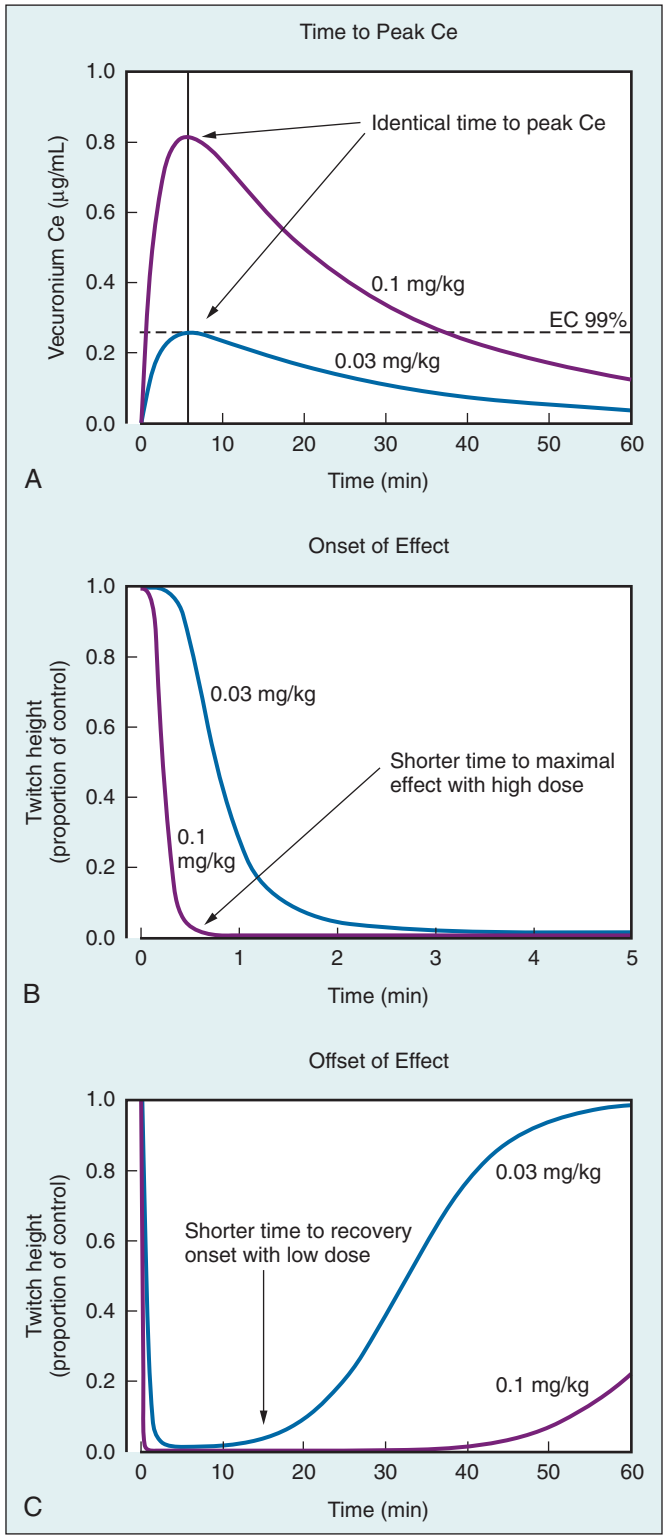
The simulations presented graphically in Fig. 2.17 summarize the influence of dose on the onset and offset of drug effect using the



• **Fig. 2.16** A pair of simulations exploring propofol's infusion back-end kinetic behavior. The upper panel simulates the effect site concentration decay curves after continuous, steady-state infusions of propofol targeted to 3 µg/mL for infusions lasting 60, 120, and 300 minutes. The lower panel illustrates how the infusions simulated in the upper panel map to a 75% decrement time simulation for propofol. T_1, T_2, and T_3 are the 75% decrement times for the 60-, 120-, and 300-minute infusions respectively. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[119] *Ce,* Effect site concentration.

neuromuscular blocking drug vecuronium as a prototype. The simple posologic question addressed by this simulation is "How much does a larger dose speed the onset of maximal drug effect and what is the PK "penalty" in terms of prolonging the duration of drug effect?"

Inspection of Fig. 2.17 reveals a pattern well known to clinicians. The larger "intubating" dose of vecuronium does indeed speed the onset of maximal drug effect, but it comes at the cost of prolonging the duration of muscle relaxation. A larger dose does not change the biophase behavior of the drug; predicted peak effect site concentrations occur at the same time for both the smaller and larger doses as shown in the upper panel of Fig. 2.17. The reason that maximal drug effect occurs more quickly with the larger dose is simply that the biophase concentration required for pronounced drug effect is achieved earlier (i.e., before the peak biophase concentration occurs). The rapid onset of drug effect associated



• **Fig. 2.17** A trio of simulations exploring the influence of bolus dosage on the onset and offset of neuromuscular blockade induced by vecuronium. Two doses, one larger (0.1 mg/kg, shown in *purple*) and the other smaller (0.03 mg/kg, shown in *blue*) are simulated. The upper panel (A) shows the time course of predicted effect site concentrations. The middle panel (B) plots the onset of the pharmacodynamic effect in the first few minutes in terms of the muscle "twitch" height compared with control. The lower panel (C) graphs the drug offset behavior during the first 60 minutes. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[121] *Ce,* Effect site concentration; EC_{99}, the effective concentration for 99% of maximal drug effect.

with the larger dose shown in the middle panel of Fig. 2.17 results in the prolonged recovery plotted in the lower panel.

The clinical implications of this simulation are obvious. The clinician must balance the competing clinical imperatives of rapid onset against rapid recovery of neuromuscular blockade. Depending on the duration of the scheduled procedure and other factors (e.g., full stomach considerations, need for postoperative mechanical ventilation, among others), the rapid onset of neuromuscular blockade might be more important than the potential disadvantages of a longer period of muscle relaxation, justifying the selection of a larger initial dose of drug. The advent of shorter-acting muscle relaxants and sugammadex has rendered this issue less relevant than in days past, but of course the general concepts involved apply to all intravenous anesthetic classes (not just neuromuscular blockers).

In summary, the time to peak drug effect is a function of not only plasma-biophase concentration equilibration but also pharmacokinetics and potency.[15] If a supramaximal dose is administered, peak clinical effect may be observed before peak effect site concentration is achieved simply because the concentration necessary to produce maximal effect is attained before the effect site concentration peaks (this situation represents an "overshoot" of typical target concentrations; the overshoot can be produced by design to hasten the onset of significant drug effect).

Influence of Loading Dose on Infusion Front-End and Back-End Kinetics

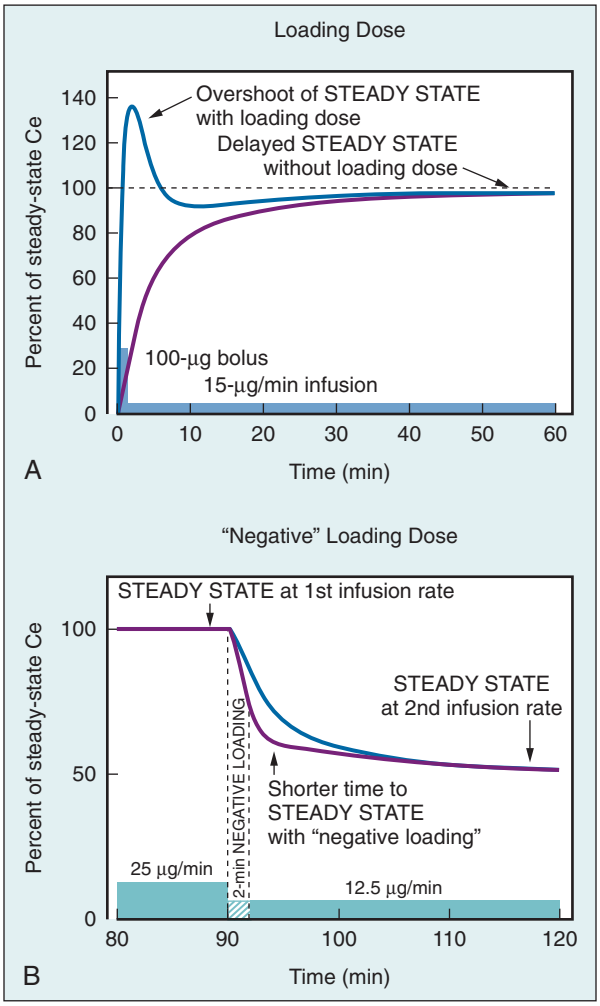
The simulations presented graphically in Fig. 2.18 illustrate the concept of "loading" doses. A bolus injection loading dose before starting an infusion shortens the time to achievement of concentrations nearer the ultimate steady state. Similarly, while the term is not firmly established, a "negative" loading dose (i.e., briefly stopping an ongoing infusion before reducing the infusion rate) can also be used to hasten establishment of the new steady-state drug concentration associated with the reduced infusion rate.

The simulations in Fig. 2.18 illustrate the effectiveness of the loading dose concept. Even for a pharmacokinetically responsive drug like remifentanil, the loading dose (and negative loading dose) technique is very effective in hastening achievement of steady-state drug concentrations. Without the loading dose (and negative loading dose), the eventual steady-state concentrations are achieved significantly later when considered in the context of the operating room where minute-by-minute adjustments of the level of drug effect are often necessary.

The clinical implications of this loading dose concept are even more important when applied to most other drugs in intravenous anesthesia. As illustrated in the simulations shown in Fig. 2.14, for drugs with less favorable PK-PD profiles in terms of the time required to achieve steady-state concentrations (e.g., fentanyl, propofol, among many others), the loading dose concept is even more important. It must be emphasized that the utility of the negative loading dose may be catastrophically overshadowed if the user neglects to resume the infusion after the brief stoppage.

Influence of Special Populations

A very common posologic issue in everyday anesthesia practice relates to the formulation of rational dosing strategies in special populations. Certain demographic factors (e.g., age, gender), anthropometric measurements (e.g., body weight, height, body mass index), and disease states (e.g., kidney or hepatic failure,

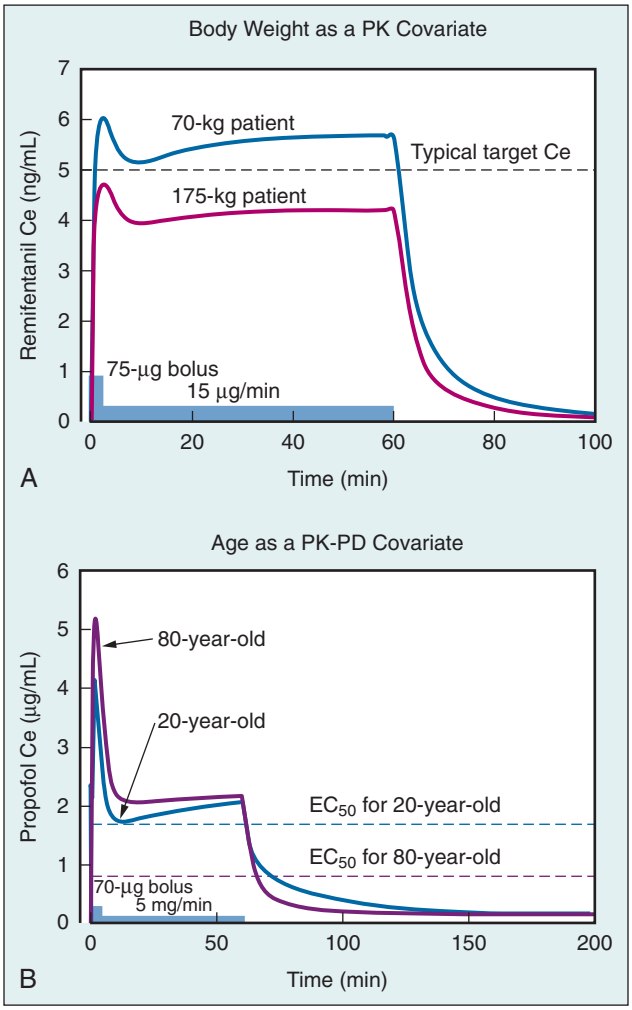


• **Fig. 2.18** A pair of simulations exploring the influence of loading doses on the time to reach steady-state effect site concentrations using remifentanil infusions as an example. The standard loading dose concept, in which a bolus injection is given before starting a continuous infusion, is illustrated in the upper panel (A). The notion of a "negative" loading dose, in which the drug infusion is briefly stopped before the existing infusion rate is decreased, is shown in the lower panel (B). See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[109] *Ce,* Effect site concentration.

hemorrhagic shock) can influence the PK-PD behavior of certain drugs. The doses required in some special populations can be dramatically different compared with the normal patient.

PK-PD modeling techniques can be used to characterize quantitatively how drug behavior is altered in a special population of interest. After building a standard PK-PD model, the influence of the special population factor of interest (e.g., age, body weight, kidney failure), referred to as a *covariate,* can be examined by exploring how the covariate relates to the individual PK-PD model parameters. The covariate can be included in the model to see if it improves model performance. For example, body weight can be related to a distribution volume, or age can be related to drug potency (EC_{50}), and so on.

The simulations presented graphically in Fig. 2.19 illustrate the important impact that covariate effects can have on PK-PD behavior and thus on rational dosing strategy. According to the upper panel



• **Fig. 2.19** A pair of simulations exploring the influence of covariate effects on drug behavior. The upper panel (A) plots the predicted effect site concentrations *(Ce)* of remifentanil when identical doses (i.e., not scaled by weight) are administered to lean and obese adults. The lower panel (B) plots the predicted effect site concentrations (Ce) of propofol when identical doses are administered to older and younger patients. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[122,123] *Ce,* Effect site concentration; EC_{50}, effective concentration for 50% of maximal drug effect; *PD,* pharmacodynamic; *PK,* pharmacokinetic.

of Fig. 2.19, significantly obese patients require more remifentanil to achieve the same effect site concentration as leaner patients (but not as much as would be suggested by total body weight). Similarly, as depicted in the lower panel of Fig. 2.19, older patients require less propofol to achieve identical effect site concentrations compared with younger patients; in this case, this dosage reduction is a function of both PK and PD factors.

The exploration of covariate effects on PK-PD behavior is perhaps one of the most important aspects of current clinical pharmacology research in anesthesia. Studies examining covariate effects in the form of demographic factors, anthropometric measurements, and disease states now constitute a large part of the anesthesia clinical pharmacology literature. Knowing what factors significantly alter the dosage requirement (and how to implement that knowledge quantitatively) is important in enabling the clinician to personalize therapy for each individual patient.

Influence of a Second Drug on Effect

Because modern anesthesia is a multidrug process, understanding how anesthetics interact quantitatively is critical to formulation of optimal dosing strategies. In particular, accounting for the PD synergy of opioids and hypnotics (both intravenous and inhaled) when used in combination is among the most important posologic issues in anesthesia given the prominent role these combinations play in most every anesthetic.

The simulations presented graphically in Fig. 2.20 illustrate the PD synergy observed when propofol and remifentanil are combined for provision of TIVA. The upper panel (C) plots the expected PD effect in terms of the probability of loss of responsiveness. Remifentanil alone at the concentrations predicted from the routine dosing regimen produces zero probability of losing responsiveness. But when the remifentanil is added to the propofol regimen, substantial synergy is evident and the likelihood of loss or responsiveness is increased dramatically. This degree of PD synergy is typical of virtually all hypnotic-opioid combinations (i.e., both intravenous and inhaled).

The clinical implications of this PD synergy are enormous. In practical terms, the synergistic interaction decreases the dosage necessary for both drug classes. The main advantage associated with reduced dosage is faster recovery. Viewed in terms of PD theory, the synergistic combinations steepen the concentration-effect relationship and make a faster recovery possible because drug levels need decrease only moderately to promote emergence from anesthesia (see Fig. 2.2).

PK-PD Models and Technology

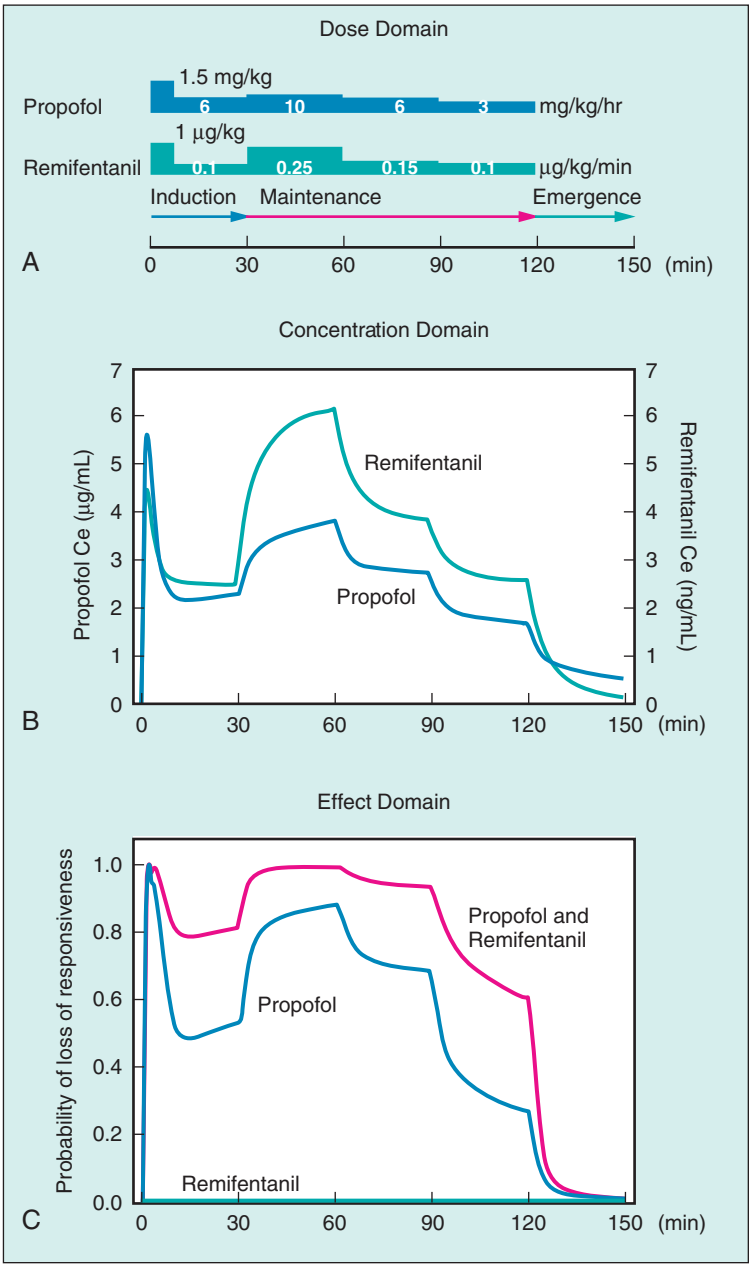
Target-Controlled Infusion

Until recently, the most sophisticated delivery system for intravenous anesthetics was the "calculator pump." Combining advances in pharmacologic modeling with modern infusion pump technology has culminated in the development of more sophisticated methods of intravenous drug delivery.[75] By coding a PK model into a computer program and linking it to an electronic pump modified to accept computerized commands, delivery according to a drug's specific PK profile can be achieved.

This concept was first applied to propofol[76]; commercial embodiments of the concept are now available for many commonly used intravenous anesthetics. The user of these target controlled infusion (TCI) systems designates a target concentration to achieve rather than specifying an infusion rate as with a traditional calculator pump. The TCI system then calculates the necessary infusion rates to achieve the targeted concentration as shown schematically in Fig. 2.21.[12]

Borrowing from inhalation anesthesia concepts, TCI pumps make progress toward the concept of a "vaporizer" for intravenous drugs because they address the fundamental limitation associated with delivering drugs directly into the circulation.[75] Constant rate infusions result in continuous drug uptake. TCI systems, in contrast, gradually decrease the rate of infusion based on the drug's PK behavior.

Known in its general form as the bolus, elimination, and transfer method (i.e., "BET" method),[77] the dosing scheme implemented by a TCI pump accounts for the initial concentration after a bolus dose and the subsequent drug distribution and clearance while an

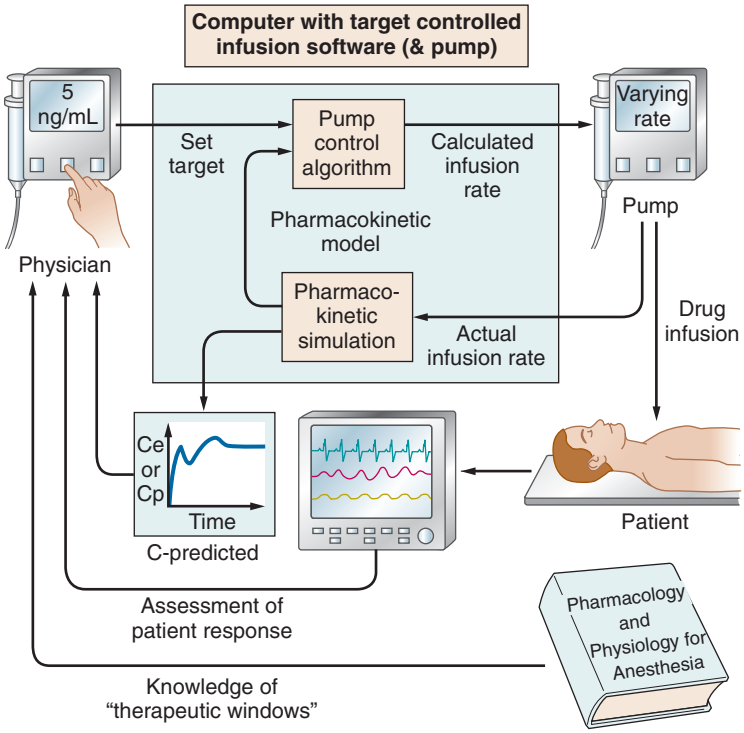


• **Fig. 2.20** Simulations exploring the influence of a second drug using propofol and remifentanil as prototypes. The dose (A), concentration (B), and effect (C) domains are presented for an entire anesthetic from induction to emergence. The effect predictions in the upper panel (C) are based on a response surface pharmacodynamic (PD) drug interaction model. Substantial PD synergy is evident when the opioid is added to the sedative. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[26,90,119,123] *Ce,* Effect site concentration.

infusion is ongoing. TCI dosing algorithms are essentially functional translations of basic PK equations into operating instructions for the infusion pump.[78] Recognizing the importance of the biophase concept, modern TCI pump algorithms have enabled targeting of effect site concentrations.[79–81]

Delivery of drug via a TCI system requires a different knowledge base of the physician. Rather than setting an infusion rate based on clinical experience and literature recommendations, the physician using a TCI system designates a target concentration and the system determines the infusion rates necessary to achieve that concentration over time. The TCI system changes the infusion rates at frequent intervals, sometimes as often as every 10 seconds. Successful use of a TCI pump thus requires knowledge of the therapeutic concentrations appropriate for the specific clinical application.[12] The clinician interfaces with the calculator pump in the dosage domain, whereas TCI systems require input in the concentration domain (Fig. 2.3). Successful use of TCI requires knowledge of PK models, the biophase concept, PD models, and the concept of covariate effects for special populations.

Computer-controlled drug delivery in the operating room is now a well-established technique internationally. Although it has not been possible to show an obvious improvement in outcome associated with the technology,[82] its popularity around the world attests to a high level of user satisfaction among clinicians. Sadly, although TCI systems are widely used in North America for research purposes, the systems are not yet commercially available for routine clinical use in the United States (unlike much of the rest of the world), in part because of perceived regulatory barriers.[16] Current research in the area is focused on perfecting drug models used by the TCI systems, such as expanding the models to include important covariate effects such as body weight, and "personalizing" population models with individualized feedback.[83,84]



• **Fig. 2.21** A schematic representation of a target-controlled infusion system for anesthetic drugs. According to knowledge of therapeutic windows, patient response, and the current prediction of drug concentration (C-predicted), the physician sets the anesthetic drug concentration target. Using a pharmacokinetic model for the drug, the computer calculates the appropriate infusion rates over time to achieve and maintain the target concentration and directs the infusion pump to administer the appropriate amount of drug. The pump reports to the computer the amount of drug administered to the patient so that the computer's pharmacokinetic simulation of the current drug concentration can be updated and confirmed (see text for details). *Ce,* Effect site concentration; *Cp,* plasma concentration. (Adapted with permission from Egan TD. Target-controlled drug delivery: progress toward an intravenous "vaporizer" and automated anesthetic administration. *Anesthesiology.* 2003;99:1214–1219.)

Emerging Developments

PK-PD Advisory Displays

Research is now being conducted to bring anesthetic pharmacology models to the operating room through automated acquisition of the drug administration scheme and real-time display of the predicted pharmacokinetics and pharmacodynamics.[13] Based on high-resolution PK-PD models, including a model of the synergistic PD interaction between sedatives (i.e., propofol and inhaled anesthetics) and opioids,[26,85] this technology automatically acquires (from pumps and the anesthesia machine) the drug doses administered by the clinician and then presents the drug dosing history (bolus doses, infusion rates, and expired concentrations), the predicted drug concentrations in the effect site (past, present and future), and the predicted drug effects, including sedation, analgesia, and neuromuscular blockade.

These "advisory" display systems potentially represent an advance compared with "passive" TCI systems in that they include not only PK predictions regarding drug concentrations but also PD predictions regarding the likelihood of certain anesthetic effects. Response surfaces constitute the fundamental basis of these display systems; that is, the information displayed is based on response surface, PD drug interaction models. Existing prototypes of these display systems actually depict two-dimensional, three-dimensional, or topographic views of response surfaces.[86,87]

These display systems can perhaps best be understood as clinical pharmacology information technology at the point of care. In terms of the unmet need that such systems are intended to address, the basic notion is that a great deal of information regarding the behavior of anesthetic drugs exists in the form of PK, PD, and response surface drug interaction models. The information contained within the multitude of pharmacologic models is complex and is by definition mathematically oriented; much of it appears in scientific journals that are not intended for the clinician. The information initially appears in original research publications and then is interpreted and integrated into textbooks, monographs, and reviews. In total, this massive volume of mathematically based information is so large and intimidating that it is very difficult for the clinician to digest and incorporate into daily practice. These pharmacology display systems are meant to bring this sophisticated body of clinical pharmacology information from scientific journals to the bedside by displaying the information in a readily understandable format in real time.[86–88] That clinicians cannot solve complex polyexponential equations in their heads "on the fly" to guide rational drug administration is a basic assumption of these advisory systems.

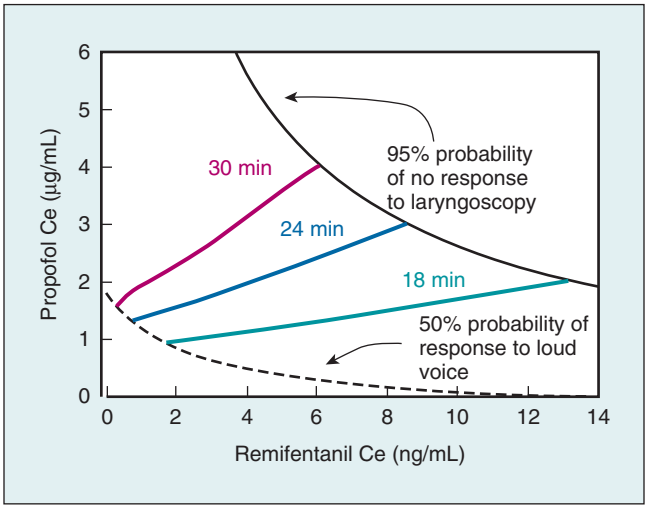
There are at least two advisory displays systems currently in development.[a,86,87] Although quite different in terms of how the information is portrayed, the two systems share in common the tabular and graphical display of predicted drug concentrations and predicted drug effect, including a prediction of the synergism between hypnotics and opioids. The systems include prediction modules that allow the clinician to simulate various dosage regimens in real time and thereby rationally choose the optimal drug administration scheme to address the dynamic nature of anesthesia and surgery. For example, as illustrated in Fig. 2.22, based on information presented by the advisory systems, it is possible to navigate to positions on the drug interaction response surface that optimize the speed of recovery, among other outcomes of interest.

This concept of "navigating" a PD drug interaction response surface is a novel way of conceptualizing how best to adjust drug dosing during an anesthetic.[88] The response surface is navigated in the sense that various points on the surface "map" are targeted at different times to achieve the goals of the anesthetic (e.g., immobility, hemodynamic control, rapid emergence, good analgesia

[a]Dr. Egan has a financial conflict (potential royalties) related to the Navigator system marketed by General Electric Healthcare, Chicago, Illinois.

upon emergence). Rather than simply thinking about hypnotics and opioids in isolation, the response surface approach enables an in-depth, clinically relevant understanding of the significant synergy that results when sedatives and opioids are administered together.

Fig. 2.23 presents a graphical example of the concept of navigating the response surface using propofol and remifentanil as prototypes. The simulation illustrates how the clinician moves to different parts of the surface during different phases of the anesthetic to match drug effect to the prevailing surgical conditions. The notion of integrating PD drug interaction models with PK models to select optimal drug combinations through simulation has been the focus of considerable investigation in recent years. Optimal concentration targets for propofol and remifentanil in combination for the provision of TIVA have been proposed.[25,26,89,90] Similar in silico approaches have also been used to identify the optimal combination of opioids and volatile anesthetics using sevoflurane and remifentanil as prototypes.[85,91] Based on the PK-PD models available for other opioids and volatile agents, it appears feasible to develop optimal concentration targets (and dosage schemes) for nearly any combination of the various opioids and inhalation agents.[92]

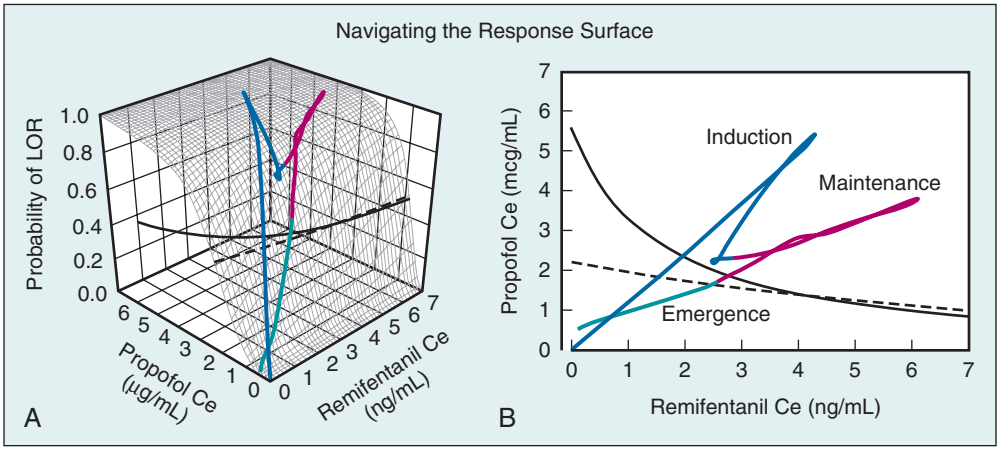


• **Fig. 2.22** A simulation exploring the recovery times associated with different combinations of propofol and remifentanil for a 10-hour intravenous anesthetic. The plot is a topographic view of a pharmacodynamic drug interaction response surface for propfol and remifentanil. The isoboles represent the combinations of the two drugs that produce a 95% probability of no response to laryngoscopy (*solid line*) and a 50% probability of response to "name spoken loudly and repeatedly" (*dotted line*). The three colored lines between the isoboles show the time required to move from "deep anesthesia" to "awake" after stopping 10-hour infusions. See the accompanying text for a detailed explanation. The simulations were conducted with pharmacokinetic-pharmacodynamic parameter estimates from the literature.[26,90,119,123] *Ce,* Effect site concentration.

The ability to simulate various "navigation" decisions immediately before they are implemented (i.e., to explore the clinical consequences of a proposed change in therapy) is a key advance that these display systems potentially bring to clinical care. Pharmacology display systems can be likened to the "heads-up" display systems frequently used as a navigational aid to pilots in commercial and military aircraft. Applying the aviation analogy to anesthesia, display systems can potentially provide increased "situational awareness," "waypoints" to fly toward, and a smooth "glide path" to landing.

Of course, there are obvious challenges to be overcome before these display systems can be adopted into clinical practice. Their utility in terms of improved clinical outcomes (e.g., faster recovery, improved analgesia on emergence) and/or user acceptance (e.g., decreased physician workload) must be satisfactorily demonstrated in clinical testing. Preliminary evidence suggests that the models displayed by these systems perform reasonably well,[85,90] but much work remains to be done. An additional barrier to implementation of these advisory systems is the typical clinician's level of understanding regarding these complex models. Education and training will likely be necessary for the clinician to embrace the technology.

Although it is too early to predict what role clinical pharmacology display technology might play in future anesthesia practice, the concept is certainly an exciting area with some potential to bring more sophisticated clinical pharmacology knowledge to the point of care. In the future real-time display of predicted pharmacokinetics and pharmacodynamics of anesthetic drugs might be found alongside traditional physiologic vital sign monitors.[11,86] Of course, the pharmacokinetic component of these systems has already been widely implemented in the form of passive TCI systems. More



• **Fig. 2.23** A simulation exploring the concept of navigating the pharmacodynamic drug interaction response surface. This simulation presents the same information as in Fig. 2.20 except that the data are plotted on a three-dimensional response surface *(left panel)* and a two-dimensional topographic view of the response surface *(right panel).* The three phases of the anesthetic are shown as *colored lines*. See the accompanying text for a detailed explanation. *Ce,* Effect site concentration; *LOR,* loss of responsiveness.

recently PK-PD simulation programs (i.e., "apps") specifically designed for implementation on smartphones are now readily available and may become increasingly visible near anesthesia workstations.

Propofol Measurement in Expired Gas

The ability to measure in real time the concentration of volatile anesthetics in the expired gas of anesthetized patients has been viewed as a significant advantage of the inhalation anesthesia approach because it enables drug administration in the concentration domain (see Fig. 2.3). Recent work by several laboratories has shown that it might be feasible to develop a device that measures the concentration of propofol in expired gas.[93]

The feasibility of the concept was first demonstrated using a variation of mass spectrometry known as proton transfer reaction mass spectrometry that can detect propofol in minute amounts (parts per billion by volume) in the expired breath of anesthetized patients.[94] More recently several groups have further refined the technology using similar techniques.[95,96] Preliminary results suggest that the overall concept and technique are indeed promising and could have far-reaching implications in anesthesia research and practice.[93] For example, real-time measurement of propofol concentration could replace the need for taking arterial blood samples during research studies in which the concentration of propofol must be controlled. Similarly, the online measured propofol concentration could replace or refine the use of TCI systems to deliver propofol. Finally, it is conceivable that real-time propofol measurement could be used as the control variable for the closed-loop, automated infusion of propofol.

Of course, there are many obstacles to be overcome before the technology moves into mainstream clinical practice. For example, the propofol versus time waveform obtained with the current technology is not ideal because it can be difficult to identify the end-tidal portion of the waveform. In addition, there is a significant delay between peak propofol concentration as determined by PK simulation (after a bolus injection) and the detection of peak propofol concentration in expired gas using the current technology.[97,98] Most importantly, the technical complexity (e.g., difficulties with miniaturization, among others) and expense of the mass spectrometry–based approaches likely represents a considerable barrier to commercialization. Recent work with an alternative technique, ion mobility spectrometry, could potentially overcome some of these barriers.[99]

Allometric Scaling in Pharmacokinetics

Recently the concept of allometric scaling has received considerable attention in the PK analysis of anesthetic drugs.[100] Allometry, at least in part, is the study of how changes in body size influence physiologic behavior. In general, the absolute metabolic rate of animals increases with body size. However, the relationship between body size and metabolic rate in not linear. It has long been recognized that an animal species' metabolic rate scales to its mass to the ¾ power; this well-validated observation is known as Kleiber's law.[101,102]

Assuming that drug clearance is somehow proportionally related to metabolic capacity, in pharmacokinetic analysis allometric concepts have traditionally been used as an approach to scale small animal–based (e.g., rats) PK information to humans in the process of drug development (i.e., "interspecies" allometry). More recently, however, this idea has been extended to "within species" scaling of drug clearance to humans of varying body weights. One obvious advantage of this approach is that total body weight can be used instead of other body size parameters, such as lean body mass, which require complex calculation. Such allometric scaling approaches have been successfully applied to pharmacokinetic models for propofol that characterize the influence of obesity on the drug's disposition.[103,104]

However, critics of the allometric scaling approach for human intraspecies pharmacokinetic analysis (e.g., to characterize the influence of obesity on a drug's disposition) point out that the scientific foundation supporting the practice is not well established and potentially flawed. Such critics contend that the rigorous science underpinning allometry was not developed for the relatively small range of body weights represented within a single species and that allometric scaling should only be used if the approach clearly improves the PK model performance.[105] Thus the proper role of within species allometric scaling in modern PK analysis is currently a matter of considerable controversy and debate.

Key Points

- Compared with other therapeutic areas, the pharmacology of anesthesia is unique because of the low therapeutic indices of anesthetic agents (a safety issue), and because the anesthesiologist must predict the temporal profile of drug effect with great accuracy and precision (an efficiency issue).
- Clinical pharmacology is the branch of pharmacology concerned with the safe and effective use of drugs and includes pharmacokinetics and pharmacodynamics. Grounded in the principles of clinical pharmacology, posology is the science of drug dosage ("dosology"). The ultimate goal of clinical pharmacology is to provide the scientific foundation for rational posology (i.e., what is the right dose for my patient?).
- Pharmacokinetics, simply described as "what the body does to the drug," is the study of the relationship between drug dose and drug concentrations produced over time (i.e., the dose-concentration relationship).
- Pharmacodynamics, simply described as "what the drug does to the body," is the study of the relationship between drug concentrations and drug effects (i.e., the concentration-effect relationship).
- The biophase is the theoretical site of drug action or effect site (e.g., target cells and receptors within the brain, neuromuscular junction, spinal cord). It is important to consider predicted drug concentrations in the biophase (and not just the plasma) because most drugs do not exert their effect in the bloodstream and thus plasma concentrations usually do not correlate well with drug effects, especially during non–steady-state conditions (such as after a bolus injection or an infusion rate change).
- Because anesthetics are rarely administered alone (i.e., modern anesthesia usually involves at least a two-drug combination consisting of a hypnotic and an analgesic), the study of drug interactions is an important part of clinical pharmacology. Most

anesthetics commonly used in combination, such as remifentanil and propofol, interact in a synergistic way so that much less of each drug is required (compared with doses necessary when the drugs are used alone).

- Pharmacokinetic-pharmacodynamic models are simplified versions of pharmacologic reality. These models are mathematical expressions of the relationship between drug dose and concentration (pharmacokinetics) and drug concentration and effect (pharmacodynamics).
- Pharmacokinetic-pharmacodynamic models are built by fitting appropriately shaped equations to actual experimental data using nonlinear regression techniques. Although pharmacologic model building is a mathematical exercise, the models can be readily understood by considering them schematically and graphically.
- The clinical implications of pharmacokinetic-pharmacodynamic models can be easily grasped and conveyed through the use of computer simulation. A proposed dosing scheme can be input into a pharmacokinetic-pharmacodynamic model, producing a "picture" of the predicted drug levels and drug effects. These computer simulations (i.e., in silico experiments) are intuitively understandable and are readily applied to clinical situations.
- A limited set of straightforward simulations form the foundation on which the answers to many routine anesthesia posology questions are based. These fundamental simulations explore bolus front-end and back-end kinetics, infusion front-end kinetics, infusion back-end kinetics (i.e., the context-sensitive half-time), the influence of loading doses, special populations, and a second drug.
- Target-controlled infusion (TCI) devices represent an important advance in drug delivery technology. By coding a pharmacokinetic model into a computer program and linking it to an electronic pump, drug delivery according to the drug's specific pharmacokinetic profile can be achieved. The TCI user designates a plasma or effect site concentration rather than an infusion rate; the TCI system then computes the appropriate infusion rates based on the kinetic model.
- Response surface models are a sophisticated method to characterize pharmacodynamic drug interactions. When integrated with pharmacokinetic information, response surface models can be used to identify target concentrations that optimize certain outcomes of interest such as the speed of recovery. The concept of navigating a pharmacodynamic drug interaction response surface is a novel way of conceptualizing how best to adjust drug dosages during an anesthetic.

Key References

Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics, and rational opioid selection. *Anesthesiology*. 1991;74:53–63. Using the fentanyl congeners as examples, this landmark paper first described the simulation techniques that would ultimately come to be known as the context sensitive half-time and the 20% to 80% decrement times. The simulation study also demonstrated the important differences in bolus versus infusion kinetic behavior. (Ref. 7).

Hughes MA, Glass PS, Jacobs JR. Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76:334–341. This important paper provided the name (i.e., the context-sensitive half-time) for the new simulation technique originally put forward by Shafer and Varvel. The simulation study first extended the concept to the sedative-hypnotics. (Ref. 6).

Sheiner BL, Beal SL. Evaluation of methods for estimating population pharmacokinetic parameters. II. Biexponential model and experimental pharmacokinetic data. *J Pharmacokinet Biopharm*. 1981;9:635–651. This landmark paper was one of the first examples of the use of NONMEM, a mixed-effects pharmacologic modeling software package that eventually emerged as a standard in population pharmacologic modeling. (Ref. 44).

Sheiner LB, Stanski DR, Vozeh S, et al. Simultaneous modeling of pharmacokinetics and pharmacodynamics: application to d-tubocurarine. *Clin Pharmacol Ther*. 1979;25:358–371. This theoretical paper using curare as the prototype example proposed the use of an effect compartment to model non–steady-state pharmacodynamic data. The biophase concept revolutionized pharmacologic modeling techniques in anesthesiology and other disciplines. (Ref. 9).

Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. *Anesthesiology*. 2000;92:1603–1616. This theoretical paper introduced the concept of response surface modeling to modern anesthesia practice. (Ref. 29).

Kern SE, Xie G, White JL, et al. A response surface analysis of propofol-remifentanil pharmacodynamic interaction in volunteers. *Anesthesiology*. 2004;100:1373–1381. This modeling study was an early description of a pharmacodynamic response surface interaction model for propofol and remifentanil that could be used for total intravenous anesthesia dose optimization through simulation. (Ref. 26).

Minto CF, Schnider TW, Shafer SL. Pharmacokinetics and pharmacodynamics of remifentanil. II. Model application. *Anesthesiology*. 1997;86:24–33. This paper illustrated the clinical utility of modern pharmacologic modeling simulation techniques in understanding drug behavior for the new opioid remifentanil. (Ref. 74).

Shafer SL, Varvel JR, Aziz N, et al. Pharmacokinetics of fentanyl administered by computer-controlled infusion pump. *Anesthesiology*. 1990;73:1091–1102. This paper was one of the first descriptions of the use of target-controlled infusion technology in anesthesia. (Ref. 106).

Pharmacokinetics of Inhaled Anesthetics

ANDREW E. HUDSON AND HUGH C. HEMMINGS, JR.

CHAPTER OUTLINE

Historical Perspective

Classes of Inhaled Anesthetics

Physical Properties

Measuring Anesthetic Potency as MAC

Monitoring Inhaled Anesthetic Delivery
- Differences Between Inhaled and Intravenous Anesthetic Delivery
- Agent Analysis
- Monitoring Neurophysiologic Effect

Metabolism and Degradation
- Metabolism
- Chemical Degradation
- Carbon Monoxide Production

Uptake and Distribution
- General Principles
- Determinants of Wash-In
- Special Factors
- Tissue Uptake
- Recovery and Elimination
- Nitrous Oxide: Concentration Effect, Second Gas Effect, Diffusion Hypoxia, and Effects on Closed Gas Spaces
- Gas Delivery Systems

Historical Perspective

The discovery of drugs with anesthetic properties was a landmark event in the history of pharmacology, medicine, and even civilization, in that it made otherwise painful surgical treatments of disease possible. Without a means of providing anesthesia, it was impossible for the modern discipline of surgery to develop. Before the discovery of anesthetic drugs, surgical intervention was limited to simple operations that could be completed quickly.

The first anesthetics were administered by inhalation before the evolution of techniques for intravenous drug administration, and anesthetics remain the most important class of inhaled drugs (barring oxygen, of course). Diethyl ether was first used clinically as a general anesthetic by Long in 1842, and was independently developed by Morton in 1846. Morton's public demonstration of the anesthetic properties of ether at the Massachusetts General Hospital on October 16, 1846, is one of the most important moments in the history of medicine and is now commemorated as Ether Day in Boston and World Anaesthesia Day throughout the world; Long's contribution is also honored as National Doctor's Day in the United States, marking the day that he administered the first ether anesthetic for surgery (March 30, 1842).

Ether remains in clinical use in developing countries given its low cost and relatively high therapeutic index, but its high volatility and explosivity limit its general use. Nitrous oxide was first used for dental analgesia by Wells in 1844, and in 1847 Simpson introduced chloroform (trichloromethane) as a nonexplosive alternative to ether. The first century of anesthesia was dominated by these drugs, of which only nitrous oxide is still widely used.[1]

Since its early origins the practice of anesthesia has been driven by the development of techniques to facilitate the safe delivery of inhaled anesthetics, and these concepts remain important. Administration of drugs by inhalation has a number of unique and important attributes primarily owing to special pharmacokinetic and chemical properties that guide the safe and effective use of inhaled anesthetics.

Classes of Inhaled Anesthetics

General anesthetics include a range of structurally diverse inhaled and injectable compounds that are defined by their ability to induce a reversible comatose state characterized by unconsciousness, amnesia, and immobility. The inhaled anesthetic drugs belong to three broad classes: ethers, alkanes, and gases (Fig. 3.1). (The latter classification is somewhat arbitrary as all inhaled anesthetics are delivered as gases, but gaseous anesthetics are those that normally exist as gases at standard temperature and pressure: nitrous oxide, cyclopropane, noble gases). The ethers and alkanes are volatile liquids (i.e., they have a vapor pressure that is less than atmospheric pressure at room temperature; see later text) and are delivered as

mebookstree

Abstract

Inhaled anesthetics, beginning with diethyl ether, were first introduced into clinical practice in the 1840s. Since then a wide variety of inhaled agents, including ethers, alkanes, nitrous oxide, cyclopropane, and xenon, have been used to induce unconsciousness, amnesia, and immobility. The pharmacokinetics of these drugs depends on their physical properties. The rate of inhaled anesthetic uptake and elimination from the alveoli is driven largely by blood solubility; both are faster with less soluble agents. The effects of inhaled anesthetics depend on the anesthetic concentration at their effect sites, which parallels the alveolar anesthetic concentration and not the total amount of absorbed anesthetic. The potency of different agents can be compared using the minimum alveolar concentration of anesthetic required to prevent movement in 50% of subjects in response to a standardized surgical stimulus. Physiologic factors that govern inhaled anesthetic uptake and elimination include alveolar ventilation and cardiac output. Extrinsic factors that affect inhaled anesthetic uptake and elimination, by determining changes in the alveolar concentration, include minute ventilation, fresh gas flow, and inspired concentration. Inhaled anesthetic tissue distribution depends on relative perfusion, the gradient between arterial and venous anesthetic concentration, and intertissue distribution. Inhaled anesthetics differ dramatically in their degree of metabolism, mostly by the cytochrome P450 system; the volatile anesthetics in use today are minimally metabolized. Emerging developments in inhaled anesthetics include alternative delivery methods and anesthetic applications outside of the operating room.

vapors (the gas phase in equilibrium with the liquid phase at a given temperature; a condensable gas). The modern era of volatile anesthetics—those halogenated with fluorine—began with the synthesis of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) by Suckling in 1951, which was successfully introduced as an anesthetic in clinical trials in 1956. Subsequent attempts to minimize the adverse effects of halothane (particularly the propensity to develop hepatitis, rare but often fatal, or ventricular arrhythmias) led to the development in the 1960s by Terrell and others of a series of halogenated methyl ethyl ethers, including methoxyflurane (2,2-dichloro-1,1-difluoro-1-methoxyethane), enflurane (2-chloro-1-[difluoromethoxy]-1,1,2-trifluoro-ethane), isoflurane (2-chloro-2-[difluoromethoxy]-1,1,1-trifluoro-ethane), and subsequently in the 1990s, desflurane (2-[difluoromethoxy]-1,1,1,2-tetrafluoro-ethane) and sevoflurane (1,1,1,3,3,3-hexafluoro-2-[fluoromethoxy] propane).[1]

Physical Properties

Inhaled drugs differ from intravenous drugs in that their delivery depends on uptake into the blood by the lungs, followed by delivery to their effect sites in the central nervous system in the case of anesthetics. The delivery of inhaled drugs to the lungs depends on the physical properties of the drugs themselves, in particular their solubility in blood and their vapor pressure (Table 3.1).[61]

Vapor pressure is the partial pressure of a vapor in thermodynamic equilibrium with a liquid—that is, the partial pressure at which the rate of liquid evaporation into the gaseous phase equals the rate of gaseous condensation into liquid. Vapor pressure varies nonlinearly with temperature according to the Clausius-Clapeyron relationship (Fig. 3.2). The boiling point is the temperature at which the vapor pressure equals ambient atmospheric pressure. Substances that have high vapor pressures at room temperature (e.g., many of the inhaled anesthetics) are volatile. Partial pressure is the portion of the total pressure of a gaseous mixture supplied by a particular gas; for an ideal gas, this is the mole fraction of the mixture multiplied times the total pressure of the gas. Inhaled anesthetic partial pressures are commonly expressed as volume percent (vol%), which is the percent of the total volume contributed by a particular gas, or for an ideal gas, the mole percent. At standard temperature and pressure, the volume percent times total pressure equals the partial pressure, but importantly, partial pressure changes with temperature.

The *solubility* of a gas is the amount of gas that can be dissolved homogenously into a solvent at equilibrium; it is a function of the partial pressure of the gas above the liquid solvent and the ambient temperature. Solubility depends on the solvent—for example, polar substances tend to be more soluble in polar solvents. According to Henry's law, for a given solvent at a given temperature the amount of gas dissolved in solution is directly proportional to the partial pressure of the gas. Relative solubilities can be described according to the partition ratio (also known as the partition coefficient), which is defined as the ratio at equilibrium of the concentration of the dissolved gas in one solvent to the concentration of the dissolved gas in the other solvent (or in the gaseous phase). At equilibrium the partial pressure of the dissolved gas in the two solvents is equal, even though the concentrations are not (Fig. 3.3). The concentration of a gas in a liquid is derived by multiplying the gas partial pressure times its solubility expressed as its solvent:gas partition ratio (at standard temperature and pressure). For inhaled anesthetics, the blood:gas partition ratio is critically important to alveolar uptake. More soluble agents, such as ether or halothane, have high blood gas partition ratios and take longer to reach an equilibrium between inhaled and exhaled partial pressure owing to their greater uptake into blood and tissues. Conversely, less soluble agents, such as nitrous oxide and desflurane, dissolve in lower quantities and approach equilibrium more rapidly (see later text). Following Henry's law, the solubility of gases such as inhaled anesthetics in aqueous liquids increases at lower temperatures. Various tissues also have tissue-specific partition ratios

TABLE 3.1 Properties of Inhaled Anesthetics

Agent	Boiling Point (°C) at 1 Atm	Vapor Pressure (mm Hg) at 20°C	MAC For 40-Yr-Old in O_2 (%)	Blood:Gas Partition Ratio at 37°C	Oil:Gas Partition Ratio at 37°C

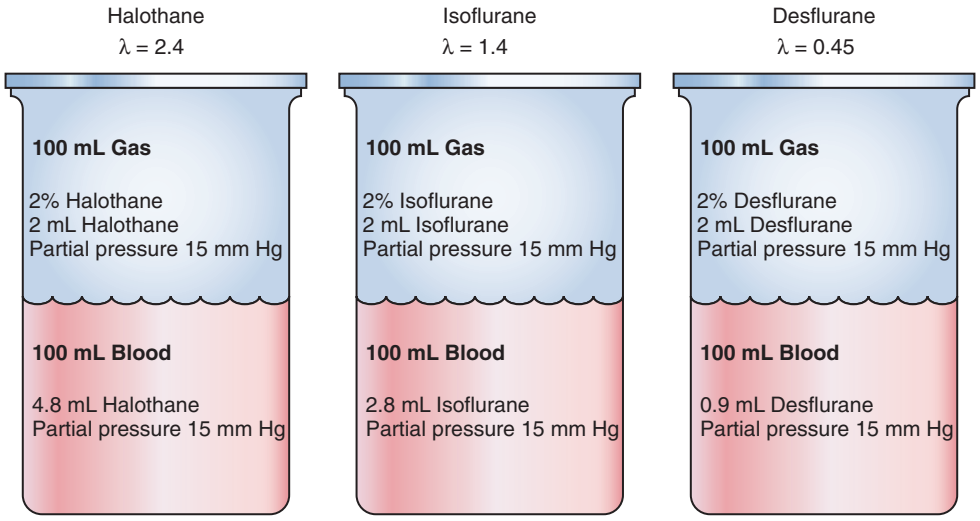
• **Fig. 3.2** Pressure and temperature relationships. A, A qualitative state diagram for water. The vapor pressure is the pressure at which the liquid and gaseous phases are in equilibrium for a given temperature, as indicated by the line between the liquid and gaseous phases in the state diagram. B, Vapor pressure data for a number of common anesthetics. Note that the vapor pressure of desflurane is much higher at a given temperature than the vapor pressure of the other agents, and that the vapor pressure of desflurane reaches 760 mm Hg (or 1 atm) at approximately 22.8°C (its boiling point), indicating that it will boil in a warm room.

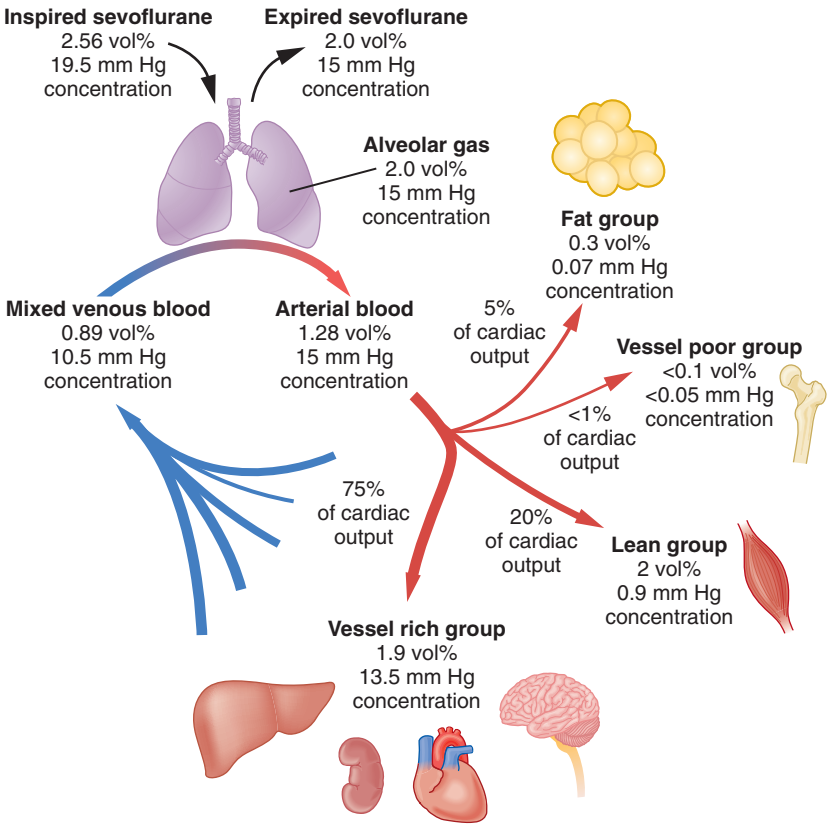
that depend largely on their biochemical composition. This determines relative anesthetic uptake and concentrations in each tissue. Because of differing partition ratios, the actual concentrations can be very different between various tissues at equilibrium even though the partial pressure will eventually be the same, and even two agents with low blood:gas partition ratios, such as nitrous oxide and desflurane, will differ in their rate of uptake into the central nervous system (CNS) because their CNS:blood partition ratios differ.[2] Fig. 3.4 demonstrates that even after a 10-minute wash-in period the differences in partial pressure are pronounced as the different tissue compartments take up the agent.

Measuring Anesthetic Potency as MAC

The potency of inhaled anesthetics is commonly expressed using the concept of minimum alveolar concentration (MAC) as described by Eger and colleagues.[3] The MAC of an anesthetic vapor is the steady-state concentration at which 50% of "normal" (healthy, nonpregnant, adult) human subjects under standard conditions (normal body temperature, 1 atm, no other drugs) do not move (are immobile) in response to a defined stimulus (surgical incision; laboratory studies often substitute application of a tail clamp to rodents). Although MAC is defined in terms of a gas concentration in volume percent or fractional atm at 1-atm ambient pressure, it is the partial pressure and resultant concentration at the effect site that is critical to the pharmacologic response (immobility). Thus anesthetic potency expressed in terms of alveolar partial pressure or tissue concentration is constant for a given physiologic state. MAC is expressed as a gas concentration at 1-atm ambient pressure. The vaporizer setting in volume percent delivers an equivalent alveolar partial pressure that varies with atmospheric pressure; this is significant at high altitudes where higher inspired concentrations



• **Fig. 3.3** Blood:gas partitioning of inhaled anesthetics at 37°C. At equilibrium, the partial pressures of the anesthetics in the gas and liquid (blood) phases (100 mL of each) are equal (15 mm Hg for 2 vol% at standard atmospheric pressure of 760 mm Hg). In contrast, blood concentrations differ depending on the drug specific blood:gas partition ratios (λ). Note that λ increases ~4% per 1°C decrease in temperature.



• **Fig. 3.4** Tissue partial pressures of anesthetics. Results of a Gas Man simulation (Med Man Simulations, Inc., Boston, MA) of a 70-kg patient administered sevoflurane for 10 minutes at 2.56 vol% in 8 L/min of 100% O_2. The delivered inspiratory and measured end-tidal concentrations of sevoflurane are shown, together with the partial pressure and concentration of anesthetic in arterial blood, mixed venous blood, the vessel-rich, vessel-poor, lean, and fat groups. If allowed to run until full equilibration between compartments, the partial pressures of anesthetic would equalize, while the concentrations measured as volume percent will differ according to the tissue:gas partition ratios.

are required to produce a given tissue partial pressure/concentration. The MAC of an inhaled agent is analogous to the EC_{50} (effective concentration in 50% of subjects) of intravenous agents; hence, more potent agents have lower MAC values. MAC is defined using only one behavioral component of anesthesia—the lack of a motor response (immobilization) to a painful stimulus—and reflects primarily spinal effect sites (see Chapter 11). The MAC concept has been extended to other endpoints including MAC awake (for emergence),[4] MAC blunted autonomic response, and so on.

Although MAC was originally developed as a simple method of comparing the potency of inhaled anesthetics, it has emerged as an important clinical tool. Anesthesiologists often formulate an anesthetic plan by targeting a certain MAC multiple for a given patient, procedure, and anesthetic technique (although strictly

speaking MAC is a single point on a nonlinear curve, so there are limitations to this approach). The pervasive influence of MAC in the daily practice of anesthesia makes it one of the most important unifying concepts in anesthetic pharmacology. Further consideration of the factors that influence MAC (e.g., age, body temperature, adjuvant drugs, genetics) is provided in Chapter 11.

Monitoring Inhaled Anesthetic Delivery

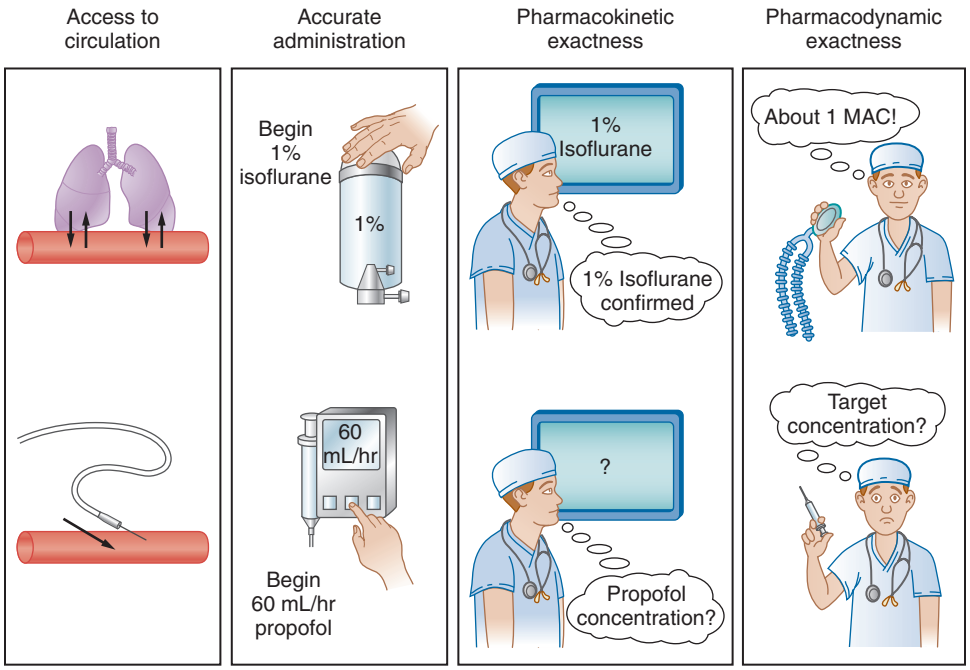
Differences Between Inhaled and Intravenous Anesthetic Delivery

Administering volatile anesthetics by inhalation using a calibrated vaporizer affords several fundamental advantages compared with intravenous drug delivery (Fig. 3.5). Because uptake of inhaled anesthetic diminishes as equilibrium between alveolar and pulmonary venous partial pressures is approached, the vaporizer setting reflects the anesthetic concentration in blood and therefore at the site of drug action owing to rapid uptake in well-perfused tissues (including the CNS). This enables accurate administration of the inhaled drug to a target concentration (with an upper limit above which the partial pressure cannot rise). Moreover, the end-expired concentration can be measured and confirmed by respiratory gas monitoring, ensuring that the targeted concentration has been achieved (pharmacokinetic exactness). The pharmacodynamic significance of the measured concentration is standardized in terms of MAC, providing pharmacodynamic exactness.

In contrast, direct access to the circulation as required in intravenous anesthesia delivery does not prevent indefinite uptake of drug (see Fig. 3.5, lower panel). Without the aid of a computer model, the infusion rate of an intravenous anesthetic does not reveal much about the resulting concentration in blood, preventing accurate administration targeted to a known concentration. There is currently no commercially available device to measure the concentration of intravenous anesthetics in real time, preventing equivalent pharmacokinetic exactness (delivering a targeted concentration). Even if concentrations of intravenous drugs were measurable in the clinical setting, the meaning of a given concentration is not common knowledge to most practitioners who practice without target controlled infusion technology (e.g., practitioners based in the United States; see Chapter 2). In contrast to the early days of total intravenous anesthesia, the therapeutic windows for most intravenous anesthetics are now well characterized (e.g., the steady-state propofol concentrations required to achieve adequate anesthesia in 50% of patients, among many others).[5,6] Despite these advances, available computer-controlled pumps, although accurate and sophisticated, fall short of the theoretical appeal and practical convenience associated with the delivery of volatile anesthetic via the lung. Target-controlled infusion technology (see Chapter 2) partly addresses these shortcomings.

Agent Analysis

A number of technologies can be used to analyze the amount of agent being delivered to the patient. These are usually implemented in a sidestream, or diverting, system that takes a sample of gas from as close to the patient as feasible. In contrast, mainstream systems require attaching the analyzer hardware directly to the end of the endotracheal tube. Delivered volatile anesthetic concentration can be determined using mass spectrometry, Raman spectral analysis, infrared spectrometry, refractometry, or oscillating crystal technology. Nitrous oxide can be detected with mass spectrometry, Raman analysis, or infrared spectrometry.[7] Monitoring of delivered anesthetic concentration allows detection of volatile anesthetic



• **Fig. 3.5** Comparison of delivery of anesthetics by inhalation *(upper panel)* or intravenous infusion *(lower panel)* at the beginning of the total intravenous anesthesia era (circa 1995). Inhalational delivery provides both pharmacokinetic and pharmacodynamic accuracy because known concentrations can be titrated by adjusting the vaporizer to known target concentrations (minimum alveolar concentration *[MAC]*) without accumulation and usually with minimal metabolism. (Modified from Egan TD. Intravenous drug delivery systems: toward an intravenous "vaporizer." *J Clin Anesth.* 1996;8(3 suppl):8S–14S.)

uptake and elimination, vaporizer malfunctions, and estimation of anesthetic depth based on MAC values and age-derived nomograms. Additionally, low-flow anesthesia can be more easily implemented if the delivered anesthetic concentration is being monitored. That said, prediction of arterial/effect site concentrations of anesthetic from end-tidal concentrations is difficult and subject to inaccuracies owing to dead-space ventilation, for example,[8] which can have significant effects on uptake times in the beginning of an anesthetic.[2]

Monitoring Neurophysiologic Effect

Although hemodynamic stability under anesthesia is relatively straightforward to monitor, it is surprisingly difficult to monitor the neurophysiologic effect of a given end-tidal concentration of an inhaled anesthetic. This is of particular concern in patients also receiving neuromuscular blockers, who could potentially be aware but unable to move.[9] Monitoring methods focus on the complexity of the electroencephalogram (EEG), which transitions from rapid disorganized activity during wakefulness to slow coherent activity with decreasing levels of arousal. A number of measures of the complexity of EEG, such as dimensional complexity, spectral edge, and spectral entropy, have all been proposed as valuable measures of arousal or awareness. The most frequently used commercial system currently is the BIS (Medtronic, Boulder, CO), which uses a proprietary algorithm to measure electromyography and correlations in power between different frequency bands of the EEG to develop an index that the manufacturer claims can predict awareness under anesthesia. That said, alternative systems that rely on processed EEG, such as the SedLine (Masimo, Irvine, CA), are making inroads into the market. Initial reports suggested that use of the BIS within an anesthetic protocol leads to an absolute risk reduction of awareness under anesthesia of 0.74% compared with anesthesia care outside of the protocol (B-Aware trial).[10] Subsequent studies that did not use BIS within an anesthetic protocol failed to reproduce this result.[11] Another randomized clinical trial that compared a structured anesthetic protocol based on the BIS with an anesthetic protocol based on end-tidal anesthetic gas concentration (B-Unaware trail) found that BIS neither lowered the incidence of anesthesia awareness nor reduced the administration of volatile anesthetic gas.[12] This conclusion was then confirmed in a separate study using patients at high risk of awareness under general anesthesia.[13] This led the study group to discourage anesthesiologists from attempting to use BIS values to titrate anesthesia.[14] The 5th National Audit Project (NAP5) of the Royal College of Anaesthetists and the Association of Anaesthetists of Great Britain and Ireland addressed accidental awareness during general anesthesia in 2014. This audit showed that practitioners in the United Kingdom were selectively using depth of anesthesia monitors, which were used in only 1% of cases involving volatile anesthetics without neuromuscular blockade but in 23% of cases involving total intravenous anesthesia with neuromuscular blockade (which had an almost fourfold increase in risk of accidental awareness during general anesthesia).[15]

Metabolism and Degradation

Metabolism

Metabolism of volatile anesthetics varies up to 1000-fold between specific agents and is catalyzed chiefly via cytochrome P450 enzymes in the liver (Table 3.2), primarily by CYP 2E1.[16,17] Hence patients exposed to agents that induce cytochrome P450 2E1 (CYP 2E1; e.g., ethanol, barbiturates) can have increased metabolism (see Chapter 4). Metabolism is inhibited by the agents themselves at the higher concentrations present during anesthesia, but it is enhanced during elimination of residual anesthetic during the recovery phase, which is more prolonged and extensive for the soluble agents.[18]

TABLE 3.2 Degree of Metabolism, Metabolites, and Enzymes Involved for Various Agents

Agent	Degree of In Vivo Metabolism (%)	Metabolites	Enzymes Catalyzing Metabolism
Halothane	15–40	Inorganic bromide, fluoride	CYP 2E1 and, to a lesser extent, CYP 3A4 and CYP 2A6
Enflurane	2.4	Inorganic fluoride	CYP 2E1
Isoflurane	0.2	Trifluoroacetic acid, inorganic fluoride	CYP 2E1
Sevoflurane	2–5	Inorganic fluoride	CYP 2E1
Desflurane	0.02	Inorganic fluoride	CYP 2E1

CYP, Cytochrome P450.
(Modified from Kharasch ED, Thummel KE. Identification of cytochrome P450 2E1 as the predominant enzyme catalyzing human liver microsomal defluorination of sevoflurane, isoflurane, and methoxyflurane. *Anesthesiology*. 1993;9:795–807; Restrepo JG, Garcia-Martín E, Martínez C, et al. Polymorphic drug metabolism in anaesthesia. *Curr Drug Metab*. 2009;10: 236–246.)

Halothane is the most extensively metabolized of the modern agents. Its extensive metabolism (up to 40% of absorbed dose) has a significant impact on its elimination kinetics, in contrast to other agents.[19] It is also unique among volatile agents in undergoing significant reductive metabolism by CYP 2A6 and 3A4, although this is minor compared with its oxidative metabolism.[20] Nitrous oxide and xenon are not metabolized.

Although the agents themselves have certain adverse effects (e.g., cardiac depression), a number of other adverse reactions to anesthesia, particularly hepatic and renal toxicity, are mediated by their metabolites. As a result, agents that undergo little metabolism have become more popular, whereas agents that undergo more metabolism, such as halothane and methoxyflurane, have fallen into disuse. Discussion of specific metabolites and their organ toxicity is found in Chapter 11.

Chemical Degradation

At temperatures exceeding 50°C in the presence of soda lime carbon dioxide (CO_2) absorbent, and somewhat even at 40°C as often exists in absorbents, sevoflurane undergoes base catalyzed degradation to produce the vinyl ether compound A (fluoromethyl-2,2-difluoro-1-(trifluoromethyl), or FDVE) and trace amounts

of compound B (2-(fluoromethoxy)-3-methoxy-1,1,1,3,3-pentafluoropropane).[21] FDVE causes renal tubular necrosis in rats, but toxicity is species-dependent. Human exposure has no clinically significant effects even with low-flow sevoflurane generating FDVE exposures of more than 400 ppm hours, although biochemical markers of renal injury have been reported with high compound A exposure in some studies.[22–25] More modern CO_2 absorbents based on lithium hydroxide have been designed to minimize production of compound A during normal use.[26]

Carbon Monoxide Production

The passage of volatile anesthetics through dry CO_2 absorbents can produce potentially life-threatening concentrations of carbon monoxide.[27,28] Severe carbon monoxide poisoning with carboxyhemoglobin levels approaching 40% has been reported in association with desflurane.[29] Carbon monoxide production is insignificant with sevoflurane and halothane, intermediate with isoflurane, and highest with desflurane and enflurane.[30] The quantity of carbon monoxide produced depends on fresh gas flow, the quantity of dry absorbent, and the water content of the absorbent; barium hydroxide–containing absorbent (Baralyme) produces more carbon monoxide than soda lime. No carbon monoxide is produced when the water content of soda lime exceeds approximately 4.8%, or the water content of Baralyme exceeds 9.7%. Baralyme has been removed from the market. With modern absorbents, this concern is largely obviated, with only small amounts of carbon monoxide production (peak concentrations <116 ppm) with desiccated Drägersorb (Dräger, Lübeck, Germany); Medisorb (Vyaire Medical, Lake Forest, IL); and Spherasorb (Intersurgical, East Syracuse, NY), and no appreciable formation with Amsorb (Armstrong Medical Ltd., Coleraine, Northern Ireland); LoFloSorb (Intersurgical, Wokingham, England); Superia, or lithium hydroxide.[26] The reaction by which carbon monoxide is produced is unclear; for desflurane the cascade probably begins with base-catalyzed extraction of a proton from the difluoromethyl ethyl group. The absence of this moiety in sevoflurane, methoxyflurane, and halothane thus explains the insignificant production of carbon monoxide by these agents.[31]

Uptake and Distribution

General Principles

During the wash-in period, the partial pressure of an inhaled gas in the alveoli increases exponentially to approach that of the inspired fresh gas concentration. This ratio reflects the uptake of anesthetic from the inhaled gas into the blood as well as from blood into the tissues. Assuming no uptake of gas, the alveolar concentration (F_A) approaches the inspired gas concentration (F_I) with first-order kinetics:

[1]

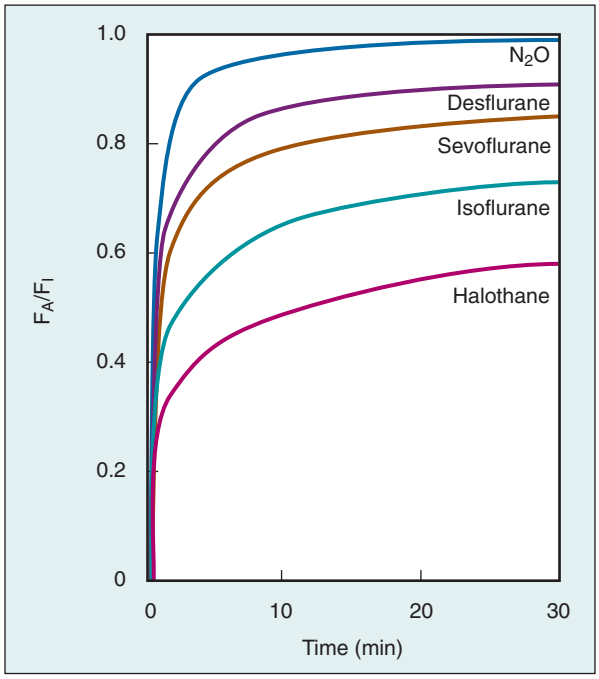
$$\frac{d}{dt}\left(\frac{F_A}{F_I}\right) = -\frac{t}{\tau},$$

where t is time and τ is the wash-in time constant, which is the ratio of the capacity of the reservoir into which the gas is delivered (the circuit volume plus the lung volume of the patient) to the flow rate at which it is delivered. Thus τ is the time it takes to fill the system once at the current fresh gas flow. If the circuit starts with no anesthetic at time zero and the inspired gas concentration does not change, then

[2]

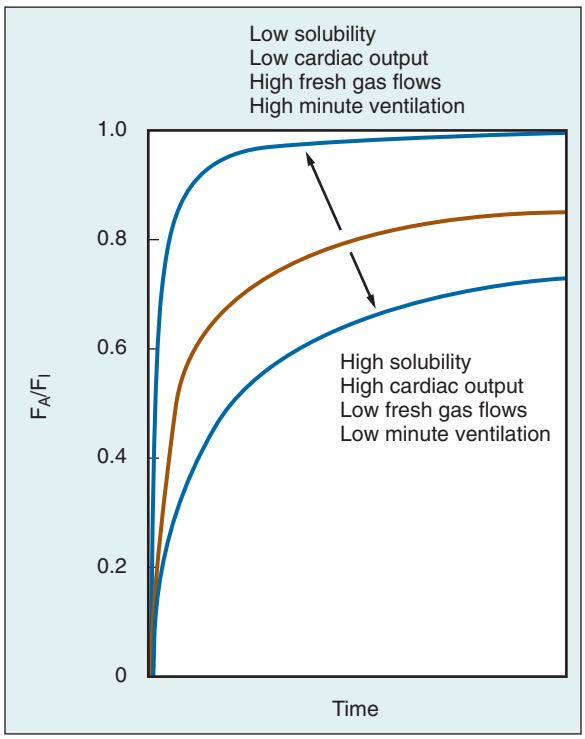
$$\frac{F_A}{F_I} = 1 - e^{-t/\tau}$$

where e is Euler's number. After a single time constant has elapsed (when $t = \tau$), F_A is 0.63 F_I; at time $t = 2\tau$, $F_A = 0.86\ F_I$; at $t = 3\tau$, $F_A = 0.95\ F_I$; and at $t = 4\tau$, $F_A = 0.98\ F_I$ (Fig. 3.6).

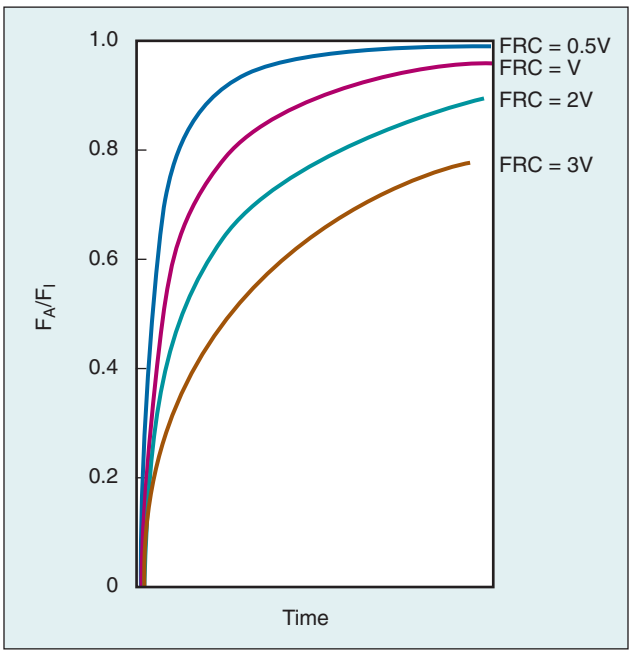


• **Fig. 3.6** Wash-in of nitrous oxide *(N_2O)*, desflurane, sevoflurane, isoflurane, and halothane. The rate at which the alveolar concentration (F_A) approaches the inhaled concentration (F_I) for a fixed minute ventilation and cardiac output reflects the solubility of the drug in blood, with wash-in of the least soluble (nitrous oxide and desflurane) being the fastest. (Modified from Yasuda N, Lockhart SH, Eger EI 2nd, et al. Comparison of kinetics of sevoflurane and isoflurane in humans. *Anesth Analg.* 1991;72: 316–324.)

The response to a drug depends on the concentration of the drug at its effect site (e.g., a receptor expressed in brain or spinal cord) and is usually not the plasma concentration (see Chapter 1). This is typically modeled by considering the human body as being made up of multiple compartments, one of which is the effect site. The concentration of an inhaled anesthetic in brain, for example, depends on the relative solubilities of the drug in brain and blood (the brain:blood partition ratio), which in turn depends on the partial pressure of the anesthetic in the alveoli measured as the end-tidal concentration. At equilibrium, the end-tidal anesthetic concentration reflects the concentration of anesthetic in the blood, and for these highly lipid-soluble drugs that easily cross membranes, at the effect site. The effect of an inhaled anesthetic thus depends on its concentration at its effect site and not on total absorbed mass of drug. The total absorbed mass is a significant determinant of the kinetics of uptake and elimination, however.



• **Fig. 3.7** Factors affecting the rate of anesthetic wash-in (equilibration between the inspired fraction and the expired fraction) include solubility, cardiac output, fresh gas flow, and minute ventilation. F_A, Alveolar concentration; F_I, inhaled concentration.



• **Fig. 3.8** Effect of functional residual capacity *(FRC)* on wash-in for a fixed minute ventilation *(V)* and cardiac output. Patients with lower FRCs relative to their minute ventilation have more rapid wash-in. F_A, Alveolar concentration; F_I, inhaled concentration.

Determinants of Wash-In

The rate of wash-in of the anesthetic is determined by both the rate of delivery to the alveoli and the rate of removal from the alveoli by uptake into blood. Factors that affect the rate of delivery to the alveoli include the inspired concentration, the time constant of the delivery system (which is determined by fresh gas flow and circuit volume), anatomic dead space, alveolar minute ventilation, and functional residual capacity (FRC). Factors affecting the rate at which anesthetic is removed from the alveoli include the solubility of anesthetic in the blood, cardiac output, and the partial pressure gradient between alveolar gas and mixed venous blood. These concepts are illustrated in the classic uptake curves shown in Fig. 3.7.

The gradient between inspired and alveolar anesthetic concentrations drives the increase in alveolar concentration of inhaled drugs. Alveolar ventilation determines the rate at which alveolar gas concentration equilibrates with the concentration in the circuit. A change in FRC changes the total volume of the system and thereby alters τ. As a result, an obese patient with reduced FRC will have faster wash-in (Fig. 3.8). The early rapid increase in F_A/F_I represents the equilibration of anesthetic with the circuit and airways unopposed by alveolar uptake. The rate of change in F_A/F_I slows as alveolar concentrations increase and uptake into blood and tissues lead to increased venous concentration, which reduces the alveolar-to-venous concentration gradient and slows uptake. For more soluble agents with greater uptake, the knee in the curve occurs at lower F_A/F_I ratios.

Special Factors

For a fixed cardiac output, a left-to-right shunt (which recycles blood through the lungs) does not affect wash-in unless it alters the ventilation to the perfused lung. A right-to-left shunt (where systemic venous blood bypasses the lungs), however, can significantly slow the rate of wash-in. Right-to-left shunt effects are much more prominent with poorly soluble anesthetics (i.e., nitrous oxide and desflurane).

A number of differences contribute to the faster wash-in observed in infants and children compared with adults. Volatile anesthetics are less soluble in neonates, likely secondary to lower serum protein and lipid concentrations. Tissue solubilities, particularly in the muscle group, are also lower in children than in adults. Finally, the cardiac output in neonates is disproportionately distributed to the vessel-rich group compared with adults, enhancing drug delivery to the CNS.

Tissue Uptake

Initially during wash-in, hydrophobic anesthetics are avidly taken up by the tissues and the anesthetic partial pressure of venous blood returning to the lungs is low. As anesthetic partial pressure in the tissues approaches the alveolar partial pressure, venous anesthetic partial pressure increases to approach alveolar partial pressure. As a result, the anesthetic partial pressure gradient between alveolar gas and venous blood decreases, diminishing the rate of uptake.

Factors that govern tissue uptake of anesthetics are analogous to those that govern uptake from the alveoli: tissue solubility, tissue blood flow and the arterial blood:tissue partial pressure gradient. Tissues can be classified into four groups based on their relative

blood flow: vessel-rich group (brain, heart, kidney, and liver; contributing 10% to body mass and receiving 75% of cardiac output); lean group (muscle and skin; contributing 50% to body mass and receiving 20% of cardiac output); vessel-poor group (bones and connective tissue; contributing 20% to body mass and receiving <1% of cardiac output); and fat (contributing 20% to body mass and receiving ~5% of cardiac output). The time constant (τ) for wash-in of each group is defined as follows:

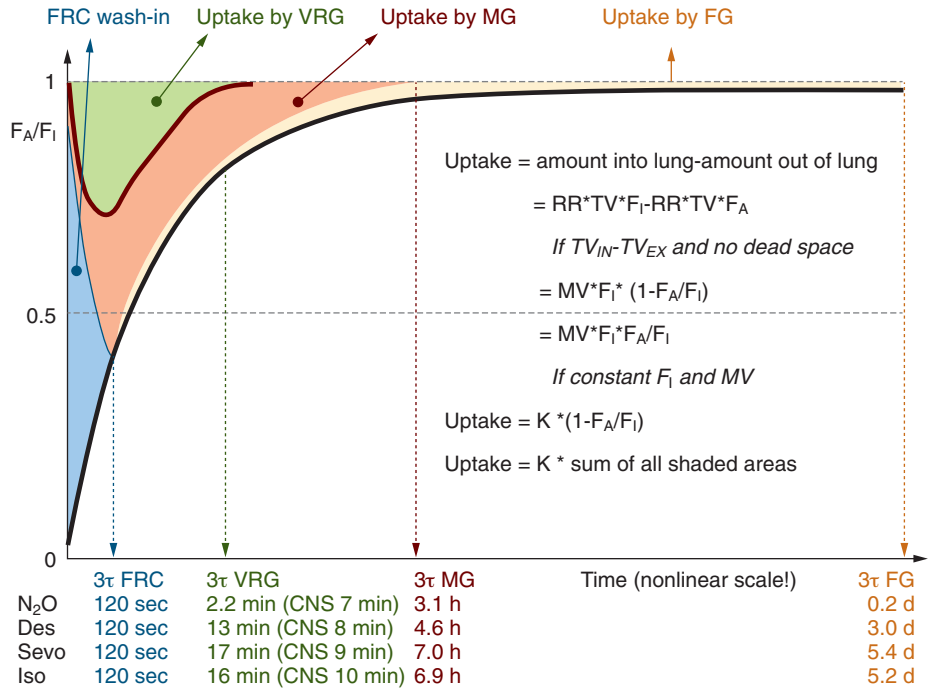
[3]

$$\tau = \frac{V\lambda}{Q}$$

where V is the volume of tissue, Q is the tissue blood flow, and λ is the tissue:blood partition ratio. Based on tissue-specific differences in each of these factors, equilibration times from shortest to longest are vessel-rich group (VRG), lean tissue group, vessel-poor group, and fat (which has such low blood flow that it usually fails to equilibrate on a clinical time scale). The large mass of the lean tissue group makes it the largest tissue reservoir, and its lower blood flow relative to the VRG means that it continues to take up anesthetic after the VRG approaches equilibrium. Again, more soluble agents have longer time constants as the result of more extensive tissue uptake. The rate of rise of the F_A/F_I curve thus is determined by the amount and rate of uptake of the different compartments of interest. (Fig. 3.9) The slower rate of rise in the second phase of uptake evident in the F_A/F_I relationship reflects saturation of the VRG and slower equilibration of other (mainly lean) tissue groups. In practice, the rate of rise of anesthetic is rarely a significant issue, however, since most anesthetic techniques begin with administration of a bolus of intravenous agent.[2]

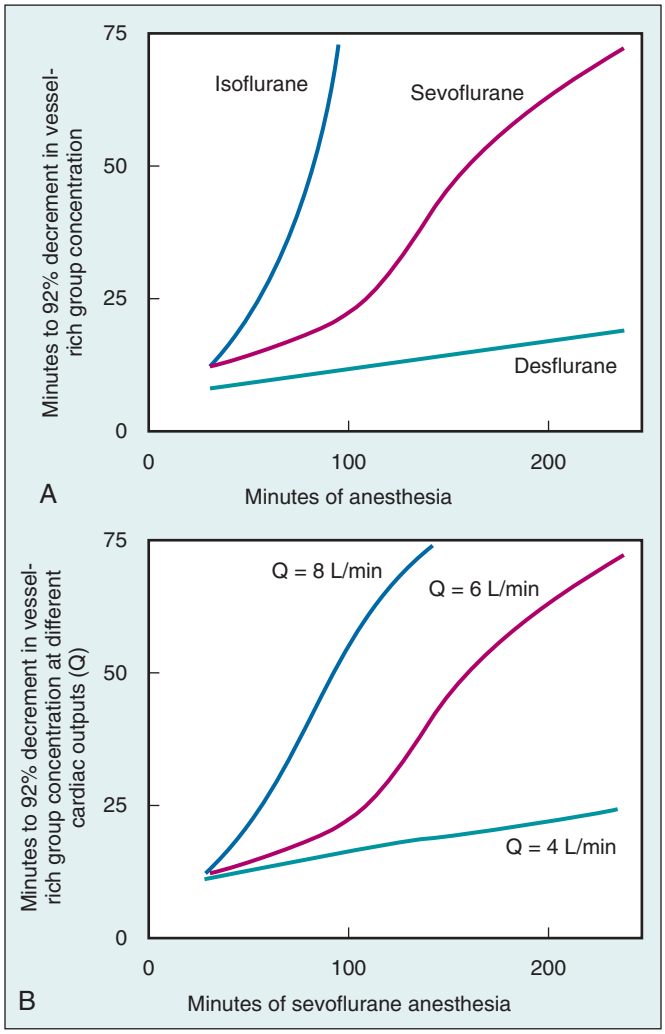
Recovery and Elimination

Recovery from anesthesia follows elimination of the inhaled anesthetic agent from the effect site. Most anesthetic is eliminated from the blood via exhalation from the lungs; other routes include transcutaneous and visceral losses (both minor) and a more significant agent-specific metabolic component. Biodegradation has a significant effect on the elimination of the most extensively metabolized agents (in decreasing order of biodegradation: methoxyflurane, halothane, sevoflurane, enflurane, isoflurane, desflurane).[32] The extensive metabolism of methoxyflurane (~75% of absorbed drug) and halothane (~40% of absorbed drug) contributes to the faster decay in alveolar concentration for these drugs compared with less metabolized drugs such as isoflurane and desflurane.[33]



• **Fig. 3.9** The *F/F*curve is determined by uptake of different compartments, for fixed *F*, minute ventilation, and cardiac output. Uptake is proportional to 1 – *F/F*, which is the area above the *F/F*curve. Each colored area thus represents schematically a different compartment: functional residual capacity *(FRC, blue)*, vessel-rich group *(VRG, green)*, muscle group *(MG, orange)*, fat group *(FG, yellow)*. *FA*, Alveolar conl centration; *FI*, inhaled concentration; *Iso*, isoflurane; *MV*, minute ventilation; *NO*, nitrous oxide; *RR*, respiratory rate; *Sevo*, sevoflurane; *TVA*, inspired tidal volume; *TVI*, expired tidal volume. (Modified from Hendrickx J, Peyton P, Carette R, et al. Inhaled anaesthetics and nitrous oxide: complexities overlooked. *Eur J Anaesthesia.* 2016;33:611–619.)

Washout of inhaled anesthetics follows a multiexponential decay time course. As with wash-in, the lower the solubility, the faster is elimination owing to the increased efficacy of ventilation in eliminating anesthetic from the blood. In contrast to wash-in, wherein the inhaled concentration can be raised above the desired target (overpressure) to speed induction by overcoming the effect of solubility to hinder the rise in alveolar concentrations, during washout the alveolar concentration of anesthetic can never be less than zero, limiting the gradient for elimination. Additionally, washout is affected by the differential elimination from the four tissue compartments discussed earlier for uptake. Anesthetics can also redistribute between various tissue groups. For anesthetics with low tissue and blood solubility, duration of anesthesia has relatively little effect on rate of elimination. But for anesthetics with greater solubility, the washout rate is proportional to duration of anesthesia as the result of accumulation in tissues with longer time constants. This can be expressed as context-sensitive decrement times (Fig. 3.10).[34] Evidence for a fifth compartment during washout has been suggested to involve diffusion from highly perfused tissues to adjacent fat that has a much larger time constant than muscle but 10 times faster than bulk fat.[18,35] Compartments with longer time constants (e.g., fat) do not equilibrate during short (<1 hour; longer with desflurane) procedures such that they can continue to take up anesthetic until alveolar elimination reduces arterial anesthetic partial pressure below tissue level. This can accelerate elimination early in recovery, but it eventually slows recovery as tissues continue to unload anesthetic into blood. Complete elimination after a long anesthetic exposure can take days.



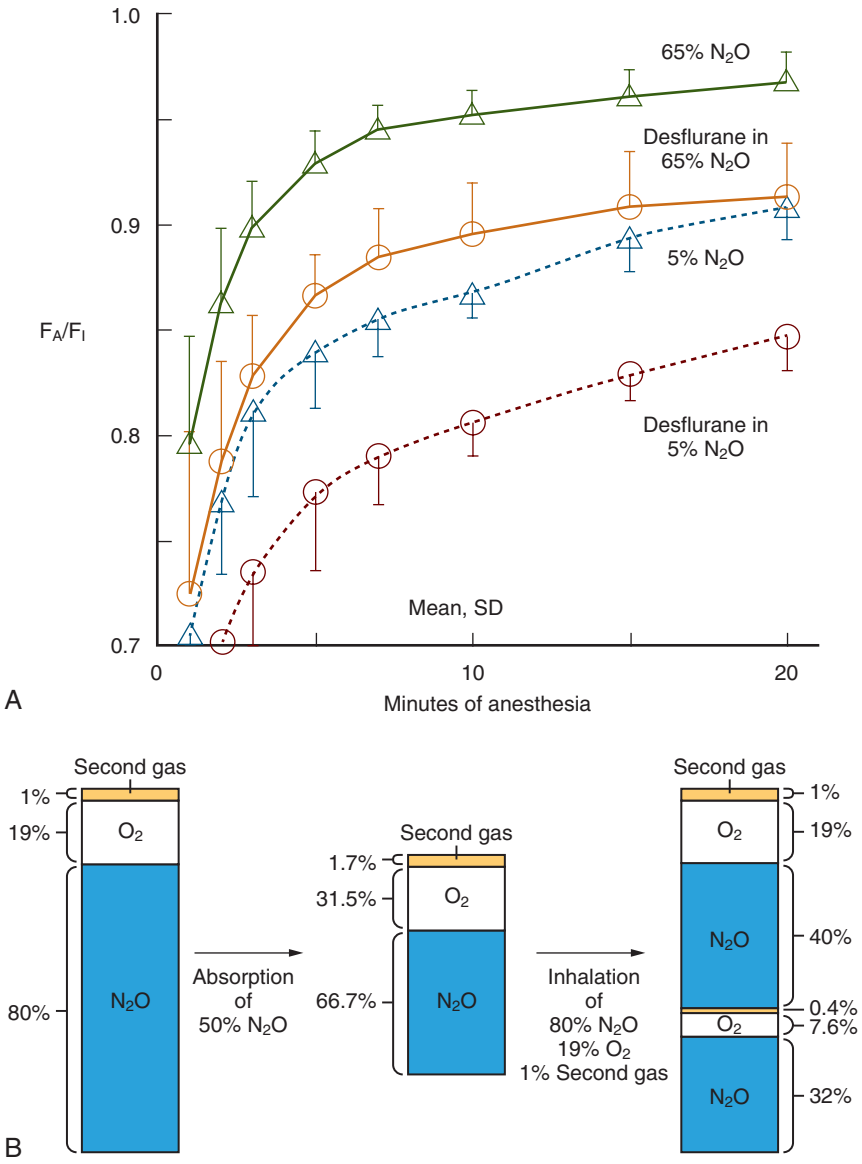
• **Fig. 3.10** Context-sensitive decrement time as a function of total anesthetic time, agent, and cardiac output. A, Time required for the vessel-rich group concentration to decrease 92% from baseline as a function of the duration of the anesthetic. Note that the washout time increases with increasing solubility, as desflurane (the least soluble agent) is the fastest to wash out, whereas isoflurane (the most soluble agent) is the slowest to wash out for all anesthetic durations. B, Increasing cardiac output *(Q)* decreases the time to washout; all curves in this panel are for sevoflurane. (Modified from Eger EI 2nd, Shafer SL. Tutorial: context-sensitive decrement times for inhaled anesthetics. *Anesth Analg.* 2005;101:688–696.)

Nitrous Oxide: Concentration Effect, Second Gas Effect, Diffusion Hypoxia, and Effects on Closed Gas Spaces

The higher the concentration of an inhaled anesthetic, the faster the alveolar concentration approaches the inhaled concentration.[36] This is termed the *concentration effect* and is only of clinical relevance with gases administered at high concentrations such as nitrous oxide and xenon. When an inhaled anesthetic, such as nitrous oxide, is administered in high concentrations, the gas is rapidly taken up into blood (for nitrous oxide, the rate is on the order of 1 L/min). Assuming that the amount of oxygen uptake is approximately balanced by the amount of CO_2 eliminated, anesthetic uptake results in reduced alveolar volume. The absorbed nitrous oxide is replaced by a volume of gas with proportions similar to the initial inhaled mixture, resulting in a more rapid rise in the alveolar concentration of nitrous oxide (the so-called concentration effect). The concentration effect is due to both a concentrating of residual gases and an effective increase in alveolar ventilation due to the large volume of anesthetic gas absorbed, which is replaced by additional inspired gas minimizing the fall in alveolar anesthetic concentration (Fig. 3.11).[37] At the extreme of 100% inspired anesthetic gas, the effects of dilution of alveolar gas during uptake is completely eliminated and uptake is limited only by alveolar ventilation (other factors staying constant).

The concentration effect also affects other gases present in the inspired gas, including the more potent volatile agents. If a second gas is administered at the same time as a low-potency gas that is taken up in large volumes like nitrous oxide, the concentration of the second gas rises faster than it would in the absence of the high-concentration gas. This is termed the second gas effect and is due to the uptake of significant volumes of alveolar nitrous oxide that serves to concentrate the residual gases in the inspired mixture and to increase alveolar ventilation (second gas effect).[37,38] This process can speed induction of inhalational anesthesia. Ironically, perhaps, induction of anesthesia tends to promote ventilation-perfusion scatter, which exaggerates the concentrating effect in those alveoli, because uptake preferentially occurs in areas with a lower ventilation-perfusion ratio. As a result, the second gas effect also has an even more profound effect on arterial than alveolar concentrations.[39]

Analogous to the second gas effect during induction, when a low-potency gas like nitrous oxide is discontinued, it diffuses rapidly



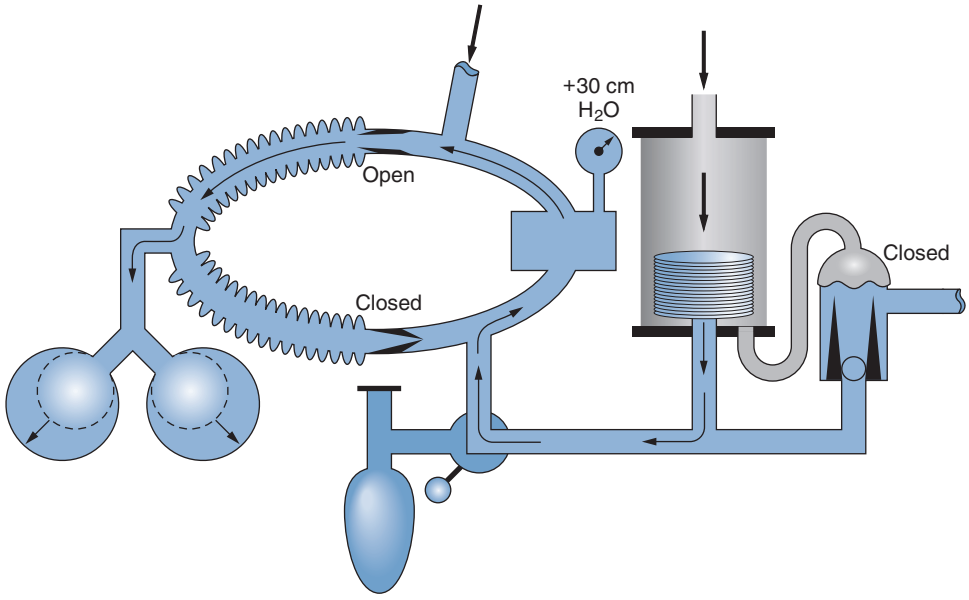
• **Fig. 3.11** Second gas and concentration effects. A, The F_A/F_I of nitrous oxide *(N_2O)* increases to a higher level when delivered at a concentration of 65% (*blue* curve, upper panel) than at a concentration of 5% (*green* curve), a demonstration of the concentration effect. Similarly, the F_A/F_I of desflurane increases to a higher level when delivered with 65% N_2O (*red* curve) than when delivered with 5% N_2O (*brown* curve), a demonstration of the second gas effect. B, Absorption of the very soluble N_2O increases the relative concentration of the second gas. Uptake of 50% of the N_2O does not reduce its concentration by half because the reduction in volume increases its concentration as well as that of the second gases (oxygen and the second gas). A subsequent breath diminishes this effect by mixing the concentrated mixture with the delivered gas, yet the second gas is still more concentrated. *F_A*, Alveolar (end-tidal) concentration; *F_I*, inspired concentration; *N_2O*, nitrous oxide; *O_2*, oxygen. (A, Modified from Taheri S, Eger EI 2nd. A demonstration of the concentration and second gas effects in humans anesthetized with nitrous oxide and desflurane. *Anesth Analg.* 1999;89:774–780. B, Modified from Stoelting RK, Eger EI 2nd. An additional explanation for the second gas effect: a concentrating effect. *Anesthesiology.* 1969;30:273–277.)

into the alveoli, contributing to second gas removal of more potent volatile anesthetics. Nitrous oxide elimination falls exponentially to low rates after about 5 minutes. The large volumes of dissolved nitrous oxide can also cause diffusion hypoxia by diluting alveolar oxygen. Up to 30 L of nitrous oxide can accumulate in the body within 2 hours, and this volume is added to the expired volumes.[40] This eliminated nitrous oxide mixes with alveolar gas, reducing the concentration of oxygen and potentially generating a hypoxic mixture (diffusion hypoxia); this can be minimized by increasing inhaled oxygen during initial recovery. The large volumes of nitrous oxide can also dilute alveolar CO_2, leading to arterial hypocarbia and reduced respiratory drive.[41] The second gas effect has also been shown to occur in reverse during emergence, where the rapid elimination of nitrous oxide dilutes alveolar partial pressure of the potent volatile anesthetic to speed emergence.[42]

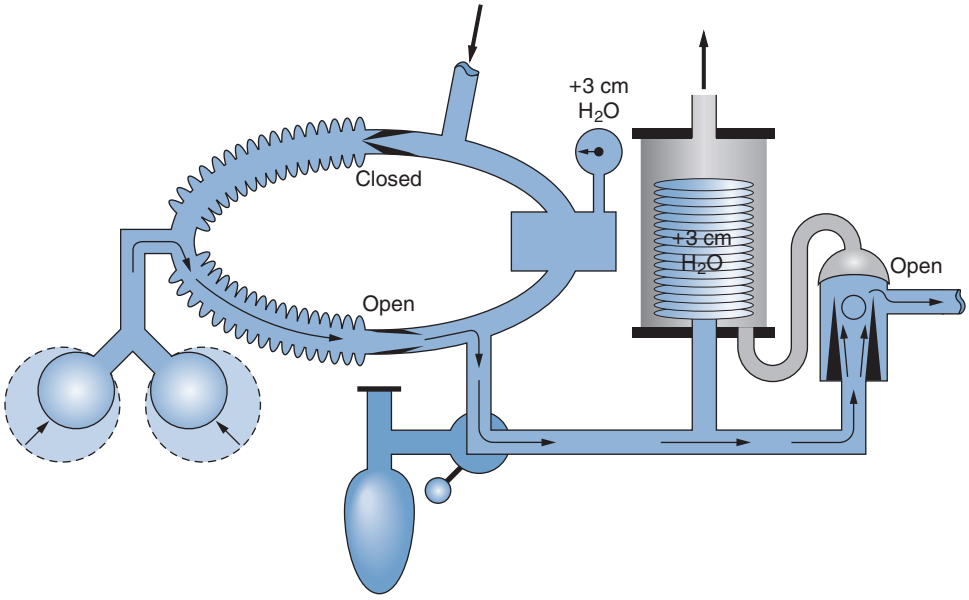
Nitrous oxide (blood:gas partition ratio of 0.47) is roughly 30 times as soluble in blood as nitrogen (blood:gas partition ratio of 0.015). As a result, nitrous oxide accumulates in closed gas spaces that contain nitrogen faster than the nitrogen can diffuse out. This can lead to distention of closed air-containing spaces such as the middle ear, bowel, pneumothorax, air emboli, or tracheal tube cuff. The volume of distensible spaces increases to the extent that the nitrous oxide concentration is equal to the alveolar, and in turn, blood nitrous oxide concentration in volume percent. Hence, the extent of this increase is proportional to the concentration of alveolar nitrous oxide at low (i.e., single-digit concentrations), but is about twofold for 50% nitrous oxide and threefold for 75% nitrous oxide. Expansion is time-dependent but can be rapid for air emboli. For poorly compliant spaces like the middle ear, diffusion of nitrous oxide can cause a potentially deleterious increase in pressure proportional to its alveolar concentration.

Gas Delivery Systems

Inhaled anesthetics are delivered to the lungs using an anesthesia circuit. This serves several functions: delivering oxygen and inhaled drugs to the patient, maintaining temperature and humidity of inhaled gases, removing exhaled CO_2, and ultimately removing



A **Inspiratory phase**



B **Expiratory phase late**

• **Fig. 3.12** The anesthetic circle system. Fresh gas flow enters the inspiratory limb, which has a one-way valve that allows flow toward the patient. The inspiratory limb meets the expiratory limb at the T-piece. The circuit dead space is determined by the volume of everything between the patient and the T-piece. A second one-way valve in the expiratory limb limits flow away from the patient. The bag and ventilator bellows affect circuit pressure on the expiratory side of the circuit. A switch valve gives the user choice between manual and mechanical ventilation. When manual ventilation is selected, an adjustable pressure-limiting valve vents excessive pressure to the scavenging system. When the ventilator is in operation, the scavenger system is cyclically opened. *Arrows* indicate direction of gas flow. During inspiration, oxygen compresses the ventilator bellows and seals the scavenger system. As a result of the one-way valves in the circuit, the increased pressure forces gas into the lungs. Release of the pressure in the ventilator bellows opens the scavenger system and allows gas to return from the patient.

drugs from the patient. Three broad classes of circuits are in use: rebreathing circuits where inspired and exhaled gases mix (Bain circuit), non-rebreathing circuits in which one-way valves separate inhaled from expired gases (self-inflating resuscitation bag-valve system), and circuits that use a CO_2 absorbent (circle systems with both inspiratory and expiratory valves). The most common inhaled drug delivery system used in modern anesthesia machines is a circle system (Fig. 3.12).

Circle systems consist of inspiratory and expiratory limbs, a reservoir bag, a canister of CO_2 absorbent (e.g., soda lime), one-way

valves to direct gas flows (one each on the inspiratory and expiratory limbs), a Y-piece that attaches the inspiratory and expiratory limbs to the respiratory tract via a mask or tracheal tube, a fresh gas inlet, and a relief valve. The CO_2 absorbent removes CO_2 in an exothermic reaction by producing water and a carbonate:

Reaction of CO_2 With Barium Hydroxide Lime (Baralyme, Obsolete)

$$Ba(OH)_2 + 8\,H_2O + CO_2 \leftrightarrow BaCO_3 + 9\,H_2O + \text{heat}$$

$$9\,H_2O + 9\,CO_2 \leftrightarrow 9\,H_2CO_3$$

$$9\,H_2CO_3 + 9\,Ba(OH)_2 \leftrightarrow 9\,BaCO_3 + 9\,H_2O + \text{heat}$$

Reaction of CO_2 With Lithium Hydroxide (in Current Use)

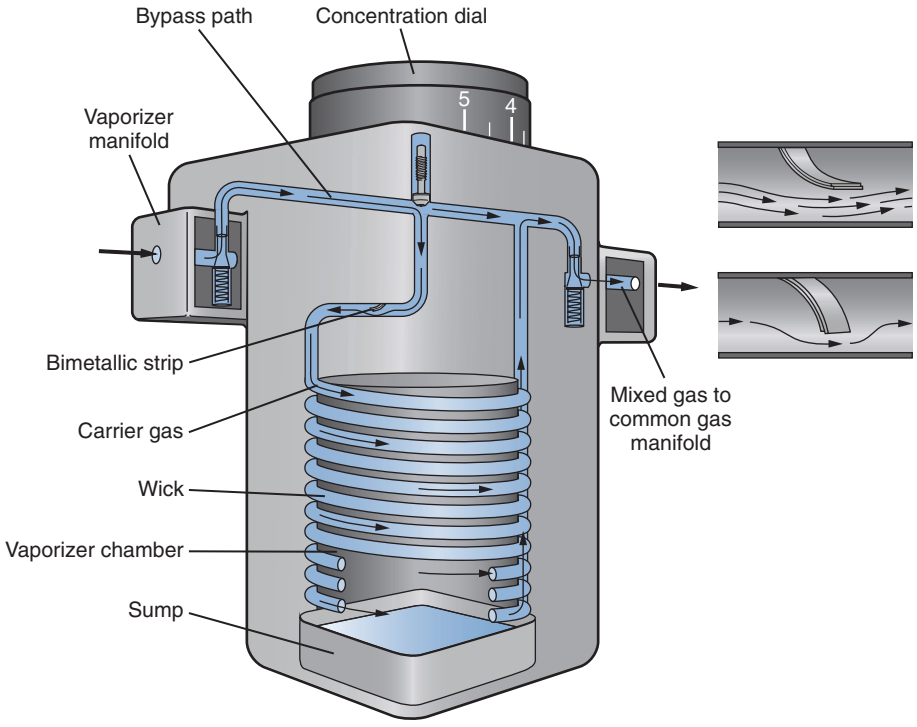
$$2\,LiOH + 2\,H_2O \leftrightarrow 2\,LiOH \cdot H_2O$$

$$2\,LiOH \cdot H_2O + CO_2 \leftrightarrow Li_2CO_3 + H_2O + \text{heat}$$

CO_2 absorbent can degrade inhaled anesthetics to potentially harmful breakdown products. Desiccated soda lime and barium hydroxide–based absorbents degrade sevoflurane (see earlier text); this can be avoided by eliminating monovalent bases from soda lime or by using a lithium hydroxide–based absorbent. Additionally, the heat produced by desiccated absorbent can be sufficient to ignite combustible degradation products, leading to absorbent canister explosion.[43,44] A number of proprietary absorbents (e.g., Amsorb, Drägersorb) have been developed that do not contain monovalent bases to minimize degradation of sevoflurane and desflurane.

Vaporizers are devices that add desired anesthetic concentrations to the fresh gas flow and ultimately to the anesthetic circuit and patient. Most modern vaporizer designs, with the notable exception of common desflurane vaporizers, use temperature-compensated variable bypass manifolds that are concentration calibrated for use with a single anesthetic agent (Fig. 3.13). These devices function by diverting a portion of the fresh gas flow through a vaporizing chamber where the flow is saturated with volatile anesthetic; the amount of flow that bypasses the chamber is determined by the ambient temperature and the desired concentration (in volume percent) of anesthetic in the vaporizer output. In contrast, desflurane vaporizers compensate for the very high vapor pressure of desflurane at room temperature by using an electric heater to warm and pressurize the desflurane into a vapor that is injected into the fresh gas flow at a rate to deliver the set desflurane concentration in the vaporizer output.

The anesthetic circuit has significant effects on the kinetics of inhaled drug delivery and elimination by determining inspired gas concentrations (F_I). Rebreathing allows mixing of inspired and expired gases (with depleted anesthetic concentration resulting



• **Fig. 3.13** A variable bypass anesthetic vaporizer. Fresh gas flows through the vaporizer and a portion of the flow is diverted through the vaporizer chamber. This carrier gas flows over a wick that ensures equilibration of the anesthetic with the carrier gas. The carrier flow, saturated with anesthetic, is then mixed back with the fresh gas that bypasses the reservoir to achieve the desired anesthetic concentration (volume percent). A temperature-compensating valve adjusts the amount of gas flow that is diverted to ensure stable temperature because vapor pressure is temperature-dependent. Note that the portion of flow diverted through the vaporizer chamber, as well as the temperature-compensation valve, must both be calibrated for each individual agent. Filling a variable bypass vaporizer with an agent other than the one for which it is calibrated can lead to delivery of a dangerous concentration of anesthetic. (Adapted from Morgan GE, Mikhail MS, Murray MJ. *Clinical Anesthesiology.* 4th ed. New York: McGraw-Hill; 2006.)

from uptake) and thus reduces delivered anesthetic concentration below that delivered by the vaporizer. This is minimized when the fresh gas flow exceeds minute ventilation. The circuit itself has a time constant (τ) for equilibration with the gas delivered from the machine (τ = volume of the breathing system/fresh gas flow). This determines the wash-in kinetics of the circuit. If the delivered gases immediately mix with the circuit gases, the anesthetic concentration in the breathing system reaches 95% of the delivered concentration in 3τ; however, more efficient circuit designs are commonly used.[45] Increased gas flow or reducing circuit volume accelerates this equilibration and speeds the rate of induction.

Low-Flow Anesthesia

The choice of fresh gas flow in the circuit can dramatically affect the amount of agent used, and hence the cost of anesthetic drugs, particularly for long cases. The lowest cost approach is to use a closed circuit, where there are no leaks in the circuit, the pressure limiting valve is closed, and the fresh gas flow uses 100% fraction of inspired oxygen (FIO_2) to exactly offset the uptake/consumption of oxygen by the patient (roughly 2.5–3 mL O_2/kg per minute for adults, or approximately 200 mL/min for a typical 70-kg adult). Closed-circuit administration minimizes the cooling and drying effects of the fresh gas flow for the patient but leaves little margin for error; any change in anesthetic concentration requires temporarily increasing the gas flow to speed equilibration. With slightly higher flow rates, small leaks in the circuit can be overcome and gradual changes in the anesthetic concentration are possible while still keeping costs down. As the fresh gas flow increases, times to equilibration of changes in inhaled anesthetic concentration are faster, but the patient is exposed to cooler and drier gases potentially compromising their pulmonary function, and more agent and inhaled gases are wasted.[46] Wasted inhaled anesthetics in the operating room are typically collected and then scavenged through a wall suction system to be vented into the atmosphere. For cost reasons, anesthesia systems using xenon actively recover as much xenon is possible from the waste gas stream before venting the residual. Anesthetic agents have substantial greenhouse gas and ozone depletion potential, so minimizing venting to the atmosphere is appropriate.[47] Sevoflurane is usually used at gas flows greater than 2 L/min out of concern for compound A production, but as discussed earlier there is minimal evidence of clinically significant nephrotoxicity in humans.[25]

As an alternative to traditional low-flow semi-closed anesthesia systems, one commercially available device, the AnaConDa (Sedana Medical, Danderyd, Sweden), inserts a filter between the patient and the Y-piece that selectively adsorbs and desorbs volatile anesthetics with each breath while passing oxygen, nitrogen, and CO_2 freely.[48] This functionally results in a breathing system that is closed with respect to volatile anesthetics but open for the remainder of the gas stream.

Pharmacoeconomic Considerations

The cost of inhaled anesthetic consumed during an anesthetic is determined by four principal factors: the cost of liquid anesthetic per milliliter, the volume of vapor that results from each milliliter of liquid, the volume percent of anesthetic delivered (determined largely by the potency), and the chosen fresh gas flow rate.[49] The volume percent delivered is determined by two factors: anesthetic potency and solubility. While potency determines the vaporizer setting at steady state (when $F_A = F_I$), solubility affects the vaporizer setting during wash-in as some degree of overpressure might be required to speed induction before equilibration to steady state occurs. The significance of the solubility issue is illustrated by a study that used a 10-minute wash-in period before initiating controlled fresh gas flows for delivery of anesthetic. Desflurane consumption was governed by fresh gas flow, and although there was a trend toward increased consumption of sevoflurane and isoflurane at higher fresh gas flows, halothane consumption was totally independent of the fresh gas flow.[50]

For most institutions in the United States, isoflurane is the least expensive anesthetic on a per milliliter basis and desflurane the most expensive, with sevoflurane slightly less expensive than desflurane. However, the lesser potency of desflurane (with an MAC of 6% compared with an MAC of 2% for sevoflurane) means that at steady state significantly more desflurane is consumed per hour for a given anesthetic depth at the same flow rates. Because most anesthesiologists are comfortable with using low flow rates for desflurane, but not sevoflurane, the cost differential for longer cases favors desflurane if low flows are used.

Emerging Developments

Intravenous Delivery of Volatile Anesthetics

Early reports suggested that intravenous delivery of liquid volatile agents incurs significant morbidity with risk of pulmonary damage or death.[51–54] Subsequently, several groups have reported that volatile anesthetics, including halothane, isoflurane, and sevoflurane, can be successfully delivered intravenously as a lipid emulsion.[52,55–58] Initial reports of nonlethal intravenous delivery of anesthetics used lipid emulsion as the carrier vehicle, but ongoing research to increase anesthetic concentrations in the emulsion has led to the development of fluoropolymer-based vehicles.[59] Volatile anesthetic emulsions can be delivered by bolus or continuous infusions, and preserve respiratory drive while causing a rapid loss of consciousness in animals. Intravenous delivery appears to preserve most properties of volatile agents, including early and late cardiac preconditioning.[58,60] The principal advantage of these preparations is the rapid onset, because there is no need to wait for uptake through the lungs and the resultant slow rise in alveolar concentration. However, intravenous delivery gives up the advantages of inhalational delivery. For example, inhalational anesthetic delivery results from equilibration with a (measurable) delivered concentration of anesthetic, and there is no accumulation of agent beyond the inhaled concentration or need for continuous adjustment of delivery rate to ensure a given blood-tissue concentration. As a result, a large amount of research has gone into developing target-controlled infusions for intravenous agents to make their use more akin to use of a vaporizer for an inhaled agent (see earlier text).[61] Adverse effects of the accumulating vehicle are also potentially problematic.

Volatile Anesthetics in the Intensive Care Unit

Volatile anesthetics offer the intensivist an additional tool for sedation in the intensive care unit (ICU). Although this may require placing an anesthesia machine in the ICU, the AnaConDa device (see the previous discussion in the "Low-Flow Anesthesia" section) will allow anesthetic delivery with a normal ICU ventilator, with potential advantages for patients requiring nontraditional ventilation modes. Volatile anesthetics are established lifesaving interventions for refractory status asthmaticus[62] and status epilepticus.[63] A recent meta-analysis showed that volatile anesthetics can shorten the

duration of mechanical ventilation,[64] presumably based on their fast washout and reduced awakening time. This should offer the advantage of minimizing complications of mechanical ventilation, with a presumed benefit in mortality and ICU length of stay. Further study will be required to justify a broad adoption of volatile anesthetics for long-term sedation, however, as all of the usual cautions with interpreting meta-analyses apply. Only one of the included trials was blinded; most of the trials had small or moderate enrollments; the majority of the studies included in the meta-analysis did not include clinically relevant outcomes such as delirium, major morbidity, or mortality; and volatile anesthetics were not compared against dexmedetomidine, which is known to have several benefits of reduced time to extubation, reduced ICU length of stay, and reduced incidence of delirium.[65,66]

Key Points

- The effects of inhaled anesthetics depend on the anesthetic concentration at their effect sites. This parallels the alveolar anesthetic concentration and not the total amount of absorbed anesthetic.
- The potency of different agents can be compared using the MAC, the minimum alveolar concentration of anesthetic required to prevent movement (immobilization) in 50% of subjects in response to a standardized surgical stimulus.
- Blood and tissue concentrations of a gas are determined by the partial pressure of the gas and its blood:gas or tissue:gas partition ratio (an index of its solubility).
- The physical properties of inhaled anesthetics, in particular solubility, determine many aspects of their pharmacokinetic behavior.
- Blood solubility is a major determinant of the rate of inhaled anesthetic uptake and elimination from the alveoli; both are faster with less soluble agents.
- Physiologic factors that govern inhaled anesthetic uptake and elimination include primarily alveolar ventilation and cardiac output.
- Extrinsic factors that affect inhaled anesthetic uptake and elimination, by determining changes in the alveolar concentration, include minute ventilation, fresh gas flow, and inspired concentration.
- Inhaled anesthetic tissue distribution depends on relative perfusion, the gradient between arterial and venous anesthetic concentration, and intertissue distribution.
- Volatile anesthetics in use today are minimally metabolized; most of this metabolism is by the cytochrome P450 system.

OUTLINE

Background
Liquids, Gases, and Vapors
Liquefaction and Vaporization
Gas Laws
Humidity
Gas Conditions

Background

Anesthesiology involves management of medications in both liquid and gaseous forms. Thus, knowledge of the gas laws that govern the behavior of liquids, gases, and vapors—and the transitions between these states—is critical to anesthetists.

Liquids, Gases, and Vapors

Substances can exist in 3 states, or phases (solid, liquid, and gaseous). The difference between these states is a matter of the kinetic energy of the molecules and the degree of their interaction.

Liquids are, for all practical purposes, incompressible. Their volume depends largely on their temperature and the structure and mass of their molecules. These properties determine the interaction between the molecules. While the molecules in a liquid can move freely within the liquid, the kinetic energy of molecules in a liquid is too low to overcome the intermolecular attractive forces, preventing transition into the gas phase.

Gases, in contrast, are compressible. Like liquids, they take on the volume of their container. Molecule kinetic energy is higher than for liquids; in fact, molecular kinetic energy in gases is so high that intermolecular interactions are much less important. **Pressure** is the force per area that a gas exerts on the walls of its container.

Vapor describes the gas form of a substance when it exists in equilibrium with its liquid form, for example, when the temperature is low enough such that the substance can exist in gaseous or liquid form.

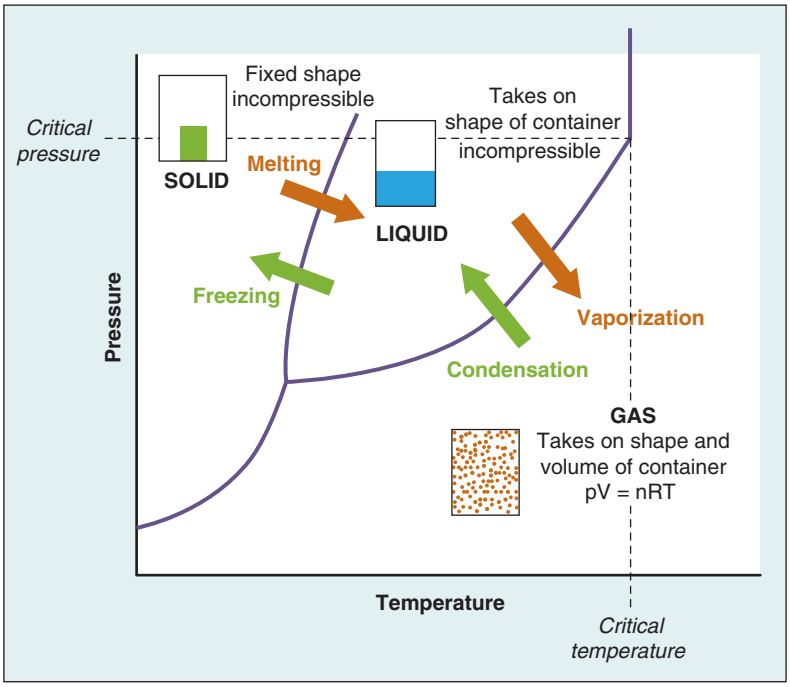
Liquefaction and Vaporization

When gases are cooled and compressed, they will at some temperature and pressure condense into liquids. The liquefaction occurs at the point when the kinetic energy of the gas molecules is insufficient to overcome the forces of intermolecular attraction. The exact temperature and pressure at which this happens depends on the molecular mass and molecular structure. The **critical temperature** is the temperature above which a gas cannot be liquefied, regardless of how much it is compressed (Fig. P1.1). The **critical pressure** is the pressure needed to liquefy a gas at exactly its critical temperature. Above its critical temperature, a substance will exist only in its gaseous form and it is commonly referred to as a gas. Below its critical temperature, a substance can exist as a solid, liquid, or gas. When below its critical temperature and gaseous, a substance is commonly referred to as a vapor**.** At room temperature, pressurized cylinders of O_2, N_2, or air contain gases only, while cylinders of CO_2 or N_2O contain both liquid and gas states in equilibrium (Table P1.1).

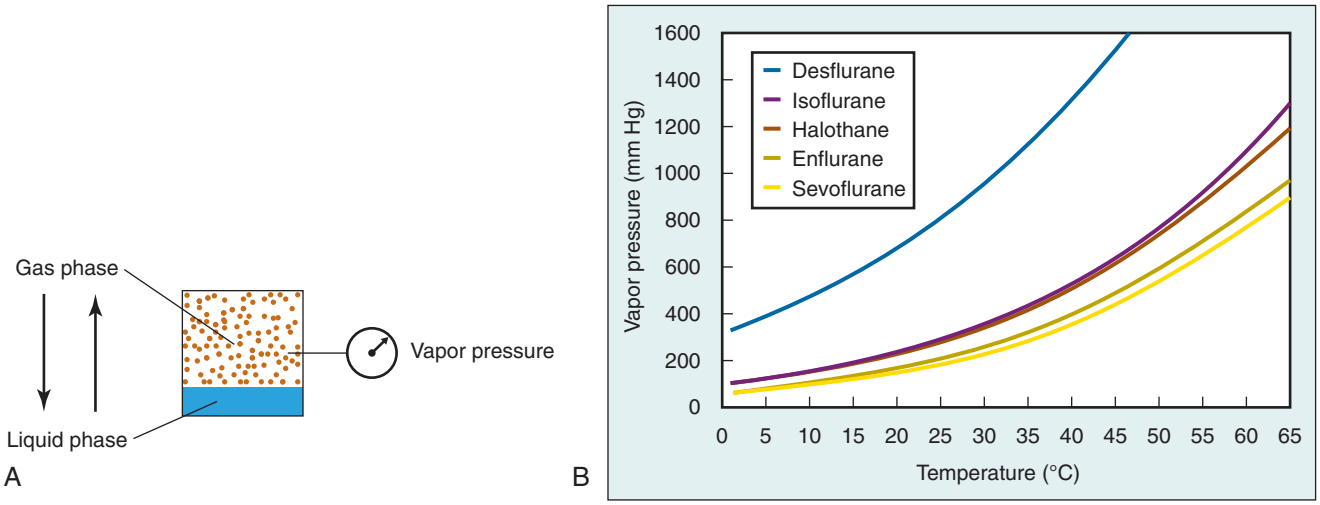
Vapor pressure is the pressure in a closed container at which the liquid and vapor phases are in equilibrium (when the vapor phase is said to be **saturated**). Vapor pressure depends on the substance itself (its molecular structure, mass, and so on) and temperature (Fig. P1.2).[3] The temperature at which vapor pressure equals atmospheric pressure is called the atmospheric **boiling point**. It takes heat for a substance to change state (e.g., from liquid to gas). The heat needed to vaporize a specific mass (1 kg) of a substance at a given temperature is known as the **specific latent heat**. Often, the vaporization process draws heat from the liquid itself or from the environment, cooling them. Since vaporization

TABLE P1.1 Critical Temperatures and Pressures of Selected Gases[1,2]

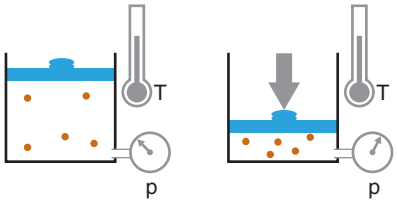
	Critical Temperature (°C)	Critical Pressure (bar)
O_2	–118.2	50.4
N_2	–147	34
CO_2	30.9	73.8
N_2O	36.5	72.5
Air	–140.7	37.86



• **Fig. P1.1** Diagram of solids, liquids, and gas phases. Substances change depending on temperature and pressure. Arrows signify the transition from one phase to another. Substances require external energy to melt and vaporize (endothermic, *red*), while condensation and freezing give off energy (exothermic, *green*). Not shown are sublimation, the transition from solid phase to gas phase, and deposition, the transition from gas phase to solid phase.



• **Fig. P1.2** (A) Diagram of vapor pressure. The vapor pressure is the pressure in a closed container in which a substance's liquid and vapor phases are in equilibrium. It depends on the substance and increases with temperature. (B) Vapor pressures of volatile anesthetic agents.[3] Desflurane exhibits not only a much higher vapor pressure than other agents—desflurane's vapor pressure also changes faster when its temperature changes and reaches the atmospheric pressure (e.g., 760 mm Hg at sea level) close to room temperature (22.8°C). This necessitates fundamentally different vaporizer designs for desflurane than for other volatile agents. (From Andrews JJ, et al. Consequences of misfilling contemporary vaporizers with desflurane. *Can J Anaesth.* 1993;40(1):71–76.)



• **Fig. P1.3** Diagram of Boyle's Law. Assuming the number of molecules and the temperature (T) of a gas do not change, its volume changes inversely with its pressure (p).

itself is dependent on temperature, vaporizers have temperature-compensation mechanisms to prevent cooling from reducing vaporizer output.

Gas Laws

The gas laws describe relationships between pressure, volume, temperature, and amount of gases. The ideal gas law describes the behavior of a gas in which molecules move randomly and do not interact with each other, except for their collisions. Many of the gases in anesthesia behave as ideal gases, with notable exceptions. An important exception is when a gas is close to its transition between the liquid and gas phases or when it exhibits strong intermolecular interactions (e.g., water).

In 1662, Boyle described Boyle's Law (Fig. P1.3): *as long as the number of molecules and the temperature of a gas do not change, its volume changes inversely with its pressure.*

$$p_1 \times V_1 = p_2 \times V_2, \text{ or}$$

$$V \propto \frac{1}{p}$$

Consider, for example, an E cylinder with an internal volume of 5.1 L (Fig. P1.4). If it is completely filled with oxygen, its internal pressure is 131 bar (or 1900 psi) at room temperature (70°F or 21°C). Boyle's law can be used to determine the volume of the oxygen in that cylinder, if the oxygen is released into an atmospheric pressure of 14.69 psi (1.013 bar) without changing temperature:

$$131\ bar \times 5.1\ L = 1.013\ bar \times V$$

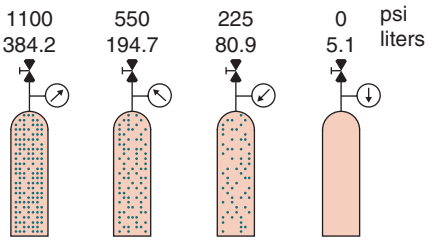
$$\rightarrow V = \frac{131\ bar \times 5.1\ L}{1.013\ bar} = 660\ L$$

In the 1700s, when hot air balloons enjoyed increasing popularity in prerevolutionary France, Charles described **Charles's Law**, sometimes also called **Charles and Gay-Lussac's Law** (Fig. P1.5), from the scientist who first published[4] Charles' discovery in the early 1800s: *as long as the number of molecules and the pressure of a gas do not change, its volume changes linearly with absolute temperature (in °K).*

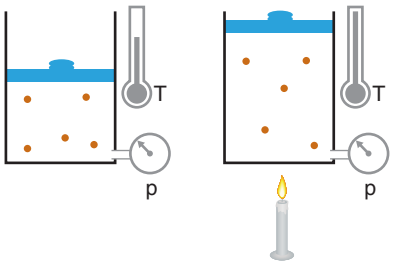
$$\frac{V_1}{T_1} = \frac{V_2}{T_2}, \text{ or}$$

$$V \propto T$$

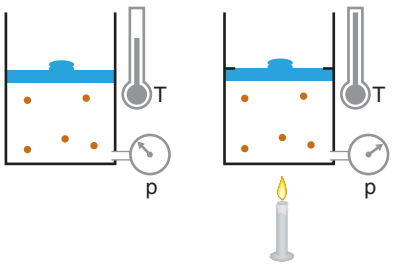
For example, in a hot air balloon, as temperature increases, the volume of the gas in the balloon expands and it becomes less dense, eventually causing enough buoyancy to float the balloon.



• **Fig. P1.4** Boyle's Law applied to E-sized cylinders. The pressure (above atmospheric pressure, measured in pounds per square inch, psi) inside of an oxygen E cylinder is linearly related to the volume of oxygen when released into atmospheric pressure.



• **Fig. P1.5** Diagram of Charles's Law. Assuming that the number of molecules and the pressure (p) of a gas do not change, its volume changes linearly with absolute temperature (T, measured in Kelvin).



• **Fig. P1.6** Diagram of Amonton's Law. The pressure (p) of a fixed amount of gas in a fixed volume container changes linearly with absolute temperature (T, measured in Kelvin).

Another example is the expansion of an inflatable laryngeal mask airway's cuff when it is heated in an autoclave (or by the patient's body heat).

Amonton's Law,[5] sometimes also referred to as **Gay-Lussac's Law**, describes the relationship between the temperature and the pressure of a gas (Fig. P1.6): *the pressure of a fixed amount of gas in a fixed-volume container changes linearly with absolute temperature (in °K).*

$$\frac{p_1}{T_1} = \frac{p_2}{T_2}, \text{ or}$$

$$p \propto T$$

This law explains how after driving some distance, when the tires of a car heat up, the tire pressure is higher compared to the pressure in cold tires.

Combining Boyle's Law, Charles's Law, and Amonton's Law yields the **General Gas Law**, or Combined Gas Equation (Fig. P1.7): *for a fixed amount of gas, its volume changes linearly*

with the change in its absolute temperature and reciprocally with the change in its pressure:

$$\frac{p_1 \times V_1}{T_1} = \frac{p_2 \times V_2}{T_2}, \text{ or}$$

$$V \propto \frac{T}{p}$$

(where T is absolute temperature in °K).

Avogadro's Law (Fig. P1.8) states that *as long as the pressure and temperature of a gas stay constant, its volume will change linearly with the number of molecules:*

$$\frac{V_1}{n_1} = \frac{V_2}{n_2}, \text{ or}$$

$$V \propto n$$

(where T is absolute temperature in °K).

The variable "n" is the amount of gas in mol, where 1 mol is the amount of a substance that contains 6.02×10^{23} molecules of that substance (Avogadro's number).

At a temperature of 0°C and a pressure of 760 mm Hg (Standard Temperature and Pressure [STP]), 1 mol of a gas occupies exactly 22.4 L.

The **Ideal Gas Law** results from combining Avogadro's Law with the General Gas Law (Fig. P1.9), which relates all the state variables of an ideal gas to each other:

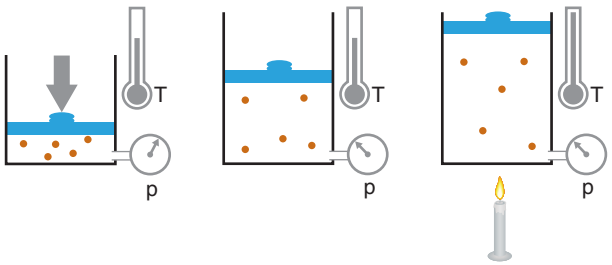
$$p \times V = n \times R \times T = N \times k \times T$$

where

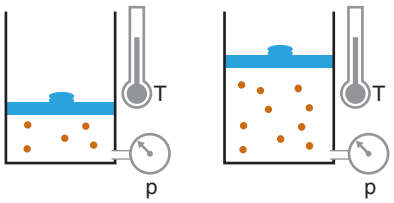
p = pressure (Pa)
V = volume (m^3)
n = amount of gas (mol)
N= number of molecules (1)
R= Universal Gas Constant 8.3145 J/(mol × K)
K = Boltzmann constant 1.381×10^{-23} J/K
T = Absolute Temperature in Kelvin (°K)

The number of molecules in 1 mol is constant and called **Avogadro's Number**, $N_{Avogadro}$:

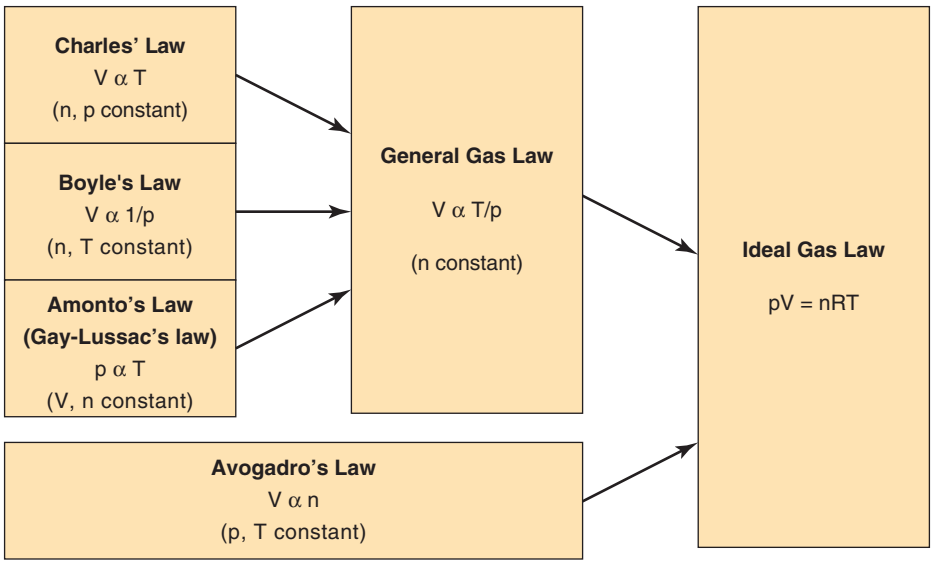
$$N_{Avogadro} = \frac{N}{n} = \frac{R}{k} = 6.02212 \times 10^{23}$$



• **Fig. P1.7** Diagram of the General Gas Law. For a fixed amount of gas, its volume will change linearly with the change in its absolute temperature (T, measured in Kelvin) and reciprocally with the change of its pressure (p).



• **Fig. P1.8** Diagram of Avogadro's Law. Assuming constant pressure (p) and temperature (T) in a gas, its volume will change linearly with the number of molecules.



• **Fig. P1.9** Diagram of the Gas Laws. The gas laws describe the relationships between the pressure, volume, temperature, and amount of gases. *n,* Amount of gas (mole); *p,* pressure (Pa); *R,* universal gas constant (8.314 J/(K × mol)); *T,* temperature (K); *V,* volume (m^3).

Avogadro hypothesized that the behavior of gases as described in the ideal gas law is independent of the identity of the gas:

$$p \times V = (n_{Gas1} + n_{Gas2}) \times R \times T.$$

From this, Dalton's Law of Partial Pressures follows directly: *the total pressure of a gas mixture is the sum of partial pressures of the constituent gases.*

$$p_{Total} = p_{Partial_{GAS1}} + p_{Partial_{GAS2}}$$

Dalton's Law, combined with Boyle's Law, allows the conversion from volume percent to partial pressures and vice versa:

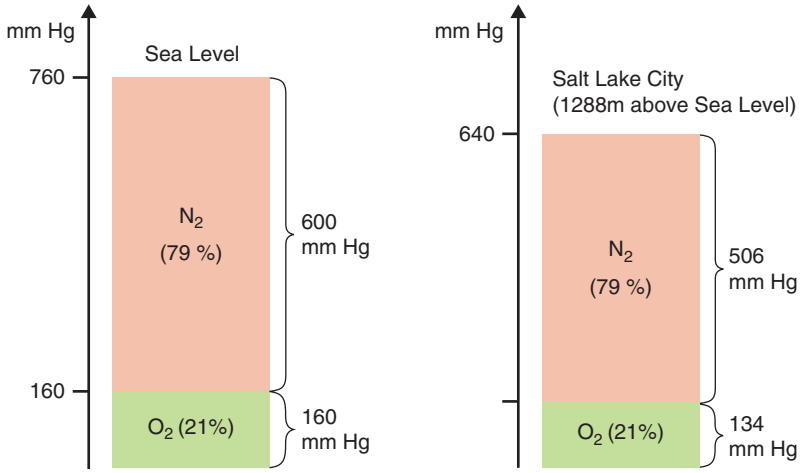
$$p_{Partial_{GAS1}} = \frac{V_{GAS1}}{V_{TOTAL}} \times p_{TOTAL}$$

Dalton's law describes, for example, how the partial pressure of oxygen in air is lower at altitude than at sea level, even though the volume percent is the same (Fig. P1.10).

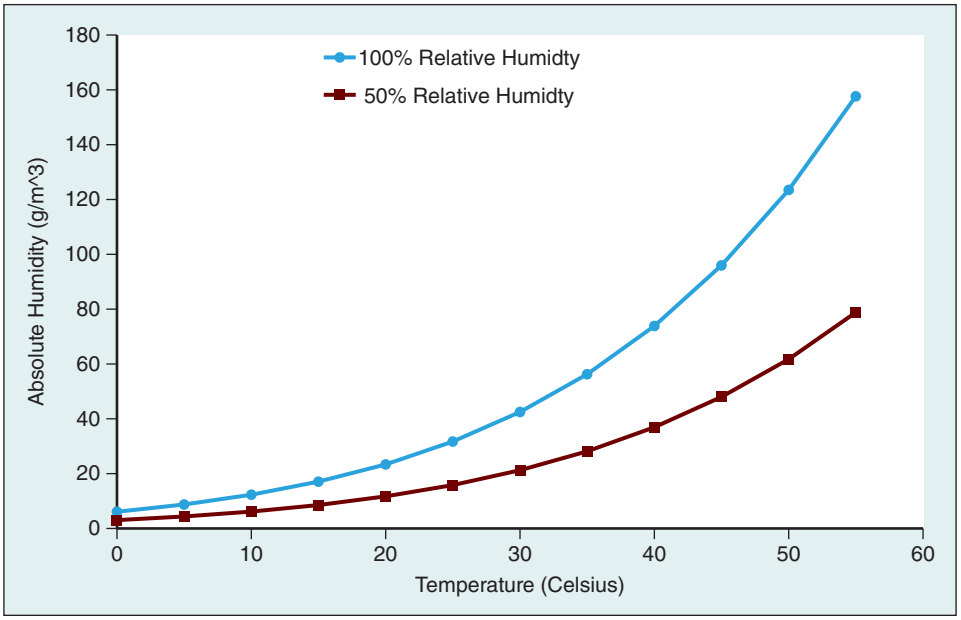
Humidity

The humidity and temperature of gas delivered to a patient are important determinants of how much moisture and heat the patient loses through respiration. Humidity can either be expressed as absolute or relative humidity.

Absolute humidity simply describes the total mass of water vapor in a given volume of gas, measured, for example, as g/m^3 or mg/L. There is a maximum capacity of gas to hold water vapor; when it is reached, the gas is said to be fully saturated.



• **Fig. P1.10** Example of Dalton's Law of Partial Pressures. The volume percent of nitrogen (N_2) and of oxygen (O_2) in ambient air do not change when going from sea level to altitude. However, because the total ambient pressure decreases (in this example, from 760 mm Hg at sea level to 640 mm Hg in Salt Lake City), the partial pressures of both gases also decrease.



• **Fig. P1.11** Maximum absolute humidity and relative humidity as a function of temperature.

TABLE P1.2 Most Commonly Used Gas Conditions

	STPD	BTPS	ATPS
Temperature	0°C (273.15 K)	37°C (310.15 K)	(Ambient Temperature)
Pressure	760 mm Hg	760 mm Hg	(Ambient Pressure)
Humidity	Dry (partial pressure of water vapor: 0 mm Hg)	Saturated (partial pressure of water vapor: 47.1 mm Hg)	Saturated (partial pressure of water vapor depends on the ambient temperature)

ATPS, Ambient temperature and pressure, saturated; *BTPS,* body temperature and pressure, saturated; *STPD,* standard temperature and pressure, dry.

The maximum amount of water that can be in a given volume of gas increases with temperature (Fig. P1.11). At room temperature (20°C or 68°F), fully saturated air contains 17 mg/L water vapor. Expiratory gas, that is, fully saturated and at body temperature (37°C or 98.6°F), contains 44 mg/L of water vapor.

Relative humidity is the total mass of water vapor in a given volume of gas but expressed as a percentage of the maximum amount of water vapor the gas can hold at that temperature. The amount of water vapor is linearly related to n, the number of moles of water. Applying the gas laws (see earlier discussion), the relative humidity can also be calculated as the ratio of the actual water vapor pressure divided by the water vapor pressure of saturated gas at the given temperature. The vapor pressure of water at room temperature (20°C or 68°F) is 17.5 mm Hg and at body temperature (37°C or 98.6°F) 47.1 mm Hg.

An important function of the upper respiratory tract is to humidify inspiratory gas. With the use of an endotracheal tube, the upper respiratory tract is not involved in respiration, which can lead to drying of the lower airways. Humidifiers and heat moisture exchangers (HME) are often used to avoid this. If gas in the anesthesia breathing circuit is at higher temperatures (e.g., close to body temperature) and saturated, liquid water can condense out of the gas in parts of the breathing circuit that have lower temperatures. Because humidification of dry air (as occurs in the lungs) requires energy to vaporize the water, patient temperature can fall under anesthesia as a result of this humidification process (among other more influential reasons).

Gas Conditions

Volumes and concentrations of gases in mixtures are, as described in the gas laws, affected by the temperature, pressure, and water vapor of the gas. These conditions can differ dramatically between different parts of the anesthesia breathing circuit and between inspiration and expiration. Thus, it is customary to describe the conditions under which gas measurements are taken. The most commonly used conditions are **STPD** (Standard Temperature and Pressure, Dry), **BTPS** (Body Temperature Pressure, Saturated), and **ATPS** (Ambient Temperature and Pressure, Saturated; Table P1.2).

Physics: Monitoring Gas Concentrations

Kyle Burk and Kai Kuck

OUTLINE

Background

Calibration and Preparation Before Use

Monitoring Methods
- Sidestream
- Mainstream

Technologies
- Infrared Absorption
- Paramagnetic Oxygen Sensor
- Electrochemical Oxygen Sensor
- Mass Spectrometry
- Raman Scatter Analysis

Background

This section introduces gas monitoring methods commonly or historically used during anesthesia and reviews the physics principles underpinning these methods. Monitoring of oxygen and carbon dioxide (CO_2) concentrations is a basic and well-entrenched monitoring standard in anesthesia.[1] Volatile anesthetic agent concentrations are also routinely monitored and clinicians have come to rely on this capability as an essential feature of anesthesia workstations.

Commonly derived variables of gas monitoring include fraction of inspired oxygen (FiO_2), end-tidal oxygen concentration, inspired CO_2 concentration, end-tidal carbon dioxide concentration, respiratory rate, and end-tidal volatile anesthetic concentration, where end-tidal refers to the measurements made at the end of expiration. These measurements provide valuable information about the adequacy of oxygen delivery and ventilation. Monitoring CO_2 can indicate adequacy of ventilation, confirm correct positioning of a tracheal tube or laryngeal mask airway, and allow conclusions about metabolism and cardiorespiratory performance. Perhaps the most important function of real-time measurement of airway gases is confirmation of the integrity of the oxygen delivery system. An important nuance of airway gas monitoring relates to nitrogen. If nitrogen concentration is detected in a patient breathing 100% oxygen, it can indicate air emboli (e.g., during sitting intracranial procedures) or a circuit leak.

As with the other measured variables, such as end-tidal CO_2 concentrations, measurement of end-tidal anesthetic agent concentrations has substantial clinical utility. It enables clinicians to confirm that the targeted minimum alveolar concentration (MAC) fraction of anesthetic vapor has been achieved.[2] These measurements also have important patient safety implications. Anesthetic gas measurement detects inadvertent filling of a vaporizer with the wrong anesthetic agent and unintentional excessively high or low vaporizer settings. Monitoring inhaled anesthetic thresholds (with alarms activated) has also been demonstrated to reduce the incidence of awareness with recall after general anesthesia.[3]

Calibration and Preparation Before Use

Gas monitors should be calibrated regularly according to the manufacturer's specifications to ensure accuracy. Calibration can be performed using a calibration canister that contains a precise, set mixture of gases. Some gas monitoring technologies require warm-up time before they can accurately display gas concentrations. The length of warm-up time necessary varies depending on the technology used.

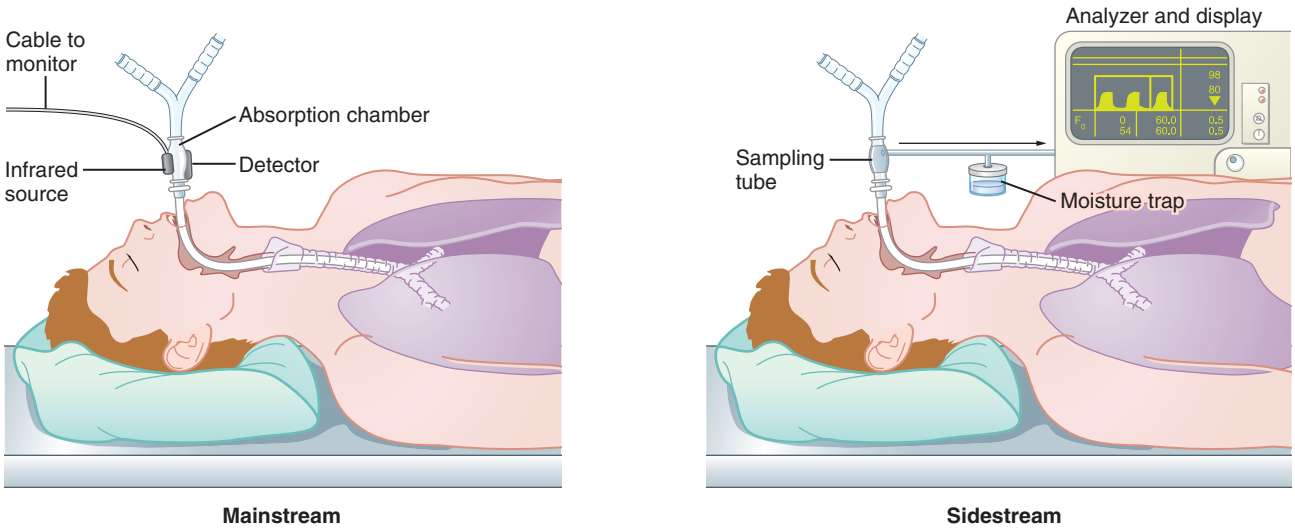
Monitoring Methods

Gas monitoring is done using one of two methods (Fig. P2.1): either diverting (i.e., **sidestream**) or nondiverting (i.e., **mainstream**).

Sidestream

Most anesthesia gas monitoring techniques use the sidestream technique to sample gas. Sidestream measurement is also commonly used with a nasal cannula to measure CO_2. A sidestream monitor uses a pump to sample gas from the breathing circuit and draw the sample into the sensor within the monitor. The length of tubing through which the sample is drawn affects the delay in the gas measurements. Because sidestream monitoring is delayed relative to flow measurements, gas monitoring using the sidestream method allows only measurement of gas concentration and not the flow rate of the gases. One advantage of sidestream monitors is that they can measure both CO_2 and anesthetic agent concentrations.

Certain compounds commonly found in breathing circuits can artifactually interfere with gas measurements. For example, water has a wide infrared (IR) absorption band and can affect the accuracy of gas monitoring. For this reason, a water trap is typically used in sidestream monitors to prevent excessive humidity in the optical measurement chamber. Similarly, the aerosol propellants in bronchodilator inhalers have overlapping absorption spectra for



• **Fig. P2.1** Mainstream gas monitors *(left)* measure gas concentrations directly in the breathing circuit. Sidestream gas monitors *(right)* use a pump that samples the gas from the main circuit and draws the sample into the sensor in the monitor.

TABLE P2.1 Gas Measurement Technologies and Their Capabilities

	Oxygen	Nitrogen	Carbon Dioxide	Volatile Anesthetics
Infrared absorption			Yes	Yes
Electrochemical oxygen analysis	Yes			
Paramagnetic oxygen analysis	Yes			
Mass spectrometry	Yes	Yes	Yes	Yes
Raman scatter analysis	Yes	Yes	Yes	Yes

carbon dioxide and certain inhaled anesthetics and can thus be misinterpreted by these monitors.[4] For example, use of an albuterol inhaler during anesthesia can result in a transient halothane reading on the gas monitor.

Standard sidestream monitors typically sample gas at 200 mL/min. Microstream monitors sample gas at 60 mL/min, allowing sidestream monitoring during very small tidal volumes (e.g., neonatal ventilation). Some monitors, especially those that are integrated with anesthesia machines, return the sampled gas back into the breathing circuit.

Mainstream

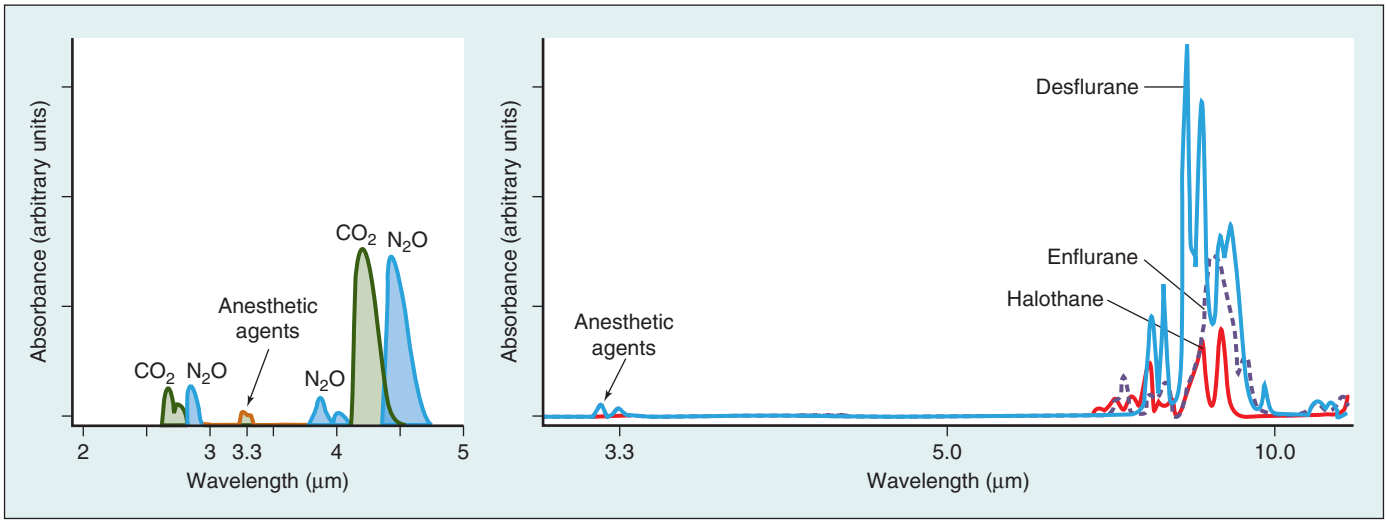
Mainstream gas monitors measure gas concentrations directly in the breathing circuit, typically close to the patient (e.g., between the endotracheal tube and the Y piece). Most mainstream monitors measure only CO_2. Mainstream monitoring coupled with flow measurements allows monitoring of volumetric excretion of CO_2. Placing a mainstream adapter in the breathing circuit increases dead space and can become problematic when delivering small tidal volume.[5]

Technologies

Several technologies exist for measuring gas concentrations. Table P2.1 contrasts the different gas measurement technologies in terms of the gases that they can measure.

Infrared Absorption

Infrared absorption is the most common technology in use today. It is based on the **Lambert-Beer Law**, which explains that when light passes through a gas, absorption increases with the optical path length through the gas, the gas concentration, and an extinction coefficient (which is specific to the gas and the light's wavelength). The gas concentration is measured by determining the amount of IR light that is absorbed (Fig. P2.2) and comparing that to a reference measurement. Each gas has a specific absorption spectrum (e.g., the amount absorbed over a spectrum of wavelengths). These spectra are the basis for the measurement techniques. The approach assumes that only a limited number of compounds will be present in the measured gas (i.e., too many compounds interfere with the reliability of the measurements because of overlapping absorption spectra).

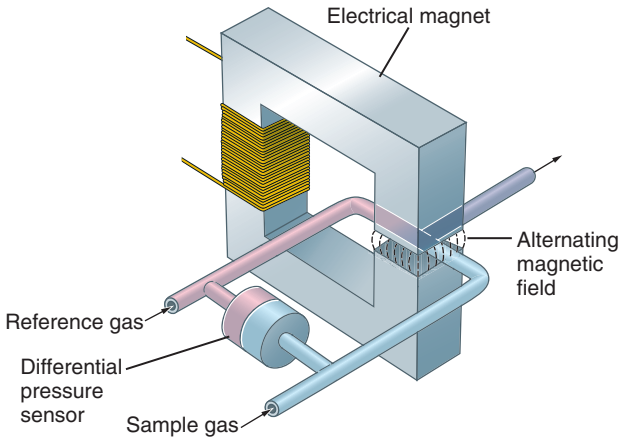


• **Fig. P2.2** Absorption spectra for gases commonly found when providing anesthesia care. *Left:* Carbon dioxide (CO_2) and nitrous oxide (N_2O) have pronounced absorption characteristics for light of smaller wavelengths. *Right:* Volatile anesthetics show some absorption for light around a wavelength of 3.3 micrometers (μm) but show much stronger absorption spectra for light of wavelengths between 5 μm and 10 μm. (Modified from Eisenkraft JB, Reich D. Respiratory gas monitoring. In: Reich D, ed. *Monitoring in Anesthesia and Perioperative Care*. Cambridge: Cambridge University Press; 2011; and modified from Levin PD, Levin D, Avidan A. Medical aerosol propellant interference with infrared anaesthetic gas monitors. *Br J Anaesth*. 2004;92(6):865–869.)

IR absorption is useful for determining concentrations of CO_2 and volatile anesthetics whose molecules have dipolar characteristics and can be excited into vibrations by light of certain wavelengths, thereby absorbing some of the light's energy. However, IR absorption cannot be used to measure concentrations of nondipolar molecules such as nitrogen and oxygen. Water molecules' strong dipoles absorb IR light so well that it can interfere with the measurement of anesthetic gases or CO_2. Recent technological advances have enabled the development of a small, lightweight IR mainstream analyzer that is capable of measuring CO_2, N_2O, isoflurane, sevoflurane, and desflurane.[6]

Paramagnetic Oxygen Sensor

Oxygen is a paramagnetic gas. When introduced into a magnetic field, oxygen positions itself in the strongest part of the field. A gas sample containing oxygen in a switched magnetic field generates a pressure signal that is proportional to the partial pressure of oxygen. Adding a reference gas increases the accuracy of the oxygen analysis (Fig. P2.3). The typical gas monitoring setup in modern anesthesia machines includes sidestream IR analysis of CO_2 and anesthetic agents along with paramagnetic analysis of oxygen.



• **Fig. P2.3** A sample containing oxygen in a switched magnetic field generates a pressure signal that is proportional to the partial pressure of oxygen.

Electrochemical Oxygen Sensor

Electrochemical sensors are made up of a hydrophobic membrane and two electrodes, anode and cathode, surrounded by an electrolyte solution. Oxygen passes through the membrane and electrolyte solution and is reduced at the cathode. Electrons for the reduction are supplied by the anode, which is oxidized in the process. The electrons travel through an external circuit from anode to cathode. This current is proportional to the concentration of oxygen. The response time of most of these sensors is slow and cannot be used to determine end-tidal concentrations. They are primarily placed in the inspiratory limb of anesthesia machines for monitoring of inspiratory oxygen concentration (FiO_2). Because the anode in these *galvanic cells* is oxidized, they have a limited lifespan, often measured in % oxygen-hours (% oxygen concentration times the number of hours the sensor is exposed to that concentration; a sensor specified with a lifetime of 500,000 % oxygen-hours should last 1000 hours exposed to 100% oxygen or 2000 hours exposed to 50% oxygen). Replacing these oxygen sensors is an important component of the proper maintenance of anesthesia workstations.

Mass Spectrometry

Mass spectrometry is no longer routinely used in anesthesia gas monitoring but is of significant historical importance. It is composed of gas sample tubing, a sample pump, vacuum pump, an ion source, and a mass spectrometry analyzer. Accelerated electrons are used to ionize the molecules in the sample gas. These ions are then separated in accordance to their mass-charge ratio, (e.g., by deflecting the moving ions in an electrical or magnetic field). The ionized molecules hit the detector at different places depending on their mass-charge ratio, creating a "spectrum." The spectrum is characteristic for different molecules and is used to determine the composition of the gas sample.

Mass spectrometry technology is expensive and cumbersome. Because of the considerable expense, only one mass spectrometry machine was typically used for numerous operating rooms. This meant that the sampled gas had to travel some distance through the sampling tubing to finally arrive at the central mass spectrometry machine for gas measurement. In addition, the machine was "time shared" with all the connected operating rooms. The resulting measurement delay was problematic for the dynamic needs of anesthesia practice. The substantial expense was another important drawback. Because of these suboptimal features, IR techniques gradually replaced mass spectrometry as IR technology improved.

Raman Scatter Analysis

Raman scatter analysis is another technology that is of some historical significance but is no longer commonly used in modern operating rooms. When the gas sample enters the analysis chamber, it is exposed to monochromatic light generated by an argon laser. The light interacts with the gas molecules, producing light at new wavelengths, a phenomenon known as Raman scattering. The wavelength shift and amount of scattering can be used to determine the gas composition of the gas sample, because specific compounds have characteristic Raman scattering behavior. A key clinical advantage of Raman scattering analysis is that it is the only gas analysis approach besides mass spectrometry that is capable of detecting nitrogen, which can be important in the diagnosis of air embolism. The inability to detect nitrogen is a key disadvantage of the IR spectroscopy method.

Emerging Developments

Evolutionary Perspective

The biotransformation of foreign substances is based on ancient evolutionary defense mechanisms. Hundreds of millions of years ago, animals evolved to terrestrial life and began ingesting new varieties of plant life with nutrient and toxic potential. These early organisms had to detoxify and eliminate any novel toxic compounds or perish. Enzyme systems that originally existed to maintain homeostatic functions gradually adapted to process exogenous toxins.[1] The genetic heterogeneity of these metabolic enzymes exponentially increased as animals survived exposures to evermore diverse xenobiotics. The genetics of human metabolic enzymes today reflect both the foundational homeostatic role they played and the diversity of ancient evolutionary pathways. This has resulted in a wide range of interindividual variation in phenotypic responses to both xenobiotics and endogenous organic compounds. In this age of targeted drug development and precision medicine, the study of pharmacokinetics, pharmacodynamics, and pharmacogenomics has become increasingly interconnected to better understand the variation in drug effects (Tables 4.1 and 4.2).

Pharmacogenetics, Pharmacogenomics, and Variability in Drug Responses

Pharmacogenetics arguably began with Pythagoras, the sixth-century BCE mathematician who reported an association between the ingestion of fava beans and hemolytic anemia in certain individuals. The field grew rapidly in the 1950s, with the first reports of genetically determined responses to succinylcholine (scoline apnea) in 1956 and the birth of the term *pharmacogenetics* in 1959, coined by the German geneticist Friedrich Vogel. Subsequent investigations focused on identifying single-gene associations with variable drug responses: an early focus of study was the apparent bimodal half-life of isoniazid, an antituberculosis treatment, resulting from polymorphisms in N-acetyltransferase.

With the sequencing of nearly the entirety of the human genome in 2003, deeper analysis of the relationships between multiple genes and drug responses became possible (Fig. 4.1). This has led to the evolution of *pharmacogenomics,* the study of the relationships between the entire genome, drug responses and human diseases (see Table 4.1). Although conditions with single-gene associations still exist (Fig. 4.2), it is increasingly evident that many unexplained variations in drug efficacy result from sources affecting multiple steps in the gene expression and biotransformation pathway (Tables 4.2 and 4.3; Fig. 4.3 and 4.4).

Pharmacokinetic Considerations

Classification of Drug Metabolism Reactions

Pioneering studies in drug metabolism in the 1800s focused on identifying altered forms of ingested substances that were excreted in the urine. It was not until the 1950s that the enzyme systems responsible for these chemical reactions were identified. In 1959, R.T. Williams, a Welsh pharmacologist, first proposed

Abstract

Biotransformation is an ancient and vital process that governs a drug's pharmacokinetics and pharmacodynamics. The enzymes and transporters that control each step in the metabolic pathway are highly polymorphic. This can cause significant variability in drug effects between individuals, or when certain drugs are given in combination. Specific pharmacogenomics considerations apply to the majority of medications that are in clinical use today, including those particularly relevant to the practice of anesthesiology such as neuromuscular blockers, opioids, anesthetic agents and anti-emetics. Future developments in the fields of precision medicine, systems biology and bioinformatics can produce new models for characterizing complex genome-phenome associations, and improve understanding of interindividual variability in drug responses.

phase II metabolism

TABLE 4.1 Key Definitions

Biotransformation: Chemical alteration of a foreign molecule by the body
Drug metabolism: The alteration of a drug by the body to allow for excretion
Xenobiotics: A substance that is foreign to the body
Pharmacokinetics: Study of the disposition of a drug within the body
Pharmacodynamics: Study of the effects of the drug on the body
Pharmacogenetics: Study of genetic (often single-gene) causes of variability in drug responses
Pharmacogenomics: Genome-wide study of the determinants of variability in drug responses

TABLE 4.2 Outcomes of Drug Metabolism

Cessation of active drug effect
Conversion of prodrug to active form
Enhance suitability for elimination
Conversion to toxic form

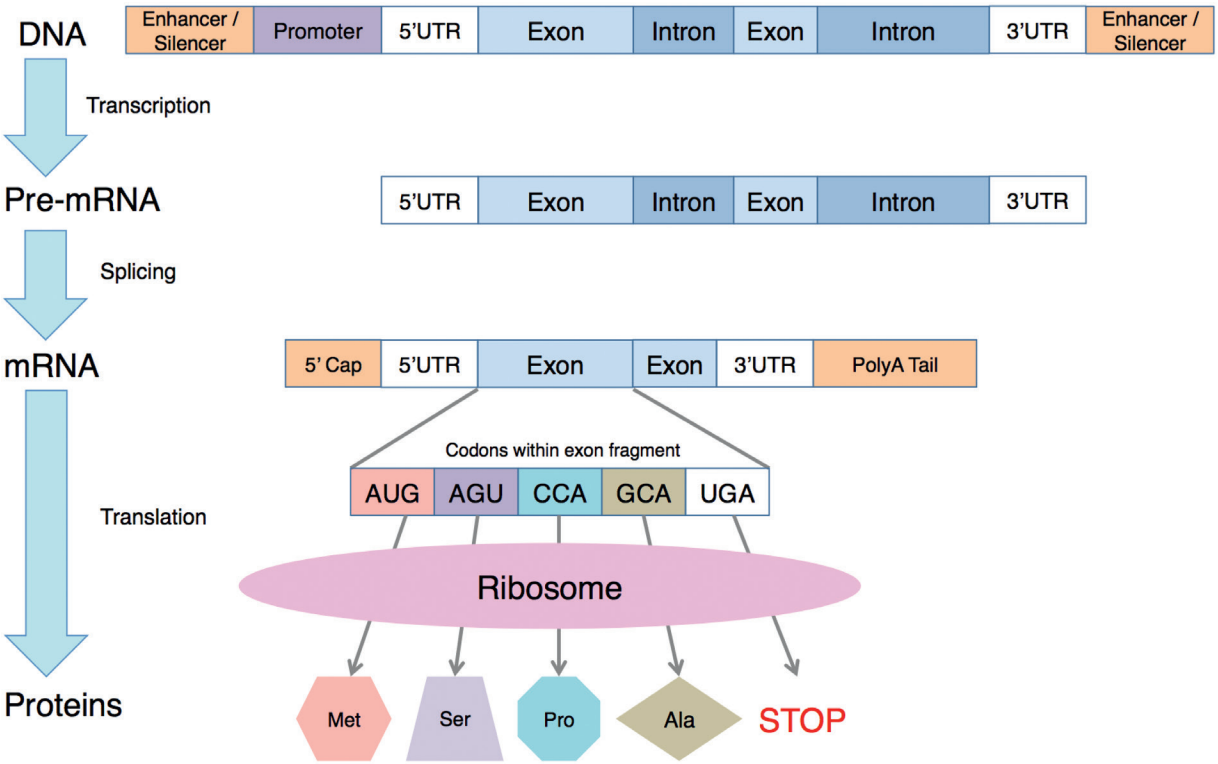
organizing these chemical processes into two phases of drug metabolism (Table 4.4).

Phase I Metabolism

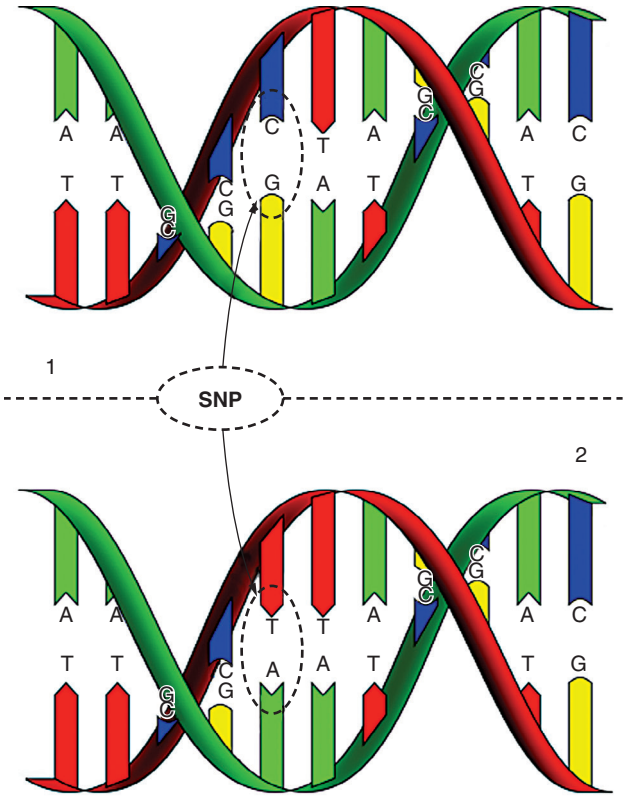
Phase I metabolism broadly describes enzymatic reactions that alter biologic activity via the addition or alteration of a functional molecular group. For lipophilic compounds, this usually introduces a polar functional group that forms a substrate for subsequent metabolic handling. These alterations can inactivate or enhance the biologic effects of the parent drug, or they can introduce new activity such as in the case of prodrugs and certain carcinogenic compounds.

Phase II Metabolism

Phase II metabolism involves the addition of a cofactor to a compound. This typically results in a molecule that is highly water-soluble and amenable to excretion within the urinary or biliary tract. These enzymes usually require specific functional groups on their substrates for conjugation to occur: products of phase I metabolism are often good candidates for subsequent phase II reactions. However, it is not necessary for drugs to undergo both phase I and II metabolism, such as in the case of morphine, oxymorphone, and hydromorphone, which are readily glucuronidated by uridine diphosphate (UDP)-glucuronyltransferase (Fig. 4.5).



• **Fig. 4.1** Schematic of gene, messenger ribonucleic acid *(mRNA)* and codon structures. Information within a gene must be transcribed into mRNA, which interacts with ribosomes to form proteins. During DNA transcription, regulatory regions within the DNA strand determine the genes to be transcribed and the amount of mRNA to produce. This initial pre-mRNA contains information from both exons and introns: once the introns are spliced out, the final mRNA is transported into the cytosol. Ribosomes on the endoplasmic reticulum then translate this mRNA into amino acids. Triplets of bases within mRNA, called *codons*, encode a single amino acid. Codons can also have regulatory functions in protein synthesis. There are 64 possible codon combinations and 20 amino acids; a single amino acid can have one or more corresponding codons. *UTR,* Untranslated region.



• **Fig. 4.2** Single-Nucleotide Polymorphisms (SNPs). An SNP is a form of genetic variation in which one base pair is substituted for another. In diploid organisms, this results in more than two genetic alleles for each locus, which, if expressed, can lead to the formation of a protein with altered function.

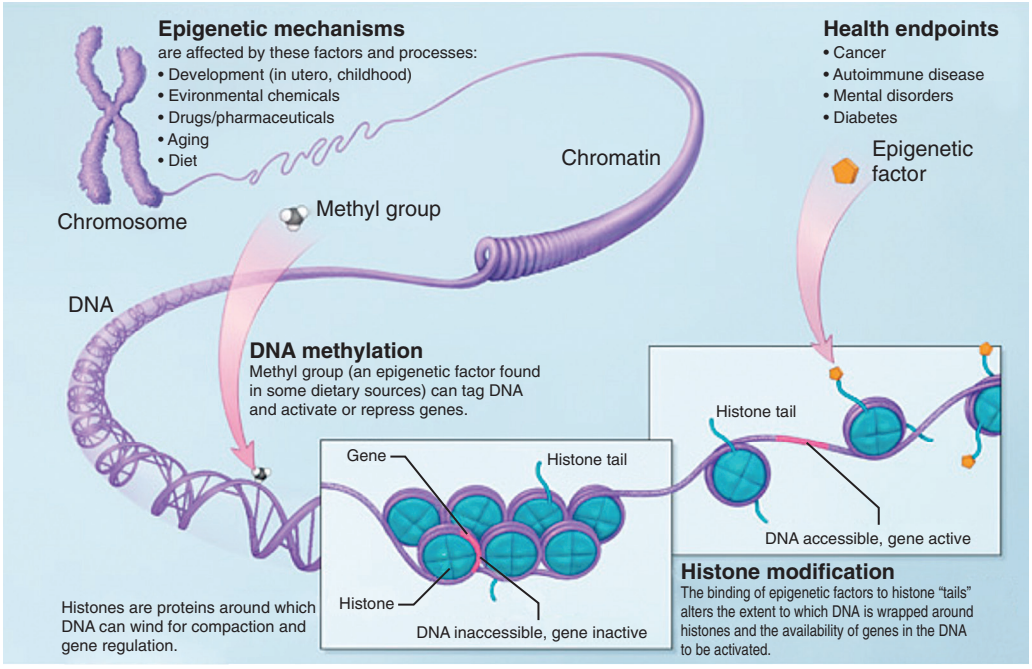
Phase I Enzymes

Cytochrome P450

A group of major biotransformational enzymes in many organisms, including humans, is the cytochrome P450 (CYP) system. The CYPs are a superfamily of heme-containing proteins that contain several hundred distinct forms, located in cellular membranes in the endoplasmic reticulum and the inner mitochondrial membrane. Genetic studies of CYP DNA across a variety of organisms suggest that all currently known CYP originated from a common ancestor over two billion years ago, around the time that single-celled life forms evolved into complex, multi-organellar eukaryotes.[1] This long history has led to a vast array of genetic subfamilies within the CYP system.

In humans, approximately 50 to 100 CYP enzymes are encoded by 57 functional genes and 58 pseudogenes spread across multiple autosomal chromosomes.[8] These gene sequences are the basis for the classification of CYP families and subfamilies (Tables 4.5 and 4.6). This diversity is also seen in the vast array of CYP variants, which together with age, gender, and disease, is a major contributor to the variability in drug responses between individuals.

CYPs are highly versatile enzymes capable of catalyzing numerous reactions, including reduction and hydrolytic reactions. This, combined with their affinity for many different substrates, makes CYPs the key biotransformational enzymes for a vast array of both xenobiotics and endogenous signaling molecules. More than 95% of oxidative metabolic processes in the body are performed by CYPs.[9] In humans, a core cluster of enzymes in the CYP1, 2, and 3 families is responsible for the biotransformation of about 75% of all drugs currently used in clinical practice[8] (see Figs. 4.4 and 4.5). CYPs are the primary metabolic enzyme for numerous drug groups commonly used in anesthesia, including volatile anesthetics,



• **Fig. 4.3** Epigenetic Modifications. Epigenomics is the study of inherited chromosomal changes that resulted in changes in phenotype without alteration in DNA sequences. The most common events are in form of DNA methylation and histone modification.

TABLE 4.3 A Brief Review of Genetics

Proteins are pivotal in sustaining life: enzymes, receptors, second-messenger systems, and cellular structural components are all proteins. The blueprint to individual protein structures is encoded by a specific sequence of DNA. DNA is composed of a deoxyribose backbone containing complementary base pairs, arranged in a double helical, ladder-like structure with 5′ to 3′ directionality. These base pairs are made up of adenine-thymine and cytosine-guanine. The DNA strand is coiled into chromosomes, which are found in the cell nuclei.

Within the DNA strand, there are sequences that code for proteins and those that do not. DNA sequences that encode proteins are termed ***genes***. Noncoding sequences can have structural or regulatory roles in gene expression or no function at all. A gene is organized into regulatory regions bracketing the open reading frame, consisting of exons and introns with 5′ to 3′ directionality (see Fig. 4.1).

The human genome has approximately 20,000 protein-coding genes, accounting for less than 2% of the human genome.[2] Variations in pre-mRNA splicing, with selective inclusion of exons, result in many alternate mRNA sequences potentially coded from a single gene. This allows for a great many more proteins than the number of protein-coding genes currently identified.

Mutation vs. Polymorphism vs. Variant

The human genome has been highly preserved through the ages, with only 0.5% discordance between two unrelated individuals.[3] In its simplest definition, a ***genetic mutation*** is any variation in the DNA base sequence within a gene. By convention, mutations are rare (<1% of a population), allowing for the existence of a putative normal genotype. ***Polymorphisms*** are also mutations; however, they are much more common (>1% of a population) and can be considered "normal variant" forms resulting from natural selection. The use of the term ***genetic variant*** is considered neutral. Variant forms of genes are called ***alleles***, with the common allele termed ***wild-type*** and lesser forms termed ***minor alleles***. Humans are diploid organisms (with two sets of paired chromosomes) and therefore carry two alleles of the same gene. Allelic variation in a single locus is responsible for the patterns described by simple Mendelian inheritance, but the addition of polygenic traits, polyallelic loci, and non-Mendelian patterns of inheritance add substantial complexity to the ultimate phenotype.

The most common type of allelic variation is the ***single-nucleotide polymorphism*** (SNP), accounting for >70% of variations.[4] This involves the variation in a single nucleotide base pair within the DNA strand (see Fig. 4.2). Sequence variants, including SNPs, are classified according to the affected domain (DNA, RNA, protein), their location in the sequence, and the alteration.[5] There is currently no consensus nomenclature system established, which leads to potential confusion as the same variant can be described in multiple ways.

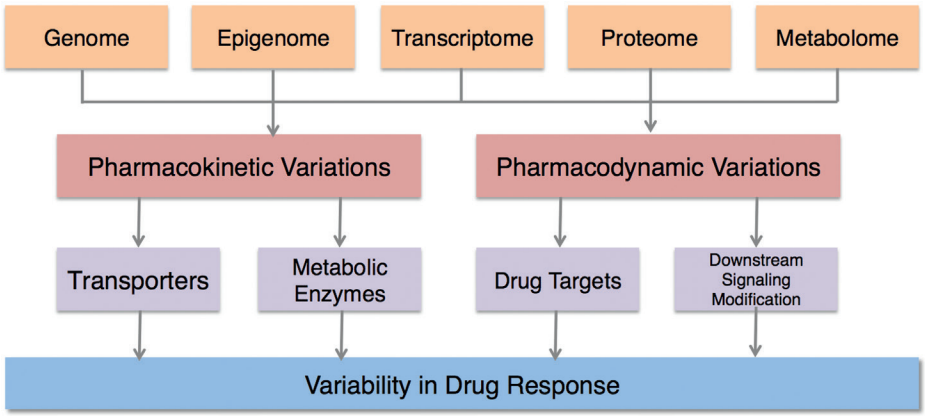
SNPs can occur in coding and noncoding regions; coding region SNPs can be synonymous (not affecting the protein sequence) or nonsynonymous (affecting protein sequence). Nonsynonymous SNPs can be either missense or nonsense types; missense SNPs result in the substitution with an alternate amino acid, whereas nonsense SNPs usually result in a prematurely truncated, nonfunctional protein. As of 2017, more than 10 million SNPs have been identified,[6] which corresponds to an average of one SNP for every 300 base pairs in the human genome.

Genotype vs. Phenotype vs. Clinical Effect

Most genetic variants do not result in any appreciable change in phenotype. The large proportion of noncoding sequences within the genome and the redundancy of translation systems reduce the possibility of clinically apparent sequelae. Conversely, heritable phenotypic differences can result between two populations without apparent alterations in their respective DNA sequences. This latter phenomenon is often the result of **epigenetic modifications**—that is, inherited variants in the chromosome rather than the DNA sequence itself. Epigenetic mutations result from events such as DNA methylation (which alters DNA transcription) and histone modification (which affects the packaging of DNA into chromatin) (see Fig. 4.3).

Integrative "Omics": Epigenomes, Transcriptomes, Proteomes, Metabolomes

As genetic assaying and sequencing technology continues to advance, additional fields of study have opened to detail the steps along the path of genetic expression. **Epigenomics** is the study of heritable chromosomal alterations resulting in phenotypic changes, while **transcriptomics** investigates the total mRNA transcripts generated by a cell or organism under defined conditions. A **proteome** refers to the entire collection of proteins expressed by a particular cell or organism, which may greatly outnumber the genome; **proteomics** is the study of the proteins produced by the cell under different physiologic states, and the factors that determine the translation and post-translational modifications. Finally, **metabolomics** focuses on the dynamic array of metabolites formed by the enzymes coded within an organism's genome. The integration of these fields into **systems pharmacology and quantitative biology** allows for large-scale modeling of complex physiologic or disease states, which has enormous potential to inform the study of drug interactions, and drug design, in the decades to come[7] (see Fig. 4.3).



• **Fig. 4.4** Systems Pharmacology and Variable Drug Responses. Systems pharmacology integrates knowledge from multiple fields of quantitative biology and bioinformatics to fully understand the factors contributing to interindividual variations in drug response.

TABLE 4.4 The Phases of Drug Metabolism

	Broad Function	Specific Reactions	Typical Enzymes
Phase I	Alteration of a functional group (addition, or removal) Alters biologic activity (decrease, or increase)	Oxidation	Oxidases Dehydrogenases
		Reduction	Reductases CYP
		Hydrolysis	Esterases Phosphatases Hydrolases Lipases
Phase II	Alters water solubility for excretion	Glucuronidation	UDP-glucuronyltransferase
		Sulfonation	Sulfotransferase
		Acetylation	N-Acetyltransferase
		Glutathione conjugation	Glutathione S-transferase
		Methylation	Methyltransferase

CYP, Cytochrome 450; *UDP,* uridine diphosphate

TABLE 4.5 Cytochrome P450: Essential Facts

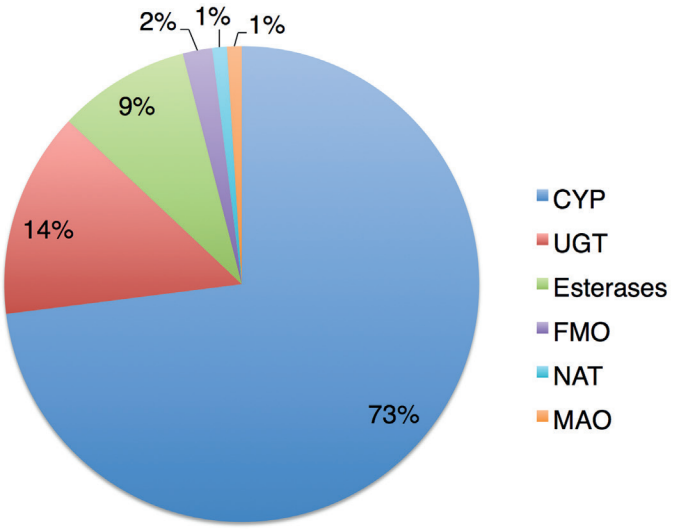
Cytochrome P450

- First discovered in the 1960s.
- Named for their appearance; when reduced and bound to carbon monoxide has a pinkish hue, with peak ultraviolet light absorption at 450 nm.
- Humans have ~50–100 CYP enzymes across 18 families and 44 subfamilies; many of them have homeostatic or unknown functions.
- Isoform families are designated by letter, subfamilies by number.

Homeostatic Roles of Cytochrome P450

1. Biosynthesis of lipophilic hormones and signaling molecules, including:
   - Steroid hormone
   - Prostaglandins, Thromboxane, Eicosanoids
   - Bile and fatty acids
   - Retinoids
   - Vitamin D derivatives
   - Porphyrins
2. Defensive detoxification against reactive intermediates and xenobiotic toxins
3. Potential unknown endogenous roles
   - 13 CYP families with unknown "orphan" substrates

CYP, Cytochrome 450.



• **Fig. 4.5** Contributions of Different Enzymes to Drug Metabolism. Cytochrome P450 enzymes are responsible for the vast majority of biotransformation reactions for drugs currently used today. This is closely followed by the uridyl-glucuronyltransferases and esterases. The flavin-containing oxygenases and monoamine oxidases *(MAOs)* make up a comparatively small percentage of overall drug metabolism, although limited research data suggest that their contribution is likely underestimated. *CYP,* Cytochrome P450; *FMO,* flavin-containing monooxidase; *NAT,* N-acetyltransferase; *UGT,* uridine phosphate-glucuronosyltransferase. (Data from Guengerich FP. Human cytochrome P450 enzymes. In: Ortiz de Montellano PR, ed. *Cytochrome P450*, 4th ed., Vol. II. Cham, Switzerland: Springer International Publishing; 2015: 523–785.)

intravenous hypnotics, opioid analgesics, and local anesthetic agents (see Table 4.6 and Fig. 4.6).

Inducers and inhibitors influence the function of many CYPs. CYP inhibition is possible in almost all isoforms and can be reversible, irreversible, or partially irreversible. Conversely, only a select group of CYPs are inducible. Reversible inhibition is typically a result of competition at the substrate-binding active site. Other drugs can affect downstream oxygen-transferring functions of the CYP, which causes fully or partially irreversible enzyme inhibition. In contrast, CYP induction occurs in a time-dependent manner, usually as a result of a stimulus to increasing gene transcription and enzyme production, but the exact mechanism is unknown. This is believed to be an evolutionary defensive mechanism to toxin exposure by increasing the capacity to degrade the offending substance. In the case of toxins and certain drugs, this leads to a diminution of effect. For prodrugs and substances with active metabolites, however, enzyme induction can confer the risk of exaggerated drug effects and potential harm.

Flavin-Containing Monooxidases

Flavin-containing monooxidases (FMOs) are a second major family of enzymes important in oxidative drug metabolism. Long-overlooked because of technologic constraints limiting their study, the role of FMOs in drug metabolism and homeostasis is increasingly being recognized, and is now shown to be responsible for approximately 2.5% of all metabolic reactions in the human body and about 6% of phase I metabolic reactions.[10]

FMOs contain a flavin adenine dinucleotide prosthetic group, which catalyzes oxidative reactions with reduced nicotinamide adenine dinucleotide phosphate as a cofactor. FMOs are found in all eukaryotes and appear to have followed an evolutionary development similar to CYPs[11]; however, in contrast to the vast genetic variety of CYPs, the six known human FMOs are encoded by six genes and six pseudogenes located on chromosome 1 (Table 4.7). Of the FMO subtypes, *FMO3* has both the highest expression in the adult liver and the highest functional activity, and as a result is a major focus for pharmaceutical development.

FMOs are distinct from CYPs in that they have a narrow specificity but high catalytic activity (Table 4.8). Whereas CYPs

TABLE 4.6 Cytochrome P450 Subfamilies, Substrates, Inhibitors, and Inducers

Family	Subfamily	Major Substrates Relevant to Anesthetic Practice	Inhibitor	Inducer

can bind readily to a broad variety of substrates, FMOs have a selective affinity for nucleophilic molecules (those containing a free pair of electrons, such as amines, sulfites, phoshites) but with approximately double the catalytic velocity of CYPs.[11] Another characteristic of FMOs is that they are resistant to induction or inhibition, making them less prone to drug interactions and an attractive target for drug design.

TABLE 4.8 Characteristics of Cytochrome P450 and Flavin-Containing Monooxygenases

Cytochrome P450	Flavin-Containing Monooxygenases
Catalyzes ~75% of all metabolic reactions	Catalyzes ~1%–2% of all metabolic reactions
Can catalyze broad range of substrates	Narrow substrate range
Substrate affinity varies between isoforms	High affinity for nucleophilic molecules (containing N, S, P, Se)
Neutralize molecules via electrophilic reactions	Neutralize molecules via nucleophilic addition
Lower catalytic rate	High catalytic rate
Highly inducible and inhibited	Resistant to inducers and inhibitors
50–100 CYP enzymes, encoded by 57 genes and 58 pseudogenes	6 FMO enzymes, encoded by 6 genes and 6 pseudogenes

CYP, Cytochrome 450; *FMO,* flavin-containing monooxygenase.

To date, FMOs have been identified as key metabolic enzymes for antidepressants, antipsychotics, and antihistamines. Although the primary role of FMOs continues to be defined, they are known to play a complementary role to CYPs.[12] In particular, FMO3 has been shown to work in tandem with CYP3A4,[10] performing the same reactions on similar substrates but with a higher reaction capacity and velocity. It has been speculated that FMOs may play a role in mitigating CYP3A4 drug interactions and interindividual variations in activity.[12]

Amine Oxidases, Including Monoamine Oxidase

Amine oxidases catalyze oxidative deamination reactions, producing ammonia and an aldehyde. These enzymes are critical to both homeostatic and xenobiotic metabolic pathways and are involved in the biotransformation of aminergic neurotransmitters (such as catecholamines, histamine, and serotonin) as well as toxins and carcinogens in foods and the environment.

The **monoamine oxidases (MAOs)** are well studied and have been targets for drug therapy for more than 60 years. MAOs are flavin-containing mitochondrial enzymes distributed throughout the body. In humans, two isoenzymes of MAO have been identified, encoded by two genes located on the X chromosome: *MAO-A* and *MAO-B.* Each isoenzyme can be distinguished by certain substrate specificities and anatomic distribution (Table 4.9), although MAO-A has the distinction of being the sole catecholamine metabolic enzyme in sympathetic neurons. In neural and other selective tissues, MAOs catalyze the first step in the degradation of catecholamines into their aldehyde intermediaries, which is further processed by catechol-*O*-methyltransferase.

The ubiquity of biogenic amines and their central role in neural and cardiovascular function make MAOs highly relevant to clinical anesthesia. The interactions between MAO inhibitors and drugs commonly used in anesthesia have been well described. Although genetic polymorphisms in MAO genes exist and are of great interest in the fields of neurology and psychiatry, to date none have been identified that specifically concern the handling of anesthetic agents.

TABLE 4.9 Monoamine Oxidases

	MAO-A	MAO-B
Location	CNS: sympathetic and catecholaminergic neurons Liver Pulmonary endothelium Gastrointestinal tract Placenta	CNS: glia, serotoninergic neurons Platelets
Specific Substrates	Serotonin Melatonin Epinephrine Norepinephrine	Dopamine Phenylethylamine Benzylamine
Substrates for both MAO-A and MAO-B	Dopamine Tyramine Tryptamine	

CNS, Central nervous system; *MAO,* monoamine oxidase.

Further details on the agents that alter the function of MAO, and their effects on biotransformation of catecholamines, can be found in Chapter 12).

Esterases, Including Butyrylcholinesterase (Pseudocholinesterase)

Esterases catalyze hydrolysis of specific molecules containing the R1-CO-O-R2 ester group, as well as amides, hydrazides, and carbamates. In human physiology, esterases are distributed in the liver, erythrocytes, plasma, and the gastrointestinal tract. Proteases are specialized esterases and are involved in the activation of proenzymes such as those secreted by the pancreas.

Cholinesterases are serine hydrolases with particular relevance to the practice of anesthesiology. Two types of cholinesterases have been identified, each encoded by a single gene: acetylcholinesterase (AChE) and butyrylcholinesterase (BChE, also known as plasma cholinesterase or pseudocholinesterase). AChE has a key physiologic role in regulating cholinergic transmission and is a target for drug therapy in autonomic, central nervous system, and neuromuscular disorders (see Chapters 13, 14, and 21).[13]

BChE has been of great interest to anesthesiologists since the first description of variable responses to succinylcholine in the 1950s. Widely expressed in the liver, lung, brain, heart and plasma, it is also involved in the metabolism of mivacurium, cocaine, chloroprocaine, and tetracaine. Although the BChE gene shares 54% of the same amino acids as AChE,[13] BChE appears to have a separate, albeit undefined, biologic role. Discussion of pseudocholinesterase deficiency continues later in this chapter (also see Chapter 21).

Phase II Enzymes

Transferases are the predominant enzyme type for phase II drug reactions. Functionally, transferases attach water-soluble sugars, amino acids, or salts to their substrates. This forms a metabolite that is more easily excreted by the kidneys or the biliary tract.

Phase II reactions are classified according to the endogenous conjugate being catalyzed by its specific transferase enzyme (see Table 4.4). In the adult, glucuronidation is the most common phase II process and is involved in the metabolism of approximately 40% to 70% of drugs in current clinical use.[14] In the fetus and neonate, glucuronidation activity is nearly absent and does not reach adult levels until 2 to 6 months of age.[15] This increases the risk of toxicity of compounds dependent on this pathway for metabolism, such as morphine and chloramphenicol. Sulfonation is well developed in the newborn and is the dominant conjugation pathway until UDP-glucuronyltransferase activity matures; this is demonstrated by the metabolism of acetaminophen, which is metabolized into sulfate conjugates in the first months of life, after which glucuronides become the major metabolite.

Drug interactions involving the transferases are rare, but they are subject to genetic and environmental variations that are of clinical relevance. The **UDP-glucuronyltransferases** (UGTs) are involved in the metabolism of many drugs as well as endogenous substances, such as bilirubin, steroid hormones, bile acids, and fat-soluble vitamins. UGTs are membrane enzymes that are most concentrated in the liver and gastrointestinal tract but are also active in kidney, brain, pancreas, and placenta. Four UGT enzyme families have been identified in humans, with UGT1 and UGT2 the most heavily involved in drug metabolism. UGT 2B7 is the main isoform responsible for opioid glucuronidation, and although genetic polymorphisms have been identified for this enzyme, the large overlap in substrate specificity between the UGT enzymes has minimized any substantive phenotypic manifestation of these variants.[14]

Arylamine N-acetyltransferases (NATs) are cytosolic enzymes found in many tissues throughout the body and are associated with the metabolism of hydralazine, caffeine, procainamide, sulfonamides, and isoniazid. In humans, this enzyme family is encoded by the *NAT1* and *NAT2* genes, which are highly polymorphic. *NAT2* gene polymorphisms have a higher degree of functional variation than *NAT1* and multiple mutations result in three distinct phenotypes: **fast (or wild-type), intermediate, and slow acetylators**[16] (Table 4.10). "Slow acetylators" carry at least one reduced-function allele and are much more susceptible to drug toxicity. For example, slow acetylators who are administered hydralazine experience not only a greater degree of hypotension and tachycardia, but they are also at increased risk of hydralazine-induced lupus erythematosus. The current understanding is that in those with the slow-acetylator phenotype, the parent drug accumulates and is diverted to oxidative metabolic pathways. This produces reactive intermediaries, haptens, and carcinogens at levels that would be much lower in the intermediate- and fast-acetylator counterparts. This mechanism has been attributed to not only the development of drug-induced autoimmune disorders such as those seen with hydralazine and sulfonamides, but also the pathogenesis of bladder, breast, and colorectal cancer with chronic exposure to environmental carcinogens[17] (Table 4.10).

The **methyltransferases** include thiopurine S-methyltransferase (TPMT) and **catechol *O*-methyltransferase (COMT)**. COMT is a magnesium-dependent enzyme that exists in soluble and membrane-bound forms found throughout the body. The soluble form is highly concentrated in the liver, while the membrane-bound form is predominantly found in the central nervous system and the chromaffin cells of the adrenal glands. It is one of the major metabolic pathways of catecholamines and related compounds such as levodopa and α-methyldopa. COMT is also a target for drug therapy: entacapone, a reversible inhibitor of COMT, is used in the treatment of Parkinson disease to increase the duration of action of levodopa (see Chapter 12).

TABLE 4.10 Variant N-Acetyltransferase Phenotypes

Phenotype	Genotype	Approximate Frequency	Clinical Effect Example
Fast (wild-type)	Two copies of the increased function allele	70% East Asians 70% Native Americans	Normal activity of hydralazine
Intermediate	One copy each of an increased-function and a reduced-function allele		Mild decrease in serum hydralazine levels, no recommendation for dose adjustment
Slow	Two copies of the reduced function allele	>80% Scandinavians >80% Egyptians 70% South Asians 40%–70% Western Europeans 40%–70% African Americans	Exaggerated drug effect of hydralazine Increased risk of hydralazine-induced lupus

TABLE 4.11 Drug Transporters

Functionally, drug transporters mediate the uptake of drugs into cell, and the export of drugs and metabolites outside of cells. There are two major drug transporter superfamilies in humans: **ABC (ATP-binding cassette)** and **SLC (solute carrier)**, each containing hundreds of transporter proteins whose function as yet is not fully understood (see Table 4.12).

Phylogenetically, **the ABC superfamily** is among the oldest proteins associated with earth-bound life: member transporters are found across all current extant prokaryotic and eukaryotic life forms. They are especially important in oncologic pharmacogenomics as they determine the uptake and efficacy of chemotherapeutics. The **P-glycoprotein (P-gp) efflux transporter** is an ATP-dependent drug transport protein from the ABC transporter superfamily encoded by the *ABCB1* gene, located in close proximity to the genes for the cytochrome P450 (CYP) 3A enzymes. It is located in the apical membranes of many epithelial cell types, including those of the gastrointestinal tract and brain and cerebrospinal fluid capillary endothelium. It is theorized that the wild-type P-gp works synergistically with CYP 3A enzymes within the gastrointestinal tract as a defense mechanism against xenobiotics and other toxic compounds, preventing their entry. They also likely contribute to maintaining the integrity of the blood-brain barrier. This efflux transporter has a broad specificity and extrudes a wide variety of substrates from cells, including opioids, β-blockers, calcium channel blockers, dexamethasone, ondansetron, digoxin and tricyclic antidepressants, as well as endogenous compounds such as conjugated bilirubin.

The ***ABCB1* gene** is highly polymorphic, with more than 100 single-nucleotide polymorphisms currently identified in humans.[20] Patients with loss of function mutations in the ABCB1 gene can have increased clinical effects of P-gp substrates, and this finding is supported by several human studies. Similarly, many inducers and inhibitors of P-gp exist and can alter their function. For example, loperamide is a substrate for P-gp and is normally excluded from the enterocyte, which localizes its effect in the gastrointestinal tract. When coadministered with the P-gp inhibitors, the central effects of loperamide, such as sedation and respiratory depression, can occur.

Organic anion-transporting peptides (OATPs), organic cation transporters (OCTs), and organic anion transporters (OATs) belong to the SLC transporter superfamily. These are genetically and structurally heterogeneous structures that are united by their function as uptake (and occasionally bidirectional) transporters.[21] SLC transporters are located widely throughout the body in the liver, intestine, brain, heart, kidney and placenta. Drug-drug interactions are best described for orally administered medications, and those with a renal site of action or excretion such as diuretics and antihypertensives.

One of the challenges in studying the effects of drug transporter variants in vivo is the overlapping substrate range of transporters and downstream metabolic enzymes. An example of this is the close genetic and functional relationship between P-glycoprotein and CYP 3A enzymes, and between several members of the SLC family and uridyl-glucoronyltransferase (UGT) 1A1.[21] It is anticipated that with ongoing improvements in bioinformatics, these complex relationships will be unraveled and understood in the near future.

ATP, Adenosine triphosphate.

Variants of the *COMT* gene, located on chromosome 22, are typified by a complex spectrum of neuropsychological associations commensurate with the central role that catecholamines play in human behavior. The G472A polymorphism results in a methionine for valine substitution within the enzyme that diminishes its activity by approximately 25%.[18] This increases the cortical neuronal levels of dopamine and has been linked to various disorders of executive functioning and cognition, including autism, attention deficit disorders, and schizophrenia.[18,19] Anesthetic considerations for the G472A polymorphism are discussed further later in the chapter.

Sites of Drug Metabolism

Traditional thinking in pharmacokinetics and pharmacology summarize the factors influencing the disposition of a drug into four phases: absorption, distribution, metabolism, and excretion (ADME). This convenient but linear mnemonic overlooks the overlapping mechanisms that govern these processes. Drug transporters (Table 4.11) involved in absorption are essential for substrate delivery in metabolism and for drug excretion (Table 4.12). Biotransformational enzymes are widely present throughout the body and influence the absorption of certain drugs well before

TABLE 4.12 Selected Drug Transporter Systems

Family	Transporter	Substrates	Inducer	Inhibitor
ABC	P-glycoprotein (ABCB1 gene)	Opioids, including • Morphine • Fentanyl • Methadone • Sufentanil Cardiovascular drugs, including • Calcium channel blockers • β-Blockers • Statins • Digoxin Antiemetics, including • Ondansetron • Dexamethasone	St. John's wort Trazodone Aspirin Rifampin	Midazolam Amiodarone Dronedarone Carvedilol Lidocaine Verapamil Grapefruit juice
SLC	OATP	Antihypertensives, including • Aliskiren • ACE inhibitors • Angiotensin II receptor blockers		Clarithromycin Erythromycin Grapefruit juice Pravastatin
	OAT	Diuretics, including • Furosemide • Bumetamide		Probenecid Benzylpenicillin
	OCT	Antiarrhythmics, including • Procainamide • Dofetilide		Cimetidine Trimethoprim
		Other • Metformin • Ranitidine		

ABC, Adenosine triphosphate-binding cassette; *ACE,* angiotensin-converting enzyme; *OAT,* organic anion transporter; *OATP,* organic anion-transporting peptide; *SLC,* solute carrier.

they reach the circulation and biophase. Although the liver remains an important site for drug metabolism, many other locations are heavily involved in the metabolism of oral, inhaled, and intravenous drugs.

Liver

The liver is the largest organ in the body and the principal site of drug metabolism (see Chapter 31), and has a sinusoidal structure that creates a large blood-tissue interface. Almost all known metabolic enzymes are located in the smooth endoplasmic reticulum of the hepatocyte, including the major oxidases (see later). It receives 25% to 30% of total cardiac output and almost the entirety of portal vein flow, which carries substances absorbed through the gastrointestinal tract to the liver. This so-called first-pass exposure to enterally absorbed drugs functions as an important metabolic barrier between the gut and the systemic circulation. "First pass" may be a misnomer, as before this there is significant drug metabolism that occurs in the intestinal enterocyte. The total hepatic clearance of a specific compound is a function of the liver's intrinsic capacity to metabolize and excrete that substance, the fraction of unbound drug, and hepatic blood flow (Table 4.13). The **hepatic extraction ratio** expresses hepatic clearance as a ratio of hepatic blood flow and is an indicator of the amount of drug removed during one pass through the liver.

Active, energy-requiring drug transport is required for both entry into the hepatocyte (sometimes termed **phase 0 metabolism**)

TABLE 4.13 Hepatic Clearance and Extraction Ratio

$$\text{Hepatic clearance} = Q \times \frac{[(\text{Unbound drug} \times \text{Metabolic capacity})]}{[(Q + \text{Unbound drug} \times \text{Metabolic capacity})]},$$

where Q = hepatic blood flow.

Drugs with high hepatic extraction ratio (> 0.7):
- Will have high first pass metabolism with oral administration
- Are highly sensitive to changes in liver blood flow: **"flow-limited" clearance**
- Less sensitive to alterations in drug binding or "intrinsic clearance"
- Examples: Morphine, lidocaine, verapamil, and nitroglycerin

Drugs with low HER (<0.3):
- Minimal first pass metabolism with oral administration
- Highly sensitive to changes in drug binding or "intrinsic clearance": **"capacity-limited" clearance**
- Insensitive to changes in liver blood flow
- Examples: Warfarin, phenytoin

Drugs with Intermediate HER (0.3–0.7):
- Examples: Aspirin, codeine, and nortriptyline

and for biliary excretion. The expression of these transporter systems is subject to genetic polymorphisms, which can contribute to variations in drug effect, some of which are summarized in Table 4.12.

Intestinal Mucosa

Orally administered medications must first withstand chemical and bacterial degradation before they are absorbed from the gut. Absorption occurs via diffusion, pinocytosis, or transport. Active transport across gut epithelium involves similar drug transporter systems found in the liver and in other organs (Table 4.12).

Gastrointestinal mucosal epithelium contains many of the metabolic enzymes seen in the liver and other organs, and is the first site of biotransformation for many ingested compounds before they reach the portal circulation. Enzymes present in enterocytes include CYPs, FMOs, carboxylesterases, and the transferases.[22] While the gut has a much lower overall enzyme content compared with the liver, the enormous surface area and the obligatory exposure of orally absorbed compounds results in small intestinal intrinsic clearance rates that may be two to three times that of the liver.[23]

As with the liver, CYPs contribute to the largest portion of intestinal drug metabolism. Clinically important enzymes in the gut include CYP3A (making up 80% of small intestinal CYP content).[24] The highest levels of metabolic enzyme activity occur in the villi of duodenal (50% that of liver) and jejunal (30%) mucosal epithelium.[22] Together with the liver, these enzymes contribute to the first-pass metabolism of orally administered midazolam, calcium channel blockers, statins, and calcineurin inhibitors.

Grapefruit and other citrus fruits such as pomelos and certain orange varieties (bergamot, Seville) contain a number of compounds that can cause inadvertent variations in oral drug bioavailability when ingested. There are two identified compounds responsible, each with different effects on intestinal absorption. **Furanocoumarins** are toxic phytochemicals produced by these plants as a defense mechanism against predators and are found throughout the fruit, with the highest concentration in the peel.[25] Furanocoumarins are potent, irreversible inhibitors of CYP3A4 and 3A5[26]; because grapefruits are usually ingested orally, their effects are most marked on intestinal CYP3A activity. This increases the oral bioavailability of drugs that have extensive first-pass metabolism by intestinal CYP3A4 (see Table 4.6). Normal CYP activity is restored following the physiologic turnover of gut epithelium, which can take up to 3 days.[26] **Flavonoids** are a second group of compounds found in these fruits that contribute to their color and flavor. They are inhibitors of key drug transporters including P-glycoprotein and organic anion-transporting polypeptide, which results in a decrease in oral bioavailability of drugs dependent on these transporters for gut absorption (see Tables 4.11 and 4.12).[26]

Lung

The lungs participate in both the biotransformation and uptake of therapeutic compounds. Pulmonary endothelial cells contain low levels of the monooxidases, transferases, and esterases.[22] These have been exploited in the pharmaceutical design of inhaled corticosteroids and bronchodilators to limit their systemic absorption and extend their local activity.[27] The cytochromes are also involved in the biotransformation of the many substances found in tobacco and cannabis smoke, which are also CYP inducers.[28] Aside from these few examples, the lungs do not significantly contribute to the overall systemic clearance of xenobiotics.

The lungs metabolize many endogenous substances with therapeutic effects. They are a site of angiotensin-converting enzyme (ACE) activity, which metabolizes angiotensin I to angiotensin II, and bradykinin to its degradation products. The lungs also inactivate prostaglandins $F_{2\alpha}$ (dinoprost) and E_1 (alprostadil, misoprostol) and are an important location for the inactivation of biogenic amines, albeit with a unique selectivity that is not fully explained. Pulmonary tissues contain high levels of MAO but remove approximately 98% of all serotonin and 30% of norepinephrine in first-pass pulmonary clearance while leaving epinephrine, isoproterenol, and dopamine unaffected.[29] Since MAO has little to no selectivity in its metabolism of biogenic amines, this points to an unknown selective uptake mechanism in pulmonary endothelium prior to metabolism.

The lungs exert a significant first-pass uptake effect on certain drugs, many of which are commonly used in anesthesia (Table 4.14). Passive diffusion of low-molecular-weight (100–1000 Da) molecules is known to occur, but the exact cellular pathways remain unclear.[30] Increasing lipophilicity of small compounds enhances transcellular diffusion and may be the primary mechanism of transient pulmonary uptake of unionized fractions of amide local anesthetics.[31] Organic cation and cation/carnitine transporters (OCT, OCTN) from the SLC superfamily are present in luminal aspect of tracheobronchial and alveolar epithelium.[32,33] P-glycoprotein and other ATP-binding cassette (ABC) family efflux transporters are also present on the basolateral membrane of respiratory epithelium as well as alveolar macrophages.[32] However, the exact roles that these and other drug transporters play in mediating pulmonary drug uptake are unclear.

Blood

Several drugs commonly used in anesthetic practice are metabolized via organ-independent biotransformation pathways. **Esterases**, which degrade bioactive molecules by splitting their ester bonds, are widely distributed in red blood cells and plasma. Esterases terminate the actions of succinylcholine, remifentanil, and esmolol (discussed in greater detail later). **Monocytes and macrophages** are involved in the clearance of unfractionated and low-molecular-weight heparins, as well as colloid intravenous fluids such as dextran

and hydroxyethylated starches. **Hofmann elimination** is a series of spontaneous chemical degradation steps that break down quaternary amines into a tertiary amine and an alkene. It is enzyme-, organ- and age-independent but is affected by pH and temperature. Hofmann elimination is the main metabolic pathway for atracurium and cisatracurium.

Pharmacogenomics and Drugs Commonly Used in Anesthesia (Table 4.15)

Neuromuscular Blockers

Butyrylcholinesterase Deficiency

Congenital BChE (or pseudocholinesterase) deficiency was one of the first pharmacogenetic disorders described in the medical literature. It is a result of a single mutation in the *BChE* gene on chromosome 3q26 and follows Mendelian inheritance patterns. Depending on the genotype, BChE deficiency results in prolongation of the effects of succinylcholine and mivacurium.

Currently more than 60 allelic variants of the *BChE* gene have been identified[34]; a selection of clinically important alleles is summarized in Table 4.16. In the past, different forms of BChE deficiency were identified based on phenotypic studies. These measured the inhibition of BChE activity by dibucaine (an ester local anesthetic) and fluoride. Normal BChE activity is decreased by 80% on exposure to dibucaine and 60% with fluoride; this degree of inhibition is reported as *dibucaine and fluoride numbers,* respectively (Table 4.17). Since then, the phenotypic BChE deficiency has been further defined as a qualitative or quantitative defect in BChE activity.

The overall prevalence of mild heterozygous BChE deficiency is highest in Caucasian populations (4%), which results in modest prolongation of succinylcholine activity (up to 1 hour). More severe heterozygous variants causing apnea lasting 1 hour or longer are rare, and homozygous forms, with complete absence of BChE activity, are rarer still.

Increased Butyrylcholinesterase Activity

Inherited conditions causing increased BChE activity have been described, which result in either a quantitative or qualitative change in the enzyme.[35] Two rare but distinct genetic variants were identified in the 1960–1970s that are associated with 30% and 400% increased activity compared with wild-type BChE and inherited in an autosomal dominant pattern.[36,37] The latter Cynthiana variant was later found to be due to increased production of enzyme.[36,37] An additional isoform discovered in the 1970–1980s appears to have

normal levels of a hyperactive enzyme.[38] Patients with these variants are resistant to the paralytic effects of succinylcholine and mivacurium and display normal inhibition when exposed to dibucaine and fluoride.

Opioids

Pharmacokinetic Alterations

Opioid Absorption and Distribution

The P-glycoprotein (P-gp), encoded by the *ABCB1* gene, is an important transporter of macromolecules across not only the intestinal epithelium but also brain capillary endothelium, which forms the functional blood-brain barrier. Substrates for P-gp include morphine, fentanyl, sufentanil, methadone, oxycodone, and buprenorphine; both oral and brain uptake are affected by polymorphisms in the *ABCB1* gene. The few human studies investigating the impact of ABCB1 polymorphisms on opioid effect have some contradictory results. ABCB1 C3435T, G2677T/A, and C1236T polymorphisms are associated with variations in the analgesic and respiratory depressant effects of morphine and fentanyl,[39,40] and differences in efficacy and side effects in patients on chronic oral morphine.[41] However, the same single-nucleotide polymorphisms (SNPs) were not associated with differences in morphine or fentanyl dose requirements or pain scores in postoperative patients.[42,43]

Opioid Metabolism

CYP 2D6 is responsible for handling approximately 25% of all drugs in current usage[44] and is highly involved in the metabolism of opioids to both active and inactive forms. There are currently more than 100 allelic variants of CYP 2D6; in addition, multiple gene duplications and multiplications can exist in an individual, resulting in up to 13 copies of the *2D6* gene and an overexpression of the enzyme. The population can be divided into four phenotypic groups based on their enzyme activity (Table 4.18).

Codeine achieves its analgesic effect only after it has been demethylated by CYP 2D6 to morphine, which has 200 times the affinity and 50 times the intrinsic activity at the μ-opioid receptor. In extensive metabolizers, approximately 10% of an administered codeine dose is metabolized to morphine; the remainder is converted to codeine-6-glucuronide and norcodeine, which are both inactive metabolites. In comparison, ultrarapid metabolizers, who make up 1% to 2% of Caucasians but up to 29% of people from Ethiopia and Saudi Arabia, can have approximately 50% higher plasma concentrations of morphine.[46] This can result in respiratory depression and death, especially in the postoperative pediatric tonsillectomy population.[47,48] These effects are also important for breastfeeding mothers who are ultrarapid metabolizers. It should be noted, however, that significant variability exists even within the extensive metabolizer phenotype, with some patients producing plasma morphine levels approaching or exceeding those found in ultrarapid metabolizers.[46] Poor metabolizers do not experience analgesic effect from codeine owing to lack of 2D6-mediated metabolism to morphine, but they can still experience side effects from non-2D6 mediated metabolites such as codeine-6-glucuronide.[49]

CYP 2D6 is also important in the metabolism of tramadol and oxycodone. **Tramadol** exerts analgesic effects via the μ-opioid receptor as well as serotonin and noradrenaline reuptake inhibition. It is also metabolized by CYP 2D6 to O-desmethyltramadol, which has a much higher affinity for the μ-receptor than its parent compound.[45] In cases of fatal tramadol overdose, the number of functional CYP 2D6 alleles strongly correlates with the ratio of tramadol metabolite to the parent compound.[50]

Oxycodone is metabolized by CYP 2D6 to oxymorphone, which has three times the half-life of oxycodone but makes up only 15% of total oxycodone metabolites. Oxycodone consumption in postsurgical patients correlates with the number of functional CYP 2D6 alleles, although there was no difference in pain scores.[51] For reasons similar to codeine, tramadol and oxycodone should be avoided in ultrarapid metabolizers to avoid unexpected opioid overdose.

Pharmacodynamic Alterations

Opioid Receptors

Variants of the *OPRM1* gene, which encodes for the μ-opioid receptor, are associated with variations in experimental and clinical pain responses as well as opioid side effects. The A118G SNP has an allelic frequency of 10% to 30% in Caucasians[52] and up 36% to 60% in East Asians.[53] Compared with the wild-type OPRM1 gene, this variant increases the affinity and intrinsic activity of β-endorphin for the μ-receptor approximately threefold.[54] In vitro animal experiments also suggest that this SNP alters receptor binding and signal transduction at the level of the sensory neurons.[55] Human trials, however, have not clearly linked this or other SNPs with alterations in pain perception or opioid efficacy. In studies investigating East Asian women undergoing gynecologic surgery, the 118GG genotype is associated with statistically significant but clinically modest increases in intravenous morphine and fentanyl consumption to achieve pain relief in the first 24 hours, but no difference in opioid side effects.[56,57] These findings were supported in a study of adult Japanese patients, 57% of whom were male, undergoing colorectal surgery under general and epidural anesthesia.[58]

Western European women receiving *intrathecal fentanyl for labor analgesia* have a 1.5- to 2-fold difference in the effective concentration for 50% effect (ED_{50}) of intrathecal fentanyl depending on the A118G genotype; those who are heterozygous or homozygous for the 118G SNP (termed A304G in those studies) showed an increased sensitivity to the analgesic effects of intrathecal fentanyl.[59] In addition, there is a significant difference in the degree of cervical dilatation at time of request for analgesia, with 118G homozygotes requesting analgesia at a later progression of labor.[59] Although many factors contribute to this difference, it is in keeping with the findings of enhanced β-endorphin binding to the variant μ-receptor *in vitro*.[54] However, a larger multicenter study of including Caucasian, Asian. and African American parturients did not show any difference in the duration of intrathecal fentanyl for labor analgesia, nor in the requirements of supplemental analgesia following cesarean delivery with neuraxial anesthesia and intrathecal morphine.[60] Confounders that may account for the heterogeneity of human clinical data include different mechanisms of noxious stimulus, gender, and ethnicity, all of which are independent predictors of pain perception.[53,61] Furthermore, differences between intravenous and neuraxial routes of opioid administration may contribute to the incongruent findings, as well as the possibility that the A118G SNP may in fact be a marker for, but not the causative mutation of, the observed differences.

Catecholamines including norepinephrine and dopamine are mediators in the central and peripheral pain pathways, and are metabolized by catechol O-methyltransferase. *Variations in the* COMT *gene* on chromosome 22 are postulated to affect pain perception, although almost all human studies suffer from small sample sizes and other methodologic problems. A prospective trial of 221 patients investigating a range of MAO and COMT polymorphisms show a weak genetic contribution to individual variations in acute surgical pain responses.[62] Smaller studies looking specifically at the G472A SNP show decreased COMT activity and increased sensitivity to nociceptive stimuli induced by heat and hypertonic saline solution.[63,64] A broader "low COMT activity" haplotype group made up of varying allelic variations predicted pain catastrophizing behavior following shoulder surgery.[65]

Intravenous Anesthetics

Pharmacokinetic Alterations

Most **benzodiazepines**, with the exception of oxazepam and lorazepam, are metabolized by the CYP system via N-dealkylation or hydroxylation. Midazolam is a highly specific substrate for CYP 3A4/5, and its clearance can vary 5- to 11-fold in Caucasian and African American populations.[66] Despite in vitro evidence to the contrary, this interindividual variability does not appear to result from polymorphisms of CYP 3A4/5.[67] The reasons for this have been attributed instead to gender and environmental factors,[67] the presence of inducers,[68] and alternate pathways of metabolism and excretion.[69]

Diazepam is primarily demethylated into active metabolites by CYP 2C19, an enzyme encoded by a gene with over 25 alleles currently identified.[70] Alleles can confer normal, loss, or gain in enzyme function, resulting in ultrarapid, normal, and poor metabolizer phenotypes (Table 4.19). Poor metabolizers have a fourfold increase in the half-life of diazepam compared with extensive metabolizers,[71] placing them at risk of prolonged sedation.

Oxazepam and lorazepam are metabolized via glucuronidation and have been considered a safe alternative in hepatic impairment, but their handling is also altered by genetic polymorphisms. Compared with wild-type UGT2B15, the UGT2B15*2/*2 genotype reduces systemic clearance of lorazepam by approximately 50%, resulting in higher visual analog scales for sedation.[72] The same polymorphism also causes a decrease in oxazepam glucuronidation,

TABLE 4.19 Variant CYP 2C19 Phenotypes

Phenotype	Genotype	Approximate Frequency	Effect on Diazepam and Clopidogrel
Ultrarapid	Two copies of increased-function allele	5%–30%	**Diazepam**: Increased production of desmethyl-diazepam, with extremely long half-life. Concern for prolonged duration of action, no formal recommendation on dose adjustment **Clopidogrel:** Increased production of active metabolite, increased risk of bleeding
Extensive	Two copies of a normal-function allele	35%–50%	Normal handling of diazepam and clopidogrel
Intermediate	One copy of a reduced-function allele One copy of a normal-function allele	18%–45%	Normal handling of diazepam and clopidogrel
Poor	Two copies of a reduced-function allele	2%–15%	**Diazepam:** Concern for prolonged duration of action, no formal recommendation on dose adjustment **Clopidogrel:** Decreased conversion into active form; risks no treatment effect, suggest change to alternate antiplatelet agent

Data from Scott SA, Sangkuhl K, Gardner EE, et al. Clinical Pharmacogenetics Implementation Consortium guidelines for cytochrome P450-2C19 (CYP2C19) genotype and clopidogrel therapy. *Clin Pharmacol Ther.* 2011;90:328–332.

although correlation with clinical variability in drug response has not been described to date.[73]

Propofol is hydroxylated in the liver primarily by CYP2B6 and, to a lesser extent, CYP2C9.[74] It also undergoes transformation via UGT 1A9 to form propofol glucuronide, an inactive metabolite. The CYP 2B6 c.516G>T polymorphism decreases propofol metabolism and contributes to variations in propofol clearance when corrected for age, height, and weight.[75,76] However, there appears to be little correlation between this and other genotypes with differences in clinical outcome.[77,78] Similarly, the 766G>A SNP of UGT 1A9 decreases the glucuronidation of propofol but does not account for clinical variability in the effects of propofol.[76,78]

Pharmacodynamic Alterations

The *gamma-aminobutyric acid (GABA)$_A$ receptor* is the molecular target for many intravenous and volatile anesthetics (see Chapters 10 and 11). In vitro studies of variant $GABA_A$ receptors with the epsilon subunit, encoded by the *GABRE* gene, show resistance to the effects of benzodiazepines, barbiturates, etomidate and propofol.[79,80] Human studies, however, have so far been unable to show any association between the *GABRE* gene and variations in response to propofol anesthesia.[77,78]

Inhalational Anesthetics

Pharmacokinetic Alterations

The hepatic metabolism of halothane, sevoflurane, isoflurane, and desflurane occurs almost exclusively through CYP 2E1 oxidation.[81] Although there are many known CYP 2E1 variants, to date no polymorphisms have been shown to cause clinically significant effects on the metabolism of volatile anesthetics. This can partly be attributed to the overall low contribution from liver metabolism to the disposition of sevoflurane, isoflurane, and desflurane (see Chapter 3).

Halothane Hepatitis

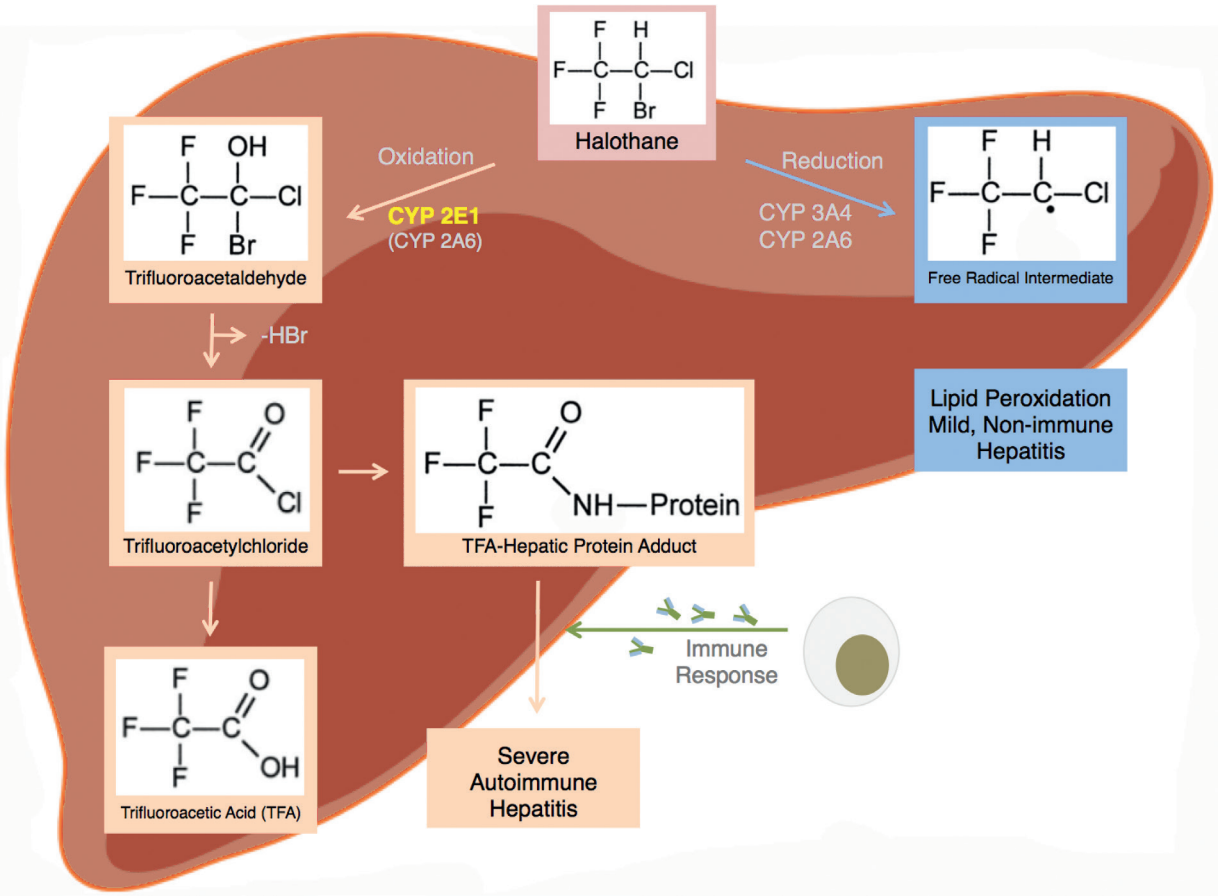
Reports of halothane hepatitis have become rare since the 1980s, but it remains relevant in those countries where halothane is still available for clinical use. The pharmacogenetic link between volatile anesthesia and acute, often fatal, liver injury remains elusive. Up to 20% of administered halothane is metabolized by hepatic CYP 2E1 and 2A6/3A4 via both oxidative and reductive pathways, respectively.[81] Trifluoroacetyl chloride, an oxidative metabolite of halothane, is linked to the development of fulminant hepatocellular damage by covalently binding to hepatic proteins to form trifluoroacetylated neoantigens, which subsequently become a target for autoimmune attack (see Fig. 4.7). Risk factors include hypoxia and HLA tissue types, but there is little information on the pharmacogenetic features that predispose an individual to oxidative, rather than reductive, metabolism of halothane. To date, the single study investigating the CYP profiles of known survivors of halothane hepatitis have not demonstrated differences in activity between survivors and controls across a range of isoenzymes, including 2A6 and 3A4.[82] An important omission, however, is the impact of CYP 2E1 activity in this survivor group.

Pharmacodynamic Alterations

Malignant Hyperthermia

Malignant hyperthermia (MH) is an inherited, multifactorial channelopathy marked by uncontrolled release of calcium ions (Ca^{2+}) from the sarcoplasmic reticulum of skeletal muscle in response to volatile anesthesia and succinylcholine (see Chapter 7). The main channels implicated in the pathogenesis of MH include the ryanodine receptor (encoded by the *RYR1* gene), and the L-type calcium channel within the T-tubules containing the voltage-sensing $Ca_V1.1$ and beta1a subunits (encoded by the CACNA1S and CACNB1 genes, respectively). Many other defects in chromosomal loci not currently associated with genes are associated with MH.[83] Given the complexity of Ca^{2+} homeostasis, it is likely these loci encode for other regulators of Ca^{2+} transport in skeletal muscle whose role in MH is still unknown.

The pharmacogenetics of MH are complex and likely polygenetic. Approximately 50% to 85% of MH cases are linked to mutations in the *RYR1* gene, although this varies depending on geographic population and study design.[84] Inheritance is autosomal dominant, with unknown penetrance, but it is likely highly variable. The



• **Fig. 4.7** Pharmacogenetics of Halothane Hepatitis. Liver injury can occur as a result of oxidative and reductive metabolism of halothane, although it is the oxidative pathway that is most associated with more severe forms of hepatitis. Oxidative metabolism of halothane via CYP 2E1 results in trifluoroacetylated metabolites that covalently bind to liver proteins, resulting in neoantigens that stimulate an autoimmune response. While there are immunologic risk factors that predispose to halothane hepatitis, the role of CYP 2E1 isoforms and the production of trifluoroacetylated proteins has yet to be fully elucidated.

prevalence of genetic variants in *RYR1* predisposing to MH is estimated to be 1:2000,[85] but the incidence of MH is much lower, between 1 and 1.3 per 100,000 anesthetics in the United States, and even lower in ambulatory surgical settings.[86,87] Of the approximately 200 *RYR1* mutations currently known,[88] 66 have been detected in known MH families in the United Kingdom.[83] In approximately 10% to 20% of families, no *RYR1* gene defect could be found. With regard to the *CACNA1S* gene, 6 of more than 50 known variants have been linked to MH,[89] with approximately 1% of MH presentations attributed to defects in *CACNA1S*.

What is increasingly clear from the genotype-phenotype discordance in both laboratory and human clinical studies is that there are additional modulators that influence the manifestation of MH. Post-translational modification of calcium channels by fatty acids[90] and the interaction between these channels and other membrane proteins[91,92] are implicated. When combined, the clinical manifestation of MH is likely a "threshold model" in which the presence of an *RYR1* variant is but one of many other contributors that lead to symptoms.

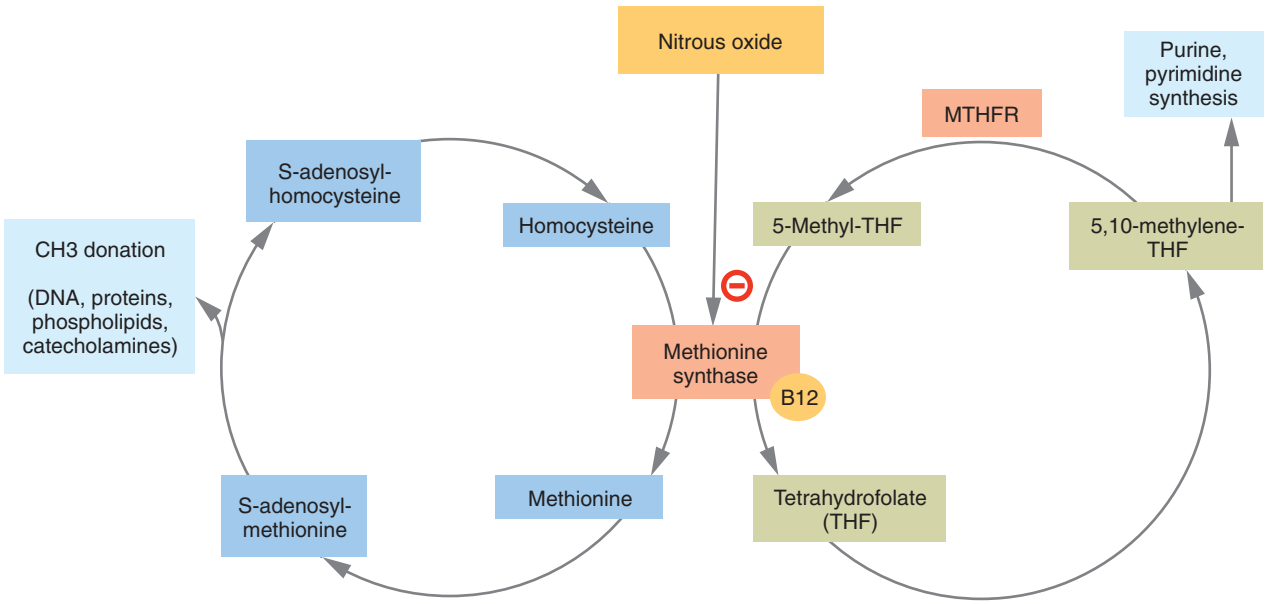
Melanocortin-1 Receptor Gene Variants

Reduced-function variants of the melanocortin-1 receptor *(MC1R)* gene are associated with the red hair phenotype.[93] The red hair trait occurs as a result of an overabundance of pheomelanin (red) pigment relative to eumelanin (dark brown)[93] and is a convenient physical marker for reduced *MC1R* activity. In both knockout mice and humans, reduced-function *MC1Rs* are associated with increased volatile anesthetic and analgesic requirements.[93–95] Whether these *MC1R* variants are directly responsible, or are markers for other determining characteristics common among red-haired individuals, is currently unknown.

MTHFR Gene Variations

Nitrous oxide irreversibly inhibits vitamin B_{12} (cobalamin), which leads downstream effects on enzymes that require vitamin B_{12} as a co-factor. Methionine synthase is one such enzyme, and is central to both the methylation of homocysteine to methionine, and to the conversion of 5-methyl-tetrahydrofolate (THF) to THF. Both metabolic reactions are crucial steps in methylation reactions critical to neurotransmitter, myelin sheath, and nucleic acid synthesis, which particularly affects central nervous system function and rapidly dividing cells such as those in bone marrow (Fig. 4.8). Furthermore, increased plasma homocysteine levels predispose to endothelial cell injury and vascular thrombosis.

Methylenetetrahydrofolate reductase (MTHFR) is an enzyme in the folate cycle that demethylates 5,10-methylene-THF to 5-methyl-THF, the substrate for methionine synthase. MTHFR deficiency occurs as a result of SNPs in the *MTHFR* gene located



• **Fig. 4.8** Nitrous Oxide and MTHFR Deficiency. Nitrous oxide inhibits vitamin B_{12}, which is required by methionine synthase as a cofactor for catalyzing the conversion of 5-methyl-tetrahydrofolate to tetrahydrofolate (THF). Methylene tetrahydrofolate reductase (MTHFR) is an enzyme that converts 5,10-methylene-THF to 5-methyl-THF. In the presence of MTHFR deficiency, the administration of nitrous oxide can result in disorders of purine and pyrimidine synthesis, as well as other downstream reactions that depend on methyl donors from this metabolic cycle.

on chromosome 1. The two common SNPs, 677C>T and 1298A>C, have a cumulative prevalence of approximately 5% to 10% in Western Europe, 20% to 25% in Southern Europe and East Asia, and up to 36% in Mexico.[96,97]

It has been postulated that nitrous oxide imposes a "second hit" to vulnerable patients with preexisting defects in folate or homocysteine-methionine metabolism pathways.[98] Several case reports of repeated nitrous oxide anesthesia administered to patients with *MTHFR* gene mutations describe acute demyelination causing severe neurologic injury and megaloblastic anemia.[98,99] Similar pathology is seen when nitrous oxide is administered to patients with severe vitamin B_{12} deficiency.[100] Although an increase in plasma homocysteine levels is also seen in these patients, there is no correlation with increased risk of perioperative myocardial injury as a result of nitrous oxide anesthesia in these patients.[101] Because of the potentially devastating effects of acute methionine synthase dysfunction, it has been suggested that nitrous oxide be avoided in patients who have a personal or family history of *MTHFR* gene mutation.[102]

Serotonin Receptor Antagonists

Ondansetron and tropisetron are commonly used for the prevention and treatment of postoperative nausea and vomiting (see Chapter 34). Both are transformed into inactive metabolites: ondansetron by multiple CYPs, including 3A4, 1A2, and 2D6, and tropisetron exclusively by 2D6. Populations with the CYP 2D6 ultrarapid metabolizer phenotype can experience failure of antiemetic therapy when ondansetron and tropisetron are used. Within a group of 250 North American women undergoing general anesthesia treated with prophylactic ondansetron, those who were 2D6 ultrarapid metabolizers had a significantly higher incidence of postoperative nausea and vomiting (45%) compared with extensive metabolizers (15%).[103] A similar failure of tropisetron for prevention of chemotherapy-induced nausea and vomiting occurs in 2D6 ultrarapid metabolizers.[104] Interestingly, while poor metabolizers have increased serum drug levels compared with other phenotypes, there is no increase in side effects reported.[103,104] Currently, expert opinion recommends avoidance of 5-HT_3 antagonists primarily metabolized by CYP 2D6 in known ultrarapid metabolizers (ondansetron, tropisetron, dolasetron, palonosetron). Granisetron, an intermediate-acting 5-HT_3 antagonist, is metabolized by CYP 3A4 and 1A1 and is a suitable alternative in these patients. As yet, there are insufficient data to recommend specific changes in practice for poor metabolisers.[105]

Emerging Developments

Precision medicine is an exponentially growing field that is increasingly bridging the gap between laboratory science and clinical application. The term, introduced into common usage in 2011, emphasizes the integration of population genomics with individual clinical and socio-environmental data to guide research and treatment of disease.[106] An example of precision medicine in practice is the use of large-scale genetic databases and multiple patient biomarkers to individualize cancer chemotherapeutic regimens.[107] Another example is point-of-care buccal swab testing for CYP 2C19 polymorphisms, used to predict non-responders to clopidogrel therapy in patients after percutaneous coronary intervention.[108]

It is increasingly recognized that for many drugs, the "one gene, one defect" paradigm is insufficient to fully explain the variability in drug responses between individuals. The use of massive data repositories for systems biology analysis is one approach that better characterizes these complex genome-phenome associations.[109] The creation of robust, intricate biologic models is another approach; one example of this is the use of chimeric mice with "humanized"

livers.[110] Xu and Peltz describe several methods that involve transplanting human liver cells into immunosuppressed transgenic mice, resulting in a biologically active liver that expresses mRNA encoding for human phase I and II enzymes, drug transporters, and other transcription factors.[110] This exciting development expands horizons not only for more accurate prediction of in vivo drug handling, but also the promise of personalized, functional hepatic models through the engraftment of an individual's hepatocytes in these chimeric mice.

In the near future, a fully integrated approach with contributions from the various "omic" bioinformatics branches can bring about virtual models of complex physiologic and disease states that can transform pharmaceutical development, clinical drug trials, and medication prescribing. In an era when guidelines and protocols are pervasive in clinical practice, precision medicine has the potential to be the personalized counterweight that brings about innovations in safety and cost-effectiveness in health care and research in the years to come.

Key Points

- The transporters and enzymes involved with drug metabolism are closely related to ancient defense mechanisms against xenobiotics found across Archaea, bacteria, and eukaryotes.
- Pharmacogenetics is a term that refers to the study of genetic causes of variability in drug response; more recently, a genome-wide approach has been adopted (pharmacogenomics) to more fully understand interindividual differences in drug effect.
- Genomic variants can alter the function of membrane transporters, metabolic enzymes, and target receptors to alter the disposition and effects of many commonly used anesthetic drugs.
- Genetic variants of membrane transporters are an important determinant of differential drug effect between individuals. While these variations alone can cause altered drug behavior, it is increasingly recognized that transporter variants may also alter the function of other enzymes and metabolites to contribute to changes in phenotype.
- Drug metabolism takes place predominantly in the liver, but begins with entry into the body via natural barriers of the gastrointestinal and respiratory tracts, and also occurs in many locations throughout the body.
- Drug metabolism processes can be classified into three phases: drug transport, phase I reactions, and phase II reactions. Phase I reactions alter biologic activity of drugs via alteration of a functional molecular group. Phase II reactions do so by conjugating a water-soluble adjunct to the drug.
- Important metabolic enzymes with variant phenotypes that have an impact on clinical care include CYP 2D6, 2C19, N-acetyltransferase, and butyrylcholinesterase. By overcoming current limitations in bioinformatics, laboratory technology, and study design, it is likely other similar associations will be found.
- The future of pharmacogenomics lies in systems pharmacology, using data from many "omic" fields to model and systems biology to model complex biologic states to guide drug development, test for efficacy, and minimize adverse side effects.

- Anesthetic Toxicity in Neonates and Infants

Elderly Patients
- Physiologic Changes in the Elderly
- Anesthetic Pharmacology in the Elderly
- Postoperative Cognitive Dysfunction

Emerging Developments
- Open Target-Controlled Infusion

Anesthesiologists frequently care for patients at the extremes of age and size. These patient groups have unique features that require special consideration when formulating an anesthetic plan. The purpose of this chapter is to highlight alterations in physiology associated with these special populations, focusing in particular on how the altered physiology influences the behavior of anesthetic drugs as covered in other chapters. To translate this information into the clinical domain, the chapter aims to summarize dosing adjustments that account for body habitus (obese and morbidly obese) and age at both extremes (neonates and elderly).

Obese Patients

Physiologic Changes in Obese Patients

Obesity presents anesthesiologists with numerous challenges that affect their care throughout the perioperative period. Excess body weight affects virtually every system of the body, including the cardiovascular, respiratory, endocrine, digestive, and hematologic systems, among others. In particular, increased chest wall mass, redundant airway tissue, and increased incidence of obstructive sleep apnea make this patient group at increased risk for adverse airway and respiratory events among many other weight-related issues (Table 5.1, Fig. 5.1).

In response to the increasing frequency of obese patients presenting for surgery, the American Society of Anesthesiologists (ASA) updated the ASA's Physical Status Classification System to include obesity as a metric to consider when determining a patient's physical status (Table 5.2).[1] This modification encourages clinicians to acknowledge how obesity-related conditions can lead to adverse events in the perioperative period. Of particular relevance to anesthesiology, obesity can alter the pharmacokinetics and effects of intravenous agents (opioids, sedatives, neuromuscular blockers) and inhalation agents. Increased fat mass, increased blood volume and cardiac output, and reduced tissue perfusion change drug disposition that can lead to changes in the magnitude and time course of drug effect[2,3] (Table 5.3, see Fig. 5.1).

The fact that most anesthetics are highly lipophilic (i.e., as measured by their octanol-water coefficient) raises concerns about accumulation of anesthetics into fatty tissue over the course of an anesthetic. When exploring differences between drugs, however, lipophilicity alone does not reliably predict volume of distribution. Lipophilic drugs can have increased, unchanged, or reduced distribution volumes[4] because drug distribution also depends on other properties, such as protein binding, molecular size, ionization at physiologic pH (pKa), among other factors.

Understanding the relationship between total body weight, lean body weight, and fat weight is also important. As total body weight increases beyond ideal body weight (i.e., as body mass index [BMI] increases), the proportion of lean and fatty tissue begins to diverge (Fig. 5.2). Above a BMI of 30 kg/m^2, lean body weight begins to plateau, and the curve flattens even further as BMI exceeds 40 kg/m^2 as the body has proportionally less lean tissue. Obesity influences the physiology of most organ systems that can alter the pharmacologic behavior of anesthetic drugs. Although drugs from the same class (e.g., opioids) are likely to be influenced by obesity in

Abstract

Anesthesiologists are frequently asked to care for patients at the extremes of age and size. These patient groups have unique features that require special consideration when formulating an anesthetic plan. The purpose of this chapter is to highlight alterations in physiology associated with these special populations, focusing in particular on how the altered physiology influences the behavior of anesthetic drugs. To translate this information into the clinical domain, the chapter aims to summarize dosing adjustments that account for body habitus (obese and morbidly obese) and age at both extremes (neonates and elderly).

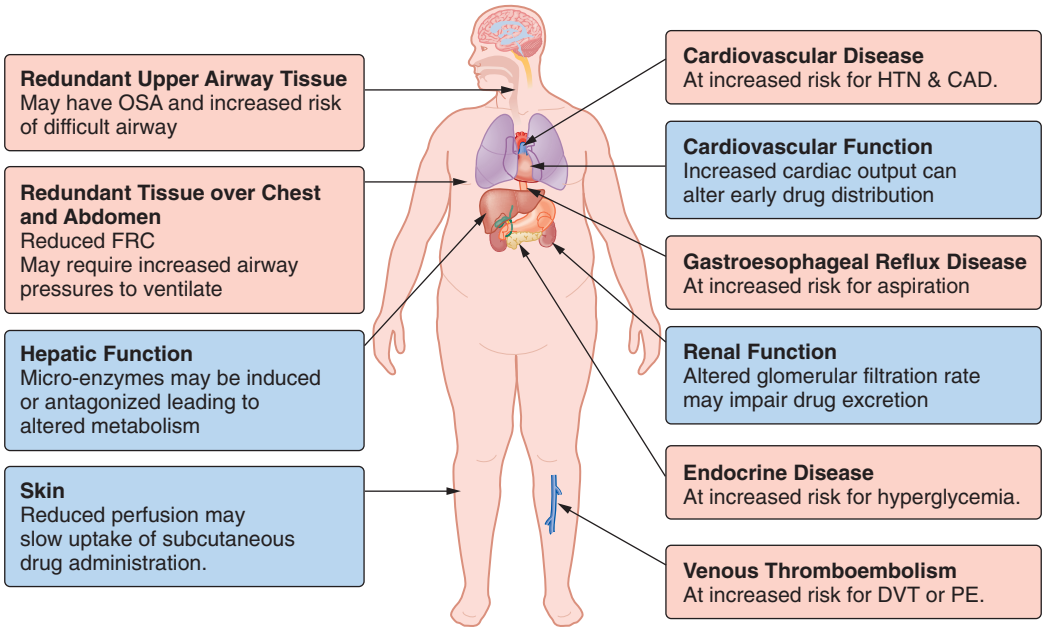
TABLE 5.1 Anesthetic Considerations and Perioperative Challenges in Obese Patients

Weight-Related Condition	Challenge	Management Considerations
Redundant upper airway tissue	Obstructive sleep apnea Potential difficulty with airway management (more likely in males[107])	Continuous positive airway pressure to stent open the airway when appropriate (procedures requiring sedation, recovery from general anesthesia) Immediate availability of airway adjuncts (e.g., video laryngoscope, supraglottic airways, elastomeric bougie, fiberoptic bronchoscope) and patient positioning
Redundant tissue over chest and abdomen	Reduced functional residual capacity[108] With mechanical ventilation, may require high airway pressures to achieve adequate ventilation,[109] leading to an increased risk of barotrauma	*Induction of anesthesia:* Anticipate rapid drop in oxygen hemoglobin saturation once rendered apneic despite effective preoxygenation *Emergence from anesthesia:* Extubate to continuous positive airway pressure. Place head of bed to 45° to optimize pulmonary mechanics. Maintain plateau airway pressures <30 cmH_20, tidal volumes between 6-8 mL/kg, and judicious titration of positive end-expiratory pressure[110]
Gastroesophageal reflux disease[111]	Increased risk of aspiration	Avoid use of supraglottic airway devices.[112] Consider preoperative administration of a H_2-histamine antagonist[113]
Cardiovascular disease (hypertension,[114] coronary artery disease[115])	Increased likelihood of intraoperative myocardial ischemia and arrhythmias	Maintain mean arterial blood pressure within 10%-20% of preoperative blood pressure. When appropriate, monitor hemoglobin concentration, hemoglobin oxygen saturation, systolic and diastolic blood pressures, and heart rate to maintain adequate coronary artery perfusion, myocardial oxygen delivery, and reduced myocardial afterload.
Venous thromboembolism[116]	Deep vein thrombosis or pulmonary embolism	Prophylactic anticoagulation and intermittent pneumatic leg compression
Hyperglycemia/insulin resistance[117]	Perioperative hyperglycemia[118]	Consider insulin administration to maintain blood sugar concentrations in the 140-180 mg/dL range[119]



• **Fig. 5.1** Schematic summary of obesity-related physiologic changes that may alter anesthetic drug behavior *(blue)* and anesthetic considerations and perioperative challenges *(red). TABLE 5.2 Obesity Considerations for the American Society of Anesthesiologists (ASA) Physical Status Classification System

ASA Physical Status	BMI Range (kg/m^2)
1	≤30
2	31-39
3	≥40

TABLE 5.3 Selected Obesity-Related Physiologic Changes That Alter Anesthetic Drug Behavior

Physiologic Change
Increased cardiac output can alter early drug distribution (e.g., front-end kinetics)[120,121]
Reduced tissue perfusion slowing uptake of subcutaneous injections[2]
Increased or decreased hepatic cytochrome P450 microsomal enzyme function[122,123]
Alterations in hepatic drug biotransformation via uridine diphosphate glucuronosyltransferase[123,124]
Alteration in the glomerular filtration and/or renal tubular-mediated drug excretion[123,125]

similar ways, it is difficult to generalize obesity-related changes across all classes of anesthetics.

Anesthetic Pharmacology in Obesity

Pharmacology is the study of drug dosing (see Chapters 2 and 3). Anesthetic pharmacology in the morbidly obese is challenging. Although many anesthetic drugs are traditionally dosed according to total body weight (e.g., in milligrams per kilogram or micrograms per kilogram per minute), most weight-based dosing guidelines (i.e., drug labeling in the official "package insert") are founded on data collected in subjects with normal body habitus. For most anesthetic drugs, the guidance that the dose should be altered as body weight increases might never have been tested in a rigorous way. In fact, when formulating an anesthetic regimen for a morbidly obese patient, using total body weight to calculate an appropriate dose is likely to lead to an overdose. This observation is a practical reality that anesthesiologists intuitively understand based on clinical experience. For example, a 120-kg patient does not require twice as much anesthetic as a patient of the same height who weighs 60 kg.

To address this, researchers have explored numerous weight scalars in an effort to minimize the risk of inadequate or excessive dosing in obese patients. The goal is to identify a dose for an obese patient that would behave similar to a conventional dose for a normal-sized patient. Some examples include ideal body weight (IBW), lean body mass (LBW), fat-free mass (FFM), adjusted body weight (ABW), and pharmacokinetic mass (PK mass). Table 5.4 presents the formulas used to calculate selected weight scalars. To provide a clinical context for these weight scalars, Table 5.5 presents examples of scaled weights for an obese and lean individual of the same height and the respective induction doses of commonly used intravenous anesthetics.

Of note from Table 5.5, using the IBW scalar yields doses that are equivalent, regardless of body habitus, the doses would likely be adequate for the lean but insufficient for the obese individual. Using LBW or FFM scalars yields doses that are lower for the lean individual but higher for the obese individual compared with IBW, but both may be inadequate, because LBW or FFM is what remains after fat mass is subtracted from TBW. Using LBW or FFM consistently results in underdosing for both lean and obese patients. Using ABW or PK mass scalars by contrast recommends doses that may be sufficient for induction for both the lean and obese individuals. Lean-scaled weight (LSW) is another weight scalar proposed for use in the operating room for drugs that scale consistent with LBW. It is based on LBW, TBW, and BMI and allows estimation of doses based on a percentage of TBW. LBW has not been validated in vivo.[5]

Identifying the optimal weight scalar has proven to be complex. To add to the complexity, the appropriate weight scalar for a bolus dose can differ from the scalar best suited for continuous infusion. Furthermore, weight scalar choice can vary by drug or drug class. Table 5.6 presents suggested weight scalars for selected anesthetics. Some have been identified through direct experimentation in obese patient populations, whereas others are assumed based on the premise that drugs of a similar class are likely to behave similarly because they often share similar physicochemical characteristics.

For anesthesia clinicians who use target-controlled infusions (TCI), obesity introduces the additional issue of selecting the appropriate pharmacokinetic model to drive the infusion. Although suitable pharmacokinetic models exist for many commonly used sedative-hypnotics, opioids, and neuromuscular blockers, some models are suboptimal when applied to special populations (e.g., extremes of weight or age). Furthermore, recent studies aimed at building new models for these special populations have not yet been incorporated into the software of TCI pumps.[6-8] This problem has forced the clinician to develop creative work-arounds to address the shortcomings of TCI models.[9]

The remainder of this section briefly discusses pharmacokinetic changes associated with obesity for selected sedative-hypnotics, opioids, and potent inhaled agents, reviewing examples of weight scalars and their limitations when used to formulate a rational dosing scheme. A brief review of available pharmacokinetic models used to drive TCI pumps is also provided.

TABLE 5.4 Selected Weight Scalars

Weight Scalar	Comments	Formula[126-128]
Total body weight (TBW)	The total weight of an individual	None
Real body weight (RBW)	The total weight of an individual	None
Ideal body weight[a] (IBW)[127]	The ideal weight associated with maximum life expectancy for a given height. Does not account for total body weight.	$IBW = 0.0022 * Ht^2$
Lean body weight (LBW)[129]	Accounts for total weight, height, and sex. An artifact of this formula is that at extremes of weight, lean body weight becomes increasingly smaller.	$LBW(male) = 1.1 * TBW - 128 * \left(\frac{TBW}{Ht}\right)^2$ $LBW(female) = 1.07 * TBW - 148 * \left(\frac{TBW}{Ht}\right)^2$
Fat-free mass (FFM)[126]	Like LBW, accounts for total weight, height, and sex. The FFM formula has addressed the limitation of the LBW formula at extremes of weight.	$FFM(men) = \frac{9270 * TBW}{6680 + (216 * BMI)}$ $FFM(women) = \frac{9270 * TBW}{8780 + (244 * BMI)}$
Adjusted body weight (ABW)[128]	Accounts for increased lean body mass and likely increased volume of distribution in obese individuals.	$ABW = IBW + 0.4 * (TBW - IBW)$
Pharmacokinetic mass (PK mass)[26,27]	Formulated for fentanyl only. Estimates the apparent pharmocokinetically (PK) active equivalent dosing weight	$PK\ mass = \frac{52}{\left[1 + \frac{196.4 * e^{-0.025 * TBW} - 53.66}{100}\right]}$
Lean-scaled weight (LSW)[5]	Proportional to LBW and normalized for sex, weight, and height.	LSW (men) = 11,432 * TBW/(6,680 + 216 * BMI) LSW (women) = 14,148 * TBW/(8,780 + 244 * BMI)

BMI, Body mass index (kilograms per meter squared); *Ht,* height (in centimeters).
[a]One of many formulas available for IBW.

TABLE 5.5 Scaled Weights and Induction Doses of Common Intravenous Anesthetics for a Lean and Obese Male Individual of the Same Height[a]

	Scaled Weight (kg)		PROPOFOL (2 mg/kg) Total mL of Propofol at 10 mg/mL[b]		FENTANYL (2 mg/kg) Total mL of Fentanyl at 50 µg/mL[b]		ROCURONIUM (0.6 mg/kg) Total mL of Rocuronium at 10 mg/mL[b]	
Dosing Scalar	Lean	Obese	Lean	Obese	Lean	Obese	Lean	Obese
Total body weight	60	120	12	24	2	5	4	7
Ideal body weight	66	66	13	13	3	3	4	4
Lean body weight	51	70	10	14	2	3	3	4
Fat-free mass	51	73	10	15	2	3	3	4
Adjusted body weight	64	88	13	18	3	4	4	5
Pharmacokinetic mass	58	93	12	18	2	4	4	6

[a]Induction doses are shown in milliliters. The lean individual weight 60 kg with body mass index of 20 kg/m^2. The obese individual body mass index is 40 kg/m.^{2} The lean and obese individuals are of the same height (173 cm)
[b]Dosed to the nearest milliliter.

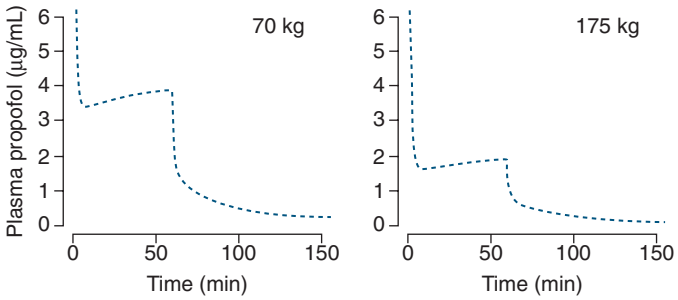
Sedative-Hypnotics

Propofol is the most comprehensively studied sedative-hypnotic in the obese population. TBW has been recommended for calculation of maintenance continuous infusion rates,[10] although recent work suggests using ABW to account for the nonlinear relationship between propofol clearance and TBW.[11] There are also many facets to consider when choosing a scalar for bolus dosing for induction of anesthesia. To avoid medication overdose, LBW has been proposed.[12] As illustrated in Table 5.5, however, use of this scalar might result in underdosing and ABW might be more appropriate.[13] With no established optimal weight scalar, recent work has explored other methods to determine the optimal bolus dose of propofol in obese patients.[14]

TABLE 5.6 Recommended Weight Scalars for Selected Intravenous Anesthetics

Drug	Bolus	Infusion
Sedatives		
Propofol	Loading dose titrated to target processed EEG level[14a]	ABW[11]
Midazolam	TBW[21b]	IBW[b]
Etomidate		IBW[130]
Opioids		
Fentanyl	PK mass	PK mass[26,27]
Remifentanil	FFM	FFM[22]
Sufentanil	TBW[28]	
Hydromorphone	LBW[131,132]	
Morphine	LBW[131,132]	
Neuromuscular Blocking Agents and Reversals		
Succinylcholine	TBW[133]	
Rocuronium	IBW[134]	
Vecuronium	IBW[135]	
Cisatracurium	IBW[136]	
Sugammadex	IBW[137]	

EEG, Electroencephalogram; *FFM,* fat-free mass; *IBW,* ideal body weight; *LBW,* lean body weight; *PK,* pharmacokinetic; *TBW,* total body weight in kg;
Weight scalars in parentheses are assumed based on data from other similar class drugs.
[a]Prior work has explored the use of several weight scalars for propofol. See text for details.
[b]Based on a single pharmacokinetic study.



• **Fig. 5.3** Pharmacokinetic simulation of an identical propofol dose (150-mg bolus injection followed by a 10-mg/min infusion for 60 minutes) administered intravenously to a 70-kg and a 175-kg patient (both 50 years old, 170 cm tall). Note the lower plasma levels in the larger patient. The simulation is based on the pharmacokinetic model of Cortinez et al.[15] (From Cortinez LI, Anderson BJ, Penna A, et al. Influence of obesity on propofol pharmacokinetics: derivation of a pharmacokinetic model. *Br J Anaesth.* 2010;105:448–456.)

One study compared induction of anesthesia with propofol based on LBW versus a loading dose (rapid propofol infusion) titrated to a target processed electroencephalographic (EEG) signal (bispectral index scale [BIS]). Patients induced using the LBW scalar required additional propofol doses to reach the same level of sedation[14] compared with patients titrated to a BIS value of 50. The bolus technique required substantially less time to administer but was not as effective. The loading dose approach led to a more consistent induction of anesthesia and no need for supplemental doses. Thus titrating to a target BIS might be a useful approach in this patient group because of the lack of clear dosing guidelines on a per kilogram basis.

It is clear that significantly obese patients require a moderately higher dose of propofol to achieve the same propofol concentration compared with lean patients. As illustrated in the pharmacokinetic simulation shown in Fig. 5.3, when an exceptionally obese patient receives the same absolute dose of propofol as a lean patient of the same height (i.e., a typical induction and infusion dose for a lean patient), lower propofol blood concentrations are produced. This conclusion is generally consistent with emerging knowledge regarding the impact of extreme obesity on the disposition of most intravenous anesthetic drugs.

With regard to TCI, there are several propofol pharmacokinetic models available to drive TCI pumps.[8,15-18] Data used to build these models included a variety of patient groups (i.e., lean and obese patients, pediatric and elderly patients). When constructing these models, several patient variables (i.e., age, TBW, LBW, and sex) were introduced into selected models to assess whether they improve model performance as determined by how well the model predicted measured plasma propofol concentrations.

When using a TCI pump in an obese patient, two important questions emerge: which pharmacokinetic model is optimal in the obese patient and what weight should be used (i.e., IBW, LBM, TBW)? Cortinez and colleagues studied how well selected propofol pharmacokinetic models predicted plasma propofol concentrations in a morbidly obese patient group[11] in an effort to identify the best model and weight scalar. They found that two models, the Schnider model and the Marsh model, performed best when using ABW. For propofol, using a modified weight scalar with the Schnider or Marsh model may be best suited for TCI in obese and morbidly obese patients. Both of these models are available in many commercial TCI pumps.

Perhaps the most versitile pharmacokinetic model for propofol was recently developed by Eleveld and colleagues.[8] They combined data from 21 propofol pharmacokinetics datasets that included elderly adults, obese adults, children, and normal-sized adult patients and volunteers. From these data they built a propofol pharmacokinetic model incorporating age, sex, and weight as covariates that performs well compared to other propofol models designed for specific-patient populations. This generalizable propofol pharmacokientic model has the abilty to cover a wide range of patient groups. An important caveat to consider when selecting a pharmacokinetic model is that differences in model predictions are likely overshadowed by significant interindividual variability. Many of the available propofol pharmacokinetic models will likely yield similar clinical results if titrated to effect in conjunction with processed EEG monitoring.

Unlike propofol, the influence of obesity of the pharmacokinetic behavior of other sedatives is not as well studied. Weight scalars for thiopental[19,20] and midazolam,[21] but not ketamine and etomidate, have been reported. Work with midazolam in obese patients found that as patient size increases, so does volume of distribution. However, the time to peak plasma concentrations and metabolism were the same regardless of body size. Elimination half-life for midazolam more than doubled compared with normal-sized counterparts, probably because of the large volume of distribution in morbidly obese patients. The clinical implications of this long elimination half-life were not evaluated, but the authors recommended that bolus doses be scaled to TBW and continuous infusion be dosed to IBW.

Opioids

Similar to propofol, remifentanil is perhaps the most well-studied opioid in terms of its pharmacologic behavior in obese patients.

Overall, the disposition of remifentanil in obese and lean patients is similar, but obese patients do indeed require a higher dosage. Researchers have identified that FFM provides a reasonable weight scalar for continuous infusions.[22] With regard to TCI, several pharmacokinetic models[6,22,23] have been devleoped from data collected in a wide range of patient sizes optimizing model predictions using weight, age, and sex as covariates. Many of the model parameters were scaled to LBM (Minto model),[23] modifications of LBM (La Colla model)[22] or an allometric scaling of TBW among other covariates (Kim model).[6] Although the Minto model is the most widely used model for TCI administration of remifentanil, it is known to have serious problems when applied to very obese patients, in part because not many obese patients were included in the dataset from which the model was built (and because of faulty equations for the estimation of LBM).[24] Because of these shortcomings in the Minto model, various work-arounds have been proposed that include entering "fictitious" body weights during initiation of TCI therapy; this approach can be useful but is obviously suboptimal.[22,25] The Kim model addresses the problems associated with the Minto model by including numerous obese subjects into the model dataset and by using updated equations for estimation of body mass indices such as LBM. As the Eleveld model for propofol, the Kim model for remifentanil may prove advantageous in obese patients but has not been clinically validated.

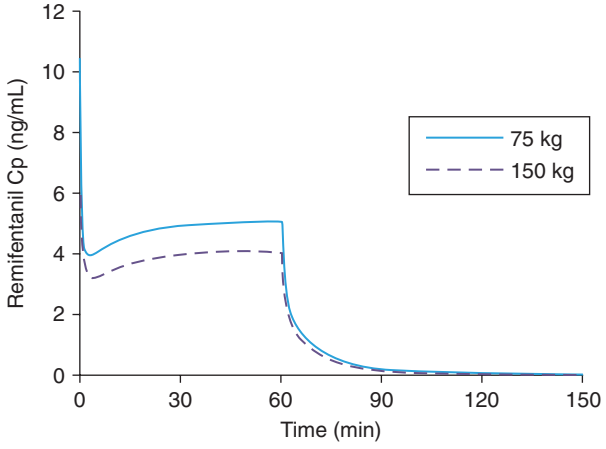
Recent work has combined previously published datasets to refine pharmacokinetic models (see the "Emerging Developments" section). Consider the series of simulations based on the model of Kim and colleagues to visualize the influence of weight on the pharmacologic behavior of remifentanil (see Figs. 5.4 through 5.6). In the first simulation, predicted remifentanil plasma concentrations are plotted over time for an equivalent bolus dose followed by a 60-minute infusion administered to a lean and obese individual of the same age and height (Fig. 5.4). Predicted plasma concentrations were approximately 78% lower in the obese individual. In the second simulation (Fig. 5.5), the authors explore what infusion rate (in micrograms per minute) would be necessary to maintain a target plasma concentration of 5 ng/mL for 30 minutes, a concentration known to provide analgesia across weights of 50 to 200 kg. Infusion rates were nearly doubled to achieve the target concentration over this weight range. Because of remifentanil's rapid clearance, the required infusion rates stabilize after approximately 25 minutes. In a third simulation, the authors predicted the cumulative remifentanil dose for three individuals (lean young individual, lean elderly individual, and obese young individual) to maintain a target plasma concentration of 5 ng/mL for a 5-hour infusion (Fig. 5.6). The cumulative dose for the young obese individual was approximately 125% of the young lean individual. This set of simulations provides a visual illustration of the increased dosing requirements for heavier patients.

Unlike propofol and remifentanil, relatively little work has explored how obesity affects fentanyl pharmacokinetics. Shibutani and colleagues[26,27] characterized a nonlinear relationship between fentanyl clearance and TBW and recommended use of a modified weight, called the *pharmacokinetic mass,* which resulted in effect site concentrations in obese patients that were similar to effect site concentrations in lean patients.

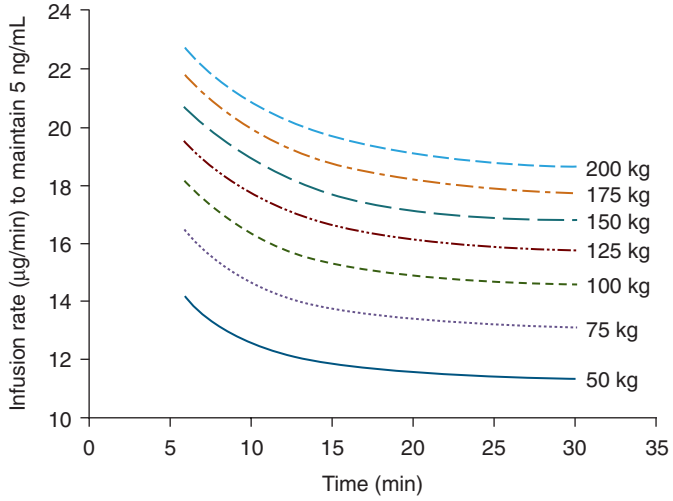
For other opioids, even less information is available. Some work has explored sufentanil pharmacokinetics in obese patients, and similar to midazolam, a linear increase was reported in the volume of distribution with an increase in TBW but similar clearance between lean and obese individuals.[28] The authors suggest that for bolus dosing TBW be used and continuous infusions be judiciously reduced. Use of a sufentanil pharmacokinetic model[29] may be suitable for sufentanil TCIs in morbidly obese patients.[30]

Inhaled Anesthetics

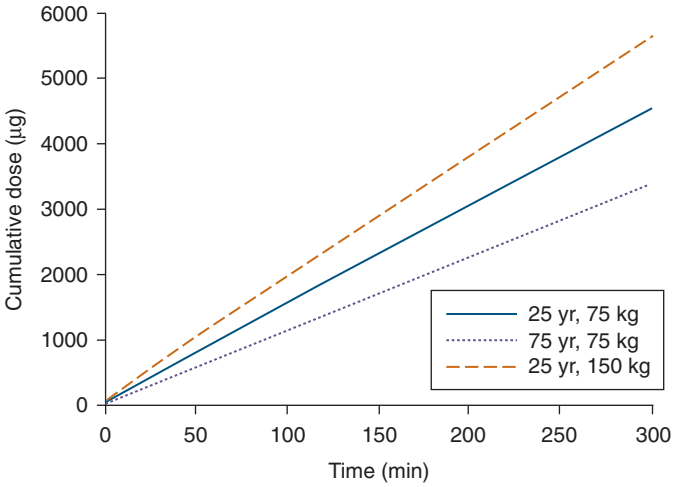
A common perception of potent inhaled agents is that they accumulate in obese more than lean patients and that this prolongs emergence. Research, however, has not confirmed this perception.[31]



• **Fig. 5.4** Computer simulations of plasma concentration *(Cp)* predictions versus time for an identical dose (not weight-adjusted) administered intravenously to 75- and 150-kg subjects (both 25 years of age and height 175 cm) using the Kim model. The simulated dosing regimens consisted of a 50- µg bolus injection followed by a 15-µg/min continuous infusion for 60 minutes. (Reprinted with permission from Kim KT, Obara S, Egan TD, et al. Disposition of remifentanil in obesity: a new pharmacokinetic model incorporating the influence of body mass. *Anesthesiology.* 2017;126:1019–1032.)



• **Fig. 5.5** Simulation of infusion rate (in micrograms per minutes) requirements to achieve a target plasma concentration of 5 ng/mL over 30 minutes for a range of body weights assuming an age of 50 years and height of 175 cm. (Reprinted with permission from Kim TK, Obara S, Egan TD, et al. Disposition of remifentanil in obesity: a new pharmacokinetic model incorporating the influence of body mass. *Anesthesiology.* 2017; 126:1019–1032.)



• **Fig. 5.6** Simulation of the cumulative remifentanil doses (in micrograms) required to achieve and maintain a plasma concentration of 5 ng/mL over time when administered by target-controlled infusion for a 25-year-old, 75-kg subject *(solid line)*; a 75-year-old, 75-kg subject *(dotted line);* and a 25-year-old, 150-kg subject *(dashed line).* All subjects for these simulations are assumed to be 175 cm tall. (Reprinted with permission from Kim TK, Obara S, Egan TD, et al. Disposition of remifentanil in obesity: a new pharmacokinetic model incorporating the influence of body mass. *Anesthesiology.* 2017; 126:1019–1032.)

Two pharmacokinetic factors contribute to this observation. First, the time required for adipose tissue to equilibrate with the inspired volatile anesthetic concentration is long; the times required to achieve 63% of the final equilibrium in adipose tissue for desflurane and isoflurane exceed 22 and 35 hours, respectively.[32,33] Second, blood flow to adipose tissue *decreases* with increasing obesity,[34] reducing the overall delivery of drug to this tissue bed.

Based on their pharmacokinetic profiles, there could be some advantage to choosing one potent inhaled agent over others. Desflurane has a faster washout and improved recovery compared with sevoflurane in obese individuals when no premedication is used.[35] With a quicker recovery,[36] desflurane might be well suited for use in this patient group to minimize adverse effects related to slow emergence in patients with limited oxygen reserves as a result of a reduced functional residual capacity. Given the pronounced interaction between volatile anesthetics and opioids or sedatives, addition of midazolam or fentanyl will likely reduce desflurane's advantages over sevoflurane.[37]

Neuromuscular Blocking Drugs

Formulating a rational dosage scheme for neuromuscular blockade in obese patients can be challenging given the increased likelihood of difficult intubation, the need for excellent intubating conditions on the first attempt, and the need to provide mask ventilation should intubation be unsuccessful. Prior work suggests that TBW is appropriate for succinylcholine and IBW is appropriate for nondepolarizing agents (see Table 5.6). As a rule of thumb, clinicians sacrifice onset time with a lower total dose but gain a faster recovery (see Chapter 22).

Succinylcholine was studied in 45 morbidly obese patients (BMI > 40 kg/m^2) comparing a dose of 1 mg/kg using three different weight scalars: IBW, LBW, and TBW. Across groups, there was no difference in onset time. Longer recovery time correlated with the larger overall dose (e.g., 1 mg/kg using TBW being the largest), although recovery times were relatively short compared with other longer-acting neuromuscular blocking drugs. Intubating conditions were adequate in all groups, but laryngoscopic view was better in the group dosed to TBW. The authors recommended dosing succinylcholine based on TBW,[38] prioritizing the laryngoscopic view over duration of blockade.

Studies comparing TBW and IBW as the basis for dosage calculation for rocuronium in morbidly obese patients found that at a dose of 0.6 mg/kg using TBW led to a prolonged duration of action but did not improve intubating conditions compared to IBW.[39,40] Similar results have been observed with vecuronium.[41-43] Thus the consensus is to dose rocuronium and vecuronium to IBW to achieve a shorter duration of blockade without compromising intubating conditions.

For neuromuscular blockade reversal with sugammadex, weight scalar recommendations vary. Some authors recommend using IBW and others suggest using ABW,[44,45] whereas a pooled analysis of 1418 adult obese patients led to a recommendation that sugammadex be dosed according to TBW.[46] Given the favorable sugammadex safety profile, dosing to TBW is a reasonable approach. Reversal doses are a function of blockade depth. Use of a peripheral nerve stimulator capable of quantitative train-of-four monitoring allows accurate determination of blockade depth and the appropriate sugammadex dose. In brief, profound (no train-of-four, no posttetanic twitch), deep (no train-of-four, one or more posttetanic twitches), moderate (one to three train-of-four count), shallow (train-of-four ratio 0.1-0.4), and minimal (train-of-four ratio > 0.4) blockade are reversed with 16, 4 to 8, 2, 2, and 2 mg/kg of sugammadex, respectively.

An interesting feature of sugammadex reversal is that it can be used to provide rapid reversal after administration of high-dose rocuronium (e.g., 1.2 mg/kg) following a rapid sequence induction. In an emergency setting of "can't intubate and can't oxygenate," deep blockade by rocuronium can be completely reversed faster than spontaneous recovery from an intubating dose of succinylcholine (1 mg/kg).[47] Although sugammadex reversal is fast regardless of blockade depth, a simulation study concluded that residual effects from induction doses of sedatives and opioids may persist after blockade reversal.[47] Thus, although they are no longer paralyzed, patients can remain unresponsive or have significant respiratory depression. If both unresponsiveness and respiratory depression exist, patients might not be able to self-rescue from a "can't intubate–can't oxygenate" scenario. Given that obese patients have reduced functional residual capacity and a shortened time to oxygen-hemoglobin desaturation when rendered apneic despite adequate preoxygenation, they are at increased risk for hypoxia.[47] Another important consideration when administering a large sugammadex dose (e.g., 16 mg/kg) is that the dose might not be immediately available at the point of care without proper preoperative planning and preparation.

Local Anesthetics

The safe dose of local anesthetics varies with the route of administration, the properties of the local anesthetic, and the addition of epinephrine. Plasma concentrations are the highest after intercostal nerve block and decrease as follows: intercostal > caudal > epidural > brachial plexus > sciatic/femoral.[48] Plasma concentrations of local anesthetics do not correlate well with body weight or BMI in adults but correlate better with weight in children.[49-51] Local anesthetic toxic doses have not been well studied in obese patients. The widely recommended axiom of the smallest effective dose is appropriate in this patient population.

Pediatric Patients

When formulating an anesthetic dosing regimen for a pediatric patient, an important consideration is that children are not miniature adults. Anatomic and physiologic changes that occur between the newborn period and adult life have important pharmacologic implications. In part because the early drug development process is focused on adult volunteers and patients, these developmental changes are often not well accounted for in available dosing guidelines. Ideally, dosing recommendations should be based on research in children along all phases of development and maturation to characterize drug pharmacokinetics and pharmacodynamics properly. Unfortunately, detailed information along these lines is not available for most anesthetics.

Given the cost of drug development, pharmaceutical companies often seek approval from regulatory agencies for adults, but not children. As such, many anesthetics are administered "off-label" using adult doses scaled to pediatric patients. In response, the United States National Institute of Childhood Health and Human Development formed the Pediatric Pharmacology Research Unit Network in 1994, and in 1997, the U.S. Food and Drug Administration (FDA) developed the Modernization Act[52] to incentivize drug research in pediatric patients by extending the duration of market exclusivity for approved drugs.

One challenge is to account for changes in body composition, metabolic capacity, and body surface area that occur with age. Several approaches have been explored (e.g., dosing based on body surface area or allometric scaling), but the most common approach is to use weight-normalized dosing according to age (e.g., where available milligrams per kilograms for neonates up to 44 weeks' postconception in age), infants (1-12 months of age), and children (up to 12 years of age).

Physiologic Changes in Pediatric Patients

Neonates, infants, and children present anesthesiologists with challenges throughout the perioperative period. Selected physiologic changes such as differences in airway anatomy, chest wall and respiratory system function, and cardiovascular function place this patient group at increased risk for adverse airway and respiratory events as well as other pediatric issues (Table 5.7, Fig. 5.7). For many of these physiologic changes, inherent variability is associated with maturation and interpatient and intrapatient differences that influence anesthetic drug behavior and alter dosing considerations.

For example, neonates and infants have greater total body water than their adult counterparts, resulting in a larger volume of distribution with water-soluble drugs such as succinylcholine and many antibiotics. With a larger volume of distribution, a higher initial loading dose is required to achieve therapeutic plasma concentrations. Neonates also have lower serum albumin and total protein concentrations, resulting in higher free plasma levels of highly protein-bound drugs, such as bupivacaine, opioids, sedatives, and antibiotics. The kidneys and liver of neonates are immature compared with those of adults. The developmental physiology of the liver is complex, but in general hepatic enzymatic drug metabolism is decreased in neonates, and the neonatal liver receives disproportionately less cardiac output than an older child or adult. The neonatal kidney is less efficient, prolonging the half-life of drugs primarily excreted through the kidneys. Neonates also have a decreased proportion of body mass as fat and muscle, which can prolong drug effects depending on redistribution into those tissues.

Anesthetic Pharmacology in Pediatric Patients

In general, anesthesiologists can expect significant variability in anesthetic dosing of pediatric patients.[53] Thus only general dosing guidelines are possible for most anesthetic drug classes. A brief discussion of dosing recommendations for selected anesthetics is provided in the following text and summarized in Table 5.8.

Inhaled Anesthetics

Potent inhaled agents are frequently used in pediatric anesthesiology because of their utility for mask induction. The minimum alveolar concentration (MAC) varies with age (see Table 5.8): neonates have a MAC 20% less than that of infants,[54] and premature infants have an even lower MAC.[55] MAC increases through infancy until age 3 to 5 and then declines steadily with age.[56,57] In general, the MAC of an infant is 1.6 to 1.8 times the MAC of a 40-year-old adult, and the MAC of a premature infant is 1.2 to 1.6 times lower than that of an infant. With significant interpatient variability, anesthesiologists titrate the dose of inhaled agents and administer intravenous adjuncts (e.g., opioids, nonsteroidal antiinflammatory drugs) to meet anesthetic requirements (e.g., minimize patient movement, maintain blood pressure, blunt or block the response to a painful stimuli).

Propofol

Comparison to other anesthetics, propofol has been well characterized in neonates and children. Prior work has established that dosing by TBW is best and that children can require up to 50% to 100% more propofol than in adults.[58] For example, neonates required a 3-mg/kg bolus to tolerate chest tube removal. Of note, propofol is metabolized more slowly in neonates compared with children until about 3 months of postnatal life or 54 weeks' postgestational age.[59]

A serious concern with propofol when administered to pediatric patients for sedation during mechanical ventilation is propofol infusion syndrome. Development of the syndrome is more likely when propofol is administered at rates above 67 μg/kg per minute (4 mg/kg per hour) for more than 48 hours. Presenting signs include hyperlipidemia, rhabdomyolysis, refractory bradycardia leading to asystole, and/or lactic acidosis.[60] The syndrome is often lethal; treatment consists of discontinuing propofol and supportive care. Early diagnosis of propofol infusion syndrome is key to achieving a good outcome. The mechanism of propofol infusion syndrome is unclear, but one hypothesis is that propofol disrupts mitochondrial fatty acid metabolism to cause an accumulation of fatty acids that can induce life-threatening ventricular arrhythmias.[61] Another hypothesis suggests that propofol impairs mitochondrial function, disrupting electron transport and oxidative phosphorylation, causing metabolic acidosis and cellular hypoxia.[62]

Midazolam

Midazolam is a useful adjunct and premedication to minimize separation anxiety and fear and can be administered by multiple routes (intranasal, intravenous, rectal, oral, intramuscular, or sublingual, see Table 5.8). When administered as an intravenous bolus, its anxiolytic effect begins within 1 to 2 minutes, giving the impression that it is a fast-acting drug. Although it has a rapid onset of anxiolytic effect, it requires 6 to 9 minutes to reach peak effect and has a long decrement time. When administered by mouth, midazolam has a slower onset of effect (20-30 minutes). Suggested oral doses of 0.5 to 0.75 mg/kg should be administered

TABLE 5.7 Anesthetic Considerations and Perioperative Challenges in Neonates and Infants[138]

Neonate-/Infant-Related Condition	Challenge	Management Considerations
Airway anatomy • Large head with prominent occiput • Large tongue • Preferential nose breather—breathing difficult with excessive secretions • Glottic opening at level of C3-C4 • Long epiglottis—can flop posteriorly • Narrowest segment of the airway is subglottic	Airway obstruction Difficult laryngoscopy	Position head and neck to maintain in a neutral position Where feasible, maintain patent nasal passages Consider small endotracheal tube to minimize postextubation stridor Position endotracheal tube to avoid inadvertent extubation or endobronchial intubation with head movement (target 1 cm above the carina)
Chest wall anatomy and pulmonary physiology • Compliant chest wall • Ventilation is primarily from the diaphragm • Ventilation is rate dependent • Closing volume is larger than the functional residual capacity (until age 6 years) • Work of breathing may exceed 15% of oxygen delivery • Thick-walled alveoli • Fewer alveoli (10% of adult) • Frequent postoperative apneas in premature infants	Limited respiratory reserve Reduced functional residual capacity that is further reduced with apnea and anesthesia Airway closure at expiration and rapid respiratory muscle fatigue Apneas longer than 15 seconds or associated with hypoxia and bradycardia	*Induction of anesthesia:* Anticipate rapid drop in oxygen hemoglobin saturation once rendered apneic despite effective preoxygenation Consider decompressing stomach if abdominal pressure is limiting diaphragm movement. Caution with aggressive bag mask ventilation Consider using positive end-expiration pressure, continuous positive airway pressure, or intermittent positive-pressure ventilation to stent open airway and reduce work of breathing Vigilant postoperative respiratory monitoring in high-risk neonates and infants Consider caffeine 10-20 mg/kg oral or intravenously
Cardiovascular system • Fixed stroke volume • Cardiac output is heart rate dependent • High vagal tone	Prone to bradycardia and low cardiac output	Treat neonates with heart rate <100 beats/min with restoration of oxygenation and epinephrine 10 μg/kg
Volume status • Immature renal function • Large surface area relative to weight • Larger extracellular volume	Dehydration	Maintain urine output 1-2 mL/kg
Hepatic function	Decreased opioid metabolism	Prolonged opioid effect
Metabolism • Limited glycogen reserves • Immature thermoregulation	Hypoglycemia Hypothermia	Glucose infusion in neonates at risk Consider techniques to increase core body temperature (ambient temperatures of 32°C-34°C for neonates and premature infants)
Central nervous system • Immature blood brain barrier • Opioids and antibiotics easily cross the blood-brain barrier	Prolonged and variable duration of action	Consider judicious dosing of opioids

30 minutes before parental separation to achieve anxiolysis and sedation for children between the ages of 1 and 10 years.[63]

When considering use of midazolam as an anxiolytic, a few features of its pharmacologic profile merit consideration. Midazolam is metabolized primarily by the hepatic microsomal enzyme cytochrome P 450 (CYP) 3A4 and has an active metabolite, α-hydroxy-midazolam. Patients with impaired hepatic function can have an altered response. Although the pharmacokinetics of midazolam have been well characterized, the pharmacokinetics of α-hydroxy-midazolam are not well known. This active metabolite may be responsible for an unexpectedly long duration of midazolam's effect, although this is largely speculative.

Etomidate

Pharmacokinetic information on etomidate in pediatric patients is limited. A study of the pharmacokinetics of etomidate in 49 children older than 6 months of age concluded that younger children have greater clearance and an increased central compartment volume and thus require a larger bolus dose than older children. The authors recommend an age-based dose rather than weight-based.[64] In a study of neonates and infants with cardiac disease, a significantly lower clearance of etomidate was observed than in the previous study, as well as a high degree of variability in etomidate pharmacokinetics.[65]

Ketamine

Similar to midazolam, ketamine can be administered as a premedication via several routes (intravenous, transmucosal, oral, or intramuscular; see Table 5.8). Ketamine can provide sedation and analgesia with minimal respiratory or cardiovascular depression but does have adverse side effects such as dysphoria and excessive salivation. To minimize salivation, ketamine can be combined with

TABLE 5.8 Dosing Considerations of Selected Anesthetics in Pediatric Patients

Drug	Route of Administration	Dose
Sedatives		
Propofol[139,140]	IV: Induction (age >3 yr)	2.5-3.5 mg/kg
	IV: Sedation (infusion)	125-150 µg/kg/min
Midazolam[140-143]	PO: Premedication	0.25-0.5 mg/kg (maximum 20 mg)
	Intranasal: Premedication	0.2-0.3 mg/kg
	IV: Premedication	0.05 mg/kg
	Intranasal: Sedation	0.2-0.3 mg/kg (maximum 10 mg per dose)
	IM: Sedation	0.1-0.15 mg/kg
	IV: Sedation (age 6 mo to 5 yr)	0.05-0.1 mg/kg (maximum 6 mg)
	PR: Sedation	1 mg/kg
	SL: Sedation	0.5-0.75 mg/kg
	IV infusion: Sedation (neonates <32 wk)	0.03 mg/kg per hour
	IV infusion: Sedation (neonates >32 wk)	0.06-0.12 mg/kg per hour; titrate to effect
Etomidate[65,140,144,145]	IV: Induction	0.3 mg/kg (0.2-0.6 mg/kg)
	IV: Sedation	0.1-0.3 mg/kg; repeat as needed
Ketamine[140,146-148]	PO: Premedication	6-10 mg/kg
	IM: Premedication	3-7 mg/kg
	IV: Sedation	0.5-2 mg/kg per dose
	IV: Induction	1-2 mg/kg
	IV: Analgesic	0.1 mg/kg
	IV: Analgesic (infusion)	0.1-0.3 mg/kg per hour

TABLE 5.8 Dosing Considerations of Selected Anesthetics in Pediatric Patients—cont'd

Drug	Route of Administration	Dose
Opioids		
Fentanyl[149-151]	IV bolus: Analgesic	1-2 μg/kg
	IV bolus: Loading dose	5-10 μg/kg
	IV: Infusion	1-3 μg/kg per hour
	Intranasal	1-2 μg/kg
	Oral transmucosal fentanyl	5-15 μg/kg
Remifentanil[149,152,153]	IV: Bolus	1 μg/kg
	IV: Infusion	0.25-3.0 μg/kg per minute
Sufentanil[154-156]	IV bolus: Loading dose	1-2 μg/kg
	IV: Infusion	0.1-0.2 μg/kg per hour
	Intranasal	2 μg/kg
Hydromorphone[149,157]	PO (children)	0.05 mg/kg q4-6h
	PO: (adolescents)	1-4 mg-dose q4-6h
	IV: Bolus	5-10 μg/kg q4-6h
	IV: Continuous	3-5 μg/kg per hour
	Caudal	10 μg/kg
Morphine[158-160]	PO: Immediate release	0.3 mg/kg per dose q4-6h
	PO: Continuous release	0.3-0.6 mg/kg per dose q12h
	IV: Infusion (neonates)	0.01-0.02 mg/kg per hour
	IV: Infusion (children)	0.01-0.04 mg/kg per hour
	Caudal	30-50 μg/kg
	Intrathecal	5-7.5 μg/kg
Neuromuscular Blocking Agents and Reversal		
Succinylcholine[161-163]	IV: Fast onset	1.5-2 mg/kg
	IM	4 mg/kg
Rocuronium[164,165]	IV: Intubation	0.3-1.0 mg/kg
	IV: Maintenance	0.1 mg/kg
Vecuronium[166,167]	IV: Intubation	0.05-0.1 mg/kg
	IV: Maintenance	0.02 mg/kg
Cisatracurium[168,169]	IV: Intubation	0.1-0.2
	IV: Maintenance	0.02-0.05
Sugammadex[170,171]	IV (train of four 1-2/4)	2-4 mg/kg
	IV (profound paralysis)	16 mg/kg

Inhaled Anesthetics

Drug	Indication	MAC
Isoflurane	Preterm (<32 wk)	1.28[172]
	Preterm (32-37 wk)	1.41[172]
	7-30 mo	1.69[173]
	Effect of N_2O	MAC = 1.69 − 1.45 × N_2O fraction[173]
	4-10 yr	1.69[174]
	Effect of temperature	1.47 (34°C), 1.22 (31°C)[174]
	4-9 yr	1.27 (MAC_{EXT})[175]
Sevoflurane	Neonates	3.3[176]
	1-6 mo	3.2[176]
	6-12 mo	2.5[176]
	1-3 yr	2.6[176]
	2-12 yr	2.3-2.5,[176,177] 2.90 (MAC_{INT}),[178] 1.60-1.70 (MAC_{EXT})[179,180]
	1-3 yr with N_2O 60%	2[56]
	2-6 yr	1.45 (MAC_{BAR})[181]
		0.57 (with fentanyl 2 μg/kg) (MAC_{BAR})[181]
		0.35 (with fentanyl 4 μg/kg) (MAC_{BAR})[181]
Desflurane	Neonates	9.16[182]
	1-6 mo	9.42[182]
	6-12 mo	9.92[182]
	1-3 yr	8.72[182]
	3-5 yr	8.62[182]
	5-12 yr	7.98,[182] 7.7 (MAC_{EXT})[179]

an antisialogogue, and to minimize dysphoria it can be combined with a benzodiazepine.

Like midazolam, ketamine is also metabolized primarily by the hepatic microsomal enzyme enzymes CYP 3A4 and to a lesser extent 2B6 and 2C9. Ketamine has two active metabolites: norketamine and dehydronorketamine. When administered intranasally, S-ketamine achieves peak effect in approximately 18 minutes, but there is significant interpatient variability in plasma concentrations and absorption times.[66]

For intramuscular injection, the time to peak concentration is shorter (15 minutes). For this route of administration, ketamine bypasses the portal circulation. As such, ketamine concentrations are much higher than norketamine concentrations, and without the first-pass effect, norketamine concentrations peak at 1 to 2 hours. By way of comparison, equianalgesic plasma concentrations for orally administered versus intramuscularly administered ketamine are 40 and 150 ng/mL. These discrepancies are likely a function of differences in norketamine concentrations.[67]

Opioids

Although morphine pharmacokinetics in neonates are well established, the efficacy of morphine at clinically used doses is more ambiguous. A study of 140 preterm neonates randomly assigned to receive an intravenous loading dose of morphine 100 μg/kg or saline solution placebo during endotracheal suctioning revealed only a mild analgesic benefit (as determined by multiple validated pain measurement instruments).[68] A study of 20 children aged 3 days to 6 years given 0.15 mg/kg morphine intravenously after congenital cardiac surgery showed an increased dose per kilogram needed in children 1 to 6 months of age but a high degree of variability in morphine disposition.[69]

Clinical experience suggests that younger patients, particularly infants, are quite sensitive to the effects of opioids such that opioids typically produce more profound and longer duration of effect in younger children. Because the enzymatic metabolism of remifentanil is largely mature in children, some experts have asserted that remifentanil is well suited for use as an intraoperative opioid in children.[70]

Neuromuscular Blocking Drugs

Intravenous rocuronium 0.6 mg/kg generally produces intubating conditions 1 to 4 minutes after administration in children, and 1.2 mg/kg decreases the time to less than 1 minute to 3 minutes. Succinylcholine 2 mg/kg IV bolus produces 100% block in less than 1 minute after administration.[71]

Anesthetic Toxicity in Neonates and Infants

A major emphasis of anesthetic clinical pharmacology research in recent years has been the exploration of anesthetic toxicity in neonates and infants. There is concern that exposure to anesthetics early in life, especially repeated exposure, may be associated with decreased cognitive performance later in life. Major sources of evidence include in vitro toxicity studies, clinical studies in animal models, and retrospective, hypothesis-generating data-mining studies in humans. This effort has gained worldwide attention and has prompted regulatory agencies to issue practice advisories regarding the use of common anesthetics in pediatric patients. Prospective, longitudinal studies are ongoing.

Research exploring formation of neuronal networks and synaptic contacts (developmental synaptogenesis) indicates that this process primarily occurs during the last trimester in utero and the first few years of life, with the first several months of neonatal life being the most intense period as the brain increases in size and neuronal connections.[72,73] The neurotransmitters gamma-aminobutyric acid and glutamate play an important role in developing these neuronal connections. Central nervous system depression by anesthetics alters the balance of excitatory and inhibitory synaptic transmission. Although transient, this imbalance can cause apoptosis of developing neurons and glia.

The neurodegenerative effect of anesthetics on infants has been confirmed across several mammalian species, resulting in neurotoxicity and both short- and long-term behavioral changes. The relationship between the duration of synaptogenesis and the length and number of anesthetic exposures is complex, but even a single exposure during active synaptogenesis can produce neurodegeneration. In rodents, timing seems more critical than duration as a determinant of damage. In higher mammalian brains, both a single long exposure and multiple shorter exposures impair neurocognitive development. Although behavioral studies suggest cognitive and emotional deficits in addition to morphologic changes, causality between the observed morphologic changes and behavioral problems has not been demonstrated. Although this has implications not only in providing general anesthesia for procedures in pregnant women and children but also in children requiring sedation in the intensive care unit, there are limitations to the animal data, including the difference between anesthetizing healthy animals in contrast to children with comorbidities requiring anesthesia and attention in the intensive care unit. Furthermore, there are questions about the generalizability of daily anesthetic exposures in animals.[74,75]

Retrospective clinical studies have explored potential connections between early anesthetic exposure and cognitive changes in humans to include failure to reach developmental potential, an increase in hyperactive disorders, learning disabilities, and other cognitive and behavioral impairments.[76] Age at exposure and duration and number of exposures appear to be important factors in the development of these deficits. Given that this body of work is retrospective, it does not control for confounders that might influence interpretation of the findings. Thus, as there is insufficient evidence that anesthetic exposure up to age 3 years of age in humans is associated with cognitive deficits, it remains controversial as to whether findings in animal studies can be applied to humans.

Several clinical studies are investigating the relationship between exposure to anesthesia and neurocognitive deficits. Some of these include the Pediatric Anesthesia and Neurodevelopment Assessment (PANDA), the Mayo Anesthesia Safety in Kids (MASK) study, and the General Anaesthesia compared to Spinal anaesthesia (GAS) study. PANDA, a multicenter study, explored the long-term cognitive effects of anesthesia between two groups: those who receive an anesthetic for an inguinal hernia repair up to 3 years of age and their siblings who have not had an exposure to an anesthetic before age 3 years. The neurocognitive effects were evaluated from ages 8 to15 years and no difference was found between the groups. The GAS study compared awake-spinal anesthesia to sevoflurane-based general anesthesia in children younger than 60 weeks but born at more than 26 weeks' gestational age who required inguinal hernia repair. Interim findings from the GAS study showed that sevoflurane anesthesia less than 1 hour in duration did not increase the risk of adverse neurodevelopmental outcome at age 2 years compared to awake-regional anesthesia, with further assessment at 5 years.[77] Thus far, the PANDA study has not shown any difference in mean scores of the secondary assessments.[78] The MASK study compared results from neurocognitive tests in children younger than the age of 3 years who have received one or more anesthetics with age-matched children with no exposure to anesthesia. Results

from the MASK study showed no significant difference in intelligence quotient as adolescents between singly and multiply exposed children, although processing speed and fine motor skills were reduced in children who had multiple exposures.[78a]

Although informative, these observational studies are not able to account for inherent differences between children who require procedures with exposure to anesthesia and children who do not. Children who require surgery and anesthesia at a young age may be predisposed to neurodevelopment delays related to the severity of an illness and/or the surgical procedure and not the anesthetic exposure itself.[79] Some have voiced concern that the FDA warning might cause unnecessary delays in procedures that require an anesthetic, leading to poor patient outcomes.[80] Multiple European societies also recently published a consensus statement in response to the FDA warning stating that although anesthesiologists should provide adequate information and try to avoid unnecessary risks, there is no compelling evidence to change anesthetic practice.[81]

Given that the PANDA and GAS studies provide some clinical evidence that a single, relatively brief exposure to general anesthesia in otherwise healthy children is unlikely to cause clinically detectable deficits in global cognitive function or serious behavioral disorders, the FDA acknowledges that anesthetic drugs are at times needed for young children and pregnant women who require painful procedures. As such they recommend that patients in their third trimester of pregnancy or young children proceed with medically necessary procedures. However, they recommend giving strong consideration to delaying elective procedures in these patient groups until the individuals at risk are older than 3 years of age.[82]

Further research is warranted to explore possible subtle behavioral effects, vulnerable ages of exposure, gender differences, and variability among specific anesthetic drugs. Specifically, studies that explore the use of protocols that minimize anesthetic exposure through the use of short-acting drugs, adjuvants, multimodal pain therapy, and/or local or regional techniques might provide important insights into optimizing care for this patient group.

Elderly Patients

Anesthesiologists recognize that elderly patients require reduced anesthetic doses to produce a desired effect and avoid unwanted adverse effects. Although the mechanisms underlying this increase in anesthetic drug sensitivity are incompletely understood, the dose of most anesthetics can by reduced by 25% to 75% to achieve a near-equivalent effect compared with young healthy adults. We briefly discuss physiologic changes that influence anesthetic drug behavior (Table 5.9, Fig. 5.8) and considerations of dosing of common anesthetics (Table 5.10) in the elderly.

Physiologic Changes in the Elderly

Several important age-related physiologic changes likely influence how elderly patients respond to anesthetics. Physiologic changes include a loss of important anatomic units, such as neurons, nephrons, and alveoli, and a deterioration of metabolic regulatory processes at a molecular level,[83] among many others. In general, healthy elderly people maintain reasonable basal physiologic organ function. However, under the stress of anesthesia and surgery, their physiologic reserves are tested and can be substantially diminished. Although age is an independent risk factor for poor outcomes, it does not provide a consistent predictor of how anesthetic drugs behave. In fact, genetics, socioeconomic status, and environmental conditions (among many others) are likely to influence organ function in this patient group. Furthermore, comorbidities, such as preexisting neurologic, hepatic, or renal disease, can increase patient sensitivity to anesthetics.[84] Chronologic age does not consistently correlate with physiologic age, and there can be substantial variability in organ function across individuals of the same age.[85] Healthy elderly patients without significant coexisting disease and with normal body habitus and good exercise tolerance might not require a reduction in anesthetic dose.[86,87]

Anesthetic Pharmacology in the Elderly

In general, anesthetic agents work by reducing neuronal activity and disrupting network connectivity by either reducing excitatory currents (such as by N-methyl-D-aspartate receptor) or increasing inhibitory currents (such as by gamma-aminobutyric acid receptors) in the brain.[88,89] There are several possibilities for how aging might influence anesthetic effect. Reduced cardiac output in the elderly is known to reduce drug mixing[90] such that anesthetic drugs develop higher than expected peak drug concentrations.[90,91] Reduced cardiac output also diminishes perfusion to metabolic organs, thereby slowing drug clearance, as observed with propofol and etomidate. Reduced cardiac output can also reduce the volume of distribution.[18,92-94]

Although there is a relative paucity of detailed information describing how age influences anesthetic drugs, for selected modern anesthetics (e.g., propofol and remifentanil) pharmacologic models have been developed that account for age.[18,95-97] Using these models, simulations can compare the time course of drug concentration and effect over a wide range of doses and ages with the goal of understanding how the dosage scheme should be modified for these various age groups. For example, numerous previously published remifentanil pharmacokinetic datasets have been combined to build a pharmacokinetic model that predicts plasma remifentanil concentration for any intravenous dosage scheme using age as a covariate.[23] For example, simulations suggest that at steady-state the infusion rates necessary for a 50- or 75-year-old individual of normal body habitus are 87% or 74%, respectively, of what is required in a healthy 25-year-old individual (Figs. 5.9 and 5.10).

Similar model-building studies have been conducted for propofol, examining the influence of advanced age on its pharmacokinetic and pharmacodynamic behavior. As shown in Fig. 5.11A, a given infusion rate yields a modestly higher plasma propofol concentration in the elderly, although the steady-state concentration is reached slightly faster and blood concentrations decline slightly faster in the elderly patient once the infusion is terminated.[18] A subsequent study confirmed that the concentration-effect relationship is substantially shifted to the left in the elderly (i.e., the concentration producing 50% of maximal effect is much lower in the older patient) as shown in Fig. 5.11B Thus propofol doses in the typical elderly patient must be adjusted significantly lower compared with younger patients, although considerable variability is to be expected.

Postoperative Cognitive Dysfunction

Postoperative cognitive dysfunction (POCD) is a heterogeneous disorder of mental processing and executive functioning that has been frequently described in older adults, particularly those undergoing cardiac surgery. A systematic review found that 22%

TABLE 5.9 Physiologic Changes in the Elderly and Potential Perioperative Consequences[183]

Organ System	Physiologic Changes	Perioperative Consequences
Neurologic System	• Increased neuronal degradation from increased enzymatic activity • Decreased brain mass • Decreased neurotransmitter synthesis • Ill-defined changes in receptor function • Decreased functional connectivity between neurons	• Increased sensitivity to anesthetic drugs[184] • Decreased hypoxic drive, hypercarbic ventilatory drive • Increased likelihood for postoperative delirium and cognitive dysfunction. especially in the presence of infections, blood loss, fever, opioids, anticholinergics, opioids, anticholinergics, preexisting cognitive impairment, or renal failure
Cardiovascular System	• Alterations in blood pressure, pulse pressure, and sinoatrial node conduction • Reduced left ventricular compliance, increased wall thickness and size • Increased myocardial oxygen demand • Reduced aortic and great vessel compliance[185] • Decreased baroreceptor sensitivity, decreased responsiveness to β-adrenoreceptors and renin-angiotensin-aldosterone system[34]	• Increased risk of hypotension on induction and greater lability during anesthesia[89,186] • More sensitive to the cardiovascular depression from propofol[187] • Hemodynamic lability is associated with more adverse outcomes during surgery[188,189] • Decreased chronotropic response to noxious stimuli. Decreased ability to increase in cardiac output • Reduced response to β_1-agonism[185]
Pulmonary System	• Physiologic shunt, ventilation-perfusion mismatch, closing capacity, and work of breathing are increased • Chest wall compliance, minute ventilation, respiratory muscle strength, and vital capacity are decreased	• Decreased forced expiratory volume in 1 second • Increased likelihood of atelectasis and hypoxia • Decreased reserves in presence of adverse respiratory events from decreased gas exchange and pulmonary mechanics
Hepatic System	• 10% decrease in hepatic blood flow per decade of life • 20%-40% decrease in liver mass in elderly patients[185]	• Anesthetic drugs metabolized by hepatic microsomal enzymes have reduced metabolism (up to 40% by age 80 yr) • Clearance of drugs where metabolism is limited by flow to the liver may be reduced by 30%-40%. Drugs that are highly extracted by the liver or highly protein bound (e.g., midazolam, fentanyl, lidocaine, and propofol) are likely to be more affected[190] • Decreased: onset/effectiveness of prodrugs (e.g., angiotensin-converting enzyme inhibitors)
Renal System	• Decreased renal mass and number of nephrons • Reduced renal blood flow (30%-50% by age 70 yr) and glomerular filtration rate[191,192] • Reduced concentrating ability	• High urine volume is required to excrete waste • May be prone to volume overload and pulmonary edema • Less able to respond to changes in sodium load • Less able to conserve water under conditions of water deprivation. More prone to hyponatremia
Body Composition	• 10%-15% decrease in total body water[193] • 20%-40% increase in body fat increases with decrease in muscle mass[190] • Decreased blood albumin concentration	• A decrease in initial distribution volume can lead to higher anesthetic drug plasma concentrations after intravenous bolus administration[185] • Lipid-soluble anesthetic drugs may have a larger distribution that can prolong effect • Increase in the unbound fraction of selected drugs (e.g., warfarin, phenytoin). Of note, other drugs are primarily bound to α_1-acid glycoproteins (e.g., lidocaine)[194]

of patients undergoing coronary artery bypass graft operations experience statistically significant cognitive decline, although it may be as high as 53% of patients at discharge.[98,99] In this area, statistical significance may not equate to clinical significance, and most patients do not experience any functional decline.[99] However, some patients experience such intellectual or memory decline that they are unable to return to employment. Most patients who incur POCD return to their baseline within weeks or months, but a small subset of patients never fully recovers.[99,100]

Patients at high risk for POCD after cardiac surgery include those of increased age, those with chronic disabling neurologic disease or peripheral vascular disease, those living alone, and those with postoperative complication(s). Protective factors include greater number of years of education and shorter cardiopulmonary bypass time.[101] POCD can only be objectively assessed when a battery of tests of mental status and multiple cognitive domains has been performed before surgery and anesthesia as a baseline. This is done for research purposes but is rarely done in clinical practice. Further complicating the matter is the lack of agreement on which tests should be performed, the learning effect that confounds results, and what level of decline constitutes POCD.[98,102]

In a large, prospective study after noncardiac surgery, POCD was common at hospital discharge (30% to 41%, depending on the age group) and decreased over time. Independent risk factors

for POCD in noncardiac patients were similar to those described in cardiac patients: increased age, lower educational level, and history of stroke. The elderly are at greater risk of long-term problems related to POCD, and patients with POCD are more likely to die in the first year after surgery.[102]

Delirium is defined as a transient syndrome with complete return to function. However, patients with delirium seem to be at increased risk of long-term cognitive and functional decline, and the relationship between postoperative delirium (POD) and POCD is an area of active research.[98] The two disorders share some risk factors (older age, peripheral vascular disease, cerebrovascular disease, and low level of education), leading some to postulate that they are manifestations of the same disorder.[100,103] One study found that delirium developed in 46% of patients after cardiac surgery but that patients with POD returned to baseline on cognitive tests within 6 months after surgery. However, patients with POD were less likely to return to preoperative functional levels than patients without delirium.[103] Another recent study showed a similar pattern of POD increasing the risk for early cognitive decline, with a general return to function by 1 year. This

TABLE 5.10 Dosing Considerations of Selected Anesthetics in the Elderly

Sedatives

General considerations
- For induction of anesthesia, consider small incremental bolus doses.[195,196]
- Pharmacokinetics: reduced clearance and distribution volume.
- Pharmacodynamics: left shift in the concentration-effect relationship increasing sensitivity.[197]

Propofol
- Pronounced hypotension with bolus dosing.[195] Consider 20% or more reduction in bolus dosing.
- Less propofol is required for moderate sedation and to maintain general anesthesia. The effect site concentration necessary to achieve loss of responsiveness in a 75-year-old may be 50% of the concentration necessary in a 20-year-old.[197]
- With equivalent doses, older patients develop more profound changes in the electroencephalogram, require more time to reach deeper states of anesthesia, and require more time to regain responsiveness.[198]
- Pharmacokinetic changes may be more pronounced in women than men.[199]

Etomidate
- Well-suited for elderly population owing to less hemodynamic instability when compared with propofol.
- Consider potential adverse effects from adrenal suppression, even after a single induction dose.

Midazolam
- Can have prolonged duration of effect and contribute to postoperative delirium. Consider risks and benefits before administering.[200]
- May lead to pronounced ventilatory depression even with anxiolytic doses. May be worrisome in an unmonitored setting.
- Reduce dose by up to 75% in elderly patients.[196]

Opioids

General considerations
- Respiratory depression is a primary concern, which increases with age[201] and in the presence of other sedating drugs.
- Impaired hepatic and renal function might influence opioid choice to minimize prolonged analgesia or adverse side effects.
- Pharmacokinetics: reduced clearance and distribution volume.
- Pharmacodynamics: left shift in the concentration effect relationship, increasing sensitivity.

Fentanyl
- Pharmacokinetics are not well described in elderly, but have limited change with age. To account for increased sensitivity,[202] reduce bolus dosing and titrate to effect.

Remifentanil
- Reduce bolus doses by 50% and infusion rates by 33%.[95] Can have slower onset of effect with bolus administration: 2-3 min versus 90 sec in young adults.
- Appropriate for elderly as it has a short duration of action and does not depend on renal or liver function to be cleared.

Meperidine
- Not recommended because of increased risk of postoperative delirium.[203] With high concentrations, associated with agitation, seizures, anticholinergic effects (e.g., dementia-like effects), and negative inotropic properties.

Neuromuscular Blocking Agents

- Pharmacodynamics are not significantly altered (e.g., elderly have the same 50% effective dose as younger individuals).
- Onset to maximal effect may be delayed 30 to 60 sec owing to decreased cardiac output.
- Recovery time may be prolonged by 50%.[204] This might be a function of age-related impairment of liver metabolism and/or renal excretion.
- Consider cisatracurium as it is not dependent on renal or hepatic funciton.[204]

Inhaled Anesthetics

- Minimum alveolar concentration decreases with age: for potent inhaled agents, 6% per decade of age after 40; for nitrous oxide, 7.7% per decade of age.

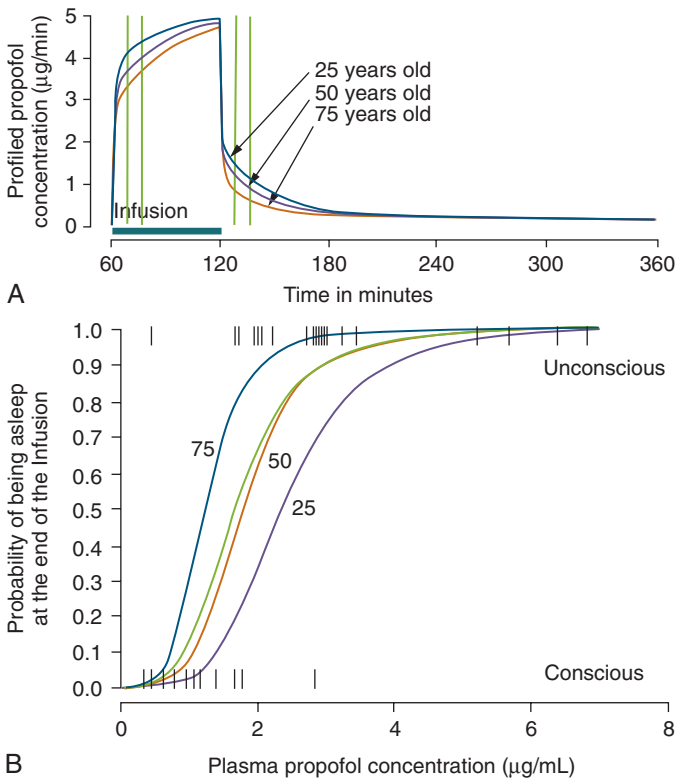
study demonstrated that worse performance in attention-requiring tasks predicted POD, which might help clinicians prevent POD.[100]

The development of POCD is a multifactorial process and involves factors including circulating hormone levels, microembolic events, maintenance of cerebral perfusion, and direct effects of anesthetics on the brain. The last factor has led to studies comparing POCD after regional anesthesia or general anesthesia, with interesting results. Despite the logical conclusion that anesthetics acting on the brain affect cognition in the elderly and the widespread concern about neurotoxicity of anesthetics on the developing brain, neuraxial techniques have not been shown to better preserve cognitive function than general anesthesia.[104-106]

Emerging Developments

Open Target-Controlled Infusion

A key shortcoming of pharmacokinetic/pharmacodynamic modeling studies is that they often include a small number of patients. These smaller datasets are suboptimal in investigating the influence of



• **Fig. 5.11** A, Pharmacokinetic model of propofol comparing plasma concentrations produced by a given infusion over a range of ages in adults. B, Pharmacodynamic model of propofol demonstrating effect of a given infusion over a range of ages in adults. (From Schnider TW, Minto CF, Gambus PL, et al. The influence of method of administration and covariates on the pharmacokinetics of propofol in adult volunteers. *Anesthesiology*. 1998;88:1170–1182. Used with permission.)

various "special populations," such as age, body weight, and sex. In response to this limitation, clinical pharmacology enthusiasts worldwide combined efforts to create a data warehouse called Open Target-Controlled Infusion (TCI*) and invited investigators to contribute their data. The goal of the Open TCI project is to provide investigators with larger datasets that can be exploited to refine and perfect the pharmacokinetic/pharmacodynamic models used for target-controlled infusions.

Recent work has taken advantage of Open TCI to build more comprehensive pharmacokinetic/pharmacodynamic models, particularly as TCI relates to determining the influence of special populations, such age and body weight, on selected intravenous anesthetic behavior. For example, a propofol pharmacokinetic model was constructed from 21 previously published datasets with data from elderly, children, adults, and obese individuals of both sexes.[8] The data spanned an age range of 0.25 to 88 years, a weight range of 5.2 to 160 kg, and contained nearly 11,000 drug concentration measurements from 660 individuals. A remifentanil model has also been constructed from nine previously published datasets including lean, obese, and morbidly obese adults.[6] The data spanned an age range of 20 to 85 years, a weight range of 40 to 220 kg, and contained nearly 4500 blood concentration measurements from 229 individuals. These new "super" pharmacokinetic models show promise as useful tools in driving TCIs and real-time pharmacologic drug displays but they will require prospective validation to ensure efficacy and safety in clinical practice among these various patient subgroups.

Key Points

- Obesity and extremes of age modify physiology such that anesthetists must make dosage adjustments to optimize therapy.
- Obesity alters the pharmacokinetic behavior of anesthetic agents. These changes are not uniform across all drug classes.
- Various scalars (total body weight, lean body mass, ideal body weight, and so on) have been proposed as the basis for calculating anesthetic dosing in obese patients. Pharmacologic modeling efforts have attempted to determine which scalar is most appropriate for specific drugs.
- In general, obese patients require higher drug dosages but not nearly as high as would be suggested by total body weight. A heuristic rule of thumb is that dosage calculations should account for approximately 30% of body weight in excess of ideal body weight.
- Anatomic and physiologic changes that occur between the newborn period and adult life have important pharmacologic implications. These ontogenetic-related changes (in circulatory physiology, drug metabolic capacity, body tissue composition, and so on) mandate that clinicians apply age-specific knowledge to the formulation of dosing schemes in pediatric patients.
- Anesthetic toxicity in neonates and infants is a topic of major concern and controversy in contemporary anesthesiology. Evidence from in vitro studies, in vivo animal models and retrospective data-mining studies in humans suggest that repeated anesthetic exposure in the young might decrease cognitive function in adult life. Ongoing, longitudinal, prospective, human studies will perhaps help clarify this controversy in the future.
- Physiologic changes in elderly patients generally result in a reduced dosage requirement based on both pharmacokinetic and pharmacodynamic mechanisms. For many drugs, the reduced dosage requirement is substantial (e.g., by 50%-75% for remifentanil).

Cortinez LI, De la Fuente N, Eleveld DJ, et al. Performance of propofol target-controlled infusion models in the obese: pharmacokinetic and pharmacodynamic analysis. *Anesth Analg*. 2014;119:302–310. This article used five of the available pharmacokinetic models for propofol in morbidly obese patients to characterize the bispectral index response (BIS) in this population. Propofol concentration was underestimated in all of the models. Using adjusted body weight improved the performance of two of the models, and there was no apparent effect of obesity on the time profile of BIS response or the propofol concentration-BIS relationship. (Ref. 11).

Davidson AJ, Disma N, de Graaff JC, et al. Neurodevelopmental outcome at 2 years of age after general anaesthesia and awake-regional anaesthesia in infancy (GAS): an international multicentre, randomised controlled trial. *Lancet*. 2016;387:239–250. The secondary outcomes reported in this ongoing study helped abate concerns over the impact of a single anesthetic on the developing brain by showing that 1 hour of sevoflurane anesthesia in infancy does not increase the risk of adverse neurodevelopment at outcome at 2 years of age compared to awake-regional anesthesia. (Ref. 77).

Minto CF, Schnider TW, Egan TD, et al. Influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanil. I. Model development. *Anesthesiology*. 1997;86:10–23. This landmark study clearly demonstrated the influence of advancing age on both the dispostion and effects of remifentanil. The age effect is substantial, translating into a 50% to 80% decrease in dose requirement for elderly patients. (Ref. 23).

Schnider TW, Minto CF, Shafer SL, et al. The influence of age on propofol pharmacodynamics. *Anesthesiology*. 1999;90:1502–1516. This article determined the effects of age on propofol pharmacodynamics, including characterization of the relation between plasma concentration and the time course of drug effect. Propofol had a faster onset in older patients and older patients were more sensitive to the hypnotic and electroencephalographic effects of propofol than were younger patients. (Ref. 97).

Shibutani K, Inchiosa MA Jr, Sawada K, et al. Pharmacokinetic mass of fentanyl for postoperative analgesia in lean and obese patients. *Br J Anaesth*. 2005;95:377–383. The authors suggest an innovative dosing scalar for obese patients, pharmacokinetic mass, which was created using plasma concentrations and observed opioid effects in obese and lean patients. (Ref. 27).

History

Pharmacology is characterized by detailed descriptions of the actions of individual drugs. In the case of anesthesia, no single drug has been found to be universally satisfactory and indeed general anesthesia is now regarded as a set of desirable clinical endpoints rather than a discrete phenomenon of its own. Useful endpoints include lack of awareness and a pleasant induction and recovery; lack of movement, adequate muscle relaxation, reasonable blood pressure control; and maintenance of homeostasis by suppressing autonomic reflexes while balancing the narrow therapeutic index of many of the drugs to ensure positive outcomes. Consequently, multiple drugs are used for all but the simplest of procedures.

This concept of multiple drug use was first described by Lundy in 1926, who used the term *balanced anesthesia*.[1] His concept included the liberal use of local or regional anesthesia as well as hypnotics, volatile anesthetics, and opioids. At the time, use of volatile agents as a sole anesthetic was common, but unacceptable cardiovascular and respiratory depression frequently accompanied the high doses required to suppress movement to noxious stimuli—a finding still true of the volatile anesthetics in use today.[2]

The theory behind balanced anesthesia is that using desirable drug combinations reduces dose requirements of individual drugs, minimizing the incidence of unwanted side effects in those with a narrow therapeutic index and so improving the quality of anesthesia. A review of the contribution of anesthesia to perioperative mortality found evidence to support this notion with the relative risk of dying within 7 days of surgery being 2.9 times greater if one or two anesthetic drugs were used, compared with the use of three or more.[3] Today, balanced anesthesia is the standard approach to general anesthesia.

Many drugs used in anesthesia have overlapping actions and, when given in combination, can be used to produce effects distinct from those they create individually. To maximize the clinical utility of any drug, it is important to understand its effects when used alone and in combination. The interaction between propofol and fentanyl is a notable example. Propofol alone is effective at causing unconsciousness without intolerable adverse effects. The much larger doses required to prevent movement in response to surgical pain also suppress respiration and can unacceptably reduce blood pressure. On the other hand, fentanyl is incapable of reliably causing unconsciousness and even in very high doses does not reliably suppress movement to pain. When these two drugs are used in combination, there is only a modest reduction in the dose of propofol required to cause unconsciousness, but a dramatic reduction in the dose required to suppress movement to pain with less reduction in blood pressure. The relative dosage of the combination of propofol and opioids also allows a degree of independent control of two critical variables—unconsciousness and lack of movement in response to pain.

Early studies of drug interactions include that by Fraser in 1872,[4] who described pharmacologic antagonism between physostigmine and atropine, and by Frei in 1913,[5] who used isobolographic analysis to demonstrate increased effectiveness of combinations of disinfectants for killing bacteria compared with individual agents. The response surface method, which is now used to describe the entire dose response relationship of two drugs, was first proposed by Loewe in 1928,[6] who described synergy as an "inflated sail" and additivity as a "tense sail." The concept was introduced into modern anesthetic clinical pharmacology analysis by Minto et al. in 2000.[7] The seemingly daunting task of describing an entire response surface for the interaction between two drugs was found to be tractable and as few as 20 intensively studied subjects are needed to adequately describe the interaction between two drugs.[8] The tedious calculations are easily performed on a modern computer,

Abstract

Modern balanced anesthesia consists of the use of a number of drugs to achieve the desired clinical endpoints, such as no awareness, no movement, muscle relaxation, control of blood pressure and control of heart rate in the face of the noxious surgical stimulus. Understanding the methodology used for the study of drug interactions and knowing the interactions that occur between commonly used anesthetic drugs is important for using them effectively and safely.

something Loewe clearly lacked. Response surface methodology is now the basis of many studies of commonly used drug combinations. Although outwardly complex, the models can be used to increase the accuracy of anesthetic doses and improve prediction of expected effects in patients. They have been incorporated into some anesthetic monitors for real-time display and can be used to optimize drug titration, promoting outcomes such as reduced wake-up times or increased cardiovascular stability without increasing hypnotic depth.

This chapter introduces terminology used to describe drug interactions, the methodology used to study drug interactions, and the important interactions between commonly used anesthetic drugs. Some of these interactions are covered in other chapters of this text in more detail (see Chapters 2, 10, 11, and 17). Interactions among combinations of analgesics or antiemetics as used postoperatively are not reviewed in this chapter; however, similar methodologies and rules can be applied when considering their use in combination.

Study of Drug Interactions

Terminology

Drug interactions are usually considered in the dose or concentration domain. A simple experiment that illustrates interactions between two drugs takes half the *dose* of each that alone causes a certain level of effect. Assume that level of effect is equal to 1. If the drugs are additive, one would expect these two half doses given together to produce the same effect as giving the whole dose of either drug alone (i.e., 0.5 + 0.5 = 1). This expected effect for a dose combination becomes the null hypothesis against which one can assess the presence (or absence) of a positive or negative interaction. If the observed effect is greater than expected (<0.5 + <0.5 = 1), synergy exists. A commonly used drug combination in which this occurs is propofol and midazolam. Together, the individual doses are reduced to about one third so that 0.33 + 0.33 ≡ 1. If the observed effect was less than expected (>0.5 + >0.5 = 1), infra-additivity exists (Fig. 6.1). If instead one combines half the *effect* of two drugs, the answer would be very different. This is because the sigmoid log-dose effect relationship is highly nonlinear, meaning drug *effects* cannot be simply added.

The term *infra-additive* is used when less effect than that expected from simple additivity is observed. The combination of midazolam and ketamine exemplifies the effect of infra-additivity. Midazolam has only a moderate effect on the ketamine dose required to suppress response to verbal command and no effect on the ketamine dose required to suppress movement to a noxious stimulus.

The term *antagonism* is reserved for interactions in which there is an absolute reduction in the effect of one drug in the presence of the other. For instance, the analgesic effect of fentanyl is reduced in the presence of naloxone. In this example, naloxone is incapable of causing analgesia when given alone. An underlying assumption of this definition of additivity is that a drug cannot interact with itself, so two half doses of the same drug must be additive.

$$\text{Interaction Index} = \frac{da}{DA} + \frac{db}{DB}$$

• **Fig. 6.1** General equation for additivity as defined by Loewe. D_A and D_B are the doses of drugs *A* and *B*, respectively, that create a given effect alone, while *da* and *db* are the doses of drugs *A* and *B*, respectively, that create that same effect when given in combination. The median effect dose or median effective concentration are the most commonly used values for D_A and D_B. An interaction index of 1 = additivity, <1 = synergy, and >1 = infra-additivity. (Reprinted with permission from Loewe S. The problem of synergism and antagonism of combined drugs. *Arzneimittelforschung.* 1953;3:285–290.)

Shift in Dose-Response Curve

The dose-response relationship for most anesthetic drugs can be described using the standard *sigmoid* E_{max} model. Its characteristics include (1) a threshold drug concentration that must be surpassed before any effect is seen, (2) an increase in effect proportional to logarithmic increases in drug concentration, and (3) saturation after which additional increases in drug concentration no longer produce an increase in effect (Fig. 6.2).

When a second drug is introduced, the simplest model of an interaction describes its influence, at a single fixed dose, on the dose-response relationship of the first drug. Using the previous example, intravenous fentanyl 1 μg/kg, administered immediately before intravenous propofol, shifts the propofol dose-response curve for unconsciousness to the left. This equates to a 20% reduction in dose for that endpoint. Likewise, the curve for suppression of movement to a noxious stimulus shifts to the left by 50%. This model demonstrates that fentanyl affects the noxious endpoint more than the hypnotic endpoint, which is expected from our knowledge of the individual drugs.

This approach to studying interactions accounts for the dose requirements for the two drugs when given together, but describes the interaction at only one dose of fentanyl. It does not describe whether the interaction with the second drug is additive or synergistic or whether there is a therapeutic advantage to using the combination. To quantitate the interaction, and to decide whether synergy exists, a description is needed of the drug's effects when given individually, as well as when given together, and for a range of doses. Use of isobolograms is an alternative approach to interaction analysis that partly addresses these limitations.

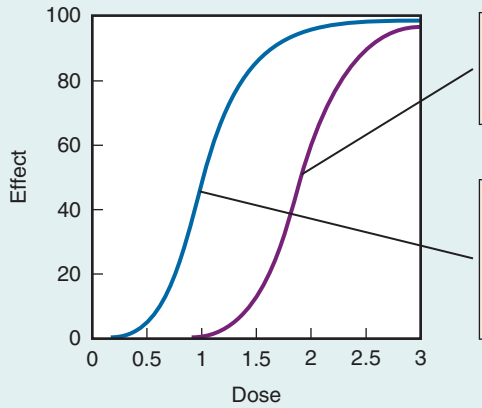
Isobolograms

The traditional approach to quantitating a drug interaction for two drugs is to construct graphs of the dose pairs that together produce a single level of effect. These isoeffect lines are called *isoboles*. Comparison of an isobole with a line of additivity signals the interaction type: a straight line indicates additivity; inward bowing indicates synergy; outward bowing indicates infra-additivity or antagonism (see Fig. 6.2).

Isobolograms are easy to construct and analyze when both drugs are individually capable of producing the endpoint in question. Numerous studies in the literature use this methodology and their conclusions are comparable to those of studies using more complex methodologies. Typically a departure from additivity of less than 10% has been regarded as additive on the basis that even if statistically significant, it is clinically irrelevant. When one drug cannot achieve the endpoint in question, it is still possible to determine whether synergy exists, but the exact degree of departure from additivity cannot be accurately determined.[9] A limitation of using isobolograms is that the result is only applicable to the effect level investigated. To gain a full understanding of the interaction between two drugs for all effect levels, it is possible to overlay a series of isoboles ranging from minimal effects to the maximal effect attainable (E_{max}).[10]

Analysis of isobolograms involves determining the dose-response relationship for each drug individually and then exploring the

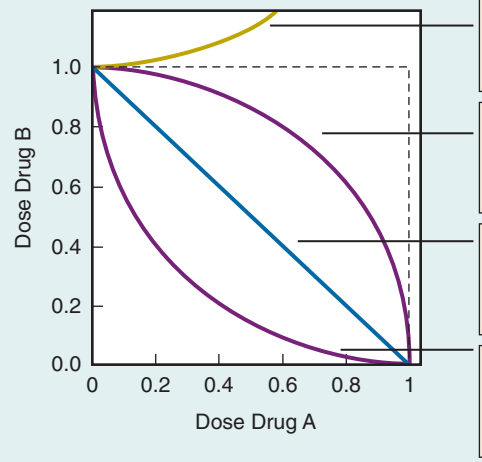
Shift in dose-response curve
The standard dose response curve for a single drug is shifted to the left along the horizontal axis by the presence of a second drug.



Drug A alone, for example: ED_{50} Drug A = 1.9
This is a standard *sigmoid* E_{max} dose-response curve.
(e.g., Propofol for immobility)

Drug A + Drug B e.g., ED_{50} Drug A = 1.0
in presence of drug B
In the presence of Drug B, dose requirements of Drug A are reduced.
(e.g., Propofol in the presence of fentanyl 1 μ/kg at an endpoint of immobility)

The isobologram
An isobologram is an iso-effect line whereby all the combinations of each drug along the line give the same observed effect. Multiple isobolograms can be drawn for different effect levels such as ED_{50} or ED_{95}. The doses required of each drug individually are on the X and Y axes respectively.



Antagonistic
Drug A increases dose of drug B to achieve the same effect
(e.g., Naloxone and fentanyl for analgesia)

Infra-additive e.g., >0.5 + >0.5 = 1
Together the individual doses of each drug are slightly reduced to achieve the same effect
(e.g., Ketamine and midazolam for sedation)

Additive e.g., 0.5 + 0.5 = 1
Together, half the dose of each drug will achieve the same effect
(e.g., Isoflurane and nitrous oxide for immobility)

Synergistic e.g., <0.5 + <0.5 = 1
Together, less than half the expected dose of each drug is required to achieve the same effect
(e.g., Propofol and midazolam for hypnosis)

The response surface
The response surface is a three dimensional graph with drugs A and B on the horizontal axes and effect on the vertical axis. The concept embraces shift in dose-response curves and the isobologram, and describes effects for the complete set of doses for the endpoint in question. Responses may be either continuous such as bispectral index and blood pressure, or quantal such as a sedation scale, awake/sleep and movement/immobility.

dose-response relationship of the drugs in combination. Simple experiments investigate dose pairs that maintain a fixed dose ratio of the individual drugs. It is also possible to combine any number of dose combinations and responses and to calculate an isoeffect line using nonlinear regression—this is now the preferred method[11,12] (Fig. 6.3). The standard isobologram assumes that the potency ratio of the two drugs remains constant for all dose pairs. In some instances this assumption does not hold true, such as when individual dose-response curves reach different levels of maximum effect. These cases require special consideration in that the line of additivity may in fact be curved.[13] Consequently this can lead to false identification of synergistic relationships. Although isobolographic methodology is appropriate for studying interactions of these types, they are better described by more sophisticated analyses.

Response Surface Models

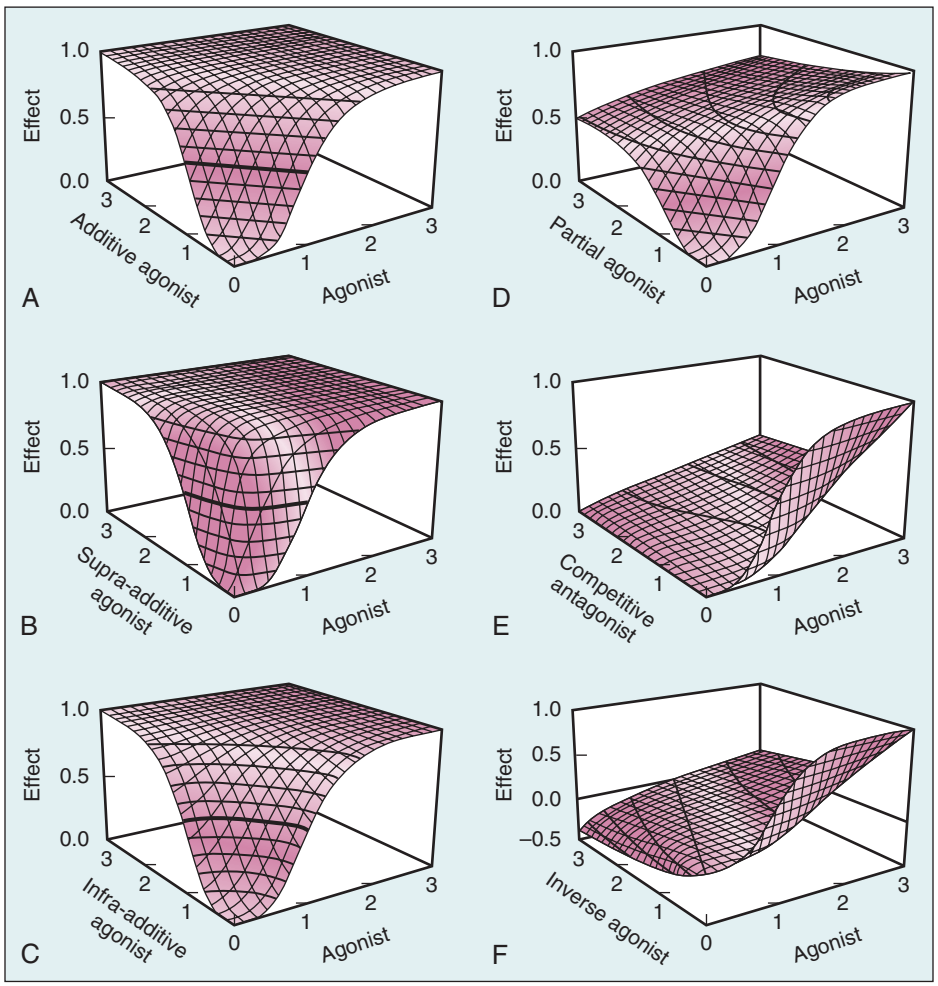
Response surface methodology allows one to create a complete description of the dose-response relationship between two drugs for all levels of effect for a given endpoint. That response surfaces characterize the entire spectrum of drug effect is an important advantage of this approach in anesthesia clinical pharmacology. Anesthesia practice is unique in that anesthetists must target profound drug effects during an operation and then reverse the effect rapidly when the operation is finished. Thus to study anesthetic clinical pharmacology fully, it is necessary to understand the entire concentration-effect relationship and how to transition from full effect to recovery efficiently.

These models all assume that the interaction is constant over time (i.e., stationary). In creating response surfaces, it is also assumed that the surface is smooth and that individuals in the study population show a similar degree of drug interaction. The latter is important because it is not practical to study more than a small part of the entire dose-response surface in each patient. Response surface models are typically built in carefully controlled volunteer studies in which multiple measurements can be made; the resulting models are then validated in patients. The concept embraces previous approaches to drug interaction analysis, including the shift in the dose-response curve and the isobologram. It also provides a strong visual representation of the interaction that is easy to remember given the complexity of the mathematics involved. Response surfaces give a mathematical description of the magnitude of an interaction for all dose pairs of two drugs, which enables these models to be used in real time to predict the likely response of patients to the drugs used. They also allow identification of optimal drug dose combinations. For example, remifentanil 0.8 ng/mL:propofol 2 to 3 µg/mL was the optimal concentration pairing to prevent movement and blood pressure changes in response to esophageal instrumentation without causing intolerable ventilatory depression.[14] The study is significant because it identifies the optimal dose ratio for a useful clinical endpoint while minimizing the risk of an unwanted side effect.

Response surface methodology is suitable for studying all the common types of drug interactions among agonists, partial agonists, antagonists, and inverse agonists (Fig. 6.4).

Trial Design

The basic steps to deriving a response surface are described in Fig. 6.5. Three different mathematical approaches have been chosen—Greco, Minto, and Bouillon et al.—but the basic principles underlying them are similar. There are also other valid approaches.[7,10,15–19] Although each model draws a slightly different



• **Fig. 6.4** Response surfaces for a variety of drug interactions. All drugs have an initial effect = 0. A is an additive interaction between two agonists; B is a synergistic interaction between two agonists; C is an infra-additive interaction between two agonists; D is the interaction between a partial agonist and a full agonist; E is the interaction between an agonist and antagonist; F is the interaction between an inverse agonist and a full agonist. (Reprinted with permission from Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. *Anesthesiology.* 2000;92:1603–1616.)

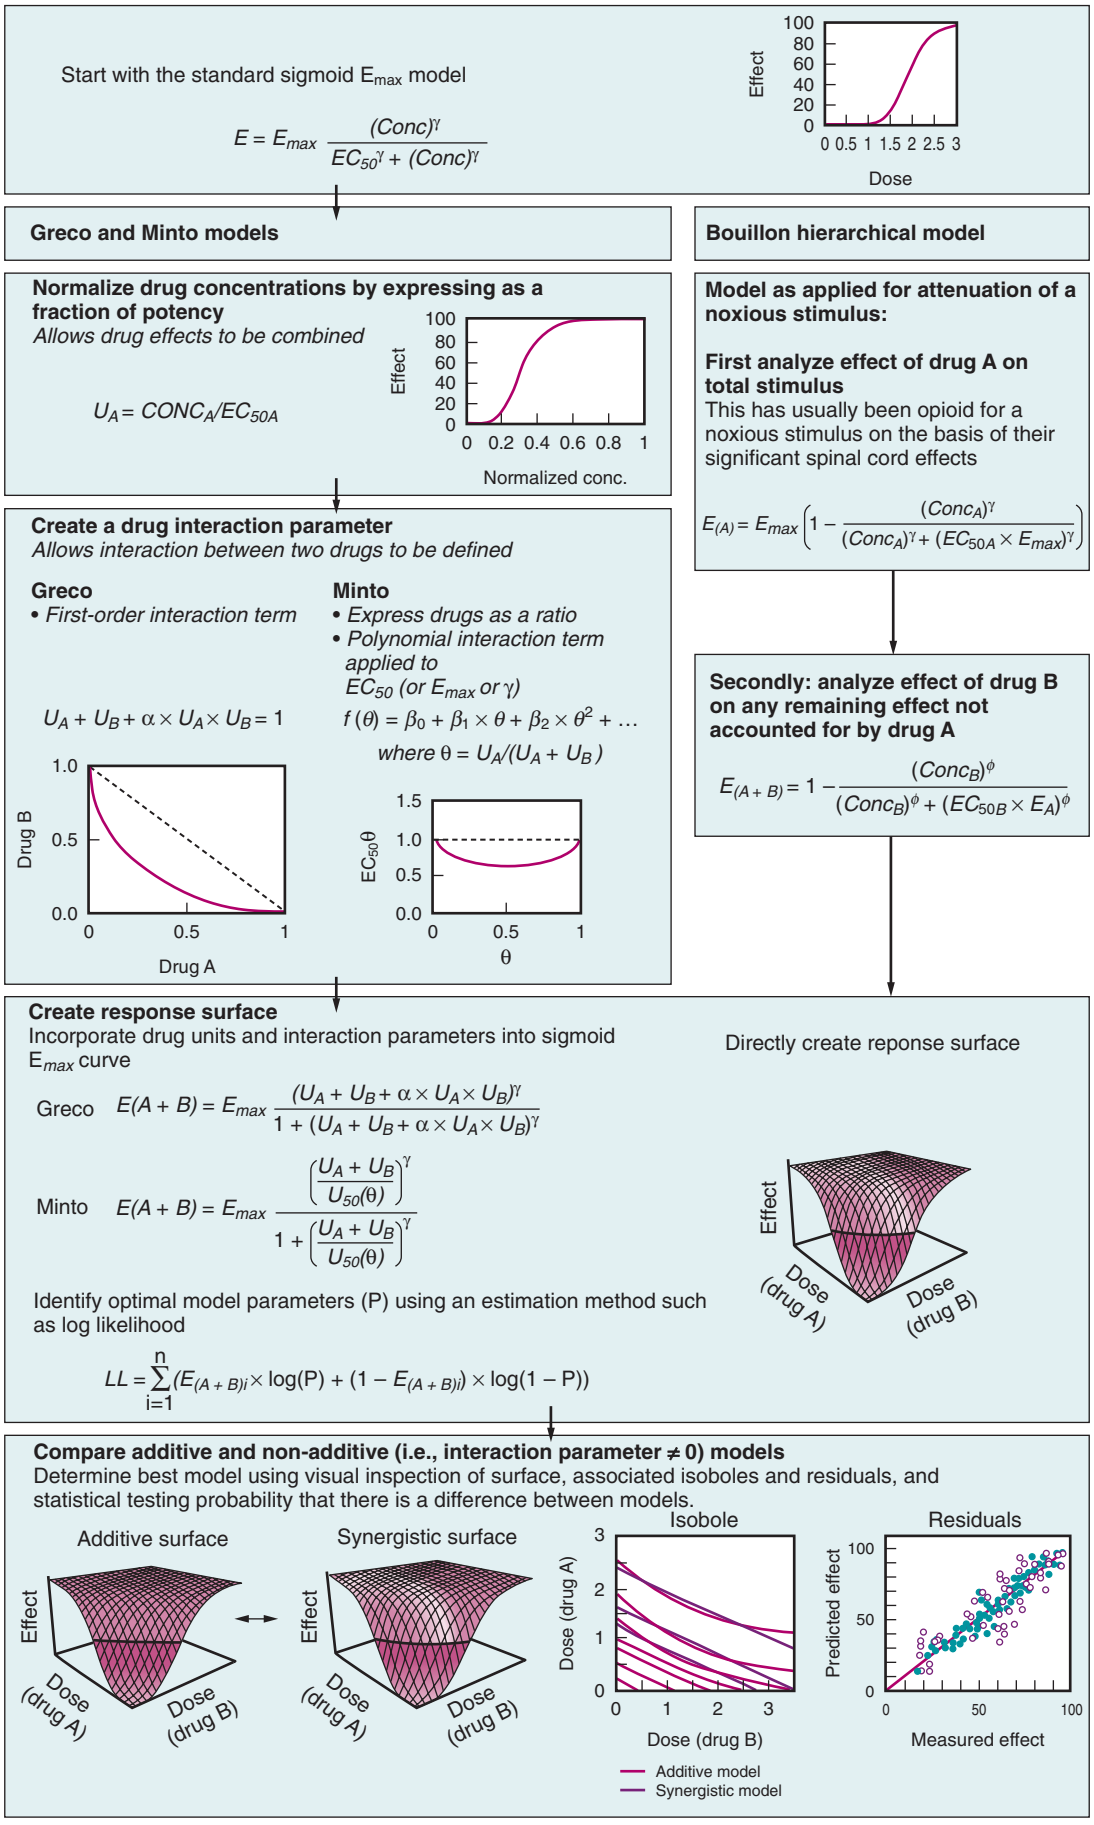
shape for the surface, the differences are not large. The three approaches are empirical in that they make no assumption about the nature of the underlying interaction.

The Greco model is simple to apply and uses a single interaction parameter.[10] In doing so, it assumes the interaction is constant for all drug pairs and gives the surface a symmetric shape. This is an advantage when coverage of the surface is uneven but may lead to forcing the data to fit a shape that the data do not actually possess. (This model is used in Fig. 6.11 and 6.12.)

The Minto model is capable of capturing virtually any shape across the response surface.[7] It preserves the sigmoid shape of the dose-response curve for all drug combinations and is suitable for describing all commonly encountered drug interactions in anesthesia, including those between a pharmacologic agonist-antagonist combination (see Fig. 6.4). Interactions can be applied to each of the variables in the sigmoid E_{max} equation individually. This facilitates describing interactions between those drugs whose individual response curves are diverse in terms of curve shape, slope, and maxima, and allows the investigator to determine the required level of model complexity, although the model has been criticized for having too many parameters. (This model is used in Fig. 6.7.)

The model of Bouillon et al., also known as the hierarchical model, sequentially processes drug effects for one drug, then the other drug.[19] It is simple to implement but has the quirk that parameter estimates will vary depending on their order of introduction into the model. Although the order by which drugs should be introduced into the model might appear logical, there are no formal criteria established and the order of analysis that results in the best fit to the data can vary for different endpoints within the same dataset. The model makes the assumption that the relationship follows a sigmoid dose-response curve but does not make a mathematical assumption about the shape of the combined surface. There is no interaction parameter, but instead goodness-of-fit can be assessed against other models describing the data. (This model is used in Fig. 6.9.) This model has also been extended to describe the effects of three or more drugs.[20]

Generic trial designs for the three methods for studying drug interactions are summarized in Fig. 6.6. Suitable methodology and power analysis for response surface trial design have been determined by simulation analysis. It is essential that trials cover most of the surface for robust models to be derived.[8] Endpoints can be either continuous (e.g., blood pressure or bispectral index)



• **Fig. 6.5** Three mathematical approaches to creating a response surface model for a pair of anesthetic drugs. *Conc.,* Concentration; E_{max}, maximal effect attainable; EC_{50}, median effective concentration. Shift in dose-response curve
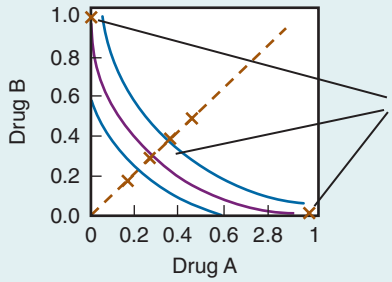
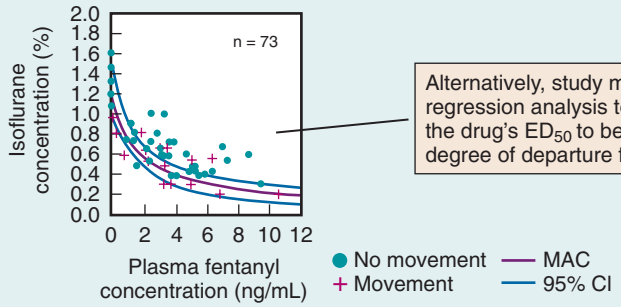
The standard population dose-response curve for a drug is determined

Drug A *in presence of drug B*
This is then repeated in the presence of a second drug. The approach is suitable for either quantal data where patients are given a range of fixed doses, or continuous data where the entire dose-response curve can be described in each patient (e.g., propofol ED_{50} alone and in the presence of fentanyl 1 μg/kg at an endpoint of immobility).[11] In this example, drug B has reduced dose requirements of drug A by 50%.

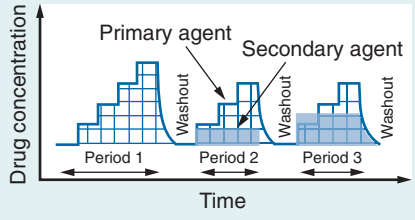


An isobologram
1. Study each drug individually to obtain individual ED_{50}s.
2. Study fixed ratios of the two drugs to find the combined ED_{50}.
3. Iso-effect lines for ED_{50}, ED_5, and ED_{95} are interpolated. There is a 33% reduction in expected dose using the combination. This degree of synergy is found when propofol and midazolam are given together for hypnosis.[43]

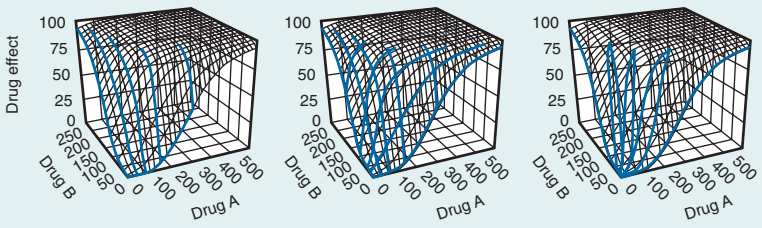


Alternatively, study multiple dose pairings of the drug and perform a nonlinear regression analysis to find the isobologram.[12] Note that it is not essential for each of the drug's ED_{50} to be known to demonstrate synergy with the combination, but the degree of departure from additivity cannot be precisely estimated.

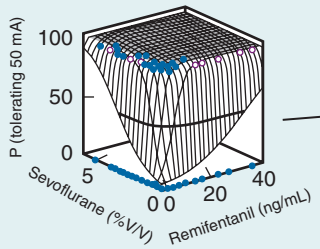
A response surface
These can be created for quantal or continuous data. Studying just 20 patients has been found adequate to characterize response surfaces using a continuous measure such as bispectral index. It is essential to cover most of the surface. The optimal design criss-crosses the surface giving the most robust result.



Study plan for individual patients[15]
1. Use stepped infusions of first drug, wait for steady state, make effect measurements such as bispectral index, movement to pain, blood pressure, etc.
2. Repeat using fixed concentrations of second drug.



Three designs for covering the surface using continuous data[8]
The criss-crossed design (center) requires fewer patients to capture the interaction than do the alternative designs (using fixed concentrations of one drug with varying concentrations of the second drug, or varying both drug concentrations together in a fixed dosing ratio).



For quantal data
The effect is either 0 or 100%.
The figure shows the interaction between remifentanil and sevoflurane for a noxious stimulus.[15]

or quantal (e.g., response to verbal command or surgical incision). The type of interaction is identified by comparing an additive model, where the interaction parameter is excluded or is made to equal zero, with one that has an active interaction parameter. The choice of the best model is made by visual inspection of the surface, comparison of residual plots, and statistical testing of the reduction in log likelihood between related models.[7,8] The response surface method can be extended to three or more drugs, although clear visualization becomes impractical beyond three drug interactions (Fig. 6.7).

Pharmacologic Basis of Drug Interactions

The interactions described in this chapter are based on observational data rather than being derived from an understanding of underlying pharmacologic mechanisms. They are important because the degree of synergy is often large and cannot usually be inferred from knowledge of the individual drug actions. Synergy may also be present for undesirable side effects such as hypotension or respiratory depression. Drugs with known effects at gamma-aminobutyric acid $(GABA)_A$ and opioid receptors usually show additivity or synergy when given together.[9] It is thought that this synergy is mostly a result of drugs with separate mechanisms acting to produce the same effect. However, drugs with known primary actions at N-methyl-D-aspartate (NMDA) receptors such as ketamine or nitrous oxide do not interact synergistically with GABAergic drugs. Evidence supports both pharmacokinetic and pharmacodynamic explanations for drug synergy.

The most extensive research into the mechanisms for synergy is for propofol and midazolam. In the presence of propofol, midazolam concentrations are increased by 25%; the reverse also holds true for propofol in the presence of midazolam.[21,22] This pharmacokinetic effect is not large enough to explain all of the observed interactions. Observations of sedative and hemodynamic endpoints found synergy for sedation and additivity for hemodynamic effects. In vitro studies of $GABA_A$ receptors have also shown

a similar degree of pharmacodynamic interaction, with midazolam markedly reducing propofol requirements to hyperpolarize the postsynaptic membrane potential.[23] The interaction occurred only when GABA concentrations were low, disappearing at high GABA concentrations. The extensive study of this drug combination using a variety of methods and the consistency of the finding of synergy also indicates that the various methods used to study interactions are robust. In vitro testing of propofol and sevoflurane in combination has also found additivity at $GABA_A$ receptors.[24]

When intravenous propofol was used for induction, a small dose of propofol given 2 minutes before a subsequent dose reduced total propofol requirement by 30% compared with a single bolus dose of propofol.[25] The study introduces the concept of temporal relationships in drug interactions, which can be clinically important at anesthetic induction. It is unknown whether this effect was due to pharmacokinetic or pharmacodynamic causes.

Understanding Drug Interactions Among Commonly Used Anesthetic Drugs

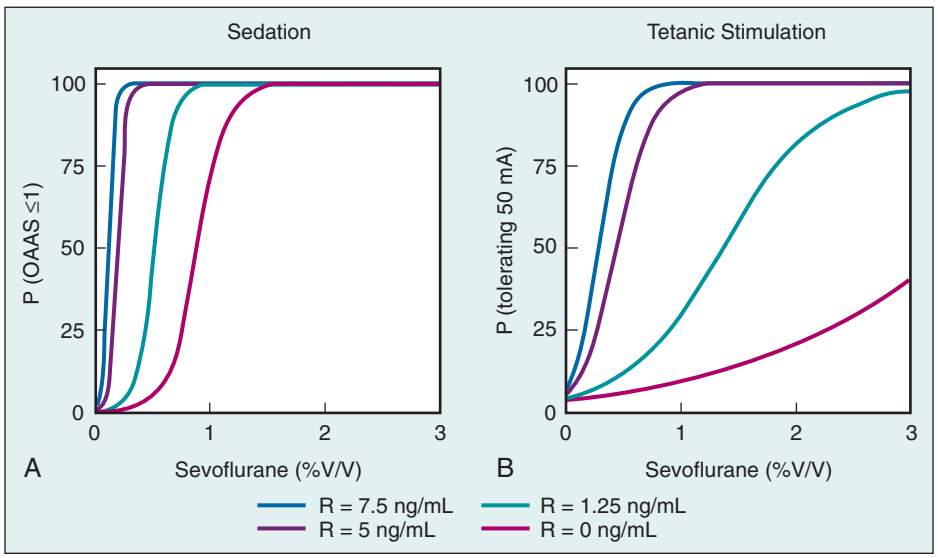
Inhaled Anesthetics and Opioids

Inhaled anesthetics and opioids are the most commonly used drug combination for anesthesia maintenance. As stated, at a hypnotic endpoint, low concentrations of fentanyl 1 to 2 ng/mL have a minor effect on volatile anesthetic dose.[12] At larger doses of fentanyl, there is increasing sedation and a ceiling effect becomes apparent, after which no further increases in effect are seen despite increasing concentration. As even high doses of opioids alone cannot guarantee unconsciousness, supplementation with 0.1 to 0.2 minimum alveolar concentration (MAC) of volatile anesthetic is required to ensure that this endpoint is achieved.[12,26–29] Similarly, on emergence, small doses of opioid have little effect on waking concentrations of volatile anesthetic.[30]

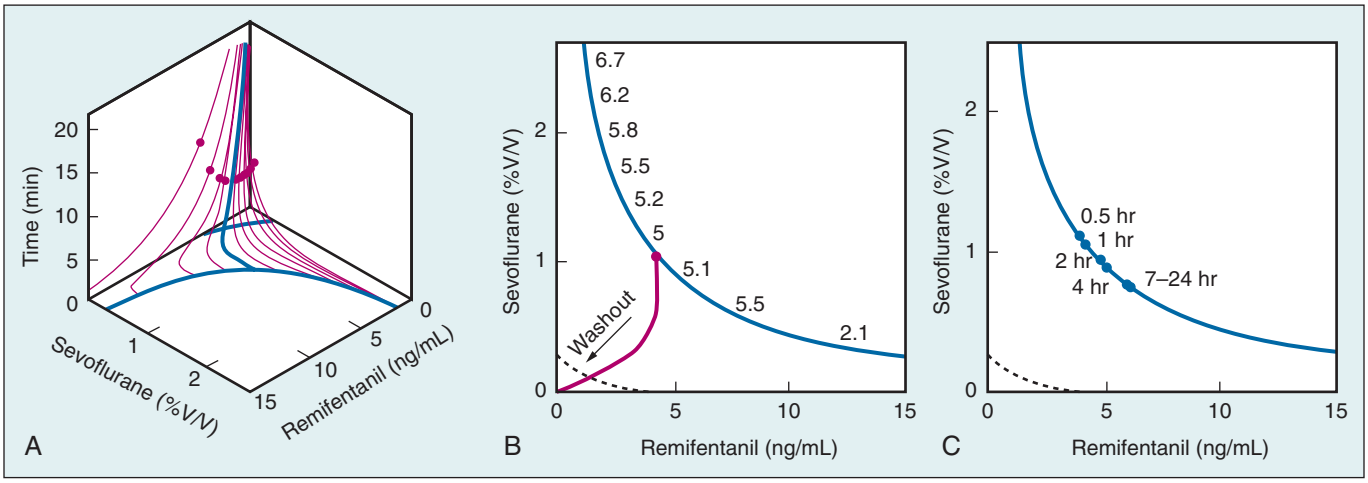
For noxious endpoints there is marked synergy. This is usually expressed as opioid infusion requirements to reduce MAC by 50%. This value is equivalent to the MAC suppression produced by 60% to 70% nitrous oxide and provides a useful reference point for comparing the relative analgesic effects of opioids.[31] Again there is a ceiling to the opioid effect with even very large doses of opioid not guaranteeing a lack of movement to noxious stimulus when given as a sole agent.[12,26,27] Isoflurane has been the most frequently studied drug, but similar results have been found for sevoflurane-fentanyl and desflurane-fentanyl combinations.

Models for a variety of volatile anesthetic-opioid combinations have been created that can be implemented in real time for any dose combination and to make predictions of optimal dose pairings. There are therapeutic benefits to the combination in terms of reduced volatile anesthetic use, more rapid emergence, and improved hemodynamic stability in response to surgery without excessive cardiac depression or unnecessarily deep anesthesia.

Sevoflurane and remifentanil are synergistic in preventing movement to pain with remifentanil at 1.25 ng/mL more than halving sevoflurane requirements when given alone (Fig. 6.8).[32] Remifentanil also decreases variability in sevoflurane requirements with increasing concentrations of remifentanil, reflected by much steeper population dose-response curves. These results can be generalized within drug classes, allowing isoflurane and fentanyl to be substituted for sevoflurane and remifentanil without affecting the model's ability to predict the effects of the combination.[33] The model can be used to make predictions of recovery times after anesthesia (Fig. 6.9). Although the spread in actual recovery times was 6 to 15 minutes, 50% of patients woke within 2 minutes of predicted recovery time. Using a pharmacodynamic model of



• **Fig. 6.8** Dose-response curves for sevoflurane-remifentanil combinations for a sedative endpoint (A) and a noxious endpoint (B). Remifentanil markedly reduces dose requirements and also steepens the dose-response curve, making dosage more predictable. *OASS,* Observer assessment of alertness-sedation; *P,* probability; 1 = no response to moderate prodding or shaking; 50 mA is a tetanic stimulus of 50 mA applied for 5 seconds, a noxious stimulus similar to surgical incision. *R,* remifentanil. (Reprinted with permission from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile synergy: a response surface model with remifentanil and sevoflurane as prototypes. *Anesthesiology.* 2006;105:267–278.)



• **Fig. 6.9** Modeling of sevoflurane-remifentanil combinations that suppress response to a noxious stimulus in 95% of patients with most rapid emergence after a 1-hour procedure. Graph A shows the predicted decline in effect site and alveolar concentrations for remifentanil and sevoflurane after stopping drug administration regimens targeted to reach the EC_{95} isobole for tetanic stimulation for 1 hour. The EC_{95} isobole is on the "floor" of the cube; the vertical axis represents time elapsed since stopping the administration of the drugs. The isobole representing an 80% probability of the return of responsiveness (Observer's Assessment of Alertness/Sedation score >4) is shown by dots superimposed on the concentration decay curves. The *highlighted curve* is the sevoflurane and remifentanil target concentration pair that resulted in the fastest return of responsiveness. In graph B, the numbers on the isobole are wake-up times (in minutes) for a variety of dose pairs; the minimum wake-up time in 50% of patients was 5 minutes. The effect of increasing duration of infusion is shown in graph C, where a small increase in the ratio of remifentanil to sevoflurane is required for earliest wake-up owing to greater accumulation of sevoflurane after prolonged use. (Reprinted with permission from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile synergy: a response surface model with remifentanil and sevoflurane as prototypes. *Anesthesiology.* 2006;105:267–278.)

sevoflurane concentration rather than relying on end-tidal anesthetic concentrations has further improved the model.[34] End-tidal concentrations do not allow forward prediction of effects caused by volatile anesthetic accumulation over time.

Inhaled Anesthetics and Other Agents

Benzodiazepines reduce volatile anesthetic requirements. Premedication with midazolam 0.05 mg/kg reduces desflurane MAC by 20% during brief procedures. The nature of the interaction has not been determined.[35] Ketamine has been formally studied only in animals, wherein marked synergy was demonstrated in the MAC of isoflurane in dogs.[36] The α_2-adrenergic agonists clonidine and dexmedetomidine decrease dose requirements of isoflurane and sevoflurane in clinical studies.[37–40] Oral clonidine 5 μg/kg reduced isoflurane MAC by 20%. A dexmedetomidine infusion of 0.6 ng/mL reduced sevoflurane MAC by 20%. The nature of the interaction has not been determined. Studies of nitrous oxide combined with volatile anesthetics have found mild infra-additivity for an endpoint of MAC, but additivity in processed electroencephalogram (median power).[41,42]

Propofol

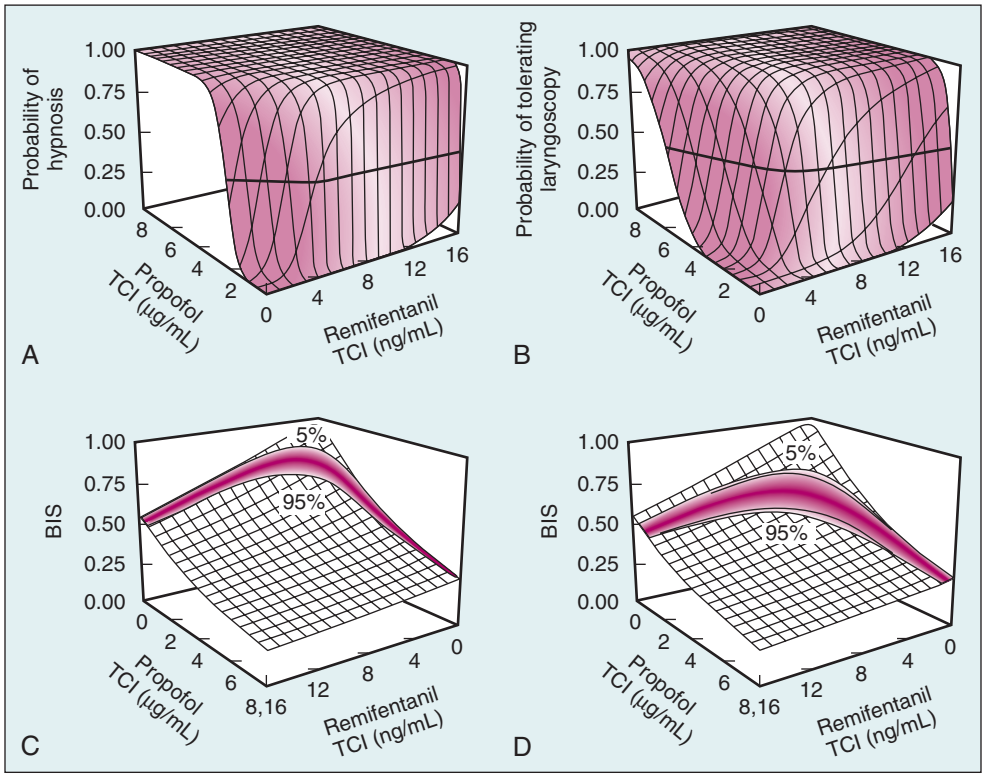
Propofol drug interactions with midazolam, opioids, and volatiles have been extensively studied at a variety of endpoints, including light sedation, lack of movement to a noxious stimulus, and change in blood pressure.

Propofol and Midazolam

This combination acts synergistically at an endpoint of hypnosis, causing a 37% decrease in expected dose at anesthesia induction (see Fig. 6.7).[43] The effect is present both following bolus doses and during infusions and does not depend on the order of administration of the drugs.[20,21] A response surface was constructed using infusion of the combination and found the optimal ratio for hypnotic synergy to be propofol 4.7 ng/mL:midazolam 1 ng/mL.[22] The hemodynamic effects of the combination were additive, with propofol depressing blood pressure 3.1 times more than an "equihypnotic" dose of midazolam. Because of the hypnotic synergy, this meant that the combination caused less hemodynamic depression than propofol did as a sole agent, indicating a therapeutic benefit from use of the combination. Hemodynamic responses after a noxious stimulus were not studied. Midazolam also markedly decreases the amount of propofol required to produce immobility to a noxious stimulus, while lacking the ability to produce immobility when given as a sole agent, even at the high dose of 1 mg/kg.[43] This interaction can be used to reduce total propofol dose during prolonged procedures and might also provide a cost benefit.

Propofol and Opioids

This is the most commonly used drug combination for intravenous induction of anesthesia and total intravenous anesthesia; it is also used in low doses for procedural sedation. At anesthesia induction, small doses of opioids, such as fentanyl 1 μg/kg, have a small effect



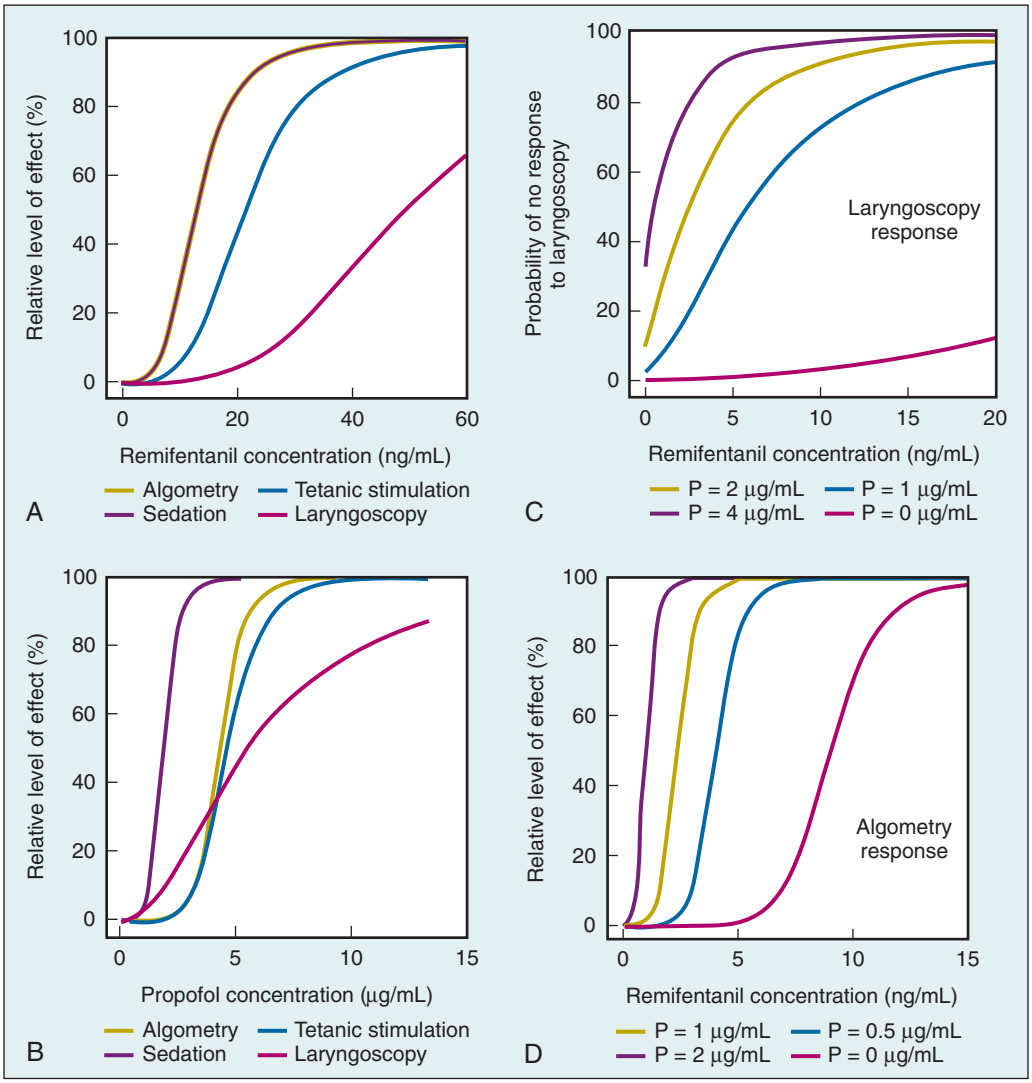
• **Fig. 6.10** Response surfaces for propofol-remifentanil interaction at an endpoint of hypnosis (A) defined as no response to shouting and shaking, and response to a noxious endpoint (B) defined as no response to laryngoscopy. The isoboles for the two endpoints have been superimposed on the bispectral index *(BIS)* response surface in C and D, respectively. The authors have reversed the orientation of the response surface in C and D, with maximum dose at the back and maximum effect at the bottom of the graph. The study shows a high degree of synergy at both endpoints and the inability of remifentanil when given as a sole agent to reliably achieve either endpoint, even at high doses. The synergy seen in the hypnotic and noxious endpoints does not extend to the BIS, where the interaction is additive. This is possibly due to remifentanil having little effect on the electroencephalogram in the clinical dose range used. Overlaying these two clinical endpoints on the BIS surface demonstrates the difference between synergy at the noxious endpoint and additivity in the BIS. *TCI,* Target Controlled Infusion. (Reprinted with permission from Bouillon TW, Bruhn J, Radulescu L, et al. Pharmacodynamic interaction between propofol and remifentanil regarding hypnosis, tolerance of laryngoscopy, bispectral index, and electroencephalographic approximate entropy. *Anesthesiology.* 2004;100:1353–1372.)

on the hypnotic dose of propofol, reducing dose requirements by 20%, but a large effect on propofol dose to suppress movement to pain, reducing dose requirements by 50%. There have been five detailed studies of combined propofol and remifentanil infusion using response surface models.[19,44–47] The combination is synergistic at all clinical endpoints and is strongest at concentrations of remifentanil up to 4 ng/mL (equivalent to the effect of a steady-state infusion rate of approximately 0.15 μg/kg per minute in a young adult), where there is a 66% reduction in expected dose with little further synergy shown by higher doses of remifentanil. The bispectral index is additive in this concentration range, presumably because remifentanil causes little sedation when used as a sole agent in low doses; studies using very high concentrations of remifentanil have shown synergy (Figs. 6.10 and 6.11).[45]

Response surface models have been used to optimize drug-dose ratios for useful clinical endpoints.[46] Optimal combinations for early wake-up times show that using relatively more remifentanil to propofol is advantageous when compared with using fentanyl with propofol. Equipotent optimal dose ratios were approximately propofol 2 μg/mL:remifentanil 5 ng/mL compared with propofol 3.5 μg/mL:fentanyl 1.5 ng/mL (Fig. 6.12). A study of respiratory effects showed marked synergy for this undesirable side effect and that it is not possible to reliably suppress response to noxious stimuli with the combination without inducing significant respiratory depression in most patients (Fig. 6.13). Note that blood pressure changes in response to sustained noxious stimuli such as surgical incision have not been studied. These recommendations might also need to be modified depending on the degree of hemodynamic suppression allowed. For clinical purposes, equivalent doses of the phenylpiperidine opioids fentanyl, alfentanil, sufentanil, and remifentanil can be used interchangeably as the degree of interaction with propofol is thought to be the same.[46]

Propofol and Inhaled Anesthetics

This combination is used at non–steady state at the beginning of all anesthetics where intravenous induction is followed by volatile maintenance. Sevoflurane and propofol have been studied at a

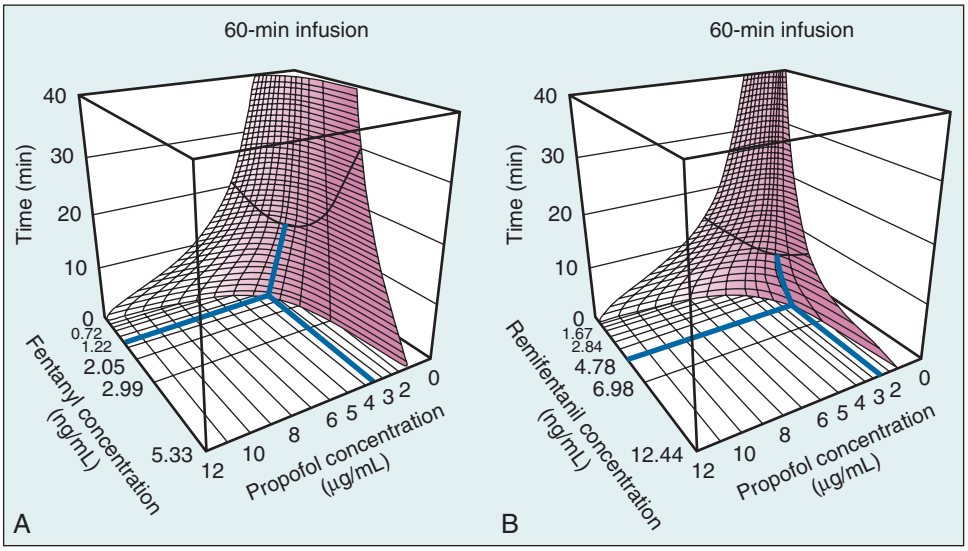


• **Fig. 6.11** Change in propofol requirement with increasing doses of remifentanil. The concentration-effect relationships for remifentanil and propofol alone for various endpoints are shown in A and B (these represent the far right and far left axes of response surface plots for each endpoint). Plots C and D are concentration-response curves derived from response surfaces (i.e., these graphs are "cuts" through the surfaces at various propofol concentrations); this representation allows simplified interpretation. Note the very high concentration of remifentanil in graph A compared with graphs C and D; in the standard clinical range up to 10 ng/mL target concentration, remifentanil is only mildly sedative, whereas propofol potently suppresses all but the most painful stimuli. In combination, remifentanil potently decreases the amount of propofol required to suppress noxious stimuli such as laryngoscopy, but there was little additional synergy gained by increasing remifentanil concentrations above 4 ng/mL as illustrated in the study in Fig. 6.11. *P,* Steady-state propofol concentration. (Reprinted with permission from Kern SE, Xie G, White JL, et al. A response surface analysis of propofol-remifentanil pharmacodynamic interaction in volunteers. *Anesthesiology.* 2004;100:1373–1381.)

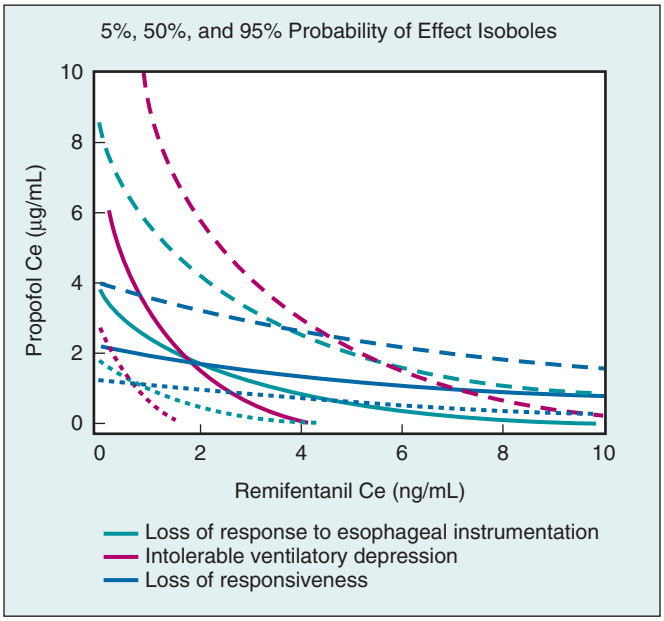
variety of endpoints ranging from response to shaking and shouting to response to surgical incision.[48–50] The combination is additive at all endpoints. Additivity was also shown for the bispectral index and other processed electroencephalogram indices such as spectral entropy and response entropy, both in volunteer studies and in the clinical setting. It is thought that other volatile agents such as desflurane and isoflurane behave similarly, but they have not been formally studied. Nitrous oxide 67% decreases propofol requirements by 25% to 35% for the endpoint of surgical incision. Two studies of target controlled infusions of propofol in the presence of nitrous oxide 67% have found the median effect dose (ED_{50}) of propofol to be 4.5 and 4.9 µg/mL, respectively. This is an example of an infra-additive drug interaction.[51,52] The three-drug combination of propofol, remifentanil, and sevoflurane has also been studied and found to be additive.[53]

Midazolam and Opioids

This combination has not been studied in detail using response surface methodology. Basic studies using isobolographic analysis



• **Fig. 6.12** Optimization of propofol-opioid total intravenous anesthesia for fentanyl (A) and remifentanil (B). The optimal dose ratios to provide 95% probability of no movement to surgical stimulus with earliest wakeup times were propofol 3.4 µg/mL: fentanyl 1.3 ng/mL and propofol 2.5 µg/mL:remifentanil 4.8 ng/mL. The superimposed *blue lines* indicate these optimal doses. The estimated time to 50% of patients being awake is 12 minutes for propofol-fentanyl and 6 minutes for propofol-remifentanil. The rapid offset of remifentanil compared with fentanyl means a higher ratio of opioid to propofol results in earlier wake-up times. Data are only displayed for a 1-hour infusion, with the differences smaller after brief infusions and greater with prolonged infusions. (Reprinted with permission from Vuyk J, Mertens MJ, Olofsen E, et al. Propofol anesthesia and rational opioid selection: determination of optimal EC50-EC95 propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. *Anesthesiology.* 1997;87:1549–1562.)



• **Fig. 6.13** Adequate suppression of response to shaking and shouting *(blue)* and to a noxious stimulus (esophageal instrumentation, *red*) without unacceptable respiratory depression. The latter is defined as a respiratory rate less than 5 breaths/min *(green).* Note that the spread of concentration targets is very wide with the ED_{95} being double the ED_{50}, and the ED_5 being less than half the ED_{50}. The *solid lines* are for ED_{50}, the *dotted lines* ED_5, and the *dashed lines* ED_{95}. *ED_5,* Effective dose, 5% response *ED_{50},* median effect dose; *ED_{95},* effective dose, 95% response. (Reprinted with permission from LaPierre CD, Johnson KB, Randall BR, et al. An exploration of remifentanil-propofol combinations that lead to loss of response to esophageal instrumentation, a loss of responsiveness, and/or onset of intolerable ventilatory depression. *Anesth Analg.* 2011;113(3):490–499.)

have shown midazolam and fentanyl or alfentanil to act synergistically to produce hypnosis.[54–56] Midazolam also potently suppresses opioid requirements to reduce movement to a noxious stimulus. The triple combination of propofol, alfentanil, and midazolam has been studied for an endpoint of hypnosis.[7,54,55] The triple combination caused no more effect than expected from the individual drugs and their paired interactions, which all showed synergy (see Fig. 6.7). Note that although the data are shown here as a response surface, the coverage of the surface is not good; only a single fixed dose ratio has been studied using each combination.

Ketamine and Midazolam or Propofol

Ketamine and propofol are known to have distinctly different modes of action. Midazolam is often used to suppress emergence phenomena related to ketamine and can also be used in combination for sedation or induction of anesthesia. Midazolam has an infra-additive effect on ketamine hypnosis and no effect on the ketamine dose required to suppress movement to a noxious stimulus.[57] The combination of propofol and ketamine has an additive effect for an endpoint of sedation, and propofol has only a small influence on ketamine doses required to block movement to a noxious stimulus (i.e., infra-additive).[58] The drugs have opposing effects on hemodynamic variables. At an optimal propofol:ketamine dose ratio of 3:1 there is minimal change in both heart rate and blood pressure when used for anesthesia induction in healthy patients.

Other Drugs and Applications

The use of response surface models to describe pharmacodynamic interactions is spreading beyond investigating anesthetic drug pairs

and into other drug combinations. Recently response surface methodology was used to quantify synergy for rocuronium- and cisatracurium-induced muscle relaxation using train-of-four as the effect signal.[59] In pediatrics, response surface models have been used to suggest optimal propofol-ketamine combinations for light sedation requiring analgesia and to predict wake-up times,[60] and have been integrated with other information such as study attrition and models of baseline pain to interpret combined analgesic data in children following tonsillectomy.[61] There are currently no studies that test whether adult interaction studies also apply to children.

Emerging Developments

Drug Interaction Displays on Monitors

Manufacturers have incorporated response surface models of drug action into new anesthesia monitor displays (Navigator Applications Suite, GE Healthcare, Helsinki, Finland; SmartPilot View, Intelligent Display, Dräger Medical AG & Co. KG, Lübeck, Germany). These systems display probabilities of hypnosis and movement to pain based on population models for the drugs used (Fig. 6.14). The models contain adjustments for age, weight, height, and sex and

• **Fig. 6.14** Real-time displays of predicted anesthetic drug effects. The top screen shows the interaction between propofol and sevoflurane in a patient induced with propofol for endpoints of sedation and analgesia. Notice the gap in our knowledge soon after induction, because the three-drug interaction among propofol, remifentanil, and sevoflurane has not been studied. The lower display shows propofol-remifentanil anesthesia. The isobologram on the left has shaded scales showing the population ED_{50} for light anesthesia and deep anesthesia and the ED_{95} for deep anesthesia. The line on the isobologram shows the effect course the patient has taken, including a prediction of the future effect course given the current dosage. *ED_{50}*, Median effect dose; *ED_{95}*, effective dose, 95% response. (Navigator Applications Suite, GE Healthcare, Helsinki, Finland; and SmartPilot View, Intelligent Display, Dräger Medical AG & Co. KG, Lübeck, Germany.)

display the influence of opioids on MAC of the volatile anesthetic used and the interaction between propofol and opioid to make predictions of anesthetic effect and time to waking. As well as providing a probability of response, they also display the variation in response expected in a typical patient population with ED_{50} and ED_{95} displayed. The calculations are done in real time with adjustments in dosage continuously incorporated into the model to predict likely effects. This real-time modeling greatly increases the dosing information available to anesthetists and is an improvement on current displays, which are often limited to a single number for MAC that is not adjusted for age. These prediction modules are intended to bring the detailed knowledge about anesthetic drug behavior found in textbooks and the modeling literature to the clinical domain by applying the models in real time in a user-friendly display.

Such information can be used to guide a more accurate titration of volatile and opioid dose. The population modeling of the drug interactions also allows prediction of a probability of movement, something that current depth monitors such as the bispectral index cannot do.[19,32] The displays provide information at both sedative and noxious endpoints and also provide predictions of recovery time. The inclusion of probabilities of movement and time to waking might appear overly detailed, but they give a more accurate appraisal of the sedative effects of the drugs given and their likely time course than was previously available. They also reduce task load in the operating room.[62] The library of drugs incorporated into these displays is currently limited to commonly used opioids, volatile anesthetics, and propofol. It has been shown that isoflurane can be substituted for sevoflurane and fentanyl for remifentanil without loss of fidelity of the model, providing further evidence that phenylpiperidine-based opioids behave similarly and can be used interchangeably.

Pharmacodynamic-Based Target Control and Closed-loop Infusions

Pharmacodynamic model, target-controlled infusion of propofol and remifentanil has been studied in trials experimentally using a response surface model to control the concentrations of the two drugs to produce a predicted level of effect (bispectral index) rather than a predicted blood concentration.[63] The concept allows drug titration to alter reflex suppression with an opioid without altering anesthetic depth. Analogous to this, a dual closed-loop controller that achieves the same objective by titrating propofol and remifentanil in response to both bispectral index and arterial pressure targets.[64] These devices both carry the promise of improved accuracy in the titration of anesthetic drugs to patient need.

Key Points

- Current anesthetic practice is based on the use of drug combinations, a concept termed *balanced anesthesia* by Lundy in 1926. Study of the pharmacology of common combinations of drugs has greatly increased our knowledge of clinical anesthetic pharmacology.
- Drug interactions can be described by (1) shifts in dose-response curves, where one drug influences the dose-response curve for a second drug; (2) isobolograms, which are isoeffect lines for two drugs both capable of influencing the endpoint in question; and (3) response surfaces, which create models of all possible combinations of two or more drugs for a given effect.
- Drug interaction studies can be used to define optimal dose ratios for desired outcomes such as maximum synergy (or lowest total dose), most rapid emergence, and least respiratory or hemodynamic depression.
- The combinations of propofol with an opioid, and a volatile agent with an opioid, show a small additive effect at hypnotic endpoints and a large degree of synergy in suppression of response to a noxious stimulus. The combination of propofol with a volatile anesthetic such as sevoflurane is additive.
- Response surface models can be used in real time to create predictions of likely anesthetic effect in the operating room. These models have been incorporated into a new generation of monitor displays and are a sophisticated advance on the simple display of a predicted MAC value on most current anesthesia monitors.

Adverse Drug Reactions

ABHINAV KANT, JONATHAN BILMEN, AND PHILIP M. HOPKINS

CHAPTER OUTLINE

Definition

Drug Administration Errors

Types of Adverse Drug Reactions
- Type A Reactions: Augmented (Dose-Related)
- Type B Reactions: Bizarre (Drug Idiosyncrasy, Non–Dose-Related)
  - *Acetylator Status*
  - *Cytochrome P450 Variants*
  - *Plasma Cholinesterase Variants*
  - *Glucose-6-Phosphate Dehydrogenase Deficiency*
  - *The Porphyrias*
  - *Malignant Hyperthermia*
  - *Allergic Drug Reactions*
- Type C Reactions: Chronic (Direct Organ Damage, Dose-Related, and Time-Related)
- Type D Reactions: Delayed (Time-Related)
  - *Type E Reaction: End of Use (Withdrawal)*
  - *Type F Reactions: Drug Failure*

Emerging Developments
- "Swiss Cheese" Model in Adverse Drug Reactions
- New Technology to Decrease Drug Errors in Anesthesia

Definition

No medicine is risk free, yet the definition of an adverse drug reaction may not be straightforward. The World Health Organization (1972 Technical Report No. 498) defines an adverse drug reaction as "A response to a drug which is noxious and unintended, and which occurs at doses normally used in man for the prophylaxis, diagnosis, or therapy of disease, or for the modifications of physiological function." One particular problem with this vague definition is that it assumes that all individuals are the same and hence the "normal dose" of a drug is to be comparable within a population. It does not consider differences in pathophysiology within individuals that can alter the way a drug behaves in terms of its pharmacokinetics or pharmacodynamics. Another problem is that it can be difficult to distinguish an adverse drug reaction from what is commonly known as a "side effect." A side effect can occur within or outside the normal dose of a medication. One particular aspect of a side effect, which may differ from an adverse drug reaction, is that the effect can be beneficial. An example in anesthetic practice is the use of lidocaine as an antiarrhythmic.[1] This drug was originally licensed for its use as a local anesthetic, yet its inhibitory effects on cardiac sodium channels can be used to dampen cardiac conduction. Further confusion with the definition of an adverse drug reaction is when a drug is being researched or is under surveillance after its initial commercial release. The European Medicines Agency good clinical practice guidelines state that "In the pre-approval clinical experience with a new medicinal product or its new usages, particularly as the therapeutic dose(s) may not be established: all noxious and unintended responses to a medicinal product related to any dose should be considered adverse drug reactions."

The majority of adverse drug reactions can be attributed to a drug interacting with another or several other drugs. The practice of anesthesia involves the coadministration of several drugs alongside any drugs a patient may already be taking. The potential for drug interaction is therefore very high and this topic is covered elsewhere in this book (see Chapter 6).

With regard to anesthetic adverse drug reactions, a large analysis of more than 11,000 adverse drug reactions in more than 6600 patients in the United Kingdom showed a mortality of 9% with the largest proportion (>40% of deaths) associated with inhalation anesthetics and the smallest proportion (8% of deaths) from local anesthetics.[2] The most frequently reported adverse drug reactions were associated with the use of intravenous induction agents.

Historically, adverse drug reactions were classified into two distinct categories; type A and type B.[3] Type A reactions were classed as "dose-related" and included pharmocokinetic and pharmacodynamic variations within populations as well as drug interaction. Type B described reactions that were not dose related but idiosyncratic or allergic and often in genetically susceptible individuals. Type A reactions are more common than type B reactions and count for more than 80% of all reactions. This classification has evolved into one described neatly by Edwards and Aronson[4] and a modification is shown in Table 7.1. This chapter focuses on the general principles of the mechanisms of adverse drug reactions that can be applied to a wide range of drugs used in the practice of anesthesia. For ease, the layout of the chapter reflects the classification as described in Table 7.1.

Drug Administration Errors

Adverse drug reactions can occur if the drug is incorrectly administered to a patient. Note that this does not fall into the classification described previously. Over the past 2 decades, NHS England (and formally the National Patient Safety Agency [NPSA]) and the Institute of Medicine in the United States have both compiled massive data highlighting that this is a serious and widespread

Abstract

In the 16th century, Paracelsus recognised that any medicinal substance has the potential to do harm, defining the dose as the determinant of whether the substance is a remedy or a poison. Despite this prescient and succinct observation, the intervening 450 years have failed to yield an agreed definition of an adverse drug reaction, although they all encompass the notion that intended therapeutic use of a medicine has resulted in unintended harm. We now know that not all adverse drug reactions are dose-related and the distinction between dose-related and non-dose-related reactions is commonly used in classification systems. Dose-related adverse drug reactions reflect inter-individual pharmacokinetic and pharmacodynamic variability. The risks of such reactions occurring with a particular drug depend on the difference between the effective therapeutic dose and the toxic dose, often described as the therapeutic index or certain safety factor. Although dose-related adverse drug reactions are more common during anaesthetic management than non-dose-related reactions, the latter can be the most dangerous, for example malignant hyperthermia or anaphylaxis. Across all branches hospital practice the greatest incidence of adverse drug reactions (total incidence and fatal outcomes) arises from drug administration errors. In anesthetic practice there have extensive analyses of the causes of drug errors and proposals to mitigate the human factors responsible: these include several technological innovations.

anaphylaxis

TABLE 7.1 Classification of Adverse Drug Reactions

Mnemonic	Type of Reaction	Features
A: Augmented	Dose-related	Common Related to pharmacologic action of the drug Predictable Low mortality
B: Bizzare	Drug idiosyncrasy, non–dose-related	Uncommon Not related to pharmacologic action of the drug Unpredictable High mortality
C: Chronic	Dose-related, time-related, direct organ damage	Uncommon Usually dose-related
D: Delayed	Time-related	Uncommon Usually dose-related Becomes apparent sometime after the administration of the drug
E: End of use	Withdrawal	Uncommon Occurs soon after withdrawal of the drug
F: Failure	Unexpected failure of therapy	Common Dose-related Often caused by drug interactions

Modified from Edwards R, Aronson JK. Adverse drug reactions: definitions, diagnosis, and management. *Lancet.* 2000;356:1255–1259.

issue in hospitals and drug administration errors are the single most preventable cause of patient harm. Although the majority of these reported errors lead to minimal or no harm, in anesthesia they have the potential to cause devastating effects. A U.K. study of 12,606 reported incidents showed medication errors occurred in 1,120 patients.[5] Of these, only 15 (1.3%) resulted in severe harm or even death. A further 6-month analysis of reports to the NPSA regarding drug errors in intensive care showed of the 2428 incidents reported, 355 different drugs were involved, with morphine, gentamicin, and norepinephrine the most common.[6] A review of anesthetic drug errors states that an error can happen as frequently as every 133 anesthetics.[7] Much work is being done to prevent administration errors and recent evidence suggests that double-checking of drugs with a second person may reduce errors.[8,9]

Drug errors need not be as late as the administration phase but can occur during the prescription. Illegible handwriting, inaccurate medication history, confusion with the drug name, inappropriate use of decimal points, use of abbreviations, and use of verbal orders have all been implicated in prescribing errors.[10]

For some drugs, inaccurate knowledge of dosing information among prescribers can lead to erroneous dosing.[11] A drug developed in a nonanesthetic context could have its dosing regimen inappropriately applied to the perioperative situation. This applies to some drugs that were introduced into clinical practice at a time when licensing legislation was less vigorous. A good example of this is morphine, for which the traditional quoted dose for severe postoperative pain is 0.15 mg/kg given intramuscularly. This dose was deemed the effective dose for battlefield casualties. However, one can now accept that battlefield casualties are an inappropriate model for postoperative pain as the pain tolerance of those injured in battle is high as a result of the psychological and neurohumoral response to the situation.[12]

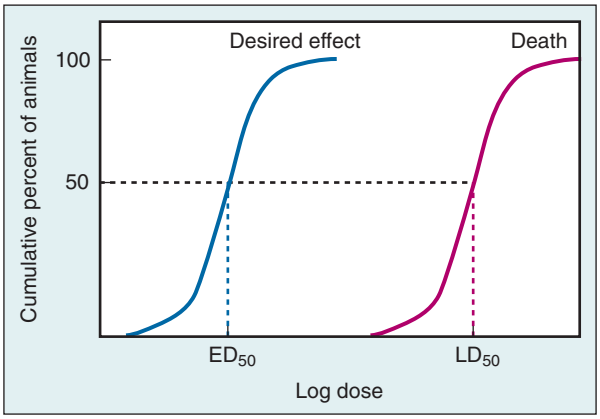
Another example is antiemetic medication. None of the currently available antiemetics was developed primarily for perioperative use. Many were first introduced as treatments for motion sickness, vestibular disorders, migraine, or for the treatment of side effects of radiation therapy or cytotoxic chemotherapy. The butyrephenone droperidol was introduced into anesthetic practice as a neuroleptic agent in a dose of approximately 0.1 mg/kg.[13] Neuroleptanesthesia as a technique is now rarely performed; however, it does still demonstrate the antiemetic efficacy of droperidol. This efficacy is maintained at doses 10 times lower than those used for the neuroleptic effect. It may well be that more commonly used antiemetics such as phenothiazines and antihistamines (see Chapter 34) are also being used in inappropriately high doses in the perioperative setting with potentially avoidable side effects.

Types of Adverse Drug Reactions

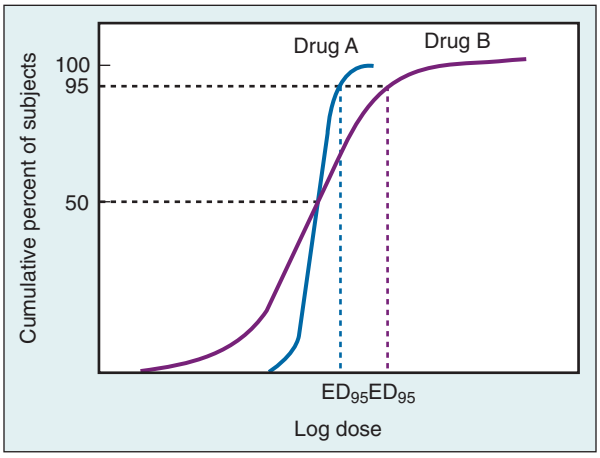
Type A Reactions: Augmented (Dose-Related)

Paracelsus (1493-1541) once noted "All substances are poisons: there is none which is not a poison. The right dose differentiates a poison and a remedy." Despite the administration of a drug in its intended therapeutic dose range, some patients exhibit an adverse effect. This may occur as a result of variation of an individual's drug response within a unimodal population variation in response.[14] This phenomenon is termed *drug intolerance.* The causes of drug intolerance are multifactorial with environmental and genetic factors involved. The intolerance of the drug is invariably related to the dose administered and there are numerous examples of these in anesthesia. One example is the intrathecal administration of a local anesthetic that can result in either a desired, low, or high block level dependent on patient characteristics.[15-17] The most common dose-related reactions seen with anesthetic agents (inhalation or intravenous) are dampening of the normal cardiovascular and respiratory functions, and indeed these reactions are sometimes used for clinical benefit.[18,19] This relationship between desired effect and unwanted effect remains at the forefront of toxicology.

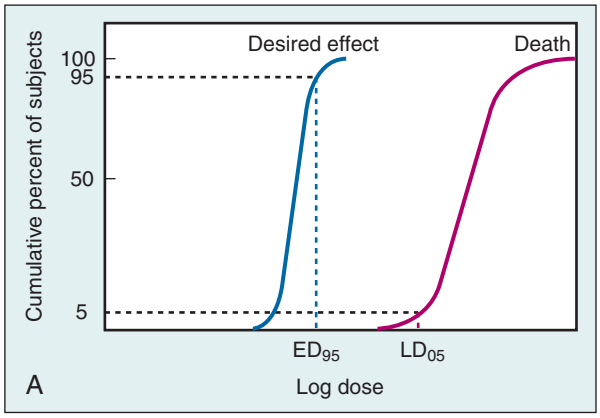
Conventionally we measure the propensity for adverse effects of drugs by the therapeutic index. In the preclinical testing of new drugs, the *therapeutic index* provides a ratio of the LD_{50} (the dose that causes death in 50% of animals) to the ED_{50} (the dose that produces the desired effect in 50% of animals). The LD_{50} and ED_{50} are calculated from cumulative quantal dose-response curves as illustrated in Fig. 7.1. Although widely established within toxicology, the therapeutic index does have its limitations. Consider two drugs A and B with the same ED_{50} value. If the population variability on response to drug B is greater than drug A (Fig. 7.2), then there will be a larger ED_{95} (dose that produces the desired effect in 95% of subjects) value in drug B. Clinically the ED_{95} or even the ED_{99} is far more useful than the ED_{50} as we would want as many patients as possible being treated with a beneficial effective dose, yet the dose must not reach levels that produce important unwanted effects. It also becomes clear that the ED_{50} is not an ideal dose for clinical purposes as one would not want to produce an unwanted/lack of effect in 50% of patients. Figs. 7.3 and 7.4

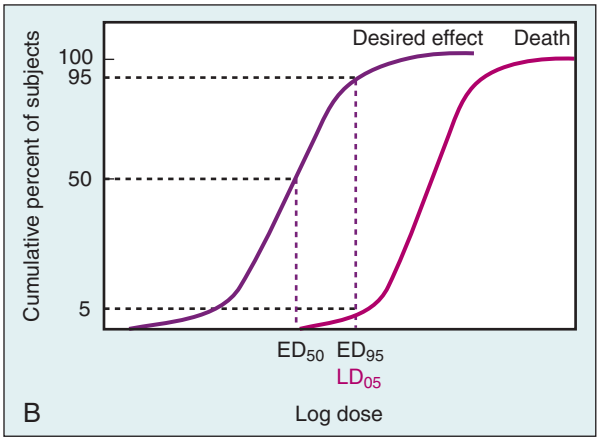


• **Fig. 7.1** Quantal dose-response curves to illustrate derivation of the therapeutic index from the ratio of the LD_{50} (dose that causes death of 50% of animals) to the ED_{50} (the dose that produces the desired effect in 50% of animals).



• **Fig. 7.2** Quantal dose response curve of two drugs with identical ED_{50} but different ED_{95} doses. This results from the greater population variability in response to drug B compared with drug A and illustrates how therapeutic effectiveness can vary between two drugs with similar potency, when potency is defined on the basis of the ED_{50}. *ED_{50}*, Dose that produces the desired effect in 50% of subjects; *ED_{95}*, dose that produces the desired effect in 95% of subjects.





• **Fig. 7.3** Illustration of the principle of the certain safety factor in animal studies. Each panel shows the quantal dose response curves for two effects of the same drug, the desirable therapeutic effect and an unwanted effect, in this case death. For the drug in panel A, there is good separation between the ED_{95} and LD_{05}. The drug in panel B, however, has a reduced certain safety factor because the ED_{95} is identical to the LD_{05}. *ED_{50}*, Dose that produces the desired effect in 50% of animals; *ED_{95}*, dose that produces the desired effect in 95% of animals; *LD_{05}*, dose that is lethal in 5% of animals.

further illustrate this principle. A more useful pharmacologic concept revolves around the *certain safety factor*. This is the ratio of the dose to produce an unwanted effect in a defined proportion of the population (usually 1%) to the dose to produce a desired effect in a proportion 100 minus that defined. In other words, the certain safety factor is most commonly described as TD_{01}/ED_{99}, where TD is the toxic dose. The certain safety factor can be adjusted if the unwanted effect of the drug is particularly serious; hence $TD_{0.1}/ED_{99.9}$ or $TD_{0.01}/LD_{99.99}$, and so on could be used.

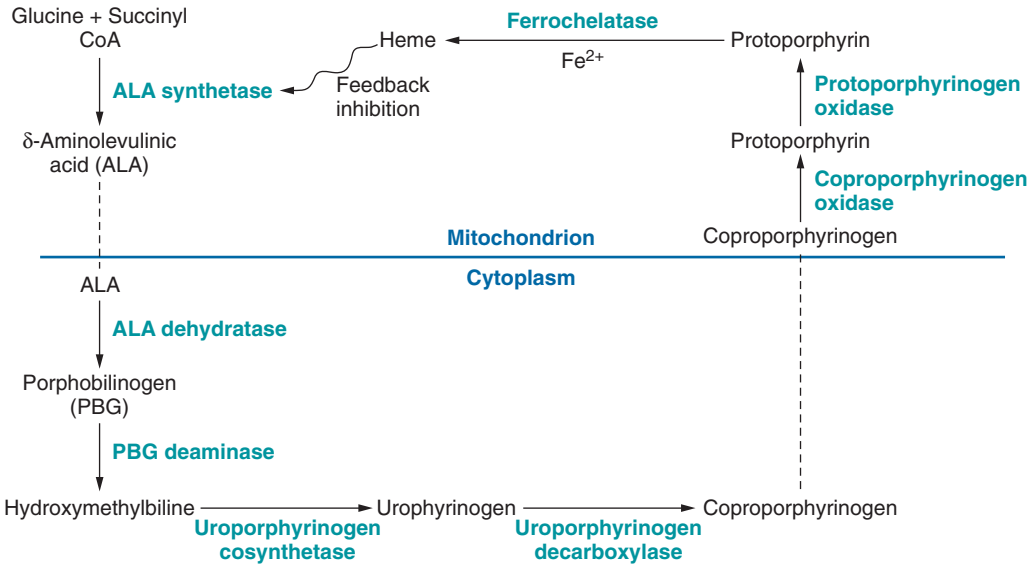
The doses used in the calculation of the certain safety factor also define the limits of the therapeutic window. Dose-response relationships remain a popular area for anesthetic research.[20,21] Newer drugs, combinations of drugs, and techniques to administer them are slowly being introduced in all areas of anesthetic practice and each will undoubtedly have the ability to cause harm.

Type B Reactions: Bizarre (Drug Idiosyncrasy, Non–Dose-Related)

Some adverse drug reactions are not dose related and occur within individuals with genetic susceptibility. Pharmacogenetic variation has been identified in drug metabolism (acetylation, cytochrome P450 variants, plasma cholinesterase variants), inability to compensate for drug effects (glucose 6-phosphate dehydrogenase deficiency, acute porphyrias) in drug effects themselves (malignant hyperthermia), or even immune mediated responses (allergies). Each of these examples is discussed separately (also see Chapter 4).

Acetylator Status

Drugs such as isoniazid, hydralazine, procainamide, some sulfonamides, sulfasalazine, nitrazepam, and caffeine undergo acetylation, which is a phase 2 nonmicrosomal conjugation reaction. The enzyme group responsible are the N-acetyltransferases. There are two different isozymes in humans, encoded by the genes *NAT1* and *NAT2*. *NAT1* is ubiquitously expressed and has 28 polymorphisms described to date, most of which have a similar acetylation rate as the reference gene. Currently there are 88 polymorphisms of *NAT2* recognized. *NAT2* is expressed in the liver, small intestine,



• **Fig. 7.4** The metabolic pathway for heme synthesis. A block in any of the enzymes in the pathway will result in accumulation of porphyrin precursors, especially following metabolic stress or hemorrhage. Fe^{2+}, Ferrous ion.

and colon and is thus regarded as the enzyme responsible for processing xenobiotics. These polymorphisms are responsible for the observed enzyme processing behavior, which defines human individuals as fast, intermediate, or slow acetylators. The prevalence of slow acetylation can be as high as 60% in Caucasians and 10% to 20% in Asians.[22] Slow acetylation, resulting in a prolonged half-life of the drug, can predispose individuals to a greater risk of side effects such as peripheral neuropathy (isoniazid), lupus syndrome (hydralazine and procainamaide), allergic reactions and hemolysis (sulfonamides), and gastrointestinal effects (sulfasalazine).

Cytochrome P450 Variants

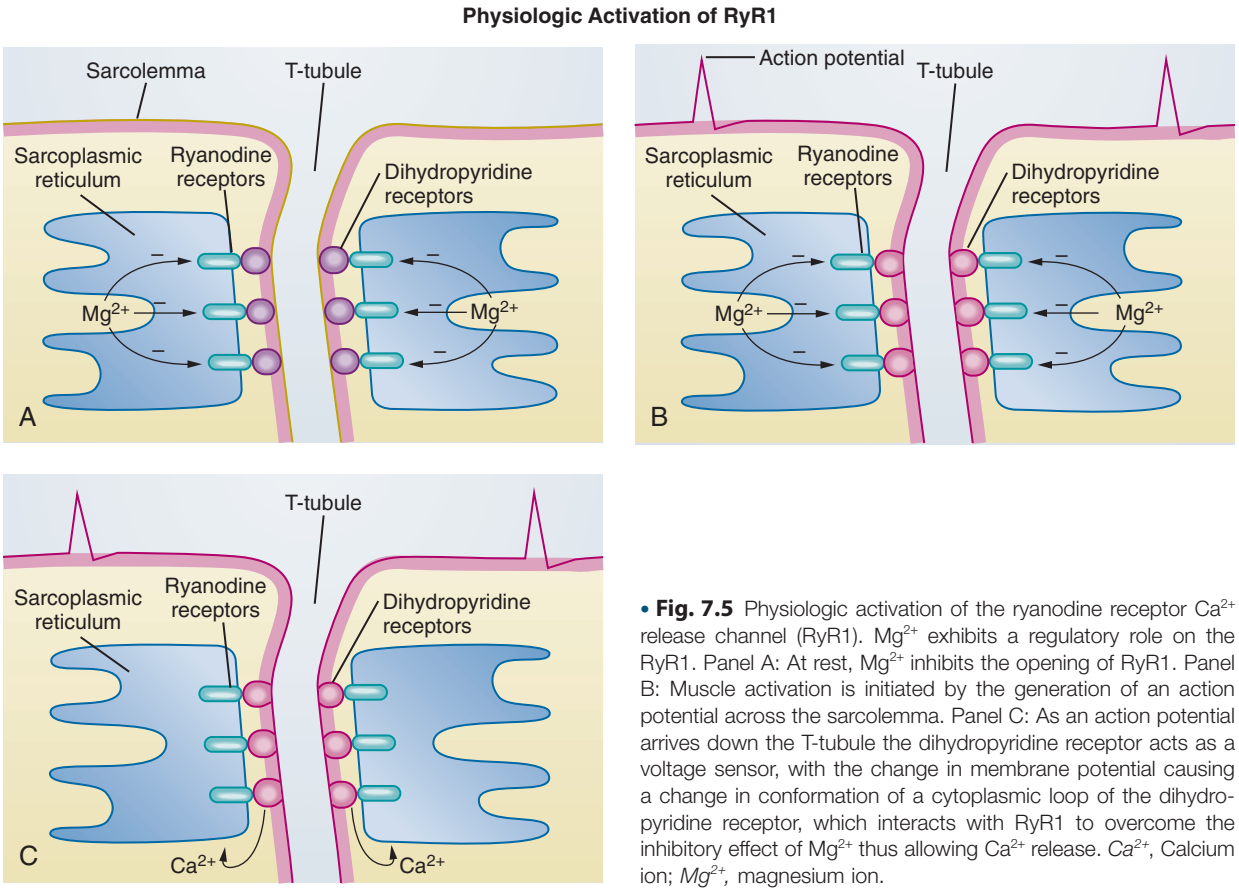
The cytochrome P450 family of enzymes is responsible for microsomal phase I oxidation reactions. They exist in four classes (CYP 1-4), each with several subgroups.[22] Most drugs can be metabolized by one or more of these subgroups. However, important polymorphisms have been found in four enzymes; therefore drugs metabolized predominantly by one of these enzymes could show a reduced clearance. Enzymes of particular interest to anesthesiologists include CYP 2D6, CYP 2C9, CYP 2C19, CYP 3A4-5, and CYP 2E1. The CYP 2D6 group is responsible for 25% of drug metabolism—most notably metoprolol, propranolol, amiodarone, flecainide, tricyclic and selective serotonin reuptake inhibitor antidepressants, phenothiazines, butyrophenones, and opioids. There is racial variation; 6% of Caucasians and 1% of Asians have reduced activity.[23] The CYP 2C9 enzyme group is important for warfarin metabolism and individuals with reduced activity of CYP 2C9 are prone to hemorrhagic complications.[24] CYP 2C19 is involved in the oxidation of diazepam and proton pump inhibitors with reduced activity more prevalent in Asians (20% vs. 3% in Caucasians).[25,26] Important for the metabolism of midazolam, lidocaine, fentanyl, and alfentanil is CYP 3A4-5, which is responsible for 50% of drug oxidation reactions and has reduced activity in 6% of Caucasians. The metabolism of acetaminophen and the fluorinated volatile anesthetics are predominantly by the CYP 2E1 enzyme.[27]

Plasma Cholinesterase Variants

Plasma cholinesterase (also known as pseudocholinesterase, serum cholinesterase, nonspecific cholinesterase, butyrylcholinesterase, S-type cholinesterase) is most notably responsible for the hydrolysis of the depolarizing muscle relaxant succinylcholine to succinyl monocholine and choline. It also accounts for the metabolism of the nondepolarizing muscle relaxant mivacurium and, to a lesser extent, ester local anesthetics, diamorphine, aspirin, and methylprednisolone. Genetic variation has accounted for reduced activity of this enzyme and is most clinically relevant to prolonged succinylcholine paralysis or *scoline apnea.* Investigating scoline apnea involves using inhibitors of plasma cholinesterase such as dibucaine (cinchocaine) and sodium fluoride and quantifying the reduction in activity that one should encounter in a normal enzyme. Four alleles—usual normal (Eu), atypical dibucaine-resistant (Ea), silent absent (Es), and fluoride-resistant (Ef)—have been identified on chromosome 3. Single–amino acid substitutions have resulted in each of these variants. Although most individuals are homozygous for Eu, up to 4% of the population have at least one deleterious allele, thus increasing the risk of a prolonged neuromuscular block, which can last between 10 minutes and several hours.

Glucose-6-Phosphate Dehydrogenase Deficiency

Erythrocytes are obligate glucose users and rely on the pentose phosphate pathway for its metabolism. Glucose-6-phosphate dehydrogenase (G6PD) is the rate-limiting enzyme in this pathway converting glucose-6-phosphate to 6-phosphoglucono-δ-lactone. The reaction usually provides energy for the cell in the form of reduced nicotinamide adenine dinucleotide phosphate, which is needed for the maintenance of reduced glutathione levels (Fig. 7.5). Reduced glutathione has an important role in combating hydrogen peroxide produced within the cell during periods of oxidative stress. Individuals with G6PD deficiency therefore can have dangerously high levels of hydrogen peroxide (resulting in protein damage and cell death) under periods of oxidative stress. This can occur when oxidizing drugs such as primaquine, chloroquine, chloramphenicol, some sulfonamides, and vitamin K analogs



• **Fig. 7.5** Physiologic activation of the ryanodine receptor Ca^{2+} release channel (RyR1). Mg^{2+} exhibits a regulatory role on the RyR1. Panel A: At rest, Mg^{2+} inhibits the opening of RyR1. Panel B: Muscle activation is initiated by the generation of an action potential across the sarcolemma. Panel C: As an action potential arrives down the T-tubule the dihydropyridine receptor acts as a voltage sensor, with the change in membrane potential causing a change in conformation of a cytoplasmic loop of the dihydropyridine receptor, which interacts with RyR1 to overcome the inhibitory effect of Mg^{2+} thus allowing Ca^{2+} release. *Ca^{2+}*, Calcium ion; *Mg^{2+}*, magnesium ion.

are administered in susceptible individuals with the ultimate consequence being hemolytic anemia. The highest prevalence of G6PD deficiency appears in falciparum malaria zonal populations as this deficiency appears to confer a survival advantage against the parasite.

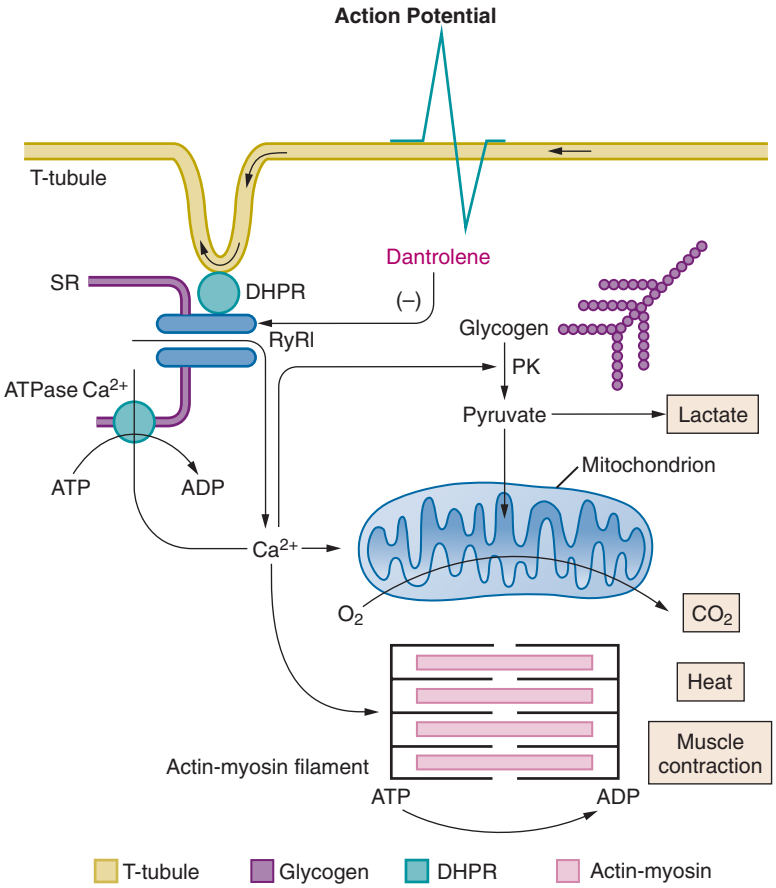
The Porphyrias

The porphyrias are a group of rare conditions caused by the excessive buildup of porphyrinogens, which are the precursors of heme. In affected individuals these porphyrinogens are excreted in urine and on exposure to light change color, resulting in the classic purple urine. The metabolic pathway for heme synthesis is shown in Fig. 7.6. Under normal circumstances heme tightly controls its own production by feedback inhibition of the first of the seven enzymes in the pathway, δ-aminolevulinic acid (ALA) synthetase. This feedback inhibition can be disrupted in periods of bleeding or metabolic stress (infection, dehydration, fasting) resulting in induced ALA synthetase activity. A block in any of the enzymes in the pathway will result in accumulation of porphyrin precursors. An acute attack can result in porphyrinogen disrupting the nervous system leading to motor, sensory and autonomic dysfunction. Of particular importance to anesthesia is the potential for many drugs to induce the activity of ALA synthetase. Drugs such as barbiturates, etomidate, halothane, clonidine, metoclopramide, lidocaine, prilocaine, diclofenac, and ranitidine have all been implicated in precipitating an acute attack in susceptible individuals.[28] There is some controversy surrounding the porphyrinogenicity of propofol. Animal experiments have shown it to induce ALA synthetase activity, and propofol infusions have resulted in raised porphyrin levels in humans with acute porphyria. Nevertheless, there are anecdotal reports of its safe use in patients with porphyria.[29,30]

Malignant Hyperthermia

Malignant hyperthermia (MH) is a potentially lethal pharmacogenetic disorder attributable to faulty skeletal muscle intracellular calcium homeostasis. The disorder is genetically heterogeneous, but the final common pathophysiologic path is a loss of regulation of the calcium-release units of the myocytes. Fundamental to normal functioning of the calcium-release units is a tightly regulated bidirectional interaction between the voltage sensor of the T-tubular sarcolemmal membrane (dihydropyridine receptor [DHPR]) and the calcium release channel of the sarcoplasmic reticulum (ryanodine receptor isoform 1 [RyR1]). A majority of families with MH subjected to genetic investigations have potentially causative variants in *RYR1*, the gene encoding RyR1. In other families, pathologic variants in *RYR1* have been excluded. A small minority of these have variants in *CACNA1S*, the gene encoding the α_1-subunit of DHPR. In the remaining 10% to 25% of families the gene or genes underlying MH remain to be identified. Potential candidate genes encoding proteins known to interact with RyR1 and DHPR number more than 30, but there is currently no evidence that any of these are implicated in MH. Further elucidation of the genetic etiology of MH will require genome-wide "next-generation" sequencing approaches.

Direct intracellular calcium measurements of muscle cells from humans and transgenic mouse models suggest, contrary to previous assumptions, that calcium cycling is abnormal even without exposure to triggering agents. Even though calcium sequestration



• **Fig. 7.6** Site of dantrolene action preventing a chain of intracellular mechanisms leading to muscle contraction, generation of heat, lactate, and CO_2. Release of Ca^{2+} is central to glycogen metabolism, mitochondrial respiratory function, and contraction of actin-myosin filaments. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate, *ATPase,* adenosine triphosphatase; *Ca^{2+},* calcium ion; *CO_2,* carbon dioxide; *DHPR,* dihydropyridine; *O_2,* oxygen; *PK,* pyruvate kinase; *SR,* sarcoplasmic reticulum; *RyR1,* ryanodine receptor isoform 1.

is upregulated, cytoplasmic resting calcium ion concentration is elevated and evidence is emerging that this may predispose to sarcopenia or even frank myopathy in the long term. The most obvious manifestation of MH susceptibility is, however, a pharmacologically triggered massive and persistent increase in cytoplasmic calcium ion concentration (see Fig. 7.6). This results in metabolic stimulation and sustained contractile activity with disruption of sarcolemmal integrity. The clinical consequences are increased oxygen consumption, carbon dioxide production and tachycardia, hyperthermia, acidosis, rhabdomyolysis, and muscle rigidity. A critical stage appears to be related to mitochondrial failure brought about by mitochondrial calcium accumulation secondary to the cytoplasmic calcium accumulation. Death results from any one, or a combination, of hyperkalemia, disseminated intravascular coagulopathy (secondary to hyperthermia), profound acidosis, or hyperthermia per se.

The pharmacology of MH triggering has been reviewed.[31] Essentially, the primary triggers of MH are the potent inhalation anesthetics, including all the currently available agents (isoflurane, sevoflurane, desflurane). They appear to act on RyR1 by overriding the physiologic magnesium inhibition of the channel. The clinical effect may be almost immediate and rapidly progressive or more insidious with signs in some reports delayed for more than 6 hours into anesthesia. Succinylcholine is likely to cause generalized or jaw muscle rigidity and also seems to enhance the onset and severity of a reaction triggered by subsequent exposure to a volatile anesthetic, but at worst is only a weak trigger of the hypermetabolic MH response when administered without a potent inhalation agent. There is no convincing evidence that any other drugs can trigger MH.

Successful treatment of MH depends on early recognition of the evolving reaction. A combination of unexplained tachycardia and an unexplained increase in carbon dioxide (CO_2) production makes the diagnosis likely. An increasing body temperature may be observed almost simultaneously or can be delayed for several minutes. Treatment involves discontinuation and enhancement of elimination of volatile anesthetics (including the use of adsorbents such as charcoal filters inserted in the anesthetic breathing circuit), hyperventilation with 100% oxygen (O_2), body cooling, and administration of dantrolene, a drug that reduces sarcoplasmic reticulum calcium release. General supportive measures are used to treat acidosis, hyperkalemia, myoglobinemia, arrhythmias, and disseminated intravascular coagulation.

Allergic Drug Reactions

Allergic reactions to drugs administered intravenously are acute type I hypersensitivity reactions. This requires an allergen to be exposed to an individual for a second or subsequent time. Epidemiologic data for anesthetic allergic reactions are divergent as some confusion remains as to the definitions of allergy and anaphylaxis. Indeed, some reactions that are accepted as side effects of certain drugs—for instance, histaminergic reactions owing to atracurium and mivacurium—may be underreported.[32] The European Academy of Allergy and Clinical Immunology defines allergy as follows:

> Allergy is a hypersensitivity reaction initiated by immunological mechanisms. Allergy can be antibody- or cell-mediated. In the majority of cases the antibody typically responsible for an allergic reaction belongs to the IgE isotype and these individuals may be

TABLE 7.2 Anaphylaxis Grades Defined for the NAP6 Project of the Royal College of Anaesthetists (2015)

Grade	Features
1 Not life-threatening	Rash, erythema, and/or swelling
2 Not life-threatening	Unexpected hypotension—not severe (e.g., not requiring treatment) And/or bronchospasm—not severe (e.g., not requiring treatment) ±Grade 1 features
3 Life-threatening	Unexpected severe hypotension And/or severe bronchospasm And/or swelling with actual or potential airway compromise ±Grade 1 features
4 Life-threatening	Fulfilling conditions for cardiopulmonary resuscitation
5 Life-threatening	Fatal

NAP6, Sixth National Audit Project.
(www.nationalauditprojects.org.uk/NAP6home#pt)

referred to as suffering from an IgE-mediated allergy. Not all IgE associated 'allergic' reactions occur in 'atopic' subjects. In non-IgE-mediated allergy the antibody can belong to the IgG isotype, e.g. anaphylaxis due to immune complexes containing dextran, and the classical, nowadays rare, serum sickness previously referred to as a Type III reaction. Both IgE and IgG antibodies are found in allergic bronchial pulmonary aspergillosis (ABPA). Allergic contact dermatitis is representative of allergic diseases mediated by lymphocytes.[33]

Anaphylaxis is essentially a severe, life-threatening, generalized or systemic hypersensitivity reaction.[34] It has recently been reclassified as a spectrum of disease, and for the purposes of recent national audits in the United Kingdom, was categorized into five grades based on severity of reaction and need of intervention (Table 7.2). The clinical features (hypotension, tachycardia or bradycardia; cutaneous flushing, rash or urticaria; bronchospasm; hypoxia; angioedema and cardiac arrest) usually occur within a few minutes but may be delayed for up to an hour. True allergic anaphylactic reactions involve mast cell degranulation resulting from production of allergen-specific immunoglobulin (Ig) E, IgG, or complement activation. Nonallergic anaphylactic reactions can occur through a direct drug action on the mast cell itself. True allergic anaphylaxis can occur after exposure to the smallest dose of antigen. Direct mast cell degranulation (non–IgE-mediated response) is probably dependent on the mass of drug and its rate of administration. However, in these circumstances there is unlikely to be any response to a test dose, but the full dose will cause the reaction. It is advisable, therefore, to administer intravenous drugs slowly.

The products of mast cell degranulation that are the mediators of the anaphylactic response include principally histamine and other vasoactive amines but also proteases (such as tryptase) and lipid-derived mediators (such as leukotrienes and prostaglandins). These mediators can affect the skin (flushing and urticaria), the vasculature (vasodilatation and increased capillary permeability), and the respiratory system (bronchoconstriction, inflammation, and increased bronchial secretions). Not all of these features occur in every anaphylactic reaction. Some reactions are characterized by the predominance of vasodilatation, whereas bronchoconstriction predominates in others. This probably reflects the presence of two main types of mast cells: mucosal mast cells that are located in the lungs and the gut and connective tissue mast cells that are ubiquitous.[35] The relationship between individual drugs and the spectrum of clinical features is not consistent between patients with reactions, although some drugs (e.g., atracurium, morphine) frequently produce cutaneous reactions without systemic vasodilatation or bronchoconstriction. This suggests that cutaneous connective tissue mast cells are particularly sensitive to these drugs.

Our ability to investigate suspected anaphylactic reactions is imprecise. Histamine release is difficult to measure because the half-life in the serum of the amine is so short. Its metabolite, methylhistamine, is more stable and can be detected in the urine. Alternatively, mast cell degranulation can be demonstrated by serum mast cell tryptase levels (taken as soon as practical after the reaction and compared with a baseline 24 hour later), whereas complement assays might point to a particular mechanism. The availability of allergen specific radioallergosorbent tests for drugs used during anesthesia is limited, although they are available for succinylcholine, penicillins, and chlorhexidine. Interestingly a radioallergosorbent test using morphine as the allergen has been shown to be a useful marker of sensitization to neuromuscular blocking drugs, where the quaternary ammonium group is the allergenic epitope. Cross-sensitization between IgE antibodies to pholcodine and neuromuscular blocking drugs has been proposed to explain the increased incidence of anaphylaxis to neuromuscular blocking drugs in countries where pholcodine-containing cough mixtures are used.[36]

The mainstay for diagnostic testing to identify the causative agent following perioperative anaphylaxis is skin testing in the form of skin-prick testing and/or intradermal tests. Skin-prick tests tend to be less sensitive but more specific than intradermal tests and guidelines generally recommend initial skin-prick testing, progressing to intradermal tests if skinprick test results are negative.[37]

There continues to be great controversy surrounding the anaphylactic potential of nondepolarizing neuromuscular drugs. A study in France demonstrated that muscle relaxants were implicated in 60% of anesthesia-associated type I hypersensitivity reactions; the largest proportion of these were caused by succinylcholine followed by rocuronium.[38] In North America and Australia the incidence of reactions to muscle relaxants other than succinylcholine is low. One explanation for this epidemiologic disparity is the conduct and interpretation of intradermal testing. A growing body of evidence suggests that using the correct dilutions for each drug may improve the specificity of this test.[39-41]

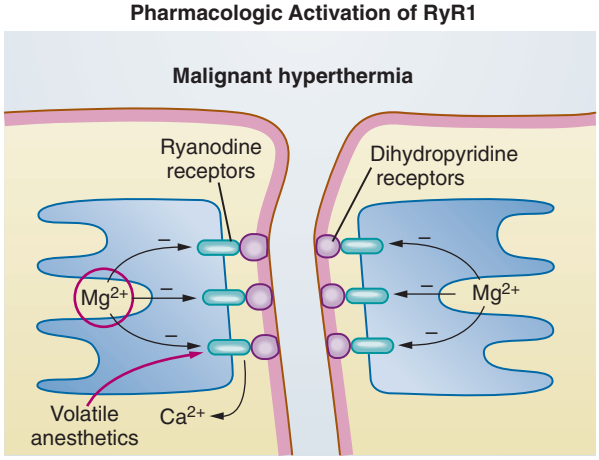
The difficulty in making an accurate diagnosis makes quantifying the incidence of anaphylaxis rather challenging, with estimates typically in the range of 1 : 4,000 to 1 : 13,000 anesthetics.[42,43] However, these estimates are based on reported cases and recent data suggest that 1 : 350 patients develop signs of anaphylaxis during anesthesia.[44] Other drug groups commonly implicated are intravenous anesthetic agents, plasma substitutes, and antibiotics. The emergence of teicoplanin as an alternative antibiotic for patients reporting a penicillin allergy has resulted in an increasing number of allergic reactions to teicoplanin.[45] With the decline in use of latex gloves, sensitivity to this allergen is becoming less of a problem. Reactions to latex are characterized by their development after 30

to 60 minutes of surgery, whereas drug reactions tend to occur within seconds or a few minutes of drug administration. The use of chlorhexidine as an antiseptic skin wash but also as an antibacterial coating to bladder and central venous catheters can be associated with severe systemic hypersensitivity reactions.[46] Anaphylactic reactions to local anesthetics are extremely uncommon; the esters more likely than amides to induce a reaction. Similarly, it is unlikely that a cutaneous histamine reaction to opioids (particularly morphine, meperidine, and codeine) is attributable to anaphylaxis. A careful history in this instance can prevent a patient from being labeled as allergic, thus limiting them from effective perioperative analgesia. It is well known that reactions to nonsteroidal antiinflammatory drugs can occur in susceptible individuals owing to the inhibition of the prostaglandin (PG) E_2 pathway, resulting in excessive leukotriene synthesis.[47] The subsequent mediator release is associated with bronchospasm and urticaria, yet an IgE-mediated reaction is reportedly rare. A U.K. guideline is a useful resource for managing allergy and anaphylaxis.[48]

Type C Reactions: Chronic (Direct Organ Damage, Dose-Related, and Time-Related)

Over time drugs can exert a cumulative unwanted effect. Examples in anesthesia include bleomycin resulting in oxygen-induced lung damage and volatile anesthetics causing hepatocellular (halothane) and renal (methoxyflurane) toxicity.

Bleomycin is a chemotherapeutic agent used to treat metastatic germ cell cancer and, in some regimens, non-Hodgkin lymphoma. The principal problem associated with the use of bleomycin is progressive pulmonary fibrosis in 10% of patients. This is dose related, occurring more commonly at cumulative doses greater than 400 units, creatinine clearance less than 35 mL/min, and in the elderly.[49] Both iron and oxygen are cofactors for DNA cleavage by bleomycin (Fig. 7.7). Basal lung crepitations or suspicious chest radiograph changes are an indication to stop therapy. Patients who have received extensive treatment with bleomycin are at risk of developing respiratory failure if subsequently exposed to a high inspired oxygen concentration. A case series of five patients by Goldiner and colleagues in 1978 highlighted that intraoperative inspired concentrations between 0.35 and 0.42 led to respiratory failure and subsequent death.[50] This resulted in a recommendation to use low concentrations of oxygen in such cases. In contrast, a 6-year audit of 13 patients similar to Goldiner's group showed no difference in lung complications between bleomycin-treated patients undergoing surgery with either 24% or 41% inspired oxygen.[51] One difference between these two studies was that Goldiner and colleagues had documented restricted lung disease and decreased CO_2 diffusion capacity secondary to bleomycin treatment. The other study did not perform pulmonary function tests on all their patients, and the majority of those who were tested had normal function. This would suggest that preexisting bleomycin lung damage as shown on lung function tests is a key factor in the risk of hyperoxic lung injury. Several case reports using differing fractions of inspired oxygen in patients with varied cumulative bleomycin exposure have shown mixed results, but it appears prudent to use the lowest concentration of oxygen possible for the shortest duration that the clinical condition can allow, a worthy practice in all patients.



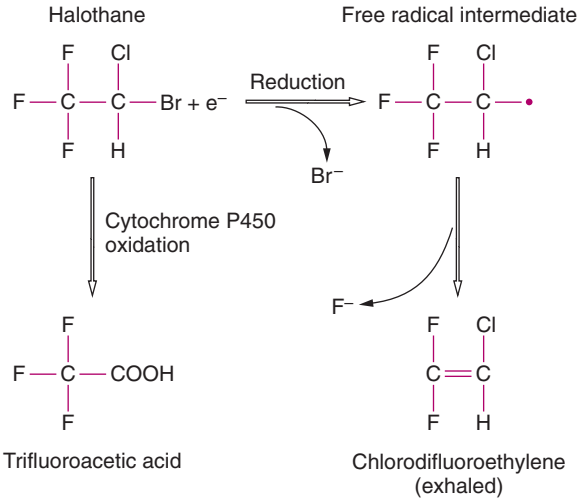
• **Fig. 7.7** Loss of inhibitory effect of Mg^{2+} on ryanodine receptor from inhalational anesthetics. The result is sustained Ca^{2+} release from the sarcoplasmic reticulum. Dantrolene acts by reducing pathologic release of Ca^{2+} from the sarcoplasmic reticulum that leads to muscle contraction, generation of heat, lactate, and CO_2. Release of Ca^{2+} is central to glycogen metabolism, mitochondrial respiratory function, and contraction of actin-myosin filaments. *Ca^{2+}*, Calcium ion; *CO_2*, carbon dioxide; *Mg^{2+}*, magnesium ion; *RyR1*, ryanodine receptor isoform 1.

The volatile anesthetics used in current practice can also lead to direct end-organ damage. All contain at least one fluorine atom, and following metabolism the fluorine ion (F^-) ion created can lead to nephropathy. Halothane undergoes the greatest amount of metabolism by hepatic cytochrome P450 (up to 25%) and desflurane the least (0.02%). Fluoride toxicity was first recognized in the 1960s with the introduction of methoxyflurane. A serum fluoride level greater than 50 µmol/L over a prolonged time was associated with polyuria, proteinuria, glycosuria, and impaired renal concentrating ability. However, about 5% of inhaled sevoflurane undergoes metabolic biotransformation (oxidative defluorination), readily releasing fluoride concentrations exceeding 50 µmol/L and yet studies have failed to demonstrate subsequent renal damage.[52]

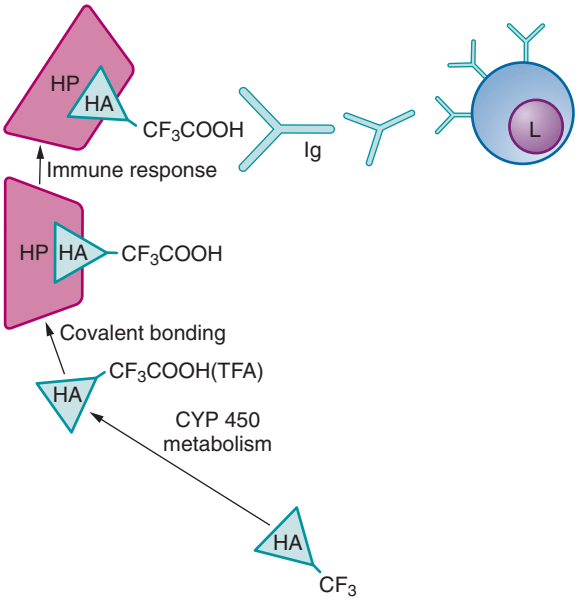
Another by-product of sevoflurane metabolism is compound A (fluoromethyl-2,2-difluoro-1-[trifluoromethyl] vinyl ether), which is produced by its interaction with CO_2 absorbents (see Chapter 3). There is debate surrounding the mechanism leading to renal toxicity with the renal cysteine conjugate β-lyase pathway (involved in the biotransformation of compound A) playing a significant role. The β-lyase pathway is up to 30-fold less active in humans than in rats. If this pathway is responsible, humans may be less susceptible to compound A renal toxicity than rats. Studies in humans have shown that long (8-hour) sevoflurane exposures and low fresh gas flow rates can result in significant production of compound A.[53] Urinalysis revealed transient changes in biochemical markers of renal injury; however, other studies using prolonged sevoflurane administration at low flow rates suggest no risk of this compound. A useful review of the association of sevoflurane and renal injury is available.[54]

Direct liver damage from halothane (halothane hepatitis) is becoming less of a problem in the developed world because of its decline in use. Its estimated incidence is 1:35,000 administrations, with risk factors including late middle age, female sex, and obesity. There are two reported types of halothane hepatitis. Type 1 is an asymptomatic, spontaneously resolving rise in serum transaminases within 2 weeks of exposure. It is most likely attributed to hepatic hypoxia secondary to hypoperfusion. A reductive pathway leading to an insertion of a single electron into the halothane molecule produces a highly reactive metabolite that undergoes debromination to another free radical intermediate (Fig. 7.8). These free radicals then lead to destruction of hepatocytes.

Type 2 hepatitis leads to fulminant hepatic necrosis with a mortality rate of 50% to 75%. There appears to be a correlation between the amount of halothane used and the severity of liver failure but not the likelihood of it occurring. An immune basis is responsible with the oxidative metabolite (trifluoroacetyl chloride) behaving as a hapten, covalently bonding to hepatic proteins and inducing antibody formation (Fig. 7.9). Onset can be by the seventh day after administration or relatively delayed compared with direct hepatotoxic drugs such as acetominophen for up to 28 days.



• **Fig. 7.8** Proposed metabolic pathway implicated in halothane hepatitis. A reductive pathway leading to addition of a single electron into the halothane molecule produces a highly reactive metabolite that then undergoes debromination to another free radical intermediate. These free radicals lead to destruction of hepatocytes and trifluoroacetic acid can react with proteins to form neoantigens. *Br^-*, Bromide ion; *e^-*, electron; *F^-*, fluoride ion.



• **Fig. 7.9** Neoantigen (hapten) formation. Halogenated anesthetics *(HA)* are metabolized by cytochrome P450 *(CYP 450)* enzymes into metabolites such as trifluoroacetic acid *(TFA)* that form covalent bonds with hepatic proteins *(HP)*. The modified proteins act as neoantigens that trigger an immune response, with immunoglobulin *(Ig)* production by lymphocytes *(L)* that then interact with the newly formed neoantigen.

Type D Reactions: Delayed (Time-Related)

Certain adverse drug reactions are not apparent until a significant amount of time has elapsed since the initial administration of the drug. Nitrous oxide (N_2O), one of the earliest inhalational anesthetic agents introduced, has been well reported to increase the risk of megaloblastic bone marrow changes and subsequent neurologic complications (subacute combined degeneration of the spinal cord) owing to vitamin B_{12} deficiency. Short exposure for a few hours can lead to bone marrow changes, and more prolonged exposure of several days can lead to agranulocytosis. The cobalt ion (Co^+) present in vitamin B_{12} is oxidized by N_2O (to Co^{2+}), thus preventing it from activating methionine synthase. This enzyme is responsible for the conversion of homocysteine into methionine, thymidine, tetrahydrofolate, which are essential steps in DNA synthesis (Fig. 7.10). The subsequent accumulation of plasma homocysteine could in theory increase the risk of perioperative myocardial events but no strong evidence appears to support this. An attempt to prevent this adverse effect with preoperative vitamin B infusions was not successful.[55]

The use of etomidate as an induction agent with sepsis continues to be a matter of debate. There is no doubt that a single dose of etomidate suppresses adrenocortical function by inhibiting enzymes (11β-hydroxylase and 17α-hydoxylase) essential for cortisol and aldosterone synthesis (Fig. 7.11). The effect can appear as early as 30 minutes after administration but may not occur until several hours later. These hormones play an important role in the stress response, and although there is evidence of increased mortality if etomidate is used in patients with sepsis, the studies are limited by their observational design.

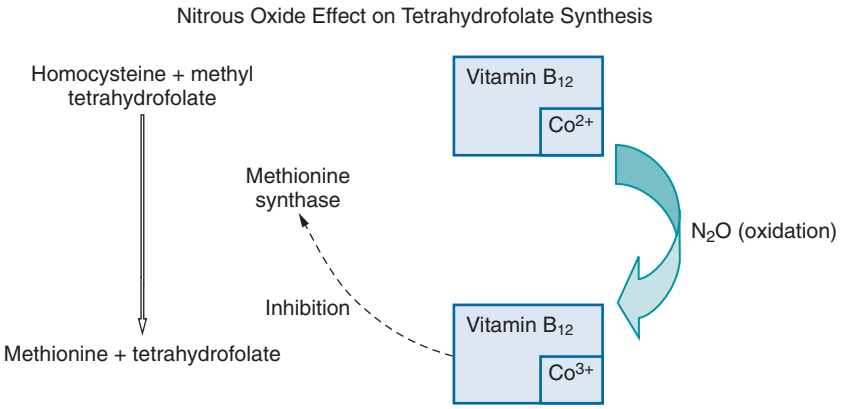
Type E Reaction: End of Use (Withdrawal)

Acute withdrawal of drugs is recognized to cause harmful effects. Of interest to anesthesiologists is the withdrawal of common drugs in the community such as alcohol, nicotine, and opioids to which patients become dependent. These effects usually result in detrimental psychiatric, neurologic, and cardiorespiratory consequences. Acute opioid withdrawal in patients on intensive care has also been shown to induce allodynia and hyperalgesic pain states. More recently the withdrawal of cardioprotective agents such as β-blockers and statins has been suggested to increase the risk of perioperative cardiac events, and certain centers advocate continuation of preoperative antihypertensive medication for the same reason.

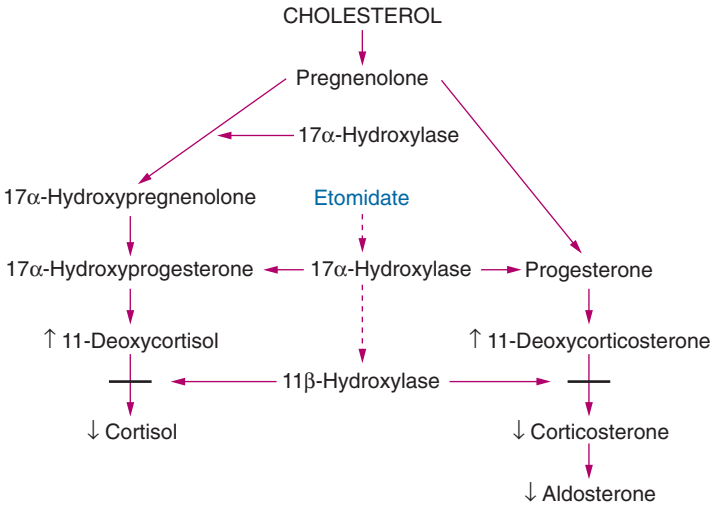
Owing to differences in blood-gas partition coefficients, acute withdrawal of inhaled N_2O can in theory lead to diffusion hypoxia. At the end of anesthesia, if an N_2O/O_2 mixture is replaced by air/O_2, the volume of N_2O that enters the alveolus from the blood will be greater than the volume of N_2 (from the air) entering the pulmonary capillaries. This can create an unwanted dilution of all the alveolar gases; thus supplemental oxygen is advised to prevent this (see Chapter 3).

Type F Reactions: Drug Failure

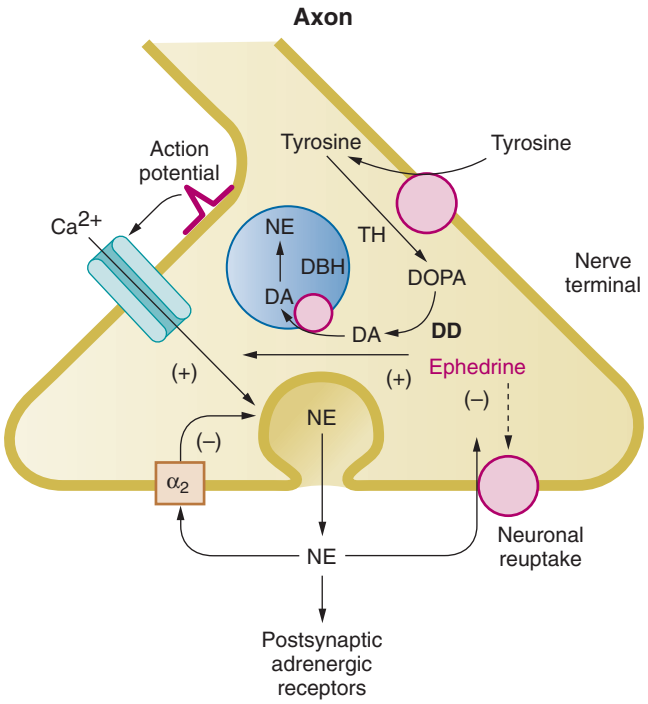
Any drug can fail. There can be a multitude of reasons why a drug fails to produce its desired effect, but by far the most common reason is inadequate dosing. As mentioned earlier, the response to a given dose range can vary within a population. Those at the lower end of the dose-response curve may not attain the desired effect of the drug. Another common reason for drug failure is



• **Fig. 7.10** Mechanism of nitrous oxide *(N_2O)* toxicity. The cobalt ion in vitamin B_{12} is oxidized by nitrous oxide, thus preventing it from activating methionine synthase. This enzyme is responsible for the conversion of homocysteine to methionine, and subsequently thymidine and tetrahydrofolate, which are essential for DNA synthesis. *Co^{2+}*, Cobalt (II) ion; *Co^{3+}*, cobalt (III) ion.



• **Fig. 7.11** Mechanism of immunosuppression by etomidate. The steroid synthetic pathway is shown highlighting enzymes (11β-hydroxylase and 17α-hydroxylase) essential for cortisol and aldosterone synthesis. 11β-Hydroxylase is inhibited by etomidate arrows leading to reduced adrenocortical steroid synthesis with possible adverse effects. (Dashed line = inhibitory.)



• **Fig. 7.12** Tachyphylaxis with ephedrine. Synthesis of norepinephrine *(NE)* depends on the hydroxylation of tyrosine by tyrosine hydroxylase *(TH)* to dihydroxyphenylalanine *(DOPA)*. DOPA is metabolized to dopamine *(DA)* by DOPA decarboxylase *(DD)*. DA enters vesicles where it is hydroxylated by dopamine β-hydroxylase *(DBH)* into NE. Release of NE is enhanced by ephedrine; if the rate of release exceeds norepinephrine synthesis, then ephedrine can fail to work. *Ca^{2+}*, Calcium ion.

interaction with other medications (e.g., antagonists as in the use of β-agonists in patients taking β-blockers; also see Chapter 6).

Despite the aforementioned reasons, there are other specific reasons a drug might fail in an individual depending on the pharmacogenomic profile of the patient. Many drugs rely on active enzyme systems for activation. As alluded to earlier, the cytochrome family of enzymes is responsible for metabolism of numerous drugs of relevance to anesthesiologists. An example is cytochrome CYP 2D6, which is responsible for metabolism of the weaker opioids codeine, dihydrocodeine, tramadol, oxycodone, and hydrocodone (see Chapter 4). The clinical effect of these drugs relies on the formation of more potent hydroxyl metabolites, such as morphine, dihydromorphine, and oxymorphone. The gene encoding CYP 2D6 exhibits significant polymorphism, with 100 variant alleles. This results in a number of clinical phenotypes: poor metabolizers, intermediate metabolizers, extensive metabolizers, and ultrarapid metabolizers. Approximate frequencies of these phenotypes for the Caucasian population are 5% to 10% for poor metabolizers, 10% to 15% for intermediate metabolizers, 65% to 80% for extensive metabolizers, and 5% to 10% for ultrarapid metabolizers.[56] Poor metabolizers are unlikely to attain beneficial effects of these drugs.

Another mechanism of drug failure includes depletion of critical substrates for drug action. *Tachyphylaxis*, the loss of effect with repeated or continuous use, describes this phenomenon with ephedrine (which depends on vesicular norepinephrine release, nitroglycerin, dobutamine, and hydralazine, for example). Tachyphylaxis with repeated ephedrine use is illustrated in Fig. 7.12. Similar loss in drug efficacy can occur with receptor *desensitization*, which results from post-translational modification or downregulation of receptors (Chapter 1). An example of this is densensitization to the effects of the β-agonist dobutamine with continuous infusion,

which results from downregulation of β_2-adrenoreceptor number. Drug-free intervals can replenish stores of necessary substrates or resensitization or transport of necessary receptors, allowing the drug to take effect once more.

Emerging Developments

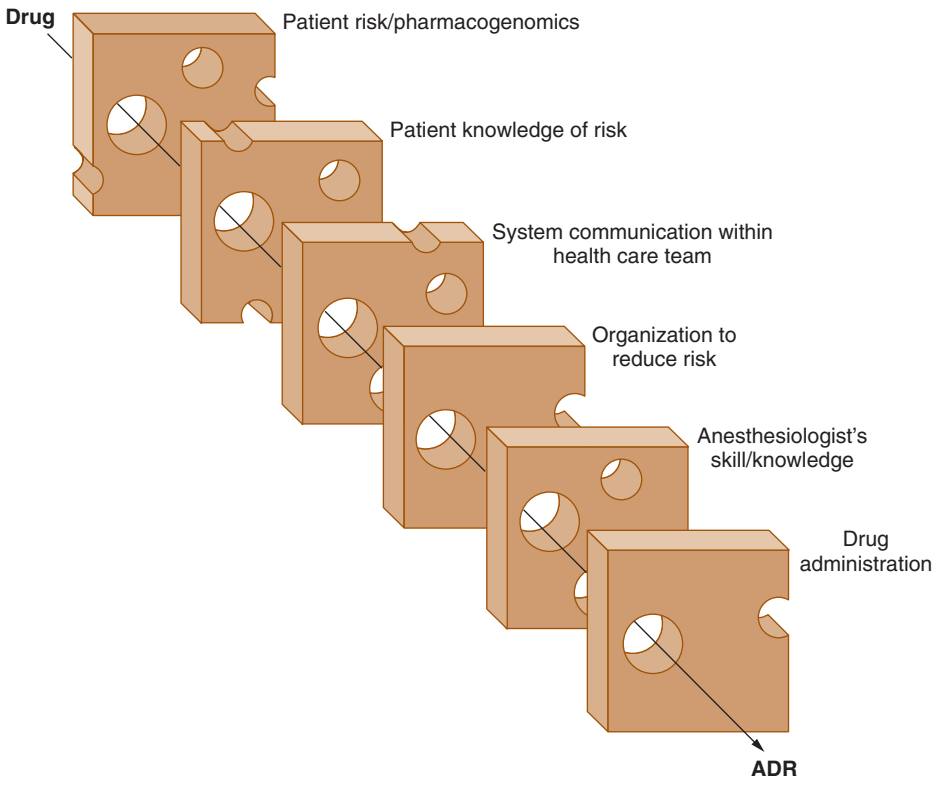
"Swiss Cheese" Model in Adverse Drug Reactions

Much current and future work surrounding adverse drug reactions focuses on prevention, in particular the prevention of drug errors. In practice there are many stages where error can occur, ultimately leading to an adverse drug reaction. A Swiss cheese model depicting human error has been described.[57] In the anesthetic context, patients can present for emergency surgery involving a multidisciplinary health care team whereby the anesthesiologist will ultimately administer a drug (Fig. 7.13). An adverse drug reaction can occur if all the deficiencies in the system (or holes in the cheese slices) align. The focus of modern medical practice is on the delivery of safe, effective care. Any adverse event or serious untoward incident is usually subject to an investigation or root cause analysis. The aim of these investigations is not to blame individuals but to understand deficiencies in a patient's care pathway that led to the unwanted incident. This is based on the logic that humans are prone to error and a system should be created to mitigate that error. The hope is that lessons learned from previous mistakes will guide alterations in future management, thus preventing further harm. A perfect flawless pathway is a goal that health care systems continue to strive for.

New developments that might prevent adverse drug reactions include toxicogenomics, which embraces the latest technology for compound classification, mechanistic studies, and detection of toxicity markers.[58] In addition, pharmacogenomics may help us understand more about genetic polymorphisms that underpin individual variance in drug response; however, this rapidly expanding field brings new ethical considerations regarding informed consent for clinical trials, pharmacogenomic profiling, and storage of genetic material.[59] Another developing area is metabonomics.[60] This is a powerful tool for translating disturbances in normal homeostasis of metabolic processes into drug-induced pathology. Using the latest advances in mass spectrometry and nuclear magnetic resonance spectroscopy, specific biomarkers can be detected, which is resulting in traditional chemical laboratories being replaced.

New Technology to Decrease Drug Errors in Anesthesia

Extensive work has been undertaken to research the causes and possible preventions of drug errors. Anesthesia is a unique specialty in which, for most cases, the same person prescribes, draws up, and administers medications to a patient without any secondary checks. Therefore such a process is more vulnerable to human error and any precautions that can be taken to prevent this should



• **Fig. 7.13** Swiss cheese model of anesthetic drug errors. Error can occur at any point in the medical care pathway, appearing as holes in cheese slices. If a patient has the genetic profile or an unknown risk factor for an adverse drug reaction *(ADR),* it is up to the health care team to elucidate this potential risk, communicate it to the team, and arrange appropriate measures to mitigate the risk of a hazardous drug being administered. If the anesthesiologist is unaware of which drugs are potentially hazardous or how to administer, then all the holes in the cheese slices align and an ADR occurs.

be considered. In a recent review, 138 recommendations from 74 articles were compiled and considered to help prevent drug errors.[61] Action has already been taken on some these in recent years; for example, efforts are being taken to remove the Luer-lock connectors on neuraxial injection devices to prevent accidental injection of the incorrect drug intrathecally/epidurally. Other suggestions (barcode labeling of drug syringes, for example), while using new technologies, have not been universally embraced.[61]

One area where technology has advanced in reducing medication errors is with infusion pumps. Although infusion pump technology has advanced, so has the potential for errors arising from more complex pump programming. Work undertaken by Syroid et al.[62] demonstrated that by simplifying programs using a graphic user interface, errors were reduced significantly, although this study was performed only in simulated scenarios.

Infusion pumps with built-in drug error–reducing software (DERS) have been available since 2004. This software is essential in helping to reduce the risk of overdosing/underdosing drug delivery to the patient based on a set of parameters entered into the program. Although efforts are continuing to promote the use of this type of pump, incorporating their use in the U.K. health care sector has been slow (39% in 2014).[63] Research into the effectiveness of this class of pumps is still ongoing, with some studies suggesting that, despite the presence of DERS, errors are still quite high, although better than when previously assessed.[64]

A trial involving the creation of an anesthetic medication template for anesthetists to place their drawn-up drugs and thereby standardize drug placement before administrations has recently been reported.[65] The results suggest that the system has the potential to reduce the rate of drug administration errors.

Key Points

- A large proportion of adverse drug reactions is due to preventable administration error. The latest trend is to ensure that drugs are double- or even triple-checked. This is of particular importance in pediatric anesthesia where the margins for error with some drugs are extremely small.
- Drugs can exhibit predictable dose-dependent adverse reactions, yet unpredictable idiosyncratic reactions are often the most life-threatening and most challenging to manage.
- Some drugs exhibit adverse effects over a period of time, occasionally a long time after initial administration. In the case of bleomycin, knowledge of prior use is important so administration of high concentrations of oxygen can be minimized.
- Anaphylaxis remains a relatively unpredictable and potentially fatal complication. The ability to investigate allergic and nonallergic anaphylaxis remains crude.
- Genetic variations within populations can have a major influence on the effect of the drug in an individual and can be a basis for an adverse drug reaction. Well-known genetic variations responsible for adverse drug reactions in anesthesia include pseudocholinesterase deficiency and malignant hyperthermia.
- The volatile anesthetics can lead to direct damage to the kidneys and liver; halothane hepatitis is the most severe complication.
- Withdrawal effect from a drug is a serious complication, which is of interest to anesthesiologists who usually have direct control over withholding a patient's medication.
- Genetic variations within populations can have a major influence on the effect of the drug in an individual. The genetic makeup that determines how individuals metabolize drugs can mean that some drugs have a greater effect or some will simply fail to act.
- The Swiss cheese model of adverse event evolution is applicable to understanding adverse drug reactions of some types. New technology and guidelines are emerging to mitigate and prevent adverse drug reactions in anesthesia that sometimes occur because of human error.

The neuron is the fundamental unit of information processing and transfer in the central nervous system (CNS). It is, however, the collective activity of hierarchically organized neuronal circuits and networks that underlies its behavioral and homeostatic functions. These functions are *emergent* properties of a complex system. Therefore the CNS has to be examined on different organizational levels: properties characteristic of a functional unit on one level of organization are absent from lower-level elements and cannot predict properties of a higher-level unit. How exactly behavior emerges from the activity of individual neurons, circuits, and networks is a question at the cutting edge of research.

Individual neurons and/or their organelles carry the primary molecular targets of anesthetic drugs. Current thinking attributes most of the desirable effects of general anesthetics to the modulation of membrane proteins. Drug-induced alterations in the function of many voltage-, transmitter-, and otherwise gated channels are relatively well characterized. By contrast, how these alterations propagate through increasing levels of complexity to finally result in sedation, amnesia, hypnosis, and immobility is less well understood. General anesthetics also affect second-messenger systems either directly or via effects on G-protein–coupled receptors and mitochondria. The significance of the latter effects for anesthesia is unclear.

Historical Perspective

The brain: ancient Egyptians tossed it when preparing the body for the journey into the afterworld. Aristotle thought it a radiator to cool the heart. But more than 2000 years and dozens of Nobel Prizes later, the American Society for Neuroscience alone counts more than 35,000 members, many of whom devote their lives to its study.

Except for the last decade of the 19th century, brain science in the 1800s was dominated by physicians such as Broca, Wernicke, Fritsch, and Brodmann. They and others started the process of a functional localization of the brain. Pavlov linked psyche to behavior and learning with the development of the concept of the conditioned reflex, which is still widely used in neuroscience today. His achievements were honored with the Nobel Prize in 1904. In 1906, Golgi shared the 1906 Nobel Prize with Ramón y Cajal, two central protagonists in the grand debate on the cellular versus reticular organization of the brain. The debate was settled in favor of Cajal's view that discrete cells as opposed to a reticulum formed the structure of the brain. However, as nature is not doctrinaire, some neurons (and parts of the glia) do act syncytially by maintaining specialized intercellular channels, common during embryogenesis, into adulthood. In 1897, Sherrington postulated communication via the synapse on theoretical grounds. This turned out to be a fundamental characteristic of the nervous system, which however, was incontrovertibly proven only decades later with the aid of electron microscopy.

The 20th century witnessed an exponential growth of science as a collaborative endeavor. Therefore individual names, no matter how outstanding, give progressively less and less justice to all those who contribute to important advances in science. Nevertheless, we use the names of Nobel Prize laureates to anchor a flash review of concepts particularly relevant to this chapter.[1] In 1915, while held in a Russian prisoner of war camp, Bárány received the Nobel Prize for his studies of the physiology and pathology of the vestibular system. In 1932, Adrian and Sherrington shared the Nobel Prize for their contributions to neuronal signal propagation. Dale and Loewi shared the Prize in 1936 for work on transmitter release,

Abstract

Novel tools in neuroscience (genetic, optical, pharmacological) are being used to advance our understanding of the complexity and functioning of the brain, the primary target of general anesthesia.

Anesthesiologists administer drugs to facilitate procedures that dramatically alter brain function on a daily basis to create loss of consciousness, amnesia, analgesia and immobility. Novel neuroscientific approaches are targeted towards decoding consciousness and memory, and are thereby contributing to our understanding of the mechanisms of anesthetic actions. This chapter reviews the neuroscientific understanding of the brain and the technical approaches leading to these discoveries. After a brief review of the major milestones in brain research, we describe the cellular mechanisms that govern neuronal activity as well as the neurophysiological basis of global network activity. The major structures of the brain and their neurophysiological roles as they pertain to anesthesia are then described.

but Dale's principle (which states that each neuron releases only one type of neurotransmitter) was proven false by the end of the 20th century. Nevertheless, it underlies the familiar classification in widespread use today (e.g., adrenergic, gamma-aminobutyric acid [GABA]ergic). Hodgkin and Huxley shared the Nobel Prize with Eccles in 1963 for discovering the ionic mechanisms involved in excitation and inhibition of the nerve cell membrane. Their biologic model—the giant axon of the Atlantic squid—was so central to this quantum leap in understanding that a contemporary remarked that *Loligo pealei* should have been awarded the prize. Axelrod, von Euler, and Katz shared the prize in 1970 for work on neurotransmitter storage, release, and inactivation in the axon terminal. The Nobel Prize to Hubel, Wiesel, and Sperry in 1981 marked a shift in neuroscience toward a comprehensive, system-level understanding of the brain that remains the frontier of neuroscience today. Hubel and Wiesel suggested a hierarchical model for the identification of complex visual themes. Sperry was awarded the prize for his work on lateralized specialization of brain function. Advances in our understanding of the mammalian brain's navigation system were recognized by the 2014 Nobel Prize to O'Keefe and the Mosers underlining the increased attention of the neuroscience community to system- and network-level approaches.

Glia

Glial cells (or neuroglia: "nerve glue") are nonneuronal cells that outnumber neurons and are ubiquitous in the CNS. Glial cells take up, metabolize, respond to, and release neurotransmitters and modulators; control the microenvironment that surrounds neurons; and support communication. Glial cells also play a number of other roles in CNS homeostasis. However, glial cells are not known to actively transfer and process discrete information.

Two basic types of neuroglial cells can be distinguished: *macroglia* (oligodendrocytes, astrocytes) and *microglia*. Oligodendrocytes fulfill in the CNS the role that Schwann cells play in the peripheral nervous system with some adaptations. To conserve space, one oligodendrocyte cell body myelinates multiple axons and the myelin itself consists of a single sheet of oligodendrocyte plasma membrane without cytoplasm wrapped tightly around an axonal segment. Each myelinated segment is termed an internode because of the bare segments of axon present at each end of it—the node of Ranvier. The action potential can leap from node to node—a process known as saltatory conduction, allowing rapid conduction even along thin axons.[2]

Astrocytes constitute 20% to 50% of the volume in most brain regions. Two main forms predominate: protoplasmic in the gray and fibrous in the white matter. Astrocytes isolate the brain from the rest of the body by covering the surface of capillaries and ensheathing the nodes of Ranvier, synapses, and dendrites with extensions of their bodies, creating the blood-brain barrier. Astrocytes are connected to each other by gap junctions forming a syncytium that facilitates the diffusion of small molecules across the CNS. They also communicate with neurons via calcium ion (Ca^{2+})-induced transmitter release.[3] Astrocyte precursors (radial glia) guide neuronal migration in early development. Throughout life, astrocytes synthesize a plethora of growth factors and are the major source of extracellular matrix proteins and adhesion molecules.

Microglial cells are immune-competent cells, termed the *macrophages of the CNS*. They are the least understood cell type of the CNS even though they account for a substantial fraction of all cells (5%-20% in the mouse brain; human white matter has more microglia than its rodent counterpart).[4,5]

Glial cells are not known to be materially affected by anesthetics in a way that can be linked to acute behavioral changes.

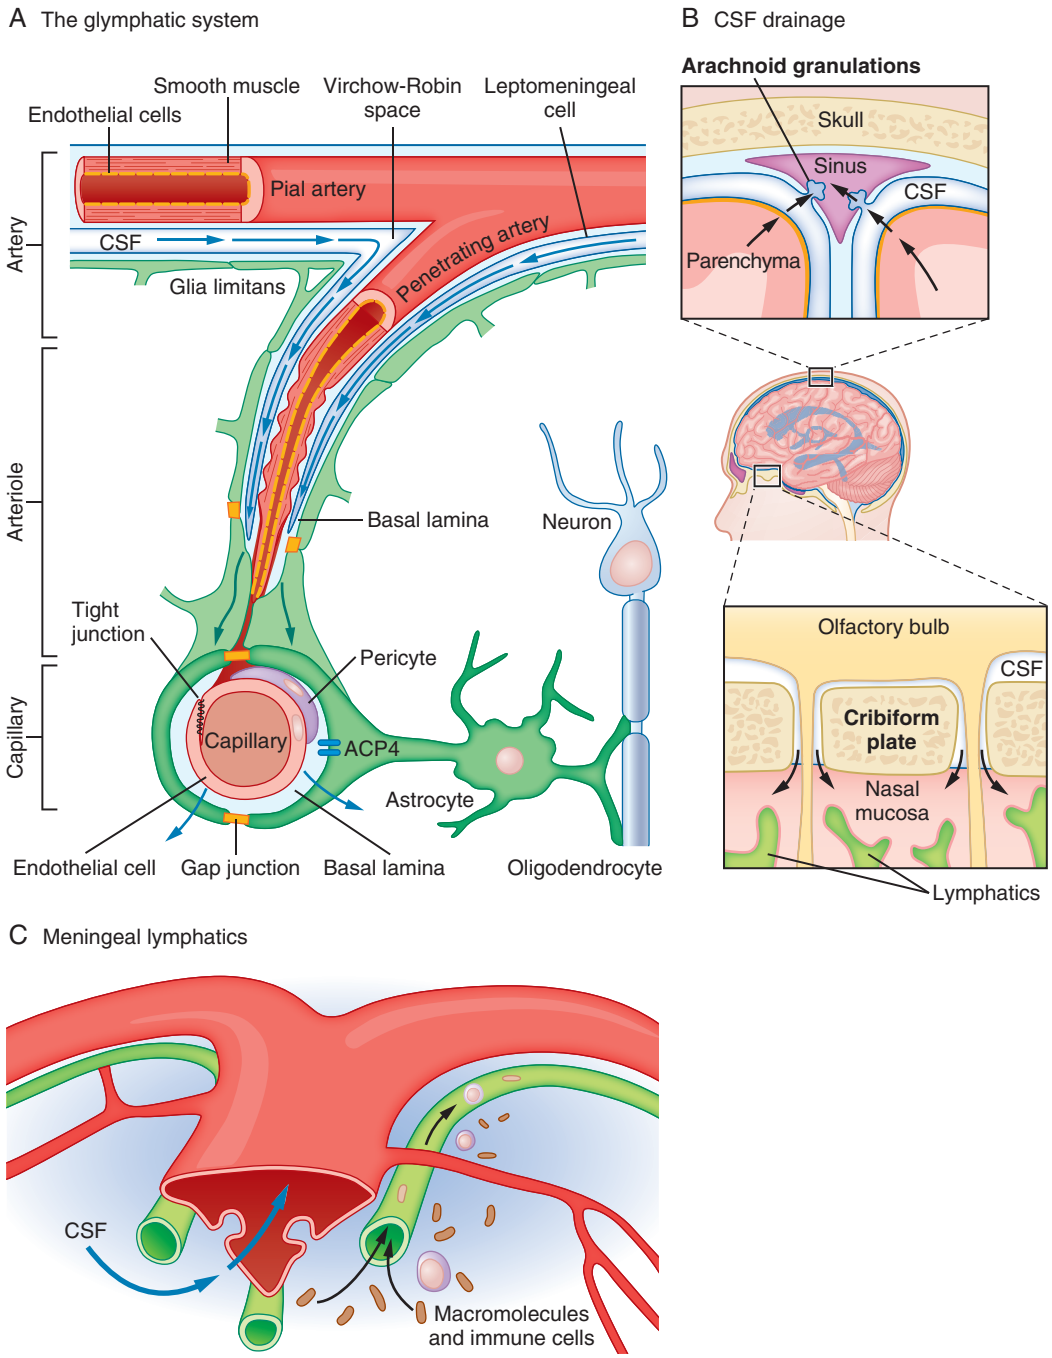
CSF, Interstitial Fluid, and the Glymphatic System

Over the past decades renewed interest in certain peculiarities of brain physiology, especially its immune-privileged status and the puzzling lack of a lymphatic system, has led to a series of elegant experiments that have added cutting-edge experimental techniques to older observations and are redefining important aspects of brain physiology with important implications for pathophysiology.

The brain's high metabolic rate (the average neuron is estimated to consume 4.7 billion adenosine triphosphate [ATP] molecules per second) results in proportional waste accumulation in the interstitial fluid. While the density of lymph vessels outside the brain correlates with the rate of tissue metabolism (lymph flow is essential for clearing waste from metabolically active tissues), the complete lack of conventional lymphatic vessels has been a conundrum of CNS physiology.[6] Related to the problem of waste disposal is the question of how the CNS fulfills the immunologic functions, which in the periphery, are carried by the flow of interstitial fluid and immune cells through the lymphatic vessels and lymph nodes.

The standard model postulates that small molecules and hydrophobic compounds move across the blood-brain barrier relatively unrestrictedly and specific blood-brain barrier transporters readily clear other molecules from the brain. For compounds not falling into these two categories, diffusion by way of the interstitial fluid to CSF-containing spaces (ventricles, subarachnoid space) was assumed to suffice. Clearance from the cranium was accomplished by CSF reabsorption into the dural sinuses via the arachnoid granulations and into peripheral lymphatic vessels of the nasal mucosa and neck along perineural spaces surrounding the cranial nerves. An important weakness of the model, however, is that the distances between much of the brain tissue and the CSF compartments are far too great for efficient clearance by simple diffusion, particularly for large molecules with low diffusion coefficients (such as peptides and proteins).

Recent research is providing a coherent, albeit not yet exhaustive, solution to these issues. Contrary to previously held views, the new model postulates that CSF is produced not only in the choroid plexus but also by filtration of water through capillary walls governed by hydrostatic and osmotic forces. CSF flows from the subarachnoid space along a system of perivascular tunnels known as the Virchow-Robin spaces (Fig. 8.1). These perivascular spaces act as low-resistance paths for CSF influx. Endfeet of astrocytes ensheathe the brain vasculature forming tunnels around the vessels. Fluid from these tunnels is taken up by aquaporin 4 water channels, which are expressed in a highly polarized manner in astrocytic endfeet and transferred into the interstitial fluid of the dense brain parenchyma. Influx of CSF on the arterial/capillary side of the circulation drives the flux of interstitial fluid toward the perivenous spaces surrounding the large veins. The interstitial fluid then drains out of the brain into peripheral lymphatic vessels into the deep cervical lymph nodes as described in the standard model. Acknowledging the central role of glia, the term "*glymphatic*" has been coined to describe this system. Moreover, while it remains accepted that no lymphatic vessels in the classic sense exist within the brain and spinal cord parenchyma, a network of lymphatic-like vessels has been identified in the dura mater of the mouse brain. Endothelial cells in these vessels share similarities with conventional



• **Fig. 8.1** The glymphatic system**.** A, The neurovascular unit allows bidirectional communication between the microvasculature and neurons, with astrocytes playing an intermediary role. Pial arteries in the subarachnoid space bathed in cerebrospinal fluid (CSF) become penetrating arteries upon diving into the brain parenchyma. The perivascular space around penetrating arteries is termed the Robin-Virchow space. As the penetrating arteries branch into arterioles and capillaries, the CSF-containing Virchow-Robin spaces narrow and finally disappear. CSF from the Robin-Virchow spaces continues its flow into the perivascular spaces around arterioles, capillaries, and venules, where the extracellular matrix of the basal lamina provides a continuity of the fluid space. Astrocytic vascular endfeet expressing aquaporin 4 *(AQP4)* surround the entire vasculature and form the boundary of the perivascular spaces. B, The CSF, flowing between the arachnoid and the pia mater of the meninges, can drain into the bloodstream through the arachnoid granulations located along the superior sagittal sinus and the transverse sinuses, or reach the lymphatic vasculature of the nasal mucosa by crossing the cribriform plate, localized under the olfactory bulbs, along the olfactory nerves. Not shown: CSF also drains through the perineural spaces of other cranial nerves. C, Macromolecules and immune cells localized within the CSF drain primarily through the recently rediscovered meningeal lymphatics to reach the deep cervical lymph nodes *(black arrows).* CSF drains back into the bloodstream *(blue arrow).* Note: the exact location of the lymphatics with respect to the meninges is still being clarified. (From Jessen NA, Munk AS, Lundgaard I, et al. The glymphatic system: a beginner's guide. *Neurochem Res.* 2015;12:2583–2599.)

lymphatics (e.g., expression of traditional markers of tissue lymphatic endothelial cells)[7] but with distinct adaptations to their function in the CNS. Meningeal lymphatics enable the drainage of the macromolecules and immune cells originating from the CNS to the deep cervical lymph nodes (see Fig. 8.1).[8,9] Remarkably, genetic ablation of this system did not lead to increased intracranial pressure, indicating the existence of separate specialized systems for CSF volume regulation (arachnoid villi, cribriform plate, perineural spaces) and immune surveillance (meningeal lymphatics).

Intriguingly, the glymphatic system functions mainly during sleep and appears to be largely quiescent during wakefulness. The biologic need for sleep across all species may therefore reflect the necessity to enter a state of activity that enables elimination of potentially neurotoxic waste products (including β-amyloid, a mediator of Alzheimer disease). Flux through the glymphatic system is energy-consuming and assisted by arterial pulsatility. It diminishes with age and undergoes changes associated with a number of conditions affecting the CNS (e.g., traumatic brain injury, neurodegenerative diseases, and diabetes mellitus).[10] The effect of anesthetics on flux through this system is unknown with the exception of ketamine-xylazine anesthesia, which increases flux similarly to sleep.[11]

In addition to waste elimination, the glymphatic system also facilitates the brainwide distribution of glucose, lipids (including cholesterol and its degradation products), amino acids, growth factors, neuromodulators, as well as β-amyloid.

The Neuron

The neuron is the fundamental building block of the nervous system. Neurons are diverse in nature, interconnected, adaptive, and therefore, as ensembles, give rise to the stunning complexity of the brain. A *complex* system is endowed with *emergent properties*—that is, properties that appear only in ensembles as opposed to being present fully in the individual element. The human brain contains more than 10^{11} neurons. Their cell bodies are located in gray matter areas of the CNS, whereas the white matter consists of fibers connecting neurons from different regions.

Neurons are excitable cells. This property is harnessed to receive, process, integrate, and transmit signals. Their structure is optimized to integrate multiple inputs and deliver what formerly was considered an all-or-none (binary), digital signal in the form of an action potential to other, potentially distant, elements. Action potentials, however, should not be interpreted as isolated events where information transfer is concerned. Both their rate modulation and their phase relationship with respect to ongoing oscillations encode information. Neurons in the CNS are connected by approximately 10^{14} synapses, which are specialized structures allowing information transfer and hence networking.

Basic Structure

The generic neuron contains three basic elements: dendrites (signal reception and processing), soma or cell bodies (signal integration and cellular housekeeping apparatus), and axons (information output). These three elements vary in complexity, shape, and length, giving rise to a dazzling variety of neuronal morphology (Fig. 8.2).

The *soma* is the part of a neuron that is most reminiscent of a conventional cell. It contains all the standard cellular components found in other cells, such as nucleus, protein production (ribosomes), and modification machineries and energy generators (mitochondria). The soma also undergoes neuron-specific long-term changes during development, plasticity, degeneration, and aging. In addition, the soma is the hub linking signal input to information output.

The *dendrites* are elongated cytoplasmic processes. Usually a neuron has more than one dendrite. Each dendrite bifurcates multiple times, creating a dendritic arbor in the vicinity of the soma; it can stretch to other cortical layers but does not spread to distant regions of the brain. The dendritic arbor creates a large, intricately organized membrane surface area to receive input from other neurons. The arbor hosts vast numbers of the postsynaptic component of chemical synapses—transmitter receptors—targeted by incoming axon terminals that form the presynaptic side. A typical pyramidal cell (e.g., in the hippocampus or in cortical layer V) receives many thousand synapses: excitatory inputs on dendrites, inhibitory on soma and dendrites. The structure of the dendritic tree and the location of each synapse on it determine the nature of input summation and local integration and hence their relative strength. Spines are small processes of varying shapes found on many dendrites. These processes are specialized sites of synaptic connections, increasing the dendritic membrane and subdividing the subsynaptic structures (Figs. 8.3 and 8.4). Spines are highly dynamic and can change their size and composition on a time scale of minutes in response to neuronal activity, thereby creating, changing, or eliminating synaptic points of contact.

The *axon* is a very thin cytoplasmic process that carries the output signal of the neuron (the action potential) to its targets. Typically, a single axon originates from and terminates in specialized structures termed *axon hillocks* at the soma and *presynaptic terminals* at its destination. Normally, it bifurcates multiple times on the way and creates an axonal arbor connecting with many other neurons. Axonal lengths range from less than a millimeter (local interneurons) to more than 1 m (spinal α-motoneurons).

Axons are usually much longer and thinner than dendrites; hence they require mechanisms that enable them to reliably and efficiently transfer information over long distances, supporting the presynaptic machinery in the terminal at the target while maintaining their own structural integrity. The myelin envelope and the axonal transport system are two mechanisms to this end.

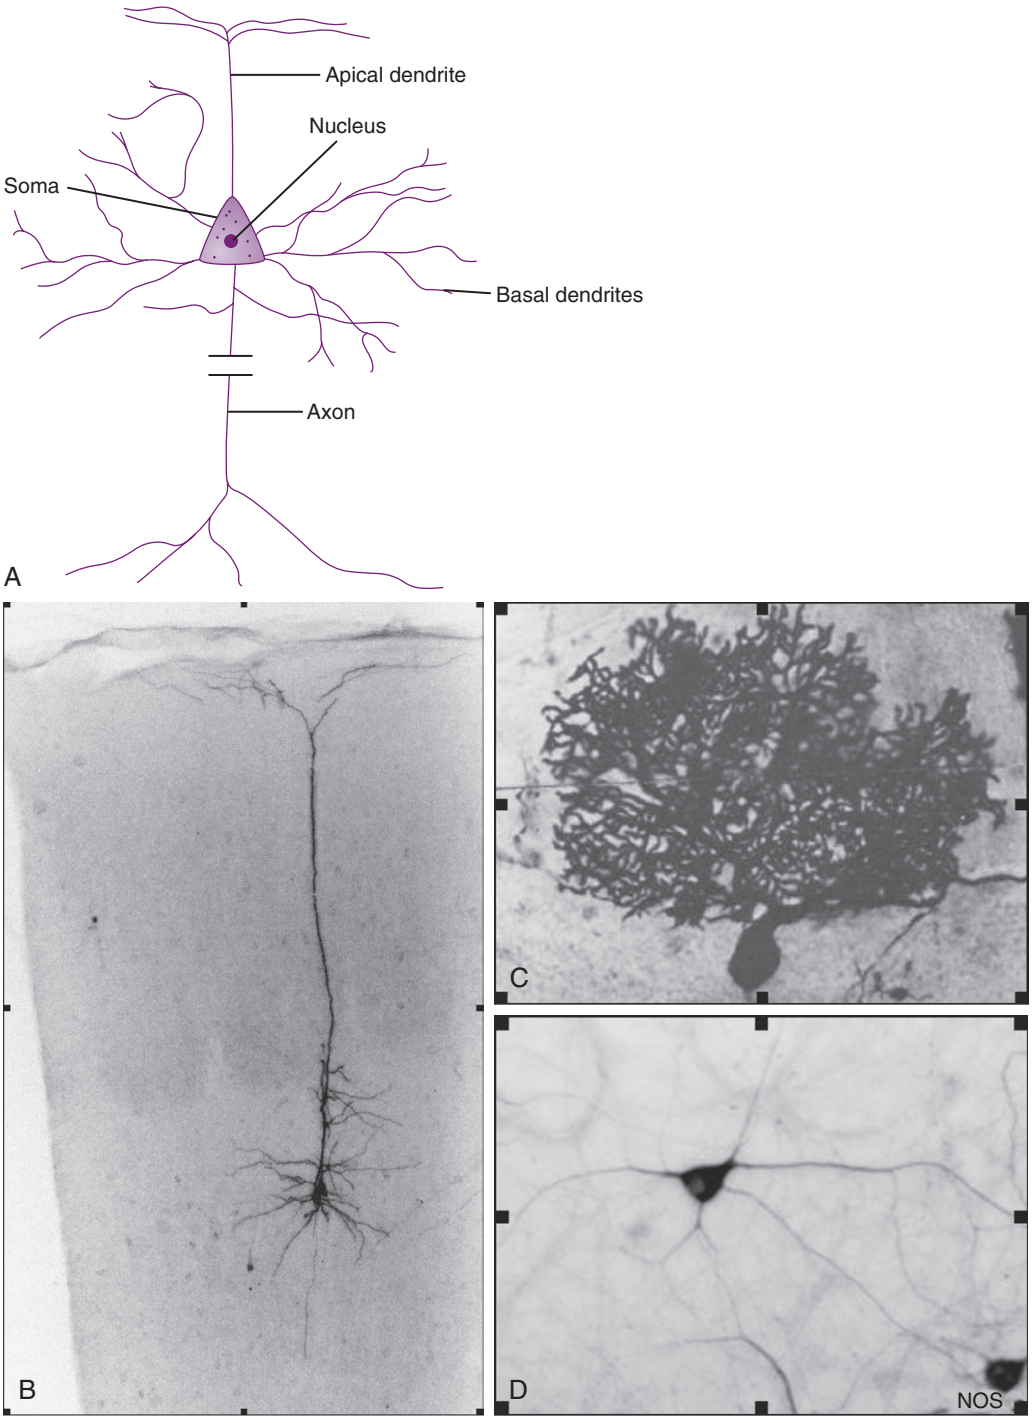
Myelin is a composite of multiple layers of lipid membranes formed by the oligodendroglia in the CNS (Schwann cells in the peripheral nervous system). Myelin electrically insulates the axon, enabling high-speed propagation of action potentials with minimal energy expenditure (varying with the degree of insulation).

Axonal transport is a "housekeeping" mechanism that moves vesicles and proteins from their site of synthesis in the soma along the whole length of the axon, and reverse transport relays signals back to the soma. It is an active, energy-consuming process using the cytoskeleton (e.g., microtubules) to meet the metabolic needs of the axon, its collaterals, and the presynaptic terminals because diffusion alone would not suffice.[12]

Excitability

Excitable cells are characterized by the ability to dynamically change the electrical potential across their cell membrane. Typical examples are muscle cells and neurons. Neurons use this property to integrate and disseminate information with precise and independent control of excitability in different functional compartments. Alterations in excitability are an important aspect of anesthetic drug action.

A living cell is defined by its ability to remain segregated from its environment. This fundamental property is made possible by the selective permeability of *the cell membrane* (the lipid bilayer and the proteins embedded into it). The intracellular ions are



• **Fig. 8.2** The neuron. A basic plan (A) underlies the stunning variety of neuronal shapes found in the mammalian brain. The morphology reflects individual computational needs and architectural constraints. Three examples are shown to illustrate this diversity. A, Schematic plan of a pyramidal neuron; notice the apical and basal dendritic arbors providing ample space for synaptic inputs and the long axon projecting to a distant location (symbolized by the interruption). B, Photomicrograph of a biocytin-filled cortical pyramidal neuron. Notice the dendritic arbor stretching toward the superficial layers. C, Golgi-impregnated Purkinje cell in the cerebellum. • **Fig. 8.3** Schematic representation of synaptic connections between two neurons. The action potential travels along the axon of neuron A (upper right side) and leads to the release of neurotransmitter containing synaptic vesicles from the presynaptic terminal of A. Neurotransmitter molecules diffuse across the synaptic cleft to activate receptors on the postsynaptic membrane of neuron B (lower left side) . The axon of A contributes to multiple synapses on B and also innervates many other neurons. The axons of interneurons in particular target specific areas of the postsynaptic neuron (e.g., distal apical dendrites, proximal basal dendrites, or soma). This target specificity has been well characterized in hippocampal interneurons (not shown). The content of one vesicle is thought to lead to a miniature postsynaptic potential that can be either inhibitory or excitatory. (Adapted from drawing illustrating the process of synaptic transmission in neurons, cropped from original in a National Institute on Aging brochure. http://en.wikipedia.org/wiki/File:Chemical_synapse_schema_cropped.jpg#file.)

dominated by potassium ions (K^+), while extracellularly high sodium ions (Na^+) and chloride ions (Cl^-) hark back to the ionic composition of sea water (Table 8.1). Because of its hydrophobic interior, the lipid bilayer prevents charged molecules and most ions from crossing the membrane. By contrast, water and other small uncharged molecules (e.g., urea) diffuse freely. Membrane-spanning proteins selectively control the movement of ions and other small molecules across the membrane, rendering this lipid envelope semipermeable. Membrane transport systems can be divided into two principal categories: catalytic and stoichiometric.[13] The proteins responsible for this property are traditionally grouped into pores and channels (catalytic) on one hand and pumps and transporters (stoichiometric) on the other. Catalytic systems carry out movement only "downhill"—that is, toward the electrochemical equilibrium—while stoichiometric systems can carry out transport "uphill" —away from the equilibrium with energy expenditure. Cells also have special mechanisms to transport large molecules across the cytoplasmic membrane. Excitable cells in particular are endowed with a rich assortment of ion channels.

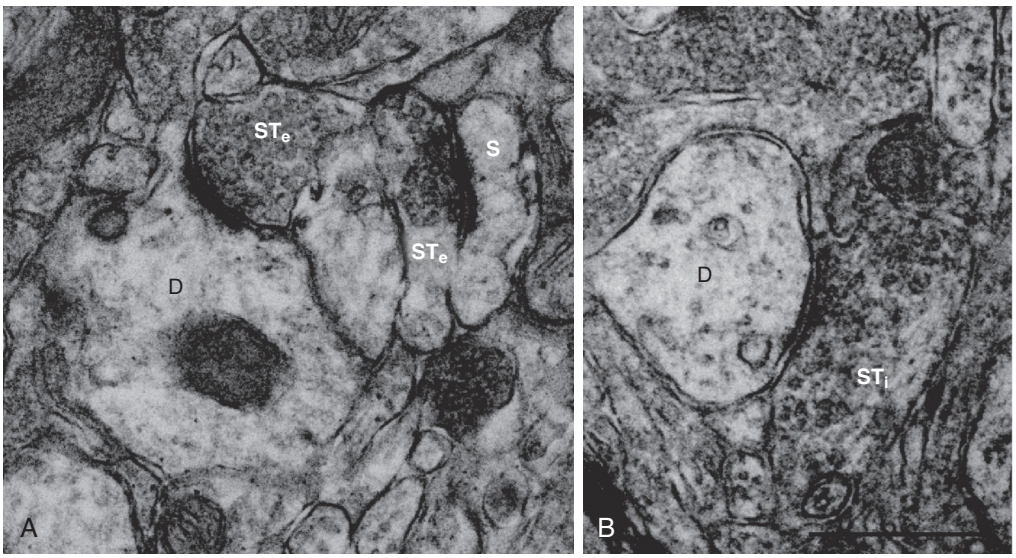
The differential distribution of ions inside and outside the cell creates chemical concentration gradients. For example, the concentration of K^+ is high inside and low outside the neuron. This creates a tendency for K^+ ions to diffuse out of the cell through K^+ channels that are typically open at *the resting membrane potential (RMP)*. Because K^+ is positively charged, this creates a redistribution of electrical charge, with the inside of the cell becoming more negative because the membrane is impermeable to large molecules like negatively charged proteins. The excess negative charge inside the cell attracts K^+ ions and, at some point, the tendency to diffuse out of the cell along the chemical concentration gradient will be offset by the electrical attraction from inside the cell, reaching electrochemical equilibrium. This equilibrium is dynamic as ions continuously cross the membrane while the net flow of charge is zero. The relation between an ion's concentration gradient and the electrical gradient it creates was described in the 19th century by Nernst in his classic equation:

$$E = \frac{RT}{zF} \ln\left(\frac{[Ion]_{out}}{[Ion]_{in}}\right), \quad [1]$$

TABLE 8.1 Cytoplasmic and Extracellular Ion Concentrations

Ion	Intracellular Concentration (mm)	Extracellular Concentration (mm)	Steady-State Potential at 37°C (mV)
Na^+	10	145	+70
K^+	140	5	–87
Ca^{2+}	10^{-4}	1.5	+125
Mg^{2+}	6.5	2	–15
Cl^-	4	110	–86
HCO_3^-	12	25	–19

Na, Sodium, *K,* Potassium; *Ca,* Calcium; *Mg,* magnesium, *Cl,* chloride; HCO_3^-, bicarbonate.



• **Fig. 8.4** Chemical synapses are the mainstay of interneuronal communication. Morphology of excitatory (A) and inhibitory (B) synapses as seen with the electron microscope. Note that in A one excitatory terminal *(ST$_e$)* forms an asymmetric synapse with a dendrite *(D)* and a dendritic spine *(S)*. Note the cloudlike electron-dense material known as the postsynaptic density, which is characteristic of excitatory synapses. The inhibitory terminal *(ST$_I$)* forms a symmetric synapse with a dendrite *(D)*. Scale bar = 500 nm. (Courtesy S.L. Feig, PhD, University of Wisconsin, Madison, Wisconsin.)

where E is the electric potential across the membrane (in millivolts) at equilibrium, R is the ideal gas constant, T is the temperature in degrees Kelvin, z is the ion's charge, F is Faraday's constant, and $[\text{ion}]_{out}$ and $[\text{ion}]_{in}$ are the concentration of the ion on the two sides of the membrane. All the ions that are differentially distributed between the inside and the outside of a neuron create electrical gradients/potentials across the cell membrane.[14]

Because most of the values in the Nernst equation are constant under biologic conditions, the equation can be simplified assuming intracellular and extracellular K^+ concentrations of 140 and 5 mmol/L at 37°C as:

[2]

$$E = 60\log\left(\frac{[K^+_{out}]}{[K^+_{in}]}\right) = 60\log\left(\frac{5}{140}\right) = -86.8\,mV$$

This means that, at −86.8 mV and the K^+ concentrations given above, no net flow of K^+ occurs even if the membrane is freely permeable to K^+. Similarly, for each ion there is a membrane potential at which its concentration gradient will be balanced by its electrical gradient. These equilibrium potentials become significant determinants of the membrane potential when opening of appropriate channels renders the membrane permeable to a specific ion (e.g., Na^+). Table 8.1 lists the Nernst potential of some common ions that influence the neuronal membrane potential.

The membrane potential of a cell is determined by the gradients of all the intracellular and extracellular ions, scaled in proportion to their permeability through the membrane: the greater the permeability of the cell membrane to a specific ion, the stronger its effect on the membrane voltage. This is described by the Goldman-Hodgkin-Katz equation[15]:

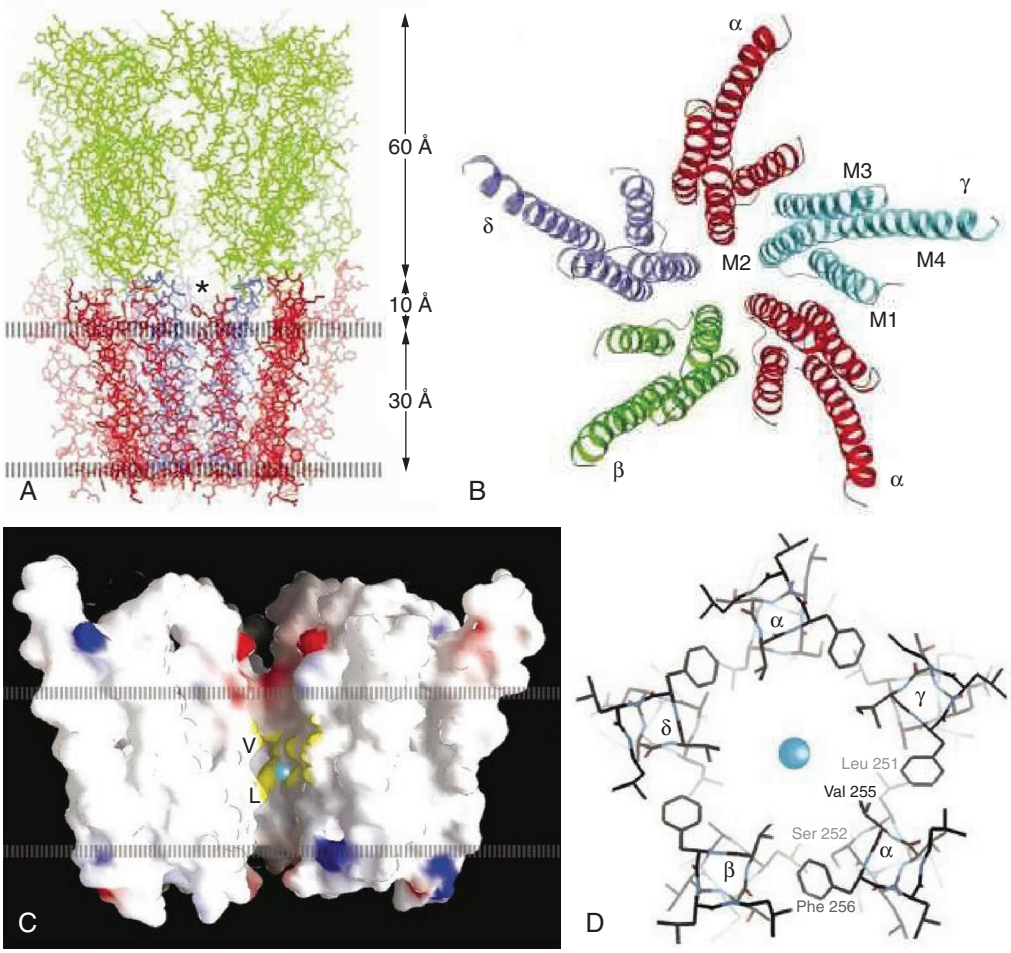
[3]

$$E = \frac{RT}{F}\ln\left(\frac{\sum_i^N P_{Ci}[Ci]_{out} + \sum_j^M P_{Aj}[Aj]_{in}}{\sum_i^N P_{Ci}[Ci]_{in} + \sum_j^M P_{Aj}[Aj]_{out}}\right),$$

where P is the permeability, Ci the cations, and Aj the anions; the rest of the variables are the same as in the Nernst equation. In a "resting" neuron, the membrane potential typically is −60 to −70 mV. An increase in membrane permeability to K^+ (equilibrium potential of −90 mV) will "pull" the membrane potential toward −90 mV, hyperpolarizing the cell. An increase in permeability to Na^+ (equilibrium potential of +70 mV) will depolarize it. Under resting conditions, the permeability of the cell membrane for K^+ dominates and therefore the RMP is largely determined by the equilibrium potential for K^+.[14]

Ion channels are pores allowing diffusion of ions across the cell membrane along their electrochemical gradient. Typically, these proteins are composed of a number of subunits, each containing multiple transmembrane domains (Fig. 8.5). The three-dimensional folding of the subunits and their arrangement with respect to each other create a hydrophilic pore across the membrane lined by specialized sections of the transmembrane domains, which determine the ion selectivity of the channel. When open, channels are typically permeable to either cations or anions, but within each group the degree of permeability can vary widely depending on the selectivity of the specific channel.

Changes in the structural conformation of the subunits lead to opening and closing of the channel pore. The state of a channel is controlled by the electrical potential gradient across the membrane (voltage-gated channels), by the action of a chemical substance on receptors linked to the channel (ligand-gated receptor-channel



• **Fig. 8.5** The structure of a ligand-gated ion channel. Like other members of the cys-loop ligand-gated ion channel superfamily that also includes the gamma-aminobutyric acid $(GABA)_A$, $5\text{-}HT_3$, and glycine receptors, the nicotinic acetylcholine receptor-channel complex consists of five subunits (i.e., it is a pentamer), with each subunit containing multiple transmembrane domains and their intracellular and extracellular connecting loops. A, View along the receptor axis showing the pore structure (*blue,* pore-facing; *red,* lipid-facing helices) in relation to the membrane surfaces *(broken lines)* and the β-sheet structure *(green)* comprising the ligand-binding domain; the *asterisk* denotes open space at a subunit interface. B, View of the pore from the synaptic cleft, with the five subunits shown in different colors (note two α-subunits in *red*). C, Molecular surface of the pore domain with front subunit removed. *Red* and *blue* indicate areas of high negative and high positive charge, respectively; the hydrophobic gate-containing area is highlighted in *yellow;* the letters *V* and *L* identify individual amino acids (α-Val 255 and α-Leu 251). D, Symmetric arrangement of side chains forming the gate. The blue spheres in C and D indicate the size of a sodium ion. (Adapted from Miyazawa A, Fujiyoshi Y, Unwin N, et al. Structure and gating mechanism of the acetylcholine receptor pore. *Nature.* 2003;423:949–955.)

complexes) (see Fig. 8.5), by the intrinsic gating properties of the channel itself (e.g., many voltage-gated Ca^{2+} ions exist within the presynaptic terminal sharing voltage sensitivity and ion selectivity but nevertheless having different functional properties), and by its sensitivity to modulation. Channel modulators include intracellular and extracellular factors, such as neuromodulators, phosphorylation state, pH, temperature, membrane tension, metabolic products, and the preceding activity of the neuron. Table 8.2 shows a partial list of ion channels that are abundant in the CNS and are implicated in anesthetic action.

Ion pumps are proteins that deliver ions across the cell membrane against their electrochemical gradient. The coupling of transport to an external energy source in an energy-consuming process distinguishes transporters. Maintenance of gradients across the cell membrane may account for more than 50% of the total energy expenditure in a spiking neuron. The most common ion pump—the sodium-potassium adenosine triphosphatase (Na,K-ATPase) pump—uses energy released by hydrolysis of one ATP molecule to pump three Na^+ ions out in exchange for admitting two K^+ ions into the cell. This process, resulting in the net transfer of one positive charge out of the cell for each ATP molecule, generates a hyperpolarizing current.

Transporters carry molecules across the membrane along or against their electrochemical gradient following enzyme kinetics.

TABLE 8.2 Common Ion Channels of the Brain

Receptor (R)/Channel	Ion Permeability and Normal Flow Direction	Transmitter/Gating Mechanism	Principal Roles
$GABA_AR$	Cl^- ↓ HCO_3^- ↑	GABA	Major inhibitory transmitter
Nicotinic Acetylcholine R	Na^+, K^+ ↓	Acetylcholine	Synaptic transmission in the brain and at the neuromuscular junction
Glutamate R			Major excitatory transmitter
AMPA-type GluR	Na^+, K^+ ↓	Glutamate, provides depolarization for NMDAR	Depolarization
NMDA-type GluR	Na^+,Ca^{2+} ↓	Glutamate/glycine is coagonist depolarization (to release the Mg^{2+} block) required	Depolarization, synaptic plasticity, excitotoxicity if excessive
Voltage-gated Na	Na^+ ↓	Membrane depolarization	Action potential initiation/propagation
Voltage-gated K^+	K^+ ↑	Membrane depolarization	Action potential termination and repolarization of the membrane
Voltage-gated Ca^{2+}, many subtypes	Ca^{2+} ↓	Membrane depolarization	Burst firing (T-type); dendritic depolarization (H-type) neurotransmitter release (P, N, R types)
Ca^{2+}-activated K^+ channels	K^+ ↑	Intracellular Ca^{2+} concentration increase	Synaptic plasticity, after hyperpolarization and smooth muscle tone
Hyperpolarization-activated cyclic nucleotide-gated channels (HCN)	K^+ ↑ (I_{funny})	Membrane hyperpolarization Intracellular cAMP	Pacemaker/rhythmic oscillation activity Synaptic plasticity
Cyclic nucleotide gated ion channels	Na^+, K^+, Ca^{2+}, Mg^{2+}	Intracellular cGMP and cAMP	Light detection in photoreceptors
Two-pore domain K^+ channel	K^+ ↑	Oxygen tension, pH, mechanical stretch, etc.	Resting membrane potential, "leak channels"

The table shows common ion channels of neuronal cell membranes. Transmitter-activated receptor channel complexes are organized by the principal transmitter, voltage-activated channels by principal ion. Down/up pointing arrows indicate the inward/outward flow of ions.
AMPA, 2-Amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid; *Ca,* calcium; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *Cl,* chloride; *GABA,* gamma-aminobutyric acid; *HCO_3^-,* bicarbonate; *K,* potassium; *Mg,* magnesium, *Na,* sodium, *NMDA,* N-methyl-D-aspartate; *NMDAR,* NMDA receptor.

Transportation against the gradient is achieved by transporting two substrates simultaneously, using the energy from the downhill transport of one substrate to drive the uphill transport of another substrate. This type of transporter is termed *cotransporter* or *symporter*—for example, the potassium-chloride cotransporter (KCC2). KCC2 delivers one K^+ together with one Cl^- across the membrane along their combined electrochemical gradient. Because the internal K^+ concentration is kept high by the activity of the Na,K-ATPase, the transporter carries K^+ and Cl^- out of the cell. In this example, the transporter allows the cell to use energy stored in the K^+ gradient to create a Cl^- gradient across the membrane.

Communication

The nervous system is a network of units communicating on each organizational level, from the individual neuron to the whole brain. An important part of integration and communication is carried by changes in electrical potentials that can be either depolarizing or hyperpolarizing and shunting carried out by increasing the membrane permeability for ions with a Nernst potential more positive and more negative than the RMP, respectively.

Membrane Time Constant

The cell membrane of the neuron can be modeled as an electrical circuit composed of a resistor and a capacitor (RC circuit). The lipid bilayer functions as a capacitor. Ion channels and transporters that allow ion flow across it function as resistors. When ions pass through a channel, the potential across the membrane does not change instantly. Rather, as in the RC circuit, the current needs time to charge the capacitance of the membrane. The inverse process occurs after a channel closes. The rise and fall of the membrane potential follow exponential patterns and lag behind the current. The time course of voltage change is described in the following equation:

[4]

$$\Delta V = IR_m\left(1 - e^{\frac{-t}{R_m C_m}}\right),$$

where V is the potential, I is the current, R_m is the resistance, and C_m is the capacitance of a membrane segment. The term R_mC_m is the time constant of the membrane, the dimensionless τ. The larger the value of τ, the faster the change in voltage. τ is an important factor in the ability of a cell to perform temporal summation of different inputs.[16]

Current spreads spatially as charged molecules diffuse along the membrane. This spread allows neurons to perform summation of inputs from neighboring synapses—one type of intraneuronal integration. The electrical potential caused by the current decays along a segment of membrane with a first-order exponential (determined by the length constant λ). λ depends on the membrane properties (e.g., its conductance or permeability) and determines the spread of the potential change.[17]

Action Potential

Frequently referred to as a "spike," describing its rapid time course, the action potential (AP) is driven by the sudden opening of fast voltage-gated Na^+ channels, activated by a local depolarization of the cell membrane beyond the activation "threshold" (typically around −50 mV) when a positive feedback loop results in an extremely fast regenerative process. Within 1 ms, the cell membrane potential is driven beyond 0 mV and toward the Nernst equilibrium for Na^+. The AP is rapidly terminated by inactivation of Na^+ channels and opening of slower K^+ channels limiting the duration of an AP to a few milliseconds (Fig. 8.6).[18]

The threshold of AP generation is the basis of "neuronal calculation." A neuron integrates the barrage of many inputs it constantly receives: positive (depolarizing) and negative (hyperpolarizing) and shunting (increase in conductance without voltage change). Whenever the sum of these signals pushes the membrane potential beyond the threshold, the neuron "fires" an AP. After an AP, Na^+ channels are inactivated for a few milliseconds. During this refractory period the cell cannot fire again. The firing threshold is dynamic: the amount of available voltage-gated Na^+ channels and the threshold for AP generation change depending on the activity of the cell. For example, hyperpolarization increases the number of available Na^+ channels, thereby facilitating AP generation once hyperpolarization terminates. Subthreshold depolarization, by contrast, inactivates Na^+ channels and a stronger depolarizing current is necessary to force the cell to fire.

An AP is initiated in a specialized membrane area extending from the axon hillock to the end of the unmyelinated axon initial segment (Fig. 8.7). Synaptic inputs impinge on the distal end of the axon initial segment and, in conjunction with a diverse set of ion channels, suggest that the axon initial segment is capable of signal integration in addition to being a low-threshold area for AP triggering.[19] From the axon initial segment, the AP invades and rapidly travels along the axon either by a rolling depolarization or by saltatory conduction. In principle, any segment of axon can conduct APs in either direction. The directionality of spread is given by the gating state of Na^+ channels on both sides of the depolarized segment. The AP will spread in the direction of nonrefractory channels (exogenous stimulation can initiate "retrograde" spread of APs, see Chapter 17).

Synapses

The synapse is an information relay between two neurons. It usually connects the axon terminal of the presynaptic cell with the dendrite of the postsynaptic cell. Signal transmission can be either electrical or chemical and synapses are also found between axon and soma, two axons, and two dendrites.

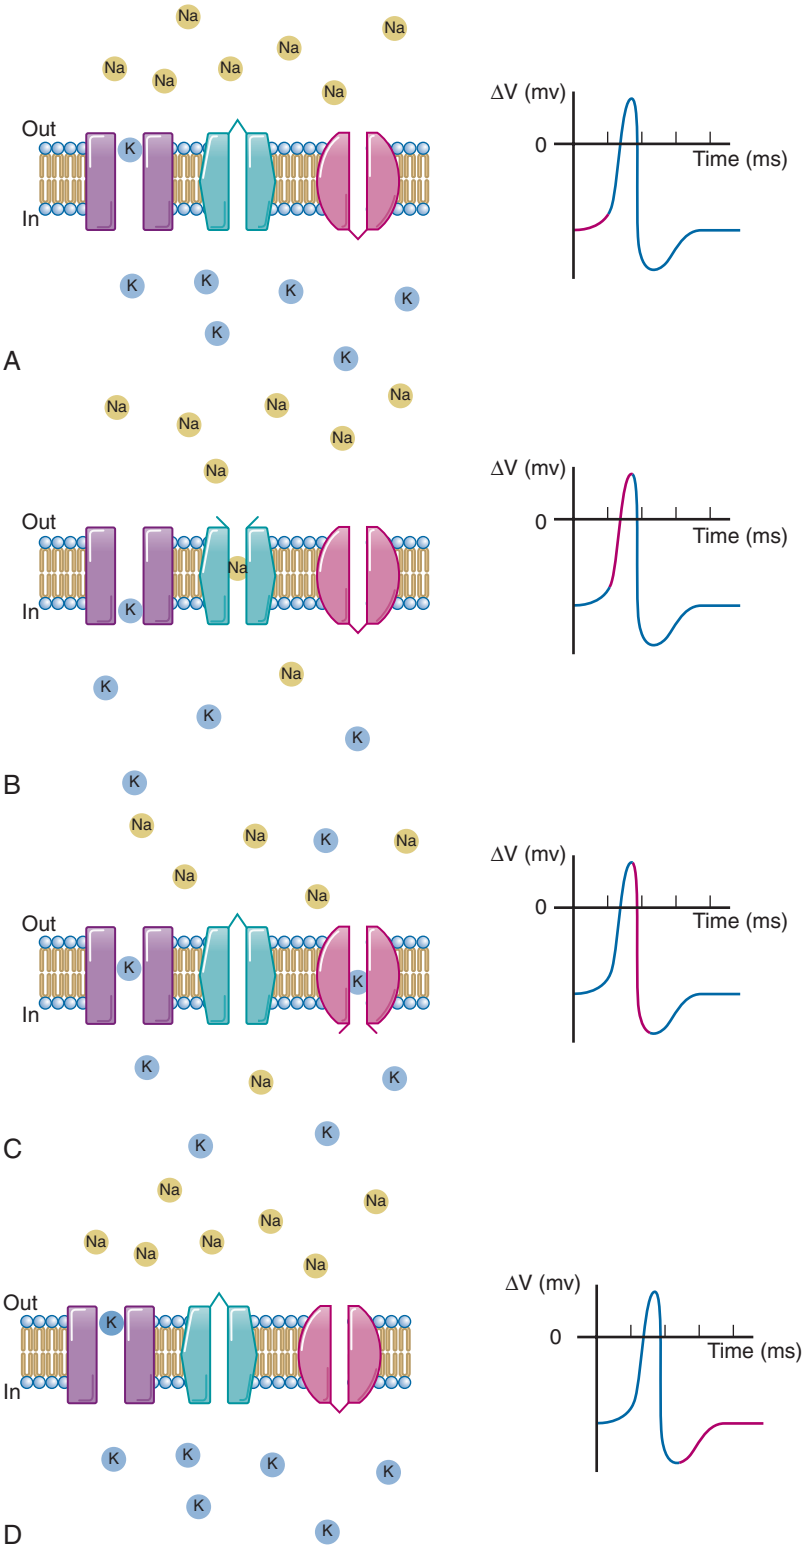
The *electrical synapse* (also called the *gap junction*) is a channel formed of proteins. Electrical synapses form a minority of all synapses and are enriched in specific brain areas—for example, the thalamus where they create a syncytium-like continuity of cytoplasm and membrane directly passing electrical current between neurons. They can transmit action potentials, as well as subthreshold membrane potential fluctuations practically without any delay. Gap junctions also undergo plasticity.[20]

The chemical synapse consists of specialized presynaptic and postsynaptic elements separated by the synaptic cleft. Communication across the cleft is via a neurotransmitter stored in presynaptic vesicles. An AP initiates a cascade of events that leads to the release of a neurotransmitter. The neurotransmitter then diffuses through the synaptic cleft, binds to transmitter-specific receptors on the postsynaptic membrane, and sets off a signaling cascade. Release, diffusion, and activation of receptors impose a delay of approximately 1 ms on signal transfer. The transmitter may bind to an ionotropic receptor, which is a receptor-ion channel complex. Binding to this receptor type leads to the opening of the ion channel (fast synaptic transmission), which will hyperpolarize or depolarize the cell depending on the ions conducted by the receptor channel. A different type of receptor is the metabotropic receptor, which does not directly open an ion channel but rather exerts its effect via a second-messenger cascade (slow synaptic transmission). These receptors are often G-protein–coupled but may be coupled to other enzymes (e.g., tyrosine kinase). Transmitter-specific mechanisms ensure that the chemical signal is limited to a brief pulse that barely outlasts the incoming electric signal but exceptions are well known (see later text).

Neurotransmitters are typically small organic molecules, some derived from amino acids (GABA, L-glutamate, dopamine). Each transmitter can activate multiple receptor subtypes, providing a tremendous flexibility of signal transmission. For example, GABA, glutamate, and acetylcholine all activate different subtypes of both ionotropic and metabotropic receptor classes. Anatomically defined synapses are typically excitatory or inhibitory in nature, but neurotransmitters act also on receptors outside classic synapses where their action is more modulatory in nature. Some synapses simultaneously release more than one transmitter (e.g., the release of GABA and substance P from the same striatal spiny projection neurons). In addition to falsifying Dale's rule with respect to transmitter exclusivity, recent research has also shattered the long-held belief that the identity of the transmitters expressed by neurons is unchanging. Electrical activity can respecify the neurotransmitter phenotype of an individual neuron both during development and in the mature nervous system.[21]

Transmitter Release and Action

Release of neurotransmitter can be either conventional (quantal) or unconventional. *Conventional (quantal) release* indicates that transmitter release occurs in discrete quantities or quanta (singular: quantum) dictated by the storage of transmitter in synaptic vesicles, discrete membrane vesicles of defined capacity within the terminal. An AP depolarizes the terminal opening voltage-gated Ca^{2+} channels. The subsequent Ca^{2+} increase in the terminal leads, via a complex cascade, to fusion of transmitter-loaded vesicles with the presynaptic membrane and release of neurotransmitter into the synaptic cleft. The amount of neurotransmitter released is determined by the number of vesicles that fuse with the membrane. Spontaneous fusions of individual vesicles with the membrane are observable as "quantal" postsynaptic events when APs are blocked.[22] Some ionotropic channels (e.g., the



• **Fig. 8.6** The action potential (AP, schematic A-D) originates in the axon initial segment (AIS, E). A, Membrane at rest; voltage-activated sodium ion (Na^+) *(triangular)* and potassium ion (K^+) *(circular)* channels are closed. K^+ leak current *(square)* dominates the membrane potential. B, When the membrane potential crosses the threshold for activation, Na^+ channels open. Because during this phase Na^+ permeability dominates, the membrane rapidly depolarizes. C, Na^+ channels slowly become inactivated and voltage-activated K^+ channels open. The membrane potential rapidly hyperpolarizes to below baseline. D, Na^+ and K^+ channels are inactivated. The cell is refractory and an AP cannot be initiated.

Synaptic input onto the AIS is shown in *blue.* B, Electron micrograph of the AIS (in *red*) of a cortical pyramidal neuron, including the soma and the axon hillock. *Blue* areas indicate presynaptic terminals onto the AIS. *Arrows* (white) point to the beginning of the AIS. (Adapted from Peters A, Proskauer CC, Kaiserman-Abramof IR. The small pyramidal neuron of the rat cerebral cortex. The axon hillock and initial segment. *J Cell Biol*. 1968;39:604–619; Kole MH, Stuart GJ. Signal processing in the axon initial segment. *Neuron*. 2012;73:235–247.)

N-methyl-D-aspartate [NMDA] type of glutamate receptor) can pass Ca^{2+} in addition to Na^{+}. Ca^{2+} is a universal second messenger triggering complex physiologic or pathologic cascades ranging, in the case of NMDA receptors, from synaptic plasticity to necrosis (Table 8.3).

Unconventional release and action is frequently associated with slower and longer-lasting but spatially localized modulatory effects: a slow background "offset" signal as opposed to the brief quantal information packet. The terms *paracrine* and *neurocrine* are used to describe this mode of release. Typically still AP-dependent, this mode allows rapid communication with larger population of cells over long distances while remaining more selective than neuroendocrine communication via the bloodstream. Small, gaseous molecules, including carbon monoxide, hydrogen sulfide, and nitric oxide as well as others, that are difficult to store such as cannabinoids (and probably other, yet undiscovered, substances) are released in a nonquantal fashion.[23] Some of these mediators make feedback communication from the postsynaptic to the presynaptic side of a chemical synapse possible (e.g., endocannabinoids modulate transmitter release from hippocampal GABAergic synapses).[24] Nonquantal release of conventional neurotransmitter such as acetylcholine also occurs under certain circumstances (e.g., during embryonic development.)[25]

Transmitter diffusing out of the synaptic cleft can activate receptor populations located extrasynaptically, as best described for GABA. Extrasynaptic $GABA_A$ receptors have distinct gating properties: they are activated by low concentrations of ambient GABA and they inactivate very slowly.[26] This mode of transmitter action is called *tonic* as opposed to the classic phasic action outlined earlier. Intermediate forms of transmitter action, such as on receptors located perisynaptically, also exist and give rise to slow phasic synaptic potentials.[27] Extrasynaptic NMDA receptors have also been described.

Termination of transmitter action can be effected either by diffusion away from the synapse, by active enzymatic degradation, and/or reuptake either into the terminal or into glial cells. The latter processes allow local recycling.

Plasticity

Structural and functional refinements of neural circuits, including those underlying learning and memory, are essential processes throughout the entire life of an organism. With few known exceptions, no new neurons are generated after the neonatal period. Therefore modifications of connections between existing neurons underlie all forms of behavioral modification based on experience. Information is stored by modifying the synaptic strength of

TABLE 8.3 Common Neurotransmitter Receptors

Neurotransmitter	Receptor	Type	Effect	Structure
Glutamate	NMDA	Ionotropic	Na^+, K^+, Ca^{2+} permeability	4 subunits: 2 GluN1, 2 GluN2
	AMPA	Ionotropic	Na^+, K^+ permeability	4 subunits:
	KA	Ionotropic/metabotropic	Na^+, K^+, Ca^{2+} permeability	out of GluA1-4, usually
	$mGluR_{1-8}$	Metabotropic	Different types exert different second-messenger effects	2 GluA2 and 2 of either GluA1, 3, or 4
Acetylcholine	Nicotinic	Ionotropic	Na^+, K^+, Ca^{2+} permeability	5 subunits: 3α, 2β (neuron) 2α, β, ε, δ (NMJ)
	Muscarinic	Metabotropic	↑ IP_3/DAG	
GABA	$GABA_A$	Ionotropic	Cl^- permeability	5 subunits: 3α:2β:γ
	$GABA_B$	Metabotropic	↓ cAMP	
Glycine	Glycine	Ionotropic	Cl^- permeability	5 subunits: 3α,2β or 4α,1β
Serotonin (5-hydroxytryptamine)	$5\text{-}HT_1$	Metabotropic	↓ cAMP	
	$5\text{-}HT_2$	Metabotropic	↑ IP_3/DAG	
	$5\text{-}HT_3$	Ionotropic	Na^+, K^+, Ca^{2+} permeability	5 subunits
Norepinephrine	$\alpha_{1,2}$	Metabotropic	↑ IP_3/DAG	
	$\beta_{1,2}$	Metabotropic	↑ cAMP	
Dopamine	$D_{1,5}$	Metabotropic	↑ cAMP	
	$D_{2,3,4}$	Metabotropic	↓ cAMP	
Substance P	NK_1	Metabotropic	↑ IP_3/DAG	
Opioids	μ, δ, κ	Metabotropic	↓ cAMP	

AMPA, 2-Amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid; *Ca,* calcium; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *Cl,* chloride; *DAG,* diacylglycerol; *GABA,* gamma-aminobutyric acid; *IP_3,* inositol triphosphate; *K,* potassium; *Na,* sodium; *NK_1,* neurokinin 1; *NMDA,* N-methyl-D-aspartate; *NMDAR,* NMDA receptor; NMJ, neuromuscular junction.

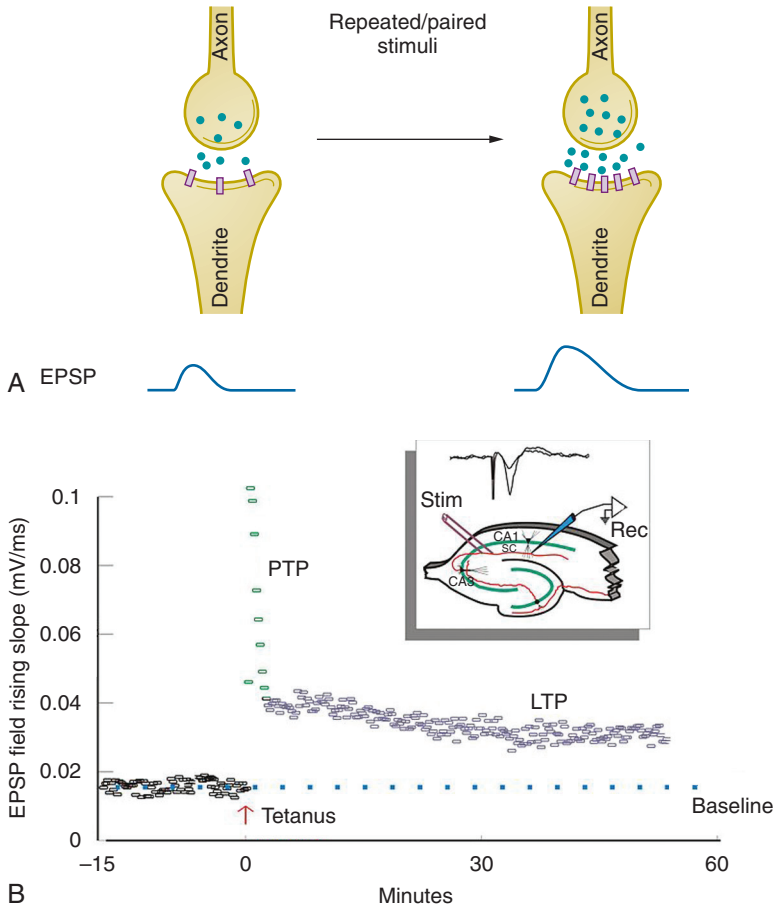
connections in a process called *synaptic plasticity*. Synaptic plasticity occurs on a number of time scales and is present from the ganglion of an invertebrate to the neocortex of a mammal. The forms of plasticity usually associated with long-term storage in the mammalian brain are termed long-term potentiation (LTP) (Fig. 8.8) and long-term depression (LTD). LTP and LTD have been best described at glutamatergic synapses but occur also at GABAergic synapses. The fundamental principle of synaptic plasticity was postulated by Hebb in 1949.[28] In the most generic terms, rapid repeated depolarization of a glutamatergic presynaptic terminal will depolarize the postsynaptic neuron (with or without actual spiking) and cause Ca^{2+} entry.[29] Depending on the circumstances the synaptic strength between these neurons will be either upregulated or downregulated, resulting in LTP and LTD, respectively.

The temporal requirements of plasticity are captured in the concept of spike-timing–dependent plasticity (STDP): LTP results when a synaptic input is followed within a narrow temporal window by spiking of the postsynaptic cell. The length of this window varies depending on the nature of the connection and the cell types involved.[30,31] Spiking outside this window has either no effect or results in LTD. Obviously, synchronization between cell populations is necessary for appropriate timing of synaptic inputs and spikes for STDP to occur and might be one of the functions of high-frequency brain oscillations.[32] Depotentiation/LTD-like processes are thought to occur during slow-wave sleep to "reset" the brain for a new day of learning.[33]

Transmitters and Receptors

Release of the major excitatory transmitter L-glutamate activates both ionotropic and metabotropic receptors. The three major types of ionotropic glutamate receptors (KA, AMPA, and NMDA) are named after their selective agonists (kainic acid, α-amino acid-3-hydroxy-5-methyl-4-isoxazole, and N-methyl-D-aspartate). The non-NMDA group (KA and AMPA) is permeable to monovalent cations and underlies fast excitatory postsynaptic potentials (EPSPs).[34]

NMDA receptors are blocked by extracellular Mg^{2+} at the concentration present in the extracellular fluid (see Table 8.1). Therefore the NMDA channel does not contribute substantially to a regular EPSP. However, as the Mg^{2+} block is relieved by depolarization, repetitive or particularly strong stimuli can depolarize the postsynaptic membrane sufficiently to open NMDA receptor-associated channels, such as when the postsynaptic cell fires an AP. Open NMDA channels allow Ca^{2+} into the cell. NMDA receptors act therefore as "voltage sensors" and allow a "conditional" Ca^{2+} signal to occur. For this reason, NMDA receptors play a pivotal role in processes that lead to synaptic plasticity. The Ca^{2+} influx via NMDA receptors is also responsible for glutamate toxicity (excitotoxicity) that occurs when high levels of glutamate are sustained for a long time, such as during status epilepticus. NMDA receptors have slower kinetics than their non-NMDA counterparts and, under appropriate conditions such as when the cell is depolarized or when Mg^{2+} is omitted from the extracellular fluid, slow



• **Fig. 8.8** Synaptic plasticity illustrated by long-term potentiation *(LTP)*. A, LTP can be caused by a variety of mechanisms that can be primarily presynaptic or postsynaptic. The preponderance of mechanisms varies between circuits and the exact mechanisms are still debated. The end result is a use-dependent increase in the postsynaptic response illustrated here as occurring via an increase in both the number of postsynaptic receptors and the amount of transmitter release. Typically, an individual synapse shows only one of these changes. B, Time course of experimental LTP induction in the CA1 area of the hippocampus where plasticity has been studied since the 1970s. The inset shows the iconic cross section of the hippocampus as seen in a transverse slice. Areas of projection neurons are shown in *green* and the principal excitatory pathways in red. Tetanic stimulation of the Schaffer collaterals (excitatory axon collaterals connecting the hippocampal areas CA3 and CA1) with one electrode (Stim) leads to an increase in field excitatory postsynaptic potentials *(EPSPs)* recorded by a second electrode (Rec) placed in the termination zone of the Schaffer collaterals in the dendritic arbor of CA1. Stimulation using a different pattern results in long-term depression *(LTD)* of the same pathway. *Rec,* recording electrode; *Stim,* stimulating electrode. (From An example of long-term potentiation recorded at Schaffer collateral/CA1 synapses in the hippocampus of rat brain. http://en.wikipedia.org/wiki/File:LTP_exemplar.jpg.)

NMDA EPSPs can be observed. The NMDA receptor is a target of the hallucinogen phencyclidine (PCP) and of the anesthetic drug ketamine.[35]

Metabotropic G-protein–coupled glutamate receptors can be excitatory or inhibitory. Glutamate binding to the receptor stimulates the activity of phospholipase C, leading to the formation of inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG), which function as intracellular second messengers. Similar to NMDA receptors, this pathway leads to increase in intracellular Ca^{2+}, but in this case by release of Ca^{2+} from intracellular stores. This release causes a slow depolarization by reducing membrane permeability to K^+. On the other hand, glutamate binding to these receptors on the presynaptic terminal (autoactivation) causes presynaptic inhibition.[35]

GABA is the major inhibitory neurotransmitter in the brain and follows the ionotropic and metabotropic pattern with $GABA_A$ and $GABA_B$ receptor types, respectively. $GABA_A$ receptors are receptor/channel complexes passing anions: mostly Cl^-, but also HCO_3^-. The receptor has two binding sites for GABA, and the channel opens when both sites are occupied. This channel is the major target for a variety of drugs, including many anesthetics.[36] Interneurons are the main source of GABAergic synaptic transmission. They display a remarkable morphologic and neurochemical diversity that reflects a "computational" role of GABAergic transmission.[37,38] $GABA_B$ receptors are G-protein–coupled receptors, the activation of which leads to opening of K^+ channels via a second-messenger cascade.[39]

Glycine is also a major inhibitory neurotransmitter, primarily in the spinal cord. It is released by local inhibitory interneurons and activates ligand-gated Cl^- channels. Metabotropic glycine receptors have not been described. The structure of the glycine

receptor is very similar to that of $GABA_A$ and nicotinic acetylcholine receptors (they are all members of the cys-loop family of pentameric ligand-gated ion channels). However, it requires three glycine molecules to open the channel.[40] Glycine also acts as coagonist of glutamate at NMDA receptors.

Acetylcholine also follows the ionotropic-metabotropic scheme with nicotinic and muscarinic receptors, respectively. Nicotinic receptors are ionotropic and are present at the CNS in addition to their well-known role at the neuromuscular junction and in the autonomic nervous system. Structurally, they are related to $GABA_A$ and glycine receptors.[40] There are several types of muscarinic G-protein–coupled receptors. Acetylcholine is released by neurons of brainstem nuclei that send projections to wide areas of the cortex and striatum. It is involved in regulation of wakefulness, attention, learning, and motivation.[41,42]

Neuronology

The brain displays a large variety of neurons of many different shapes and functions. Principal neurons, also referred to as projection neurons, send their projections to distant locations, either at a different brain structure or, for some cortical neurons, to a different area of cortex. The white matter is composed of their axons crossing from their origin to their targets. Projection neurons can be glutamatergic (e.g., layer V pyramidal neurons, hippocampal pyramidal cells) or GABAergic (e.g., cerebellar Purkinje cells, striatal medium spiny neurons). Pyramidal neurons are the major excitatory neurons in the cortex and hippocampus. They are named so due to the triangular shape of their soma. They have an axon leaving the base of the pyramid, a long dendrite arising from the apex to higher layers of the cortex, and a number of basal dendrites arising from the base and branching in the same layer. The populations of pyramidal and principal neurons overlap to a large degree. Interneurons typically synapse within local circuits. Their axons do not cross via the white matter. Interneurons in the cortex are mostly inhibitory. However, excitatory and modulatory interneurons exist in other brain areas. In some areas of the brain such as the hippocampus, interneurons display a dazzling variety that is reflected in the picturesque nomenclature (e.g., chandelier cells, ivy cells, neurogliaform cells). Recent work has begun to unravel the functional implications of their highly diverse anatomy (especially the highly selective projections of their axons).

The Brain: Structure Determines Function

For obvious reasons, the brain is frequently compared to a computer.[43] While the similarities are obvious on a superficial level, the fundamental differences illuminate why brains, unlike computers, are complex (in addition to being complicated) systems.

- Diversity: individual transistors are homogenous while neurons are diverse.
- Adaptation: transistors lack adaptability while neurons and their connections adapt constantly and on different time scales.
- Connectivity: the interconnectivity of transistors is very low, typically in the single digits per gate, while interneuronal convergence and divergence rates range in the (tens of) thousands.
- Integration: strict separations between memory and computation as well as hardware and software are standard features of computer architecture but are interwoven on multiple levels in the brain.
- Last but not least, in contrast to computers, brains wire themselves up during development and continue to "rewire" during their functional life.

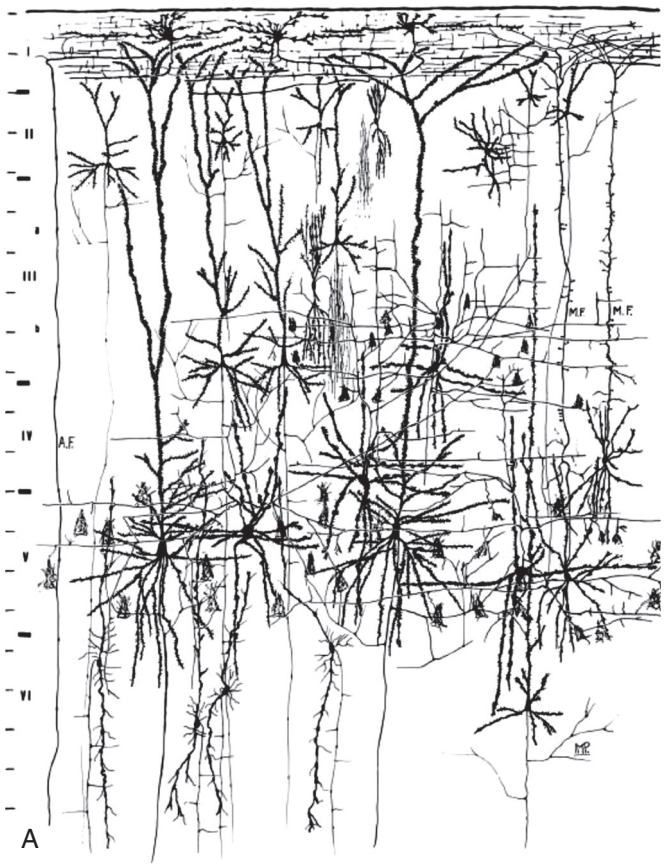
Structure

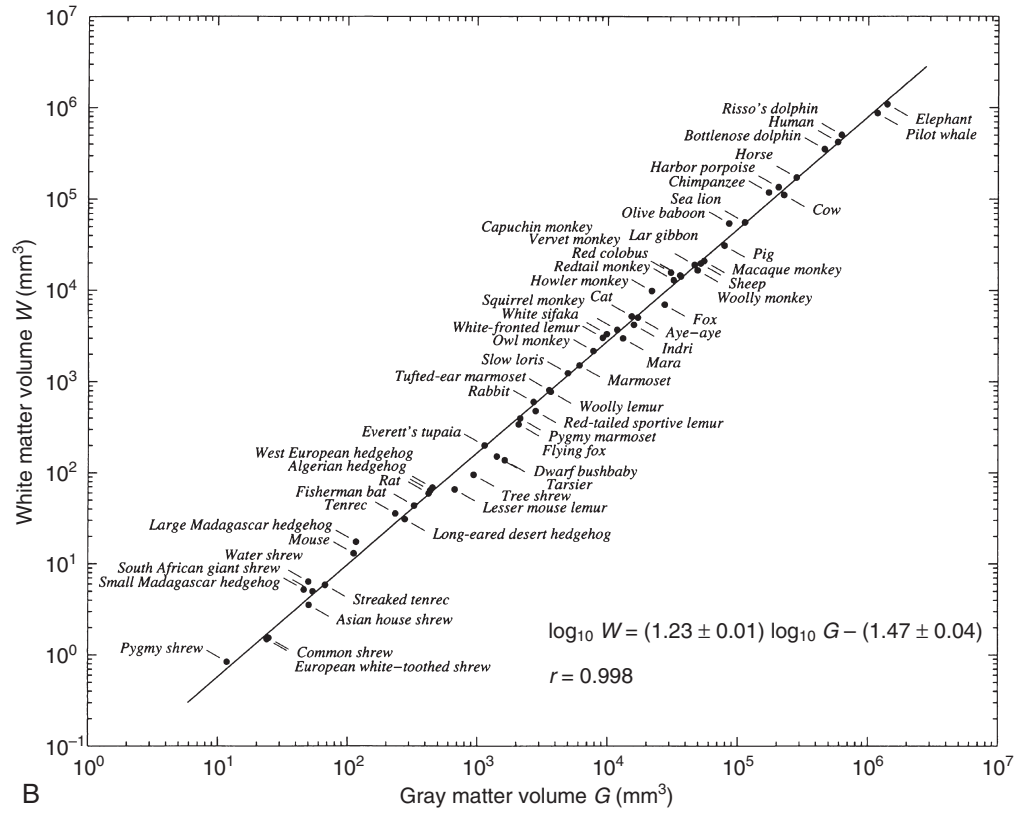
Brains evolved to allow movement. Once in place, sensors to find food and avoid harm as well as adjusting activity to the dark/light cycle became indispensable for evolutionary success. On top of the basic circuitry necessary to allow the aforementioned functions, additional parallel circuits (neuronal loops) were superimposed during evolution and linked "vertically," generating a hierarchical organization among parallel loops. Older loops are located at the bottom while the more recently added rest on top. The more layers (i.e., the more complex the animal), the more complex and controlled the response to an identical stimulus becomes.

Connectivity is the essential challenge as the number of potential connections between the 10^{11} neurons of the human brain is both unimaginable and inefficient. The solution has to accommodate two competing principles: the degree of local clustering (the density of connections) and the degree of separation (synaptic path length) between distant parts of the brain. High clustering is desirable for coordinated computation—as between neurons in a single visual column. Low synaptic path length is also essential for fast integration of information between physically remote areas, a particular feature of the cortex. Both are expensive with respect to axonal length. The proposed solution is known as "small world networks" (originally proposed outside the field of neuroscience) in which, by replacing a small fraction of local connections with random long-distance connections, the average path length can be dramatically shortened with minimal reduction of clustering.[44] Furthermore, the larger the network, the greater the impact of each random link: a smaller fraction of random connections is required in the human brain than in the mouse brain to achieve the same short synaptic path length despite the difference in size. Nevertheless, cortical white matter volume expands more than gray matter volume with increasing brain size (Fig. 8.9).[45]

The *cortex* is a scalable structure that has expanded greatly during mammalian evolution: the neocortical gray matter and the adjacent white matter occupy 10% to 20% of total brain volume in insectivores but 80% in humans. It has been suggested that the smallest functional division of the monkey cerebral cortex (analogous to a single nephron) that can perform the typical "cortical" computational tasks (e.g., a single location in visual space) is about 1 mm^2.[46] Even though the boundaries of a module are difficult to determine, it can be estimated that the total number of cortical modules increases about 10,000-fold from the smallest mammal to the human brain. The human brain, however, is of course not like thousands of mouse brains lumped together.

The cortex can be subdivided into the isocortex, which has a six-layer structure, and the allocortex (heterotypical cortex), which has a variable number of layers. The modular plan of the cortex is identical in all mammals: the isocortex consists of five layers of neurons and a superficial layer of mostly dendrites and axons. Its thickness is only about 1 to 3 mm. The cortex is built up by multiplication of fundamentally identical "modules" that are variably referred to as *columns, barrels,* or *stripes,* and each contains roughly 50,000 to 100,000 neurons. The allocation of space to different functions is a compromise of evolutionary needs, metabolic and wiring costs, and spatial constraints. This is optimized for making predictions and inferences most valuable in the physical niche inhabited by the owner of the brain: echolocation for bats, accurate topography using snout whiskers for many rodents, or pictorial representation of the environment in the primarily visual primates.[38] In the most complex brains, a large proportion of the cortical mantle specializes in processing and generating activity



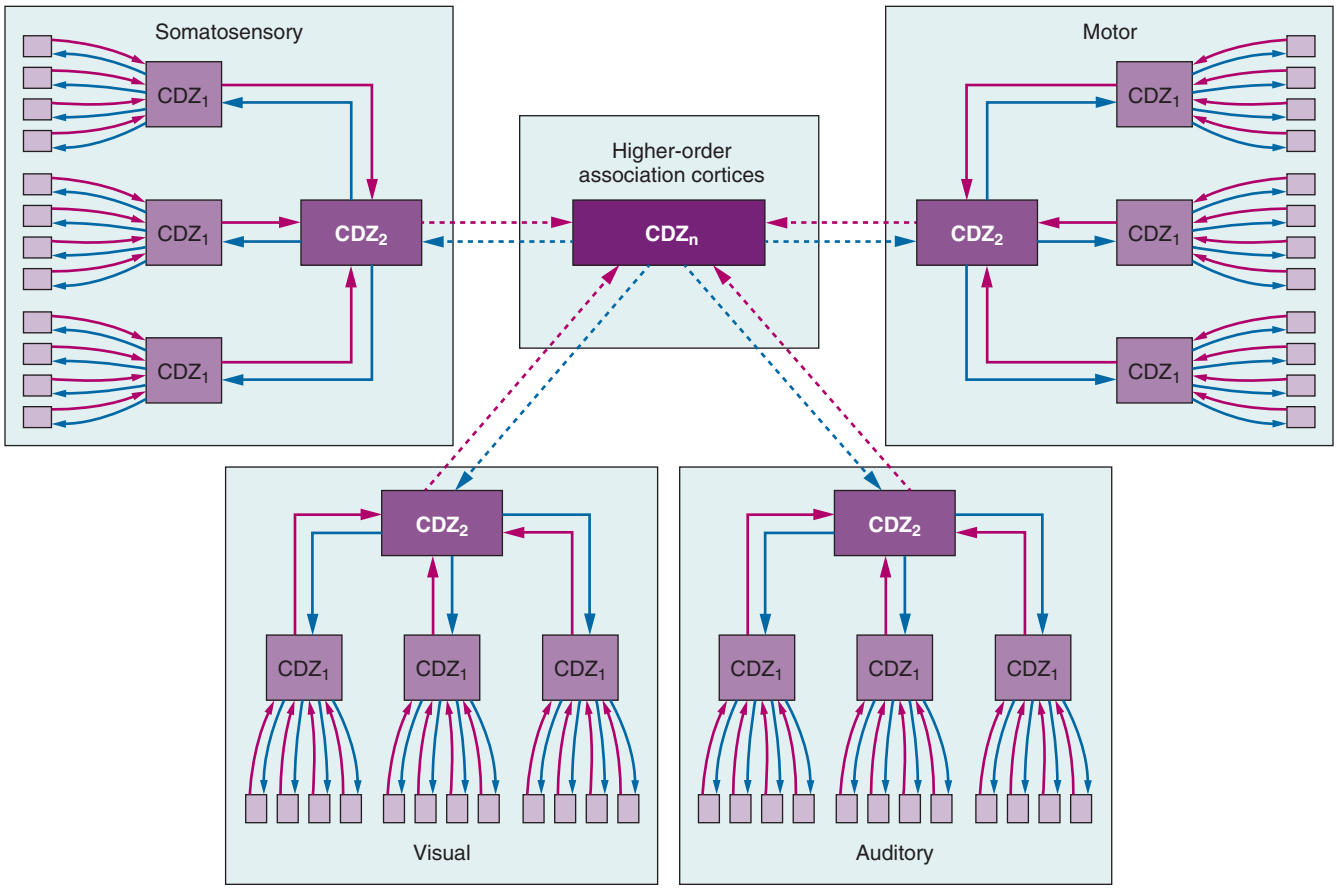


• **Fig. 8.9** The neocortex: layers and the demands of connectivity. A, Camera lucida drawing based on a Golgi preparation of the motor cortex. Note the layered organization with diverse types of neurons dominating in the different horizontal layers. This basic structure is typical for the neocortex. Neurons are tightly packed: a column with a cortical surface area of 1 mm^2 is populated by thousands of neurons. To function, cortical modules must be well connected to their neighbors and to more distal areas. B, With increasing cortical size, more space is required for efficient communication pathways. The cortical white and gray matter volumes are related by a power law that spans five to six orders of magnitude in extant mammals demonstrating the "real estate" cost of maintaining high interconnectivity characteristic of advanced brains. (A, Adapted from Marin-Padilla M. Prenatal and early postnatal ontogenesis of the human motor cortex: a Golgi study. I. The sequential development of the cortical layers. *Brain Res*. 1970;23:167–183; B, Adapted from Zhang K, Sejnowski TJ. A universal scaling law between gray matter and white matter of cerebral cortex. *Proc Natl Acad Sci U S A*. 2000;97:5621–5626.)

only indirectly related to immediate sensory input or direct motor output; these areas are referred to as *associational areas* and are also hierarchically organized. Importantly, connections between functional brain areas are always bidirectional. With ascending hierarchy, an area becomes ever less directly linked to it sensory modality and ever more interconnected with associational areas of other modalities, as proposed in the convergence-divergence-zone framework (Fig. 8.10).[47]

The hippocampal formation includes the hippocampus proper, dentate gyrus, subiculum, and entorhinal cortex and is the main constituent of the allocortex. In addition to being part of the limbic circuit, it is the brain's ultimate memory machine specialized for, on the one hand, forming quickly updatable cognitive maps of the environment and, on the other hand, forming the flexible expression of declarative, episodic memories.[48] As a corollary, it is also essential for projecting one's experience forward in time and space, thereby "predicting the future." While it is not the long-term storage site for memories, the hippocampal formation remains the "librarian of the brain," facilitating the retrieval of stored memory traces.

The need to organize individual experiences within temporal space is shared by both spatial and episodic memories. Coincidentally, the hippocampal formation expresses one of the most prominent synchronized rhythmic oscillations of the mammalian CNS—the theta (θ) rhythm that serves as a timing mechanism (see later text). The distinct anatomy of the allocortex reflects these specialized computational needs. Contrary to the small-world organization of the neocortex, the whole hippocampus forms a single huge neuronal space, analogous to one oversized cortical module creating a giant random connection space that is necessary for combining arbitrary information (analogous to RAM in computers). The circuitry is dominated by the famous trisynaptic excitatory loop from the entorhinal cortex to dentate gyrus granule cells to pyramidal cells of the hippocampal CA3 and on to CA1 pyramidal cells, which then project back to the entorhinal cortex. The distribution of contacts in the dentate gyrus/CA3/CA1 network is reminiscent of a random graph with very low clustering—only about 2% to 5% connection probability—but with equal likelihood of contacting near and remote neurons (unlike the small-world arrangement of the neocortex). The axon of a CA3 neuron in the



• **Fig. 8.10** Hierarchical organization of the brain. Contrary to the Jamesian view, the model proposed by Damasio's laboratory in the "convergence-divergence zone" *(CDZ)* framework accentuates the bidirectionality and cross-modality of intracortical communication on each level of information processing. Neuronal ensembles in early sensorimotor cortices of different modalities (represented by the smallest *rectangles*) send converging forward projections *(red arrows)* to first-order CDZs (CDZ_1s), which, in turn, project back divergently *(blue arrows)* to the early cortical sites. Similar convergent-divergent connectivity patterns interlink CDZ_1s with CDZ_2s and CDZ_2s with CDZ_ns in higher-order association cortices (via several steps not represented here; *dashed arrows*). (Reprinted with permission from Meyer K, Damasio A. Convergence and divergence in a neural architecture for recognition and memory. *Trends Neurosci*. 2009;32:376–382.)

rat is between 150 and 400 mm long establishing 25,000 to 50,000 synapses within the ipsilateral and about half as many within the contralateral hippocampus. This amounts to a total of 40,000 meters of axon collaterals and 5 to 10 billion synaptic contacts in each hemisphere of the walnut-sized rat brain.[49] The mnemonic functions of the hippocampal formation can be conceptualized and allocated to the components of the trisynaptic circuit as follows: dentate gyrus—pattern separation or disambiguation, that is, differentiation between similar-appearing contexts; CA3—pattern completion, that is, reconstruction of a whole representation based on fragmentary information; CA1—mismatch detection, that is, detection of unpredicted novelty in the environment, a task essential for survival.

Sequential, recurrent, and reentrant excitatory connections have the propensity to create runaway excitation. However, through tight control by intricate multifaceted inhibitory networks, excitation can be harnessed into useful computation.[50,51] Because these powerful excitatory loops are notorious for becoming unbalanced, the medial temporal lobe has become the preferred substrate for in vitro studies of epilepsy, and the target of surgical attempts to cure this disease. In the healthy brain, a complex array of inhibitory loops consisting of diverse, specialized interneurons precisely controls the balance and timing of excitation and inhibition.

The *thalamus* is located in the very center between the two hemispheres, minimizing the length of reciprocal wiring and maximizing communication speed, which is optimal to function as a relay of information transmission to the cortex. It is a collection of nuclei that receives and processes all primary sensory input to the neocortex with the exception of olfaction; however, there are many more nuclei than sensory modalities and a large part of the thalamic circuitry is unrelated to early processing of sensory information. Thalamocortical neurons send their axons predominantly to layer 4 of the neocortex but also to layers 5 and 6. In return, thalamic nuclei are the only target outside the cortex of cortical layer 6 pyramidal cells. Thalamocortical neurons support a complement of membrane channels that can convert them into oscillators—nature's delta-frequency clocks. Unlike the cortex, most GABAergic inhibitory cells are localized in the reticular nucleus, forming a shell surrounding the thalamic space. Reticular thalamic neurons are connected not only by classic chemical synapses but also by dendrodendritic synapses and gap junctions.[52,53] The dense reciprocal connectivity with the cortex paired with the special oscillatory propensity of thalamocortical neurons generates the diverse array of thalamocortical oscillations in different frequency bands. These oscillations show dramatic transitions between waking and sleep states and, in fact, might be the driving force behind them. A pivotal role of these thalamocortical oscillations in the mechanisms underlying consciousness and anesthetic action has been suggested.[54]

The *cerebellum* is, from the point of view of circuitry, the antipode of the neocortex in that its distinctive computational arrangement is in parallel loops favoring autonomic (as opposed to interactive) activity. The cerebellum contains as many cells as the rest of the human brain combined—the granule cells alone are more numerous ($\sim 10^{11}$) than all neurons of the neocortex. The cerebellum continuously monitors the activity of skeletal muscles and communicates with brain areas controlling these muscles. These computations, carried out in the anterior and posterior lobes, are largely subconscious and can therefore take place at speeds unattainable via conscious sensory systems. The phylogenetically older flocculonodular lobe attends to posture and eye movement. The cerebellum exists in all vertebrates. Deep cerebellar nuclei (interposed, fastigial, and dentate) act as relays for incoming and outgoing information, controlling ipsilateral limb movements, trunk movements, and motor planning, respectively. There is no equivalent to the corpus callosum and no intermediate or long-range associational paths within the cerebellum.

The granule cells are the only intrinsic excitatory neurons; the other four neuron types (Purkinje, basket, stellate, and Golgi) involved in computation are all inhibitory and target deep cerebellar nuclei, soma of Purkinje cells, and dendrites of Purkinje and granule cells, respectively. The elaborate dendritic arbor of the Purkinje cell is one of the most recognizable features of CNS histology. In diametric difference to the three-dimensional expansion and rich lateral connectivity of cortical pyramidal cell dendrites, Purkinje cells appear two-dimensional with minimal contacts to their neighbors providing for maximal computational autonomy. Purkinje cells receive a direct excitatory input by way of the climbing fibers that originate in the inferior olivary nucleus of the brainstem. This pathway can be seen as a shortcut. The overall organization of the cerebellum results in two parallel feed-forward inhibitory loops that control the output of deep cerebellar nuclei.[55]

The *basal ganglia* are a group of nuclei located below the cerebral cortex. They includes the striatum (caudate and putamen), globus pallidus (external and internal segments), subthalamic nucleus, and substantia nigra (pars compacta and pars reticulata). These nuclei create a feed-forward loop that receives information from most of the cerebral cortex, and after processing returns its output to the frontal and motor cortex via the thalamus. These nuclei are unique in that the major neurotransmitter they use is GABA, which is used in this system not only locally by interneurons but by the projection neurons as well, creating a variety of inhibitory and disinhibitory responses (inhibition of inhibition that leads to excitation). Other important neurotransmitters in this system are the neuromodulator dopamine that is released in the striatum by substantia nigra neurons and acetylcholine released from local interneurons.[56]

The basal ganglia play a major role in the motor system. This was deduced from the clinical manifestations of basal ganglia disorders: loss of dopaminergic cells in the substantia nigra leads to Parkinson disease, a disease manifested by difficulty initiating movement, slowness of movement, and tremor during rest. Loss of striatal neurons in Huntington disease, on the other hand, leads to uncontrollable jerking movements. Basal ganglia also play a role in other tasks such as procedural learning, motivation, and response to reward and addiction.[56]

Spinal Cord

Despite the anatomic separation, the spinal cord and the brain share most of the molecular targets of anesthetic drugs. The spinal cord does, however, have distinct arrangements on the circuit and network levels that can influence its responsiveness to anesthetic drugs. The spinal cord is organized segmentally (31 segments in the human); pairs of spinal nerves exit the cord at each segment. The nerve rootlets forming the sensory (dorsal) and motor (ventral) component combine into a mixed nerve. Each segment of the spinal cord is associated with a pair of dorsal root ganglia located just outside the cord and harboring the cell bodies of sensory neurons.[55]

Behavior is determined by the motor output of the CNS, and the absence of movement is an important component of anesthesia. Motor output, in turn, is the function of three inputs: sensory (reflexive), cognitive (voluntary), and intrinsic (behavioral) state. The relative importance of these inputs varies from species to species and between individuals. All three are affected by anesthesia.

The main determinant of movement in the context of anesthesia is the skeletal muscle system. It is organized hierarchically with the α-motoneurons (their cholinergic axons synapse directly on muscles) on the bottom. The next higher level consists of motor pattern generators (MPGs)—circuits of interneurons that innervate unique sets of motoneuron pools. MPGs are also organized hierarchically. For locomotion, simple MPGs coordinate antagonistic muscle movement across one joint, more complex MPGs coordinate activity of simpler MPGs for all joints of an extremity, and higher-order MPGs coordinate activity between limbs. A still higher level consists of motor pattern initiators that "plan" movements. Each of the three types of inputs (sensory, voluntary, intrinsic) can go directly to each hierarchical level.[57]

Interneurons are the critical components of MPGs; in the spinal cord, interneurons have many convergent and divergent connections allowing them to integrate signals from different sources, including both supraspinal and primary sensory. The most common fast inhibitory transmitters in the spinal cord are glycine and GABA, whereas glutamate dominates excitation (with one notable exception being the cholinergic α-motoneuron to Renshaw-cell synapse). Interneurons are also organized in pools that can be partially activated by an input. The activation by two inputs can produce a greater output than the sum of the individual inputs. This can lead to spatial and/or temporal facilitation depending on timing and origin of the stimuli. However, once the whole pool is activated, further increases in stimulation intensity have no effect. On the output side, interneurons connect to several different targets, including other interneurons and motoneurons. Those interneurons synapsing on motoneurons are called *last-order interneurons*.[57]

For a movement to be considered valid for the purpose of minimum alveolar concentration (MAC) determination of anesthetic potency (see Chapter 3), it has to be "gross and purposeful."[58] This definition, while practical, disregards the "neural content" of a movement. Considering the complexity of circuitry underlying any but the most basic reflexes (which are excluded by the definition of MAC), it is almost surprising that systematically reproducible results are obtained at all. Nevertheless, more in-depth analysis reveals that accurate interpretation of the movement response under anesthesia is more complicated than the deceptively simple all-or-none definition suggests.[59] Moreover, whether explicitly stated or not, an assumption implicit in the definition is that anesthetic suppression of movement involves a "higher agency" and hence that the state of the brain should be predictive of the occurrence of movement in response to noxious stimulation under general anesthesia. However, in the decades since the introduction of the MAC concept into research and clinical practice, it became obvious that, regardless of which analytical techniques were applied to extract information from the electroencephalogram (EEG), attempts to predict movement under anesthesia remained unsuccessful.[60] The reason for this conundrum was discovered in the 1990s—anesthetic-induced immobility (with the exception of some injectable agents) is mediated by action in the spinal cord.[61,62] It is noteworthy that experiments early in the 20th century had already indicated that the spinal cord contains circuits, now collectively referred to as *central pattern generators*, capable of generating coordinated patterns of muscle activity including actual locomotion. Therefore the spinal cord even on the segmental level provides a rich substrate for anesthetic action.

Interestingly, the brain, far from mediating anesthetic-induced immobility, appears to counteract it. After the description of this finding in goats, the site mediating this antagonism has been identified (at least in the rat): the mesencephalic locomotor region facilitates ventral spinal locomotor centers—a potential mediator of the "anti-immobilizing" effect of the brain on anesthetic action in the spinal cord.[63]

Function

The traditional Jamesian view of the brain as an organ whose function is primarily determined by responses to sensory input is undergoing a thorough revision. The brain is a foretelling, not a reflecting, device whose power to predict relies on a variety of synchronous rhythmic activities it constantly generates internally. Simultaneously, the brain is also a highly adapted observational device of the environment, with an ability rooted in flexible neuronal firing patterns within rhythmic oscillatory activity of networks organized in hierarchical structures. Central pattern generators of varying complexity have long been recognized as underlying rhythmic activities from peristalsis of the gut, writhing of lampreys to locomotion—from bipedal to centipede walking, respiration, and so on. An exciting breakthrough in the neurosciences of the past 20 years was the recognition that (complex) rhythmic activity patterns (but without an easily definable generator) also underlie higher cognitive functions. A corollary of this view is that, far from being primarily driven by external inputs, the brain constantly generates a dynamic internal state that is only gradually perturbed by exogenous input. However, these external perturbations are necessary to generate behaviorally useful computations that sculpt the familiar "real-world" experience.

Default Mode Network

The advent of magnetic resonance imaging (MRI) in its manifold permutations, and especially functional MRI (fMRI, see later text), has opened a new dimension of in vivo human brain structure and activity investigation. fMRI has revealed a task-independent constellation of brain areas that are functionally linked in a distributed network during "intrinsic" brain activity—that is, in the absence of goal-directed behavior. This network is reproducible both within and across subjects and has come to be called the default mode network.[64] The default mode network includes discrete brain regions whose metabolic activity (which is indirectly measured by fMRI) predictably covaries during seemingly "idle" (not directed at specific activity) states of the brain. The exact nature of the processes underlying this signal and their quantitative contribution to it have not been fully clarified because the fMRI signal is a composite measure of changes in cerebral oxygenation, blood volume, and blood flow. Recent research indicates that fMRI signal changes in the cerebral cortex are linked closer to synaptic than to spiking activity.[65] Whatever its underlying content, the existence of the default mode network supports the notion of a dynamic intrinsically generated state of the brain.

Brain Rhythms

The brain constantly generates macroscopic electrical signals that vary with physiologic activities and pathologic states. With the exception of high-resolution implantable electrodes, all electrical brain signals reflect the sum of the activity of large neuronal pools. The surface EEG, in particular, is driven by the activity of layer V cortical pyramidal cells. The dendritic trees of these neurons extend toward and then parallel to the surface of the cortex. The synaptic inputs to these dendrites cause alternating potential differences that are the predominant basis of the EEG signal rather than action potentials (somewhat similar to the fMRI blood oxygenation level–dependent [BOLD] signal). The activity in the dendritic trees of approximately 50 to 500,000 pyramidal neurons is reflected in each surface EEG electrode.

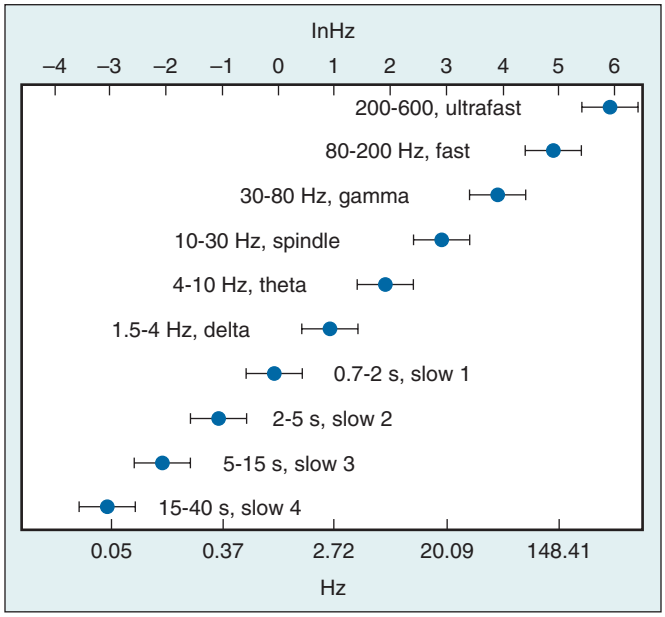
TABLE 8.4 Electroencephalogram Wave Categorization by Frequency

Rhythm	Frequency (Hz)	Typical Occurrence	Comments
Slow	<1	SWS	Cortical up/down states, generated by corticothalamocortical loops
δ	0.5-4	Frontal, SWS, deep sedation	
θ-	4-8	Frontal and midline Hippocampal θ difficult to record in humans unless implanted electrodes used	Hippocampal θ linked to mnemonic function; Surface θ appears with altered states of vigilance, also meditation
α-	8-13	Occipital with eyes closed and mental relaxation	Intermittent, waxing-waning pattern during SWS stage II as sleep spindles
β	13-30	Frontal, sensorimotor systems	Preparation and inhibitory control
γ	30-90	Diffuse, generated by local circuitry	Awake, hypervigilant desynchronized EEG; REM sleep; nested into hippocampal θ
γ	>100		Hippocampal ripples during non-θ states

EEG, Electroencephalography; *REM,* rapid eye movement; *SWS,* slow-wave sleep.
The table shows commonly described rhythms observable in mammals. The frequency range varies somewhat between species. The δ-range has been recently further subdivided into various slow rhythms, particularly during sleep. Slower rhythms have higher power density than faster ones. Rhythms faster than slow γ-spectrum cannot be resolved with surface electrodes. Rhythms of different frequencies occur concurrently: θ-γ nesting, sleep spindles during δ. The same frequency does not indicate the same mechanism and physiology: continuous α and intermittent sleep spindles share frequency but nothing else.

A summary of commonly observed EEG rhythms is presented in Table 8.4. Oscillations in a mammalian brain do not present a continuum even though their period ranges from seconds to milliseconds. As illustrated in Fig. 8.11, discrete oscillation bands form a linear progression on a natural logarithmic scale (a geometric progression on a linear scale), thereby avoiding unwanted harmonic interference that would be a hazard with integer steps between peak frequencies. As a general rule, higher frequency patterns emerge locally, whereas slower frequencies involve larger brain areas.[66]

While the functional significance of these rhythms has long been questioned—they were seen as mere epiphenomena with respect to higher cognitive functions—research in the past 20 years has changed this interpretation dramatically. Synchronized activity in different frequency bands is now thought to allow communication and integration of information between physically separate brain areas, an indispensable functionality for all manifestations of the mind, even though it remains elusive to conclusively demonstrate a causal relationship between specific brain processes and synchronous oscillations.



• **Fig. 8.11** Brain electrical oscillations. The mammalian brain generates oscillations in electroencephalographic recordings ranging from ultraslow to ultrafast without major gaps to allow neuronal networks of different sizes to cooperate in a coordinated manner. Slower frequencies are thought to allow more complex integrations. Higher frequencies enable more precise and spatially limited representations. The analysis of Pentonen and Buzsáki demonstrates the peak frequencies of discrete oscillation bands forming a geometric progression on a linear scale or a linear progression on a natural logarithmic scale. (From Penttonen M, Buzsáki G. Natural logarithmic relationship between brain oscillators. *Thalamus Relat Syst*. 2003;2:145–152.)

Emerging Developments

Probing the Brain

Recently developed methodologies applied to the study of anesthetic effect on the brain on a wide range of scales: from point mutations that enable the study of a single locus in a specific gene to measuring the activity of thousands of neurons using the fMRI BOLD signal.

Gene knock-ins, knockouts, and point mutations refer to genetic engineering techniques. In knock-in animals novel externally supplied genes are expressed, whereas in knockouts native genes are deleted or suppressed. Point mutations involve the expression of genes with targeted modifications in the nucleotide sequence of the DNA leading to changes in the amino acid sequence of the protein product. These models are useful in understanding the effects of specific genes: a loss of behavior following a gene knockout suggests that the gene is involved in that specific behavior. For example: TREK-1 knockout mice display a reduced sensitivity to volatile anesthetics but not to barbiturates, suggesting that TREK channels are a target of volatile anesthetic action.[67]

Nonsynonymous point mutations provide molecular-level resolution of drug-receptor interaction. Replacing the asparagine residue at position 265 in the β3 subunit of the $GABA_A$ receptor to

methionine renders the mutated mice insensitive to etomidate and propofol, strongly suggesting a critical role of β3 subunit–containing $GABA_A$ receptors in the mechanism of action of two important anesthetics.[68,69]

A variety of electrophysiologic tools are available with a resolution ranging from individual neuron activity to averaging of hundreds of neurons and performing simultaneous recording from multiple locations possible,[70] providing high temporal and spatial resolution at the price of being resource-intensive and analytically complex. Intracellular recordings allow unparalleled access to and control of an individual neuron's activity,[71] and cutting-edge advances of this technology make it feasible to record simultaneously from multiple neurons, from dendrites, from certain presynaptic terminals, and also in vivo.[72]

Optogenetics and Pharmacogenetics

Genetic engineering in vivo opened the door to a new generation of experimental interventions. Initially genes encoding fluorescent proteins were used as reporters to verify the expression of knock-in genes.[73] The subsequent insertion of functional genes encoding light-activated channels represented a major advance in our ability to exogenously control neuronal function. Channelrhodopsin,[74,75] a light-activated cation channel originating from algae, followed by halorhodopsin and archaerhodopsin, made it possible to activate and silence neurons using light sources of different wavelengths. Combining these techniques with genetic engineering methods (such as Cre-Lox recombination technology) allows the expression of these genes in specific neurons and hence targeted exogenous control of entire cell populations[76] (Fig. 8.12). Combining these genetically introduced activators/inhibitors of neuronal activity with sensitive fluorescent biosensors for neuronal activity, such as intracellular Ca^{2+} or membrane potential, heralds an era of optophysiology.

Designer receptors exclusively activated by designer drugs (DREADDs) technology uses G-protein-coupled receptors originally mutated from muscarinic receptors. These receptors are insensitive to naturally occurring neurotransmitters, but are activated by the synthetic drug clozapine N-oxide (CNO). When transgenically expressed, administration of CNO to an animal expressing DREADDs will specifically activate only subsets of cells that express. These receptors[77] allowing noninvasive, external control of neurons by administration of CNO. Using receptors that activate different G proteins allows flexibility in the effects that CNO administration will cause.[78]

Electroencephalography is a noninvasive technique in which the electrical activity of the brain is measured using scalp electrodes. The measured signal reflects synchronized activity of thousands of neurons over a large area. High-density EEG, with up to 256 contacts, is often used to improve the spatial resolution and source localization. Frequency content analyses and new advanced analysis such as transfer entropy and complexity measures are often used to investigate the signal.[79,80] Electrocorticography and depth electrodes use electrodes implanted directly on the surface of the brain (electrocorticography) and deep inside the brain (depth electrodes), respectively. The result is a signal with no interference from skull and scalp, which allows precise localization of the signal source. At the extreme, depth electrodes can record the activity of a single neuron in an identified brain region. The location of the electrodes is governed by the clinical setting that led to the procedure, limiting wider utilization of these tools.

fMRI creates a BOLD image,[81] reflecting the increased blood flow that follows neuronal activation. As multiple areas are imaged simultaneously, maps of coherent changes in activity are sometimes used to evaluate the "functional connectivity." Conditions that change vascular responsiveness and blood flow (including anesthesia[82]) affect the image obtained. Table 8.5 provides an overview of clinically used techniques.

TABLE 8.5 Clinically Used Techniques to Study the Effects of Anesthetics on the Brain

Technique	EEG	ECoG	Depth Electrodes	fMRI
Signal	Electric potential	Electric potential	Electric potential	Change in magnetic field
Brain activity underlying the signal	Neuronal activity —synaptic potentials	Neuronal activity —synaptic potentials	Neuronal activity— either spikes or synaptic potentials	Blood oxygen level– dependent (BOLD), reflecting the change in metabolic requirements following neuronal activity
Signal generated by	Thousands to millions of neurons	Thousands of neurons	From single neuron up to thousands of neurons	Thousands to millions of neurons
Temporal resolution	Milliseconds	Milliseconds	Submillisecond	Seconds
Spatial resolution	Centimeter range, improved with high density EEG	Better than EEG (few mm)	Very good—specific location or sometimes single neuron	Limited—mm up to a centimeter (depending on the strength of the magnet), higher spatial resolution decreases the temporal resolution
Invasiveness/cost	Noninvasive, cheap	Very invasive and expensive (requires neurosurgery)	Very invasive and expensive (requires neurosurgery)	Noninvasive, expensive
Studied brain regions	Superficial, cortex	Cortex—usually in areas with underlying pathology (epileptic foci)	Depending on the site of implantation cortex and deep nuclei	Whole brain

EEG, Electroencephalography; *ECoG*, electrocorticography; *fMRI*, functional magnetic resonance imaging.

Key Points

- Neuroglial cells are nonneuronal support cells that outnumber neurons in the central nervous system. Oligodendrocytes, astrocytes, and microglia form myelin sheaths, create the blood-brain barrier, and attend to immune functions, respectively.
- The recently (re)discovered glymphatic system plays an important but not yet fully characterized role in brain homeostasis.
- The generic neuron receives and integrates information in the dendrites and soma and sends out information via its axon.
- The synapse is the physical contact point between neurons that mediates intercellular communication.
- A generic cortical neuron receives thousands of synaptic inputs on its dendrites that form dendritic arbors to provide the

necessary surface area. The axon is typically ensheathed in myelin, making rapid communication with hundreds to thousands of other, sometimes remote, neurons.

- The typical neuron has a resting membrane potential of −60 to −70 mV (inside relative to outside). The underlying electrochemistry is described in the Nernst and Goldman-Hodgkin-Katz equations. The resting cell membrane is permeable mostly to K^+; hence the resting membrane potential is close to the K^+ equilibrium potential.
- Focal changes in membrane potential, such as depolarization and hyperpolarization from excitatory and inhibitory synaptic inputs, respectively, spread along the membrane, decaying exponentially over time and space.
- Chemical synapses are the mainstay of communication between neurons. Physiologic transmitter release occurs in response to an action potential that depolarizes the presynaptic terminal and allows Ca^{2+} entry through voltage-gated channels to trigger synaptic vesicle fusion and transmitter release.
- Transmitter release occurs in discrete increments (quanta) that reflect the fusion of prepackaged transmitter-containing synaptic vesicles with the membrane of the terminal. Electrical synapses are common in certain brain areas.
- The strength of synaptic connections between neurons undergoes constant, use-dependent modification—both increase and decrease—termed synaptic plasticity.
- L-glutamate and gamma-aminobutyric acid are the major excitatory and inhibitory neurotransmitters, respectively, in the brain.
- The architecture of neuronal circuits and the mode of long-range connectivity differ strikingly between brain areas. The modular "small-world" organization of the neocortex, the random synaptic space of the hippocampus, and the strictly parallel organization of the cerebellum are examples.

Physics: Basic Electronics and Electrical Hazards

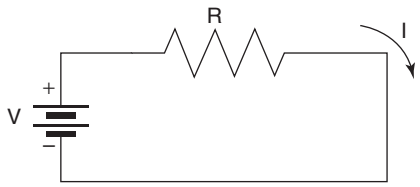
Kai Kuck

OUTLINE

Background

Basic Electrical Concepts
- Simple Circuits
- Electrical Circuit Elements

Electrical Hazards



• **Fig. P3.1** A simple electrical circuit. The voltage V supplied by the battery drives the current I through the resistance R. Ohm's Law stipulates that $V = I \times R$. Even though the electrons making up the current flow from the negative terminal toward the positive one, by convention, the current is drawn in the opposite direction (the flow of positive charges).

Background

Electrical and electronic equipment play an important role in anesthesia and are abundant in the operating room (OR). It is important that the anesthetist understands basic electrical concepts and electrical hazards for patients and OR personnel.

Basic Electrical Concepts

Electrical current, often denoted by the letter I and measured in **amperes** (abbreviated "A"), is the flow of electrical charges between points of different potential electrical energy. **Voltage** is the difference in potential electrical energy, or electromotive force, measured in **volts** (abbreviated "V"). Electrical current flows in a closed circuit, driven by a voltage source, and through a resistance. A **resistance** opposes the flow of electrical current; the unit of resistance is Ohm (Ω). **Ohm's Law** states that in a simple electrical circuit, the voltage V required to drive a current I flowing through a resistance R is proportional to the current and the resistance (Fig. P3.1):

$$V = I \times R.$$

Power is needed for a current to pass through a resistance. Power is dissipated, often as heat or light, and is expressed as **electrical power**, measured in watts (abbreviated "W") and often symbolized by the letter P. It is determined as the product of voltage and current:

$$P = V \times I.$$

Substituting relationships from Ohm's Law and relating them to P,

$$P = V \times I = I \times R \times I = I^2 \times R$$

$$P = V \times I = V \times V/R = V^2/R.$$

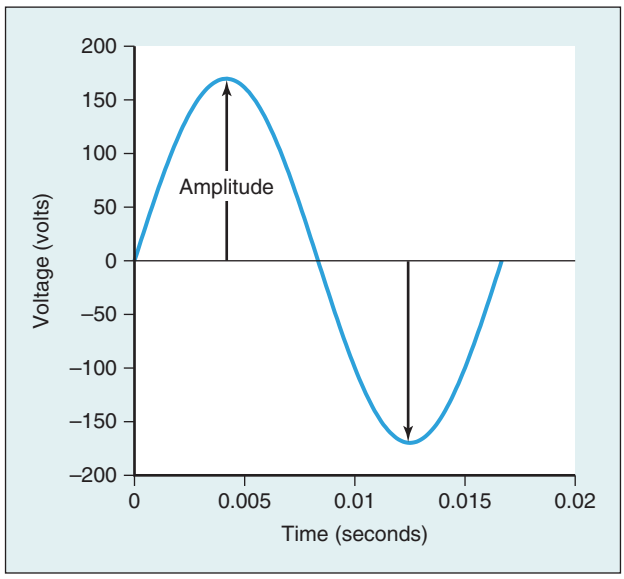
This rearrangement confirms that electrical power (and heat) varies with voltage squared and is inversely proportional to resistance. These relationships govern the possible flow of hazardous electrical current or the generation of dangerous levels of heat from electrical devices in the OR.

Thermodynamically, power is work done per unit time. **Electrical work** is measured in watt-seconds as, for example, the energy discharged by a defibrillator. On a larger scale (e.g., when measuring the energy used in an OR) watt-seconds are scaled to kilowatt-hours, kWh. **Electrical energy** is measured in the same terms but describes a potential to do work.

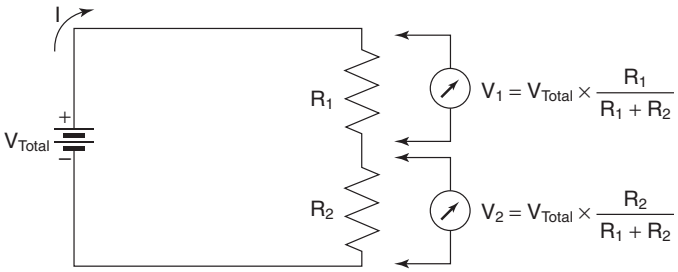
If electrical current flows in only one direction, as depicted in Fig. P3.1, it is referred to as **direct current (DC)**. Current that frequently changes its direction is called **alternating current (AC)**. The line electricity supplied by power companies, for example, changes sinusoidally, and its voltage and current are described by their amplitude and root mean square (RMS) value, which is the average of the squared values of the waveform value (Fig. P3.2). In addition to the current and voltage, AC is also described in terms of its frequency (f), measured in Hertz (Hz), where 1 Hz indicates that the current is changing its direction once per second. These concepts are important because AC and DC forms of electrical current have substantially different characteristics in terms of the propensity for device interference and injury to humans.

Simple Circuits

For two or more resistances placed in series (Fig. P3.3), the voltage that can be measured across each resistor is proportional to its respective resistance. The sum of these voltage drops is the total



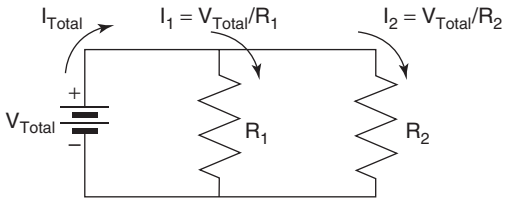
• **Fig. P3.2** One cycle of alternating current (AC) electricity. The electricity supplied by power companies to hospitals is an example of AC electricity. It is sinusoidal in shape. In the United States, it changes direction 60 times per second (60 Hz) and has an amplitude of 169.7 V. The voltage of AC electricity is often described as its RMS value, the average of the squared value of the waveform (e.g., 110 V for electrical power supplied in the United States).



• **Fig. P3.3** A basic circuit with two resistors (R_1 and R_2) in a series with a battery that supplies a voltage V_{Total}. The voltage that can be measured across each resistor R_1 and R_2 is proportional to its respective resistance if the resistors are placed in a series. V_{Total} equals the sum of V_1 and V_2. The same amount of current (I) flows through both resistors.

voltage across the resistors. If a patient completes a circuit and represents the largest resistance in that circuit (e.g., because the other circuit elements are wires that have low resistance), the voltage experienced by the patient will be a large portion of the total supply voltage. The current is the same for both resistances. According to the **Kirchhoff voltage law**, the directional sum of all voltages in the circuit is zero (e.g., in Fig. P3.3: $V_1 + V_2 - V_{Total} = 0$).

For 2 or more resistances placed in parallel (Fig. P3.4), both experience the same voltage, but the current through them is reciprocal to their resistance. This is illustrated by the colloquial, if not completely accurate, expression "the current seeks the path of least resistance." For example, in case of an electrical fault, a high-voltage wire contacting the metal outer case of a device presents a danger to a person touching the case, because the high voltage would drive a current through the body toward ground. Such devices are required to be grounded (i.e., the metal case must have a connection through a ground wire in the device power cable to



• **Fig. P3.4** A basic circuit with two resistors (R_1 and R_2) in parallel to a battery supplying a voltage V_{Total}. When resistors are placed in parallel, the current (I_1 and I_2, respectively) through them is reciprocal to their respective resistance. The smaller the resistance, the more current will flow through it. The total resistance is calculated as the reciprocal of $1/R_1 + 1/R_2$.

the ground). The ground wire provides a very low resistance path to the ground that is in parallel to the person so that the majority of the current will flow through the ground wire instead of the person. The **Kirchhoff current law** states that at any node in a circuit, the sum of the currents flowing into that node equals the sum of the currents flowing out of the node (e.g., in Fig. P3.4, $I_1 + I_2 = I_{Total}$).

Electrical Circuit Elements

In addition to resistances, important basic concepts in electrical circuits are conductance, capacitance, inductance, and impedance. Electrical current requires movement of charged particles. Substances that allow such movement are **conductors**. Metals are typically excellent conductors, as are ions in water. Conductivity is measured in **Siemens** (S) and is the reciprocal of resistance (Ω).

In its simplest form, a **capacitance** consists of 2 parallel metal plates that are a short distance from each other with a nonconducting substance between (e.g., a capacitor). A capacitance can store an electrical charge. The larger the metal plate's surface area and the shorter the distance between the plates, the greater is the electrical charge that can be stored in a capacitance. Capacitances are denoted "C" in electrical circuits and measured in **Farad** (abbreviated as "F").

Direct current (DC) cannot flow through capacitances, with the exception of a brief current while the capacitance changes its charge. Since alternating current (AC) constantly reverses direction, it charges and then discharges the capacitance, resulting in movement of electrons (i.e., current). As a consequence, capacitances appear to AC as complex resistances, called **impedance**. A capacitance's impedance is lower for higher frequencies of AC current.

Capacitances can be used to store electrical energy, which can then be quickly discharged, for example, in defibrillators. Unintentional **capacitive coupling** of AC signals (e.g., from building power lines or from electrocautery) can add noise to sensitive physiologic signals (e.g., electrocardiogram, processed electroencephalogram) and can also lead to hazards from small leakage currents.

Inductance describes the effect exerted by a magnetic field that builds up around an electrical wire with electrical current flowing through it. To the current, this is effectively a resistance. This effect is particularly strong if the electrical current changes rapidly, as with AC, or if the wire is coiled and made of ferromagnetic material, such as iron. Electrical extension cords used for high-wattage appliances should not be coiled up to avoid the cord from heating up and melting its insulation (and perhaps presenting a fire risk).

The term **impedance** is a more general term for resistance and is used to describe the resistive effects to AC current of not only linear resistors but also capacitances and inductances. Impedance

changes with the frequency of AC, but its effect on the amplitude of AC current and voltage follow Ohm's Law. For example, small changes in electrical impedance across the thorax resulting from the changes in lung volume during breathing or in heart volume during the cardiac cycles are exploited for measuring respiratory rate and cardiac output, respectively.

Electrical Hazards

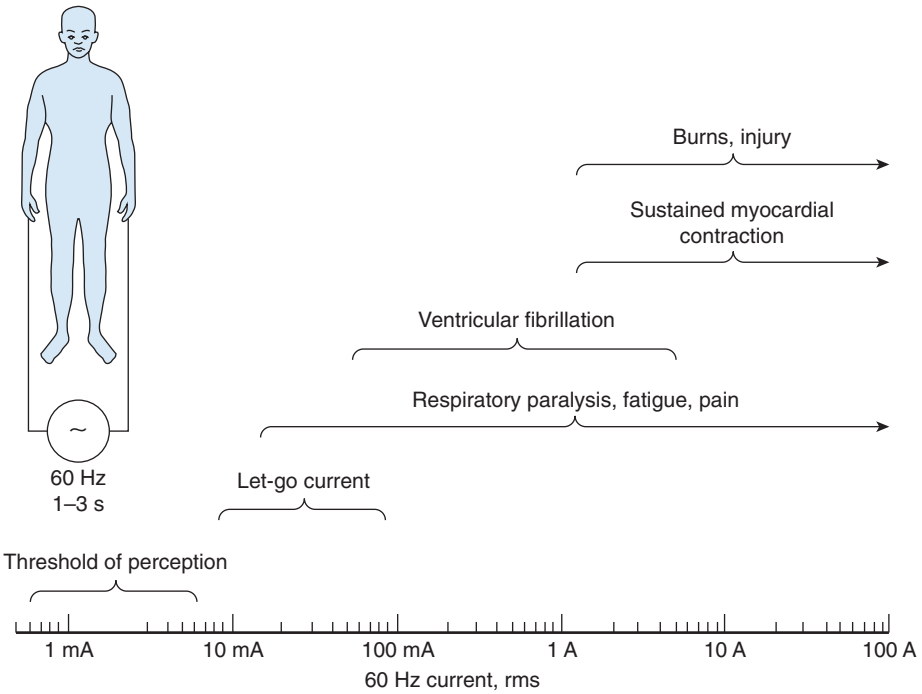
Anesthetized patients in the OR are particularly vulnerable to electrical hazards. They are unclothed, wet, surrounded by and connected to electrical devices, and unable to withdraw from electrical contacts or let it be known that they are experiencing an electrical shock.

If a part of the human body closes (i.e., completes) an electrical circuit, damaging effects of electricity can occur as a result of energy delivered by electricity (e.g., causing burns) or through effects on the electrophysiologic properties of tissue, especially nervous and muscular tissue (including the myocardium, central nervous system, and skeletal muscles). The degree of damage, if any, depends on the duration of the exposure, the voltage, the current, the frequency, and the **current density** (amount of current per area). Neuromuscular tissue is particularly sensitive to stimulation by electricity from standard electrical outlets (e.g., in the United States, from AC current flowing at 60 Hz). Electricity of very high frequencies does not cause stimulation of neuromuscular tissue. Electrocautery units apply ultra-high frequencies to avoid dangerous stimulation of electrically sensitive tissues.

Macroshock occurs when electrical currents flow through the body, usually from a skin entry site to a skin exit site. Damage can occur when current flows through the heart, electrically stimulating the heart. Because the current is distributed over a larger cross-sectional area, substantial current is required for inflicting significant injuries. Fig. P3.5 shows the damaging effects of different currents at 60 Hz AC. Dry skin has a typical resistance of about 50,000 Ω, which would result in a current of 2.4 mA if the macroshock is caused by electricity from an electrical outlet of 120 V, 60 Hz.[1] This is above the perception threshold but would not cause damage in most instances. Wet skin and electrodes reduce skin resistance to about 1000 Ω, resulting in a current of 120 mA under the same conditions, which is well within the range known to cause ventricular fibrillation.

Typically, electricity supplied through standard electrical outlets is grounded (i.e., there is a voltage of 120V between the "hot" wire and ground or earth). If a high-resistance circuit is unintentionally completed between a person and the electrical outlet, current can flow through the lower-resistance ground wire (and also trip the circuit breaker, arresting current flow). For similar reasons, most metal cases of electrical devices are also grounded. In the case of faulty wiring, the majority of the electrical current will flow through the ground wire instead of through an individual touching the metal case. In many macroshock situations, an individual is connected to the hot wire and touches the ground at the same time. This is why it is important to avoid grounding the patient (e.g., by preventing the patient from touching any metal equipment that is grounded).

In isolated electrical systems, the hot wire has no relationship to the ground (i.e., even if a person were to touch the hot wire and the ground at the same time, no current would flow). In some ORs, where it is very difficult to completely avoid having the patient "touch" the ground, using an isolated electrical system provides additional safety. In these systems, electrical power is supplied through an "isolation



• **Fig. P3.5** Effects of electrical macroshock by electrical 60 Hertz (Hz) AC of different current levels (measured in milli-Ampere, mA). Let-go current refers to the current level above which sustained muscle contractions occur, which do not allow the victim to let go of the wire that delivers the electricity. (From Webster JG, ed. *Medical Instrumentation: Application and Design*. 4th ed. Hoboken, NJ: Wiley; 2009.)

transformer" that isolates ("ungrounds") the electrical power from the ground. A line isolation monitor continuously monitors the integrity of this isolation and reports the amount of leakage current that would occur in the case of faults in devices or wiring.

Microshock damage is due to electrical current delivered directly to myocardial tissue (e.g., through a pulmonary artery catheter filled with an electrolyte solution). Due to the larger current density in close proximity to susceptible tissue, much smaller currents are sufficient to cause adverse effects. Ventricular fibrillation can be caused by microshock currents as small as 100 μA. The minimum acceptable microshock current is less than 10 μA. Current flow sufficient for injury can occur in part because the circuits involved in microshock are typically low resistance.

Electrical hazards from electrocautery are often due to the return plate inadequately contacting the patient or being disconnected. During proper operation, the current flows from the tip of the electrocautery instrument through the body to leave the body through the return pad. The return pad is large by design so that the current density (the amount of electrical current per square centimeter) at the exit site is decreased, reducing the heat generated from current flow. If part of the return pad is disconnected from the patient, all the current flows through the smaller area that is touching the patient. The current density in that area is much higher than normal and can result in burns. If the connection to the return pad is disrupted, the current from the electrocautery will flow through alternate routes to leave the body (e.g., through ECG electrodes, through parts of the patient touching metal parts of the OR table, or through catheters that are connected to an electrical device). The high frequencies used in electrocautery (500 kHz to > 1 MHz) increase the chance of alternate current pathways through unintentional capacitive coupling even if the electrosurgery device is electrically isolated from the ground. Electrocautery devices include resistance-sensing mechanisms to detect return plate failures (alternative circuits for current flow are virtually always higher resistance than the resistance in the return pad). Because current flow from electrocautery units can disturb the function of implanted electronic equipment, such as pacemakers, the return pad should be placed to prevent current flow from the operative site through the implanted device to the return pad.

This chapter focuses on central nervous system (CNS) physiology and pharmacology relevant to anesthesiology. The molecular and cellular substrates of specific drugs affecting the nervous system are covered in Chapter 8 and in the appropriate chapters in this section.

Cerebrovascular Anatomy

The cerebral arterial vasculature is divided into anterior and posterior circulations that are interconnected through a vascular loop referred to as the *circle of Willis*. This anastomotic loop provides potential for collateral blood flow between the anterior and posterior circulations, as well as between cerebral hemispheres in case of impaired flow in one of the proximal feeding vessels. As one of the most highly perfused organs in the body, the brain is supplied by two paired arteries: the right and left vertebral and the right and left internal carotid arteries. Flow is then distributed throughout the cranium primarily by three paired cerebral arteries arising from the *circle of Willis:* the anterior cerebral, middle cerebral, and posterior cerebral arteries (Figs. 9.1 and 9.2). However, a complete circle of Willis may be present in only about 40% to 50% of the population.[1] A variety of incomplete (containing a noncontinuous, hypoplastic, or absent segment) variants that can compromise collateral flow have been identified. In such cases, secondary sources of collateral flow can occur through distal leptomeningeal connections, or by way of retrograde flow though the ophthalmic artery from the external carotid circulation to the internal carotid artery.

Vascular Architecture

Arteries and Arterioles

The cerebral arteries distributing flow from the circle of Willis continuously branch into smaller arteries and arterioles that course along the surface of the brain. At their distal end, before entering the brain parenchyma, they are known as leptomeningeal vessels. The leptomeningeal vessels are found within the pia-arachnoid membrane and are surrounded by cerebral spinal fluid (CSF). The highly branched pial arterioles form an extensive collateral network on the surface of the brain before giving rise to a relatively unbranched system of penetrating intraparenchymal arterioles.

Venous Circulation

The venous circulation consists of an interconnected system of veins and sinuses. Venous outflow from the cerebral hemispheres

Abstract

The metabolic demands of the brain are substantial and must be met with a continuous supply of glucose and oxygen. The cerebrovascular anatomy and physiology is designed to distribute and regulate the flow of blood throughout the cranium to continuously meet these demands. Distribution occurs through a well-developed system of conducting vessels that form a proximal anastomotic loop referred to as the circle of Willis. Adjacent vascular territories also communicate via small leptomeningeal collaterals on the surface of the brain. Cerebral blood flow is regulated and influenced by chemical mediators, myogenic regulation, neurogenic input, blood viscosity, patient age, vasoactive agents, anesthetics, and various CNS injury states. Neuronal dysfunction occurs when CBF is reduced below 20 mL/100 g/min. Further reductions below 15 mL/100 g/min result in a progressive decrease in energy supply that will lead to membrane failure and death over the time course of hours to minutes depending of the level of CBF. Energy failure is characterized by cell membrane depolarization, influx of Na^+, and Ca^{2+}, and downstream cell signaling pathways that result in cell damage and death. Ischemia induced cell death may be apoptotic or necrotic depending on various factors involved. More recent understanding of ischemic injury suggests that it is a dynamic process that continues well beyond the initial ischemic event. While anesthetic agents can reduce the vulnerability of the brain to ischemic injury, maintenance of physiologic homeostasis is of greater importance in the prevention or exacerbation of ischemic injury.

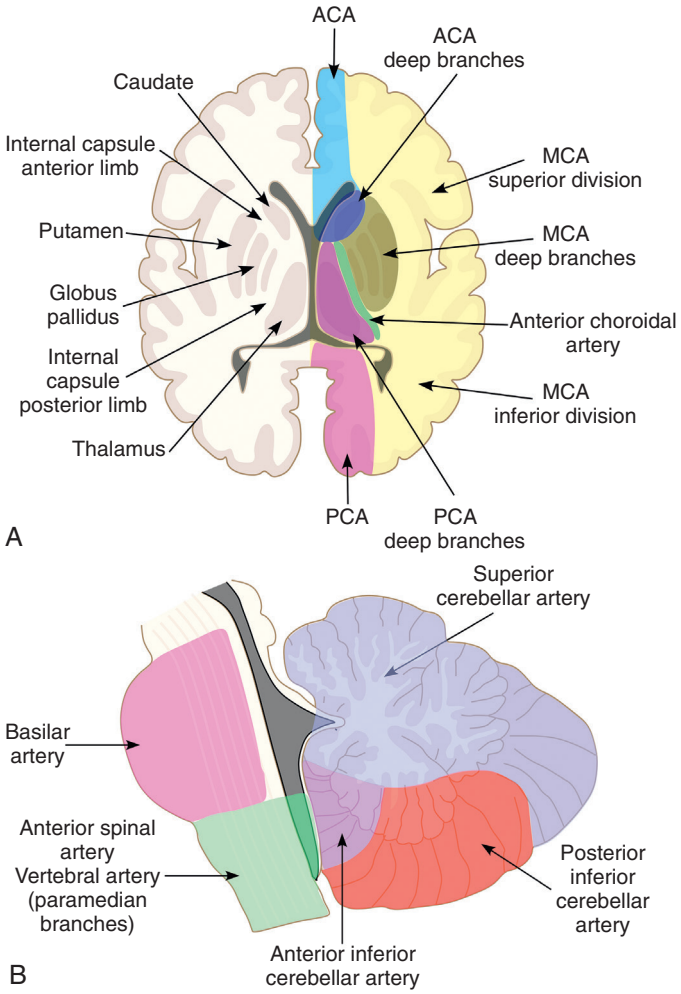
• **Fig. 9.1** *Circle of Willis,* major cranial supply and distributing vessels. Supply vessels include the left and right internal carotid arteries *(ICA)* and the left and right vertebral arteries. The major distributing vessels include the anterior cerebral arteries *(ACA),* middle cerebral arteries *(MCA)*, and posterior cerebral arteries *(PCA).* The anterior and posterior communicating arteries *(ACom, PCom)* complete this vascular loop and allow for collateral blood flow between vascular territories. The major branches of the vertebrobasilar system are also labeled. *AICA,* Anterior inferior cerebellar artery; *PICA,* posterior inferior cerebellar artery; *SCA,* superior cerebellar artery.



• **Fig. 9.2** Anatomic distribution of blood flow from major intracranial vessels in the cerebral hemispheres (A) and infratentorial structures (B). *ACA,* Anterior cerebral artery; *MCA,* middle cerebral artery; *PCA,* posterior cerebral artery; *AICA,* anterior inferior cerebellar artery; *PICA,* posterior inferior cerebellar artery; *SCA,* superior cerebellar artery.

occurs via cortical veins within the pia mater on the surface of the brain as well as deep central veins. Cortical and deep veins may empty into the superior sagittal sinus. Deep veins may also empty into either the inferior sagittal sinus or great vein of Galen. Venous flow is directed toward a confluence of sinuses (torcular herophili) then on toward the central circulation via the transverse sinus, sigmoid sinus, and jugular vein (Fig. 9.3). Cerebellar drainage occurs primarily via the inferior cerebellar veins and occipital sinuses. Extensive collateralization between cortical veins as well as the deep veins and sinuses can augment venous drainage when primary routes are compromised.

Anterior Circulation

The anterior circulation arises from the intracranial extension of the internal carotid arteries. The most prominent branches of the anterior circulation are the anterior cerebral, middle cerebral, and posterior communicating (PCom) arteries. The PCom provides communication with the posterior circulation through direct connection with the posterior cerebral artery (PCA). An absent or hypoplastic PCom potentially compromises collateral flow between the anterior and posterior circulations. Likewise, collateral flow between the left and right anterior circulation can be compromised by a hypoplastic or aplastic anterior communicating (ACom) artery.

Posterior Circulation

The posterior circulation arises from paired vertebral arteries. At their rostral end, the vertebral arteries typically join together on the anterior surface of the brainstem to form the basilar artery. The vertebral and basilar arteries have multiple branches that supply the thalami, brainstem, cerebellum, and spinal cord. The basilar artery branches distally into the left and right PCAs. The branches of the PCA provide blood flow to the thalami, brainstem, choroid plexus, and cerebrum (occipital and portions of parietal and temporal lobes see Fig. 9.2A, B) and provide a point of connection with the anterior circulation. Like the anterior circulation, there are many anatomic variants that may compromise collateral blood flow and predispose to ischemia in various clinical scenarios.

Regulation of Cerebral Blood Flow

The adult brain represents about 2% of total body weight (1350 g), but receives almost 15% of cardiac output. This high blood flow:mass ratio reflects the significant metabolic demand of the brain. At rest, it consumes oxygen at an average rate of 3.5 mL/100 g of brain tissue per minute, or 50 mL/min overall. This represents nearly 20% of total body oxygen utilization. Normal values for cerebral blood flow (CBF), cerebral metabolic rate (CMR), and other physiologic variables are provided in Table 9.1.

TABLE 9.1 Normal Cerebral Physiologic Variables

Cerebral Blood Flow	
Global	45–55 mL/100 g per minute
Cortical (mostly gray matter)	75–80 mL/100 g per minute
Subcortical (mostly white matter)	20 mL/100 g per minute
Cerebral metabolic rate of oxygen ($CMRO_2$)	3–3.5 mL/100 g per minute
Cerebral venous Po_2	32–44 mm Hg
Cerebral venous So_2	55%–70%
Intracranial pressure (supine)	10–15 mm Hg

Po_2, Partial pressure of oxygen; *So_2*, oxygen saturation.

• **Fig. 9.3** Cerebral venous anatomy. The venous drainage of the brain is composed of an interconnected system of superficial and deep veins and sinuses that return blood to the central circulation. Superficial veins, such as the vein of Trolard (most often found in the postcentral sulcus), typically empty into the superior sagittal sinus. The vein of Labbé is a superficial vein of the temporal convexity with drainage toward the transverse/sigmoid sinus. Many of the deep veins, including the inferior sagittal sinus, internal cerebral vein, and the vein of Galen, are directed toward the confluence of sinuses via the straight sinus. Flow from the confluence is directed through the transverse sinus, sigmoid sinus, and internal jugular vein before reaching the right atrium. The petrosal sinus provides drainage of the cavernous sinus directly into the sigmoid sinus.

Approximately 60% of cerebral energy consumption is used to support electrophysiologic function in the form of maintenance and restoration of ionic gradients as well as the synthesis, transport, and reuptake of neurotransmitters.[2] This *functional* component of cerebral energy consumption is reflected as electrical activity on electroencephalography (EEG) and is reduced by most anesthetic drugs. Maintenance of cellular homeostasis, which includes synthesis and transport of cellular components, accounts for the remainder of oxygen consumption. This *basal* component of neuronal energy consumption related to basic cellular housekeeping function is independent of electrophysiologic activity but is responsive to temperature manipulation.[3]

Glucose is the primary substrate of brain metabolism. In the presence of adequate oxygen delivery, glucose is metabolized to pyruvate by oxidative phosphorylation. In the absence of sufficient oxygen delivery, glucose is anaerobically metabolized, resulting in insufficient adenosine triphosphate (ATP) production and subsequent energy failure. Therefore the brain's considerable metabolic demands must be met by adequate and continuous delivery of both oxygen and glucose. There are elaborate mechanisms in place for regulating CBF to ensure these demands are met. The various mechanisms, which include chemical, myogenic, and neurogenic factors, are listed in Table 9.2.

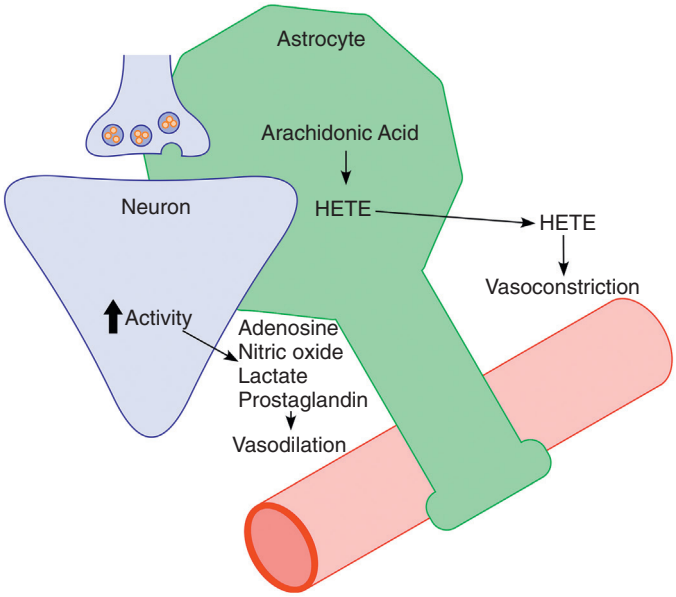
Chemical Regulation of Cerebral Blood Flow

A number of factors, by altering the biochemical milieu of the brain, modulate CBF; these include CMR, partial pressure of carbon dioxide in arterial blood ($PaCO_2$), and alveolar oxygen partial pressure (PaO_2).

Cerebral Metabolic Rate

CMR is directly proportional to neuronal activity.[4] Although the mechanism is not entirely understood, an increase in neuronal activity and CMR is tightly coupled to increased CBF.[3,4] This physiologic process, wherein blood flow and metabolism are matched, is referred to as *flow-metabolism coupling.* The cellular mechanisms involved continue to be investigated, but likely involve



• **Fig. 9.4** Cerebral flow-metabolism coupling. Neuronal activity results in metabolic by-products such as adenosine, lactate, nitric oxide, and prostaglandin that may influence local vessel resistance and cerebral blood flow. More recent data suggest the role of astrocytes both in modulating neuronal synaptic activity and serving and a conduit of this activity to the vascular endothelium. *HETE*, Hydroxyeicosatetraenoic acid.

processes mediated by a combination of neuronal activity and metabolic by-products, glial integration and modulation of neuronal synaptic activity, and vascular factors. Specific by-products of metabolism considered influential in this process include potassium ions (K^+), hydrogen ions (H^+), calcium ions (Ca^{2+}), lactate, adenosine, ATP, and nitric oxide (NO).[5–7] Glia are in direct contact with both neurons and capillaries, and mounting data highlight the role of glia as a likely conduit for coupling neuronal activity with regional blood flow (Fig. 9.4).[8] Cerebral vessels are also densely innervated, and peptidergic neurotransmitters released by nerves also contribute to vascular regulation and flow-metabolism coupling.[9] In the neurosurgical and critical care environments, CMR is influenced by the functional state of the nervous system, anesthetic agents, and temperature.

Functional State

CMR decreases during sleep and increases during sensory stimulation, mental tasks, or arousal of any cause. CMR is markedly increased during epileptic activity and substantially reduced in coma.

Anesthetic Agents

In general, with the exception of ketamine and nitrous oxide (N_2O), anesthetics suppress CMR. Specifically, the component of CMR related to electrophysiologic function is reduced.[10] With several agents, including barbiturates, isoflurane, sevoflurane, desflurane, propofol, and etomidate, increasing plasma concentrations cause progressive suppression of EEG activity with a concomitant reduction in CMR.[10–14] However, increasing the plasma level beyond that required to achieve suppression of the EEG results in no further CMR reduction. The component of CMR related to basic cellular homeostatic activities is unaffected by anesthetics (Fig. 9.5).

Temperature

CMR decreases by 6% to 7% per degree Celsius of temperature reduction, and can cause complete suppression of the EEG at about 18°C to 20°C.[15] In contrast to anesthetic agents, temperature reduction beyond that at which EEG suppression first occurs does produce a further decrease in CMR. This occurs because hypothermia decreases the rate of energy utilization associated with both electrophysiologic function and basal maintenance of cellular integrity (Fig. 9.6). These decreases were once assumed to be proportional, but subsequent data demonstrate preferential suppression of the basal component (with mild hypothermia).[2] The global cerebral metabolic rate of oxygen ($CMRO_2$) at 18°C is less than 10% of normothermic control values, which likely accounts for the brain's tolerance of circulatory arrest for moderate periods at these temperatures.

Hyperthermia leads to substantial increases in CMR and CBF.[16] However, above 42°C a dramatic reduction in $CMRO_2$ occurs, possibly owing to neuronal injury and protein denaturation.

$Paco_2$

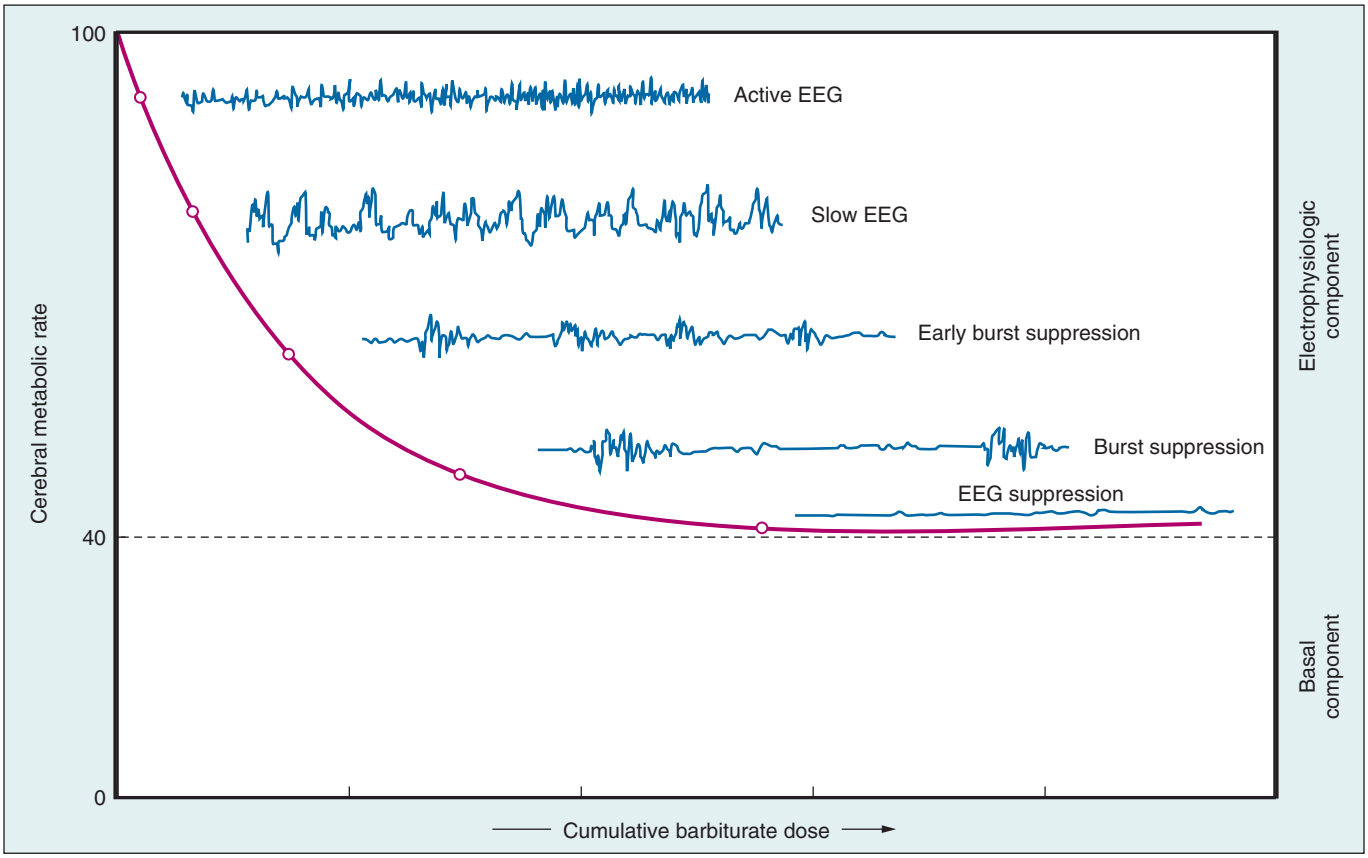
CBF varies directly with $PaCO_2$ (Fig. 9.7). For each change of 1 mm Hg in $PaCO_2$ from normal values, CBF changes 1 to 2 mL/100 g per minute.[17] This response is attenuated outside the physiologic range of about 20 to 80 mm Hg and is sensitive to the baseline CBF. For example, hyperventilation causes a greater reduction in CBF when the resting CBF is high (as can occur with volatile anesthetics), an effect that is attenuated with lower resting CBF. Therefore anesthetic agents have the capacity to alter CO_2 responsiveness of the cerebral circulation by changing basal CBF.

The changes in CBF caused by $PaCO_2$ depend on the pH in the extracellular fluid of the brain.[17,18] Extracellular pH and CBF changes occur rapidly after $PaCO_2$ adjustments because CO_2 (neutral charge) diffuses freely across the cerebrovascular endothelium. In contrast, acute systemic *metabolic* acidosis has little immediate effect on CBF because the blood-brain barrier (BBB) excludes H^+ from the perivascular space.

Although changes to CBF induced by $PaCO_2$ are rapid, they are not sustained. Despite maintenance of increased arterial pH (through hyperventilation), CBF returns toward baseline over 6 to 18 hours because CSF pH gradually normalizes through bicarbonate extrusion (Fig. 9.8).[19,20] Therefore patients with sustained periods of hyperventilation or hypoventilation deserve special consideration. Acute normalization of $PaCO_2$ results in a significant CSF acidosis (after hypocapnia) or alkalosis (after hypercapnia). The former results in increased CBF with a concomitant increase in intracranial pressure (ICP), depending on the prevailing intracranial elastance. The latter conveys the theoretical risk of ischemia.

Pao_2

The effects of PaO_2 on CBF are minimal within the normal physiologic range (PaO_2 from 60 to more than 300 mm Hg). Below a PaO_2 of 60 mm Hg, CBF increases rapidly (see Fig. 9.7). The mechanisms mediating cerebral vasodilation during hypoxemia remain elusive, but they appear to be influenced by metabolites produced by nonvascular cerebral tissue (e.g., NO), hypoxic effects directly influencing cerebral vascular endothelium and smooth muscle (e.g., hypoxia-induced hyperpolarization of smooth muscle), and stimulation of the receptors in the rostral ventrolateral medulla.[21,22] The response to hypoxemia is synergistic with hypercarbia-induced hyperemia.



• **Fig. 9.5** Barbiturate-induced suppression of cerebral metabolism. Administration of various intravenous anesthetic agents results in a dose-related reduction in the electrophysiologic component of cerebral metabolic rate (CMR) and thus cerebral blood flow through flow-metabolism coupling. Anesthetic induced-reductions are maximal at the point of electroencephalographic silence. At this point, additional drug administration does not result in a further reduction of the cerebral metabolic rate of oxygen. The basal component of CMR responsible for maintaining cellular homeostasis is not altered. *EEG,* Electroencephalogram.

Myogenic Regulation (Autoregulation) of Cerebral Blood Flow

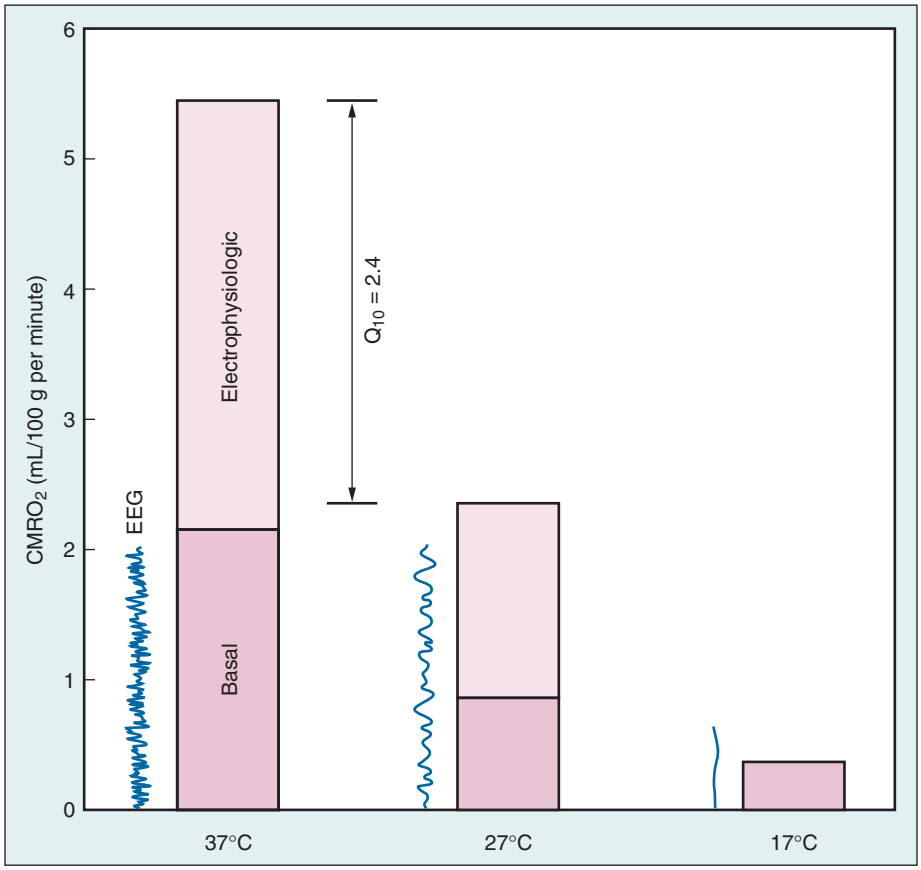
Autoregulation refers to the capacity of the cerebral circulation to alter vascular resistance to maintain a relatively constant CBF over a range of mean arterial pressure (MAP). Although animal models suggest a lower limit of autoregulation (LLA) near a MAP of 50 mm Hg, available human data suggest a higher threshold (with considerable interindividual variation).[23] In normal nonanesthetized humans, the limits of autoregulation occur near MAPs of approximately 70 and 150 mm Hg (see Fig. 9.7).[22] These limits are shifted toward the right in patients with poorly controlled, longstanding hypertension.[24] Note that the units used on the *x*-axis of "autoregulation curves" will influence the correct inflection points of the curve. When the *x*-axis is MAP, the normal average LLA is near 70 mm Hg. Cerebral perfusion pressure (CPP) is the ideal independent variable. However, ICP is usually not measured in normal subjects, so CPP (MAP-ICP) is rarely available. Assuming a normal ICP in a supine subject of 10 to 15 mm Hg, an LLA of 70 mm Hg MAP corresponds to 55 to 60 mm Hg expressed as CPP. Above and below the autoregulatory limits, CBF becomes pressure-dependent (pressure-passive) and varies linearly with CPP. The autoregulatory response to a change in arterial pressure occurs over the course of 1 to 2 minutes, such that a rapid change in arterial pressure will transiently alter CBF even within the normal autoregulatory range.[25]

The mechanisms governing autoregulation are unclear. According to the myogenic hypothesis, changes in CPP directly influence alterations in vascular smooth muscle tone independent of extrinsic factors. However, autonomic innervation of cerebral blood vessels might also contribute to autoregulation (discussed in later text).

Autoregulatory mechanisms may be absent or significantly attenuated in pathologic conditions, such as cerebral ischemia, traumatic brain injury, and subarachnoid hemorrhage (Fig. 9.9). In addition, volatile anesthetics dose dependently attenuate autoregulation, an effect attributable to direct vasodilation.

Neurogenic Regulation of Cerebral Blood Flow

The cerebral vasculature is extensively innervated; the density of this innervation declines with decreasing vessel size.[26] Innervation includes cholinergic (parasympathetic and nonparasympathetic), adrenergic (sympathetic and nonsympathetic), serotonergic, and vasoactive intestinal polypeptide (VIP)ergic systems of both extraaxial and intraaxial (e.g., fastigial and dorsal raphe nucleus) origin.[27–31] Animal studies have established both extracranial sympathetic and



• **Fig. 9.6** Temperature-induced suppression of cerebral metabolic rate. Hypothermia reduces both components of cerebral metabolic activity: that associated with neuronal electrophysiologic activity and that associated with the maintenance of cellular homeostasis (*Basal*). This is in contrast to anesthetic agents that alter only the electrophysiologic component. The ratio of CMR at 37°C to that at 27°C, the Q_{10} ratio, is shown in the graph. *$CMRO_2$,* Cerebral metabolic rate for oxygen; *EEG,* electroencephalogram. • **Fig. 9.7** Cerebral autoregulation. Changes in cerebral blood flow *(CBF)* caused by independent alterations in $PaCO_2$, PaO_2, and mean arterial pressure *(MAP). PaO_2,* Alveolar oxygen partial pressure; *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood.

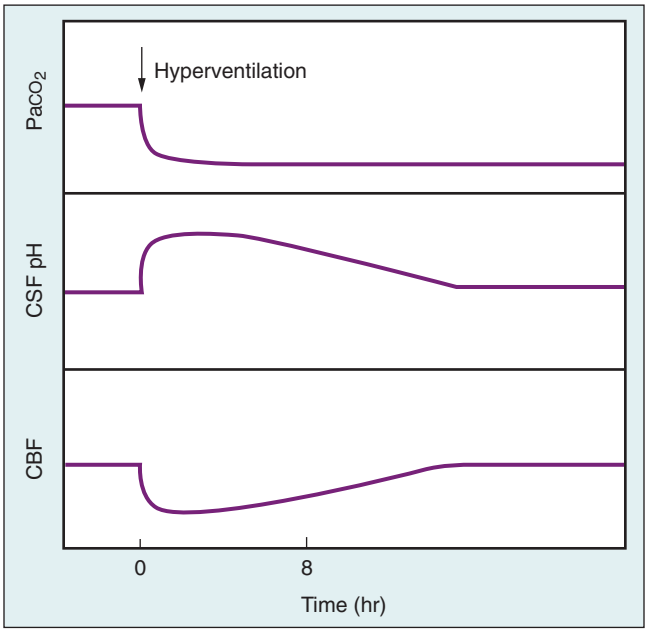
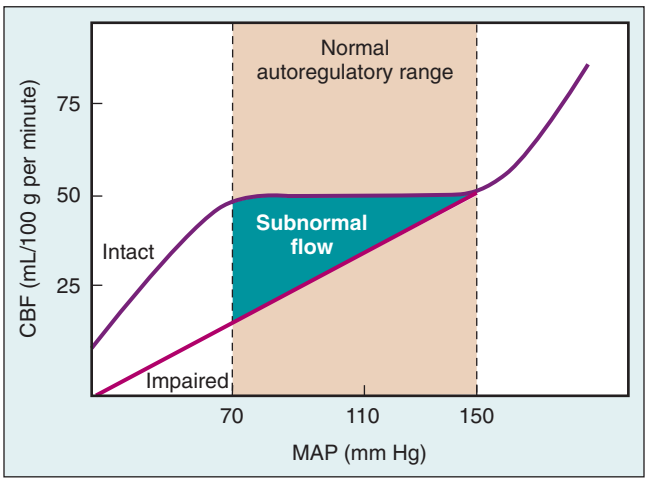
parasympathetic influence on CBF autoregulation.[27,29] In experimental animals, activation of sympathetic fibers shifts the autoregulation curve to the right. Beyond the upper limit of autoregulation, sympathetic activation is considered to be protective in that cerebral vasoconstriction limits the increase in CBF and reduces injury to the BBB. By contrast, in hemorrhagic shock, sympathetic activation may further limit CBF. In humans, stellate ganglion blockade in the setting of subarachnoid hemorrhage increases CBF considerably.[32] The role of parasympathetic innervation on human CBF is less clearly defined. However, in animals, parasympathetic activation can be induced by stimulation along its pathway (sphenopalatine ganglion, facial nerve) and results in increased cerebral blood flow independent of cerebral metabolic activity.[33]

Viscosity Effects on Cerebral Blood Flow

Blood viscosity variation, primarily determined by hematocrit, likely influences CBF modestly in healthy subjects (hematocrit range 33%–45%).[34] The benefit of improved CBF resulting from reduced viscosity appears relevant in the setting of focal cerebral ischemia when vasodilation in response to impaired oxygen delivery is probably already maximal.[35] In this setting, a hematocrit of 30% to 34% probably results in optimal oxygen delivery; however,



• **Fig. 9.8** Effect of sustained hyperventilation on cerebrospinal fluid pH and cerebral blood flow. Sustained hyperventilation results in almost immediate pH change in cerebrospinal fluid *(CSF)*/brain extracellular fluid and cerebral blood flow *(CBF)* as indicated in this nonquantitative graph. These changes are relatively brief, with return toward baseline over a period of 6 to 18 hours. *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood.



• **Fig. 9.9** Impaired cerebral autoregulation. The *"impaired" curve* indicates a pressure-passive condition in which cerebral blood flow *(CBF)* varies directly with cerebral perfusion pressure. This curve is drawn to indicate subnormal CBF *(teal area)* despite mean arterial pressures within the typical autoregulatory range. This has been demonstrated following various central nervous system insults such as traumatic head injury and subarachnoid hemorrhage. The potential for even modest hypotension to cause ischemia is apparent. *MAP,* Mean arterial pressure.

manipulation of viscosity in patients with acute ischemic stroke has not been shown to reduce cerebral injury.[36]

Vasoactive Agents

A number of pharmacologic agents have cerebrovascular effects (Table 9.3). Paramount in the care of patients with intracranial pathology are anesthetic agents (see Chapters 10 and 11) and vasoactive drugs used specifically for hemodynamic manipulation (see Chapters 25 and 26).

TABLE 9.3 Vasoactive Agents and Their Effects on Cerebral Metabolic Rate and Blood Flow

Systemic vasodilators (e.g., nitroglycerine, nitroprusside, nicardipine)	Increase CBF/CBV[a]
Catecholamine agonists/antagonists	
α_1 agonist	Minimal direct effect on CBF
β agonist (BBB intact)	Minimal direct effect on CBF
β agonist (BBB disrupted)	Increase CMR/CBF
β antagonist	Minimal effect; can reduce CMR/CBF
Dopamine	Poorly defined; minimal increase in CBF at low dose?
Intravenous anesthetics	
Ketamine	Increase rCBF; global effects minimal when coadministered with other sedatives/controlled ventilation[b]
Others	Decrease CMR/CBF
Inhaled anesthetics	Decrease CMR/variable effect on CBF[b]

BBB, Blood-brain barrier; *CBF,* cerebral blood flow; *CBV,* cerebral blood volume; *CMR,* cerebral metabolic rate; *rCBF,* regional cerebral blood flow.
[a]Most systemic vasodilators result in cerebral vasodilation and increased CBF/CBV. The notable exception is enalapril, which does not cause cerebral vasodilation.
[b]See text for discussion.

Systemic Vasodilators

The majority of the drugs used to lower systemic blood pressure (including sodium nitroprusside, nitroglycerin, hydralazine, adenosine, and calcium channel blockers) also induce cerebral vasodilation. Agents that vasodilate both the cerebral and systemic circulations can increase cerebral blood volume (CBV), and therefore ICP, by two mechanisms: direct cerebral vascular smooth muscle relaxation and autoregulation-mediated vasodilation. The result is either increased CBF or maintenance of CBF despite inducing systemic hypotension. The hypotensive threshold at which CBF begins to decrease is lower if hypotension is induced with a cerebral vasodilator compared with hypovolemia or a noncerebral vasodilator. In contrast to direct cerebral vasodilators, the angiotensin-converting enzyme inhibitor enalapril has no significant impact on CBF.[37]

Adrenergic Receptor Agonists/Antagonists

Numerous drugs with activity at adrenergic receptors (α_1, α_2, β, and dopamine) have effects on cerebral physiology that depend on basal blood pressure, the systemic blood pressure change induced, the autoregulatory capacity, and the status of the BBB. A given agent can have direct effects on cerebral vascular smooth muscle and/or indirect effects mediated by cerebral autoregulation. When autoregulation is preserved, increases in systemic pressure increase CBF only if arterial pressure is below or above the limits of autoregulation. When the basal pressure is within the normal autoregulation range, systemic pressure changes do not significantly affect CBF as a result of cerebral vasodilation or vasoconstriction. When autoregulation is defective, CBF varies in direct relation to the systemic pressure (see Fig. 9.9).

α_1-Receptor Agonists

A frequent clinical concern is that the administration of agents with α_1-agonist activity (phenylephrine/norepinephrine) will reduce CBF by direct cerebral vasoconstriction. However, when used in the typical clinical dose ranges, neither intraarterial nor intravenous injection of potent α_1 agonists significantly affects CBF.[38,39]

Increases in CBF attributable to norepinephrine can occur when autoregulation is defective or MAP is beyond the limits of autoregulation. Agonists of β-adrenergic receptors (such as norepinephrine and epinephrine) can also increase cerebral metabolism with a coupled increase in CBF. This effect is most apparent in the presence of a defective BBB, which allows greater access to the brain parenchyma.[38,40]

β-Receptor Agonists

In low doses, β-receptor agonists have little direct effect on the cerebral vasculature. In large doses, particularly in the presence of a defective BBB, they can cause an increase in CMR accompanied by an increase in CBF.[38,40] These effects are likely mediated by the β_1 receptor.[41]

β-Receptor Blockers

β-Blockers have been reported to either reduce CBF or have no effect on CBF (and/or CMR). Catecholamine levels at the time of β-blocker administration and/or the status of the BBB may influence these findings. Adverse effects caused by β-blocker administration to patients with intracranial pathology are unlikely, apart from effects related to changes in perfusion pressure.

Dopamine

The effects of dopamine on CBF and CMR have not been defined with certainty. The available data suggest slight vasodilation with minimal change in CMR when administered in low doses with normal cerebral vasculature and the absence of cerebral vasoconstriction in high doses (100 μg/kg per minute).

Intravenous Anesthetics

In general, the intravenous anesthetic agents (propofol, etomidate, lidocaine, barbiturates, benzodiazepines, dexmedetomidine) produce parallel reductions in CMR and CBF.[42] With controlled ventilation and maintenance of normocapnia, it is likely that opioids have relatively little effect on CBF and CMR in the normal, unstimulated nervous system. Many investigations involving ketamine suggest that it increases CBF, particularly within the anterior cingulate cortex possibly through dilation of medium/large-sized intracranial vessels.[43] This has the potential to increase ICP; based on this concern, it has been suggested to avoid ketamine for neurosurgical anesthesia. More recent data, however, suggest that ketamine does not increase ICP when patients are sedated and ventilation is controlled.[44,45] In fact, ICP can be effectively reduced in patients with increased ICP that is refractory to conventional management.[46] Nonetheless, caution should be exercised with ketamine as the sole anesthetic in patients with impaired intracranial elastance.

Intravenous anesthetic-induced changes in CBF largely reflect coupling between CMR reduction and CBF. In addition, variable direct effects on cerebral vascular smooth muscle make minor contributions to the net CBF:CMR ratio. In general, autoregulation and $PaCO_2$ responsiveness are preserved.

Volatile Anesthetics

All volatile anesthetics, in a manner similar to intravenous sedative-hypnotic agents, suppress cerebral metabolism in a dose-related manner.[11] In contrast, they also directly affect vascular smooth muscle, resulting in cerebral vasodilation.[47] The net effect on CBF is a balance between reduction caused by CMR suppression and augmentation caused by direct cerebral vasodilation. Although the data vary depending on the agent (isoflurane vs. desflurane vs. sevoflurane), method/location of measuring CBF, and level to which systemic pressure is maintained, they may be best conceptualized in the following way in patients with preserved cognitive function. At low doses (about 0.5 MAC), the CMR-reducing effect likely predominates over direct vasodilation, resulting in a net decrease in CBF compared with the awake state. In an intermediate range (roughly 0.5–1.0 MAC), direct cerebral vasodilation offsets the effects of CMR suppression, and CBF is relatively unchanged compared with the awake state. In high doses (>1.0 MAC), the direct vasodilatory effect can predominate and CBF can be increased.

Although the available data suggest that volatile anesthetics have minimal effect on intracranial pressure dynamics when intracranial elastance is normal, they have the potential to induce increases in CBV and ICP in certain clinical scenarios (intracranial hypertension significant enough to produce changes in the level of consciousness). Furthermore, when near-maximal reduction of CMR has occurred because of antecedent drug administration or significant electrophysiologic suppression has occurred as the result of CNS pathology, introduction of a volatile agent may have a predominantly vasodilating effect even at relatively low doses.

The cerebrovasculature responsiveness to $PaCO_2$ is well maintained during anesthesia with all volatile anesthetic agents.[17] By contrast, increasing a volatile anesthetic dose progressively impairs autoregulation of CBF. At high doses, autoregulation is abolished and CBF becomes pressure-passive.

Age

Aging, from childhood to late adulthood, is associated with progressive reduction of CBF and $CMRO_2$. This may reflect the progressive reduction in gray matter volume that occurs with increasing age. The precise mechanism underlying this reduction is not clear; loss of neurons, loss of dendritic spines and synapses, and shrinkage of dendritic spines may play a role.[48]

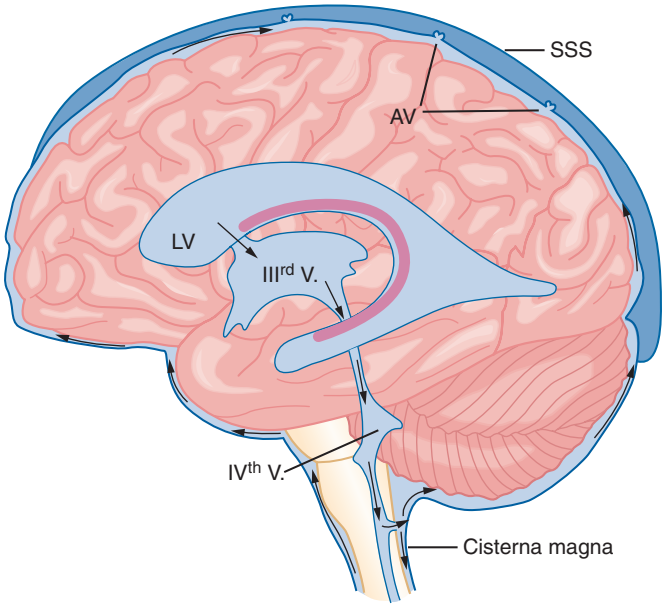
Cerebral Spinal Fluid Dynamics

Production

The volume of CSF in human adults is about 150 mL, half of which resides within the cranium and the other half in the spinal subarachnoid space. Approximately 70% is produced by the choroid plexus, and the remainder is largely a product of transependymal diffusion from the brain interstitium. The choroid plexus refers to a vascular proliferation with ependyma-lined epithelium found in the third and fourth ventricles as well as the medial walls of the lateral ventricles. The vasculature of the choroid plexus is characterized by relatively large-diameter capillaries with thin fenestrated walls. Although various drugs are capable of altering the rate of CSF formation, total CSF volume is typically turned over three to four times per day.

Circulation

CSF circulates primarily from sites of production in the lateral and third ventricles toward the fourth ventricle (by way of the aqueduct of Sylvius). CSF then exits the fourth ventricle, located between the brainstem and cerebellum, by way of paired lateral



• **Fig. 9.10** Cerebrospinal fluid (CSF) flow. The overall flow of CSF is demonstrated by *black arrows*. At the level of the cisterna magna, CSF can flow upward around the cerebral hemispheres or downward into the spinal subarachnoid space. The overall direction of flow in the spinal subarachnoid space is caudal posteriorly and rostral anteriorly. CSF is primarily absorbed into the superior sagittal sinus *(SSS)* through small arachnoid protrusions called arachnoid villi *(AV)*. *LV,* Lateral ventricle; *IIIrd V,* third ventricle; *IVth V,* fourth ventricle.

openings (foramina of Luschka) and a single midline opening (foramen of Magendie) into the cisterna magna. From the cisterna magna, CSF fluid flows superiorly in the subarachnoid space bathing the cerebral hemispheres or inferiorly toward the spinal subarachnoid space (Fig. 9.10). Caudal movement of CSF in the spinal subarachnoid space occurs primarily posterior to the spinal cord, whereas the overall direction of flow ventral to the cord is cephalad. Movement for circulation of CSF is provided by hydrostatic pressure created at the sites of production, coordinated ciliary movement on the surface of ependymal cells, and ventricular excursion created by respiratory variation and vascular pulsations. CSF is absorbed primarily through arachnoid villi into the superior sagittal sinus and returned to the central circulation.

Function

The CSF functions both as a supportive and protective cushion for the CNS and as an excretory system for unwanted and potentially harmful substances. The buoyancy afforded the brain by the specific gravity difference between the brain and CSF acts to reduce the effective weight of the brain to approximately 4% of its mass. The CSF may also help provide the brain parenchyma a stable biochemical environment essential for proper function. Differences in composition between plasma and CSF (Table 9.4) are maintained by the BBB.

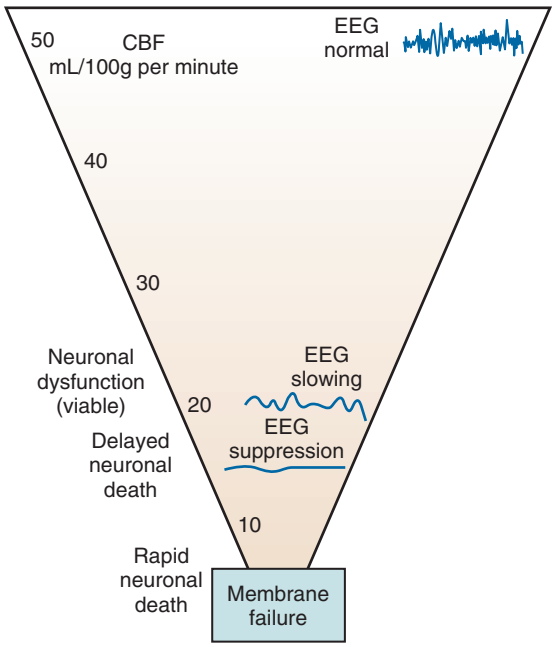
Blood-Brain Barrier

Most capillary beds contain fenestrations between endothelial cells that are approximately 65 Ångstroms in diameter. In the brain, with the exception of the choroid plexus, pituitary, and area postrema, tight junctions reduce this pore size between endothelial cells to approximately 8 Ångstroms. This significantly limits the passage of solutes (including pathogens) from the blood into the brain. As a result, most drugs primarily cross into the brain by transmembrane diffusion, which is influenced by characteristics such as molecular weight, the presence of ionic charge, and lipid solubility.

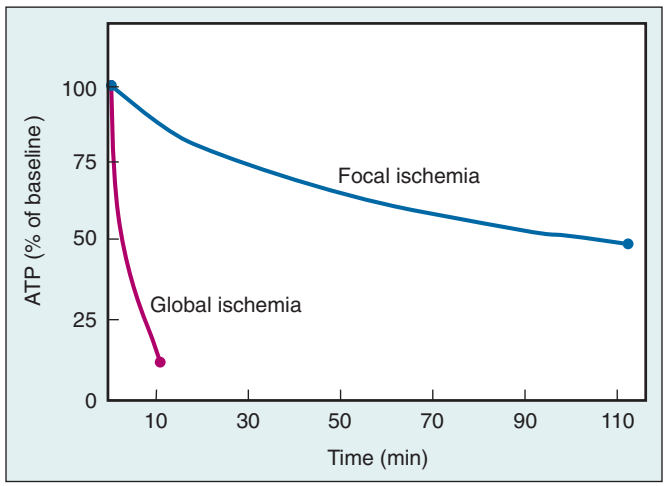
Pathophysiology of Cerebral Ischemia

Critical CBF Thresholds

The brain has a high demand for metabolic substrate (oxygen and glucose) and is quite vulnerable to interruptions in substrate supply. With declining CBF, and therefore oxygen delivery, neuronal function deteriorates in a progressive fashion (Fig. 9.11).[49] Normal CBF typically provides a substantial reserve in energy substrate delivery; it is not until CBF reaches 20 mL/100 g per minute that clinical and EEG evidence of ischemia are evident. Further reduction in CBF to about 15 mL/100 g per minute results in complete cessation of cortical electrical activity as indicated by a suppressed (flat) EEG. When CBF reaches about 6 mL/100 g per minute, indicators of irreversible membrane failure occur (elevated extracellular K^+, loss of the direct cortical response).[50] Between 15 and 6 mL/100 g per minute there is a progressive decrease in energy supply that will result in membrane failure and death over the time course of hours on one end and minutes on the other.[49] Regions of brain within this intermediate flow range, termed the



• **Fig. 9.11** Relationships between cerebral blood flow *(CBF),* electrophysiologic dysfunction, and neuronal viability. As CBF decreases, there is a progressive deterioration in electrophysiologic function, which is perhaps best demonstrated with electroencephalogram *(EEG)* recordings. Evidence of electrophysiologic dysfunction manifests in the form of EEG slowing at CBF less than 20 mL/100 g per minute. CBF in the range of 6 to 15 mL/100 g per minute provides insufficient metabolic substrate delivery to support electrophysiologic function (EEG suppression), but is adequate to prevent immediate membrane failure and neuronal death. When CBF is reduced below 6 mL/100 g per minute, irreversible and rapid membrane failure ensues, resulting in rapid neuronal death.



• **Fig. 9.12** Relative rates of ischemic energy failure. Energy failure rates following experimental global (decapitation) and focal ischemia (middle cerebral artery occlusion). In the presence of residual cerebral blood flow, energy failure is substantially delayed. *ATP,* Adenosine triphosphate.

ischemic penumbra, encompass tissue with potentially reversible dysfunction that will progress to neuronal death if flow is not restored.[51]

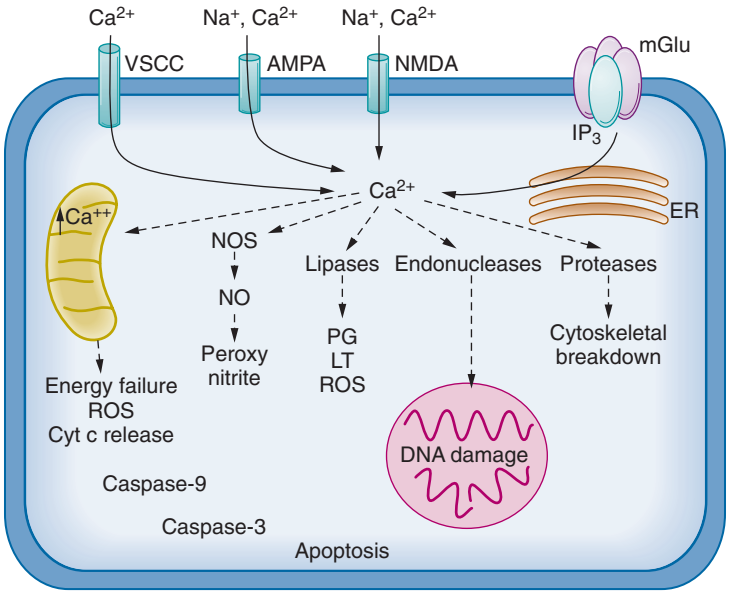
Cerebral ischemia can occur as a result of complete global ischemia (e.g., cardiac arrest) or focal ischemia from reduced flow within a specific vascular territory. With the former, there is cessation of CBF and there is a rapid reduction in cellular ATP.[52] In focal ischemia, the severity of ischemia is greatest within the core of the ischemic territory and irreversible cell injury is rapid. Surrounding the core is a region (the penumbra) in which ischemia is severe enough to abolish electrical activity but in which the neurons are viable for short periods of time. From a clinician's perspective, the difference is that incomplete ischemia can allow adequate ATP generation to stave off the catastrophic irreversible membrane failure that occurs within minutes during normothermic complete global ischemia (Fig. 9.12).[52,53] The duration of the period of potential viability in the penumbra region is dependent on residual CBF through the feeding vessel and the extent of collateral circulation. Importantly, autoregulation is abolished in the penumbra and collateral perfusion is critically dependent on cerebral perfusion pressure. Hypotension can dramatically increase the size of the penumbra, whereas modest increases in perfusion pressure may reduce the extent of injury.

Energy Failure and Excitotoxicity

Central to the pathophysiology of cerebral ischemia is energy failure. ATP supply is critical for maintaining normal membrane ion gradients within neurons. Energy failure therefore is rapidly associated with membrane depolarization and influx of Na^+ and Ca^{2+} with subsequent activation of voltage-gated Ca^{2+} channels, which further increase intracellular $[Ca^{2+}]$.[54] Depolarization also results in release of massive quantities of excitatory neurotransmitters, particularly glutamate, into the synaptic cleft from presynaptic terminals. Postsynaptic activation of glutamate receptors then further augments Na^+ and Ca^{2+} influx.[55] Activation of metabotropic glutamate receptors leads to the release of stored Ca^{2+} from endoplasmic reticulum via inositol 1,4,5-triphosphate receptors. Ionic influx is accompanied by water and results in neuronal swelling, called *cytotoxic* edema.[56] Neuronal injury that is augmented by excessive glutamate receptor activation is referred to as *excitotoxicity*.

Ca^{2+}, a ubiquitous second messenger, is required for the activation of a number of enzyme systems. The rapid, uncontrolled increase in cytosolic Ca^{2+} concentration initiates a number of cellular processes that contribute to neuronal injury (Fig. 9.13). Activated proteases degrade cytoskeletal proteins and other proteins. Lipases hydrolyze cellular lipids and thus cause damage to cellular membranes. Phospholipase A_2 releases fatty acids such as arachidonic acid that are metabolized into prostaglandins and leukotrienes by cyclooxygenase and lipoxygenase with the subsequent generation of superoxide free radicals. The latter, in combination with other free radicals generated in response to mitochondrial injury, can lead to lipid peroxidation and further membrane injury. Prostaglandins and leukotrienes evoke an inflammatory response and are powerful chemotactic agents. Platelet activation within cerebral microvessels, as well as inflammatory cell adhesion and infiltration into damaged areas, aggravates ischemic injury through microvasculature occlusion.

DNA damage is also an important consequence of ischemic neuronal injury (see Fig. 9.13). Generation of free radicals from arachidonic acid metabolism, from injured mitochondria, and from the production of peroxynitrite (from nitric oxide) leads to oxidative DNA injury. Ischemia-induced activation of endonucleases also produces DNA strand breaks. Under normal circumstances, these breaks are repaired through activation of poly-adenosine diphosphate ribose-polymerase (PARP), a DNA



• **Fig. 9.13** Pathophysiology of neuronal energy failure. During ischemia, inadequate neuronal adenosine triphosphate (ATP) supply, required for maintenance of ionic gradients, leads to presynaptic depolarization and the subsequent excessive unregulated release of excitatory neurotransmitters, especially glutamate. Activation of voltage-gated calcium ion *(Ca^{2+})* channels and excessive stimulation of ligand-gated ion channels result in rapid Ca^{2+} entry. Stimulation of metabotropic glutamate receptors *(mGlu)* generates inositol 1,4,5-triphosphate *(IP_3),* which causes endoplasmic reticulum *(ER)* release of Ca^{2+}. Activation of the α-amino-3-hydroxy-5-methyl-4-isoaxolepropionic acid *(AMPA)* receptor-gated subtype of glutamate receptors also permits excessive entry of sodium ions *(Na^+).* Excessive free Ca^{2+} results in activation of numerous enzymes detrimental to the neuron: protease activation causes cytoskeleton breakdown; lipases damage plasma membrane lipids and release prostaglandins *(PG),* leukotrienes *(LT),* and reactive oxygen species *(ROS);* activation of nitric oxide synthase *(NOS)* leads to formation of nitric oxide *(NO)* and the generation of peroxynitrite, a highly reactive free radical; and activated endonucleases cleave DNA. Mitochondrial injury leads to energy failure, *ROS,* and mitochondrial release of cytochrome c *(Cyt c);* the latter is one of the means by which neuronal apoptosis is initiated. *LT,* Leukotrienes; *NMDA,* N-methyl-D-aspartate; *NOS,* nitric oxide synthetase; *PG,* prostaglandins; *VGCC,* voltage-gated Ca^{2+} channels.

repair enzyme. However, with excessive DNA injury, depletion of the PARP substrate nicotinamide adenine dinucleotide (NAD) limits the capacity for DNA repair. NAD is an important coenzyme in energy metabolism and its depletion further exacerbates energy failure.

Lactate formation is an additional component to the pathophysiologic process of energy failure. Lactic acid is formed as a result of anaerobic glycolysis that takes place after oxygen supply failure. The associated pH decline contributes to the deterioration of the intracellular environment. Increased preischemic serum glucose can exacerbate this process by providing additional substrate for anaerobic glycolysis and, indeed, it has been associated with increased ischemic neurologic injury.[57]

Collectively, the simultaneous and unregulated activation of a number of cellular pathways overwhelms reparative and restorative processes and ultimately leads to neuronal death.

The Nature of Neuronal Death

Neuronal death that occurs as a result of ischemia can be either necrotic or apoptotic depending on the ischemic insult duration or intensity as well as the cell type and its life cycle stage. The excitotoxic injury described previously characteristically leads to necrosis, which is associated with local inflammatory cell infiltration and considerable "collateral damage." Neuronal necrosis mediated by excitotoxic injury is characterized by rapid cellular swelling, condensation and pyknosis of the nucleus, and swelling of the mitochondria and endoplasmic reticulum.

Neuronal apoptosis, a form of programmed cell death or cellular suicide, has also been demonstrated in a variety of cerebral ischemia models. Apoptosis is characterized by chromatin condensation, involution of the cell membrane, swelling of mitochondria, and cellular shrinkage. In the later stages of apoptosis, neurons fragment into apoptotic bodies that are then cleared from the brain. The absence of a substantial inflammatory response to apoptotic death limits injury to surrounding neurons that have survived the initial insult. Neuronal injury in response to ischemia cannot easily be divided into necrosis or apoptosis, but encompasses a spectrum in which some neurons undergo necrosis or apoptosis while others undergo cell death that has features of both necrosis and apoptosis.

Timing of Neuronal Death

Initial concepts of ischemia-induced neuronal death were restricted to the time of ischemia and early reperfusion period. More recent data indicate that postischemic neuronal injury is a dynamic process extending for a long period after ischemic insult.[58–60] Delayed

neuronal death, which was first demonstrated in models of global cerebral ischemia, also occurs following focal ischemia.[60] The extent of delayed neuronal death depends on the severity of the ischemic insult. With severe ischemia, most neurons undergo rapid death. With more moderate insults, neurons that survive the initial insult may undergo delayed death, which contributes to the gradual expansion of cerebral infarction after focal ischemia. Evidence of cerebral inflammation, which theoretically can contribute to further injury, has been demonstrated even 6 to 8 months after the primary ischemic event.

Key Points

- The brain has a high metabolic rate and is dependent on elaborate mechanisms that ensure continuous and adequate metabolic substrate delivery.
- CBF is autoregulated such that flow is normally constant over a range of mean arterial pressures (70-150 mm Hg). CBF is pressure-passive below or above the limits of autoregulation.
- Autoregulation can be impaired or absent following insults such as traumatic brain injury or subarachnoid hemorrhage. In such cases, CBF is pressure-passive and may be reduced despite a normal mean arterial pressure.
- CBF is under chemical regulation: it varies directly with arterial carbon dioxide tension ($PaCO_2$) in the range of 20 to 80 mm Hg and inversely with arterial partial pressure of oxygen (PaO_2) below 60 mm Hg.
- CBF is tightly coupled to local cerebral metabolism. When cerebral activity in a particular brain region increases, a corresponding increase in blood flow to that region occurs. Conversely, reduced activity/metabolism leads to reduced blood flow.
- About 60% of brain energy consumption supports electrophysiologic functions; the remainder supports cellular homeostasis.
- Intravenous anesthetics such as barbiturates, propofol, and etomidate can decrease the electrophysiologic component CMR up to 60% and thus substantially reduce CBF through flow-metabolism coupling. The effect is maximal at the point of electroencephalographic silence.
- Hypothermia reduces both the functional and basal components of CMR; CMR decreases about 6% to 7% per degree Celsius temperature reduction.
- The net effect of volatile anesthetics on CBF is a reflection of the relative contribution of two opposing effects: CMR reduction versus direct cerebral vasodilation. At subanesthetic doses, reduced metabolic rate offsets direct cerebral vasodilation and CBF is not significantly altered. Above minimum alveolar concentration, direct cerebral vasodilation may exceed CMR reduction and thus increase CBF/CBV.
- Systemic vasodilators (nitroglycerin, nitroprusside, hydralazine, calcium channel blockers) cause cerebral vasodilation and, depending on the MAP, can increase CBF.
- Vasopressors such as phenylephrine, norepinephrine, ephedrine, and dopamine do not have significant direct cerebrovascular effects.
- Focal cerebral ischemia is better tolerated than global ischemia because collateral blood flow may be sufficient to stave off neuronal injury until CBF can be restored.

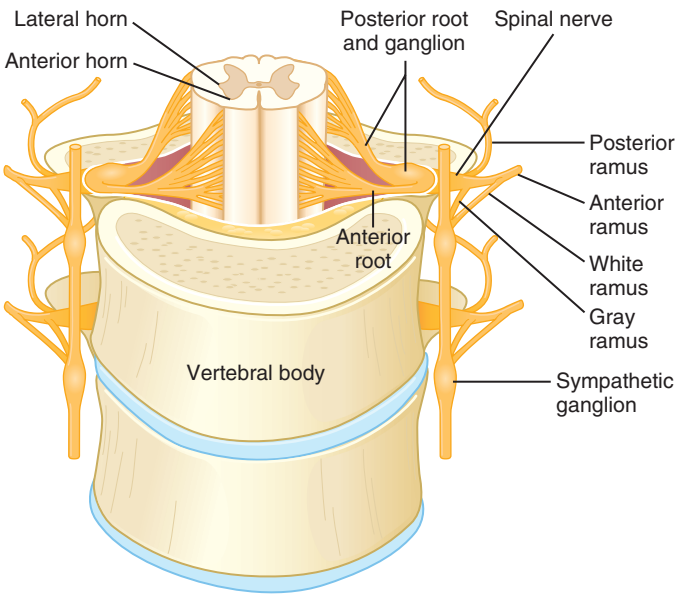
Anatomy and Imaging: The Nervous System

Nicholas Pierson, Sarah E. Stilwill, Elizabeth Ryals, and Jeffrey D. Swenson

This section outlines important anatomic structures and imaging techniques for the nervous system. Imaging techniques such as magnetic resonance imaging (MRI), computed tomography (CT), and plain radiography are presented to demonstrate their clinical roles.

Technical and clinical considerations exist for imaging in the acute care setting. For example, there are unique advantages and limitations for methods such as MRI and CT. Likewise, the decision to use contrast versus noncontrast techniques may vary based on the clinical setting. The choice of which imaging technology to use depends not only on the pathology in question but also on patient age, the speed at which the clinical question needs to be answered, the patient's clinical stability, the presence of surgical hardware, and any underlying comorbidities.

The effective use of all imaging techniques presupposes a knowledge of anatomy. For the nervous system, a fundamental structure is the spinal nerve and its relation to the spinal cord and surrounding vertebral structures (Fig. AI1.1). **Anterior and posterior spinal roots** carry motor and sensory fibers, respectively. These roots combine to form the **spinal nerve**. The **posterior root** is unique in that it includes a **ganglion** made up of the cell bodies of sensory nerves. By contrast, motor cell bodies are in the **anterior horn** of the spinal cord. Each **spinal nerve** gives rise to an **anterior** and **posterior ramus,** which carry both motor and sensory fibers.

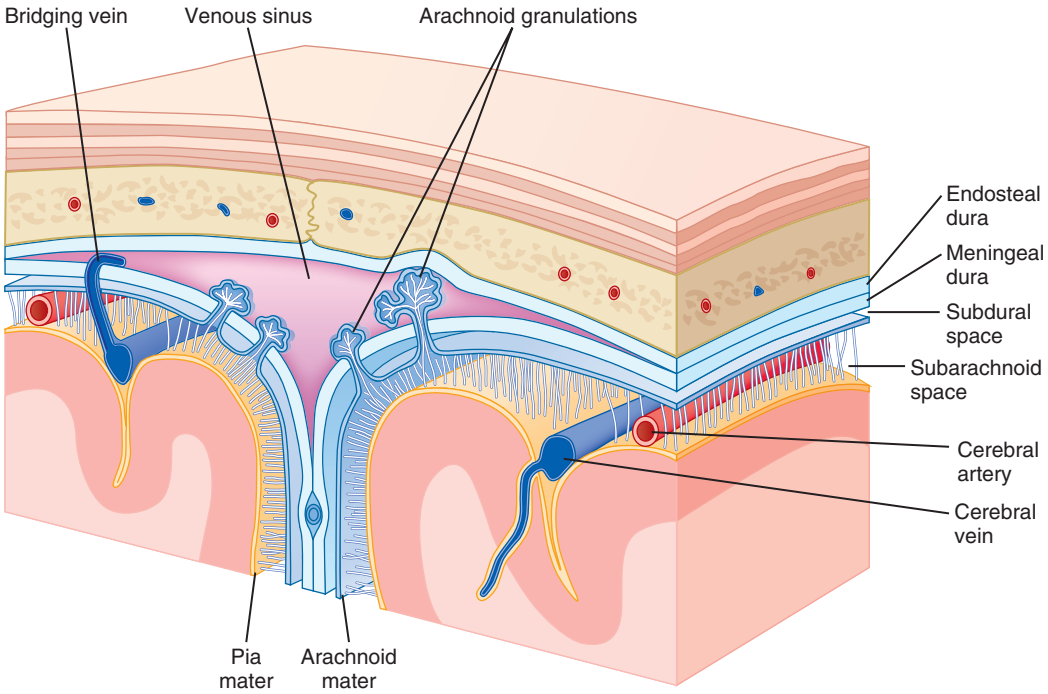


• **Fig. AI1.1** Anatomy of the spinal nerves, spinal cord, and vertebral body in an idealized anatomic drawing.

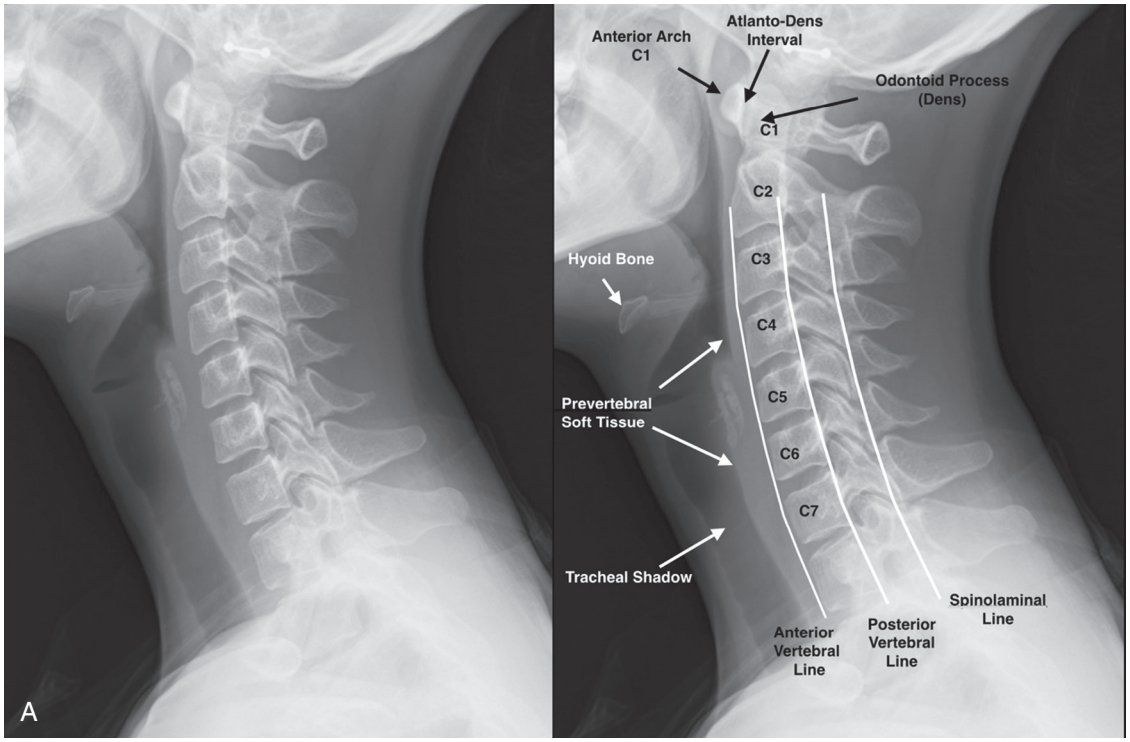
White rami connect presynaptic sympathetic fibers (whose cell bodies are in the **lateral horn** of the spinal cord) from the **anterior rami** to the **sympathetic ganglia**. **White rami** are present between the first thoracic and second lumbar levels of the spinal cord**. Gray rami** carry postganglionic sympathetic fibers at all levels from the **sympathetic ganglia** to **spinal nerves**.

Important vascular and meningeal structures of the head are displayed in a coronal plane (Fig. AI1.2). The **venous sinus** is formed by a separation of the **dura** into **endosteal** and **meningeal** layers. **Venous sinuses** are unique in that they have no valves or muscular tissue. They receive cerebral spinal fluid (CSF) through **arachnoid granulations**, which are projections of the **arachnoid mater** into the **venous sinuses** through which CSF enters the bloodstream. **Bridging veins** cross from the **subarachnoid space** to the **venous sinus**. Subdural hematoma can result from disruption of bridging veins in the subdural space. **Cerebral arteries and veins** are visible in the **subarachnoid space** overlying the **pia mater**. Hemorrhage in the **subarachnoid space** may result from cerebral artery aneurysm or trauma.

Advances in imaging of the nervous system can be demonstrated in the cervical spine. The upper left panel (A) of Fig. AI1.3 is a lateral radiograph of the cervical spine. The right panel shows the same radiograph with key anatomic structures labeled. The lower panels of Fig. AI1.3 show computed tomography (CT) and magnetic resonance imaging (MRI), which have now become standards in evaluation of cervical trauma. Although CT imaging is recognized as a standard for initial evaluation of cervical trauma, **MRI** is very sensitive for detection of spinal cord, ligamentous, and soft tissue injuries. The left panel is a **noncontrast CT** midline image showing a flexion-distraction injury at C6–C7. There is a burst fracture of C7, subtle traumatic anterior listhesis of C6 (*horizontal arrow*) and posterior interspinous space widening (*vertical arrow*). In the right panel, a **sagittal midline MRI** clearly shows fracture-related marrow edema within the **C7** and **T1** vertebral bodies, C6–C7 interspinous ligamentous edema (*paired white arrows*) and extensive posterior supraspinous soft tissue edema (*paired yellow arrows*) consistent with trauma soft tissue injury. **CT** is superior for cortical fractures, whereas **MRI** is more sensitive for detection of soft tissue injuries. Fig. AI1.4 compares CT and computed tomography angiography (CTA) in the setting of subarachnoid hemorrhage. The left panel shows a standard noncontrast CT image with extensive subarachnoid hemorrhage diffusely filling the basal cisterns (*double arrows*). The upper right panel shows a midline sagittal CTA image with a large bi-lobed aneurysm (*white arrow*) arising from the anterior communicating artery (ACOM). In the lower right panel, conventional angiography identifies the aneurysm (*white arrow*) prior to coil embolization.

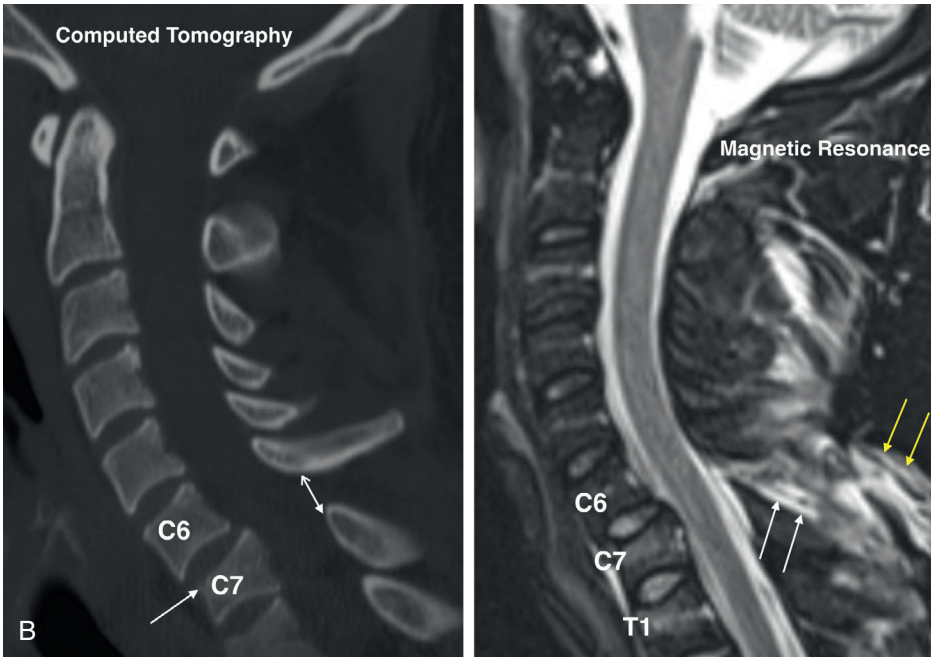


• **Fig. AI1.2** Anatomy of the meninges and its vasculature in an idealized anatomic drawing.

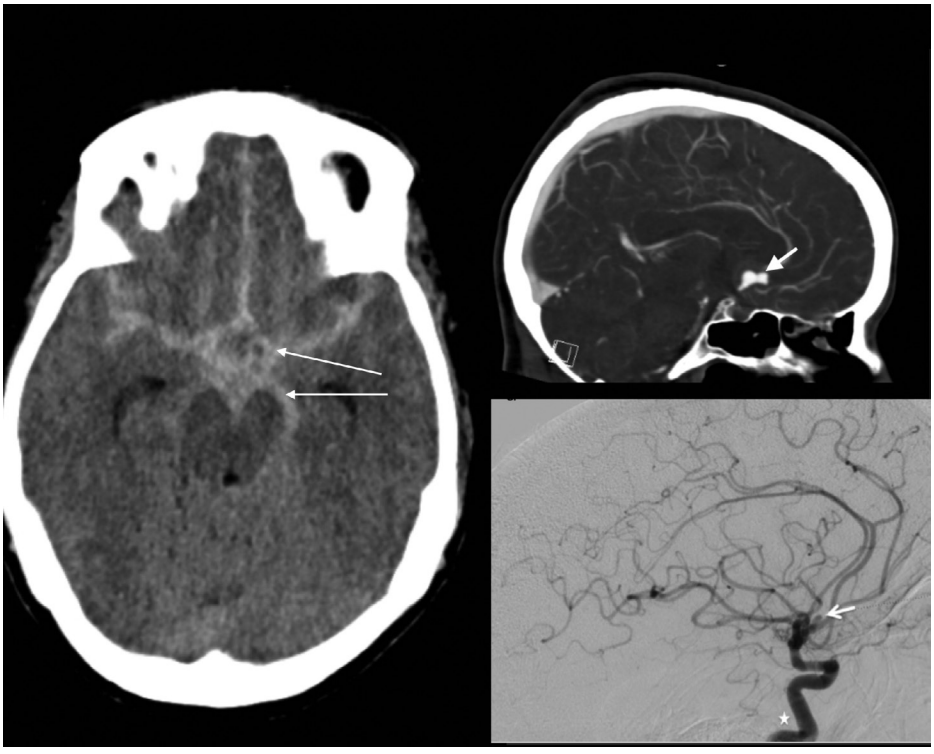


• **Fig. AI1.3** (A, B) The anatomy of cervical bony structures and soft tissues is visualized using plain radiography (A), computed tomography (B, left), and magnetic resonance imaging (B, right). (From Goradia D, Linnau KF, Cohen WA, et al. Correlation of MR imaging findings with intraoperative findings after cervical spine trauma. *AJNR Am J Neuroradiol*. 2007;28:209–215.)

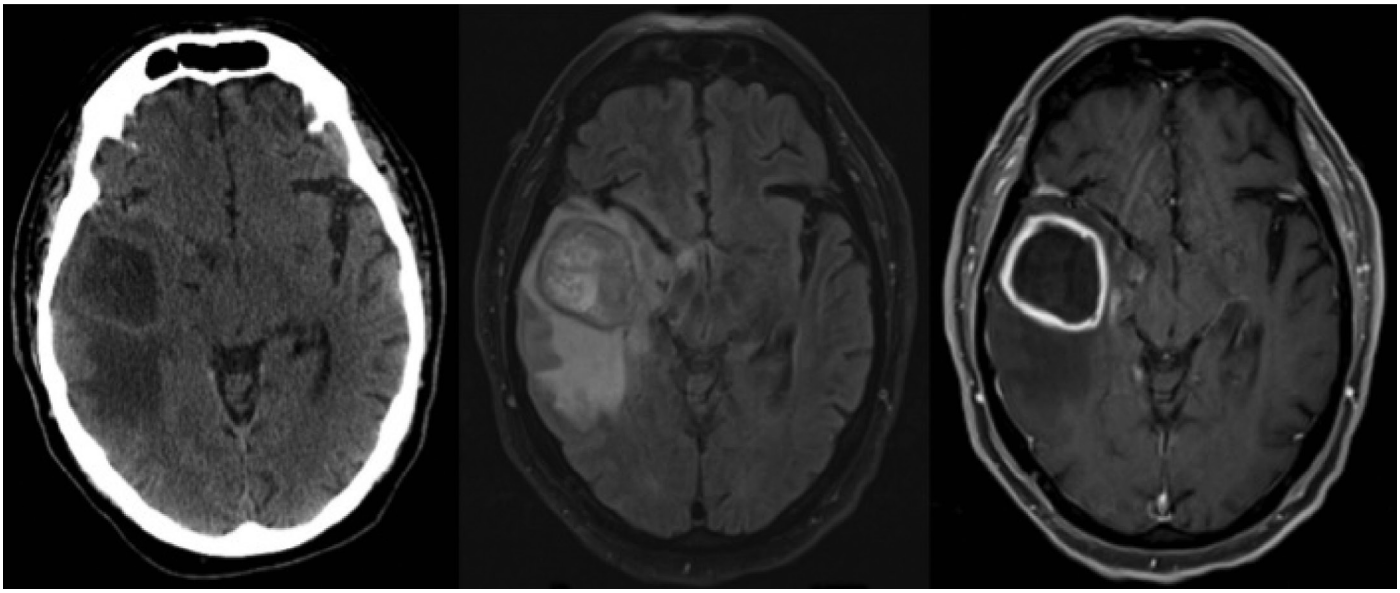
Continued



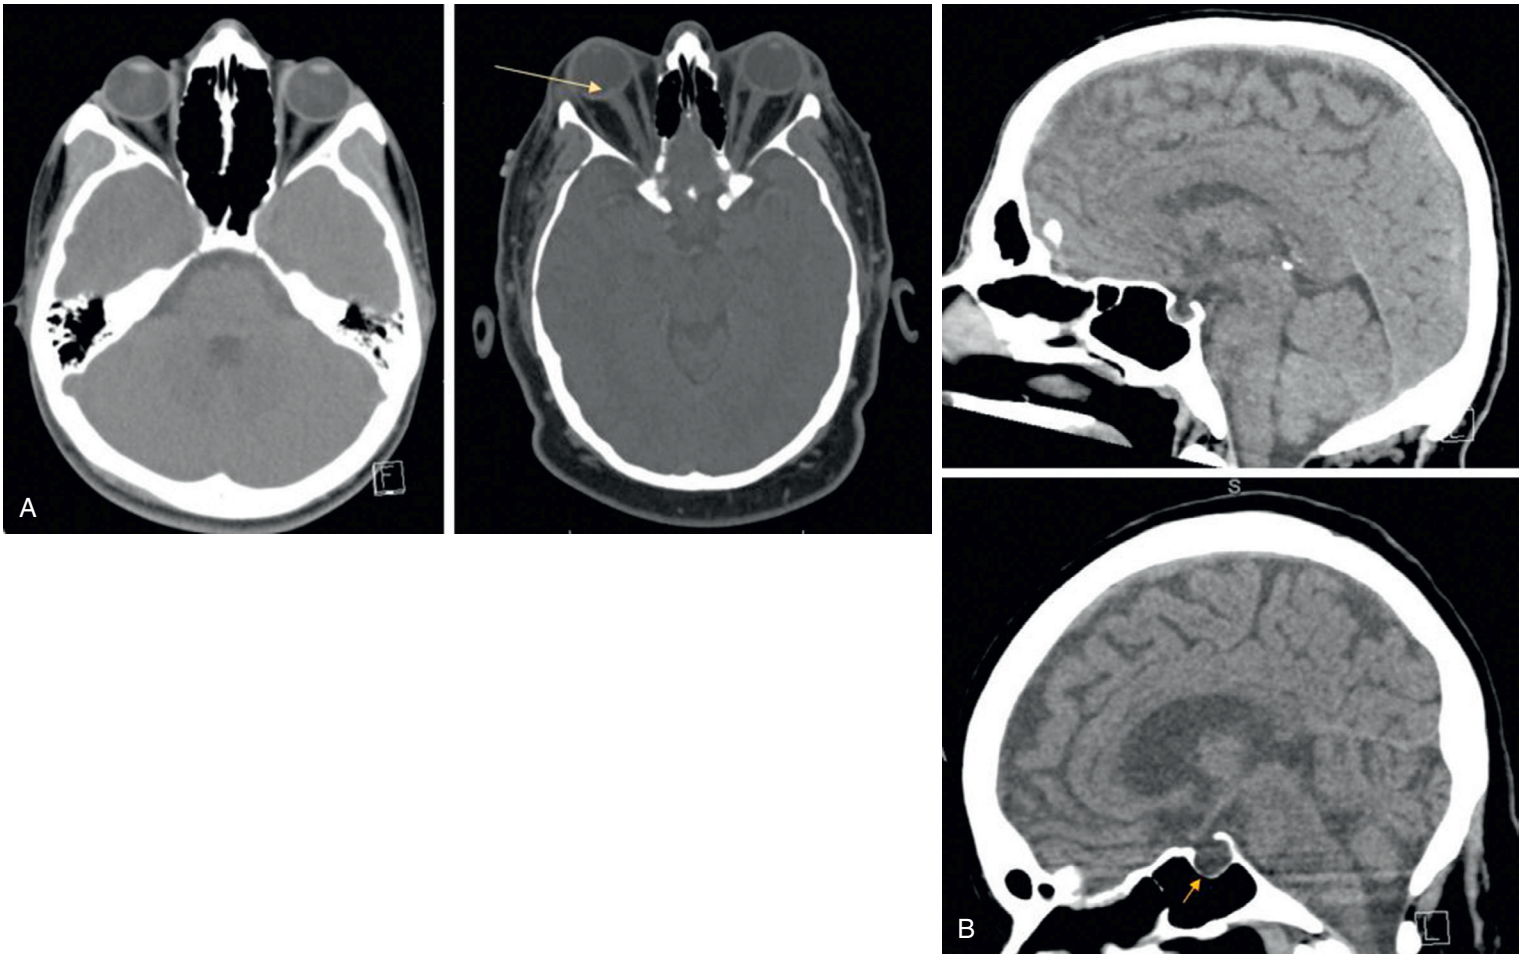
• **Fig. AI1.3, cont'd**



• **Fig. AI1.4** Anatomic changes associated with subarachnoid hemorrhage as visualized by computed tomography, computed tomography angiography, and cerebral angiography. (From McKinney AM, Palmer CS, Truwit, et al. Detection of aneurysms by 64-section multidetector CT angiography in patients acutely suspected of having an intracranial aneurysm and comparison with digital subtraction and 3D rotational angiography. *AJNR Am J Neuroradiol*. 2008;29:594–602.)



• **Fig. AI1.5** Anatomic changes associated with an intracranial mass lesion as visualized by standard magnetic resonance imaging, contrast-enhanced magnetic resonance imaging, and computed tomography. (From Smirniotopoulos JG, Murphy FM, Rushing EJ, Rees JH, Schroeder JW. Patterns of contrast enhancement in the brain and meninges. *Radiographics* 2007;27(2):525–551.)



• **Fig. AI1.6** Image findings associated with increased intracranial pressure.

Aneurysms are an important cause of subarachnoid hemorrhage. Noninvasive CTA provides highly accurate detection of aneurysms in addition to delineation of intracranial vascular anatomy. CTA has largely replaced conventional angiography for diagnostic evaluation of traumatic and atraumatic vascular pathology, including aneurysms, pseudo-aneurysms, dissection, uncontrolled hemorrhage, and vessel occlusion or stenosis. Additionally, CTA provides an anatomic road map for vascular anatomy and is applicable to pregnant and breast-feeding patients.

Fig. AI1.5 illustrates the advantage of **contrast-enhanced MRI** in comparison to **noncontrast MRI** and **CT** in the setting of an intracranial mass lesion. Gadolinium contrast–enhanced MR imaging improves the detection of both extra-axial and intra-axial infections compared to CT. Blood–brain barrier breakdown leads to increased vascularity/permeability and therefore contrast enhancement at sites of infection and inflammation. *Left panel:* A noncontrast CT image through the temporal lobe demonstrates a poorly defined space-occupying mass lesion with surrounding vasogenic edema and mass effect. *Middle panel:* Routine noncontrast MR image through the temporal lobe shows a well-defined circular mass lesion with extensive surrounding vasogenic edema and mass effect on the adjacent midbrain structures. *Right panel:* Contrast-enhanced MR image through the lesion demonstrates classic "ring-like" enhancement of this intracranial abscess with surrounding nonenhancing edema.

The CT images in Fig. AI1.6 show findings of the orbit and skull base associated with increased intracranial pressure. In Fig. AI1.6A, the left panel is an axial image at the level of the orbit showing a normal globe and optic nerve. In the right panel, an arrow highlights intraocular protrusion of the optic nerve consistent with elevated intracranial pressure. In Fig. AI1.6B, the top panel shows a sagittal image of a normal-appearing sella turcica. In the bottom panel, an arrow highlights flattening of the sella turcica (otherwise known as the "empty sella sign") secondary to increased intracranial pressure.

History of Intravenous Anesthesia

The concept of blood delivery of medication can be traced to the middle of the 17th century soon after Harvey described the function of the vascular system. Not only did Sir Christopher Wren study blood transfusions in dogs, but he also experimented with intravenous delivery of injected opium solution into these animals via a feather quill.[1] In the mid-19th century, technologic advancements in needle and syringe manufacturing led to injectable morphine for analgesia, but attempts to produce general anesthesia through intravenous drugs came later. Initial attempts with agents such as diethyl ether, chloral hydrate, magnesium sulfate, barbituric acid, and ethyl alcohol were stalled by prolonged side effects and limited techniques for ventilatory support.[2] Local anesthetics were also tested as intravenous agents for general anesthesia in the early 20th century before their primary clinical application in regional anesthesia was established.[3] The major historical developments in intravenous agents for general anesthesia lagged behind those of the inhaled anesthetics until Lundy and Waters began using barbiturates in the 1930s.[4]

General Anesthesia by Intravenous Agents

For the pedagogic purposes of this chapter, *intravenous anesthetic* is defined as a clinically available substance that when administered directly to the patient via the bloodstream can be used to induce or maintain a state of general anesthesia. Many injectable substances, such as antihistamines or antipsychotics (see Chapter 12), have obvious effects on the central nervous system (CNS) and can depress cognitive status and induce sleep. These drugs are potentially useful for several perioperative situations where sedation is required, but they are neither appropriate nor safe as primary agents for producing general anesthesia. Similarly, medications like the benzodiazepines can be classified as intravenous anesthetics yet are currently used primarily in the perioperative setting for premedication and sedation, not anesthesia. The intravenous opioids (see Chapter 17) form the backbone of modern surgical analgesia yet are not considered true intravenous anesthetics because awareness and recall can occur despite very high doses that produce deep sedation.[5]

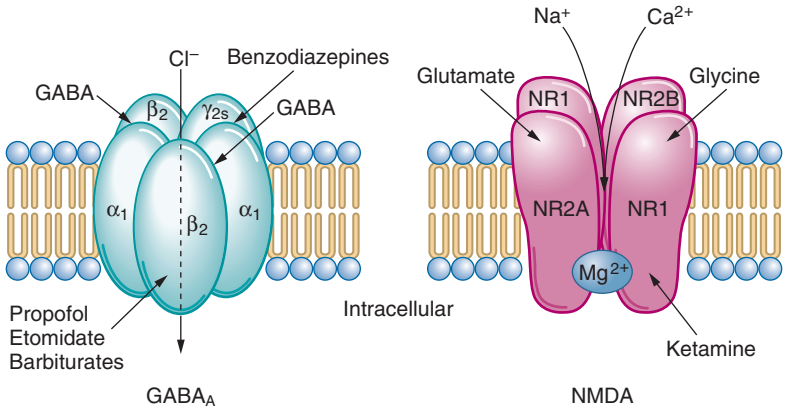
The concept of balanced anesthesia was originally used by Lundy to describe premedication and light sedation as adjuncts to regional anesthesia,[6] but the term was almost universally adopted when nitrous oxide anesthetics supplemented with thiopental and d-tubocurarine grew in popularity in the middle of the 20th century. At present, it is usually accepted that the state of general anesthesia can best be described as a delicate balance of the following effects: unconsciousness, analgesia, amnesia, suppression of the stress response, and sufficient immobility. The relative importance of each of these separate components varies for each case depending on specific surgical and patient factors; anesthesiologists must tailor combinations of intravenous drugs to match these priorities.

Abstract

Recent advances in molecular pharmacology and neuroscience have led to a greater understanding of how anesthetic chemicals can alter the function of the nervous system. Anesthesia through intravenous agents is a clinical state in which multiple behavioral endpoints are caused by a structurally diverse group of drugs. Certain membrane proteins possess specific binding sites that interact with injectable drugs currently used for clinical anesthesia. This chapter explores what is known and touches on what is unknown regarding the clinical use and neuropharmacologic mechanism of intravenous anesthetics.

Keywords

$GABA_A$
receptors
benzodiazepines
propofol
ketamine
dexmedetomidine



• **Fig. 10.1** Key targets of intravenous anesthetics. $GABA_A$ receptors are critical targets for benzodiazepines, barbiturates, etomidate, and propofol. Although it is possible for the drugs and ligands to interact with this protein in multiple areas, it is generally agreed that the endogenous ligand GABA binds to the receptor in a pocket between the α and β subunits. Many of the intravenous anesthetics have their main influence on the activity of this protein in the transmembrane portion of the β subunit, whereas the benzodiazepines modulate the protein through interactions with transmembrane amino acids between the α and γ subunits near the intracellular side. NMDA receptors are activated by the agonist glutamate and co-agonist glycine only when voltage changes displace Mg^{2+} from the ion channel pore. Ketamine also acts primarily by a pore-blocking mechanism. *Ca^+,* Calcium ion; *Cl^-,* chloride ion; *GABA,* gamma-aminobutyric acid type A; *Mg^{2+},* magnesium ion; *NMDA,* N-methyl-D-aspartate.

Intravenous Anesthesia Mechanisms and Theory

Modern anesthetic techniques have transformed surgery from a traumatic and barbaric affair to an acceptable, routine, and essential part of modern medicine. Despite the technologic advances made in perioperative medicine and surgical techniques, the drugs administered by anesthesiologists to render patients unconscious continue to be used without a clear understanding of how they produce anesthesia. Fortunately, through recent advances in molecular pharmacology and neuroscience, clinicians and investigators understand better than ever before how anesthetic chemicals can alter the function of the nervous system.

The elucidation of general anesthetic mechanisms was not accessible to traditional pharmacology methods; anesthesia is a clinical state in which multiple behavioral endpoints are caused by a structurally diverse group of drugs. Nevertheless, it appears that certain membrane proteins (Fig. 10.1) possess binding sites that interact with many of the currently used anesthetics (Table 10.1).[7,8] In general, the halogenated volatile anesthetic agents (see Chapter 11) exhibit less specificity for molecular targets than the intravenous agents.

At the cellular and network levels, intravenous anesthetics alter signaling between neurons by interacting directly with a small number of ion channels. Under normal conditions, these specialized membrane proteins are activated by chemical signals or changes in the membrane environment. Upon activation, channels modify the electrical excitability of neurons by controlling the flow of ions across the cell membrane via channels coupled with specific receptors that sense the initial signal (see Chapter 1).

The majority of intravenous anesthetics exert their primary clinical anesthetic action by enhancing inhibitory signaling via gamma-aminobutyric acid type A ($GABA_A$) receptors. Ketamine and dexmedetomidine are notable exceptions. From a neurophysiology perspective, unconsciousness can be considered as a disruption of the precisely timed cortical integration necessary to produce what is considered the conscious state.[7] It is interesting to note that the unconsciousness produced by ketamine is phenotypically different from that produced by the GABA-ergic agents (e.g., propofol, thiopental, or etomidate). Although many talented scientists worked diligently throughout the 20th century to discover a unifying mechanism by which diverse chemicals cause what is loosely defined as the anesthetic state, molecular investigations into the action of individual drugs have revealed that this one true "grail" does not exist. It should rather be interpreted that the anesthetized state (and its separate components) can be arrived at by any disruption of the delicately constructed and precisely timed neuronal networks that underlie the normal awake, unanesthetized state.

Pharmacologic Targets of Intravenous Anesthetics in the Central Nervous System

$GABA_A$ Receptors

GABA is the most abundant inhibitory neurotransmitter in the brain. $GABA_A$ receptors represent the most abundant receptor type for this ubiquitous inhibitory signaling molecule. $GABA_A$ receptors are broadly distributed in the CNS and regulate neuronal excitability.[9] They appear to mediate unconsciousness, arguably the most recognizable phenotype associated with general anesthesia.[9] There is also strong evidence that $GABA_A$ receptors are involved in mediating some of the other classic components of general anesthesia, including depression of spinal reflexes[10] and amnesia.[11] The contribution of $GABA_A$ receptors in mediating immobility and analgesia is less clear.

$GABA_A$ receptors are ligand-gated ion channels, more specifically members of the "Cys-loop" superfamily that also includes nicotinic acetylcholine, glycine, and serotonin type 3 (5-hydroxytryptamine type 3) receptors. Each of these receptors is formed as a pentameric combination of transmembrane protein subunits (see Fig. 10.1). This superfamily is named for the fixed loops formed in each of

Data summarized from Key References.

*Asterisks indicate a complex relationship between drug and receptor—either evidence for direct allosteric interaction between these drugs and receptors is suspected but has yet to be found, or receptor activity and/or expression is known to be influenced through administration of the drugs. Isoflurane is also shown for comparison.

the subunits by a disulfide bond between two cysteine residues. In 2014, the protein crystallization of a human $GABA_A$ receptor was reported.[12] Binding pockets for neurotransmitters are located at two or more extracellular interfaces: in the case of $GABA_A$ receptors, the endogenous ligand GABA binds between the α and β subunits. Thus far, 19 genes have been identified for $GABA_A$ receptor subunits (α1-6, β1-3, γ1-3, δ, ε, θ, π, ρ1- 3).[13] Although millions of subunit arrangements are possible, only a subset of receptor configurations is expressed in significant amounts in the CNS. Preferred subunit combinations distribute among different brain regions and even among different subcellular domains.[14] Each type of $GABA_A$ receptor exhibits subtly distinct biophysical and pharmacologic properties that in turn have diverse influences on synaptic transmission and synaptic integration.

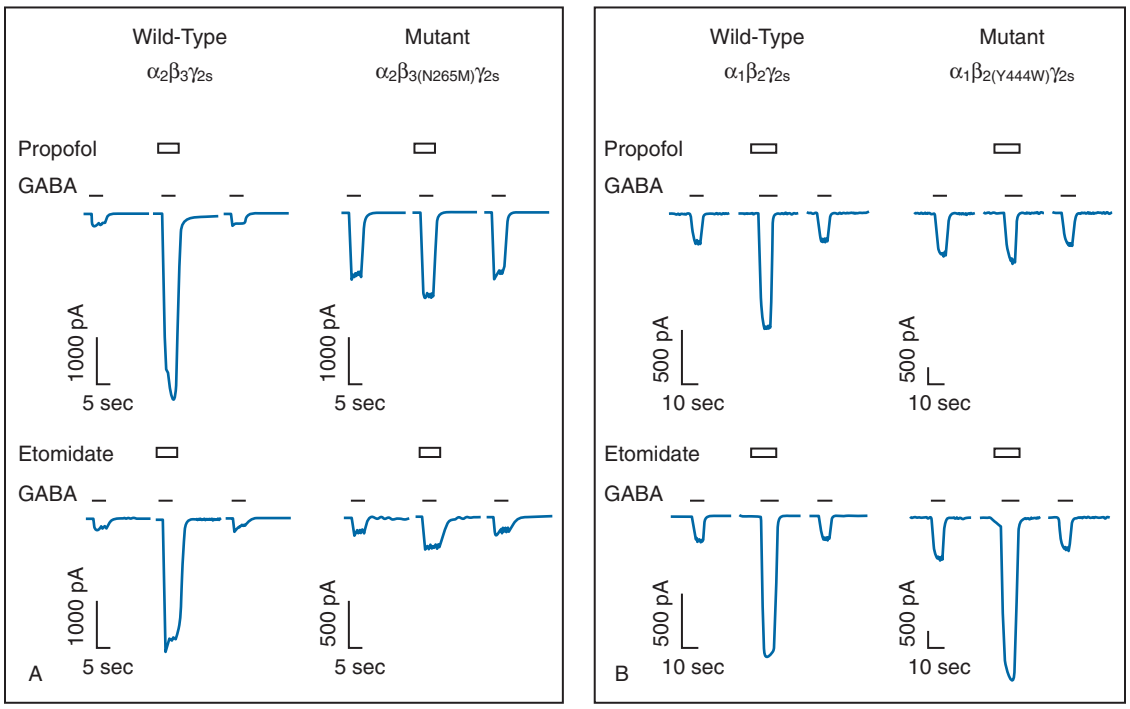
Specific behavioral effects of drugs have been linked to different subunit assemblies present in different brain regions. For example, benzodiazepines are thought to interact with $GABA_A$ receptors between the α and γ subunits[15] (see Fig. 10.1) and specific clinical effects have been linked to receptors containing specific α and β subunits. Propofol,[16] etomidate,[17] and barbiturates[18] interact with $GABA_A$ receptors within, or proximal to, β subunits. The β subunits show less specific subcellular localization compared to α subunits, and the distribution of β subunits in mammalian brain does not share the same clear distinctions as α subunits.[19] Therefore distinguishing specific differences between the GABA-mediated anesthetic effects of non-benzodiazepine intravenous anesthetics has been more elusive. However, research involving genetically manipulated mice has suggested that the sedation produced by etomidate can be primarily associated with activity at the β_2 subunit[20] while unconsciousness produced by the same drug can be associated with β_3 subunits (see "$GABA_A$ Insights from Mutagenic Studies").[21] Subtle pharmacodynamic differences between intravenous anesthetics (e.g., effects on postoperative nausea and vomiting) might also be mediated by interactions with targets in addition to $GABA_A$ receptors.

Almost all general anesthetics enhance $GABA_A$ receptor–induced chloride currents by enhancing receptor sensitivity to GABA, thereby inhibiting neuronal activation. Most of these drugs, at high concentrations, also directly open the channel as an agonist in the absence of GABA. By virtue of the specific distribution of these receptors in the cerebral cortex and other brain regions, in addition to being involved in producing anesthesia, $GABA_A$ receptors function in thalamic circuits necessary for sensory processing and attention, hippocampal networks involved in memory, and thalamocortical circuits underlying conscious awareness. Computational neuronal modeling studies have been important in revealing the impact of propofol and etomidate on dynamic changes in these networks.[22,23]

$GABA_A$ Insights From Mutagenic Studies

The critical role of the $GABA_A$ receptor in the pharmacodynamics of anesthetic drugs has been established through laboratory experimentation using genetic modifications of this protein. In the early 1990s, in vitro studies aimed at determining the interactions of the endogenous ligand GABA with its receptor revealed that specific amino acid substitutions in the $GABA_A$ receptor conferred the sensitivity of the channel to agonist or allosteric modulator activity.[24–26] By 1995, several functional domains of the $GABA_A$ receptor associated with binding of agonists and allosteric modulators were identified (reviewed by Smith and Olsen[27]). Following the discovery of the site of benzodiazepine action, investigators discovered that mutation of a pair of transmembrane amino acids on the α subunit of $GABA_A$ renders the receptors insensitive to inhaled anesthetics.[25,28] That same year, a corresponding area on the β_3 subunit was determined to be critical for the action of etomidate.[29] Further studies have determined this location to be essential to the actions of other intravenous agents such as propofol and pentobarbital.[18,30] A different amino acid residue appears to be involved with the specific actions of propofol only (Fig. 10.2).[16]

The strategy behind these discoveries was to examine the subtle differences among the amino acid sequences in receptor isoforms known to have different sensitivities to anesthetics. Originally receptor chimeras of unnatural subunit configurations were used, eventually giving way to specifically modified subunits via site-directed mutagenesis. Potential residues and amino acid sequence domains that mediate anesthetic sensitivity can be anticipated by



• **Fig. 10.2** Site-directed mutagenesis elucidates specific amino acid residues involved in anesthetic actions at the $GABA_A$ receptor in patch clamp experiments. Treatment with GABA (duration shown with *black line*) alone or in combination with anesthetics (indicated by *white box*) triggers depolarization of wild-type and mutant receptors. A, The substitution of a methionine (M) residue for an asparagine (N) residue in the 265th position on the β_3 subunit (β_3 N265M mutation) renders that $GABA_A$ receptor immune to enhancement of chloride current via etomidate and propofol administration. B, In a similar study of the β_2 subunit, substitution of tryptophan (W) for the native tyrosine (Y) blocks propofol enhancement but the receptor remains sensitive to etomidate. *GABA,* Gamma-aminobutyric acid type A. (A, Adapted from Siegwart R, Jurd R, Rudolph U. Molecular determinants for the action of general anesthetics at recombinant $\alpha_2\beta_3\gamma_2$ $GABA_A$ receptors. *J Neurochem*. 2002;80:140–148; B, Adapted from Richardson JE, Garcia PS, O'Toole KK, et al. comparing data among different mutated and chimeric receptors. Typically, functional studies are carried out in vitro by virally transfecting this DNA into living cells, which results in expression of these receptors on their cell surface. Immortal cells derived from human embryonic kidney cells and the eggs of the amphibian *Xenopus laevis* (oocytes) have been invaluable as conduits for this type of research; establishing electrical access in these cells using the conventional patch-clamp technique is relatively straightforward and measurements of their chloride currents in response to opening of the $GABA_A$ channel is robust (see Fig. 10.2).

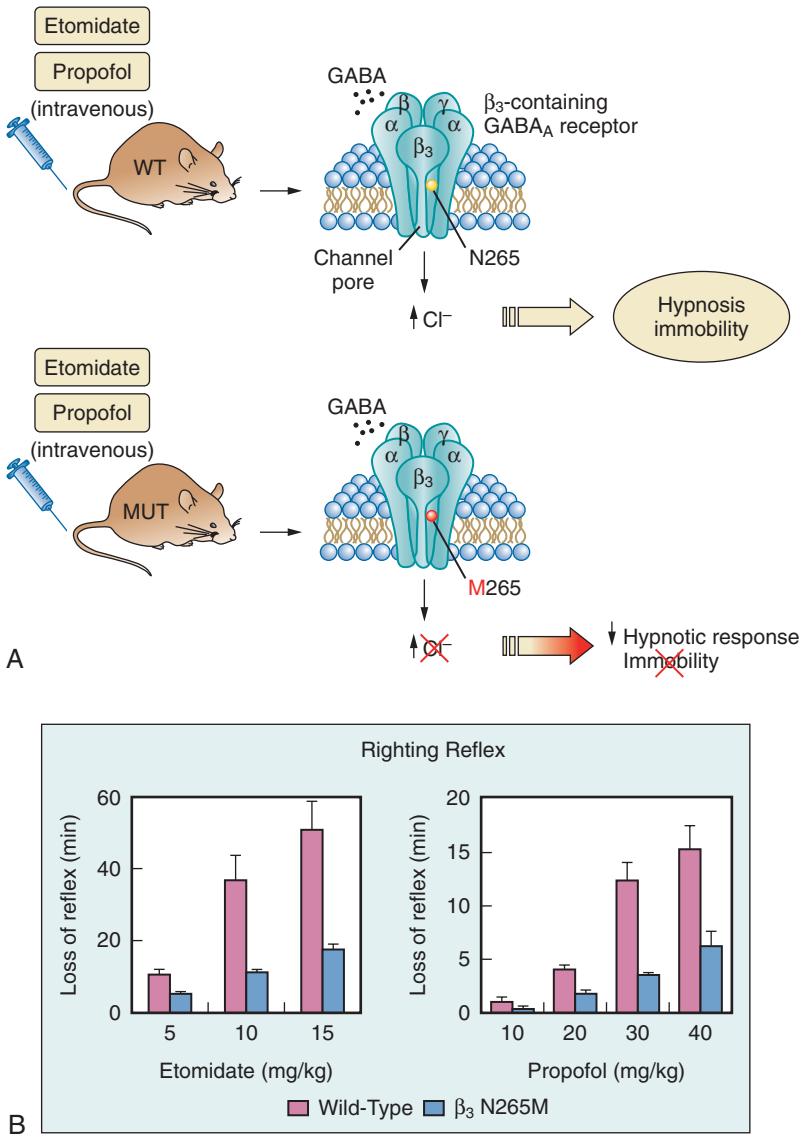
By now a great body of literature exists in which anesthetic sensitivity has been mapped to specific point mutations on $GABA_A$ receptors.[8] Some of these point mutations, so-called silent mutations, do not affect the natural function of the receptor but only its modulation by specific anesthetics. The introduction of mutations such as these into genetically modified mice can be used to determine the importance of this receptor to the production of certain qualities of an anesthetic in vivo.[31] In vivo experimentation on animals possessing these "knock-in" point mutations has advantages over traditional gene knockout studies. Specifically, if the receptor is unaltered except with respect to its response to exogenous anesthesia, there exists less potential for compensatory changes that could influence the results of in vivo experiments. Mouse geneticists have successfully bred mice with attenuated sensitivity to benzodiazepines as well as etomidate and propofol.[17,31–33]

By creating a point mutation that confers anesthetic selectivity in a single specific subunit, the phenotypic effects attributable to that drug and that subunit can be dissected (Fig. 10.3). For example, the substitution of a methionine (M) residue for an asparagine (N) residue in the 265th position on the β_3 subunit (β_3 N265M mutation) results in a phenotypically normal animal that is essentially immune to the hypnotic effects of propofol and etomidate while maintaining its sensitivity to inhaled anesthetics.[17] Similarly, substituting an arginine (R) for the histidine (H) residue in the 101st position on the α_1 subunit (α_1 H101R mutation) essentially renders that $GABA_A$ receptor unresponsive to benzodiazepines.[31] By making analogous substitutions in the other α subunits, scientists have been able to map particular behavioral effects from benzodiazepines to specific subunits. For example, the α_1 subunit appears to mediate the sedative, amnestic, and anticonvulsant actions of some benzodiazepines, whereas benzodiazepine muscle relaxation and anxiolysis are mainly mediated via α_2 and α_3 subunits.[31,32,34,35]

These amino acid substitutions (in vitro and in vivo) alter the molecular environment in the anesthetic binding cavity by reducing the number of favorable interactions between the receptor and the



• **Fig. 10.3** Genetic manipulation of $GABA_A$ receptors in mice facilitates the study of behavioral effects of different anesthetic drugs. A, In this schematic diagram, intravenous anesthetics (e.g., propofol and etomidate) are administered to a mouse with normal or wild-type *(WT)* $GABA_A$ receptors and, as expected, general anesthesia ensues. When these same drugs are administered to an animal with a specific knock-in mutation at the 265th position on the β_3 subunit, the effects of these drugs are mitigated. B, Quantitative data comparing the effect of propofol and etomidate on wild-type and β_3 N265M knock-in mutants in the loss of righting reflex test, an animal correlate of unconsciousness. *Cl^-,* chloride ion; *GABA,* gamma-aminobutyric acid type A. anesthetic molecule, thus reducing the efficacy of that anesthetic drug on enhancing GABA-ergic transmission. Although this work has greatly increased insight into anesthetic mechanisms, a complete description of the biophysical interactions between specific residues and specific anesthetics remains as incomplete as understanding of the spike-coded pattern of neuronal network activity responsible for the transitions between consciousness and unconsciousness.

N-Methyl-D-Aspartate Receptors

Whereas augmentation of endogenous inhibitory chemical signaling is important to mechanisms of anesthesia, mitigation of excitatory signaling also depresses neuronal activity. Of the many excitatory chemical signals in the CNS, blockade of the N-methyl-D-aspartate (NMDA)-type glutamate receptor appears to be most relevant to mechanisms of anesthesia. There are two broad categories of excitatory synaptic receptors that use the amino acid L-glutamate as their chemical messenger: NMDA receptors and non-NMDA receptors.[36] The latter group, which mediates fast excitatory postsynaptic currents, can be subdivided into α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors and kainate receptors. Neither AMPA nor kainite receptors have a clear effect on anesthetic-induced unconsciousness,[37] but the role of AMPA receptors in "off-target" effects of anesthetics is being actively

explored (see "Emerging Developments"). NMDA receptors, by contrast, mediate excitatory postsynaptic currents of relatively prolonged duration. NMDA receptors are found presynaptically, postsynaptically, and extrasynaptically[38]; they are important targets for xenon, nitrous oxide, and the dissociative anesthetic ketamine.[39]

NMDA receptors are tetramers consisting of four subunits arranged circumferentially around a central ion channel pore (see Fig. 10.1).[36] All NMDA receptors contain an obligatory NR1 subunit and at least one of four types of NR2 subunits (A–D). Other subunits (NR3) and numerous splice variants exist that translate to considerable variability in the kinetic and pharmacologic profile of each receptor isoform.[40] In contrast to non-NMDA glutamate receptors, which are selective for sodium ions (Na^+), the pore of NMDA receptors permits entry of both monovalent and divalent cations (Na^+ and calcium ions [Ca^{2+}]) into the cell upon activation. The Ca^{2+} flux is important for activating Ca^{2+}-dependent processes in the postsynaptic cell such as long-term potentiation, a form of synaptic plasticity thought to play an important role in memory.[41]

NMDA receptors are unique among ligand-gated ion channels in that their probability of opening depends not only on presynaptic release of neurotransmitter but also on the voltage across the membrane containing the receptor. Until membrane depolarization occurs, magnesium ions (Mg^{2+}) block the channel pore if agonist is present. High-frequency excitatory input causes membrane depolarization, so NMDA receptors play a significant role in CNS functions that require activity-dependent changes in cellular physiology such as learning and processing of sensory information.[42] In the nociceptive circuitry of the spinal cord, repeated peripheral nerve stimulation results in an increase in response to subsequent stimuli through activation of NMDA receptors. This "windup" phenomenon is associated with hyperalgesia, and both knockout and knockdown of NR1 block inflammatory pain in animals.[43,44] This, combined with their ability to modify opioid tolerance, makes NMDA receptor antagonists promising treatments for chronic pain.[45]

NMDA antagonists are classified by their mechanism of action. Volatile anesthetics may exert some of their effects as competitive antagonists by displacing the coagonist glycine from NMDA receptors.[46] The intravenous NMDA antagonists in current clinical use are primarily channel blockers that bind to the pore only in its open confirmation. They are considered uncompetitive antagonists and, because their binding requires prior activation by agonist, they are termed *use-dependent*.[36] Blockers such as ketamine, which remain bound after channel closure, cause prolonged disruption of the associative aspects of neuronal communication. High concentrations of ketamine cause sedation and loss of consciousness with a significant incidence of dysphoric effects. This may reflect a lack of selectivity among various NMDA isoforms or activity at other receptors (see Table 10.1). Noncompetitive antagonists, which bind to allosteric sites with some NMDA receptor subunit specificity, may have more specific clinical effects and a better side effect profile.[36]

Other Molecular Targets

Other receptors, such as glycine receptors, voltage-gated Na^+ channels, and two-pore domain potassium (2PK) channels, deserve attention as they probably contribute to certain components of the balanced anesthetic state with intravenous anesthetics. Glycine receptors colocalize with $GABA_A$ receptors near the cell body. Propofol, etomidate, and thiopental all have some positive modulation of the glycine receptors, but ketamine does not. Glycine receptors have an inhibitory role, particularly in the lower brainstem and spinal cord. They are likely major contributors to anesthetic immobility, especially that produced by the volatiles. An investigation of spinal neurons estimated that propofol's effects on immobility were mediated almost entirely via GABA receptors, whereas the immobility caused by sevoflurane was predominantly mediated by glycine receptors.[47] Propofol inhibits some subtypes of voltage-gated Na^+ channels, which could contribute to its antiepileptic activity.[48] In high doses, ketamine can also block Na^+ channel activity.[49]

2PK Channels modulate neuronal excitability through control of the transmembrane potential. There are 15 different 2PK isoforms, and functional channels are formed from homomeric or heteromeric dimers. Genetic deletion of several members of this channel family (TREK1, TREK2, TASK1, TASK3, and TRESK) in animal models reduces the immobilizing effect of intravenous and volatile general anesthetics, which suggests a contribution to their anesthetic mechanisms.[50]

Hyperpolarization-activated cation channels (HCN channels) are important in mediating coordinated neuronal firing between the thalamus and cortex. These channels play an important role in setting the frequency of thalamocortical rhythms critical for high-order cognitive processing and are also important for controlling burst firing in the hippocampus, thalamus, and locus coeruleus.[51] Amnesia and hypnosis are produced upon disruption of signaling in these brain areas via inhaled and intravenous anesthetics.[52,53] Some anesthetics like dexmedetomidine exert their sedating effects by activating α_2 receptors in the locus coeruleus.[54]

Novel techniques may identify a host of other targets for anesthetic drugs. For example, azipropofol is an analog that becomes covalently linked to a binding partner when exposed to light. Tadpoles given this drug had prolonged anesthesia when exposed to light and proteomic analysis of the linked molecules identified novel potential targets of propofol.[55]

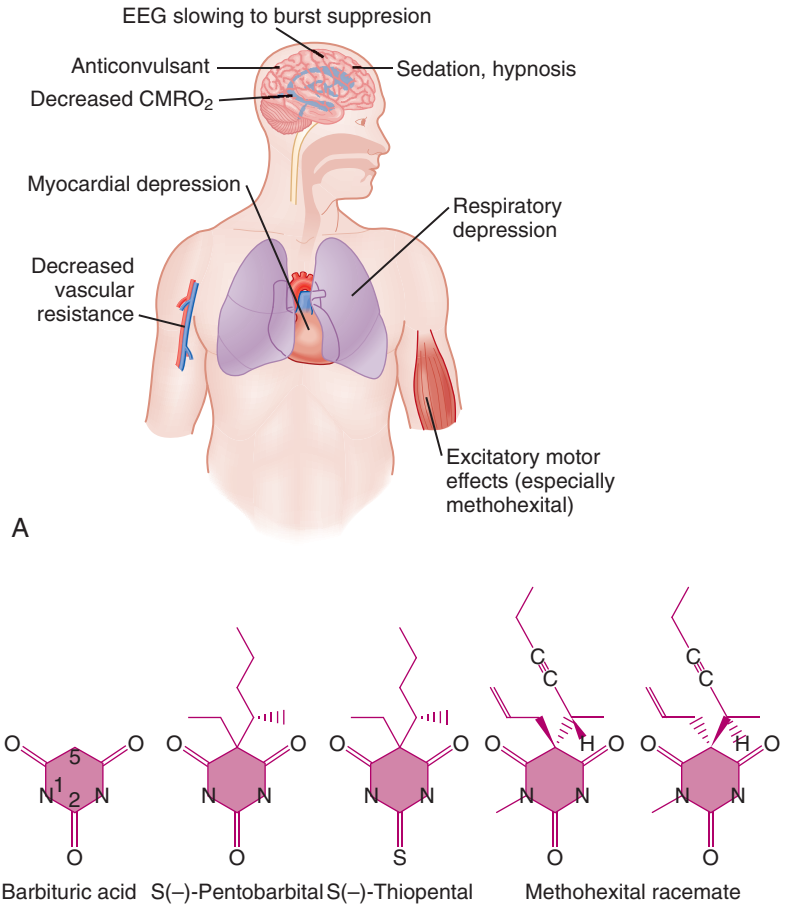
Individual Agents

Barbiturates

In 1864, some 20 years after Morton and Long independently discovered inhaled anesthesia, von Baeyer synthesized barbituric acid, which eventually led to the development of intravenous anesthesia. Barbituric acid is pharmacologically inert, but substitutions at the C5 position impart hypnotic activity. The clinical use of barbiturates as hypnotics began in 1904 with 5,5-diethyl-barbituric acid, but their adaptation to anesthesia was pioneered in the late 1920s by Bumm in Germany and Lundy in the United States.[4,56] Lundy's investigations included pentobarbital, also known as nembutal (sodium [N] 5-ethyl-5-[1-methylbutyl]) substituted barbituric acid). Thionembutal, the sulfur substitution of this compound better known as sodium thiopental, became the dominant intravenous induction agent of the next 60 years.

Thiopental was popularized by Lundy but might have been first used in a patient several months earlier in 1934 by Waters in Wisconsin. It was used in short procedures and early use was limited by the lack of reliable equipment to maintain intravenous access. Over time it evolved from a sole agent to a means of inducing anesthesia without breathing the pungent vapors of that era (e.g., ether).

Both pentobarbital and thiopental are supplied as racemic mixtures (see Chapter 2), with the S(−) isomer exhibiting roughly



• **Fig. 10.4** A, Selected effects of barbiturates. B, Structures of clinically important barbiturates. Pentobarbital and thiopental are supplied as racemic mixtures but only their more potent isomers are shown. Methohexital has two chiral centers and both of the isomers in the commercial formulation are shown. *$CMRO_2$,* Cerebral metabolic rate for oxygen; *EEG,* electroencephalography.

double the potency of the R(+) form. Methylation of the ring nitrogen of methohexital creates a second chiral center and a total of four stereoisomers. Early animal work at Eli Lilly revealed that the potent β isomers had more excitatory side effects so methohexital is marketed as a racemate of the α isomers.[57] The α-dextrorotatory form is roughly three times more potent than the α-levorotatory ($S_\alpha R_\beta$) isomer and recent stereochemical synthesis suggested that the latter is responsible for the residual excitatory effects of commercial methohexital (Fig. 10.4B).[58]

Methohexital found use in electroconvulsive therapy and pentobarbital was used as a pediatric premedication, but thiopental was the mainstay for the intravenous induction of anesthesia before the introduction of propofol. American production of thiopental ceased in 2010 and plans to import the drug from Europe stalled over the political controversy associated with thiopental's use for lethal injection in the U.S. penal system. Like etomidate, thiopental enhances $GABA_A$ receptor function in a stereoselective manner.[59] This is also true for other barbiturate sedatives/hypnotics such as hexobarbital and pentobarbital. Thiopental directly gates $GABA_A$ receptors at high concentrations (like propofol and etomidate). Thiopental discriminates between synaptic and extrasynaptic $GABA_A$ receptors in the hippocampus, suggesting a possible role for the δ subunit in barbiturate enhancement of this channel.[60] The β subunit has also been implicated as a molecular site of action of barbiturates at $GABA_A$ receptors.

In addition to $GABA_A$ receptors, barbiturates modulate a variety of ligand-gated ion channels in vitro. They block the action of the excitatory neurotransmitter glutamate at AMPA and kainate receptor subtypes, but not at NMDA receptors. They also inhibit neuronal nicotinic acetylcholine receptors. The relevance of these receptors to the clinical action of barbiturates remains unclear. Several clinical effects appear to be modulated by allosteric augmentation at $GABA_A$ receptors. Transgenic mice carrying a point mutation (N265M) of the $GABA_A$ β_3 subunit are resistant to the immobilizing effects of pentobarbital.[18] However, this mutation had no effect on the pentobarbital-induced respiratory depression and intermediate blunting of hypnotic and cardiovascular effects. Future studies are needed to determine whether these effects are mediated by some other $GABA_A$ receptor subtype, ionotropic glutamate receptors, or other receptors.

Barbiturates produce dose-dependent CNS depression with characteristic effects on electroencephalography (EEG), progressing from a low-frequency, high-amplitude pattern to isoelectric periods of increasing duration. The cerebral metabolic rate for oxygen ($CMRO_2$) is decreased to a widely quoted maximal extent of 55%, and both cerebral blood flow and intracranial pressure (ICP) are decreased as a result of flow-metabolism coupling. These factors led to widespread use of barbiturates for neuroprotection, although large trials and metaanalyses have failed to show substantial clinical benefit in humans. Thiopental and pentobarbital have anticonvulsant

effects in the setting of prolonged high-dose administration, whereas prolonged use of methohexital leads to epileptiform discharges.

Barbiturates cause venodilation with consequent decreases in preload and cardiac output. This effect is particularly pronounced in hypovolemic patients.[60] There is in vitro evidence for direct myocardial depression at doses much higher than those used for anesthesia. Selected effects of barbiturates are summarized in Fig. 10.4.

Barbiturate sodium salts require a pH greater than 10 to remain in aqueous solution and precipitate readily when mixed with nonbasic solutions such as normal saline solution. They also precipitate when combined in high concentrations with certain weak bases such as the neuromuscular blockers, forming a "conjugate salt" (e.g., sodium thiopental and rocuronium bromide precipitate to form sodium bromide). In the plasma, barbiturates are readily protonated and become quite lipophilic, which leads to unconsciousness 30 to 60 seconds after bolus injection. Kinetic modeling of bolus administration reveals a rapid peak in effect site (CNS) concentration (Fig. 10.5A). The subsequent decline in concentration results primarily from redistribution to other tissues rather than metabolism and elimination (see Chapter 2). Repeated bolus dosing or continuous infusions lead to very prolonged recovery times as depicted by plots of the context-sensitive half-time (see Fig. 10.5C).[61] When given in very high doses, thiopental can even exhibit "zero-order kinetics," wherein metabolic capacity is saturated, grossly prolonging the duration of action.

Thiopental is highly protein bound (75%–90%) in the plasma, primarily to albumin. Decreased albumin levels such as those seen in chronic renal or hepatic disease can markedly increase free drug levels and may warrant decreased dosing.[62] Thiopental undergoes some desulfurization to form its parent drug pentobarbital. This "metabolite" is likely relevant only to prolonged high-dose administration of thiopental. Both drugs are deactivated by poorly characterized pathways in the liver to form inactive carboxylic acid and alcohol derivatives. Thiopental causes some cytochrome P450 induction but this is generally of no clinical consequence when used as an induction agent. An active porphyric crisis could be exacerbated by this mechanism, but triggering an event in a patient with latent porphyria is reported to be unusual.[63] Even so, it is prudent to avoid even potential triggers in patients with porphyria.

Benzodiazepines

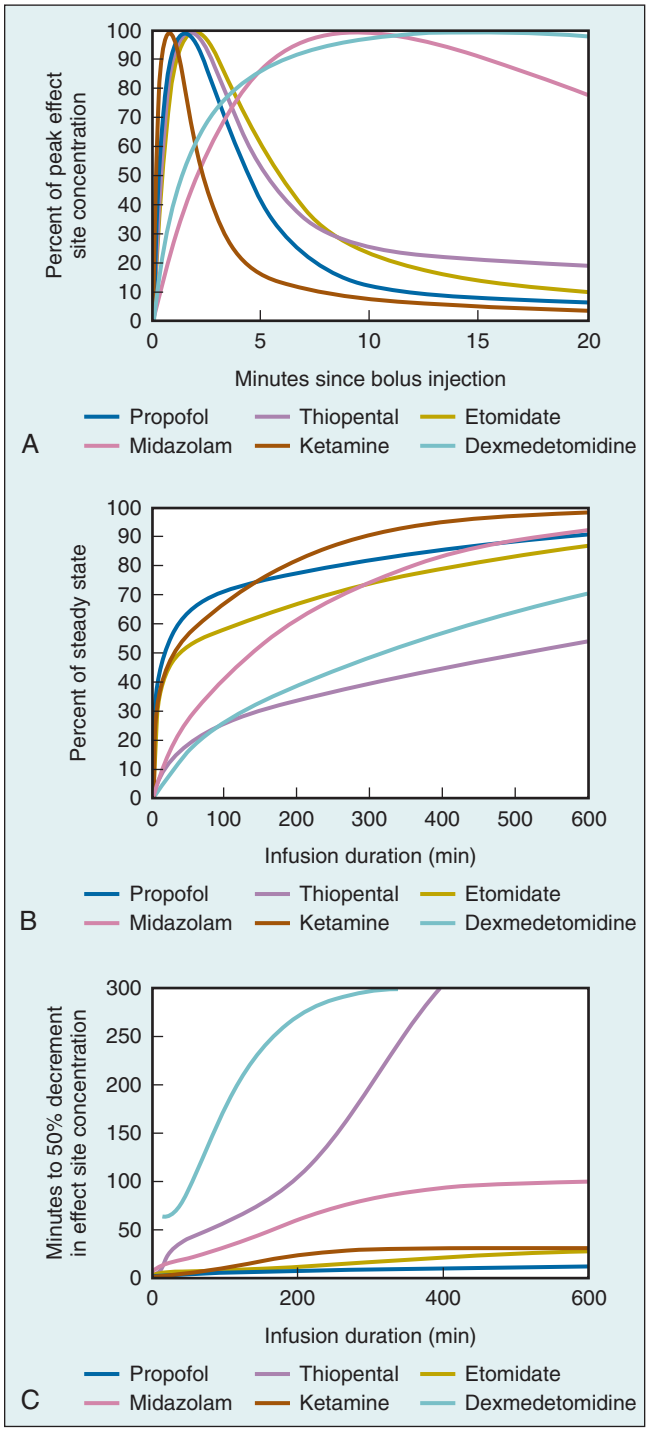
Benzodiazepines were introduced into clinical use in the 1960s and rapidly gained popularity as anxiolytics with a wider safety margin than barbiturates.[64] Diazepam, lorazepam, and midazolam are three of the most important class members in the practice of anesthesia. Diazepam and lorazepam are lipophilic and are traditionally formulated in propylene glycol because they are not soluble in water. These formulations are associated with pain on injection and long-term infusions in the intensive care unit (ICU) can lead to glycol toxicity. The imidazole ring of midazolam allows the preparation of acidic aqueous solutions, which cause minimal pain on injection.[65] Once at physiologic pH, midazolam assumes a more lipophilic ring conformation and can gain rapid access to the CNS (Fig. 10.6B).

Benzodiazepines act on a subset of $GABA_A$ receptors containing γ subunits to potentiate chloride conductance upon GABA binding. This modulatory mode of action is postulated to create a "ceiling effect" that limits CNS depression, although when combined with other drugs, benzodiazepines can lead to dangerous respiratory depression.[66] Even when respiratory drive is preserved, midazolam increases the likelihood of airway obstruction, and caution is advised in patients with obstructive sleep apnea or advanced age.[67,68] The binding pocket appears to be at the interface of the α and $\gamma 2$ subunits in receptors containing α_1, α_2, α_3, or α_5 subunits. Recent elegant studies of mutant $GABA_A$ subunits in transgenic mice have raised the possibility of dissecting the effects of the benzodiazepines at a molecular level (see earlier "$GABA_A$ Insights from Mutagenic Studies").

Benzodiazepines have anxiolytic, sedative, hypnotic, amnestic, and anticonvulsant properties in the CNS. In animals, they may either promote or block hyperalgesia depending on the model studied.[69,70] The α subunit of the $GABA_A$ receptor appears to differentially mediate the CNS effects of benzodiazepines. For example, α_2-containing receptors play an important role in anxiolysis, anti-hyperalgesia, and centrally mediated muscle relaxation, whereas α_1-containing subunits are important mediators of the sedative, amnestic, and anticonvulsive effects of benzodiazepines.[71] Although benzodiazepines can be used for the induction of anesthesia, the high doses required delay emergence unless the surgery is of prolonged duration. Combining midazolam with another induction agent can offer improved hemodynamic stability without affecting emergence. Other selected effects of benzodiazepines are depicted in Fig. 10.6.

Oral midazolam in children has an onset of action within 10 minutes and peaks in 20 to 30 minutes; its effects begin to dissipate 45 minutes after administration. This kinetic profile requires some planning to get the child to the operating room within the window of efficacy. As shown in Fig. 10.5A, intravenous midazolam does not reach peak effect site concentration until nearly 10 minutes after administration. When titrating midazolam, one must therefore be patient to avoid "stacking" the doses and oversedating the patient. The onset of intravenous diazepam is more than twice as rapid as that of midazolam, but its use is limited by an extremely long duration of action. Not only is the elimination half-life 10 times longer than that of midazolam, but about half of the parent drug is metabolized to the active compound desmethyldiazepam, which has an even longer elimination half-life. Both midazolam and diazepam are metabolized by cytochrome P450 enzyme 3A (CYP3A) family members in the liver and are subject to interactions with erythromycin and antifungal medications. Diazepam is also metabolized by CYP 1A2 and CYP 2C19.

Premedication is currently the main role of benzodiazepines in anesthesia; a majority of U.S. practitioners surveyed in the 1990s used intravenous midazolam for adults (>70%) and oral midazolam for children (80%).[72] For patients requiring long-term mechanical ventilation, combinations of an opioid and benzodiazepine have been the traditional method of sedation but the latest Society of Critical Care Medicine (SCCM) guidelines encourage use of nonbenzodiazepine alternatives.[73] Although midazolam is often considered a short-acting benzodiazepine, prolonged infusions in critically ill patients lead to markedly delayed awakening in part owing to accumulation of its active metabolite 1-hydroxymidazolam (see Fig. 10.5B and C). For this reason, the SCCM sedation guidelines recommend limiting midazolam use to 2 to 3 days.[74] For longer periods of sedation, the benzodiazepine of choice is lorazepam, but some formulations of lorazepam are formulated in a glycol-based vehicle and prolonged infusions lead to glycol toxicity. An emerging body of literature links benzodiazepine use to delirium in critically ill patients.[75,76] Because delirium increases time on mechanical ventilation, length of stay, and morbidity and mortality, there has been some movement toward other sedatives in the ICU.



• **Fig. 10.5** A, Bolus front- and back-end kinetics comparing the time courses of effect site concentrations after bolus injection based on the pharmacokinetics and rate of plasma effect site equilibrium. The curves have been normalized to the peak effect site concentration, permitting comparison of the relative rate of rise (and fall) independent of dose. B, Infusion front-end kinetics expressed as a percentage of eventual steady-state effect site concentration. After 10 hours, no intravenous anesthetic has reached steady-state concentration. C, Infusion back-end kinetics (i.e., the context-sensitive half-times) of intravenous anesthetics based on the pharmacokinetics and rate of plasma effect site equilibrium. (Simulations courtesy of Dr. Shinju Obara, Fukushima University, Japan, performed with PKPDtools [www.pkpdtools.com].) Note that dexmedetomidine is not approved for bolus dosing, but the curve was derived from the data of Dyck et al.,[168] using PKPDtools with an assumed time to peak effect of 15 minutes. Benzodiazepines also have some immunomodulatory effects on monocytes and T cells in vitro.[77,78] There are several studies linking outpatient benzodiazepine use to increased infection, but it is unknown whether brief perioperative use carries any risk.[79]

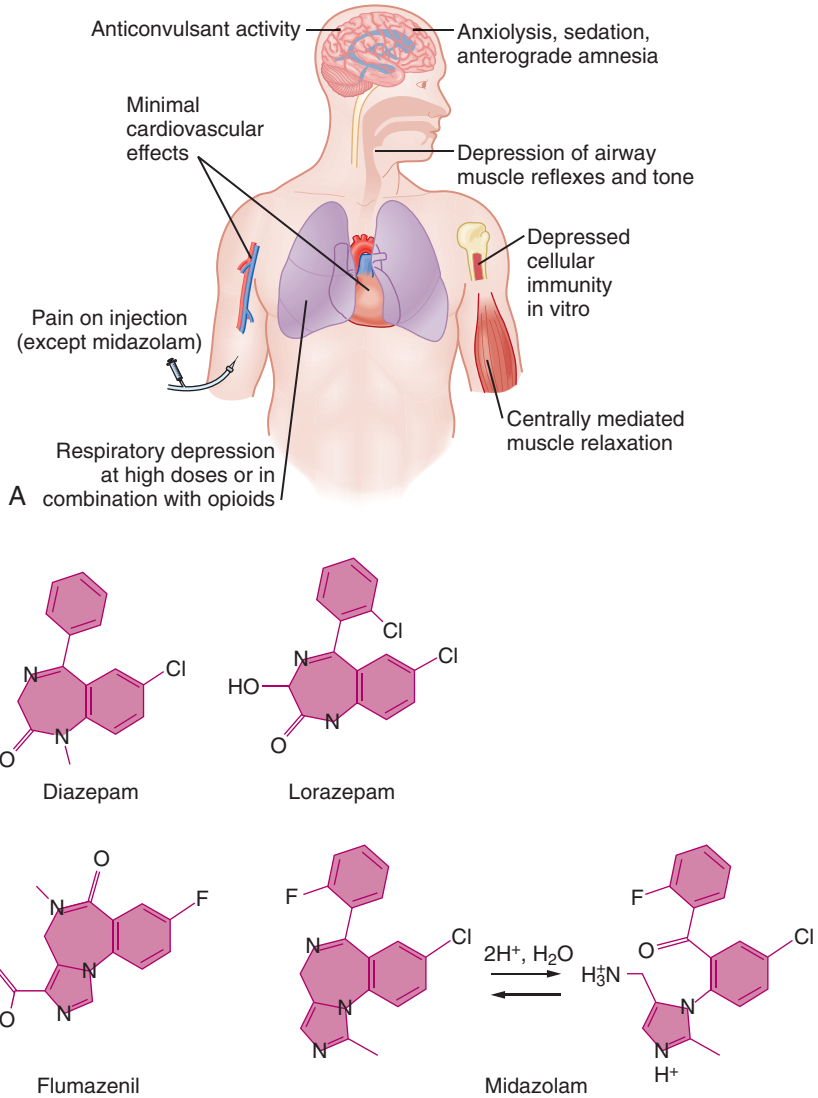
An important and unique feature of the benzodiazepines compared to the other GABA-ergic sedative hypnotics is that a competitive antagonist for the reversal of benzodiazepine effects is available. As an intravenous rescue agent, flumazenil can rapidly reverse the CNS depression associated with benzodiazepine intoxication. Routine administration of flumazenil to patients presenting to the emergency department with the suspicion of overdose can lead to seizures via precipitating acute withdrawal in chronic benzodiazepine users.[80] But there is some evidence that flumazenil has anticonvulsant properties suggesting that this drug may have mixed or partial agonist effects on the $GABA_A$ receptor, even in the absence of benzodiazepine administration.[81] In support of this phenomenon is the potential for high doses of flumazenil to potentiate the hypnosis of other positive GABA modulators such as propofol.[82] Its use to augment recovery from general anesthesia is being explored with mixed results (see "Emerging Developments"). Although flumazenil can be lifesaving in cases of benzodiazepine overdose, its short-acting kinetic profile creates the possibility of resedation after the effects of flumazenil dissipate.

Etomidate

Etomidate is a rapidly acting intravenous agent that was introduced into clinical practice in the 1970s. Compared with other induction agents, it has minimal effects on the cardiovascular system.[83] Because of its association with nausea and prolonged suppression of adrenocortical synthesis of steroids, its main clinical use is for inductions in which hemodynamic stability is essential.[84] The R(+) isomer has much greater hypnotic effects (Fig. 10.7), and it is formulated as a single enantiomer. Like propofol, etomidate interacts with $GABA_A$ receptors in a stereoselective manner.[85] Its enhancement of GABA-mediated current is smaller on receptors containing the β_1 subunit.[86] Of all the clinically used intravenous anesthetics, etomidate exhibits the greatest selectivity for $GABA_A$ receptors and has the fewest relevant interactions with other ion channels (see Table 10.1).



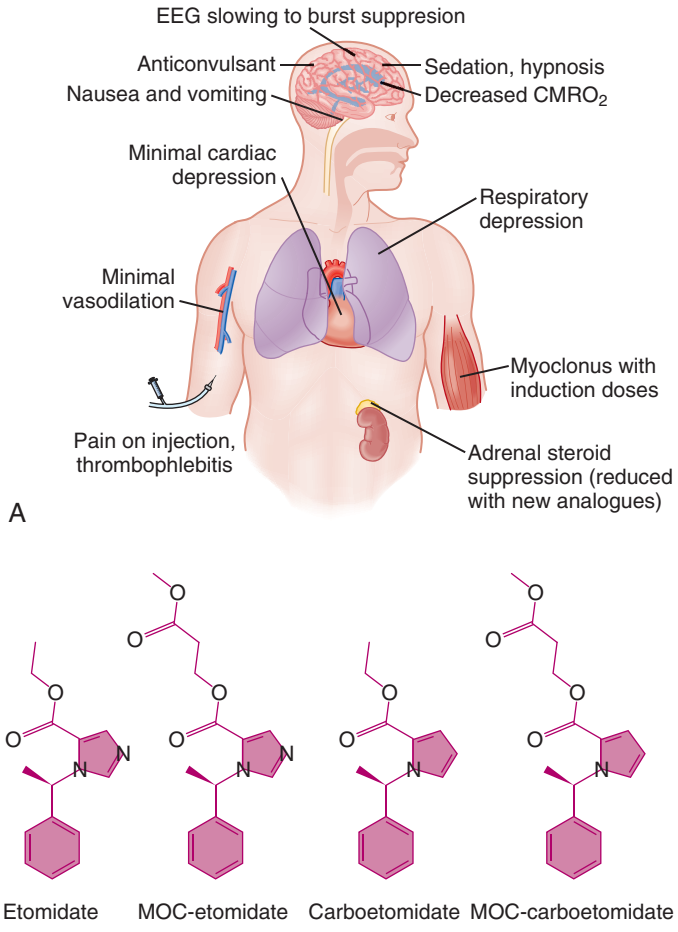
• **Fig. 10.6** A, Selected effects of benzodiazepines. B, Structures of clinically important benzodiazepines, including both the hydrophilic prodrug *(right)* and lipophilic *(left)* conformations of midazolam. Flumazenil is generally considered a benzodiazepine antagonist but has demonstrated some partial agonist effects (see text). *H^+,* Hydrogen ion.

Following intravenous injection, etomidate is tightly bound to plasma proteins such as albumin. The uncharged drug is highly lipophilic so etomidate rapidly penetrates the blood-brain barrier; peak brain levels are achieved within 2 minutes of injection (see Fig. 10.5A). Etomidate is metabolized in the liver by ester hydrolysis to a pharmacologically inactive metabolite.

The effects of etomidate on the CNS are similar to those of propofol and the barbiturates. Induction doses are associated with a high incidence of myoclonus, possibly via a loss of cortical inhibition during the transition from consciousness to unconsciousness. Although this myoclonic activity could be mistaken for generalized tonic-clonic seizures, etomidate has anticonvulsant activity in several experimental models. Epileptic attacks occur less frequently during etomidate anesthesia, but it is likely that propofol and thiopental possess greater anticonvulsant effects; etomidate is therefore a viable option for electroconvulsive therapy.

Etomidate causes less depression of ventilation compared with the barbiturates (see Fig. 10.7).[87,88] Despite its favorable hemodynamic profile, it should be noted that patients with high sympathetic tone such as those with shock, intoxication, or drug withdrawal can have a precipitous drop in blood pressure even when etomidate is used to induce anesthesia.

In 1983, investigators reported increased mortality in ICU patients sedated for days with etomidate.[89] The increased mortality was attributed to suppression of cortisol synthesis since etomidate is a potent inhibitor of the synthetic enzyme 11β-hydroxylase in the adrenal cortex. The original retrospective study has been criticized for failing to control for the severity of illness and for the potential role played by concurrent administration of adjuncts to ICU sedation (e.g., opioids) in those patients. Randomized controlled trials in elective cardiac surgery and critically ill patients verified the adrenal suppression but did not show differences in clinical outcome.[84,90] A large retrospective study of cardiac surgery patients using propensity matching also found no link between etomidate use and increased length of stay or arrhythmia.[91] However, the same group found etomidate carried an odds ratio for death of



• **Fig. 10.7** A, Selected effects of etomidate. B, Structures of etomidate and its analogs. *$CMRO_2$,* Cerebral metabolic rate for oxygen; *EEG,* electroencephalography; *MOC,* methoxycarbonyletomidate.

2.5 in a retrospective, propensity-matched analysis of more than 7000 American Society of Anaesthesiologists (ASA) class III and class IV patients undergoing noncardiac surgery.[92] Another study of nearly 6000 patients (approximately 40% ASA class III and class IV) before and after increased etomidate use in the setting of the 2010 propofol shortage found no such association.[93] Although the most recent metaanalysis reported no statistically significant association between etomidate use and mortality in critically ill patients,[94] new etomidate analogs are currently under development to avoid endocrine disturbance (see "Emerging Developments").

Propofol

Propofol (Fig. 10.8) is the most widely used intravenous agent. While it is most often used for inducing anesthesia, it also is used for procedural/ICU sedation and for total intravenous anesthesia (TIVA). Since its introduction in the late 1980s TIVA use has dramatically increased. Propofol is listed as an essential medicine by the World Health Organization.

Pharmacology

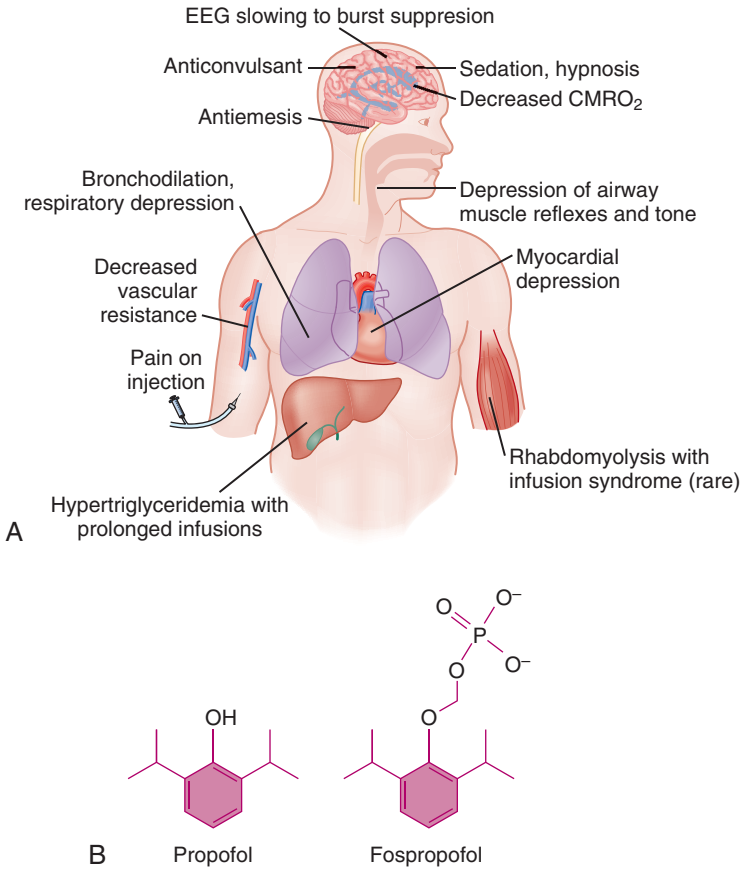
Propofol (2,6, diisopropylphenol) potentiates GABA-mediated responses in neurons and directly activates $GABA_A$ receptor function.[95] Other receptors respond to propofol in the therapeutic concentration range, but the majority of its clinical effects are likely mediated through GABA receptors. The specific interaction between propofol and $GABA_A$ receptors is not fully characterized, but likely involves residues in the transmembrane domains on β subunits.[16] Site-directed mutagenesis studies with recombinant $GABA_A$ receptors have contributed to precise knowledge regarding the molecular interactions between this drug and $GABA_A$ receptors. Initially, only the property of direct activation of the $GABA_A$ receptor by propofol was thought to depend on the β subunit, whereas the modulatory effects were considered to involve other subunits.[96] There is now evidence that α, β, and γ subunits all contribute to $GABA_A$ sensitivity to propofol.[97,98]

Formulation and Preparation

The necessity to formulate propofol in a lipid emulsion (because of its extremely poor water solubility) has some very important clinical implications. The original preparation of propofol used a polyethoxylated castor oil (Cremophor EL) in its formulation, but this mixture was abandoned because of concern for allergic reactions to the excipient.[99] The most commonly available propofol formulations today involve a mixture of soybean oil, glycerol, and purified egg phospholipid to solubilize the drug.[100] Despite initial concerns that the egg-derived lecithin might precipitate anaphylaxis in egg-allergic individuals, it appears that propofol can be safely used in egg-allergic patients.[101] Most egg allergies are related to egg albumin (in egg whites) as opposed to lecithin (primarily in the egg yolk), and a small study revealed no hypersensitivity to propofol in egg-allergic patients undergoing skin prick testing.[102]

Perhaps most important among concerns over the lipid formulation of propofol involves the promotion of rapid microbial growth. This issue received much attention after a high-impact epidemiologic investigation described unusual outbreaks of postoperative infections at seven hospitals.[103] In 2007 the U.S. Food and Drug Administration (FDA) mandated that all propofol emulsions in the United States contain an antimicrobial agent (ethylenediaminetetraacetic acid or sodium metabisulfite).[104,105] The FDA also recommended that, to minimize the potential for bacterial contamination, both the vial and prefilled syringe formulations must be used on only one patient, administration must commence immediately after the vial or syringe has been opened, and administration from a single vial or syringe must be completed within 12 hours of opening.[106] Failing to follow these practices and usual aseptic technique for intravenous administration of medication can lead to transmission of viral particles between patients and bacterial sepsis.[107–110]

Although pain on injection was a contributing factor to changing the initial formulation of propofol, the change to the current isotonic, emulsified, soybean-based formulation has not eliminated pain on injection of propofol. Pain on intravenous injection of any medication has multiple etiologies and can be influenced by the temperature of the drug, the site of administration, the size of the vein, the speed of injection, and the rate of infusion of the carrier fluid. Some common hyperosmolar formulations of diazepam and etomidate also cause pain on injection, and this pain is often reduced with formulations that are closer to blood in osmolarity.[111,112] However, the modern formulation of propofol is not hyperosmolar and has a pH in the physiologic range. It is thought that the pain on injection of propofol is related to its free aqueous concentration, because the pain on injection appears to be less when the propofol concentration is reduced in its current formulation.[111] From a mechanistic perspective, investigations of propofol-induced injection pain has focused on the transient receptor potential



• **Fig. 10.8** A, Selected effects of propofol. B, Structures of propofol and the water-soluble prodrug fospropofol. *$CMRO_2$,* Cerebral metabolic rate for oxygen; *EEG,* electroencephalography.

(TRP) family of ion channels. Multiple investigators have shown a role for TRPA1 as a mediator of propofol-induced pain and TRPV1 has been implicated in some studies but not in others.[113–115] Many strategies to reduce pain have been studied, but a metaanalysis concluded that use of an antecubital vein versus a hand vein and coadministration of lidocaine (either as a pretreatment or mixed with propofol) were most effective.[116] Administration of opioids prior to propofol injection is another important way to mitigate injection pain.

Metabolism, Redistribution, Clearance, and Elimination

The rapid effects of propofol on the brain make it a frequent choice for sedation in monitored anesthesia care settings and for induction and maintenance of general anesthesia. Its rapid metabolic clearance is useful in pediatric procedures like magnetic resonance imaging, in the critical care arena for sedation during mechanical ventilation, and in neuroanesthesia to temporarily reduce cerebral metabolic rate (i.e., burst suppression or isoelectric EEG).

Propofol is metabolized via conjugation into inactive metabolites; however its clearance (total body clearance estimated at 25 mL/kg per minute) exceeds that of hepatic blood flow and continues to some extent even during the anhepatic phase of liver transplantation; this argues for some extrahepatic metabolism of the drug.[117] Like most of the intravenous anesthetics, the offset of the hypnotic effect after bolus administration occurs mainly through redistribution of propofol from the brain to less well-perfused sites. Target plasma concentrations for inducing unconsciousness are 2 to 2.5 μg/mL and for maintenance of anesthesia are 2 to 6 μg/mL. The elimination half-life of propofol is prolonged because of the slow mobilization from adipose tissue. Regardless, obesity should not be considered a contraindication to its use for induction or maintenance.

Obesity does not drastically prolong recovery, and dose adjustments based on lean body weight have been suggested.[118] However, there is some controversy about this as some groups have demonstrated total body weight (TBW) as the best predictor of propofol pharmacokinetics.[119] One of the newest pharmacokinetic models for propofol by Eleveld et al. used TBW and was superior to previous models in obese patients.[120] Another group validated the Eleveld model in an independent group of obese patients and found that the older Schnider and Marsh models performed better when TBW was replaced with adjusted body weight (defined as ideal body weight + 0.4 × [TBW − ideal body weight]).[121]

Moderate hepatic or renal impairment has little effect on the duration of clinical effect. The dose requirement for propofol is reduced in the elderly because of reduced metabolic clearance of drugs and reduced relative volume of the central compartment. Dosing is increased in pediatric populations because relative central compartment volume is larger and clearance and metabolism are increased. Sex differences for the pharmacokinetics[122] and pharmacodynamics[123,124] of propofol have been reported, and men sometimes emerge more slowly from propofol total intravenous anesthesia. The mechanisms underlying this observation may involve sex-linked polymorphisms in liver microsomal enzymes.[122,125,126]

Advantages and Disadvantages of Propofol as an Induction Agent

Propofol has a number of advantages over other intravenous agents for induction. It depresses airway reflexes, reduces nausea, and does not induce adrenocortical suppression.[127] Simulations of bolus kinetics indicate that it is second only to ketamine in speed of onset and offset (see Fig. 10.5A).

The primary disadvantage of propofol is its depressive effect on the cardiovascular system. Patients who are hypovolemic, debilitated, or reliant on high sympathetic tone to maintain blood pressure require careful titration of propofol to avoid severe hypotension. Animal models of severe hemorrhagic shock suggest that the induction dose should be reduced by a stunning 80% to 90% of usual doses if given before fluid resuscitation and decreased 50% if given after resuscitation.[128,129] Use of propofol in patients with cardiac tamponade or critical aortic stenosis can result in hemodynamic collapse.

Mixtures of low-dose ketamine infusions (10–20 μg/kg per minute) with propofol infusions (100–200 μg/kg per minute) have been used to mitigate the cardiovascular effects of both drugs, especially in pediatric anesthesia.[130] A recent metaanalysis of this mixture in the emergency department suggested a reduced rate of respiratory side effects compared with propofol alone.[131] A reduction in induction dose (1–1.5 mg/kg) is recommended for patients older than 65 years of age; however, there is evidence that older patients often receive greater than this recommended dose.[132,133]

Clinical Features of Anesthesia Maintenance With Propofol

Early clinical trials in the late 1980s and early 1990s consistently reported faster time to eye-opening and other recovery criteria for propofol-based TIVA anesthetics compared with "traditional" regimens of thiopental and volatile agents such as enflurane or isoflurane. Until the development of propofol, TIVA for surgeries with planned extubation was rarely performed owing to prolonged emergences. Propofol maintains a short context-sensitive half-time even after prolonged infusion (see Fig. 10.5C). More recent studies comparing propofol-based techniques to newer inhaled agents with lower blood and tissue solubility (desflurane and sevoflurane) have either failed to show benefit or have shown only minimal benefits in speed of recovery, but there are environmental benefits to avoiding the greenhouse gas effects of volatiles.[134,135] The carbon footprint of TIVA is orders of magnitude lower than that of inhaled anesthetic techniques.[135] The updated consensus guidelines for nausea and vomiting recommend propofol-based TIVA as part of a multimodal approach for patients at high risk for nausea and vomiting.[136] In addition to its benefits for patients at high risk for malignant hyperthermia or postoperative nausea and vomiting, propofol appears to confer improved operating conditions for endoscopic sinus surgery and decreased postoperative pain.[137] For example, in gynecologic procedures postoperative pain and opioid administration were reduced in those receiving propofol TIVA.[138] Similar trends were observed in two recent metaanalyses of surgeries of varying types, but more research is needed to determine if this is a clinically meaningful effect.[139,140]

Anesthetic depth is an important consideration when comparing propofol-based TIVA techniques with volatile anesthesia. The concentration of expired anesthetic gases measured by modern anesthesia monitors correlates with the concentration of inhaled agent in the CNS.[141] Because propofol blood concentrations are not easily measured in the operating room, many practitioners choosing TIVA with propofol as their maintenance anesthetic attempt to control for individual variability in drug clearance through the use of an EEG-based depth of anesthesia monitor because it has been shown to decrease anesthetic use and facilitate postoperative recovery.[142] Favorable pharmacokinetic properties and effects on cerebral blood flow (CBF) and cerebral metabolic requirement for oxygen have made propofol popular for neuroanesthesia. In animal studies, reduction of CBF occurs even when mean arterial blood pressure is held constant, and propofol can reduce ICP even when cerebral perfusion pressure is fixed.[143] Cerebral autoregulation also appears to be preserved in the setting of propofol anesthesia.[144] In comparison, the volatile agents tend to increase ICP and at high doses compromise cerebral autoregulation. Although propofol and thiopental have similar effects on brain physiology, propofol might suppress apoptosis in models of ischemia in vitro (see Chapter 9).[145–147]

The latest Society of Critical Care Medicine sedation guidelines recommended the use of propofol when rapid or frequent interruptions of sedation are required, such as serial neurologic evaluations.[73] Awakening times were similar after 24-, 48-, 72-, and 96-hour constant rate infusions of propofol. Prolonged, high-dose infusions can lead to hypertriglyceridemia or a constellation of metabolic acidosis, rhabdomyolysis, renal failure, and hemodynamic instability, known as propofol infusion syndrome. These complications are not common, but patients should be monitored closely for propofol infusions greater than 48 hours. Although moderate-dose infusions (>40 μg/kg per minute) can increase triglyceride levels in critically ill patients after just 3 days, low-dose propofol infusions (<33 μg/kg per minute) showed no detectable increase in triglycerides after 2 weeks of constant infusion.[125]

It is difficult to imagine the practice of anesthesia without propofol. It is also essential outside the operating room in settings such as the ICU, pediatric imaging procedures, and endoscopy suites. Propofol has numerous advantages (see Fig. 10.8), but its depression of respiration makes it potentially dangerous in unskilled hands. Propofol appears to have greater relaxation effects on the pharyngeal musculature than thiopental and should be administered only by persons trained in the rescue of patients who experience deeper-than-intended sedation, including general anesthesia (and who are not involved in the conduct of the procedure).[106,127]

Currently, no widely accepted method is available to anesthesia providers in the United States that allows estimates of blood concentrations of intravenous drugs being infused for maintenance of anesthesia during TIVA. This presents a disadvantage of intravenous anesthetics compared with inhaled anesthetics, which are typically used in conjunction with monitors equipped with gas sampling for measurements of expired concentrations. Using computer-based models of drug pharmacokinetics, mathematical modeling of a drug's disposition can provide a convenient way to estimate these blood concentrations of intravenous agents.[148] Target-controlled infusion devices (e.g., Diprifusor) have been used successfully in maintaining anesthesia for both inpatient and outpatient surgery.[149] Despite obvious advantages of these devices in predicting blood concentrations, some controversy exists in regard to which pharmacokinetic model should be used.[150,151] Another impediment to widespread use of these devices has been the unfamiliarity of providers in targeting an actual blood concentration range, as it is more common to think in terms of infusion rates rather than blood concentrations for infusions of other medications in the hospital.[152] There have been some attempts to improve the adoption of these devices by targeting the calculated index from processed EEG devices used to estimate anesthetic

"depth" rather than targeting a desired blood concentration (see "Emerging Developments").[153]

Fospropofol

Circulating phosphatases metabolize the water-soluble prodrug, fospropofol, into propofol, formaldehyde, and a phosphate group (Fig. 10.12A).[154] It was envisioned during the drug development process that the slower onset of drug effect associated with the metabolism of the propofol prodrug would allow safe bolus administration in the setting of procedural sedation. However, the FDA product labeling ultimately recommended that fospropofol should be administered only by persons trained in general anesthesia as unanticipated transitions to general anesthesia remain a possibility. The formaldehyde levels measured after routine fospropofol administration are indistinguishable from baseline levels.[155] After administration of the drug, formaldehyde is rapidly metabolized to formate. Although high formate levels can lead to metabolic acidosis, there has been no reported formate toxicity from fospropofol. Other supposed advantages from this alternative formulation of propofol are decreased risk of bacteremia and decreased risk of hyperlipidemia. Fospropofol does not bind TRPA1[115] and has less pain on injection, although pruritus and perineal paresthesias are reported side effects of its administration.[156]

Ketamine

Ketamine, an arylcyclohexylamine related to phencyclidine, was developed in the 1960s and approved for use in the United States in 1970. Early test subjects described a sense of disconnection from their environment, leading to the term "dissociative anesthesia."[157] Its combination of hypnosis and analgesia showed great promise as a complete anesthetic with minimal effects on cardiovascular function, respiratory drive, and airway reflexes. Concern over psychologic side effects such as hallucinations and emergence delirium limited its clinical use as a primary anesthetic agent, but there is an increasing body of evidence supporting the use of subanesthetic doses for treatment of acute and chronic pain (see following text).

Ketamine was originally produced as a racemic mixture, and most commercial preparations continue to be a racemic mix of the R and S enantiomers (see Chapter 2). S(+) ketamine, a single-enantiomer formulation available in some areas of Europe and South America, is more potent in most clinical and experimental settings (Fig. 10.9).

Despite more than 40 years of clinical use, the key site or sites of ketamine action have not been fully elucidated. The diverse effects of ketamine are likely mediated by a variety of receptors and signaling pathways. Landmark studies in the 1980s identified ketamine as an NMDA receptor antagonist in the spinal cord and brain.[158,159] Ketamine binds uncompetitively within the ion channel pore in a use-dependent fashion, but there is some evidence for allosteric binding as well.[36,160] Experimental data support a role for NMDA receptors in mediating analgesia, but their role in ketamine anesthesia is unclear.[43,44] Ketamine also inhibits nicotinic acetylcholine receptors at clinically relevant concentrations, which could contribute to analgesia but does not appear to influence its sedative properties.[161] Ketamine has some local anesthetic properties on Na^+ channels and binds μ- and κ-opioid receptors.[162] Although blunted responses to ketamine have been noted in μ-opioid receptor knockout mice, the limited effect of naloxone on ketamine actions in humans suggests a limited role for these receptors. Finally, knockout of the HCN1 receptor in mice abolishes the hypnotic effect of ketamine and propofol but not of etomidate.[53] Further research is needed to confirm the significance of this pathway in humans.

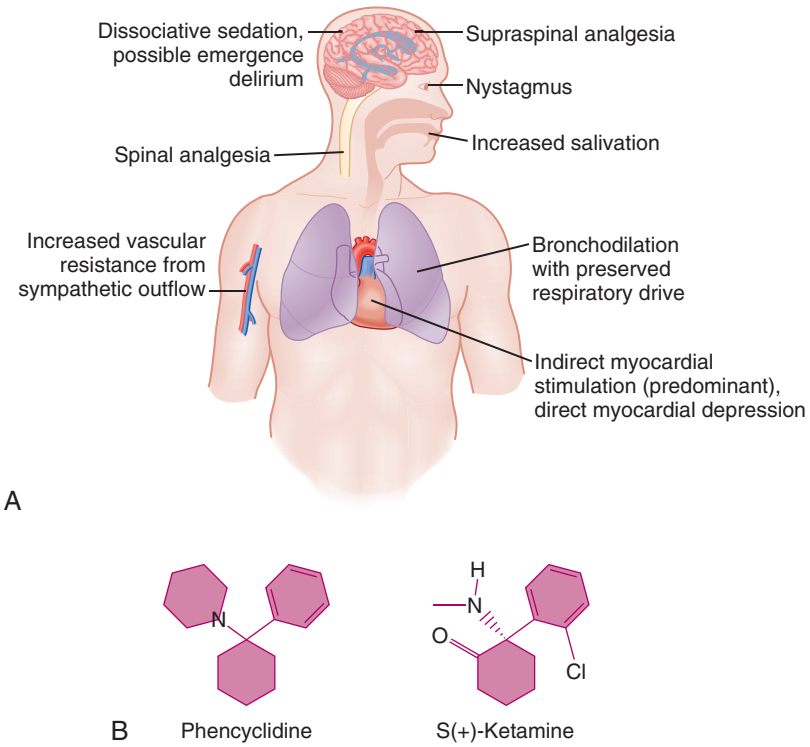
In the brain, ketamine has a unique profile combining depressed consciousness with increased sympathetic tone. This sympathetic activation leads to increases in cardiac output in patients with normal catecholamine stores, which can make ketamine a useful induction agent in patients with hypovolemia. In patients with shock and depleted catecholamine reserves, the inability to mount a sympathetic surge unmasks a direct myocardial depressant effect of ketamine.[163] Respiratory effects of ketamine include bronchodilation, preservation of respiratory drive, and maintenance of respiratory muscle tone.[164,165] It produces direct relaxation of airway smooth muscle ex vivo but may also cause bronchodilation indirectly through the modulation of vagal tone.[166,167] Ketamine has a number of other effects detailed in Fig. 10.9.

Compared with other intravenous anesthetics, ketamine has relatively low plasma protein binding. This, in conjunction with its lipid solubility, allows rapid accumulation in the CNS. Intravenous bolus administration leads to peak effect site concentration within a minute (see Fig. 10.5A). Peak effects for other routes of administration are 10 to 15 minutes for intramuscular injection and 15 to 30 minutes following oral administration. Hepatic cytochrome P450 enzymes (especially CYP 3A4) metabolize ketamine to norketamine by N-methylation in a perfusion-limited manner. Extensive first-pass metabolism leads to less than 20% bioavailability of orally administered ketamine. Norketamine is roughly one-third as potent as ketamine; its contribution to clinical effects appears relatively more significant in settings of long infusions or chronic use.

Concerns over side effects limited ketamine's use in developed nations for many years but recently there has been renewed interest in the drug. Low doses are frequently used to augment regional anesthesia during cesarean sections when the regional block is inadequate. Subanesthetic infusions may decrease postoperative pain in patients using opioids long periods. It can be used for inductions in patients with asthma or hypovolemia; in a randomized controlled trial of acutely ill patients requiring rapid sequence intubation it was as effective as etomidate.[84] Ketamine is sometimes used in critical care in cases of status asthmaticus as an adjunctive bronchodilator, and as an analgesic for dressing changes in the burn ICU.

The role of ketamine in patients with neurologic injury is controversial. Its blockade of NMDA receptors could attenuate excitotoxicity, but animal studies have demonstrated neurotoxic effects on the developing brain.[168] The trade-offs are presently unclear but recent German guidelines have outlined a role for ketamine in brain injured patients whose partial pressure of carbon dioxide in arterial blood is being controlled with mechanical ventilation.[169] The sympathomimetic properties of ketamine allow sedation with preserved or augmented blood pressure to improve cerebral perfusion. Ketamine has traditionally been avoided in neuroanesthesia (see Chapter 9) but that may be changing. Ketamine may confer some antiinflammatory effects and its coadministration has been associated with a reduction in postoperative delirium in high-risk patients.[170]

Ketamine's use as an opioid-sparing adjunct for decreasing postoperative pain has played a key role in its resurgence in modern operating rooms. Although ketamine has analgesic properties of its own, some of the benefits may come from the prevention of opioid-induced hyperalgesia. This effect has been shown for fentanyl[171] and remifentanil and may be mediated by NR2B subunit of NMDA receptors in the spinal cord.[172] A small clinical study



• **Fig. 10.9** A, Selected effects of ketamine. B, Structures of S(+) ketamine and its parent drug phencyclidine. Ketamine is usually supplied as a racemic mixture but the more active S(+) isomer is available in some countries.

reported the dose required to achieve the desired effect in 95% of the population for ketamine to prevent remifentanil-induced hyperalgesia was 0.33 mg/kg.[173] A review of intraoperative single-dose or low-dose infusions reported a 40% decrease in postoperative opioid consumption across numerous studies.[174] It has also been used postoperatively as an opioid adjunct in patient-controlled analgesia. A recent metaanalysis of this indication found that adding ketamine to the opioid decreased pain intensity, opioid consumption, and postoperative nausea and vomiting without a significant increase in hallucinations.[175]

In addition to its use for acute pain, ketamine may have some benefits to patients with chronic pain. In opioid-tolerant patients undergoing back surgery, intraoperative ketamine reduced pain scores and opioid consumption not only in the acute postoperative period, but also 6 weeks after the operation.[45] Post hoc analysis suggested that the greatest benefit was in those patients whose preoperative opioid consumption exceeded the equivalent of 0.55 mg/hr of intravenous morphine. Ketamine has been used in the treatment of complex regional pain syndrome, but a recent systematic review concluded that the current evidence to support its use is of moderate to low quality.[176] There has also been interest in the potential for ketamine to reduce the development of chronic postoperative pain. A metaanalysis suggested some benefit of intravenous ketamine over placebo, but it is likely that a multimodal approach is needed for this issue.[177]

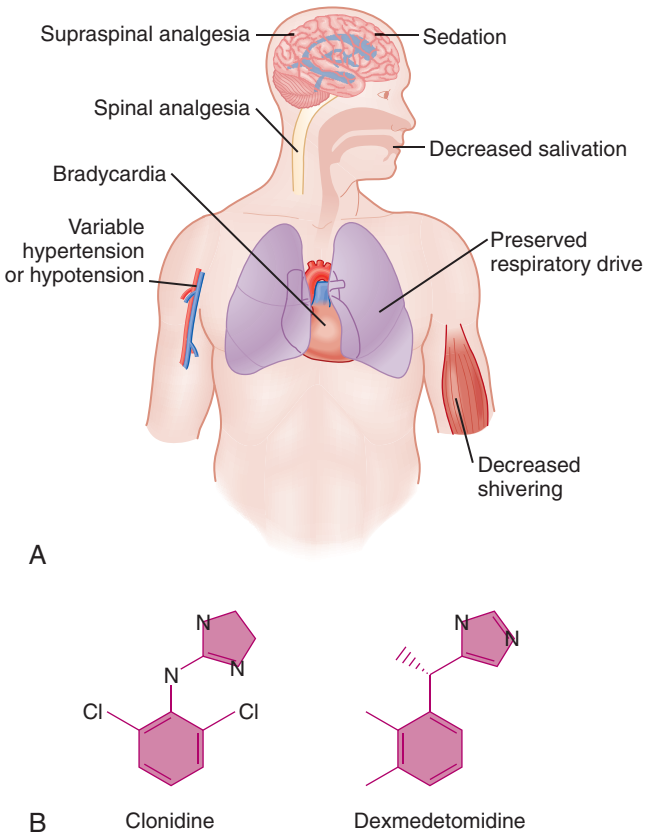
The analgesic properties of ketamine and preservation of respiratory drive are also useful for procedures in which it is critical to maintain spontaneous ventilation and preserve airway reflexes. These cases include patients with large anterior mediastinal masses who may sustain airway collapse if they become apneic or those patients whose airways must be secured while awake. Ketamine increases salivation and airway secretions that can impair visualization during fiberoptic intubation; dexmedetomidine has emerged as an alternative with antisialagogue effects.[178]

Dexmedetomidine

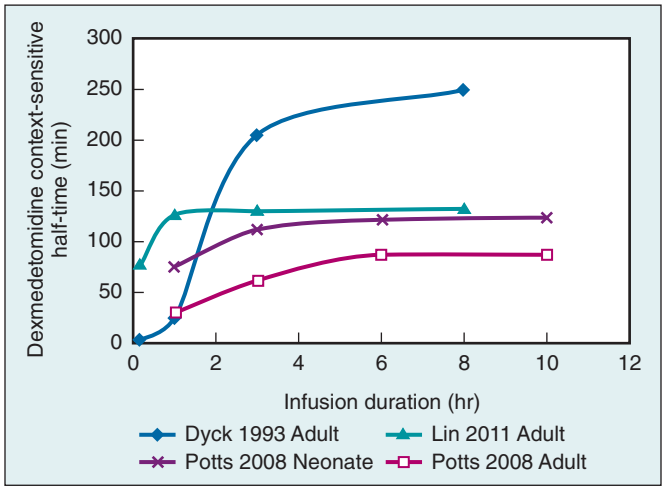
Evidence of analgesic effects of the α-adrenergic agonist clonidine emerged in animal studies in the 1970s and led to the development of agents with greater α_2 specificity. Medetomidine was developed in the 1980s and found to have an α_2/α_1 selectivity ratio of 1620, almost eight times higher than clonidine's ratio. The α-adrenergic effects were mediated exclusively by the d-enantiomer now known as dexmedetomidine (Fig. 10.10).[179] Even at high doses it does not produce general anesthesia but it is a valuable sedative in a number of settings.

Dexmedetomidine has effects both on the spinal cord and in the locus coeruleus. A number of elegant studies in transgenic mice suggest that the α_{2A}-subtype receptor mediates the majority of the analgesic and sedative effects on the CNS.[180] Dexmedetomidine leads to hyperpolarization via influx of potassium ions with a subsequent decrease in neuronal firing as well as reduced norepinephrine release mediated by inhibitory presynaptic autoreceptors. It also decreases cyclic adenosine monophosphate (cAMP) concentration by inhibiting adenylyl cyclase. Many of its effects stem from this decreased sympathetic outflow, but in some cases direct effects on peripheral α_{2B} and α_{2A} receptors predominate and blood pressure increases.[181] This hypertensive response is sometimes seen during loading doses and is the reason that dexmedetomidine should not be administered as a bolus.

The sedation produced by dexmedetomidine is different in that patients tend to be easily arousable. This feature, in combination



• **Fig. 10.10** A, Selected effects of dexmedetomidine. B, Structures of the α_2 agonists clonidine and dexmedetomidine.



• **Fig. 10.11** Context-sensitive half-times of dexmedetomidine reported in adults and neonates based on various pharmacokinetic models. (Modified from Dyck JB, Maze M, Haack C, et al. Dexmedetomidine disposition in children: a population analysis. *Paediatr Anaesth*. 2008;18:722–730; and Lin L, Guo X, Zhang MZ, et al. Pharmacokinetics of dexmedetomidine in Chinese post-surgical intensive care unit patients. *Acta Anaesthesiol Scand*. 2011;55:359–367.)

with its minimal effects on respiratory drive, allows continuation of infusions during weaning from mechanical ventilation and after extubation without the need for dose titration.[182] It has some analgesic qualities and augments the effects of opioids by both spinal and supraspinal mechanisms.[54,183] In contrast to other agents, dexmedetomidine has limited amnestic effect and so should be avoided as a sole agent in patients with neuromuscular blockade. Dexmedetomidine also reduces shivering in an additive fashion with meperidine, raising the possibility that effects of both are mediated by α_2 receptors.[184]

The sympatholytic effects of dexmedetomidine lead to decreased heart rate and blood pressure, which can be helpful, harmful, or of no clinical consequence. In many scenarios these effects are minimal and well tolerated. In patients with cardiac disease there is a potential benefit of decreased myocardial demand in response to painful stimuli, and in some studies this was associated with a mortality benefit.[185] Bradycardia can be dangerous in the setting of heart block and dexmedetomidine should be used with caution in this setting. Significant hypotension is more likely in patients with high sympathetic tone such as patients with diabetes, the elderly, and those with hypovolemia. Selected other effects are shown in Fig. 10.10.

Dexmedetomidine is metabolized in the liver primarily by glucuronidation with a small portion undergoing hydroxylation by CYP 2A6. The distribution half-life is 6 to 8 minutes and its lipophilicity leads to a high volume of distribution. The context-sensitive half-times range from 25 to 120 minutes for a 1-hour infusion to 87 to 250 minutes for infusions greater than 6 hours (Fig. 10.11).[186–188]

Dexmedetomidine sedation is increasingly used in the ICU and is associated with less delirium than benzodiazepine sedation.[189,190] Dexmedetomidine may reduce delirium in part because its sedation closely mimics physiologic sleep in adults and children.[191,192] This concept has been extended to the perioperative period, with a recent trial showing a decrease in postoperative delirium in elderly surgical patients.[193] The ability to extubate patients without weaning dexmedetomidine can facilitate earlier extubation in those patients who become agitated when sedation is held. In the United States, dexmedetomidine is approved for infusions up to 24 hours, but much longer infusions have been reported in the literature. There are case reports of withdrawal phenomena, including agitation, tachycardia, and hypertension, which may be treated with clonidine.[194]

Controversy over the use of propofol by nonanesthesiologists (see "Emerging Developments") has prompted a number of studies of dexmedetomidine as an alternative in sedation practice.[195] A small clinical trial suggested it was comparable to propofol but had longer recovery times; conventional doses up to 1 μg/kg per hour often require supplementation with other drugs. One group reported success of dexmedetomidine as a sole agent in more than 97% of pediatric magnetic resonance imaging scans by escalating the loading dose to 3 μg/kg and the infusion to 2 μg/kg per hour.[196]

Although initially approved by regulatory agencies only for ICU sedation, the clinical applications of dexmedetomidine have continued to expand since dexmedetomidine was approved for monitored anesthesia care sedation in the United States. The antisialagogue effect of dexmedetomidine represents an advantage over ketamine for awake fiberoptic intubations.[178] It has also been administered intranasally for premedication of children and adults.[197,198] The specific and distinctive mechanism of action of dexmedetomidine provides an important alternative amid ongoing uncertainty about short- and long-term cognitive effects of more established anesthetics in both young and old patients.[76]

Emerging Developments

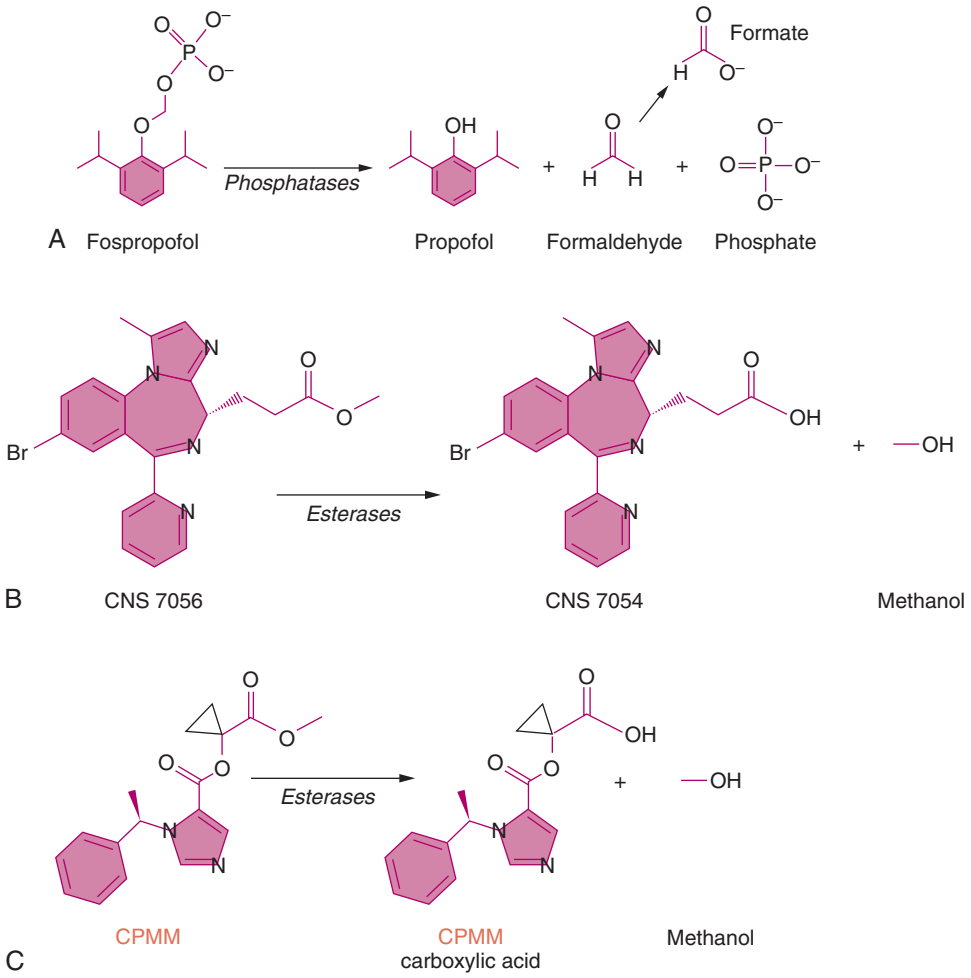
High-Tech Delivery Systems

The development of a computer-aided device that dynamically adjusts anesthetic administration based on measured physiologic parameters has been explored for both inhaled and intravenously administered drugs.[199–201] Commonly referred to as closed-loop anesthesia delivery systems, these devices are typically associated with feedback controls based on predicting depth of hypnosis via EEG analysis or other brain monitor (e.g., auditory evoked potentials).[202] A recent meta-analysis has shown some benefit to closed-loop anesthesia delivery systems over manual infusion rates and open-loop target-controlled infusions, but there is some controversy regarding their economic efficiency and the choice of physiologic parameters to which dosage is titrated.[203] The first FDA-approved device in the United States (Sedasys) was withdrawn by the manufacturer in 2016 for lack of market receptivity (the device performed as designed), but other devices are likely to follow.[204] Controversy surrounding the supervision of these automated devices for use in endoscopic and other office-based procedures will also necessitate discussions regarding the safety of traditional anesthesia drugs in the hands of nonanesthesiologists.

Novel Sedatives

The rapid growth in outpatient and office-based procedures has stimulated the development of several new drugs. Many so-called soft drugs have been designed to mimic the rapid, end-organ independent metabolism of drugs such as remifentanil.[205,206] The benzodiazepine CNS-7056, also known as remimazolam, undergoes ester hydrolysis to form a carboxylic acid metabolite that is 300 times less potent (Fig. 10.12B).[207] It may offer sedation with less postprocedure cognitive effects than midazolam and is now at an advanced stage of clinical development in humans.

A similar strategy has been applied to modify etomidate and reduce its adrenal suppression effects. Investigators have developed an ultrarapid metabolizing etomidate named methoxycarbonyl-etomidate (MOC-etomidate), which is broken down via nonspecific esterases.[208] The in vitro half-life of MOC-etomidate is approximately one-tenth that of its parent compound etomidate. The rapid metabolism of MOC-etomidate into a carboxylic acid metabolite, which has low affinity for 11β-hydroxylase, results in less adrenocortical suppression than its parent compound.[209] This compound, as well as carboetomidate (see Fig. 10.7), a pyrrole analog of etomidate specifically designed not to bind 11β-hydroxylase with



• **Fig. 10.12** Metabolism of next-generation intravenous anesthetics. Fospropofol (A) is a prodrug that is activated by phosphatases.[172] The benzodiazepine remimazolam/CNS-7056 (B) and the etomidate analog cyclopropyl methoxycarbonyl metomidate (C) are rapidly metabolized by esterases to carboxylic acid derivatives with very low activity.[212] *MOC,* Methoxycarbonyletomidate.

high affinity, both maintain the beneficial qualities of etomidate, including rapid induction of general anesthesia with significant hemodynamic stability in animal models.[210] MOC-carboetomidate combines rapid esterase metabolism with the minimal adrenal effects of carboetomidate.[211] Although metabolites of these etomidate analogs may have some sedative effects, it appears that the metabolites of cyclopropyl methoxycarbonyl metomidate (CPMM) (Fig. 10.12C) do not readily accumulate in the CNS.[212] Thus, CPMM emerged as the lead candidate molecule for clinical development among these short acting etomidate analogs. Unfortunately, the CPMM development program was complicated by the appearance of neuroexcitatory phenomenon in animal models and humans which resulted in cancellation of the program. Whether other short acting etomidate analogs related to CPMM will undergo clinical development is unclear. In terms of mechanism, all of these etomidate analogs modulate current through the $GABA_A$ receptor, like their parent compound.[213]

Recently ketamine analogs have been modified for ultrarapid metabolism.[214,215] These analogs appear to mediate a similar dissociative anesthesia appropriate for surgery in animal models.[215,216] The intent is that some of the negative psychological side effects can be mitigated with rapidly decreasing blood levels.

Reversal of General Anesthesia

Anesthesiologists have several intravenous "antidotes" for certain features of the anesthetized state at their disposal (e.g., neostigmine for neuromuscular blocking agents or naloxone for opioids). Since the arrival of flumazenil, reversal of general anesthesia or sedation has been investigated to facilitate and expedite recovery from benzodiazepine-based procedural sedation or general anesthesia.[217,218] Early studies showed little effect on recovery from enflurane or propofol anesthesia, but concurrent opioid administration may have contaminated the results.[219,220] More recent studies have shown improvements in the quality of recovery, including reduced shivering and expedited recovery endpoints, in unpremedicated patients receiving volatile anesthesia.[221,222] Interestingly, flumazenil may also find a role in reducing postoperative narcotic usage.[223] Although the $GABA_A$ receptor may play a prominent role in emergence and recovery, the partial agonist properties of this drug may make it difficult to study as a pure reversal agent of general anesthesia.[224] Studies investigating the role of dopamine in anesthesia recovery are also promising.[225]

Non-Anesthesia Uses of Intravenous Anesthetics

Intravenous ketamine has been shown to rapidly reverse symptoms of depression even in patients who have failed conventional therapy.[226] Several NMDA blocking drugs are in current human trials for treatment-resistant depression,[227] but preclinical data suggest that ketamine may exert some of its antidepressant effect through activation of AMPA receptors.[228] In addition to therapeutic applications, some intravenous anesthetics are being used for diagnostic purposes. Drug-induced sleep endoscopy has been used to aid in the diagnosis and evaluation of treatment options in obstructive sleep apnea.[229,230] Typically, propofol is given, but other regimens (e.g., dexmedetomidine) have been used. Recently administration of intravenous agents in the sedation range was shown to unmask focal neurologic deficits related to cranial tumors. Propofol and midazolam elicited stroke-like symptoms with greater frequency than dexmedetomidine.[231]

Key Points

- Intravenous anesthetics are used both to induce and maintain general anesthesia in the operating room, for sedation and anxiolysis preoperatively, for procedures outside the operating room, and in the ICU.
- Potentiation of the effect of the inhibitory neurotransmitter GABA at $GABA_A$ receptors is the most important mechanism of action for barbiturates, benzodiazepines, etomidate, and propofol.
- Ongoing molecular studies are dissecting not only the specific binding pockets for intravenous anesthetics but also the receptor subunit combinations that differentially mediate effects such as sedation, anxiolysis, and amnesia.
- Etomidate plays an important role in the induction of anesthesia in patients with significant cardiovascular comorbidities such as congestive heart failure or hemorrhagic shock.
- Propofol-based TIVA has advantages over anesthetic maintenance with volatile anesthetics in some patient populations.
- Ketamine blocks glutamate signaling at NMDA-type glutamate receptors, but its clinical effects are broader and more profound than those of more specific NMDA receptor antagonists.
- Subanesthetic doses of ketamine are useful adjuvants for patients with chronic pain; its combination of low cost, analgesia, and preserved respiratory drive make it an important anesthetic, especially in developing nations.
- Dexmedetomidine is a highly specific α_2-adrenergic receptor agonist that produces sedation with preserved respiratory drive. Dexmedetomidine has seen an increasing role in perioperative and ICU sedation.
- The combination of intravenous anesthetics can be tailored for each patient and procedure to optimize the key aspects of the anesthetic and minimize toxicity.

- Closed-Loop Anesthetic Delivery
- Accelerated Emergence

This chapter focuses on the pharmacology of the inhaled anesthetics, including their mechanisms of action and clinical effects (pharmacodynamics). Related pharmacokinetic principles of inhaled anesthetics are covered in Chapter 3.

Historical Perspective

Discovery of Inhaled Anesthetics

The German physician and botanist Valerius Cordus (1515–1544) described a method for preparing ether by combining sulfuric acid with alcohol, which he called *oleum dulci vitrioli* or "sweet oil of

Abstract

Inhaled anesthetics as single agents provide all of the essential features of general anesthesia, including amnesia, unconsciousness, and immobility. Each of these components results from agent-specific actions on distinct neuronal pathways in the central nervous system. The characteristic immobilizing effect of volatile anesthetics involves a site in the spinal cord. Amnesia and unconsciousness involve incompletely understood supraspinal mechanisms. The precise mechanisms by which inhaled anesthetics alter synaptic transmission have not been fully elucidated despite a number of promising candidate molecular targets. The typical anesthetic binding site is hydrophobic and amphipathic. In contrast to intravenous anesthetics, inhaled anesthetics can act at a number of membrane bound ion channels and receptors at clinically relevant effect-site concentrations. Volatile anesthetics have potentiating effects on inhibitory $GABA_A$ and glycine receptors and K^+ channels, and inhibitory effects on excitatory Na^+ and Ca^{2+} channels. The gaseous anesthetics nitrous oxide and xenon have predominant NMDA-type glutamate receptor blocking effects. Inhaled anesthetics have a diverse range of clinically significant effects on multiple organ systems, both beneficial and potentially adverse. Potentially beneficial effects include organ protection, while adverse effects include respiratory and cardiovascular depression. Inhaled anesthetics have agent-specific pharmacologic, pharmacokinetic, and side-effect profiles that determine their optimal clinical applications based on patient and procedure specific applications. Anesthetic-induced neurotoxicity occurs in animal models at critical periods in early brain development with unclear clinical significance.

vitriol." Paracelsus (1493–1541), the father of toxicology, recognized the analgesic properties of ether:

> *[I]n diseases which are treated by allaying the pain, it cures all of the disorders, relieves all of the pains, reduces the fever, and prevents the disagreeable complications of all sicknesses.*[1]

Paracelsus was unknowingly close to the discovery of the anesthetic effects of ether. Two centuries later in the 18th century, despite flammability issues and the lack of appropriate delivery systems, Friedrich Hoffmann of Halle (1660–1742) recommended the introduction of ether into medicine.

In 1772 nitrous oxide (N_2O) was discovered by the English philosopher and chemist Joseph Priestley (1733–1804). He and other scientists such as Joseph Black (1728–1799) and Antoine Lavoisier (1743–1794) identified many other atmospheric gases, including oxygen, hydrogen, and carbon dioxide, pioneering the field of "pneumatic medicine" and elucidating the basic properties of gases. In 1799 Thomas Beddoes (1760–1808) established the Pneumatic Institution for Relieving Diseases by Medical Airs in England. Together with young assistant Humphry Davy (1778–1829), who ultimately became more successful than him, Beddoes experimented with N_2O. Davy performed numerous experiments on himself and discovered both the mood-enhancing effects, leading to the name *laughing gas,* and the analgesic effect of N_2O. Despite these pain-relieving effects and its potential use for surgical procedures, N_2O did not meet expectations as a cure for diseases, and the Pneumatic Institution soon closed.

Decades later Gardner Quincy Colton (1814–1898), a self-proclaimed professor of chemistry, went on tour with his (lucrative) "scientific exhibits" and public demonstrations of N_2O. In 1844 dentist Horace Wells (1815–1848) attended one of Colton's demonstrations of the effects of laughing gas and observed its analgesic effects in a fallen volunteer. The next morning, a fellow dentist removed one of Wells' molars with only little pain while Colton administered N_2O.[2] Wells saw potential in N_2O and scheduled a demonstration at Harvard Medical School in 1845 with help of his assistant William T.G. Morton (1819–1868). During the demonstration the patient cried out and moaned, probably owing to failure of continuous delivery of the gas, an incident that discredited N_2O as an anesthetic. Wells later committed suicide.

Morton was searching for another suitable substance to relieve pain during tooth extractions. He met Charles T. Jackson (1805–1880), a Harvard professor in chemistry who introduced him to ether. Morton's experiments on himself and on his pet animals were promising, and in September 1846 he performed a painless tooth extraction. This caught the attention of Harvard surgeon Henry J. Bigelow (1818–1890), who helped schedule a successful public demonstration at Massachusetts General Hospital on October 16, 1846, which is considered by many the beginning of the era of anesthesia. Morton did not reveal the identity of the substance he called *Letheon,* which was ether he masked with additional fragrances and colors. Most likely he saw a potential for profit and unsuccessfully attempted to patent Letheon. Under pressure from the hospital, Morton revealed the identity of the main ingredient ether, and after further procedures with ether followed, Bigelow published the results of ether as a suitable agent for use in surgical procedures.[3] The term *anesthesia* is derived from Greek *αn-* "without" and *aisthētikos* "perception" or "sensation."

Controversy regarding who first discovered anesthesia arose with contenders including Wells, Jackson, and especially Crawford W. Long (1815–1878), a physician in rural Georgia who had used ether anesthesia since 1842 but did not publish his work until after Bigelow's report.[4] Morton with his perseverance is generally credited with the discovery of anesthesia, although there are regional sentiments favoring Wells or Long. The use of both ether and N_2O was quickly adopted by many institutions, revolutionizing surgery and defining the field of anesthesia.

The science of anesthesia began with the introduction and development of chloroform as an anesthetic by John Snow (1813–1858) in England.[5] He conducted experiments on the physical and pharmacologic properties of chloroform and other inhaled anesthetics, developed methods for their administration by introducing the chloroform inhaler, studied their side effects and complications, and developed specific clinical applications. His work established the scientific basis of anesthesia by determining the relationships between anesthetic solubility, vapor pressure, and potency. He also described five stages of etherization in response to increasing doses, presaging Guedel's description, and the first dose-response relationship for an anesthetic. These are among the seminal foundation studies of inhalational anesthesia.[6]

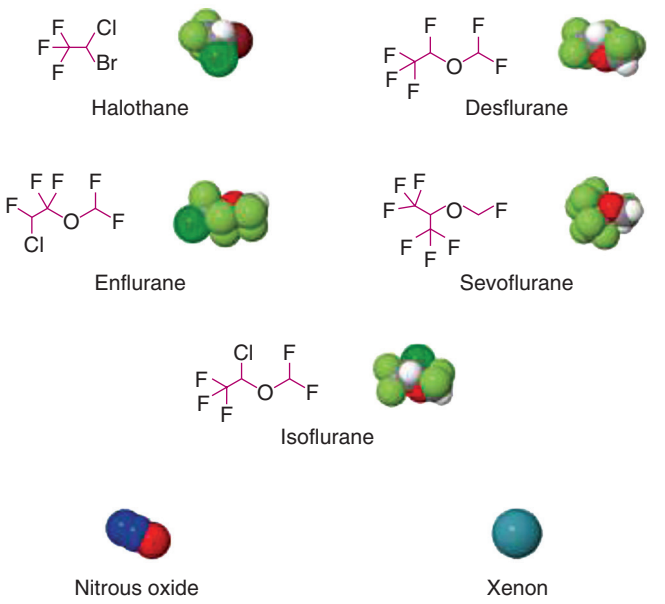
Development of Modern Inhaled Anesthetics

The development of the modern potent inhaled anesthetics was facilitated by developments in fluoride chemistry that accelerated with the atomic weapons program in the mid-20th century. This allowed the synthesis and testing of many fluorinated alkane and ether compounds that were safer and less combustible than ether or cyclopropane. Robbins demonstrated the potential of fluorinated hydrocarbons as nonflammable inhaled anesthetics with greater therapeutic ratios than ether or chloroform.[7] This work led to the synthesis and testing of the polyhalogenated alkane halothane, which showed outstanding anesthetic properties in animals and humans.[8] This was followed by the pioneering work of Ross Terrell (1925–2010) and colleagues who synthesized and evaluated more than 700 fluorinated compounds that included the essential agents of the past 40 years of modern inhalational anesthesia, the fluorinated methyl ethyl ethers: enflurane, isoflurane, sevoflurane, and desflurane (Fig. 11.1).[9]

Structure-Activity Relationships

Meyer-Overton Correlation

At the beginning of the 20th century, Meyer and Overton independently observed that the potency of volatile anesthetics for sedating tadpoles is closely correlated with their solubility in olive oil (Fig. 11.2A). Subsequent investigations confirmed that for a majority of anesthetic agents potency is proportional to lipid solubility as measured by the oil-gas partition coefficient. Remarkably, this correlation holds across multiple animal phyla from invertebrates to humans and spans over five orders of magnitude in potency. Another way of stating this correlation is that the product of the oil-gas partition coefficient and anesthetic potency defined as minimum alveolar concentration (MAC; see Chapter 3) is constant between anesthetics. This implies that at MAC the concentration of inhaled anesthetic molecules in the hydrophobic phase is approximately 50 mM. This observation formed the basis for a unitary hypothesis that argued that the mechanism of action of inhaled anesthetics was derived from their effects on bulk lipid membrane properties. A more modern, mechanistic form of the lipid-based hypothesis suggests that anesthetic-induced changes in the bilayer lateral pressure profile of lipids in the vicinity of membrane proteins alter their functional properties.[10,11]

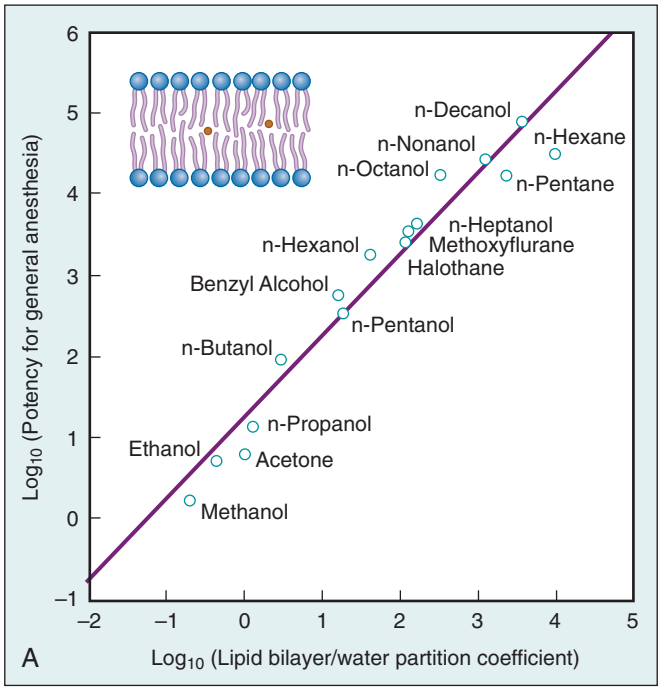


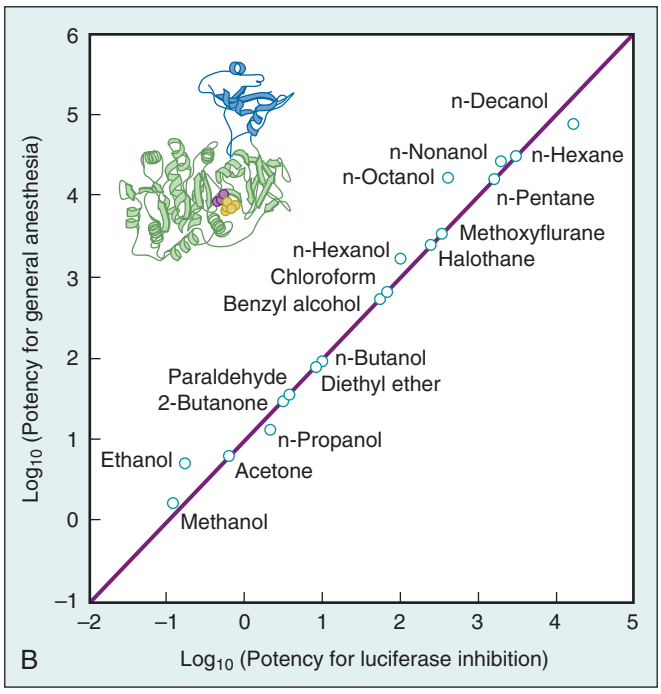
• **Fig. 11.1** Structure of representative inhaled anesthetics shown as two-dimensional and space-filling models. Note the similarities among the modern methyl ethyl ethers, in particular desflurane and isoflurane, which differ by a single substitution.

Despite its central position in mechanistic theories of anesthesia, the Meyer-Overton correlation had limitations. Although Meyer and Overton both used olive oil as their reference solvent, similar correlations have been obtained using other hydrophobic solvents that are more hydrophobic than olive oil, such as benzene, which do not produce as strong a correlation as olive oil. The amphipathic (having both hydrophobic and hydrophilic qualities) solvents methanol, octanol, and lecithin produce even better correlations than olive oil, correctly predicting that enflurane is less potent than isoflurane. However, lipid solubility alone does not predict anesthetic potency in that a number of chemically similar compounds with lipid solubilities comparable to known anesthetics lack anesthetizing capacity themselves. These so-called nonimmobilizers have been useful experimentally as a negative test in evaluating potential anesthetic targets.[12] Although the Meyer-Overton correlation does constrain the possible mechanisms of action of anesthetics (the site at which anesthetics bind must be hydrophobic, and likely amphipathic), in practice this is not a particularly restrictive constraint on possible anesthetic binding sites because lipid bilayers, membrane proteins, and most water-soluble proteins have amphipathic domains. Functional studies indicate that volatile anesthetics do not alter bulk lipid bilayer properties at clinically relevant concentrations that do modify ion channel function.[13,13a]

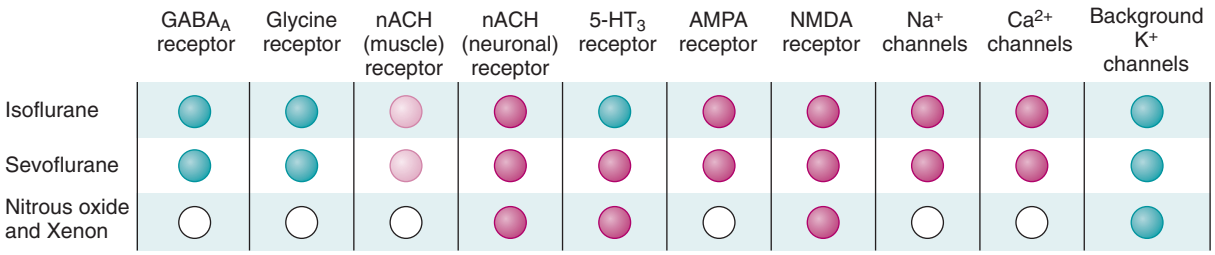
Stereoselectivity

Isoflurane, enflurane, halothane, and desflurane all have a chiral carbon atom, and thus they exist as racemic mixtures of enantiomeric pairs that are mirror images of each other, but with identical physical and chemical properties other than their ability to polarize light in opposite directions (see Chapter 1). While they are synthesized as racemic mixtures, separation of the enantiomers of isoflurane and halothane by gas chromatography allowed testing of the





• **Fig. 11.2** General anesthetics act by binding directly to proteins. A, The Meyer-Overton correlation (c. 1900) suggested that lipids were the principal target for anesthetics based on the correlation between anesthetic potency and lipid-water partition coefficients. B, General anesthetic potencies correlate equally well with their potency for inhibition of the soluble enzyme firefly luciferase. The crystal structure of luciferase is shown in the inset. (Reprinted with permission from Macmillan Publishers Ltd. *Nature* copyright 2007. Franks NP. Molecular targets underlying general anaesthesia. *Br J Pharmacol*. 2006;147[suppl 1]:S72–S81.)



• **Fig. 11.3** Ligand-gated and voltage-gated ion channels are thought to be among the most relevant targets for general anesthetics. The activities of representative inhaled anesthetics on these targets in vitro are summarized. A *dark green* or *pink spot* indicates significant potentiation or inhibition, respectively, by the anesthetic at clinically relevant concentrations; a *light pink* spot indicates some inhibition, and an *empty spot* indicates no effect at clinically relevant concentrations. This summary represents a synthesis of major effects, but important differences exist between various receptor and channel isoforms (not indicated here). *AMPA,* α-Amino acid-3-hydroxy-5-methyl-4-isoxazole; *CA^{2+},* calcium ion; *GABA,* gamma-aminobutyric acid; *K^+,* potassium ion; *nACh,* nicotinic acetylcholine; NMDA, N-methyl-D-aspartate; *Na^+,* sodium ion. (Modified from Rudolph U, Antkowiak B. Molecular and neuronal substrates for general anaesthetics. *Nat Rev Neurosci*. 2004;5:709–720.)

anesthetic properties of the individual enantiomers, which have identical lipid solubilities. Rats are about 1.5-fold more sensitive to the (+)enantiomer than the (–)enantiomer of isoflurane, while its lipid perturbing effects are equivalent (nonstereoselective).[14,15] A number of putative targets (see later text), including gamma-aminobutyric acid $(GABA)_A$ receptors and N-methyl-D-aspartate (NMDA) receptors, have demonstrated stereoselectivity in vitro, although not to the degree seen in vivo.[16,17] Interestingly, L-type calcium ion (Ca^{2+}) channels (which partially mediate the cardiodepressive effects of volatile agents) do not demonstrate stereoselectivity in vitro, suggesting that the more potent enantiomer should have an increased therapeutic ratio (reduced cardiovascular depression) compared with the racemic mixture.[18] Importantly, the stereoselectivity of anesthetic potency indicates that lipid solubility alone does not determine anesthetic potency.

Mechanisms of Action

From Lipid-Based to Protein-Based Mechanisms

The chemical diversity of the agents that can be used as general anesthetics historically favored a unitary mechanism to explain anesthesia. The Meyer-Overton correlation suggested that the effect sites of anesthetics were lipophilic or amphipathic. As a result, initial concepts of general anesthetic mechanisms favored effects on the bulk properties of lipid membranes, which allowed for the vast chemical diversity of agents found to produce an anesthetic state (see earlier text). However, no verifiable hypothesis of a lipid-based mechanism, which usually invoked effects on lipid membrane properties (e.g., bilayer fluidity, thickness, curvature, permeability), was developed. Moreover, comparable effects on membrane biophysical properties could be achieved by small changes in temperature that do not cause anesthesia. Subsequently, the nonimmobilizers were found to violate the basic Meyer-Overton correlation between potency and lipophilicity.[12] The improved correlation between anesthetic potency and solubility in amphipathic rather than purely hydrophobic solvents is consistent with a protein-based mechanism, or perhaps a lipid bilayer with phospholipoproteins. The proof of concept for a protein as an anesthetic target was provided by Ueda and extended unambiguously by Franks and Lieb who reported that the bioluminescent function of the protein luciferase was inhibited by a large range of anesthetic molecules with potencies predicted by the Meyer-Overton correlation (see Fig. 11.2B).[19,20] This concept was strengthened by demonstration of stereoselective anesthetic effects, which imply specific anesthetic chiral binding sites.[21]

Diversity of Molecular Targets

Anesthesia is a composite pharmacologic endpoint that is commonly defined as reversible amnesia, loss of consciousness, and immobility. It is not surprising then that these diverse effects result from multiple mechanisms, and that the relative potency and efficacy of various general anesthetics in producing each of these endpoints vary between specific anesthetics (Fig. 11.3). The prevailing view is that inhaled anesthetics have multiple, agent-specific effects on a number of molecular targets critical to neuronal communication and excitability, as summarized in Table 11.1.[22,23] These multiple actions work in concert or individually to produce the pleiotropic effects characteristic of inhaled anesthetics.[24]

Criteria for identifying the molecular targets of inhaled anesthetics are shown in Table 11.2. Volatile anesthetics at clinically relevant concentrations positively modulate inhibitory $GABA_A$ receptors and inhibitory glycine receptors, inhibit excitatory NMDA-type glutamate receptors and neuronal nicotinic acetylcholine receptors (nAChRs), activate certain two-pore domain potassium (K_{2P}) and leak potassium ion (K^+) channels, and inhibit multiple voltage-gated sodium ion (Na^+) channel (Na_v) and Ca^{2+} channel (Ca_v) subtypes. The gaseous inhaled anesthetics (cyclopropane, N_2O, xenon) at clinically relevant concentrations do not affect $GABA_A$ receptors but block NMDA receptors and activate K_{2P} channels.[25,26]

Putative anesthetic targets are not distributed evenly throughout the nervous system. For example, multiple subtypes of $GABA_A$ receptors exist, each with its own expression profiles at the regional, cellular, and subcellular levels. Specific receptor isoforms appear to mediate various anesthetic endpoints, as shown for certain intravenous anesthetics (see Chapter 9).

Multiple Behavioral Endpoints

Anesthesia is a drug-induced comatose state with multiple behavioral components, including the essential triad of unconsciousness,

TABLE 11.1 Overview of Putative Sites of Inhaled Anesthetic Action

Level	Site	Effect	Target(s)
Proteins	Amphipathic binding sites	Conformational flexibility, ligand binding	Ion channels, receptors, signaling proteins
Action potential	Nervous system	Small reduction in amplitude	Na^+ channels
	Cardiovascular system	Reduced amplitude, duration	Ca^{2+} channels, K^+ channels
Synaptic transmission			
Inhibitory	Presynaptic terminal	Enhanced transmitter release	
	Postsynaptic receptors	Enhanced transmitter effects	Glycine, $GABA_A$ receptors
Excitatory	Presynaptic terminal	Reduced transmitter release	Na^+ channels, Ca^{2+} channels, K_{2P} channels
	Postsynaptic receptors	Reduced transmitter effects	NMDA receptors, nicotinic acetylcholine receptors
Neuronal networks	Neuronal circuit	Altered long-term potentiation/ depression	Synaptic plasticity
	Neuronal integration	Altered rhythmicity, coherence	HCN channels, K_{2P} channels, extrasynaptic $GABA_A$ receptors, and so on
Central nervous system	Neocortex, hippocampus, amygdala	Sedation, amnesia	θ rhythms, γ rhythms, synchrony
	Diencephalon (thalamus), brainstem (reticular formation)	Unconsciousness	γ-band transfer entropy? Thalamic deafferentation?
	Spinal cord	Immobility	Nocifensive reflex
Cardiovascular system	Heart		
	Myocardium	Negative inotropy	Excitation-contraction coupling
	Conduction system	Dysrhythmias	Cardiac action potential
	Vasculature	Vasodilation	Direct and indirect vasoregulation
Pulmonary system	Vasculature	Vasodilation, reduced	Direct and indirect vasoregulation
	Bronchioles	Bronchodilation	Direct and indirect bronchiolar smooth muscle tone

Ca^{2+}, Calcium ion; *GABA*, gamma aminobutyric acid; *HCN*, hyperpolarization-activated cyclic nucleotide-gated; *K^+*, potassium ion; *K_{2P}* two-pore domain potassium; *Na^+*, sodium ion.

TABLE 11.2 Criteria for Identifying Molecular Targets of Anesthetic Action

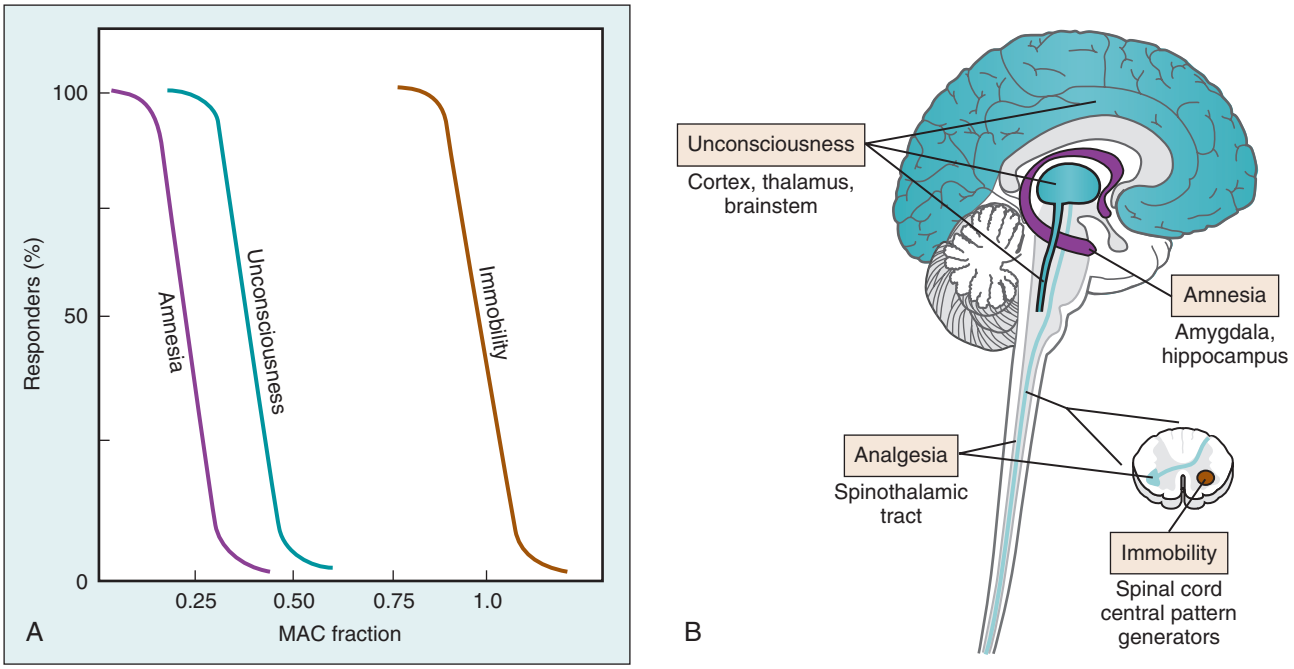
The anesthetic reversibly and directly alters target function at clinically relevant concentrations (sensitivity).
The target is expressed in appropriate anatomic locations to mediate the specific behavioral effects of the anesthetic (plausibility).
Stereoselective effects of the anesthetic or nonimmobilizer in vivo parallel effects on the target in vitro.
Pharmacologic or genetic disruption of the anesthetic sensitivity of the target abolishes the effect of the anesthetic on the relevant endpoint.

amnesia, and immobility; in some cases analgesia and autonomic stability occur, but these endpoints are not universal.[27] These effects are dose-related: amnesia at low doses is followed by sedation, unconsciousness, and eventually immobility (Fig. 11.4A). Current evidence favors the hypothesis that the multiple behavioral endpoints of anesthesia result from multiple distinct molecular targets and distinct anatomic sites of action (see Fig. 11.4B). Unconsciousness is likely due to enhanced inhibition at multiple sites in the cerebral cortex, thalamus, and brainstem involved in arousal. Although the neuronal correlates of consciousness remain unclear, it has been proposed that anything that sufficiently perturbs activity in thalamocortical loops, and hence long-range cortical connectivity, could disorder consciousness.[28] Moreover, individual lesions to brainstem arousal areas and intralaminar thalamus result in transient coma, suggesting that pharmacologic inhibition of these areas is also likely to induce a state of unarousable unresponsiveness.[29]

Amnesia is likely due to altered neurotransmission in the frontal cortex, hippocampus, and amygdala critical to memory acquisition and storage. Immobility is due to effects on spinal cord networks, likely through suppression of central pattern generators critical to coordinated movement.[30,31] Analgesia is likely due to disruption of spinothalamic tract transmission and possible effects on peripheral nociception. A shortcoming of the volatile anesthetics is their poor control of the autonomic nervous system response to painful stimuli. In the modern era, inhalation anesthesia is routinely supplemented with opioids to achieve optimal anesthetic conditions.[32]

Molecular and Cellular Sites of Action

Because of the ability to precisely define and monitor immobilization, this anesthetic endpoint has been investigated more completely



• **Fig. 11.4** Multiple sites of volatile anesthetic action. A, Volatile anesthetics lead to multiple dose-dependent behavioral endpoints. Cardiovascular responses occur at even greater doses (not shown). B, Amnesia, the most sensitive anesthetic endpoint, probably involves the hippocampus, amygdala, medio-temporal lobe, and possibly other cortical structures involved in learning and memory. Unconsciousness likely involves the cerebral cortex, thalamus, and brainstem reticular formation essential to consciousness and arousal. Immobility occurs by anesthetic action on the spinal cord central pattern generators. Anesthetic effects on the spinal cord blunts ascending impulses arising from noxious stimulation, leading to analgesia, and might indirectly contribute to anesthetic-induced unconsciousness.

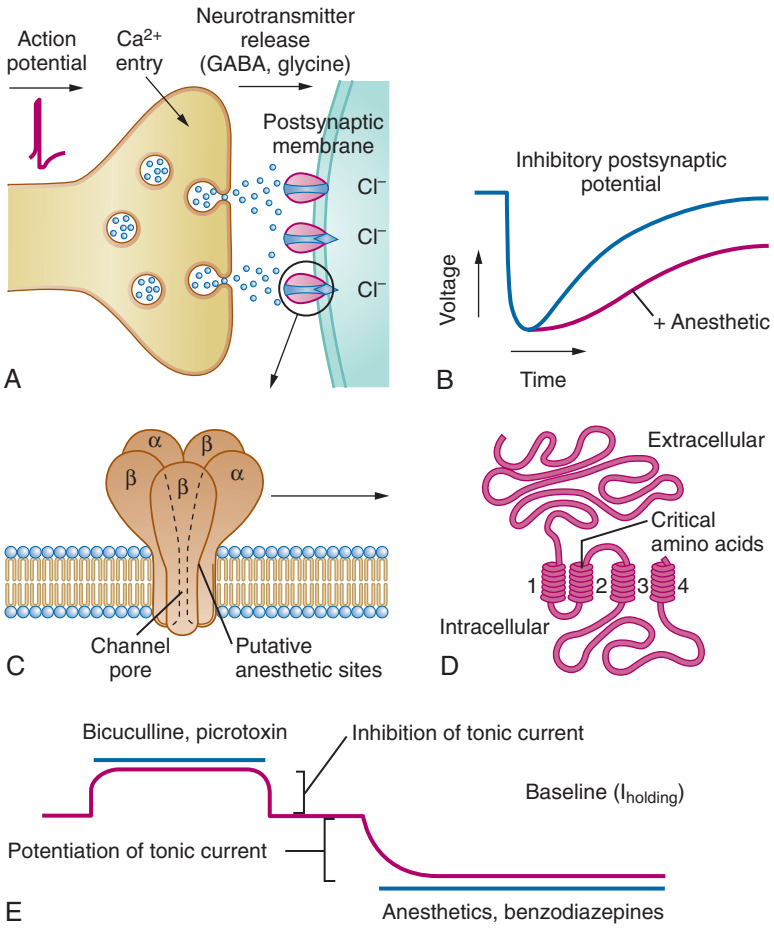
than amnesia and unconsciousness. Inhaled anesthetics produce immobilization at increasing doses primarily via effects on the spinal cord. A series of elegant experiments in vivo showed that the potency of volatile anesthetics for immobilization was determined by effects on the spinal cord.[30,31] Volatile anesthetic immobility does not appear to be mediated by $GABA_A$ receptor effects. Thus the $GABA_A$ receptor antagonist bicuculline does not antagonize the immobility induced by isoflurane.[33] This is in contrast to the intravenous anesthetics propofol and etomidate, whose immobilizing effects are mediated primarily by $GABA_A$ receptors, as evident in their effective antagonism by bicuculline (see Chapter 10). In contrast, mice harboring mutations that reduce sensitivity of $GABA_A$ receptor α_1 or β_3 subunits to volatile anesthetics exhibit only slight resistance to the immobilizing and hypnotic effects of volatile anesthetics, whereas analogous mutations that greatly reduce the effects of propofol or etomidate on the β_3 $GABA_A$ receptor subunit essentially abolish their hypnotic and immobilizing effects.[34,35] This indicates that other targets likely play a more important role in these volatile anesthetic actions.

The amnestic effect of volatile anesthetics, like that of the intravenous anesthetics, probably involves potentiation of specific $GABA_A$ receptor subtypes (Fig. 11.5). For example, amnesia during anesthesia has been attributed to enhanced activation of α_5-subunit–containing $GABA_A$ receptors, which are known to regulate hippocampal-dependent synaptic plasticity and short-term memory.[36] Long-term potentiation (LTP), a cellular model of hippocampal memory, is suppressed by isoflurane, an effect that is reversed by the $GABA_A$ receptor antagonist bicuculline.[37] The finding that both β_3- and α_4-subunit knockout mice are resistant to the amnestic effects of isoflurane indicates a role for $GABA_A$ receptors containing these subunits in the amnestic action of volatile anesthetics.[38,39]

Glycine receptors, members of the ligand-gated ion channel superfamily that are closely related to $GABA_A$ receptors both structurally and functionally, are likewise potentiated by volatile anesthetics (see Fig. 11.5). Their high level of expression in the spinal cord makes glycine receptors putative targets for the immobilizing effects of anesthetics. Partial antagonism of the immobilizing effect of isoflurane by the glycine receptor antagonist strychnine provides pharmacologic evidence supporting a contribution to this anesthetic endpoint.[40]

Neuronal nAChRs are, like $GABA_A$ and glycine receptors, pentameric cys-loop ligand-gated ion channels, but in contrast they are cation-selective excitatory channels (rather than anion-selective inhibitory channels) and are inhibited (rather than potentiated) by volatile anesthetics. Mecamylamine (an antagonist of nAChRs) does not affect MAC for several inhaled anesthetics, suggesting that nAChRs do not contribute to inhaled anesthetic immobility.[41,42] However, they might contribute to the amnestic and hyperalgesic effects of very low doses of volatile anesthetics. This is consistent with the roles of nAChRs in learning and memory in that isoflurane and nonimmobilizers, both of which produce amnesia, block nAChRs.[43,44]

Voltage-gated Na^+ channels are integral to all facets of central nervous system (CNS) function and thus are well positioned to mediate multiple aspects of general anesthesia. Clinical



• **Fig. 11.5** Effects of volatile anesthetics on inhibitory synaptic transmission. A, On binding of released gamma aminobutyric acid *(GABA)* or glycine *(blue dots)* to the pentameric $GABA_A$ or glycine receptor complexes, chloride *(Cl^-)* flows into the postsynaptic neuron, leading to hyperpolarization. B, Volatile anesthetics prolong channel opening and increase postsynaptic inhibition. C, A pentameric $GABA_A$ receptor complex in the lipid bilayer membrane showing the likely binding sites in the transmembrane domains and the chloride conducting ion channel pore. D, Membrane topology of a single receptor subunit showing the extracellular domain that forms the ligand binding site, and the four transmembrane domains, including the critical amino acid residues in transmembrane domain 2 that potentially contribute to the anesthetic binding site. E, Synaptic $GABA_A$ receptors have a low potency and a high efficacy, whereas extrasynaptic $GABA_A$ receptors have a high potency and a low efficacy for GABA and contribute to tonic inhibitory currents in response to low ambient extrasynaptic GABA. Extrasynaptic $GABA_A$ receptors usually contain the δ subunit, have increased sensitivity to anesthetics, and might be important targets for general anesthetics. The role of the tonic current is demonstrated schematically in the depolarization in response to the $GABA_A$ receptor inhibitors bicuculline and picrotoxin, and the hyperpolarization in response to anesthetics and benzodiazepines. *Ca^{2+},* calcium ion.

concentrations of volatile anesthetics inhibit Na^+ channels in isolated rat nerve terminals and neurons. Although not as sensitive to volatile anesthetics as cys-loop ligand-gated ion channels, Na^+ channels are inhibited in vitro in a clinical concentration range.[23,45] Moreover, reductions in neurotransmitter release from presynaptic terminals by volatile anesthetics involve inhibition of presynaptic action potentials through Na^+ channel blockade.[46,47] The presynaptic effects of isoflurane are selective for inhibition of release of the excitatory transmitter glutamate over the inhibitor transmitter GABA, consistent with their neurodepressive actions.[48,49] Intrathecal administration of the specific Na^+ channel blocker tetrodotoxin reduces MAC in rats, whereas the activator veratridine increases MAC, supporting a role for Na^+ channel block in immobility produced by isoflurane.[50,51] Voltage-gated Ca^{2+} channels, which are structurally homologous to Na^+ channels, have also been implicated as targets for volatile anesthetics,[52–54] and for isoflurane-induced immobility in particular.[55] These channels mediate Ca^{2+} entry in excitable tissues and are critical to many anesthetic-sensitive functions such as synaptic transmission and cardiac contractility.

There is also evidence for K^+ channels as targets for inhaled anesthetics. The MAC of chloroform, desflurane, halothane, and sevoflurane is variably increased in a knockout of the TREK-1 K_{2P} K^+ channel.[56] This variable effect on MAC is not paralleled by the effect of these anesthetics to increase channel opening in vitro, which argues against an exclusive causal connection between TREK-1 and

anesthetic effects.[56,57] N_2O, xenon, and cyclopropane also activate TREK-1. The MAC of halothane is increased significantly by knockout of the TASK-3 channel, but the MAC of isoflurane is not.[58] Increased pH opens TASK K^+ channels, but decreases in arterial partial pressure of carbon dioxide ($PaCO_2$) (with associated increases in pH) do not decrease MAC.[59,60] Reduced pH blocks TASK channels, but increases in $PaCO_2$ that decrease pH also decrease MAC.[61] Finally, intravenous and intrathecal infusions of the KCNK-type K^+ channel activator riluzole decrease isoflurane MAC equipotently in rats, which suggests that although activation of K^+ channels might affect anesthetic requirement, the effect is primarily on higher centers rather than the spinal cord.[62] The issue is complicated by the nonspecificity of riluzole, which blocks slowly inactivating Na^+ channels (important for maintaining repetitive firing, and thus likely MAC) even more potently than KCNK channels.[63]

Blockade of receptors for glutamate, the principal excitatory neurotransmitter in the CNS, provides a plausible mechanism for depression of excitatory synaptic transmission and thereby CNS depression by inhaled anesthetics. NMDA-type and α-amino acid-3-hydroxy-5-methyl-4-isoxazole (AMPA)-type receptors are critical for all forms of synaptic function and plasticity, including learning, memory, and nociception among other roles. Blockade of NMDA receptors, as well as hyperpolarization-activated cyclic nucleotide-gated 1 (HCN1) channels, appears important to the anesthetic mechanisms of ketamine (see Chapter 10), and might contribute to inhaled anesthetic effects as well. Isoflurane and xenon inhibit NMDA and AMPA receptors in vitro due to competitive blockade of the glycine coagonist site.[64,65] In addition to K_{2P} channels and nAChRs, NMDA receptors are among the most sensitive targets in vitro to N_2O and xenon and are therefore important to their anesthetic actions, although this conclusion awaits confirmation in vivo.[66] Thus N_2O, xenon, and cyclopropane have a distinct pharmacologic profile with little or no effect on $GABA_A$ receptors but strong inhibition of NMDA and activation of the K_{2P} channel TREK-1.[67]

Compared with the intravenous anesthetics (see Chapter 10), inhaled anesthetics are generally more promiscuous in their molecular targets, lacking the receptor-specific, and sometimes receptor subtype–specific, effects of certain intravenous anesthetics. This complicates their pharmacologic characterization, but might also provide considerable redundancy contributing to their marked efficacy across phyla and within species. Such redundancy might also explain the relatively minor effects on anesthetic potency in vivo of mutations that reduce sensitivity of specific molecular targets to inhaled anesthetics in vitro. It is likely that actions on multiple targets rather than a single specific target contribute to the immobilizing effect of volatile anesthetics.[23]

Drug Class Effects

Inhaled anesthetics are characterized by their diverse chemical classes, including the volatile ethers and alkanes, and the gases N_2O and xenon. The molecular effects of inhaled anesthetics are also diverse in that their low potency leads to pleiotropic interactions with multiple molecular targets. This includes a large number of systemic (nonanesthetic) effects. It is instructive to consider the effects of the volatile ethers and alkanes, which exert predominantly GABAergic effects (Fig. 11.6), separately from the gases (Fig. 11.7), which exert predominantly NMDA blocking effects (see Fig. 11.3).

• **Fig. 11.7** Major sites of action of the gaseous anesthetics nitrous oxide and xenon are shown schematically. *$CMRO_2$,* Cerebral metabolic rate of oxygen.

Nonanesthetic Effects

Bronchodilation

Volatile anesthetics relax airway smooth muscle through block of voltage-gated Ca^{2+} channels, depletion of Ca^{2+} stores in the sarcoplasmic reticulum, and possibly through potentiation of GABAergic mechanisms.[68] Because the airways normally have low tone, this effect is evident almost exclusively in the setting of bronchospasm. Baseline pulmonary resistance and dynamic pulmonary compliance are unchanged by 1 or 2 MAC halothane, enflurane, isoflurane, or sevoflurane. However, in subjects challenged with intravenous histamine, volatile anesthetics attenuate the increase in pulmonary resistance.[69] Unlike other volatile anesthetics, this effect is not observed with desflurane.[70] Volatile anesthetics also have antiinflammatory effects on airway epithelial cells mediated by $GABA_A$ receptor potentiation.[71]

Neuromuscular Effects

In contrast to intravenous anesthetics, which can either have excitatory myoclonic effects or produce weak myorelaxation (propofol), volatile anesthetics produce dose-dependent skeletal muscle relaxation and potentiate both depolarizing and nondepolarizing neuromuscular blockers. The mechanisms of skeletal muscle relaxation include decreasing the depolarizing current at the neuromuscular junction in response to acetylcholine owing to direct inhibition of nAChRs and enhancement of spinal cord glycine receptors.[40,72,73] Potentiation of nondepolarizing neuromuscular blocker effects is likely due to potentiation of antagonist affinity at the nAChR.[74] Residual volatile anesthetic can potentiate residual neuromuscular blockade, while elimination facilitates recovery from neuromuscular blockade.

Analgesia and Neuroprotection

Inhibition of NMDA receptors by N_2O, xenon, and cyclopropane probably underlies their unique analgesic properties, and their propensity to produce excitement and euphoria, and therefore abuse as psychotomimetics. In addition, NMDA receptor blockers including xenon and N_2O are both neuroprotective and neurotoxic in animal models (see the "Emerging Developments" section).[66]

Adverse Effects

The promiscuous pharmacologic actions of inhaled anesthetics result in numerous undesirable effects summarized in the following text by system.

Respiratory Depression

All halogenated ethers cause dose-dependent respiratory depression. Even subanesthetic concentrations blunt both the hypoxic and hypercarbic ventilatory responses, though in general hypoxic drive is more sensitive.[75] The acute hypoxic response can remain suppressed for several hours after anesthesia owing to depressant effects of subanesthetic concentrations (0.1 MAC).[76] These effects are multifactorial. The peripheral drive from hypoxia detected by the carotid bodies is blunted. There is a general depression of the central respiratory centers and arousal centers, and motor neuron and respiratory muscle function is suppressed, both leading to reduced respiratory drive and upper airway muscular tone and patency.[77] Minute ventilation is reduced at anesthetic doses mainly through a reduction in tidal volume, while respiratory rate is maintained or increased. These effects are mediated primarily centrally through enhanced postsynaptic inhibitory GABAergic and depressed presynaptic and postsynaptic excitatory glutamatergic transmission.

Hypoxia is sensed by glomus type I cells of the carotid bodies by reduced opening of K^+ channels, although the specific type is difficult to determine and might be species dependent.[78] Volatile anesthetic suppression of peripheral hypoxic respiratory drive might be mediated by reactive oxygen species (ROS), altering the redox state of K^+ channels that detect hypoxia. Halothane, with a relatively large degree of peripheral metabolism and associated production of ROS, dramatically suppresses the carotid body response to hypoxia. Desflurane, with minimal metabolism, minimally suppresses the carotid body reflex.[79] Isoflurane, with an intermediate degree of metabolism, moderately inhibits the carotid bodies. Pretreatment with a mixture of antioxidants prevents suppression of the respiratory response by subanesthetic doses of halothane and isoflurane.[78,80,81]

Cardiovascular Depression

Volatile anesthetics universally produce concentration-dependent myocardial depression, especially halothane. This is due primarily to altered Ca^{2+} entry and sarcoplasmic reticulum Ca^{2+} handling.[82,83] The most significant cardiodepressant effect of halothane is direct myocardial depression. The negative inotropy is compounded by decreases in systemic vascular resistance (SVR) by enflurane, isoflurane, desflurane, and sevoflurane to further reduce blood pressure. In contrast, N_2O and especially xenon have minimal direct cardiovascular effects (Table 11.3). Xenon does not affect the major cation currents in isolated cardiomyocytes, which probably explains the minimal cardiovascular depression. Reduced SVR is most prominent with isoflurane, leading to suggestions that it could promote a steal phenomenon in patients with coronary

artery disease. However, there is no convincing clinical evidence that isoflurane is riskier than other inhaled anesthetics in patients with coronary artery disease as long as perfusion pressure is maintained.[84] Rapid increases in inhaled concentrations of isoflurane and especially desflurane can lead to increases in heart rate and blood pressure secondary to sympathetic activation as the result of an irritant effect.[85] Sevoflurane has minimal effects on heart rate.

Cardiac Dysrhythmias

Isoflurane, desflurane, and sevoflurane all prolong the electrocardiographic QT interval, potentially increasing the risk of *torsades de pointes* polymorphic ventricular tachycardia. There is some controversy as to whether halothane presents a similar risk.[86] Prolongation of the QT interval is likely due to inhibition of the delayed rectifier K^+ current through human ether-à-go-go–related gene (hERG) channels that normally contribute to cardiomyocyte repolarization (see Chapter 27).[87] Halothane and cyclopropane are well known for myocardial sensitization to catecholamine-induced arrhythmias. This has been proposed to result from disruption of muscarinic regulation of myocardial adenylyl cyclase.[88,89] These arrhythmias are suppressed by calcium channel blockers and β-adrenergic blockers.[90] The ether anesthetics, xenon, and N_2O have minimal proarrhythmic effects.

Neurophysiologic Effects

Volatile anesthetics decrease the cerebral metabolic rate of oxygen consumption ($CMRO_2$; see Chapter 9). Because of flow-metabolism coupling this should result in reduced cerebral blood flow (CBF) and intracranial pressure. However, these effects are offset by the direct vasodilation effect of volatile anesthetics on cerebral vasculature, particularly at higher doses. N_2O increases CBF with a mild increase in $CMRO_2$. Coadministration of propofol, barbiturates, or opioids counteracts these vasodilatory effects.

Volatile anesthetics lead to characteristic changes in the electroencephalogram (EEG; see Chapter 8). During quiet wakefulness, α and β activity predominate. As anesthetic concentration increases, the EEG shifts to larger-amplitude, lower-frequency activity in the θ and δ range. As concentration increases further, the EEG shows burst suppression, alternating periods of isoelectric activity, and bursts of activity. By the time concentration reaches 1.5 to 2 MAC, the EEG becomes isoelectric. These characteristic shifts in the EEG power spectrum have been exploited to create multiple measures of depth of anesthesia, including the bispectral index (BIS), spectral entropy, and spectral edge. Unfortunately, none has proven to be a compelling monitor for awareness, in that the BIS or Anesthetic Gas to Reduce Explicit Recall (BAG-RECALL) trial failed to demonstrate superiority for awareness prevention when following BIS compared to a protocol to maintain a minimum end-tidal volatile anesthetic concentration.[91] Ketamine and N_2O do not reduce the BIS or suppress midlatency auditory evoked potentials, whereas xenon does. Thus anesthetic depth monitors are inaccurate when ketamine or N_2O is used.

Sevoflurane, isoflurane, and enflurane are notable for producing epileptiform EEG activity at high concentrations.[92,93] This effect is particularly pronounced with hyperventilation and has been detected during pediatric inhalational induction with sevoflurane. This activity is of unclear clinical significance, but it raises concerns of possible neurotoxicity.

Immunomodulatory Effects

Postoperative immunocompromise in surgical patients is primarily related to the neuroendocrine stress response to surgery through activation of the autonomic nervous system and the hypothalamic-pituitary-adrenal axis.[94,95] Monocytes, macrophages, and T cells all have β_2-adrenoreceptors and glucocorticoid receptors through which the perioperative surge in catecholamines, adrenocorticotropic hormone, and cortisol can directly suppress function. This immunomodulatory effect has the potential for significant impact on postoperative outcome, particularly for cancer surgery, because pain and surgery increase tumor metastasis in cancer surgery when comparing groups that received systemic or epidural analgesia in addition to general anesthesia during surgery.[96] This argues that the immune effects of anesthesia are significantly smaller than the effects of surgery, but volatile anesthetics also have immunomodulatory effects.[97]

Data concerning the immunomodulatory effects of volatile anesthetics are somewhat contradictory, but the majority of studies show that they have immunosuppressive properties (see Chapter 38). Volatile anesthetics generally inhibit inflammatory cytokines, either directly or through stimulation of helper T-cell cytokines such as interleukin (IL)-4 and IL-10 that normally function to limit the inflammatory response. Studies have shown decreased lymphocyte proliferation, inhibition of neutrophil function, and suppression of alveolar monocyte responses to cytokines.[98–103] Additionally, volatile anesthetics reversibly inhibit voltage-gated Ca^{2+} channels, decrease intracellular Ca^{2+} concentration, and reduce expression of inducible nitric oxide synthase (iNOS) in lymphocytes, while iNOS expression is increased in alveolar macrophages exposed to isoflurane.[104,105]

Volatile anesthetics inhibit human neutrophil bacterial killing in vitro by reducing production of ROS.[101,106,107] The resulting decrease in ROS suppresses the initial inflammatory response by directly limiting neutrophil-mediated local tissue injury, which itself is responsible for upregulation of endothelial adhesion molecules that recruit more immune cells and launch the systemic immune response. Whereas inhibition of neutrophil ROS production could compromise the immune response, neutrophil ROS release is also a significant contributor to the initial tissue injury that is responsible for reperfusion injury.

Hepatotoxicity

Anesthetic-induced hepatitis was first recognized in the 19th century as a specific risk of chloroform but not ether. Hepatotoxicity has been traced to biotransformation of volatile agents by cytochrome P450 enzymes, producing trifluoroacetylated protein antigens (see Chapter 7).[108] Halothane-induced hepatitis is most common and is classified into two types. Type I occurs commonly (estimates range from 5% to 30% of patients) and results in asymptomatic elevation of serum transaminases 1 to 2 weeks after exposure. No prior exposure is required, and the mechanism of injury is unclear. Leading explanations include a direct toxic effect of halothane itself or an indirect effect as halothane metabolism produces free radicals that interact with cellular components, leading to an autocatalytic peroxidative chain reaction.

Type II halothane hepatitis is much less common (1 in 35,000 halothane anesthetics). An immune-mediated response directed against hepatocytes leads to fulminant hepatitis with high mortality. In most cases there is prior exposure to halothane. Delayed-onset jaundice or postoperative fever is also common. The presentation

can be delayed up to 1 month following anesthesia. Cytochrome P450 2E1 (CYP 2E1) oxidation of halothane produces trifluoroacetyl chloride, which is highly reactive and covalently binds to hepatic proteins, producing trifluoroacetylated protein neoantigens that initiate the immune response responsible for the hepatitis.[109] The trifluoracetylated sites act as haptens to establish an antibody reaction, and serum from patients with type II halothane hepatitis contains antibodies that react with acyl halides bound to liver proteins. Patients also develop autoantibodies against CYP 2E1, but the same autoantibodies have been found in unaffected pediatric anesthesiologists who were routinely exposed to halothane during inhalational inductions, suggesting that these CYP 2E1 antibodies do not have a pathogenic role.[110]

Nephrotoxicity

There are two potential pathways by which volatile anesthetics contribute to nephrotoxicity, either by metabolism leading to inorganic fluoride production or via degradation products, as described earlier for sevoflurane. Fluoride production has a well-documented history of inducing nephrotoxicity, whereas the other degradation product pathways lack reported clinical significance in humans.

Methoxyflurane was withdrawn after reports of severe nephrotoxicity owing to production of inorganic fluoride. A high-output renal failure unresponsive to vasopressin develops in association with serum fluoride concentrations in excess of 50 μM. Sevoflurane is the modern anesthetic with the highest associated serum fluoride concentrations, with some reports of serum levels exceeding 50 μM after as little as 2 MAC hours of exposure, although nephrotoxicity from sevoflurane exposure has not been reported and controlled studies have failed to detect an impact of sevoflurane anesthesia on renal function.[111–113] This is likely secondary to the metabolism of methoxyflurane by cytochrome P450 enzymes 2E1, 2A6, and 3A4 within the kidney, producing fluoride locally within the nephrons themselves. In contrast, there is less renal metabolism of sevoflurane.[114] Sevoflurane metabolism leads to formation of compound A, a nephrotoxic vinyl halide (see Chapters 4 and 7). However, the dose-dependent nephrotoxicity of compound A has been demonstrated only in rats and multiple human studies have not shown evidence of renal impairment.[115]

Malignant Hyperthermia

Malignant hyperthermia is an uncommon inherited genetic disorder of skeletal muscle that can produce a potentially lethal hypermetabolic state after certain triggers (see Chapter 7), which include all the volatile anesthetics, but not N_2O or xenon. A trigger leads to excessive release of Ca^{2+} from intracellular stores, which leads to muscle rigidity and rhabdomyolysis. The associated hypermetabolism increases body temperature, CO_2 production, and O_2 consumption. If left untreated, malignant hyperthermia has an estimated mortality rate of 80%. Mortality is reduced to near 10% by early dantrolene treatment to terminate the hypermetabolic reaction by blocking intracellular Ca^{2+} release and supportive care to manage the sequelae of rhabdomyolysis. A molecular lesion underlying malignant hyperthermia was first traced to a single point mutation in the ryanodine receptor RyR1 in pigs, but it is now known that a variety of mutations, most commonly in RyR1 but also in the α_1 subunit of the dihydropyridine receptor (Cav2.3) and rarely in calsequestrin or sarcoplasmic endoreticular calcium ATPase (SERCA), can lead to this pharmacogenetic reaction (discussed further in Chapter 7).[116]

Postoperative Nausea and Vomiting

All inhaled anesthetics are emetogenic, including the volatile anesthetics, N_2O and xenon; there are no significant differences between the modern volatile ether inhaled agents in their propensity for inducing postoperative nausea and vomiting (PONV). General anesthesia increases the risk of PONV significantly relative to regional anesthesia techniques (see Chapter 34). The incidence of PONV following general inhalational anesthesia involving the use of two triggering agents (opioids and volatile anesthetics) is 25% to 30%. Substituting propofol, which is not emetogenic (but rather is antiemetic) for the volatile anesthetic reduces the relative risk of PONV by 19%, and using nitrogen as a carrier gas rather than N_2O reduces the relative risk by 12%.[117,118]

Metabolic Effects

N_2O can produce megaloblastic bone marrow changes and neurologic complications owing to vitamin B_{12} deficiency (see Chapter 7). The cobalt ion in vitamin B_{12} is oxidized, which inhibits the activity of methionine synthase, which is responsible for conversion of homocysteine to methionine, thymidine, and tetrahydrofolate. Accumulation of plasma homocysteine could in theory increase the risk of perioperative myocardial events, but its clinical significance is unlikely.[119,120]

Unique Features of Individual Agents

Agents With Prominent $GABA_A$ Receptor Activity

Halothane, Enflurane, Methoxyflurane

Halothane, enflurane, and methoxyflurane are no longer used in clinical practice in North America, although halothane is still widely used in the developing world because of its low cost and is on the World Health Association (WHO) Model Lists of Essential Medicines (http://www.who.int/medicines/publications/essentialmedicines/en/) of general anesthetics (along with isoflurane and N_2O). The following information is included for historical interest.

Halothane, a halogenated alkane, is not very pungent and hence is compatible with inhalational induction. Use of halothane is associated with a lower risk of nausea and vomiting than the flourinated methyl ethyl ether agents. Its principal limitations include sensitizing myocardium to catecholamine-induced arrhythmias and occasional, but severe, hepatic necrosis. In pediatric patients, halothane causes bradyarrhythmias. Enflurane, a halogenated methyl ethyl ether, is relatively pungent and high concentrations are associated with seizure-like EEG activity. Enflurane metabolism can release fluoride, which rarely can inhibit renal concentrating ability. Methoxyflurane is a halogenated methyl ethyl ether that provides more analgesia than other volatile agents. However, methoxyflurane produces significant levels of inorganic fluoride because of its high degree of metabolism, and it is associated with high-output renal failure.

Isoflurane

Isoflurane is an isomer of enflurane (see Fig. 11.1), introduced into clinical practice almost simultaneously, with a more favorable

side effect profile. Isoflurane is highly pungent. It is also chemically quite stable.

Sevoflurane

Sevoflurane is a fluorinated methyl isopropyl ether. It is sweet smelling and minimally pungent, and hence well suited to inhalational inductions. Because of its complete fluorination, sevoflurane has a very low blood solubility (among commonly used volatile anesthetics, only desflurane has a lower solubility). It is approximately half as potent as isoflurane. Metabolism of sevoflurane leads to release of inorganic fluoride, similar to enflurane and methoxyflurane. Sevoflurane can form carbon monoxide when exposed to certain dehydrated CO_2 absorbents in an exothermic reaction that can ignite a fire (see Chapter 3). Sevoflurane appears to induce the least cerebral vasodilation of the modern agents, which makes sevoflurane the preferred volatile agent for neurosurgical patients with elevated intracranial pressure.[121]

Desflurane

Desflurane is a fluorinated methyl ethyl ether that is identical to isoflurane save for the substitution of a fluorine atom for the α-ethyl chlorine in isoflurane. The complete fluorination greatly reduces blood solubility and potency, and increases vapor pressure relative to isoflurane, to near atmospheric pressure (672 mm Hg at 20°C). The low boiling point of desflurane requires a specialized pressurized vaporizer (see Chapter 3). Desflurane is the most pungent of the inhaled anesthetics, potentially causing coughing, sialorrhea, breath holding, and laryngospasm. Rapid increases in desflurane concentration cause increased sympathetic activity, with associated tachycardia and hypertension.[85] Desflurane undergoes almost no metabolism, minimizing the risk of hepatitis and nephrotoxicity, but is degraded to carbon monoxide by certain dehydrated CO_2 absorbants (see Chapter 3).

Ether and Chloroform

Diethyl ether (ether) is notable for its high aqueous solubility compared with other anesthetic ethers. Ether is sweet smelling and mildly pungent; although it can be used for inhalational induction, an ether induction is very slow and risks laryngospasm. Ether is still used as an anesthetic in some developing countries because of its low cost and high therapeutic index with minimal cardiac and respiratory depression, but its explosive flammability has eliminated its use in most developed nations. Ether is not a cardiac depressant and maintains the baroreceptor reflex, making it relatively safe in patients with septic shock. Ether has a high incidence of PONV.

Chloroform (trichloromethane) is a sweet-smelling volatile anesthetic that can be used for inhalational induction. Although it was initially developed as an alternative to ether, chloroform was abandoned because of its association with hepatotoxicity and fatal cardiac arrhythmias.

Agents With Prominent NMDA Receptor Activity

Nitrous Oxide

N_2O is a sweet-smelling gas with low solubility, low anesthetic potency (MAC of 104 vol%), and good analgesic properties. Although N_2O is not flammable, it is a powerful oxidizing agent that supports combustion. N_2O is usually used as an anesthetic adjuvant because its low potency prevents it from being used as a sole agent. It does not produce skeletal muscle relaxation. N_2O should be avoided in pregnant patients because of its teratogenic effects. Because of the high delivered concentrations and solubility of N_2O, it has a tendency to rapidly accumulate in closed spaces (see Chapter 3). It is associated with stable hemodynamics in that it does not produce cardiac depression.

Xenon

Xenon is an odorless and nonpungent noble gas with low solubility, leading to rapid induction and emergence, and was first demonstrated to produce human anesthesia in 1951.[122] It is nontoxic and lacks teratogenicity, produces excellent analgesia, and is associated with stable hemodynamics in that it does not produce cardiac depression. Xenon is relatively expensive to obtain and deliver and has low potency (MAC ~ 71 vol%), and hence is not in common use. Systems designed to minimize waste either by recycling or using closed breathing circuits might eventually make its widespread use practical.

Cyclopropane

The cycloalkane cyclopropane is a sweet-smelling and nonpungent gas, and hence is suitable for inhalational induction. Because of the large amount of potential energy attributed to the strain in the carbon-carbon bonds of cyclopropane, it is prone to explosive decomposition when stored in large quantities or when mixed with an oxygen-enriched atmosphere; hence it is no longer in clinical use. Cyclopropane is associated with a high risk for PONV.[123]

Environmental Considerations

All of the inhaled anesthetics except xenon are greenhouse gases with potential global warming effects based on their infrared absorption and atmospheric lifetimes. The impact of the volatile anesthetics is relatively small compared with that of N_2O, which is usually used at higher concentrations and flow rates and is also destructive to the ozone layer.[124,125]

Drug Interactions

Given their multiple mechanisms and pleiotropic effects, it is not surprising that inhaled anesthetics are subject to a number of drug interactions.

Reduction in MAC by Anesthetic Adjuvants

Sedative and hypnotic drugs decrease the MAC of volatile anesthetics (see Chapter 6). GABAergic agents (propofol, benzodiazepines, and barbiturates), opioids, NMDA antagonists (ketamine, N_2O, xenon), and α_2 agonists (dexmedetomidine, clonidine) all reduce the MAC of volatile anesthetics (Table 11.4).[126–129] This fact is exploited in balanced anesthesia to minimize the hemodynamic side effects associated with high-dose volatile agents. The β blocker esmolol appears to potentiate the MAC-reducing effect of opioids.[130]

MAC Additivity

When more than one agent in used, MAC equivalents of anesthetic agents combine additively with no synergism between inhaled anesthetics. For example, the combination of 0.5 MAC desflurane and 0.5 MAC sevoflurane sums to 1 MAC equivalent and thus inhibits movement in response to incision in 50% of subjects. In practice, modern anesthetic vaporizers have a lockout to prohibit

There is a progressive increase in anesthetic potency with age older than 1 year, with minimum alveolar concentration *(MAC)* decreasing by 6.7% with each increasing decade of life. (Modified from Eger EI. Age, minimum alveolar anesthetic concentration, and minimum alveolar anesthetic concentration-awake. *Anesth Analg*. 2001;93:947–953.)

delivery of multiple volatile agents at the same time to reduce the risk of overdose. Hence the most common application of MAC additivity is the delivery of a volatile anesthetic with N_2O.

Synergy With Opioid-Induced Respiratory Depression

The combination of volatile anesthetic and opioid causes synergistic respiratory depression. For example, the combination of alfentanil and sevoflurane leads to more depression of minute ventilation and heart rate than does the summed effect of each drug administered separately.[131]

Factors Influencing MAC

Despite the surprisingly narrow population range in sensitivity to inhaled anesthetics, certain subject-dependent factors consistently influence individual susceptibility to inhaled anesthetics. MAC is increased by anxiety, thyrotoxicosis, and stimulants (e.g., amphetamines). MAC is decreased by hypothyroidism, hypothermia, hypotension, and pregnancy (see Table 11.4), as well as pharmacogenetic factors.

Age

A major physiologic determinant of MAC is age.[27] In humans, MAC increases in the first few months of life, peaks, and then declines approximately exponentially with age, with a drop of 6% to 7% per decade of life (Fig. 11.8). When quoting MAC for an anesthetic, the standard age of 40 years is the usual default unless otherwise specified. Older patients generally require lower absolute doses to obtain equivalent anesthetic effects, so the MAC fraction should be adjusted for age to avoid overdosing.

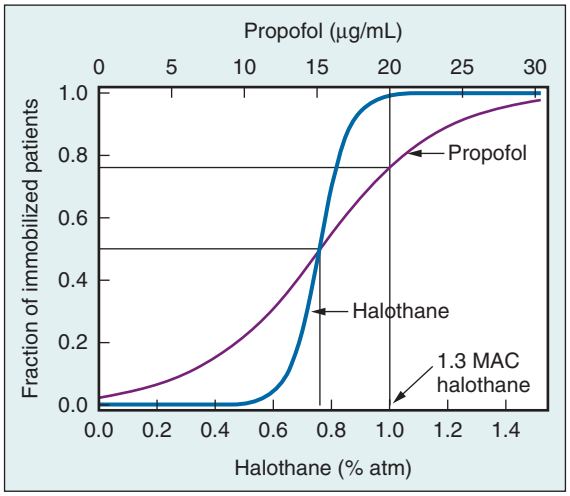
Temperature

The MAC for potent inhaled anesthetics decreases with decreasing body temperature by 4% to 5% per 1°C decrease, with complete elimination of the requirement for anesthesia at 20°C in laboratory mammals. Interestingly, this effect is not observed for N_2O.[27]

Pharmacogenetic Effects on Potency

The population range in anesthetic potency around the median is narrow, with a standard deviation of ~10% of its median value (MAC). This is much narrower than the distribution of effects for most other drugs (Fig. 11.9). Additionally, MAC is roughly the same order of magnitude across multiple species that are widely separated phylogenetically, including *Caenorhabditis elegans* (nematode), *Drosophila* (insect), and vertebrates. This argues that susceptibility to general anesthesia evolved in a very early, likely unicellular, common ancestor and its persistence must contribute to reproductive fitness or is an epiphenomenon of a beneficial trait, although at present it is unclear how.[132]

Given that metabolic factors affect MAC, it should not be surprising that genetic differences can contribute to anesthetic sensitivity. There is a statistically significant difference in MAC among Jews of three different ethnicities (European, Caucasian, and Asian) with the Caucasian population having a 24% higher MAC than the European population.[133] Additional evidence for specific mutations affecting anesthetic requirements originates with the observation that red-haired patients have greater analgesic requirements. Interestingly, 75% of individuals with red hair and pale skin carry at least two inactivating variants of the melanocortin-1 receptor (MC1R).[134] MC1R mediates kappa opioid receptor-induced analgesia, which appears to be more effective in women than men.[134–136] This probably explains the observation that redheads are both more sensitive to thermal pain and relatively resistant to



• **Fig. 11.9** Potency population responses of halothane compared to propofol. The curves are drawn so the minimum alveolar concentration *(MAC)* for halothane *(lower scale)* corresponds to the plasma median effect dose *(EC_{50})* for surgical incision for propofol *(upper scale).* The *vertical lines* indicate the 1.0 MAC and 1.3 MAC (resulting in 99% immobilization) for halothane. At 1.3 times the EC_{50} for propofol, only 75% of subjects are immobilized by propofol *(upper horizontal line).* (Modified with permission from Dilger JP. From individual to population: the minimum alveolar concentration curve. *Curr Opin Anaesthesiol*. 2006;19:390–396.)

subcutaneous lidocaine.[137] A functional consequence of these differences in pain sensation is that redheaded women are more difficult to sedate. Redheaded subjects are less sedated by a plasma-concentration–targeted midazolam infusion than non-redheads.[138] The concentration of desflurane required to suppress movement to a noxious electrical stimulus is significantly higher in redheaded as opposed to dark-haired women; 9 of the 10 redheaded women in the study were either MC1R homozygous or compound heterozygous mutants.[139]

Common Clinical Indications and Considerations

Choices of anesthetic agent for induction and maintenance of anesthesia depend on multiple patient- and procedure-dependent factors. Type and length of surgery, expected disposition, patient comorbidities, and economic factors all figure into the decision-making process for agent selection.

Induction and Maintenance of Anesthesia

Induction of anesthesia with an inhaled anesthetic requires a nonpungent, nonirritating agent, such as halothane, sevoflurane, or N_2O. Because the MAC of N_2O exceeds 1 atm, sevoflurane is frequently used to reliably induce general anesthesia by inhalation owing to its lower solubility—and thus more rapid equilibration—compared with halothane.

Neuroanesthesia and Neuromonitoring

Neuromonitoring can be substantially affected by the potent inhaled anesthetics. Somatosensory evoked potential magnitude is diminished and latency prolonged, such that a balanced anesthetic approach that limits total MAC fraction of inhaled anesthetic is used, depending on the signal quality for the particular patient. Effective communication with the clinical neurophysiology team is important.

Cardiac Anesthesia

Anesthetic preconditioning (see "Emerging Developments: Anesthetic Preconditioning"), which limits the extent of postanesthetic exposure ischemic infarction, represents a potential advantage of using volatile anesthetics in cardiac surgery patients who are predisposed to ischemia. Volatile anesthetics can induce coronary vasodilation. This prompted a theoretical fear of coronary steal, whereby blood flow distal to a fixed, atherosclerotic lesion would decrease when the surrounding, normal vasculature dilated in response to isoflurane, triggering ischemia. Multiple studies have confirmed that this concern is unfounded with isoflurane.[140–142] Interestingly, data from a recent randomized controlled clinical trial suggest patients given sevoflurane anesthesia for surgery requiring cardiopulmonary bypass have better cognitive performance in the immediate postoperative period than patients given propofol.[143] A separate meta-analysis suggested that lower mortality was associated with volatile anesthesia compared with total intravenous anesthesia in cardiac surgery,[144] but no difference was seen in the composite endpoint of prolonged stay in the intensive care unit or death at 1 year in a subsequent multicenter randomized controlled comparison of sevoflurane with propofol anesthesia.[145]

Pediatric Anesthesia

Most pediatric cases are initiated with inhalational induction using sevoflurane, particularly in day surgery cases where the patient arrives without intravenous access. Maintenance of anesthesia can be provided using the agent of choice, adjusting for the higher MAC in children.

Obstetric Anesthesia

The choice of agent for the pregnant patient should take into account safety for the mother and fetus (see Chapter 37). Throughout pregnancy efforts should be maintained to ensure adequate uterine blood flow, so blood pressure should be maintained in a normal range. In the first trimester, teratogenic agents such as N_2O should be avoided. Finally, during delivery, maintenance of uterine tone is essential to achieve adequate postpartum hemostasis. The volatile agents all decrease smooth muscle tone, although this effect might be less with desflurane.[146,147] Hence it has been recommended that volatile agent concentration be minimized, ideally to less than 0.5 MAC with sevoflurane or less than 1 MAC with desflurane, to ensure adequate uterine muscle tone.[147]

Ambulatory Anesthesia

Ambulatory cases represent an increasing fraction of all anesthetic procedures performed. To maximize throughput in busy surgery centers, it is essential to provide a cost-effective anesthetic that minimizes side effects and allows a rapid recovery. Use of the minimally soluble agents desflurane, sevoflurane, and N_2O improves recovery time and drug cost compared with propofol infusion.[148–151] Although the intermediate and late recovery profiles of desflurane, sevoflurane, and propofol are similar for the majority of patients,

desflurane might have the best intermediate recovery profile for obese patients.[152–154] Using a prophylactic antiemetic regimen to minimize PONV when using a volatile anesthetic-based technique can avoid discharge delays.[155,156]

Thoracic Anesthesia

The volatile anesthetics offer several advantages for thoracic surgery, including bronchodilation and decreased airway irritability, as well as the ability to maintain a high fraction of inspired oxygen compared with anesthetics using N_2O. Rapid clearance of volatile anesthetics after the procedure minimizes the need for postoperative ventilation (especially when combined with local anesthetic-based analgesic techniques). Volatile anesthetics cause a dose-dependent attenuation of hypoxic pulmonary vasoconstriction (HPV).[157] This is of particular significance for thoracic surgery given the frequent use of one-lung ventilation, during which HPV diminishes the shunt fraction and hence tends to improve the arterial partial pressure of oxygen (PaO_2). However, the clinical significance of this effect appears low at sub-MAC doses, because anesthetic choice minimally affects the PaO_2 in humans during one-lung ventilation.[158–160] The gaseous anesthetics N_2O and xenon do not affect HPV during one-lung ventilation.

Emerging Developments[161–163]

It has generally been assumed that anesthetics have minimal or no persistent effects after pharmacokinetic elimination. However, general anesthetics act on multiple receptors and second-messenger systems in the CNS with increasing evidence for more durable changes in gene and protein expression, posttranslational modification, and epigenetic effects.[22] On an intermediate timescale, some effects of anesthesia persist after drug clearance even on a cellular level: a single dose of etomidate or a single exposure to isoflurane is capable of increasing the expression of α_5- subunit $GABA_A$ receptors and increasing the tonic-inhibitory current through extrajunctional $GABA_A$ receptors, with resultant impairment of a memory performance task for at least a week after exposure in a murine model.[164] It is therefore not surprising that the assumption that volatile anesthetics have no lasting effects has been called into question. This is particularly true at the extremes of the human life cycle[165] Data are accumulating that neonatal exposure to anesthetics is neurotoxic in animals, although evidence remains uncertain in humans. In older adults, there is concern that anesthesia contributes to postoperative cognitive dysfunction (POCD) and possibly to the progression of neurodegenerative diseases, although again there is a lack of direct evidence in humans.

Developmental Neurotoxicity

Animal data in multiple species indicate that inhaled anesthetics have profound and long-lasting effects when administered during key developmental periods.[166] In the perinatal period, mammals undergo a brain "growth spurt," characterized by a burst of neurogenesis and synaptogenesis. The neural network is then pruned to produce an adult functional architecture through synaptic pruning and programmed cell death, or apoptosis, with ultimate removal of 50% to 70% of neonatal neurons.[167,168] In immature rodents and monkeys at critical developmental periods, exposure to either NMDA antagonist and/or GABAergic agents can lead to increased apoptosis. In rodent and monkey models, anesthetic exposure can lead to long-term cognitive deficits, but translating these findings to humans is difficult because of differences in neurodevelopment and difficulty in comparing duration of exposure.

Although data for some drugs are conflicting, early exposure to most anesthetic agents produces increased apoptosis.[169] NMDA receptor blockade by ketamine in the developing rodent brain causes excessive apoptosis.[170,171] A compelling study of more commonly used drugs exposed postnatal day 7 (P7) rat pups to a cocktail of isoflurane, midazolam, and N_2O at levels sufficient to maintain a surgical plane of anesthesia for 6 hours. The rat pups developed excessive and widespread neuronal apoptosis immediately following exposure. This had persistent behavioral consequences with impairment of hippocampal long-term potentiation and of spatial reference memory as juveniles that lasted into adulthood. Even though isoflurane exposure in isolation led to significant apoptosis, the addition of other agents to the cocktail substantially increased the degree of apoptosis, suggesting that drug combinations might be more detrimental.[172]

The increased neuronal death with additional agents from other drug classes suggests that the significant event might be the pharmacologically induced coma itself rather than the particular agent used to achieve the anesthetic state. Consistent with this hypothesis, equipotent exposure of neonatal mice to desflurane, isoflurane, and sevoflurane produced similar increases in apoptotic cell death.[173] Disruption of neurotrophic factor secretion in the developing nervous system by anesthetic suppression of spontaneous activity might underlie anesthetic neurotoxicity.[174] At sensitive ages (P0-14 rats), the chloride gradient is reversed compared to adults owing to developmental changes in expression of the potassium-chloride cotransporter. Hence, in the immature brain the increase in chloride permeability associated with $GABA_A$ receptor activation leads to depolarization of neurons, with resultant excitation and possibly excitotoxicity (however, this does not explain the neurotoxic effect of perinatal ketamine). A significant number of P7 rats have seizures with sevoflurane anesthesia, and postanesthetic apoptosis that could be mitigated by bumetanide, a N^+-K^+-$2Cl^-$ cotransporter 1 inhibitor, which suggests that apoptosis after anesthesia involves excitotoxicity rather than withdrawal of trophic factors.[175] Subsequent investigations have found other interventions to mitigate long-term cognitive deficits after neonatal anesthesia, including cotreatment with nitric oxide synthase inhibitors,[176] synthetic ROS scavengers,[177] and even post-exposure environmental enrichment.[178]

Despite robust laboratory evidence of increased apoptosis after anesthesia in neonatal animal models, the clinical significance of these observations remains controversial. It remains unclear what the minimum required exposure is for a significant effect on neurodevelopment. Cognitive deficits have been demonstrated in rhesus monkeys after exposure to 24 hours of ketamine anesthesia at P5-6,[179] yet a smaller exposure of 3 hours at P5 demonstrated no neurodegeneration.[180] Significant apoptotic and necrotic cell death occurred in neonatal monkeys exposed to ketamine for 9 hours or isoflurane for 5 hours.[180,181] Anesthetic exposure must occur during the critical period of neurogenesis and synaptogenesis to have significant apoptotic sequelae and it is unclear when this period is in humans. The rat peak critical period for anesthesia exposure approximates the 20th week of gestation in humans, whereas the rhesus critical period approximates the 26th week of gestation in humans.[182] Translation to humans suggests that anesthetic neurotoxicity is likely most significant for the premature human fetus rather than term neonates or infants.

A number of retrospective analyses have examined the possible association between exposure to general anesthesia (and by necessity

with surgery) at an early age with delayed neurocognitive deficits in children. In one series, children exposed to multiple anesthetics before the age of 4 years had twice the incidence of learning disability diagnoses later in life.[183] Another retrospective cohort study found that children who underwent hernia repair before 3 years of age were more than twice as likely as controls to have a developmental or behavioral disorder diagnosis.[184] Because of the retrospective nature of these studies, the relative contributions of surgery, anesthesia, and comorbid conditions and other potentially confounding factors remain undefined.

Recently investigations are beginning to move beyond just retrospective data in humans. Thus far, prospectively collected data appear reassuring regarding single, limited exposures to anesthesia. The PANDA (Pediatric Anesthesia and Neurodevelopment Assessment) study was a multisite, sibling-matched cohort study that compared retrospectively identified siblings exposed to general anesthesia before 36 months of age to unexposed control siblings who were then followed prospectively for neurocognitive deficits. Intelligence quotient assessed at approximately 10.5 years of age did not differ significantly between exposed and unexposed siblings.[185] The GAS (General Anaesthesia compared to Spinal anaesthesia) study is a multisite randomized clinical trial that assigned infants younger than 60 weeks postgestational age to receive either awake-regional anesthesia via spinal or sevoflurane general anesthesia to compare cognitive function at 5 years of age. Only the secondary outcome of 2-year cognitive assessment with the Bayley Scales of Infant and Toddler Development III has been reported, with no evidence of adverse neurodevelopmental outcomes with an average of about 1 hour of sevoflurane exposure.[186] Further delineation of possible early anesthetic exposure phenotypes in humans is expected to come from the ongoing MASK (Mayo Anesthesia Safety in Kids) study, which is following a cohort of all children born in Olmsted County, Minnesota, between 1994 and 2007 to compare neuropsychological testing in children with no, single, or multiple anesthetic exposures.[187]

Anesthesia and Neurodegenerative Disease

The existence and prevalence of postoperative cognitive dysfunction (POCD) in older adults were established in the International Study of Post-Operative Cognitive Dysfunction,[188] although the definition has continued to evolve, making interpretation of the literature difficult. Although short-term cognitive dysfunction was associated with multiple comorbid medical conditions, the predominant risk factor for prolonged cognitive decline (at 6–12 months) was advanced age. Some groups have responded with doubts that POCD is even an actual entity,[189] given that a recent retrospective cohort study found that long-term cognitive decline could be independently attributed to illness or surgery with neither apparently speeding progression to dementia. However, patients who had initial dementia declined more rapidly over the course of the study than those who did not.[190] Research to determine what role, if any, anesthesia plays in POCD is ongoing, with suggestive laboratory models finding parallels between neurodegenerative disorders and effects of anesthesia exposure on neuropathologic mechanisms.

POCD could reflect altered drug responses, loss of functional reserve, or cumulative effects of chronic disease over time. With aging, neurogenesis and synaptogenesis slow, the total number of neurons decreases, and potentially toxic by-products accumulate. These processes gradually deplete physiologic reserves, potentially increasing brain vulnerability to insults, including exposure to perioperative stressors. Current hypotheses of POCD posit roles for direct toxic effects via alterations in Ca^{2+} homeostasis, systemic inflammatory effects secondary to surgical insults leading to neuroinflammation, age-sensitive suppression of neuronal stem cell function, and/or acceleration of ongoing endogenous neurodegenerative processes such as production of aggregated amyloid beta (Aβ) peptide oligomers and tau hyperphosphorylation, thereby unmasking preexisting pathophysiology.[191–196]

Alzheimer disease (AD) is a neurodegenerative process resulting in diffuse atrophy of the cerebral cortex characterized neuropathologically by plaques composed of Aβ and accumulation of neurofibrillary tangles made up of hyperphosphorylated tau protein.[197] Research has focused on the toxic effects that result from selective proteolysis of amyloid precursor protein (APP) into Aβ peptide oligomers.[198] Aβ formation and apoptosis are increased in rodent brains exposed to isoflurane, isoflurane with N_2O, sevoflurane, and desflurane with hypoxia.[196,199–202] However, not all data implicate a postanesthetic Aβ mechanism for POCD. In a transgenic mouse model of AD, increased production of amyloid plaque had no associated cognitive deficits after daily exposure to halothane or isoflurane, whereas wild-type mice developed cognitive impairment after repeated isoflurane exposure.[203] Aβ might not be the only neurodegenerative component increased by anesthetic exposure, in that multiple anesthetic agents appear to promote hyperphosphorylation of the microtubule-associated protein tau, either with hypothermia or normothermia.[204,205] Interpreting these data is further complicated in that the choice of anesthetic exposure duration and total dose vary, with several studies suggesting a potential neuroprotective preconditioning effect with lower exposures.[206–208]

Neuroinflammation and Cognitive Dysfunction

Systemic inflammation resulting from a surgical insult could lead to neuroinflammation and resultant postoperative delirium, which could possibly progress to POCD. Adult rats undergoing splenectomy with neuroleptanesthesia had impaired cognitive function on postoperative days 1 and 3 compared with rats anesthetized without surgery (which were indistinguishable from nonanesthetized controls). Increased IL-1β expression in hippocampus suggests that systemically triggered neuroinflammation contributes to cognitive impairment.[192] In a similar model, memory dysfunction after surgery was mitigated both by nonspecific immunosuppression with minocycline or by pretreatment with an IL-1 receptor antagonist, and was less prominent in IL-1 receptor knockout mice.[209] This IL-1 response appears to be mediated by tumor necrosis factor α (TNFα) as peripheral TNF-α blockade attenuates both the neuroinflammatory response mediated by IL-1 and its associated POCD, suggesting that pretreatment with an anti-TNF antibody might prevent POCD. This neuroinflammatory response appears to be more prominent in older mice, consistent with POCD in humans.[210,211] However, anesthesia might also contribute to the neuroinflammatory response, as increased levels of TNF-α, IL-6, and IL-1β have been observed following isoflurane anesthesia alone. This increase was more marked in transgenic AD model mice, suggesting that neuroinflammation might contribute to the increase in neurodegenerative markers after anesthesia.[212] Finally, intervening to prevent high-mobility group box 1 protein from activating and trafficking circulating bone marrow–derived macrophages to the brain prevented postoperative neuroinflammation and memory decline in a mouse model.[213]

Despite animal data linking AD pathophysiology to anesthesia exposure, data in humans are contradictory. There was no significant

difference in mean cumulative duration of general anesthesia between control and AD patients and no association between the number of surgical operations and the risk of AD, or between anesthesia exposures over a 1- to 5-year window preceding the onset of AD.[195,214] However, an association between cumulative anesthesia exposure before age 50 years and earlier onset of AD suggests that the time horizon for accumulating effects might be quite long.[195]

Although clinical and animal model data suggest an association between anesthesia, surgery, and detrimental cognitive changes in the aged brain, the data do not yet support a claim of causation.[215] Some investigators have found an association of postoperative delirium, which is associated with POCD, with very low BIS values (<20), but POCD incidence was not reported.[216] Perhaps the strongest evidence to date that anesthetic technique could be causally linked to POCD comes from a prospective cohort study with a nested, randomized controlled intervention trial that used intraoperative BIS and cerebral oxygen saturation monitoring in the intervention arm and showed a reduction in mild and moderate POCD incidence in the intervention arm.[217] This will need to be confirmed in multicenter prospective clinical trials to determine the contributions of anesthesia, surgery, and illness to cognitive dysfunction if we are to resolve the association between anesthesia and POCD and progression of neurodegenerative disease.

Inhaled Anesthetic Sensitivity: Triple Low

One of the major questions with adverse cognitive outcomes after anesthesia is whether the stress of the perioperative period is revealing patients with particular vulnerability to anesthetics who might benefit from depth of anesthesia monitoring. A substudy of the B-Unaware trial (see Chapter 3) found no evidence of harm associated with cumulative duration of BIS values less than 45 in noncardiac surgery,[218] though there was association with mortality in cardiac surgery.[219] Perhaps most concerning in this regard, a retrospective analysis of the Cleveland Clinic database found that the conjunction of low bispectral index (BIS < 46), low blood pressure (defined, rather liberally, as mean arterial pressure < 87), and low administered anesthetic dose (MAC fraction < 0.56), which the investigators labeled "triple low," was associated with a threefold increased in 30-day mortality.[220] Analysis of an independent database found that accounting for patient disease severity eliminated any association of mortality with duration of the triple low condition.[221] At present it does not appear that the triple low is a consistent predictor of high mortality after surgery, but further exploration is warranted.

Anesthetic Preconditioning

Volatile anesthetic exposure before induction of myocardial ischemia decreases severity of the ensuing ischemia-reperfusion injury, a property known as *anesthetic preconditioning*. Isoflurane concentrations as low as 0.25 MAC confer protection, although higher concentrations might have greater efficacy.[222] Preconditioning appears to involve production of ROS during the anesthetic exposure, as bracketing the anesthetic exposure with ROS scavengers attenuates the anesthetic preconditioning effect.[223] A similar phenomenon known as *ischemic preconditioning* has been observed whereby brief episodes of ischemia minimize the ischemia-reperfusion injury sustained from a subsequent, more profound episode of ischemia. (Indeed, a criticism of numerous early reports is the failure to report avoidance of hypotension induced by the anesthetics.) Although exposure to isoflurane and to brief episodes of ischemia upregulates several common cell defense signaling pathways and genes, ischemic and anesthetic preconditioning appear to have distinct phenotypes.[224] The magnitude of the anesthetic preconditioning effect diminishes with age in animal models.[225] Exposure to anesthetic agents after the ischemic event also diminishes ischemia-reperfusion injury, an effect known as *anesthetic postconditioning*. It appears that anesthetic preconditioning and postconditioning have similar effects and are not additive.[226] In addition to cardiac protection, anesthetic preconditioning by volatile anesthetics has been demonstrated in other organs as well, including brain, kidney, and lung.[227]

Immunomodulation and Cancer

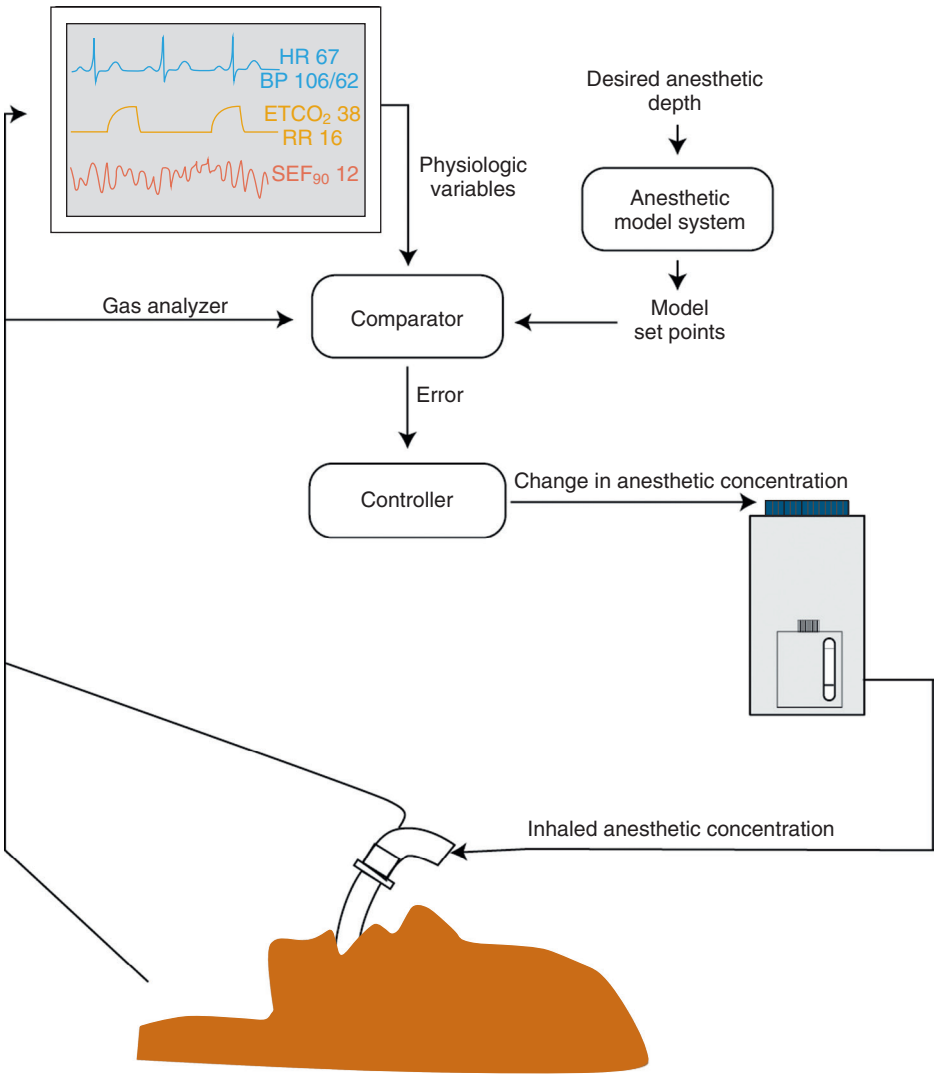
Volatile anesthetics suppress the activity of natural killer (NK) cells.[228] Significant suppression of NK cell function in the perioperative period has been associated with increased cancer patient mortality.[228–231] This argues that volatile anesthetics might increase the risk of retained tumor metastasis owing to reduced immune surveillance by NK cells, but on balance the effect is significantly smaller than the immune suppression triggered by the stress response to surgery without general anesthesia.[96] There is currently insufficient evidence to avoid volatile anesthetics for cancer patients. Yet anesthesiologists should remain aware of their possible contributions to postoperative immune function, particularly in patients who are immunosuppressed at baseline.

Closed-Loop Anesthetic Delivery

Anesthetic delivery systems continue to evolve beyond those based on population pharmacokinetic models. Substantial investigator interest has focused on developing "closed-loop" anesthetic delivery, where anesthetic delivery is titrated automatically via an algorithm based on real-time physiologic information (Fig. 11.10). (This titration to individual patient responsiveness contrasts with target-controlled drug delivery that attempts to replicate a target serum concentration using a population model of pharmacokinetics.) Principal challenges in the development of meaningful closed-loop technology focus on patient safety, user interface, and regulatory concerns.

Key safety concerns in automated anesthetic delivery include graceful degradation without harming patients, with a transparent and predictable approach that offers a meaningful advantage to the anesthesiologist in reducing cognitive workload. Although automated closed-loop systems, like a thermostat, may be more reliable than a human in maintaining measured variables within a target range,[232] they will not reduce the need for vigilance within an operative environment.[233]

The development of closed-loop technology has been aided on the regulatory front by the introduction in 2007 of an international standard for physiologic closed-loop control[234] and subsequent U.S. Food and Drug Administration engagement to develop a consistent regulatory perspective focused on the risk-benefit ratio of the technology.[233] Closed-loop control of inhalational anesthetics based on maintaining an end-tidal concentration has been in clinical use for more than a decade outside the United States.[235] Within the United States, computer-assisted personalized sedation using propofol was approved in 2013 in the form of the Sedasys system, developed and marketed by Johnson and Johnson. Although strictly speaking the system was not closed loop, the propofol delivery was kinetic model based and semiautomated using feedback signals from the monitoring package. Although the system performed as



• **Fig. 11.10** A closed-loop anesthesia system. A closed-loop system depends on a feedback controller that automatically changes anesthetic delivery based on real-time feedback about a targeted anesthetic state. In this theoretical system, an anesthesiologist interacts with the system by choosing a desired anesthetic depth. This value is used to generate desired model set points for physiologic variables that are compared to the currently measured vital signs from the patient (such as heart rate *[HR],* blood pressure *[BP],* respiratory rate [RR], electroencephalographic [EEG] waveforms, and values derived from the EEG, such as spectral edge frequency [SEF90]). A comparator computes the difference between the current and targeted vital sign values and incorporates information about the current delivered drug value (from the gas analyzer) to derive an integrated error signal. This error signal is then fed to a controller that changes the vaporizer (and potentially fresh gas flow) to change the delivered anesthetic concentration to move the vital signs and delivered anesthetic toward desired targets. Subsequent measurements refine the anesthetic delivery rate to converge on the target physiologic state. *$ETCO_2$,* End-tidal carbon dioxide.

designed,[236] the device was eventually withdrawn because of poor market uptake.

Accelerated Emergence

Recent work has begun to focus on whether unconsciousness caused by volatile anesthetics can be pharmacologically antagonized, offering a pharmacologic reversal agent to speed emergence, also termed active emergence or "reanimation." The most promising work to date has focused on the norepinephrine-dopamine reuptake inhibitor methylphenidate. Motivated by the well-established observation that stimulants increase MAC requirement, Solt and colleagues have demonstrated that emergence can be actively induced in a rat model at a steady state of isoflurane anesthesia,[237] with demonstration of cognitive recovery in addition to recovery of a righting reflex. (Note that, because the emergence from anesthesia happens at a lower end-tidal anesthetic concentration than induction,[238] this is not a foregone conclusion.) This effect appears to result from the dopaminergic effect of methylphenidate as droperidol blocks the effect[237] and optogenetic stimulation of the dopaminergic population in the ventral tegmental area can produce the same behavioral effect.[161] Early results suggest that the parabrachial nucleus may also offer a target for reanimation from isoflurane anesthesia.[239]

Key Points

- Inhaled anesthetics as single agents provide all of the essential features of general anesthesia, including amnesia, unconsciousness, and immobility. Each of these components results from agent-specific actions on distinct neuronal pathways in the central nervous system.
- The characteristic immobilizing effect of volatile anesthetics involves a site in the spinal cord. Amnesia and unconsciousness involve incompletely understood supraspinal mechanisms.
- The principal effects of inhaled anesthetics on the nervous system involve alterations in synaptic transmission, the mechanism for chemical transmission between neurons.
- The precise mechanisms by which inhaled anesthetics produce each of their principal actions have not been fully elucidated despite a number of promising candidate molecular targets.
- The physicochemical nature of the typical anesthetic binding site is hydrophobic and amphipathic.
- In contrast to intravenous anesthetics, inhaled anesthetics can act at a number of membrane-bound ion channels and receptors at clinically relevant effect site concentrations. Volatile anesthetics have potentiating effects on inhibitory $GABA_A$ and glycine receptors and K^+ channels, and inhibitory effects on excitatory Na^+ and Ca^{2+} channels. The gaseous anesthetics nitrous oxide and xenon have predominant NMDA-type glutamate receptor blocking effects.
- Inhaled anesthetics have a diverse range of clinically significant effects on multiple organ systems, both beneficial and potentially adverse. Potentially beneficial effects include organ protection, while adverse effects include respiratory and cardiovascular depression.
- Inhaled anesthetics have agent-specific pharmacologic, pharmacokinetic, and side effect profiles that determine their optimal clinical applications based on patient and procedure specific applications.
- Anesthetic-induced neurotoxicity occurs in animal models at critical periods in early brain development with unclear clinical significance.

- Cocaine
- Amphetamines

Emerging Developments
- Ketamine in the Treatment of Depression

Historical Perspective

In 2016, 395 million prescriptions for drugs used in the treatment of mental health were dispensed in the United States. A further 387 million prescriptions were dispensed for other neurologic disorders. Combining these two therapeutic classes, neuropharmacologic agents represent the most prescribed family of drugs, exceeding antihypertensives (721 million), antinociceptives (460 million), antibacterials (270 million), lipid regulators (264 million), and diabetes treatments (224 million).[1] Antidepressants are the most frequently used drugs in adults aged 18 to 44 years and are taken by 13% of persons aged 20 years and older.[2,3] Neuropharmacology also includes a heterogeneous and expanding collection of antipsychotics, mood stabilizer agents, psychostimulants, and drugs used in the treatment of epilepsy, Parkinson disease, and addiction. Considered together, drugs used to treat mental health and neurologic disorders are encountered by anesthesiologists as a matter of routine daily practice. They have diverse effects on neuronal systems, including those that are the principal targets of anesthetic agents, and many are associated with significant unwanted actions on central and peripheral signaling across broad transmitter classes. Many alter hepatic cytochrome P450 isoenzyme (CyP)

activity and thus can have significant drug interactions by affecting metabolism of other agents. The potential impact of psychopharmacologic drugs on perioperative physiology is enormous. In addition to altering the central nervous system (CNS) response to sedative and hypnotic agents, they can alter autonomic responsiveness, cardiac conduction, bleeding, seizure potential, the endocrine response to stress, and multiple other physiologic variables that fall under the purview of anesthesiology. Similar considerations apply to the anticonvulsant and anti-parkinsonian therapeutic classes. Finally, drugs of abuse, with wide-ranging short- and long-term effects on the CNS, have critically important implications for the safe delivery of anesthesia in both the acutely intoxicated and addicted patient.

Because the core aspects of clinical practice in both psychiatry and neurology are distinct from those of anesthesiology, and because many psychopharmacologic agents have emerged only very recently, anesthesiologists might have an incomplete baseline awareness of the actions and adverse effects associated with these drugs and be less likely to encounter timely updates. This chapter presents a focused introduction to most of the neuropsychiatric drugs encountered in perioperative patients. An exhaustive description can be found in dedicated reference texts.[4]

Antidepressant Drugs

Tricyclic Antidepressants

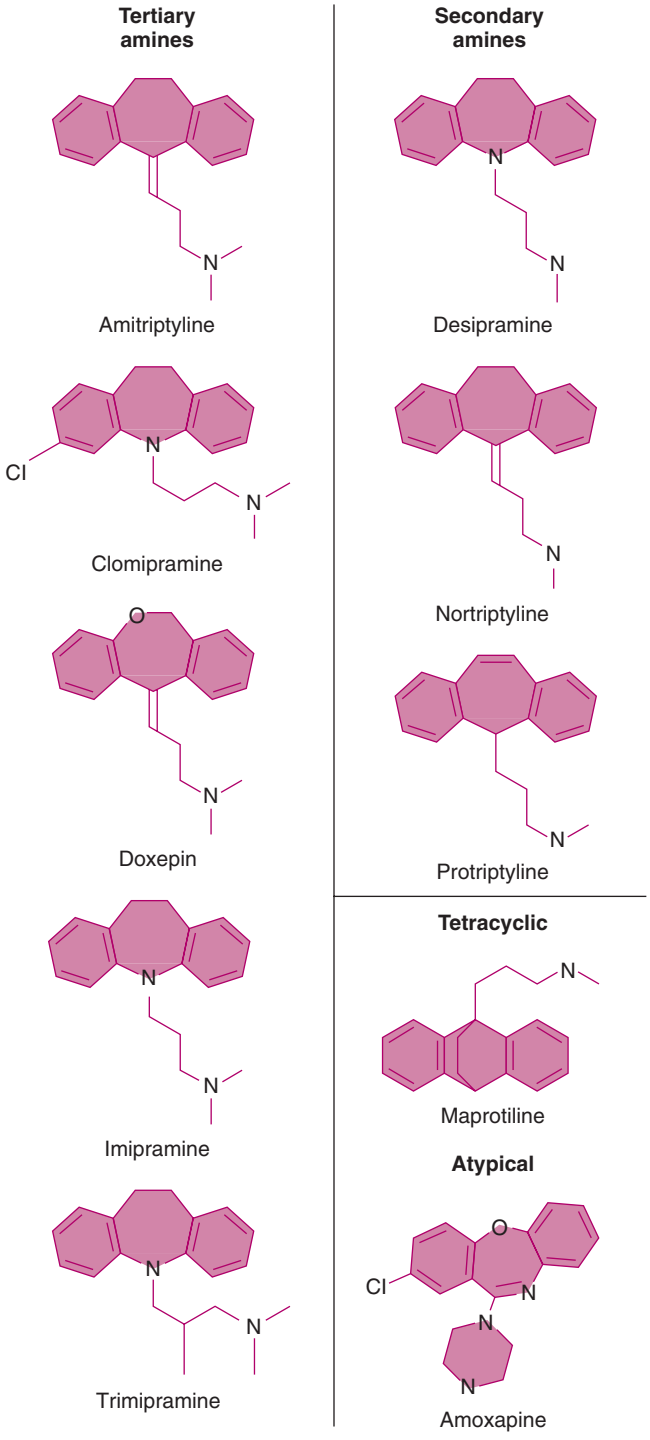
History

The iminodibenzyl derivatives were initially investigated in humans in the 1950s for their sedative and antihistaminic properties. The sedative properties of the archetypal drug imipramine proved to be of little benefit in the treatment of agitated patients, but serendipitously it was noted to relieve the symptoms of depression.[5] Subsequently, several other tricyclic compounds were developed, and the class remained the first-line treatment for depression until the rapid expansion in use of selective serotonin reuptake inhibitors (SSRIs) in the 1990s. Early advances in the neuropsychopharmacology of depression—including the importance of the serotonin and noradrenergic pathways—owed much to the study of this class of compounds.

Basic Pharmacology

Structure-Activity

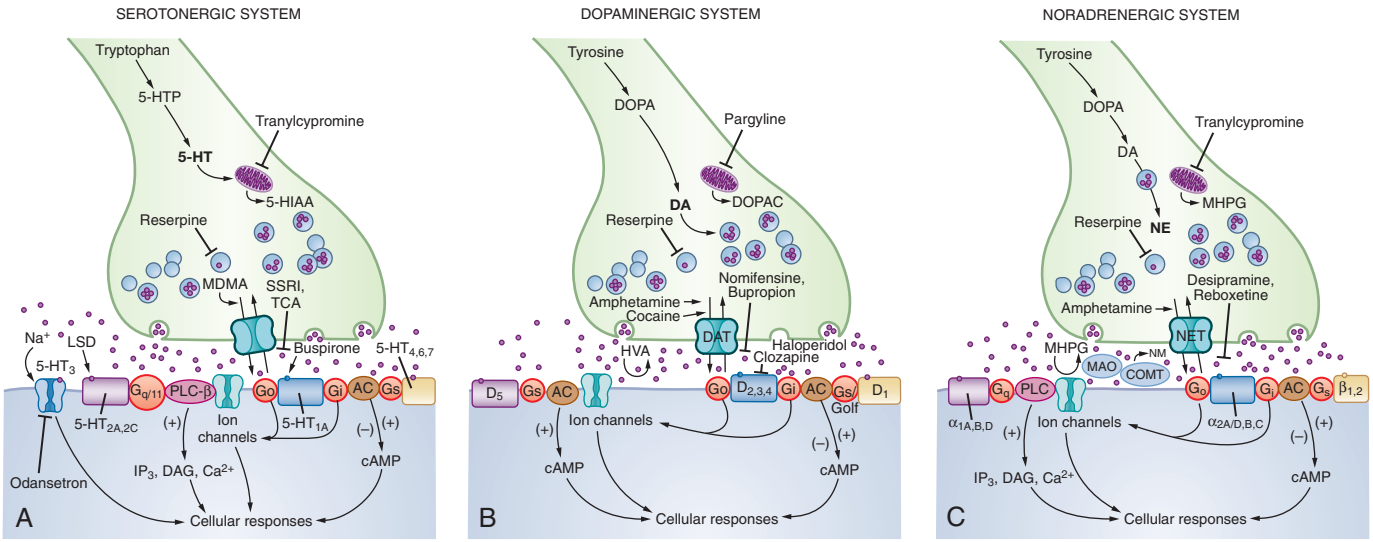
The tricyclic antidepressants are named because of their central three-ring complex with a single side chain. The class is then further divided into two subgroups on the basis of the side chain: the *tertiary amines* have two methyl groups at the end of the side chain, whereas the *secondary amines* possess a single methyl group (Fig. 12.1). Although these compounds block both the serotonin transporter and the norepinephrine transporter, the relative potency for each is largely determined by the nature of the side chains. The tertiary amines have dominant effects on serotonin reuptake, whereas the secondary amines have greater potency on norepinephrine reuptake.[6] Amoxapine is a structurally unique tricyclic antidepressant derived from the antipsychotic loxapine; it is characterized by potent inhibition of norepinephrine reuptake and dopamine receptor block by the metabolite 7-hydroxy-amoxapine.[7] Maprotiline is unique in possessing a four-ring central structure and is referred to as a tetracyclic or heterocyclic. It possesses the secondary amine side chain and predictably has dominant effects on norepinephrine transport.



• **Fig. 12.1** Chemical structure of the tricyclic and tetracyclic antidepressants.

Mechanism

The antidepressant effects of the tricyclic drugs are mediated by effects on two monoaminergic systems—serotonin and norepinephrine—although it is not clear to what extent this implicates specific abnormalities of serotonin and norepinephrine signaling and pharmacology in the biochemical pathogenesis of depression (Fig. 12.2). Although modulation of reuptake occurs rapidly, clinical benefit is not seen until several weeks of treatment,



• **Fig. 12.2** The serotonergic, dopaminergic, and noradrenergic systems in psychopharmacology. A, In the serotonergic system, L-tryptophan is converted to 5-hydroxytryptophan *(5-HTP)* and then to serotonin *(5-HT).* Presynaptic regulation occurs through somatodendritic 5-HT_{1A} and 5-$HT_{1B,1D}$ autoreceptors (not shown). Binding to G-protein–coupled receptors (G_o, G_i, etc.) that are coupled to adenylyl cyclase *(AC)* and phospholipase C-β *(PLC-β)* results in a cascade of second-messenger and cellular effects. Reuptake occurs via the 5-HT transporter (5-HTT), after which 5-HT is either repackaged into vesicles or metabolized to 5-hydroxyindolacetic acid *(5-HIAA)* by mitochondrial monoamine oxidase (MAO). The SSRIs and TCAs block reuptake at the 5-HTT. Tranylcypromine inhibits mitochondrial MAO. Reserpine, an antipsychotic, causes depletion of storage vesicles. Buspirone is a presynaptic and postsynaptic partial 5-HT_{1A} agonist. Lysergic acid diethylamide *(LSD)* likely interacts with numerous 5-HT receptors, while MDMA ("ecstasy") alters 5-HTT function. B, In the dopaminergic system, L-tyrosine is converted to L-dihydroxyphenylalanine (L-DOPA), and then to dopamine *(DA).* Presynaptic regulation occurs through somatodendritic and nerve terminal D_2 receptors (not shown). Reuptake is via the dopamine transporter *(DAT),* after which DA is either sequestered into vesicles or metabolized to dihydroxyphenylalanine *(DOPAC)* by mitochondrial MAO. DA can also be degraded to homovanillic acid *(HVA)* through synaptic MAO and catechol-*O*-methyltransferase *(COMT).* Reserpine causes depletion of storage vesicles. Pargyline inhibits MAO selectively in DA neurons. Haloperidol is a D_2 antagonist, and clozapine is a nonspecific D_2/D_4 antagonist. Bupropion interacts with the DA system, but its exact action is unclear. Cocaine and amphetamine alter DAT function. C, In the noradrenergic system, L-tyrosine is metabolized through L-DOPA and DA to norepinephrine *(NE).* Presynaptic regulation occurs through somatodendritic and nerve terminal α_2-adrenoreceptors (not shown). Reuptake occurs via the NE transporter *(NET),* after which NE is either sequestered into vesicles or metabolized to 3-methoxy-4-hydroxyphenylglycol *(MHPG)* by mitochondrial MAO and aldehyde reductase. Metabolism also occurs synaptically to MHPG via MAO or to normetanephrine (NM) via COMT. Reserpine causes depletion of NE in storage vesicles. Tranylcypromine inhibits mitochondrial MAO. The selective NE reuptake inhibitor and antidepressant reboxetine and TCA desipramine interfere with the reuptake of NE. Amphetamine facilitates NE release by altering NET function. *cAMP,* Cyclic adenosine monophosphate; *DAG,* Diacylglycerol; *IP3,* inositol-1,4,5-triphosphate; *NMDA,* N-methyl-d-aspartate; *SSRI,* selective serotonin reuptake inhibitor; *TCA,* tricyclic antidepressant. (Modified from Schatzberg AF, Nemeroff CB. *The American Psychiatric Publishing Textbook of Psychopharmacology*. 4th ed. Arlington, VA: American Psychiatric Publishing; 2009.)

suggesting that downstream changes in gene expression and neuroplasticity are critically involved. The decreased uptake initially causes feedback inhibition via presynaptic 5-HT_{1A} autoreceptors, but this is followed by desensitization and a return to normal firing rate after 2 weeks.[8] Postsynaptic 5-HT_{1A} receptors become sensitized, while antagonism of postsynaptic 5-HT_2 receptors further increases the effects of serotonin.[9] In contrast, presynaptic α_2-receptors do not desensitize, and the firing rate of noradrenergic neurons remains inhibited throughout treatment.[10] The noradrenergic mechanism likely includes complex modulatory effects on the expression of postsynaptic α_1-, α_2-, and β-adrenergic receptors and on their second-messenger systems. Tricyclic antidepressants also have variable antagonist activity at 5-HT_6, 5-HT_7, N-methyl-D-aspartate (NMDA)-type glutamate, H_1- and H_2-histaminergic, and muscarinic acetylcholine receptors. They also have variable agonist activity at μ_1-opioid receptors.[11] Accumulating evidence also suggests that the antidepressant effects of the tricyclics, and other classes of antidepressants, may involve transduction by the neurotrophin brain-derived neurotrophic factor (BDNF) and the tropomysin-related kinase B (TrkB) receptor.[12,13]

Metabolism

Metabolism is almost exclusively hepatic and dominantly involves either hydroxylation of the ring structure or demethylation of

the side chain. The tertiary amines are demethylated to active secondary amines (e.g., imipramine to desipramine), which incurs an increase in noradrenergic activity. Many of the hydroxylated metabolites are also active. The principal CYP) isoenzymes involved are 2D6, 1A2, 3A4, and 2C19. Variability in metabolism and plasma levels can be dramatic, owing to both exogenous modulation of the CYP system and to genetic polymorphisms that occur in up to 20% of Asian and 10% of Caucasian and African black populations.[14,15]

Clinical Pharmacology

Pharmacokinetics

The tricyclic antidepressants are rapidly absorbed from the small intestine and mostly attain peak plasma levels in 2 to 8 hours. They are highly protein bound (>90%) and lipophilic, with large volumes of distribution up to 60 L/kg. Bioavailability is variable, with on average about 50% to hepatic first-pass metabolism. Plasma half-life is longer than 24 hours for most drugs (the exception being amoxapine), allowing for once-a-day dosing. However, variation is significant and determined largely by genetic and phenotypic variability. The daily dose is thus not a reliable determinant of steady-state plasma levels. Further, a relationship between plasma concentration and therapeutic response, while demonstrated for some drugs, has not been established across the entire class.[16] Monitoring of plasma levels, though often suggested, remains controversial because of the lack of validated interpretation studies. The level of recommendation for plasma monitoring is highest for amitriptyline, nortriptyline, clomipramine, and imipramine.[17] Dosing is often started low and increased gradually based on therapeutic response, with monitoring of plasma levels reserved for patients suspected to be at the extremes of rapid and slow metabolizers.

Pharmacodynamics

Therapeutic Effects. Tricyclic antidepressants have demonstrated efficacy in the treatment of major depression. Response rates for patients completing treatment with imipramine, the most studied drug, exceed 65%. However, substantial caution must be implied in the interpretation of efficacy studies, as the response to placebo is ~40%; a recent Cochrane review suggests that compared with placebo, the median number needed to treat was 9.[18] They are also effective for maintenance therapy, with up to 80% of patients successfully maintained for 3 years.[19] Relative to other classes of antidepressants, the tricyclics might have an efficacy advantage in patients with severe or endogenous depression, or in those who are hospitalized, although this is not clearly established. Low doses (75–100 mg) of tricyclics are as effective as higher doses.[20] They have no particular advantage over other agents in the treatment of anxious, atypical, psychotic, bipolar, or late-life depression. Because of its high serotonergic activity, clomipramine is effective and is used for the treatment of obsessive-compulsive disorder.[21] The tricyclics are also used in panic disorder. Desipramine is effective in the treatment of attention deficit/hyperactivity disorder,[22] but its use is contraindicated in children because of reports of sudden cardiac death. Tricyclics are also widely used in the treatment of chronic and neuropathic pain syndromes (see Chapter 19), and are more effective than the SSRIs in this regard. A recent Cochrane review showed a number-needed-to-treat of 3.6 and a relative risk of 2.1 for at least moderate relief of neuropathic pain with tricyclic antidepressants.[23] The effects appear independent of those on depression, and generally occur at lower doses, consistent with a distinct underlying mechanism, with antinociceptive actions mediated by effects on descending serotonin and norepinephrine spinal pathways.[24]

Adverse Effects. The most common side effects associated with tricyclic antidepressants result from their antimuscarinic and antihistaminic actions. Amitriptyline and clomipramine have the greatest antimuscarinic potency and desipramine the lowest. Dry mouth, urinary hesitancy, decreased gastric motility, and blurred vision are relatively common. Ocular crisis can be precipitated in patients with narrow-angle glaucoma. H_1-histaminic blockade results in sedation. Confusion and delirium are dose-dependent and result from the combination of anticholinergic and antimuscarinic activity. Patients with preexisting dementia or psychotic depression are especially at risk, and the incidence is highest with amitriptyline. There is also a dose-dependent risk of seizure, although the incidence is poorly defined. It is less than 1% across the drug class if plasma level monitoring is appropriately used.[25] A recent study of more than 150,000 patients found the incidence of seizure to be no greater than in nonusers of antidepressants.[26] Nonetheless, use of these drugs in patients with elevated seizure risk is not advisable. The overall incidence of CNS toxicity is approximately 6%.[27] Tricyclic antidepressants cause orthostatic hypotension, especially in patients receiving antihypertensive therapy, and also cause a persistent increase in heart rate. They inhibit sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) and act like class Ia (quinidine-like) antiarrhythmics by stabilizing excitable membranes and delaying His bundle conduction, and so must be used cautiously in patients with a prolonged QTc interval. In overdose, sudden death can occur from cardiac arrhythmia at doses of only 10 times the therapeutic dose.[28] Largely because of this arrhythmia risk, the mortality associated with tricyclic overdose is approximately 15 times that associated with SSRI overdose[29] a significant factor in the rapid acceptance of SSRIs as first-line therapy for treatment of depression.

Drug Interactions

The complex effect of tricyclic antidepressants on presynaptic and postsynaptic noradrenergic signaling can alter the response of patients to sympathomimetic drugs used in the perioperative period (see Chapter 25). During initial treatment, patients can have an exaggerated response to indirect-acting sympathomimetics such as ephedrine owing to increased presynaptic availability of norepinephrine. In contrast, adrenergic desensitization and catecholamine depletion can result in a relatively refractory response to sympathomimetics in patients treated long term; such patients might respond best to the potent direct-acting sympathomimetic norepinephrine.[30] Tricyclic antidepressants can exaggerate rebound hypertension following discontinuation of antihypertensives, likely owing to changes in norepinephrine uptake.[31] Tricyclic antidepressants can increase arrhythmogenicity in the presence of volatile anesthetics, although these observations are dominantly with halothane and have not been seen with newer volatile anesthetics.[32,33] The anticholinergic effects of tricyclic antidepressants are expected to be additive to those of other drugs used in the perioperative period, and special caution should be used in administering centrally acting anticholinergics in those patients taking tricyclics who are at increased risk of delirium and dementia. Chronically administered barbiturates are potent inducers of CYP3A4 and can increase metabolism of tricyclic antidepressants, but significant effects are unlikely after a single anesthetic administration. Tricyclics are not known to have any effects on CYP isoenzyme induction or inhibition that are of significance to common anesthetic management.

Selective Serotonin Reuptake Inhibitors

History

The SSRIs were developed in the early 1970s when series of compounds derived from 3-phenoxy-3-phenylpropylamine—which is structurally similar to diphenhydramine—were tested for selective inhibition of serotonin (5-HT) reuptake.[34] The most potent and selective of the compounds was identified and named fluoxetine, and was eventually approved by the U.S. Food and Drug Administration (FDA) for the treatment of major depression in 1987 (Prozac). This was followed by sertraline (Zoloft) in 1991, paroxetine (Paxil), citalopram (Celexa) in 1998, and escitalopram (Lexapro) in 2002. Fluvoxamine (Luvox) was approved in 1993, and is distinctive because its FDA approval is restricted to the treatment of obsessive-compulsive disorder; it is, however, approved for the treatment of depression in other countries. A highly favorable safety profile compared with the tricyclic antidepressants rapidly propelled fluoxetine and later SSRIs to become the dominant antidepressant agents, although in recent years their commercial success relative to their clinical efficacy has been questioned.[35,36]

Basic Pharmacology

Structure-Activity

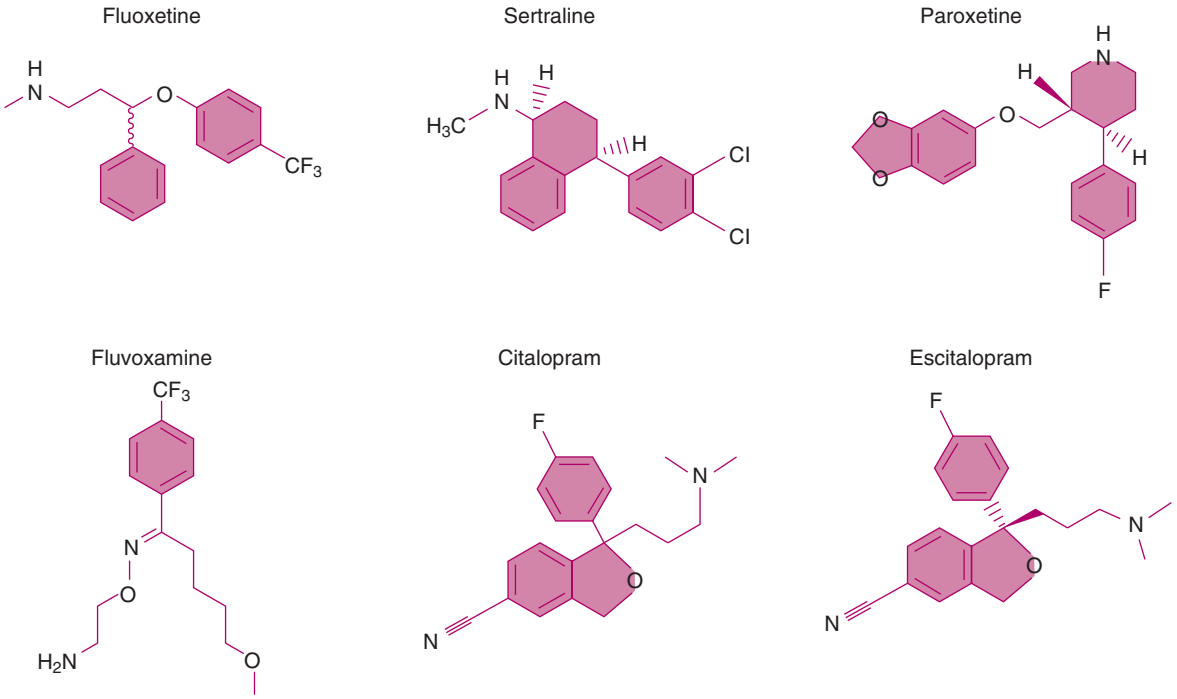
There is considerable diversity in the chemical structure-activity relations among the SSRIs (Fig. 12.3). Fluoxetine exists as a racemate, with both the *(S)*- and *(R)*-enantiomers pharmacologically active. Citalopram was initially introduced as a racemate, with the more potent *(S)*-enantiomer (escitalopram) subsequently isolated. All SSRIs possess relatively high affinity for serotonin uptake sites, low affinity for norepinephrine uptake sites, and very low affinity for neurotransmitter receptors, although there is considerable variability. Fluoxetine is the least selective of the class, with citalopram and escitalopram the most selective.[37] Sertraline is unique as a more potent inhibitor of dopamine uptake than any of the SSRIs or tricyclic antidepressants. Activity at H_1-histaminergic, α_1-adrenergic, and muscarinic receptors is minimal and unlikely to be of clinical significance, which is responsible for the absence of many of the side effects associated with tricyclic antidepressants.

Mechanism

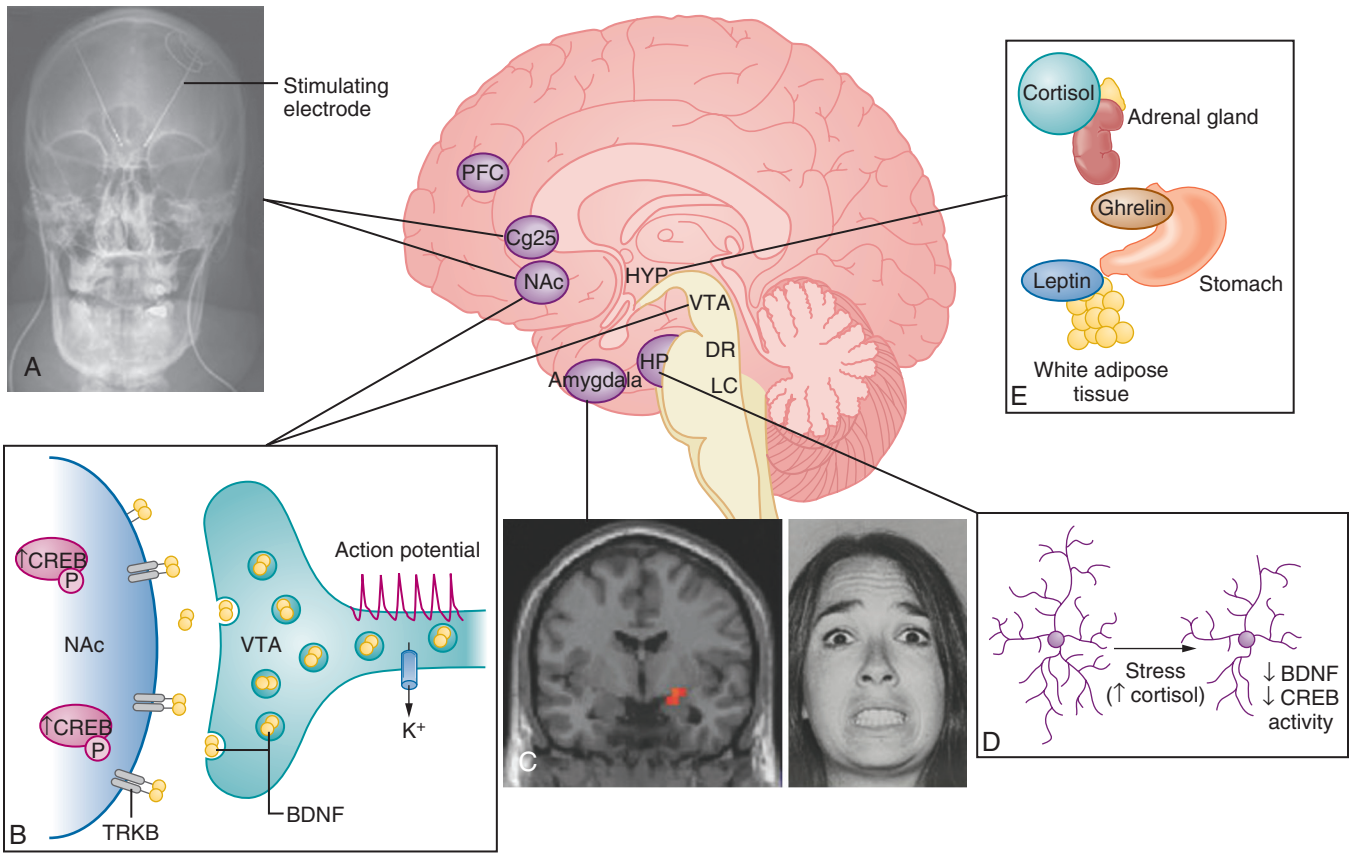
The mechanisms for the therapeutic effects of the SSRIs are not clearly established, but were initially believed to derive from blockade of 5-HT reuptake into serotonergic neurons, prolonging the duration of exposure to 5-HT at postsynaptic binding sites (see Fig. 12.2).[38] In contrast to direct 5-HT receptor agonists, the action of SSRIs depends on presynaptic 5-HT release, and they are ineffective if release of 5-HT is compromised. Because therapeutic effects are not fully realized within 2 to 8 weeks, it is unlikely that reuptake inhibition, which occurs far sooner, is mechanistically sufficient. Several downstream effects have been mechanistically postulated. Initially, inhibitory autoreceptors in the soma ($5\text{-}HT_{1A}$) and terminals ($5\text{-}HT_{1B}$) are stimulated, and neuronal firing rates decrease. Normalization of firing rates occurs with downregulation of these autoreceptors and decreased production of $5\text{-}HT_{1B}$ messenger ribonucleic acid (mRNA), and coincides temporally with the onset of therapeutic efficacy.[39] In the same temporal window there is increased production of neuroprotective proteins, including BDNF (Fig. 12.4).[40] SSRIs also possess significant antiinflammatory properties, which may target proinflammatory signaling associated with the onset of depression.[41]

Metabolism

SSRIs are oxidatively metabolized in the liver. Several CYP isoenzymes are involved, including 2D6, 2C9, 2C19, 1A2, and 3A4, with significant differences among the drugs in relative importance. While all SSRIs except fluvoxamine have pharmacologically active



• **Fig. 12.3** Chemical structure of selective serotonin reuptake inhibitors.



• **Fig. 12.4** The neural circuitry of depression beyond monoamines. Several brain regions are implicated in the pathophysiology of depression. A, Deep brain stimulation of the subgenual cingulate cortex *(Cg25)* or the nucleus accumbens *(NAc)* has an antidepressant effect on individuals with treatment-resistant depression thought to be mediated through inhibition of these regions either by depolarization blockade or by stimulation of passing axonal fibers. B, Increased activity-dependent release of brain-derived neurotrophic factor *(BDNF)* within the mesolimbic dopamine circuit (dopamine-producing ventral tegmental area *[VTA]* to dopamine-sensitive NAc) mediates susceptibility to social stress, occurring in part through activation of the transcription factor *CREB* (cyclic adenosine monophosphate response element-binding protein) by phosphorylation *(P).* C, Neuroimaging studies implicate the amygdala (*red pixels* show activated areas) as an important limbic node for processing emotionally salient stimuli, such as fearful faces. D, Stress decreases the concentrations of neurotrophins (such as BDNF), the extent of neurogenesis, and the complexity of neuronal processes in the hippocampus *(HP).* These effects are mediated in part through increased cortisol concentrations and decreased CREB activity. E, Peripherally released metabolic hormones in addition to cortisol, such as ghrelin and leptin, produce mood-related changes through their effects on the hypothalamus *(HYP)* and several limbic regions. *DR,* Dorsal raphe; *LC,* locus coeruleus; *PFC,* prefrontal cortex; *TRKB,* tropomyosin-related kinase B. major metabolites, only that of fluoxetine (norfluoxetine) is likely of therapeutic significance.

Clinical Pharmacology

Pharmacokinetics[42]

The SSRIs are well absorbed from the small intestine and most attain peak plasma levels in 2 to 8 hours. Protein binding is high (>80%), except with escitalopram, with volumes of distribution mostly in the range of 10 to 20 L/kg, somewhat less than seen with the tricyclic antidepressants. Plasma half-life is mostly around 20 to 30 hours, with fluoxetine somewhat longer (24–72 hours) and fluvoxamine shorter (15 hours). Norfluoxetine, the active metabolite of fluoxetine, has a half-life of 1 to 3 days. Once-a-day dosing is commonly used for all drugs except fluvoxamine, for which twice-daily dosing is preferred. There are known age and sex effects on plasma concentrations: sertraline concentrations are approximately 40% lower in young males than in older males or females, while fluvoxamine concentrations are 40% to 50% lower in males across all ages. Because no clear relationship between therapeutic efficacy and steady-state plasma concentrations has been established and because the therapeutic index is wide, plasma level monitoring is not used.[43]

Pharmacodynamics

Therapeutic Effects. SSRIs are efficacious in the initial treatment of major depression. There is little evidence to support that SSRIs as a class are more efficacious than other classes of antidepressants, including the tricyclic antidepressants, although one 2009

meta-analysis suggests that sertraline and escitalopram could have therapeutic advantages over other drugs, including other SSRIs.[44] There is little evidence to support efficacy in children and adolescents, with a 2016 meta-analysis identifying that only drug in the class with possible benefit over placebo is fluoxetine.[45] Although frequently prescribed for less severe depression, recent meta-analyses—some including trial data submitted to the FDA—question whether SSRIs have any significant therapeutic benefit.[35,36,46] The onset of clinical improvement takes 2 to 3 weeks and might not be maximal for up to 8 weeks, suggesting that downstream effects, rather than 5-HT reuptake inhibition per se, are responsible.

SSRIs are also prescribed and are probably efficacious in several other psychiatric disorders believed to involve abnormalities of 5-HT systems. Meta-analysis has demonstrated SSRIs, and especially sertraline, to be effective in the initial treatment of obsessive-compulsive disorder, although it is unclear how serotonergic selectivity confers therapeutic benefit.[47] SSRIs are also used for the prevention of panic attacks in panic disorder, and, because of postulated involvement of 5-HT in feeding behaviors, have been used in bulimia nervosa, anorexia nervosa, and obesity.[48] They reduce symptoms of premenstrual dysphoric disorder and post-traumatic stress disorder, and are effective in the treatment of premature ejaculation.[49–51]

Adverse Effects. The SSRIs have a highly favorable side effect profile compared with other classes of antidepressants. The most common side effects include sexual dysfunction, weight changes, dizziness, and insomnia. Although the effects of SSRIs on suicidality in adults are unclear,[52] they increase suicidality in patients younger than 24 and carry an FDA black box warning for use in this age group.[53] SSRIs have effects on cardiac Na^+, K^+, and Ca^{2+} channels and can theoretically cause QTc prolongation, but there is no observable increase in the risk of dysrhythmia.[54] SSRIs decrease platelet 5-HT content and inhibit platelet aggregation, and can increase bleeding, especially when combined with other anticoagulants.[55,56] One retrospective study of orthopedic patients demonstrated a significantly increased risk of transfusion in patients taking serotonergic antidepressants, but not with those taking nonserotonergic agents,[57] while another demonstrated a significant, though not clinically important, increase in bleeding in patients undergoing hip arthroplasty.[58] However, there is insufficient consensus to support perioperative changes in SSRI therapy on the basis of bleeding risk. SSRIs have effects on bone metabolism and are associated with increased risk of fracture.[59] Overdose with a single SSRI is very rarely fatal and is usually associated with minimal sequelae. Citalopram is the most likely to cause QTc prolongation, but even with extremely high doses, arrhythmias are exceedingly rare.[60]

Serotonin syndrome is a potentially fatal adverse reaction to serotonergic drugs resulting in mental status changes, autonomic hyperactivity, and neuromuscular hyperactivity. Initially this can be very difficult to distinguish from malignant hyperthermia.[61] Although theoretically possible, induction of serotonin syndrome by a single SSRI is rare, and they are usually only implicated in combination with other drugs. Several drugs used in the perioperative period—notably cocaine, ondansetron, and fentanyl—have the potential to directly or indirectly augment serotonergic activity, and this should be considered when assessing patients exhibiting hypermetabolic activity.

Drug Interactions

Significant drug interactions are less likely with SSRIs than with earlier classes of antidepressants. Perhaps the most likely source of interaction results from SSRI-induced inhibition of specific CYP isoenzymes, notably 2D6 and 2C19. However, this effect is of little relevance to the vast majority of drugs handled by anesthesiologists. Anesthesiologists should be aware of the potential for SSRIs to potentiate the QTc prolongation and antiplatelet effect of other drugs used in the perioperative period, and the serotonergic effect of methylene blue.

Monoamine Oxidase Inhibitors

The antidepressant actions of monoamine oxidase inhibitors (MAOIs) were identified in the 1950s. One member of this class—iproniazid—historically represents one of the earliest attempts to treat depression pharmacologically. MAOIs continue to have clinical utility in the treatment of resistant depression, and can be particularly effective in treating atypical depression. However, because of their severe and dangerous food and drug interactions, the classic MAOIs remain a treatment of last resort and are encountered relatively rarely. However, it is critical for anesthesiologists to recognize and be aware of these drugs, in that the potential for adverse interactions with agents used in the perioperative period exceeds that of any other psychopharmacologic class.

Basic Pharmacology

Monoamine oxidase (MAO) exists as two isoenzymes, MAO-A and MAO-B. MAO-A preferentially deaminates serotonin, epinephrine, norepinephrine, and melatonin, whereas MAO-B preferentially deaminates phenylethylamine, phenylethanolamine, tyramine, and benzylamine. Dopamine and tryptamine are deaminated by both isoenzymes. In the CNS, MAO-A is concentrated in dopaminergic and noradrenergic neurons, whereas MAO-B is concentrated in serotonergic neurons.[62] Both are also found in glial cells. Outside the CNS, MAO-A is found in the gastrointestinal tract, liver, and placenta, and MAO-B in platelets. The reason for the apparent discrepancy between the dominant substrates and localization is unknown.

MAOIs act by inhibiting MAO, thereby increasing the availability of monoaminergic transmitters (see Fig. 12.2). All MAOIs currently available in the United States bind irreversibly, inhibiting enzyme activity for up to 2 weeks. Changes in α_1-, α_2-, 5-HT_1, and 5-HT_2 receptors emerge after several weeks. Phenelzine is a hydrazine derivative and nonselective, while tranylcypromine is nonselective and chemically related to amphetamine. Selegiline is selective for MAO-B at lower doses but becomes nonselective at higher doses; metabolites of selegiline include L-amphetamine and L-methamphetamine. In 2006, selegiline became available as a transdermal patch. This system avoids inhibition of intestinal and hepatic MAO-A, thereby reducing food-drug interactions and obviating the need for dietary restriction.

Clinical Pharmacology

MAOIs are used to treat a variety of psychiatric conditions but have received greatest acceptance for atypical depression, which is characterized by early age of onset, dysthymia, alcohol abuse, and sociopathy. They are more effective than the tricyclic antidepressants in treating this disorder.[63] MAOIs are also therapeutic in typical major depression, panic disorder, bulimia nervosa, atypical facial pain, and treatment-resistant depression.[64] The transdermal patch form of selegiline is approved for use in major depression, although its efficacy relative to other drugs is not well studied.[65]

Adverse Effects, Dietary Interactions, and Drug Interactions

Common adverse effects of MAOIs include dizziness, headache, dry mouth, nausea, weight gain, peripheral edema, urinary hesitancy, and myoclonic movements. Orthostatic hypotension is common in older patients and can necessitate mineralocorticoid treatment. MAOIs can augment the response to insulin and other hypoglycemic agents increasing the risk of hypoglycemia. Phenelzine has anticholinergic action.

Dietary Interactions

Orally ingested MAOIs inhibit the catabolism of dietary amines. The consumption of foods containing tyramine can lead to severe hypertensive crisis within an hour of eating. Decreased first-pass breakdown of tyramine leads to elevated systemic levels. Tyramine is transported via vesicular monoamine transporter (VMAT) into synaptic vessels, where it displaces norepinephrine, and the release of norepinephrine precipitates the hypertensive crisis.[66] Patients using oral MAOIs must adhere to dietary restrictions to avoid precipitation of a crisis. Key foods that must be avoided include cheese, sausage meats, red wine, overripe fruits, fermented products, and some yeasts. Transdermal selegiline does not require dietary restrictions.

Drug Interactions

Irreversible inhibition of MAO by MAOIs leads to several potentially dangerous drug interactions when therapy is combined with sympathomimetic agents. In the outpatient setting, significant caution is required when crossing over to or from other psychopharmacologic agents that alter monoaminergic activity, such as SSRIs, tricyclic antidepressants, or stimulants. Several over-the-counter medications contain indirect-acting sympathomimetics and are able to precipitate a hypertensive crisis. In the perioperative setting, several drugs have the potential for dangerous interactions. The most notable of these is meperidine, which can precipitate a type I excitatory response with hypertension, clonus, agitation, and hyperthermia, or a type II depressive response with hypotension, hypoventilation, and coma.[67] This effect is believed to result from meperidine's serotonin reuptake inhibition properties. Members of the phenylpiperidine opioids, which include tramadol, fentanyl, alfentanil, sufentanil, and remifentanil, are also serotonin reuptake inhibitors and have been associated with perioperative serotonergic toxicity, as has methadone. Morphine does not appear to precipitate serotonergic crisis and is perhaps the drug of choice when opioids must be used in patients taking MAOIs. Indirect sympathomimetics, such as ephedrine, can precipitate an exaggerated pressor response owing to increased release of norepinephrine and so should be avoided. Direct-acting drugs such as phenylephrine are preferable, although the response can be exaggerated owing to receptor hypersensitivity.[68] Ketamine should similarly be avoided, although its safe use has been described.[69]

Atypical Antidepressants

Several drugs currently used in the treatment of depression and related disorders have structures and mechanisms that cannot be placed in any of the broad classes described and are commonly referred to as atypical, second-generation antidepressants. The most important of these are summarized in Table 12.1. Like the tricyclic antidepressants and SSRIs, the therapeutic mechanism of these agents is poorly understood. All drugs share effects on signaling or transmitter availability in at least one monoaminergic (serotonergic, noradrenergic, or dopaminergic) pathway.

Anxiolytic Drugs

Benzodiazepines

History

The first benzodiazepine, chlordiazepoxide (Librium), was introduced in 1960. This was followed in 1963 by diazepam (Valium), the archetypal compound from which many derivatives were synthesized. The benzodiazepines were rapidly embraced as treatments for anxiety because they were considerably safer than the barbiturate alternatives and were extensively prescribed until the 1980s. In the past 25 years, benzodiazepine use has declined, partly because of awareness and concerns regarding addiction, withdrawal, and recreational abuse, and also because of the evolution of the SSRIs as a safe and effective first-line therapy for anxiety and panic disorder. Nonetheless, alprazolam (Xanax), a triazolobenzodiazepine introduced in 1981 for the treatment of panic disorder, remains the single most prescribed psychiatric medication, with 48 million prescriptions in 2016.[1]

Basic Pharmacology

Structure-Activity

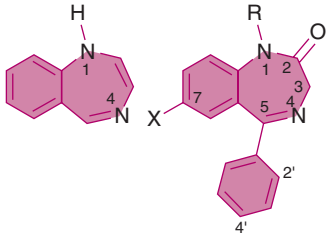
The core structure of the benzodiazepines is the fusion of benzene and diazepine ring systems. All therapeutically active drugs are substituted 1,4-benzodiazepines, with many containing a 5-phenyl-1 *H*-benzo[*e*][1,4]diazepin-2(3*H*)-one substructure (Fig. 12.5).

Mechanism

Benzodiazepines act by binding at the interface of the α and γ subunits of the $GABA_A$ receptor. This binding site is distinct from that of endogenous agonist GABA (which binds between the α and β subunits), and also from other GABAergic drugs, such as barbiturates (Fig. 12.6). Benzodiazepines allosterically modulate the receptor such that it has greater affinity for GABA. This increases the opening time of the associated chloride channel, which leads to hyperpolarization or stabilization of the resting membrane potential near the chloride equilibrium potential. Because binding requires a specific histidine residue in the α subunit, benzodiazepines act only at receptors containing α_1, α_2, α_3, or α_5 subunits, and have no action on receptors containing α_4 or α_6 subunits. Benzodiazepines are heterogeneous in their affinities for various $GABA_A$ receptor subtypes, which underlies the differences in their pharmacologic effects. For example, anxiolysis is associated with greater relative affinity for the α_2 subunit.[70]

Metabolism

Most benzodiazepines are highly protein bound and undergo microsomal oxidation in the liver via CYP enzymes, especially



• **Fig. 12.5** Benzodiazepine structure. The 1,4-benzodiazepine ring system is shown on the left side of the figure. The right side shows the most common skeleton, which contains a 5-phenyl-1 *H*-benzo[*e*][1,4]diazepin-2(3*H*)-one substructure.

TABLE 12.1 Atypical Antidepressants

	Bupropion	Trazodone	Mirtazapine	Venlafaxine	Duloxetine	Vortioxetine
Structure						Common trade name	Wellbutrin	Oleptro	Remeron	Effexor	Cymbalta	Brintellix
Class	Dopamine and norepinephrine reuptake inhibitor	Serotonin antagonist and reuptake inhibitor (SARI)	Noradrenergic and specific serotonergic antidepressant	Serotonin-norepinephrine reuptake inhibitor (SNRI)	SNRI	Serotonin modulator and stimulator
Metabolism	CYP2B6 to hydroxybupropion (active)	CYP3A4 to *m*-chlorophenylpiperazine (active)	CYP 1A2, 2C9, 2D6, 3A4	CYP 2D6 to *O*-desmethylvenlafaxine (active) and others	CYP 1A2, 2D6	CYP 2D6 to inactive metabolite
Half-life	21 hours	7-10 hours	20-40 hours	5 hours	12 hours	66 hours
Approved therapeutic indications	Major depression Seasonal depression Smoking cessation	Major depression	Major depression	Major depression Generalized anxiety Social anxiety Panic disorder	Major depression Generalized anxiety Diabetic neuropathy Fibromyalgia Musculoskeletal pain	Major depression
Adverse effects	Common: nausea, dry mouth Dose-related increase in seizures May cause increased blood pressure and tachycardia.	Common: sedation, headache, dizziness May cause orthostatic hypotension, priapism, and QT prolongation. Arrhythmias have been reported. May impair platelet aggregation and increase bleeding risk.	Common: sedation, weight gain, hypercholesterolemia May cause decreased gastric motility, urinary retention, hyponatremia, and akathisia. Agranulocytosis is rare.	Common: nausea, dry mouth, dizziness, sexual dysfunction May cause increased blood pressure, tachycardia, and hypercholesterolemia. May impair platelet aggregation and increase bleeding risk.	Common: nausea, sexual dysfunction May impair platelet aggregation and increase bleeding risk. May increase serum glucose in diabetic patients. May cause hepatotoxicity in at-risk patients.	Common: nausea, sexual dysfunction, dizziness May cause abnormal bleeding May cause hyponatremia.
Drug interactions	May reduce the effectiveness of codeine and tramadol due to CYP 2D6 inhibition. Caution should be used when combining with other drugs that lower the seizure threshold.	May potentiate action of antiplatelet drugs, drugs that prolong QTc, antihypertensives, and sedatives, including anesthetic drugs, and drugs that can trigger serotonin syndrome. Should not be combined with MAOIs.	May potentiate action of sedatives, including anesthetic drugs, anticholinergic drugs, drugs that lower the seizure threshold, and drugs that can trigger serotonin syndrome. May potentiate the effect of warfarin. Should not be combined with MAOIs.	May potentiate action of antiplatelet drugs, drugs that lower seizure threshold, and drugs that can trigger serotonin syndrome. Should not be combined with MAOIs. No known significant anesthetic interactions.	Ciprofloxacin may significantly increase serum concentration and toxicity. May potentiate action of antiplatelet drugs, drugs that lower seizure threshold, and drugs that can trigger serotonin syndrome. Should not be combined with MAOIs. No known significant anesthetic interactions	May potentiate action of antiplatelet drugs, drugs that lower seizure threshold, and drugs that can trigger serotonin syndrome. Should not be combined with MAOIs. No known significant anesthetic interactions

MAOIs, Monoamine oxidase inhibitors.

Structural requirements for eszopiclone and zolpidem binding to the gamma-aminobutyric acid type-A ($GABA_A$) receptor are different. *J Med Chem*. 2008;51:7243–7252.)

CYP 3A4. Their metabolism is therefore altered by the presence of drugs that either inhibit or induce CYP activity, as well as by age and disease. Several benzodiazepines have active metabolites, including a number with half-lives considerably longer than the parent compound; the half-life of the partial agonist N-desmethyldiazepam, the principal metabolite of diazepam, can exceed 100 hours. Three benzodiazepines—oxazepam, lorazepam, and temazepam—are metabolized by glucuronidation and have no significantly active metabolites; these are therefore preferred in older adults and in patients with hepatic disease.

Clinical Pharmacology

Pharmacokinetics

Benzodiazepines vary substantially in their absorption and rate of elimination (Table 12.2). Although differences in affinities for specific $GABA_A$ receptor subtypes lead to greater or lesser propensity to alter a particular cognitive function, heterogeneity in pharmacokinetic properties largely determines the clinical application of individual drugs. Duration of action is principally a function of α phase (distribution-redistribution) dynamics rather than rate of elimination in most applications.

Pharmacodynamics

Therapeutic Effects. Benzodiazepines have a wide spectrum of uses in psychopharmacology owing to their sedative, hypnotic, amnesic, anxiolytic, anticonvulsant, and muscle-relaxant properties. They are efficacious in the short-term treatment of panic disorder, but have largely been replaced by SSRIs as the first-line pharmacotherapy and are generally not regarded as appropriate for long-term monotherapy or combination therapy.[71,72] Similarly, they are effective in the initial management of generalized anxiety disorder, but do not modify the course when used long term.[73] Benzodiazepines remain a common therapy for short-term treatment of insomnia, although their use has declined with greater awareness of dependence and cognitive side effects in older adults. The time to onset and duration of sleep are prolonged, but there is a characteristic reduction in rapid-eye movement (REM) sleep, increase in non-REM sleep, and reduction in delta electroencephalographic activity.[74] They are also used as second-line treatment in the nonacute management of seizure disorders and as first-line treatment in alcohol withdrawal syndrome.[75] Benzodiazepines are also used for their muscle relaxant properties. Despite clear evidence that long-term benzodiazepine use is rarely helpful and can be harmful, long-term use remains common.

Adverse Effects. Benzodiazepines can cause prolonged sedation, impaired cognition, and psychomotor performance, and unwanted amnesia. In older patients, they can precipitate delirium states and increase the risk of accidents and falls. Drugs with long-acting metabolites pose the greatest risk. However, the most significant risks associated with benzodiazepine use occur owing to dependence and withdrawal effects. Abrupt withdrawal can precipitate delirium, anxiety, panic, seizures, insomnia, and muscle spasm.[76]

TABLE 12.2 Benzodiazepine Pharmacokinetics

Class	Drug	Common Trade Name	Onset (min)	Duration (hr)	Vd (L/kg)	Protein Binding (%)	$t_{1/2}$ (hr)
Desmethyldiazepam	Diazepam	Valium	30	2–3	0.8–1.0	98	20–50
	Chlordiazepoxide	Librium	60–120	≤24	3.3	90–98	6.6–25
Desalkylflurazepam	Flurazepam	Dalmane	15–20	7–8	3.4	97	74–90
	Clonazepam	Klonopin	20–60	≤12	1.5–4.4	85	19–50
Triazolobenzodiazepine	Triazolam	Halcion	15–20	6–7	0.8–1.8	89	1.5–5.5
	Alprazolam	Xanax	60	3.5–7	0.9–1.2	80	11.2
Thienodiazepine	Nitrazepam	Mogadon	20–50	6–10	2.4	87	30
	Flunitrazepam	Rohypnol	15–30	7–8	4.6	78	22
Oxazolobenzodiazepine	Oxazepam	Serax	45–90	6–12	1.0–1.3	86–99	2.8–5.7
	Lorazepam	Ativan	5–20	6–8	1.3	85	12.9
	Temazepam	Restoril	20–40	6–8	1.4	96	9.5–12.4

$t_{1/2}$, Half-life; *Vd*, volume of distribution.

Drug Interactions

Although widely believed, it is not clear that patients on chronic benzodiazepine therapy have significant cross-tolerance to non-benzodiazepine GABAergic anesthetic agents, or that the risk of intraoperative recall is elevated with long-term use.[77] Acutely, benzodiazepines augment the CNS depressant effects of sedative-hypnotic anesthetic drugs and opioids, such that dosage reduction is appropriate. Although many benzodiazepines are metabolized by CYP 3A4, they are generally not strong inducers or inhibitors, and effects on the metabolism of other drugs used in the perioperative period are generally not significant.[77]

Antipsychotic Drugs

First-Generation (Typical) Antipsychotics

The introduction of chlorpromazine (Thorazine) in 1952 arguably represents the most significant single development in psychopharmacology. Before that, treatment for psychosis was largely supportive and ineffective, with only electroconvulsive therapy and psychosurgery standing as controversial therapeutic options. The ability to treat psychosis effectively with drugs heralded massive deinstitutionalization as patients were discharged from psychiatric long-term care facilities and integrated into the community.

Pharmacology

The first-generation, or *typical,* antipsychotics include drugs from several classes: phenothiazines, butyrophenones, thioxanthenes, dihydroindolones, dibenzepines, diphenylbutylpiperidines, benzamides, and iminodibenzyls (Table 12.3). The butyrophenone class includes haloperidol (Haldol) and droperidol, two of the only psychopharmacologic agents commonly administered by anesthesiologists, although the latter is usually used for its antiemetic rather than its antipsychotic actions (see Chapter 34).

The principal mechanism for treatment of schizophrenia and other psychoses is blockade of D_2 dopamine receptors in the mesolimbic dopamine system. Dopamine receptors are G-protein–coupled receptors that exist in multiple subtypes (Table 12.4). They can be grouped as D_1-like (activate adenylyl cyclase) or D_2-like (inhibit adenylyl cyclase) based on their signaling mechanisms. However, first-generation antipsychotic (FGAs) are not selective and have variable effects on D_1, D_3, and D_4 receptors; M_1 muscarinic cholinergic receptors; H_1-histamine receptors; α_1- and α_2-adrenergic receptors; and both 5-HT_1 and 5-HT_2 serotonergic receptors. The effects on these other receptors appear to have little influence on the therapeutic efficacy, but they are of considerable importance to the side effect profile of individual drugs. Most FGAs are highly protein bound and lipophilic, and have large volumes of distribution (10–40 L/kg) with very significant variation in steady-state plasma concentrations. Oral preparations undergo extensive hepatic first-pass metabolism through hydroxylation, demethylation, and glucuronidation via CYP enzymes, and metabolites are dominantly eliminated in urine and bile. Elimination half-lives vary from 18 to 40 hours, allowing for once-a-day dosing. In the United States, depot preparations of haloperidol and fluphenazine are available as the decanoate ester suspended in sesame oil. After intramuscular injection, the esterified drug is slowly excreted from the oil and hydrolyzed, permitting dosing at intervals of 2 to 4 weeks.

Side Effects

Extrapyramidal Side Effects

First-generation antipsychotics are associated with a spectrum of potentially severe side effects involving multiple organ systems. The most characteristic are a cluster of movement disorders termed extrapyramidal symptoms (EPS) with an overall incidence exceeding 50%.[78] The precise mechanism of EPS is unclear, but is in part related to D_2 receptor effects in the nigrostriatal pathway.[79] *Dystonia* is the earliest of the acute-onset EPS and is characterized by involuntary and frequently painful sustained muscle contractions, most often involving head and neck muscles. Although dystonic torticollis appears to have no significant effect on anesthetic airway management, sudden death resulting from laryngeal dystonia has been described.[80,81] Dystonic reactions are most likely following treatment with high-affinity D_2 receptor antagonists, which include haloperidol and droperidol. Acute dystonic reactions are usually responsive to the anticholinergic benztropine (2 mg every 30 minutes

TABLE 12.3 First-Generation Antipsychotic Drugs

Class	Structure	Potency	Drugs
Phenothiazines			
Aliphatic		Low/medium	Chlorproethazine, chlorpromazine, cyamemazine, levomepromazine, promazine, triflupromazine
Piperidine		Low/medium	Mesoridazine, pericyazine, piperacetazine, pipotiazine, peopericiazine, sulforidazine, thioridazine
Piperazine		Medium/high	Acetophenazine, butaperazine, dixyrazine, fluphenazine, perazine, perphenazine, prochlorperazine, thiopropazate, thioproperazine, trifluoperazine
Butyrophenones		High	Benperidol, bromperidol, droperidol, fluanisone, haloperidol, melperone, moperone, pipamperone, timiperone, trifluperidol
Thioxanthenes		Low/medium	Chlorprothixene, clopenthixol, flupenthixol, thiothixene, zuclopenthixol
Dihydroindolones		Low/medium	Molindone, oxypertine
Dibenzepines		Low/medium	Clotiapene, loxapine

TABLE 12.3 First-Generation Antipsychotic Drugs—cont'd

Class	Structure	Potency	Drugs
Diphenylbutylpiperidines		High	Fluspirilene, penfluridol, pimozide
Benzamides		Low	Nemonapride, sulpiride, sultopride, tiapride
Iminodibenzyl		Medium	Clocapramine, mosapramine

until symptom abatement) or the antihistamine diphenhydramine (25–50 mg). *Akathisia* is an unpleasant sensation of motor restlessness with an irresistible urge to move, leading patients to continuously perform patterns of complex motor activity. Symptomatically, akathisia resembles restless legs (Wittmaack-Ekbom) syndrome. Propranolol (20–120 mg/day) is the most consistently effective treatment, although antihistamines, anticholinergics, benzodiazepines, and serotonin antagonists are also used.[82]

Neuroleptic-induced pseudoparkinsonism mimics classical Parkinson disease and must further be distinguished from depression or the negative symptoms of schizophrenia. Symptoms usually develop after several weeks of treatment, and acute events are rare. Approaches to treatment resemble those for akathisia, with the addition of dopaminergic agents such as amantadine. *Tardive dyskinesia* is a late development following chronic use of FGAs and is characterized by persistent and often stereotyped choreoathetoid movements that can involve any part of the body, but most commonly involve conspicuous oral and facial dyskinesias. Tetrabenazine is considered first-line treatment but is associated with significant side effects; other agents include amantadine, benzodiazepines, β-blockers, vitamin E, and botulinum toxin for focal dystonias.[83] The overall effectiveness of treatment is poor, and the development of symptoms can be irreversible. Patients in whom tardive dyskinesia develops while taking FGAs can change medications to clozapine or another second-generation antipsychotic (SGA, see later text), as these agents decrease the incidence and severity of symptoms. In contrast to their efficacy in other forms of EPS, anticholinergics worsen tardive dyskinesia and should be avoided. Furthermore, anesthesiologists must be aware that the D_2-receptor antagonist metoclopramide, used perioperatively for its antiemetic and gastroprokinetic properties, can also trigger or exacerbate tardive dyskinesia and is contraindicated in patients receiving FGAs.[84]

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a life-threatening emergency that closely resembles malignant hyperthermia (MH). It is characterized by hyperthermia, muscle rigidity, severe hypermetabolic dysautonomia, and mental status changes. It can be triggered by a single dose of any antipsychotic, but is most commonly associated with the high-potency FGAs, including haloperidol and droperidol. Rhabdomyolysis with elevated creatine kinase and renal failure are common secondary features. Overall mortality has been reported as in excess of 50%, but is probably closer to 10% to 20%.[85]

As with MH, first-line management is dantrolene (0.5–2.5 mg/kg every 6–12 hours), aggressive hydration, and supportive management. The dopamine agonist bromocriptine is also used. Although NMS is sometimes described as a neurogenic form of MH, the genetic and mechanistic relationship between the two is unclear.[86] Evidence relating MH susceptibility on muscle contraction testing with a history of NMS is inconsistent but is sufficient to manage such patients with full MH precautions.[87]

Other Side Effects

Several of the FGAs—notably thioridazine, haloperidol, droperidol, and pimozide—are associated with QTc prolongation and sudden cardiac death caused by *torsades de pointes,* likely via blocking the rapidly activating component of the delayed rectifier K^+ current.[88] In December 2001, the FDA issued a black box warning for droperidol, and a safety alert was issued for haloperidol in September 2007. The warning for droperidol refers to doses greater than 2.5 mg, which is greater than the common antiemetic dose of 0.625 to 1.25 mg.[89] Nonetheless, its use in anesthesia has virtually disappeared in the United States. The risk with haloperidol is greatest with intravenous administration, which although off-label, is commonly used in the treatment of delirium in the intensive care setting. The QTc should be assessed in all patients before the administration of droperidol or intravenous haloperidol with the electrocardiogram monitored following administration.

The M_1 anticholinergic activity of FGAs contributes to cognitive impairment, such as sedation, decreased memory function, and delirium, as well as to gastrointestinal effects, such as nausea, vomiting, ileus, dry mouth, and urinary retention. Weight gain, dyslipidemia, hypertension, and the induction of diabetes mellitus secondary to H_1 histaminic, M_1 cholinergic, and 5-HT_{2C} serotonergic blockade are most pronounced with the SGAs, but can occur with the FGAs. Antagonism of tuberoinfundibular dopaminergic tracts causes hyperprolactinemia, with several secondary endocrine effects. The α_1-adrenergic blockade can cause orthostatic hypertension and dizziness, especially early in the treatment course.

Second-Generation (Atypical) Antipsychotics

The description of an antipsychotic medication as *atypical* is pharmacologically imprecise, but is historically based only on a lower incidence of EPS. The group is, in fact, pharmacologically heterogeneous. When clozapine was introduced in 1961, there was little interest in conducting human trials because primate studies had demonstrated minimal EPS, and the prevailing theory was that EPS were a necessary (albeit unwanted) feature of antipsychotic efficacy. Clozapine was introduced in Europe in the early 1970s, but withdrawn in 1975 following reports of fatal agranulocytosis. However, a large trial demonstrated that it was effective in otherwise treatment-resistant schizophrenia, and clozapine received cautionary approval from the FDA in 1990.[90] The search for agents with a similarly low incidence of EPS but lower risk of agranulocytosis led to several other SGA drugs during the 1990s and 2000s. The newer SGAs—largely under patent protection and considerably more expensive—have replaced FGAs as the dominant pharmacotherapy for schizophrenia and other psychotic disorders. However, the Clinical Antipsychotic Trials of Intervention Effectiveness CATIE) and Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study (CUtLASS) trials suggest that, perhaps with the exception of clozapine, SGAs have no better therapeutic efficacy than FGAs and offer no consistent advantage in long-term quality of life indicators,[91–93] although meta-analyses have suggested that other agents may have efficacy and have a lower withdrawal rate owing to side effects.[94]

Individual Agents

Clozapine (Clozaril)

Clozapine is a dibenzodiazepine that is structurally related to loxapine. The mechanism of its low incidence of EPS and unique efficacy in treatment-refractory patients remains unclear. It is a weak antagonist at D_1, D_2, D_3, and D_5 dopamine receptors, but a strong antagonist at D_4 receptors. Positron emission tomography ligand studies demonstrate that clozapine is therapeutically effective when it occupies 20% to 67% of D_2 receptors, in contrast to FGAs, which become therapeutic only at 80% D_2 occupancy.[95] This reduced affinity for D_2 receptors might underlie the lower incidence of EPS and further suggests that the therapeutic efficacy is related to activity other than D_2-receptor antagonism. Clozapine

also has high affinity for adrenergic, cholinergic, and 5-HT_{2C} and 5-HT_{2A} serotonergic receptors. Like most SGAs, it has a pK_i (5-HT_{2A})/pK_i (D_2) ratio higher than is observed with FGAs, an observation central to the *serotonin–dopamine hypothesis* of SGA action. This hypothesis suggests that interactions between the serotonin and dopamine systems play an important role in the mechanism of action of SGAs because relatively potent blockade of 5-HT_{2A} receptors coupled with weaker antagonism of dopamine D_2 receptors has been found as the only pharmacologic feature shared by most atypical antipsychotic drugs.[96–98] Clozapine is highly protein bound and is extensively metabolized in the liver via CYP 1A2; monitoring of plasma levels and adjustments in dosage must be considered when agents that induce or inhibit CYP activity are added or removed.

Clozapine carries five FDA black box warnings. Agranulocytosis is most likely in the first 3 months of treatment. The incidence in the absence of monitoring is as high as 1% to 2%; however, strict adherence to monitoring reduces the incidence to less than 0.5%.[99] Treatment should not be initiated if the white blood cell count is less than 3500 cells/μL or the absolute neutrophil count is less than 2000 cells/μL, and cell counts should be monitored. A number of cardiovascular side effects are reported, and a boxed warning exists for myocarditis. Myocarditis and cardiomyopathy are most common in the first 2 months of therapy and might involve an immunoglobulin E–mediated hypersensitivity reaction.[100] Boxed warnings also exist for orthostatic hypotension, seizures, and an increased risk of death in older patients receiving clozapine for dementia-related psychosis. Hyperglycemia and other diabetogenic effects, including ketoacidosis, are also seen. Because of the severity and incidence of these and other adverse effects, although clozapine is clearly the most effective antipsychotic in the treatment of schizophrenia, its use is usually restricted to patients in whom therapy with at least two other pharmacologic agents has failed.

Olanzapine (Zyprexa)

Olanzapine is a thienobenzodiazepine structurally similar to clozapine that received FDA approval in 1997 and in 2004 was approved for the long-term treatment of bipolar disorder. Olanzapine is also available in a combined preparation with fluoxetine. Like other SGAs, selectivity for D_2-dopamine receptors is significantly less than for FGAs, although it does have relatively greater selectivity for D_2 than does clozapine. Antagonist affinity for the 5-HT_{2A} receptor is greater than for dopamine receptors, while affinity for the 5-HT_{2C} receptor is similar to that for D_2. There is also antagonism of α_1-adrenergic, H_1-histaminergic, and $M_{1\text{-}5}$ muscarinic receptors. Olanzapine also has weak activity at $GABA_A$ receptors. Although interaction with GABAergic anesthetics is not defined, olanzapine is considered to potentiate the effects of benzodiazepines, and fatalities from cardiorespiratory depression have been reported when intramuscular olanzapine has been combined with benzodiazepines.[101] Olanzapine is highly protein bound and predominantly metabolized by CYP 1A2.

Olanzapine is associated with weight gain, diabetogenesis, and dyslipidemia, with an incidence and magnitude greater than other SGAs or FGAs.[102,103] Boxed warnings exist for increased risk of death in older patients receiving olanzapine for dementia-related psychosis, and for excessive sedation and delirium following intramuscular injection. The incidence of EPS is less than that of the FGAs, but greater than that with clozapine. Although a small number of cases of olanzapine-induced leukopenia and agranulocytosis have been reported, scheduled monitoring is not required. Similarly, while cardiac conduction abnormalities have been reported, myocarditis and cardiomyopathy are not features, and the overall cardiac risk is significantly less than that associated with clozapine.

Quetiapine (Seroquel)

Quetiapine is a dibenzothiazepine approved by the FDA for the treatment of schizophrenia in 1997 and for the treatment of bipolar disorder in 2004. At 12 hours after the last dose, positron emission tomography ligand studies demonstrate that quetiapine occupies only 30% of D_2 receptors, which is significantly less than that considered necessary for therapeutic efficacy.[104] However, occupancy is higher when measured at shorter intervals; this has led to the theory that transient occupancy of D_2 receptors provides clinical potency, but also permits dynamics of dopamine release in nigrostriatal and tuberoinfundibular pathways, accounting for the low incidence of EPS and hyperprolactinemia.[105] Quetiapine has high affinity for 5-HT_{2A} receptors but relatively weak affinity for 5-HT_{2C} or 5-HT_1 receptors. It has very strong affinity for H_1-histamine receptors, which likely accounts for it being the most sedating of the SGAs, and also for α_1-adrenergic receptors, accounting for postural hypotension. Protein binding is 83%, and it is metabolized by CYP 3A4. Its active metabolite, norquetiapine, has similar or even greater potency than the parent compound at many receptors. The most characteristic side effect of quetiapine is sedation. It is associated with weight gain, diabetogenesis, and dyslipidemia, although the effect is not as great as that seen with clozapine or olanzapine. It can also cause orthostatic hypotension, but unlike clozapine it does not carry a boxed warning for this effect. Boxed warnings exist for an increased risk of death in older patients receiving quetiapine for dementia-related psychosis and for suicidality in children, adolescents, and young adults. The incidence of EPS and hyperprolactinemia is especially low compared with other FGAs and SGAs.[106] Dysrhythmias have been reported, but earlier concerns that quetiapine causes prolongation of QTc are probably unfounded.[88]

Aripiprazole (Abilify)

Aripiprazole is a dihydroquinolinone antipsychotic that is chemically and pharmacologically distinct from other first- and second generation antipsychotic drugs. It received FDA approval for the treatment of schizophrenia in 2002, for acute manic and mixed episodes associated with bipolar disorder in 2004, as an adjunctive therapy for major depression in 2007, and for irritability in autistic children in 2009. In contrast to other antipsychotics, which are D_2- and 5-HT_{1A} receptor antagonists, aripiprazole is a *partial agonist* at these receptors and at 5-HT_{2C} receptors.[107,108] It is a strong antagonist at 5-HT_{2A}, 5-HT_7, and D_3 receptors, and has moderate effects at D_4, H_1-histamine, and α_1-adrenergic receptors. It has virtually no affinity for muscarinic cholinergic receptors. Protein binding is at least 99%, and it is metabolized by CYP 2D6 and CYP 3A4. Its active metabolite, dehydro-aripiprazole, has similar affinity for D_2 receptors. Because of its partial agonist activity on nigrostriatal and tuberoinfundibular pathways, aripiprazole causes minimal EPS or hyperprolactinemia despite D_2-receptor occupancy of 70% to 95%. It also appears to be largely free of the adverse weight gain, diabetogenesis, and dyslipidemia associated with other SGAs. Aripiprazole does not cause prolongation of the QTc.[109] It is generally well tolerated. As with all the SGAs, aripiprazole carries a boxed warning for increased risk of death in older patients receiving antipsychotics for dementia-related psychosis and for suicidality in children, adolescents, and young adults.

Risperidone (Risperdal)

Risperidone is a benzisoxazole derivative approved by the FDA for treatment of schizophrenia in 1994, for short-term treatment of the mixed and manic states of bipolar disorder in 2003, and for treatment of irritability in children with autism in 2006. In 2007 it was approved as a treatment for schizophrenia and bipolar disorder in children. Its pharmacology is characterized by binding affinity for 5-HT_{2A} receptors that is 20 times that for D_2-dopamine receptors. D_2-receptor affinity is approximately 50 times, and 5-HT_{2A} receptor affinity approximately 20 times that of clozapine. Risperidone also has strong affinity for α_1-/α_2-adrenergic and H_1-histamine receptors. Affinity for D_1 receptors is low, and it has no affinity at muscarinic receptors. Protein binding is 90%, and it is metabolized by CYP 2D6. D_2-receptor occupancy at therapeutic doses is 63% to 89%, which would be expected to be associated with a significant incidence of EPS.[110] The addition of strong serotonergic antagonism, with a 5-HT_2 receptor occupancy of 95%, is thought to confer protection against D_2 antagonist effects on the nigrostriatal pathway, and the incidence of EPS is low. Nonetheless, unlike other SGAs with relatively lower affinities for D_2 receptors that permit dynamic responses to surges in dopamine, risperidone is tightly bound and does cause significant hyperprolactinemia.[111,112] It can also cause orthostatic hypotension during early treatment. Risperidone does not cause prolongation of the QTc and is less arrhythmogenic than other antipsychotics. It carries a boxed warning for increased risk of death in older patients receiving antipsychotics for dementia-related psychosis.

Mood Stabilizer Drugs

Lithium

History

Lithium was first used medicinally in the late 19th century as a treatment for gout and other disorders, and was used as a substitute for table salt in the first half of the 20th century until several deaths from toxicity were reported. Just as cocaine was initially added to Coca-Cola for medicinal purposes, lithium was part of the original recipe for the beverage 7 Up. It was first identified as a treatment for mania in 1949, but at least partly because of concerns about toxicity, did not receive FDA approval for the treatment of acute mania until 1970 and for prophylaxis in bipolar disorder in 1974.

Basic Pharmacology

Structure-Activity. Lithium is the third element of the periodic table and exists as a monovalent cation. It shares some properties with sodium and potassium, and substitution or competition with other cations can contribute to its effects.[113]

Mechanism

The therapeutic mechanism of lithium remains fundamentally unknown, although several proposals have been developed. Lithium depletes free intracellular inositol through noncompetitive inhibition of inositol monophosphate. This depletion can lead to changes in G-protein–coupled second-messenger systems and protein kinase C actions linked to inositol phosphate signaling, which are important in adrenergic, serotonergic, and cholinergic signaling.[114,115] Lithium also inhibits glycogen synthase kinase-3 (GSK-3), mimicking the Wnt protein signaling pathway to stimulate protein kinase C activity.[116,117] Effects on glutamate, Na^+-K^+-ATPase, cyclic adenosine monophosphate response element-binding protein, and gene expression have also been described.[118] Lithium has effects on serotonin and norepinephrine signaling and is an antagonist at 5-HT_{1A} and 5-HT_{1B} autoreceptors, increasing serotonin availability.[119,120] Lithium also causes a resetting of hypothalamic circadian oscillators, which are dysfunctional in bipolar disorder and depression.

Metabolism

As a monovalent cation, lithium undergoes no metabolism, but is excreted renally.

Clinical Pharmacology

Pharmacokinetics[121]

Lithium is rapidly and completely absorbed from the gastrointestinal tract and attains peak plasma concentration in 1 to 2 hours with rapid-release preparations and 4 to 12 hours in extended-release preparations. It is not protein bound and is evenly distributed in the total body water. The initial volume of distribution is 0.3 to 0.4 L/kg and in steady state is 0.7 to 1 L/kg. Bioavailability is nearly 100% for the rapid-release preparations and 60% to 90% with the extended-release preparations. It is excreted unchanged in the urine with an elimination half-time of 18 to 24 hours or longer in older adults and those with renal impairment. Time to steady-state is 5 to 7 days. Filtered lithium ion (Li^+) (80%) is reabsorbed in the proximal convoluted tubule, which is competitive with Na^+ reabsorption. As a consequence, changes in renal functional dynamics such as diuretic therapy, sodium intake, and hydration status can alter plasma concentration, so monitoring of serum Li^+ concentrations is required. The target concentration is 0.8 to 1.2 mM. Although there is no clear recommendation for therapeutic monitoring in surgical patients, there are numerous pharmacologic and physiologic events in the perioperative period that can affect Li^+ plasma concentrations.

Pharmacodynamics

Therapeutic Effects

Lithium remains a first-line therapy for the treatment of acute mania, with a response rate in excess of 70%, and it is at least as effective as other first-line agents.[122–125] It is also first-line treatment for bipolar depression and significantly reduces suicide attempts and successful suicide.[126–128] It is effective as prophylaxis and maintenance therapy in bipolar disorder, which is usually a lifelong disease characterized by recurrent acute mood episodes.[129,130] Lithium can also be effective as adjunctive therapy in treatment-resistant unipolar depression.[131] Although it is less well tolerated in older adults, lithium appears to have neuroprotective effects, and in animal models it is protective against Alzheimer disease. Some data suggest that it might modify the course of Alzheimer disease in humans.[132,133] Lithium enhances remyelination of peripheral nerves.[134]

Adverse Effects. Lithium is associated with a number of significant adverse effects and has a narrow therapeutic index. The most common side effects at therapeutic concentrations are weight gain and disturbed cognition and coordination. Lithium impairs renal concentrating ability, and a significant number of patients experience diabetes insipidus with polyuria and polydipsia, which is usually responsive to amiloride.[135] Renal tubular damage and even acute renal failure are reported. Neurotoxic reactions such as encephalopathy, delirium, memory changes, and movement disorders are possible and can be irreversible. Hypothyroidism is common and is more prevalent in females. Abnormal thyroid function occurs in excess of 35% of patients using long-term lithium therapy.[136]

Clinically significant cardiac conduction abnormalities are unusual in patients without preexisting cardiac disease, but sinus node dysfunction, atrioventricular block, and T-wave flattening can occur.[137] Caution and monitoring is essential in patients with elevated cardiac risk. Tremor may occur in up to 65% of patients.[138]

Drug Interactions

A number of drugs used in the perioperative period can alter plasma lithium concentrations. Thiazide diuretics increase concentrations by a compensatory increase in proximal tubule reabsorption, whereas loop diuretics such as furosemide generally have minimal effect, as do the potassium-sparing diuretics. Osmotic diuretics lower lithium concentrations and so are useful in the treatment of toxicity. Angiotensin-converting enzyme inhibitors increase lithium levels, as do angiotensin II receptor blockers, many nonsteroidal antiinflammatory agents, and several antibiotics.[139,140] Caution should be observed in using neuroleptic medications such as droperidol and haloperidol, in that the risk of extrapyramidal side effects and neuroleptic malignant syndrome is increased. Lithium prolongs the action of both depolarizing and nondepolarizing neuromuscular blocking drugs.[141,142]

Anticonvulsant Mood Stabilizers

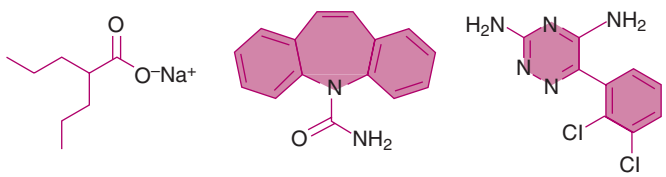
Several heterogeneous compounds used initially as anticonvulsants possess or have been investigated for therapeutic benefit in bipolar disorder (Fig. 12.7). The anticonvulsant properties of valproate were serendipitously established in 1963 when its incidental mood-enhancing effects stimulated interest in its use as a mood stabilizer. It received FDA approval for the treatment of mania in 1995. Lamotrigine was approved for maintenance therapy of bipolar disorder in 2003, and carbamazepine for the treatment of mania and mixed episodes in 2004. Valproate and carbamazepine are considered alternative first-line agents to lithium for the treatment of mania, although they are frequently used in combination therapy.[143,144] Valproate might be superior to lithium in the treatment of patients with mixed states.[145] Several other anticonvulsant drugs, including gabapentin, pregabalin, and topiramate have been investigated but do not have clearly established efficacy.

Individual Agents

Valproate (Depakote)

Valproate is an eight-carbon, branched-chain carboxylic acid that suppresses seizures without affecting focal activity. The therapeutic mechanism for suppression of mania is unclear. Valproate facilitates GABAergic transmission through increased expression of mRNA for glutamate decarboxylase (the GABA synthetic enzyme), reduces protein kinase C activity in manic patients, and inhibits inositol cycling and GSK-3, although via different pathways than lithium.[114,146–148] It is 80% to 90% protein bound and attains peak plasma concentration in approximately 4 hours. It is hepatically metabolized via glucuronide conjugation and mitochondrial β oxidation. Elimination half-life is 9 to 16 hours.

Valproate carries FDA black box warnings for hepatic failure, acute pancreatitis, and use in pregnancy. Hepatotoxicity is greatest in children younger than 2 years of age, but fatalities have been reported in adults. Fatal acute pancreatitis has been reported in both adults and children, including in those who have been on stable, long-term therapy. Hyperammonemia with encephalopathy is reported. Of special significance to surgical patients, valproate can cause thrombocytopenia, inhibition of platelet aggregation, and increased bleeding, but modification of therapy during the perioperative period is not recommended.[149] No drug interactions specific to anesthetic care are known.



• **Fig. 12.7** Anticonvulsant mood stabilizers.

Carbamazepine (Tegretol)

Carbamazepine is an iminostilbene derivative with a dibenzazepine nucleus, and thus has a tricyclic structure similar to imipramine. Like lithium and valproate, carbamazepine increases limbic $GABA_B$ receptors and has effects on inositol cycling. It has unique effects at peripheral-type benzodiazepine receptors, increases stimulatory G-protein alpha subunits ($G_s\alpha$), and decreases inhibitory G-protein subunits ($G_i\alpha$). It appears to lack the effects on GSK-3 and protein kinase C possessed by lithium and valproate. It has anticholinergic, antidiuretic, and muscle relaxant properties. Carbamazepine is 75% to 90% protein bound, with a volume of distribution of 0.6 to 2 L/kg in adults. It is hepatically metabolized via CYP 3A4 to an active epoxide metabolite and is a strong CYP inducer. Elimination half-life is highly variable and is initially 25 to 65 hours but decreases to 12 to 17 hours after several weeks of therapy owing to autoinduction. Plasma level monitoring is not required.

Carbamazepine carries two FDA black box warnings for blood dyscrasias and dermatologic reactions. A spectrum of hematologic abnormalities, including agranulocytosis, aplastic anemia, neutropenia, leukopenia, and thrombocytopenia, have been reported and monitoring standards similar to those for clozapine are recommended.[150] Severe dermatologic reactions include fatal toxic epidermal necrolysis and Stevens-Johnson syndrome. The risk of dermatologic reactions is strongly linked to the HLA-B*1502 allele, which is prevalent in Asian populations. Patients of Asian descent should be screened for HLA-B*1502 and carbamazepine should be voided if the test result is positive.[151] A syndrome resembling that of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is occasionally observed in older patients. Cardiac conduction abnormalities, including atrioventricular nodal block, have also been reported. Carbamazepine has strong induction effects on CYP 1A2, 2B6, 2C8, 2C9, 2C19, 3A4, and P-glycoprotein and thus has the potential for significant drug interactions. The metabolism of midazolam, alfentanil, fentanyl, methadone, tramadol, and most nondepolarizing muscle relaxants is increased, but the effect of reduced plasma concentration is countered by generalized enhancement of the CNS depressant effects of anesthetic drugs.[152]

Lamotrigine (Lamictal)

Lamotrigine is a phenyltriazine that is structurally unrelated to the other anticonvulsant mood stabilizers. It reduces folate activity via inhibition of dihydrofolate reductase. It suppresses paroxysmal bursts from Na^+ channels, and inhibits glutamate release in response to ischemia and to the Na^+ channel activator veratrine.[153] It has no demonstrated effects on reuptake of dopamine, norepinephrine, or serotonin, and has minimal affinity for α_1, α_2, β, D_1, D_2, GABA,

H_1, M_1, M_2, or κ and σ opioid receptors. It is a weak inhibitor of 5-HT_3.[154] Lamotrigine is 55% protein bound, with a volume of distribution of 0.9 to 1.3 L/kg. It undergoes hepatic and renal metabolism, primarily via glucuronic acid conjugation to inactive metabolites. Elimination half-life is 25 to 33 hours. Plasma level monitoring has been suggested[155] but is not required.

Lamotrigine carries an FDA black box warning for dermatologic reactions, including potentially fatal Stevens-Johnson syndrome and toxic epidermal necrolysis. Other significant concerns include an increased risk of aseptic meningitis and the development of blood dyscrasias, including neutropenia, leukopenia, thrombocytopenia, and pancytopenia.[156,157] Most of the common adverse effects are relatively mild. No characteristic cardiac conduction defect is described, although rare events of arrhythmias in patients taking lamotrigine have been reported. When used as monotherapy, induction and inhibition of CYP isoenzymes does not occur, and changes in the metabolism of other drugs are not of significance. In general, lamotrigine augments the CNS depressant effects of drugs used in the perioperative period, but no interaction with any specific anesthetic drug is known.

Psychostimulants

Amphetamine, first synthesized in 1887, was available without prescription as a decongestant inhalant under the trade name Benzedrine from the 1930s to 1960s. Its utility as a stimulant was recognized during World War II, when it was used to combat fatigue in soldiers. Methylphenidate, identified as a stimulant in the 1950s, was used to treat children with the conditions that would subsequently be named attention deficit disorder (ADD) or attention deficit/hyperactivity disorder (ADHD), marketed under the name Ritalin. Diagnosis and treatment of ADD/ADHD has exploded over the past 25 years and has expanded to include a greater number of adult patients. Modafinil was approved for use in the United States in 1998 and has significantly improved the pharmacologic treatment of narcolepsy and other disorders of wakefulness.[158] The psychostimulant drugs are briefly summarized in Table 12.5.

Long-term use of amphetamine and methylphenidate leads to catecholamine depletion, which can blunt the sympathetic response to hemodynamic stress. Significant perioperative events, including cardiac arrest during induction of anesthesia, have been rarely reported.[159] However, there is no basis to recommend discontinuation of therapy before surgery.[160] Direct-acting sympathomimetics such as phenylephrine are preferred, and pretreatment with atropine can be used in selected pediatric patients.

Pharmacologic Treatment of Parkinson Disease

Levodopa

History

The discovery in the 1950s that the loss of dopaminergic neurons in the substantia nigra leads to Parkinson disease (PD) was swiftly followed by the introduction of the dopamine precursor levodopa for the treatment of motor symptoms.[161] Levodopa has remained the gold standard treatment for the past 50 years, but concerns about the development of long-term motor complications led to the preferential use of dopamine agonists and MAO-B inhibitors as initial therapy in patients with milder motor symptoms. More recent studies have supported the use of levodopa for all stages of the disease.

Basic Pharmacology

Structure-Activity

Levodopa is the levorotatory isomer of 3,4-dihydroxyphenylalanine. The dextrorotatory isomer has no biologic activity. Levodopa is an intermediate in the biosynthesis of dopamine. It is formed endogenously in humans by the action of tyrosine hydroxylase on the amino acid L-tyrosine.[162]

Mechanism

Unlike exogenous dopamine that cannot cross the blood-brain barrier, levodopa is actively transported into the CNS and is rapidly converted to dopamine by the enzyme aromatic L-amino acid decarboxylase (AAAD). The converted dopamine is available throughout the CNS and binds to presynaptic and postsynaptic dopamine receptors. In the corpus striatum, increased levels of dopamine normalize the levels of this neurotransmitter caused by dopaminergic neuronal loss.

Metabolism

Only a fraction of levodopa reaches the CNS, while the majority is converted to dopamine peripherally by AAAD. For this reason, levodopa is always coadministered with an AAAD inhibitor (carbidopa or benserazide). These agents increase cerebral bioavailability and reduce adverse effects associated with peripheral excesses of dopamine, including nausea and hypotension.

Decarboxylation of levodopa by endogenous catechol-*O*-methyltransferase (COMT) reduces bioavailability and shortens half-life. This leads to phasic stimulation of dopamine receptors in the basal ganglia, which can contribute to the development of motor fluctuations and dyskinesias. To ameliorate this, COMT inhibitors (entacapone or tolcapone) are often given concurrently. Tolcapone is rarely associated with severe liver injury and frequent monitoring of liver function is now recommended on initiation of therapy.

Clinical Pharmacology

Pharmacokinetics

The absorption of levodopa approaches 100% in the presence of an AAAD inhibitor. The duration of action of the immediate-release formulation is 2 to 4 hours and of the sustained-release formulation is 3 to 6 hours.[162] It is not appreciably bound to plasma proteins. Elimination of levodopa and metabolites is primarily renal.

Because of the short half-life and the absence of a parenteral formulation, levodopa should be continued perioperatively including shortly before induction of anesthesia.[163] Interruption of administration can lead to exacerbation of motor symptoms and interfere with ventilation. During longer procedures, consideration should be given to administration of levodopa via a gastric tube. Intrajejunal therapy with levodopa (Duodopa) is now registered for treatment of motor fluctuations and dyskinesia. Because of the expense and technical challenges associated with maintenance of this therapy in an outpatient population, it is usually reserved for those with advanced PD that cannot be controlled with oral pharmacotherapy.[164]

Pharmacodynamics

Therapeutic Effects. Levodopa is effective in treatment of bradykinesias, gait disturbances, and tremor at all stages of PD.

TABLE 12.5 Psychostimulants

	Amphetamine	Methylphenidate	Modafinil
Structure			Common trade names	Adderall (amphetamine, dextroamphetamine mixed salts) Dexedrine (dextroamphetamine) Desoxyn (methamphetamine)	Ritalin Metadate Concerta Focalin (dexmethylphenidate)	Provigil Nuvigil (armodafinil)
Class and mechanism	Noncatecholamine sympathomimetic amine. Enhances dopaminergic, serotonergic, and noradrenergic release in neural network specific regions via complex transporter effects	Norepinephrine and dopamine (dominant) reuptake inhibitor. Blocks the dopamine transporter (DAT). Has regionally specific effects similar to amphetamine	Mechanism is unclear. Does not appear to involve dopamine or noradrenergic pathways. May involve glutamatergic and GABAergic effects.
Metabolism	CYP 2D6 with no significantly active metabolites	Hepatic via carboxylesterase CES1A1 to inactive metabolites	CYP 3A4
Half-life (hours)	10–15	1–4	15
Approved therapeutic indications	ADHD Narcolepsy Obesity (methamphetamine)	ADHD Narcolepsy	Narcolepsy Shift work sleep disorder Obstructive sleep apnea/ hypopnea syndrome (OSAHS)
Adverse effects	Common: insomnia, headache, anxiety, weight loss, tachycardia, hypertension May cause cardiac arrhythmia, seizure, and hyperpyrexia in susceptible patients. High potential for abuse Abrupt discontinuation may precipitate withdrawal.	Common: insomnia, headache, anxiety, weight loss, tachycardia, hypertension May cause cardiac arrhythmia, seizure, and hyperpyrexia in susceptible patients. High potential for abuse Discontinuation symptoms generally less pronounced than for amphetamine.	Common: headache, nausea Generally less arrhythmogenic than amphetamine and methylphenidate, but events are described. May cause severe rashes, including Stevens-Johnson syndrome.
Drug interactions	May reduce the sedative effect of drugs used in anesthesia, and potentiate the analgesic effect of opiates. May unpredictably alter the response of the sympathomimetic drugs. May potentiate the action of arrhythmogenic drugs and drugs that lower the seizure threshold.	May reduce the sedative effect of drugs used in anesthesia, and potentiate the analgesic effect of opiates. May unpredictably alter the response of the sympathomimetic drugs. May potentiate the action of arrhythmogenic drugs and drugs that lower the seizure threshold.	May unpredictably alter the response to sympathomimetic drugs. No known significant anesthetic interactions.

ADHA, Attention deficit/hyperactivity disorder; *GABA*, gamma aminobutyric acid.

It does not have any appreciable effect on non-dopaminergic aspects of the disease such as dementia or autonomic dysfunction.

Adverse Effects. Adverse effects not already mentioned include somnolence, psychosis, cardiac irritability, and orthostatic hypotension. Neuroleptic malignant syndrome has been reported on sudden discontinuation and responds to reinstatement of levodopa.[165] Earlier concerns that levodopa hastens progress of PD have not been borne out by recent clinical studies.

Dopamine Agonists

History

Motor complications arising from PD treatment with levodopa led to the search for other agents. The ergot derivative and dopamine agonist, bromocriptine, was first used for the treatment of PD in the mid-1970s. Since that time a number of other ergot (cabergoline, lisuride) and non-ergot derivatives (pramipexole and ropinirole)

have been approved for PD therapy. The association of the oral ergot derivatives with pulmonary, valvular, and retroperitoneal fibrosis has severely curtailed their use for the management of PD.[166] One of the oldest known non-ergot derivatives, apomorphine, was approved for PD management in 2004 but the technical challenges of delivery due to high first pass metabolism have prevented wider use.

Basic Pharmacology

Structure-Activity

Agents from this class have chemically distinct structures. Pramipexole is a synthetic aminothiazole while ropinirole is an indole derivate. Apomorphine is a derivative of the quinolone alkaloid aporphine. The name refers to its historical derivation as a morphine decomposition product but there are no structural elements of morphine present in apomorphine. Apomorphine has two stereoisomers with only the R-enantiomer having dopaminergic activity. All three of these agents are chemically unrelated to the ergoline dopamine agonists.

Mechanism

The dopamine agonists activate presynaptic and postsynaptic dopamine receptors directly. The enteral non-ergot derivatives preferentially bind D_2 and D_3 receptors. The affinity for D_3 receptors is up to 10 times higher than for D_2 receptors. Apomorphine has affinities for the D_1, D_2, D_3, and D_4 receptors similar to those of dopamine.[167] Enteral ergot derivatives not only bind D_1 and D_2 but also some serotonin and adrenergic receptors.

Metabolism

Ropinirole is inactivated in the liver by CYP 1A2 with none of the major metabolites having pharmacologic activity. Pramipexole has negligible metabolism and more than 90% is excreted unchanged in the urine. Apomorphine undergoes extensive first-pass inactivation in the liver and is largely metabolized by systemic oxidation.

Clinical Pharmacology

Pharmacokinetics

The two most commonly used enteral agents, pramipexole and ropinirole, have distinct pharmacokinetic profiles. Bioavailability for pramipexole is greater than 90%, whereas that of ropinirole is around 50%. These agents remain in the body longer than levodopa; the immediate-release formulations of pramipexole and ropinirole have elimination half-lives of 8 hours and 6 hours, respectively. Pramipexole is largely renally cleared, whereas ropinirole is predominantly cleared by the liver. Because apomorphine has extensive first-pass metabolism, it is not effective as an oral agent. Instead it is most commonly administered subcutaneously or intranasally. The drug has a clinical effect within 20 minutes of subcutaneous administration and has an elimination half-life of 30 to 60 minutes.

Pharmacodynamics

Therapeutic Effects. The oral dopamine agonists in clinical use are effective in the treatment of the major motor symptoms of PD, in particular bradykinesias and tremor. They are used as sole agents in PD patients with mild-moderate motor symptoms and as an adjunct to levodopa in more severe disease. Ropinirole and pramipexole are also approved for the treatment of restless legs syndrome. Apomorphine can be used as a rescue therapy to improve mobility in patients experiencing "off" periods. It is as effective as levodopa in the management of motor symptoms but technical difficulties associated with long-term subcutaneous delivery have limited its clinical utility. Apomorphine can be used as an alternative to gastric administration of levodopa during longer anesthetics.[163]

Adverse Effects. As a class the dopamine agonists are generally well tolerated and have a side effect profile similar to levodopa. The prevalence of dyskinesias and motor fluctuations is reduced, which is postulated to result from longer elimination half-lives of the enteral agents. Unlike levodopa, the enteral agents can cause headaches and psychiatric symptoms, including confusion, compulsive gambling, and hypersexuality.[167] Some caution is required in the advanced stages of PD owing to the likelihood of cognitive impairment since these agents have the potential to induce or enhance hallucinations. Apomorphine is associated with nausea and vomiting, necessitating the concurrent administration of domperidone. There are no significant interactions between the dopamine agonists and anesthetic agents. Because of the longer half-life of the enteral agents, concerns regarding interruption of administration are not as pertinent as for levodopa.

MAO-B Inhibitors

MAO-B inhibitors act by reducing synaptic and glial metabolism of dopamine, leading to enhanced activity and reuptake. They are effective as monotherapy in early PD and are used as adjuncts to either dopamine agonists or levodopa in more severe disease. Selegiline and rasagiline are approved for PD treatment. Unlike selegiline, rasagiline has no amphetamine metabolites, which may account for the lower incidence of cognitive side effects.[168] Details of the pharmacology of these agents have been presented earlier in this chapter.

Pharmacologic Treatment of Myasthenia Gravis

Myasthenia gravis (MG) is an antibody-mediated disorder of neuromuscular transmission. Modern therapy is based on increasing the availability of acetylcholine (ACh) at the neuromuscular junction with anticholinesterases and modulating the immune response. Agents used to moderate autoimmune injury include corticosteroids, cyclosporine, azathioprine, tacrolimus, and rituximab (see Chapter 38 and Gilhus[169]).

Anticholinesterases

History

In 1934, the anticholinesterase physostigmine was demonstrated to markedly improve muscle strength in a patient with myasthenia. This finding strongly implicated the neuromuscular junction in the etiology of MG. Physostigmine was the mainstay of treatment for three decades before the introduction of the longer-acting oral agent pyridostigmine. Substantial improvements in the life expectancy of patients with MG during the middle of last century owed much to the introduction of the anticholinesterases and improved therapies for respiratory failure. Pyridostigmine remains the most frequently used anticholinesterase for MG treatment, with neostigmine only rarely used because of its shorter duration of action and higher rate of gastrointestinal side effects. The short-acting edrophonium is used as an aid in the diagnosis of MG and cholinesterase inhibitor overdose.

Basic Pharmacology

Structure-Activity

Pyridostigmine, neostigmine, and edrophonium all contain a quaternary ammonium group, limiting lipid solubility and preventing passage through the blood-brain barrier. Physostigmine lacks the quaternary ammonium group enabling it to pass freely into the CNS.[170] The longer-acting agents, pyridostigmine, neostigmine, and physostigmine, contain a carbamate group that forms a reversible covalent bond with acetylcholinesterase. Edrophonium, lacking a carbamate group, forms short-lived electrostatic and hydrogen bonds with acetylcholinesterase, accounting for its shorter activity.

Mechanism

Binding of acetylcholinesterase inhibits the breakdown of ACh, increasing the amount of neurotransmitter available to stimulate the reduced number of ACh receptors in the synaptic cleft of the neuromuscular junction.

Metabolism

The carbamate-containing anticholinesterases undergo hydrolysis by cholinesterases and are also metabolized by microsomal enzymes in the liver. Although physostigmine is extensively metabolized, the majority of neostigmine and pyridostigmine is excreted unchanged by the kidneys.

Clinical Pharmacology

Pharmacokinetics

Agents containing a quaternary ammonium group are poorly absorbed and have oral bioavailabilities of only 2% for neostigmine and between 7% and 25% for pyridostigmine.[171] The duration of action is between 3 to 6 hours and elimination half-life varies from 2 to 4 hours. Slow-release formulations can help patients who become symptomatic during the night but owing to variable absorption are not used for awake patients. Around 90% of pyridostigmine is renally cleared unchanged, and dose reductions are recommended for MG patients with reduced renal function and in older adults.[172] Edrophonium acts within 2 minutes of administration. It has an elimination half-life of 30 to 110 minutes but a duration of action much shorter owing to transient binding to acetylcholinesterase. It is predominantly renally cleared.

Pharmacodynamics

Therapeutic Effects. Pyridostigmine is the most commonly used initial treatment for MG. It is particularly effective at reversing muscle weakness and fatigability early in the course of the disease. Over time tolerance can develop, necessitating higher doses. Beyond single doses of 120 mg, little clinical benefit is seen and the rate of adverse effects increases significantly. Infants of myasthenic mothers can have muscle weakness lasting for up to 4 weeks that responds to pyridostigmine but occasionally requires mechanical ventilation.

Adverse Effects. Pyridostigmine is well tolerated in most patients, but at standard doses the muscarinic side effects of nausea and abdominal cramps are frequent. For some, intractable diarrhea prevents continued usage. Uncommonly bradycardia can lead to orthostatic hypotension and require dose reduction. An increase in airway secretions can worsen reactive airway disease and can be confused with respiratory muscle involvement with MG.[169] The development of respiratory failure requiring intubation during a myasthenic crisis often leads to discontinuation of the cholinesterase inhibitors owing to excessive airway secretions. Increased nicotinic activity can lead to muscle cramps and fasciculation that rarely leads to dose adjustment. Excessive administration of an anticholinesterase can lead to increased muscle weakness and muscarinic side effects ("cholinergic crisis"). Increased weakness in response to edrophonium can be used to help differentiate this from a myasthenic crisis.

Drug Interactions

The decision to continue anticholinesterase treatment perioperatively should be individualized. These agents interfere with neuromuscular blockers, if used, during general anesthesia. The cholinesterase inhibitors also act on plasma cholinesterase and can slow the metabolism of ester-type local anesthetics and succinylcholine.

Antiepileptic Drugs

The chronic neurologic disorder of epilepsy, which affects more than 50 million people worldwide, is characterized by seizures and hypersynchronous firing of neuronal networks. The antiepileptic drugs (AEDs) constitute a chemically diverse class. Some of these agents (carbamazepine, valproate, and lamotrigine) are also approved for use as mood stabilizers and details of their pharmacology are reviewed earlier in this chapter.

History

In the latter half of the 19th century, bromides were introduced as the first AEDs. While effective, they had numerous toxicities and were supplanted by phenobarbital on its introduction after World War I. The low cost of phenobarbital has helped it remain a popular first-line antiepileptic in developing countries to this day. In 1938 the antiseizure properties of phenytoin were discovered. With an efficacy similar to phenobarbital but without excessive sedation, it continues to be widely used.[173] Through the 1990s the discovery of new AEDs was infrequent but saw the introduction of the benzodiazepines, valproate, and carbamazepine to the armamentarium. Since then, a continuing stream of drugs has been released, including lamotrigine, topiramate, gabapentin, pregabalin, levetiracetam, and the carbamazepine-derivative oxcarbazepine.[174] In the past 5 years, a prodrug similar to oxycarbazepine (eslicarbazepine) and three drugs with novel action (ezogabine, perampanel, and brivaracetam) have seen FDA approval. It remains unclear where these newest agents fit within established epilepsy treatment protocols and comparative efficacy trials are lacking.

Basic Pharmacology

Structure-Activity

All of the AEDs are synthetic compounds. Individual structural details are listed in Table 12.6. Phenytoin is related to the barbiturates but contains a five-member carbon ring instead of the four-carbon basic structure. Gabapentin and pregabalin are both cyclic analogs of GABA, although pregabalin is around three times more potent. Oxcarbazepine is a keto-analog of carbamazepine.

Mechanism

Agents in this class act through a variety of mechanisms. Molecular targets of action include voltage-gated Na^+, K^+, and Ca^{2+} channels; $GABA_A$ receptors; glutamate receptors; some enzymes; and synaptic proteins. Table 12.7 summarizes the targets of each member of the AEDs. They all act by tilting the balance in favor of synaptic inhibition,[175] thereby preventing abnormal neuronal excitation

TABLE 12.6 Pharmacokinetics of the Antiepileptic Drugs

Drug	Structure	Elimination	Bioavailability (%)	Half-Life (hours)	Protein Binding (%)
Phenytoin	Related to barbiturates	Hepatic	Oral and IV: 70–100	Highly variable avg. 20–30	90
Oxcarbazepine	Carbamazepine derivative	Renal	>95	1–2.5 active metabolite (MHD): 9	40
Topiramate	Aminosulfonic derivative of monosaccharide	Renal	>90	19–23	9–17
Gabapentin	Cyclic analog of GABA	Renal	55–65	6–8	<5
Pregabalin	Cyclic analog of GABA	Renal	>90	5–7	<5
Levetiracetam	Pyrollidine derivative	Renal	>95	7	10
Ezogabine	Carbamic acid ethyl ester	Renal	60	8	60–80
Perampanel	Bipyridine	Hepatic	100	45	95
Brivaracetam	Pyrollidine derivative; analog of levetiracetam	Hepatic	>95	7–8	20
Eslicarbazepine	Carbamazepine derivative	Renal	95	10–12	30

and suppressing the spread of ongoing pathologic activity. The AEDs also affect neuroplastic processes and have genetic and epigenetic effects with longer-term changes on the evolution of the disease.

Metabolism

Phenytoin is extensively metabolized in the liver to an inactive metabolite by CYP 2C9. This process is capacity-limited and at higher doses demonstrates zero-order kinetics. Around 20% of topiramate is also metabolized by CYP 3A4 but most is renally cleared unchanged.[175] Oxcarbazepine and eslicarbazepine are rapidly metabolized by reduction to pharmacologically active metabolites, which are subsequently glucuronidated and renally excreted. Ezogabine is metabolized in the liver by glucuronidation and acetylation by enzymes independent of the CYP system. It has an active metabolite with some antiepileptic activity but lower potency than the parent drug. The agents levetiracetam, gabapentin, and pregabalin are not appreciably metabolized and are excreted unchanged in the urine. Perampanel and brivaracetam are extensively metabolized to pharmacologically inactive metabolites.

Clinical Pharmacology

Pharmacokinetics

Pharmacokinetic parameters of the AEDs are summarized in Table 12.7. At therapeutic doses, the metabolism of phenytoin is nonlinear (first-order kinetics) but becomes linear at toxic doses. Plasma level monitoring is required owing to its unpredictable pharmacokinetics and narrow therapeutic index.

Pharmacodynamics

Therapeutic Effects. There are no placebo-controlled trials of the AEDs as monotherapy for seizure control but there is widespread consensus that these drugs are effective.[175] The addition of newer AEDs as second-line agents in epilepsy refractory to standard monotherapy is supported by clinical data, but is associated with a higher rate of adverse effects. With optimal pharmacotherapy, around 50% of patients achieve total seizure control and a further 25% have significant improvement. AEDs are often used prophylactically in patients with brain tumors, severe traumatic head injuries, and intracerebral hemorrhages.[176] Definitive data demonstrating efficacy for brain tumors and hemorrhages are lacking and there is a paucity of information on the use of the newer AEDs for prophylaxis.

Adverse Effects. Unlike older AEDs, some of which carry FDA black box warnings (see earlier), with the exception of perampanel, the newer AEDs are generally well tolerated. Adverse effects that are common to most agents in the group include dizziness, somnolence, headaches, and memory impairment.

Phenytoin is more frequently associated with adverse effects than other members of this class. Specific problems include gingival hyperplasia, nystagmus, Stevens-Johnson syndrome, and osteomalacia. Phenytoin is also linked with an increased risk of congenital birth defects. Rapid intravenous administration of phenytoin can lead to hypotension and arrhythmias, hence the recommendation to limit delivery rate to 50 mg/min in adults. Gabapentin and pregabalin are associated with an increased risk of depression and suicide. Sudden withdrawal of these agents can precipitate seizures, even in patients who have not had seizures previously. Rarely, hepatotoxicity is linked to gabapentin use. Oxcarbazepine causes SIADH in around 3% of patients. It has been associated with photosensitivity and, given its similarity to carbamazepine, is considered to be a potential teratogen.

Perampanel carries a black box warning that some patients, including those without preexisting psychiatric illness, can develop psychosis or behavioral changes that include suicidal and homicidal ideation. It also has potential for abuse given that very high doses produce euphoric and dissociative effects similar to ketamine, earning it a schedule III classification by the U.S. Drug Enforcement Agency.

Drug Interactions

Phenytoin, oxcarbazepine, and eslicarbazepine induce CYP enzymes, increasing the metabolism of commonly used anesthetic agents, including midazolam, fentanyl, alfentanil, and aminosteroidal muscle relaxants. All drugs in this class enhance the CNS depressant effects of agents used in the perioperative period.[177]

Drugs of Abuse

The abuse of legal and illicit substances remains an intractable problem in modern society. The number of Americans abusing or dependent on ethanol exceeds 17 million and an estimated 24 million are current users of illicit drugs. Drugs of abuse are used for their pleasurable effects, which are due to activation of the mesolimbic dopaminergic reward system, either directly or indirectly. Anesthesiologists often see acutely intoxicated patients during anesthesia for trauma. In the elective setting, many patients abuse drugs chronically and if acutely intoxicated or withdrawing should have their procedures postponed.

The social history is often unreliable in detecting substance abuse. A history of alcohol abuse in younger patients should raise concerns over concurrent use of illicit substances. For nonurgent procedures in which suspicion is high, urine drug screening is useful. Routine drug screens do not test for designer drugs unless regional prevalence makes this cost-effective. It is important to understand how these substances adversely interact with anesthetic agents and to recognize withdrawal syndromes.

Ethanol

Ethanol (C_2H_5OH) has been consumed since prehistoric times. It is produced for human consumption by fermentation. Historically, it was thought that ethanol acted by perturbing the neuronal lipid membrane. More recent evidence suggests that there are multiple sites of action, including $GABA_A$ and glycine receptor potentiation and NMDA glutamate receptor inhibition.[178] Ethanol is rapidly absorbed into the bloodstream and metabolized by alcohol dehydrogenase in the liver to acetaldehyde. Acetaldehyde might mediate some of the neurologic and the changes in dopaminergic transmission that lead to alcoholism. This unstable intermediate is metabolized to acetic acid by aldehyde dehydrogenase. Ethanol is also oxidized by CYP 2E1 in the liver. This pathway is minor except under conditions of chronic consumption, in which CYP 2E1 is dramatically upregulated.

Acutely intoxicated patients have decreased anesthetic requirements, whereas chronic abusers can have higher requirements, partly owing to CYP induction. Perioperative concerns for the alcoholic patient include cardiomyopathy, alcoholic hepatitis, cirrhosis, and varices. Postoperatively generalized grand mal withdrawal seizures can occur around 24 to 36 hours after abstinence. Within 72 hours of cessation, delirium tremens occur in around 5% to 10% of alcoholics and is characterized by confusion, hallucinations, agitation, and autonomic hyperactivity. Treatment and prophylaxis are with the benzodiazepines. The older chronic alcoholic is also at an increased risk for postoperative cognitive dysfunction.

Cocaine

Since the time of the Incas, cocaine has been used as a stimulant. Originally consumed by chewing the leaves of the South American plant *Erythroxylum coca,* it was popularized in Europe and North America by its use in Coca-Cola and Vin Mariani. Modern pharmaceutical techniques allowed purification of the active ingredient in the 1880s, and cocaine hydrochloride was marketed as a panacea for a wide range of illnesses. Identification of the anesthetic properties of the drug saw its widespread use for local and regional anesthesia (see Chapter 20). Early experimenters including Freud and Halsted often self-administered to study the drug but succumbed to its addictive potential. With increasing evidence of problems associated with abuse, cocaine fell out of favor for medicinal use and was banned from distribution in 1914. It remains the second most commonly abused illicit substance, with around 1.5 million adults in the United States reporting recent use.

Cocaine produces intense euphoria and feelings of increased energy. The drug acts by blocking the reuptake of the neurotransmitters dopamine, serotonin, and norepinephrine into nerve terminals, thereby increasing the synaptic concentrations of these neurotransmitters. Effects on dopaminergic neurons are thought to be responsible for the high addictive potential of this drug.[179]

Cocaine is usually consumed orally or by snorting. The alkalinized form ("crack cocaine") can be injected, smoked, or snorted and has even greater addictive potential owing to very rapid absorption with high peak plasma levels. The elimination half-life is 0.5 to 1.5 hours and metabolism is by liver and plasma cholinesterases.

The sympathetic effects of cocaine can precipitate vasoconstriction or vasospasm in arteries supplying the brain and heart, leading to strokes and myocardial infarction or ischemia. Higher doses lead to ventricular arrhythmias and death. Users who smoke crack cocaine can induce asthma or develop pulmonary hemorrhages. Several serious complications are associated with anesthesia in the setting of acute cocaine use. Patients can become severely hypertensive, particularly during laryngoscopy.[180] Direct-acting vasodilators including nitroglycerin and hydralazine or calcium channel blockers are appropriate for treatment and prophylaxis although they worsen preexisting tachycardia. Caution should be exercised in the use of β-blockers, in that unopposed α-receptor action can worsen hypertension and lead to myocardial ischemia. The induction agents, ketamine and etomidate, can exacerbate the underlying hemodynamic abnormalities. Halothane should be avoided in that it sensitizes the myocardium to catecholamines, with a potential for arrhythmias.

Chronic cocaine users can develop intraoperative hypotension that is unresponsive to ephedrine that will usually respond to direct acting vasoconstrictors such as phenylephrine. Physical and psychological dependence to the drug develops, and abrupt cessation perioperatively is associated with a non–life-threatening withdrawal syndrome characterized by depression and fatigue.

Amphetamines

Amphetamine derivatives from the plant *Ephedra sinica* have been used for medicinal purposes for millennia. Modern pharmaceutical processes allowed the synthesis of amphetamine in 1887. Other members of the class, methamphetamine and 3,4-methylenedioxymethamphetamine (MDMA) were first synthesized in the early 20th century. Methamphetamine was used widely by the German military during World War II as a stimulant to prevent fatigue. Over the past 2 decades, methamphetamine ("crystal meth") abuse has become a vast social problem, particularly in the American Midwest. MDMA (ecstasy) was first used as an appetite suppressant before finding use in psychotherapy circles during the 1970s. The euphoric and energizing effects of the drug led to use in the club and bar scene. Although classified as Schedule 1 in the United States in 1984, usage spread to the mainstream and around the world, with ecstasy being among the top four most widely consumed illicit substances.

The basic amphetamine structure is composed of a phenethylamine backbone with a methyl group attached to the alpha carbon. Substitutions generate the related compounds, methamphetamine and MDMA. Methamphetamine abusers commonly administer the drug intravenously, by smoking, or by snorting. Less commonly it is taken orally. MDMA is usually taken orally but can be snorted or delivered rectally. Metabolism of the amphetamines is by CYP 2D6 in the liver. The elimination half-life is 6 to 10 hours for MDMA and 10 to 15 hours for methamphetamine.[180] The effects of amphetamines are mediated by enhanced neuronal release of dopamine, serotonin, and norepinephrine in specific regions of the brain.

Abuse of methamphetamine is associated with cognitive impairment, psychosis, Parkinson disease, extensive dental disease, and hypertension. Amphetamine and methamphetamine have high addictive potential, particularly when administered intravenously or by smoking. Idiosyncratic effects of MDMA include severe hyperthermia that can lead to rhabdomyolysis and disseminated intravascular coagulation. On occasion, patients present with seizures or obtundation caused by severe hyponatremia. Ecstasy is commonly adulterated with other agents, leading to a wide range of other adverse effects.

In the setting of acute intoxication, amphetamines increase volatile anesthetic requirements and reduce the duration of thiopental. These agents have unpredictable effects on the response to sympathomimetic drugs. Hypertensive effects akin to those seen with cocaine can be observed and are managed similarly. Severe hyperthermia is treated by supportive measures. It is unclear if dantrolene or clozapine are useful in this setting. Postoperatively discontinuation of amphetamine and methamphetamine can lead to a withdrawal syndrome similar to that seen with cocaine.

Emerging Developments

Ketamine in the Treatment of Depression

Ketamine was first used as a general anesthetic in the late 1960s and its unique properties have ensured its continued presence within the group of essential intravenous anesthetics. While anesthesiologists are familiar with ketamine's action as a general anesthetic, the drug has recently become the focus of much interest within the field of psychiatry as a potential treatment for depression.

Traditional antidepressants have an efficacy of only 60% to 70% in the treatment of mood disorders and are associated with prolonged delay of onset of action and high remission rates.[181] The search for novel antidepressants has proved unrewarding in recent years; thus it was not surprising that promising results from preclinical and clinical studies with ketamine would generate considerable excitement.

The effectiveness of some NMDA antagonists in animal models of depression led to the conduct of a small randomized controlled trial of ketamine in the treatment of severe unipolar or bipolar depression in 2000.[182] Seven patients received 0.5-mg/kg intravenous ketamine infusions or placebo at two different time points. Immediately after receiving ketamine, patients demonstrated clinically significant improvements in depression rating scores—effects that persisted up to 72 hours after administration.

This initial study prompted the conduct of large numbers of open-label trials demonstrating a 25% to 78% reduction in depressive symptom severity.[183] The difficulty of blinding patients to ketamine treatment has led to a paucity of placebo-controlled, double-blind randomized clinical trial data. Systematic reviews[181,183] of the available high-quality trial data have concluded that ketamine does have a rapid antidepressant effect but it remains unclear whether this is durable. Promisingly, most of these studies have been conducted in patients with severe or treatment refractory depression.

The psychotomimetic properties of the drug have led to fears of abuse potential in this patient population. Other practitioners deem the intravenous administration of ketamine impractical and

have trialed the use of oral ketamine therapy despite a bioavailability of 23% by this route.[184]

The recognition that not all NMDA antagonists are effective as antidepressants emphasizes that considerable work remains to be done to elucidate the mechanisms of ketamine in mood disorder treatment. A recently published study[185] has shown that metabolism of R-ketamine to 2R/6R-hydroxynorketamine is essential for antidepressant effects in a mouse model. These effects appear to be independent of NMDA receptor inhibition and instead rely on early and sustained activation of AMPA receptors, implicating a novel mechanism and suggesting new avenues for next-generation rapid-acting antidepressants.

Key Points

- Neuropharmacologic drugs represent the most prescribed class of agents, with more than 750 million prescriptions written in the United States in 2016. The pharmacology and clinical significance of these drugs in the perioperative setting are often underappreciated.
- The underlying mechanisms for most of the drugs remains elusive, although theories for many converge in effects centered in serotonergic, noradrenergic, and dopaminergic pathways; other receptor groups important to anesthetic pharmacology, including GABA, acetylcholine, and glutamate receptors, are also frequently implicated.
- A number of psychopharmacologic agents are potent inducers or inhibitors of specific cytochrome P450 isoenzymes and thus have the potential to alter the metabolism of many drugs used in the perioperative period.
- Many antipsychotic and mood stabilizer drugs have a narrow therapeutic index with multiple warnings in the product labeling. Pharmacologic and physiologic changes in the perioperative period have the potential to alter plasma concentrations and therapeutic/toxic effects.
- Several psychopharmacologic agents are associated with effects on cardiac conduction, seizure threshold, CNS depression, autonomic and serotonergic activation, the neuroendocrine response to stress, bleeding tendency, and other parameters relevant to anesthetic care. Interaction between some drugs, such as meperidine with monoamine oxidase inhibitors, can be severe or fatal.
- Neuroleptic malignant syndrome (NMS), which can be triggered by many antipsychotics, very closely resembles malignant hyperthermia (MH) and is treated similarly. Patients with a history of NMS should be regarded as MH-susceptible.
- Most psychopharmacologic drugs, including the commonly prescribed antidepressants and anxiolytics, cause changes in receptor expression and function and are associated with withdrawal syndromes if discontinued abruptly. Psychopharmacologic agents should almost always be continued during the perioperative period.
- Levodopa for Parkinson disease should be continued perioperatively and consideration given to enteral administration for longer procedures.
- The decision to continue anticholinesterase therapy for myasthenia gravis should be individualized. These agents interact with neuromuscular blockers and inhibit metabolism of ester-type local anesthetics and succinylcholine.
- Substance abuse is common in patients undergoing anesthesia for emergency procedures. Acute intoxication can lead to adverse interactions with anesthetic agents and vasoactive drugs.
- An emerging development in the field is the use of ketamine as a treatment for refractory depression. Data supporting the application of the technique are mixed and thus the therapy must still be considered in development.

- Sacral Nerves Part of Sympathetic System

Historical Considerations

A specialized taxonomy of the autonomic nervous system (ANS) has been developing since the time of Galen (AD 130–200). In the early 1900s, Langley first referred to the ANS.[1] He used the term *sympathetic nervous system* (SNS) as described by Willis in 1665, and introduced the second division as the *parasympathetic nervous system* (PNS) in 1921.[2] Although Langley initially described only the visceral motor system (efferent fibers), the existence of visceral reflex arcs necessitated the inclusion of the sensory (afferent) portions of the ANS.[3] Early anesthesia textbooks did not contain explicit information dealing with the ANS, but dealt with the practice of anesthesia, elucidating basic considerations of pharmacology and anesthetic technique. The evolution of the comprehensive anesthesia textbook has led to extensive chapters on the ANS.[3,4]

The ANS maintains cardiovascular, thermal, and gastrointestinal homeostasis. A firm understanding of the basic anatomy and physiology of the ANS forms an important foundation for the practice of anesthesiology. ANS structure, function, and reflexes are critical to the support of the circulation under anesthesia. This chapter reviews anatomy and physiology of the ANS relevant to anesthesia.

Anatomy and Physiology

ANS anatomy is composed of central control and feedback areas, sensory receptors, peripheral effectors, and reflex conduction pathways. In addition, complex interactions occur between the ANS and the endocrine system (see Chapter 36).[4] The renin-angiotensin system, antidiuretic hormone, glucocorticoid and mineralocorticoid responses, and insulin interact via an increasing number of receptor subtypes to maintain physiologic homeostasis (Fig. 13.1).

There are no distinct centers of autonomic function in the cerebral cortex. However, input from various sensory systems can affect higher cortical centers, be processed, and result in efferent autonomic activity. Tachycardia and peripheral vasoconstriction heralding a "fight-or-flight" response or a vasovagal response (fainting) are well-known examples of this higher cortical sensory processing.[5] External stimuli representing a threat or danger are detected by the senses of hearing, touch, smell, or sight. These signals are sent to the brainstem, where reflex responses are processed in the hypothalamus and the limbic forebrain. Higher cortical centers provide descending input to the paraventricular nucleus of the hypothalamus, which has projections to sympathetic and parasympathetic nuclei. Chronic stress alters these structures and their function, leading to both sensitization and habituation of the stress response.[6,7]

The hypothalamus is the midbrain center that processes sympathetic and parasympathetic functions, temperature regulation, fluid regulation, neurohumoral control, and stress responses. Hunger, sleep, and sexual function are also regulated by the hypothalamus, dependent on both cortical input and complex feedback control. The anterior hypothalamus controls temperature, while the posterior hypothalamus is involved in water regulation. The

Abstract

This chapter presents a concise description of the autonomic nervous system (ANS) with a focus on clinical elements related to anesthesiology. Beginning with a review of the anatomic divisions of the sympathetic (SNS) and parasympathetic (PNS) systems, the narrative links these structures to the interplay between the seemingly antagonistic physiologic actions of the two divisions. A close look at ANS cellular physiology reveals the receptor and effector mechanisms responsible for these differential effects, leading the reader to understand where anesthetic pharmacology might affect cardiovascular, pulmonary, gastrointestinal and humoral systems. Well-known ANS reflexes that are seen during the conduct of an anesthetic highlight the interaction between the SNS and the PNS. A review of the effect of anesthetics and ANS disease outlines the importance of the ANS in anesthetic practice. Emerging developments, including a radical change in the anatomic structure of the ANS, concludes the chapter.

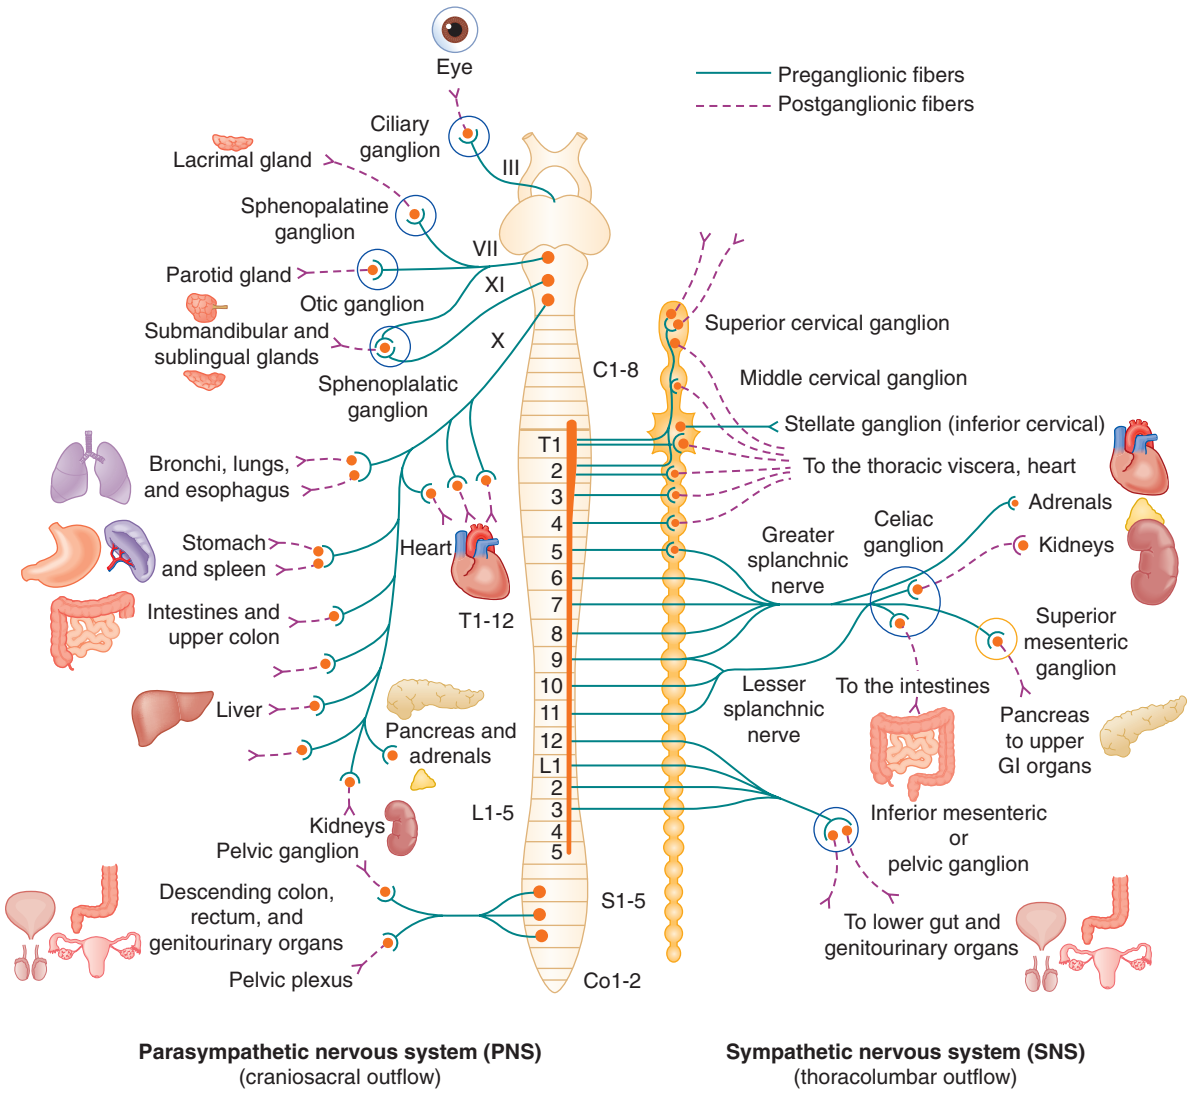
disease states



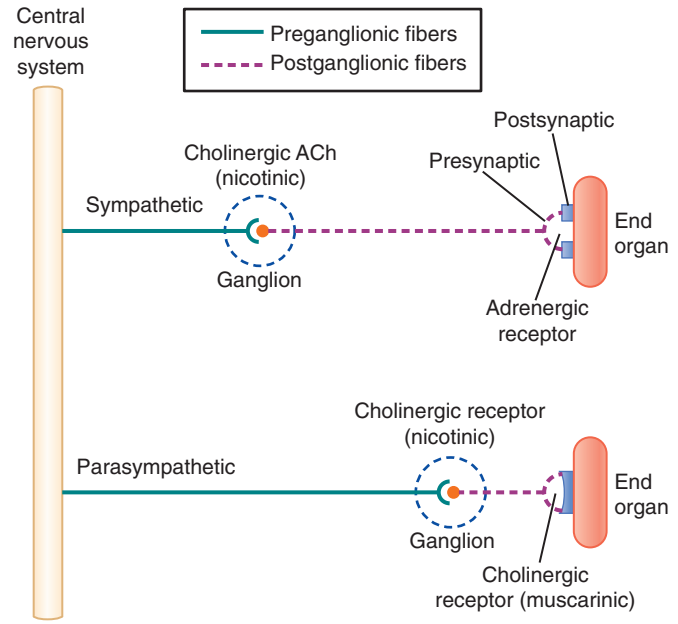
• **Fig. 13.1** Schematic representation of the autonomic nervous system consisting of the parasympathetic nervous system *(PNS, left)* and the sympathetic nervous system *(SNS, right)*.

hypothalamic-pituitary axis is a part of the ANS that ultimately regulates long-term blood pressure control and stress responses.[7]

The output centers of the ANS reside in the medulla oblongata and the pons of the brainstem. Immediate control of blood pressure, heart rate, cardiac output, and ventilation is organized and integrated in specific nuclei. Tonic impulses from nuclei such as the nucleus tractus solitarius maintain blood pressure and respond to afferent signals from the sensory side of the ANS. These afferent impulses from the vagus (X) and glossopharyngeal (XI) nerves result in vasodilation and bradycardia (see the section on ANS reflexes).

The ANS is anatomically and functionally divided into two complementary systems, the SNS and the PNS (see Fig. 13.1). The peripheral SNS is controlled by the thoracolumbar segment of the spinal cord, while PNS control arises from the brainstem nuclei and sacral segments (see Fig. 13.1). Activation of the SNS produces diffuse physiologic responses, while the PNS exerts local control of innervated organs.[8] Both systems have efferent pathways through peripheral ganglia; the SNS ganglia are located close to the thoracolumbar spine, and the PNS ganglia are situated near or inside the innervated organs (see Fig. 13.1; Fig. 13.2). Ganglia serve as synaptic relay stations, and in the SNS coordinate an efferent mass action response through signal amplification. Thus one preganglionic SNS fiber can activate 20 to 30 postganglionic sympathetic neurons and their fibers. In contrast, PNS preganglionic fibers terminate in ganglia located in proximity to the innervated organs and affect only one to three postganglionic neurons.[2] The close proximity of PNS ganglia to their effector organs is the anatomic basis of the more focused and specific responses elicited by PNS activation.

Most organs are affected by both the SNS and the PNS. Different organs have their resting tone dominated by the SNS or the PNS, and this ratio can change depending on pathophysiologic states and also can change over the lifetime of an individual. For instance, newborns are dominated by parasympathetic responses; hence bradycardia can be seen in 20% of unpremedicated infants during stressful situations such as anesthetic induction and airway manipulation, while it is uncommon in adults.[9] As another example, vasoreactivity of the major blood vessels, arteries, and arterioles is primarily responsive to the SNS, while PNS cardiovascular effects reside mainly at the level of the heart. The differential effects of



• **Fig. 13.2** Differences between the location of the ganglia in the sympathetic and parasympathetic branches of the autonomic nervous system. The 22 paired sympathetic ganglia are located close to the vertebral column in the sympathetic chain. The unmyelinated postganglionic fibers innervate their respective organs. The exception is the adrenal gland, where the sympathetic preganglionic nerve fibers travel directly to the adrenal medulla. The parasympathetic preganglionic fibers travel directly to the organ of innervation to synapse with postganglionic neuronal cell bodies. *ACh,* Acetylcholine.

the ANS in various organs and organ systems are summarized in Table 13.1.

In general, the SNS modulates the activity of vascular smooth muscle, cardiac muscle, and various glands (especially the adrenal gland); this modulation is critical for the fight-or-flight response. In contrast, the PNS modulates "rest-and-digest" functions such as salivation, lacrimation, urination, digestion, defecation, and sexual arousal.

Sympathetic Nervous System

The SNS is formed from preganglionic fibers in the thoracolumbar segments (T1-L3) of the spinal cord arising from the intermediolateral gray column (see Fig. 13.1). These myelinated fibers enter the paravertebral ganglia and travel a variable distance up or down the sympathetic chain to synapse with the neuronal cell bodies of postganglionic sympathetic neurons. The unmyelinated postganglionic fibers then innervate their respective organs. An exception to this rule is the adrenal gland, where the preganglionic fibers do not synapse in the thoracic ganglia, but course through the sympathetic chain into the adrenal medulla. The chromaffin cells in the adrenal medulla are derived from neuronal tissue and essentially function as the postganglionic cells.

The stellate ganglion consists of postganglionic neurons that provide sympathetic innervation to the head and neck. Preganglionic fibers from the first four or five thoracic segments form this ganglion as well as the superior and middle cervical ganglia. Local anesthetic injected in the vicinity of the stellate ganglion blocks the sympathetic fibers coursing to the ipsilateral head and neck and may result in Horner syndrome, characterized by ptosis, miosis, enophthalmos, and anhydrosis on the affected side.[10] This syndrome might be seen as a direct effect of a stellate ganglion block or be experienced as a side effect of a brachial plexus block owing to its close proximity to the stellate ganglion.[10] Similarly, blockade of the lumbar plexus produces a sympathectomy in the lower extremities, and peripheral nerve block often produces a sympathectomy in the affected limb because the postganglionic sympathetic nerve fibers travel along the somatic nerves.

TABLE 13.1 Autonomic Nervous System Receptor Types and Subtypes

Receptor	Effector	Response to Stimulation
Sympathetic Nervous System		
α_1	Smooth muscle (vascular, iris radial, ureter, trigone, bladder sphincters)	Constriction
α_2	Presynaptic SNS nerve endings	Inhibition of NE release
	Brain	Neurotransmission
β_1	Heart	Increase rate, contractility, conduction
	Adipose tissue	Lipolysis
β_2	Blood vessels	Dilation
	Bronchioles	Dilation
	Kidney	Renin secretion
	Liver	Gluconeogenesis, glycogenolysis
	Endocrine pancreas	Insulin secretion
	Uterus	Relaxation
D_1	Blood vessels	Dilation
D_2	Presynaptic SNS nerve endings	Inhibition of NE release
Parasympathetic Nervous System		
M_1	Skeletal prejunctional nerve endings	Facilitate ACh release
M_2	Lung–presynaptic PNS nerve endings	Inhibits ACh release
	Visceral organs	Increase
M_3	Lung smooth muscle, postsynaptic	Bronchoconstriction
N_1	PNS and SNS ganglion	Ganglionic blockade
N_2	Skeletal muscle	Muscle contraction

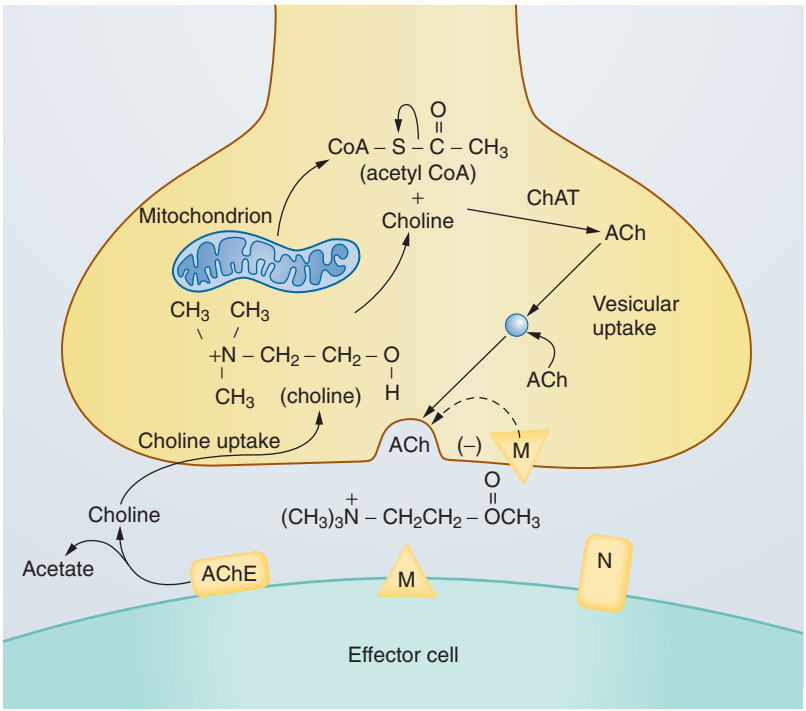
Parasympathetic Nervous System

Preganglionic fibers in the PNS arise from the midbrain, medulla oblongata, and sacral segments of the spinal cord. Cranial nerves II, VII, IX, and X carry preganglionic parasympathetic fibers directly



• **Fig. 13.3** The cholinergic synapse. Acetylcholine *(ACh)* is produced in the presynaptic terminal by the combination of acetyl coenzyme A *(CoA)* and choline through the action of choline acetyltransferase *(ChAT).* This neurotransmitter is stored in vesicles located in the presynaptic terminal and released upon nerve stimulation. ACh can bind to either nicotinic *(N)* or muscarinic *(M)* postsynaptic receptors to elicit an effector response (after summation in the postsynaptic membrane). In addition, ACh interacts with presynaptic muscarinic receptors to provide negative feedback on ACh release. ACh is broken down in the synapse by acetylcholine esterase *(AChE),* and choline is taken up into the presynaptic terminal to be reused.

to ganglia located near or directly in innervated organs. The sacral segments S2-S4 provide innervation to the rectum and genitourinary tissues (see Fig. 13.1).

The vagus nerve (X) is the major carrier of parasympathetic neuronal traffic. These preganglionic fibers affect the heart, lungs, and abdominal organs with the exception of the distal portion of the colon. A combination of the distal location of the ganglion and the smaller two- to threefold amplification factor between preganglionic and postganglionic fibers causes parasympathetic effects to be specific to each organ.

Cellular Physiology

Preganglionic Neurons

Synaptic transmission through ANS ganglia is similar in both the SNS and the PNS. Preganglionic neurons in both the SNS and PNS are cholinergic. Acetylcholine (ACh) is stored in synaptic vesicles and released by a calcium ion (Ca^{2+})-dependent process upon nerve terminal depolarization (Fig. 13.3). ACh then interacts with postsynaptic receptors to depolarize the postsynaptic membrane. The principal ganglionic receptors are excitatory nicotinic ACh receptors, related to the ACh receptors at the neuromuscular junction (see Chapter 21). Thus many neuromuscular blocking agents have cardiovascular side effects mediated by their actions at the level of ANS ganglia. Recent advances in the pharmacology of these drugs have been directed at decreasing these ganglionic actions (see Chapter 22).

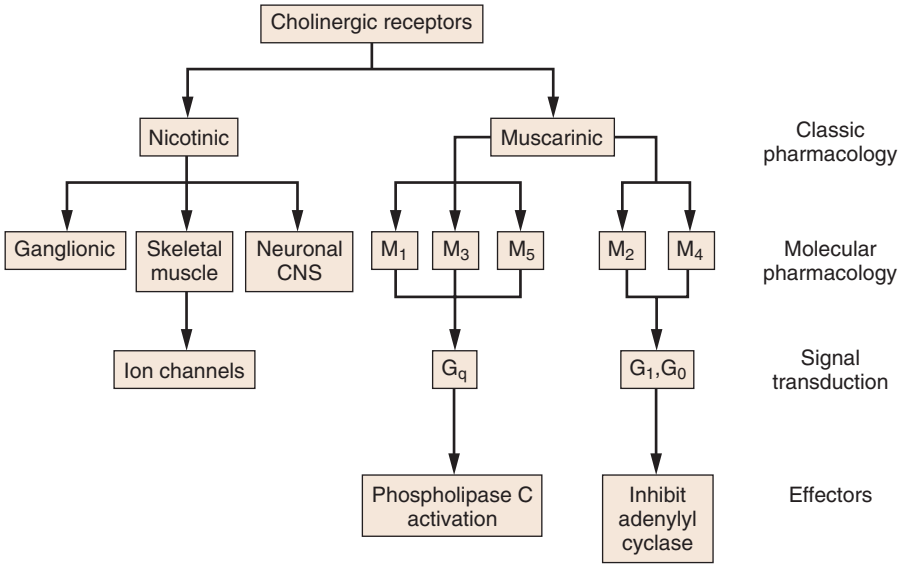
There are two distinct nicotinic receptor types, designated neuronal and muscle nicotinic ACh receptors (Fig. 13.4).[11] Neuronal ACh receptors expressed in the autonomic ganglia are composed of $\alpha_3\beta_4$ subunits and are blocked by older neuromuscular blockers (e.g., gallamine), leading to ganglionic blockade. The neuromuscular junction has muscle nicotinic ACh receptors (composed of $\alpha\beta\delta\varepsilon$ subunits in adults) that are blocked selectively by the newer neuromuscular blocking agents, resulting in few side effects. Volatile anesthetics and ketamine are potent inhibitors both at $\alpha_4\beta_2$ in the central nervous system (CNS) and ganglionic $\alpha_3\beta_4$ receptors.[11] The development of neuromuscular blocking agents has been focused on reduction of muscarinic side effects and elimination of ganglionic blockade. Structure-activity relationships indicate that the presence of quaternary ammonium moieties facilitates binding at the ACh site, whereas interionic distances may play a role in diminishing ganglionic as well as muscarinic cross-reactivity.[12]

Both nicotinic and muscarinic agonists and blockers interact at the level of the ganglia, the effects of which summate to either excite or inhibit the postganglionic neuron, and subsequently inhibit the effector organ. Thus the ganglionic synapse serves complex integrative and processing functions during normal physiology and while under the influence of anesthetic agents.

Postganglionic Neurons

Sympathetic Nervous System

Epinephrine, norepinephrine, and dopamine are the classic neurotransmitters of sympathetic synaptic transmission released from

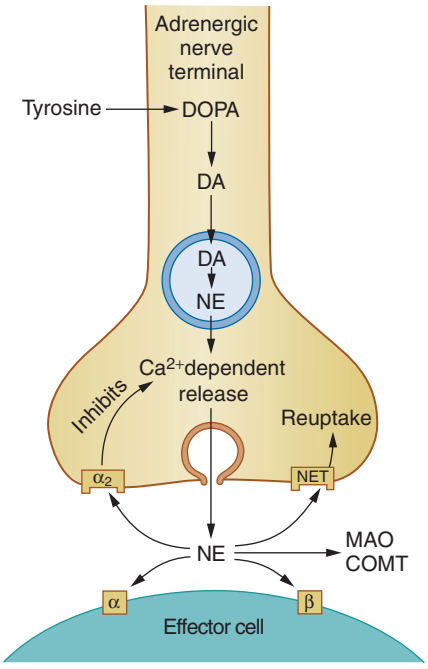


• **Fig. 13.4** Classification of cholinergic receptors. Receptor classification is pharmacologic or based on second messenger signal transduction. *CNS,* Central nervous system.

postganglionic neurons (Fig. 13.5); they interact with adrenergic receptors to effect sympathetic physiologic responses. As shown in Fig. 13.6, these neurotransmitters and their receptors can be characterized at different levels. Building on the original observation by Ahlquist, adrenergic "receptors" are of two different types (α and β) classified in terms of the overall physiologic response they elicit (the "classic pharmacology" approach).[13] Modern pharmacology further categorizes these receptors in terms of their molecular biology (e.g., DNA sequence and protein structure). From a mechanistic perspective, these receptors can also be classified in terms of how their signals are transduced (i.e., which G-protein subtype is involved) and how the response is effected (i.e., what ion channels or enzymes are involved).

For example, norepinephrine released from sympathetic postganglionic neurons stimulates both α- and β-adrenergic receptors, eliciting classic adrenergic responses. α_2 Receptors located presynaptically, provide a negative feedback loop to modulate further release of neurotransmitter (see Fig. 13.5). The postsynaptic receptors regulate effector cells through second-messenger signaling. The various and widespread physiologic actions of adrenergic and dopaminergic receptors are summarized in Table 13.1.

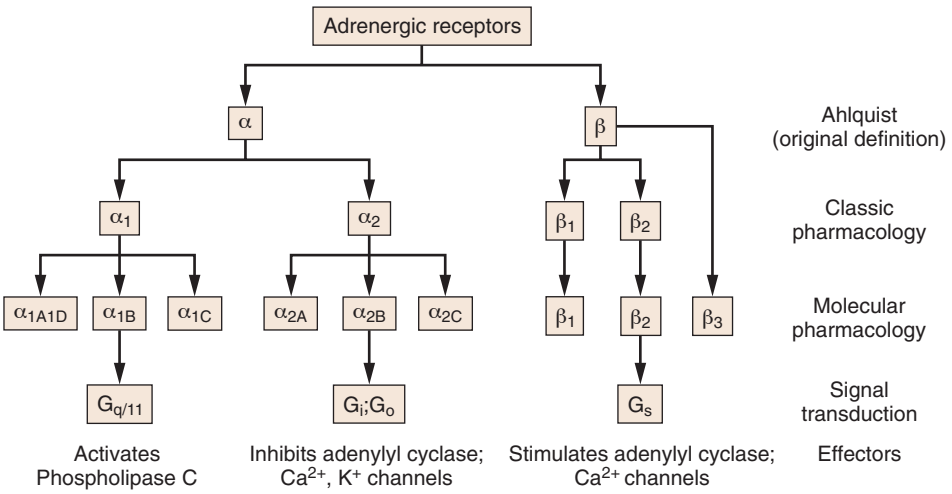
Synthesis of the adrenergic neurotransmitters takes place in the presynaptic varicosities of postganglionic sympathetic neurons. The steps in the enzymatic synthesis of norepinephrine are depicted in Fig. 13.5. The neurotransmitters are stored and released from synaptic vesicles, and reuptake into presynaptic nerve endings assists in the termination of transmitter action. In addition, diffusion of transmitters away from the synaptic cleft and metabolism by monoamine oxidase and catechol-*O*-methyl transferase quickly terminate the action of norepinephrine.



• **Fig. 13.5** The adrenergic presynaptic terminal. Tyrosine is converted to dihydroxyphenylalanine *(DOPA)* by tyrosine hydroxylase. DOPA decarboxylase produces dopamine *(DA)* in the cytoplasm, which is taken up into synaptic vesicles. Inside the synaptic vesicles, DA is converted to norepinephrine *(NE)* by dopamine β-hydroxylase. When NE is released from the presynaptic site by calcium *(Ca^{2+})*-dependent exocytosis, the released neurotransmitter interacts with the effector cell adrenergic receptors and receptors located on the presynaptic membrane. Presynaptic α_2 receptors inhibit further NE release. Presynaptic β receptors enhance NE reuptake, the major factor in removal of NE from the synaptic cleft. NE synthesis is controlled by a negative feedback loop at the level of tyrosine hydroxylase (not shown). Small amounts of NE escape into extraneuronal tissues, where it is inactivated by monoamine oxidase *(MAO)* and catechol-*O*-methyltransferase *(COMT). NET,* norepinephrine transporter.

Parasympathetic Nervous System

ACh is the primary neurotransmitter at the postganglionic effector sites of the PNS. The postsynaptic receptors for ACh are classified as nicotinic or muscarinic. As with the adrenergic receptors, cholinergic receptors can be classified in terms of classic



• **Fig. 13.6** Classification of adrenergic receptors. Receptor classification is pharmacologic or based on second-messenger signal transduction. *Ca^{2+},* Calcium ion; *K^{+},* potassium ion.

TABLE 13.2 Homeostatic Balance Between the Parasympathetic and Sympathetic Nervous Systems by Organ System

Organ System	Effector	SNS Stimulation	PNS Stimulation
Cardiovascular	Sinoatrial node	Increase heart rate	Decrease heart rate
	Atrioventricular node	Increase conduction velocity	Decrease conduction velocity
	His-Purkinje fiber	Increase automaticity, conduction	None or minimal
	Myocardial tissue	Increase contractility	None or minimal
	Coronary arterioles	Constriction (α_2), dilation (β_2)	Dilation and constriction
Gastrointestinal	Salivary glands	Little increase in secretion	Stimulates secretion
	Gall bladder	Relaxation	Contraction
	Smooth muscle	Inhibits	Stimulates
	Sphincters	Constricts	Relaxes
Ophthalmologic	Iris	Mydriasis	Miosis
	Ciliary muscle	Relaxation (for far vision)	Contraction (for near vision)
Pulmonary	Bronchial smooth muscle	Relaxation	Contraction
Genitourinary	Bladder walls	Relaxes smooth muscle	Smooth muscle contraction
	Bladder sphincter	Contraction	Relaxation
	Ductus deferens, seminal vesicle, prostatic and uterine musculature	Contraction of smooth muscle	Vasodilation and erection
Thermal regulation	Blood vessels	Constriction	Dilation
	Sweat glands	Diaphoresis (postganglionic sympathetic fibers are cholinergic)	Little effect

PNS, Parasympathetic nervous system; *SNS,* sympathetic nervous system.

pharmacology, molecular biology, and/or cellular mechanisms (see Fig. 13.4). Nicotinic receptors, which function at the neuromuscular junction, are also present in autonomic ganglia (see earlier text).

Muscarinic receptors mediate the majority of PNS physiologic effects (Table 13.2). After release into the synaptic cleft, the action of ACh is quickly terminated by the extracellular enzyme acetylcholinesterase (AChE) through hydrolysis (see Fig. 13.3). AChE is postsynaptically membrane-bound; hydrolysis of ACh produces choline and acetate. Choline is taken up by the presynaptic nerve endings to be reused, while acetate diffuses away from the synaptic cleft.

There are five distinct subclasses of muscarinic receptors, three of which have pharmacologic significance in the PNS, designated M_1, M_2, and M_3.[14] M_1 receptors exist in autonomic ganglia and the CNS and are present in the airway. M_1, M_2, and M_3 receptors have effects on the airway smooth muscle with the majority of receptors being M_2 and M_3. M_2 receptors are located presynaptically and function as part of a negative feedback loop to limit release

of ACh. M_3 receptors are located postsynaptically and mediate bronchoconstriction.

Enteric Nervous System

The gastrointestinal tract is innervated by sympathetic and parasympathetic efferents arising from preganglionic and postganglionic sites. These neural inputs, along with visceral afferents, interact with intrinsic neural elements (often referred to as the enteric nervous system) to control gut function. The SNS contributes nerve fibers from cell bodies located within the prevertebral sympathetic ganglia and from celiac, inferior mesenteric, and pelvic ganglia. Vagal (parasympathetic) innervation consists of both sensory and motor fibers. The vagal efferents end on smooth muscle within the walls of the gut, interacting with the intrinsic myenteric ganglion to control motility (see Chapter 31). Efferent outflow from the sympathetic and the parasympathetic systems modulate blood flow, secretory activity, and motility.[15,16] Vagal afferent traffic responds to normal gut function, whereas sympathetic afferents respond to painful stimuli such as distention and injury.

Anesthetic effects on the enteric nervous system can be divided into direct pharmacologic effects on the intestinal smooth muscle and effects resulting from spinal or epidural anesthesia. Muscarinic cholinergic receptors in the gut can be modulated by AChE inhibitors and anticholinergics used for reversal of neuromuscular blockade.[17] Postoperative ileus can be decreased by the use of thoracic epidural anesthesia.[18] Autonomic dysfunction causing gut dysmotility occurs because the SNS exerts more influence in the postoperative period than the parasympathetic system. This inhibitory sympathetic reflex can be interrupted by division of the splanchnic nerves, destruction of afferent sensory nerves, or chemical sympathectomy via thoracic epidural anesthesia. The clinical result of thoracic epidural anesthesia has been shown to be a shortened time to resolution of postoperative ileus.[18]

Second Messengers in the Autonomic Nervous System

The interaction of neurotransmitters with their postsynaptic receptors results in signal transduction, which translates receptor binding into an effector cell response. In the adrenergic system, transduction is mediated by G proteins, which then regulate adenylyl cyclase and phospholipase C to generate second messengers and/or directly modulate various ion channels (see Chapter 1). In contrast, nicotinic ACh receptor binding leads to opening of its intrinsic ion channel, which results in changes in the cell electrical potential. Muscarinic ACh receptors are G-protein–coupled receptors similar to adrenergic receptors. Second-messenger responses to muscarinic receptor stimulation depend on the effector site and the muscarinic receptor subtypes expressed (see Table 13.2).

Adrenal Medulla

The paired adrenal medullae are specialized portions of the SNS. Chromaffin cells are homologous to the sympathetic ganglion neurons and are similarly derived from the neural crest. The adrenal medulla can be thought of as a functional sympathetic ganglion in direct communication with the systemic circulation. Stimulation of the SNS results in the release of epinephrine and norepinephrine from the medulla into the bloodstream, eliciting a diffuse (nontargeted) sympathetic response from various effector organs expressing adrenergic receptors. In this way, the adrenal gland represents the general effector of the SNS; stimulation results in a 20- to 30-fold amplification essential to the stress response.[19]

Autonomic Nervous System Reflexes

The ANS maintains homeostasis using the SNS and PNS as counteracting regulators (see Table 13.2). The relative tone of each of the two subsystems varies with age, sex, organ system, and environmental effects such as stress.[20] The challenge facing anesthesiologists is to maintain homeostasis while the ANS is modulated by medications, coexisting disease, surgical stimulation, and anesthetic drugs. Understanding of the pathways of ANS reflexes, and the anesthetic/surgical circumstances under which they are accentuated or attenuated, provides a conceptual framework for maintaining homeostasis during anesthesia and critical care.

Central Nervous System Reflexes

Cushing's Triad

Cushing's triad is the physiologic association of increased intracranial pressure, bradycardia, and hypertension.[21] Intracranial hypertension leads to sympathetically mediated increases in blood pressure; the increase in vascular tone results in bradycardia. Activation of parasympathetic medullary centers via the baroreceptor reflex (see later text) slows the heart but does not overcome sympathetically mediated hypertension. The result is a homeostatic increased blood flow to the brain.

Autonomic Dysreflexia

Historically termed *autonomic hyperreflexia,* this condition results from chronic disruption of efferent impulses down the spinal cord, as seen in spinal cord trauma or tumor impingement.[22] Autonomic hyperreflexia is uncommon if the level of disruption is below T5. Inciting stimuli such as bladder distention, bowel distention, or surgical stimulation can produce an exaggerated sympathetic response. This occurs because there is a loss of normal inhibitory impulses from areas above the level of the lesion. A portion of the exaggeration in the response is due to adrenergic receptor supersensitivity secondary to denervation. Management of the quadriplegic or high paraplegic patient consists of either spinal or general anesthesia combined with careful manipulation of blood pressure.[23]

Thermogenesis Reflex

Autonomic control of thermoregulation in mammals consists of reflex pathways from sensory cells originating in diverse tissues, including the skin, core organs, and the CNS. These signals are processed by the hypothalamus, which maintains body temperature within a narrow range of a few tenths of a degree around 37°C. Daily circadian rhythms result in a sinusoidal variation of about 1°C. The output of the hypothalamus controls effector responses, including peripheral vasculature action (vasodilation or vasoconstriction), sweating, and shivering.[24]

The preoptic area in the anterior hypothalamus receives thermal afferent signals from peripheral receptors as well as sensors located in the core (spinal cord, some organs). Efferent traffic goes to the principal thermoregulatory effectors: (1) cutaneous blood vessels, which vasoconstrict to reduce heat loss and vasodilate to facilitate heat loss; (2) brown fat and skeletal muscle for thermogenesis and shivering; and (3) sweat glands to provide for evaporative heat loss.[25]

Sweating is controlled by cholinergic fibers that can be blocked by muscarinic antagonists such as atropine or by peripheral nerve block.[26] Shivering can be blocked by the use of neuromuscular blockers and is diminished in old age and neuromuscular diseases. Shivering does not occur in newborns and is limited in infants.

Nonshivering thermogenesis occurring in newborns and infants is modulated by norepinephrine from adrenergic nerve terminals. Vasoconstriction is controlled by the ANS at the level of the arteriovenous shunts and is the result of sympathetic nerve traffic and not circulating catecholamines.

All general anesthetics impair thermogenesis reflexes. The sweating threshold is slightly increased and vasoconstriction and shivering thresholds are decreased markedly. These effects of anesthetics can lead to hypothermia during surgery if heat loss through radiation, conduction, convection, and evaporation is not minimized.[27]

Cardiac Reflexes

Baroreceptor Reflex

Stretch receptors in the walls of the carotid artery (carotid sinus) and aorta sense an increase in pressure (either endovascular or external, such as carotid massage). Afferent impulses are carried via the nerve of Hering and the vagus nerve to the medulla. In the medulla the excitatory baroreceptor inputs interact at the nucleus of the solitary tract to disinhibit inhibitory interneurons, which then send increased signals to the rostral ventrolateral medulla and onward to the intermediolateral nucleus.[28] A decrease in heart rate, blood pressure, myocardial contractility, and total peripheral vascular resistance is mediated by efferent vagal activity (see Chapter 24). This effect is seen during anesthesia when phenylephrine, an α_1-receptor agonist, is administered intravenously, causing a rise in blood pressure and a fall in heart rate. Halothane attenuates this reflex.[29]

Chemoreceptor Reflex

Central chemoreceptors are sensitive to increases in arterial carbon dioxide and decreases in arterial pH. Hypercarbia elicits a rapid and vigorous increase in minute ventilation (see Chapter 29). Volatile anesthetics, opioids, and nitrous oxide attenuate this response in a dose-dependent fashion. Even subanesthetic concentrations of volatile anesthetics have an effect on the ventilation response; thus patients given halogenated agents in the operating room can continue to have an impaired response to hypercarbia in the postanesthesia care unit.[30] Peripheral chemoreceptors are present in the carotid body; volatile anesthetics also produce dose-dependent attenuation of the ventilatory response to hypoxia mediated by these receptors.[31] Hypoxia elicits afferent impulses from the carotid and aortic bodies through the nerve of Hering and the vagus to the nucleus tractus solitarius, increasing respiratory rate, tidal volume, and thus minute ventilation. Sympathetic activation causing increased heart rate and cardiac output can also occur.[32]

Bainbridge Reflex

An increase in central venous pressure activates stretch receptors in the atria. Afferent impulses through the vagus nerve have an impact on cardiovascular centers in the brain, which then inhibit tonic parasympathetic output, resulting in tachycardia.[33] The Bainbridge reflex can be seen during childbirth when autotransfusion increases central venous pressure.[34] Steep Trendelenburg positioning, such as that seen with laparoscopic hysterectomy, may also precipitate this reflex.

Bezold-Jarisch Reflex

This cardiac reflex is characterized by hypotension, bradycardia, and peripheral vasodilation (see Chapter 10). The Bezold-Jarisch reflex occurs in response to noxious stimuli detected in the ventricle; historically this was studied using *Veratrum* alkaloids administered intravenously. Chemoreceptors located in the ventricles respond to myocardial ischemia, resulting in an increase in blood flow to the myocardium and a decrease in the work of the heart. This appears to be a cardioprotective reflex, as coronary vasodilation occurs. The pathway for this cardioprotective reflex begins with receptors in the ventricles of the heart, which detect mechanical and chemical stimuli. Afferent unmyelinated C-fibers travel through the vagus to enhance the baroreceptor reflex mechanisms, inhibit sympathetic output, and inhibit vasomotor tone, leading to peripheral vasodilation. The significance of this reflex in the presence of anesthetics continues to be debated, particularly in relation to regional anesthesia. As a cardioinhibitory reflex, the Bezold-Jarisch reflex might be functioning in parallel with the baroreceptor reflex but is probably not a predominant cause of physiologic change in humans.[35]

Valsalva Maneuver

Forced expiration against a closed glottis leads to multiple ANS-mediated responses. Increased intrathoracic pressure leads to a decrease in venous return, causing an abrupt decrease in cardiac filling and blood pressure. The baroreceptor response leads to an increase in heart rate and inotropy through sympathetic stimulation. Upon glottic opening, the increase in venous return leads to an increase in blood pressure (contractility is still increased). This is detected by the baroreceptors, causing a parasympathetically mediated decrease in heart rate.[36]

Oculocardiac Reflex (Trigeminal Nerve–Mediated Reflexes)

The trigeminal nerve (V) is associated with several autonomic reflexes; the best known is the oculocardiac reflex. Pressure on the globe or pulling on the extraocular musculature elicits afferent signals in the short and long ciliary nerves. These signals converge on the Gasserian ganglion, causing a parasympathetic response, notably severe bradycardia. Release of the stretch results in a return of normal heart rate. This muscarinic receptor–mediated response can be blocked with glycopyrrolate or atropine or by retrobulbar nerve block. In addition to the oculocardiac reflex, parasympathetic activation has been reported during intranasal stimulation and is an important part of the diving reflex.[37,38] During anesthesia, the trigeminal-mediated reflex may often be terminated by cessation of the stimulation.

Anesthesia, Disease, and the Autonomic Nervous System

Effects of Anesthetics on the Autonomic Nervous System

General anesthetics tend to suppress the ANS, as they do the CNS. Many specific drugs used in anesthesia directly or indirectly interact with systems, organs, and receptors of the ANS, which then modify the function of the ANS. For instance, administration of the α_2-agonist clonidine decreases the dose of halothane required to produce general anesthesia.[39] Dexmedetomidine, an agonist of α_2 receptors in the CNS, is often used as an anesthetic adjunct to augment both sedation and analgesia.[40]

Anesthetics depress the ANS, in part by attenuating homeostatic reflexes and by decreasing the normal variability in measurements seen owing to the balance between the sympathetic and

parasympathetic systems. Heart rate variability, pulse-to pulse interval, and pulse plethysmography amplitude have been used to characterize the state of the ANS.[41,42] Administration of a potent opioid such as fentanyl decreases normal beat-to beat variability, depresses sympathetic tone, and promotes vagal activation.[43] Potent inhaled anesthetics such as desflurane depress the ANS as measured by heart rate variability.[44] Xenon, an anesthetic that has less hemodynamic depression than potent inhaled agents, causes increased parasympathetic and decreased sympathetic activity compared with total intravenous anesthesia with propofol.[45] Thus, although inhaled anesthetics have variable effects on the ANS, depression of the SNS appears to dominate.

General anesthesia and regional anesthesia also have differential effects on the ANS. The balance of sympathetic with parasympathetic tone in the upper body (unaffected by a lumbar epidural block) and the lower body, or the change in the balance between the intraoperative and postoperative state can have consequences in critical cardiac patients.[46] ANS dysfunction in the intensive care unit complicates the perioperative course in the surgical patient.[47]

Autonomic Failure

Aging, diabetes mellitus, and dysautonomia can result in failure or dysfunction of the ANS that affects perioperative management.

Aging

The cardiovascular effects of aging are characterized by hypertension and orthostatic hypotension, two conditions regulated by the ANS.[48] In addition, loss of temperature control can lead to heat stroke or hypothermia. All of these conditions lead to an inability of the older patients to adequately adapt to environmental stress. While the amount of circulating epinephrine and the number of β-adrenergic receptors are not reduced in older adults, the amount of norepinephrine is increased. This leads to a cyclic decline in responsiveness of adrenergic receptors as circulating plasma norepinephrine increases and receptors downregulate, requiring more stimulation.[48] Because older adults have decreased levels of plasma renin and aldosterone and increased levels of atrial natriuretic factor, they are prone to salt-wasting and hypovolemia.[49] The resultant labile blood pressure, particularly with orthostatic changes, makes pharmacologic management challenging. For instance, β-adrenergic agonists have a markedly decreased effect on heart rate, cardiac output, and vasodilation as a result of reduced affinity of the β-adrenergic receptor and a decline in the efficacy of second-messenger coupling.[48]

Temperature regulation in older patients is also altered as a consequence of changes in the ANS, and as a result of reduced ability of the body to respond physiologically with shivering and vasoconstriction. Older patients have reduced muscle mass so they are unable to generate heat effectively. They also have reduced subcutaneous fat (even though total fat as measured as a proportion of body weight is increased), leading to a decrease in thermal insulation.[50] Thermoregulatory control of skin blood flow in the elderly is also altered as a result of changes in the ANS. Reflex vasoconstriction and vasodilation are impaired because of diminished sympathetic output and reduced vascular responsiveness.[51] As a consequence, older adults can experience more stress related to hypothermia and hyperthermia.

Diabetes Mellitus

Autonomic neuropathy is common among diabetic patients. Between 20% and 40% of insulin-dependent diabetic patients have significant peripheral neuropathy, characterized by labile blood pressure, thermoregulatory deficits, and gastroparesis (possibly vagal nerve dysfunction).[52] This constellation of problems can require modification of the typical anesthetic plan, including pretreatment to mitigate the consequences of aspiration of stomach contents, cardiovascular support, and proactive efforts to prevent hypothermia. Perhaps in part because of autonomic dysfunction, diabetic patients experience more stress and are at increased risk for perioperative complications.[53]

Autonomic Dysautonomia

Dysautonomia can occur as a result of a genetic defect (e.g., familial dysautonomia, Shy-Drager syndrome), viral infection (Guillain-Barré syndrome), malignancy (Lambert-Eaton syndrome), or diseases of unknown etiology (Parkinson disease). Orthostatic hypotension, supine hypertension, and a decreased beat-to-beat variability in heart rate are common signs. This can lead to rapid changes in blood pressure and an exaggerated response to sympathomimetic drugs under anesthesia as the result of an alteration in adrenergic receptor number or function.[54]

Emerging Developments

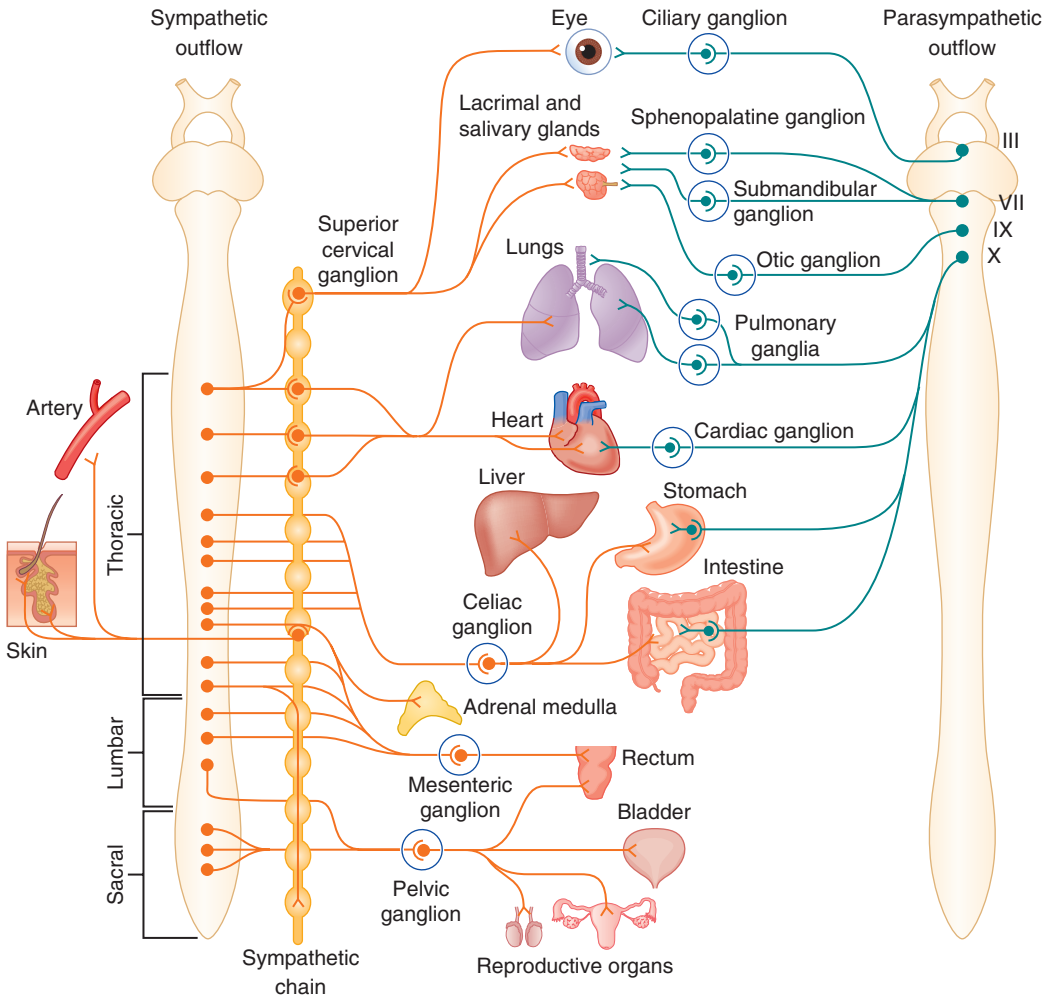
The Role of the Autonomic Nervous System in Obesity and Inflammation

Obesity has been associated with chronic neuroinflammatory changes in the hypothalamus, impairing neuroendocrine and autonomic control of elements related to occurrence of metabolic syndrome. In particular, chronic hypothalamic inflammation results in an upregulation of sympathetic activity, glucose intolerance, insulin resistance, and β-cell dysfunction. The increase in sympathetic activity leads to obesity-related hypertension and a sympathetically mediated modulation of visceral adipose tissue.[55]

Metabolic syndrome is associated with high rates of cardiovascular, pulmonary, and renal perioperative adverse events. Research relating to anesthetic care of the patient with metabolic syndrome is currently lacking; recognition of patient characteristics (central obesity, atherogenic dyslipidemia, hyperglycemia) and the associated heightened sympathetic activity will alert the practitioner to the added risks.[56]

Sacral Nerves Part of Sympathetic System

Recent investigations may lead to a simplification of the long-held anatomic structure of the ANS. Using a mouse model, Espinosa-Medina and colleagues demonstrated that the genetic signature of the sacral outflow tract neurons was better characterized as being of sympathetic origin, rather than parasympathetic.[57] The genetic makeup of sacral preganglionic neurons shares features with the thoracic (sympathetic) preganglionic neurons and both neuron types appear to have arisen from similar progenitor cells. There is anatomic evidence that both thoracic and sacral preganglionic cell types occupy sites in the mediolateral region of the spinal cord and exit the spinal cord from a ventral position (compared with the dorsal exit sites of preganglionic parasympathetics of the cranial nerves). The complex neurotransmitter phenotypes and pharmacologic responses of the sacral section of the spinal cord also appear to be primarily of sympathetic origin. This leads to a revised depiction of the anatomy of the ANS that is elegant and easier to understand (Fig. 13.7).



• **Fig. 13.7** Anatomic structure of the autonomic nervous system based on recent findings indicating that the sacral neural output is sympathetic in both phenotype and pharmacology.

Key Points

- The ANS maintains cardiovascular, metabolic, thermal, and gastrointestinal homeostasis.
- Central control of the ANS is primarily mediated in the hypothalamus and medulla oblongata.
- Emerging from the spinal cord, the SNS acts primarily by the effector neurotransmitter norepinephrine to increase critical organ blood flow (i.e., muscles, heart, brain) in response to external challenges. The distribution of sympathetic ganglia close to the CNS facilitates a rapid amplification of this generalized fight-or-flight response.
- Emerging from select cranial and sacral nerves, the PNS acts primarily by the effector neurotransmitter acetylcholine (and muscarinic cholinergic receptors) to modulate activities that occur when the body is at rest (e.g., salivation, urination, defecation, sexual function). The distribution of parasympathetic ganglia close to effector organs facilitates the more focused rest-and-digest functions of the parasympathetic system.
- The adrenal medulla is functionally a sympathetic ganglion in direct communication with the systemic circulation that contributes to the amplification of the fight-or-flight response by delivering epinephrine and norepinephrine throughout the body.
- ANS reflexes (e.g., baroreceptor reflex, oculocardiac reflex) have important implications for anesthetic management.
- Anesthetics generally depress the ANS, in part by attenuating homeostatic reflexes.
- Autonomic dysfunction associated with aging, diabetes, obesity, and other disease states can have important implications on anesthetic management, especially as it relates to the support of the circulation during anesthesia.
- New studies have questioned the craniosacral location of the PNS, outlining a simpler concept that the PNS arises from the cranial nerves, while the SNS is represented in the spinal cord, thoracic to sacral.

  - *Phentolamine and Tolazoline*
  - *Prazosin*
  - *Doxazosin, Terazosin, Tamsulosin*
- β-Antagonists
  - *Esmolol*
  - *Labetalol*
  - *Metoprolol and Atenolol*

Inhibition of Synthesis, Storage, and Release of Norepinephrine

Parasympathetic Pharmacology
- Cholinergic Receptors
- Muscarinic Receptor Agonists
- Muscarinic Receptor Antagonists

Emerging Developments
- Active Emergence and Enhanced Recovery Using CNS Stimulants

The autonomic nervous system (ANS) maintains homeostasis by integrating signals from peripheral and central sensors to modulate organ perfusion and function. Autonomic "tone" maintains cardiac muscle, visceral organs, and vascular smooth muscle in a state of intermediate function. From this state, rapid increases or decreases in autonomic outflow can adjust blood flow and organ activity in response to the environment. The rapidity of the ANS response is impressive considering that neurotransmitters must be released from terminals, cross a synaptic cleft to an effector site, bind to a receptor, and initiate an intracellular event. For example, in just a few seconds, ANS activation can double heart rate (HR) and arterial blood pressure (BP). In a nearly similar time frame it can cause sweating, nausea, loss of bladder control, and fainting. The sympathetic nervous system (SNS) has been called the "fight-or-flight" response system and is activated under stress. In contrast, the parasympathetic nervous system is responsible for "rest and digest." The anatomy and physiology of the ANS are discussed in Chapter 12.

In the perioperative and intensive care settings, multiple factors disrupt the typically tight ANS control of organ and vascular homeostasis. Thus pharmacologic manipulation of the ANS is commonplace in these settings. For example, both general and regional anesthesia have powerful influences on normal ANS function. When an inhaled anesthetic acts to directly relax vascular smooth muscle and lower BP, the ANS reacts to counteract hypotension via baroreflex adjustments of ANS activity. However, a second

effect of volatile anesthetics is to impair baroreflex function. The net effect of these influences requires treatment of unwanted hypotension with sympathomimetic or vagolytic drugs. Laryngoscopy and tracheal intubation or surgical incision powerfully activate the SNS; adrenergic receptor blocking drugs are used to dampen these responses.

Historical Perspective

The sympathomimetic properties of the ma huang plant were appreciated in China as early as 3000 BC. Ma huang was used as a diaphoretic, circulatory stimulant, antipyretic, and sedative for cough.[1] Ephedrine, the main alkaloid of ma huang, was isolated in 1886.[2] Over the next 25 years, adrenal extracts were described and analyzed and the term *sympathomimetic* was coined. Adrenergic receptors were identified and subdivided into two primary types (α and β) according to their responses to epinephrine and norepinephrine.[3] The β receptors were further divided into β_1, β_2, and β_3 receptors based on their actions at receptors and sensitivities to inhibitors.[4–6] The α receptors were similarly subdivided into α_1 andα_2 receptors, but they have been further subdivided into α_{1a}, α_{1b}, α_{1d}, α_{2a}, α_{2b}, and α_{2c} receptors based on their pharmacology and associated second-messenger systems.[7,8]

The history of parasympatholytic drugs dates back to ancient times when *Mandragora*, the mandrake plant, was used for wounds and sleeplessness. Henbane, which contains atropine, was used in ancient Egyptian times as a mydriatic. In the Middle Ages, henbane extract was used to enhance the inebriating qualities of beer and by "witches" to produce flushed skin and vivid hallucinations.

Muscarine, the first parasympathomimetic drug, derives from the fungus *Amanita muscaria* and was described in 1869. It was found to bind receptors that would be called *muscarinic* and had the same effect on the heart as did stimulation of the vagus nerve. Originally discovered by Loewi, the "heart-inhibiting" substance that decreased HR and contractility was acetylcholine (ACh).[9] Muscarinic receptors are activated by ACh and are thus called *cholinergic*.

Structure and Mechanism of Adrenergic Receptors

The basic catecholamine structure consists of an aromatic phenylethylamine with two hydroxyl groups. The name *catecholamine* derives from the molecule 3,4-dihydroxylphenyl, known as *catechol*. Epinephrine and norepinephrine have a chiral center at the hydroxyl group on the β- carbon, where the L-isomer is active, while dopamine has no chiral center (Fig. 14.1). Intravenous formulations of epinephrine and norepinephrine consist of the L-isomer; a racemic formulation of epinephrine is available for inhalation.

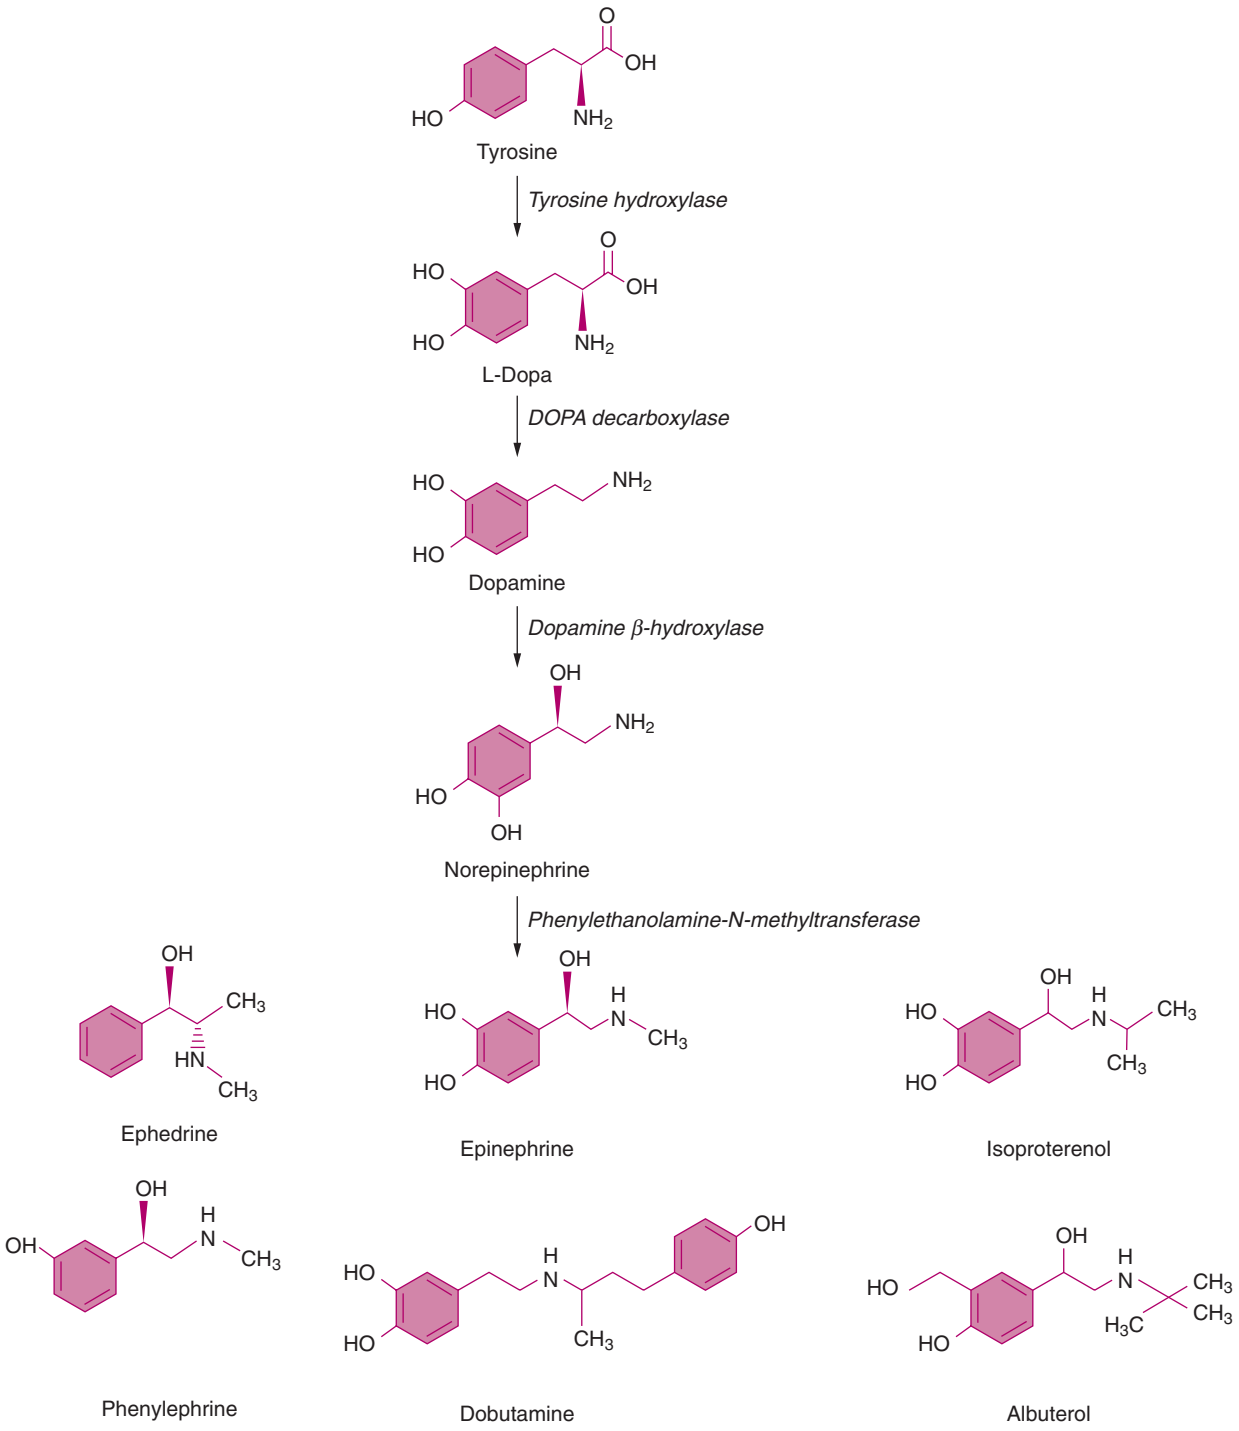
Epinephrine and norepinephrine are predominantly charged molecules at physiologic pH owing to their amine moiety and are unable to cross lipid cellular membranes on their own (although they can cross via transporters). Their actions are mediated following signal transduction by transmembrane receptors that initiate intracellular signaling events. Adrenergic receptors are coupled to guanine nucleotide binding proteins (G proteins) that couple the receptor to an effector system (see Chapter 1). Adrenergic G-protein–coupled receptors (GPCRs) are classified according to their actions on adenylyl cyclase and their sensitivity to pertussis toxin. The structure of the β-adrenergic receptor is consistent with most GPCRs, with seven transmembrane segments.[10] The signaling cascade of β_1- andβ_2-adrenergic receptors begins with ligand binding to the amino terminus of the receptor on the extracellular surface, then proceeds to the intracellular carboxyl terminal loop of the receptor coupling to G_s-proteins, which stimulate adenylyl cyclase to convert adenosine triphosphate (ATP) to the second-messenger cyclic adenosine monophosphate (AMP). The resulting phosphorylation by cyclic AMP (cAMP)-dependent protein kinase produces cellular responses.[11,12] The atomic resolution structure of the β_2-receptor bond to G_s has recently been determined and shows the involvement of the amino- and carboxy-terminal alpha helices of G_s as the main interaction between the two proteins. The activated receptor demonstrates outward movement of the sixth transmembrane segment and the presence of a second intracellular loop between the β_2-adrenergic receptor/G_s complex. The receptor is stabilized extracellularly by fusion of the amino terminus to T4 lysozyme, and intracellularly by numerous interactions with G_s. The Gβ and Gγ subunits of G_s do not directly interact with the β_2-adrenergic receptor.[13]

The α_2 receptors are coupled to G_i-proteins to inhibit adenylyl cyclase. The α_1 receptors are coupled to G_q-proteins activating phospholipase C that hydrolyzes phosphatidylinositol diphosphates (PIP_2) to the second messengers inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 activates calcium ion (Ca^{2+}) release from intracellular stores via IP_3 receptors, while DAG activates lipid mediated signaling pathways including members of the protein kinase C family.[14]

Dopamine receptors also are GPCRs and are classified as D1-type (D1 and D5) and D2-type (D2, D3, and D4) receptors.[15] These receptors are located throughout the central nervous system (CNS), on SNS postganglionic nerve terminals, on afferent and efferent arterioles of the nephron, and in the adrenal glands. D1-like receptors stimulate adenylyl cyclase via G_s, and D2-like receptors inhibit adenylyl cyclase via G_i. D1-receptors are postsynaptic and stimulation mimics β_2 effects, leading to regional vascular dilation. D2-like receptors occur at presynaptic and postsynaptic sites. Presynaptic D2-like receptor activation inhibits norepinephrine release from sympathetic terminals, an effect similar to the presynaptic effects of ACh and α_2-agonists. Postsynaptic sites mimic α1 and α_2 vasoconstriction on blood vessels, but this action is relatively weak.

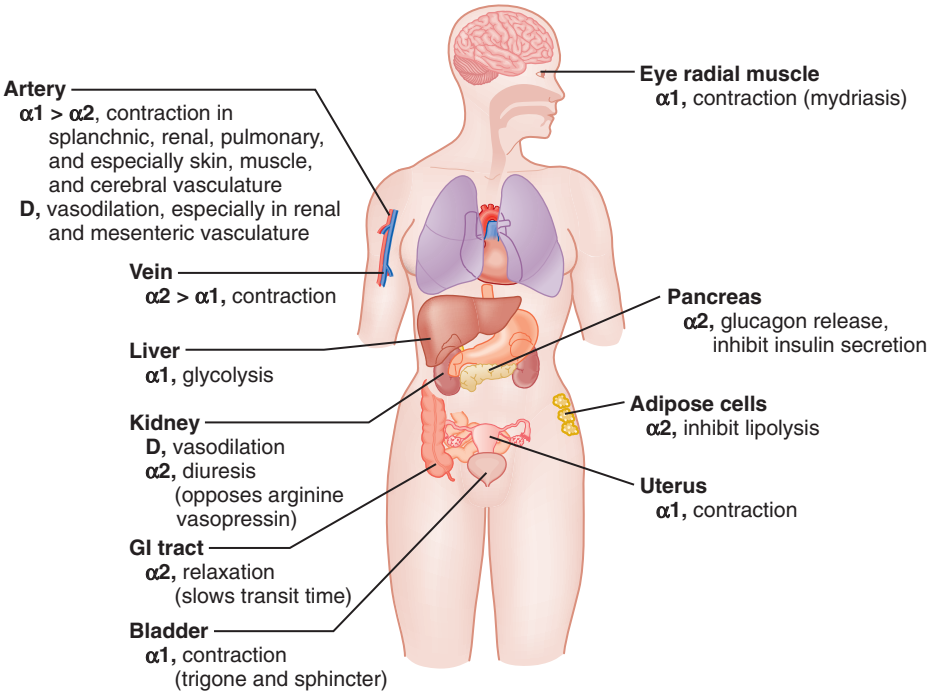
The α_1 adrenoceptors are activated by the selective α_1-receptor agonists phenylephrine and methoxamine and are inhibited by low concentrations of the antagonist prazosin. The α_1-receptors are widely distributed, and when stimulated mediate primarily arterial and venous vascular constriction (Table 14.1). The α_2-adrenoceptors are activated by the selective α_2-receptor agonists clonidine and dexmedetomidine and are blocked by the antagonist yohimbine; they exist as three subtypes: α_{2a}, α_{2b}, and α_{2c}.[16] The α_2 receptors are located presynaptically on sympathetic neurons where they inhibit the release of norepinephrine. Postsynaptic α_2 receptors are located on blood vessels and in tissues, including liver, pancreas, platelets, kidney, adipose tissue, and the eye (Fig. 14.2). Within the CNS, receptors in the locus coeruleus likely account for the sedative properties of α_2 agonists, and receptors in the medullary dorsal horn area for the reduction in sympathetic outflow.[17] The α_2 receptors are also on the vagus nerve and in the intermediolateral cell column and the substantia gelatinosa. The dorsal horn of the spinal cord contains α_{2a} adrenoceptors colocalized with opioid receptors that modulate afferent pain signals.

Both β_1- and β_2-adrenergic receptors are characterized by their stimulation by epinephrine and norepinephrine and are heavily expressed in myocardial tissue, including atria, ventricular papillary



• **Fig. 14.1** Biosynthesis and structures of the catecholamines, and their structures compared to common adrenergic drugs. Stereochemical structure is indicated as shown; isoproterenol, dobutamine, and albuterol are racemates.

muscle, sinoatrial and atrioventricular nodes, left and right bundles, and Purkinje fibers. They have inotropic (increased contractility), chronotropic (increased HR), and dromotropic (increased conduction velocity) effects (Fig. 14.3). Activation of $\beta_1$receptors increases renin and aqueous humor production. The β_2-receptors are the major β receptors in arterioles and the only β receptors in the vena cava, aorta, and pulmonary artery.[18] Activation of β_2 receptors leads to uterine smooth muscle relaxation and relaxation of vascular smooth muscle, including splanchnic, muscular, and renal vasculature, resulting in a reduction in diastolic pressure and decreases in systemic vascular resistance. Activation of β_2 adrenoceptors causes relaxation of bronchial smooth muscle and increased liver glycogenolysis. β_2 Receptor activation also reduces the plasma [potassium ion (K^+) concentration by promoting uptake into skeletal muscle



• **Fig. 14.2** Predominant physiologic effects of α_1-adrenergic and dopamine (D) receptors.

[c]Dose-dependent; dopamine and β effects predominate at low doses.

and reducing aldosterone secretion, leading to renal losses of K^+ (see Fig. 14.3). The β_3 receptors are expressed in visceral adipocytes, gallbladder, and colon. Their activation mediates lipolytic and thermogenesis in brown and white adipose tissue.[19]

Endogenous Catecholamines

The biosynthesis of the naturally occurring catecholamines (epinephrine, norepinephrine, and dopamine) begins with the conversion of tyrosine to 3,4-dihydroxyphenylalanine (DOPA) (see Fig. 14.1). The rate-limiting step in catecholamine synthesis is conversion of tyrosine to DOPA by the enzyme tyrosine hydroxylase.

Epinephrine

Epinephrine, also known as adrenaline, is an endogenous monoamine with broad clinical applications. Epinephrine is present in chromaffin cells in the adrenal medulla, where it is synthesized, stored, and released upon sympathetic stimulation. On average, 80% of the secreted catecholamine in the adrenal medulla is epinephrine and 20% is norepinephrine. The normal resting rate of secretion by the adrenal medulla is about 0.2 μg/kg per minute of epinephrine and about 0.05 μg/kg per minute of norepinephrine. These rates are sufficient to support arterial BP fully if the SNS is denervated. Because of slow removal from the circulation, the effects of secreted epinephrine and norepinephrine on organ function last 5 to 10 times longer than the effect from a burst of sympathetic activity to an organ or vascular bed. Epinephrine has a large β-receptor effect that increases cardiac function (i.e., HR and contractility) far more than norepinephrine (Table 14.2). The β-receptor effect also constricts precapillary blood vessels and large veins. Epinephrine has a weaker effect on blood vessels in skeletal muscle than norepinephrine because of the greater affinity of epinephrine for β_2- (relaxation) than α_1-receptors (contraction). The β effects of epinephrine can increase the metabolic rate to twice normal and promote glycogenolysis in liver and muscle, thereby raising blood glucose levels.

Infusions of epinephrine have dose-dependent actions at α and β receptors. Low doses (2–10 μg/min) predominantly stimulate β_1 and β_2 receptors (see Table 14.2). At higher doses of epinephrine (>10 μg/min), α receptors are activated, leading to vasoconstriction of the skin, mucosa, and renal vascular beds. Blood flow

redistribution occurs away from these circulations, reversing many of the β_2 effects to vasodilate. Further stimulation of α receptors decreases skeletal muscle and splanchnic blood flow and inhibits insulin secretion.

Epinephrine has broad clinical effects and its use has often been supplanted by more selective synthetic adrenergic agonists. However, epinephrine is still commonly added to local anesthetics to prolong their duration of action. Epinephrine is also indicated in anaphylactic shock, localized bleeding, bronchospasm, and stridor related to laryngotracheal edema. Subcutaneous doses of 0.2 to 0.5 mg can be used in early anaphylaxis to stabilize mast cells and reduce degranulation. Epinephrine also stimulates cellular K^+ uptake via β_2 receptors and for short periods can be used to treat life-threatening hyperkalemia.

Norepinephrine

Norepinephrine is the principal endogenous mediator of SNS activity secreted from postganglionic terminals to act on adrenergic effector organs. Intravenous administration (4–12 μg/min) results in dose-dependent hemodynamic effects on α_1 and β adrenoceptors (see Table 14.2). Compared with the effects of epinephrine, norepinephrine has a greater effect at α_1-receptors and no effect on β_2 receptors, thereby creating greater arterial and venous vascular constriction than epinephrine (see Table 14.1). In lower doses, β_1 actions predominate, and BP increases due to augmented cardiac output. Larger doses of norepinephrine stimulate the α_1 receptors and result in arterial and venous smooth muscle contraction in hepatic, skeletal muscle, splanchnic, and renal vascular systems. At these larger doses, HR and cardiac output can decrease via baroreflex mechanisms.

Intravenous administration of norepinephrine is most often used therapeutically for treatment of profound vasodilation, as in septic shock unresponsive to fluid administration. It increases BP, left ventricular stroke work index, cardiac output, and urine output. When given to patients already exhibiting marked vasoconstriction, further increases in vascular resistance can lead to compromised limb and organ blood flow, resulting in ischemia. Norepinephrine is less arrhythmogenic than epinephrine. Its effect on pulmonary α_1 receptors combined with its effect to increase venous return can result in pulmonary hypertension and right heart failure. To minimize this effect during open heart surgery, it can be given directly into the left atrium along with a selective pulmonary vasodilator such as prostaglandin E_1.

Dopamine

Dopamine is an endogenous catecholamine that is also involved in central and peripheral neural transmission. Dopamine is synthesized from tyrosine and is the immediate precursor to norepinephrine (see Fig. 14.1). Parenteral administration of dopamine does not cross into the CNS; therapy of Parkinson disease requires use of the precursor L-DOPA that can cross the blood-brain barrier. When dopamine is used for hemodynamic support and maintenance of adequate perfusion during shock, it must be given via continuous infusion because of rapid metabolism. At low infusion rates (1–3 μg/kg per minute), vasodilation of coronary, renal, and mesenteric vasculature occurs and renal blood flow, glomerular filtration, and Na^+ excretion increase owing to D1-like receptor agonism (see Fig. 14.2). Although this "renal dose" of dopamine was purported to improve kidney function in patients at risk for acute renal failure, meta-analysis has failed to show improvement in renal dysfunction or mortality.[20] At doses of 3 to 10 μg/kg per minute, β_1-receptor stimulation leads to positive inotropic and chronotropic effects, and at presynaptic terminals promotes the release and inhibits the reuptake of norepinephrine. At higher doses (>10 μg/kg), α_1-receptor activation causes peripheral vasoconstriction and can reduce renal blood flow.

Metabolism of Catecholamines

The catecholamines are metabolized by catechol-*O*-methyltransferase (COMT) and monoamine oxidase (MAO). COMT is an intracellular enzyme located in postsynaptic neurons. MAO is concentrated in the mitochondria of nerve terminals, resulting in a constant turnover of norepinephrine even in the resting nerve terminal. Metabolites can be detected in urine as metanephrines or vanillylmandelic acid. Urine collections and analysis can be useful to follow progress in treatment of pheochromocytoma. There are two primary termination routes for norepinephrine released from nerve terminals: simple diffusion (and metabolism in plasma, kidney, or liver) and reuptake into noradrenergic nerve terminals (which can be blocked by cocaine and most tricyclic antidepressants). Synthetic sympathomimetic drugs that mimic endogenous catecholamines can have longer durations of action because of their resistance to metabolism by MAO or COMT.

Synthetic Catecholamine-Like Drugs

Synthetic catecholamines, which are also included as sympathomimetic drugs, are a mainstay of critical care and perioperative medicine for support of the circulation. Depending on their selectivity and potency for different subtypes of α, β, and dopamine receptors, their route of administration, their lipid solubility, and their metabolism, sympathomimetic drugs can be used to achieve a variety of clinical effects. Certain drugs also have indirect sympathomimetic action; these include ephedrine, tyramine, and the amphetamines. They cause release of norepinephrine from its storage vesicles in the sympathetic nerve endings, thereby increasing synaptic concentration and postsynaptic effects.

D1-Receptor Agonists

Fenoldopam is a synthetic, selective D1-agonist without significant D2-, α-adrenergic, or β_2-adrenergic effects (see Table 14.2 and Fig. 14.2).[21] It is 10-fold more potent than dopamine at the D1 receptor. The principal use of fenoldopam is to manage hypertension in doses of 0.1 to 0.8 μg/kg per minute, with upward titration in 0.1-μg/kg per minute steps as needed. A low-dose infusion of fenoldopam (~0.1–0.2 μg/kg per minute) produces renal vasodilation and increases renal blood flow, glomerular filtration rate, and Na^+ excretion without changes in systemic BP. A renal protective effect has been observed in aortic and cardiac surgery involving cardiopulmonary bypass.[22,23] When compared with dopamine in acute early renal dysfunction, fenoldopam is more effective at reversing renal hypoperfusion.[24] A meta-analysis indicated that fenoldopam reduces both the need for renal replacement therapy and in-hospital death in cardiovascular surgery.[25]

α_1-Receptor Agonists

Agonists of α_1 adrenoceptors exert vasoconstrictor actions on arteries and veins, leading to BP increase and redistribution of blood flow (see Fig. 14.2).[26] In healthy individuals, cardiac output is maintained because of increased preload. HR typically slows via the baroreflex response to increased BP. Myocardial blood flow and oxygen delivery can be improved owing to the longer diastolic filling time from the lower HR and from improved diastolic coronary blood flow because of the increased aortic BP. In patients with impaired ventricular function, increases in afterload can impair myocardial function. Topical use of α_1 agonists can be used for vasoconstriction (e.g., on nasal mucosa).

Phenylephrine

The effects of phenylephrine were described in the 1930s, and it was first used to maintain BP during spinal anesthesia.[27] It is a nearly pure α_1-selective agonist, only affecting β receptors at very high doses (see Table 14.2). It has similar potency to norepinephrine for α_1 receptors but has a longer duration of action. Phenylephrine

produces greater venoconstriction than arterial vasoconstriction and therefore increases venous return and stroke volume. Cardiac output typically does not change owing to baroreflex slowing of HR. Phenylephrine can be useful as a bolus or continuous infusion for treatment of hypotension, and can be used to reverse unwanted right-to-left shunt in tetralogy of Fallot. Newer evidence suggests that phenylephrine is not detrimental to fetal oxygen delivery in pregnant patients who are hypotensive after neuraxial blockade. However, although not harmful, it still might be inferior to ephedrine in maintaining placental blood flow during cesarean delivery.[28,29] A 0.25%, 0.5%, or 1% phenylephrine solution can be used topically as a nasal decongestant; 2.5% or 10% phenylephrine solutions are used to produce mydriasis when administered into the eye. Both these routes can raise BP. Rarely more serious side effects such as pulmonary edema and adverse cardiac events result. Thus α_1-adrenergic antagonists, such as phentolamine or tolazoline, or direct vasodilating drugs, such as hydralazine or nicardipine, should be available. β-Blockers are contraindicated to treat a hypertensive crisis from phenylephrine (such as an accidental overdose). β-Blockers in this situation can reduce myocardial contractility and produce acute pulmonary edema in the face of high afterload.[30]

Methoxamine

First described in 1948 and used to maintain BP during spinal anesthesia, methoxamine has a longer duration of action, more arterial vasoconstriction, and less venoconstriction compared with phenylephrine.[31] It is not typically used to support BP acutely because it can increase afterload and has a long half-life. Doses of 1 to 5 mg every 15 minutes are described. Untoward hypertension can occur following its use to treat regional anesthetic-induced hypotension because sympathetic tone returns as the spinal anesthetic recovers before the action of methoxamine dissipates.

Midodrine

Midodrine is an orally absorbed α_1 agonist with a half-life of about 3 hours and duration of action of 4 to 6 hours. It is used to treat dialysis-related hypotension or autonomic failure resulting in postural hypotension, but hypertension is a possible effect when patients are supine.

α_2 Receptor Agonists

Agonists of α_2 receptors such as clonidine were originally used as antihypertensive agents because of their central effect to decrease sympathetic outflow from the CNS and to reduce presynaptic norepinephrine release. The α_2 receptor mediates sedation and hypnosis, sympatholysis, neuroprotection, diuresis, and inhibition of insulin and growth hormone secretion.[32–34] Rapid intravenous administration of α_2 agonists such as dexmedetomidine can transiently increase BP through vasoconstriction at postsynaptic α_{2b} receptors on arteries and veins. This receptor subtype might also account for their antishivering effect. Postsynaptic α_2 receptors exist in a number of other tissues and organs, including liver, pancreas, platelets, kidney, fat, and eye (see Fig. 14.2).

Within the CNS, a large density of α_2 receptors is located in the medullary dorsal motor complex and in the locus coeruleus. The locus coeruleus is an important modulator of wakefulness and the major site of the sedative/hypnotic actions of the α_2 agonists. Among the many desirable properties of α_2 agonists that promote their use in the perioperative period are anxiolysis, sedation, reductions in minimal alveolar concentration (MAC) of volatile anesthetics, reduced chest wall rigidity from opioids, reduction in intraoperative BP variability from intubation, extubation and surgical stress response, and reductions in postanesthetic shivering.[35] A meta-analysis found that α_2-receptor agonists reduce perioperative cardiac mortality and ischemia, a benefit likely attributable to reduced sympathetic outflow and reduced shivering.[36] Side effects include sedation, dry mouth, and bradycardia via reduced sympathetic "tone" and a slight vagomimetic effect. It is likely that some of the effects from α_2-receptor agonists are from actions at nonadrenergic imidazoline receptors.

TABLE 14.3 Classification of α-Receptors and the Relative α1/α2 Selectivity

	ORDER OF SELECTIVITY	
	Agonists	**Antagonists**
α_1 ↕ β_1	Methoxamine Phenylephrine Norepinephrine Epinephrine Dopamine Clonidine (220:1) Dexmedetomidine (1620:1)	Prazosin Phenoxybenzamine Phentolamine Tolazoline Yohimbine

Clonidine

Clonidine, first synthesized in the 1960s, has an onset time after oral administration of 30 to 60 minutes, with a half-life of 6 to 24 hours. The α_2-:α_1-receptor affinity is ~220:1 (Table 14.3). It is available in 100-, 250-, and 300-μg tablets for oral administration, a transdermal patch releasing 150 to 200 μg over 24 hours, and an injectable solution of 150 μg/mL. Oral dosing is typically every 8 hours. Clonidine should not be withheld before surgery because acute withdrawal can result in rebound hypertension.[37] Neuraxial administration can be used to lessen the requirement for opioids when treating acute and chronic pain. Epidural clonidine is indicated for treatment of severe cancer pain (0.5 μg/kg per hour). When given in this manner, bradycardia and sedation can occur but respiratory drive is maintained. Clonidine also is beneficial in the treatment of opioid withdrawal in an intensive care unit (ICU) setting.[38]

Dexmedetomidine

Dexmedetomidine is highly selective for α_2 adrenoceptors (see Table 14.3), with an α_2-: α_1-receptor affinity of 1620:1. Intravenous administration in the ICU setting is useful for continuous sedation and analgesia while sparing respiratory drive. Sedation is described as "arousable sedation" much like natural sleep, consistent with effects on central sleep mechanisms. Patients receiving dexmedetomidine for postsurgical pain have slower early postoperative HRs and require 50% less morphine in the postanesthesia care unit.[39] In a prospective randomized study, dexmedetomidine initiated at the end of coronary artery bypass surgery and continued into the ICU resulted in reduced use of analgesics, β-blockers, diuretics, antiemetics, and epinephrine, and achieved adequate sedation compared with propofol sedation.[40] In the ICU setting following cardiac surgery, the combination of opioid/dexmedetomidine sedation resulted in less delirium compared with opioid/benzodiazepine sedation.[41,42] Recommended dosage is a 1-μg/kg loading dose given

over 10 to 20 minutes followed by a 0.2- to 0.7-μg/kg per hour infusion. Hypotension and bradycardia are common side effects, and bradyarrhythmias and sinus arrest are rare but potential serious adverse events. Newer applications for dexmedetomidine include pediatric sedation for hospital procedures, treatment of emergence agitation, and sedation in the ICU setting. Additionally, the FDA approved the use of dexmedetomidine for MAC sedation in 2010.[43]

β_1-Receptor Agonists

Isoproterenol

Isoproterenol, the isopropyl derivative of norepinephrine, was the first synthetic β-receptor agonist in clinical use. It is given parenterally because of its short duration of action (<1 hour).[44] It has almost purely β-receptor activity, with minimal α-receptor affinity. It is nonselective for β_1 and β_2 receptors (see Table 14.2). Isoproterenol produces positive chronotropic and inotropic cardiac effects via β_1-adrenoceptor stimulation, and bronchodilation and vasodilatation in vascular smooth muscle through β_2 activation. Large doses cause tachycardia and decrease diastolic BP, which reduces coronary blood flow and thus can compromise myocardium at risk or worsen dysrhythmias. Dobutamine is a common substitute for isoproterenol owing to lesser effects on HR, thereby preserving diastolic filling time and coronary blood flow and reducing myocardial oxygen demand. The emergence of phosphodiesterase inhibitors to improve myocardial performance has also reduced the need for isoproterenol as an inotropic agent.[45] The β_2 response from isoproterenol can be used for bronchodilation, although other β_2 drugs are more typically used. Isoproterenol has been used to manage heart failure secondary to bradycardia, cor pulmonale, pulmonary hypertension, as a chemical "pacer" in third-degree heart block, and in torsades de pointes ventricular tachycardia.

Dobutamine

Dobutamine is a synthetic catecholamine obtained by substitution of a bulky aromatic group on the side chain of dopamine. Dobutamine is a racemic mixture of the (+) and (−) isomers. The (−) isomer acts on α_1-adrenergic receptors and increases vascular resistance, and the (+) isomer is a potent β_1-adrenergic receptor agonist and a potent α_1-adrenergic receptor antagonist that blocks the effects of (−) dobutamine (see Table 14.2). Compared with dopamine, dobutamine has less notable venoconstriction and is less likely to increase HR and more likely to decrease pulmonary vascular resistance. The most prominent effects with increasing infusion rates of dobutamine (2–20 μg/kg per minute intravenously) are a progressive increase in cardiac output, decrease in left ventricular filling pressure, minor increases in HR until higher doses are given, and decreases or no change in systematic vascular resistance. However, when dobutamine is given to patients using β-blockers, systemic vascular resistance can increase, leading to increases in BP from the unmasked α_1-effect. Dobutamine has minimal β_2 effects. Thus it often improves cardiac output without major adverse effects on the myocardial oxygen supply/demand ratio because afterload is maintained, thereby improving coronary blood flow.[46] It enhances automaticity of the sinus and atrioventricular nodes and facilitates intraventricular conduction. It does not affect dopamine receptors. Dobutamine is prepared in 5% dextrose in water because it is inactivated in alkaline solutions. Tachyphylaxis can occur with infusions longer than 72 hours. Dobutamine is often used for nonexercise cardiac stress testing and for the treatment of acute heart failure, especially in patients being weaned from cardiopulmonary bypass.

Selective β_2-Receptor Agonists

Selective β_2-receptor agonists are indicated in the treatment of acute asthma and chronic obstructive pulmonary disease. These agents work by reducing bronchial airway resistance via smooth muscle relaxation. By changing the catechol ring (3,4-dihydroxylphenyl) to a resorcinol ring (3,5-dihydroxylphenyl), there is improved bioavailability as the result of the reduced action of COMT. Further substitutions on the amino group increase β-receptor activity, reduce α-receptor activity, and increase the duration of action by decreasing metabolism by MAO.

Metaproterenol (orciprenaline), albuterol, salmeterol, and isoetharine (isoetarine) are inhaled, thereby reducing their systemic side effects. These reach therapeutic concentrations in the bronchi with minimal activation of cardiac and peripheral β_2 receptors. In addition to bronchodilation, therapeutic effects include suppression of release of leukotrienes and histamine from mast cells and decreased microvascular permeability. However, at higher concentrations all currently used β_2-selective agonists also stimulate β_1 receptors, which increases the risk for arrhythmias (predominantly atrial fibrillation). Other potential adverse effects, particularly when given orally or parenterally, are skeletal muscle tremor, tachycardia, mismatching of pulmonary ventilation and perfusion, and pulmonary edema. Long-term use can lead to tolerance, bronchial hyperreactivity, and hyperglycemia in diabetic patients.

Terbutaline and Ritodrine

Terbutaline can be administered orally, subcutaneously, or by inhalation. It is rapidly effective by the latter two routes and its effects persist for 36 hours, in part owing to its structure with a resorcinol ring preventing COMT action. A subcutaneous dose of 0.25 mg can be useful to treat status asthmaticus. Terbutaline is used primarily long term for obstructive pulmonary disease, and acutely for status asthmaticus, bronchospasm, and acute anaphylactic shock, where it does not have the cardiac stimulating effects of epinephrine.

Terbutaline and ritodrine are also tocolytic drugs used to manage premature labor contractions through relaxation of the myometrium via their β_2 effect. Ritodrine is usually started intravenously and is continued orally if tocolysis is achieved. It is metabolized in the liver to inactive conjugates, and about half the drug is excreted unchanged in the urine. Albuterol is similar to terbutaline, although it cannot be given subcutaneously. Use of β_2 agonists has been associated with hypokalemia as well as tachyphylaxis. The mechanism of hypokalemia involves an insulin-mediated increase in uptake of extracellular K^+ and/or increased sodium-potassium adenosine triphosphatase activity.[47] Angina, cardiac arrhythmias, hyperglycemia, hypokalemia, and pulmonary edema with normal pulmonary capillary wedge pressures have been attributed to terbutaline and ritodrine therapy.[48]

Indirect-Acting Sympathomimetics

Some of the synthetic catecholamine-like drugs have an indirect sympathomimetic action. These drugs include ephedrine, tyramine, and the amphetamines. Because their effects are to cause release of norepinephrine from synaptic vesicles in sympathetic nerve endings, care must be taken when they are administered to patients taking tricyclic antidepressants (TCAs) or monoamine oxidase inhibitors (MAOIs).[49] The TCAs inhibit catecholamine reuptake and the MAOIs inhibit catecholamine breakdown. MAOIs in combination with serotonin reuptake inhibitors can also lead to

neuromuscular and autonomic hyperactivity and altered mental status (serotonin syndrome).[50]

Ephedrine

Ephedrine is one of the most commonly used noncatecholamine sympathomimetic drugs in the perioperative period. Ephedrine is a natural product of the ephedra plant *(Ephedra sinica),* and is a mixed-acting, noncatecholamine sympathomimetic with both direct and indirect stimulating effects on α- and β-adrenergic receptors. It acts indirectly by competing with norepinephrine for local reuptake into synaptic vesicles, resulting in elevated concentrations of norepinephrine at receptor sites. Intravenous effects resemble those of epinephrine, albeit with a less potent but longer-lasting effect. It causes increases in HR, cardiac output, and BP that last 10 to 15 minutes. Tachyphylaxis owing to catecholamine depletion can occur with repeat doses.

Ephedrine relaxes bronchial smooth muscle, increases trigone and sphincter muscle tone in the urinary bladder, and has a stimulatory effect on the CNS that increases MAC. Uterine and placental artery blood flow are not adversely affected when ephedrine is used to sustain BP during spinal anesthesia for cesarean section, and umbilical artery vascular resistance remains unchanged. This is due to an effect of ephedrine to cause venoconstriction, thereby improving preload, cardiac output, and uterine blood flow.

Amphetamine and Other Central Nervous System Stimulants

Amphetamine and methamphetamine are powerful stimulants of the CNS, in addition to having peripheral α and β actions common to indirect acting sympathomimetics. They cause release and inhibit reuptake of stimulatory neurotransmitters in the cortex, motor nuclei, and reticular activating system. Acute effects include wakefulness, alertness, mood elevation, decreased sense of fatigue, and increased initiative, self-confidence, euphoria, and elation. Peripheral indirect activity leads to acute increases in BP with reflex bradycardia; large doses can cause arrhythmias. Chronic use leads to a decrease in BP because the metabolites are false neurotransmitters. Even though therapeutic use has declined, their respective methylenedioxy derivatives (3,4-methylenedioxyamphetamine [MDA] and 3,4-methylenedioxymethamphetamine [MDMA]) remain popular illicit recreational drugs. Treatment of acute intoxication consists of acidification of urine to enhance elimination, administration of sedatives, and control of cardiovascular side effects. Dantrolene is indicated to prevent hyperthermia.

Methylphenidate (Ritalin, Methylin) is structurally related to amphetamine but has milder CNS-stimulating activity and less effect on motor function. It is used to treat narcolepsy and attention deficit/hyperactivity disorder. Side effects of insomnia, anorexia, weight loss, suppression of growth, and abdominal pain have been described in children. Overdose causes symptoms similar to those of overdose with amphetamine, including restlessness, agitation, irritability progressing to confusion, aggressive behavior, delirium, and paranoid delusions.

False Transmitters and Monoamine Oxidase Inhibition

MAOIs are powerful drugs used to treat depression and Parkinson disease. They include phenelzine, iproclozide, isocarboxazid, tranylcypromine, selegiline, rasagiline, and moclobemide. MAO catalyzes the oxidation of monoamines such as norepinephrine, serotonin (MAO-A), phenylethylamine (MAO-B), and dopamine (MAO-A,B). Dietary amines (e.g., tyramine derived from fermentation processes in cheese, wine, and beer) can cause a hypertensive reaction in patients taking MAOIs. In the presence of MAOIs, tyramine displaces norepinephrine from synaptic vesicles, leading to profound hypertension. When an indirect-acting sympathomimetic drug such as ephedrine is administered, an exaggerated BP increase can occur, especially in the first weeks of therapy with an MAOI. With long-term use, there is downregulation of adrenergic receptors, and TCAs and selective serotonin reuptake inhibitors are usually continued through the perioperative period given their rapid excretion and long latency period for effectiveness.[51] MAOIs require discontinuation before surgery to allow restoration of enzyme activity. Irreversible MAOIs should be discontinued 2 weeks before surgery or switched to a reversible MAOI (moclobemide), which needs to be stopped only 24 hours before surgery.[52] Because dopamine is a substrate for MAO, it should be administered at much lower doses in patients taking an MAOI or TCA. Use of meperidine with an MAOI can lead to hypertension, convulsions, and coma. Because of their risk for lethal dietary and drug interactions, MAOIs are generally used only when patients are unresponsive to first-line antidepressants.

Ergot Alkaloids

Poisoning caused by the fungus *Claviceps purpurea* on wheat or rye in the Middle Ages was associated with mental disturbances and severe, painful peripheral vasoconstriction frequently leading to gangrene of the extremities. Often termed *St. Anthony's fire,* this effect is from ergot alkaloids that stimulate contraction of a variety of smooth muscles, both directly and indirectly via adrenergic and serotonergic receptors. Contraction of vascular smooth muscle leads to coronary, cerebral, and peripheral vasoconstriction. In clinical practice, the ergot alkaloids are taken orally and are slowly absorbed from the gut with bioavailability of approximately 10%; they are hepatically metabolized and eliminated primarily in the bile. The oral dose of ergotamine to treat an acute migraine is 2 mg, followed by a 1-mg dose every half hour to a maximum of 6 mg. The intramuscular dose is 0.5 mg, repeated every half hour to a maximum of 3 mg. Intramuscular administration of ergonovine is used to enhance postpartum uterine contractions. The usual dose of 0.2 mg can be continued up to a week postpartum as an oral preparation. Ergot alkaloids are contraindicated in patients with sickle cell disease, peripheral and coronary artery disease, thyrotoxicosis, and porphyria.

Other Sympathomimetic Drugs

Pseudoephedrine and phenylpropanolamine are commonly used as oral preparations to treat nasal congestion via vasoconstriction. These sympathomimetic drugs are similar to ephedrine in releasing norepinephrine and epinephrine but have fewer CNS effects. Several drugs are used primarily as vasoconstrictors via α_1-receptor agonism for local application to the nasal mucous membranes or to the conjunctiva, including propylhexedrine, tetrahydrozoline, oxymetazoline, naphazoline, and xylometazoline. Their systemic absorption is minimal compared with topical phenylephrine solutions. Cocaine is another sympathomimetic still used clinically for its analgesic and vasoconstrictive properties. Intranasal cocaine with a topical local anesthetic has been shown to provide adequate pain control during repair of nasal fractures.[53] However, given the

potential for abuse and toxicity, the aforementioned topical drugs have largely replaced the use of cocaine-containing topical solutions for vasoconstriction.

Vasopressin

Vasopressin, commonly known as arginine vasopressin (AVP), is an endogenous hormone that regulates urine volume and plasma osmolality. Although not a sympathomimetic, it too is used as a potent vasoconstrictor that preserves splanchnic perfusion.[54,55] It acts on V2 receptors on the collecting ducts to promote water reabsorption and concentration of urine. Higher concentrations of AVP can occur via a baroreflex response to hypotension and will act on $V1_a$ receptors located on vascular smooth muscle to promote vasoconstriction via a phosphoinositol pathway. Vasopressin is available in an aqueous solution of 20 units/mL. Vasopressin is no longer recommended as an alternative to a first or second dose of epinephrine during resuscitation from cardiac arrest, but it can be useful in small doses to treat refractory intraoperative hypotension in patients using angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers. Doses of 1 to 8 units are typical. Vasopressin also has been cited as a useful pharmacologic aid in hemorrhagic shock because of its augmentation of the neuroendocrine stress response and can reverse severe hypotension, restore cardiovascular function, and decrease catecholamine requirements.[56–59] Furthermore, use of vasopressin can be an effective strategy in persistent hypotension that had been resistant to fluids and exogenous catecholamines.[59]

Adrenergic Blocking Drugs

Sympatholytic drugs oppose the effects transmitted by postganglionic fibers of the SNS. Most drugs of this class act postsynaptically to compete reversibly with agonists for α- and β-adrenergic receptors. Adrenergic activity can be disrupted at several points in the stimulatory process, as follows:

1. Blockade of α receptors, resulting primarily in dilation of vascular tissue; examples are phenoxybenzamine and phentolamine.
2. Blockade of β-receptors, the major pharmacologic target being the heart and vascular smooth muscle. Propranolol blocks β_1- and β_2-receptors; atenolol and metoprolol block mainly β_1 receptors.
3. Blockade of sympathetic activity by drugs that block transmission of nerve impulses through autonomic ganglia at nicotinic receptors; hexamethonium blocks both sympathetic and parasympathetic transmission through the ganglia.
4. Inhibition of synthesis and storage of norepinephrine in sympathetic nerve endings; examples are reserpine and α-methyldopa.
5. Blockade of release of norepinephrine from sympathetic endings; an example is guanethidine.

α-Antagonists

The "α-blockers" play an important role in regulating the activity of the SNS both peripherally and centrally. Blockade of α_2-adrenergic receptors with selective antagonists such as yohimbine can potentiate release of norepinephrine to activate both α_1 and α_2 receptors. Antagonists of α_1-adrenergic receptors such as prazosin also stimulate release of norepinephrine, but the α_1-receptor effect is blocked.

Phenoxybenzamine

Phenoxybenzamine is an irreversible, noncompetitive blocker of α-adrenergic receptors (see Table 14.3). It forms a covalent link with the α receptor such that recovery of receptor function requires synthesis of new receptor molecules with a half-life of 18 to 24 hours. The consequent reduction in peripheral vascular tone leads to orthostatic hypotension and is accompanied by baroreflex-mediated sympathetic activation resulting in increases in HR and cardiac output. Phenoxybenzamine may also improve cardiac output by other mechanisms. It blocks presynaptic inhibitory α_2 receptors in the heart and decreases elimination of myocardial norepinephrine by inhibition of reuptake. Overdoses are treated with norepinephrine when unopposed β_1-receptor effects are present. Epinephrine is not recommended for this purpose in that its β_2 effects lead to further hypotension. Oral doses of phenoxybenzamine are used to manage pheochromocytoma or urinary retention caused by neurogenic bladder or benign prostatic hypertrophy. For adults, initial dosing is 10 to 20 mg bid for pheochromocytoma and 10 to 20 mg per day for relief of obstruction in neurogenic bladder.

Phentolamine and Tolazoline

Phentolamine and tolazoline are competitive, nonselective α-receptor antagonists (see Table 14.3). Although these drugs have cardiovascular effects similar to those of phenoxybenzamine, α-blockade is short-lived and the effects are reversible with α-receptor agonists. Phentolamine and tolazoline can be used to treat hypertensive crisis caused by ingestion of tyramine-containing substances in patients taking MAOIs or owing to clonidine withdrawal. Phentolamine can be given as a 5- to 15-mg intravenous bolus and has an onset in 12 minutes and duration of 10 to 30 minutes. The recommended dose of tolazoline for treatment of neonatal persistent pulmonary hypertension is a 0.5 to 2 mg/kg loading dose administered over 10 minutes followed by 0.5 to 2 mg/kg per hour. The use of these antagonists to treat pulmonary hypertension has fallen out of favor with the advent of newer agents (see Chapter 26). Phentolamine can be infiltrated into tissues to reduce the vasoconstriction from accidental extravasation of norepinephrine.

Prazosin

Prazosin is the prototype of a family of α-adrenergic drugs that contain a piperazinyl quinazole nucleus. Prazosin has a very high affinity for most subtypes of α_1-receptors (see Table 14.3). Its α_{1B}-receptor antagonism results in dilation of arteries and veins with a decrease in peripheral vascular resistance and venous return and cardiac filling. The unexpectedly blunted reflex HR response to the hypotensive effect of prazosin might be due to a CNS effect to suppress sympathetic outflow. Prazosin is given orally (15 mg); the starting dose to treat hypertension is usually 0.5 mg at bedtime. The effects of a single dose last about 10 hours.

Doxazosin, Terazosin, Tamsulosin

Doxazosin has hemodynamic effects similar to prazosin, but its duration is about three times longer. Terazosin is less potent than prazosin but has higher bioavailability, so its effects last longer. Selectivity of α_{1A}-subtype over $\alpha 1_B$-subtype receptors for relaxation of bladder neck, prostate capsule, and prostatic urethra make doxazosin and tamsulosin useful for treating benign prostatic hypertrophy with little effect on BP.

β-Antagonists

The β-adrenergic receptor blockers have a range of lipid solubilities that influence their absorption and distribution (Table 14.4). The prototype drug propranolol, developed in the early 1960s, has

TABLE 14.4 β-Adrenergic Blocking Drugs

Drug	Receptor Selectivity	ISA	Plasma Half-Life (hr)	Oral Availability (%)	Lipid Solubility	Elimination	Oral Dose	IV Dose
Propranolol	$\beta_1\beta_2$	0	3–4	36	+++	Hepatic	40–320 mg	0.5–1 mg to maximum 3 mg
Metoprolol	β_1	0	3–4	38	+	Hepatic	100–400 mg	5 mg q2 min to 15 mg total
Atenolol	β_1	0	6–9	57	0	Renal	50–100 mg	2.5 mg over 2.5 min q5 min to 10 mg or 0.15 mg/kg over 20 min
Esmolol	β_1	0	9 min	–	?	RBC esterase	NA	50–100 mg Bolus, 0.05–0.3 mg/kg per minute infusion
Timolol	$\beta_1\beta_2$	0	4–5	50	+	Hepatic > renal	15–45 mg; 60 mg maximum	Ophthalmic preparation for glaucoma, 0.25–0.5 mg/mL
Carvedilol	$\alpha_1\beta_1\beta_2$		2–8			Hepatic	12.5–50 mg	NA
Labetalol	$\alpha_1\beta_1\beta_2$		~6			Hepatic	400–1200 mg	5–20 mg IV q5–10 min to maximum 300 mg; start infusion at 2 mg/min

ISA, Intrinsic sympathomimetic activity; *NA*, not applicable; *RBC*, red blood cells.

high lipid solubility and attains high brain concentrations. The lipid-insoluble β-blockers such as atenolol are less well absorbed orally, have fewer CNS side effects, and are excreted primarily via the kidneys (with prolonged excretion in renal failure). β_2-Blockade can cause bronchospasm and peripheral vasoconstriction; this can be problematic in patients with chronic obstructive pulmonary disease, reactive airway disease, and peripheral vascular disease.

Modifications of the molecular structure of β-blockers can lead to a range of desired pharmacodynamic effects, including enhanced selectivity for β_1-receptors, partial agonist activity at β_2-receptors (known as intrinsic sympathomimetic activity, ISA), α_1-receptor antagonism, and/or quinidine-like membrane stabilizing activity. ISA from drugs such as pindolol leads to less reduction of HR, cardiac output, and peripheral blood flow and reduced risk of bronchoconstriction. Most β-adrenergic antagonists do not block α-adrenergic receptors. Two exceptions are labetalol and carvedilol, which have both nonselective β-receptor antagonist and α-receptor antagonist activity. Blockade of stimulatory presynaptic β_2-receptors reduces release of norepinephrine and contributes to the hypotensive effect of β-receptor antagonists.

The β-receptor antagonists have a number of predictable side effects. They can lead to profound bradycardia, asystole and heart failure. They inhibit gluconeogenesis; in diabetic patients receiving β-blockers, the common signs of hypoglycemia such as tremors and tachycardia can be masked. Hypoglycemia-induced perspiration, mediated by cholinergic mechanisms, can remain the only warning sign in these patients. Blockade of peripheral β_2-receptors can precipitate Raynaud vascular spasm in susceptible patients. The use of β-blockers to attenuate adrenergic crisis can worsen hypertension (from β_2-receptor blockade) if α-receptor blockade is not adequate due to unopposed α effects. Combination of β-blockers with non-dihydropyridine calcium channel blockers can significantly reduce cardiac conduction, and when also combined with H_2-receptor blockers, severe negative inotropism can result.

Even though myocardial depression from volatile or intravenous anesthetics is additive with that of pure β-blockers, perioperative use of β-blockers reduces morbidity and mortality in patients with documented coronary artery disease and in patients at high risk for coronary artery disease.[60–65] However, there has been some controversy regarding β-blockade with metoprolol in particular. The Perioperative Ischemic Evaluation (POISE) trial showed that while those starting metoprolol in the perioperative period experienced fewer myocardial infarctions, this group also had more deaths and nonfatal cerebrovascular accidents. A meta-analysis has shown significant heterogeneity across studies, suggesting that the benefits and risks of initiating a perioperative β-blockade should be carefully weighed for each patient.[65] Clinically both partial and pure antagonists are used in the treatment of hypertension and tachyarrhythmias, and both decrease mortality after myocardial infarction. Sudden withdrawal of β-receptor blockers can lead to rebound adrenergic effects, including tachycardia, hypertension, arrhythmias, myocardial ischemia, and infarction. The enhanced adrenergic state occurs 2 to 6 days after withdrawal.[66] This has led to the current recommendation to continue β-blockers in the perioperative period to avoid withdrawal.[51]

Esmolol

Esmolol is a selective β_1-adrenoceptor antagonist with a rapid onset of 90 seconds. Owing to rapid hydrolysis by red blood cell esterase, it has a short duration of action with a half-life of only 9 to 10 minutes (see Table 14.4). Esmolol is not metabolized by plasma cholinesterase. The brevity of esmolol makes it useful as a bolus of 1 to 2 mg/kg to reduce cardiac effects from transient β-adrenergic stimulation in the perioperative period and as an infusion in critically ill patients in whom it can be withdrawn quickly if adverse cardiac effects (congestive heart failure, bradycardia, hypotension) occur. As an infusion for supraventricular tachycardia or hypertensive crisis, a loading dose of 500 μg/kg over 4 minutes followed by a 50- to 300-μg/kg per minute infusion results in steady-state concentrations in 5 minutes.[67,68] β_1-Selectivity allows esmolol to be used safely in patients with bronchospastic and vascular disease.

Labetalol

Labetalol is a mixture of four stereoisomers that block α_1, β_1, and β_2 receptors, and is therefore considered a mixed antagonist (see Table 14.4). It is considered a peripheral vasodilator that does not cause reflex tachycardia.[69] It has an $\alpha:\beta$ antagonistic potency ratio of 1:7 when given intravenously and a ratio of 1:3 after oral administration. It is lipid soluble and has substantial first-pass hepatic metabolism. The peak hypotensive effect from intravenous labetalol occurs within 5 to 15 minutes and the duration of action is 4 to 6 hours. It can be used to treat hypertension in pregnancy. Despite HR slowing from labetalol, the decreased afterload helps maintain cardiac output. It may be given in 5- to 10-mg bolus doses at 5-minute intervals to control a hypertensive crisis. Uterine blood flow is not affected, owing in part to preserved cardiac output.

Metoprolol and Atenolol

Metoprolol is cardioselective with a ratio of 30:1 in affinity for β_1 and β2-receptors (see Table 14.4). It is lipid soluble and has a high first-pass hepatic metabolism resulting in the need for high oral doses (100–200 mg/day) compared with intravenous doses of 2.5 to 5 mg, titrated to effect. It is roughly half as potent as propranolol, and maximum β_1-blockade effect is achieved at 0.2 mg/kg. Atenolol is also β_1 selective, is lipophilic and has an elimination half-life of 6 hours. Even so, the effect of an oral dose of 25 to 100 mg lasts 24 hours. In a recent study, perioperative blockade with atenolol resulted in a reduced short- and long-term mortality in high-risk patients undergoing noncardiac surgery compared with metoprolol.[70] The differences might be explained by the longer metabolic half-life of atenolol and a lower chance of missing a dose and/or experiencing a "withdrawal" sympathetic response when compared with metoprolol.

Inhibition of Synthesis, Storage, and Release of Norepinephrine

α-Methyldopa is one of a group of antihypertensive drugs called *false neurotransmitters* that replace norepinephrine in the synaptic vesicles located in postganglionic nerve endings of the SNS. It is metabolized to α-methyldopamine and then to α-methylnorepinephrine, which are less potent at adrenergic receptors than dopamine and norepinephrine, thus accounting for some of their antihypertensive effects. Central effects of the metabolites result from action on α_2 receptors to decrease sympathetic outflow and to reduce anesthetic requirements by 20% to 40%. *Reserpine* prevents uptake of norepinephrine into vesicles, thereby inhibiting storage of dopamine and norepinephrine. *Guanethidine* acts by reducing norepinephrine release from sympathetic terminals and by depleting norepinephrine storage. It does not have sedating effects because it does not cross the blood-brain barrier. Side effects from the false transmitters include orthostatic hypotension, drowsiness, diarrhea, bradycardia, hepatitis, and autoimmune hemolytic anemia. Thus their use as antihypertensive drugs has fallen out of favor.

Parasympathetic Pharmacology

Cholinergic Receptors

The neurotransmitter ACh acts at distinct receptor types: nicotinic and muscarinic. The naturally occurring substances, muscarine and nicotine, were originally used to define and name the two receptor families. They have distinctly different tissue locations (see Chapter 13). Muscarinic receptors are GPCRs with a typical seven-transmembrane configuration. There are five subtypes, M_1-M_5. The odd-numbered subtypes are defined by *Pertussis* toxin insensitivity, coupling to G_q/G_{11} protein and stimulating phospholipase C to alter one or more ion channels. This effect generally leads to depolarization or increased excitability.[71,72] The even-numbered subtypes M_2 and M_4 are *Pertussis* toxin–sensitive, are coupled to the G_i/G_0 protein, and inhibit adenylyl cyclase to initiate a presynaptic inhibitory effect. Muscarinic subtypes M_1 and M_4 are found primarily in brain; M_3 and M_4 are found in lung, gastrointestinal tract, and glandular tissue; and M_2 receptors are located in cardiac tissue. Muscarinic receptor activation by ACh at the postsynaptic junction in heart and smooth muscle leads to bradycardia, salivation, bronchoconstriction, miosis, and increased gastrointestinal motility and secretion (Table 14.5). In addition, "adrenergic" muscarinic receptors are located on presynaptic sympathetic terminals in the cardiovascular and coronary systems, and their activation reduces norepinephrine release. In brain, release of ACh is subject to substantial ongoing autoinhibition as a result of coactivation of presynaptic muscarinic receptors on cholinergic terminals.

Nicotinic receptors activate postganglionic junctions of both the sympathetic and parasympathetic nervous systems (see Chapter 13). Nicotinic receptors are also located at the neuromuscular junction (see Chapter 21). Nicotinic cholinergic receptors are heteropentameric ligand-gated ion channels that allow depolarizing inward flow of monovalent cations.[73] The nicotinic receptor agonists consist primarily of the depolarizing neuromuscular-blocking drugs (e.g., succinylcholine [suxamethonium], hexamethonium) and can

TABLE 14.5 Antimuscarinic Drugs

Drug	IV	IM	CNS[a]	GI Tone	Gastric Acid	Airway Secretions[b]	Heart Rate

[b]Secretions may be reduced by inspissation.
[c]May decelerate initially.

simultaneously stimulate autonomic ganglia. The neuromuscular-blocking drugs are considered in Chapter 19.

Muscarinic Receptor Agonists

Muscarinic agonists are divided into two general groups:

1. The choline esters (ACh, methacholine, carbachol, bethanechol) and alkaloids (pilocarpine, muscarine, arecoline) that act directly on muscarinic receptors
2. Acetylcholinesterase inhibitors or anticholinesterases (physostigmine, neostigmine, pyridostigmine, edrophonium, echothiophate) that act indirectly by inhibiting ACh hydrolysis

The anticholinesterase drugs are frequently used to reverse the action of nondepolarizing neuromuscular-blocking drugs (see Chapter 22), to improve neuromuscular function in myasthenia gravis, and for colonic pseudo-obstruction. Newer drugs have been designed to improve cognitive function in Alzheimer disease.

Owing to rapid hydrolysis, direct-acting agonists such as ACh have few clinical applications, with the exception of topical application to produce miosis. Longer activity of the direct-acting agonists can be achieved by methylation of the choline moiety as noted with the synthetic drug methacholine. This modification prevents significant nicotinic receptor effects and slows acetylcholinesterase metabolism (Table 14.6). Carbachol and bethanechol are long-acting synthetic parasympathetic agonists; the carbamic-linked ester moiety significantly reduces metabolism. Carbachol has significant nicotinic activity at autonomic ganglia. Bethanechol is similar to methacholine and is highly specific for muscarinic receptors. It is used orally or parenterally, has only minimal cardiac negative chronotropic and inotropic effects, and is useful therapy for postoperative urinary retention and neurogenic bladder from spinal cord injury.

Pilocarpine is a tertiary amine alkaloid with actions similar to methacholine (see Table 14.6). Clinical use includes treatment for xerostomia and glaucoma, where it is used as a topical drug to produce miosis and reduce intraocular pressure. Pilocarpine has minimal nicotinic effects unless given systemically, in which case hypertension and tachycardia can result.

Echothiophate, a long-acting irreversible anticholinesterase, is instilled into the eye to reduce resistance to aqueous humor outflow and lower intraocular pressure. Echothiophate is absorbed into the circulation and therefore can prolong the duration of succinylcholine because of a reduction in cholinesterase levels. The action of ester-based local anesthetics can also be lengthened in patients receiving echothiophate through slower metabolism of the local anesthetic. Enzyme activity might not return to normal for 4 to 6 weeks after discontinuation of long-term therapy.

Muscarinic Receptor Antagonists

Anticholinergic drugs (atropine, scopolamine, glycopyrrolate) competitively inhibit the action of ACh by reversibly binding at muscarinic receptors. Nicotinic ACh receptors are not affected by doses that are usually used. The naturally occurring anticholinergic drugs atropine and scopolamine are tertiary amines derived from the belladonna plant. Low doses of atropine and scopolamine (up to 2 μg/kg) have typically undesired effects within the CNS to augment vagal outflow, which can result in bradycardia.[74]

At usual clinical doses (0.5–1 mg), atropine acts at peripheral muscarinic receptors to block the action of ACh, thereby increasing HR, producing mydriasis (pupil dilation) and cycloplegia (paralysis of accommodation), and inhibiting salivary, bronchial, pancreatic, and gastrointestinal secretions (see Table 14.5). It reduces gastric secretion of acid, mucin, and proteolytic enzymes, slows gastric emptying, reduces lower esophageal tone, and slows gastric motility. Atropine reduces the activity of sweat glands and thus evaporative heat loss, even in small doses. It relaxes bronchial smooth muscle, reduces airway resistance, inhibits mucociliary clearance in the airways, and thickens bronchial secretions.[75] Atropine and scopolamine are tertiary amines that cross the blood-brain barrier and the placenta. There is no harmful effect on the fetus. Their central effects might account for their antiemetic properties and control of nausea triggered by the vestibular apparatus.[76] Scopolamine skin patches are used to control motion sickness and postoperative nausea and vomiting (see Chapter 34). Atropine can block presynaptic muscarinic receptors on adrenergic terminals, leading to a sympathomimetic effect. These drugs should be used with caution in patients with cardiac tachyarrhythmias or severe coronary artery disease, and are contraindicated in narrow-angle glaucoma because they can increase intraocular pressure. They are considered safe when given parenterally to patients with the more common open-angle glaucoma.

Scopolamine in the usual clinical doses of 0.3 to 0.6 mg displays stronger antisialagogue and ocular activity, but is less likely than glycopyrrolate or atropine to increase HR (see Table 14.5).[77] Scopolamine crosses the blood-brain barrier more effectively than atropine and is commonly associated with amnesia, drowsiness, fatigue, and non–rapid eye movement sleep. One limitation imposed by the central actions of higher doses of scopolamine (and atropine) is an infrequent side effect termed the *central anticholinergic syndrome*. The origin of the syndrome is due to blockade of the abundant muscarinic ACh receptors in the CNS, which leads to agitation, disorientation, delirium, hallucinations, and restlessness. It can manifest as somnolence and should be considered in the differential diagnosis of delayed awakening from anesthesia. Physostigmine is a tertiary amine anticholinesterase that crosses into the CNS and can be administered in intravenous doses of 15 to 60 mg/kg for the treatment of central anticholinergic syndrome.

Glycopyrrolate is a synthetic quaternary amine that does not cross into the CNS and does not produce the CNS side effects noted with atropine and scopolamine (see Table 14.5). It is more potent and longer-acting at peripheral muscarinic receptors than atropine. It is used clinically as an antisialagogue to treat bradycardia and to inhibit cardiac muscarinic receptor side effects when anticholinesterase agents are used to reverse the effects of muscle relaxants. The antisialagogue dose of 0.004 mg/kg can last up to 8 hours. The recommended dose to reverse neuromuscular blockade is 0.2 mg for every 1 mg of neostigmine. The vagal blocking effect lasts 2 to 3 hours. Similar to atropine, low doses can cause initial bradycardia.

Inhalation of anticholinergics is the most effective route of administration when bronchodilation without systemic side effects is desired. Ipratropium, a derivative of methylatropine, is an inhaled anticholinergic that inhibits muscarinic receptor subtypes with a peak effect of 30 to 60 minutes and a duration of action of 3 to 6 hours.[78] Low doses of ipratropium decrease airway size via preferential blockade of neuronal M_2-muscarinic receptors. However, following large ipratropium doses, bronchodilation results from blockade of M_3-muscarinic receptors on airway smooth muscle. Ipratropium, unlike atropine, does not affect mucociliary clearance of respiratory secretions. In chronic obstructive pulmonary disease, ipratropium is beneficial in improving pulmonary function, and tachyphylaxis with long-term use has not been demonstrated.[79] In acute asthma exacerbations, ipratropium can provide additional benefit when used with inhaled β_2-agonists.

• **Fig. 14.4** Spectral analysis of electroencephalogram data reveals a shift in power induced by methylphenidate. Warm colors (*red*) represent higher power at a given frequency, whereas cool colors (*blue*) represent lower power. A representative spectrogram computed from a rat in the awake state shows predominance of θ power (4–8 Hz) (A). A representative spectrogram computed from a rat inhaling isoflurane (1.0%) shows predominance of δ power (<4 Hz) before and after administration of normal saline solution. However, administration of intravenous methylphenidate (5 mg/kg) promptly induced a shift in power to an active θ-dominant pattern similar to that observed during the awake state. This animal began to move vigorously approximately 5 minutes after methylphenidate administration, generating significant motion artifacts (*B*). (Adapted with permission from Solt K, Cotton JF, Cimenser A, et al. Methylphenidate actively induces emergence from general anesthesia. *Anesthesiolgy.* 2011;115:791–803.)

Emerging Developments

Active Emergence and Enhanced Recovery Using CNS Stimulants

Active emergence from anesthesia to avoid the numerous complications that can occur during emergence (e.g., emergence delirium, slow awakening, stage II adverse events) while also enhancing operating room turnovers and patient satisfaction is the goal of recent research efforts. This amounts to "turning on the lights" actively after an anesthetic is completed, rather than awaiting passive recovery from anesthesia. Mechanisms involved in emergence from anesthesia are not well understood but appear to be amenable to pharmacologic manipulation of the nervous system. Pharmacologic agents used in the treatment of attention deficit/hyperactivity disorder and used to treat narcolepsy can promote emergence for anesthesia. Dopamine is a neurotransmitter that elicits wakefulness. When a pharmacologic inhibitor of dopamine reuptake such as methylphenidate is given to rats anesthetized with propofol, a shift in the electroencephalogram to higher frequencies is observed along with a faster time to the righting reflex.[80] A similar effect can be seen in isoflurane-anesthetized rats where methylphenidate will shift the electroencephalogram to higher frequencies as noted in Fig. 14.4 and will shorten the time to emergence.[81] The effect of methylphenidate is inhibited by droperidol, an antagonist of the dopamine receptor.[81] Another research approach to further validate the role of dopamine in "active emergence" is to directly stimulate the ventral tegmental area containing dopamine neurons in rats anesthetized with isoflurane. This stimulus restores conscious behaviors and the righting reflex.[82] Modafinil is a Food and Drug Administration–approved schedule IV drug prescribed to improve wakefulness in patients with narcolepsy and has an off-label use to enhance cognitive function. Its precise mechanism of action is unknown but it has a weak atypical dopamine reuptake inhibitory effects. When given before surgery or after surgery, patient benefits of alertness and improved energy have been noted.[83,84] These studies in both rats and humans are leading to clinical trials to determine the efficacy and benefits of pharmacologic interventions to hasten emergence from anesthesia and improve early recovery.

Key Points

- The naturally occurring catecholamines epinephrine, norepinephrine, and dopamine are derived from the amino acid L-tyrosine. Their sites of action are on adrenergic and dopaminergic receptors.
- Adrenergic receptors have been subdivided based on their effector responses. β_1-receptors are localized in cardiac tissue and mediate increases in HR, contractility, and conduction velocity, whereas β_2-receptors are found on arterioles, vena cava, pulmonary artery, aorta, and uterine smooth muscle; both types mediate smooth muscle relaxation. The α_1-receptors mediate arterial and venous smooth muscle contraction. The α_2-receptors also mediate vascular constriction but have additional actions in the CNS to reduce sympathetic outflow and pain perception and to produce sedation.

- Dopamine is an endogenous catecholamine involved in neural transmission. Parenteral administration can be used for hemodynamic support and, depending on the infusion rate, activates D1 receptors to dilate renal and coronary vessels and β_1 receptors to cause chronotropic and inotropic effects, or, at high doses, activates α_1 receptors to mediate vasoconstriction. Fenoldopam is a synthetic selective D1 agonist used to treat hypertension or to improve renal function via selective vasodilation.
- Dexmedetomidine is a highly selective α_2 agonist used for sedation. It produces an "arousable" sedation much like natural sleep and is associated with less delirium compared with benzodiazepine sedation.
- Dobutamine is a racemic synthetic catecholamine. The (−) isomer acts on α_1 receptors to increase vascular resistance and the (+) isomer acts on β_1 receptors to increase contractility while antagonizing the increase in vascular resistance. It increases cardiac output, decreases pulmonary vascular resistance, and is unlikely to increase HR.
- Selective β_2 agonists are indicated for the treatment of acute asthma and chronic obstructive pulmonary disease by reducing smooth muscle tone and bronchial airway resistance. They are most commonly given via inhalation, and owing to structural changes that reduce metabolism, typically have a long duration of action.
- Ephedrine is a noncatecholamine sympathomimetic drug with both direct and indirect actions on α- and β-adrenergic receptors.
- Vasopressin is an endogenous hormone that acts on V1 and V2 receptors to promote water reabsorption and to preserve coronary, cerebral, and pulmonary blood flow while constricting splanchnic vessels during severe hypotension and shock.
- β-Adrenergic receptor blockers have a number of predictable effects to slow HR and inhibit gluconeogenesis. Their effects to reduce myocardial oxygen demand and myocardial infarction can be overshadowed in select circumstances by their association with a higher risk of stroke and death.
- Muscarinic receptor antagonists inhibit the action of ACh at muscarinic receptors to increase HR and pupil dilation and reduce production of secretions.
- Using CNS stimulants such as methylphenidate and modafinil as a means of increasing the rapidity of recovery from general anesthesia (and also enhancing recovery) is a topic of contemporary research interest.

CHAPTER OUTLINE

Normal Physiologic Thermoregulation
Anesthetic Effects on Thermoregulation
Effects of Anesthetic Techniques and Agents
Consequences of Thermal Dysregulation Related to Anesthesia
Measuring Temperature Intraoperatively
Prevention and Correction of Intraoperative Hypothermia
Emerging Developments

Core body temperature is highly regulated in humans by the autonomic nervous system and the hypothalamus. General anesthesia, neuraxial anesthesia and analgesia, and drugs such as opioids all reduce the ability of the hypothalamus to regulate core temperature. Thus without intervention, hypothermia (and, less commonly, hyperthermia) is a common consequence of anesthetic management. In this chapter, we review normal thermoregulation, the mechanisms responsible for anesthesia-related hypothermia and hyperthermia, and the consequences of perioperative hypothermia. We use this framework to discuss methods to reduce, prevent, or correct perioperative hypothermia and hyperthermia.

Normal Physiologic Thermoregulation

Human body core temperatures are regulated by the hypothalamus in response to sensory inputs from the autonomic nervous system. Ambient and internal temperature is sensed by temperature-sensing elements in the skin and the dorsal root ganglia. The signals travel via ascending spinothalamic tracts and afferent somatosensory pathways, through the lateral parabrachial nucleus to the hypothalamus.[1,2] Exercise, nutrition, infection, hypothyroidism or hyperthyroidism, and drugs such as opioids and general anesthetic agents affect temperature thresholds through inhibitory postsynaptic signals in the hypothalamus.[3]

Core temperature in humans represents a balance between heat production via metabolism and heat loss mostly through the skin but also via gas exchange and urine output.[4,5] Basal heat production is about 0.83 kcal/kg per degree centigrade.[6,7] Well-perfused tissues are also generally the most metabolically active and produce the most heat.[8,9] Heat production is increased during exercise, mostly as a result of increases in muscle metabolism.[3] It is decreased during anesthesia owing to decreased metabolism, primarily in the brain, muscles, and heart.[10,11] Mechanical ventilation and neuromuscular blocking agents further reduce metabolic rate.[12,13]

There are four primary mechanisms for heat loss: radiation, convection, conduction, and evaporation (Fig. 15.1). Radiation makes the largest contribution.[14] Air movement displaces heat near the skin surface by displacing warm air with cooler air. Heat distribution from the core includes both blood-borne longitudinal convection and radial conduction into adjacent tissues.[15] Heat transfer to peripheral tissues is slower than core heat transfer because of the lower rate of perfusion. Longitudinal convection via the blood is the primary mechanism for peripheral redistribution of heat, although radial diffusion also contributes. Administration of intravenous fluids that are below core temperature increases heat loss via conduction because the administered fluid is warmed to body temperature by surrounding blood and tissues. Evaporation via intact skin and exhalation of warmed, humidified air dissipates less than 15% of the basal metabolic rate during normal circumstances but increases substantially during sweating.[16] The microenvironment around the skin surface influences heat loss through conduction, convection, and radiation.[17] Likewise, heat loss may be augmented by relatively cool operating rooms,[12,13] cool intravenous and irrigating fluids,[18] and evaporation from large surgical incisions.[19]

A useful model for understanding thermoregulation divides the human body into core and peripheral thermal compartments (Fig. 15.2). The core consists of the well-perfused organs—that is, the brain and those within the trunk—and makes up about 60% of body mass.[10] Because these organs are well perfused, heat distribution across the core is rapid and uniform. The hypothalamus normally regulates core temperature to the range of 36.5°C to 37.5°C.[3] In a given individual, core temperature varies with diurnal rhythms, cytokines produced during inflammation, and other stimuli. The peripheral compartment consists of the skin and subcutaneous

Abstract

Core body temperature is highly regulated in humans by the autonomic nervous system and the hypothalamus. General anesthesia, neuraxial anesthesia and analgesia, and drugs such as opioids all reduce the ability of the hypothalamus to regulate core temperature. Intraoperative hypothermia is common and is caused by (1) redistribution of heat from the core to the periphery, (2) decreased metabolism, leading to decreased heat production, and (3) increased heat loss, primarily via radiation, convection, and in large, open surgeries, evaporation. Thus without intervention hypothermia (and, less commonly, hyperthermia) is a common consequence of anesthetic management. Although mild or moderate hypothermia may be protective in certain circumstances (e.g., after cardiac arrest), perioperative hypothermia is associated with multiple adverse outcomes, including increased postoperative discomfort and postanesthesia recovery time, blood loss and transfusion, cardiovascular morbidity, surgical site infection, deep vein thrombosis, and hospital length of stay. Intraoperative hypothermia can be prevented, mitigated, or corrected by preoperative and intraoperative active warming, which has also been shown to reduce complications.

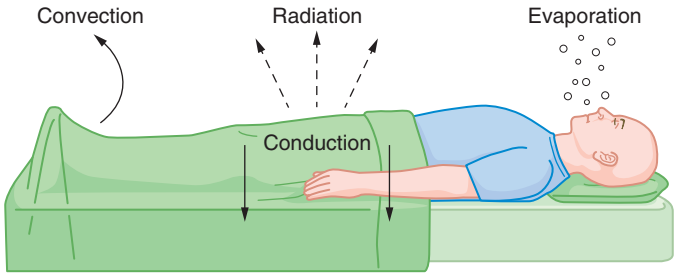
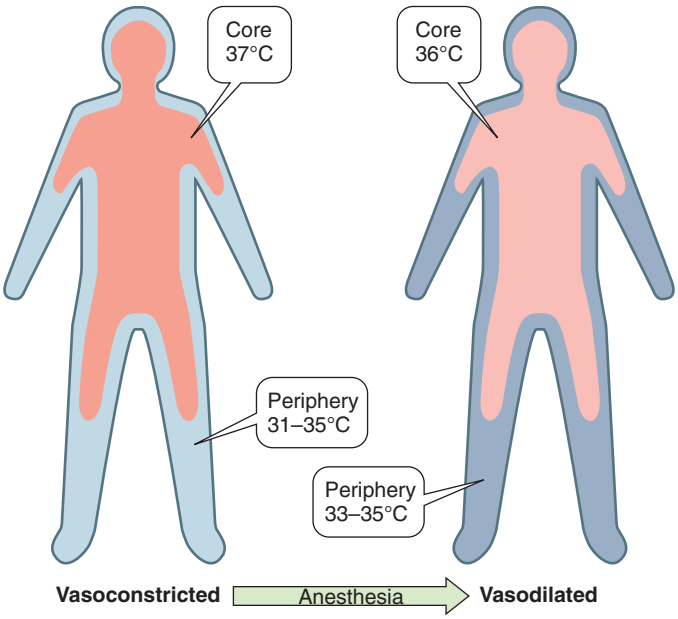
thermoregulatory vasoconstriction



• **Fig. 15.1** Mechanisms of intraoperative heat transfer include convection, radiation, evaporation, and conduction. Radiation makes the largest contribution to heat loss in anesthetized patients, with convective heat loss next in importance. Respiratory evaporation accounts for less than 10% of heat loss. With a large incision, however, evaporative heat loss can be substantial. Conductive heat loss plays almost no role in heat loss under anesthesia. (Adapted with permission from Sessler DI. Perioperative heat balance. *Anesthesiology.* 2000;92:578–596.)



• **Fig. 15.2** Redistribution hypothermia is responsible for the initial decrease in core temperature over the first 30 to 60 minutes after induction of general anesthesia. The degree of core temperature decrease is related to the degree of thermoregulatory vasoconstriction preoperatively. Preoperative active warming works by reducing thermoregulatory vasoconstriction, thereby reducing redistribution hypothermia. (Adapted with permission from Sessler DI. Temperature monitoring. In: Miller RD, ed. *Anesthesia.* 4th ed. New York: Churchill Livingstone; 1994:363–382.)

tissue, resting muscle, and the upper and lower extremities. The hypothalamus does not regulate peripheral temperature, but it does receive sensory temperature input from the periphery.[7] Peripheral temperature under normal circumstances is usually about 2°C to 4°C less than core temperature, largely as a result of peripheral vasoconstriction to regulate heat loss to the environment.

Exposure to a cold environment causes peripheral vasoconstriction. Peripheral vasoconstriction directly reduces heat loss, which helps to maintain the balance of heat production and heat loss. Peripheral vasoconstriction also causes redistribution of heat content (tissue temperature) from the periphery to the core,[20] thus immediately increasing core heat content while reducing peripheral heat content. This thermoregulatory response increases the core-to-peripheral temperature gradient, which may increase to more than 10°C in extreme circumstances.[21,22] Conversely, exposure to a hot environment or an increase in heat production, as with increased metabolism, induces thermoregulatory vasodilation to increase heat loss, as well as to transfer heat from the core to the periphery. Under these circumstances, the core-to-peripheral temperature gradient may be less than 2°C.

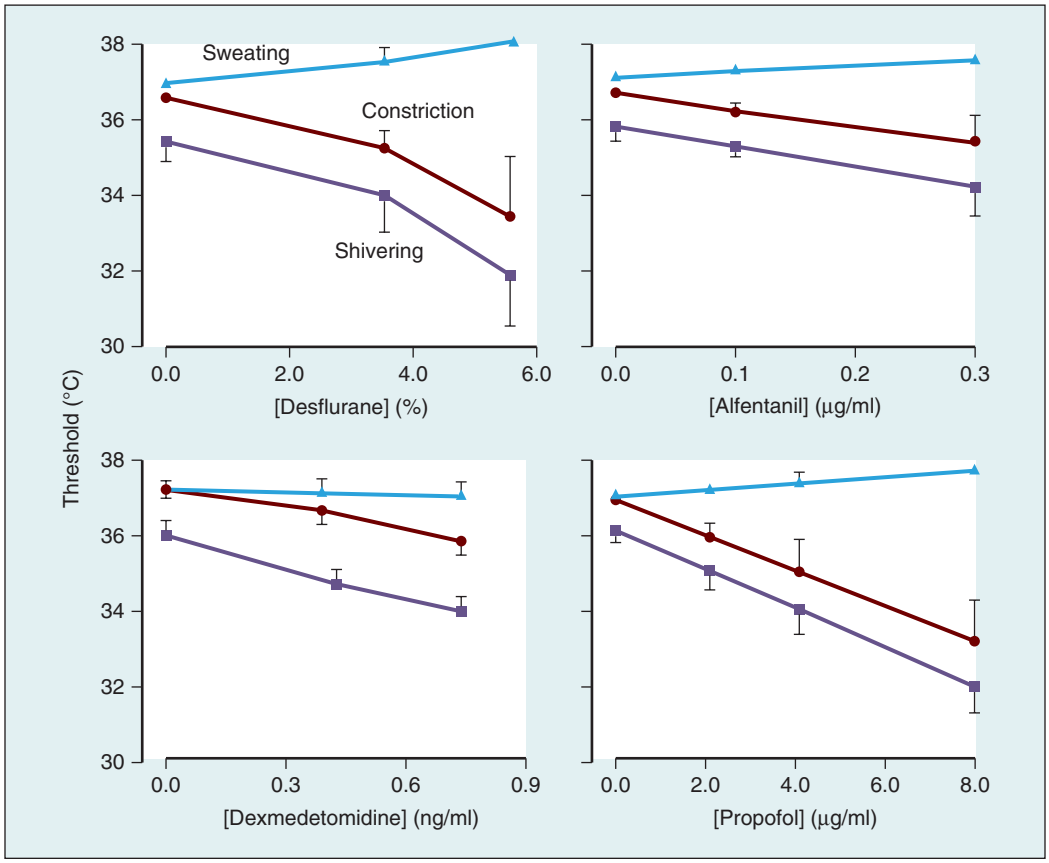
Hormonal, cytokine, and endocrine inputs to the hypothalamus define the core temperature set point, which varies diurnally and in response to fever triggers such as interleukin (IL)-2.[23,24] The hypothalamus integrates tissue and environmental temperature signals and maintains core temperature within a tight interthreshold range of about 0.2°C above or below the set point.[25] Modification of heat production (shivering, behavioral modification) and modification of heat loss (behavioral modification, vasoconstriction or vasodilation, and sweating) facilitate this tight temperature control.[3] Behavioral modification includes adding layers (e.g., clothing or covers) to reduce heat loss in response to cold exposure or a reduction in core temperature, and removing layers to increase heat loss in response to heat exposure or an increase in core temperature. It also includes reducing physical activity to reduce heat production or increasing physical activity, which may be voluntary or involuntary (shivering), to increase heat production.[26-28]

In summary, normal thermoregulatory mechanisms tightly control human body core temperature within a narrow interthreshold range of about 0.2°C. Next, we consider the important ways that anesthetic agents alter these mechanisms.

Anesthetic Effects on Thermoregulation

Intravenous and inhaled anesthetic agents, neuraxial anesthesia and analgesia, and opioids all blunt the hypothalamic responses to changes in core and environmental temperature, thus increasing the interthreshold range (i.e., the range of tolerated temperatures) in a dose-dependent manner (Fig. 15.3).[29] A major mechanism for this is through inhibition of changes in vascular tone. Virtually all anesthetic techniques and agents induce vasodilation. Vasoconstriction in response to a reduction in core temperatures is inhibited until the core temperature is decreased by ~3°C to 4°C. Anesthetic agents not only increase the interthreshold range but also inhibit or eliminate responses to changes in core temperature. General anesthesia prevents behavioral modification in response to core and environmental temperature changes while the patient is unconscious, and neuraxial anesthesia and opioids reduce temperature perception, thus making behavioral modification less likely. General anesthesia abolishes the shivering response and limits sweating. Mechanisms that cause increased heat loss to the environment include cutaneous vasodilation, surgical exposure (including radiative and evaporative heat loss), inhalation of dry, cold gases that are warmed and humidified in the lungs and exhaled, and administration of ambient temperature intravenous fluids. Anesthetic agents also reliably reduce the metabolic rate and thus heat production. Neuromuscular blocking agents compound the effects of anesthetic agents by further reducing metabolic heat production.[29]

As a result of the combination of reduction in heat production and reduced capacity to decrease heat loss leading to increased heat



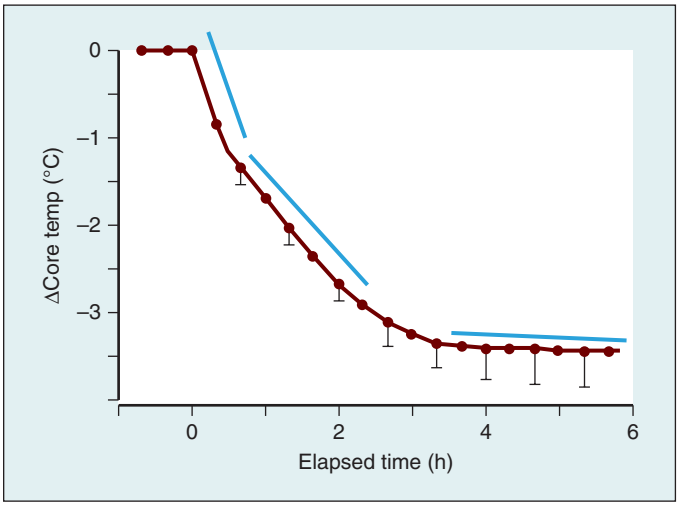
• **Fig. 15.3** Anesthetic agents and thermoregulation. Anesthetic agents with different mechanisms of action (desflurane, alfentanil, dexmedetomidine, and propofol) all inhibit thermoregulatory sweating, vasoconstriction, and shivering in volunteers in a dose-dependent fashion and with similar patterns, although to somewhat different degrees. The effect on vasoconstriction and shivering is much larger than that on sweating. (Used with permission from Sessler DI. The thermoregulation story. *Anesthesiology.* 2013;118:181–186.)

loss, in the absence of interventions to maintain normothermia, most patients exposed to general anesthesia become hypothermic, typically by 1°C to 3°C.[30] A 3°C reduction in mean body temperature translates to a heat "debt" of approximately 175 kcal in an average 70-kg patient, equivalent to about 3 hours of basal metabolic heat production.[11] Thus patients who become hypothermic intraoperatively may take hours to return to baseline thermal comfort.

Although core temperature is almost universally used as a measure of the state of thermoregulation of an individual, it does not accurately represent either total body heat content or mean body temperature because peripheral tissues are typically 2° to 4°C cooler than the trunk and the head.[10,31] This normal core-to-peripheral tissue temperature gradient is maintained by tonic thermoregulatory vasoconstriction of arteriovenous shunts in the fingers and toes[4,32] that maintain core temperature by reducing heat loss to the environment. Thus in addition to effects on normal thermoregulatory mechanisms, the direct vasodilation caused by all anesthetics causes dissipation of heat across the existing temperature gradients from the warmer core to the cooler periphery.[33] Despite the early decrease in core temperature within the first 30 minutes of anesthetic induction, body heat content during early anesthesia remains constant; that is, net heat exchange to the environment remains close to zero. The redistribution of core heat to the periphery contributes about 65% of the total decrease in core temperature during the first 3 hours of anesthesia.[10]

In the absence of interventions to minimize preinduction peripheral vasoconstriction or to add heat to the patient by active warming methods (these interventions are described in detail later), core temperatures under anesthesia typically decrease by 1°C to 1.5°C during the first hour.[6,7] This is followed by a slower linear phase of temperature decrease over the next 2 to 3 hours.[5] A plateau is then reached throughout the remainder of the procedure (Fig. 15.4).[26-28]

The initial large decrease is caused by redistribution of heat content as the result of vasodilation of previously constricted vessels. The linear phase results mainly from the decrease in metabolic rate induced by anesthesia, typically in the range of a 15% to 40% reduction.[10,11,34] In this phase, heat loss exceeds metabolic heat production, which leads to a slow, linear decrease in temperature. During this phase, patient factors such as basal metabolic rate and obesity, the type of operation, and ambient temperature all may affect the rate of decrease.[12,13] In a sufficiently long surgery (>4 hours) the linear phase is followed by a core temperature plateau, when heat loss and heat production reach equilibrium.[26,27,28]



• **Fig. 15.4** Hypothermia during general anesthesia. In the absence of active warming, hypothermia during anesthesia develops with a characteristic pattern. During the first hour, core temperature usually decreases 1°C to 1.5°C as a result of heat redistribution. This is followed by a slower, nearly linear decrease in core temperature as a result of heat loss. In the final phase, if the procedure is of sufficient duration, core temperature reaches a plateau and does not decrease further, as a result of reaching a steady state between heat production and heat loss, which may be facilitated by peripheral thermoregulatory vasoconstriction. (Used with permission from Kurz A, Sessler DI, Christensen R, et al. Heat balance and distribution during the core-temperature plateau in anesthetized humans. *Anesthesiology.* 1995;83:491–499.)

This state of equilibrium is also known as thermal steady state. Patients with sufficient initial body heat content remain relatively warm intraoperatively and tend to reach thermal steady state earlier. In patients in whom core temperature was maintained in the normal range preoperatively owing to thermoregulatory vasoconstriction, core temperature decreases by a greater amount and it takes longer to reach thermal steady state.[26-28] Core hypothermia in general or regional anesthesia is a function of the initial thermoregulatory state of the patient and the site, duration, and magnitude of surgery.

Although the core temperature plateau usually occurs at about the same time as the temperature becomes low enough to trigger thermoregulatory vasoconstriction (~34°C-35°C), vasoconstriction, surprisingly, only slightly reduces cutaneous heat loss.[35,36] The reason appears to be that constriction is largely restricted to arteriovenous shunts in the fingers and toes.[37] The distribution of heat to the periphery is influenced by peripheral blood flow, heat exchange between adjacent arteries and veins, and the core-to-peripheral temperature gradient. Once heat reaches the periphery it cannot travel back to the core against the temperature gradient. Reemergence of vasoconstriction restricts further redistribution from the core but cannot recover heat already lost to peripheral tissues. After vasoconstriction, cutaneous heat loss decreases as less heat flows peripherally from the core and peripheral tissues gradually cool. However, core temperature plateau appears well before a thermal steady state, suggesting that it is a constraint of centrally generated metabolic heat to the core, rather than a reduction in cutaneous loss. Cutaneous heat alterations therefore represent a more accurate measure of heat loss than changes in central body temperature because as mentioned redistribution is the determinant of heat balance.[38]

Thermoregulation under anesthesia is different in infants and children than in adults. Although respiratory losses are similar, infants have less mass with a high surface-area-to weight ratio. A greater fraction of their weight is distributed to their heads and torsos as opposed to their extremities.[39] With less overall mass, infants have lower metabolic heat production and cannot absorb much heat from the core. They typically lose heat from their thin scalps and skin as opposed to redistribution, which is most apparent during the linear phase of hypothermia.[3,12,13,40] Studies have also shown impaired thermoregulation in old age.[41]

As patients emerge from anesthesia postoperatively, they slowly regain thermoregulatory control and, in the absence of intraoperative active warming, regain core normothermia in about 2 to 5 hours.[42] Upon emergence, patients regain arteriovenous vasoconstriction and shivering and are able to decrease cutaneous heat loss,[36] constrain metabolic heat to the thermal core,[43] and increase metabolic heat production.[44] Recovery, however, may be limited by residual volatile anesthetics or opioids administered at the end of surgery.[26,27,45,46]

Effects of Anesthetic Techniques and Agents

General anesthesia decreases core temperature to a greater extent than neuraxial anesthesia. Patients under neuraxial anesthesia lose less heat from redistribution compared with those who have general anesthesia.[10,31,47,48] Although neuraxial anesthesia inhibits thermoregulation centrally,[49-51] more importantly, the inhibition of peripheral sympathetic motor nerves prevents thermoregulatory vasoconstriction and shivering.[52] Neuraxial anesthesia also has a lesser impact on reducing metabolic heat production.[10,31] As a result, patients under neuraxial anesthesia demonstrate a smaller initial reduction of core temperature related to redistribution and a slow, prolonged phase of linear hypothermia.[31]

Hypothermia during neuraxial anesthesia for small surgeries is usually mild because a passive plateau develops in well-insulated patients. Patients undergoing long operations under neuraxial anesthesia, on the other hand, are at risk of developing more severe hypothermia[53] comparable to that seen under general anesthesia.[54] Neuraxial anesthesia inhibits both autonomic thermoregulatory control and thermoregulatory shivering in response to hypothermia.[55,56]

Combined approaches, including anesthetic agents, analgesic/sedative agents, and/or neuraxial anesthesia/analgesia, produce a more pronounced inhibition of thermoregulation and a greater risk of perioperative hypothermia.[41] Heat redistribution may be increased because of differential and additive mechanisms. Heat may be lost at a higher rate during the linear phase. When the effects of regional anesthesia on vasoconstriction are superimposed on those of general anesthesia, vasoconstriction occurs at a lower core temperature.[57] Centrally initiated vasoconstriction will have a reduced effect on vascular tone in the lower extremities after neuraxial anesthesia.[58]

Although hypothermia is more common and appears to have more severe consequences, the disruption in thermoregulation induced by anesthesia may also lead to hyperthermia. In patients having superficial surgery of long duration in which almost all of the skin is covered by drapes, active warming can lead to hyperthermia owing to transfer of heat to the patient in excess of heat loss.[3] Adverse consequences of hyperthermia include increased heart rate and, if severe, neurologic consequences.

Consequences of Thermal Dysregulation Related to Anesthesia

Intraoperative core hypothermia was the norm in anesthesia management until at least the 1990s, and it was not thought to have adverse consequences. That view was incorrect, however. Even 0.5°C of hypothermia has adverse consequences, which include patient discomfort, prolonged duration (and cost) of immediate postoperative recovery in the postanesthesia care unit (PACU),[59] prolonged drug metabolism,[60] increased risk of blood loss and transfusion,[61] increased risk of cardiovascular and wound morbidity, and increased risk of deep vein thrombosis (Table 15.1 and Fig. 15.8).

Hypothermia may also have benefits for specific types of surgeries. Hypothermia reduces metabolism by about 7% per degree centigrade temperature reduction. A 1°C to 3°C reduction is protective in animal models of brain injury, but human trials have mostly shown no benefit. Hypothermia is commonly used for neuroprotection in cardiac surgery,[62-64] although there were no differences in mortality and hospital length of stay in coronary artery surgery patients kept hypothermic (34°C) versus normothermic (37°C) during cardiopulmonary bypass.[65] In traumatic brain injury, no benefit was found in a large, multicenter randomized, controlled trial of induced hypothermia.[66] In brain aneurysm clipping, intraoperative hypothermia was found to have no benefit in a large, multicenter randomized, controlled trial (Intraoperative Hypothermia for Aneurysm Surgery Trial [IHAST]).[67] In that trial, there was some benefit in patients in whom the aneurysm ruptured during surgery; this was offset by an increase in infectious complications, particularly because aneurysm rupture was rare. Patients rapidly cooled after cardiac arrest have improved outcomes, and induced hypothermia has now become standard of care.[68] Newborns with neonatal hypoxic-ischemic encephalopathy have also been shown to have improved outcomes with hypothermia.[69]

Although induced hypothermia may be beneficial in a few instances, adverse consequences are common and may be severe. Responses to decreased core temperature such as vasoconstriction and shivering are uncomfortable for patients,[70] increase oxygen consumption,[71] and may interfere with patient monitoring. Hypothermia is associated with increased cardiac morbidity in patients undergoing major vascular surgery.[72] Even mildly lowered temperatures reduce the function of enzymes of the coagulation cascade, including decreased levels of thromboxane B_2 and platelet surface P-selectin.[73,74] Prothrombin and activated partial thromboplastin times have been shown to be significantly prolonged at hypothermic temperatures (<35°C); temperatures less than 33°C produce a prolonged prothrombin time that is functionally equivalent to a 50% or more deficiency in factor V.[75-77] Compensatory vasoconstriction reduces both oxygen delivery and nutrient flow to peripheral tissues and affects coagulation, immune function, and the initiation phase of clot formation.[78,79] These effects on coagulation cause a concomitant increase in transfusion requirements in patients during surgery with higher blood loss such as hip replacement.[61]

Hypothermia reduces the motility of macrophages, chemotaxis, and the production of antibodies and antibacterial oxidant defenses.[80,81] Compensatory vasoconstriction decreases partial

TABLE 15.1 Major Consequences of Mild Perioperative Hypothermia in Humans

Consequence	Author	N	ΔT_{core} (°C)	Normothermic	Hypothermic	*P*
Surgical wound infection	Kurz et al.[85]	200	1.9	6%	19%	< 0.01
Duration of hospitalization	Kurz et al.[85]	200	1.9	12.1 ± 4.4 days	14.7 ± 6.5 days	<0.01

pressure of oxygen in peripheral tissues. This decreases oxidative killing by neutrophils and reduces resistance to inoculation of bacteria, including *Escherichia coli*[82] and *Staphylococcus aureus*[83] in guinea pigs.[84] In a randomized, blinded, controlled trial in 200 colorectal surgery patients, patients randomly assigned to intraoperative core normothermia (36.6°C) achieved using intraoperative active warming versus core hypothermia (34.6°C; the control group), the surgical site infection rate was reduced by two-thirds in normothermic patients and their wounds made significantly more collagen.[85]

Although the majority of studies have investigated the adverse consequences of a 2°C core temperature differential on arrival in the PACU (~34.5°C vs. ~36.5°C), a recent retrospective, large database study at one institution demonstrated that, although hypothermia in the PACU is uncommon, intraoperative hypothermia remains common (67% of patients) and that both the degree and duration of intraoperative hypothermia predict adverse consequences, including prolonged hospital length of stay and transfusion requirement (see Table 15.1).[86] Thus consideration should be given not only to correcting hypothermia by the end of surgery but also to preventing it.

Measuring Temperature Intraoperatively

Preventing and correcting intraoperative temperature requires the core temperature to be measured. Temperature monitoring is a standard of care defined by American Society of Anesthesiologist practice guidelines: "Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated or suspected."[61,87,88] Although measurement of core temperature is required, methods for measuring core temperature are variably reliable, and core temperature measurements do not provide information on thermal status and total body heat content.

Core temperature may be measured at many sites,[3,87] by using thermocouples, thermistors, and infrared sensors. There is a range of convenience and accuracy based on site and technology. The most reliable sites for measuring core temperature are the pulmonary artery, distal esophagus, nasopharynx, and tympanic membrane. Other generally reliable sites include the mouth, axilla, and bladder. Suboptimal sites include the forehead skin, infrared "tympanic" and "temporal artery" sensors, and rectal.[3]

Esophageal temperature measurements are commonly used intraoperatively because of their accuracy (provided they are advanced to the distal third of the esophagus)[89] and ease of use. The nasopharynx, axilla, and bladder are also reliable sites but may be limited by positioning.[3] Bladder temperatures are affected by urine flow. Axillary temperatures may be affected by forced-air warming.

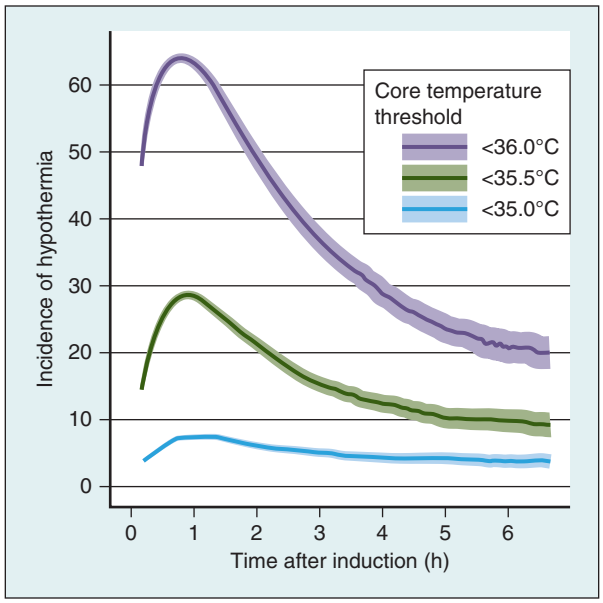
Although core temperature is useful, it does not provide information on heat content. A patient with a normal core temperature and minimal thermoregulatory vasoconstriction is quite physiologically different from a patient with a normal core temperature and severe thermoregulatory vasoconstriction and/or shivering. Therefore thermal comfort should also be assessed. Components include patient report of comfort, presence or absence of shivering, and assessment of peripheral temperature. Patients with a normal core temperature might benefit from active warming in the PACU if they report feeling cold, are shivering, or have obvious peripheral vasoconstriction because the adverse consequences are, at least in part, mediated by peripheral vasoconstriction and hypothermia of peripheral tissues.

Prevention and Correction of Intraoperative Hypothermia

Unless they are actively warmed, most anesthetized patients become hypothermic, defined as core temperature less than 36°C.[90] Because of the consequences and clinical burdens of hypothermia, anesthetists should aim to transport patients to the PACU with core temperatures of at least 36°C. Recent studies suggest avoiding intraoperative hypothermia should become a new practice standard. The reduction in metabolic rate and heat production induced by anesthesia has protective properties and is likely to be difficult to alter. Therefore the two primary ways by which perioperative hypothermia can be prevented or corrected are reducing heat loss and active warming.

Reduced heat loss can be achieved with a high ambient temperature and passive insulation. Reduced heat loss can be facilitated by keeping the preoperative holding room warm (at least 72°F). Some operating rooms have rapidly responsive thermostats; in that case, warming the operating room during induction, preparation, and draping and then reducing the temperature for surgeon comfort after the drapes are placed can be effective. Warm blankets are valuable for comfort in awake patients, although they are no more effective than unwarmed blankets in reducing heat loss (Fig. 15.5). Multiple layers similarly are not more effective than a single layer.[91] Because laundering blankets is relatively expensive and multiple layers of blankets my obscure the patient, making it more difficult to examine the patient, multiple blankets and routine replacement of blankets are not warranted.

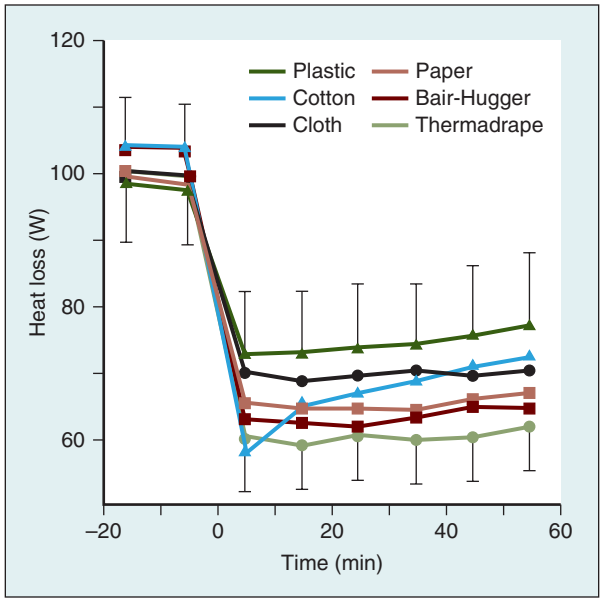
There are numerous methods and technologies for active warming, although not all are equally effective or safe. The goal of active warming is the transfer of heat to the patient without causing a burn. It can be achieved through a number of technologies,



• **Fig. 15.5** Insulating covers reduce heat loss but do not transfer heat. The magnitude of reduction is similar regardless of cover used. More layers or warmed layers also provide similar reduction in heat loss without transferring heat. (Used with permission from Sessler DI, McGuire J, Sessler AM. Perioperative thermal insulation. *Anesthesiology.* 1991;74:875–879.)

most introduced into practice in the 1980s and 1990s. These include forced-air warming, resistive heating, heating lamps, heated humidifiers, circulating water, warmed intravenous fluids, and warm fluid-containing plastic bottles. Circulating water, warmed fluids, heated humidifiers, and warmed plastic bottles may potentially cause burns, because the temperature of the water required to transfer heat actively is near the burning point for skin (>42°C-44°C). Skin warming with warmed fluid containers is discouraged by American Society of Anesthesiologists (ASA) guidelines because they have been responsible for the majority of thermal injuries as reported by the ASA.[48] Heated humidifiers have also caused burns. Circulating water blankets under the patient on the operating room table may increase the risk of pressure ulcers by increasing the metabolic rate and oxygen consumption in potentially poorly perfused skin at risk of unmet cellular demands. Warming intravenous fluids to 40°C to 42°C is effective in patients who are expected to receive more than 2 L of fluid. Patients with hypothermic trauma or hemorrhage benefit from fluid warming because of the required rapid infusion of fluids.

Skin surface active warming by forced air, resistive heating, or circulating water blankets that can be placed on the nondependent skin, on the other hand, is usually effective in transferring heat. Skin surface warmers work by increasing body heat content and decreasing the temperature gradient required for heat to flow between the core and the periphery.[48] This does not always adequately obliterate temperature gradients,[48] mainly because redistribution continues to decrease core temperature early during induction under general and regional anesthesia.[56] A retrospective analysis by Sun et al.[86] of 58,814 patients who were actively warmed during surgery demonstrated that temperatures were less than 36°C in 64% of patients and less than 35.5°C in 29% of patients 45 minutes after induction, despite more than 90% of those being normothermic by the end of the surgery (Fig. 15.6).

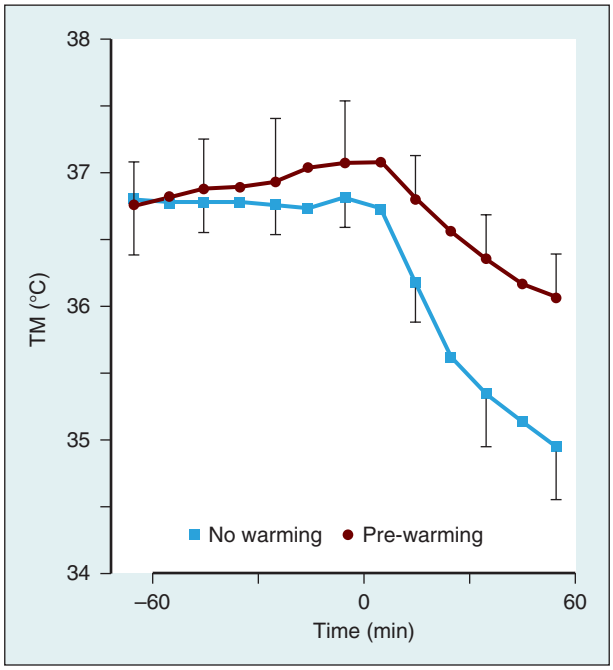


• **Fig. 15.6** The incidence of hypothermia as a function of time after induction, under progressive core temperature thresholds defining hypothermia. (Used with permission from Sun Z, Honar H, Sessler DI, et al. Intraoperative core temperature patterns, transfusion requirement, and hospital duration in patients warmed with forced air. *Anesthesiology. 2015*;122:276–285.)

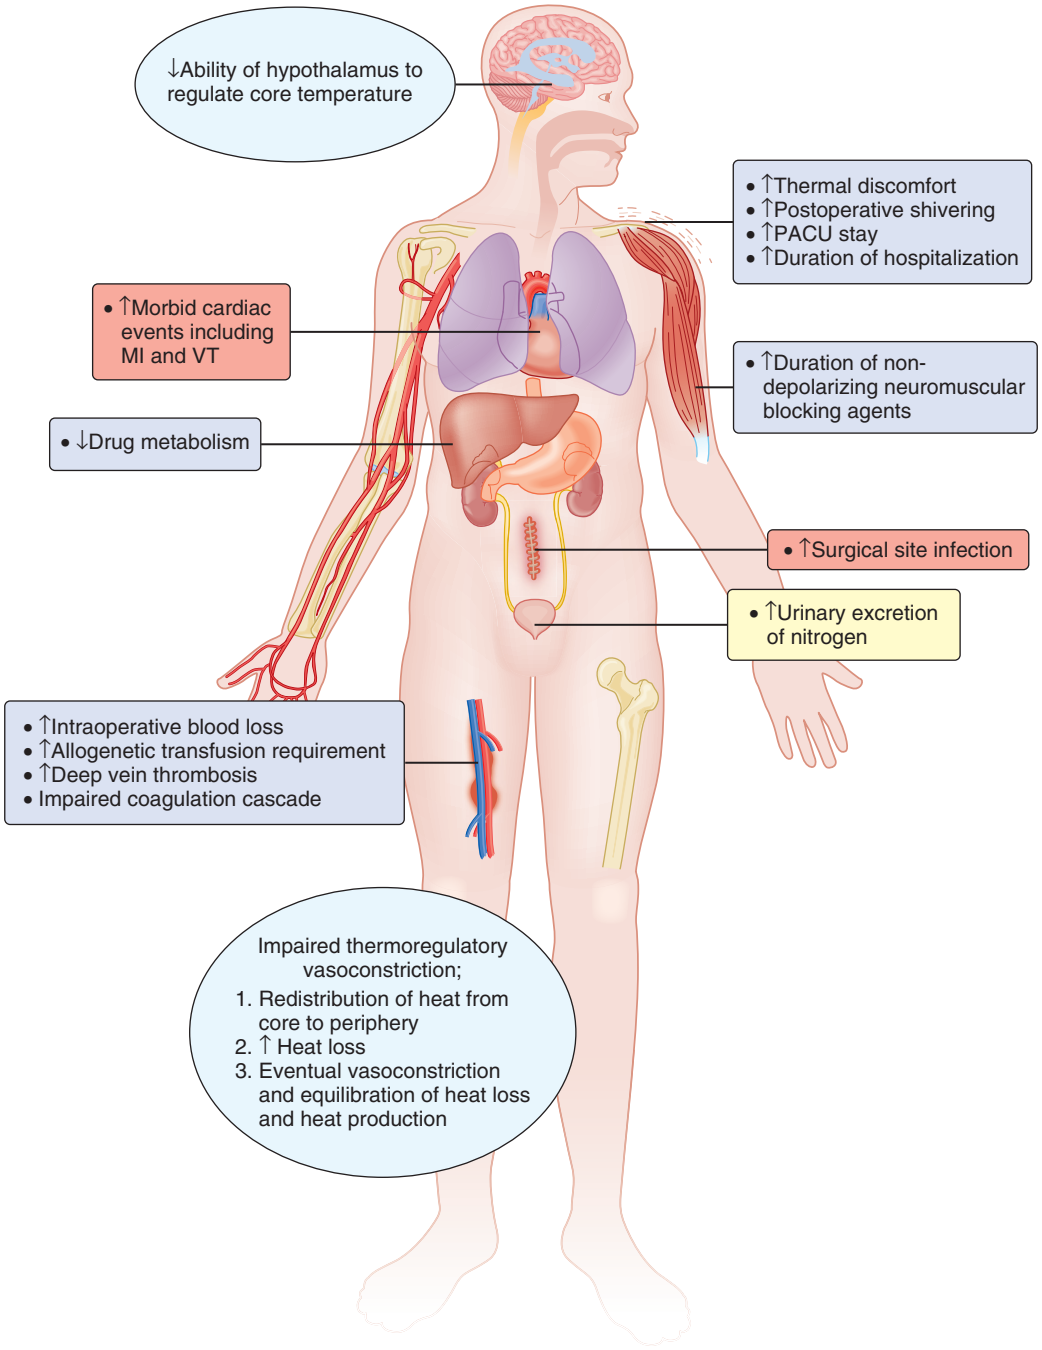
Using active warming in the preoperative holding area (prewarming) has been shown to prevent or reduce the decrease in core temperature that results from heat redistribution after induction (Fig. 15.7).[48,92] Prewarming may help prevent hypothermia during both general and neuraxial anesthesia and also helps reduce thermoregulatory shivering during neuraxial anesthesia or in the PACU.[48] Development and evaluation of prewarming protocols may improve patient outcomes by reducing perioperative hypothermia. Such protocols require policy and procedures, motivated staff, time, and patient education to be successful.

Emerging Developments

Perioperative hypothermia remains a common adverse effect of anesthesia for which more studies are needed to examine the effectiveness of preoperative warming in preventing intraoperative hypothermia and, specifically, initial core temperature redistribution. Health care centers are recognizing the adverse outcomes of hypothermia in patients beyond hospital length of stay and transfusion, including cardiac morbidity, surgical site infection, and deep vein thrombosis or pulmonary embolism (Fig. 15.8). Guidelines on monitoring and managing perioperative hypothermia are developing to establish a refined standard of care and reduce financial burdens.



• **Fig. 15.7** Prewarming minimizes redistribution hypothermia. During the preinduction period (–120 to 0 minutes), volunteers were either actively warmed or passively cooled (no warming). At induction of anesthesia (time = 0 minutes), active warming was discontinued and volunteers were exposed to the ambient environment. Initial tympanic membrane temperatures *(TM)* were similar before each preinduction treatment. During the 60 minutes after induction of anesthesia, core temperature (T) decreased less when volunteers were prewarmed ($\Delta T = -1.1°C \pm 0.3°C$) compared with when the same volunteers were not warmed ($\Delta T = -1.9 \pm 0.3°C$). These data indicate that redistribution hypothermia can be prevented by actively warming peripheral tissues before induction of anesthesia. Data are presented as mean ± SD. (Used with permission from Hynson JM, Sessler DI, Moayeri A, et al. The effects of preinduction warming on temperature and blood pressure during propofol/nitrous oxide anesthesia. *Anesthesiology.* 1993;79:219–228.)



• **Fig. 15.8** Schematic of anesthetic effects on thermoregulation and consequences of intraoperative hypothermia. Anesthetic effects are identified in *ovals,* whereas consequences are identified in *boxes.*

Key Points

- General anesthesia, neuraxial anesthesia and analgesia, and drugs such as opioids all reduce the ability of the hypothalamus to regulate core temperature.
- Intraoperative hypothermia is common and is caused by (1) redistribution of heat from the core to the periphery, (2) decreased metabolism leading to decreased heat production, and (3) increased heat loss, primarily via radiation, convection, and in large open surgeries, evaporation.
- Intraoperative hypothermia increases postoperative discomfort and post-anesthesia recovery time, blood loss and transfusion, cardiovascular morbidity, surgical site infection, deep vein thrombosis, and hospital length of stay.
- Intraoperative hypothermia can be prevented, mitigated, or corrected by preoperative and intraoperative active warming, which has also been shown to reduce complications.

Andrzejowski J, Hoyle J, Eapen G, et al. Effect of prewarming on post-induction core temperature and the incidence of inadvertent perioperative hypothermia in patients undergoing general anaesthesia. *Br J Anaesth*. 2008;101:627–631. This study provides evidence for a potential intervention to prevent intraoperative hypothermia: preoperative active warming. Warming before induction of anesthesia reduces thermoregulatory vasoconstriction and therefore reduces redistribution of heat from the core to the periphery after induction of anesthesia. Further studies are needed to define the most effective ways to prevent redistribution hypothermia. (Ref. 92).

Frank SM, Fleisher LA, Breslow MJ, et al. Perioperative maintenance of normothermia reduces the incidence of morbid cardiac events. A randomized clinical trial. *JAMA*. 1997;277:1127–1134. This is the first report of the increase in cardiovascular morbidity related to intraoperative hypothermia, as well as the reduction in cardiovascular morbidity from interventions to maintain perioperative normothermia. (Ref. 72).

Kurz A, Sessler DI, Lenhardt RA. Study of wound infections and temperature group: perioperative normothermia to reduce the incidence of surgical-wound infection and shorten hospitalization. *N Engl J Med*. 1996;334:1209–1215. This is the first randomized controlled trial of maintenance of perioperative normothermia. Maintenance of core normothermia through active warming in patients undergoing open colon surgery reduced surgical site infection by two-thirds compared with patients whose temperature was allowed to decrease ~2°C, which was standard of care at the time. (Ref. 85).

This is an excellent summary of the literature on perioperative thermoregulation and temperature monitoring. It includes the key references in the area and the key figures from those references. (Ref. 3).

Sun Z, Honar H, Sessler DI, et al. Intraoperative core temperature patterns, transfusion requirement, and hospital duration in patients warmed with forced air. *Anesthesiology*. 2015;122:276–285. Randomized controlled trials in perioperative normothermia compared groups with about a 2°C difference in core temperature on arrival in the PACU. Many patients in the "normothermic" group in these studies had a core temperature less than 36°°C intraoperatively, because induction causes vasodilation and redistribution of heat from the core to the periphery. Thus these studies looked at a larger temperature differential than would typically be seen in current practice, and intraoperative hypothermia was not considered. In the large database study by Sun et al., greater duration and degree of hypothermia were associated with increased hospital length of stay and transfusion requirements. This study opens a new avenue of research, focused on methods of preventing intraoperative hypothermia and resulting morbidity. (Ref. 86).

Systems Physiology

Management of Perioperative Pain

Despite significant progress in our mechanistic understanding of the nociceptive system, inadequately treated perioperative pain remains a significant problem. A third of patients undergoing surgery continue to suffer from moderate to severe pain, resulting in personal suffering, protracted recovery including persistent pain after surgery, delayed hospital discharge, and increased morbidity and mortality.[1–3] Improving the management of postoperative pain remains an important clinical challenge. Although opioids are the most efficacious drugs, their pharmacologic profile does not allow adequate pain control in all patients. The occurrence of adverse effects can conflict with opioid dosing strategies required to alleviate pain. This has led to the widely embraced concept of multimodel analgesia, the combined use of different drug classes and regional anesthesia techniques, for the treatment of postoperative pain. The liberal use of opioids is also associated with significant abuse potential and drug diversion, which contributes to the current opioid epidemic in the United States, a serious public health issue costing many lives.[4] As such, identifying novel analgesic drug classes that exploit alternative targets in the nociceptive system remains a high priority.

This chapter primarily covers the fundamental neuroanatomy, molecular biology, and physiologic functions of the nociceptive system as they pertain to the processing of acute pain and the practice of anesthesia. The objective is to provide a framework that facilitates the understanding of current and novel analgesic drug targets and management strategies for the treatment of *acute pain*. Given the focus of this book on the practice of anesthesia rather than the management of *chronic pain,* functional alterations of the nociceptive system in the context of chronic pain are not discussed in depth. However, it is noteworthy that the protective function of postoperative pain can be lost, as pain becomes maladaptive in patients who develop persistent postoperative pain (PPP).[3,5]

Several clinical factors are associated with PPP, including type of surgery, severity of postoperative pain, young age, female sex, preexisting chronic pain conditions, and underlying psychosocial vulnerability.[3,6] However, the molecular mechanisms underlying PPP remain poorly understood. Polymorphism of certain genes, including genes coding for catecholamine-*O*-methyltransferase, Na_V 1.7, and K_V 1.9, have been linked to the propensity for developing chronic pain.[7] Whether these polymorphisms contribute to PPP in clinically relevant ways remains to be determined. Conceptionally, PPP reflects a shift in the balance between pronociceptive and antinociceptive processes, owing either to an exaggerated amplification of nociceptive input (central sensitization) or the deficient activation of endogenous central inhibitory pathways. Accordingly, several drugs classes counteracting central sensitization and/or enhancing central inhibitory control have been examined for reducing the incidence of PPP.[8–10] They include α_2-adrenergic agonists, calcium channel $\alpha_2\delta$ ligands (gabapentin and pregabalin), and *N*-methyl-D-aspartate (NMDA)-type glutamate receptor antagonists. Among them, efficacy is best documented for the NMDA receptor antagonist ketamine.

Overview of the Nociceptive System

The nociceptive system is a sensory component of the peripheral and central nervous systems devoted to signal input that is potentially harmful. The system controls involuntary defensive and adaptive responses to injurious stimuli and mediates the perception

of pain. Nociception typically starts by activation of peripheral nerves tuned to respond to potentially harmful thermal, mechanical, or chemical stimuli. Physical or chemical input is transduced into transmembrane potential changes that can trigger action potentials (see Chapter 8). Primary sensory afferents consisting of nonmyelinated slow-conducting C-fibers and thinly myelinated faster-conducting Aδ fibers propagate action potentials to the dorsal horn of the spinal cord, where they synapse with spinal neurons. The neuronal architecture of the dorsal horn is complex and consists largely of interneurons that either amplify or inhibit transmission of incoming signals. Processed nociceptive input is relayed to supraspinal sites by projection neurons ascending in the spinothalamic and spinomedullary tracts, but the input is also transmitted to spinal sites serving autonomic and motor functions. Integration of nociceptive information in supraspinal brain regions results in complex somatic, emotional, autonomic, and endocrine responses. Finally, descending fibers emerge from supraspinal sites, including the cerebral cortex, hypothalamus, and brainstem, and project to the spinal cord where they facilitate or inhibit transmission of nociceptive signals and regulate behavior.

Peripheral Nociception

Nociceptor Classification

Nociceptors are a specific set of primary afferent nerve fibers that conduct noxious signals from peripheral somatic and visceral tissue to the spinal cord. They are pseudo-unipolar in architecture with distal and proximal projections arising from their cell bodies located in dorsal root and other sensory (e.g., trigeminal) ganglia. The peripheral nerve endings of nociceptors exhibit significant arborization and cover receptive fields from a few square millimeters to a few square centimeters, contingent on body location and fiber type. At the unmyelinated nerve endings, membrane ion channels and receptors convert nociceptive input into changes in transmembrane potential, ultimately triggering the propagation of action potentials if nociceptive input is of sufficient magnitude.

An important characteristic of nociceptors is their ability to become sensitized in injured tissue, requiring less input to initiate action potentials. Nociceptor sensitization is the neurophysiologic correlate of primary hyperalgesia, the increased sensitivity to nociceptive stimuli in injured and inflamed tissue. The term *primary* indicates that hyperalgesia is due to local events at the site of injury rather than central processes that can also amplify nociceptive input (secondary hyperalgesia is discussed later in this chapter).

Pain signals are conducted to the dorsal horn of the spinal cord via two distinct populations of peripheral nociceptors that are characterized by their fast and slow conduction velocities: small myelinated Aδ fibers (5–25 m/sec) and unmyelinated C-fibers (<2 m/sec). Aδ fibers transmit "fast" pain that is typically well localized and causes a rapid withdrawal of the affected body region, whereas C-fibers transmit "slow-onset" pain that is diffuse in character, intensifies over time, and often elicits a guarding response. These divergent responses are partially due to the difference in conduction velocities but also reflect differential neuronal integration of Aδ and C- fiber signals in the central nervous system (CNS).

Aδ fibers can be further subdivided into *type I high-threshold mechanical (HTM) nociceptors* that are activated by mechanical and chemical stimuli but exhibit a high threshold for activation by noxious heat (>50°C), and *type II* Aδ fibers that conversely exhibit low thresholds for activation by noxious heat (~43°C) but high thresholds for mechanical stimuli. *Type I* fibers are generally thought to conduct "fast" pain triggered by mechanical input (e.g., pinprick), whereas *type II* fibers conduct "fast" pain triggered to noxious heat.[11]

C-fibers are classified as peptidergic or nonpeptidergic. Peptidergic fibers constitute the largest group of nociceptors and contain the neuropeptides substance P (SP) and/or calcitonin gene-related peptide (CGRP). Upon their release after tissue injury, SP and CGRP activate receptors on capillaries and terminal arterioles, causing vasodilation (CGRP) or plasma extravasation (SP). They also trigger the release of inflammatory and nociceptive mediators by neighboring cells, which amplifies inflammation and pain. Clinically, this phenomenon is known as neurogenic inflammation, which is thought to underlie chronic pain states with prominent vasomotor components such as fibromyalgia and complex regional pain syndrome.[12,13]

Peptidergic C-fibers also express tropomyosin receptor kinase A (TrkA), the high-affinity receptor for nerve growth factor (NGF). The critical importance of peptidergic C-fibers, TrkA, and NGF in normal neuronal development is highlighted by the rare autosomal recessive disease *congenital insensitivity to pain with anhidrosis,* which is caused by loss of TrkA receptor function.[14] Patients with this disorder retain touch perception and proprioception but lack any sensory response to heat, cold, and nociceptive input (including visceral input). TrkA loss of function has wide-ranging clinical consequences, including self-mutilation and bone fractures owing to lack of nociception, frequent fevers owing to lack of adequate thermoregulation (anhidrosis), autonomic abnormalities, and cognitive impairment.

Nonpeptidergic C-fibers are stimulated by glial cell line–derived neurotrophic factors (GDNFs, neurterin, artemin, and persephin) and can be identified by the expression of the target for GDNF, the c-RET tyrosine kinase receptor. Nonpeptidergic fibers also frequently express the purinergic $P2X_3$ receptor, which is thought to mediate signals initiated by ATP released from damaged tissues, ultimately causing pain and itch.

Although fiber size and molecular markers provide some basis to differentiate nociceptive neurons, mapping specific pain modalities (heat, chemical, and mechanical) onto specific nociceptors is a challenge because of the significant heterogeneity among nociceptive neurons. Some nociceptors respond to multiple noxious modalities, whereas others are modality-specific or remain silent until activated by tissue injury or inflammation. Examples of well-characterized nociceptors are "polymodal" mechanical and heat-sensitive C-fibers *(CMH)*, and mechano-insensitive afferent *(MIA)* C-fibers, which respond only to heat and chemical stimuli. MIA C-fibers constitute up to 20% of nociceptors in human skin. They may play a particularly important role in the development and maintenance of hyperalgesia, as these mechanically silent nociceptors become responsive to mechanical stimulation in inflamed tissue.

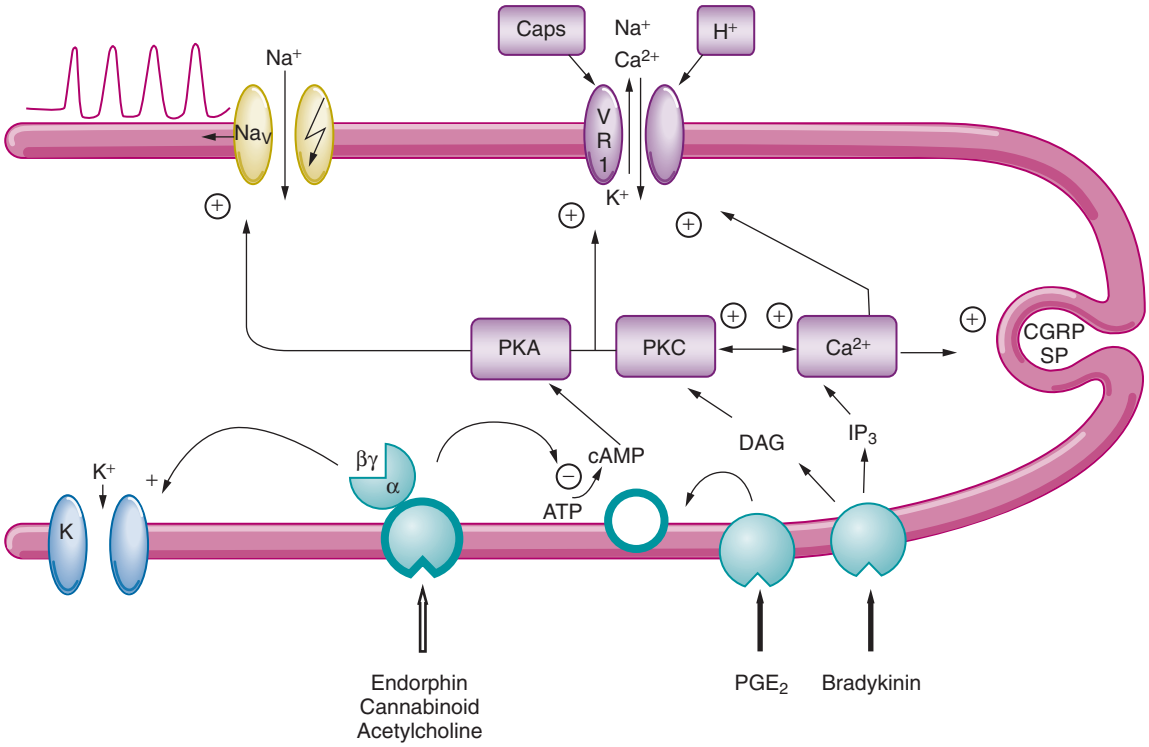
Identification of ion channels and receptors responding to specific nociceptive modalities has provided further means to group nociceptors into subpopulations that roughly correlate with their functional roles. For example, the transient receptor potential vanilloid 1 (TRPV1) receptor is the predominant sensor of noxious heat. Although genetic deletion studies in mice suggest that TRPV1 is not the sole channel responsible for transmission of nociceptive heat, chemical ablation of TRPV1-expressing neurons eliminates the response to nociceptive heat without altering responses to other nociceptive modalities. This finding implicates TRPV1 as an excellent molecular marker for nociceptors responsive to noxious heat.[15] Similar approaches targeting nociceptors that express the Mas-related G-protein–coupled (MRG) receptor demonstrate that

MRG is a specific marker for nociceptors that transmit noxious mechanical input.[16]

Nociceptor Activation

The peripheral terminals of nociceptive neurons contain a mosaic of receptors responsive to both endogenous ligands and exogenous physical or chemical stimuli. A complex set of excitatory and inhibitory signals originating from these receptors ultimately governs the degree to which a nociceptive stimulus is transduced from the periphery to the CNS. This is illustrated schematically in Fig. 16.1 for a TRPV1-expressing nociceptor.[17] TRPV1 is directly activated by exogenous input, including noxious heat, acidosis, and the pungent agent capsaicin derived from "hot" chili peppers,[18] whereas endogenous ligands, including bradykinin 2, prostaglandin E_2, and 5-hydroxytryptamine, modulate TRPV1 indirectly via second-messenger systems. Endogenous ligands are derived from nonneuronal neighboring cells, including resident cells (e.g., keratinocytes and mast cells) and migrating immune cells (e.g., neutrophils and lymphocytes). Nociceptive signaling thus involves a complex integration of exogenous cues acting directly on the nociceptor and endogenous modulators that communicate the state of the surrounding nonneuronal tissue.

The cell surface proteins responsible for encoding nociceptive signals fall into three general classes: ion channels, metabotropic G-protein–coupled receptors (GPCRs), and receptors for neurotrophins or cytokines.[19] Although significant progress has been made in elucidating the basic biophysical properties of individual channels and receptors involved in nociception, it is the complex integration of multiple channels and receptors in vivo that results in nociceptive signaling. The scale of this complexity is further amplified by variations in channel expression and activity in different tissue types (e.g., skin vs. viscera) and contexts (e.g., type and time course of injury). Processing of specific noxious inputs can also



• **Fig. 16.1** Nociceptive signal transduction. Nociceptive signal transduction involves interactions between excitatory and inhibitory molecular mechanisms at the peripheral nerve terminal. Some relevant interactions are illustrated for the transient receptor potential vanilloid 1 receptor *(VR1),* which plays a critical role in the transduction of noxious heat and directly responds to ligands such as capsaicin and hydrogen ions. Bradykinin and prostaglandin E_2 *(PGE_2)* lead to phosphorylation of VR1 by protein kinase C *(PKC)* or protein kinase A *(PKA)* via second-messenger systems, including inositol trisphosphate *(IP_3),* diacylglycerol *(DAG),* and cyclic adenosine monophosphate *(cAMP).* Receptor phosphorylation leads to increased permeability of VR1 and voltage-gated channels such as the sodium ion *(Na^+)* channel Na_V 1.8 *(Na_V).* Voltage-gated channels play an important role for the transduction of sensor potentials into spike sequences in the conductile part of the nerve. Increased concentration of intracellular calcium ions *(Ca^{2+}),* which act as a second messenger, is critical in the secretion of neuropeptides from the peripheral terminal. Calcitonin gene-related peptide *(CGRP)* and substance P *(SP)* are sentinel mediators triggering peripheral neurogenic inflammatory events. Endogenous inhibitory ligands, including endorphins, endocannabinoids, and acetylcholine, modulate the transduction process through activation of their respective G-protein–coupled receptors. Cannabinoid and opioid receptors oppose depolarization by activation of potassium ion *(K^+)* channels via the β-subunit of the G protein, while inhibition of adenylyl cyclase via the α-subunit reduces production of cAMP from adenosine triphosphate *(ATP).* cAMP is required for activating protein kinase A. (Modified from Handwerker HO. Nociceptors: neurogenic inflammation. *Handb Clin Neurol.* 2006;81:23–33.)

often involve multiple redundant channels, receptors, and second-messenger systems, further complicating our ability to *a priori* predict the efficacy of promising drug candidates acting at novel targets. Recent attempts to attenuate the activity of peptidergic C-fibers illustrate this well. Although TrkA receptor and CGRP antagonists are both promising novel analgesic agents (discussed in later text), neurokinin-1 (SP) receptor antagonists exhibit a surprising lack of analgesic efficacy for treatment of acute pain.[20]

Ion Channels

Table 16.1 lists representative ionotropic receptors that regulate nociceptive signaling. Particularly relevant examples of ion channels, including members of the TRP-family, isoforms of the voltage-gated sodium ion (Na^+) channel, and two-pore potassium (K_{2P}) leak K^+ channels, are discussed in more detail.

The family of transient receptor potential (TRP) ion channels is characterized by a conserved structural architecture consisting of a tetrameric assembly of six transmembrane-domain subunits that form a nonselective cation channels with high calcium ion (Ca^{2+}) permeability. The early discovery of the key role of TRPV1 receptors in encoding nociceptive heat and the burning pain sensation triggered by the vanilloid compound capsaicin from hot chili peppers laid the groundwork for the effective use of natural chemical compounds to probe the nociceptive sensory system.[18] Subsequent

TABLE 16.1 Ionotropic Nociceptive Transducers[a]

Abbreviation	Name	Stimulus Transduction	Activation	Sensitization
ASIC 1-4	Acid-sensing ion channels, subtypes 1-4	Chemical	Protons	Ischemia-induced pain, muscle hypersensitivity
TRPV1	Transient receptor potential vanilloid 1 receptor (URI)	Thermal Chemical	Heat, protons, vanilloids, fatty acids, arachidonic acid derivatives	Heat hyperalgesia
TRPV4	Transient receptor potential vanilloid 4 receptor	Mechanical	Osmotic challenge, stretching	Visceral and cutaneous hypersensitivity in inflammation and nerve injury
TRPA1	Transient receptor potential subfamily A1 receptor	Chemical Mechanical	Mustard oil, cinnamaldehyde, acrolein, formalin	Chemically induced hyperalgesia Mechanical hyperalgesia
TRPM8	Transient receptor potential subfamily M8 receptor	Thermal	Cold	Cold hyperalgesia
P2X3	P2X purinoceptor 3	Mechanical (indirect)	Adenosine triphosphate	Visceral and somatic pain in inflammation and nerve injury
P2X1-6	P2X purinoceptor 1-6	Chemical	Adenosine triphosphate	Pain and hypersensitivity associated with injury in various tissues
TREK 1	TWIK-related potassium channel 1	Mechanical Thermal Chemical	Stretching Heat Protons, arachidonic acid	Inflammatory hyperalgesia, mechanical hyperalgesia
TRAAK	TWIK-activated arachidonic acid potassium channel	Mechanical Thermal Chemical	Stretching Heat Protons arachidonic acid	Mechanical hyperalgesia
TMEM16A	Anoctamin calcium-activated chloride channel	Chemical Thermal	Heat Bradykinin	Roles in thermal, mechanical, and inflammatory hyperalgesia
5-HT3	5-Hydroxytryptamine receptor	Chemical	Serotonin	Most prominent role in visceral pain
nACh (multiple subunits)	Nicotinic acetylcholine receptor	Chemical	Acetylcholine	May be pronociceptive at peripheral terminals, antinociceptive at central terminals
Glutamate (GluR1-5 and NR1-2)	Ampakine (GluR1-4), kainate (GluR5), and NMDA (NR1-2) receptors	Chemical	Glutamate and subtype specific agonists	Evidence for peripheral role in pain, but most compelling evidence for role at central terminals
GABA (multiple subunits)	Gamma-aminobutyric acid receptor	Chemical	GABA and subunit specific agonists	May be inhibitory or excitatory

NMDA, *N*-methyl-D-aspartate.

[a]Metabotropic receptors exist in large numbers on nociceptive neurons and are not included in this table.

Modified from Gold MS, Gebhart GF. Nociceptor sensitization in pain pathogenesis. *Nat. Med.* 2010;16:1248–1257.

work has elucidated the role of the TRPM8 receptors, activated by the natural "cooling" compound menthol, as a critical target for transducing noxious cold stimuli.[21] TRPA1 receptors transduce the effects of numerous pungent natural agents, including the isothiocyanate compounds found in mustard, horseradish, and wasabi, and thiosulfinate found in garlic. TRPA1 is also potently activated by proalgesic agents including bradykinin and formalin, suggesting that TRPA1 is important in nociceptive signaling associated with inflammation including a wide range of exogenous and endogenous irritant compounds.[22]

Voltage-gated Na^+ channels (Na_v) play an essential role in initiating and propagating action potentials. They are large, multimeric complexes that consist of an α subunit and one or more auxiliary β subunits (see Chapter 20). The α subunit contains the ion-conducting aqueous pore that is the essential element of Na^+ channel function. The β subunits modify kinetics and voltage dependence and are involved in channel localization via interaction with cell adhesion molecules, extracellular matrix, and the intracellular cytoskeleton.[23] Nine isoforms of Na_v α subunits have been identified ($Na_v1.1$ through $Na_v1.9$), each with specific physiologic and pharmacologic functions. Numerous Na^+ channels have been found to play a role in inflammatory and neuropathic pain, including $Na_v1.1$, $Na_v1.3$., $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$.[24] Three isoforms, $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$, are expressed nearly exclusively in the peripheral nervous system, with $Na_v1.7$ expressed in sensory, sympathetic, and myenteric neurons, $Na_v1.9$ expressed in sensory and myenteric neuron, and $Na_v1.8$ expression solely in sensory neurons. The importance of $Na_v1.7$ in nociception has been highlighted by the discovery of multiple inherited pain syndromes that derive from mutations in the *SCN9A* gene encoding $Na_v1.7$, including a dominant gain-of-function mutation that causes inherited erythromyalgia, and a recessive loss-of-function mutations that causes congenital insensitivity to pain.[25,26] Gain-of-function mutations in the $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$ channels underlie various forms of painful small fiber neuropathy, further highlighting the importance of these sodium channels in human pain processing.[27] Upregulation of $Na_v1.3$ expression on peripheral axons after nerve damage or in dorsal horn neurons after spinal cord injury leads to increased neuronal excitability and likely contributes to the genesis of neuropathic pain after nerve injury.[28] While $Na_v1.1$ has not historically been considered a contributor to nociception, a recent study demonstrated that $Na_v1.1$ plays an important role regulating activity of HTM Aδ fibers.[29]

The inhibitory function of K^+ channels in nociceptive signal transduction is well established. Many GPCR ligands, including opioids and endocannabinoids, exert their antinociceptive effects by activating K^+ channels via their respective second-messenger systems. Of particular recent interest are members of the K_{2P} channel family, as these channels can be directly activated by nociceptive input, including mechanical, thermal, and chemical stimuli.[30,31] The numbing and tingling sensation produced by ingestion of Chinese peppercorns has been attributed to inhibitory effects on TASK K_{2P} channels in peripheral nociceptive fibers, whereas volatile anesthetic agents activate TASK and TREK K_{2P} channels.[32,33] A human pain syndrome, familial migraine with aura, has been linked to a dominant negative mutation in the TRESK K_{2P} channel, further emphasizing the role of these channels in pain signaling.[34] Although K_{2P} channels represent potential novel analgesic targets, expression of the K_{2P} family is not limited to the sensory nervous system. The wide distribution and functional importance of these channels throughout the body may complicate efforts to target these channels for the treatment of pain.

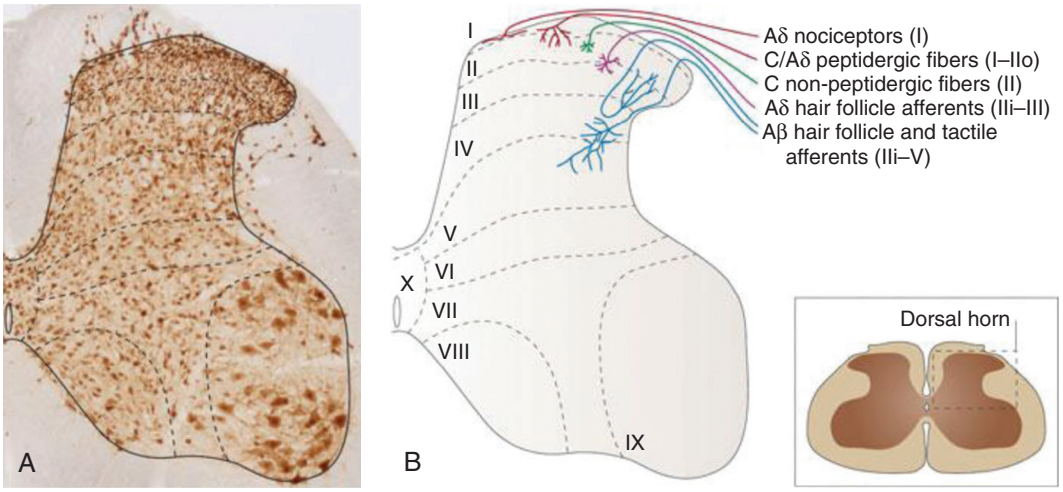
Metabotropic G-Protein–Coupled Receptors

Many excitatory and inhibitory GPCRs modulate nociceptor excitability by activating or inhibiting ion channels via second-messenger systems. Examples of *excitatory* receptors include the receptors for CGRP, bradykinin (B1 and B2), endothelin A (ET_A), protease (PAR 1-4), and prostaglandin (EP1, EP3C, and EP4). Although these GPCRs would appear to be suitable targets for novel analgesic compounds, their relative abundance and heterogeneity within nociceptors seems to account for the fact that specific receptor antagonists mostly lack efficacy.[19] CGRP antagonists and antibodies are a notable exception as they are effective for the treatment of migraine headache.[35] By contrast to the pronociceptive receptors, several *inhibitory* GPCRs are effective drug targets, including opioid receptors (μ, δ, κ), cannabinoid receptors (CB1, CB2), and serotonin receptors (5HT-1B and -D). While opioids exert broad analgesic effects, the efficacy of serotonergic antagonists is limited to migraine. Cannabinoids have been used extensively for their anxiolytic, antiemetic, and antinociceptive properties. The development of nonpsychogenic cannabinoid derivative for use in clinical pain management is an area of active study.

Receptors for Neurotrophins

Nociceptors express one of two distinct classes of neurotrophic factor receptors that are infrequently coexpressed in a specific nociceptor. Neurotrophins belong either to the NGF family expressed (NGF, brain-derived neurotrophic factor [BDNF], and neurotrophin 3 and 4) mainly in C-peptidergic fibers or the GDNF family (neurturin, artemin, and persephin) expressed in nonpeptidergic nociceptors. Neurotrophins promote the survival, growth, and maintenance of discrete populations of neurons by altering transcriptional and translational regulation of neuronal proteins, including key ion channels and GPCRs relevant for nociceptive signaling. Considering that neurotrophic factors are derived from nonneuronal tissues, they critically link tissue inflammation and nociception. Inflammation-induced surges of neurotrophic factors during tissue injury can profoundly affect nociceptor excitability and result in hyperalgesia.[36]

NGF is the most widely studied neurotrophic factor with regard to pain physiology. It is released from a host of inflammatory and resident cells upon tissue injury and binds to its high-affinity receptor TrkA on nociceptors. TrkA is a receptor tyrosine kinase able to activate multiple downstream second-messenger signaling cascades and promote nociceptor excitability via sensitization of several ion channels, including TRPV1, ASIC3, P2X3, and Na_V. The TrkA/NGF complex is also internalized within the nociceptor and transported in retrograde fashion to the cell body, where is exerts transcriptional control on numerous nociceptive pathways over the course of hours or even days. This longer-lasting action triggers the release of the neuroinflammatory peptides CGRP and SP. It also induces central sensitization via the synthesis of the centrally released neurotrophic factor BDNF.[37] In contrast to inflammatory states with elevated NGF levels, the loss of basal NGF or GDNF signaling after peripheral nerve or spinal cord injury appears to play a prominent role in the upregulation of $Na_v1.3$ that drives neuropathic pain after neuronal injury.[38] Based on the role of NGF in regulating key components of the nociceptive pathway, it has become an important drug target. Approaches sequestering NGF or antagonizing TrkA receptors are in



• **Fig. 16.2** Laminar organization of the spinal dorsal horn. The grey matter of the dorsal horn has been subdivided into 10 layers based on variations in size and neuron packing density. A, Neurons in a transverse section of the rat spinal cord have been immunostained. *Dashed lines* indicate the laminar boundaries. B, Primary afferents arborize in an orderly manner. The central terminations of the major primary afferents are shown (except proprioceptors). Aβ tactile and hair follicle afferents mainly end in laminae III-V. Aδ hair follicle afferents arborize on the border of laminae II and III. Aδ nociceptors predominantly terminate in lamina I and give some branches to laminae V and X. Peptidergic primary afferents consisting of C and Aδ nociceptors end in lamina I and the outer portion of lamina II, while nonpeptidergic C nociceptors form a band in the central part of lamina II. Inset, Illustration of the spinal cord grey matter showing the location of the dorsal horn (dashed box). (Modified from Todd AJ. Neuronal circuitry for pain processing in the dorsal horn. *Nat Rev Neurosci.* 2010;11:823–836.)

development to target chronic pain in patients with osteoarthritis, diabetic neuropathy, cancer, or back pain.[39]

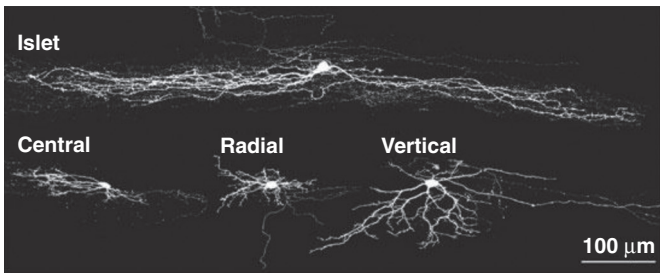
Signal Processing in the Dorsal Horn

Nociceptors transmit pain signals from the periphery to the dorsal horn of the spinal cord. The dorsal horn should not be considered a simple relay station but rather a region of complex signal processing. Incoming nociceptive signals are processed through a neuronal network built by primary nociceptive and nonnociceptive afferents, inhibitory and excitatory interneurons, and descending neurons originating in the brainstem. These neuronal circuits are ultimately linked to projection neurons, which relay nociceptive output from the dorsal horn to various supraspinal structures, including nuclei of the brainstem and the thalamus. Some processed nociceptive signals are also distributed locally within the spinal cord and underlie spinally mediated autonomic and motor responses to painful stimuli. Knowledge regarding the synaptic circuitry and function of dorsal horn neuronal structures is still quite incomplete, although some basic circuitry has been defined.

Structural Components

The spinal cord gray matter has historically been defined by 10 cyto-architecturally distinct layers (Fig. 16.2). The majority of nociceptive fibers terminate in the most superficial lamina I (the marginal layer) and lamina II (the substantia gelatinosa). The peptidergic C-fiber population that expresses TRPV1 and underlies noxious thermal responses projects to the most superficial layers of the dorsal horn (lamina I and the outer region of lamina II), whereas MRG-expressing nonpeptidergic C-fibers that mediate mechanical pain project to a deeper region within inner lamina II. This spatially distinct mapping of nociceptive modalities and specific nociceptive fibers within the dorsal horn is important to discriminate among different nociceptive modalities. Although many nociceptive Aδ fibers also terminate within lamina I, a subset project to lamina V, where they overlap with the projections of nonnociceptive low-threshold mechanosensitive Aβ and Aδ fibers within the deeper lamina (III-V). This allows for the integration of nociceptive and nonnociceptive sensory inputs.[40]

In the simplest arrangements, primary nociceptive afferents form simple axosomatic or axodendritic synapses with projection neurons, which then carry nociceptive signals forward to the brain. However, these arrangements represent only a small fraction of the neuronal network in the dorsal horn. More commonly, incoming nociceptive primary afferent fibers terminate at various excitatory and inhibitory interneurons, allowing for the complex modulation of incoming sensory information. The major neurotransmitter of excitatory interneurons is glutamate, while gamma-aminobutyric acid (GABA) and glycine are the main transmitters of inhibitory interneurons. Lamina II is enriched with interneurons, which have been studied in great detail and are classified based on morphologic criteria, as islet, central, vertical, and radial cells (Fig. 16.3). Islet and central cells tend to arborize solely within the lamina that contains their cell body. Vertical cells exhibit dendritic trees that extend over multiple laminae and thus are able to integrate multiple incoming afferent signals. Vertical cells receive afferent input from C, Aδ, and Aβ fibers, whereas islet and central cells tend to receive input only from C-fibers. Islet cells are virtually all inhibitory and invariably release GABA or glycine, whereas radial and most vertical cells are excitatory and release glutamate. Central cells can be either excitatory or inhibitory. It should be noted that the relationship between morphology and neurochemical function is not strict. Nearly 30% of interneurons do not fall into a strict morphologic category.



• **Fig. 16.3** Classification of lamina II interneurons. Confocal images of four lamina II interneurons labeled with the cell indicator neurobiotin are shown. Somatodendritic morphologic criteria allow characterizing these neurons as islet, central, radial, or vertical cells. Islet cells are inhibitory and are characterized by elongated dendritic trees, mainly spreading along the rostrocaudal axis. Central cells are similar in configuration but have much shorter dendritic trees and are either inhibitory or excitatory. Radial cells have compact dendritic trees that spread in multiple directions. Vertical cells have dendritic trees that fan out ventrally in conical shape. Radial and most vertical cells are excitatory. (Modified from Todd AJ. Neuronal circuitry for pain processing in the dorsal horn. *Nat Rev Neurosci*. 2010;11:823–836.)

Projection neurons carry nociceptive output from the dorsal horn to higher CNS structures. These efferent neurons are most densely present in lamina I, are virtually absent in interneuron-rich lamina II, and are scattered throughout the remaining laminae. Projection neurons belong to two general classes, nociceptive-specific projection neurons that exclusively transmit noxious signals, and wide-dynamic-range (WDR) projections neurons able to code for both noxious and nonnoxious signals. Nociceptive-specific projection neurons are concentrated within lamina I and are marked by the expression of the neurokinin-1 receptor (NK1R), the receptor targeted by the neuropeptide SP. SP-rich C-peptidergic nociceptors known to terminate within lamina I project to NK1R-expressing efferent neurons. While lamina III is not a significant target for nociceptive afferent fiber projections, a population of lamina III efferent neurons also expresses the NK1 receptor and receive nociceptive input by extending dendritic projections into the nociceptor-rich regions of laminae I and II. WDR projection neurons are concentrated within the deeper dorsal lamina V, where they receive inputs from nonnociceptive touch-coding Aβ fibers, nociceptive Aδ fibers, and interneurons originating in more superficial laminae. WDR neurons are unique in that they receive simultaneous input from somatic and visceral structures, allowing for the convergence of viscera-somatic signal, the neuronal substrate underlying the perception of referred pain (e.g., myocardial ischemia causing shoulder pain). Projection neurons ascend to numerous supraspinal structures, including nuclei in the brainstem and the thalamus, to mediate behavioral and emotional responses to pain.

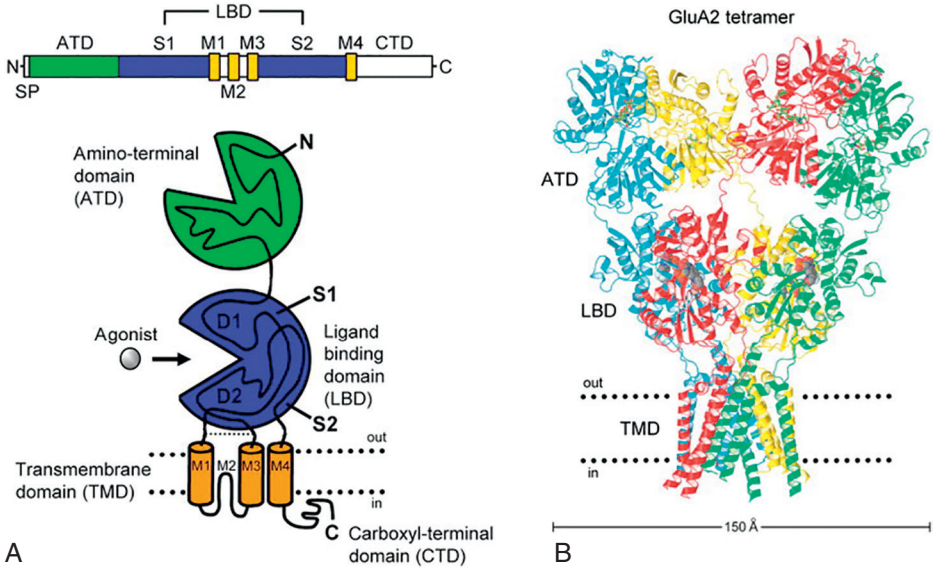
Neurochemistry

Virtually all nociceptive afferents are excitatory and signal to postsynaptic structures through the release of glutamate. Fast transmission of excitatory signals within the dorsal horn is mediated by the binding of glutamate to postsynaptic AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and kainate receptors. The AMPA and kainate receptors are glutamatergic cation-permeable ion channels that exhibit fast activation and inactivation kinetics underlying the rapid depolarization of the postsynaptic membrane. Glutamate also activates NMDA receptors, but these glutamatergic channels are activated more slowly as they are potently blocked by magnesium ions at resting hyperpolarized membrane potentials. In the setting of high-strength synaptic input, activation of AMPA and kainate receptors produces sufficient membrane depolarization to relieve the voltage-dependent magnesium ion (Mg^{2+}) block of NMDA receptors, which results in activation of these channels. NMDA receptors are permeable for calcium. The influx of calcium through NMDA receptors in the setting of high-strength synaptic signaling is a hallmark of long-term potentiation (LTP), the long-lasting use-dependent enhancement of synaptic signal transmission. LTP in the dorsal horn is one of a number of mechanisms underlying spinally mediated hyperalgesia (discussed later in this chapter) and the importance of NMDA receptors to this process is the rationale for the use of NMDA receptor antagonists like ketamine to prevent persistent pain after surgery. NMDA receptors exhibit complex pharmacologic regulation and varied subunit distributions, as further detailed in Fig. 16.4.[41]

Metabotropic glutamate receptors (mGluRs) are also present within the dorsal horn, at both presynaptic and postsynaptic terminals. Although all mGluRs are GPCRs activated by glutamate, they can be divided into subclasses based on their pharmacology and the second-messenger systems they engage. mGluR I channels are linked to the $G\alpha_q$ protein family responsible for phospholipase C activation and increased neuronal excitability. mGluR II and mGluR III channels are linked to inhibitory $G\alpha_{i/o}$ proteins and decrease neuronal excitability through inhibition of adenylyl cyclase. Consistent with these properties, mGluR I antagonists and mGluR II and III agonists produce antinociceptive effects in animal models, demonstrating a role for these channels in modulating pain.[42]

The release of glutamate from the central terminals of peripheral afferent fibers in the dorsal horn is tightly regulated as shown in Fig. 16.5. Primary afferents are able to autoregulate their activity via AMPA, kainate, and NMDA receptors expressed at their central termini. Released glutamate binds to these presynaptic receptors and inhibits further glutamate release.[43] Inhibitory interneurons act to decrease excitability through release of GABA and glycine, which bind to their receptor targets on presynaptic and postsynaptic terminals. Other modulatory receptors expressed at primary afferent central terminals include α_2-adrenergic and purinergic P2X3 receptors. Purinergic input to the central presynaptic terminal is largely the result of local adenosine triphosphate released by spinal glial cells, a means by which astrocytes and microglia increase neuronal excitability and nociceptive signaling. Presynaptic α_2-adrenergic receptors are activated by norepinephrine released from descending projection neurons, one of many targets of descending monoaminergic agents (adrenergic, dopaminergic, and serotonergic) that inhibit nociceptive signaling (discussed later in this chapter). The CB1 cannabinoid receptor and all three opioid receptor classes (μ, δ, and κ) are present at central termini of afferent fibers and oppose excitatory neurotransmitter release. Intrathecal or epidural delivery of opioids or α_2-adrenergic agonists (e.g., clonidine) is common in clinical anesthetic practice, which highlights the importance of central presynaptic receptors as analgesic targets. Intrathecal delivery of ziconotide, a synthetic peptide derivative of cone snail ω-conotoxin, selectively blocks central terminal N-type voltage-gated calcium channels, thereby inhibiting glutamate release. Ziconotide is highly efficacious but its clinical use requires intrathecal delivery. It is therefore reserved for treatment of severe refractory chronic pain conditions.[44]

The discovery of molecular markers that differentiate subclasses of interneurons in the dorsal horn has been crucial to understanding the complex neuronal network that regulates nociceptive signaling.



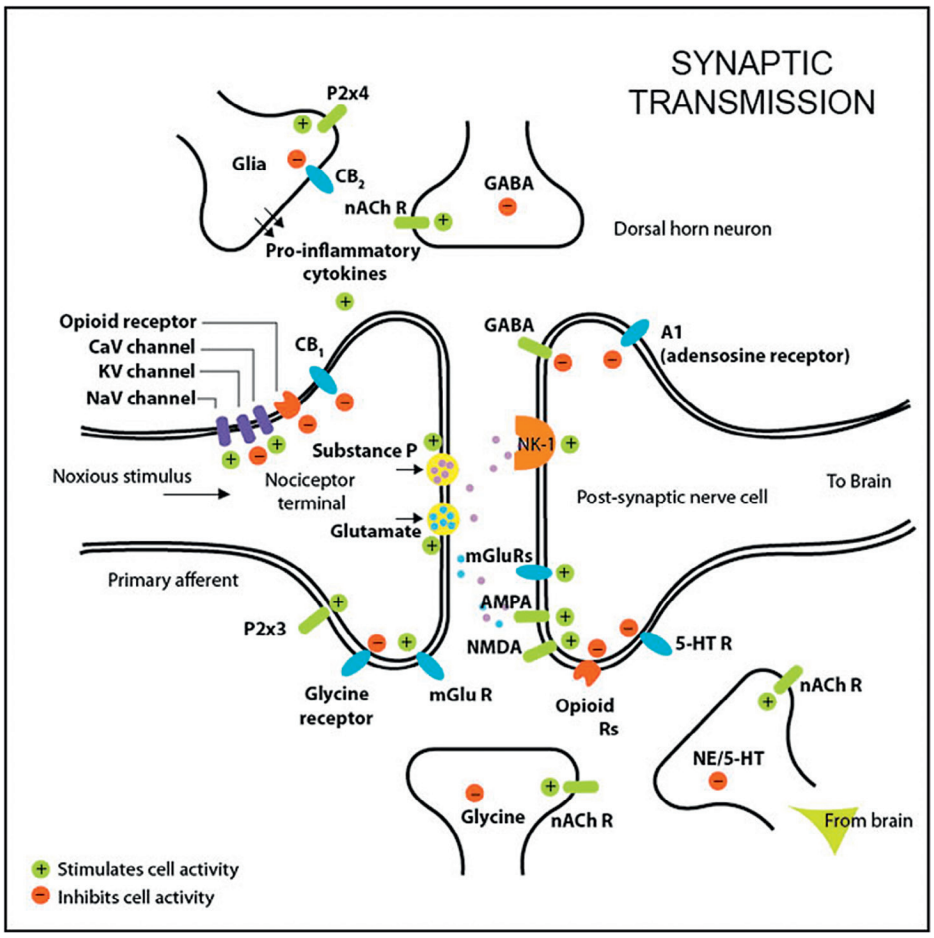
• **Fig. 16.4** Glutamate receptor structure. Glutamate receptors are formed by a tetrameric assembly of subunits. Each individual subunit contains three modular domains (A), the regulatory amino terminal domain *(ATD),* the ligand binding domain *(LBD)* responsible for binding glutamate (or glycine), and the transmembrane domain *(TMD)* that forms the ionic pore. The four subunits form a cationic channel (B) that is highly permeable to cations, including sodium ion (Na^+) and potassium (K^+) (α-amino acid-3-hydroxy-5-methyl-4-isoxazole [AMPA], kainate, and N-methyl-D-aspartate [NMDA]) and Ca^{2+} (only NMDA and some AMPA subtypes). The ATD is the binding site for numerous endogenous and exogenous channel regulators. including zinc and polyamines. In NMDA channels, two GluN1 subunits capable of binding glycine combine with two glutamate binding GluN2 subunits to form a functional channel. Although glycine does not directly open NMDA channels, it is a coagonist required for NMDA receptor activation (Modified from Traynelis SF, Wollmuth LP, McBain CJ, et al. Glutamate receptor ion channels: structure, regulation, and function. *Pharmacol Rev.* 2010;62:405–496.)

As a general rule, excitatory interneurons express the neuropeptide somatostatin, whereas inhibitory interneurons express the somatostatin receptor type 2A (SST_{2A}). The restricted distribution of somatastatin and its receptor provide a means for crosstalk between excitatory and inhibitory interneurons, an ultimately pro-nociceptive pathway due to the hyperpolarizing effect of somatastatin on SST2A expressing inhibitory interneurons. Numerous other neuropeptides exhibit functionally important and nonoverlapping expression patterns, thereby defining subclasses of interneurons. For example, neurotensin, neurokinin B, and gastrin-releasing peptide define distinct subclasses of excitatory interneurons, whereas the calcium binding proteins calretinin and protein kinase C gamma (PKCγ) are expressed less distinctively in subclasses of excitatory interneurons.[45] Inhibitory interneurons are defined by four largely nonoverlapping populations that express either neuropeptide Y, parvalbumin, neuronal nitric oxide synthase, or galanin/dynorphin.[46]

Armed with molecular markers to identify specific subpopulations of primary afferents and their targets on interneurons, attempts to map basic spinal pain circuitry are becoming increasingly informative. This is particularly true for the dorsally directed pain circuit that ultimately activates lamina I NK1R-expressing projection neurons, as shown in Fig. 16.6. Of particular interest is the recent elucidation of a circuit that underlies mechanical allodynia, the experience of pain in response to a typically nonnoxious mechanical stimulus.[47] Low-threshold mechanosensitive Aβ or Aδ fibers responsive to light touch but not to nociceptive mechanical stimuli can gain access to the nociceptive circuit through a population of excitatory interneurons that transiently express the vesicular glutamate transporter 3 (vGLUT3) during postnatal development. Under normal circumstances, inhibitory interneurons expressing parvalbumin and dynorphin prevent propagation of low-threshold A-fiber signals through the dorsally directed pain pathway. However, in the context of inflammation or nerve injury, the inhibition by parvalbumin and dynorphin inhibitory interneurons is reduced, allowing vGLUT3 excitatory interneurons to excite PKCγ, calretinin, and vertical excitatory interneurons, which ultimately drives signaling of NK1R-expressing neurons projecting to supraspinal sites. Loss of inhibitory signaling in the dorsal horn is just one mechanism underlying hyperalgesia or allodynia. Further elucidation of the complex neuronal circuits engaged in physiologic and pathologic pain conditions is an area of active investigation.

Spinal Mechanisms of Hyperalgesia and Allodynia

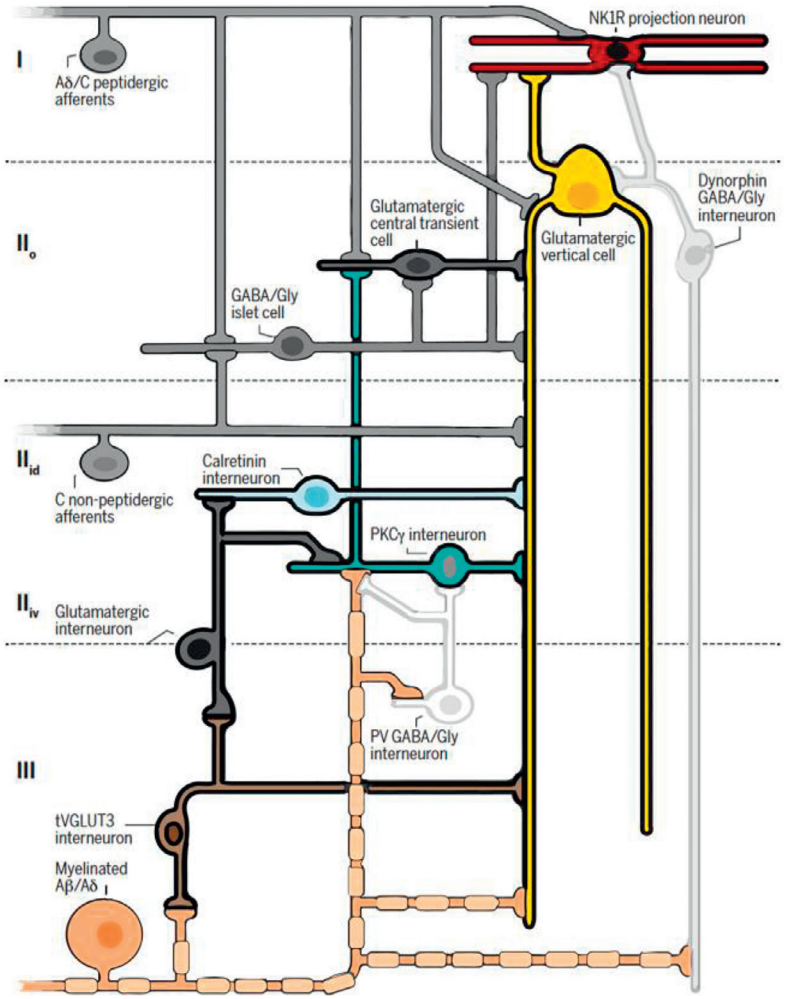
Tissue and nerve injuries are associated with the development of spontaneous pain, hyperalgesia, and allodynia. Hyperalgesia describes the occurrence of amplified pain in response to stimuli that are normally noxious. It can be visualized as a left shift of the stimulus intensity versus pain response relationship (Fig. 16.7). Allodynia describes the occurrence of pain in response to stimuli that are normally nonnoxious (e.g., light touch). These phenomena can be explained by several spinal mechanisms, including LTP, loss of inhibitory control, gain in excitatory function, and alterations in the properties of low-threshold mechanoreceptive Aβ fibers.[48,49]



• **Fig. 16.5** Dorsal horn synaptic transmission. Arrangement of a dorsal horn synapse between a primary afferent and a projection neuron are shown. The central terminal of the primary afferent contains glutamate and substance P. Release of glutamate results in activation of *AMPA* (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and kainate (KA) receptors and depolarization of the postsynaptic membrane via fast sodium ion (Na^+) influx. Release of substance P acts synergistically via metabotropic neurokinin 1 receptors (NK1) that on activation, upregulate second-messenger systems, including cyclic adenosine monophosphate and protein kinase A. Sustained synaptic input can depolarize the postsynaptic membrane sufficiently to activate the voltage-gated N-methyl-D-aspartate (NMDA) receptor. Activation of NMDA receptors is associated with long-term enhancement of synaptic transmission (long-term potentiation), which might underlie hyperalgesic states. Released glutamate also binds to metabotropic glutamate receptors *(mGluRs)* to modulate postsynaptic responsiveness. The synapse is also under control of other neuronal structures, including inhibitory interneurons and descending projection neurons. Release of *GABA* (gamma-aminobutyric acid) or glycine from interneurons enhances influx of chloride ion *(Cl^-),* which hyperpolarizes presynaptic or postsynaptic membranes and inhibits activity. Descending projection neurons modulate activity via release of serotonin and norepinephrine *(NE)* to bind to 5-hydroxytryptamine *(5-HT)* or α-adrenergic receptors. *A1,* Adenosine Receptor; CB_1, CB_2, cannabanoid receptor 1 and 2; Ca_V channel, Ca_V: Voltage gated calcium channel; *nAChR,* nicotinic acetylcholine receptors; K_V channel, Voltage gated potassium channel; Na_V channel, Voltage gated sodium channel; *R,* receptor. (Modified from Kennedy J.D. Neuropathic pain: molecular complexity underlies continuing unmet medical need. *J Med Chem.* 2007;50:2547–2556.)

LTP is triggered by high-strength synaptic input and can be described as the long-term enhancement of synaptic signal transmission (synaptic plasticity). In the dorsal horn, induction of LTP at synapses between C-fibers and NK1R projection neurons is an important driver of hyperalgesia.[50] Elevated postsynaptic intracellular calcium is the signal that ultimately causes LTP. A diverse set of postsynaptic channels and receptors contributes to this process. Postsynaptic ion channels, including NMDA receptors, T-type voltage-gated calcium channels, and calcium-permeable AMPA receptor subtypes (lacking the GluR2 subunit) facilitate cellular calcium influx when activated. By contrast, activated mGluRs and neurokinin-1 receptors facilitate release of calcium from intracellular stores via second-messenger signals. Ultimately, increased postsynaptic intracellular calcium levels activate multiple Ca^{2+}-dependent signaling pathways, which amplifies nociceptive signal transmission.

As described previously, loss of inhibitory signaling can contribute to the miscoding of tactile input as pain (allodynia). This is due to loss of regular inhibitory control over excitatory interneurons that link low-threshold mechanoreceptive Aβ afferents to lamina



• **Fig. 16.6** Chronic pain and the dorsal horn neuronal circuit. Peripheral Aδ and substance P–positive C nociceptors enter lamina I and synapse with excitatory vertical and central interneurons and NK1R projection neurons. Mechanosensitive C fibers expressing MRG enter the dorsal horn in lamina II and project to excitatory vertical cells. Incoming peripheral nociceptors also make synaptic connections with inhibitory islet interneurons to modulate circuit activity. Innocuous Aβ and Aδ fibers *(orange)* project to lamina III and are not normally integrated into the pain circuitry. In chronic pain with mechanical allodynia, loss of PV and dynorphin inhibitory interneuron activity *(shaded)* allows normally innocuous Aβ and Aδ fiber input to activate neurokinin-1 receptor *(NK1R)* projection neurons *(red)*, through a key synaptic connection with transient vesicular glutamate transporter 3 *(tVGLUT3)*-expressing interneurons *(brown)*. vGLUT3 interneurons synapse with glutamatergic vertical cells and also activate a network of protein kinase C gamma *(PKCγ)* and calretinin excitatory interneurons to link innocuous touch with NK1R pain signaling and produce mechanical allodynia. *GABA*, gamma-aminobutyric acid; *Gly*, glycine; *MRG*, Mas-related G-protein coupled receptor. I NK1R projection neurons. Tissue injury–induced release of BDNF at the central termini of primary afferents is another mechanism resulting in disruption of regular inhibitory control. BDNF binds to interneurons that express the TrkB receptor, which decreases the activity of the potassium-chloride exchanger 2 (KCC2) expressed in TrkB$^+$ interneurons. Reduced KCC2 activity leads to increased intracellular chloride concentrations, decreasing the driving force for chloride through inhibitory GABAergic and glycinergic chloride channels. This leads to dampening of inhibitory control over spinal nociceptive circuits.[47] Recent animal studies have demonstrated that viral transfer of the *KCC2* gene into the dorsal horn of animals with experimentally induced neuropathic pain eliminates hyperalgesia, raising the possibility of KCC2 as a gene therapy target for treatment in intractable neuropathic pain.[51]

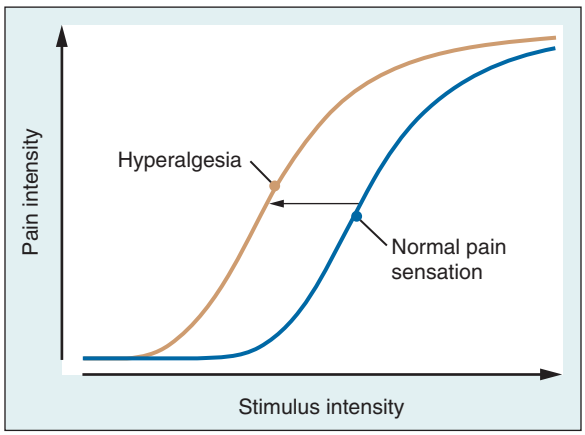
Similar to loss of inhibitory function, gain in excitatory function can also facilitate nociceptive signal transmission. In experimental models of neuropathic pain, the expression or activity of a number of potassium channels, including voltage-gated (K_v),



• **Fig. 16.7** Hyperalgesia. Sensitization of peripheral nociceptors results in hyperalgesia that is characterized by a left shift of the nociceptive stimulus versus pain response relationship. This is reflected clinically by an increased sensitivity to painful stimuli.

calcium-activated (BK), and K_{2P} channels is decreased. K^+ channels are critical for hyperpolarizing cell membranes and loss of activity allows for more pronounced neuronal depolarization and excitation.[52]

Finally, aberrant connectivity of low-threshold mechanoreceptive Aβ afferents to nociceptive pathways can contribute to tactile allodynia. Sprouting of Aβ fibers from terminals in the deeper dorsal horn to superficial laminae I and II has been observed after nerve injury.[53] Aβ-fibers can also undergo a phenotypic switch in response to injury and start synthesizing SP, which then can activate NRK1 receptors of nociceptive lamina I projection neurons.[54]

Supraspinal Structures

To reach the brain, nociceptive projection fibers exiting the spinal dorsal horn form two major ascending tracts, the spinothalamic tract (STT) and the spinomedullary tract (SMT), defined by their terminations in either the thalamus or brainstem. Thalamic or medullary subcortical waypoints serve important functions in the autonomic and descending modulation of nociceptive information and also route the ascending signals to appropriate limbic and cortical brain regions. An overview of the major supraspinal pathways underlying the nociceptive system is provided in Fig. 16.8.

There are multiple interconnected cortical and subcortical brain regions that contribute to the cognitive experience of pain. In a landmark study, Melzack asked patients to describe their experience of pain and grouped the descriptive responses into sensory, affective, and cognitive categories.[55] The sensory component refers to the ability to discriminate stimuli according to their intensity, location, and temporal relationship. The affective component relates to typically negative hedonic aspects of pain, and the cognitive component represents the evaluation of pain in terms of past experiences, environmental context, and overall significance. These three basic domains of pain remain extremely useful conventions to functionally group the supraspinal processing of nociception and synthesis of the pain experience. In this section, we identify the brain regions that process and modulate these distinct domains of pain and examine their connectivity.

Thalamus

The thalamus is the key neuroanatomical structure linking ascending nociceptive input from the STT to several cortical areas that serve distinct functions. The importance of the thalamus in nociceptive signaling is clinically highlighted by the Dejerine-Roussy syndrome that can develop in patients who sustain a thalamic stroke. The syndrome is initially characterized by the development of contralateral paresthesia and numbness that progress to intractable centrally mediated allodynia or dysesthesia.[56] The lateral thalamic nuclei play an important role in the sensory and discriminative coding of pain, while the medial thalamus exerts control over affective and motivational aspects of pain.

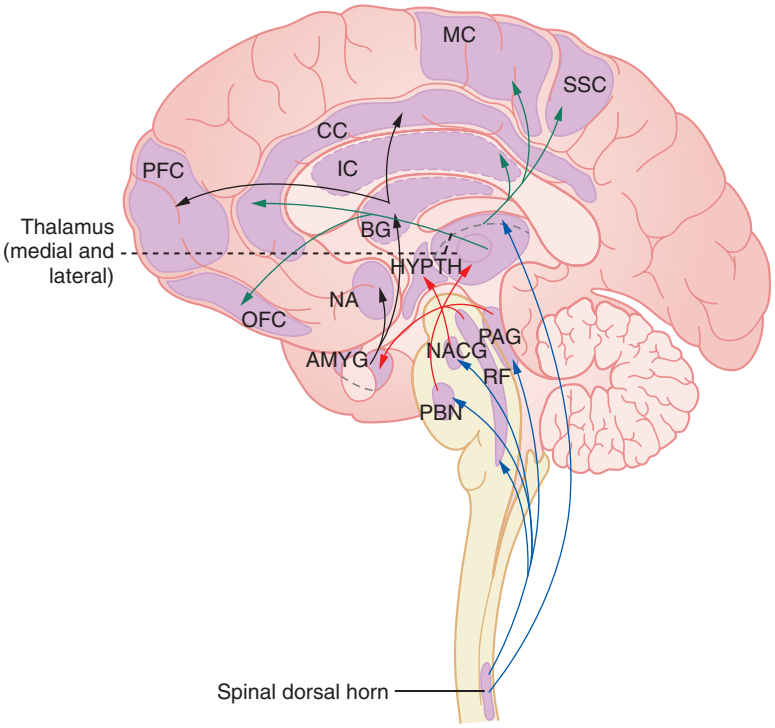
The ventral posterior nuclei (VPN) of the lateral thalamus are the target of nearly all afferent fibers carrying somatosensory information through the dorsal column via the STT, including pain, innocuous touch and proprioception. The VPN play a key role in linking ascending nociceptive input to the somatosensory cortex (SI and SII), which encodes sensory and discriminative components of pain. Afferent signals relayed via the VPN to cortical structures remain somatotopically organized to facilitate the precise topographic mapping of both innocuous and noxious sensory input from various body locations. The ventral posterior medial (VPM) nucleus receives input from the trigeminal nerve, while the most lateral portions of the ventral posterior lateral (VPL) nucleus encodes input from the feet. VPN neurons receive input from densely innervated, "high-resolution" receptive fields and encode a wide range of afferent load (signal strength) to precisely gauge sensory discriminative information. The majority of VP neurons that process nociceptive signals, which constitute about 10% of VP neurons, receive input from WDR projection neurons originating in lamina V of the dorsal horn.

A subset of spinal lamina I nociceptive projection neurons also target the lateral thalamus but innervate an alternate region, namely the posterior ventral medial nucleus (VMpo). Unlike VP nuclei, the VMpo is targeted exclusively by nociceptive fibers and projects to an alternative cortical structure, the insula. The insular cortex plays a critical role in interception, which is the awareness of the physiologic state of one's own body. The insula projects to the prefrontal cortex, anterior cingulate cortex, amygdala, hippocampus, and SII somatosensory cortex, a neuronal network merging nociceptive input with attention, memory, and emotion. Finally, the ventral lateral nucleus also receives input from STT fibers and projects to the motor cortex, likely contributing to integration of nociceptive sensory signals with the motor system.

Unlike the nuclei of the lateral thalamus, the nuclei of the medial thalamus process nociceptive input relevant for affective and motivational aspects of pain. The medial dorsal nucleus receives input from nociceptive neurons located in lamina 1 of the spinal dorsal horn and projects to the anterior cingulate cortex, a key structure regulating affective and behavioral aspects of pain. The nucleus submedius also receives input from lamina I but projects to the ventral lateral orbital cortex, a structure regulating descending antinociceptive control via the periaqueductal gray (PAG).[57]

Brainstem

Neurons in laminae I, V, and VII of the spinal dorsal horn and the trigeminal nucleus build the SMT that runs in parallel with the STT. These paired neuronal projections enable differential supraspinal modulation of spinal nociceptive input.[58] The SMT terminates at three major brainstem sites—namely, the reticular formation, the



• **Fig. 16.8** Major components of the nociceptive system. An overview of the major anatomic components that process nociceptive information from the periphery to cortical structures. Myelinated and nonmyelinated primary afferent fibers provide nociceptive input to the spinal cord. Major nociceptive projections target the brainstem (spinomedullary tract) and the thalamus (spinothalamic tract). Projections from the brainstem reach the medial thalamus, hypothalamus, and amygdala; these structures play a predominant role in regulating autonomic, neuroendocrine, and emotional states. The lateral thalamus projects to the somatosensory cortex, which decodes sensory-discriminative aspects of pain. The amygdala pairs noxious input with affective content. Its critical integrative function is underlined by connections to various cortical and subcortical structures modulating emotional and behavioral processes. *AMYG,* amygdala; *BG,* Basal Ganglia; *CC,* Cingulate Cortex; *HYPTH,* hypothalamus; *IC,* Insular Cortex; *MC,* Motor Cortex; *NA,* Nucleus Accumbens; *NACG,* Noradrenergic Cell Group; *OFC,* Olfactory Cortex; *PAG,* Periaqueductal Grey; *PBN,* Parabrachial Nucleus; *PFC,* Prefrontal Cortex; *RF,* Reticular Formation; *SSC,* Somatosensory Cortex.

noradrenergic cell group, including the locus coeruleus and the parabrachial nucleus (PBN), and the PAG.[57] Unlike STT fibers that project contralaterally, neurons of the SMT can terminate bilaterally, which is compatible with the predominant homeostatic role of the brainstem, including the modulation of autonomic, neuroendocrine, and emotional responses to nociceptive input. More specifically, the noradrenergic cell group projects to the hypothalamus and modulates the neuroendocrine and autonomic response to pain, while the PBN projects to the amygdala and modulates the affective response to pain. The PBN also projects to the VMpo of the thalamus, which allows for the integration of SMT and STT signals at the insular cortex, the ultimate projection target of the VMpo.

A significant fraction of SMT projection neurons from spinal lamina I express NK1R and receive input from peripheral afferent peptidergic C-fibers.[59] SMT input to the reticular formation, locus coeruleus, and PAG trigger reciprocal input back to the spinal dorsal horn, a key neuronal network by which SMT signals exert descending nociceptive control.

Basal Ganglia

The basal ganglia (BG) are interconnected nuclei located in the white matter of both hemispheres. They include the caudate nucleus, the putamen, the nucleus accumbens, the globus pallidus, the substantia nigra, and the subthalamic nucleus. The primary role of the BG involves coordination of motor function, but they are also thought to be involved in the processing of pain. This is exemplified by clinical disorders that feature both movement disturbance and chronic pain. For example, patients with Parkinson disease, caused by loss of the dopaminergic neurons in the substantia nigra of the BG, exhibit a high incidence of chronic pain, which improves after deep brain stimulation of the globus pallidus or pallidotomy. Complex regional pain syndrome, a disorder often caused by a relatively minor traumatic insult to a peripheral nerve, frequently manifests with movement disorders including dystonia or tremor, which suggests recruitment of the BG in nociceptive signaling associated with complex regional pain syndrome. These clinical observations are bolstered by functional imaging studies documenting nociceptive signaling activity in the BG in acute and chronic pain states.[60]

The BG provide reciprocal efferent output to several brain structures, including the anterior cingulate cortex, the prefrontal cortex, the amygdala, and the thalamus. This reciprocal neuronal network likely modulates affective and cognitive components of pain. Unlike the somatotopically organized signals arising from the thalamus, the BG do not encode detailed sensory discriminative

information. However, the BG provide graded encoding of noxious inputs to mount appropriate behavioral and emotional responses.

Pharmacologic evidence further suggests a role of the BG in nociceptive processing. Microinjections of opioids, dopamine, or GABA into BG regions, including the substantia nigra, the putamen, and the globus pallidus, alter nociceptive signaling. Similarly, reward circuitries in the nucleus accumbens are an experimental target for exploiting antinociceptive effects of opioids, dopamine, and cholinergic receptor agonists. Despite these experimental findings, the overall significance of the BG for mediating antinociceptive effects by commonly used pain therapeutics remains unknown.[61]

Amygdala

The amygdala is part of the limbic system and plays a sentinel role in pairing sensory input with emotional significance. In the domain of pain, the amygdala matches nociceptive signals with affective content and serves as the neuronal interface for the reciprocal relationship between pain and an affective state or an affective disorder.[62] The amygdala receives nociceptive information from the spinal cord, brainstem, thalamus, and several cortical regions (insular, anterior cingulate, and association areas). The lateral (LA) nucleus of the amygdala serves as the initial site of signal convergence and connects with the basolateral (BLA) nucleus, forming a LA/BLA network that attaches emotional significance to sensory input. Most signals within the LA/BLA network are transmitted to the central nucleus, the major center from which efferent signals exit the amygdala. Nociceptive signaling converges in the laterocapsular portion of the central nucleus (CeLC), a region labeled the "nociceptive amygdala" because of its high content of nociceptive neurons. Although much of the neuronal input to the CeLC arrives from the LA/BLA network, the previously described SMT neurons that traverse the parabrachial nucleus also terminate in the CeLC. From the central nucleus, efferent projections build widespread connections with the forebrain, thalamus, hypothalamus, and brainstem areas (e.g., the PAG), thereby regulating autonomic, neuroendocrine, and somatosensory functions related to emotional experiences. Although most of the output from the amygdala arises from the central nuclei, the BLA nucleus provides important projections to the medial prefrontal cortex, a brain region important for value-based decision making, including risk assessment and strategic planning. This neuronal connection has been implicated in the impaired decision-making skills of patients with persistent pain.[63]

Qualitatively negative *and* positive emotions are known to modify neuronal activity in the amygdala, such that affect can play a dual role in either amplifying or mollifying the perception of pain.[61] The biochemistry underlying nociceptive processing in the amygdala features a large number of signaling molecules and receptor subtypes, and remains incompletely understood. The most prominent receptor systems include ionotropic (NMDA and AMPA) and metabotropic glutamate receptors, $GABA_A$ receptors, and neuropeptides, including CGRP, corticotropin-releasing factor, and neuropeptide S (NPS).[64]

Cortical Structures

Interconnected and functionally distinct cortical areas process nociceptive signals to build a complex neuronal network underlying the experience of pain (Fig. 16.9). Cortical areas can be organized according to their relative contribution to the sensory, affective, and cognitive components of pain.[55] The primary sensory cortex (SI) is the major neuroanatomic region underlying the sensory component of pain, responsible for encoding the location, time course, and intensity of pain stimuli. The secondary somatosensory cortex (SII) also receives sensory discriminative input but plays a complementary role to the SI by integrating sensory discriminative information with nociceptive information processed by the limbic system. This is accomplished through reciprocal connections between SII and its neuroanatomic neighbor, the insular cortex. The insula receives limbic cortical input from brain regions that modulate affective components of pain (e.g., anterior cingulate and entorhinal cortex) and thus the SII and insular cortex act as a neuronal interface between sensory and affective components of pain. Functional magnetic resonance imaging studies documenting concurrent activation of the posterior insula and SII regions in individuals experiencing distress from acute social rejection (a recent unwanted breakup) further highlight the importance of this neuronal interface.[65]

The anterior insula appears to play a role in modulating early aspects of pain including its anticipation. Connections between the anterior insula and memory centers in the entorhinal cortex of the temporal lobe facilitate this process, as anticipation relies on recall of past experiences.[66] The entorhinal cortex and hippocampus are part of the cortical network that stores and retrieves sensory information and participates in elaborating the experience of pain based on emotional state, expectations, and past experiences.

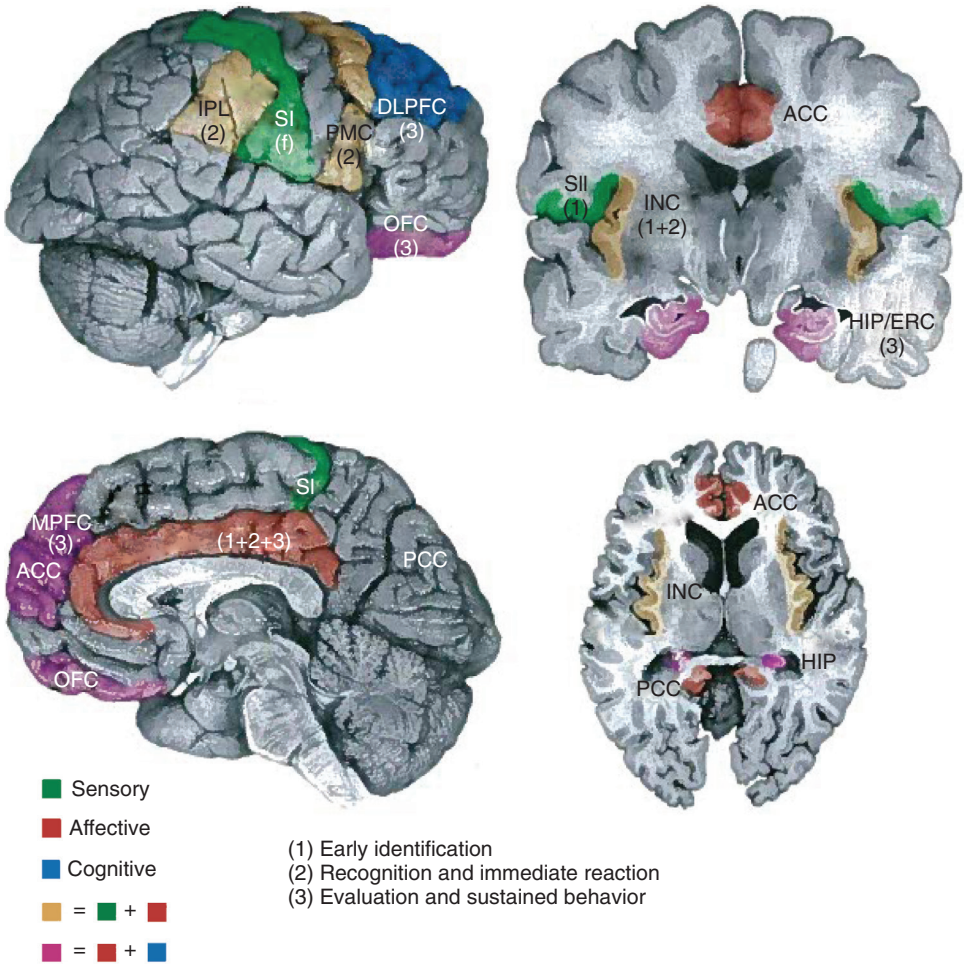
The cognitive component of pain derives from a number of neuroanatomic regions that are heavily interconnected. The dorsolateral prefrontal cortex (DLPFC) is involved in shifting attention between tasks and can thereby modulate attention to pain. This brain region has been implicated in mediating the placebo effect, as subjects given placebo treatments during noxious stimulation show functional magnetic resonance imaging activity in the dorsolateral prefrontal cortex that correlates with the magnitude of the placebo response.[67] The orbitofrontal cortex plays a critical role in the integration of emotional and sensory inputs to produce reward-seeking and punishment-aversive behaviors. Along similar lines, the medial prefrontal cortex engages in longer-term evaluation of pain and the development of cognitive adaptive strategies.

The anterior cingulate cortex (ACC) is a key relay linking brain pathways responsible for processing affective and cognitive components of pain. Whereas the ventral ACC is strongly interconnected with the amygdala and the insular cortex, the dorsal ACC forms connections with neighboring regions of the prefrontal cortex (see Fig. 16.9). The ACC exerts central modulatory control of interconnected brain regions to mediate goal-directed and reward-based cognitive behaviors. The ACC also interacts with the premotor cortex to assist in the orchestration of motor responses to pain.

Descending Pathways

The significance of descending control mechanisms in modulating pain was first recognized and incorporated into a neurophysiologic model called the "gate theory" by Melzack and Wall in 1965.[68] According to their theory, a gate built by primary afferent fibers, interneurons, and neurons descending from supraspinal sites controls and modulates nociceptive traffic. Although many of the neurophysiologic details turned out to be incorrect, the model was a conceptual breakthrough.

As proposed by Melzack and Wall, spinal synaptic transmission is modulated by descending inhibitory and excitatory pathways



• **Fig. 16.9** Cortical network regulating nociceptive processes. An anatomic and functional overview of the interconnected cortical areas of the pain processing network is shown. Areas are coded numerically and by color to indicate their temporal and functional role. For more details see text. *ACC*, Anterior cingulate cortex; *DLPFC*, dorsolateral prefrontal cortex; *ERC*, entorhinal cortex; *HIP*, hippocampus; *INC*, insular cortex; *IPL*, inferior parietal lobule; *MPFC,* medial prefrontal cortex; *OFC*; orbitofrontal cortex; *PCC*, posterior cingulate cortex; *PMC*, premotor cortex; *SI*, primary sensory cortex; *SII*, secondary somatosensory cortex. that originate in the brainstem. Descending control mechanisms either attenuate or augment nociceptive and nonnociceptive signaling contingent on overall biologic needs. For example, if a fight-or-flight response is most meaningful in the context of an injury, descending control mechanisms typically dampen spinal nociceptive processes. Alternatively, if a "guarding-and-heeling" behavior is most beneficial, descending facilitatory pathways can enhance spinal nociceptive processes (e.g., central sensitization and hyperalgesia associated with tissue injury).[69] Accordingly, the balance between inhibitory and facilitatory descending influences is highly dynamic and changes over the course of acute and chronic injuries.[70] Supraspinal modulation of nociception is integrated with related alterations in autonomic and motor responses elicited by painful stimuli, allowing for meaningful and teleologically useful responses to injury and pain.[71]

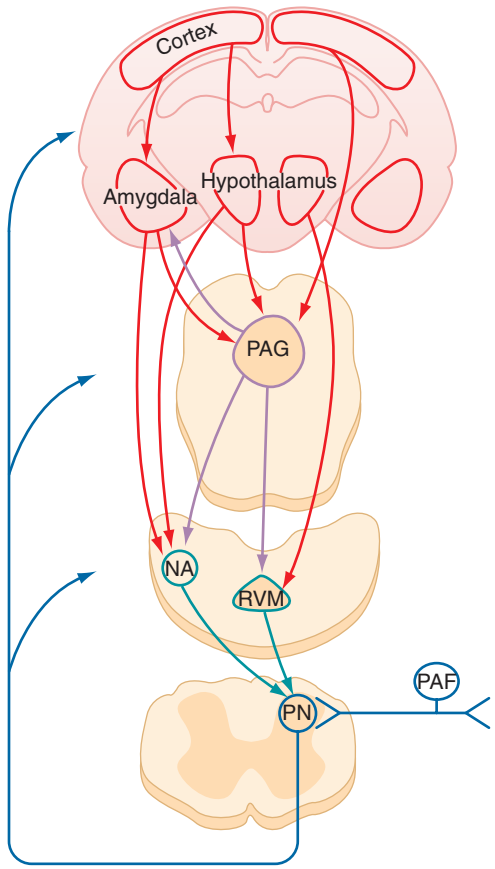
In the absence of a painful stimulus, descending inhibitory control mechanisms are dominant and dampen spinal nociceptive signaling. Upon initiation of an acute nociceptive input, inhibitory control is enhanced at all heterotopic body regions distant from the site of injury to direct attention toward the affected body site. This neuronal regulation is called *diffuse noxious inhibitory control,* which equates with the observation that pain at one body site ameliorates pain at another distant site.

The neuroanatomic architecture of the descending control system reflects its multidimensional role (Fig. 16.10). Central to the system is the rostral ventral medulla (RVM), which integrates input from several supraspinal structures and acts as the major relay between supraspinal and spinal sites. In accordance with the dynamic demands on descending inhibitory and facilitating circuits, many neuroanatomic sites exerting such control are capable of mounting both inhibitory and excitatory responses.

Structural Components

The best studied components of descending control pathways include the PAG and the RVM, regions rich in opioid receptors



• **Fig. 16.10** Major structural components exerting descending nociceptive control. The interrelationship of major neuroanatomical components exerting descending nociceptive control is shown. The periaqueductal gray *(PAG)* and rostral ventral medulla *(RVM)* are strategically located to integrate input from cerebral structures and relay processed information to the spinal dorsal horn. Noradrenergic pontine and medullary nuclei *(NA)* constitute a second important structure directly projecting to the dorsal horn. Presynaptic and postsynaptic mechanisms modulate nociceptive information that is transmitted from primary afferents *(PAF)* to spinal projection neurons *(PN)*. Alternatively, indirect actions are exerted via inhibition or excitation of spinal interneurons. Cortical areas, the amygdala, and the hypothalamus are among the cerebral structures exerting top-down control. These structures are relevant for the modulation of pain by stress, emotion, and cognition. (Modified from Millan MJ. Descending control of pain. *Prog Neurobiol*. 2002;66:355–474.)

and critical for mediating endogenous analgesia.[72,73] Numerous supraspinal regions help tune descending control signals and most act via the PAG-RVM axis. However, some descending signals are transmitted via a second important descending modulatory complex built by pontine and medullary noradrenergic nuclei including the locus coeruleus. Additionally, certain brain regions (including the parabrachial nucleus and dorsal reticular nucleus) bypass these centers and project directly to the dorsal horn.

The PAG receives input from multiple supraspinal structures, including the prefrontal cortex, hypothalamus, and amygdala. This top-down control of the PAG-RVM axis is important for the modulation of pain by cognitive influences, emotional factors, and stress. For example, projections from the amygdala and hypothalamus are relevant for hypoalgesia associated with intense fear or stress. Similarly, projections from the prefrontal cortex that are relayed via the cingulate cortex have been implicated in placebo-mediated analgesia.[74] The PAG projects to the RVM, which in turn projects profusely via the dorsolateral funiculus to superficial and deep laminae in the dorsal horn. Flow of information is bidirectional, with the PAG and RVM both receiving direct input from the spinal dorsal horn.

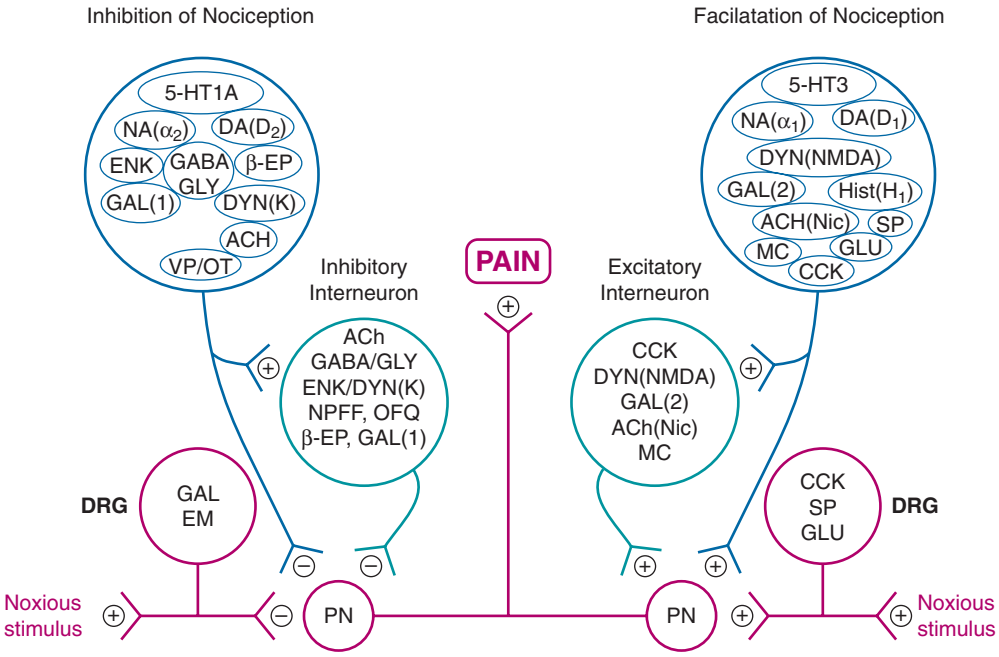
The RVM includes the nucleus raphe magnus and the adjacent nucleus reticularis gigantocellularis and paragigantocellularis lateralis. It is functionally defined as the pontomedullary area in which electrical stimulation and microinjection of opioids produce behavioral analgesia, and is a central site of action for many analgesic drug classes, including opioids, cyclooxygenase inhibitors, and cannabinoids. However, the RVM is not solely an analgesic center as it is able to exert both inhibitory and facilitating influences on spinal nociceptive processes. This is exemplified by the finding that injection of the neuropeptides cholecystokinin or neurotensin into the RVM leads to exaggerated pain responses. The dual role of the RVM in descending control is enabled by distinct neurons called ON and OFF cells. OFF cells exert inhibitory nociceptive control, whereas ON cells exert facilitating effects.[75] The PAG-RVM axis is tonically active and the balance between ON- and OFF-cell activity determines the *nociceptive response threshold* of the spinal dorsal horn.

Output from the PAG-RVM axis exerts spinal control via numerous mechanisms, including presynaptic inhibition of primary afferents, postsynaptic inhibition of spinal projection neurons, inhibition or activation of dorsal horn interneurons, or nonsynaptic release of mediators that diffuse within the dorsal horn (volume transmission). Chronically increased RVM ON-cell activity is one mechanism implicated in the pronociceptive states associated with inflammation or nerve injury.

In addition to the PAG-RVM axis, pontine and medullary noradrenergic nuclei also send projections to the dorsal horn (via the ventrolateral funiculus) and are the primary source of spinal noradrenaline.[76] Pontine and medullary centers receive input from the amygdala, hypothalamus, and the parabrachial nucleus and are also a target for some PAG output fibers, providing integration between the two descending systems. The noradrenergic system exhibits low tonic activity, which becomes significantly enhanced with tissue or nerve injury. This might explain why spinally administered α-adrenergic agonists are particularly efficacious for attenuating pain associated with significant inflammation or nerve injury. The noradrenergic pathway also plays an important role in mediating stress-induced analgesia.

Neurochemistry

The biochemistry of descending control mechanisms is complex, involving numerous neurochemical mediators, multiple sites of action, and a variety of receptor target subtypes. Fig. 16.11 provides an overview of relevant neurotransmitters and their predominant action on spinal nociceptive processes. In accordance with the dual inhibitory or facilitating role of descending control mechanisms, many neurotransmitters can exert either pronociceptive or antinociceptive effects, depending on their site of release within the descending control circuitry and the expressed receptor subtypes. For example, histamine elicits pronociceptive effects when administered spinally but exerts antinociceptive effects at supraspinal sites by enhancing descending inhibitory control. In this section, we focus on the major signaling systems involved in descending modulation, which include the monoaminergic (serotonin, norepinephrine, and dopamine) and opioidergic systems. The reader should note that many additional transmitters participate in



• **Fig. 16.11** Major biochemical components exerting descending nociceptive control. Descending control of spinal nociceptive processes is exerted by multiple neurotransmitters. Transmitters contributing to inhibition of nociceptive signaling are depicted on the left, whereas transmitters enhancing nociceptive signaling are depicted on the right. This physical separation serves didactic reasons and has no anatomic foundation. Transmitters are contained in descending pathways, in inhibitory or excitatory interneurons, and in primary afferent terminals. Only principal transmitter locations are shown (subtypes are indicated in parentheses). *ACH*, Acetylcholine; *β-EP*, β-endorphin; *CCK*, cholecystokinin; *DA*, dopamine; *DRG*, dorsal root ganglion; *DYN*, dynorphin; *EM*, endomorphin; *ENK*, enkephalin; *GABA*, gamma-hydroxybutyric acid; *GAL*, galanin; *GLU*, glutamate; *GLY*, glycine; *Hist*, histamine; *5-HT*, serotonin; *MC*, melanocortin; *NA*, noradrenaline; *NMDA*, *N*-methyl-D-aspartate; *NPFF*, neuropeptide FF; *OFQ*, orphanin FQ; *OT*, oxytocin; *PN*, projection neuron; *SP*, substance P; *VP*, vasopressin. descending control mechanisms, including glutamate, glycine, GABA, histamine, vasopressin, oxytocin, cholecystokinin, neurotensin, galanin, SP, and cannabinoids.[71]

Descending monoaminergic projection neurons are the only source of spinally released serotonin, norepinephrine, and dopamine. Serotonin has long been implicated as an important mediator in the PAG-RVM axis by studies demonstrating that electrical stimulation of either the PAG or the RVM triggers serotonin release in the spinal cord. Interestingly, serotonin plays a role in both descending inhibition and facilitation by its differential effects on 5-HT receptor subtypes. Studies with 5-HT antagonists demonstrate that 5-HT_{2A} and 5-HT_3 facilitate nociception, whereas 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, and 5-HT_7 exert inhibitory effects. Despite the importance of serotoninergic mechanisms in the PAG-RVM axis, serotonergic neurons in the RVM (approximately 20% of all neurons) are not part of the ON- or OFF-cell population relevant for opioidergic descending inhibitory control. The interplay between ON and OFF cells and serotonergic RVM neurons remains incompletely understood.

Descending projection neurons from pontine and medullary noradrenergic nuclei provide another important modulatory input to the spinal dorsal horn via the release of norepinephrine. As is the case with serotonin, norepinephrine can exert pronociceptive or antinociceptive effects depending on expressed adrenergic receptor subtype. Activation of spinal α_1-adrenergic receptors augment pronociceptive signaling, whereas activation of spinal α_2-adrenergic receptors produces antinociceptive effects. Numerous drug classes used for the treatment of neuropathic pain, including tricyclic antidepressants (amitriptyline), gabapentanoids (neurontin), and serotonin and norepinephrine reuptake inhibitors (duloxetine), may exert their clinical efficacy by enhancing spinal noradrenergic signaling.[77] Spinal release of dopamine is another mechanisms either facilitating or inhibiting nociceptive signaling via activation of dopamine D1 or D2 receptors.

The μ-, δ-, and κ-opioid receptors are differentially stimulated by exogenous agents and their endogenous ligands β-endorphin (μ), endomorphin (μ), enkephalin (μ, δ), and dynorphin (κ). Endomorphin and enkephalin elicit antinociceptive effects at both spinal and supraspinal sites. By contrast, dynorphin exerts dual actions. Activation of spinal κ receptors attenuates nociceptive signaling, whereas supraspinal activation of κ receptors exhibit both pronociceptive and antinociceptive influences on descending control mechanisms. In addition, dynorphin activates non-opioidergic spinal receptors, including NMDA glutamate receptors, which produces a pronociceptive effect.

Emerging Developments

Biased μ-Opioid Receptor Agonists

Although opioids are the cornerstone therapeutics for the treatment of moderate to severe pain, their clinical utility is hampered by

side effects, including nausea, constipation, sedation, and respiratory depression, as well as physical dependence and addiction. The use of partial opioid agonists such as buprenorphine has mitigated some of these concerns in the treatment of chronic pain. However, partial opioid agonists are by definition suboptimal analgesics. Similarly, the use of peripherally restricted opioid antagonists like alvimopan have been helpful in blocking some systemic adverse effects of opioids (most notably constipation), they do not counteract centrally mediated respiratory depression, the most detrimental opioid-related side effect. An ideal opioid agonist would be a highly efficacious analgesic agent devoid of serious adverse effects. Recent advances in our understanding of the signaling pathways downstream of the μ-opioid receptor have laid the groundwork for the design of such an agent.

While the analgesic effects of μ-opioid receptor agonists are mediated by $G\alpha_i$ G-protein signaling pathways that include activation of the G-protein–gated potassium channel (GIRK) and inhibition of adenylyl cyclase many adverse effects are mediated by an alternative pathway involving the molecule β-arrestin 2. Activation of the μ-opioid receptor by classical agonists leads to receptor phosphorylation, a signal that triggers binding of β-arrestin 2 to the μ-opioid receptor and the resultant activation of downstream signaling pathways mediating adverse effects such as constipation and respiratory depression. In an important experiment, increased analgesic efficacy was demonstrated in β-arrestin 2 knockout mice treated with morphine, while constipation and respiratory depression were diminished and antinociceptive tolerance was absent after prolonged exposure.[78,79] These findings provided the impetus for the subsequent development of a novel class of opioid agonists called biased agonists. Biased agonists activate the $G\alpha_i$ cascade but do not promote receptor phosphorylation and subsequent binding of β-arrestin 2. An example of a biased agonist is oliceridine (TRV130), developed by Trevena Inc. In a double-blind, placebo-controlled study in healthy human male volunteers, oliceridine was more efficacious in alleviating experimental pain than morphine and caused less nausea and respiratory depression.[80] Oliceridine is now in phase III clinical trials for the treatment of moderate to severe pain after abdominoplasty.

Recent structural-based docking of candidate molecules to the μ-opioid receptor crystal structure has identified PZM21, an agonist that exhibits a greater degree of bias for the $G\alpha_i$ cascade over β-arrestin 2 recruitment compared with TRV130. In preclinical studies in mice, PMZ21 outperformed both TRV130 and morphine with respect to its analgesic efficacy and the severity of observable adverse effects including respiratory depression and constipation.[81] While biased opioid agonists hold significant potential to outperform traditional opioids, they do not eliminate all relevant opioid adverse effects. Most notably, biased opioid agonists exert similar sedative effects as traditional agonists. This underscores the need for alternative, non-opiate–based strategies for the treatment of pain.

$Na_V1.7$, a Novel Drug Target at the Peripheral Nociceptor

Since the discovery that $Na_V1.7$ sodium channel mutations underlie the inherited disease congenital insensitivity to pain, attempts to develop selective $Na_V1.7$ antagonists for the treatment of acute and chronic pain have been a major focus in analgesic drug development. Individuals with congenital insensitivity to pain lack any pain sensation, while they perfectly sense touch, temperature, and pressure.[25] This remarkable clinical presentation and the restricted expression of $Na_V1.7$ on sensory neurons raised the possibility that selective blockade of $Na_V1.7$ could produce complete analgesia while preserving sensory and motor function. Such prospect is exciting as traditional nonselective sodium channel blockers including currently available local anesthetics block all sensory and motor fibers, which limits their utility as analgesic agents.

Efforts to develop clinically useful $Na_V1.7$ antagonists have proven difficult because of a number of technical challenges. One example relates to the early development of the peptide toxin ProTx-II, isolated from the Peruvian green velvet tarantula.[82] ProTx-II binds with picomolar affinity and approximately 100-fold higher specificity to $Na_V1.7$ compared with other Na_V channels. Despite these promising properties, intravenous or intrathecal administration of ProTx-II did not alleviate acute or chronic inflammatory pain in rodent models, which was due to its poor penetrance into the perineural sheath. Overcoming poor penetrance required such high doses of ProTx-II that sodium channels expressed in cardiac ($Na_v1.5$) and skeletal muscle ($Na_v1.4$ and $Na_v1.6$) were concomitantly blocked. This resulted in significant toxicity. Although diligent studies have demonstrated some analgesic efficacy of ProTx-II, the therapeutic window of this novel compound is quite small.

A second technical challenge concerns the specificity of novel $Na_V1.7$ blocking agents. An example is vixotrigine, a drug that only poorly discriminates between Na_V subtypes, currently in phase II/III clinical trials for the treatment of lumbosacral radiculopathy. Similarly, a group of aryl-sulfonamide–based agents under development by several pharmaceutical companies show only modest selectivity for $Na_V1.7$ (about 10-fold).[83,84]

A number of recent advances in the realm of $Na_v1.7$-specific antagonist development have been encouraging. A structure/activity optimization study generated a ProTX-II toxin (JNJ63955918) with increased binding specificity at $Na_V1.7$ and a promising antinociceptive profile in animal models.[85] An alternative naturally derived $Na_V1.7$ blocking toxin (Ssm6a) retrieved from the venom of the Chinese redheaded centipede exhibits greater than 600-fold specificity for $Na_V1.7$ over other Nav subtypes. Intraperitoneal injection of Ssm6a was nontoxic and produced antinociceptive effects similar to morphine in a rodent model of thermal and chemically induced pain.[86] Another promising strategy is the development of a state-specific monoclonal antibody (SVmab1) that preferentially binds to the closed $Na_V1.7$ channel and prevents its opening and activation. SVmab1 binding to $Na_V1.7$ is highly specific. Intrathecal injection of SVmAb1 exerts relevant antinociceptive effects in animal models.[87]

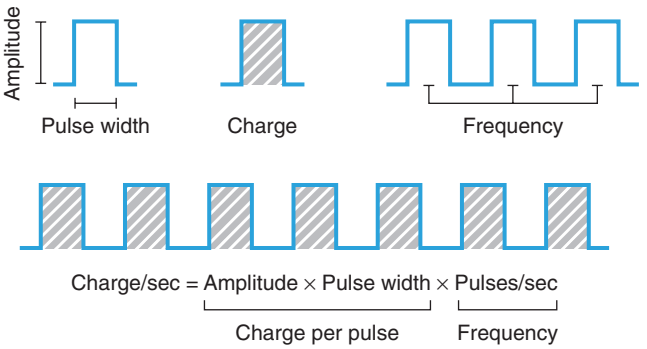
Neuromodulation

The analgesic effects of electrical neuromodulation of the dorsal spinal cord was first demonstrated in 1967.[88] Since that time, the use of spinal cord stimulators for the treatment of refractory chronic pain has become increasingly popular. Indications for the use of spinal cord stimulators include a wide range of chronic pain conditions, including failed back surgery, radiculopathies, complex regional pain syndrome, angina pectoris, and pancreatitis. In traditional systems, stimulating electrodes delivering impulses to the spinal cord at 40 to 60 Hz are placed into the epidural space to align with the somatic distributions of a patient's pain. The basic concept is to generate a paresthesia that alters the processing of nociceptive inputs and masks the perception of pain. An example supporting the efficacy of this approach for select chronic pain conditions is a study in patients with neuropathic radicular pain after failed back surgery. Spinal cord stimulation was superior to conventional medical management and decreased pain by more

than 50% in about half of studied patients along with their improved satisfaction and physical function.[89] However, 25% to 50% of patients experience complications, including lead migration or fracture, pulse generator failure, loss of paresthesia, and infection, resulting in efficacy loss and the need for corrective procedures. Additionally, some patients find the paresthesias produced by traditional spinal cord stimulators uncomfortable with positional changes, limiting their utility or necessitating discontinuation of use.

Recent advances, including high-frequency (10,000 Hz) and selective dorsal root ganglion stimulation protocols, have overcome some of the traditional limitations, shown improved efficacy, and expanded the applicability of spinal cord stimulators.[90,91] A major breakthrough in the field enabling the development of high-frequency stimulators was the realization that analgesic efficacy was not dependent on evoking paresthesias but on delivering an adequate electrical charge to the spinal cord. As shown in Fig. 16.12, the electrical charge delivered per second is defined by pulse width × amplitude × frequency.[92] In contrasting to traditional spinal cord stimulators, high-frequency/low-amplitude protocols deliver electrical impulses that do not trigger action potentials and consequently, do not evoke paresthesias. Additional advantages of high-frequency stimulation protocols include simplified lead placement (as high-frequency stimulating electrodes do not need to overlap with the somatic region in which the patient experiences pain) and reduced risk of device failure resulting from lead migration.

Historically, clinical studies examining the efficacy of spinal cord stimulation were hampered by an inability to properly blind study participants because of evoked paresthesias. However, proper blinding is more readily achieved in studies examining the efficacy of high-frequency spinal cord stimulators as paresthesias are absent. Such studies are ongoing to better understand how to configure pulse width, amplitude, frequency, and burst pattern to maximize analgesic efficacy. Pairing advanced algorithms with mechanistic studies shedding light on the poorly understood molecular and neuronal processes affected by spinal cord stimulation hold significant promise to further advance the utility of this neuromodulatory strategy.



• **Fig. 16.12** Neuromodulatory stimulation parameters. Pulse width and pulse height (amplitude) contribute to the energy (charge) per pulse. By altering either the charge per pulse or the frequency of pulses, the total delivered charge per second can be controlled. (Modified from Miller JP, Eldabe S, Buchser E, et al. Parameters of spinal cord stimulation and their role in electrical charge delivery: a review. *Neuromodulation* 2016;19:373–384.

Key Points

- The transduction of pain signals in peripheral nociceptors is a complex process involving a mosaic of receptors and ion channels that are directly or indirectly activated by multiple ligands.
- Nociception-related signal transduction is highly interactive, redundant, tissue-specific, time-dependent, and contingent on the type of injury. This complexity poses significant challenges—and opportunities—for identifying novel and broadly effective analgesic compounds.
- Most effective might be compounds targeting structures conveying information from multiple nociceptive processes, such as certain ion channels. Analgesic strategies might also be tailored toward specific indications such as pain conditions arising from certain types of tissue or injury.
- Anatomic and neurochemical details of dorsal horn neurocircuits processing nociceptive signals are still quite limited. Recent studies shed light on the synaptic connections between primary afferents, interneurons, and projection neurons, as well as on the receptors and ion channels involved.
- Comprehensive functional characterization of neuronal networks in the dorsal horn explains available analgesic therapies and should facilitate identification of novel analgesic drug targets.
- Descending control mechanisms regulating nociceptive traffic at the level of the dorsal horn involve both pronociceptive and antinociceptive effects of some neurotransmitters contingent on release site and available receptor subtypes. Interactions and redundancies of different neurotransmitter systems are subject to dynamic modulation by tissue or nerve injury.
- Descending control mechanisms are not restricted to nociception but also involve projections to spinal sites exerting autonomic and motor control. The simultaneous actions on nociceptive, autonomic, and motor processes raise the possibility that compounds targeting this system might cause significant adverse effects.
- Multitarget strategies, including agonist and antagonist approaches simultaneously exploiting mechanisms of descending inhibition and facilitation, are promising for achieving clinically effective analgesia without exerting unacceptable side effects.
- The top-down control of spinal and supraspinal nociceptive processes also provides a rational for nonpharmacologic approaches, including behavioral therapies or brain stimulation techniques (e.g., magnetic or electrical).
- A complex network of cortical and subcortical structures is required to process and integrate pain at the conscious and subconscious level. Pain elicits integrated autonomic, endocrine, and motor responses at the subconscious level, as well as sensory, affective, and cognitive responses at the conscious level that are normally tailored to protection of the body, but can be pathologically activated in chronic pain states.
- Appreciation of the multifaceted nature of pain is critical to providing the multidimensional approaches required for its successful alleviation.

Melzack R, Wall PD. Pain mechanisms: a new theory. *Science*. 1965;150:971–979. This article introduced the gate-control theory. This theory broke with the idea that pain signaling from peripheral tissue to the brain was a hard-wired process and consequently was the product of an invariant relationship between input intensity and response magnitude. Instead, Melzack and Wall proposed that nociceptive signals were modulated at the level of the spinal cord. (Ref. 68).

Melzack R. The McGill Pain Questionnaire: major properties and scoring methods. *Pain*. 1975;1:277–299. Melzack systematically analyzed the language used by patients to describe their pain, established the multidimensional character of pain, and built the basis for the definition of pain along the three experiential axes of sensation, affect, and cognition. An important consequence of this work was the insight that the multifaceted nature of pain requires a multidimensional approach for treatment including pharmacologic, behavioral, and cognitive strategies. (Ref. 55).

Reynolds DV. Surgery in the rat during electrical analgesia induced by focal brain stimulation. *Science*. 1969;164:444–445. This article provided early proof for the existence of a powerful endogenous analgesic system. Electrical stimulation of midbrain structures in nonanesthetized rats allowed for surgical interventions without provoking nociceptive behaviors. Today the critical role of the periaqueductal gray, the region stimulated by Reynolds, for controlling nociceptive signaling is well established. (Ref. 72).

Pert CB, Snyder SH. Opioid receptor: demonstration in nervous tissue. *Science*. 1973;79:1011–1014. This article provided direct evidence for the expression of opioid receptors in the central nervous system and demonstrated their functional relevance in mitigating analgesia upon stimulation. This work clearly documented that opioids exert their analgesic actions via central mechanisms. (Ref. 73).

Woolf CJ. Evidence for a central component of postinjury pain hypersensitivity. *Nature*. 1983;306:686–688. Woolf demonstrated that hyperalgesia associated with tissue injury (increased sensitivity to pain) was partly due to the amplified processing of nociceptive signals at the level of the spinal cord. This early work documented that structures in the central nervous system can undergo plastic changes and become sensitized (central sensitization) in response to tissue injury. (Ref. 48).

Historical Perspective

The white "latex" juice of the poppy plant is the source of more than 20 opiate alkaloids. *Opium,* a word derived from the Greek word for juice, is the brownish residue observed after the poppy's juice is desiccated. *Opiate* is the older term classically used in pharmacology to mean a drug derived from opium. *Opioid,* a more modern term, is used to designate all substances, both natural and synthetic, that bind to opioid receptors (including antagonists).

Opium and its derivatives have been known for millennia to relieve pain. Laudanum, or tincture of opium (a mixture of opium and alcohol), was used as early as the 1600s as an analgesic. Sir Christopher Wren, the acclaimed Englishman of arts and letters, was the first to inject opium into a living organism using a hollow feather quill as the delivery system in 1659. Sertürner, a German pharmacist, isolated morphine from opium in 1805. Having initially called morphine "somniferum" (after the Latin botanical name *Papaver somniferum*— the poppy that brings sleep), the name was later changed to *morphine,* alluding to Morpheus, the Greek god of dreams.

Opium and its derivatives have sometimes been the basis of international conflict. The Opium Wars of the 1800s were fought between China and the Western powers in large part in response to Western importation of opium into China. The opium houses of 19th century China, where opium was freely available for sale and consumption, illustrated the frightening societal consequences of large-scale drug abuse. Recognition of these problems in the United States eventually culminated in the Harrison Narcotics Tax Act of 1914 that criminalized narcotic possession. The prevalence of addiction clinics and drug-related violence and crime in modern society emphasizes the chronicity of the societal difficulties that stem from this drug class and others. The ongoing opioid abuse epidemic in the United States is a recent reflection of the complexity and recalcitrance of the problems associated with opioid addiction despite nearly a century of research devoted to the conundrum.

Despite their abuse potential, opioids play an indispensable role in the practice of medicine, especially anesthesiology, critical care, and pain management. A sound understanding of opioid pharmacology, including both basic science and clinical aspects, is critical for the safe and effective use of these important drugs. This chapter focuses almost exclusively on intravenous opioids used perioperatively.

Abstract

This chapter reviews the basic and clinical pharmacology of intravenous opioids in the context of anesthesiology and perioperative medicine. Unique features of commonly used opioids are discussed and the principles underlying rational drug selection and administration are outlined. Emerging developments of contermporary interest are briefly examined.

Basic Pharmacology

Structure-Activity

The opioids of clinical interest in anesthesiology share many structural features. Morphine, the principal active compound derived from opium, is a benzylisoquinoline alkaloid; the benzylisoquinoline structural backbone is present in many important naturally occurring drugs including papaverine, tubocurarine, and morphine. Morphine's benzylisoquinoline based structure is shown in Fig. 17.1. Many commonly used semisynthetic opioids are created by simple modification of the morphine molecule. Codeine, for example, is the 3-methyl derivative of morphine. Similarly, hydromorphone, hydrocodone, and oxycodone are also synthesized by relatively simple modifications of morphine. More complex alteration of the morphine molecular skeleton results in mixed agonist-antagonists such as nalbuphine and even pure competitive antagonists such as naloxone.

Some of the morphine derivatives have chiral centers and thus are typically synthesized as racemic mixtures of two enantiomers; only the levorotatory enantiomer is significantly active at the opioid receptor. The naturally occurring, stereospecific enzymatic machinery in the poppy plant produces morphine only in the levorotatory form.

The fentanyl series of opioids are chemically related to meperidine. Meperidine is the first completely synthetic opioid and can be regarded as the prototype clinical phenylpiperidine. As shown in Fig. 17.1, fentanyl is a simple modification of the basic phenylpiperidine structure found within meperidine; the other commonly used fentanyl congeners such as alfentanil and sufentanil are somewhat more complex versions of the same phenylpiperidine skeleton. As these drugs have no chiral center and therefore exist in a single form, the pharmacologic complexities of stereochemistry do not apply.[1]

As shown in Fig. 17.2, evidence from x-ray crystallography investigations and other techniques suggests that distinct parts of the opioid agonist or antagonist molecule confer specificity (i.e., addressing) and efficacy (i.e., messaging).[2] Agonists and antagonists have similar addressing segments in their structures; their action at the receptor is determined by the messaging portion of the molecule (see Chapter 1).

As outlined in Table 17.1, opioids share many physicochemical features in common, although some individual drugs have unique features. In general, opioids are highly lipid soluble, weak bases that are highly protein bound and largely ionized (protonated) at physiologic pH. Opioid physicochemical properties are thought to have important implications on their clinical behavior. For example, highly lipid soluble, relatively unbound, un-ionized molecules such as alfentanil and remifentanil have a shorter latency to peak effect after bolus injection presumably because of their more rapid transfer across cellular membranes.

Mechanism

Opioids produce their main pharmacologic effects by interacting with opioid receptors. Investigation of opioid receptor genetics, structure, and function over the past several decades has greatly enhanced understanding of opioid pharmacology.

Cloning of the opioid receptors, first accomplished in rodents and subsequently in humans, was an important first step in eventually elucidating opioid receptor structure and function. Using the rat μ-opioid receptor complementary DNA sequence as a guide, investigators were able to identify its human homolog, describing the amino acid sequence, strong binding affinity for an endogenous opioid ligand (i.e., enkephalin) and chromosomal assignment (i.e., chromosome 6).[3]

Opioid receptors are typical of the G-protein–coupled family of receptors widely found in biology (e.g., β-adrenergic, dopaminergic, among others). Like other G-protein–coupled receptors, opioid receptors have seven transmembrane portions, intracellular and extracellular loops, an extracellular N-terminus, and an intracellular C-terminus. There is considerable amino acid sequence homology among the various opioid receptor subtypes; most of the nonhomologous sequences occur in the extracellular portions of the protein. The extracellular domains are thought to be important in discriminating between the various receptor ligands.

Expression of cloned opioid receptors in cultured cells has facilitated analysis of the intracellular signal transduction mechanisms activated by opioid receptors.[4] As shown in Fig. 17.3, binding

• **Fig. 17.3** Opioid mechanisms of action. The endogenous ligand or drug binds to the opioid receptor and activates the G protein (three distinct protein subunits), resulting in multiple effects that are primarily inhibitory. The activities of adenylate cyclase and the voltage-dependent calcium ion *(Ca^{2+})* channels are depressed. The inwardly rectifying potassium ion *(K^+)* channels and mitogen-activated protein kinase *(MAPK)* cascade are activated. *AMP,* Adenosine monophosphate; *ATP,* adenosine triphosphate.

of opioid agonists with the receptors leads to activation of the G-protein (actually three distinct G-protein subunits), producing effects that are primarily inhibitory (decreased cyclic adenosine monophosphate production, decreased calcium ion influx, increased potassium ion efflux); these effects ultimately culminate in membrane hyperpolarization of the cell and reduction of neuronal excitability.

Three classical opioid receptors have been identified using molecular biology techniques: μ, κ, and δ receptors. These receptors are also described by an international nomenclature scheme as MOP, KOP, and DOP (mu, kappa, or delta opioid peptide). The μ-opioid receptor is commonly abbreviated in the scientific literature as MOR. More recently, a fourth opioid receptor, ORL1 (also known as NOP), has also been identified, although its function

• **Fig. 17.4** Receptor distribution and response to morphine in μ-opioid receptor knockout mice. On the left side are computer-enhanced color autoradiograms of coronal sections of mice brain demonstrating diminished μ-opioid receptors in the heterozygotes (+/–) and complete absence of μ-opioid receptors in the homozygotes (–/–) compared with wild-type littermates (+/+). The right panel shows the antinociceptive responses to morphine administration during the "hot-plate" test in μ-opioid receptor knockouts (–/–) and their wild-type littermates. The knockouts are represented by the *solid squares*; the wild-type are the *open squares*. The two *stars* indicate a highly significant difference between groups ($P < 0.01$). The knockouts exhibit no analgesic response to morphine. (Adapted with permission from Matthes HW, Maldonado R, Simonin F, et al. Loss of morphine-induced analgesia, reward effect and withdrawal symptoms in mice lacking the mu-opioid-receptor gene. *Nature.* 1996;383:819–823.)

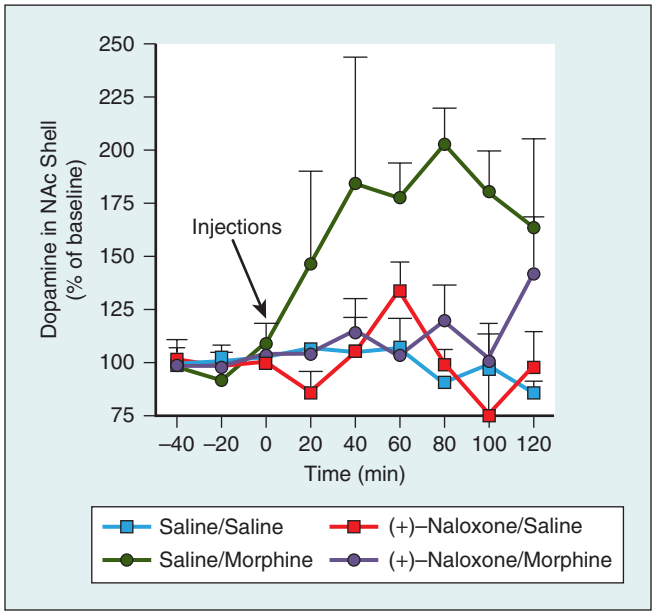
appears to be quite different from the classical opioid receptors. As shown in Table 17.2, each of these opioid receptors has a commonly used experimental bioassay, associated endogenous ligand(s), a set of agonists and antagonists, and a spectrum of physiologic effects when the receptor is activated. Although the existence of opioid receptor subtypes (e.g., μ-1, μ-2, and so on) has been proposed, it is not clear from molecular biology techniques that distinct genes code for them. Posttranscriptional and post-translational modification of opioid receptors certainly occurs and could be responsible for conflicting data regarding opioid receptor subtypes. It is well known, for example, that the messenger RNA coding for the human μ-receptor undergoes alternative splicing, resulting in subtle differences in the final receptor.[5]

As confirmed by autoradiographic and binding techniques, opioid receptors are widely expressed in the central nervous system (CNS). In the spinal cord, they are mainly localized to the substantia gelatinosa of the dorsal horn. In the brain, they are especially concentrated in the periaqueductal gray region, the limbic system, area postrema, thalamus, and cerebral cortex. Opioid receptors are also found outside the CNS in gastrointestinal, biliary, and other tissues. Action by agonists at these peripheral receptors accounts for some of the adverse effects of opioids such as constipation.

In accordance with the wide distribution of opioid receptors in the CNS, opioids appear to exert their therapeutic effects at multiple sites. Opioid agonism at the level of the spinal cord inhibits the release of substance P from primary sensory neurons in the dorsal horn, mitigating the transfer of painful sensations to the brain. Opioid actions in the brainstem modulate nociceptive transmission in the dorsal horn of the spinal cord through descending inhibitory pathways. Opioids are also thought to change the affective response to pain through actions in the forebrain; decerebration prevents opioid analgesic efficacy in rats.[6] Furthermore, functional magnetic resonance imaging studies in humans have demonstrated that morphine induces signal activity in reward structures in the brain.[7]

Studies in genetically altered mice have yielded important information about opioid receptor function. In μ-opioid receptor knockout mice, morphine induced analgesia, reward effect, and withdrawal effect are absent.[8,9] Fig. 17.4 demonstrates the simple power of these site-directed mutagenesis techniques, confirming how MOR knockout mice exhibit no analgesic effect to morphine as assessed by measuring the time to jumping off a hot plate. Importantly, MOR knockout mice also fail to exhibit respiratory depression in response to morphine.[10] Confirming the importance of opioid receptor ligands in the biology of "endogenous" analgesia systems, β-endorphin knockout mice fail to show naloxone-reversible, stress-induced analgesia but maintain a normal analgesic response to morphine.[11]

Opioid addiction, as with many addictive drugs and practices, involves dopamine-related reward mechanisms. As shown in Fig. 17.5, microdialysis techniques in a rodent model demonstrate an opioid-induced, naloxone-reversible increase in dopamine levels in the nucleus accumbens region, a brain area known to be important in addiction (see Chapter 12).[12] Toll-like receptors (i.e., TLR4), a receptor system involved in the identification of foreign molecules and the inflammatory response in the CNS, may play a role in the



• **Fig. 17.5** Rodent model evidence of opioid-induced, naloxone-reversible increases in dopamine in the nucleus accumbens region. (+)-Naloxone suppresses morphine-induced dopamine release in the nucleus accumbens shell. In vivo microdialysis was used to test the effect of (+)-naloxone (1 mg/kg subcutaneous) on morphine (6 mg/kg subcutaneous)-induced increases in extracellular dopamine in the nucleus accumbens shell. After three baseline samples, rats received saline solution plus saline solution, saline solution plus morphine, (+)-naloxone plus saline solution, or (+)-naloxone plus morphine. Repeated-measures analysis of variance revealed a significant effect of treatment condition ($P < 0.01$). Data are means per group ± standard error of the mean; $n = 4$/group. (Adapted with permission from Hutchinson MR, Northcutt AL, Hiranita T, et al. Opioid activation of toll-like receptor 4 contributes to drug reinforcement. *J Neurosci.* 2012;32:11187–11200.)

biology of opioid addiction; in silico evidence confirms that opioids such as remifentanil can interact with this receptor complex.[12]

Metabolism

The intravenous opioids in common perioperative clinical use are transformed and excreted by a wide variety of metabolic pathways. In general, opioids are metabolized by the hepatic microsomal cytochrome P450 (CYP) system, although hepatic conjugation and subsequent excretion by the kidney are important for some drugs. The major and minor metabolic enzymes involved in the metabolism of a number of commonly used opioids are shown in Fig. 17.6.[13] For certain opioids, the specific metabolic pathway involved has important clinical implications in terms of active or toxic metabolites (e.g., morphine, meperidine) or an ultrashort duration of action (e.g., remifentanil). For others opioids, genetic variation in the metabolic pathway can drastically alter the clinical effects (e.g., codeine). These nuances are addressed in a subsequent section focused on individual drugs.

Clinical Pharmacology

Pharmacokinetics

Because in most respects opioids are pharmacodynamically similar, pharmacokinetic differences form the scientific foundation for the rational selection and administration of opioids in anesthesia practice. Key pharmacokinetic behaviors to consider are the latency-to-peak effect after bolus injection (i.e., bolus front-end kinetics), the time to offset of effect after bolus injection (i.e., bolus back-end kinetics), the time to steady-state after starting a continuous infusion (i.e., infusion front-end kinetics), and the time to offset of effect after stopping a continuous infusion (i.e., infusion back-end kinetics).

Applying opioid pharmacokinetic concepts to clinical anesthesiology requires recognition of several fundamental principles. First, a table of opioid pharmacokinetic parameters can rarely be instructive in terms of understanding how the pharmacokinetic behavior of the individual drugs compares (see Chapter 2). Understanding pharmacokinetic behavior is best achieved through computer simulation. Second, because opioid clinical behavior differs depending on whether the drugs are administered by bolus injection or continuous infusion, these two clinical conditions must be considered separately.[14] Third, the time course of drug levels predicted through pharmacokinetic simulation cannot be considered in a vacuum; pharmacokinetic information must be integrated with knowledge about the concentration-effect relationship and drug interactions (pharmacodynamics) to be clinically useful.

The latency-to-peak effect and the offset of effect after bolus injection of various opioids can be explored by predicting the time course of effect site concentrations after a bolus is administered. Because the opioids differ in terms of potency (and thus the required dosages), for comparison purposes the effect site concentrations must be normalized to the percent of peak concentration for each

drug. Considering morphine, hydromorphone, fentanyl, sufentanil, alfentanil, and remifentanil as among the most commonly used intravenous opioids intraoperatively, the top panel of Fig. 17.7 illustrates how these opioids differ in terms of latency-to-peak effect (i.e., bolus front-end kinetics); the simulations are based on pharmacokinetic-dynamic parameters from the literature.[15-21]

The simulation of a bolus injection (Fig. 17.7A) has obvious clinical implications. For example, when a rapid onset of opioid effect is desirable, morphine may not be a good choice. Similarly, when the clinical goal is a brief pulse of opioid effect followed by a rapid dissipation of effect, remifentanil or alfentanil is preferred. Note how remifentanil's concentration has declined substantially before fentanyl's peak concentration has been achieved (bolus back-end kinetics). The simulation illustrates why the front-end kinetics of fentanyl make it a drug well suited for patient-controlled analgesia (PCA). In contrast to morphine, the peak effect of a fentanyl bolus is manifest before a typical PCA lockout period has elapsed, thus mitigating a "dose stacking" problem.

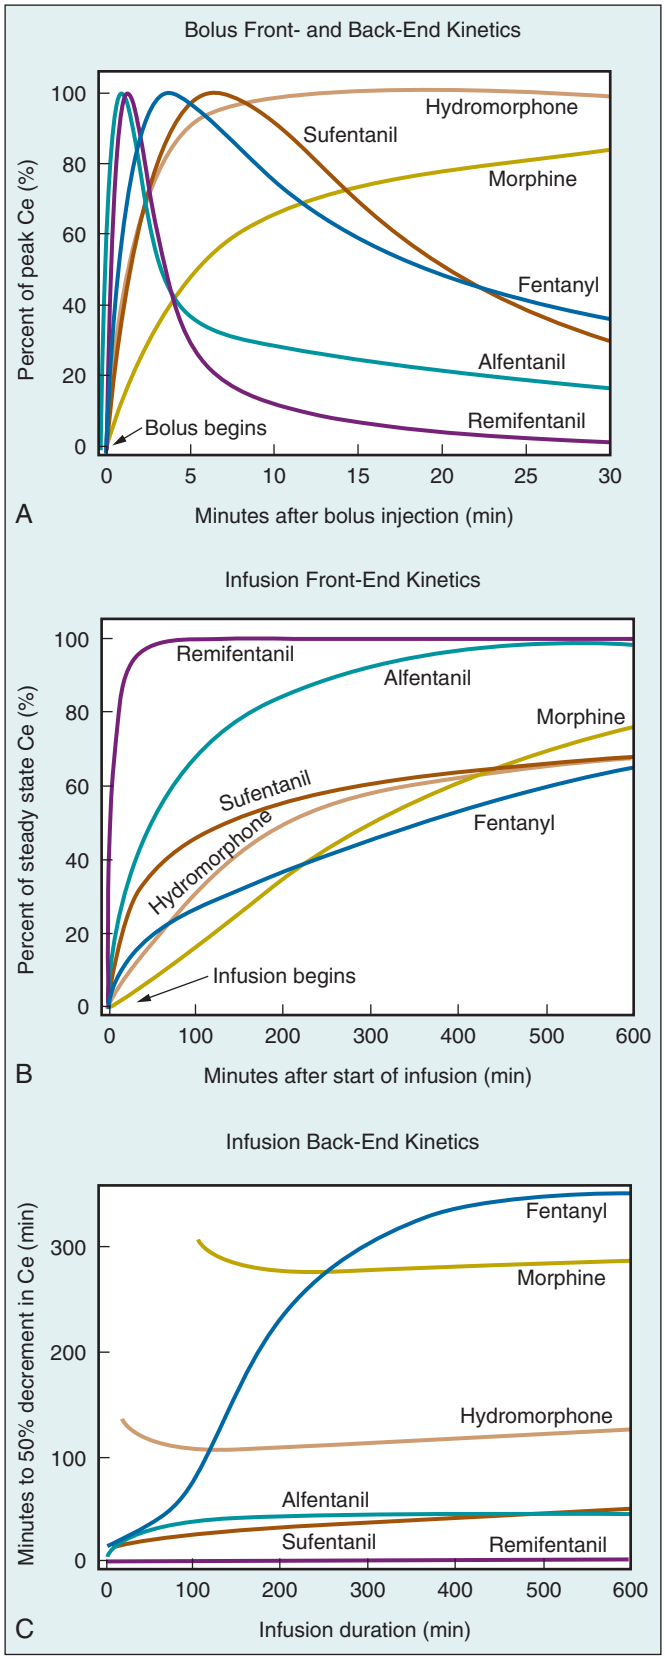
The latency-to-peak effect is governed by the speed with which the plasma and effect site come to equilibrium (the k_{eo} parameter). Drugs with a more rapid equilibration are thought to have a higher "diffusible" fraction (the proportion of drug that is un-ionized and unbound). It is important to emphasize that a substantial limitation of these latency-to-peak effect simulations is that a very large dose of any opioid can produce a rapid onset (because a supratherapeutic drug level in the effect site is reached even though the peak concentration comes later).

The time to steady-state after beginning a continuous infusion is also best explored through pharmacokinetic simulation. Again, because the potency of the various opioids differs, the predicted effect site concentrations must be normalized to the final steady-state concentrations to contrast the behavior of the drugs. Using the same prototypes, Fig. 17.7B shows the time required to achieve steady-state effect site concentration (infusion front-end kinetics).

The simulation of simple, constant rate infusions has obvious clinical implications. First, it is clear that for most commonly used intravenous opioids, the time required to reach a substantial fraction of the ultimate steady-state concentration is very long in the context of intraoperative use. To reach a near steady-state more quickly requires a bolus be administered before the infusion is commenced (or increased). Remifentanil perhaps represents a partial exception to this general rule. Another extremely important clinical application of this simulation is that concentrations will rise for many hours after an infusion is commenced (without a bolus); thus practitioners must be aware that concentrations are typically rising even though the infusion rate may have been the same for hours. That remifentanil achieves a near steady-state relatively quickly makes it an especially useful drug for total intravenous anesthesia because it is thus more "titratable."

The time to offset of effect after stopping a steady-state infusion is often explored through context-sensitive half-time simulation (CSHT).[22] Defined as the time required to achieve a 50% decrease in plasma concentration after stopping a continuous, steady-state infusion, the CSHT is a means of normalizing the pharmacokinetic behavior of drugs so that rational comparisons can be made regarding the predicted offset of drug effect. The CSHT is thus focused on infusion back-end kinetics.

Fig. 17.7C shows a CSHT simulation for commonly used opioids (strictly speaking, it is the 50% decrement time because the simulation is for effect site concentrations).[23] Several clinically important points are obvious. First, for most drugs, the time to a



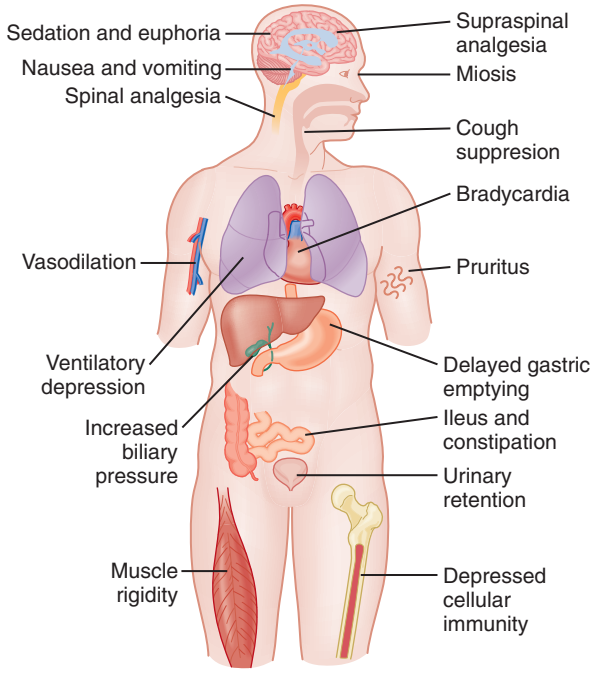
• **Fig. 17.7** Opioid pharmacokinetics. Simulations illustrating front-end and back-end pharmacokinetic behavior after administration by bolus injection or continuous infusions for morphine, hydromorhpone, fentanyl, alfentanil, sufentanil, and remifentanil using pharmacokinetic parameters from the literature (see text for details). *Ce,* Effect site concentration. (Data from references 15–21.)

50% decrease in concentration changes with the length of the infusion. Thus for very brief infusions, the predicted back-end kinetics for the various drugs do not differ much (remifentanil is a notable exception). As the infusion time lengthens, the CSHTs begin to differentiate, providing a rational basis for drug selection. Second, depending on the desired duration of opioid effect, the clinician can choose the shorter-acting drugs or the longer-acting ones. Finally, the shapes of these curves differ depending on the degree of concentration decline required; in other words, the curves representing the time required to achieve a 20% or an 80% decrease in concentration (e.g., the 20% or 80% decrement time simulations) are quite different.[14] Thus, depending on the anesthesia technique applied, the CSHT simulations (or 50% decrement time) are not necessarily the clinically relevant simulations. It is also important to recognize that the CSHT simulation for morphine does not account for its active metabolite (see the section on individual drugs in later text).

Pharmacodynamics

Given that μ-receptor agonists share a common mechanism of action, in most respects the commonly used MOR agonists can be considered pharmacodynamic equals with important pharmacokinetic differences. In other words, their effect profiles, both therapeutic and adverse, are very similar. Their efficacy as analgesics and their propensity to produce ventilatory depression are indistinguishable when one μ-agonists is compared with another at equipotent concentrations. Where pharmacodynamic differences exist, they are typically a function of non-opioid receptor mechanisms, such as histamine release, among others.

Clinically important μ-agonist pharmacodynamic effects are observed in many organ systems. Fig. 17.8 summarizes the major pharmacodynamic effects of the fentanyl congeners. Depending on the clinical circumstances and clinical goals of treatment, some of these widespread effects can be viewed as therapeutic or adverse.



• **Fig. 17.8** Opioid pharmacodynamics. A summary chart of selected effects of the fentanyl congeners (see text for details).

For example, in some clinical settings the sedation produced by μ-agonists might be viewed as a goal of therapy; in others, this would clearly be thought of as an adverse effect.

Therapeutic Effects

The relief of pain is the primary therapeutic effect of opioid analgesics. Acting at spinal and brain μ-receptors, opioids are thought to provide analgesia both by attenuating the nociceptive traffic from the periphery and also by altering the affective response to painful stimulation centrally. μ-agonists are most effective in treating "second pain" sensations carried by slowly conducting, unmyelinated C fibers; they are less effective in treating "first pain" sensations (carried by small, myelinated A-δ fibers) and neuropathic pain. A unique aspect of opioid-induced analgesia (in contrast to drugs like local anesthetics) is that other sensory modalities are not affected (e.g., touch, temperature, among others).

Perioperatively (certainly intraoperatively), the sedation produced by μ-agonists is also one of the targeted effects. The brain is the anatomic substrate for the sedative action of μ-agonists. With increasing doses, μ-agonists eventually produce drowsiness and sleep (the relief of pain no doubt contributes to the promotion of sleep in uncomfortable patients both preoperatively and postoperatively, independent of the intrinsic sedative effect). With sufficient doses (higher than typically used clinically), the μ-agonists produce pronounced δ wave activity on the electroencephalogram that resembles the pattern observed during natural sleep.

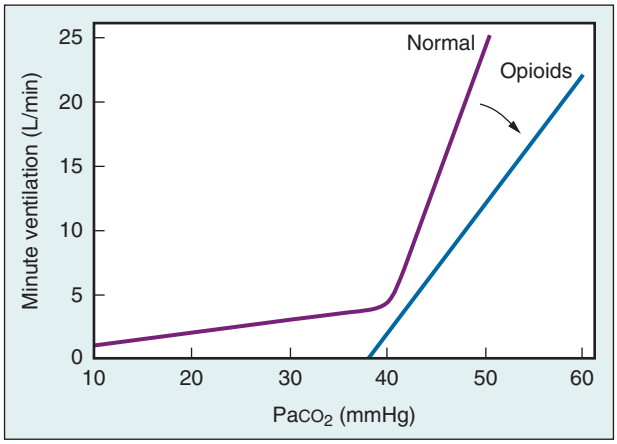
μ-agonists produce significant pain relief at doses that do not produce sleep; this is the basis of their clinical utility in the treatment of pain in ambulatory patients. On the other hand, the fact that increasing doses eventually produce drowsiness (and therefore the inability to request additional doses) is the essential scientific foundation for the safety of patient controlled analgesia devices. It is important to emphasize that μ-agonists, even when given in very high doses, do not reliably produce unresponsiveness and amnesia; thus they cannot be viewed as complete anesthetics when used alone.[24]

Suppression of the cough reflex is another important therapeutic effect of the μ-agonists in the practice of anesthesia. This antitussive effect is mediated through the cough centers in the medulla. Attenuation of the cough reflex presumably makes coughing and struggling against an indwelling endotracheal tube less likely. This effect is particularly important during fiberoptic intubation of the trachea in an awake patient as an approach to the difficult airway. Curiously, dextrorotatory isomers of opioids (e.g., dextromethorphan) produce this effect even though they do not have analgesic activity. Opioids can sometimes be associated with a paradoxical increase in coughing, typically after a bolus dose is administered. This poorly understood phenomenon is often briefly observed during induction of anesthesia when opioids are used as part of the induction regimen.

Adverse Effects

Depression of ventilation is the most significant adverse effect associated with μ-agonist drugs. Of course, when the airway is secured and ventilation is controlled intraoperatively, opioid-induced depression of ventilation is of little consequence. However, in the postoperative period, significant depression of ventilation associated with opioid analgesia can be a life-threatening complication and is a major source of morbidity and mortality, especially in high-risk populations such as patients with obstructive sleep apnea.

μ-agonists alter the ventilatory response to arterial carbon dioxide. That depression of ventilation is mediated by the MOR is supported



• **Fig. 17.9** Opioid-induced ventilatory depression study methodology. The method characterizes the relationship between the partial pressure of carbon dioxide in arterial blood *($Paco_2$)* and minute volume. The curve labeled *Normal* represents the expected response of minute volume to rising $Paco_2$ levels in an awake human. Note the dramatic increase in minute volume as carbon dioxide *(CO_2)* tension rises. The curve labeled *Opioid* represents the blunted response of minute volume to rising CO_2 levels following administration of an opioid. Note that the slope of the curve decreases and the curve no longer has a "hockey-stick" shape; this means that at physiologic $Paco_2$ levels, the patient receiving sufficient opioid may be apneic or severely hypoventilatory. (Adapted with permission from Gross JB: When you breathe IN you inspire, when you DON'T breathe, you…expire: new insights regarding opioid-induced ventilatory depression. *Anesthesiology.* 2003;99:767–770.)

TABLE 17.3 Factors Increasing the Magnitude or Duration of Opioid-Induced Ventilatory Depression

High dose
Sleep
Old age
Central nervous system depressants
Inhaled anesthetics, alcohol, barbiturates, benzodiazepines
Hyperventilation, hypocapnia
Respiratory acidosis
Decreased clearance
Reduction of hepatic blood flow
Renal insufficiency

by the observation that μ-receptor knockout mice do not exhibit the effect when they receive morphine.[25] Central pattern generators in the brainstem are the main anatomic substrate for depression of ventilation by the μ-agonists (see Chapter 29). Detailed studies of the brainstem anatomy involved in the control of ventilation reveal multiple, anatomically proximate collections of cells that are responsive to opioid agonists and antagonists, including the pre-Bötzinger complex in the rostral medulla, and the parabrachial nucleus and Kölliker-Fuse nucleus in the rostral pons.[26] An important nuance of these investigations is that these brainstem nuclei control not only the ventilatory pattern, but also influence the muscles that maintain airway patency.[27]

The depression of ventilation is studied by artificially increasing inspired carbon dioxide while maintaining normal oxygen tension.[28] As shown in Fig. 17.9, an increase in arterial carbon dioxide partial pressure dramatically increases the minute ventilation. Under the influence of opioid analgesics, the curve is flattened and shifted to the right such that at a given carbon dioxide partial pressure the minute ventilation is lower. More importantly, the "hockey-stick" shape of the normal curve is lost such that under the influence of μ-agonists there may be a partial pressure of carbon dioxide below which the patient does not breathe (this point can be thought of as the "apneic threshold"). μ-agonists also depress the hypoxic drive to breathe, although this effect is less important clinically than the effect on carbon dioxide–controlled ventilatory drive.[29]

The clinical signs of depressed ventilation are quite subtle with moderate opioid doses. Postoperative patients receiving opioid analgesic therapy can be awake and alert and yet sensitive testing will reveal significantly decreased minute ventilation. Moderate doses of μ-agonists produce a decrease in the ventilatory rate (often associated with a slightly increased tidal volume). As the opioid concentration is increased, both ventilatory rate and tidal volume progressively decrease, eventually culminating in an irregular ventilatory rhythm and then complete apnea.

A variety of factors can increase the risk of opioid-induced ventilatory depression (Table 17.3). Clear risk factors include high opioid dose, advanced age, concomitant use of other CNS depressants, and renal insufficiency (for morphine). Natural sleep also appears to increase the ventilatory depressant effect of μ-agonists.[30]

Opioids can alter cardiovascular physiology by a variety of mechanisms. Compared with many anesthetic drugs (e.g., propofol, volatile anesthetics), however, the cardiovascular effects of opioids, particularly the fentanyl congeners, are relatively mild (the unique cardiovascular effects of morphine and meperidine are discussed in the section on individual drugs). In fact, in some clinical circumstances, such as when anesthetizing patients with ischemic heart disease, the cardiovascular effects of the fentanyl congeners can be viewed as therapeutic.

The fentanyl congeners produce a slowing of heart rate by directly increasing vagal nerve tone in the brainstem. In experimental animals this effect can be blocked by microinjection of naloxone into the vagal nerve nucleus or by peripheral vagotomy.[31,32] If the bradycardia is considered undesirable in patients, it can be readily treated with antimuscarinic drugs.

Opioids also produce vasodilation by depressing vasomotor centers in the brainstem (i.e., by decreasing central vasomotor tone) and, to a lesser extent, by a direct effect on vessels. This action affects both the venous and arterial vasculature, thereby reducing both preload and afterload. The resulting decrease in blood pressure, while typically mild in healthy patients, is much more pronounced in patients with elevated sympathetic tone such as patients with congestive heart failure or hypertension. At typical clinical doses, opioids do not appreciably alter myocardial contractility.

Opioid-induced muscle rigidity is another potentially serious adverse effect of this drug class. Typically observed during the rapid administration of high bolus doses of the fentanyl congeners, opioid-induced muscle rigidity can make bag-mask ventilation during anesthesia induction impossible; the difficulty with bag-mask ventilation appears to be in large part a function of vocal cord rigidity and closure.[33] The rigidity tends to coincide with the onset of unresponsiveness.[34] Although the mechanism of opioid-induced muscle rigidity is unknown, it does not appear to be a direct action on muscle fibers because it can be prevented and treated with neuromuscular blockers.

In the perioperative setting, perhaps one of the most vexing (although not life-threatening) adverse effects associated with the μ-agonists is nausea and vomiting. Opioids stimulate the chemoreceptor trigger zone in the area postrema on the floor of the fourth ventricle (opioid receptors are expressed here) in the brain. This can lead to nausea and vomiting, an effect that is exacerbated by movement (this is perhaps why ambulatory surgery patients are more likely to be troubled by postoperative nausea and vomiting [PONV]). The use of postoperative opioids is a clear risk factor for the occurrence of PONV.[35] Numerous effective therapies exist for both the prophylaxis and treatment of PONV associated with opioids and other risk factors (see Chapter 28).[36]

Although it is of no clinical consequence in terms of patient safety or suffering, the pupillary constriction induced by μ-agonists can be a useful diagnostic sign indicating some ongoing opioid effect. Opioids stimulate the Edinger-Westphal nucleus of the oculomotor nerve to produce miosis. Even small doses of opioid elicit the response and very little tolerance to the effect develops. Thus miosis is a useful albeit nonspecific indicator of opioid exposure even in opioid-tolerant patients. Opioid-induced pupillary constriction is naloxone reversible.

The μ-agonists have important effects on gastrointestinal physiology. Opioid receptors are found throughout the enteric plexus of the bowel; their activation causes tonic contraction of gastrointestinal smooth muscle, thereby decreasing coordinated, peristaltic contractions. Clinically, this results in delayed gastric emptying and presumably higher gastric volumes in patients receiving opioid therapy preoperatively. Postoperatively, patients can develop opioid-induced ileus that can potentially delay the resumption of proper nutrition and discharge from the hospital. An extension of this acute problem is the chronic constipation associated with long-term opioid therapy.

Similar effects are observed in the biliary system, which also has an abundance of μ-receptors. The μ-agonists can produce contraction of the gallbladder smooth muscle and spasm of the sphincter of Oddi, potentially causing a falsely positive cholangiogram during gallbladder and bile duct surgery. These untoward effects are completely reversible by naloxone and can be partially reversed by glucagon treatment. The mixed agonist-antagonists (e.g., butorphanol) appear to produce less pronounced biliary effects.[37]

In contrast to the gastrointestinal system, the urologic effects of opioids are regarded as minimal. Opioids can cause urinary retention by decreasing bladder detrusor tone and by increasing the tone of the urinary sphincter. These effects are at least in part centrally mediated, although peripheral effects are also likely given the widespread presence of opioid receptors in the genitourinary tract.[38,39] Although the urinary retention associated with opioid therapy is not typically pronounced, it can be troublesome in males, particularly when the opioid is administered intrathecally or epidurally.

The euphoria produced by μ-agonists must be viewed as an adverse effect because it is the primary reason this drug class is so widely abused. Opioid addicts experience a euphoria that drives a drug-seeking lifestyle that often ends tragically in death or incarceration. The physical tolerance and dependence that inevitably develop in chronic users result in an increased dose requirement and a withdrawal syndrome upon cessation of drug intake. The withdrawal syndrome is characterized by intense drug craving, restlessness, body aches and pains, runny nose, lacrimation, and perspiration. An acute withdrawal syndrome can be precipitated by the administration of opioid antagonists (e.g., naloxone) during routine clinical care to patients who are not openly known to be opioid addicts.

Although perhaps not typically thought of as an acute effect that would be relevant to perioperative practice, opioids are known to depress cellular immunity. This effect is particularly well documented for morphine, although data exist for other μ-agonists as well. Morphine and the endogenous opioid β-endorphin, for example, inhibit the transcription of interleukin 2 in activated T cells, among other immunologic effects.[40] It appears that individual opioids (and perhaps classes of opioids) differ in terms of the exact nature and extent of their immunomodulatory effects. The clinical implications of opioid-induced impairment of cellular immunity are not well understood, but these effects might influence wound healing, perioperative infection risk, and cancer recurrence, among other outcomes. How this rapidly expanding knowledge will eventually impact clinical practice is evolving.

Drug Interactions

Drug interactions can be based on two mechanisms: pharmacokinetic (i.e., where one drug influences the concentration of the other) or pharmacodynamic (i.e., where one drug influences the effect of the other). In anesthesia practice, although unintended pharmacokinetic interactions sometimes occur, pharmacodynamic interactions occur with virtually every anesthetic and are produced by design.

The most common pharmacokinetic interaction in opioid clinical pharmacology is observed when intravenous opioids are combined with propofol. Perhaps because of the hemodynamic changes induced by propofol and their impact on pharmacokinetic processes, opioid concentrations are expected to be modestly higher when given in combination with a continuous propofol infusion.[41]

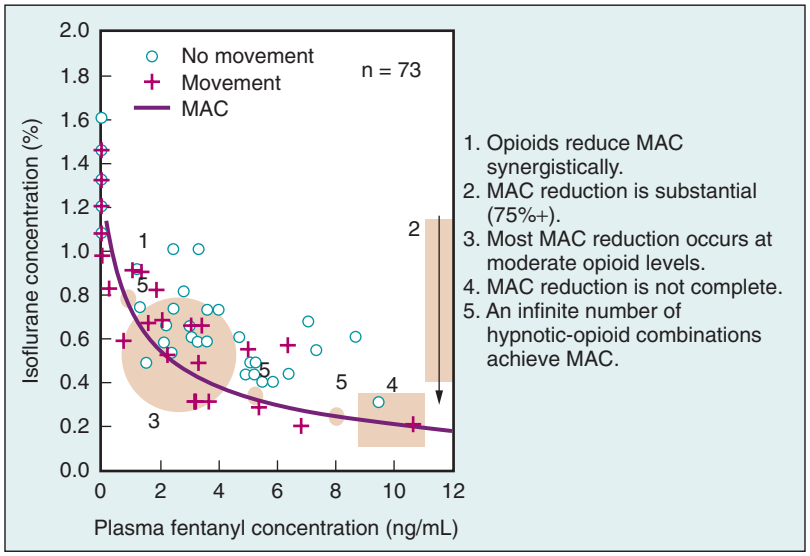
The most important pharmacodynamic drug interaction involving opioids is the synergistic interaction that occurs when opioids are combined with CNS depressants (see Chapter 5).[42] As illustrated in Fig. 17.10 for fentanyl and isoflurane, opioids dramatically reduce the minimum alveolar concentration (MAC) of a volatile anesthetic. Careful examination of "opioid-MAC reduction" data such as in Fig. 17.10 reveals several clinically critical concepts. First, opioids synergistically reduce MAC. Second, the MAC reduction is substantial (depending on the dose, as much as 75% or more). Third, most of the MAC reduction occurs at moderate opioid levels (i.e., even modest opioid doses substantially reduce MAC). Fourth, the MAC reduction is not complete; that is, opioids are not complete anesthetics. The addition of the opioid cannot completely eliminate the need for the other anesthetic. And fifth, there are an infinite number of hypnotic-opioid combinations that will achieve MAC (this implies that clinicians must choose the optimal combination based on the goals of the anesthetic and operation). As one might expect based on first principles, the synergistic interaction applies to both therapeutic and adverse effects such as depression of ventilation and hemodynamic variables.[43]

Because general anesthesia in the modern era is a least a two-drug process consisting of a sedative and an opioid, these MAC reduction concepts form an important part of the scientific foundation of anesthesia clinical pharmacology. All of these concepts also apply when opioids are used in combination with propofol for total intravenous anesthesia (TIVA).[44] Recent work has advanced the understanding of opioid-sedative pharmacodynamic interactions by applying response surface analysis methods.[45] This approach enables the investigator to identify optimal target concentrations of the sedative and the opioid through simulation (see Chapter 2).

Special Populations

Hepatic Failure

Perhaps surprisingly, even though the liver is the metabolic organ primarily responsible for the biotransformation of most opioids,



• **Fig. 17.10** Volatile anesthetic minimum alveolar concentration *(MAC)* reduction by opioids: the prototype example of isoflurane and fentanyl. The *solid curve* is MAC (see text for details). (Adapted with permission from McEwan AI, Smith C, Dyar O, et al. Isoflurane minimum alveolar concentration reduction by fentanyl. *Anesthesiology.* 1993;78:864–869.)

the degree of liver failure typically encountered in perioperative patients is usually not severe enough to have a major impact on the disposition of the fentanyl congeners.[13] The anhepatic phase of orthotopic liver transplantation is a notable exception to this general rule. With ongoing drug administration, concentrations of opioids that rely on hepatic metabolism are expected to rise significantly when the patient has no liver. Even after partial liver resection a decrease in the ratio of morphine glucuronides to morphine is observed, indicating a decrease in the rate of morphine metabolism.[46] Because remifentanil's metabolism is completely unrelated to hepatic clearance mechanisms, its disposition is not affected during liver transplantation.[47]

Of course, pharmacodynamic considerations can be important for opioid therapy in patients with severe liver disease. Patients with ongoing hepatic encephalopathy are thought to be particularly vulnerable to the sedative effects of opioids and thus this drug class must be used with caution in these patients.[13]

Kidney Failure

Renal failure has implications of major clinical importance with respect to morphine and meperidine (see the later section on individual drugs). For the fentanyl congeners, the clinical importance of kidney failure is much less marked, but nonetheless measurable. As with hepatic failure, remifentanil is also an exceptional case with respect to renal failure. Remifentanil's metabolism is not affected by kidney disease (although the inactive acid metabolite does accumulate in such patients).[48]

Morphine is principally metabolized by conjugation in the liver; the resulting water-soluble glucuronides (i.e., morphine 3-glucuronide and morphine 6-glucuronide [M3G and M6G] are excreted via the kidney. The kidney also plays a role in the conjugation of morphine and may account for as much as half of its conversion to M3G and M6G.

M3G is inactive, but M6G is an analgesic with a potency rivaling morphine. Very high levels of M6G and life-threatening respiratory depression can develop in patients with renal failure as illustrated in Fig. 17.11.[49] In view of these pharmacokinetic changes induced by renal failure, morphine may not be a good choice in patients with severely altered renal clearance mechanisms.

The clinical pharmacology of meperidine is also significantly altered by renal failure. Normeperidine, the main metabolite, has analgesic and excitatory CNS effects that range from anxiety and tremulousness to myoclonus and frank seizures. Because the active metabolites are subject to renal excretion, CNS toxicity secondary to accumulation of normeperidine is especially a concern in patients with renal failure. This shortcoming of meperidine has caused many hospital formularies to restrict its use or to remove it from the formulary altogether.

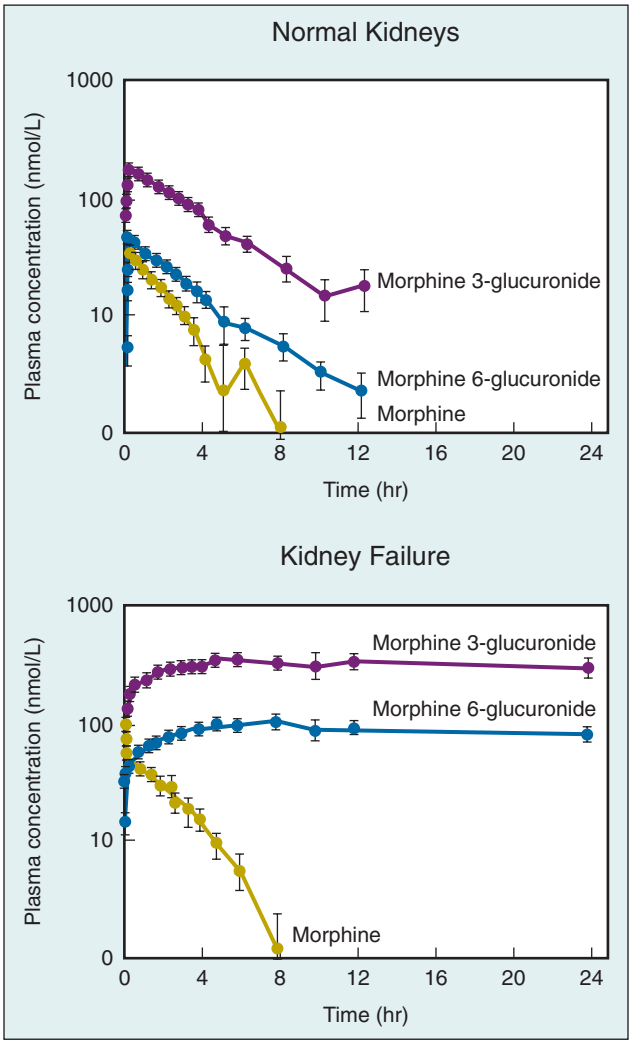
Gender

Recent data suggest that gender may have an important influence on opioid pharmacology. There is evidence, for example, that morphine is more potent in women than in men (i.e., that a lower concentration is required to produce comparable analgesia) and that it has a slower onset of action in women.[50] Although this information is clearly incomplete and emerging, some of these differences may be related to cyclic gonadal hormones.

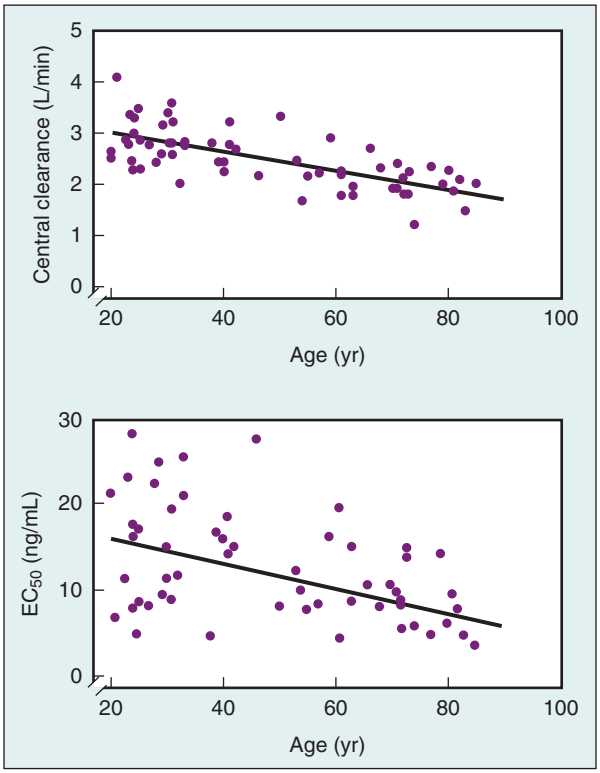
Age

Advancing age is undoubtedly an important factor influencing the clinical pharmacology of opioids. As shown in Fig. 17.12, kinetic-dynamic model-building studies in volunteers using the processed electroencephalogram as a surrogate measure of opioid effect have reproducibly shown that the fentanyl congeners are more potent in older patients.[19,21] Pharmacokinetic differences have also been described, including decreases in clearance and central distribution volume in older patients.

Although pharmacokinetic changes also play a role, pharmacodynamic differences are primarily responsible for the decreased dose requirement in older patients (e.g., >65 years of age). These combined pharmacokinetic and pharmacodynamic changes mandate



• **Fig. 17.11** The pharmacokinetics of morphine and its metabolites in normal volunteers versus kidney failure patients. Note the significant accumulation of the metabolites in renal failure. (Adapted with permission from Osborne R, Joel S, Grebenik K, et al. The pharmacokinetics of morphine and morphine glucuronides in kidney failure. *Clin Pharmacol Ther.* 1993;54: 158–167.)



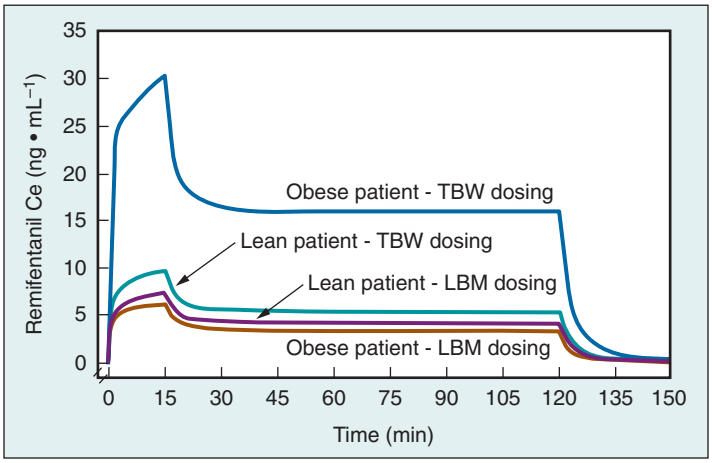
• **Fig. 17.12** The influence of age on the clinical pharmacology of remifentanil. Although there is considerable variability, in general, older subjects have a lower central clearance and a higher potency (lower EC_{50}). *EC_{50}*, Effective concentration for 50% of maximal effect. (Adapted with permission from Minto CF, Schnider TW, Egan TD, et al. Influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanil. I. Model development. *Anesthesiology.* 1997;86:10–23.)

a reduction in remifentanil dosage by at least 50% or more in seniors. Similar dosage reductions are also prudent for other μ-agonists.

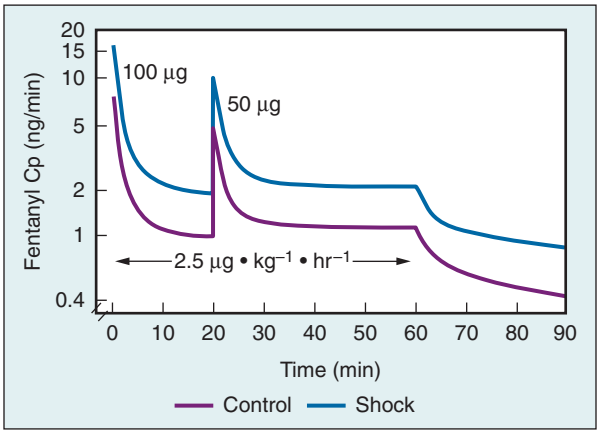
Obesity

Although detailed information is unavailable for many commonly used opioids, evidence from the study of drugs introduced more recently suggests that body weight is an important factor influencing the clinical pharmacology of opioids. Opioid pharmacokinetic parameters, especially clearance, are more closely related to lean body mass than to total body weight (TBW). In practical terms, this means that morbidly obese patients do indeed require a higher dosage than lean patients to achieve the same target concentration, but the very obese patients do not need nearly as much as would be suggested by their TBW.[51]

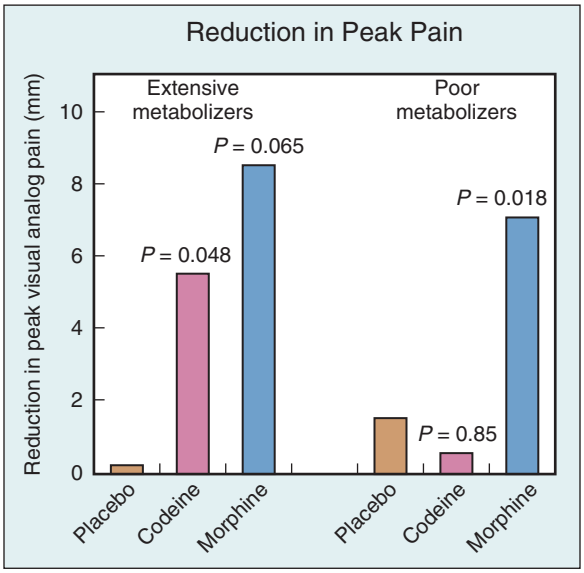
For example, as illustrated in the pharmacokinetic simulation shown in Fig. 17.13, a TBW- based dosing scheme in an obese patient results in excessive remifentanil effect site concentrations



• **Fig. 17.13** A pharmacokinetic simulation illustrating the consequences of calculating the remifentanil dosage based on total body weight *(TBW)* or lean body mass *(LBM)* in obese and lean patients (1-μg/kg bolus injection followed by an infusion of 0.5 μg/kg per minutes for 15 minutes and 0.25 μg/kg per minute for an additional 105 minutes). Note that TBW-based dosing in an obese patient results in dramatically higher concentrations. *Ce,* Effect site concentration. (Adapted with permission from Egan TD, Huizinga B, Gupta SK, et al. Remifentanil pharmacokinetics in obese versus lean patients. *Anesthesiology.* 1998;89:562–573.)



• **Fig. 17.14** A pharmacokinetic simulation illustrating the influence of severe hemorrhagic shock on the disposition of fentanyl. Animals in shock achieve substantially higher blood concentrations when receiving the same fentanyl dose. *Cp,* concentration in the plasma. (Adapted with permission from Egan TD, Kuramkote S, Gong G, et al. Fentanyl pharmacokinetics in hemorrhagic shock: a porcine model. Anesthesiology 1999;91:156–166.)



• **Fig. 17.15** A volunteer study demonstrating that codeine is no more effective than placebo in patients who cannot convert codeine to morphine (i.e., poor metabolizers). Morphine retains its normal analgesic efficacy in such patients. Both codeine and morphine are effective in normal subjects (i.e., extensive metabolizers). The *bars* represent the median of the maximal reduction in peak pain as assessed by the cold pressor test using a visual analog scale. (Adapted with permission from Poulsen L, Brosen K, Arendt-Nielsen L, et al. Codeine and morphine in extensive and poor metabolizers of sparteine: pharmacokinetics, analgesic effect and side effects. *Eur J Clin Pharmacol.* 1996;51:289–295.)

compared with dosing calculation based on lean body mass.[52] In contrast, for lean patients, the concentrations that result from TBW-based dosing regimens are not much greater than those based on lean body mass. Recent evidence based on a large pharmacokinetic modeling study has confirmed these general impressions regarding remifentanil dosing guidelines in obese patients.[53]

Hemorrhagic Shock

Although the data are from animal studies, it is clear that severe hemorrhage significantly alters the pharmacokinetic behavior of opioids. Both the clearance and distribution parameters are affected. As shown in the pharmacokinetic simulation presented in Fig. 17.14, subjects experiencing severe hemorrhage can be expected to achieve blood concentrations that are approximately double those observed in control subjects when they receive identical doses.[54] Even a drug that does not require delivery to a metabolic organ like remifentanil is affected, although the effect is not as dramatic.[55] There is clear evidence from case reports that these observations apply to human pharmacology as well.[56]

Unique Features of Individual Agents

Codeine

Codeine, while not commonly used intraoperatively, has special importance among opioids because of a well-characterized pharmacogenomic nuance associated with it. Codeine is actually a prodrug that is metabolized in part by O-demethylation into morphine, a metabolic process mediated by the liver P450 isoform CYP 2D6.[57] As demonstrated in Fig. 17.15, patients who lack CYP 2D6 because of deletion, frame shift or splice mutations (approximately 10% of the Caucasian population), or those whose CYP 2D6 is inhibited (e.g., patients taking quinidine) do not respond normally to codeine even though they exhibit a normal response to morphine.[58,59]

Interestingly, Asians have less CYP 2D6 activity and thus may be an ethnic group particularly resistant to codeine therapy.[60] Conversely, certain ethnic groups (e.g., Ethiopians) are thought to be particularly susceptible to the effects of codeine because they carry frequently duplicated, functional CYP 2D6 genes, resulting in the ultrarapid conversion of codeine to morphine.[61]

In addition to therapeutic failure, pharmacogenetic variants in codeine metabolism can result in tragic adverse drug reactions. Functional CYP 2D6 gene duplication has recently been implicated in fatalities among infants breastfed by mothers who are ultrarapid metabolizers.[62] Deaths in children who received codeine after tonsillectomy and who, upon postmortem genotyping, were confirmed to be ultrarapid metabolizers have been reported; morphine levels in these children at autopsy were well beyond the toxic threshold.[63] Ironically, codeine was presumably prescribed to these children to avoid the respiratory depression typically associated with more powerful opioids.

More than 80 different alleles for CYP 2D6 have now been identified, creating numerous possible phenotypes for codeine metabolism. Consensus guidelines for the interpretation of CYP 2D6 diplotypes enable the clinician to categorize patients into one of four categories, reflecting a range of codeine conversion to morphine, from none to extensive.[64] Unfortunately, for the vast majority of patients who are candidates for codeine therapy, their diplotype is unknown at the time of treatment. Until an era dawns when most patients have their entire genome sequenced so that the pharmacogenetic information is available to the clinician at the point of care as part of a "personalized medicine" approach to health care, codeine's decline in popularity among prescribers is likely to continue.

Morphine

Morphine is the prototype opioid against which all newcomers are evaluated. Despite a century of opioid research, there is no

evidence that any synthetic opioid is more effective in controlling pain than nature's morphine. Were it not for the histamine release–mediated hypotension observed intraoperatively with high doses of morphine, it is conceivable that fentanyl would not have replaced morphine as the most commonly used opioid in anesthesia practice.

An important detail relating to morphine's clinical pharmacology is its slow onset time. Morphine's pK_a renders it almost completely ionized at physiologic pH. This property, combined with its low lipid solubility, presumably accounts for morphine's prolonged latency to peak effect; morphine penetrates the CNS slowly. This feature has both advantages and disadvantages. The prolonged latency to peak effect (see Fig. 17.7A) means that morphine is less likely to cause acute respiratory depression after bolus injection of typical analgesic doses compared with the more rapid-acting drugs because the relationship between minute ventilation and the partial pressure of carbon dioxide changes more slowly (thus there is more time for carbon dioxide to rise and sustain ventilatory drive). On the other hand, the slow onset time means that clinicians are more likely to inappropriately "stack" multiple morphine doses in a patient experiencing severe pain, thus creating the potential for a toxic "overshoot."[65]

Morphine's active metabolite, M6G, also has very important clinical implications. Although conversion to M6G accounts for only 10% of morphine's metabolism, M6G contributes to morphine's analgesic effects even in patients with normal renal function, particularly with longer-term use. Because of morphine's high hepatic extraction ratio, the bioavailability of orally administered morphine is significantly lower than after parenteral injection. The hepatic first-pass effect on orally administered morphine results in high M6G levels; in fact, it appears that M6G may be the primary active compound when morphine is administered orally.[66] Accumulation of M6G to potentially toxic levels in dialysis patients is another important implication of this active metabolite.

Methadone

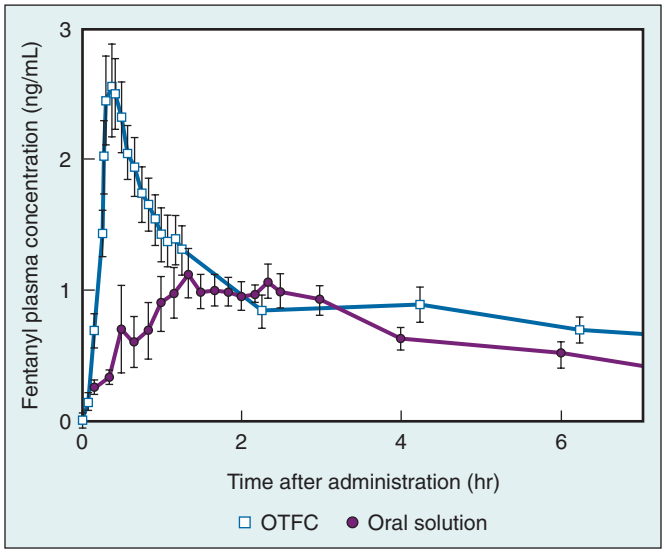
Available in both intravenous and oral forms, racemic methadone has long been a mainstay in the treatment of opioid addicts because its long-acting pharmacokinetic profile makes the development of an acute withdrawal syndrome less likely (i.e., methadone maintenance therapy). The N-methyl-D-aspartate (NMDA) receptor antagonism action of the dextrorotatory isomer of methadone may also serve to attenuate the effects of opioid tolerance and withdrawal syndrome.[67,68]

Methadone is also increasingly used in the treatment of patients with chronic pain, particularly cancer-related pain.[69] Methadone's propensity to prolong the QT interval of the electrocardiogram by blocking the delayed rectifier potassium ion channel may contribute to increased mortality in this patient population.[70]

Fentanyl

As the original fentanyl congener, its clinical application is well entrenched and highly diverse. Perhaps the most unique aspect of fentanyl's clinical application is the numerous ways in which fentanyl is delivered. In addition to the intravenous method, fentanyl has also been delivered by transdermal, transmucosal, transnasal, and transpulmonary routes.

Oral transmucosal delivery of fentanyl citrate results in the faster achievement of higher peak levels than when the same dose is swallowed as seen in Fig. 17.16.[71] It is the avoidance of the first-pass effect through transmucosal absorption that results in this significantly greater bioavailability. That oral transmucosal delivery of fentanyl citrate is noninvasive and rapid in onset has made it a successful therapy for breakthrough pain in opioid-tolerant cancer patients, often in combination with a transdermal fentanyl patch.



• **Fig. 17.16** A volunteer study contrasting the bioavailability and peak plasma concentrations of an identical dose (15 mcg/kg) of fentanyl delivered either orally or through the oral mucosa (i.e., oral transmucosal fentanyl *[OTFC]*). Note that the transmucosal approach yields higher peak concentrations earlier. (Adapted with permission from Streisand JB, Varvel JR, Stanski DR, et al. Absorption and bioavailability of oral transmucosal fentanyl citrate. *Anesthesiology.* 1991;75:223–229.)

Alfentanil

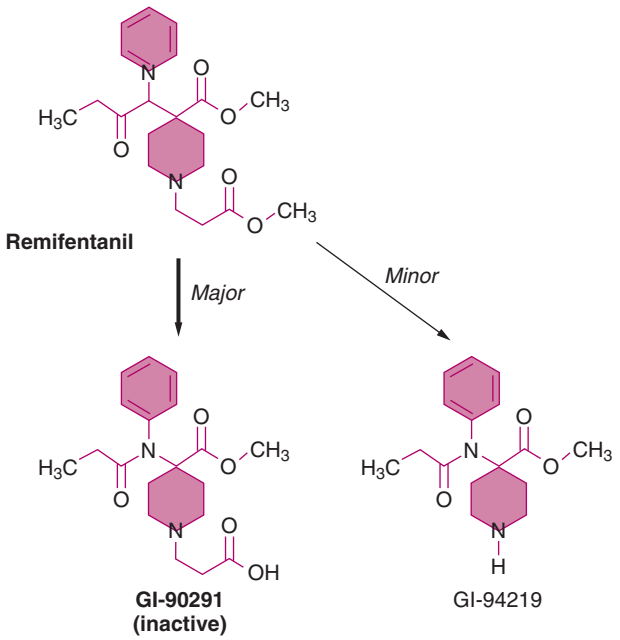
Alfentanil was the first opioid to be administered almost exclusively by continuous infusion. Because of its relatively short terminal half-life, alfentanil was originally thought to be an opioid with a rapid offset of effect after termination of a continuous infusion.[72] Subsequent advances in pharmacokinetic theory (i.e., the CSHT) proved this assertion to be false.[14] However, alfentanil is in fact a short-acting drug after a single bolus injection because of its high diffusible fraction; it reaches peak effect site concentrations quickly and then begins to decline (see earlier "Pharmacokinetics" and Fig. 17.7). Alfentanil illustrates how a drug can exhibit different pharmacokinetic profiles depending on the method of administration (i.e., bolus vs. continuous infusion). Relative to fentanyl and sufentanil, hepatic metabolism of alfentanil is more unpredictable because of the significant interindividual variability of hepatic CYP3A4, the primary enzyme responsible for alfentanil biotransformation. Because alfentanil has a relatively low hepatic extraction ratio compared with fentanyl, it is more vulnerable to variations in CYP 3A4 activity.[73]

Sufentanil

Sufentanil's distinguishing feature is that it is the most potent opioid commonly used in anesthesia practice. Because it is more intrinsically efficacious at the opioid receptor, the absolute doses used are much smaller compared with other less potent drugs (e.g., 1000-fold less than morphine).

Remifentanil

Remifentanil is a prototype example of how specific clinical goals can be achieved by designing molecules with specialized



• **Fig. 17.17** Remifentanil metabolic pathway. De-esterification (i.e., ester hydrolysis) by nonspecific plasma and tissue esterases to an inactive acid metabolite *(GI-90291)* accounts for the vast majority of remifentanil's metabolism. (Adapted with permission from Egan TD, Lemmens HJ, Fiset P, et al. The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. *Anesthesiology.* 1993;79: 881–892.)

structure-activity (or structure-metabolism) relationships. As shown in Fig. 17.17, the medicinal chemists responsible for the development of remifentanil sought to produce a potent opioid that would lose its μ-receptor agonist activity upon ester hydrolysis, thereby creating an intravenous opioid with a very short-acting pharmacokinetic profile.[74] The perceived unmet need driving remifentanil's development was that the practice of anesthesia requires a degree of pharmacokinetic responsiveness unnecessary in most medical disciplines and that anesthetics (opioids included) therefore ought to be short-acting so that they can be titrated during the rapidly changing conditions of anesthesia and surgery.

Compared with the currently marketed fentanyl congeners, remifentanil's CSHT is short, on the order of about 5 minutes (Fig. 17.7C).[75] Pharmacodynamically, remifentanil exhibits a short latency-to-peak effect similar to alfentanil and a potency slightly less than fentanyl (Fig. 17.7A).[76]

Remifentanil's role in modern anesthesia practice is now relatively well established; its unique pharmacokinetic profile makes it possible to manipulate rapidly the degree of opioid effect in a way that could not be achieved with the previously marketed fentanyl congeners. Remifentanil is therefore perhaps best suited for cases where its responsive pharmacokinetic profile can be exploited to advantage (e.g., when rapid recovery is desirable, when the anesthetic requirement rapidly fluctuates, when opioid titration is unpredictable or difficult, when there is a substantial danger to opioid overdose, or when a "high-dose" opioid technique is advantageous but the patient is not going to be mechanically ventilated postoperatively).[77] Today, remifentanil's most common clinical application may be the provision of TIVA in combination with propofol. It is also commonly used by bolus injection when a brief pulse of opioid effect followed by rapid recovery is advantageous (e.g., in preparation for local anesthetic injection during Monitored Anesthesia Care).

Opioid Agonist-Antagonists and Pure Antagonists

Because they bind to opioid receptors, the "mixed" agonist-antagonists and the pure antagonists are also classified as opioids. Opioid agonist-antagonists, of which nalbuphine is perhaps the modern prototype, are structurally related to morphine but do not behave as full agonists. These drugs serve as analgesics with more limited ventilatory depression and a lower potential for dependence as they demonstrate a "ceiling effect," producing less analgesia compared with pure agonists. The lower abuse potential was the primary perceived unmet need underlying the development of these drugs. Drugs in this category are used for the treatment of chronic pain, as well as the treatment of opioid addiction. These drugs cause some degree of competitive antagonism (i.e., withdrawal symptoms) when administered in the presence of ongoing full agonist activity (e.g., when administered after morphine and other pure agonists).

Pure opioid antagonists, of which naloxone is the prototype, are complete competitive antagonists of the opioid receptor that are devoid of any intrinsic agonist activity. These pure antagonists are used in the management of acute opioid overdose and chronic abuse.

Nalbuphine and Others

This group of synthetic and semisynthetic opioids includes nalbuphine, pentazocine, and butorphanol; these drugs are partial agonists at the κ receptor and complete, competitive antagonists at the μ-receptor. Both the analgesic and ventilatory depressant effects of these drugs exhibit a ceiling effect when compared to morphine[78] and they do not reduce MAC as powerfully as morphine or fentanyl.[79]

As a class, these opioid agonist-antagonists (or "partial agonists") were developed with the hope that they would be effective analgesics but less subject to diversion and abuse. These drugs are indeed efficacious in the treatment of mild to moderate pain (and they do have less abuse potential), but the analgesic ceiling effect has limited their more widespread use. Perhaps their most common perioperative use is the reversal of excessive opioid-induced ventilatory depression (μ-antagonism) while maintaining some analgesic effect (partial κ agonism).[80] As μ-antagonists, these drugs will of course precipitate a withdrawal syndrome in opioid-dependent patients[81] and are thus sometimes used in the maintenance treatment of opioid addicts.

Buprenorphine is a related drug that is an antagonist at the κ receptor but a partial agonist at the μ-receptor.[82] Buprenorphine is increasingly used in the treatment of opioid addiction.

Naloxone and Naltrexone

Naloxone, a derivative of oxymorphone, is a competitive antagonist of all opioid receptor types, but its greatest affinity is for the μ-receptor.[83] When administered in typical doses in the absence of ongoing opioid therapy (or abuse), naloxone has no discernable pharmacodynamic effects. When opioid effects are present, naloxone given in sufficient doses can reverse all effects mediated by opioid receptors.[84]

The most common clinical use of naloxone perioperatively is the reversal of excessive opioid-induced ventilatory depression.[85] Its important role in this regard has merited naloxone's inclusion on the World Health Organization's List of Essential Medicines. Other uses include the emergency reversal of ventilatory depression in neonates whose mothers received opioids for labor analgesia,

and in cases of accidental or intended opioid overdose (e.g., heroin) in the emergency department. Naloxone is also sometimes used in much smaller doses during emergence from anesthesia to restore adequate ventilatory effort and thereby expedite extubation of the trachea. The treatment of opioid-induced pruritus using small doses is another common therapeutic application.

A few nuances of naloxone's clinical pharmacology are extremely important for safe use. Naloxone is rapidly metabolized in the liver and has a very high clearance; thus its duration of action is nearly always shorter than that of the opioid whose effects it is intended to reverse. Patients who receive naloxone for the emergency reversal of life-threatening ventilatory depression must be monitored for recurrence of the opioid effects. Repeated naloxone dosing may be necessary to sustain adequate ventilation. Also, rarely, naloxone administration has been complicated by severe adverse hemodynamic effects including pulmonary edema and even sudden death in previously healthy individuals (some tachycardia is to be expected).[86] Other adverse effects include acute withdrawal syndrome, nausea, vomiting, and seizures, among others.[84]

In response to the opioid abuse epidemic in the United States, new naloxone delivery systems have been developed that are intended for emergency use by lay persons in the event of opioid overdose; these include nasal spray and autoinjector preparations.[87,88]

Several drugs closely related to naloxone have been developed for other purposes. Naltrexone, a longer-acting μ-opioid antagonist available in oral, injectable, and implantable forms, is used in the long-term management of previously detoxified opioid addicts in combination with other nonpharmacologic therapies.[89] Methylnaltrexone and alvimopan, permanently charged opioid antagonists that do not easily enter the CNS, were developed for the prevention and treatment of opioid-induced bowel dysfunction (see later text).

Clinical Application

Opioids play a vital role in virtually every area of anesthesia practice. In the treatment of postoperative pain, opioids are the primary therapeutic agent, whereas in most other settings in perioperative medicine opioids are therapeutic adjuncts used in combination with other drugs.

Common Clinical Indications

Postoperative analgesia is the longest standing indication for opioid therapy in anesthesia practice and of course dates back to the earliest days of the specialty. In the modern era, opioid administration via PCA devices is perhaps the most common mode of delivery. In recent years, opioids are increasingly combined postoperatively with various other agents such as nonsteroidal antiinflammatory drugs to increase efficacy and safety (see Chapter 16).

Internationally, the most common clinical indication for opioids in anesthesia practice is their use as part of what came to be known as "balanced anesthesia." The term connotes the use of multiple agents (e.g., inhalation agents, volatiles, neuromuscular blockers, and opioids) in smaller doses to produce the state of anesthesia. With this technique, the opioids are primarily used for their MAC reduction effects. A basic assumption underlying this balanced anesthesia approach is that the drugs used in combination mitigate the disadvantages of the individual drugs (i.e., the inhaled agents) used in higher doses as monotherapy.

"High-dose opioid anesthesia," a technique originally described for morphine in the early days of open heart surgery[90] and later associated with the fentanyl congeners,[91] is another common application of opioids. The original scientific underpinning of this approach was that high doses of opioids enabled the clinician to reduce the volatile agent to a minimum, thereby avoiding the direct myocardial depression and other untoward hemodynamic effects associated with high concentrations of volatile anesthetics in patients whose cardiovascular systems were already compromised. That the fentanyl drugs often produce a relative bradycardia is also thought to be helpful in mitigating against myocardial ischemia. Although the general concept is still applied, the opioid doses used today are more moderate. In this setting opioids are also administered for their possible beneficial effects in terms of cardioprotection (i.e., preconditioning).

TIVA is a more recently developed and increasingly popular indication for opioids in anesthesia practice. As the name implies, this technique relies entirely on intravenous agents for the provision of general anesthesia. Most commonly, continuous infusions of remifentanil or alfentanil are combined with a propofol infusion. Both the opioid and the sedative are often delivered by target-controlled infusion (TCI)-enabled pumps. A clear advantage of this technique, perhaps among others, is the enhanced patient well-being in the early postoperative period, including less nausea and vomiting and often a feeling of euphoria.[92]

Rational Drug Selection and Administration

In articulating a scientific foundation for rational opioid selection, it is most important to recognize that pharmacokinetic considerations are paramount. Indeed, the μ-agonists can be considered pharmacodynamic equals with important pharmacokinetic differences.[93] In other words, for practical purposes all μ-agonists are essentially equally efficacious when equipotent concentrations are achieved, but they differ in terms of their pharmacokinetic behavior. Thus rational selection of one μ-agonist over another requires the clinician to identify the desired temporal profile of drug effect and then choose an opioid that best achieves it (within constraints such as pharmacoeconomic concerns).

In selecting the appropriate opioid, among the key questions to address are as follows: How quickly must the desired opioid effect be achieved? How long must the opioid effect be maintained? How critical is it that opioid-induced ventilatory depression or sedation dissipate quickly (e.g., will the patient be mechanically ventilated postoperatively)? Is the capability to raise and lower the level of opioid effect quickly during the anesthetic critical? Will there be significant pain postoperatively that will require opioid treatment? All of these questions relate to the optimal temporal profile of opioid effect. The answers to these questions are addressed through the application of pharmacokinetic concepts.

For example, when a brief pulse of opioid effect followed by rapid recovery is desired (e.g., to provide analgesia for a retrobulbar block), a bolus of remifentanil or alfentanil might be preferred. When long-lasting opioid effect is desired, such as when there will be significant postoperative pain or when the patient's trachea will remain intubated, a fentanyl infusion is a prudent choice. In cases where it is critical that the patient be awake and alert shortly after the procedure is finished (e.g., a craniotomy in which the surgeons hope to perform a neurologic exam in the operating room immediately postoperatively), a remifentanil infusion might be advantageous.

The formulation of a rational administration strategy also requires the proper application of pharmacokinetic principles. An important goal of any dosing scheme is to reach and maintain a steady-state

level of opioid effect. To achieve a steady-state concentration in the site of action, opioids are frequently administered by continuous infusion. This is increasingly accomplished through the use of TCI technology (see later text), which requires familiarity with the appropriate pharmacokinetic model for the opioid of interest. When these systems are not available, the clinician must remember that infusions must be preceded by a bolus to come to a near–steady state in a timely fashion.

Computerized Delivery Methods

Advances in pharmacologic modeling and infusion pump technology have now made it possible to administer injectable anesthetics via a computer-controlled infusion pump.[94] By coding a pharmacokinetic model into a computer program and linking it to an electronic pump modified to accept computerized commands, delivery according to a drug's specific pharmacokinetic parameters can be achieved. The physician operating a TCI system designates a target concentration to achieve rather than specifying an infusion rate. The TCI system then calculates the necessary infusion rates to achieve the targeted concentration. The system changes the infusion rates at frequent intervals (i.e., as often as every 10 seconds). Successful use of a TCI pump thus requires knowledge of the therapeutic concentrations appropriate for the specific clinical application.

Computer-controlled drug delivery in the operating room is an exciting area with well-established clinical utility, although it is admittedly difficult to demonstrate obvious outcome improvements compared to traditional delivery methods. TCI administration of opioids is common for all of the fentanyl congeners. Although TCI systems are widely used in North America for research purposes, they are not yet commercially available for routine clinical use (unlike much of the rest of the world).[95]

Emerging Developments

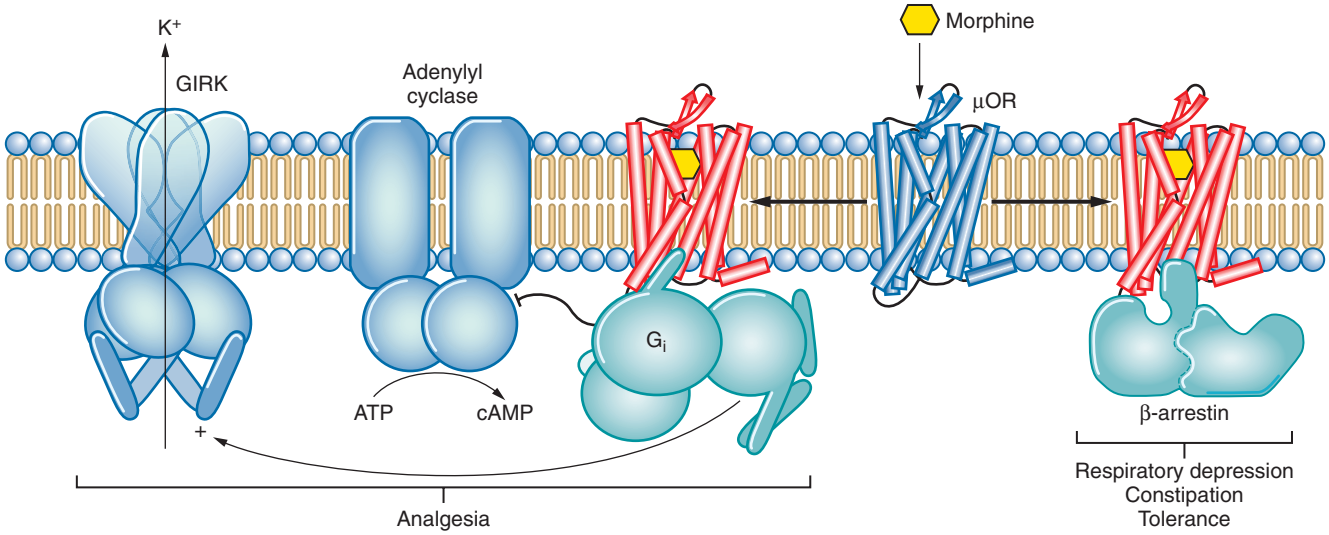
Opioids and Cancer Recurrence

Concerns have been raised recently that opioids administered as part of a general anesthetic for cancer surgery may have an adverse impact on cancer recurrence rates. This concern is supported by considerable in vitro and animal data demonstrating immunosuppressive and angiogenic effects of opioids (particularly morphine). Some early, retrospective data comparing prostate cancer recurrence rates in patients receiving standard postoperative opioid analgesia with those receiving alternative techniques (e.g., epidural pain management) generated the hypothesis that perioperative opioid use may promote cancer recurrence.[96] Some more recent, larger, retrospective studies focused on other types of cancer have failed to corroborate these earlier findings,[97,98] whereas other investigations have yielded supportive evidence.[99]

Confirmation of the hypothesis that perioperative opioid therapy promotes cancer recurrence would presumably have a major impact on the anesthesia techniques applied to cancer surgery patients, including a more prominent role for regional postoperative analgesia techniques to reduce the overall opioid load. At this stage, this hypothesis is unproven and the data must be interpreted with caution until more definitive information from ongoing controlled, randomized trials is available.[100,101] Ferreting out this dilemma is a major goal of contemporary anesthesiology research.

Biased μ-Opioid Agonists

There is evidence that the signaling pathways for opioid therapeutic and selected adverse effects may be distinct. As shown in Fig. 17.18, studies in animal models and in vitro techniques suggest



• **Fig. 17.18** The role of the β-arrestin pathway in μ-agonist adverse effects. Opiate-induced MOR signaling through Gi activates G-protein–gated inwardly rectifying potassium channels (GIRKs) and inhibits adenylyl cyclase, leading to analgesia. Conversely, recruitment of β-arrestin is implicated in tolerance, respiratory depression, and constipation. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophospate; *Gi,* G protein alpha subunit; *MOR,* μ-opioid receptor. (Adapted with permission from Manglik A, Lin H, Aryal DK, et al. Structure-based discovery of opioid analgesics with reduced side effects. *Nature.* 2016;537:185–190.)

that opioid-induced analgesia results from MOR signaling through G proteins, while many side effects, including respiratory depression, tolerance, and constipation, may be mediated by β-arrestin pathway signaling downstream of MOR agonism.[102-104] That separate pathways may mediate analgesic and adverse effects of μ-agonists presents an opportunity to create molecules that are "biased" toward the G-protein pathway, thereby minimizing respiratory depression while maintaining analgesic efficacy.

Using detailed knowledge of the crystal structures of the opioid receptors, medicinal chemists have taken a computational approach to identify potential candidate molecules that may have the desired biophysical properties in terms of how these molecules interact with the MOR (i.e., minimizing β-arrestin-2 signaling). In silico screening of millions of commercially available molecules resulted in identification of some candidate molecules structurally unlike currently available opioids that have intriguing clinical potential based on preclinical testing (e.g., PZM21).[105] Although this drug development effort is in its infancy, there are exciting basic science and clinical implications if this line of research can be carried forward.

Opioid Antagonists for Ileus and Constipation Therapy

An important development in the treatment of opioid-induced adverse effects is the use of μ-receptor antagonists to treat opioid-induced postoperative ileus and constipation.[106,107] Methylnaltrexone and alvimopan are μ-receptor antagonists whose physicochemical properties prevent them from crossing the blood-brain barrier in appreciable amounts. These drugs thus block the μ-receptors in the gut without antagonizing the therapeutic μ-agonist effects that are mediated in the CNS. Controlled, randomized trials have demonstrated their efficacy in the prevention and treatment of postoperative ileus and the constipation associated with chronic opioid use. A recent metaanalysis has confirmed their efficacy,[108] but treatment guidelines regarding patient selection are still evolving.[109]

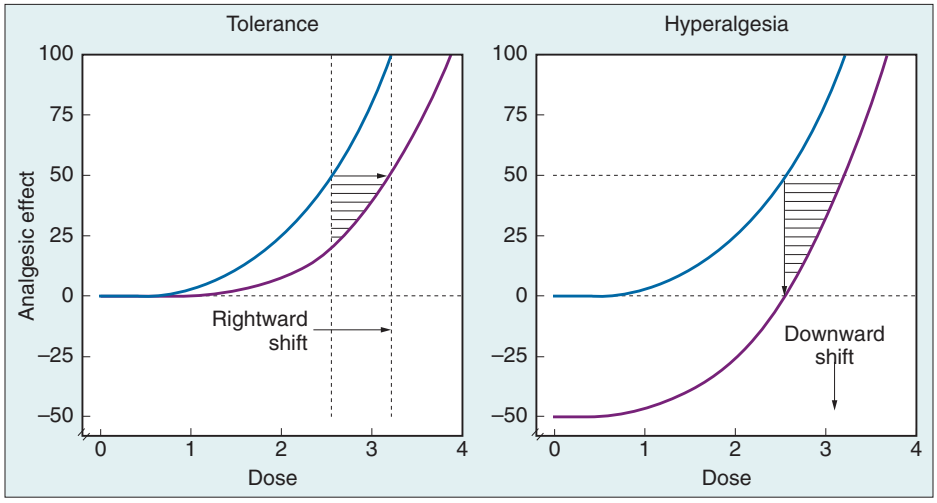
Opioid-Induced Hyperalgesia and Acute Tolerance

It is well known that long-term exposure to opioids produces tolerance to opioid effects; huge opioid doses may be needed to provide adequate perioperative analgesia in patients receiving chronic, high-dose opioid therapy.[110] However, more recent evidence suggests that even brief exposure to opioids may result in an increased dose requirement.

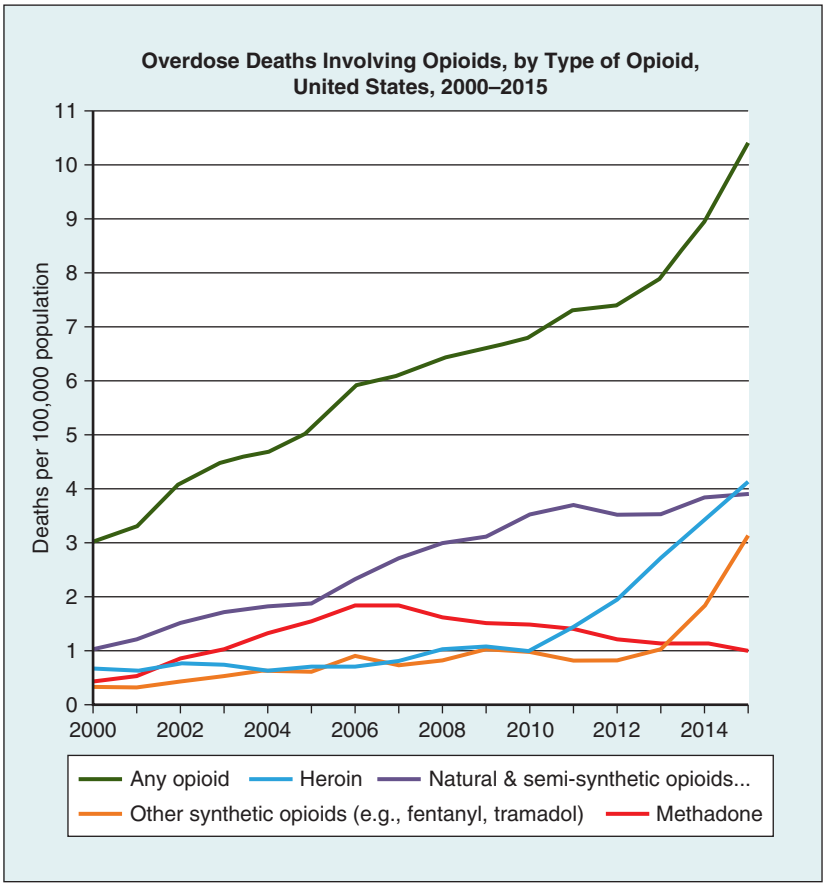
Acute tolerance and opioid-induced-hyperalgesia are pharmacologically distinct phenomena that can both result in the need for a dose escalation to maintain adequate analgesia. In general pharmacologic terms, tolerance is a decrease in the analgesic response to an opioid owing to its continued administration. Hyperalgesia, in contrast, is an increased response to a stimulus that is normally painful.[111]

Considered in terms of the dose-response relationship, opioid tolerance shifts the curve to the right, whereas opioid-induced hyperalgesia shifts the curve downward because of a change in pain sensitivity (Fig. 17.19).[112] Both phenomena manifest clinically as a need for a higher dose to achieve the same analgesic effect. Distinguishing between the two can be therapeutically important because tolerance calls for an increased dosage, whereas opioid-induced hyperalgesia may be more prudently addressed with non-opioid analgesics and other adjuncts (i.e., because opioids exacerbate the problem).

Whether acute tolerance and opioid-induced hyperalgesia play important roles in the management of perioperative patients is controversial.[111] Although numerous animal studies have demonstrated the occurrence of opioid-induced hyperalgesia, the data in humans are more ambiguous.[113-117] Current thinking suggests that both phenomena may coexist to some degree in certain perioperative settings.[111] Risk factors for their occurrence include high opioid dose, prolonged use, and perhaps inhalation anesthesia (i.e., propofol may mitigate risk).[118-120] There is increasing evidence that NMDA receptor antagonism mediated through drugs such



• **Fig. 17.19** Tolerance versus opioid-induced-hyperalgesia in terms of the dose-effect relationship changes. Tolerance shifts the dose-response curve to the right (but does not alter pain sensitivity). Opioid-induced hyperalgesia shifts the dose-response curve downward because of increased pain sensitivity. The *striped area* represents the net increase in dose required to achieve 50% of the maximal analgesic effect. (Adapted with permission from Chu LF, Angst MS, Clark D. Opioid-induced hyperalgesia in humans: molecular mechanisms and clinical considerations. *Clin J Pain.* 2008;24:479–496.)



• **Fig. 17.20** Overdose deaths involving opioids by type in the United States, 2000–2015. (Adapted from the Centers for Disease Control and Prevention National Vital Statistics database, 2016.)

as ketamine may also mitigate the severity of opioid-induced hyperalgesia.[121]

The mechanism of opioid-induced hyperalgesia is unclear. It likely involves both central and peripheral nervous system adaptation including processes involving the NMDA receptor.[112] It appears that endogenous opioid systems do not play a role in its pathogenesis,[122] whereas neuroinflammation induced by activation of microglia and astrocytes may contribute to the phenomenon.[123] Some evidence suggests that different opioids (i.e., morphine, fentanyl, and remifentanil) do not behave uniformly with regard to opioid-induced hyperalgesia, and that the mechanisms underlying the hyperalgesia may also involve spinal 5-hydroxytryptamine type 3 receptors.[124] An especially intriguing recent observation is that opioid agonism at MOR expressed by peripheral nociceptors may trigger the pronociceptive, maladaptive changes that result in opioid-induced hyperalgesia.[125] The administration of methylnaltrexone, a peripherally restricted opioid antagonist, was sufficient to block the development of opioid-induced hyperalgesia in this rodent model.

Opioid Overdose Epidemic

In recent years, deaths related to the abuse and diversion of both illicit and prescription opioids have skyrocketed in the United States and elsewhere as illustrated in Fig. 17.20.[126] Opioid overdose now constitutes a major cause of death in certain demographic groups; opioid-related deaths now exceed deaths from motor vehicle accidents in the United States. In addition to fatalities, this pervasive pattern of prescription and illicit opioid abuse has resulted in a huge surge in admissions to opioid use disorder treatment facilities.[127]

The disturbing trend is at least in part thought to be due to opioid prescribing practices for acute and chronic pain conditions that may predispose some patients to addiction.[128,129] It is increasingly clear that opioid prescribing patterns have been too liberal; over the decade from approximately 2000 to 2010, the number of opioid prescriptions written in the United States quadrupled.[130] These copious prescribing patterns were likely driven in part by a greater emphasis on the treatment of pain by professional societies and accreditation bodies (e.g., pain as the "fifth vital sign"). There is increasing recognition that the risk of opioid addiction stems primarily from the drugs, rather than from some obviously identifiable risk factor in the patient.[130]

The epidemic is now termed a national emergency in the United States,[131] prompting federal and state government authorities to enact legislation and set aside funding to support research, prevention, and treatment of the problem.[132,133] State-approved, pharmacy-based naloxone dispensing (without a physician's prescription) for patients filling opioid prescriptions is a notable example of the efforts supported by such legislation.[134] In addition, professional societies and the United States Centers for Disease Control and Prevention have produced new guidelines for opioid prescribing.[135,136] This is currently an area of intense public discussion and medical investigation.

Key Points

- Most of the clinically useful opioids are chemical modifications of morphine (e.g., hydromorphone, codeine, oxycodone) or meperidine (e.g., the fentanyl family of opioids).
- Opioids produce their primary effects by interacting with opioid receptors. Existing in three distinct types (i.e., μ, κ, and δ), these receptors are coupled with G proteins that, when activated by drugs or endogenous ligands (e.g., β-endorphins), produce inhibitory effects that hyperpolarize the cell and thereby attenuate nociceptive impulses.
- For certain opioids, the metabolic pathway has very important clinical implications. M6G and normeperidine are active metabolites that accumulate in renal failure, potentially causing toxicity. Remifentanil's high clearance because of esterase metabolism results in an extremely short duration of action.
- Opioids can be differentiated pharmacokinetically by their latency to peak effect after bolus administration, the time required to reach a steady state after beginning an infusion, and the time required to achieve a specified level of drug concentration decline after stopping a continuous infusion (i.e., CSHT).
- Pharmacodynamically, the primary therapeutic effects for the perioperative use of opioids are analgesia and sedation. The most dangerous adverse effect in nonventilated patients is depression of ventilation. Other opioid effects can be observed in virtually every organ system, in part because of the wide distribution of opioid receptors.
- The most important drug interaction for opioids is the synergism for both therapeutic and adverse effects that results when opioids are combined with sedatives (e.g., volatile anesthetics and propofol). These "MAC-reducing" effects are a fundamental concept underpinning modern anesthesia.
- When treating certain special populations (e.g., the elderly, patients with severe hepatic or renal disease, morbid obesity, severe bleeding), significant dosage adjustments are necessary.
- The most common clinical applications of opioids in perioperative medicine include postoperative pain therapy, "balanced anesthesia," and total intravenous anesthesia.
- The rational selection of opioids for perioperative use focuses on pharmacokinetic considerations. The commonly used perioperative opioids can be considered pharmacodynamic equals with important pharmacokinetic differences (e.g., differences relating to the onset and offset of effect). TCI of opioids is an important new delivery model.
- The influence of perioperative opioid use on cancer recurrence after oncologic operations, the treatment and prevention of opioid-induced ileus with poorly absorbable opioid antagonists, the search for "biased" opioid agonists with less potential for ventilatory depression, and the phenomena of acute tolerance and opioid-induced hyperalgesia are among the most important emerging developments and areas of investigation in opioid pharmacology.
- Opioid addiction and abuse is a major public health problem that has reached epidemic proportions, particularly in the United States. This public health crisis is an area of intense public interest and research activity.

This human volunteer study first described the unique pharmacokinetic profile of remifentanil, the esterase metabolized fentanyl congener that became the first true "ultrashort-acting" opioid. In combination with propofol, remifentanil revolutionized the practice of TIVA and has become a mainstay of modern anesthesia practice, particularly in regions where intravenous anesthesia techniques are popular. (Ref. 75).

Matthes HW, Maldonado R, Simonin F, et al. Loss of morphine-induced analgesia, reward effect and withdrawal symptoms in mice lacking the mu-opioid-receptor gene. *Nature*. 1996;383:819–823. Using site-directed mutagenesis techniques, these investigators demonstrated that μ-receptor knockout mice failed to exhibit therapeutic effects to morphine but were otherwise phenotypically normal, confirming the importance of the μ-receptor in opioid pharmacology. The μ-receptor knockouts also showed no reward or withdrawal behavior or respiratory depression with morphine administration. (Ref. 8).

McEwan AI, Smith C, Dyar O, et al. Isoflurane minimum alveolar concentration reduction by fentanyl. *Anesthesiology*. 1993;78:864–869. This study quantitatively characterized the extent of isoflurane MAC reduction by fentanyl in humans, thus serving as a prototype pharmacodynamic drug interaction study. The concept of reducing the dose requirement of volatile anesthetics with opioids is one of the most important and widely applied concepts in anesthetic pharmacology. (Ref. 42).

Osborne R, Joel S, Trew D, et al. Morphine and metabolite behavior after different routes of morphine administration: demonstration of the importance of the active metabolite morphine-6-glucuronide. *Clin Pharmacol Ther*. 1990;47:12–19. This human volunteer study confirmed the importance of M6G as an active morphine metabolite, particularly after oral administration. Subsequent investigation has established M6G's role in patients with renal failure or in patients receiving longer-term morphine therapy. (Ref. 66).

Poulsen L, Brosen K, Arendt-Nielsen L, et al. Codeine and morphine in extensive and poor metabolizers of sparteine: pharmacokinetics, analgesic effect and side effects. *Eur J Clin Pharmacol*. 1996;51:289–295. This human volunteer study demonstrated the importance of pharmacogenetic factors in determining the response to codeine, a prodrug of morphine. "Poor metabolizers" do not convert codeine to morphine in significant amounts and thus have no analgesic response to codeine, although they respond to morphine normally. This polymorphism relating to codeine metabolism is perhaps the best-described pharmacogenetic issue in this area of therapeutics and serves as a prototype in understanding the potential clinical impact of these genetic nuances. (Ref. 57).

Shafer SL, Varvel JR. Pharmacokinetics, pharmacodynamics, and rational opioid selection. *Anesthesiology*. 1991;74:53–63. This simulation study demonstrated the importance of pharmacokinetic considerations in rational opioid selection for perioperative use. The context sensitive half-time was an outgrowth of this work. Two key points of this article are that opioid behavior is quite different for bolus administration compared with continuous infusion and that pharmacokinetic simulation is necessary to understand the implications of these pharmacokinetic differences. (Ref. 14).

Wang JB, Johnson PS, Persico AM, et al. Human mu opiate receptor. cDNA and genomic clones, pharmacologic characterization and chromosomal assignment. *FEBS Lett*. 1994;338:217–222. These investigators first cloned the human μ-receptor and identified its chromosomal location, launching the era of genomic research in opioid pharmacology. (Ref. 3).

Nonintravenous Opioids

JILL E. SINDT AND ROBERT H. JENKINSON

CHAPTER OUTLINE

Historical Perspective

Basic Pharmacology
- Structure-Activity
- Mechanism of Action
- Metabolism

Clinical Pharmacology
- Pharmacokinetics
- Pharmacodynamics
  - *Therapeutic Effects*
  - *Adverse Effects*
  - *Drug Interactions*
  - *Special Populations*
  - *Unique Features of Individual Agents*

Clinical Applications
- Common Clinical Indications
  - *Acute Pain*
  - *Cancer Pain*
  - *Opioids for Chronic Pain*
- Rational Drug Selection and Administration

Emerging Developments
- Buprenorphine for Opioid Dependence
- Peripherally Restricted μ-Receptor Antagonists
- Opioids and Immunosuppression
- Opioids and Sleep-Disordered Breathing
- Opioids and Endocrine Dysfunction

Historical Perspective

The use of opium for treating pain dates back to at least ancient Egypt, but the modern opioid era began in 1804 when German pharmacist Friedrich Wilhelm Sertürner discovered the naturally occurring opioid morphine.[1,2] Morphine and opium were widely sold over the counter in liquid, pill, and powder forms throughout the 19th century, and in 1898 the Bayer Company released the first semisynthetic opioid, heroin, as a cough suppressant. Initially touted as less habit-forming than morphine, within a few years heroin was widely crushed and snorted.[3] This, in addition to the rising tide of iatrogenic morphine addiction, led to the Harrison Narcotics Tax Act of 1914 in the United States, requiring physician and pharmacist registration for distributing opioids and largely criminalizing possession of these drugs for nonmedical uses.

In addition to regulatory action, the "opium problem" of the early 1900s led to increased focus on drug development both in the United States and abroad. The desire to identify a substitute for morphine, a drug that would separate the analgesic and addictive properties, led to the synthesis of oxycodone in 1917 in Germany.[4] In the United States the Committee on Drug Addiction was formed in 1921 and tested a number of newly developed synthetic and semisynthetic opioids over the next 50 years, yet a powerful opioid pain reliever without habit-forming properties remains elusive.[5]

The second heroin epidemic of the mid-1900s led to the Controlled Substances Act of 1970 in the United States, requiring manufacturers, distributors, and providers who dispense or administer controlled substances to register with the Drug Enforcement Administration (DEA). Later, in response to the need for opioid abuse treatment, the Narcotic Addict Treatment Act of 1974 decriminalized the use of opioids, primarily methadone, to permit legally treating opioid dependence with opioid replacement therapy.[6]

The 1990s ushered in growing attention to the problem of undertreated chronic pain. With this came aggressive marketing of opioids by the pharmaceutical industry, new pain management standards implemented by The Joint Commission on the Accreditation of Health Care Organizations, and relaxed laws governing prescribing of opioids by state medical boards. Prominent physicians and medical societies promoted the use of opioids to treat chronic pain with the misinformed assertion that opioids are safe and effective, with no dose ceiling or long-term untoward effects. These and other factors culminated in a rapid rise in the number of opioid prescriptions dispensed in the early 2000s, followed by an even more rapid rise in opioid-related overdose deaths.[7]

While opioids unquestionably have a role in the treatment of some types of pain, it is now clear they carry tremendous risks if not used judiciously. This chapter focuses on the clinical application of oral and transdermal preparations of opioid analgesics (for a discussion of basic opioid pharmacology and intravenous opioids, see Chapter 17).

Basic Pharmacology

Structure-Activity

Clinically relevant nonintravenous opioids can be categorized into three structural groups: naturally occurring alkaloids, semisynthetic alkaloids, and synthetic opioids. Naturally occurring opioids can be extracted from the seeds of the poppy plant and include morphine and codeine (Fig. 18.1). Although the majority of codeine available worldwide is manufactured from morphine as a semisynthetic

Abstract

Oral opioids have been used for centuries for treating pain, with the modern era beginning in the 19th century with the discovery of morphine. Nonintravenous opioids can be categorized into three structural groups: naturally occurring alkaloids, semisynthetic alkaloids, and synthetic opioids. Most nonintravenous opioids are metabolized by the cytochrome P450 enzyme into inactive metabolites; however, morphine undergoes glucuronidation to produce metabolites that are renally cleared and may accumulate with renal insufficiency. Nonintravenous opioids have many routes of administration, including the ultrashort-acting transmucosal opioids, short-acting, extended-release and long-acting oral opioids, and continuous-acting transdermal opioids. Common side effects include constipation, nausea, sedation, pruritus, and respiratory depression. Tolerance develops to most of these effects, with the notable exception of constipation. Concomitant use of opioids and other central nervous system depressants can lead to profound sedation, respiratory depression, and death, particularly with benzodiazepines, propofol, and alcohol. Acute pain and cancer-related pain are long-standing indications for the use of nonintravenous opioids. However their use for chronic pain is controversial without established long-term efficacy and concerns for development of addiction and increases in opioid overdose deaths. Selection of a nonintravenous opioid is based on time to onset, needed duration, available routes of administration, opioid tolerance, and side effect profile. Emerging developments in nonintravenous opioids include buprenorphine for opioid dependence, peripherally restricted μ antagonists for opioid-induced constipation, concerns about suppression of immune and endocrine function, and increasing recognition of sleep-disordered breathing with opioids.

alkaloid, codeine is found naturally along with morphine in the poppy seed. Note that codeine simply adds a methyl group on the 3-hydroxyl of morphine.[8]

Semisynthetic alkaloids include hydromorphone (Dilaudid), hydrocodone (Norco, Vicodin), oxycodone (Percocet, Oxycontin), oxymorphone (Opana), and buprenorphine (Suboxone, Subutex). These drugs are derived from morphine, typically with substitutions of ester, hydroxyl, keto-, or methyl groups at the 3 and 6 carbon or 17 nitrogen positions of morphine (Fig. 18.2).[9]

Synthetic opioids are further characterized as phenylheptylamines, including methadone, and phenylpiperidines, including fentanyl. Tramadol and tapentadol are also included in this group. These drugs have unique chemical structures that do not follow a morphine-like pattern (Fig. 18.3).[10]

Mechanism of Action

All opioids exert their primary pharmacologic effects by interactions with opioid receptors at multiple sites in the central nervous system (CNS). The classic μ, κ, and δ opioid receptors are typical G-protein–coupled receptors (see Chapter 17). Binding of the opioid leads to an overall reduction in neuronal excitability via membrane hyperpolarization as the result of decreased cyclic adenosine monophosphate production, decreased calcium ion influx, and increased potassium ion efflux.

Tramadol and tapentadol are unique among nonintravenous opioids in that they bind to opioid receptors, but they also exert an analgesic effect through inhibiting reuptake of serotonin and norepinephrine; tramadol primarily inhibits serotonin reuptake and tapentadol primarily inhibits norepinephrine reuptake.[11] Fentanyl also inhibits serotonin reuptake, although the contribution to its clinical analgesic effect is unclear.[12]

Metabolism

The majority of nonintravenous opioids are metabolized by the cytochrome P450 system, primary via the 3A4 and 2D6 isoforms. Notable exceptions include morphine, hydromorphone, and oxymorphone. Morphine is chiefly metabolized via glucuronidation to the metabolites morphine-3-glucuronide (M3G), which has CNS neuroexcitatory effects, and morphine-6-glucuronide (M6G), an analgesic 50 times more potent than morphine. Hydromorphone and oxymorphone are the cytochrome P4502D6 metabolites of hydrocodone and oxycodone, respectively. They undergo glucuronidation as well as some reduction. Less is known about the activity of their metabolites, although hydromorphone-3-glucuronide may have CNS neuroexcitatory effects.

Most opioids are metabolized to inactive metabolites, although some, such as tramadol and codeine, are prodrugs that require metabolism to an active metabolite for clinical effect. Morphine is again a notable exception in having active metabolites. See Table 18.1 for a summary of opioid metabolism, metabolites. and their activity.[8–11,13–15]

TABLE 18.1 Metabolism of Opioid Analgesics

Medication	Metabolism	Metabolites	Metabolite Activity
Morphine	Glucuronidation	M3G M6G	Neuroexcitatory Active
Codeine	Glucuronidation (80%) CYP2D6 CYP3A4	C3G C6G Morphine Norcodeine	Possibly neuroexcitatory CNS-toxic Active Active Inactive

Clinical Pharmacology

Pharmacokinetics

Opioids are unique in their availability across many routes of administration. In addition to intravenous and neuraxial administration, covered in previous chapters, they can be administered clinically by transmucosal (buccal, sublingual, or intranasal), oral, and transdermal methods. Experimental methods include inhaled opioids.

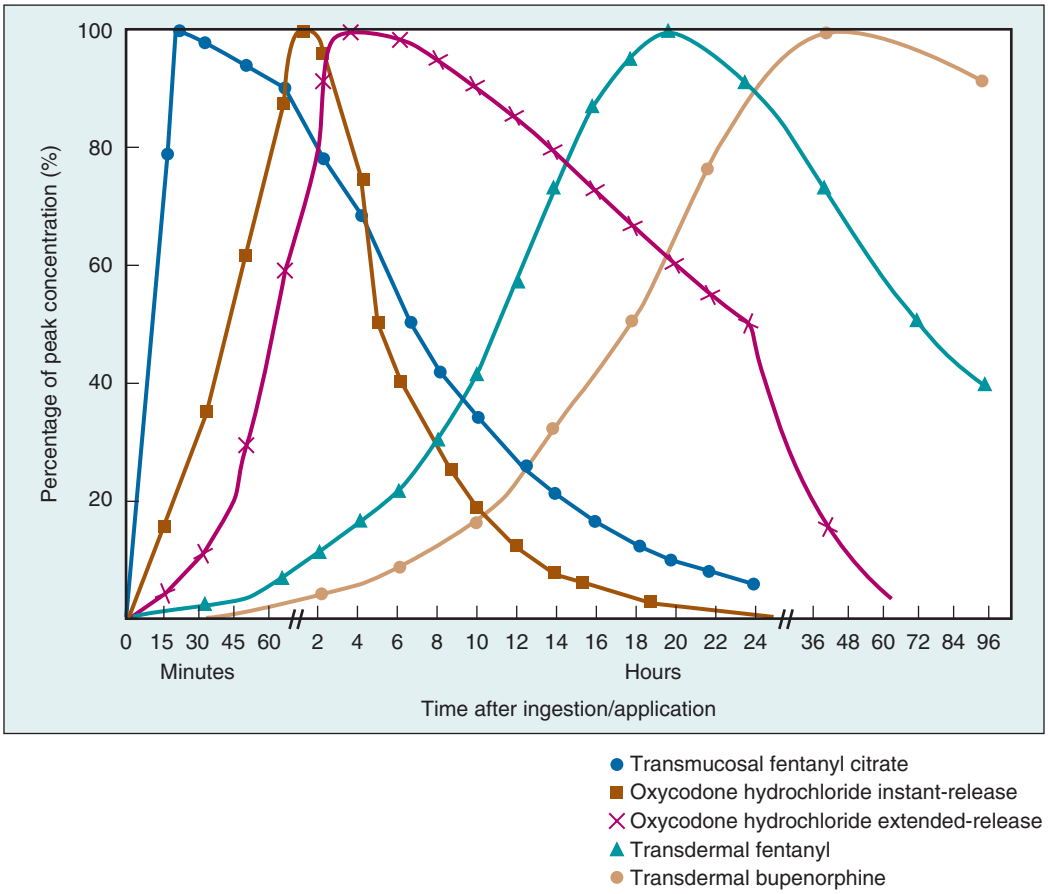
Transmucosal opioids are considered ultrashort-acting as they achieve peak plasma concentration within 10 to 20 minutes with an analgesic effect of 60 to 120 minutes.[16] Among oral opioids there are both short-acting and extended-release formulations of multiple agents such as hydrocodone, hydromorphone, and oxycodone. There are also long-acting agents such as methadone and buprenorphine. Short-acting oral opioids allow for "as-needed" dosing for episodic or breakthrough pain and generally achieve peak plasma concentrations within 30 to 60 minutes. Extended-release formulations and long-acting agents allow for less frequent dosing and more stable analgesia in patients with constant pain as they can ameliorate large fluctuations in serum opioid levels or the so-called "peak-and-trough" effect seen with short-acting opioids. However, they differ widely in their individual pharmacokinetic properties (Fig. 18.4 and Table 18.2).[17–26]

Fentanyl and buprenorphine are unique because transdermal delivery systems enable continuous delivery. Modern transdermal patches use an inert polymer matrix impregnated with dissolved drug that has evolved from early transdermal systems that consisted of a simple drug reservoir separated by a rate-limiting membrane. Drug delivery with transdermal patches is a result of the concentration gradient between the patch and skin, is proportional to the area of exposed skin, and allows for a near zero-order delivery of medication at steady state without being subject to first-pass metabolism.[27] This reduces, though does not eliminate, variability in serum opioid concentration. Additionally, this gradient is in part temperature-dependent, with increased absorption occurring at higher temperatures. Serious adverse effects and deaths have occurred with concurrent application of external heat, such as with electric heating blankets, saunas, and hot tubs.[28]

Pharmacodynamics

Like intravenous opioids, nonintravenous opioids exert their activity through agonism of the μ-opioid receptor (see Chapter 17). Given their common mechanism of action, most μ-opioid receptor agonists are pharmacodynamically equivalent and produce similar effects when used in equivalent equipotent doses.

The μ-opioid agonist-antagonists are exceptions to this general rule because of their more complicated μ-receptor activity profile. Buprenorphine, the most commonly used partial agonist outside the perioperative setting, is a partial agonist at the μ receptor



• **Fig. 18.4** Comparison of common nonintravenous opioid pharmacokinetics.

TABLE 18.2 A Comparison of Pharmacokinetic Properties Among Opioids

Opioid	Time to Peak Plasma Concentration	Duration of Effect	$t_{1/2}$
Transmucosal			
Buccal fentanyl	10–20 min	1–2 hr	4.5 hr
Intranasal fentanyl	5–10 min	60–90 min	4.5 hr
Oral Short-Acting			
Oxycodone	1–1.5 hr	2–4 hr	3.5 hr
Hydrocodone	1–1.5 hr	2–4 hr	3.5 hr
Oral Extended-Release			
Morphine	4.5 hr	8–12 hr	2–3 hr
Oxycodone	4.5–5 hr	12 hr	3.5 hr
Oral Long-Acting			
Methadone	1–7 hr	6–12 hr[a]	8–59 hr
Buprenorphine	100 min	24–36 hr	24–42 hr
Transdermal			
Fentanyl	24 hr	48–72 hr	24 hr
Buprenorphine	~48 hr	7 days	26 hr

[a]Methadone has a duration of analgesia that is much shorter than the duration of effect used to suppress withdrawal symptoms when used as maintenance therapy for opioid dependence.

and an antagonist at the κ receptor. Buprenorphine exhibits a ceiling effect for analgesia and respiratory depression compared with full agonists. Tramadol has a low affinity for the μ receptor, and analgesia is only partially reversed by administration of the specific μ-receptor antagonist naloxone, presumably because of its serotonin reuptake inhibition activity. Because of this low μ-receptor affinity, the analgesia produced by tramadol might be suboptimal for severe pain.

Therapeutic Effects

Activation of μ-opioid receptors produces analgesia, which is the primary therapeutic effect of opioids. Other effects such as sedation, decreased gastrointestinal motility, and antitussive properties have clinical applications but are typically secondary considerations for opioid selection and administration (see Chapter 17).

Adverse Effects

Common side effects of opioid analgesics prescribed in the ambulatory setting include constipation, nausea, sedation, confusion, dry mouth, pruritus, and respiratory depression. Less frequent side effects include urinary retention, myoclonus, and mood effects, both euphoria and dysphoria. These side effects can be dose-limiting and even life-threatening, but tolerance to most side effects occurs with continued opioid therapy, the major exception being opioid-induced constipation (OIC).

Respiratory Depression

Respiratory depression is the most dangerous adverse effect associated with μ-agonist drugs in either ambulatory or inpatient settings. Unrecognized respiratory depression when manifest in its severe

form can lead to fatal respiratory arrest. More than 165,000 deaths were attributed to overdoses related to prescription opioid medications from 1999 to 2014 in the United States; the overwhelming majority of these deaths are due to respiratory arrest.

Managing and monitoring opioid-induced respiratory depression in the ambulatory setting is challenging. The Centers for Disease Control and Prevention (CDC) Guideline on Prescribing Opioids for Chronic Pain released in 2016 recommends an increase in the frequency of follow-up as well as consideration of prescribing naloxone for emergency rescue if a patient's dosage from all combined sources of opioids reaches or exceeds 50 mg oral morphine equivalents (OME) per day because of the higher likelihood of respiratory depression.[29]

Sedation

Centrally mediated μ-receptor agonism is responsible for the sedation observed with opioid administration. Sedation is a common dose-limiting side effect outside the perioperative setting, particularly in the setting of patients with cancer pain and pain in the elderly, although it is generally temporary as tolerance occurs over time with stable opioid dosing. Combining oral and transdermal opioids with other CNS-active medications can lead to a greater than anticipated sedating effect.

Constipation

μ Receptors are highly concentrated throughout the mucosa and submucosa of the gastrointestinal tract. The concentration of μ and κ receptor is most dense in the stomach and proximal colon.[30] OIC is multifactorial but is due in part to an increase in nonperistaltic motility, delayed transit time, and increased sphincter tone at the pylorus and ileocecal junction. Given the high frequency of OIC, a prophylactic bowel regimen should be considered when initiating opioid therapy. In addition to traditionally used agents such as stool softeners, osmotic laxatives, and stimulant laxatives, newer therapies are available for treatment of OIC (see "Emerging Developments").

Nausea

Opioid-induced nausea and vomiting are common side effects, particularly for opioid-naive patients. Fortunately, habituation frequently occurs within several days but may necessitate treatment with antiemetic medications. Ultimately, switching to an alternative opioid, altering the route of administration, or reducing the dose may be required to manage the nausea effectively.[31] Patients can have idiosyncratic responses to different opioid analgesics and switching to a different opioid may reduce or resolve nausea, although the scientific foundation for this observation is not well established.

Pruritus

More commonly seen with parenteral or neuraxial administration, pruritus can still occur with oral, transdermal, and transmucosal administration. Patients typically become tolerant to opioid induced pruritus and infrequently require treatment. With rotation to another opioid, pruritus often resolves. If opioid-induced pruritus does require treatment, antiemetics such as ondansetron or promethazine or antihistamines such as diphenhydramine or hydroxyzine, can be used.[32]

Tolerance and Dependence

Tolerance and dependence are considered normal adaptive physiologic responses to ongoing opioid therapy. Tolerance is the need for increased dosing to maintain a defined degree of analgesia in the absence of disease progression or changes in other external factors. Dependence can be physical and/or psychological. Physical dependence occurs from a progressive tolerance to both the therapeutic and adverse effects of opioids and is characterized by the appearance of withdrawal symptoms with rapid dose reduction, abrupt discontinuation, or exposure to opioid antagonists.[33]

Tolerance and dependence should be distinguished from opioid abuse. As defined by numerous professional societies, opioid addiction is "a primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving."[33]

Other Adverse Effects

Myoclonus can occur with high-dose opioid therapy, particularly with morphine, secondary to accumulation of the metabolite M3G. Transitioning to a new opioid often results in improvement or resolution of myoclonus. Urinary retention can result from opioid administration, although this effect is variable. μ Agonists increase urinary tract smooth muscle tone, although in some cases this can produce urinary urgency as opposed to true urinary retention. Conversely, opioids reduce gastrointestinal tract sphincter tone. This can result in dysfunction of the sphincter of Oddi, which controls the flow of bile and pancreatic secretions into the duodenum. Acute biliary-type pain attacks and dilation of bile duct have been reported and these effects are reversed with naloxone.[34] Opioids can affect reward pathways in the brain and induce euphoria in select patients, but can cause dysphoria in others. These responses are due in part to opposing effects of μ receptor and κ receptor agonism on dopamine levels in the nucleus accumbens, substantia nigra, and striatum, offering an explanation for seemingly idiosyncratic dysphoric reactions to different opioids.[35,36]

Drug Interactions

Concomitant use of opioids and other CNS depressants can lead to profound sedation, respiratory depression, and death, particularly with gamma aminobutyric acid $(GABA)_A$ agonists such as benzodiazepines, barbiturates, propofol, and alcohol. These interactions are synergistic. Opioid-associated urinary retention and constipation are compounded by the coadministration of drugs with significant anticholinergic activity. Of particular clinical significance is the increased incidence of constipation in the setting of concomitant use of opioids and ondansetron owing to the effect of ondansetron on serotonin-mediated gastrointestinal peristalsis.[37] Constipation is a common adverse effect associated with ondansetron, occurring in nearly 10% of patients treated for nausea and vomiting associated with chemotherapy, and can be worsened by opioid therapy in this patient population. The synthetic opioids, including fentanyl, methadone, tramadol, and meperidine, are all weakly serotonergic and have been implicated in multiple reports of serotonin syndrome when used in combination with other serotonergic medications such as monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, serotonin-noradrenaline reuptake inhibitors, tricyclic antidepressants, and lithium.[38,39]

Multiple opioids undergo phase I metabolism via the cytochrome P450 system, particularly CYP2D6 and CYP3A4. These enzymes are affected not only by allelic variations but also by many other medications that act as substrates, inhibitors, and inducers. Common inducers include anticonvulsant agents and pentobarbital. Calcium channel blockers, selective serotonin reuptake inhibitors, benzodiazepines, many psychotropic agents (see Chapter 12), and multiple antibiotics act as both a substrate and an inducer of CYP 450

enzymes, and many opioids have substantial interaction potential with these commonly used agents. See Table 18.3 for a summary of these interactions.

Special Populations

Renal Insufficiency

The liver is the major site for biotransformation and elimination of most opioids; however, the majority of opioid metabolites are renally cleared. Although these metabolites are often inactive or minimally active, an important exception is morphine. Morphine is metabolized to the inactive metabolite M3G and the active analgesic metabolite M6G, which has an analgesic potency near that of morphine. Accumulation of M6G leading to respiratory depression in patients with altered renal clearance mechanisms constitutes the basis for avoiding morphine therapy in patients with renal failure. Because codeine is metabolized to morphine it should also be avoided in patients with renal insufficiency.

Oxycodone and oxymorphone both have active metabolites. In uremic patients the elimination half-life is lengthened and excretion of metabolites is impaired; however, the clinical relevance of this is largely unstudied in the setting of renal insufficiency.[40] Tramadol produces the metabolically active metabolite M1, and an increased dosing interval of 12 hours is recommended in patients with compromised renal function.

Fentanyl, methadone, and buprenorphine are considered safe in patients with renal insufficiency and do not require dose adjustment. Hydromorphone is also a preferred opioid in patients with renal impairment, although it has a potentially active metabolite. In the setting of dialysis, hydromorphone levels are reduced to 40% of predialysis levels, whereas fentanyl and buprenorphine are not dialyzable and levels remain unchanged following dialysis.[41–43]

Hepatic Impairment

The liver is the major site of metabolism for most opioids; thus patients with liver disease who require opioid treatment present unique challenges. Impaired liver function not only leads to changes in the pharmacokinetic properties of drugs but can also lead to alteration in plasma protein binding and the plasma concentration of unbound "free" drug.[44] This altered drug disposition can lead to increased therapeutic effect and an increase in adverse effects, potentially manifest as sedation, respiratory depression, and potentiation of hepatic encephalopathy. Unfortunately, there is limited data to guide specific dosing recommendations of opioids in the ambulatory setting in patients with liver failure.

Because their metabolites are inactive, fentanyl and hydromorphone are often the preferred agents in patients with liver disease. However, lower starting doses, slower dose titration, and increased dose intervals are recommended when initiating ambulatory therapy with any of the commonly used opioids in patients with significant hepatic insufficiency. Limited data exists for buprenorphine, although it has been used without adverse effect in patients with concurrent liver dysfunction owing to hepatitis C and, with caution and close monitoring, appears to be safe in patients with liver disease.[45] See Table 18.4 for a summary of recommendations.

Elderly

Advanced age is known to be an important covariate that alters both the pharmacokinetic and pharmacodynamics properties of opioids. In general, opioid clearance is lower and opioid potency is greater in the elderly.[46,47] Compared with younger patients, a given dose produces higher plasma concentrations and more pronounced effects, both therapeutic and adverse, in the older patient.

Among elderly patients falls, fractures, sedation, and impaired cognition dominate concerns about the use of opioids. Unpredictable or greater than expected opioid effects can result from age-related reduction in renal function, drug-drug interactions owing to use of multiple prescription medications, and overall increased frailty in this population. Opioids as a class have been associated with an increased risk of falls and fractures and it does not appear that one opioid is vastly superior to another, although there is a lower incidence of fractures with transdermal buprenorphine compared with other opioids.[48]

In terms of selecting a specific opioid for elderly patients it appears that transdermal fentanyl and transdermal buprenorphine

TABLE 18.3 Opioid Analgesics in Hepatic Impairment

Medication	Dose	Dose Interval	Notes
Morphine	Reduced	Increased	
Codeine	Avoid	Avoid	Metabolized to morphine with unpredictable serum concentrations
Hydrocodone	Reduced	Increased	
Hydromorphone	Reduced	No change	Preferred agent
Oxycodone	Reduced	Increased	
Oxymorphone	Reduced	Increased	
Buprenorphine	Unknown	Unknown	Appears safe but limited data
Methadone	Reduced	Increased	
Fentanyl	Reduced	Increased	Preferred agent
Tramadol	No change	Increased	

TABLE 18.4 Morphine Equivalent Doses for Commonly Prescribed Opioids

Medication	Route	Equivalent Dose
Morphine	PO	30 mg
Hydrocodone	PO	30 mg
Hydromorphone	PO	7.5 mg
Oxycodone	PO	20 mg
Oxymorphone	PO	10 mg
Buprenorphine	SL	Unpredictable Approximately 0.8–1 mg
Methadone	PO	Unpredictable Approximately 7.5–10 mg
Fentanyl	TD	12 µg/hr

PO, Oral, *TD*, transdermal.

are generally safe and well-tolerated, with a lower incidence of constipation. The transdermal route, with infrequent need to change patches, also increases compliance. Transdermal buprenorphine (available in the United States) offers the advantage of a low dosage option (the 5-μg/hr patch is equivalent to approximately 15 mg of oral morphine over 24 hours) for the elderly patient. It is prudent to avoid morphine in the elderly to avoid M6G accumulation in patients with unrecognized, age-related renal impairment. All opioid analgesics in the elderly should be started at lower doses, with increased dosing intervals and slower up-titration with close monitoring of the therapeutic response and side effect proflie.[49]

Unique Features of Individual Agents

Morphine

Both short-acting and extended-release forms of enteral morphine are available. The two metabolites, M3G and M6G, are cleared by the kidney. M6G can contribute to sedation, hallucinations, and even respiratory depression in patients with altered kidney function. M6G is the primary active analgesic metabolite and crosses the blood-brain barrier.[50] M3G has no clinically significant analgesic effects but does have neuroexcitatory effects accounting for the myoclonus observed with high daily doses of morphine.[51] Approximately 10% of morphine is excreted unchanged in the kidneys with a small component of biliary excretion and enterohepatic recycling.

Morphine typically serves as the dosing reference for all other opioids used in ambulatory therapy. The OME is the standardized metric to compute "equianalgesic" doses of other opioids. The concept is useful when comparing the potential risks of adverse effects between opioids. Although widely applied when converting patients from one opioid to another, the main limitation of the OME concept is that the different pharmacokinetic and receptor profiles of the various drugs make the determination of "equal" doses difficult to achieve over time.

Codeine

Codeine is a prodrug that requires conversion by CYP2D6 in the liver to its active metabolites, codeine-6-glucuronide and morphine, that are ultimately responsible for codeine's analgesic effects. Patients with diminished or absent CYP2D6 activity have limited response to codeine, whereas patients who are ultrarapid metabolizers (e.g., CYP2D6 gene duplications) can have exaggerated responses to codeine owing to more extensive metabolism to morphine (see Chapter 17).[52,53] Because of this pharmacogenetic variability, codeine is now much less commonly prescribed in contemporary pain management.

Oxycodone

Oxycodone is a semisynthetic opioid synthesized from the opiate alkaloid thebaine. It is available in short-acting and extended-release formulations as well as preparations compounded with acetaminophen or aspirin. Oxycodone undergoes low first-pass metabolism and has a higher bioavailability (60%-87%) compared with morphine. It undergoes *O*-demethylation via both CYP3A4 and CYP2D6 to oxymorphone, its primary active metabolite, which is three times more potent than morphine.[54] Oxycodone also undergoes metabolism by CYP3A4 to noroxycodone, which has weak μ-opioid receptor activity compared with oxycodone or oxymorphone. It has been suggested that individuals with decreased CYP2D6 activity because of genetic polymorphisms require higher doses of oxycodone as the result of lower oxymorphone production, but there is limited evidence to support this assertion.[55] Oxycodone and its metabolites primarily undergo urinary excretion with less than 10% of the parent compound excreted unchanged.

Hydrocodone

Hydrocodone is a semisynthetic opioid structurally similar to codeine. It is available in short-acting and extended-release versions as well as preparations compounded with acetaminophen or ibuprofen. Hydrocodone undergoes a complex pattern of metabolism by CYP2D6 and CYP2C19 to hydromorphone, and by CYP3A4 to norhydrocodone, an inactive metabolite.[56] Although the parent compound hydrocodone exerts most of this drug's therapeutic effect, hydromorphone (which circulates at <3% of the original parenteral hydrocodone dose) contributes to the overall analgesic effect, and allelic variations in CYP2D6 can decrease the efficacy of hydrocodone.[57] Hydrocodone and its metabolites primarily undergo renal excretion, with only 6.5% excreted unchanged by the kidneys.

Oxymorphone

Oxymorphone is a semisynthetic opioid and is the primary active metabolite of oxycodone. It is available in both short-acting and extended-release formulations. It has poor oral bioavailability (approximately 10%), but it is much more potent that morphine. Oxymorphone primarily undergoes phase II metabolism via conjugation with glucuronic acid to form oxymorphone-3-glucuronide but is also metabolized to 6-hydroxy-oxymorphone, an active metabolite. Approximately 99% of the total administered dose is excreted in the urine in its conjugated form, while less than 1% is metabolized and undergoes renal elimination as 6-OH-oxymorphone; the active metabolite thus does not reach levels that contribute meaningfully to drug effect.[56] Therefore no dose adjustment is necessary for anticipated changes in cytochrome P450 activity as oxymorphone has no known pharmacokinetic drug-drug interactions.

Hydromorphone

Hydromorphone, a hydrogenated ketone of morphine, has very similar pharmacokinetic and pharmacodynamic properties compared with morphine and is similarly excreted by the kidneys. However, hydromorphone is four times more potent than morphine. Hydromorphone is available in short-acting and extended-release formulations. Hydromorphone primarily undergoes phase II conjugation with glucuronic acid to form hydromorphone-3-gulcuronide (H3G).[58] H3G has a low affinity for opioid receptors, and because of its hydrophilic properties and lower blood-brain barrier permeability, might cause fewer adverse cognitive effects compared with morphine. However, H3G can have a neuroexcitatory potential similar to M3G with accumulation in patients with renal failure, although this does not appear to be as clinically relevant as with morphine.[57]

Tramadol

A weak μ-receptor agonist, tramadol exerts additional central-acting analgesic effects via serotonin reuptake inhibition (and norepinephrine to a lesser degree). It is considered a weak opioid and is recommended for the treatment of mild to moderate pain.

Tramadol undergoes extensive metabolism by CYP2D6 and CYP3A4 as well as glucuronidation. The primary pharmacologically active metabolite is O-desmethyltramadol (M1) formed by CYP2D6.[59] Tramadol is thus affected by genetic polymorphisms of CYP2D6. Tramadol and M1 both exert analgesic effects, although M1 is a more potent μ-receptor agonist, and tramadol itself is a

more potent serotonin-norepinephrine reuptake inhibitor.[57] Tramadol and its metabolites are excreted in the urine with 30% excreted unchanged.

Because of this unique serotonin reuptake inhibition, clinicians must be aware of the potential for serotonin syndrome if tramadol is combined with monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, tricyclic antidepressants, or other serotonergic medications. Short-acting and extended-release oral formulations are available in the United States as well as a combination tablet with acetaminophen.

Tapentadol

Tapentadol is a synthetic analgesic indicated for the treatment of moderate to severe pain. It acts via both μ-opioid agonism and norepinephrine reuptake inhibition. It can be more effective for patients with primary or coexisting neuropathic pain such as painful diabetic peripheral neuropathy. It is available in short-acting and extended-release formulations and is less potent than morphine. There are no pharmacologically active metabolites. Tapentadol undergoes glucuronidation and is therefore less reliant on the cytochrome P450 system.[60] It then undergoes almost exclusively renal excretion with only 3% excreted in the urine unchanged.

Buprenorphine

Buprenorphine is unique in that it is available in enteral, transdermal, and transmucosal formulations. Buprenorphine is a partial agonist at the μ receptor but binds with higher affinity and slower dissociation than full agonist opioids. It also has κ-receptor antagonist properties. Because of its pharmacodynamic properties, it has been suggested that there is a ceiling effect for analgesia and also for respiratory depression, although profound respiratory depression and respiratory arrest can still occur with buprenorphine therapy, particularly with coadministration of benzodiazepines, alcohol or sedative hypnotics. The CYP3A4 isoenzyme plays a major role in metabolism of buprenorphine, and CYP3A4 inhibition can lead to a decrease in clearance of the drug. Norbuprenorphine is the only known active metabolite, but it produces analgesia or adverse effects only at concentrations well above clinically applicable dose ranges.[59] Buprenorphine undergoes hepatic metabolism and subsequent biliary and renal excretion.

For the transdermal formulation, the lowest available starting dose is a 5-μg/hr patch (available in the United States) that delivers drug for 7 days. In Europe the transdermal preparation is available in higher doses and delivers drug for 4 days. Buprenorphine is associated with QTc interval prolongation in higher doses and its use should be carefully considered in patients with a personal or family history of long QT syndrome or who are taking class IA or class III antiarrhythmics. As a partial μ-receptor agonist, buprenorphine can precipitate acute withdrawal in opioid-dependent patients; the severity of withdrawal depends on the degree of physical dependence and dose of buprenorphine administered.

Suboxone, a combination product of buprenorphine and naloxone, was approved in the United States in 2002 for use in the treatment of opioid dependence and maintenance therapy for opioid addiction. Naloxone has poor bioavailability with enteral administration owing to marked first-pass hepatic metabolism and was included in the formulation to deter intravenous abuse of buprenorphine.

Fentanyl

Fentanyl is a synthetic opioid that is frequently administered in injectable form but is also available in transdermal and transmucosal formulations. Fentanyl is primarily metabolized by CYP3A4 to norfentanyl and other inactive metabolites; CYP3A4 inhibitors can decrease the clearance of fentanyl. These metabolites primarily undergo renal excretion, although there is a small fraction that undergoes biliary excretion, and less than 10% of fentanyl is excreted unchanged.

Transdermal fentanyl is not indicated for opioid-naive patients and should be started after dose titration with a short-acting opioid. The lowest available starting dose is a 12-μg/hr patch that is intended for 72-hour use. Although as an intravenous formulation fentanyl is considered a short-acting drug, the transdermal preparation is considered a continuous opioid. Achievement of steady-state plasma levels can vary depending on patient characteristics such as variations in skin and subcutaneous tissues, skin temperature, and perspiration but generally requires 12 to 48 hours after initial placement. Peak plasma concentrations might not be reached until 72 hours after initial application in some patients. Some patients require more frequent patch replacement (e.g., every 48 hours instead of every 72 hours). Transdermal preparations have a more favorable side effect profile for constipation and higher patient satisfaction owing to convenience, particularly in cancer pain.[31]

In 2015 a novel transdermal fentanyl formulation using inotophoresis, a process in which low-intensity electric current is used to transport ionized drug molecules from the patch into the systemic circulation, was approved in the United States. The fentanyl HCI inotophoretic system (ITS) is a form of patient-controlled analgesia in which the patch is placed on the chest or outer upper arm. The ITS delivers a preprogrammed 40-μg dose over 10 minutes when the patient activates it by pressing a recessed button. It is indicated for the management of acute, moderate to severe postoperative pain in hospitalized adults.[61] Safe and effective pain control using the fentanyl ITS has been reported with multiple procedural types in both adult and geriatric populations.[1]

Transmucosal fentanyl delivery products are also available that allow for rapid-onset analgesia. These formulations include a buccal film and tablet, sublingual spray and tablet, oral lozenge, and nasal spray. The transmucosal delivery route avoids first-pass metabolism, substantially increasing the bioavailablity and speed of onset (see Chapter 17). Transmucosal fentanyl products are indicated for cancer-related breakthrough pain in opioid-tolerant patients only and their use is regulated under the U.S. Food and Drug Administration's (FDA) Risk Evaluation and Mitigation Strategies program.

Sufentanil

Sufentanil is a potent synthetic μ-receptor agonist currently available in a sublingual formulation in Europe and awaiting FDA approval in the United States. It has an onset of action similar to transmucosal fentanyl and substantially faster than that of other opioids such as hydromorphone and morphine. It undergoes extensive metabolism by cytochrome P450 3A4 and has no active metabolites. Inactive metabolites are excreted in the urine and feces. Small studies have not reported significant changes in sufentanil clearance in the setting of renal or hepatic impairment, although there are limited data in these populations.

Because of its rapid onset of action, sublingual sufentanil has been used and studied primarily for moderate to severe acute postoperative pain. The sufentanil sublingual tablet system is a novel method of patient-controlled analgesia in which a preprogrammed handheld device distributes a 15-μg sublingual microtablet with a preprogrammed lockout interval of 20 minutes. The device uses a radiofrequency identification thumb tag to ensure only

the patient operates the device. It has been shown to be at least as efficacious as intravenous morphine patient-controlled analgesia with a faster onset of action. Side effect profiles have been reported to be similar to intravenous morphine patient-controlled analgesia with greater patient and provider satisfaction and ease of use.[62]

Methadone

Methadone is a synthetic opioid for use in both opioid dependence as maintenance therapy and in chronic pain owing to its long duration of action, low cost, and lack of active or neurotoxic metabolites. Methadone is primarily metabolized by CYP3A4 and CYP2B6 but also undergoes metabolism by four additional cytochrome P450 enzymes. This complex metabolism profile complicates its interaction potential with other drugs.[63] Methadone undergoes both renal and biliary elimination.

Methadone is a μ-receptor agonist but additionally acts as a *N*-methyl-D-aspartate (NMDA) receptor antagonist and a weak serotonin and norepinephrine reuptake inhibitor. Methadone is dosed once daily for prevention of opioid withdrawal symptoms in the setting of opioid replacement therapy for opioid dependence. However, when used in the treatment of pain, its analgesic effect is much shorter, typically requiring dosing every 8 hours.

Methadone's clinical pharmacologic profile exhibits high interindividual variability.[31] Dose conversion ratios between other opioids and methadone are complex, and there is no clear expert consensus about dosing recommendations for converting patients to methadone from other opioids. Slow dose titration is necessary as the long and variable half-life increases the risk of unintended accumulation that can occur as the serum concentration slowly rises toward steady state once a dose is selected. Unfortunately, the increase in the utilization of methadone in the United States has been paralleled by an increase in methadone-related deaths, perhaps due in part to incomplete appreciation of its variable dose requirement.[64] The significant increase in iatrogenic overdoses with methadone therapy led the FDA to issue a black box warning cautioning clinicians regarding the risk of cardiac and respiratory related deaths when initiating and converting patients to methadone therapy. Methadone requires careful monitoring and slow dose titration by experienced clinicians.

Methadone has negative chronotropic properties and can prolong the QTc interval leading to torsades de pointes. Because of this risk, the American Pain Society, College on Problems of Drug Dependence, and the Heart Rhythm Society developed consensus guidelines for methadone use. These guidelines call for a pretreatment electrocardiogram (ECG) in patients with risk factors for QTc prolongation, documented prior QTc longer than 450 msec or a history suggestive of ventricular arrhythmias, and recommend considering a pretreatment ECG in all patients.[64] A follow-up ECG should be conducted in high-risk patients 2 to 4 weeks after initiation of methadone and some recommend annual ECGs, especially with dose increases above 30 to 40 mg/day or if the daily dose exceeds 100 mg/day.[66] Alternative therapy should be considered for patients with baseline QTc longer than 450 msec, and methadone should not be used in patients with QTc longer than 500 msec, as the risk of torsades de pointes increases substantially above this threshold.[65,66]

Combination Agents

Many combination agents exist in which select opioids—namely, hydrocodone, oxycodone, or codeine—are compounded with a nonopioid analgesic including ibuprofen, acetaminophen, or aspirin (e.g., codeine/acetaminophen, hydrocodone/acetaminophen, hydrocodone/ibuprofen, oxycodone/acetaminophen, oxycodone/aspirin). These agents provide some degree of convenience but present many challenges by combining opioids with agents that have clearly defined ceiling doses and their own unique side effect profiles. In 2014, the FDA began requiring that products containing acetaminophen limit the maximum amount of acetaminophen to no more than 325 mg per dose for nonintravenous agents to limit the risk of hepatotoxicity from inadvertent acetaminophen overdose.

Clinical Applications

Common Clinical Indications

Acute Pain

Acute pain related to surgery, illness, or trauma is the most common indication for nonintravenous opioid analgesics. Over the past two decades the importance of treating acute pain has been increasingly recognized. Unrelieved acute pain is associated with reduced quality of life, reduced social function, poor sleep, and impaired physical functioning. Additionally, severe acute pain has been identified as a risk factor for the development of chronic pain states. Although the mechanism for this phenomenon is poorly understood, it has been observed in various patient populations, including those with postsurgical pain, burn injury, acute herpes zoster ("shingles") infection, whiplash injury, after childbirth, and in patients hospitalized with severe medical illnesses.[67,68]

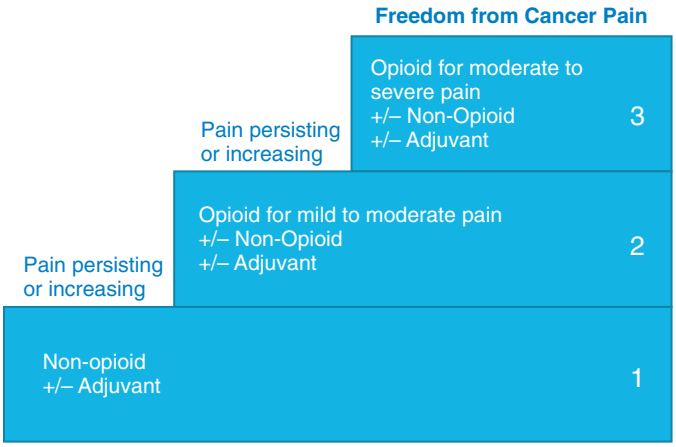
Opioid analgesics are reserved for patients whose moderate to severe acute pain is not relieved by acetaminophen and/or nonsteroidal antiinflammatory drugs and in combination with other nonopioid adjuvant medications and therapies.[69] Although most patients discontinue opioids themselves after recovery from illness, injury, or surgery within a matter of days, in patients who continue to experience pain it is less clear how long opioids should be reasonably continued. Although severe acute pain is a risk factor for the development of chronic pain, use of opioids for acute pain is associated with long-term opioid use, and this association is dose-related. In a study of patients hospitalized for medical opioid detoxification, 51% reported starting opioids for acute pain related to injury or surgical/dental procedure.[70] The Centers for Disease Control and Prevention (CDC) Guideline on Prescribing Opioids for Chronic Pain released in 2016 specifically addresses this issue and offers the following recommendation[29]:

> *Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.*

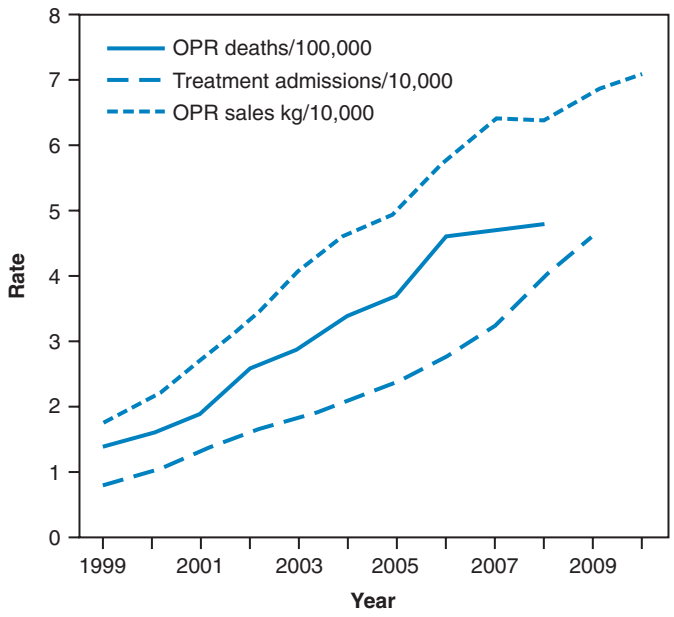
Cancer Pain

Pain is a significant burden in cancer patients; nearly 60% of patients with cancer report pain during their treatment, and among patients with advanced cancer nearly half describe their pain as moderate or severe. Cancer-related pain is associated with a reduced ability to tolerate treatment, depression, reduced life expectancy, and diminished quality of life for both patients and caregivers.[71]

In accordance with the World Health Organization's cancer pain ladder, opioids are the medication of choice for the treatment



• **Fig. 18.5** WHO Pain Relief Ladder for Cancer Pain. (From World Health Organization. WHO Pain Relief Ladder for cancer pain relief.)



* Age-adjusted rates per 100,000 population for OPR deaths, crude rates per 10,000 population for OPR abuse treatment admissions, and crude rates per 10,000 population for kilograms of OPR sold.

• **Fig. 18.6** Rates of opioid pain reliever *(OPR)* overdose death, OPR treatment admissions and kilograms of OPR sold—United States 1999-2010. (From *Morbidity and Mortality Weekly Report (MMWR).* This series is prepared by the Centers for Disease Control and Prevention. Available at http://www.cdc.gov/mmwr/pdf/wk/mm6043.pdf. Accessed October 22, 2016.)

of moderate or severe cancer pain (Fig. 18.5)[72] For pain that is not relieved by nonopioid medications such as acetaminophen or nonsteroidal antiinflammatory drugs, a weak opioid agonist such as tramadol, codeine, or hydrocodone should be initiated. If pain persists or worsens, a strong opioid agonist such as morphine, hydromorphone, or oxycodone should be used. Numerous studies, systematic reviews, and meta-analyses have confirmed the efficacy of this approach.[73,74]

Opioids for Chronic Pain

Chronic pain is defined as pain lasting for longer than 3 months, or past the time of normal tissue healing. Chronic pain is common in the United States, affecting approximately 20% of the population at any given time. Chronic pain is associated with reduced quality of life, lost productivity, martial and family discord, social isolation, impaired sleep, increased medical costs, financial stress, mood disturbance, and disability.[75]

The use of opioids for chronic, noncancer pain is a controversial topic. Comprehensive systematic reviews have reported unclear and/or weak evidence on the efficacy of long-term use of opioids for chronic pain. Despite this, prescribing opioids for chronic pain is a common practice; it is estimated that 20% of patients who present to physicians with chronic, noncancer pain receive an opioid prescription.[76] Opioid prescriptions dispensed by retail pharmacies rose in the United States from 76 million in 1991 to 219 million in 2011.[77] This trend was paralleled by a rapid rise in admissions for opioid abuse treatment and an even steeper rise in opioid overdose deaths (Fig. 18.6).[78]

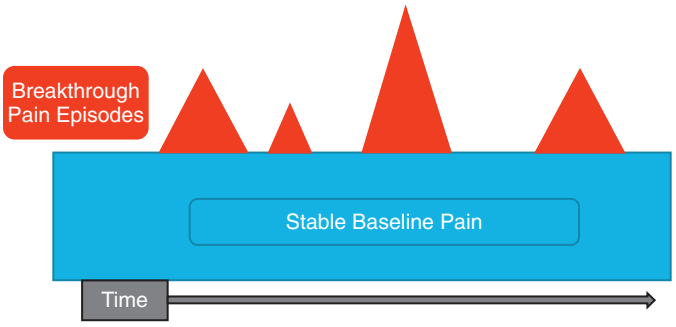
The CDCs Guideline for Prescribing Opioids for Chronic Pain lays out principles for navigating competing concerns. These include using opioids in combination with nonpharmacologic and nonopioid therapies, defining realistic goals for pain and function, discussing the risks of opioids frankly with patients, using the lowest effective dose, evaluating for objective improvements in function after initiating opioids when the OME dose exceeds 50 mg/day, and avoiding prescribing greater than 90 mg OME/day. The guideline also recommends screening for aberrant opioid-related behavior through use of drug testing and review of state prescription drug monitoring databases. Finally, avoiding concurrent use of benzodiazepines and offering take-home naloxone when the dose exceeds 50 mg OME/day are recommended to reduce the risks of opioid overdose and death.[29]

Rational Drug Selection and Administration

Similar to the choice of intravenous opioids, the selection of one oral or transdermal opioid over another is largely based on the desired temporal profile of effect, which is determined by its pharmacokinetic behavior. The time to onset of analgesia and needed duration of effect are primary considerations. However, unlike intravenous opioids, there are additional variables when selecting a nonintravenous opioid, including available routes of administration, level of baseline opioid tolerance, and the side effect profile.

For example, treatment of acute or cancer-related pain in an opioid-naive patient should start with a short-acting, low-dose opioid. Additionally, if pain is episodic, a short-acting oral opioid is appropriate, with escalation of dose as needed to achieve analgesia. However, if pain is continuous in nature such that frequent doses of short-acting opioids are required, initiation of a long-acting opioid should be considered. Long-acting opioids have the advantage of mitigating the "up-and-down" cycle of repeated dosing of short-acting opioids. However, these longer-acting formulations carry greater risk for serious side effect, such as respiratory depression and sedation, in opioid-naive patients.

Furthermore, there is the problem of breakthrough pain (Fig. 18.7), commonly defined as "a transitory exacerbation of pain experienced by the patient who has relatively stable and adequately controlled baseline pain."[79] It is seen most in cancer patients, 40% to 80% of whom report breakthrough pain, with



• **Fig. 18.7** Breakthrough pain.

increased rates among patients with advanced cancer and in patients with more severe baseline pain.[80] Opioids are the rescue medication of choice in managing cancer-related breakthrough pain; opioids that act quickly but have a shorter duration are preferred. These include the short-acting or so-called immediate-release oral opioids, most ideal for opioid-naive patients, pain episodes lasting more than 60 minutes, and for preemptive dosing before volitional incident or procedural pain. For opioid-tolerant patients the transmucosal fentanyl products have been shown to be efficacious, safe, and well-tolerated and carry the advantage of a much more rapid onset and shorter duration, better matching the temporal profile of most breakthrough pain episodes.[81]

Finally, the optimal route of administration must be considered. Patients with impaired gastric or intestinal absorption, ileus, oral or esophageal irritation, gastrointestinal tract obstruction, or impaired swallowing may be unable to use oral formulations or may have unpredictable bioavailability and analgesic effect with oral formulations. Transdermal delivery of opioids is well suited for this population.

Emerging Developments

Buprenorphine for Opioid Dependence

Buprenorphine was approved in the United States for the outpatient management of opioid dependence in 2002. It is available as an abuse-deterrent sublingual film or tablet in combination with naloxone under the trade name Suboxone, or without naloxone as Subutex. It is typically taken as a once-daily dose of 8 mg to 32 mg and, when used for opioid dependence, must be prescribed by a physician who has completed specific training and holds a specialized Drug Enforcement Administration license.

Compared with in-person daily methadone dosing at a methadone maintenance clinic, buprenorphine permits more flexibility to patients and increases the availability of opioid replacement therapy to smaller towns and rural areas. Additional advantages include its long half-life (24–60 hours), lower incidence of euphoria, safety in renal insufficiency, possible ceiling for respiratory depression, and lower rates of tolerance.[82,83]

The efficacy of buprenorphine for opioid dependence is well established with numerous studies demonstrating reductions in cravings for opioids, withdrawal symptoms, and illicit drug use. A recent Cochrane review concluded that it is superior to placebo and, at doses greater than 7 mg/day, is equally effective as methadone for opioid dependence treatment retention and for suppressing illicit opioid use.[84,85] However, although buprenorphine is effective for opioid dependence, it appears most patients require long-term treatment. Rates of relapse to prescription opioid or heroin abuse with buprenorphine discontinuation are very high, approaching 80% in some studies.[86]

Illicit and accidental use of buprenorphine has raised safety concerns. Calls to U.S. Poison Centers regarding buprenorphine exposure or poisoning rose from 771 in 2010 to nearly 3500 in 2014.[87] There is an increasing number of reports of pediatric hospitalizations and deaths related to accidental ingestion of buprenorphine.[88] Additionally, owing to its high affinity for the μ receptor, typical doses of naloxone might not reverse the respiratory depression seen with buprenorphine overdose. Dose requirements of 2 to 4 mg of naloxone have been reported in several studies, with repeated doses or continuous infusion required.[89]

Finally, because of the long half-life and potency of buprenorphine (30–50 times as potent to morphine) there are anesthetic implications for pain control in the perioperative period. Patients treated with buprenorphine have significant tolerance/resistance to opioids. Additionally, full agonist opioids, both intravenous and oral/transdermal, often have diminished effects as the partial agonist buprenorphine acts as a competitive antagonist at the μ receptor. Several management strategies have been proposed, including discontinuing buprenorphine before planned surgery, continuing buprenorphine and adding full agonist opioids for perioperative pain control, and continuing buprenorphine and using additional supplemental buprenorphine postoperatively. At this time the preponderance of evidence supports continuing buprenorphine and adding full agonist opioids, sometimes at high doses, for perioperative pain control with close monitoring.[90–92]

Peripherally Restricted μ-Receptor Antagonists

μ-Receptor antagonists such as naloxone seem like a logical choice for the reversal of OIC. Unfortunately, naloxone easily crosses the blood-brain barrier, thus carrying a risk of inducing opioid withdrawal symptoms. Peripherally restricted μ-opioid receptor antagonists are a new class of medications developed in part to treat OIC. They are less likely to cross the blood-brain barrier owing to their hydrophilic nature and have low oral bioavailability. Two agents in this class include methylnaltrexone and naloxegol. Naloxegol was the first oral agent approved in the United States for OIC in 2014. An oral formulation of methylnaltrexone was approved for use in 2016 after being previously available only for subcutaneous or intravenous administration. A third peripherally restricted μ-opioid receptor antagonist, alvimopan, is restricted to short-term use because of an increased incidence of myocardial infarction. Alvimopan is approved only for the treatment of postoperative ileus and is contraindicated for use in patients taking opioids for more than 7 consecutive days, and therefore has a limited role for the treatment of OIC. These agents do not reverse analgesia in clinically relevant doses and do not cause opioid withdrawal syndrome.[93]

Opioids and Immunosuppression

In addition to the concerns regarding perioperative opioid administration and cancer recurrence (see Chapter 17), there is developing concern that exogenous opioid administration might lead to long-term immunomodulation. Opioids produce immune modulation in both animal and human studies; however, there are conflicting study results on the presence of μ, κ, or δ receptors on immunocytes.[94] There is no evidence of expression of opioid receptor messenger ribonucleic acid in peripheral blood mononuclear cells.[95]

Individual opioids differ in terms of immunomodulation; whereas most studies have examined the effects of morphine, other opioids can be either more or less immune-active. Limited data exist on the immunologic consequences of long-term opioid therapy. Paradoxically, both immunosuppressive and immunostimulatory effects have been reported in different groups of patients such as cancer survivors treated with long-term opioids and patients receiving methadone maintenance therapy.[96] Duration of therapy, as well as dose, likely has an impact on the nature of the immunomodulatory effect. However, existing data are variable and often conflicting such that more investigation is needed to refine our understanding.

Opioids and Sleep-Disordered Breathing

There is a growing body of evidence describing sleep-disordered breathing (SDB) in patients treated with oral and transdermal opioids, including both obstructive sleep apnea (OSA) and central sleep apnea (CSA) patterns. OSA is characterized by respiratory effort despite an obstructed airway, whereas in CSA there is cessation of both air flow and respiratory effort. CSA is commonly associated with a pattern of variable respiratory drive that may include periods of hyperventilation and hypocapnia. Patients with CSA can also have underlying airway obstruction, and in many patients both CSA and OSA contribute to the overall syndrome of SDB.

Chronic opioid use can lead to a disruption and imbalance between hypoxic and hypercapnic drivers of ventilation.[97] In a study of patients using stable methadone maintenance therapy, the incidence of CSA alone was found to be 30%.[98] In another study of 32 chronic pain patients using chronic opioid therapy, opioid dosage was found to be correlated with SDB and subsequent cessation of opioid therapy significantly reduced SDB.[99] A recently published review reported an overall prevalence of SDB in 70% to 85% in patients taking opioids, with moderate or severe SDB occurring in a high proportion of these patients.[100] Unfortunately, until recently this was a neglected and poorly described area and consensus recommendations for the screening and treatment of opioid-related SDB have yet to emerge.

Opioids and Endocrine Dysfunction

Although hypogonadism associated with chronic opioid use has been recognized for many years, there is an evolving understanding that long-term opioid therapy contributes to a variety of endocrine deficiencies. Opioids, administered by any route, disrupt the hypothalamic-pituitary-gonadal axis and have a well-documented effect on levels of gonadotrophin-releasing hormone (GnRH), luteinizing hormone (LH), and testosterone.[101] Exogenous opioids interfere with the release of GnRH from the hypothalamus. GnRH stimulates the release of follicle-stimulating hormone and LH from the pituitary. In males, LH stimulates testosterone release from Leydig cells in the testes. In females, LH drives ovarian follicular maturation and estrogen secretion. Evidence of hypogonadism associated with opioids has been shown in animals, healthy human volunteers, heroin abusers, patients with chronic pain, cancer survivors, and patients undergoing methadone maintenance therapy.[102] These effects can contribute to reduced libido, erectile dysfunction in males, menstrual irregularity in females, loss of muscle mass, and depression and anxiety.[103]

There is also a long-established association between opioid use and an increased incidence of fractures. The recent literature has suggested that the risk may be due in part to a direct effect via opioid-induced osteopenia. Studies have shown an association between opioid use and reductions in bone mineral density.[104] Although the mechanism by which opioids induce osteopenia has yet to be fully elucidated, there is a clear association between hypogonadism and osteoporosis. Additionally, some literature points to a possible direct effect on osteoblast growth and activity.[105]

Given this budding understanding of endocrine deficits observed in patients using chronic opioid therapy, some have called for recommendations for clinicians to screen patients for symptoms of hypogonadism and consider measuring serum hormone levels for patients on opioid therapy equal to or greater than 100 mg OME daily.[106] Screening thresholds for osteopenia in these patients are less well defined but should be considered as a clinical risk factor for early bone density testing.

Key Points

- Nonintravenous opioids can be categorized into three groups based on their chemical structures: naturally occurring alkaloids, semisynthetic alkaloids, and synthetic opioids.
- Most nonintravenous opioids are metabolized by cytochrome P450 enzymes into inactive metabolites. However, morphine is a notable exception in that it undergoes glucuronidation to produce metabolites M3G, which may have neuroexcitatory effects, and M6G, a potent analgesic. M6G is renally cleared and can accumulate in the setting of renal insufficiency with potentially deleterious clinical effects.
- Nonintravenous routes of opioid administration include transmucosal, oral, and transdermal. Transmucosal opioids are considered ultrashort-acting, whereas oral opioids are available in short-acting, extended-release, and long-acting forms. Transdermal preparations allow for continuous delivery of opioid medication.
- Common side effects of nonintravenous opioid analgesics include constipation, nausea, sedation, pruritus, and ventilatory depression. Tolerance develops to most of these effects, with the notable exception of constipation.
- Acute pain and cancer-related pain are long-standing indications for the use of nonintravenous opioids. Use of opioids in the treatment of chronic pain is controversial; clear evidence supporting their efficacy is lacking and there are concerns for the development of addiction and overdose related death.
- Selection of a nonintravenous opioid is based on the targeted time to onset, required duration of action, available routes of administration, baseline opioid tolerance, comorbidities, and side effect profile.
- Emerging developments in nonintravenous opioids include buprenorphine for opioid dependence, peripherally restricted μ antagonists for opioid-induced constipation, and concerns about suppression of immune and endocrine function and sleep-disordered breathing in patients treated with opioids.

The term *nonopioid analgesics* seems to imply a motley group of agents self-consciously trying to establish their parity with their famously potent cousins: the opioid family. With contemporary understanding of the complexities of both acute and chronic pain, the importance of a multimodal approach to pain management pharmacotherapy has emerged, and the former outcasts have slowly been incorporated into the armamentarium of the anesthesiologist.

With the exception of the nonsteroidal antiinflammatory drugs (NSAIDs), most nonopioid analgesics have stumbled awkwardly from other specialties such as psychiatry and neurology into the field of pain medicine. As the specialty of pain medicine learned that opioids were not a panacea for all chronic pain conditions because of their long-term inefficacy, toxicities, and a propensity for misuse, greater emphasis was placed on nonopioid analgesics either as first-line treatment or as an adjunct to opioids.

Abstract

The role of nonopioid analgesics have become increasingly important given mounting evidence against the use of opioids in chronic, non-malignant pain. Furthermore, recent Centers for Disease Control guidelines for opioid prescribing recommend preferential use of nonopioid analgesics prior to initiation of opioid therapy. Nonopioid analgesics are a disparate group of compounds including nonsteroidal anti-inflammatories, anti-epileptic drugs, and tricyclic agents. This chapter will discuss each of these drug classes in detail with an emphasis on the evidence that supports their utility in the perioperative and pain management setting. Careful consideration will also be given to some of the perioperative controversies of certain agents; for example, the issues of surgical hemostasis and bone healing with nonsteroidal anti-inflammatories. A brief discussion on novel and emerging agents will also be presented.

Tricyclic antidepressants

In March 2016 the Centers for Disease Control and Prevention (CDC) released guidelines for prescribing opioids in chronic pain.[1] While these guidelines were directed at primary care physicians, all medical providers have likely felt the effects of the far-reaching effort to curb what has become known as an epidemic of opioid misuse and overdose. Paramount among these recommendations is the role of nonopioid analgesics in treating chronic pain, as evidenced by the first of 12 guidelines:

> *Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.*

Because of the pharmacologic heterogeneity of nonopioid analgesics, this chapter is broadly divided into two sections: one describing NSAIDs and another describing drugs used for treatment of neuropathic pain. An additional section discusses emerging developments of various drugs with potential utility in the perioperative and chronic pain population.

NSAID History

NSAIDs have been used for millennia in the form of the prototypical agent, aspirin. Hippocrates wrote about using powdered willow bark for pain and fever in the fifth century BC. In the late 18th century, Stone isolated salicylic acid from willow, myrtle, and a number of other plants. However, it was not until early in the 20th century that Hoffmann, a chemist with Bayer Pharmaceuticals, discovered acetylsalicylic acid and marketed aspirin for fever, pain, and inflammation. It was not until later in the 20th century that aspirin became the generic name for this compound. Aspirin continues to be an important drug, but now more for its antiplatelet activity than for its original indications.

The newer NSAIDs were released in the 1960s, the first being indomethacin, closely followed by ibuprofen. Since then several dozen agents have been released in the United States and elsewhere, competing for a lucrative commercial market. Over time, some of these agents have been withdrawn because of major toxicities, including hepatotoxicity, nephrotoxicity, and blood dyscrasias. The recent voluntary withdrawal of the blockbuster drug rofecoxib (Vioxx) generated considerable controversy and media coverage amid concerns of increased cardiovascular risk.

Despite these controversies, NSAIDs remain very useful and widely used drugs for their analgesic and antipyretic effects. In the management of postoperative pain, NSAIDs are probably underused despite good evidence for their safety and efficacy.[2]

Nonsteroidal Antiinflammatory Drugs and Acetaminophen

Basic Pharmacology

Structure-Activity Relationships

Nonsteroidal antiinflammatory agents are a diverse group of drugs broadly categorized into salicylates, acetic acid derivatives, propionic acid derivatives, oxicam derivatives, and the cyclooxygenase (COX)-2 selective agents (Fig. 19.1). All act by blocking prostaglandin synthesis, both in the periphery and in the central nervous system (CNS).

Mechanism

Prostaglandins are lipid-based compounds derived enzymatically from fatty acids that have important physiologic functions, including the mediation of the inflammatory response, the transduction of pain signals, and a central pyretic effect. The primary source of prostaglandins in humans is arachidonic acid, a 20-carbon polyunsaturated essential fatty acid that is, in turn, derived from cell membrane phospholipids. The NSAIDs act by inhibiting COX enzymes that catalyze the conversion of arachidonic acid to prostaglandins, thromboxanes, and prostacyclin (Fig. 19.2).

The COX enzymes are now known to exist as three isoforms: COX-1, COX-2, and COX-3. COX-3 is a splice variant of COX-1 and is now recognized as the once elusive enzyme inhibited by acetaminophen.[3] However, controversy still exists about the existence of COX-3 inhibition in humans and the mechanism by which acetaminophen-mediated analgesia occurs. COX-1 and COX-2 are the isoforms targeted by the traditional NSAIDs, while the more selective COX-2 inhibitors preferentially block COX-2. COX-1 is considered to be the constitutive enzyme (often called the *housekeeping enzyme*), generating prostanoids involved in normal physiologic functioning such as gastrointestinal mucosal protection and hemostasis. COX-2, on the other hand, has low baseline expression but is inducible during physiologic stress by agents including proinflammatory cytokines, neurotransmitters, and growth factors.

However, this schema is acknowledged to be an oversimplification in that there are exceptions to this rule: for example, COX-2 is constitutively expressed in the kidney and CNS, and COX-1 can be induced by certain stress conditions in nerve tissue.[4] Although both enzymes are structurally similar and act basically in the same fashion, their respective gene expression profiles and selective inhibition can determine NSAID side effects and toxicity.

Metabolism

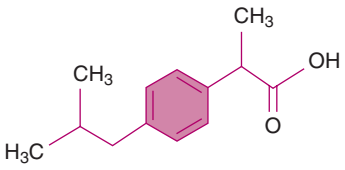
The primary mode of NSAID elimination is by hepatic biotransformation by cytochrome P450 (CYP 450)-mediated oxidation or glucuronide conjugation. Renal excretion of unmetabolized drug is much less important, accounting for less than 10% of the administered dose. Biliary excretion has been described for certain NSAIDs, although this route plays a small role. Because NSAIDs share common metabolic pathways, nuances relating to metabolism are not a basis for therapeutic decisions regarding the appropriate NSAID for a given patient.

Clinical Pharmacology

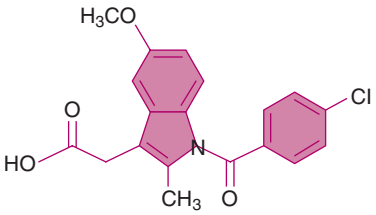
Pharmacokinetics

NSAIDs are weak acids with pK_a values typically lower than 5, and therefore they exist mostly in the ionized form at physiologic pH. NSAIDs, except aspirin, which is 50% to 80% bound, are highly bound to plasma proteins, primarily albumin. NSAID half-lives vary significantly between drugs (Table 19.1). Because oral NSAIDs are often prescribed for long-term use, a focus of modern NSAID development has been to design compounds that are relatively long-acting to facilitate improved patient compliance.

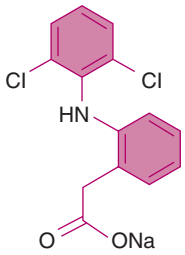
Most NSAIDs are rapidly absorbed following oral administration, with peak plasma concentrations generally reached within 2 to 3 hours. Factors affecting gastric emptying can profoundly affect the time course of the clinical effects of NSAIDs. In part because



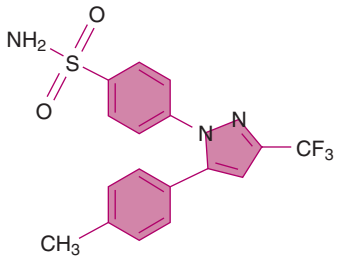
Propionic acid derivative – ibuprofen



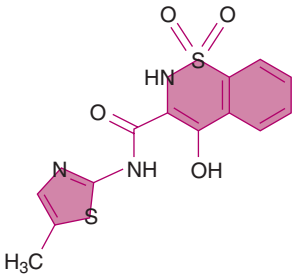
Acetic acid derivative – indomethacin



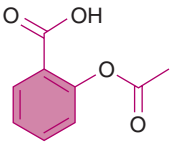
Fenamate NSAID – diclofenac



COX-2 selective NSAID – celecoxib

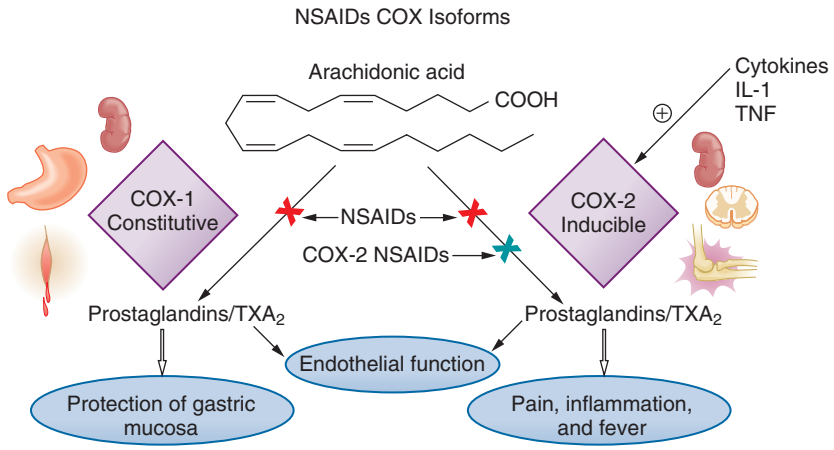


Enolic acid derivative (oxicam) – meloxicam



Salicylate – aspirin

• **Fig. 19.1** Nonsteroidal antiinflammatory drugs *(NSAIDs).* Molecular structures of an agent from each class of NSAID. Note the disparate chemical structures between classes.



• **Fig. 19.2** Mechanism of action of nonsteroidal antiinflammatory drugs *(NSAIDs),* with comparison of cyclooxygenase *(COX)*-1 and COX-2 inhibition effects. COX-3 effects not shown. *IL-1,* interleukin 1; *TXA_2,* thromboxane A_2; *TNF,* tumor necrosis factor.

TABLE 19.1 Summary of Nonsteroidal Antiinflammatory Drugs and Acetaminophen

Drug	Common Trade Name	Half-Life (hr)	Protein Binding (%)	Typical Daily Dose Range	Typical Dosing Schedule	Typical Pediatric Dosing (mg/kg per 24 hr)	Notes
Acetaminophen/ paracetamol	Tylenol, Panadol Ofirmev (IV)	2	20–50	2–4 g	325–650 mg q4hr	10–15 mg/kg q6–8 hr prn	No antiinflammatory effect
Propionic Acid Derivatives							
Fenoprofen	Nalfon	2–3	99	1.2–2.4 g	300–600 mg qid	NA	
Flurbiprofen	Ansaid	2	99	200 mg	100 mg bid	NA	
Ibuprofen	Motrin, Advil, Brufen, others	6	99	1.2–2.4 g	400–800 mg qid	7.5–10 mg/kg qid	Higher doses sometimes used for inflammatory conditions; maximum dose 3200 mg/day
Ketoprofen	Orudis	2–4	99	225 mg	75 mg tid	NA	
Naproxen	Naprosyn	14	99	750–1000 mg	250–375 mg bid	5–10 mg/kg bid	
Naproxen sodium	Alleve, Anaprox	14	99	550–1100 mg	275–550 mg bid	5–10 mg/kg bid	
Fenamates							
Diclofenac	Voltaren	1–2	99	150–200	50 mg tid 75 mg bid	2–3 mg/kg per 24 hr	Hepatotoxicity rarely reported. Also has topical formulations
Tolmetin	Tolectin	5	99	600–1800 mg	200–600 mg tid	20–30 mg/kg per 24 hr as 3–4 doses	
Ketorolac	Toradol	4–6	99	IV: 60 mg/day[a]	30 mg first dose; then 15 mg q6hr[a]	IV: 0.5 mg/kg per day, single dose only	[a]Half the dose if age >65 yr or weight <50 kg
Enolic Acid Derivatives (Oxicams)							
Meloxicam	Mobic	15–20	99	7.5–15	7.5–15 mg qd	NA	Higher dose typically used for rheumatoid arthritis Intermediate COX-1 and COX-2 selectivity
Piroxicam	Feldene	40–50	99	20 mg	10–20 mg qd	NA	
Nabumetone	Relafen	24	99	1000–1500 mg	500–750 mg bid	NA	
Acetic Acid Derivatives

of the variability in the time course of oral absorption, the use of rectal NSAIDs is popular in Europe for the management of postoperative pain and has the added advantage of being possible even when oral intake is not.[5] Ketorolac and ibuprofen are the only parenteral NSAIDs currently available in the United States, but intravenous diclofenac and parecoxib are available elsewhere. Parenteral administration is advantageous in renal colic because of its more rapid onset than with oral administration, but it has demonstrated no obvious advantage over oral administration for any other indication.[6]

Pharmacodynamics

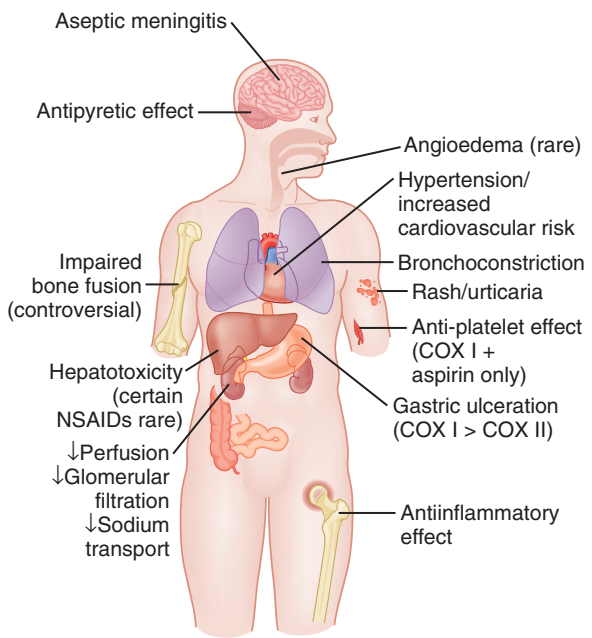
Therapeutic Effects

NSAIDs are widely used for their analgesic properties, particularly when pain has an inflammatory component such as in certain rheumatologic conditions. Tissue trauma results in cell membrane disruption and release of arachidonic acid, the substrate for COX enzymes, and consequently a rise in local prostaglandin (PG) concentrations. These prostanoids, particularly PGE_2, result in sensitization of nociceptors to mechanical stimuli and other chemical mediators such as bradykinin, leading to increased nociceptor firing and pain perception. COX enzyme activity has also been identified in the CNS, including the dorsal horn of the spinal cord, and it is postulated that COX inhibition also provides a central analgesic mechanism.[3]

The antipyretic effect of the NSAIDs is very predictable and has utility in the treatment of fever, both in adults and children. Perioperatively, NSAIDs are indicated in a multimodal analgesic approach, and the American Society of Anesthesiologists (ASA) recent practice guidelines for acute pain management in the perioperative setting encourage the use of NSAIDs unless contraindicated.[2] A less common NSAID indication (indomethacin is typically used) is in the prevention of ductus arteriosus closure when this would be detrimental in certain neonatal congenital heart conditions where an ongoing right-to-left shunt is desired before corrective surgery. Fig. 19.3 provides an overview of the pharmacodynamic effects of NSAIDs, including both therapeutic and adverse effects.

Adverse Effects

NSAIDs have a number of nonspecific adverse effects, including rash and gastrointestinal upset (e.g., dyspepsia, abdominal pain, and diarrhea), that are not related to their targeted mechanism.



• **Fig. 19.3** Overview of the common pharmacokinetic and pharmacodynamic effects of nonsteroidal antiinflammatory agents. *COX,* Cyclooxygenase; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

Other adverse effects are manifest in multiple organ systems, reflecting the widespread expression of the COX enzymes.

Cardiovascular Effects

All NSAIDs, and not just the COX-2 selective agents, can increase the risk of serious cardiovascular thrombotic events such as myocardial infarction and stroke.[7,8] The mechanisms underlying these adverse effects are complicated but likely include an imbalance between the prothrombotic and vasoconstricting activity of thromboxane A_2 (TXA_2), and the antithrombotic and vasodilatory effects of prostacyclin (PGI_2), thereby favoring deleterious thromboxane effects.[9] In addition, NSAIDs increase blood pressure in a dose-dependent fashion, which may also be linked to the increased cardiovascular risks associated with their use.[10] Prolonged administration of COX-2–selective NSAIDs can cause adverse events through inhibition of PGI_2, including development of hypertension and the promotion of thrombus development in a ruptured plaque.[7] Recent reviews of both nonselective NSAIDs and COX-2 inhibitors have found that nonselective NSAIDs and celecoxib carry little risk of ischemic stroke, whereas rofecoxib and valdecoxib (both discontinued) are associated with significant risk.[11,12] However, the cerebrovascular safety of nonselective NSAIDs has been questioned in other studies, suggesting that all NSAIDs should be used with caution in patients with high risk for cerebrovascular disease.[8]

The perioperative administration of NSAIDs, especially the COX-2 selective agents for short-term use, has been subject to some controversy owing to their possible role in increasing morbidity after cardiac surgery.[13,14] However, a recent meta-analysis of studies using parecoxib and valdecoxib compared with placebo in noncardiac surgery concluded that there were no differences in cardiovascular events between groups.[15]

In 2005, a consensus statement issued by the Food and Drug Administration (FDA) Arthritis Advisory Committee and the Drug Safety and Risk Management Advisory Committee concluded that COX-2 selective agents are important treatment options for pain management and that the preponderance of data demonstrates that the cardiovascular risk associated with celecoxib is similar to that associated with commonly used, older, nonselective NSAIDs. The committee also concluded that short-term use of NSAIDs does not appear to increase cardiovascular risk and that rigorous scientific studies are needed to characterize the longer-term cardiovascular risks of these therapies. With respect to the longer-term use of NSAIDs, a careful risk-benefit analysis should be performed, particularly in those already at risk for cardiovascular events.[16]

Bone Healing

Bone healing is dependent on an inflammatory response involving numerous cytokines, including interleukin (IL)-1, IL-6, tumor necrosis factor, and fibroblast growth factor, so it is not surprising that agents that disrupt normal cytokine function can impair bone homeostasis and repair.[17] There are convincing animal data that nonselective and COX-2 inhibitor NSAIDs inhibit bone healing.[18–20] This inhibition of healing response has been used therapeutically to prevent heterotrophic bone formation after arthroplasty.[21] In a rat model of femoral fracture healing, celecoxib or rofecoxib delayed fracture healing compared with indomethacin.[22] At 8 weeks postoperatively, there was still evidence of the original fracture in these two groups.

However, human data on possible detrimental effect of NSAID use in the perioperative period are conflicted and controversial.[23] The issue of bone healing and NSAIDs has been addressed mostly in the spinal fusion literature. Successful spinal fusion surgery

demands a robust bone healing process, so spine surgeons place great importance on mitigating all risk of nonunion with measures such as smoking cessation and NSAID avoidance. A retrospective analysis of 288 patients who underwent instrumented spinal fusion from L4 to the sacrum demonstrated a five times higher nonunion rate when ketorolac was used in the immediate postoperative period.[24] In contrast, another retrospective study found that, in 405 consecutive patients who underwent primary lumbar spinal fusion, a subset of patients who had ketorolac 30 mg intravenously every 6 hours for 2 days had similar fusion rates to a group that had no NSAIDs.[25] A recent meta-analysis of five retrospective studies explored the relation of ketorolac dose and successful spinal fusion rates and concluded that high-dose ketorolac (>120 mg/day) might be associated with poor outcomes, whereas standard dose ketorolac (<120 mg/day) was not.[26] In the absence of any prospective or randomized studies, and realizing that bony nonunion is a high-morbidity outcome, use of perioperative NSAIDs in spinal fusion cases should be considered carefully, particularly when other risk factors for poor bone healing (e.g., smoking) exist. In nonspine orthopedic surgery, there is good evidence of NSAID analgesic efficacy and no significant association with compromised bone healing.[23,27]

Allergy and Hypersensitivity

All NSAIDs, including aspirin, can induce hypersensitivity reactions of two general types, both likely related to the inhibition of prostaglandin synthesis. Provocation of asthmatic attacks in patients with vasomotor rhinitis and nasal polyposis is likely related to inhibition of normal production of the bronchodilator PGE_2. NSAIDs also rarely induce the syndrome of urticaria and angioedema related to inhibition of prostaglandin effects that normally stabilize histamine stores in mastocytes and inhibit the inflammatory response.[28] In susceptible individuals, this unchecked inflammation can result in spontaneous degranulation of mastocytes with release of histamine in the respiratory tract and skin, which leads to bronchoconstriction and urticaria. This process is COX-1 mediated, and therefore COX-2 selective NSAIDs may be used, but with caution, in NSAID-intolerant patients.[29,30]

Gastrointestinal Toxicity

The long-term use of oral NSAIDs inhibits production of prostaglandins that maintain normal gastrointestinal mucosal integrity and results in gastric and colonic mucosal damage, including erosion and ulceration. In addition, oral NSAIDs can cause local irritation, and when erosion and/or ulceration is present, hemostasis is compromised by COX-1 inhibition. This constellation of physiologic derangements results in a spectrum of gastrointestinal problems, ranging from mild gastritis to peptic ulceration with perforation.

The morbidity and mortality of NSAID use is a significant public health problem, although it appears to be abating in recent years, likely because of the more widespread use of proton pump inhibitors, rather than the use of COX-2 inhibitors.[31] Risk factors identified for the development of NSAID-induced ulcers include advanced age, history of previous ulcer, concomitant use of corticosteroids, higher doses of NSAIDs (including the use of more than one NSAID), concomitant administration of anticoagulation agents, serious systemic disorders, cigarette smoking, consumption of alcohol, and concomitant infection with *Helicobacter pylori*. Short-term use of NSAIDs in the perioperative period carries little risk of mucosal injury, although intolerance or nausea can be an issue in patients given NSAIDs on an empty stomach.

Hemostatic Effects

Platelets, lacking a nucleus and the ability to generate new proteins like COX, are particularly susceptible to the effects of COX inhibitors. Aspirin irreversibly acetylates COX enzymes and inhibits platelet aggregation for the 10- to 14-day life span of the platelet. Other nonselective NSAIDs reversibly inhibit COX, causing only transient reduction in TXA_2 formation. Consequently, inhibition of platelet activation resolves after most of the drug is eliminated. For example, a single 300- to 900-mg dose of ibuprofen can inhibit platelet aggregation for 2 hours after administration, and the effect is largely dissipated by 24 hours. Overall, with the exception of aspirin, NSAIDs cause transient, dose-dependent, and modest bleeding time abnormalities, which often do not exceed normal limits.[9] However, clinical studies have revealed some significant issues with perioperative hemostasis and nonselective NSAID use. In total hip arthroplasty, patients taking nonselective NSAIDs had more intraoperative and postoperative blood loss than those who did not.[32] Despite concern on the part of many ear, nose, and throat surgeons regarding the use of NSAIDs for pain control after pediatric tonsillectomy, a thorough meta-analysis of studies addressing this concern failed to find any significant association between NSAIDs and perioperative bleeding requiring return to the operating room.[33] Importantly, the COX-2 enzyme has not been identified in platelets, so the COX-2 inhibitors are not thought to have deleterious antiplatelet effects.[34]

Renal Toxicity

Aspirin and all other NSAIDs, including COX-2 inhibitors, can transiently decrease renal function in selected patients, resulting in hypertension, edema, and even acute renal failure. These effects occur more often in patients with underlying renal disease and in those with intravascular volume depletion.[35] Renal perfusion and glomerular filtration are closely regulated by renal prostaglandin synthesis, particularly in the fluid-depleted state. Inhibition of this system is the postulated mechanism of NSAID-induced sodium ion (Na^+) retention and renal dysfunction. In the perioperative setting, NSAIDs seldom cause clinically significant renal impairment, but should be withheld in patients who are significantly volume depleted, have intraoperative oliguria, or have preexisting renal impairment.

Other Toxicities

Aspirin and diclofenac are the most potentially hepatotoxic NSAIDs and should be avoided in patients with preexisting hepatic failure.[36] NSAIDs have been implicated in hypersensitivity-induced aseptic meningitis, generally manifesting with meningeal signs commencing within weeks of starting therapy. It is a diagnosis of exclusion after ruling out an infectious cause of the meningeal irritation.

Drug Interactions

Hypoalbuminemia increases the free fraction of NSAIDs in the plasma, thus affecting their distribution and elimination. The high degree of serum protein binding increases interaction risk with other highly protein bound drugs. In clinical practice, however, this is rarely significant, and NSAIDs can be used safely in conjunction with other agents commonly used in perioperative practice. One exception is the potential for nephrotoxicity when NSAIDs are used concomitantly with other potentially nephrotoxic drugs such as the aminoglycosides, radiographic contrast media, and diuretics. Nonselective NSAIDs should be used with caution in patients who have been using other platelet-inhibiting drugs or anticoagulants.

Special Populations

Renal Failure

In general, NSAIDs are avoided in patients with renal failure. The use of NSAIDs in patients with preexisting renal insufficiency can have deleterious effects as discussed earlier. Renal failure influences NSAID kinetics by reducing renal excretion of the drugs and metabolites normally eliminated in the urine and by affecting their distribution and biotransformation.[37] All NSAIDs are very highly bound to plasma proteins, and hemodialysis will not likely increase elimination of these agents. No dosage adjustments are therefore necessary for hemodialysis patients receiving NSAIDs.

Liver Disease

The majority of NSAIDs have low hepatic clearance, so mild to moderate liver disease should theoretically not interfere with their oral bioavailability. Because NSAIDs are so avidly protein-bound, alteration of liver albumin synthesis would be expected to cause alterations in the unbound drug fraction in plasma. Diclofenac has been the agent most implicated with hepatic dysfunction and should be avoided in patients with liver disease.

Older Age

Advanced age is an independent risk factor for both cardiovascular disease and NSAID gastropathy, so NSAIDs should be used with additional caution in this population. However, the opioid-sparing effects of NSAIDs in the postoperative period make NSAIDs an attractive pain management adjunct, particularly when concerns exist regarding oversedation, delirium, or respiratory depression in older patients receiving opioids. In older adults, the relatively high lipid solubility of NSAIDs, potentially decreased plasma protein levels, and reduced renal function all contribute to an increased likelihood of toxicity. Therefore the lowest effective dose of NSAID should be administered, with frequent follow-up (sometimes including renal function tests) for assessment of side effects or toxicity.[38]

Unique Features of Individual Agents

Meloxicam

Meloxicam, an NSAID of the enolic acid type, is unique in that it selectively blocks COX-2 over COX-1, and is therefore considered an intermediate between COX-2 selective agents and the nonselective NSAIDs. Consequently, meloxicam might have a better gastrointestinal tolerability profile compared with nonselective agents and can be considered if celecoxib is unavailable or contraindicated.[28]

Ketorolac

Ketorolac, until recently, was the only parenteral NSAID available in the United States and was therefore used quite extensively in the perioperative period. Pharmacologically, it is a member of the pyrrolo-pyrrole group and is avidly protein bound, resulting in a low volume of distribution. Ketorolac is extensively conjugated in the liver and then excreted in the urine. Time to measurable effect is about 30 minutes, with a peak effect noted at 1 to 2 hours and a duration of action of 4 to 6 hours.

In the management of postoperative pain, ketorolac has proven very useful, with an opioid-sparing effect and efficacy similar to morphine in the treatment of moderate pain.[39,40] Concerns exist regarding the renal safety profile of ketorolac in the perioperative setting that have necessitated modifications of dosing guidelines. Previously, the drug was administered at a 60-mg initial dose followed by 30 mg every 4 hours, and cases of acute tubular necrosis were reported. Gastrointestinal bleeding and operative site bleeding have also been reported and are mostly associated with advanced patient age, duration of therapy beyond 5 days, and higher dosing regimens.[41] Subsequently, dosing recommendations were decreased by more than 50%. The ketorolac product labeling now advises the following intravenous dosing protocol: for a single dose, 30 mg intravenously or 15 mg if patient age is greater than 65 year or body weight less than 50 kg; for multiple dosing, patients should be commenced on 30 mg every 6 hours, not to exceed 120 mg in a 24-hour period; in those older than 65 years or weighing less than 50 kg, the dosing should be 15 mg every 6 hours, not to exceed 60 mg in 24 hours.[42] In no circumstance should dosing go beyond 5 days of therapy, and ketorolac is best avoided in patients with a history of peptic ulcer disease or renal impairment.

Acetaminophen

Acetaminophen, while strictly speaking is not an NSAID, is generally grouped in this therapeutic class and plays a major role in analgesic therapy. Acetaminophen is a para-aminophenol derivative with analgesic and antipyretic properties similar to aspirin. The very useful antipyretic effect is thought to be a direct effect on the hypothalamic heat-regulating centers via inhibiting action of endogenous pyrogens. Recent reports suggest that acetaminophen acts via serotonergic pathways, COX-3 inhibition, and/or endogenous cannabinoid potentiation to provide analgesia, but its mechanism of action remains poorly understood.[43–45] Although equipotent to aspirin in inhibiting central prostaglandin synthesis, acetaminophen has no significant peripheral prostaglandin synthetase inhibition and is therefore less useful than NSAIDs for painful inflammatory disorders.

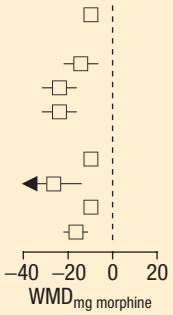
Acetaminophen has few side effects in the usual dosage range; unlike NSAIDs, no significant gastrointestinal toxicity or platelet function inhibition occur. Acetaminophen has, however, been associated with the development of hypertension but has not yet been associated with increased cardiovascular risk.[46] Nephrotoxicity also can occur with acetaminophen but less frequently than it occurs with NSAIDs.[47]

Acetaminophen is completely and rapidly absorbed following oral administration, and peak serum concentrations are achieved within 2 hours. About 90% of acetaminophen is hepatically metabolized to sulfate and glucuronide conjugates for renal excretion with a small amount secreted unchanged in the urine. Minor metabolites are responsible for the hepatotoxicity seen in overdose.[48] CYP 450 enzyme system induction in the liver by any agent, including ethanol, increases the formation of toxic free radial metabolites and thereby increases hepatotoxicity. In the healthy individual, daily doses of 2.6 to 3.2 g are generally considered safe, but acetaminophen dosing should not exceed 4 g/day.[49,50] In patients with a history of ethanol abuse or liver disease, acetaminophen should generally be avoided.

The bioavailability of rectal acetaminophen is variable and is approximately 80% of that following oral administration. The rate of rectal absorption is slower, with maximum plasma concentration occurring 2 to 3 hours after administration. Doses of 40 to 60 mg/kg of rectal acetaminophen have been shown to have an opioid-sparing effect in the management of postoperative pain.[51] In Europe, an intravenous prodrug form of acetaminophen, propacetamol, and intravenous acetaminophen are available for clinical use and have been shown to reduce

TABLE 19.2 24-Hour Morphine Consumption (in milligrams)

Regimens	NO. OF PATIENTS WITH Active	Control	Change in Morphine Requirement	WMD (95% CI)
Acetaminophen				
Multiple dose	379	334		–8.31 (–10.9 to –5.72)
NSAIDs				
Single dose	553	496		–8.31 (–10.9 to –5.72)
Multiple dose	495	398		
Continuous	276	253		–8.31 (–10.9 to –5.72)
COX-2 Inhibitors				
Single dose	70	69		–8.31 (–10.9 to –5.72)
Single dose	91	91		
Multiple low dose	272	273		–8.31 (–10.9 to –5.72)
Multiple high dose	535	411		



A weighted mean difference (WMD) less than 0 indicates less morphine consumption with active compared with control. When the 95% confidence interval (CI) does not include 0, the difference is considered statistically significant. COX-2 inhibitor = 200 mg celecoxib, or 50 mg rofecoxib; multiple high dose = valdecoxib and parecoxib 40 mg/12 hr and parecoxib 40 mg/6 hr; multiple low dose = valdecoxib and parecoxib 20 mg/12 hr.

Does multimodal analgesia with acetaminophen, nonsteroidal antiinflammatory drugs, or selective cyclooxygenase-2 inhibitors and patient-controlled analgesia morphine offer advantages over morphine alone? Meta-analyses of randomized trials. *Anesthesiology.* 2005;103:1296–1304.

postoperative opioid consumption.[52,53] In 2011, an intravenous form of acetaminophen was introduced in the United States for the parenteral management of pain and fever.[54] Intravenous acetaminophen (1 g every 4 hours for 24 hours) was well tolerated, improved pain reporting, and decreased morphine consumption after orthopedic surgery.[55]

Oral NSAIDs

Common Clinical Indications

Postoperative Analgesia

While opioids continue to be the mainstay of analgesia during the perioperative period, NSAIDs and acetaminophen alone can be sufficient for the management of mild pain and are a very useful adjunct in the management of moderate to severe pain. The latest ASA practice guidelines for acute pain management in the perioperative setting encourage the use of NSAIDs and other adjuncts whenever possible.[2] The preoperative administration of oral COX-2 selective NSAIDs can reduce cerebrospinal fluid (CSF) and surgical site PGE_2 levels in humans during the perioperative period with an associated decrease in pain. In addition to reducing CSF PGE_2 levels, COX-2 selective NSAIDs decreased CSF IL-6 (a major proinflammatory cytokine) levels. The IL-6 modulation by COX-2 inhibitors is not well understood but is likely to be related to the PGE_2 pathway.[56]

A recent meta-analysis examined the effect of adding acetaminophen, nonselective NSAIDs, or COX-2 selective NSAIDs to opioid patient-controlled analgesia. The results suggested that all three analgesic agents provided an opioid dose-sparing effect (25% to 55%). Moreover, the addition of NSAIDs to morphine was associated with a decrease in the incidence of postoperative nausea and vomiting and sedation (Tables 19.2 and 19.3).[27] Clinical trials of COX-2 selective NSAIDs used preoperatively and into the postoperative period for patients undergoing both major surgery and minimally invasive surgery have demonstrated improved clinical outcomes, including reduction in postoperative pain, opioid use, and nausea.[27,57,58] A meta-analysis of clinical studies evaluating COX-2 inhibitors compared with nonselective NSAIDs for postoperative pain showed that the analgesic efficacy of COX-2 inhibitors in the 6 hours after surgery was similar to or better than ibuprofen.[59]

NSAIDs in Chronic Pain

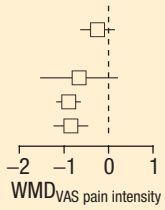
Chronic pain has been defined as pain that extends beyond the expected period of healing or beyond a certain arbitrary period of time, or more specifically as pain that extends beyond 3 to 6 months from the original injury. The use of NSAIDs in chronic pain has an important role in selected conditions. Conditions with a predominant inflammatory component such as rheumatoid arthritis are likely to respond favorably to NSAIDs, whereas noninflammatory conditions such as peripheral neuropathic pain are unlikely to respond.[60] An advantage of NSAIDs in chronic pain is their ability to offer an opioid-sparing effect so that opioid doses can be minimized, thereby lowering any potential opioid-related toxicity. However, the long-term (possibly lifelong) use of NSAIDs is not without its own risk, particularly in patients at risk for NSAID toxicity, including older adults and those with preexisting renal or cardiac disease.

Data on the long-term efficacy of NSAIDs for chronic pain are limited, whereas the long-term risk has been better defined.[16] In a meta-analysis of NSAID efficacy in chronic back pain, there was a small benefit with NSAID therapy when sciatica was not present; with sciatica, no difference was found.[61]

As is the case with all pharmacotherapeutic options for the management of chronic pain, any analgesic agent should

TABLE 19.3 Visual Analog Scale Score for Pain Intensity at Rest at 24 Hr (0–10 cm)

Regimens	NO. OF PATIENTS WITH: Active	Control	Change in Pain Score	WMD (95% CI)
Acetaminophen				
Multiple dose	175	180		–0.29 (–0.71 to 0.14)
NSAIDs				
Single dose	390	369		–0.75 (–1.61 to 0.11)
Multiple dose	288	265		–1.00 (–1.25 to –0.75)
Continuous	225	201		–0.97 (1.37 to –0.57)



A weighted mean difference (WMD) less than 0 indicates less pain with active compared with control. When the 95% confidence interval (CI) does not include 0, the difference is considered statistically significant. Meta-analyses were performed when data from at least three trials or more than 100 patients could be combined; this was not the case for cyclooxygenase-2 inhibitors.
NSAID, Nonsteroidal antiinflammatory drug.

be introduced only after careful consideration of the condition being treated and patient comorbidities. In the case of NSAIDs, close follow-up is essential to screen for efficacy and toxicity, with discontinuation if they are inefficacious or poorly tolerated.

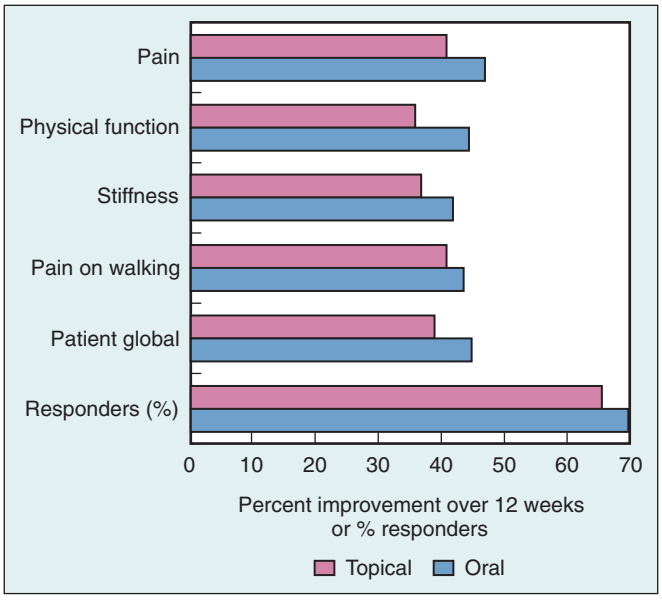
Rational Drug Selection

In general, NSAIDs have similar analgesic efficacy, and individual drug choice is more often determined by differences in tolerability, local availability, route of administration, and cost. In the perioperative setting, intravenous agents such as ketorolac and acetaminophen are often used for practical reasons, but thought should be given to alternative preoperative oral regimens that might significantly reduce cost. Many of the older nonselective NSAIDs can be purchased over the counter in the United States, whereas the COX-2 inhibitor celecoxib is available only by prescription. Celecoxib, owing to the presence of a sulfa moiety, is contraindicated in patients who report a history of sulfa allergy.

A summary table of the most commonly used agents is presented in Table 19.1. This information constitutes the rational basis for drug selection of these agents.

Topical NSAID Preparations

Because NSAIDs are the drugs of choice for musculoskeletal pain and adverse events occur commonly with systemic NSAID therapy, formulation of topical dosage forms to limit systemic exposure was a logical pharmaceutical development. Topical formulations are those that are applied locally in proximity to the affected area and that provide effective concentrations at the local target tissues without producing the systemic levels associated with common adverse effects.[62] These differ from transdermal dosage forms that deliver full systemic levels of the drug through the skin into the circulation. In the United States, diclofenac is the only approved topical NSAID and comes in gel, patch, and ointment form. Topical NSAIDs produce high drug concentration in dermis, muscle, synovium, and joint cartilage, while plasma drug concentrations are less than 10% of those obtained after oral administration. However, substantial interindividual variability exists in transdermal drug penetration. While the anatomic site of application has little effect on systemic drug absorption, individual skin and connective tissue differences can alter topical absorption of drugs. For selected conditions, topical NSAIDs have been shown to be comparable in efficacy to the oral route (Fig. 19.4).



• **Fig. 19.4** Efficacy of topical diclofenac is comparable to oral diclofenac for osteoarthritic knee pain at 12 weeks. These data illustrate that, compared to the oral route, topical administration of nonsteroidal antiinflammatory drugs may be similarly efficacious in selected indications. (Adapted from Simon LS, Grierson LM, Naseer Z, et al. Efficacy and safety of topical diclofenac containing dimethyl sulfoxide [DMSO] compared with those of topical placebo, DMSO vehicle and oral diclofenac for knee osteoarthritis. *Pain*. 2009;143:238–245.)

The specific topical NSAID formulation can greatly affect its absorption and penetration through the skin. Differences in formulations are based on the dosage form (gel, solution, or patch), different salts of the same molecule (diclofenac sodium, diclofenac potassium,

or diclofenac epolamine), carrier-mediated transport (lipid emulsions or solid nanoparticles), and penetration enhancement methods, either chemical (addition of penetration enhancer such as menthol or dimethylsulfoxide, physical [heat-mediated penetration enhancement], or electrical [charge-mediated penetration enhancement such as iontophoresis]).

The most common side effects reported in studies using topical NSAIDs are application site reactions, including dermatitis (reported in 7% of treated patients). Serious side effects are exceptionally rare.[63–65]

Drugs Used for the Treatment of Neuropathic Pain

Introduction and Historical Perspective

The International Association for the Study of Pain (IASP) defines neuropathic pain as pain that results from a lesion or disease affecting the somatosensory system.[66] It has been traditionally thought that opioids are ineffective in the treatment of neuropathic pain, but this is still considered controversial.[67,68] However, it is fair to say that opioids are generally *less* effective in the treatment of neuropathic pain compared with nociceptive pain and consequently are typically used as a second-line treatment after the typical neuropathic pain analgesics have failed to provide satisfactory results. The medical management of patients with neuropathic pain is a challenge to the medical community and has largely been steered by guidelines and systematic reviews of numerous pharmacologic interventions.

The drugs with the best efficacy in neuropathic pain are the tricyclic antidepressants (TCAs), certain anticonvulsants, selective norepinephrine reuptake inhibitors, and topical agents. Duloxetine, a selective norepinephrine and serotonin reuptake inhibitor, also is used in the management of certain neuropathic pain conditions.

The TCAs were introduced in the 1950s as the first agents used in the pharmacologic treatment of depression. Before this, they were used as antipsychotics, presumably because of their marked sedative effects. However, it was noted that TCAs sometimes produced the opposite effect, elevating the mood and even inducing mania. This stimulating effect was later harnessed in the treatment of depression, with the first publication of imipramine as an antidepressant by the Swiss psychiatrist Ronald Kuhn in 1957.[69] While often effective, the TCAs were plagued by their unpleasant antihistaminergic and anticholinergic side effects. In 1974 the first selective serotonin reuptake inhibitors (SSRIs) were discovered; the most promising of these was fluoxetine. It was not until 1986 that fluoxetine (Prozac) was released on the Belgian market, and the following year it gained FDA approval in the United States. This promptly curtailed the use of TCAs for the management of depression, and Prozac rapidly became a blockbuster drug, with more than 22 million U.S. prescriptions written in 2007 alone. However, the TCAs continue to be used, albeit at much lower doses, for the management of neuropathic pain. Perhaps surprisingly, their efficacy, in terms of numbers needed to treat, is actually better than the aggressively marketed anticonvulsant agents discussed later.[70]

Gabapentin is an anticonvulsant initially approved for the treatment of partial seizures, but in 1995 was anecdotally noted to be helpful in the treatment of certain pain conditions, leading to clinical studies in neuropathic pain conditions where it was found to be clinically helpful. Gabapentin is confusingly named because it was originally designed to be a gamma-aminobutyric acid (GABA) analog. Mechanistic studies eventually showed that it had no significant GABA activity; instead, it was involved with voltage gated N-type calcium channels. In 2005 pregabalin (Lyrica), with almost identical receptor activity to gabapentin, was released on the U.S. market with specific indications for neuropathic pain. Two years later, the FDA approved pregabalin for the management of fibromyalgia.

Tricyclic Antidepressants

Basic Pharmacology

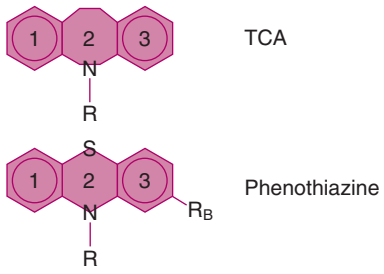
TCAs are heterocyclic compounds that were previously used in the treatment of major depressive disorder before the development of SSRIs. Since the release of the first SSRI, fluoxetine (Prozac) in 1987, TCAs are rarely used in the management of depression owing to a high burden of side effects at antidepressive doses, yet their low-dose use continues to have an important role in the treatment of chronic neuropathic pain.[70] The analgesic properties of TCAs are thought to be independent of their treatment effects on depression. TCAs are structurally related to phenothiazine antipsychotic agents and are named after their chemical structure composed of two benzene rings joined to a seven-member ring containing nitrogen, oxygen, and carbon (Figs. 19.5 and 19.6).[71]

Mechanism of Action

The mechanism of action for the analgesic properties of TCAs is unknown, but it is thought to be related to reuptake inhibition of serotonin and norepinephrine in the spinal cord and modulation of descending inhibitory pathways. In addition, many TCAs also have high affinity as *antagonists* at the 5-hydroxytryptamine (5-HT) receptors (5-HT2: 5-HT2A and 5-HT2C), 5-HT6, 5-HT7, α_1-adrenergic, and N-methyl-D-aspartate (NMDA) receptors. Sigma (σ_1 and σ_2) receptor (formally considered to be an opioid receptor) *agonism* is noted and may contribute to their efficacy as well as their side effects.[72–77]

Metabolism

The metabolism of tricyclics is dependent primarily on hepatic CYP 450 oxidative enzymes. Although the activities of some P450 isoenzymes are largely under genetic control, they may be influenced by patient variables, such as ethnicity and age, as well as the concomitant use of other medications or substances. Metabolism of TCAs, especially their hydroxylation, results in the formation



• **Fig. 19.5** The figure at the top shows the prototypical three-ring structure of a tricyclic antidepressant *(TCA)*. Notice its similarity to the structure of a phenothiazine-type antipsychotic drug pictured below it. TCAs were originally modeled after this class of antipsychotic medications. *R* and R_B represent different side chains for the various phenothiazines.

of active metabolites, which contribute to both the therapeutic and the adverse effects of these compounds. Tertiary amines like amitriptyline and imipramine are demethylated to secondary amines, which retain clinical activity. Therefore when parent compounds that generate active metabolites are prescribed, it is necessary to measure the total tricyclic concentration of clinically active substances when monitoring therapeutic concentrations.[78] The most important step in tricyclic metabolism involves forming inactive hydroxycompounds that are readily excreted in the urine. Renal clearance of TCA metabolites is reduced by normal aging, accounting for much of the increased risk of toxicity in older patients.[79]

Clinical Pharmacology

Pharmacokinetics

The most important factor influencing the pharmacokinetics of TCAs is their metabolism (discussed earlier). The pharmacokinetics of TCAs are characterized by substantial first-pass metabolism, a large volume of distribution, extensive protein binding, and an elimination half-life averaging about 1 to 3 days. The mean half-lives of amitriptyline and nortriptyline are about 21 and 32 hours, respectively, allowing for convenient once-daily dosing.[80] All of the tricyclic drugs are rapidly absorbed after oral administration and, at therapeutic plasma concentrations, are 90% to 95% bound to plasma albumin. They also bind to extravascular tissues, accounting for their large volumes of distribution.[81] TCAs are highly lipid-soluble drugs, are extensively metabolized in the liver, and are bound to tissues where their concentration is 10 to 20 times higher than plasma levels.[78]

Plasma concentrations of TCAs in the therapeutic range are thought to be between 50 and 300 ng/mL. Desipramine and nortriptyline, both secondary amines, have higher tissue and red blood cell concentrations compared with the tertiary amines.[81] Repetitive oral administration of TCAs at fixed doses and intervals increases the plasma concentration successively until a steady-state level is reached, which is generally attained within 1 to 3 weeks. The time required to achieve steady-state depends on the elimination rate and should be determined after five times the elimination plasma half-life. Individuals who metabolize TCAs very slowly ("slow hydroxylators") can manifest with unexpectedly high serum levels and toxicity and may require more than 3 weeks to reach steady-state plasma levels; these individuals, when identified, will require lower dosing and more stringent monitoring.[78]

Pharmacodynamics

Therapeutic Effects

Numerous clinical trials have shown the efficacy of TCAs in treating chronic pain conditions. It is postulated that TCAs exert their therapeutic effects by increasing the levels of serotonin and norepinephrine in the spinal cord, enhancing the descending inhibitory pathways of pain modulation. The dorsolateral pontine tegmentum is the major source of noradrenergic neurons that project to the spinal dorsal horn, while the rostral ventromedial medulla is the primary source of serotonergic neurons that project to the spinal dorsal horn. Both norepinephrine and serotonin can inhibit nociceptive dorsal horn neurons when applied locally. Additional studies conclude that opioid analgesia is enhanced in the presence of antidepressant therapy.[82]

Adverse Effects

The pharmacodynamic effects of TCAs on norepinephrine and serotonin reuptake are complicated by their simultaneous activity at multiple other receptor types, including muscarinic, α_1-adrenergic, dopaminergic, and histamine H_1 (Fig. 19.7), resulting in the side effect profile listed in Table 19.4.

Common adverse effects of TCAs include sedation, urinary retention, gastrointestinal distress, dry mouth, and weight gain. Major adverse effects, typically only observed at higher doses, include QT prolongation, conduction abnormalities, cardiac arrest, hepatic failure, paralytic ileus, hyperthermia, orthostatic hypotension, and decreased seizure threshold (see Fig. 19.7 and Table 19.4).[83]

Therapeutic plasma concentrations of TCAs are in the 50- to 300-ng/mL range. Patients with plasma TCA concentrations greater

TABLE 19.4 Common Side Effects Associated With Selected Tricyclic Antidepressants

	Sedation	Anticholinergic Effects	Hypotension	Cardiac Effects	Seizures	Weight Gain
Amitriptyline	+++	+++	+++	+++	++	++
Clomipramine	++	+++	++	+++	+++	+
Desipramine	0/+	+	+	++	+	+
Nortriptyline	+	+	+	++	+	+

0/+, Minimal; *+*, mild; *++*, moderate; *+++*, moderately severe.
Note marked differences in the toxicity of certain tricyclic antidepressants compared with others.

than 450 ng/mL tend to develop CNS toxicity consisting of agitation, confusion, and memory impairment. Major toxicity and death is associated with concentrations above 1000 ng/mL.[81]

Drug Interactions

The degree of drug interactions with TCAs is largely dependent on the specific tricyclic agent used and its relative inhibitory potential of hepatic CYP 450 oxidative enzymes. Desipramine and nortriptyline have the least drug interactions because they are weak CYP 450 2D6 inhibitors and are unlikely to be involved in clinically relevant interactions unless the serum levels are high—for example, following overdose or in "slow hydroxylators." Amitriptyline, imipramine, clomipramine, dothiepin, and doxepin, all tertiary amines, are more potent CYP 450 inhibitors and therefore are more problematic in terms of drug interactions.[81]

It is important to use extreme caution when prescribing TCAs in patients taking monoamine oxidase inhibitors (MAOIs), SSRIs, or other anticholinergics. Cimetidine, haloperidol, and phenothiazines can increase TCA plasma levels. Drugs such as carbamazepine, a CYP 450 inducer, may reduce plasma levels of tricyclics. Concomitant use of NSAIDs or warfarin can increase the risk of gastrointestinal bleeding owing to the inhibitory effect of serotonin on platelet aggregation.[84–86]

TCAs are known to prolong the QTc interval, so care should be taken with the concomitant use of other agents associated with QT prolongation, potentially proarrhythmic medications, sodium channel blockers, cardiac glycosides, and noradrenergic drugs, such as cocaine and amphetamines.

Special Populations

In patients with cardiovascular diseases (e.g., coronary artery disease, hypertension, arrhythmias), the previously discussed cardiovascular risks of tricyclics are compounded. Older patients receiving TCAs may be more predisposed to orthostatic hypotension and falls, and they are more susceptible to the cognitive side effects related to factors such as altered renal metabolism and protein binding.[87] Selection of a TCA with less anticholinergic activity, a low initial dose, slow titration, and follow-up of blood pressure (measured both when supine and standing) is recommended in older patients.[81] Observational studies showed increased mortality after myocardial infarction in patients using type 1A antiarrhythmic agents; therefore TCAs are contraindicated after a recent myocardial infarction.[88]

It is recommended that patients with liver disease have laboratory screening of serum electrolytes and liver function tests before initiation of TCA treatment with caution advised during dose titration.

TCAs should be used with caution in patients with renal dysfunction because metabolites are excreted in the urine. Chronic kidney disease affects TCA elimination by changing glomerular blood flow and filtration, tubular secretion and reabsorption, and renal bioactivation and metabolism. It is therefore recommended to reduce the drug dose and slowly titrate based on serum drug concentration monitoring (including the active metabolites).[88]

Unique Features of Individual Agents
