Fig. 28.7 B-line artifact. B-lines appear as vertical, hyperechoic lines emanating from the pleural surface and extending to the end of the screen. B-line patterns indicate abnormal lung aeration at the point of probe placement

resulting from the reflection of ultrasound waves between the pleura and the ultrasound transducer (Fig. 28.1). They are therefore seen as equidistant horizontal hyperechoic lines below the pleural line (Fig. 28.6). The presence of A-lines suggests an absence of significant alveolar/interstitial edema and the absence of lung consolidation. Visualization of one or more A-lines therefore indicates normal lung aeration at the point of probe placement. Furthermore, sonographically normal lungs are defined as having lung sliding throughout with bilateral A-line predominance. Depending on the depth visualized on the screen, it is often possible to view multiple A-lines that are equidistant below the pleural line. However, the number of A-lines does not provide any additional diagnostic information.

In contrast B-lines are the results of a ring down or comet-tail artifact originating from the subpleural lung parenchyma (Fig. 28.2). B-lines are described as hyperechoic, vertical, laser-like lines that travel down to the bottom of the screen (Fig. 28.7). These commonly reflect the presence of pockets of fluid in the interlobular septa and indicate pulmonary edema. Other pathological processes that may cause the accumulation of protein, connective tissue, cells, or blood in the interlobular septa will also produce a sonographic B-line pattern. These include pneumonia, pulmonary fibrosis, pulmonary contusions, and lung neoplasms. Lastly, subsegmental atelectasis may produce localized B-lines, especially in the dependent portions of the lungs [9, 10].

B-lines have several defining features that are important to note. B-lines originate from the pleural line, extend to the periphery of the far field without fading, and move synchronously with lung sliding (Video 28.5). B-lines also dominate over A-lines, and when both are visible, B-lines will obliterate A-lines to reach the end of the screen. It is not uncommon to see a few scattered B-lines even in healthy aerated lungs. As a clinical threshold, however, three or more B-lines present in one field of view or a large coalescence of B-lines is considered pathological [4].

It is important to distinguish B-lines from Z-lines. Z-lines are short faint vertical lines that attenuate before reaching the end of the screen, do not obliterate A-lines, and are independent of lung sliding. Z-lines are a common artifact that is devoid of any pathological significance and should be disregarded [11].

If it is not possible to see either an A-line pattern or B-line pattern, it is likely that the transducer is not perpendicular to the pleura. In order to generate a reverberation A-line artifact, it is important to acknowledge that the ultrasound beam needs to fall perpendicular on the pleural surface. It may be necessary to adjust the angle of the probe by means of sliding and tilting as described above, until either an A- or B-line artifact pattern is generated.

A third pattern that can be identified is that of pulmonary consolidation. It is common to identify consolidated lung in the dependent regions in patients that have been ventilated for long periods of time. By ultrasound, a consolidated lung has a tissue density that appears similar to the liver. Some have called this appearance “hepatized lung” (Fig. 28.8). The differential diagnosis of lung consolidation includes lobar atelectasis and pneumonia [12].

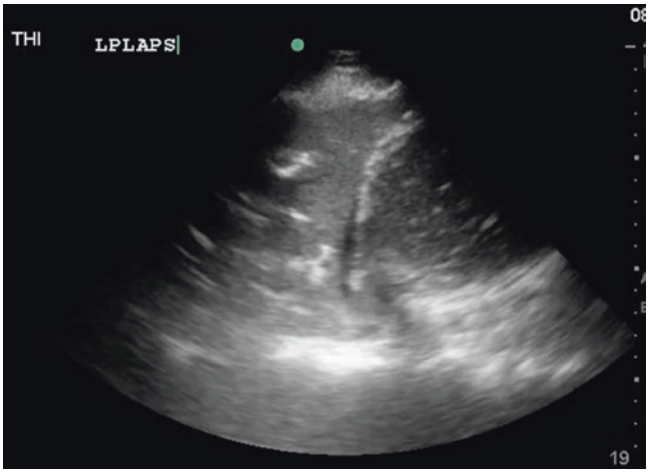

Fig. 28.8 Hepatized lung. Consolidated lung takes the appearance of a solid organ or a liver-like appearance, hence the name "hepatized lung." Note the small rim of pleural effusion inferior the lung

Table 28.3 Differential diagnosis of lung ultrasound findings in patients with respiratory failure

A-lines with lung sliding	Bilateral diffuse B-lines	Consolidation
COPD Asthma exacerbation Pulmonary embolism Extrathoracic process (e.g., acidosis)	Pulmonary edema (homogeneous B-lines) ARDS (heterogeneous B-line pattern)	Pneumonia (late/severe) Lobar atelectasis ormucus plug (late) Compressive atelectasis (due to large pleural effusion)
A-lines with absent lung sliding	**Unilateral or localized B-lines**	
Pneumothorax Mainstem intubation Post-pleurodesis Post pneumonectomy Lobar atelectasis or mucus plug (early)	Pneumonia (early/mild) Pulmonary contusions Lung neoplasm Subsegmental atelectasis	

Clinical Applications

Assessment of the Patient in Undifferentiated Respiratory Failure

Frontline clinicians know that there can be at times diagnostic uncertainty to the cause of respiratory failure despite a properly conducted history, physical examination, and chest radiograph. Pulmonary ultrasound is a modality that can provide additional and often diagnostic information. It can be conducted rapidly, and once it becomes part of routine practice, it can even be done while conducting the patient history and physical examination.

As a bedside diagnostic tool, we find it often provides an opportunity to develop positive physician-patient interactions. This is perhaps the most underappreciated aspect of point-of-care ultrasound in general. Patients seem to appreciate their physician spending time at the bedside, as opposed to spending time reviewing test results or radiographs. If it is appropriate, the patient can even be shown in real time their pathology. Table 28.3 lists the differential diagnosis of respiratory failure in patients with a predominantly A-line, B-line, and consolidation pattern.

It is important to conduct a thorough examination bilaterally. The presence of unilateral findings, such as unilateral B-lines, or unilateral absence of lung sliding can help localize pathology such as pneumonia or pneumothorax, respectively [7].

Respiratory failure with an ultrasound pattern of bilateral A-line predominance is analogous to respiratory failure with a normal chest X-ray. This is usually secondary to non-parenchymal lung disease, e.g., chronic obstructive pulmonary disease (COPD) exacerbations, acute asthma exacerbations, and pulmonary embolism. In these clinical scenarios, the utility of pulmonary ultrasound is in ruling out other causes of dyspnea. The additional ultrasound skill of detecting deep vein thrombosis by ultrasound is also a useful skill in the workup of dyspnea [4].

Assessment of Pneumothorax

As described above the presence of a pneumothorax can be assessed by the presence or absence of lung sliding. In the unstable patient with cardiovascular or respiratory compromise, there is often a clinical need to rule out a large pneumothorax. This can be accomplished with pulmonary ultrasound in a more time-efficient manner than a chest X-ray and with greater confidence than clinical exam alone.

If present in the supine patient, a physiologically significant pneumothorax is unlikely to be present only in the anterior chest. A positive finding of lung sliding rules out a pneumothorax within the field of view of the transducer [6]. In a time-efficient manner, the clinician can examine significant portions of the anterior chest wall bilaterally and rule out a large pneumothorax as a cause of cardiac or respiratory compromise.

Additional diagnostic certainty can be gained by the presence of B-lines. B-lines are not present when there is a pneumothorax within the field of view. Using CT imaging as a control in 73 ICU patients, Lichtenstein et al. showed that the presence of B-lines ruled out a pneumothorax with a 100% negative predictive value [13]. Lastly, another finding used to rule out a pneumothorax at the site of probe application is a lung pulse [14].

As described above, the presence of a lung point may be used to rule in/diagnose a pneumothorax. In an ICU study of 66 cases of pneumothorax and 233 controls, the presence of

a lung point had a sensitivity of 66% and 100% specificity [15]. Although a very specific finding, being unable to elicit a lung point does not rule out a pneumothorax.

The ultrasound assessment of pneumothorax is helpful tool in trauma patients [16]. It can be completed in the trauma bay, while resuscitation is ongoing and while other diagnostic modalities are also being employed. This may allow for faster diagnosis without patient transfer to the CT scanner for the diagnosis of occult pneumothorax missed by chest radiographs. In a recent review of the trauma literature, the sensitivity of ultrasound to detect pneumothorax ranged from 86 to 98%, while the specificity ranged from 97 to 100%. For comparison, this review found the sensitivity of chest radiographs in the diagnosis of pneumothorax to be only 28–75% [17].

Assessment of Pulmonary Edema and Fluid Tolerance

Patients in shock states are often given large volumes of fluid resuscitation as a matter of course. Pulmonary ultrasound presents a means of interval scanning of the lungs to determine if the presence of pulmonary edema is developing. After a baseline scan is taken and further fluid resuscitation is given, the lungs can be reexamined to look for the interval development of B-lines. If an A-line pattern is dominant and the patient is still in a shock state, this would indicate fluid tolerance and serve as an invitation for further fluid administration. If, however, there has been an interval development of B-lines, this finding may give the clinician a signal to stop giving additional fluid and instead utilize other means of hemodynamic support. The concept of fluid tolerance should not be confused with fluid responsiveness. Whereas fluid tolerance is a marker of pulmonary edema, fluid responsiveness indicates an increase in cardiac output as the result of fluid resuscitation.

The presence of A-lines has been correlated with a low pulmonary artery occlusion pressure (PAOP) in certain conditions. In a study of ICU patients with septic shock, Lichtenstein et al. found that the presence of an A-line dominant pattern was associated with a PAOP <18 mmHg, while a B-line dominance, however, was observed in a wide range of PAOP patterns [8]. In a more recent study of mixed ICU patients, the presence of B-lines was shown to correlate with extravascular lung water as measured by the transpulmonary thermodilution method (PiCCO system). In this study, however, A-lines were found to be predictive of a low PAOP (<18 mmHg) only in patients with a normal ejection fraction [18].

Previous attempts have been made to incorporate findings from pulmonary ultrasound with point-of-care echocardiography to develop protocols for the management of shock patients [5, 19]. In the critically ill patient with cardiorespiratory failure, it is unlikely that pulmonary ultrasound alone will provide a complete clinical picture. Incorporating pulmonary ultrasound with assessments of LV size and function, RV size and function, and IVC dynamics allows for a more thorough assessment of patient status. For this reason, we incorporate pulmonary ultrasound findings with bedside echocardiography findings, and we encourage our trainees to do the same.

When a patient is being diuresed during the de-resuscitation phase of shock, the presence or absence of B-lines can also be useful. In a patient that cannot be weaned from ventilatory support, the presence of B-lines may indicate the need for continued/additional diuresis. The absence of B-lines may lead the clinician to look for additional causes of respiratory failure such as those listed in Table 2.3. At a minimum, the use of pulmonary ultrasound in the ICU setting has been shown to minimize the need for radiographs and CTs [20].

Assessment for the Presence of Pneumonia and Atelectasis

The presence of pneumonia can create a wide range of pulmonary ultrasound findings. It can present as B-lines (unilateral or bilateral) or consolidated "hepatized" lung tissue, with or without lung sliding [4]. The presence of dynamic air bronchograms can often be seen, but they are not specific to pneumonia (Video 28.6). In a recent systematic review, the sensitivity and specificity of pulmonary ultrasound for the diagnosis of pneumonia were 85% and 93%, respectively [21].

Consolidation patterns secondary to atelectasis are extremely common in patients undergoing long-term ventilation, especially those with dependent pleural effusions. Even patients undergoing short-term ventilation for surgical procedures have atelectasis that can be detected by ultrasound [22]. Tusman et al. published a suggested protocol for using lung ultrasound to titrate recruitment maneuvers and PEEP to minimize atelectasis and ventilator-associated lung injury [23, 24]. Once atelectasis is confirmed by ultrasound, recruitment maneuvers are done with a stepwise increase in pressure in order to determine the opening pressure of the lungs. Following this, PEEP is decreased incrementally to until the reappearance of atelectatic lung by ultrasound. The level of PEEP is then chosen to be 2 cm H20 above this closing pressure.

Assessment of Acute Respiratory Distress Syndrome

The B-line appearance pattern created by cardiogenic edema differs from that of acute respiratory distress syndrome

(ARDS). While the B-line pattern associated with cardiogenic pulmonary edema is fairly uniform throughout the chest, ARDS sonography findings are less homogeneous with spared areas of A-line dominance, other areas with significant B-lines, areas with consolidation (usually dependent), and pleural line abnormalities [25]. In patients presenting with undifferentiated respiratory failure, pulmonary ultrasound has been validated as a diagnostic tool, differentiating both clinical entities (ARDS vs. cardiogenic pulmonary edema) with good discriminatory power [26]. Furthermore, pulmonary ultrasound may be of potential value in assessing the effectiveness of positive end expiratory pressure (PEEP) titrations and lung recruitment maneuvers in hypoxemic mechanically ventilated patients [27].

Assessment of Pleural Effusions

Point-of-care ultrasound very accurately distinguishes pleural from parenchymal pathology and is therefore of great value in patients with undifferentiated lung field opacification on chest X-ray. In addition, patients presenting with acute respiratory failure may benefit from an expedited ultrasound diagnosis and quantification of a pleural effusion, knowledge of which has immediate clinical applications. Lastly, ultrasound allows for safe pleural drainage at the bedside and can be used to demarcate the pleural space boundaries and guide needle placement. Assessment of pleural effusions is therefore an important skill to master and is relatively easy to learn for the novice sonographer [28].

Unlike assessment of lung aeration, where generation of artifact is the goal, pleural effusions are directly and very easily visualized with ultrasound. Fluid is generally a very good transmitter of ultrasound with very little of the incident ultrasound beam being reflected back to the probe. Pleural effusions therefore appear anechoic (black) on ultrasound, in contrast with their surrounding anatomical structures.

On ultrasound, three criteria must be fulfilled to make the diagnosis of a pleural effusion [29]. First, it must be identified as an anechoic space. Second, this anechoic space must be within the typical anatomical boundaries. The surrounding chest wall, lungs, and diaphragm must be clearly identified, and the fluid collection must be clearly visible above, and not below, the diaphragm (Fig. 28.9). Third, a dynamic component for the fluid boundaries must be demonstrated. This includes the lungs flapping in this space or diaphragmatic descent underneath the fluid with every respiration (Video 28.7).

It is possible to estimate the volume of pleural fluid in mechanically ventilated patients, using ultrasound [30]. In supine position, with a mild trunk elevation at 15°, an ultrasound view of the pleural fluid between the base of the lung and the diaphragm is obtained. Then the maximal distance between the diaphragm surface (parietal pleura) and the base of the lung (visceral pleura) is measured (Fig. 28.10). Pleural fluid volume is then calculated using the equation:

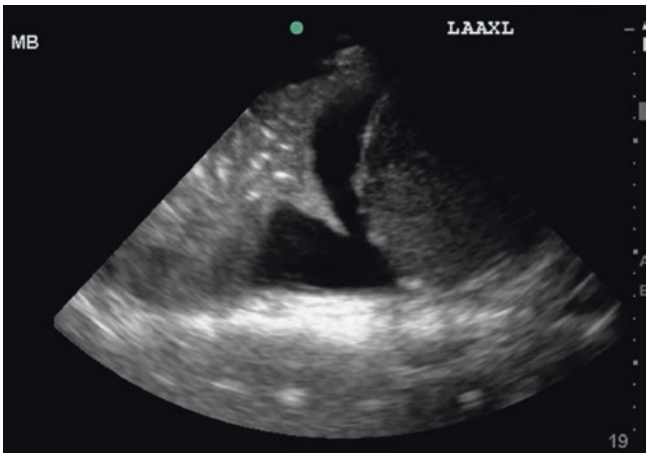

Fig. 28.9 Pleural effusion. Pleural fluid appears anechoic (black), within typical anatomical boundaries (lungs superior and diaphragm inferior), and has dynamic features

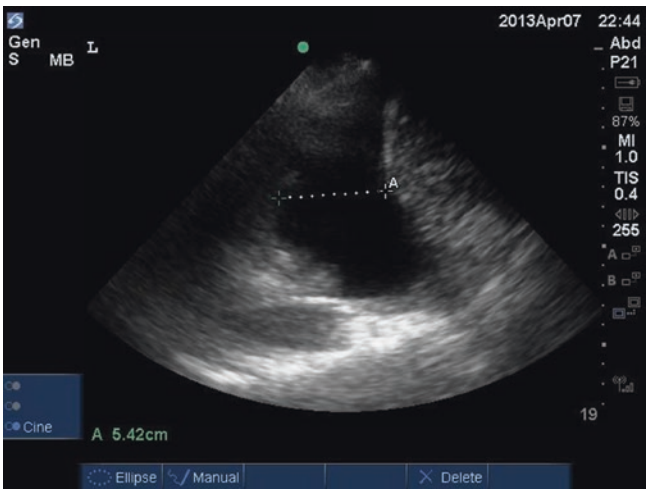

Fig. 28.10 Pleural effusion quantification. Measurement of the maximal subpulmonic distance between the visceral pleura (at the base of the lung) and parietal pleura (above the diaphragm). Distance measured = 54 mm. In this patient, pleural effusion volume estimation = 54 * 20 = 1080 ml

Pleural Fluid Volume (Ml) = Maximal Subpulmonic Distance (Mm) * 20

A 2D examination of the pleural fluid can provide important insight into the character of the effusion. Transudative effusions usually appear completely anechoic, with no evidence of cellular material or debris in the pleural fluid. Conversely, presence of echogenic components in an effusion is strongly suggestive of an exudative process. Observing swirling

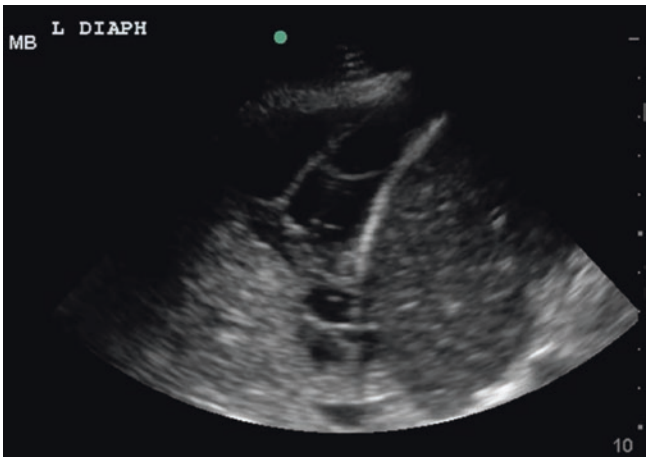

Fig. 28.11 Complex pleural effusion with septations. Septations within a pleural effusion indicate complexity and are better detected by ultrasound than CT scan. Septations and fibrin strands predict longer chest drainage times, potential need for intrapleural fibrinolytics, longer hospitalization, and greater potential for surgical intervention for adequate drainage. Early thoracic surgery consultation is warranted

debris in the pleural fluid with heart contractions or respiratory movements has been named the "plankton sign" and is evidence of an exudative effusion (Video 28.8). Other findings suggestive of a complex exudative effusion include the presence of septations (Fig. 28.11), fibrin strands, loculations, and layering of the effusion fluid into two layers of different densities. This layering is sometimes observed with empyema and hemothorax (hematocrit sign). Septations and fibrin strands are detected more readily with ultrasound than CT scan, and their presence is predictive of the need for longer periods of chest drainage, longer hospital stays, higher incidence of requiring intrapleural fibrinolytics, and higher chance of needing surgery for adequate drainage [31, 32]. We therefore recommend involving thoracic surgery early in the management of all sonographically complex pleural effusions.

Assessment of Respiratory Complications Post-brachial Plexus Blockade

Brachial plexus blockade is associated with the pulmonary complications of phrenic nerve blockade and pneumothorax, with the interscalene approach particularly associated with phrenic nerve blockade and the supraclavicular approach with pneumothorax [33]. Immediate onset of respiratory distress in a patient undergoing these blocks should lead the clinician to consider these two diagnoses. Pneumothorax can be ruled out by the methods mentioned in this chapter. Diaphragmatic weakness associated with phrenic nerve blockade is more complicated to assess. Simple assessments of lung sliding are not sufficient to assess for phrenic nerve blockade as pleural movement is the result of all total function of all the respiratory muscles. Assessments of diaphragmatic excursion and diaphragm thickening with respiration are therefore required [34, 35].

Case Presentation

The postanesthesia care unit (PACU) nurse asks for your help. A 55-year-old lady underwent a left video-assisted thoracoscopic surgery (VATS) talc pleurodesis for a chronic left pleural effusion, 2 h earlier, and has since been in the PACU with high oxygen requirements. The nurse mentions that all attempts at weaning her oxygen requirements to get her ready for ward transfer have been unsuccessful and she currently remains on an FiO2 of 0.6 by face mask. Her past medical history is significant for an ischemic cardiomyopathy with an estimated left ventricular ejection fraction of 35%. The anesthesiologists' records document stable hemodynamics throughout the procedure, minimal blood loss, and a slight positive fluid balance of only 500 ml.

The patient appears to be fully awake and has good motor strength. Her BP is 105/60 mmHg, HR 82 beats/min, and her SpO2 92%. A portable chest X-ray, performed in PACU, was inconclusive (Fig. 28.12). A lung and pleural ultrasound is performed to further delineate the cause of her hypoxemia.

Case Resolution

Using a phased array transducer, her nonoperative right lung was scanned at two points: the anterior chest wall (Video

Fig. 28.12 Plain portable chest X-ray of patient with undifferentiated hypoxia. Plain chest radiograph suggestive, but not conclusive, of pulmonary edema. As a modality, the sensitivity of plain chest X-rays in pulmonary edema detection is 50–68%

28.9) and the anterior axillary line (Video 28.10). Due to the surgical dressing covering large portions of her operative side, only her nonoperative side was scanned. Acquired images demonstrated a diffuse B-line pattern, consistent with an interstitial alveolar syndrome. With a working diagnosis of pulmonary edema, furosemide 40 mg was administered intravenously. Over the next 90 min, the patient diuresed 800 ml of urine, and her oxygen requirements were weaned to 3 L/min oxygen by nasal prongs. After meeting PACU discharge criteria, the patient was transferred safely to the ward.

The sensitivity of ultrasound in detecting pulmonary edema far surpasses that of plain chest X-rays (100% vs. 65%) [36, 37]. As a modality, ultrasound is quick and easy to use at the bedside and can be used either to make a diagnosis or, in this case, confirm a clinical suspicion. B-lines are defined as vertical hyperechoic comet tails that (a) emanate from the pleural line, (b) extend all the way to the end of the screen, (c) move with lung sliding, and (d) dominate over any other aeration patterns (i.e., dominate over A-lines). A clinically significant B-line pattern indicative of an interstitial syndrome is present when three or more B-lines or a coalescence of B-lines is visible on the same screen. The differential diagnosis for B-line predominance includes pulmonary edema, ARDS, early pneumonia, and subsegmental atelectasis. In this case, the relatively uniform B-line presence throughout the anterior and lateral chest was diagnostic of pulmonary edema.

This case highlights the value of ultrasound in dismissing diagnostic uncertainties. In general, the indications of perioperative ultrasound include assessing undifferentiated hypoxia, evaluating undifferentiated opacities on chest X-rays, and determining the safety of further fluid resuscitation. Point-of-care ultrasound empowers clinicians to make diagnoses at the bedside and may therefore expedite appropriate management and improve timely patient care.

Ultrasound for Vascular Access

29

James P. Lee, Joshua M. Zimmerman,
and Natalie A. Silverton

Key Points

- The use of ultrasound for vascular access has been shown to decrease complications and improve success rates.
- Current guidelines recommend the use of ultrasound for central venous cannulation of the internal jugular vein, but ultrasound can be used to facilitate subclavian vein and femoral vein cannulation as well.
- Anatomic relationships are important to learn with ultrasound, but anatomic variability exists; therefore care must be taken to distinguish arterial from venous structure with ultrasound prior to cannulation. Venous structures are often thin walled and easily collapsible with flow in both systole and diastole. Arterial structures have thicker walls and visually pulsatile due to systolic flow.
- The internal jugular vein (IJV) runs vertically in the neck from the jugular foramen at the base of the skull until it joins the subclavian vein (SCV) within the chest to form the innominate or brachiocephalic vein. The right and left brachiocephalic veins then join to form the superior vena cava (SVC) which drains into the right atrium of the heart.
- The IJV can be visualized in short axis or long axis. The advantage of short axis imaging is that the image allows for visualization of surrounding anatomic structures such as the carotid artery. The advantage of long axis imaging is that the needle can be introduced "in plane" allowing for visualization of the entire needle tip.
- The SCV is a continuation of the axillary vein from the deltopectoral groove to where it joins the IVJ to form the innominate vein. The SCV can be accessed on either side of the clavicle, and both infraclavicular and supraclavicular techniques can be visualized with ultrasound.
- Femoral vein (FV) cannulation is often used in emergencies when rapid access is needed or if IJV/SCV cannulation is impossible or contraindicated. Ultrasound can be used to facilitate FV cannulation with either a short axis or long axis technique.
- Although the landmark and palpation technique for radial artery catheterization is the mostly widely used technique, ultrasound may be used for difficult access or in cases where first-pass success is desired.

Introduction

Since its introduction into clinical practice in the 1970s, the use of ultrasound has grown substantially. Ultrasound today has better resolution and is more compact, user friendly, and affordable than it was in the past. One of the more widely accepted applications of ultrasound in medical practice is its use for vascular access. Central venous catheters (CVC) are placed for hemodynamic monitoring, fluid management, renal replacement therapy, drug therapy, cardiac pacemaker placement, and total parenteral nutrition. In this chapter we will discuss the use of ultrasound for the placement of CVCs

and radial artery catheters. Ultrasound for vascular access is most commonly used for internal jugular vein (IJV) cannulation. Increasingly, however, this technique is being applied to femoral vein (FV) and, more recently, subclavian vein (SCV) cannulation. We will describe ultrasound techniques for each of these access sites as well as the use of ultrasound for radial artery cannulation as the latter is also a common practice.

Why Use Ultrasound?

The Seldinger technique for vascular access was first described in 1953 [1]. What we now consider the traditional "landmark" techniques for SCV and IJV cannulations were developed shortly thereafter [2, 3]. As these techniques preceded the routine use of ultrasound, they relied solely on the anatomic relationships of vascular structures to fixed landmarks on the surface anatomy such as the clavicle and the sternocleidomastoid muscle. These techniques assumed a minimal variation in anatomy between patients. Today, from ultrasound-based studies of anatomy, we know that this assumption is not valid and can lead to an increased incidence of complications such as nerve injury, pneumothorax, hemothorax, or accidental arterial puncture [4–6]. Overall, the risk of mechanical complication with central venous cannulation (internal jugular, subclavian, and femoral) is 5–19% [7]. A recent Cochrane review of 35 randomized controlled trials and over 5000 patients concluded that the use of ultrasound for IJV cannulation was associated with a significant reduction in the incidence of accidental carotid puncture (relative risk reduction 72%) and in overall complications (relative risk reduction 71%) [8]. Ultrasound has also been associated with a decreased incidence of inadvertent subclavian artery and femoral artery puncture [9, 10]. Faster access times as well as higher first-pass and overall success rates have been reported with ultrasound-guided cannulation of all three vessels, even in emergent situations such as ongoing CPR [9–12].

Because of the strength of the evidence for the use of ultrasound in vascular access, the most recent practice guidelines from the American Society of Anesthesiologists recommend that when available, real-time ultrasound should be used for IJV cannulation (*category A1/A2 evidence*) and FV cannulation (*category A3 evidence*) [13]. Although their recommendations were "equivocal" for the use of ultrasound for SCV cannulation, they did present evidence that this technique reduces inadvertent arterial puncture, the incidence of hematomas, as well as shorter access times and higher success rates (*category A2 evidence*) [13]. The use of real-time ultrasound for central venous catheter placement has also been advocated by the American College of Surgeons [14] and Society of Critical Care Medicine [15].

Despite these guidelines and the evidence that supports them, a 2006 survey of anesthesia providers suggested that 67% have never or almost never use ultrasound for IJV cannulation. The most common reason listed as to why ultrasound was not used is it is not "necessary" [16]. More recently, a 2014 survey of emergency physicians reported that 44% "never use ultrasound when placing CVCs." The most common reason cited was lack of training, followed by the perception that ultrasound was too time consuming and the lack of equipment [17].

Which Ultrasound Probe Should I Use?

Ultrasound probes used today come in a variety of sizes, shapes, and frequencies.

The three major types of ultrasound probes, phased array, curvilinear, and the linear probe, are all used for different purposes and cannot easily be interchanged. The phased array and curvilinear probes are lower-frequency probes designed to image structures deep within the body such as the heart, gallbladder, intra-abdominal aorta, or bladder. The standard linear array probe uses high-frequency ultrasound crystals (5–13 MHz) linearly arranged on a flat footprint, thus producing sound waves in a straight line. The result is high-resolution imaging of superficial structures displayed in a rectangular image. The higher frequencies of the linear probe allow for improved image resolution but at the cost of decreased tissue penetration. Thus it is recommended to use a higher-frequency probe during vascular access as the vascular targets are usually less than 5 cm from the skin surface and image quality will be improved.

Before Placing the Probe: A Word About Aseptic Technique

Care should be taken to place a central venous catheter in an aseptic manner. The 2011 CDC recommendations for the prevention of intravascular catheter-related infections can be summarized as follows [18]. The patient's skin should first be cleaned with an antiseptic agent, as described by the CDC guidelines. The patient should then be draped in a standard sterile fashion. The provider should perform proper hand hygiene and use barrier precautions such as a cap, mask, a sterile gown, and sterile gloves. The ultrasound probe should be placed into a sterile sheath, and sterile gel should be used in the field. Care should be taken to not contaminate the field or the operator during the placement of sterile sheath onto the ultrasound probe.

Image Optimization

When performing ultrasound-guided vascular access, the probe and screen display are best oriented anatomically, that is, similar to that which is seen from the vantage point of the operator. Accordingly the left side of the probe and the image on the screen should correspond to the left side of the operator. Each probe has an indicator (usually a dot, a line, or a small LED) to identify probe laterality. A corresponding indicator dot is often displayed on the screen. Laterality can also be determined by applying external pressure to one side of the probe while simultaneously visualizing the display screen.

Once the laterality of the probe and image has been determined, the operator should adjust the depth appropriately so that the entire vein and surrounding vascular structures are visualized. The gain on the ultrasound machine should be adjusted in order to make the center of the vascular structures dark (echo lucent) and the surrounding structures appropriately bright. If the gain is increased too much (over-gained), the surrounding structures will be displayed overly bright and may make visualization of the vascular structures difficult.

Distinguishing the Vein from the Artery

With ultrasound, both veins and arteries will appear as dark (echo lucent) round structures with brighter (echo dense) borders. Veins are usually fully collapsible when pressure is applied to it by the ultrasound probe, while the arteries are often rounder in shape, more pulsatile, and not fully collapsible. Valves may also be visualized in the vein but not in the artery. Color flow Doppler may be used to determine pulsatility and the direction of flow, but the latter must be used with caution as the color displayed on the monitor (red versus blue) depends on probe orientation and may fool the beginning practitioner. Venous flow occurs in systole and diastole, whereas arterial flow is predominately in systole.

Limitations of Ultrasound Technique

Static imaging is a type of "X marks the spot" technique where ultrasound is used to mark the location of the vein prior to sterile prepping and draping. While this technique is still advocated by the American Society of Anesthesiologists [13], the use of real-time ultrasound has been shown to improve first-pass success and overall success [12]. Real-time ultrasound, however, requires some degree of practice and technical skill as simultaneous manipulation of the probe with one hand and the needle with the other hand is required.

It is also important to remember that the image displayed is in two dimensions, while the needle tip trajectory toward the vessel is a three-dimensional path. When the image is displayed in short axis (Fig. 29.1a), the shaft of the needle cannot be easily distinguished from the needle tip. Past pointing occurs when the needle tip crosses through and past the ultrasound beam because the needle shaft seen on the ultrasound screen is mistaken for the needle tip. Figure 29.1a

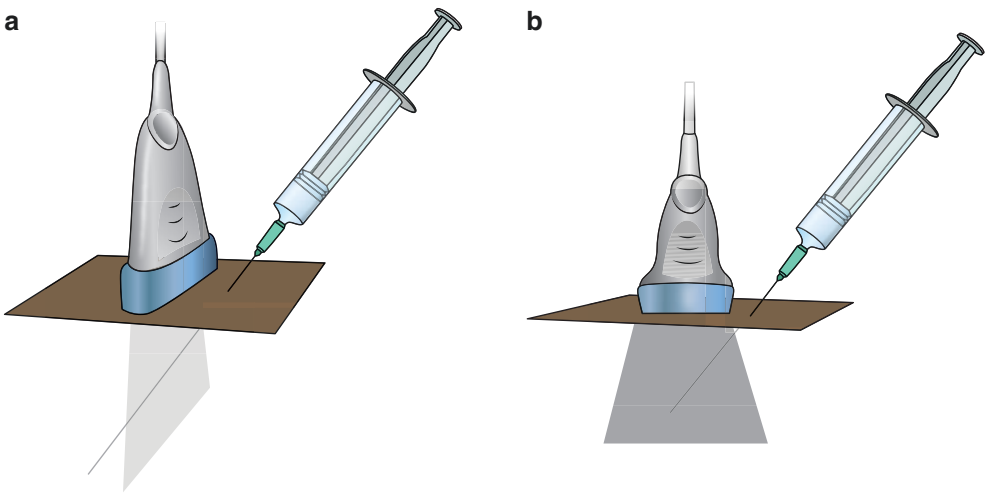

Fig. 29.1 Illustrates the technique of ultrasound imaging in short axis (**a**) and long axis (**b**). Note how in the short axis imaging (**a**) the needle tip is well beyond the ultrasound beam and out of the plane of the image. In the long axis imaging (**b**), the entire needle trajectory and needle tip are visualized

illustrates how the needle tip is no longer visualized and is actually deeper than seen on the display screen. In order to prevent past pointing, the operator can move the probe along the skin surface to ensure that the needle tip is always visualized as the needle is driven toward the target of interest. Alternatively, a long axis technique can be used to visualize the needle tip through its entire trajectory (Fig. 29.1b). Complications of unrecognized past pointing include inadvertent arterial puncture, pneumothorax, and damage to surrounding structures.

Summary

Ultrasound guidance has become the standard of care for IJ vein cannulation, and its use in vascular access in general is increasing. The advantage to using ultrasound is the ability to visualize the vessel of interest and surrounding structures. Ultrasound has been shown to decrease complications and improve success rates for central line placement, but the technique requires some acquired skill and practice in order to accurately visualize needle tip placement in real time. In this chapter, we will discuss the use of ultrasound for IJV, SCV, FV, and radial artery cannulation as these are the most common uses of this technology in daily practice.

Ultrasound for Internal Jugular Vein Cannulation

Anatomy

The internal jugular vein (IJV) runs vertically in the neck from the jugular foramen at the base of the skull until it joins the subclavian vein (SCV) within the chest to form the innominate or brachiocephalic vein. The right and left brachiocephalic veins then join to form the superior vena cava (SVC) which drains into the right atrium of the heart (Fig. 29.2a). The IJV lies within the carotid sheath along with the carotid artery (CA) and vagus nerve. Normally, the IJV is found anterior and lateral to the CA, but the anatomic variation among patients can be considerable, and frequently the IJV lies outside the path predicted by a landmark technique [4–6].

Sedillot's triangle is the anatomical landmark for IJV cannulation and is bounded by the sternal and clavicular heads of the sternocleidomastoid muscle medially and laterally, respectively, and the clavicle inferiorly. The IJV is found at the apex of this triangle, and this is a good starting point for initial ultrasound probe placement. Initial ultrasound images of the neck should show two dominant echo-lucent vessels in short axis representing the CA and IJV (Fig. 29.2b). The CA and IJV should be clearly distinguished with the CA having

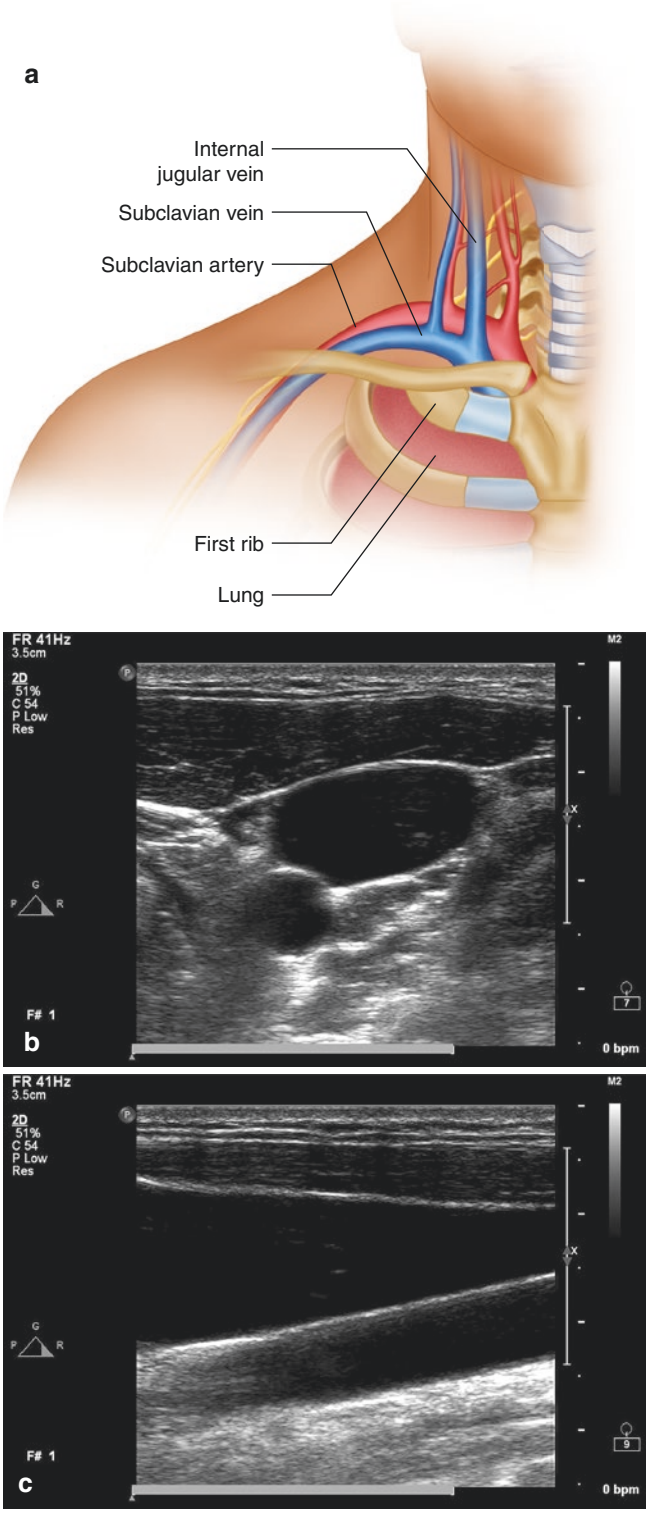

Fig. 29.2 Illustrates the anatomy of the internal jugular vein and its relationship to the carotid artery and subclavian vein (**a**). Ultrasound imaging of the internal jugular vein (IJV) and carotid artery (CA) is demonstrated in short axis (**b**) and in long axis (**c**)

a more circular shape, being less compressible, and having more pulsatile flow. The IJV is often larger and more lateral, but this is not always the case.

After adjustment for the appropriate depth and gain, and once the identity of the two major vessels is determined, the ultrasound probe should be moved up and down the neck to identify the ideal cannulation site. Because the relative anatomic relationship between the CA and the IJV changes throughout the neck from superior to inferior (Video 29.1), there may be some locations on the neck where the relationship is more favorable (i.e., the CA and the IVJ are separated anatomically with little overlap). Other considerations for cannulation site placement are the location of the external jugular vein (often found anterior and in the path of cannulation if the puncture site is too superior) and the increased likelihood of pneumothorax or inadvertent brachiocephalic, subclavian, or even aortic injury if the puncture site is too inferior [19].

Short Axis Technique

In this section we will describe the standard short axis approach to ultrasound-guided IJV cannulation. After the appropriate anatomy is identified and the cannulation site is determined (see above), lidocaine can be used to anesthetize the skin in awake patients. While the lidocaine needle can be visualized with ultrasound and this may help prevent inadvertent intravascular injection of lidocaine, finder needles in the traditional sense are not necessary with ultrasound.

The ideal needle puncture site is approximately the same distance back from the probe as the depth of the IJV when the needle is advanced at a 45-degree angle (Video 29.1). Using this triangulation technique will help facilitate finding the needle tip within the ultrasound beam. The depth of the IJV is usually 1–1.5 cm below the surface of the skin, but in larger patients with deeper vessels, the entrance point of the needle should either be farther from the transducer or the needle trajectory will need to be steeper in order to avoid past pointing the needle beyond the beam of the ultrasound (Fig. 29.1a). With traditional landmark technique, the needle direction after entering the skin was to point laterally toward the ipsilateral nipple. In a similar manner, with ultrasound technique, the needle should enter the skin on the medial side of the IJV and then advanced laterally toward the center of the vessel. This medial to lateral trajectory is meant to reduce the risk of inadvertent puncture of the more medial CA.

As mentioned above, the major limitation of the short axis technique is the difficulty of needle tip identification and the potential past pointing (Fig. 29.1a). One method to improve needle tip visualization is to move the transducer up and down the neck slightly to identify the most distal end of the needle and then to progressively move the ultrasound transducer toward the patient's feet as the needle is advanced. Ultimately as the needle is advanced, tenting of the anterior wall of the IJV is seen. This confirms placement of the needle tip and can be used to modify placement such that the needle is in the center of the vessel. Subsequently, the vessel can be either punctured in short axis or the transducer can be turned 90° to confirm needle tip placement in long axis as the needle punctures the vessel (Video 29.1).

Long Axis Technique

Although multiple studies have shown that ultrasound guidance increases first-pass success rate and decreases complications [5, 6, 12, 20], the incidence of inadvertent CA puncture is still as high as 4% [21–23]. Part of the reason for the continued risk of CA puncture even with ultrasound guidance is the inability to accurately visualize the needle tip while using the short axis technique above. One alternative is to rotate the ultrasound transducer 90°, thereby using a long axis or in-plane technique (Fig. 29.1b). The advantage to the long axis technique is that not only can the needle tip can be visualized as it punctures the vessel but also the tip of the needle can then be precisely placed in the center of the lumen avoiding "back walling" of the needle or injury to the posterior surface of the IJV.

Studies suggest that "back walling" or puncture of the posterior surface of the IJV occurs in 34–64% of procedures [24, 25]. Injury to the posterior wall of the IJV may cause neck hematoma or thrombus. In theory direct visualization of the needle tip will reduce this complication, and there is some limited evidence to support this, although large randomized studies have not been performed [26].

With the long axis technique, it is helpful to identify the CA and IJV in short axis initially as above and then centering the probe over the IJV, rotating the probe 90° to view the vessel in long axis (Fig. 29.2c and Video 29.2). The needle is then introduced in the plane of the ultrasound (Fig. 29.1b) and can be visualized in its entirety as it is advanced. Once the needle punctures the vessel, the needle tip can be precisely placed in the middle of the vessel which facilitates smooth wire placement.

The major disadvantage of the long axis technique is that while the IJV and needle are well visualized, the CA is often no longer visible. This should not matter as long as the IJV was clearly identified in the short axis view initially. A second disadvantage is that the relative medial vs lateral location of IJV puncture is difficult to determine because the probe is now oriented vertically. One way to circumvent this problem is to start in short axis and to continue advancing the needle until there is tenting of the IJV in a central location. At this point the transducer can be rotated 90°, and the needle tip can be visualized and advanced into the vessel in long

axis (Video 29.1). A second alternative is to use a "medial-oblique" approach as described by Dilisio et al. [27]. Here the ultrasound transducer is rotated only 30° to create a hybrid short/long axis view.

Wire Confirmation, Trouble Shooting, and Complications

Once the IJV is punctured, the next step in the Seldinger technique is to advance a guidewire through the needle. The needle is then removed, and after confirmation of the guidewire in the vein, the central venous cannula is introduced over the guidewire. The most reliable means of guidewire confirmation is with the use of concomitant transesophageal echocardiography (TEE) demonstrating the "J" of the wire in the right atrium. This is particularly convenient in line placement for cardiac surgery as TEE is used in many of these procedures. Transthoracic echocardiography (TTE) can also be used for this purpose with the guidewire visualized in the right atrium or inferior vena cava using a subcostal view [28]. If TEE or TTE is not part of the procedure or treatment plan, however, it is possible to visualize the guidewire in the IJV distal to the insertion point either in short or long axis. The guidewire can then be followed inferiorly and sometimes can be seen beneath the clavicle entering the brachiocephalic vein. Because of the close proximity of the proximal IJV and brachiocephalic vein to the innominate and subclavian arteries, however, confirmation using this technique does not exclude inadvertent arterial puncture within the chest. The best means of venous confirmation without the use of TEE or TTE is therefore not ultrasound but pressure monitoring either directly or through column manometry [19].

One of the more common frustrating experiences of trainees is difficult guidewire placement after a seemingly uneventful IJV puncture under ultrasound. Sometimes patients have vascular anomalies, strictures, or obstructions that prevent direct access to the right atrium from the IJV. Most times, however, the patient has no such history and still guidewire placement is difficult. Often in these cases, if the ultrasound probe is placed back on the neck and the needle is visualized again in long axis, it may be determined that the needle is up against the posterior wall of the IJV. When this occurs, blood will still draw easily from the needle, but the guidewire will not advance. If this problem is identified with a long axis view, the needle can simply be withdrawn slightly until it is again visualized in the center of the vessel and the guidewire will often go more smoothly.

Finally, ultrasound can be used to diagnose complications associated with central line placement. In some patients who have had multiple catheter placements or prior dialysis, IJV thrombus, strictures, or anomalies can be identified and avoided prior to cannulation. Neck hematomas from posterior wall or CA puncture can be easily visualized. After central line placement, the high-frequency linear probe can also then be placed on the chest, and pneumothorax can be excluded by visualization of lung sliding, lung pulse, or B lines, the description of which is beyond the scope of this chapter but is further described in Chap. 28.

Summary

Real-time ultrasound guidance for IJV central venous catheter placement has become the standard of care because it is easy to use and has been shown to improve first-pass success and reduce complications. Visualization of the IJV and CA can be accomplished with a short axis, a long axis, or a combination of both techniques. Although the long axis technique for IJV cannulation offers the advantage of needle tip visualization, the technique is more difficult to master technically, and this may limit first-pass success and lengthen procedural time compared to the short axis technique [29].

Regardless of the technique, however, the important steps to safe cannulation include confirming the anatomy, visualizing the needle tip, confirming guidewire placement, and confirming venous puncture. Ultrasound can also be used for troubleshooting difficult guidewire placement and complications such as hematoma or pneumothorax.

Ultrasound for Subclavian Vein Cannulation

Anatomy

The subclavian vein (SCV) is a continuation of the axillary vein, running from the lateral border of the first rib until it joins the IJV to form the brachiocephalic vein (Fig. 29.3a). In a recent multicenter randomized controlled trial, SCV cannulation was associated with a lower risk of infection and symptomatic thrombosis than IJV or femoral catheterization [30]. Anatomic landmarks for SCV include the deltopectoral groove and the junction of the middle to inner 1/3 of the clavicle where it enters the thorax. The SCV lies anterior and inferior to the subclavian artery (SCA) with the insertion of the anterior scalene muscle in between them. Other important surrounding structures include the brachial plexus, the pleura, and the thoracic duct (for left SCV).

Figure 29.3b shows an ultrasound image of the SCV and SCA in short axis. To generate this image, the ultrasound probe is placed on the chest approximately 1–2 cm lateral to the junction between the medial and middle 1/3 of the clavicle as would be recommended for needle placement using

the landmark technique. The probe is oriented perpendicular to the clavicle with the marker pointed toward the patient's head. The right side of the screen is superior and the left side is inferior. Here the SCV can be identified as the round echo-lucent vessel inferior to the SCA and superior and anterior to the white pleural line. The SCV should be differentiated from the SCA with the SCV as more inferior compared to the SCA, less pulsatile, and more compressible.

Infraclavicular Approach

Although the current standard of care for SCV cannulation is a landmark approach, interest in ultrasound for SCV access is increasing because of the added margin of safety it provides. In a landmark approach, the junction of the medial and middle 1/3 of the clavicle is identified, and the needle enters the skin 1–2 cm inferior and lateral to that point. The needle is then directed superficially toward the suprasternal notch until it butts against the clavicle. The needle is then redirected posteriorly to dive just under the clavicle to access the SVC. While this technique is often successful, the incidence of pneumothorax is higher than IJV cannulation [30] because the technique is blind and the pleura is often adjacent to the SCV. To avoid pneumothorax, the needle is placed just underneath the clavicle, a practice which often makes subsequent wire placement, dilation, and catheter placement difficult.

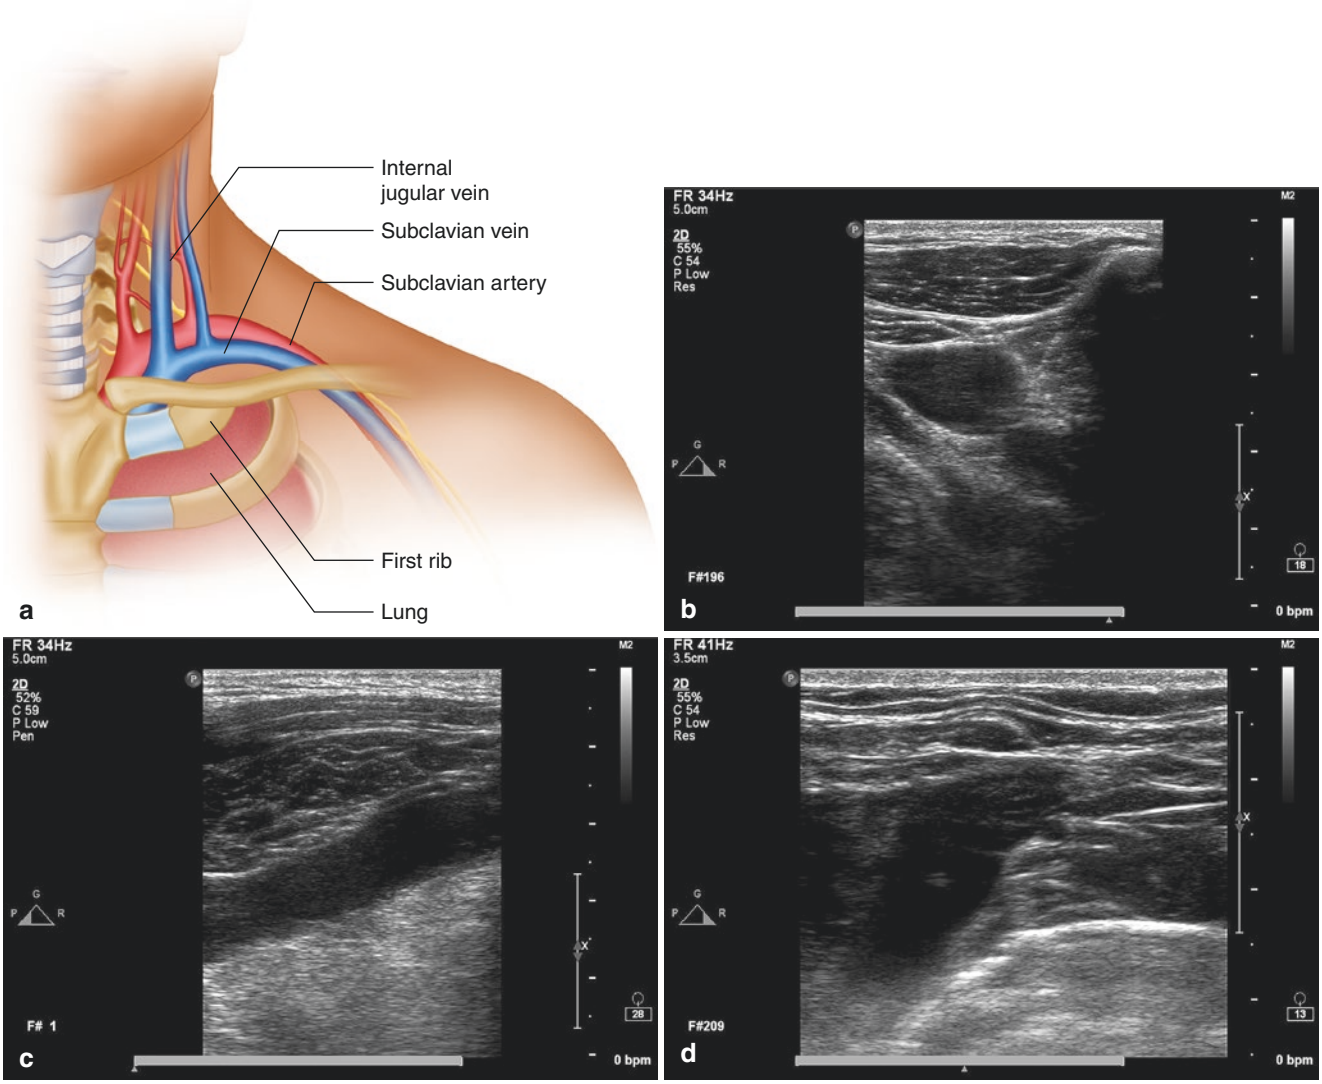

Fig. 29.3 Illustrates the anatomy of the subclavian vein and its relationship to the subclavian artery, clavicle, and lung (**a**). Ultrasound imaging of the subclavian vein is demonstrated in short axis (**b**) and long axis (**c**). It is important to note the close relationship between the subclavian vein (SCV), subclavian artery (SCA), and pleural line. Ultrasound imaging of the subclavian vein (SCV) from a supraclavicular approach (**d**) also illustrates the proximity of the subclavian vein (SCV) and the innominate vein (InV) to the pleura

When using ultrasound, the probe is placed on the chest just inferior to the clavicle approximately over the site of needle puncture for the landmark technique. As described above, the SCV and SCA can be identified in short axis, and the ultrasound probe can then be centered over the SCV (Fig. 29.3b). Turning the probe 90° counterclockwise will then create a long axis view of the SCV (Fig. 29.3c). The identity of the SCV should then be confirmed by angling the probe toward the head of the patient and visualizing the pulsating SCA in long axis and then angling the probe back toward the feet and visualizing the compressible SCV. At this point the probe will be at an oblique angle to the clavicle, parallel with the deltopectoral groove (Video 29.3). The needle can then be introduced from the distal end of the ultrasound probe and the entire shaft, and needle tip can be visualized in plane of the ultrasound as it is advanced into the SCV. Depending on the size of the patient and footprint of the ultrasound probe, the actual puncture site of the vessel may technically be in the axillary vein rather than the SCV. This should be kept in mind when determining the depth of the catheter with final placement as the entrance point of the catheter may be several centimeters more distal than standard SCV placement.

Compared to a landmark technique, ultrasound-guided SCV cannulation has been associated with reduced complications and decreased numbers of attempts [11]. A short axis technique for SCV cannulation has been described as well. As in IJV cannulation, the long axis technique has the advantage of needle tip visualization, which is particularly important with SCV cannulation because of the close proximity of the SCV to the pleura. The short axis technique has been associated with a significantly higher rate of posterior wall puncture than the long axis technique [26]. The long axis technique, however, maybe technically more difficult than the short axis technique and is associated with longer procedure time and lower first-pass success rates [31].

Supraclavicular Approach

An alternative to the traditional infraclavicular technique is the supraclavicular approach. First described in 1965 [2], the supraclavicular approach to the SCV has a number of advantages such as a straighter path to the superior vena cava, less proximity to the pleura, and the ability to keep the catheter out of the surgical field during cardiac or thoracic surgery [32, 33].

With the landmark approach for supraclavicular SCV cannulation, the needle is inserted above the clavicle, just lateral to the sternocleidomastoid muscle, and advanced superficially toward the suprasternal notch. The goal is to puncture the SCV just before it joins the IJV to form the brachiocephalic vein [34]. Figure 29.3 illustrates the close relationship between the SCV, SCA, brachial plexus, and the upper dome of the pleura highlighting the potential for complications with a blind technique. An ultrasound-guided approach has been described for supraclavicular SCV cannulation that may reduce the risk of inadvertent arterial puncture, brachial plexus injury, or pneumothorax [35–38].

Similar to the IJV and infraclavicular ultrasound techniques, the probe is placed just proximal to the needle insertion site used for the landmark approach. For supraclavicular SCV cannulation, the probe is placed just above the clavicle and directly over the sternocleidomastoid muscle. Alternatively, the ultrasound probe can be placed on the neck as one would do with IJV cannulation and then the IJV can be followed down the neck until it joins the SCV. With this technique, the IJV will be seen in short axis, and the SCV and brachiocephalic vein will be seen in long axis (Fig. 29.3d).

Some authors recommend using a special probe for the supraclavicular SCV technique, either an endocavitary probe [35] or a "hockey stick" probe [38]. While these small probes may be convenient in the small space of the supraclavicular fossa, a standard high-frequency linear probe can be used as well. Once the SCV is visualized in long axis just below the clavicle, an in-plane technique can be used for needle guidance. Head-to-head comparisons of the supraclavicular and infraclavicular techniques have suggested that the supraclavicular approach may result in better imaging of the SCV, shorter mean puncture times, fewer attempts, and less guidewire misplacement [37, 39].

Wire Confirmation, Trouble Shooting, and Complications

As with IJV cannulation, the Seldinger technique is the most widely used technique for SCV central line placement. Accordingly, after accessing the vein with the needle, the next step is wire placement. The advantage of using real-time ultrasound for SCV cannulation is that the ultrasound can also be used to confirm the path of the wire into the brachiocephalic vein than retrograde up into the IJV. Other complications such as inadvertent arterial placement, hematoma, and even pneumothorax can also be evaluated using real-time ultrasound.

Summary

While the traditional landmark approach is still widely used, there is increasing interest in the use of real-time ultrasound for SCV cannulation. The ultrasound technique for the SCV is easy to learn and allows direct visualization of surrounding

structures such as the SCA, the brachial plexus, and the pleura so that they can be avoided, and this technique may be associated with a reduced risk of arterial puncture and/or hematoma [9]. The SCV can be accessed either from a supraclavicular or an infraclavicular approach, both of which can be performed with real-time ultrasound guidance. Perhaps the biggest advantage of ultrasound guidance for SCV cannulation is the ability to immediately identify complications such as inadvertent arterial placement, hematoma, wire misdirection, or pneumothorax. Based on these advantages, it is likely that the use of ultrasound for SCV cannulation will continue to increase.

Ultrasound for Femoral Vein Cannulation

Anatomy

Although associated with increased risk of infection and thrombosis in some studies [30], femoral vein (FV) cannulation is often used in emergencies when rapid access is needed or if IJV/SCV cannulation is impossible or contraindicated. The FV is part of the neurovascular bundle that lies within the femoral triangle. The borders of the femoral triangle are the inguinal ligament superiorly, the adductor longus muscle medially, and the sartorius muscle laterally. Inside the triangle, the FV and femoral artery (FA) run within the femoral sheath with the femoral nerve just outside and lateral to the sheath (Fig. 29.4a).

With a landmark technique for FV access, the FA is palpated immediately below the inguinal ligament. The FV is then found approximately 0.5 cm medial to this point. Care must be taken to access the FV distal to the inguinal ligament in order to compress the vessel adequately to prevent hematoma formation either with posterior wall puncture and hematoma or with catheter removal. Placement too far below the inguinal ligament, however, increases the risk of inadvertent arterial puncture, as in the more distal portion of the thigh; the FV becomes posterior to the FA rather than medial to it.

Ultrasound Technique

Real-time ultrasound-guided FV cannulation has been associated with improved first time and overall success rate compared with traditional landmark technique [9], particularly when placed during CPR [10]. As with IJV cannulation, the ultrasound probe is placed on the skin in the same location as described by the landmark technique. For the FV, ideal probe placement is over the femoral triangle just inferior to the inguinal ligament. With a short axis technique, the FA can easily be identified as a round echo-lucent pulsating structure

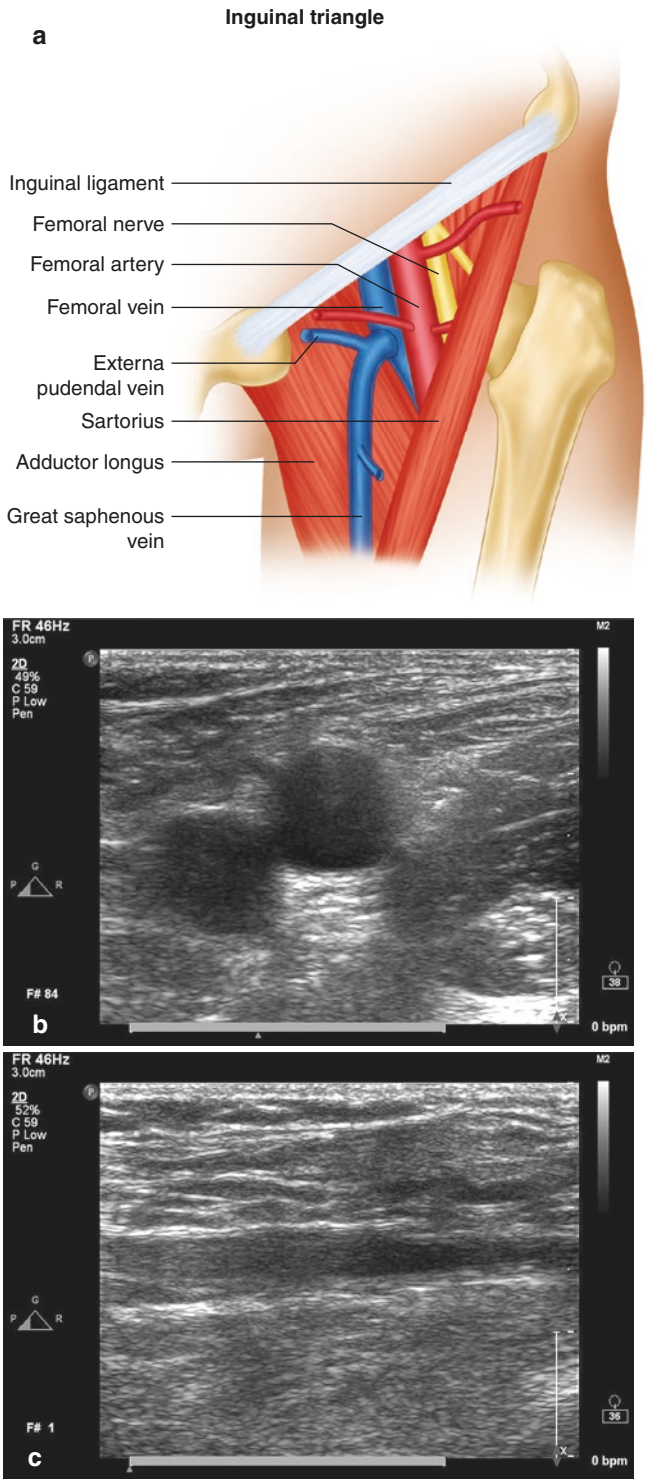

Fig. 29.4 Illustrates the anatomy of the femoral vein (**a**). Ultrasound imaging of the femoral vein in short axis (**b**) and long axis (**c**). It is important to note the close relationship between the femoral vein (FV), femoral artery (FA), and femoral nerve (FN)

in short axis (Fig. 29.4b). The femoral nerve should be identified lateral to the FA and thus avoided. The FV can be identified as the echo-lucent and compressible structure medial to the FA. The ultrasound probe should be moved up and down the femoral triangle to identify where the profunda femoris vein joins the FV as cannulation should occur proximal to this point. Branches of the superficial and deep FA should also be identified as sometimes the two arteries are seen adjacent to the FV and should not cause confusion. Once the FV is identified, the needle can be inserted approximately 1–2 cm distal to the ultrasound probe and then advanced at a 45-degree angle to the probe allowing for needle tip visualization directly under the probe. The larger the patient and the more subcutaneous the fat and muscle, the more the skin entry point for the needle will need to be farther from the probe and the steeper the angle of entry of the needle will need to be. As in IJV cannulation, the needle tip should be sought by moving the probe slightly up or down the thigh. Once the needle tip is located, the probe may need to be moved toward the inguinal ligament as the needle is advanced in order to keep the tip in view. Tenting of the vessel will confirm appropriate needle tip placement prior to puncturing the vessel.

Long Axis Technique

Once the vessel is punctured in short axis, the probe can be rotated 90° to confirm needle tip placement in the center of the vessel. Alternatively, the FV can be imaged primarily in long axis, and the needle can be introduced with an in-plane technique (Fig. 29.4c). The disadvantage of using a long axis technique is that the FA and FV may not be seen in the same plane in long axis, making identification of the FV more difficult. The main advantage, however, is avoiding posterior wall puncture because of the improved visualization of the needle tip with long axis imaging.

Wire Confirmation, Trouble Shooting, and Complications

Wire confirmation can be accomplished with ultrasound in either a short or long axis view of the FV. Confirmation can be obtained by simply visualizing the wire in the more proximal FV. Inability to advance the wire may be caused by needle placement up against the posterior wall of the vessel. This can be corrected by visualizing the needle tip in long axis and adjusting the needle under so that it is in the middle of the vessel. Complications such as hematoma or inadvertent arterial placement can also be visualized immediately with ultrasound.

Summary

Real-time ultrasound guidance for FV cannulation is easy to learn and may be associated with improved success rate. Although no large study has shown that ultrasound reduces the risk of complications with FV cannulation, avoidance of arterial puncture can easily be achieve with direct visualization, and prevention of posterior wall puncture with a long axis technique may reduce the risk of hematoma.

Ultrasound for Radial Artery Cannulation

Anatomy

The radial artery, a continuation of the brachial artery, runs down the lateral side of the forearm and wrist. The brachial artery divides into the radial and median artery just distal to the elbow. In the forearm, the radial artery runs deep to the brachioradialis muscle, lateral to the median nerve in the wrist and medial to the radial nerve at the wrist.

Ultrasound Technique

When placing a radial artery catheter, the wrist is generally secured in an extended position in order to ensure adequate access and to tether the radial artery so that it does not roll out of position when punctured. The ultrasound probe is placed on the lateral aspect of the distal wrist, right over the anatomic region where the radial pulse is normally palpated. With ultrasound, the radial artery is can be recognized as a small pulsatile vessel that is not easily collapsible when pressure is applied by the probe. The radial vein traverses along with the artery but can be easily distinguished from the artery as it is nonpulsatile and easily collapsible. Once the radial artery has been identified and the ideal location for puncture has been selected, the depth should be adjusted to maximize the size of the small artery on the ultrasound screen.

When using a sterile technique for radial artery catheterization, the skin should be disinfected and draped in a sterile fashion. The ultrasound probe should then be cleaned, sterile gel be placed on the probe, and placed in a sterile sheath before being introduced into the sterile field. Before introducing the needle into the skin, the depth of the artery from the skin as seen on the ultrasound screen should be noted. If the needle is then inserted the same distance from the probe and advanced at a 45-degree angle, this will facilitate needle tip visualization just at the point of vessel puncture. The major limitation to this short axis technique is again needle tip visualization. This can be overcome by rotating the probe

90° to visualize the long axis of the vessel. The latter will improve needle tip visualization but is technically more difficult with small vessels such as the radial artery.

If the vessel is successfully punctured in a short axis technique, once a flash of blood is seen, the ultrasound probe can also be turned 90° to view the long axis of the artery to confirm the needle tip is within the center of the vessel. The wire can then be advanced into the vessel while being visualized on the ultrasound screen, and then the catheter is advanced over the wire.

A common reason for the inability to thread the wire is through and through puncture of the posterior wall. The long axis technique may allow for troubleshooting when the wire will not advance into the vessel or the needle can be removed and the catheter slowly withdrawn until brisk pulsatile blood flow indicates that the tip of the catheter is back inside the artery. The wire can then be reintroduced and the catheter advanced over the wire until it is fully within the vessel.

Summary

Although the landmark and palpation technique for radial artery catheterization is the mostly widely used technique, ultrasound may be used for difficult access or in cases where first-pass success is desired. Real-time ultrasound when compared to the palpation technique has been shown to not only improve success rates but also reduced the time to cannulation [40–42]. The use of ultrasound in patients with low-flow states, altered anatomy, obesity, nonpulsatile arteries, and who have had multiple unsuccessful cannulations may facilitate access [43].

RUPV	Right upper pulmonary vein	TAPSE	Tricuspid valve annular plane systolic excursion
RLPV	Right lower pulmonary vein	TR	Tricuspid regurgitation
		RVSP	Right ventricular systolic pressure

Key Points

- Despite its intuitive advantages, the use of TEE in non-cardiac surgery is still limited by the availability of trained anesthesiologists. In fact, very few studies have looked at the impact of intraoperative TEE in non-cardiac surgery on patients' outcomes.
- TEE is a considered a safe technique. However, despite its relative noninvasiveness, it carries potentially severe complications and needs to be supported by congruent indications.
- Basic hemodynamic monitoring can be easily achieved with TEE. Qualitative and quantitative assessments of right and left ventricular function are feasible and can be integrated as a complete standard in intraoperative hemodynamic monitoring.
- TEE for lung transplant, while standard of care in many centers, is not specifically recommended by current guidelines. TEE provides ideal intraoperative hemodynamic monitoring, and it allows the assessment of all vascular anastomoses immediately after the reperfusion of the graft.

- TEE has a promising role in the diagnosis and follow-up of both acute and chronic pulmonary embolisms. TEE can easily detect and monitor the effects of acute and chronic pressure overload on the right ventricle and can rule out dangerous intracardiac shunts. These characteristics make it a powerful tool for intraoperative monitoring during pulmonary embolectomy and endarterectomy surgeries.
- The ability to image cardiac structures with a high spatial resolution makes TEE suitable for assessing the effect of mediastinal masses on cardiac chambers. TEE may also provide useful information to guide surgical resection.

Introduction

The use of TEE outside of the cardiac operating room has significantly increased over the last few years. Thoracic surgery is naturally becoming an exciting field for the application of this powerful technology for more than one reason. In fact, in many institutions cardiac anesthetists, most of whom are TEE trained, provide their services to thoracic surgery. Moreover, the physiology of cardiopulmonary interaction, the growing number of combined cardiothoracic operations, and the increasing complexity of patients' pathologies create the need for the complete intraoperative monitoring of cardiac function.

Guidelines for the use of TEE for intraoperative hemodynamic monitoring of non-cardiac surgery are very vague and make its practice around the world very variable. As the use of the pulmonary artery catheter is falling out of fashion, intraoperative TEE is becoming a reliable and even more powerful alternative [1].

Indications for TEE in Thoracic Surgery

Indications for TEE during thoracic surgery do not differ from other non-cardiac indications, and it is limited to "when the surgery or the patient's cardiovascular morbidities may result in severe hemodynamic pulmonary or neurological compromise" [2]. Currently, there are no scoring systems suggesting how to identify, at baseline, patients who may fit into this category. Thus, the use of TEE outside of cardiac anesthesia remains heavily based on single center resources and practice. Based on current evidence, the aim of a TEE exam during major thoracic surgery should be directed toward identification of atrial septal defect, myocardial ischemia, hypovolemia, pericardial tamponade, thromboembolic events (Category B2 evidence: high agreement members opinion), pericardial effusion, tamponade, and intrapulmonary emboli in other major surgery (i.e., lung, renal, abdominal, and head/neck/chest wall surgeries) (Category B3 evidence: intermediate agreement members opinion).

However, current guidelines suggest TEE should be performed in all open-heart surgery. Pulmonary embolectomy and lung transplant may be considered an intracardiac procedure as they involve great vessels and often the use of mechanical circulatory support.

None of the studies used to gage recommendations was specifically conducted in thoracic surgery, and some included cardiac surgical patients [3, 4]; however the care of thoracic surgery patients may share common scenarios with other surgical settings. The lack of outcome trials looking at the impact of the use of intraoperative TEE in non-cardiac surgery makes it still an interesting field for future research.

The impact of emergent TEE in the course of cardiac arrest in non-cardiac patients has been specifically assessed in the operating room [5], as well as during in-hospital resuscitation [6]. In both settings, TEE has been reported to provide prompt diagnosis of the cause of circulatory arrest in 64–86% of the cases and to guide new surgical intervention in 54% of the patients. The ability of TEE to identify the etiology of cardiac arrest has been quantified with a sensitivity and specificity of 90 and 50%, respectively [6] (Table 30.1). The release of new portable TEE equipment and the fact that TEE does not interfere with cardiopulmonary resuscitation (CPR) make TEE suitable to be integrated into advanced cardiac life support algorithms.

In North America, the need for TEE-certified anesthesiologists [7] and the availability of TEE equipment are the main limitations to the routine use of TEE outside of the cardiac operating room. Some authors have suggested that the use of a simplified focused TEE examination for transplant surgery may be adequate [8]. The American National Board of Echocardiography has introduced a new certification process in basic perioperative TEE [9] that will potentially expand the use of TEE as an intraoperative monitoring tool.

Safety and Complications of TEE Probe Insertion

Although none of the studies mentioned above reported any complication related to the use of TEE, the insertion and manipulation of the TEE probe is not free of risks [10]. Major complications in the use of TEE have been described and include esophageal dissection [11] and perforation [12].

Two large retrospective reviews on cardiac surgical patients undergoing intraoperative TEE reported incidences of major complications, respectively, of 0.2% of

Table 30.1 Use of TEE in non-cardiac surgery

Author/year	Number of patients	Indication	Type of surgery	Type of study	Change hemodynamic management	Change surgical management
Canthy/2009	13	I 4 (30%) II 9 (70%)	Gynecology, neurosurgery	Retrospective	9/13 (69%)	2/13 (14%)

patients with no associated deaths [13] and of 0.1% with a mortality of 0.02% [14].

A careful assessment of the potential benefit of an intraoperative TEE exam against its potential complications must be performed in each patient.

Preoperative assessment is very important, and patient consent should be obtained whenever possible. A patient's history should be reviewed in order to rule out gastroesophageal pathology. Esophageal narrowing should always be suspected with the presence of dysphagia. A radiological barium swallowing study remains the gold standard to rule out esophageal strictures [10] and should be performed whenever there is clinical suspicion.

The TEE probe should always be gently manipulated, and any force should be avoided in case of resistance to advancement into the esophagus. Esophageal perforation or tear may present soon after the removal of the probe with profuse bleeding from the pharynx or from a nasogastric tube and can present over 48 h after probe insertion [14].

Intubation of the esophagus, in the anesthetized patient, can be performed under direct vision or blindly with the help of jaw thrust maneuver. Esophageal intubation is a strong stimulus, and adequate depths of anesthesia and muscle paralysis are necessary to minimize the hemodynamic impact. It is a standard practice in many centers to insert the TEE probe right after the placement of the endotracheal tube.

To minimize the risk of esophageal injury, the use of a pediatric TEE probe (Fig. 30.1) should be considered in very small-sized adults.

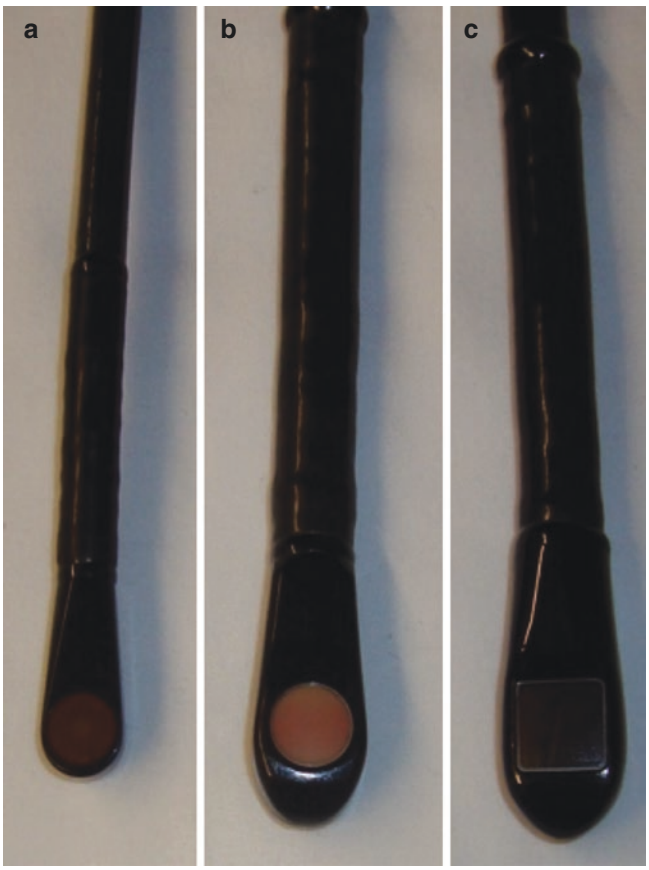

Fig. 30.1 Probes. The three types of TEE probes available: (**a**) pediatric, (**b**) adult Omniprobe, (**c**) adult 3D

Basic Hemodynamic Assessment

A complete intraoperative TEE assessment comprises the use of an omniplane TEE probe and the analysis of 28 standard TEE views [15]. It should be performed at baseline and requires an expertise in TEE. Current guidelines do not specify how often a complete exam should be repeated during the course of surgery and what views should be used for intraoperative hemodynamic monitoring.

After a complete baseline exam, many authors [3, 16–18] chose to leave the TEE probe in the stomach and use the transgastric short axis view (TG SAX) for the continuous assessment of LV function.

Visual analysis of the short axis of the LV in the TG SAX view provided adequate qualitative, online assessment of LV and RV function as well as an estimated volume status in many studies [3, 16–18].

TEE has been reported to predict postoperative myocardial infarction in patients following surgical myocardial revascularization [19], but its role in the detection of intraoperative myocardial ischemia in non-cardiac surgery has been heavily questioned by negative studies [20].

A simplified approach to intraoperative TEE hemodynamic monitoring identifies five possible hemodynamic states [21] (Table 30.2): normal, hypovolemia, LV systolic failure, LV diastolic failure, and right ventricular (RV) failure.

The differential diagnosis of hemodynamic status can be easily accomplished by combining the assessment of LV and RV function with the estimation of left atrial (LA) pressure.

An easy way of visually assessing LA pressure in mechanically ventilated patients is to determine the movement of the interatrial septum during the respiratory cycle [22] (Fig. 30.2). A fixed septum that never shifts left and right is a sign of increased LA pressure; this technique has been successfully validated against invasive monitoring [23]. We will discuss the assessment of LV and RV function in detail in the next paragraphs.

It has been reported that novices can achieve adequate confidence in assessing basic hemodynamics after a minimum number of supervised studies [24].

Assessment of Left Ventricular (LV) Function

Assessment of LV function includes assessments of the LV preload, global, and regional systolic function and diastolic function.

For the basic assessment of LV function [25], three standard views must be obtained: TG SAX, mid-esophageal four-chamber view (ME 4C), and mid-esophageal two-chamber view (ME 2C) (Fig. 30.3).

The LV end-diastolic volume (LVEDV) is the best estimate of LV preload [21, 26]. LVEDV can be easily estimated by the linear measurement of the LV infero-anterior end-diastolic diameter (LVEDD) or, more precisely, the LV end-diastolic area (LVEDA) in the TG SAX view [27] (Fig. 30.4). Complete emptying of the LV with virtualization of the LV cavity at end-systole is also a sign of decreased preload.

Table 30.2 Hemodynamic status

Status	LV EDV	LV systolic function	LV diastolic function	RV systolic function	IAS in Systole
Normal	Normal	Normal	Normal	Normal	Swing
Hypovolemia	Decreased	Normal or increased	Normal	Normal	Swing
LV failure	Increased	Decreased	Normal or abnormal	Normal	Fixed
LV diastolic failure	Decreased	Normal	Abnormal	Normal	Fixed
RV failure	Decreased	Normal	Normal or abnormal	Decreased	Fixed

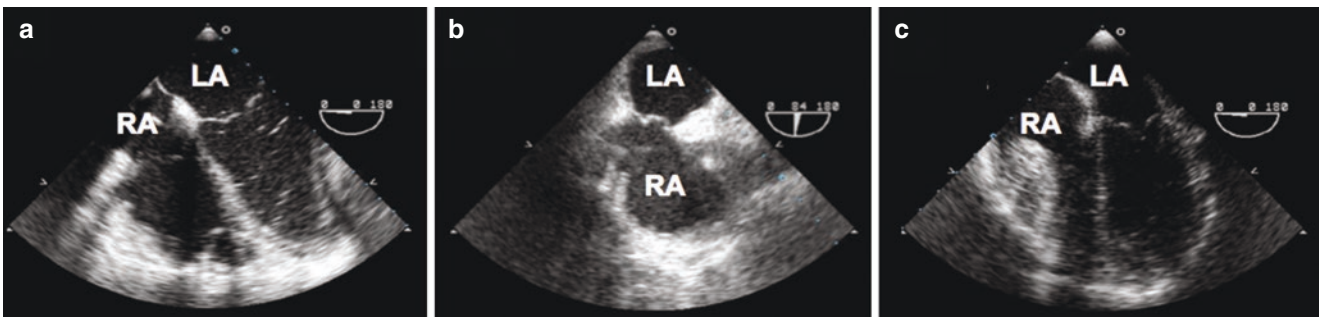

Fig. 30.2 Interatrial septum shift. In mechanically ventilated patients, the movement of the interatrial septum (IAS) during the respiratory cycle reflects the pressure in the atrial chambers. High LA pressure results in a right bulge of the IAS that remains immobile during the respiratory cycle (**a**). Low LA pressure allows left and right IAS shifting that often presents as a "wrinkled" IAS (**b**). A fixed left bulge is characteristic of high RA pressure(**c**)

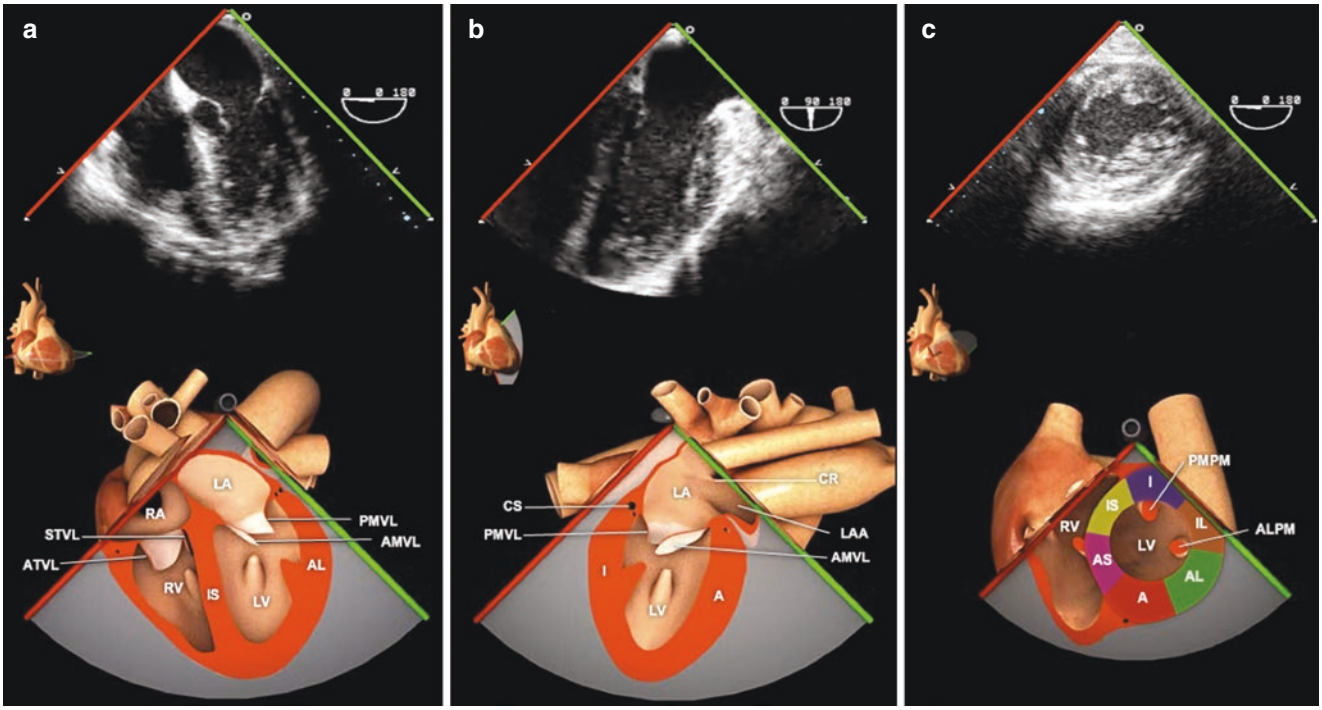

Fig. 30.3 LV views. Assessment of the left ventricular function requires obtaining the following three standard views: mid-esophageal four-chamber view (**a**), mid-esophageal two-chamber view (**b**), transgastric left ventricular mid short axis view (**c**). (Courtesy of Michael Corrin (http://pie.med.utoronto.ca/TEE))

The LV ejection fraction (LVEF) is the percentage change in LV volume during the cardiac cycle and reflects the global LV systolic function. It is defined by the equation,

LVEF = [(LVEDV-LVESV)/LVEDV] × 100, where LVESV is the LV end-systolic volume.

TG SAX allows the visual assessment of global LV systolic function and was shown to correlate well with measured LVEF even when assessed by novices [28].

The quantification of LV function can be done in one (measuring diameters), two (measuring areas), or three dimensions (measuring volumes) (Fig. 30.4).

Linear measurement of LV function consists of the measurement of fractional shortening or the percentage of change in the LV diameter during the cardiac cycle. It can be achieved by tracing a line across the maximum LV diameter in the TG SAX view, and, although based on the movement of two points in the entire LV, it correlates with LV EF.

In the same view, the fractional area change (FAC), or the percentage change in the LV cross-sectional area during the cardiac cycle, can be measured. It is easily obtained by tracing the endocardial border of the LV in the end-systolic and the end-diastolic frames. FAC is easy to calculate and correlates well with the ejection fraction. Automatic endocardial border detection and automatic continuous FAC calculation software has been developed for continuous intraoperative monitoring but, after successful testing [29], never became widely used.

Global LV function can also be assessed by deriving the LV stroke volume (SV) from the Doppler measurement of the blood flow at the level of the LV outflow tract (LVOT) [30]. This technique is complex and may underestimate LV SV by underestimating the flow across the LVOT due to the malalignment of the Doppler beam and the LVOT flow.

LV volumes can be measured using the biplane method of the disks (modified Simpson's rule). It is based on the concept of dividing the LV cavity into a stack of 20 ellipsoids whose height is directly related to the length on the LV. After manually tracing the endocardial border in the end-diastolic and the end-systolic frames of a ME 2C and a ME4C view, the modern echocardiographic machine automatically calculates LVEDV, LVESV, SV, and EF. This method is considered the gold standard [25], but it is time-consuming, requires good quality images, and necessitates experience with the technology.

To standardize the assessment of LV regional wall motion, the American Society of Echocardiography (ASE) classification divided the LV into 17 segments (Fig. 30.5) [31]. The segments are grouped into three levels, namely, the basal (six), mid-ventricular (six), and apical (four), plus an apical cap. For a complete assessment of LV regional wall motion, all segments should be displayed and individually assessed according to a rating scale (Table 30.3).

Measure	Formula	Normal values
Fractional shortening (FS) 	[(LVEDD-LVESD)/ LVEDD]×100	FS: 25–45 % LVEDD: 4–5 cm
Fractional area change (FAC) 	[(LVEDA-LVESA)/ LVEDA]×100	FAC: >55% LVEDA: 8–12 cm^2
Ejection fraction (EF) 	Automatically calculated based on Simpson's rule	EF: >55%
Stroke volume (SV) 	$TT(d_{LVOT}) \times VTI_{LVOT}$	SV: 50–70 ml

Fig. 30.4 Common methods and normals for quantification of LV function

All of the segments are attributed to the main coronary arteries (Fig. 30.5); thus, the analysis of segmental wall motion may allow the localization of individual coronary stenosis [25].

The TG SAX view allows the simultaneous visualization of the territories of the three main coronary arteries.

The quantitative assessment of diastolic dysfunction is complex and requires the assessment of multiple measures [32].

The advent of 3D TEE technology [33] offered the ability of directly and accurately measuring LV volumes [34, 35].

High-quality images of the LV are necessary and currently require the acquisition of a 3D dataset over four or eight heartbeats [36]. The acquired 3D volume "block" will subsequently be analyzed using an off-line quantification software (Philips QLab™, Tomtec™).

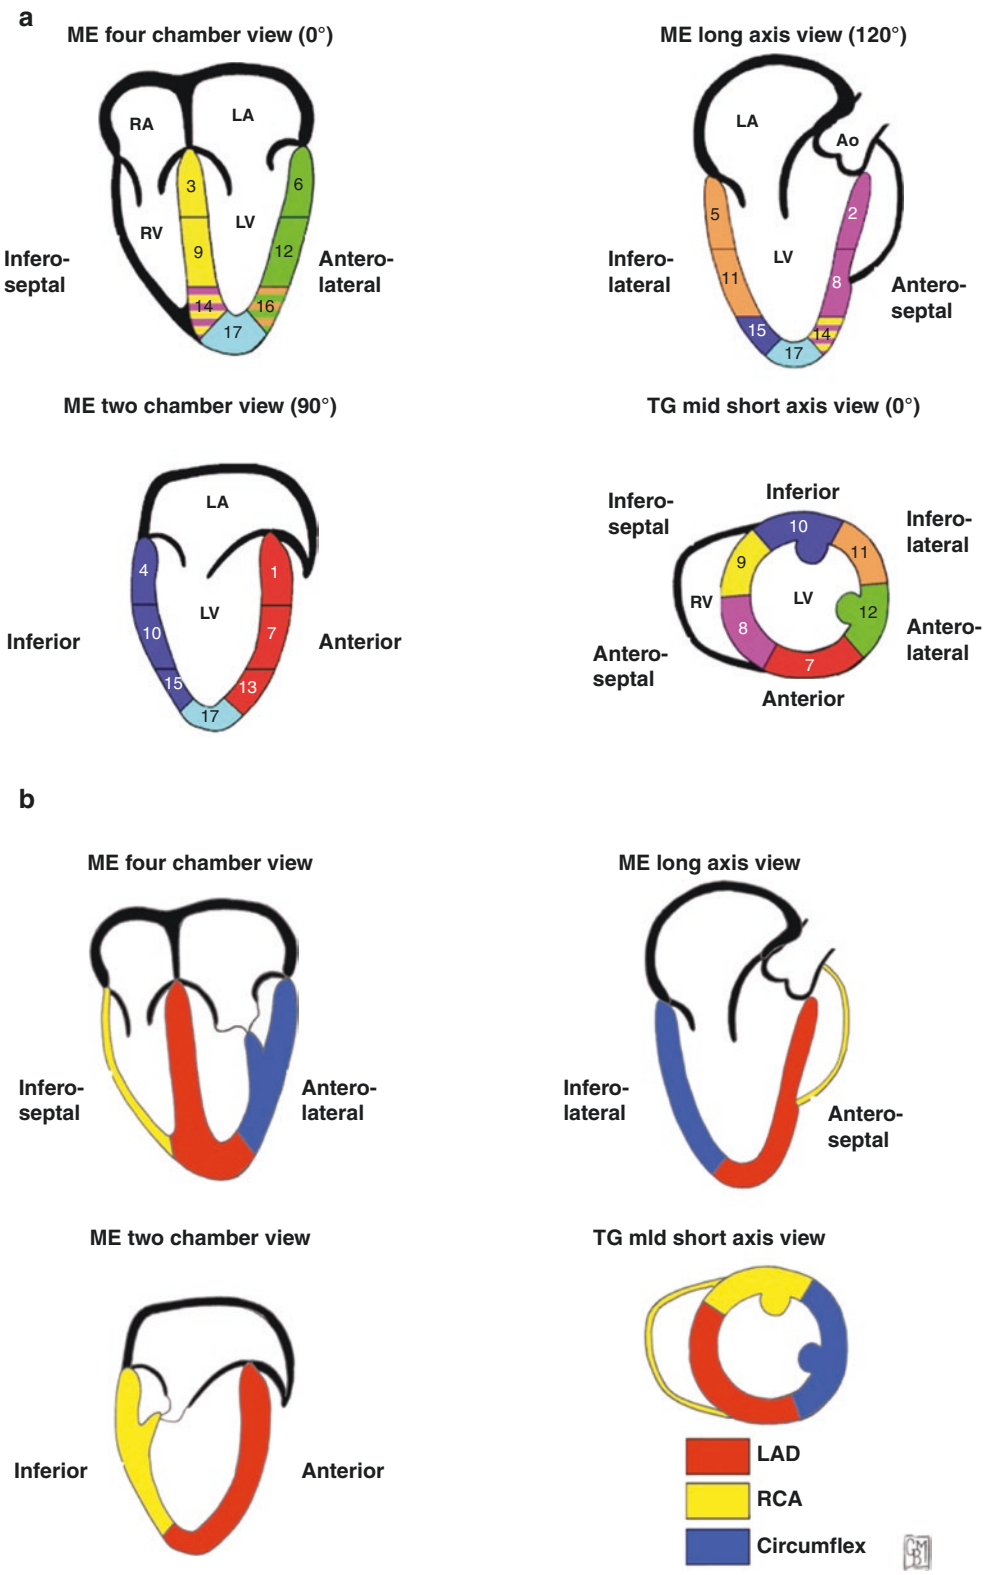

Fig. 30.5 17 Segment model and coronary distribution. The diagram explains which left ventricular segments are seen in the most common TEE views of the LV (**a**). The relative coronary distribution is displayed in panel **b**. (Photo is courtesy of GM Busato)

The current software offers a semiautomatic method for the 3D reconstruction of the LV: given six anatomical landmarks on three orthogonal cuts of the full-volume scan of the LV on the systolic and the diastolic frames, the software elaborates a moving 3D cast of the LV cavity. The change in global LV volume is immediately displayed on a graphic plot of the LV volume/time, together with measured LVEDV, LVESV, LVSV, and LVEF.

To allow the assessment of regional LV wall motion, the 3D cast of the LV cavity is divided into 17 pyramids according to the ASE 17 segment model [25], and the change in volume of each pyramid is plotted over time.

The volume/time plots of all segments are superimposed, allowing the assessment of dyssynchrony.

The validity of 3D TEE in assessing LV dyssynchrony has been extensively tested [37, 38] (Fig. 30.6).

The limitation of current 3D technology is the fact that it is not real time and requires an expertise in acquiring and manipulating the datasets. Until newer, more powerful machines will allow automatic LV reconstruction, the role of 3D TEE for the intraoperative monitoring of LV function seems to be limited.

Table 30.3 LV wall motion

Definition	Standard terminology	Sign
Normal movement	Normal	+ +
Decreased movement	Hypokinetic	+
No movement	Akinetic	0
Outward bulging in systole	Dyskinetic	−
Fixed outward bulging	Aneurysmal	− −

Intraoperative diastolic dysfunction [39] seems to correlate with poor postoperative outcome in non-cardiac surgery [40]. It is unclear how to manage low grades of intraoperative diastolic dysfunction.

However, for a basic hemodynamic assessment, it is important to recognize an increased atrioventricular gradient that corresponds to a severe degree of diastolic dysfunction.

As simplified approach to the assessment of diastolic function allowed grading of dysfunction in patients undergoing coronary revascularization and correlated with short- and long-term outcome [41]. It is based on mitral inflow early wave (*E*) peak and lateral MV annulus tissue Doppler early wave (*E*') velocities. *E*' < 10 cm/s defines DD. *E*/*E*' is used to grade DD severity: *E*/*E*' < 8, mild; *E*/*E*' 9–12, moderate; and *E*/*E*' > 13, severe.

Assessment of Right Ventricular (RV) Function

RV dysfunction is very common in patients with severe pulmonary disease [42]. TEE allows prompt diagnosis of

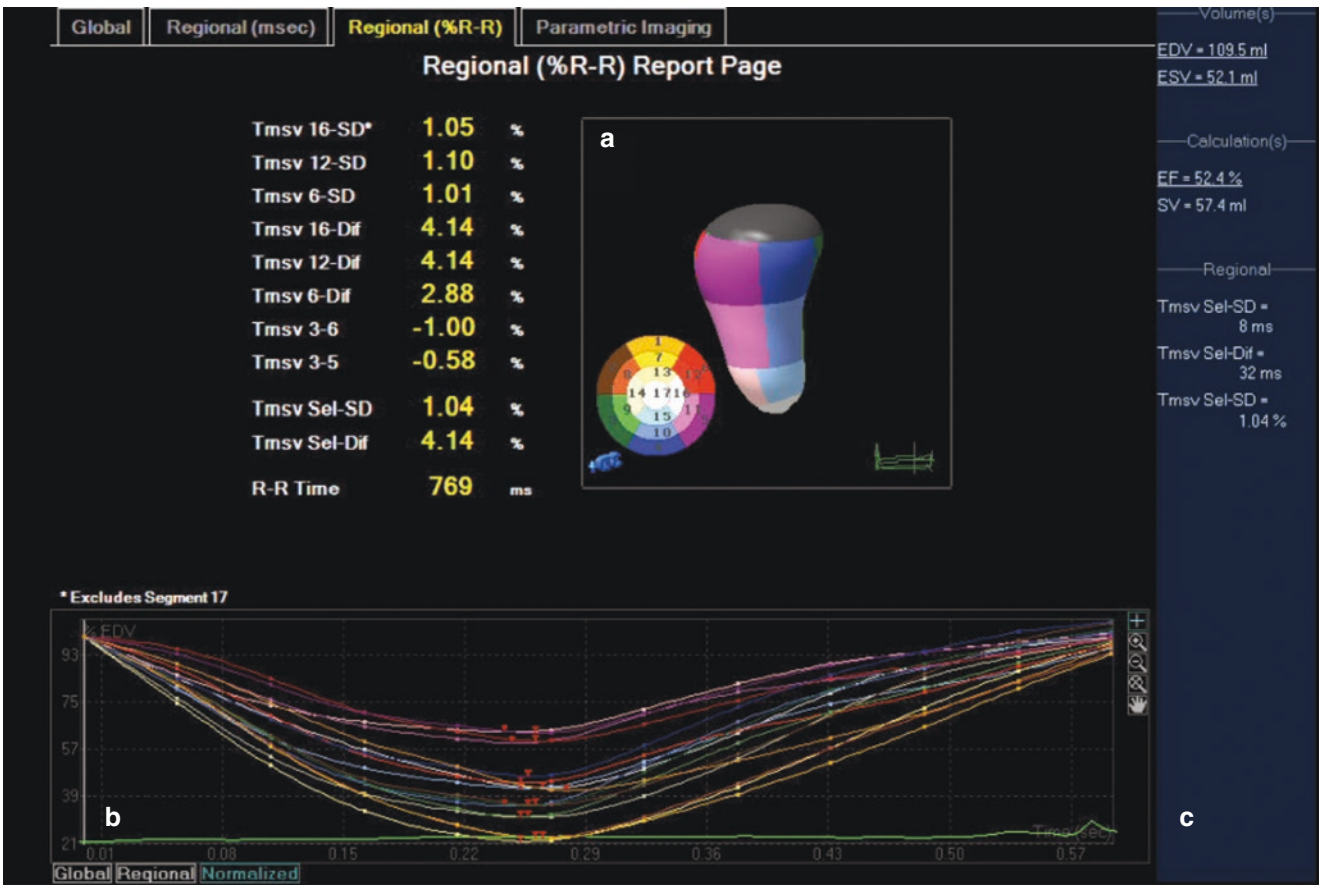

Fig. 30.6 3D TEE LV assessment. Panel **a** displays the left ventricular (LV) cast. The LV cavity is divided into 17 wedges each corresponding to one of the 17 segments. The change in shape of each on the 17 segments is plotted over time (**b**). The LV end-diastolic volume, end-systolic volume, and ejection fraction are automatically measured (**c**)

RV dysfunction but requires an understanding of the pathophysiology of RV dysfunction and the complex 3D RV anatomy [43].

RV dysfunction is characterized by increased RA pressure, venous stasis, low cardiac output, LV diastolic dysfunction, and decreased LV preload [44]. It can be the result of RV pressure or volume overload and RV ischemia. The assessment of RV function includes assessments of the RV morphology and RV systolic function [45].

The right ventricle has a complex 3D architecture as it wraps around a conical LV. The RV can anatomically be divided into three parts: the inlet, composed by the tricuspid valve (TV), the chordae, and the papillary muscles; the trabeculated muscular apex; and the outlet, composed by the smooth muscle outflow tract (RVOT).

The distinctive anatomical features of the RV are a prominent muscular band from the free wall to the IVS, the proximity of the RV apex (moderator band), the more apical attachment of the septal leaflet of the tricuspid valve (TV) in comparison to the anterior leaflet of the mitral valve (MV), and the presence of more than two papillary muscles [46, 47].

The RV is a thin-walled structure, usually exposed to low pressures. The RV is very compliant and sensitive to changes in afterload; an acute increase in afterload results in RV dilatation. Chronic RV pressure overload causes concentric hypertrophy.

The basic TEE assessment of RV function requires the collection of the following three standard views: ME 4C, TG SAX, and mid-esophageal RV inflow-outflow (ME RV in-out) (Fig. 30.7).

The ME 4C view displays the triangular-shaped RV long axis. In this view the RV end-diastolic area (RVEDA) can be measured and compared to the LV EDA (Fig. 30.8a). A nor-

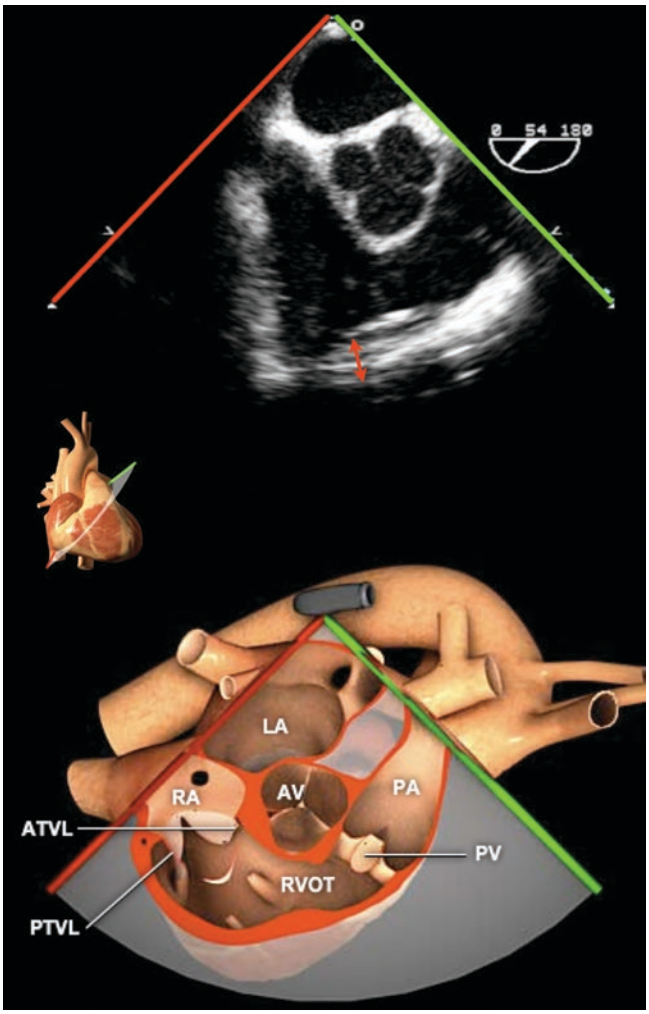

Fig. 30.7 RV inflow-outflow view. In this view the ultrasound beam cuts the RV through its entire length. The arrow indicates RV wall thickness. (Photo is courtesy of Michael Corrin (http://pie.med.utoronto.ca/TEE))

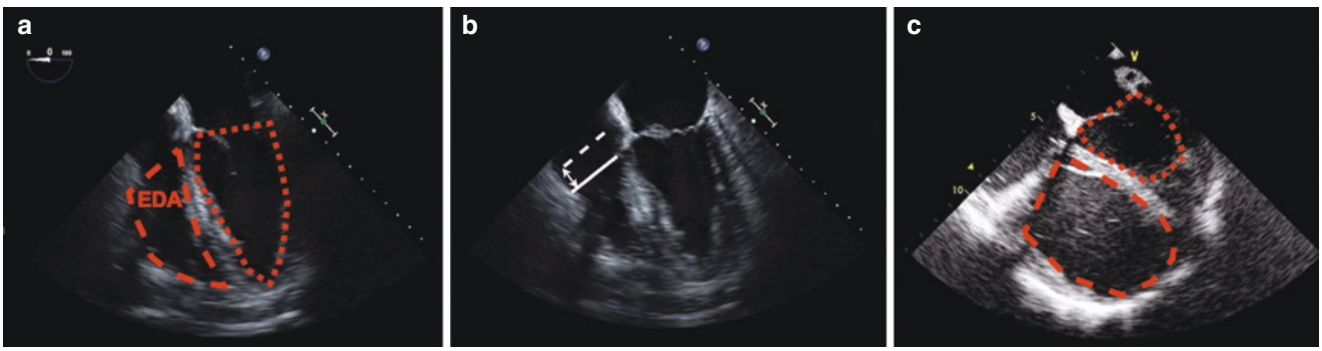

Fig. 30.8 Assessment of RV function. In the mid-esophageal four-chamber view, the right ventricle (RV) end-diastolic area can be measured and compared to LV EDA (**a**). The systolic displacement of the tricuspid valve annulus (TAPSE) (arrow) reflects RV function (**b**). With dilatation, the RV cavity loses its triangular shape and takes over the apex of the heart (**c**)

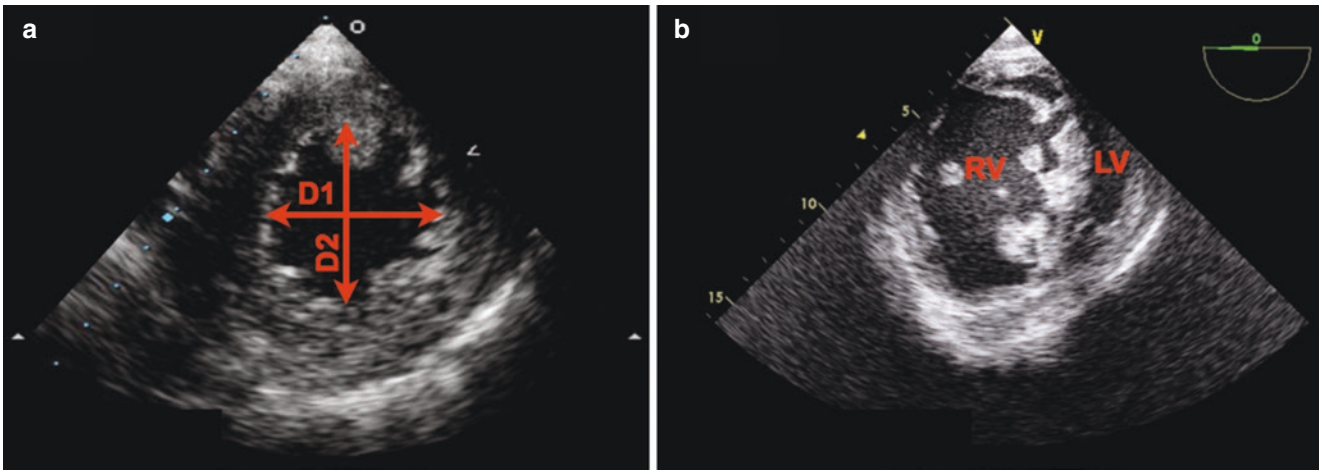

Fig. 30.9 LV eccentricity. The degree of flattening of the interventricular septum (IVS) can be quantified using the eccentricity index (EI). EI = D1/D2 where D1 is the infero-anterior and D2 is the latero-septal LV diameters (**a**). With RV dilatation flattening of the IVS results in a "D"-shaped LV gross section (**b**)

mal RVEDA/LVEDA is <0.6, and a RVEDA/ LVEDA >1 indicates severe RV dilatation [46]. In the same view, we can observe that, as the RV dilates, it loses its triangular shape, and when it is as big as the LV, it starts to share the apex of the heart, to finally take over with severe dilatation [48] (Fig. 30.8c).

The ME RV in-out view displays the RV crescent shape. In this view, the RV inlet, free wall, and outflow tract can be seen; linear measures include the RVOT diameter and the thickness of the RV free wall. A free wall thickness >5 mm at end diastole indicates RV hypertrophy [31].

The TG SAX view displays the RV short axis as a crescent shape attached to a circular LV. With RV pressure overload, RV dilatation displaces the interventricular septum (IVS) toward the left. Distortion of the IVS is measured by the LV eccentricity index, which is the ratio of the LV infero-anterior and septo-lateral LV short axis diameters (Fig. 30.9a). With severe RV dilatation, the LV loses its circular shape and instead becomes D-shaped (eccentricity index >1) (Fig. 30.9b).

RV ejection is generated by three separate mechanisms: inward movement of the RV free wall, apical displacement of the TV annulus, and traction of the free wall by contraction of the LV [49].

Qualitative assessment of RV function consists of visual determination of inward movement of the RV free wall in the ME 4C and the ME RV in-out views (Fig. 30.8).

In the ME 4C view, RV FAC can be measured as the percentage of change of the RV area during the cardiac cycle. RV FAC well correlates with the RV EF measured by cardiac MRI [50]. The predominant motion of RV free wall movement is a sequential longitudinal shortening from the inflow portion of the RV to the infundibulum which can be measured with modern technology by tracking the displacement of RV free wall muscle speckles (speckle tracking). In the ME 4C view, speckle tracking of the RV free wall allows measurement of the percentage of muscle shortening known as strain [51]. This is becoming an accurate quantification of RV function with a normal value >20% that has shown promising prognostic value in the cardiac surgical population [52] (Fig. 30.10).

In the same view, the TV annular plane systolic excursion (TAPSE) can be determined (Fig. 30.8b). In a normal heart, TAPSE is 1.5–2.0 cm, and a TAPSE <1.5 is associated with a poor outcome in patients with heart failure [53]. However, the TV annulus moves in a plane that is almost perpendicular to the TEE ultrasound beam, and this makes the accurate measurement of TAPSE with TEE very difficult.

A recent work further highlighted these limitations in a direct comparison with transthoracic echocardiography and suggested the use of speckle tracking technology [54].

The dilatation of the RV results in TV annular dilatation and regurgitation (TR) [55]. The severity of TR is not directly related to the severity of RV dysfunction. As the RV function deteriorates, the ability of RV to generate pressure is impaired; thus, a large, turbulent TR jet may turn into a low-velocity, laminar flow. In contrast, with RV remodeling following the treatment of RV pressure overload using, for example, pulmonary endarterectomy (PEA), an improvement in TR is observed [56].

Due to the complex shape of the RV, the RV volumes cannot be measured with standard TEE using polygonal models, as are commonly used for the LV.

Real-time 3D TEE overcomes some of the limitations of 2D TEE. A full-volume 3D dataset of the RV is obtained over multiple subsequent heartbeats. The 3D block obtained can then be used for the off-line measurement of right ventricular volume and function using special analytical soft-

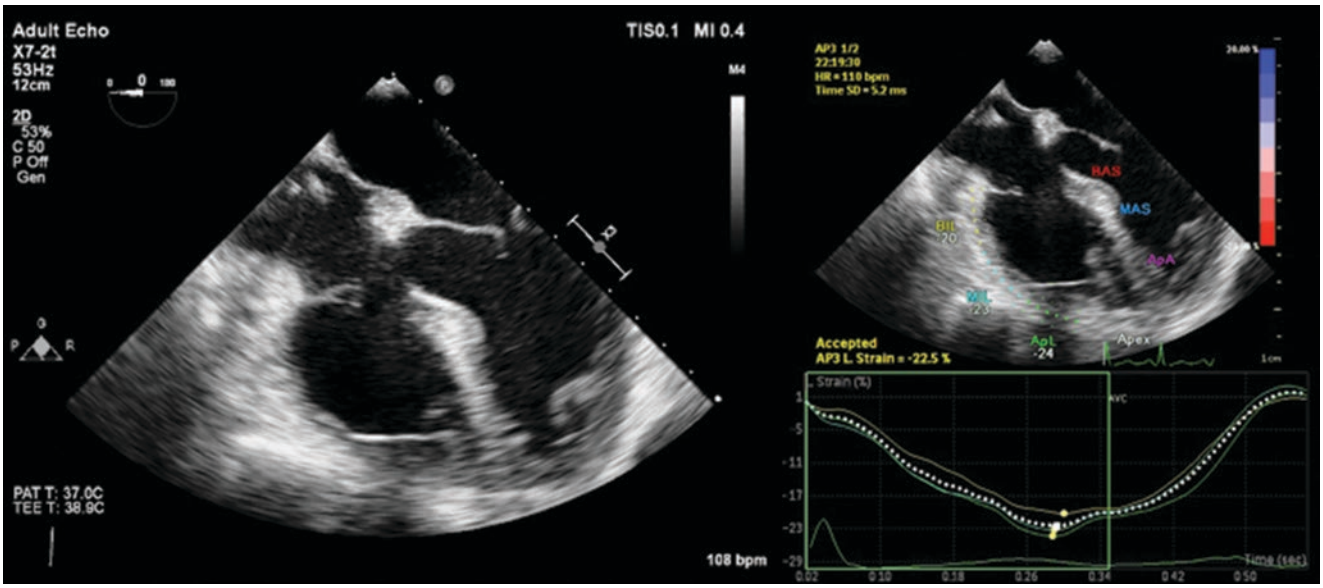

Fig. 30.10 TEE RV strain. Measurement of RV free wall strain. A ME 4C view was analyzed using the LV strain software, and the ME LAX model was applied to the RV to maintain the lateral and septal wall nomenclature. The septum was excluded from the analysis, and a global longitudinal strain was measured at 22.5%, which is considered within normal range

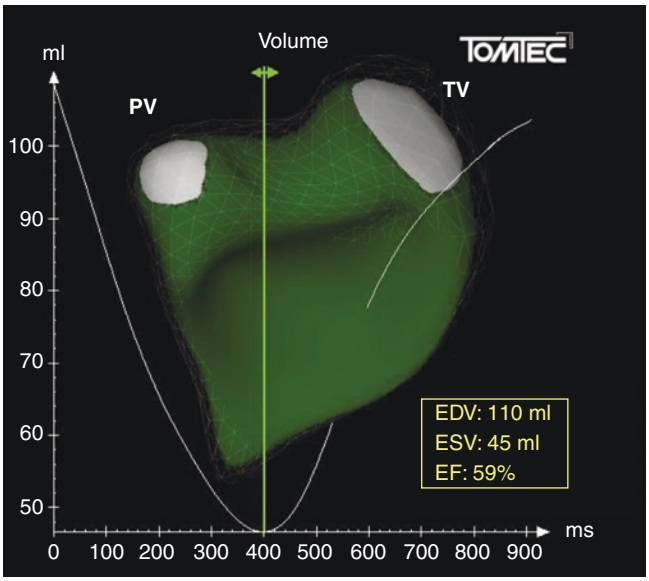

Fig. 30.11 3D TEE RV assessment. 4D RV-Function© application (TomTec Imaging Systems GmbH, Munich, Germany) allows off-line processing of 3D TEE datasets and semiautomatic reconstruction of the RV cavity. In the RV cast tricuspid annulus (TV) and pulmonary valve annulus (PV) can be recognized

ware (4D RV-Function© application; TomTec Imaging Systems GmbH, Munich, Germany). 4D RV-Function© software allows the creation of a cast of the RV cavity and provides automatic measurement of RV volumes and EF (Fig. 30.11).

The feasibility of intraoperative RT 3D TEE has been reported [57]; however, all the literature assessing the accuracy of this technique is based on transthoracic echocardiography (TTE) [58–60] with good correlation with cardiac MRI [58, 59] with better reproducibility than 2D TTE [59] for the assessment of right ventricular volume and function in adults and children [61].

TEE Assessment of PFO

Patent foramen ovale (PFO) is the result of the lack of fusion of the two interatrial septal flaps, the septum primum (left side) and the septum secundum (right side) (Fig. 30.12a). Until birth, an orifice in the septum secundum, covered by a mobile septum primum, allows maternal circulation through the heart.

At birth, as the left atrial pressure overcomes the right atrial pressure, the functional closure of the foramen ovale occurs. Through the years, a permanent fusion of the two flaps will seal the defect.

PFO is relatively common in the general population and is found in about 25% of autopsies [62].

TEE is the gold standard for the detection of PFO, with sensitivity between 80% and 100% and specificity of 100% [63–65].

To rule out the presence of a PFO, the TEE exam should focus on the careful inspection of the interatrial septum (IAS) in the ME 4C view. Once the IAS is visualized, the probe is rotated toward the right to bring the IAS into the middle of the screen. Given the normally small size, a PFO is unlikely noticed as a gap upon 2D examination. The color Doppler volume is then positioned to cover the IAS, and the

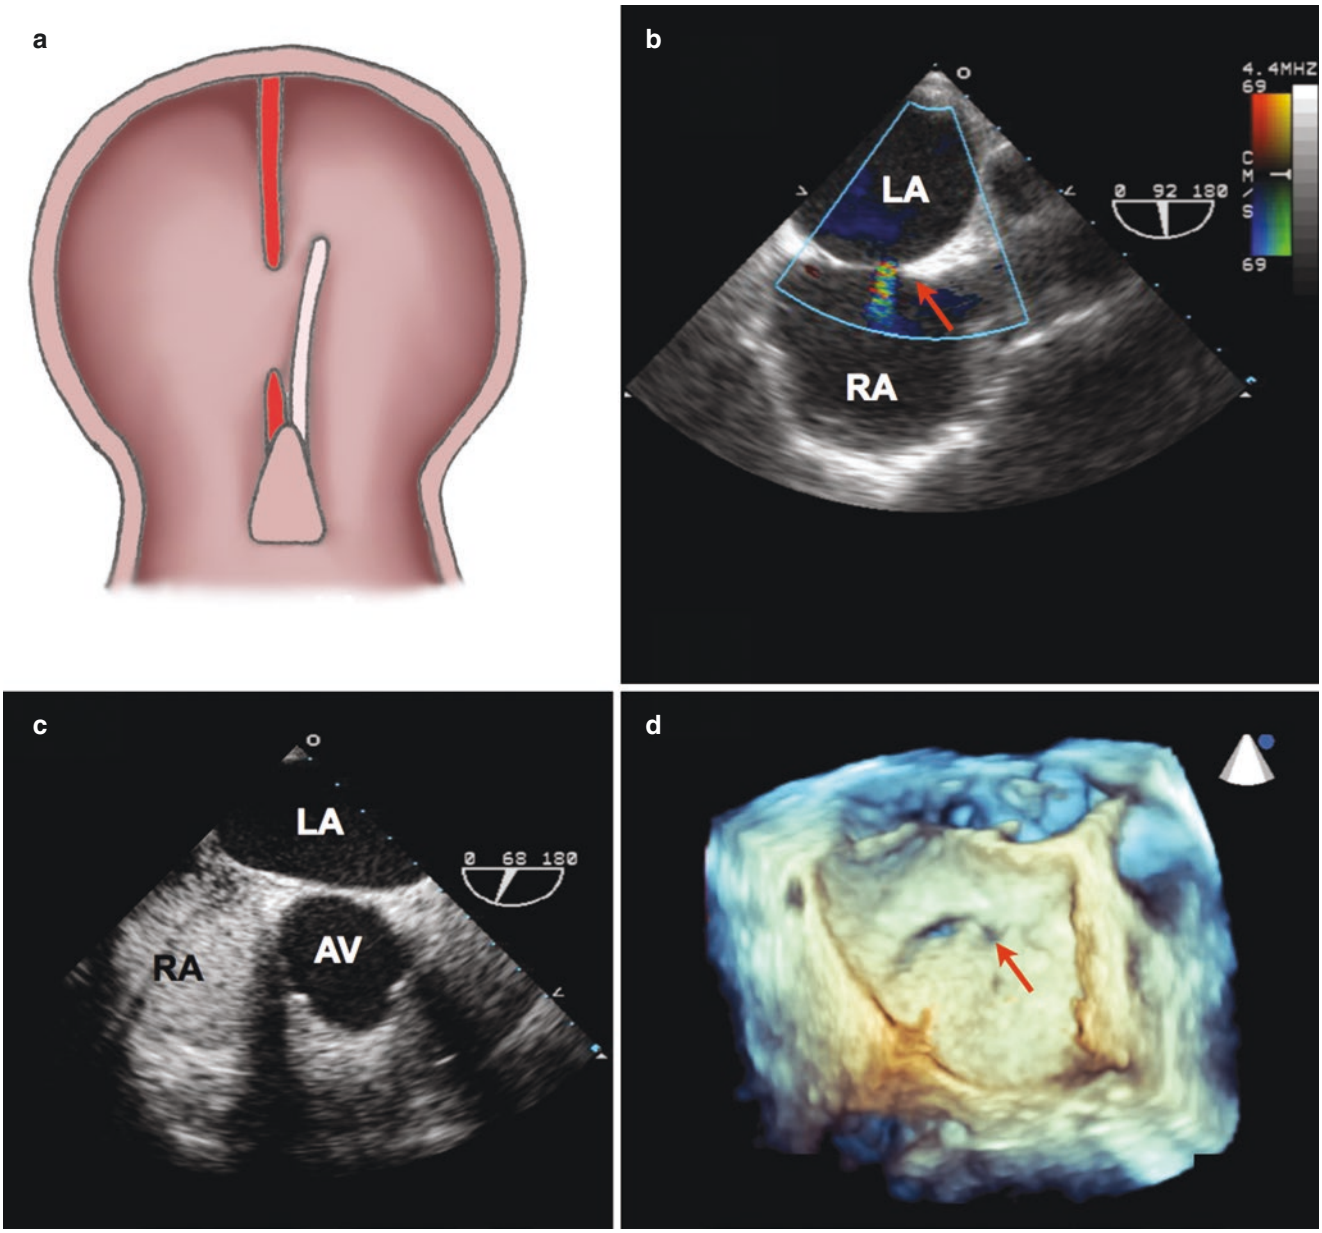

Fig. 30.12 Patent foramen ovale. Patent foramen ovale (PFO) is the result of lack of fusion of the septum primum (left side) and septum secundum (right side) (**a**) (Photo is courtesy of GM Busato). Color Doppler allows identification of flow across a PFO that commonly creates a small left-to-right shunt (**b**). Agitated saline is the contrast medium of choice to confirm and detect the presence of PFO(**c**). 3D TEE can provide an en face view of the interatrial septum. In panel **d** the PFO is seen from the left atrial side

Nyquist limit is adjusted to 45–55 cm/s (Fig. 30.12b). While maintaining the IAS in the middle of the screen, the omniplane angle is rotated to slowly scan through the IAS from 0 to 120–130°.

To increase the sensitivity of the exam, a contrast study should be done. This consists of injecting an agitated saline solution through a central or a peripheral line and visualizing the shunt of air bubbles across the IAS.

Normally, the left atrial pressure is higher than that of the right atrial pressure, and even with the injection of agitated saline, a shunt across the IAS cannot be seen. Provocative maneuvers such as a Valsalva or cough are used at the time of injection in order to increase the right atrial pressure [66] (Fig. 30.12c).

In the operating room on a ventilated patient, the sudden termination of a lung recruitment maneuver can cause an increase in the venous return and a subsequent increase in RA pressure. Thus, it is important to assess the transit of the contract in the atria right at the end of a breath-hold.

A PFO is normally a benign cardiac abnormality, and in many patients, it may remain undiagnosed for their entire life. Factors that determine the clinical significance of a PFO

are size, cryptogenic strokes, RA to LA pressure gradient, and flow from the inferior vena cava (IVC).

Smaller PFOs are less likely to be the cause of any symptoms, but they potentially allow paradoxical embolism, which may result in stroke [67]. The closure of the PFO in these circumstances has to be considered as part of the prevention strategy.

With normal RA and LA pressures, a PFO results in a left-to-right shunt. All causes of increased RA pressure can revert the left-to-right shunt and result in hypoxia. An increase in RA pressure is very common in the thoracic surgical population with pulmonary disease and increased RV pressure overload. During major thoracic procedures such as lung transplant surgery, the clamping of the pulmonary artery results in a sudden increase in RV pressure that is reflected in the RA and can cause a hypoxic right-to-left shunt.

A diversion of the IVC flow toward the PFO due to altered anatomy has been described [68] after right pneumonectomy and can be the cause of otherwise unexpected severe hypoxia.

Percutaneous closure of the PFO has become the procedure of choice given its safety and minimal invasiveness [69]. On the other hand, the surgical closure of PFO, although a simple procedure, requires opening the heart chambers under cardiopulmonary bypass.

During thoracic surgery, each patient with an intraoperative TEE diagnosis of PFO should be individually assessed. The detection of a continuous or intermittent right-to-left shunt may direct PFO closure, especially if the procedure involves the use of cardiopulmonary bypass (CPB) anyway.

The best surgical management in the case of incidental intraoperative PFO finding in asymptomatic patients is not clear. In fact, a recent study [70] showed a cardiac surgical population with worse neurological outcomes after surgical PFO closure.

Specific Applications

Lung Transplant

The number of lung transplants has been increasing due to the increased demand for lung transplantation and the use of new techniques to expand the pool of donors [71, 72].

The increase in recipient ages and comorbidities makes optimal intraoperative anesthetic management more challenging. Cardiac abnormalities are commonly associated with severe pulmonary hypertension [73]. Coronary artery disease is present in up to 30% of patients with end-stage lung disease [74], and it is not uncommon for surgical coronary revascularization to be performed at the time of lung transplant.

Extracorporeal membrane oxygenators (ECMO) [75] and pumpless extracorporeal lung support (Novalung™) [76] have been increasingly used as bridges to transplantation (see Chap. 47).

Although its impact on patient outcome is not clear, TEE provides ideal intraoperative monitoring in the course of lung transplant [8]. Current guidelines do not specifically mention this procedure as an indication for TEE; however, it may fall under the category of open-heart surgery [77]. Older ASE guidelines considered the use of TEE for lung transplant surgery as a Category II indication, as lung transplant recipients are at high risk for intraoperative hemodynamic compromise and for problems with surgical anastomoses [78].

Table 30.4 summarizes the focus of the intraoperative TEE examination at different stages of the lung transplant.

The only direct contraindication to the insertion of the TEE probe in end-stage lung disease may be scleroderma, as it is associated in up to 30% of cases with esophageal strictures [79].

Some authors [8] have suggested inserting the TEE probe at the time of endotracheal intubation, as TEE may provide prompt diagnosis of the hemodynamic instability not uncommon immediately after the induction of anesthesia for lung transplant surgery [80]. The TEE examination should be started as soon as possible after induction, as the prolonged use of electrocautery after skin incision causes artifacts, making the interpretation of TEE images very difficult.

The TEE exam should first confirm the preoperative findings, as a significant amount of time may have passed from the preoperative assessment to the day of surgery.

The baseline TEE assessment should include a complete examination with special attention to RV function and the presence of intracardiac shunts. As previously discussed, a benign left-to-right shunt, such as a small PFO, may revert and cause hypoxia during the course of surgery as the right-

Table 30.4 TEE for lung transplant

TR and RVSP Pulmonary veins LV, RV function IAS: R/O PFO and intracardiac shunts	LV, RV filling, and function	RV function	Intracardiac air and LV function	TR and RVSP RV, LV function Pulmonary veins (all four) and pulmonary artery: R/O stenosis/thrombosis

sided pressure increases after the clamping of the pulmonary artery (PA) or during the manipulation of the heart. The surgeon may decide for the elective use of CPB in these circumstances to repair the PFO.

TEE assessment of extracorporeal devices requires an understanding of the basic circuits and surgical cannulation techniques. The use of TEE for this specific indication is not considered by current ASE guidelines.

Novalung™ is in interventional lung assist device, a pumpless membrane oxygenator, used in severe respiratory failure to provide CO_2 removal and oxygenation. The inflow cannula is placed percutaneously into the femoral artery and provides arterial blood flow to an oxygenator as the outflow cannula returns the oxygenated blood to the femoral vein. Normally the short Novalung™ cannulas are not seen with TEE. In the presence of severe RV pressure overload and hypoxia, Novolung™ has successfully been implanted between the main PA and the left upper pulmonary vein, creating a septostomy-like shunt [76]. In these circumstances, TEE can easily visualize the cannulas and assess the flow (Fig. 30.13).

Whenever respiratory insufficiency is associated with heart failure, the use of ECMO becomes mandatory. An inflow cannula provides venous blood to an oxygenator that is pumped back to the patient's artery or vein by a centrifugal pump. Femoral or jugular vessels are commonly used for cannulation, which can be performed percutaneously [81]. While the short arterial cannula cannot usually be seen by TEE when inserted peripherally, TEE becomes crucial for guiding the positioning of the long venous cannulas, specifically when using the jugular Avalon™ cannula [82].

Malpositioning of the venous cannula would result in impaired venous return and an inability to provide adequate arterial blood. In lung transplant recipients, TEE should assess the position and patency of the venous cannula at baseline and, when still necessary, after CPB.

During dissection of the native lungs, significant mechanical compression of the heart and distortion of great vessels can cause hemodynamic instability. TEE can promptly exclude other causes of hypotension, and manual compression of the heart chambers can easily be detected.

The use of CPB for lung transplantation, although not associated with increased mortality [83], certainly carries significant adverse effects such as systemic inflammatory syndrome and coagulopathy [84].

One indication for the elective use of CPB during lung transplantation is the need for simultaneous open-heart procedures. Given the lack of guidelines, the threshold for the use of CPB for lung transplant varies among different institutions. CPB is used in the presence of an occurrence of acute circulatory failure that usually presents as severe right ventricular failure at clamping of the PA. In these circumstances, TEE is a very sensitive tool for assessing RV function in real time [48, 85], can detect early signs of RV failure after manual clamping of the PA, and can prompt the use of CPB, thereby avoiding dangerous circulatory collapse [86].

After the completion of graft anastomoses, it is not uncommon to observe hypotension and ventricular failure at the unclamping of arterial and venous anastomoses. TEE commonly reveals a flush of air bubbles from the transplanted lung into the LV at this phase of the operation. Coronary air embolism, hypothermia, and metabolites from the preservative solution may cause severe LV failure at this stage.

TEE will assist weaning from CPB, as for all cardiac procedures, by monitoring the proper de-airing of the heart chambers and guiding the hemodynamic management. TEE allows the prompt diagnosis of post-CPB dynamic LV outflow tract obstruction and is very useful in guiding hemodynamic management in this condition [87].

Severe pulmonary hypertension and RV failure have been observed after the administration of protamine; TEE is thus critical in monitoring RV function should, at this time and whenever during the course of the surgery, treatment with pulmonary vasodilators became necessary [88].

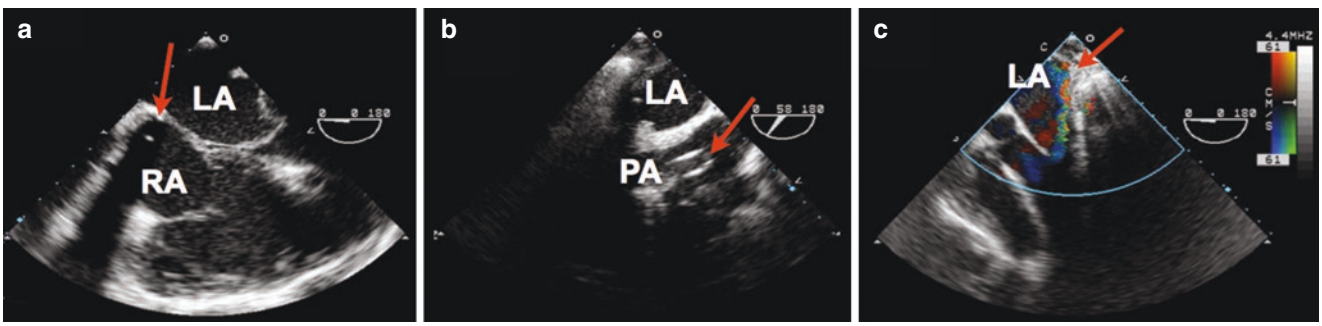

Fig. 30.13 Cannulas. TEE allows assessment of atrial cannulas for ECMO or Novalung. (**a**) the arrow indicates the ECMO venous cannula in the right atrium. When the Novalung™ is used for central bypass and decompression of the right heart chambers, the inflow cannula (flow to the Novalung) is placed in the pulmonary artery (PA) (**b**), and the outflow cannula (return to the patient) is positioned in a pulmonary vein (here the left upper pulmonary vein) and drains into the left atrium (LA) (**c**)

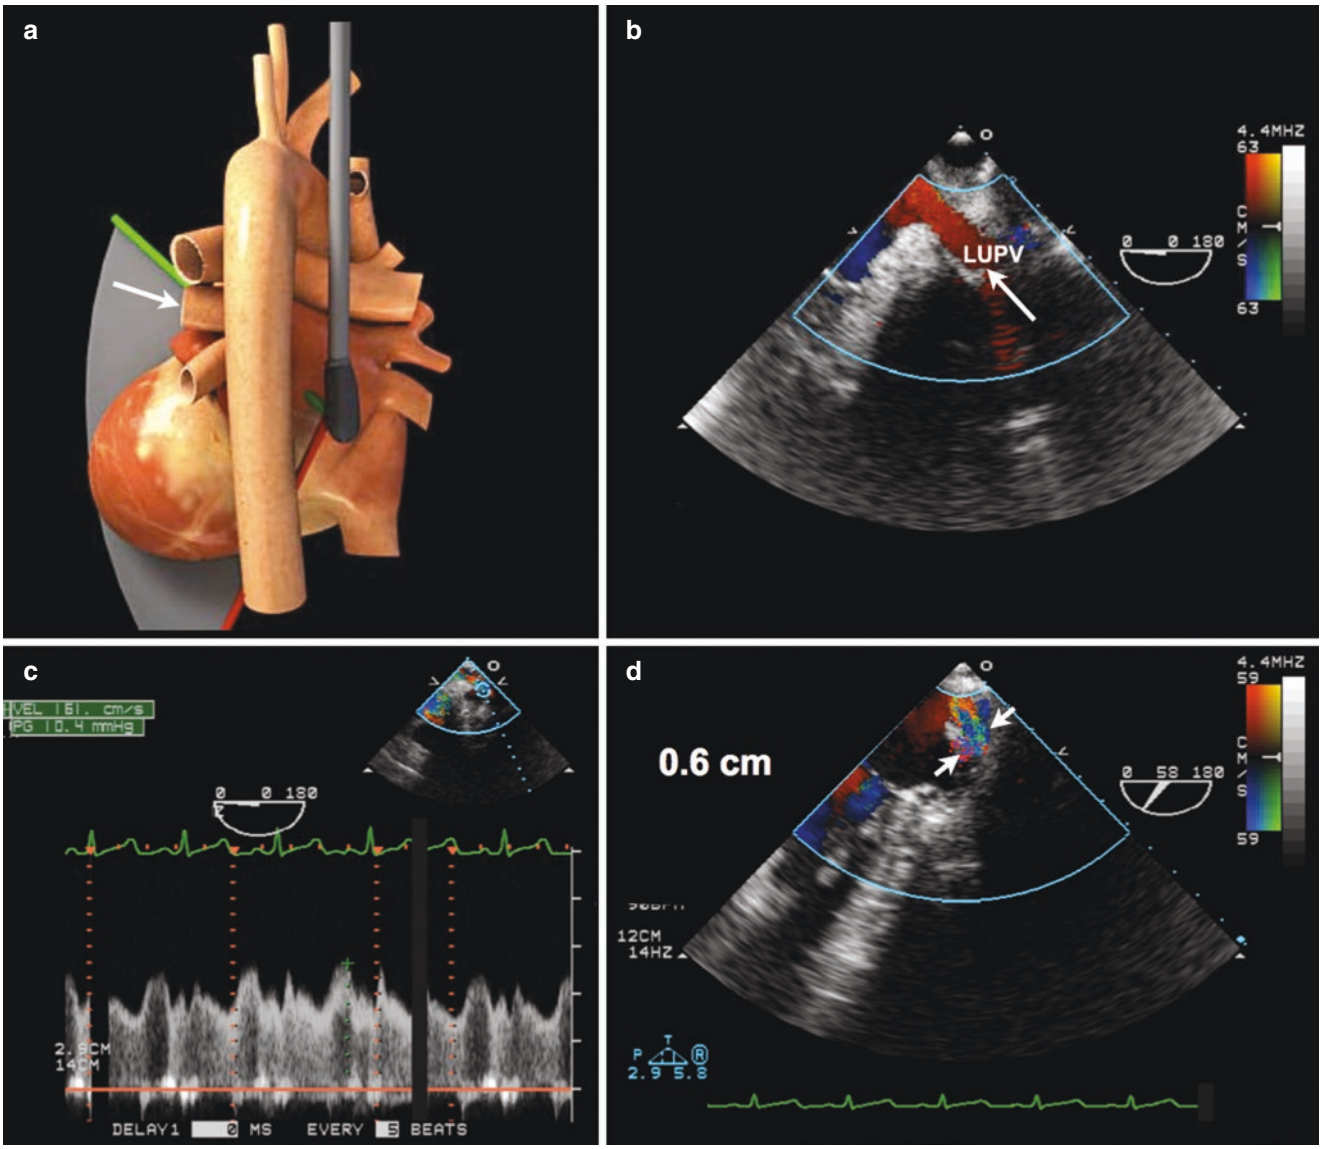

Fig. 30.14 TEE view of the pulmonary veins. After double-lung transplant the four pulmonary veins should be examined (**a**). The left upper pulmonary vein (arrow) is the easiest to image (**b**). Turbulent flow may correlate with narrowing (**d**) and normally leads to flow acceleration (**c**). (Modified from http://pie.med.utoronto.ca/TEE)

Following reperfusion of the grafts, a complete exam should be repeated. A lack of improvement of RV function following lung transplant has been associated with a poor outcome [89].

The visualization and measurement of flow in all of the pulmonary veins and pulmonary arteries is mandatory at this stage of surgery [90] and requires advanced TEE skills.

The proximal portion of the main pulmonary artery is seen with the PV and RVOT in the ME RV in-out view; in this view, its proximal diameter can be measured. Two other views should be used to assess the pulmonary artery: the mid-esophageal ascending aorta short axis (ME Asc Ao SAX) and the upper esophageal aortic arch short axis (UE Ao Arch Sax) (Fig. 30.14).

The ME Asc Ao SAX displays the PA long axis at its bifurcation and the right PA (RPA). The left PA (LPA) is rarely seen as it is shadowed by the left main stem bronchus. In this view, the diameter of the PA anastomosis and the type of flow (laminar vs. turbulent) can be assessed. The UE Ao Arch Sax view shows the long axis of the PA, the bifurcation, and the RPA, and it allows optimal alignment of the Doppler beam to the PA flow and the measurement of the flow velocity. Whenever the quality of TEE images is suboptimal or LPA could not be displayed, pericardial echocardiography should be considered [91].

Pulmonary veins can be seen starting from two standard views: ME 2C and the mid-esophageal bicaval view (ME

BiC). From the ME 2C view while slightly pulling the TEE probe, we can visualize the left upper pulmonary vein (LUPV) that lies right above the LA appendage. By advancing the probe 1–2 cm, the left lower pulmonary vein (LLPV) can be visualized. LLPV is more difficult to see and often merges with the LUPV to form a common vessel. By rotating the probe toward the right, the right upper pulmonary vein (RUPV) is visualized as it enters the LA just above the SVC. By advancing the probe and slightly rotating it to the right, the right lower pulmonary vein (RLPV) can be seen. In all of the mentioned views, the diameter as well as the flow of all PV can be measured. The stenosis and thrombosis of pulmonary venous (PV) anastomoses have been reported by several authors [92], with incidences of PA stenosis around 7% [93] and PV stenosis around 10% [94]. A diameter <5 mm and a peak systolic velocity >1 m/s are considered a cutoff for the definition of PV stenosis [92] (Fig. 30.15).

The gold standard for the diagnosis of PV stenosis and thrombosis remains angiography.

Epicardial echocardiography has also been suggested as an effective alternative to TEE in the assessment of pulmonary venous anastomoses specially when the TEE images are suboptimal [95].

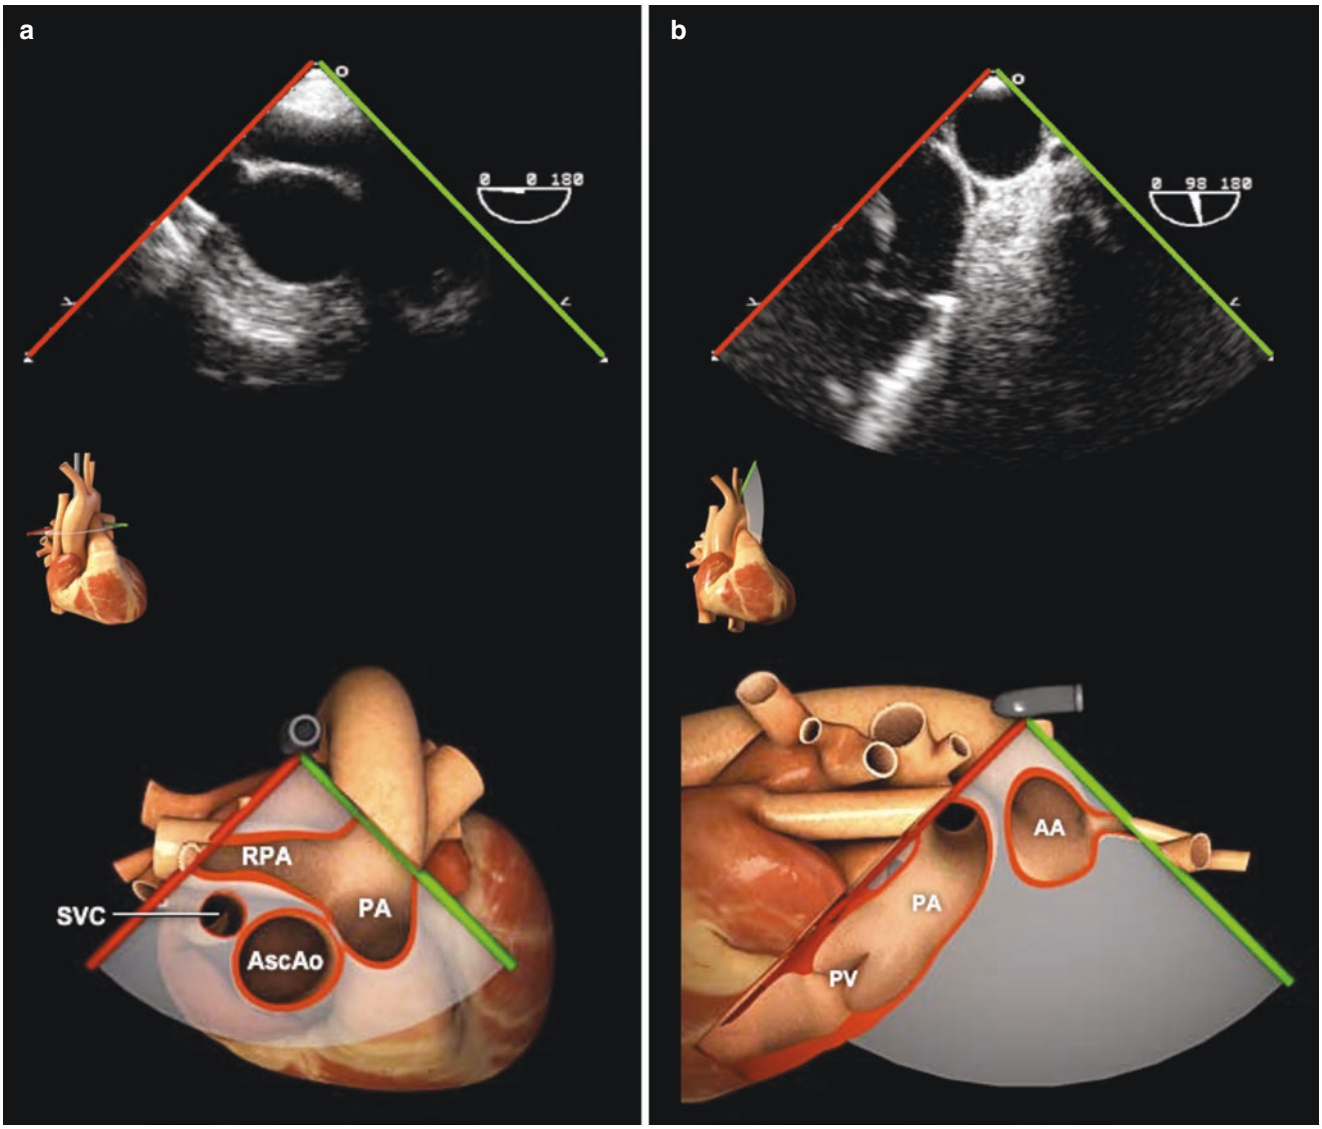

Fig. 30.15 TEE views of the right main pulmonary artery (RPA) (**a**) and the main pulmonary artery (PA) and pulmonic valve (PV) (**b**). (Modified from http://pie.med.utoronto.ca/TEE)

Heart-Lung Transplant

Heart-lung transplant is offered to some patients with congenital heart disease and/or pulmonary hypertension [96]. These patients may present to the operating room with ECMO or Novalung™. The aim of the TEE examination is to guarantee the safe transition to full CPB.

The baseline assessment includes assessments of the cannulas' positioning and flows. The surgery consists of the en bloc transplant of heart and lungs requiring four anastomoses: the trachea, ascending aorta, and inferior and superior vena cava. After weaning from CPB, flow in the IVC and SVC rules out stenoses [97]. In these cases, there is no risk of the stenosis of the pulmonary vein and PA anastomoses as they are not affected by the surgery.

Prolonged CPB may lead to significant edema of the heart and mediastinal structures; RV compression and hypotension may prevent chest closure after heart-lung transplant.

Pulmonary Embolism

The use of TEE for pulmonary embolectomy is not specifically mentioned by current SCA/ASA guidelines [2]. Although there are no outcome studies available assessing this specific application of TEE, it has been successfully used in the diagnosis of acute pulmonary embolism (PE) both in the operating room [98] and in the course of cardiopulmonary resuscitation [99].

Surgical pulmonary embolectomy is more often performed in tertiary care centers and consists of suctioning the fresh thrombi from the main PA on CPB and often positioning of an IVC filter [100].

Chronic PE leads to pulmonary hypertension and ultimately RV failure. Pulmonary thromboendarterectomy (PTE) is considered the definite treatment of pulmonary hypertension in these circumstances. It is commonly performed on CPB with deep hypothermic circulatory arrest and consists of the removal of thrombi and a thorough endarterectomy of the pulmonary circulation [101]. TEE is commonly a part of the intraoperative monitoring for both procedures [102]. Table 30.5 summarizes the focus of intraoperative TEE for PTE.

A complete TEE examination is performed at baseline, and it is focused on the detection of thrombi, the assessment of RV function, and the exclusion of other causes of pulmonary hypertension.

TEE can easily see fresh thrombi in the inferior vena cava, RA, RV, and proximal PA (Fig. 30.16). The presence of free-floating thrombi in the RA is associated with PE in the great majority of patients [103].

However, the ability of TEE in localizing thrombi in the pulmonary circulation is limited by the fact that TEE can only image the proximal pulmonary circulation and that the LPA is often completely shadowed by the left main stem bronchus. PE causes RV pressure overload that manifests with PA, RV dilatation, and TR [45] (Figs. 30.17 and 30.18). RV dysfunction in the course of PE has found to be associated with poor in-hospital outcomes [104]. The assessment of PFO is crucial due to the high risk of paradoxical emboli and, when present, predisposes to poor outcomes [105].

Basic grading of TR at baseline is very important, and it can be performed in the ME 4C and the RV in-out views. It consists of tracing the area of the TR jet and measuring the

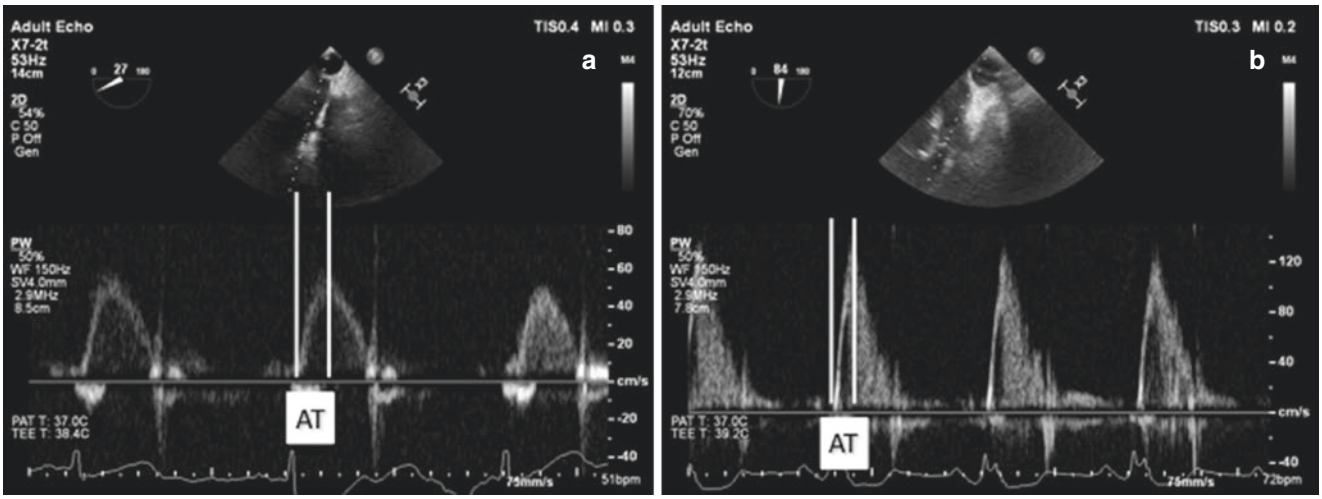

Fig. 30.18 Pulmonary hypertension. Pulsed wave Doppler interrogation of the main pulmonary artery in the UE aortic arch SAX view. Normal pulmonary artery pressure presents with an acceleration time (AT) (time from zero to peak velocity) > 100 ms (**a**). Pulmonary hypertension presents with an AT <100 ms (**b**)

TR jet width at the level of the TV leaflets (vena contracta) [106]. In the ME RV in-out view, Doppler measurement of the TV regurgitant jet peak velocity allows the calculation of the RV end-systolic pressure (RVSP). Due to the malalignment of the Doppler beam and the TR jet, the RVSP is often underestimated with TEE.

Assessment of pulmonary artery flow Doppler trace allows quantification of main pulmonary artery pressures. An increase in the upstroke slope with shortening of time to reach the peak velocity is consistent with increase in pulmonary artery pressures [107] (Fig. 30.19). Pointy traces with high peak velocity are typical in this patients' population where it is also not uncommon to identify a systolic notch. The presence of a notch seems to correlate with severely increased pulmonary vascular resistances.

At separation from cardiopulmonary bypass, TEE is used to guide the careful de-airing of the heart chambers and for hemodynamic management [107]. Preoperative late notching (later than mid ejection), calculated as a notch ratio (NR) < 1, has been associated with worse postoperative outcome, likely related to more advanced disease [108] (Fig. 30.19).

A complete exam is then repeated at the end of the surgery and is needed to grade RV function, TR, and RVSP.

Improvements in RV function and TR are signs of a successful surgery; in contrast, the persistence of RV dysfunction and the lack of improvement in TR do not constitute a reason for further surgery, as remodeling of the RV and improvement in TR often take weeks after PTE [109, 110].

Lung and Mediastinal Masses

TEE has been successfully used in the diagnosis and management of mediastinal masses:

TEE allowed the incidental diagnosis of mediastinal tumors in patients referred for drainage of pericardial effusion [110, 111]; TEE identified the presence of surgical

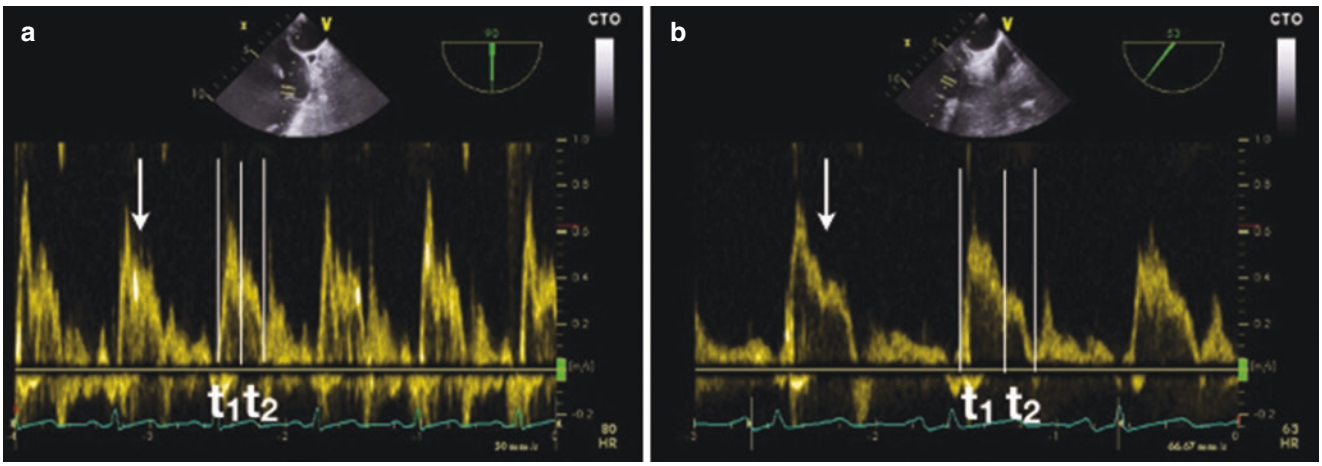

Fig. 30.19 Pulmonary hypertension Pulsed wave Doppler interrogation of the main pulmonary artery in the UE aortic arch SAX view in patients with chronic pulmonary hypertension and notching (arrow). Notching ratio (NR) is calculated as t_1/t_2. Early notching (NR < 1) (**a**) correlates with less advanced disease and better post endarterectomy outcome compared to late (NR > 1) (**b**) notching

sponges [112] and led to the diagnosis of esophageal cancer [113]; and finally, the resection of large anterior [114] and middle [115] mediastinal tumors greatly benefited from intraoperative TEE.

TEE can assess all cardiac chambers and may define extrinsic compression and tumor invasion. As previously reported [111], the presence of mediastinal masses predisposes to circulatory collapse at the induction of anesthesia, which is a Category I indication for the use of TEE.

In patients with cancer of the left lung, TEE has been used in the preoperative assessment of the invasion of the thoracic aortic wall and showed very high sensitivity when compared to CT scan [116].

Clinical Case Discussion

Case: A 54-year-old female presents for double lung transplantation. The patient has a history of end-stage lung disease secondary to bronchiolitis obliterans. Preoperative echocardiogram showed normal RV and LV function, normal valves, and RVSP of 34 mmHg. MUGA confirmed good LV function and excluded myocardial ischemia. After a smooth induction of anesthesia, a TEE probe is inserted. The ME 4C view is displayed. Color Doppler analysis is performed on the MV (Video. 30.1).

- Is there anything abnormal with the MV?
  - The base of the posterior mitral valve leaflet is calcified, a mass attached to its atrial aspect (arrow).
- What could be the differential diagnosis of this pathology?
  - Thrombus, infective vegetation, or tumor.
- What should be done to better assess the MV?
  - Obtain multiple views of the mitral valve with and without color Doppler.
- What may be the surgical implications of this finding?
  - Use cardiopulmonary bypass to surgically explore the mitral valve and eventually perform valve surgery. Gentle manipulation of the heart should prevent dislodging of the mass attached to the mitral valve. A double lung transplant is performed without CPB. No surgery is performed on the MV nor is it surgically inspected.
- What should be the focus of immediate post-CPB TEE exam?
  - Assess mitral valve for regurgitation and mass on the posterior leaflet.

After weaning from CPB, the patient is hypotensive regardless of high doses of inotropes.

TEE shows the abnormal flow in the LVOT and severe MR (Video 30.2).

- What is happening?
  - This is a case of dynamic LVOT obstruction and systolic motion of the anterior mitral valve leaflet with severe mitral regurgitation. The hyperdynamic, hypertrophic left ventricle generates a high pressure gradient across the LVOT and for a Bernoulli effect sucks in the anterior leaflet of the mitral valve.
- What is the treatment?
  - Volume load, avoid inotropes, and administer short-acting beta-blockers and vasopressor.
  - The postoperative course is complicated by decreased level of consciousness. Seven days postoperatively a CT scan of the brain showed multiple strokes. We cannot exclude that embolization of material from the MV mass may have contributed to the clinical picture.

Part VIII

Specific Patient Consideration

Anesthesia for Patients with End-Stage Lung Disease

31

Florin Costescu and Martin Ma

Key Points

- Preoperative optimization with pulmonary rehabilitation, smoking cessation, and education can improve surgical outcomes in patients with end-stage lung disease (ESLD).
- ESLD is associated with a high incidence of pulmonary hypertension and right ventricular dysfunction. The anesthetic goals for these patients include optimizing preload, maintaining a low normal heart rate, maintaining contractility, decreasing pulmonary vascular resistance, and ensuring systemic pressures that are greater than pulmonary pressures.
- Compared with general anesthesia, regional anesthesia and analgesia may reduce the risk of pulmonary complications and perioperative morbidity.
- Even mild pulmonary insults will be poorly tolerated by patients with ESLD. Ventilation strategies that utilize low tidal volumes and low airway pressures may reduce the risk of volutrauma, barotrauma, and acute lung injury.
- Intraoperative management can facilitate early recovery and early tracheal extubation after general anesthesia. Short-acting anesthetic agents are recommended. As elimination of inhalational agents is impaired by ESLD, total intravenous anesthesia (TIVA) may be preferred. Maintenance of normothermia will avoid increases in ventilatory demand associated with postoperative shivering.
- Effective postoperative analgesia is essential in patients with ESLD. Regional analgesia is preferred over parenteral opioid analgesics. Adjuvant pain medications which have an opioid-sparing effect should be used.
- Chronic obstructive pulmonary disease is a common cause of ESLD. Severe airflow obstruction results in a high risk of air trapping, pneumothorax, and dynamic hyperinflation. In addition to aggressive bronchodilation, ventilation with low inspiratory/expiratory ratios (1:3 to 1:4.5) and low respiratory rates (6–10/min) will optimize expiratory airflow.
- Cystic fibrosis is a multisystemic disease that results in abnormally viscous secretions. Inability to clear pulmonary secretions results in airflow obstruction and chronic infection. Management focuses on improving sputum clearance and minimizing airway obstruction.
- The interstitial lung diseases cause lung restriction and are characterized by chronic inflammation and fibrosis. Ventilation strategies that minimize tidal volume and airway pressures should be used.

Introduction

Providing a safe anesthetic for patients with end-stage lung disease (ESLD) is a challenge. Postoperative pulmonary complications (PPCs) are poorly tolerated in this group of patients and can result in significant morbidity and mortality. Ideally, efforts to minimize this risk begin in the preoperative period with patient education, smoking cessation counseling, and pulmonary rehabilitation programs. Although this is not always possible, participation in these programs can reduce perioperative complications. Intraoperatively, problems may

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_31

include inadequate oxygenation and ventilation, as well as barotrauma, volutrauma, and acute lung injury (ALI). In this high-risk patient population, an anesthetic technique that facilitates early recovery and tracheal extubation is also of key importance. Optimal perioperative management of patients with ESLD requires a multidisciplinary approach that includes respirologists, surgeons, nurses, physiotherapists, respiratory therapists, and of course anesthesiologists. This chapter begins with an overview of the management considerations that are applicable to all patients with ESLD. This discussion is summarized in Table 31.1. Specific considerations for the most common causes of ESLD including chronic obstructive lung disease (COPD), cystic fibrosis (CF), and interstitial lung diseases (ILDs) are then outlined.

Preoperative Optimization

Smoking Cessation

The link between smoking and increased perioperative morbidity is well established in the literature. Smoking increases the relative risk of postoperative pulmonary complications by up to six times [1]. A common concern is the increased risk of laryngospasm and bronchospasm. High levels of carbon monoxide limit the ability of hemoglobin to bind and transport oxygen, predisposing surgical patients to an increased risk of tissue hypoxia. Smoking increases airway mucous production and impairs ciliary function resulting in poor sputum clearance. This, in combination with smoke-induced impairment of immune function, increases the likelihood of developing postoperative pneumonia. The long-term pulmonary consequence of smoking is worsening airway obstruction as measured by the forced expired volume in 1 s (FEV_1) [2]. Although cessation will not reverse the degree of airway obstruction caused by smoking, it does reduce the rate at which FEV_1 subsequently declines (Fig. 31.1). Nicotine causes direct coronary vasoconstriction as well as an increase in the rate-pressure product. This contributes to the observation that smokers with no history of coronary artery disease have significantly more episodes of ST segment depression during surgery than nonsmokers [3]. Other concerns include impaired wound healing, surgical

Table 31.1 Summary of anesthetic management for patients with end-stage lung disease (ESLD)

Optimization	Encourage smoking cessation
	Enroll patients in pulmonary rehabilitation
	Educate patients on postoperative chest physiotherapy
	Ensure preoperative use of routine bronchodilators
Anesthesia	Patients may have pulmonary hypertension (see Table 31.4)
	Regional anesthesia and analgesia will minimize the risk of postoperative pulmonary complications
	Judiciously titrate short- or intermediate-acting neuromuscular blockers and ensure complete reversal before extubation
	Minimize fluid administration as clinically appropriate
	Emergence is more predictable with short-acting agents and total intravenous anesthesia (TIVA)
	Maintain normothermia
	Avoid prophylactic insertion of nasogastric tubes
Ventilation	Use lung protective ventilation with low tidal volume (6–8 mL/kg of predicted body weight)
	Maintain airway pressures as low as possible
Postoperative care	Patients will require care in a monitored setting postoperatively (e.g., step-down unit, intensive care unit)
	Encourage early mobilization, incentive spirometry, and chest physiotherapy
	Minimize opioid use while maximizing nonopioid pain medications

↓ Macrophage function ↑ Platelet aggregation ↑ Coagulation	↓ Immune function ↑ Risk of thrombosis
Impaired wound healing	

site infections, and perioperative venous thrombosis secondary to a procoagulant state caused by nicotine. The reversible effects of smoking are summarized in Table 31.2. Given the potential perioperative cardiorespiratory complications of smoking, preoperative cessation is important for patients with ESLD.

The long-term benefits of smoking cessation are undisputed, but the minimum duration of preoperative abstinence necessary to decrease the risk of postoperative complications is unclear. Despite earlier concerns about increased risk of postoperative pulmonary complications after short-term (< 4–8 weeks) preoperative smoking cessation [4, 5], more recent studies have not demonstrated this paradoxical response [6]. Data from randomized trials show a clear reduction in postoperative pulmonary complications and wound healing complications with preoperative smoking cessation interventions [7–9]. Moreover, multiple studies have shown that preoperative interventions may provide long-term benefits with increased smoking abstinence rates at 1 year follow-up [8, 10]. There is now wide consensus that the preoperative period is an excellent opportunity to promote smoking cessation, especially since the reduction in perioperative complications may provide additional motivation for patients to quit [11]. Interventions aimed at reducing or stopping cigarette use should be implemented as early as possible to have an impact on perioperative outcomes.

Effective interventions to assist patients who wish to quit smoking include medical counseling and pharmacotherapy such as nicotine replacement therapy, bupropion, and varenicline [8]. In one study, 120 smokers scheduled for elective orthopedic surgery were randomized to an intervention group including counseling and nicotine replacement therapy for 6–8 weeks or a control group [7]. In the intervention group, 89% of the analyzed patients either quit or reduced smoking by more than 50%, in contrast to only 8% in the control group. The intervention group had significantly less overall postoperative complications (18% vs. 52%, $p = 0.0003$) and less wound-related complications (5% vs. 31%, $p = 0.001$). A multicenter trial randomized 286 smokers scheduled for elective surgery to a 12-week course of varenicline starting 1 week before surgery or placebo [12]. All patients received smoking cessation counseling. At 12 months, 36.4% of patients in the varenicline group were abstinent vs. 25.2% in the placebo group ($p = 0.04$). There were no statistically significant differences in postoperative complications between the groups, but more patients receiving varenicline reported nausea.

Pulmonary Rehabilitation

Many patients with ESLD are at risk of progressive deconditioning related to dyspnea, decreased physical activity, and decreased cardiopulmonary capacity, all of which contribute to a downward cycle of worsening in dyspnea and quality of life. Pulmonary rehabilitation is a comprehensive multidisciplinary therapeutic intervention which includes exercise training, nutritional support, education, and psychological support aimed at breaking this cycle [13]. One of the key elements of pulmonary rehabilitation is improvement in muscle function and exercise capacity through both aerobic and strength training. For any given activity, this translates into decreased lactic acid production, decreased carbon dioxide (CO_2) production, and thus, decreased ventilatory demand [14, 15]. Although this benefits all patients with ESLD, it is particularly relevant to those with COPD in whom hyperventilation causes inadequate expiratory time, dynamic hyperinflation, and worsened dyspnea. The educational component of pulmonary rehabilitation aims to improve the patient's understanding of the disease and its management. Common themes include smoking cessation, the early detection and treatment of pulmonary exacerbations, the role of exercise in improving function, and promoting compliance with therapy. ESLD is often associated with poor nutritional status which results in muscle catabolism. In and of itself, aggressive nutritional support in patients with advanced lung disease has not led to clinically relevant improvements in functional outcome [16–18]. When used in conjunction with exercise, nutritional support may improve lean muscle mass function and improve exercise performance [19].

Pulmonary rehabilitation programs have been studied most extensively in COPD patients and have been shown to significantly improve exercise capacity and health-related quality of life while reducing the severity of dyspnea [18, 19]. In a recent meta-analysis of 65 randomized controlled

trials involving 3822 COPD patients, pulmonary rehabilitation programs significantly improved exercise capacity and increased the 6-min walk distance by 44 m. Dyspnea, fatigue, and emotional function were also significantly improved [20].

Although the impact of pulmonary rehabilitation is less well studied for other forms of ESLD, current evidence suggests that it is beneficial. A meta-analysis of five randomized trials including 162 patients with interstitial lung disease showed a significant and clinically important short-term improvement in 6-minute walk test by 44 m and peak oxygen consumption (VO_2 max) by 1.24 mL/kg/min. There were also significant improvements in dyspnea and quality of life. Long-term outcome data is still limited [21]. In patients with cystic fibrosis, some randomized trials have shown improved exercise capacity and quality of life after training programs [22], but these results are not consistent across studies [23]. A meta-analysis of 21 randomized trials including 772 patients with asthma concluded that physical training significantly improved maximal heart rate and VO_2 max, but had no effect on pulmonary function tests [24]. Some trials found a significant improvement in quality of life and reduced psychosocial distress in this patient population [25, 26]. In a small study of 25 patients with pulmonary hypertension, an exercise program reduced New York Heart Association dyspnea scores and improved 6-min walk test results [27]. Current evidence-based guidelines strongly recommend pulmonary rehabilitation programs for patients with COPD and other causes of ESLD [19].

In the preoperative setting, pulmonary rehabilitation is mandatory for patients undergoing lung volume reduction surgery (LVRS) and lung transplantation. For these high-risk procedures, successful completion of pulmonary rehabilitation is used not only as a marker for patient motivation and therapy compliance but also as a risk assessment tool. For example, the National Emphysema Treatment Trial (NETT) found that patients with primarily upper lobe emphysema and low maximal workload after rehabilitation benefited from LVRS. In comparison, patients with non-upper lobe emphysema and high maximal workload following rehabilitation have higher mortality rates with LVRS than conservative management with medical therapy only [28].

There is a growing interest in establishing whether preoperative pulmonary rehabilitation may play a role in either (1) improving exercise reserve sufficiently to enable borderline operative candidates to undergo surgery or (2) improving perioperative outcome. Patient suitability for lung resection is commonly based upon three factors: respiratory mechanics, lung parenchymal function, and cardiopulmonary reserve. While lung function is relatively fixed, cardiopulmonary reserve can be improved. In a small pilot study, eight COPD patients with resectable lung cancers were denied surgery as a result of poor pulmonary function (mean preoperative FEV_1% predicted = 40%). Following 4 weeks of pulmonary rehabilitation, all eight patients successfully had a lobectomy [29]. In another study, 12 patients scheduled for lung resection with a VO_2 max ≤15 mL/kg/min underwent a 4-week pulmonary rehabilitation program. Preoperative VO_2 max improved by a mean of 2.8 mL/kg/min, and 11 patient underwent lung resection without perioperative mortality [30]. A randomized trial of 40 patients undergoing lobectomy showed improved postoperative VO_2 max in patients who had preoperative high-intensity training compared to controls [31]. With respect to improving patient outcome, the role of preoperative pulmonary rehabilitation has been examined in one small study of 45 patients with COPD undergoing coronary artery bypass grafting. Pulmonary rehabilitation led to significantly lower postoperative ventilation times, postoperative complications, and hospital length of stay [32]. Although the preoperative role of pulmonary rehabilitation appears promising, there is currently very little clinical evidence to support or refute its use for improving postoperative clinical outcomes.

Medical Optimization

To minimize the risk of perioperative pulmonary complications, care must be taken to ensure that patients with ESLD are medically optimized prior to elective surgery. Bronchospasm and difficulty in clearing sputum are common problems in patients with COPD, bronchiectasis, and CF and may contribute to the development of hypoxia, atelectasis, and pneumonia. This risk may be decreased with the use of maximal bronchodilator and inhaled glucocorticoid therapy in the immediate preoperative period. During an acute exacerbation, patients may benefit from aggressive antibiotics or antivirals targeting likely infectious pathogens, and strong consideration should be made to postponing elective surgery (typically for 6 weeks). The development of pulmonary hypertension is a concern for all patients with ESLD. Appropriate medical therapy to minimize pulmonary artery pressure (PAP) and improve right ventricular function such as long-term supplemental oxygen, careful diuretic therapy, and advanced therapy agents should be instituted as indicated prior to surgery. In general, advanced therapeutic agents such as calcium channel blockers, prostacyclin agonists, endothelin receptor antagonists, and NO-cGMP enhancers are used in patients with Group 1 pulmonary arterial hypertension (see Table 31.3) but may be harmful for other groups (see Chap. 34). Riociguat, a guanylate cyclase stimulant, can also be considered in the management of patients with chronic thromboembolic pulmonary hypertension (Group 4) (see Chap. 49).

Table 31.3 Classification of pulmonary hypertension – 5th World Symposium on Pulmonary Hypertension [33]

1. Pulmonary arterial hypertension (PAH)
1.1. Idiopathic PAH
1.2. Heritable
1.2.1. Bone morphogenetic protein receptor type II gene abnormality
1.2.2. Other genetic mutations: ALK-1, ENG, SMAD9, CAV1, KCNK3
1.2.3. Unknown
1.3. Drug- and toxin-induced
1.4. Associated with
1.4.1. Connective tissue diseases
1.4.2. HIV infection
1.4.3. Portal hypertension
1.4.4. Congenital heart diseases
1.4.5. Schistosomiasis
1' Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
1"Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension due to left heart disease
2.1 Left ventricular systolic dysfunction
2.2 Left ventricular diastolic dysfunction
2.3 Valvular disease
2.4 Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. Pulmonary hypertension due to lung diseases and/or hypoxia
3.1. Chronic obstructive pulmonary disease
3.2. Interstitial lung disease
3.3. Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4 Sleep-disordered breathing
3.5 Alveolar hypoventilation disorders
3.6 Chronic exposure to high altitude
3.7 Developmental lung diseases
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms
5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
5.2 Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental pulmonary hypertension

Chest Physiotherapy

Impaired mucociliary clearance, decreased lung volumes, atelectasis, bed rest, diaphragmatic dysfunction, shallow breathing, and pain all contribute to the development of postoperative pulmonary complications. Various forms of chest physiotherapy including incentive spirometry, cough/deep breathing exercises, intermittent positive pressure breathing, and continuous positive airway pressure have been used with equal efficacy to minimize this risk [34]. In one study, 174 patients undergoing major abdominal surgery were randomized to either intervention with postoperative chest physiotherapy or control. Chest physiotherapy significantly reduced the incidence of both pneumonia and all pulmonary complications (6% vs. 27%; $p < 0.001$) [35].

The benefit of chest physiotherapy is even greater when patients participate in an intensive chest physiotherapy education session preoperatively. In a randomized controlled trial, 279 patients undergoing coronary artery bypass grafting were randomized to either "intensive muscle training" (IMT) or the control group. IMT program trained patients daily for a minimum of 2 weeks preoperatively in breathing exercises, forced exhalation techniques, and the use of inspiratory spirometry. The control group received instruction on deep breathing maneuvers, coughing, and early ambulation on the day prior to surgery. Postoperative management of both groups was similar and consisted of incentive spirometry, chest physiotherapy, and mobilization. Compared with postoperative physiotherapy only, IMT further reduced the incidence of postoperative pulmonary complications (18% vs. 48%, $p = 0.02$) and pneumonia (6.5% vs. 16.1%; $p = 0.01$) by approximately 60% [36]. These findings have been confirmed in a recent review of randomized trials [37]. The reduction in pulmonary complications with preoperative physiotherapy education and training may relate to improved compliance and performance in the postoperative period [38].

General Considerations

Preoperative Assessment

The primary focus of the preoperative evaluation in patients with ESLD is the respiratory and cardiac systems. A history of patient symptoms, functional status, and activities of daily living, not to mention the physical examination, can be a valuable source of information. As discussed in Chap. 2, the patient's respiratory function needs to be assessed in terms of (1) respiratory mechanics, (2) lung parenchymal function, and (3) cardiopulmonary reserve. In this regard, pulmonary function testing is essential in determining the intraoperative management and postoperative disposition of patients with advanced lung disease. While a detailed history is often sufficient for estimating cardiopulmonary reserve, formal exercise testing or a 6-min walk test can be used to provide a quantitative assessment. In patients with ESLD, a preinduction arterial blood gas should be drawn to establish the patient's baseline P_aO_2 and P_aCO_2. This will help guide the intraoperative management, including mechanical ventilation and monitoring, as well as postoperative care.

The preoperative workup of patients with ESLD routinely includes a recent echocardiogram to assess right ventricular size, thickness, and function. Echocardiography can also

identify signs of right ventricular pressure or volume overload, as well as the presence of intracardiac lesions which may cause right to left shunting in the face of elevated right-sided pressures. It can also rule out other pathologies that may contribute to pulmonary hypertension such as valvulopathies or left ventricular dysfunction. Multiple echocardiographic parameters have demonstrated the prognostic value of echocardiography in patients with pulmonary hypertension and right ventricular dysfunction [39]. However, while echocardiography is a common first-line tool in the assessment of pulmonary hypertension, it can be limited by uninterpretable tracings in a significant proportion of patients and a relatively low sensitivity (60–87%) and specificity (74–79%) [39]. In patients with parenchymal lung disease, the echocardiography images may also be suboptimal.

Nocturnal Hypoxemia

Sleep, even in normal individuals, is associated with physiologic changes in respiratory function. During all stages of sleep, the effectiveness of chemoreceptors and mechanoreceptors is reduced which leads to lower minute ventilation. This is particularly pronounced during rapid eye movement sleep. Decreased muscle contractility of the diaphragm as well as the accessory muscles further reduces the ventilatory response and contributes to the rapid shallow breathing observed during sleep.

Normal fluctuations in the circadian rhythm also cause nocturnal bronchoconstriction. These changes, which are summarized in Fig. 31.2, result in a hypoventilation, decreased functional residual capacity (FRC), and increased ventilation–perfusion (*V*/*Q*) mismatch [40, 41]. In normal individuals, this translates into an 8–10 mmHg drop in overnight P_aO_2 (arterial partial pressure of oxygen) levels [41].

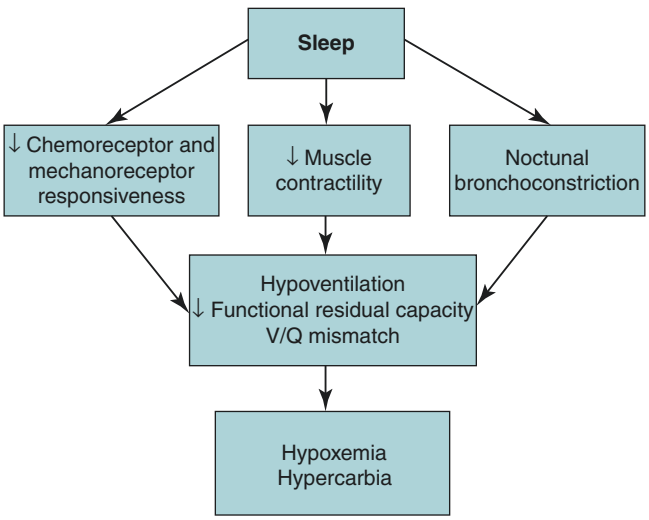

Fig. 31.2 The effects of sleep on breathing

The potential adverse cardiac (e.g., worsened pulmonary hypertension, RV failure, arrhythmia), neurologic, and hematologic (e.g., polycythemia) effects of nocturnal hypoxemia are particularly worrisome in patients with low daytime oxygen saturation. Though best studied in COPD and CF populations, other causes of ESLD including ILDs and primary pulmonary hypertension have also been associated with higher rates of nocturnal hypoxemia [41–44]. These pathophysiologic processes are of particular concern in the perioperative period, as further fall in FRC and the use of opioid analgesia places these patients at high risk of severe hypoxemia during sleep. Although oxygen therapy is used successfully to minimize the incidence of desaturation overnight, there is no clear evidence that treatment of isolated nocturnal hypoxemia improves mortality [40, 45]. In some patients oxygen therapy may exacerbate the degree of hypercapnia.

Pulmonary Hypertension and Right Ventricular Function

Although primary pulmonary hypertension may in and of itself be a cause of ESLD, this is a rare condition that has an incidence of only 1–2 per million [46, 47]. Much more commonly, pulmonary hypertension is the result of ESLD and chronic hypoxemia. The most recent classification of pulmonary hypertension is detailed in Table 31.3. While estimates vary widely depending on disease severity and the method of measurement, the prevalence of pulmonary hypertension (mean PAP >25 mmHg) in advanced COPD, IPF, and CF ranges from 35% to 50% [48–50]. As PAPs rise, evidence of cor pulmonale develops as increased strain causes the right ventricle to hypertrophy. As the disease process worsens, the limited ability of the right ventricle to compensate is overwhelmed, which leads to right ventricular dilation and dysfunction. In the United States, cor pulmonale accounts for 10–30% of all heart failure admissions, of which 84% are secondary to COPD [48]. The risk of right ventricular ischemia is also increased. The right ventricle is normally perfused throughout the cardiac cycle. However, the increased right ventricular transmural and intracavitary pressures associated with pulmonary hypertension may restrict perfusion of the right coronary artery during systole, especially if PAPs approach systemic levels.

The impact of pulmonary hypertension on right ventricular dysfunction has several anesthetic implications. The cardiac goals are similar to other conditions in which cardiac output is relatively fixed. These are summarized in Table 31.4. Care should be taken to avoid physiologic states which will worsen pulmonary hypertension such as hypoxemia, hyper-

Table 31.4 Anesthetic goals in pulmonary hypertension

Optimize preload	Hypovolemia will further impair cardiac output
	Hypervolemia will precipitate right ventricular failure and impair LV filling
Maintain a low normal HR	Tachycardia will impair ventricular filling and cardiac output
Maintain RV contractility	Consider inotropes including epinephrine, norepinephrine, dobutamine, and phosphodiesterase inhibitors
Maintain or ↓ PVR	Avoid physiologic states that ↑ PVR (hypoxia, hypercarbia, acidosis, hypothermia, high airway pressures, atelectasis)
	Avoid nitrous oxide
	Consider using intravenous dobutamine, phosphodiesterase inhibitors, or prostaglandins Consider using inhaled prostaglandins, nitric oxide, or phosphodiesterase inhibitors
Maintain or ↑ SVR	To maintain RV perfusion, SBP > PAP must be maintained
	Consider using vasopressors including norepinephrine, phenylephrine, and vasopressin

carbia, acidosis, and hypothermia. Conditions which impair right ventricular filling such as tachycardia and arrhythmias may not be well tolerated. Ideally, under anesthesia, right ventricular contractility and systemic vascular resistance (SVR) are maintained or increased, while pulmonary vascular resistance (PVR) decreases. This would ensure forward flow and minimize the risk of right ventricular ischemia. In practice, these goals can be a challenge to achieve because anesthetics are commonly associated with a decrease in SVR and a variable effect on PVR (e.g., propofol, thiopental, inhalational agents) [51]. Ketamine may be an interesting exception. Known for its sympathomimetic effects, ketamine increases cardiac contractility and SVR. However, its effect on PVR is controversial. Though concern is often raised over ketamine's potential to worsen pulmonary hypertension [52, 53], some animal in vitro and human clinical studies have suggested that it may decrease PVR or at least maintain pulmonary to systemic vascular resistance ratio [46, 51, 54, 55]. Anecdotally, at the authors' institution, ketamine is commonly and safely used to induce patients with severe pulmonary hypertension. Inotropes such as dobutamine and phosphodiesterase inhibitors (e.g., milrinone) will improve right ventricular function while reducing PVR. However, they also cause a significant decrease in systemic vascular tone, which may reduce right ventricular coronary perfusion pressure.

To maintain a systemic blood pressure (SBP) that is greater than the pulmonary, vasopressors such as phenylephrine or norepinephrine are commonly used. Of the two, norepinephrine is better suited in pulmonary hypertension because it maintains cardiac index and decreases the ratio of PAP to SBP [46, 51]. In contrast, phenylephrine causes the cardiac index to drop, while the PAP/SBP ratio remains the same. Increasingly, vasopressin is also being used to maintain systemic pressures. Vasopressin appears to significantly increase SBP without affecting PAPs in patients with pulmonary hypertension (Fig. 31.3) [56–58]. In a study of isolated human radial and pulmonary arteries, norepinephrine and phenylephrine had concentration-dependent vasoconstricting effects on both radial and pulmonary arteries, whereas vasopressin had similar effect and potency on radial arteries but no effect on pulmonary arteries [59]. Vasopressin has also been associated with less arrhythmias when compared to norepinephrine [60]. In patients with severe pulmonary hypertension, selective pulmonary vasodilators including inhaled nitric oxide and inhaled prostaglandins should be considered. The effects of medications on PVR are discussed in greater detail in Chap. 9.

The extreme ends of patient lung volumes can cause compression of the extraalveolar and alveolar vessels, both of which contribute to an increased PVR (see Fig. 4.5). As a result, a ventilation strategy that avoids atelectasis as well as lung hyperinflation should be employed.

Intraoperative Monitoring

ESLD is frequently associated with a large arterial–end tidal CO_2 gradient. Placement of an arterial line facilitates intraoperative blood gas sampling to ensure adequate oxygenation and ventilation. In patients with pulmonary hypertension, continuous blood pressure monitoring is also reassuring. A central line is useful in monitoring and managing patients with moderate-to-severe pulmonary hypertension. Pulmonary artery catheters (PAC) may be of use in patients with PAPs which approach system pressures. However, the utility of PACs is controversial. From a large randomized trial, the use of PAC in ASA III and IV patients undergoing urgent or elective non-cardiac surgery showed no effect on mortality or the incidence of postoperative pneumonia [61]. However, no studies have specifically looked at the perioperative use of PACs in patients with pulmonary hypertension. We routinely place PACs in patients with severe pulmonary hypertension undergoing major surgery as it provides valuable information on the pulmonary to systemic pressure ratio, the cardiac output, and can help guide hemodynamic management. It is important to note that PAC use in patients with pulmonary hypertension is associated with a higher risk of pulmonary artery rupture.

General Versus Regional Anesthesia

Whether surgical outcomes are altered by the use of general or regional anesthesia has been a topic of debate for decades. Although the role regional anesthesia plays in

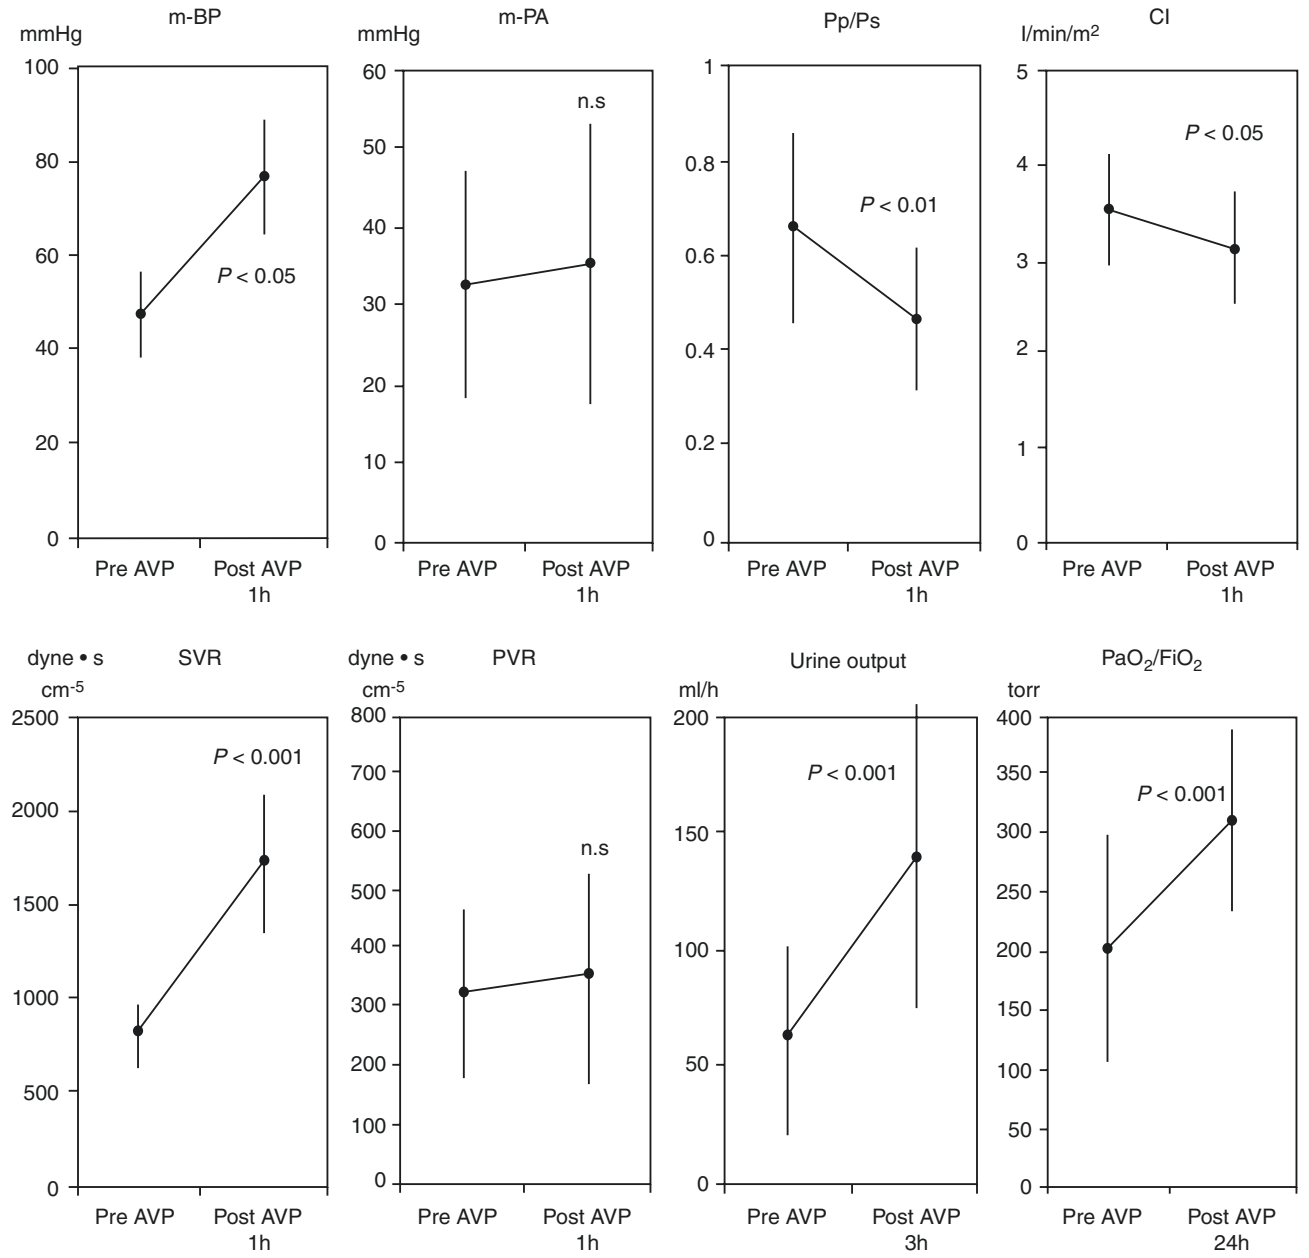

Fig. 31.3 Effect of arginine vasopressin (AVP) on mean systemic blood pressure (mSBP), mean pulmonary artery pressure (mPAP), pulmonary artery pressure/systemic blood pressure (Pp/Ps), cardiac index (CI), SVR, PVR, urine output, and P_aO_2/FiO_2. (Reprinted from Tayama et al. [56]. © 2007 with permission)

reducing mortality, deep vein thrombosis, pulmonary embolism, cardiac ischemia, and blood loss remains controversial, current evidence suggests intraoperative neuraxial anesthesia followed by postoperative neuraxial analgesia reduces the incidence of postoperative pulmonary complications [62–69]. In a meta-analysis of randomized trials, neuraxial anesthesia significantly reduced the risk of pneumonia by 39% and postoperative respiratory depression by 59% [62]. This may occur because general anesthesia decreases the number and activity of alveolar macrophages and inhibits mucociliary clearance, thereby increasing the risk of pulmonary infection [70]. General anesthesia also causes atelectasis in dependent areas of lung, decreased FRC, and an increase in *V*/*Q* mismatching, all of which contribute to the development of hypoxia. Following thoracic or upper abdominal surgery, atelectasis and the reduction in FRC may persist for up to 2 weeks as a result of postoperative diaphragmatic dysfunction. Though the precise mechanism is unclear, this dysfunction appears to result from reflex inhibition of the phrenic nerve secondary to irritation of splanchnic afferents or visceral pain. There is evidence that postoperative epidural analge-

sia blocks the stimulus for the reflex inhibition and restores normal diaphragm function [70–72].

Park et al. randomized 1021 ASA III or IV patients undergoing intraabdominal aortic, gastric, biliary, or colon operations to receive either (1) general anesthesia and systemic morphine for postoperative pain control or (2) epidural anesthesia combined with a light general anesthesia and epidural morphine for postoperative pain. Overall, no difference in death or major complications were noted, although the epidural group did have a lower incidence of respiratory failure that approached significance ($P=0.06$). In a subgroup analysis of the 374 patients who underwent aortic surgery, epidural anesthesia did significantly reduce the incidence of myocardial infarction, stroke, and respiratory failure (14% vs. 28%; $P<0.01$) [63]. The subgroup analysis also showed a trend toward lower rates of pneumonia (51% vs. 71%; $P=0.06$). In another large trial by Rigg et al., 915 patients with one of nine high-risk comorbid states were randomized to receive either (1) general anesthesia and postoperative pain control with parenteral opioids or (2) combined epidural/general anesthesia and postoperative epidural analgesia. All patients had major abdominal surgery. Of the measured endpoints, the only difference was a reduction in respiratory failure in the epidural group (23.3% vs. 30.2%; $P=0.02$) [64].

The improved respiratory outcomes associated with regional anesthesia and analgesia are particularly important in patients with preexisting lung disease for whom the risk of developing a postoperative pulmonary complication is increased tenfold [73]. Moreover, patients with ESLD may be inherently more challenging to extubate following surgery and may require a prolonged ventilator wean. In recent years, the desire to avoid general anesthesia in severely compromised respiratory patients has led to several reports of neuraxial blockade being used as the sole anesthetic for intraabdominal procedures. Van Zundert et al. [74] have successfully used a combined spinal–epidural placed at the T10 interspace to anesthetize a 47-year-old man with α-1-antitrypsin deficiency ($FEV_1/FVC=19\%$) for a laparoscopic cholecystectomy. Savas et al. [73] have reported using epidural anesthesia to facilitate awake surgery for sigmoidectomy, open cholecystectomy, incisional hernia repair, and laparoscopic inguinal hernia repair in patients with severe COPD.

To date, only a few studies have specifically compared regional anesthesia vs. general anesthesia outcomes in patients with advanced lung disease [68, 75–77]. In a retrospective cohort study examining data from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP), 2644 COPD patients were propensity-matched for comorbidities, level of dyspnea, history of bleeding disorder, and primary surgical procedure [68]. Patients who had general anesthesia as their primary anesthetic technique compared to those having regional anesthesia had higher incidence of postoperative pneumonia (3.3% vs. 2.3%, $P = 0.0384$), prolonged ventilator dependence (2.1% vs. 0.9%, $P = 0.0008$), and unplanned postoperative intubation (2.6% vs. 1.8%, $P = 0.0487$). Thirty-day mortality was similar (2.7% vs. 3.0%, $P = 0.6788$).

Ventilation and ESLD

In the last two decades, the influence of ventilation strategy on acute respiratory distress syndrome (ARDS) has become clearer. The transition from high tidal volume (V_T) ventilation [$V_T=10$–12 mL/kg predicted body weight (PBW)] and zero end-expiratory pressure (ZEEP) to low V_T lung ventilation ($V_T=6$ mL/kg PBW) with positive end-expiratory pressure (PEEP) has improved survival and become a standard therapy in the management of patients with ARDS in the intensive care setting [78]. Whether patients without ARDS may also benefit from a low V_T ventilation strategy intraoperatively has been a subject of increasing interest and debate. The largest trial to date randomized 400 patients at intermediate to high risk of PPCs undergoing major elective abdominal surgery to either intraoperative protective lung ventilation (V_T of 6–8 mL/kg of PBW, PEEP of 6–8 cmH_2O, and recruitment maneuvers (RM) every 30 min) or non-protective lung ventilation (V_T of 10–12 mL/kg of PBW, no PEEP, and no RM) [79]. The primary outcome, which was a composite of major pulmonary (pneumonia or need for mechanical ventilation) and extrapulmonary complications (sepsis or death) occurring within seven postoperative days, was lower in the protective ventilation group (10.5% vs. 27.5% $p = 0.001$). The patients in the protective ventilation group had significantly lower rates of pneumonia, atelectasis, need for noninvasive mechanical ventilation, and sepsis. There was no difference in mortality between the groups.

More recent evidence suggests that the most important parameter associated with improved outcomes may be the use of low driving pressure [80]. Driving pressure is the difference between the PEEP and the plateau pressure. Neto et al. performed a meta-analysis of 2250 patients from 17 randomized controlled trials comparing intraoperative protective ventilation vs. conventional ventilation [81]. A multivariate analysis found that the only parameters associated with PPCs were static compliance and driving pressure. Surprisingly, V_T and PEEP were not independently associated with a reduced PPC rate. Moreover, in some patients, they found that increasing levels of PEEP actually lead to an increase in driving pressure, which in turn was associated with a greater risk of PPCs (OR = 3.11, $p = 0.006$). Presumably, in patients with minimal atelectasis, recruitment with PEEP resulted in overdistension of alveoli and a shift to a steeper portion of the respiratory compliance curve. In patients where increasing the PEEP either decreased or did not affect the driving pressure, the risk of PPCs was unchanged.

No study has specifically addressed how patients with end-stage lung disease should be ventilated intraoperatively. In spite of this paucity of evidence, we believe it is prudent to apply principles of lung protective ventilation to this population while keeping in mind the specific pathophysiologic processes at play for each disease (see sections on specific diseases in this Chapter). However, the recent literature gives us clues that a "magical recipe" of blindly applying a predetermined V_T, PEEP, F_iO_2, and RM may not achieve the best possible outcomes. An individualized approach that accounts for the patient's pathophysiology, lung and respiratory system compliance, amount of recruitable atelectatic alveoli, surgical requirements, and the interplay of other organ systems may improve outcomes.

Minimally Invasive Surgery

Key advantages of minimally invasive surgical procedures include reduced postoperative pain and an earlier return to baseline activities. For cholecystectomy and colorectal bowel resection, laparoscopic surgery results in less compromise of FEV_1 and forced vital capacity (FVC), as well as a lower incidence of atelectasis on postoperative chest X-rays. In spite of these improved clinical measures, a significant difference in postoperative pulmonary complications has not been demonstrated [82, 83]. However, the anesthetic management of patients with ESLD undergoing laparoscopic surgery can be challenging. Laparoscopy causes a decrease in FRC, which results in atelectasis and hypoxemia. Insufflation of CO_2 contributes to hypercarbia and respiratory acidosis. Although this is commonly controlled with increases in minute ventilation, this intervention may be of limited value in patients with abnormal lung mechanics and impaired gas exchange. In the rare circumstance where patients with ESLD require awake laparoscopy under regional anesthesia, the additional CO_2 load may precipitate respiratory failure. The development of hypoxia, hypercarbia, and acidosis (all of which contribute to pulmonary vasoconstriction) can also significantly worsen the degree of pulmonary hypertension and right heart failure. As a result, ventilatory parameters and cardiac function must be carefully monitored, especially during abdominal CO_2 insufflation. If respiratory or cardiac decompensation occurs, abortion of the procedure or conversion to an open surgery should be considered.

Optimizing Emergence

Temperature monitoring should be used in patients with ESLD. Postoperative hypothermia and shivering significantly increase oxygen consumption and carbon dioxide production. Such an increase in ventilatory demand is poorly tolerated in ESLD and may lead to respiratory failure. Intraoperative maintenance of normothermia with warming blankets and fluid warmers is extremely important.

While a variety of techniques and drugs may be used to safely induce and maintain anesthesia in patients with ESLD, agents with a short duration of action are preferred to minimize the risk of respiratory compromise at emergence. These patients are particularly sensitive to respiratory depressants such as benzodiazepines and opioids, and thus, these drugs should be used sparingly. Drugs which bronchodilate and do not inhibit hypoxic pulmonary vasoconstriction (HPV) are also favored. In this respect, the newer inhalational agents, such as sevoflurane or desflurane, are well suited for most patients. However, as a result of diffusion abnormalities and ventilation–perfusion mismatch, the elimination of inhalational agents may be unpredictable in patients with ESLD and result in delayed awakening. In patients with baseline hypoxia and/or bullous disease, nitrous oxide should be avoided. Total intravenous anesthesia (TIVA) is an excellent alternative to inhalational anesthesia for maintenance. Intravenous anesthetics do not affect HPV and lead to a timely awakening once turned off, especially when short-acting drugs such as propofol or remifentanil are used. While ketamine offers several distinct advantages including bronchodilation, preserved respiratory effort, and analgesic properties, it is associated with a 20–30% risk of postoperative hallucinations and nightmares and should be used cautiously [52, 84].

Postoperative Management

In patients with limited pulmonary reserve, effective postoperative pain management is essential. Splinting as a result of poorly controlled pain, especially from thoracic and abdominal surgery, can contribute to increased pulmonary complications including respiratory failure. In patients without contraindications, multimodal analgesic adjuvants including acetaminophen and nonsteroidal antiinflammatory drugs should be used. Although parenteral opioid use is effective in blunting pain, the amount needed following a thoracotomy or laparotomy may cause significant sedation and hypoventilation. Clearly, this is undesirable in patients with ESLD, especially those at risk of nocturnal hypoxemia. In comparison, a well-functioning regional block (e.g., thoracic epidural, paravertebral block) consistently provides superior analgesia and improves postoperative outcomes [64, 68, 69, 85, 86]. In patients with severely compromised respiratory function, the use of regional analgesia in minimally invasive surgeries such as video-assisted thoracoscopic surgery or laparoscopy should be considered. For instance, epidural analgesia is standard for our patients with COPD undergoing video-assisted thoracoscopic lung volume reduction surgery. A complete discussion regarding postoperative analgesia is found in Chap. 59.

Although nasogastric tubes are often routinely placed intraoperatively to facilitate gastric decompression after surgery, this practice is associated with an increased risk of atelectasis and pneumonia. In a meta-analysis of 24 studies, routine nasogastric tube use was associated with a statistically significant increased risk of pulmonary complications (OR = 1.4; 95% CI = 1.08–1.93) [87]. Accordingly, the use of postoperative nasogastric tubes should be avoided when possible.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as *a common preventable and treatable disease, characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particle or gases* [88]. It is associated with chronic inflammation, parenchymal destruction, and enhanced airway reactivity that are not fully reversible. Though most commonly associated with chronic bronchitis and emphysema, the COPD spectrum also includes asthma, between which there can be considerable clinical overlap. COPD is a major cause of morbidity and mortality worldwide, affecting 5–12% of the population, and is responsible for around three million deaths each year globally. It is expected to become the third leading cause of death by 2020.

Diagnosis and Staging of COPD

COPD should be considered in any patient who has dyspnea, chronic cough or sputum production, and/or a history of exposure to relevant risk factors. The diagnosis is confirmed with spirometry if the post-bronchodilator FEV_1 to FVC ratio is less than 0.7. The FEV_1% predicted is then used to stratify patients into one of four disease stages, as outlined in Table 31.5. Although FEV_1% predicted can also be used to predict survival rates, the BODE index – a composite score that includes measures of body mass index (B), airflow obstruction (O), dyspnea (D), and exercise capacity (E) – has been shown to be a better predictor of patient survival [89]. On the basis of patient investigations and clinical status, each variable is assigned a point value according to Table 31.6. Adding these points together gives the BODE index, which can range from 0 to 10. The Kaplan–Meier survival curves based on BODE index and FEV_1 are illustrated in Fig. 31.4. The improved accuracy of the BODE index over FEV_1 alone in predicting patient survival reflects the reality that COPD is more than a pulmonary disease and that its outcome is closely related to systemic factors, including cardiopulmonary reserve.

Table 31.5 The GOLD classification of COPD based on post-bronchodilator spirometry

GOLD I	Mild	FEV_1/FVC <70%
		FEV_1 ≥80% predicted
GOLD II	Moderate	FEV_1/FVC <70%
		50% ≤ FEV_1 <80% predicted
GOLD III	Severe	FEV_1/FVC <70%
		30% ≤ FEV_1 <50% predicted
GOLD IV	Very severe	FEV_1/FVC <70%
		FEV_1 <30% predicted

Table 31.6 Variables and point values used for the computation of the BODE index

	Points on BODE index			
Variable	0	1	2	3
Body mass index	>21	≤21		
Airflow obstruction – FEV_1% predicted	≥65	50–64	36–49	≤35
Modified medical research council dyspnea scale	0–1	2	3	4
Exercise – Distance walked in 6 min (m)	≥350	250–349	150–249	≤149

Etiology of COPD

The development of COPD is strongly associated with exposure to noxious gases and particles. By far the most important risk factor for developing COPD is the amount and duration of cigarette smoking, which accounts for 75–90% of all cases in western nations [2, 90]. Worldwide, however, the use of biomass fuel (wood, charcoal, vegetable matter, animal dung) for heating and cooking is a significant risk factor for COPD. In fact, compared to the number of cigarette smokers, nearly three times as many people are exposed to biomass smoke [90]. The WHO estimates that 22% of COPD is attributable to biomass smoke [2]. Other significant contributors include air pollution, occupational exposure, and a history of pulmonary tuberculosis [90]. The inhalation of noxious fumes triggers macrophages and neutrophils to release inflammatory mediators, cytokines, as well as proteases. Although proteases play an important role in preventing infection, they can also cause damage to lung tissue. The latter is normally prevented by the presence of antiproteases enzymes such as α-1 antitrypsin. However, chronic inflammation and inactivation of antiproteases by oxidants lead to an imbalance resulting in unopposed protease activity. Long-term exposure to this process leads to fibrosis of the airway as well as destruction of alveoli [91]. The pathogenesis of COPD is summarized in Fig. 31.5.

COPD may also result from a number of genetic abnormalities, of which α-1 antitrypsin deficiency is the most well-known. Over 100 alleles have been identified for α-1

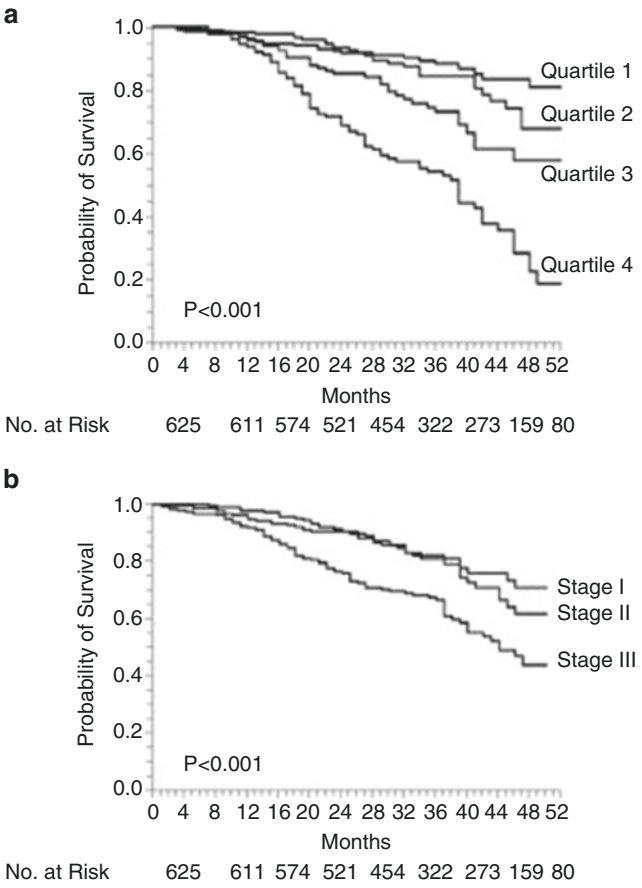

Fig. 31.4 Kaplan–Meier survival curves for the four quartiles of the BODE index (**a**) and the three stages of severity of chronic obstructive pulmonary disease as defined by the American Thoracic Society (**b**). In (**a**), quartile 1 is a score of 0–2, quartile 2 is a score of 3–4, quartile 3 is a score of 5–6, and quartile 4 is a score of 7–10. Survival differed significantly among the four groups ($P < 0.001$ by the log-rank test). In (**b**), stage I is defined by a forced expiratory volume in 1 s (FEV_1) that is more than 50% of the predicted value, stage II by an FEV_1 that is 36–50% of the predicted value, and stage III by an FEV_1 that is no more than 35% of the predicted value. Survival differed significantly among the three groups ($P < 0.001$ by the log-rank test). (Reproduced with permission from Celli et al. [89]. © 2004 Massachusetts Medical Society. antitrypsin, the most common of which are the normal allele "M" and the abnormal alleles "S" and "Z." Although, only one normal allele ("M") is needed to produce the normal phenotype, heterozygote individuals ("MZ" or "MS") tend to produce 65% less α-1 antitrypsin than normal individuals ("MM") [2, 92]. The abnormal homozygote ("ZZ") which results in no α-1 antitrypsin production occurs with a prevalence between 1/1575 and 1/5097 and accounts for 2–3% of COPD [92]. While the disease onset varies, it is usually evident by the fourth or fifth decade and even earlier in those who smoke [2]. In contrast to normal "MM" individuals who preferentially develop emphysematous changes in the apices, the distribution of emphysema in α-1 antitrypsin tends to be relatively homogeneous. Other genetic abnormalities (e.g., polymorphisms of TGF β1, Serpine2, etc.) have been linked to increased risk of COPD in smokers.

COPD has also been associated with childhood pulmonary illnesses such as neonatal bronchopulmonary dysplasia and persistent asthma [93].

Causes of Expiratory Flow Obstruction

Expiratory flow limitation results from compression of the airways by intrathoracic pressure. In normal individuals, this only occurs during forced expiration. The mechanism for this is shown in Fig. 31.6. Prior to inspiration and the initiation of flow, the airway pressure is zero throughout. With a resting intrapleural pressure of −5 cm water, a transmural pressure of 5 cm water maintains airway patency (Fig. 31.6a). With normal inspiration, both intrapleural and alveolar pressures decrease by 3 cm water, and flow begins (Fig. 31.6b). Although this pressure is transmitted into the airway, its magnitude progressively declines because of airway resistance. Assuming an airway pressure of −1 cm water during inspiration, then the airway is kept open by 7 cm water. At end-inspiration, the airway pressures return to zero as flow ceases (Fig. 31.6c). During exhalation an increase in both intrapleural and alveolar pressures occurs. As with inhalation, the transmitted pressure from the alveoli drops within the airway as a result of resistance. With quiet exhalation, the passive return of the lung and chest wall to their equilibrium positions generates a pressure of 3 cm water within the intrapleural space and alveoli (Fig. 31.6d). As a result, the pressure within the airway always exceeds the intrapleural pressure. In this example, pressures may increase up to 8 cm water without causing airway collapse. However, higher pressures associated with forced expiration will lead to airway compression when the intraluminal pressure drops below the intrapleural pressure. This is called the equal pressure point (EPP). Beyond this, further increases in expiratory effort (which will also increase intrapleural pressure) will only contribute to flow limitation and airway collapse. For example, if both intrapleural and alveolar pressures increase by 24 cm water during forced expiration, then the EPP occurs at 16 cm water, below which airway collapse will occur (Fig. 31.6e). The effective driving pressure is therefore alveolar minus intrapleural pressure.

Factors that contribute to worsening flow limitation in patients with COPD are summarized in Table 31.7. Causes that may respond to intervention include active bronchospasm and airway obstruction by secretions. The loss of elastic recoil observed in emphysema results in less negative intrapleural pressures and reduces the outward traction normally exerted by lung parenchyma on the airway. This lowers the transmural pressure which keeps the airway open as well as the effective driving pressure. In our COPD example shown in Fig. 31.7a, the intrapleural and the transmural pres-

sure at end-inspiration is −2 cm water, 6 cm water less negative than in a normal individual (see Fig. 31.6c). The propensity for airway collapse is accentuated by inflammatory and fibrotic changes which lead to contraction and narrowing of the small airways. As a result, even normal pressure increases of 3 cm water associated with quiet expiration may result in flow limitation in patients with severe COPD (Fig. 31.7b).

Dynamic Hyperinflation

In COPD individuals, acute worsening of flow limitation may be precipitated by increased respiratory rates, physical activity, or COPD exacerbations. When flow limitation occurs, individuals with COPD are unable to exhale fully to FRC before their next inspiration. The positive pressure within the lung segments with air trapping is referred to interchangeably as auto-PEEP or intrinsic PEEP ($PEEP_i$). With each subsequent inspiration, "breath stacking" occurs, and the alveoli become progressively more hyperinflated as auto-PEEP accumulates. Initially, auto-PEEP may improve respiratory mechanics and minimize the effect of flow limitation. Since patients with COPD generally expire along the maximum flow–volume loop envelop at rest, they have very limited ability to further increase expiratory flow (see Fig. 31.8) [95]. In this setting, low levels of auto-PEEP help to temporarily improve ventilation by increasing the effective driving pressure and thus expiratory flows.

However, as dynamic hyperinflation worsens, the work of breathing increases dramatically. There are two reasons for this. First, for inspiratory flow to occur, the alveolar pressure must be less than the atmospheric pressure. In normal individuals, this involves minimal effort. When auto-PEEP is present, an equivalent (and potentially large) amount of inspiratory pressure must be generated before airflow even begins. In essence, auto-PEEP is an additional inspiratory load [2, 96]. For example, if 3 cm water of auto-PEEP is present (Fig. 31.7c), then a typical inhalational effort of −3 cm water (see Fig. 31.6a, b) would only drop the alveolar pressure to atmospheric pressure. As a result, despite the pressure change, no inspiratory airflow would occur. In this example, to produce the −3 cm water pressure change required for a normal tidal volume breath (Fig. 31.6a, b), the COPD patient needs to generate an inspiratory pressure of −6 cm water (Fig. 31.7d). Second, dynamic increases in the end-expiratory lung volume results in each tidal volume breath shifting rightward of the flat portion of the volume–pressure compliance curve (see Fig. 31.9) [2, 95, 96]. This increases the work of breathing since a greater pressure must be generated in order to maintain a given tidal volume. Hyperinflation also leads to shortening of the inspiratory muscles, including the diaphragm. This mechanical disadvantage results in functional muscle weakness. Consequently, patients who develop dynamic hyperinflation experience significant dyspnea, respiratory distress, and muscle fatigue.

Hemodynamic instability is also common with high levels of dynamic hyperinflation. Increased intrathoracic pressure associated with auto-PEEP reduces the pressure gradient for venous return into the thorax and also causes direct compression of the ventricles, both of which decrease preload and impair diastolic filling. High auto-PEEP will also

increase PVR which may precipitate right ventricular dysfunction. In extreme cases, dynamic hyperinflation can cause cardiac arrest and subsequently impair resuscitation. The "Lazarus syndrome," in which patients recover from a cardiac arrest only after resuscitative efforts and positive pressure ventilation are stopped, has been attributed to resolving dynamic hyperinflation [97].

During anesthesia, dynamic hyperinflation commonly presents with increasing airway pressures and severe hypotension shortly after induction when manual or mechanical ventilation is initiated. Other complications that may produce similar clinical findings include tension pneumothorax, anaphylaxis, and cardiac ischemia. When dynamic hyperinflation is suspected, the anesthetic circuit should be disconnected from the patient to permit full exhalation.

Intraoperatively, the buildup of intrinsic PEEP can be difficult to assess. Ideally, the magnitude of auto-PEEP is measured directly at end-expiration, with an end-expiratory gas flow pause. While this function is commonly found on intensive care ventilators, it is rarely available on anesthesia gas machines. However, the presence of intraoperative breath stacking can be indirectly assessed by capnography and spirometry loops. The capnograph tracing normally plateaus at the end of a fully exhaled breath, reflecting a constant alveolar concentration of CO_2. In obstructive diseases, although the capnograph commonly upslopes as a result of air from dead space diluting the exhaled CO_2 concentration, the capnograph will still plateau when exhalation is complete. If the next breath is initiated before the CO_2 plateaus, the presence of auto-PEEP should be suspected [98]. Similarly, the presence of air trapping may be inferred from flow–volume loops when the expiratory flow does not drop to zero before the next breath (see Fig. 6.6).

Respiratory Drive in COPD

The control of ventilation is primarily regulated by the arterial partial pressure of carbon dioxide ($PaCO_2$), with each 1 mmHg rise increasing minute ventilation by 2–3 L/min [99, 100]. However, this relationship is self-limiting. Within the central nervous system (CNS), severe hypercapnia and acidosis are associated with increased glutamine and gamma-aminobutyric acid (GABA) and decreased glutamate and aspartate levels. These changes result in a decreased level of consciousness, as well as reduced minute ventilation and inspiratory drive [101]. Typically, these CNS effects manifest when the $PaCO_2$ is greater than 60–70 mmHg. In patients with chronic hypercapnia that is compensated by an increase in bicarbonate, even higher $PaCO_2$ levels may be tolerated before respiratory depression occurs. In comparison with the linear minute ventilation response to $PaCO_2$, decreases in the P_aO_2 lead to an exponential increase in minute ventilation only when levels fall below 60 mmHg.

Patients with severe COPD often have an elevated $PaCO_2$ at rest. Retention of carbon dioxide occurs because these patients are unable to maintain sufficient respiratory work to keep their $PaCO_2$ at normal levels. In these patients, clinicians have observed that oxygen administration can worsen the degree of hypercapnia. Traditionally, clinicians believed that patients with chronic hypercapnia had a blunted ventilatory response to increased $PaCO_2$ and were dependent on hypoxic drive to breath. Supplemental oxygen would therefore inhibit hypoxic drive and decrease minute ventilation. While this explanation is valid, its contributing role to the overall increase in $PaCO_2$ is overstated. In one study of patients with COPD in acute respiratory failure, oxygen administration at 5 L/min only reduced the respiratory rate and the minute ventilation by 14% – an insufficient drop to account for the entire rise in $PaCO_2$. Moreover, while ventilatory drive was reduced following oxygen supplementation, it remained three times greater than in normal individuals [102]. In another study, the rise in $PaCO_2$ that could be attributable to decreased minute ventilation was only 22%. In comparison, 48% of the $PaCO_2$ increase was attributed to an increase in dead-space ventilation, and 30% resulted from reduced Haldane effect [103]. In patients with COPD, the degree of *V*/*Q* mismatching and dead-space ventilation is minimized by HPV which redirects blood away from poorly ventilated to well-ventilated areas. The use of supplemental oxygen hinders this effect, resulting in increased dead-space ventilation and reduced CO_2 elimination. The Haldane effect describes the enhanced dissociation of CO_2 from red blood cells caused by the oxygenation of hemoglobin. Oxygenated hemoglobin has a much lower affinity for CO_2 than deoxygenated hemoglobin. As a result, deoxygenated hemoglobin facilitates the loading of CO_2 from peripheral tissue, while the oxygenation of hemoglobin in the lungs leads to offloading. The magnitude of the Haldane effect is proportional to the difference between the mixed venous oxygen saturation and the arterial oxygen saturation. In other words, more CO_2 is released in the lungs when the mixed venous–arterial gradient is large. In COPD patients, the use of high-inspired fractions of oxygen (FiO_2) leads to a significant increase in the mixed venous oxygen saturation, which limits the ability of hemoglobin to bind and eliminate CO_2 from the periphery.

In spite of the potential increase in $PaCO_2$ associated with the administration of oxygen to patients with COPD, titrated oxygen therapy must be used to avoid hypoxia. In patients with acute respiratory failure, the reduction in ventilatory drive associated with oxygen administration may actually be of benefit. A lower respiratory rate minimizes the risk of dynamic hyperinflation, the work of breathing, and the potential for respiratory muscle fatigue. Patients requiring supplemental oxygen need to be closely monitored for signs of CNS depression and CO_2 narcosis. The P_aO_2 and the $PaCO_2$ should be frequently checked. For most patients,

titrating the FiO2 to maintain an O_2 saturation of 88–92% is usually sufficient [88].

Bullae

Bullae are cystic air spaces in the lung parenchyma with a diameter greater than 1 cm. Most commonly, bullae develop as a result of worsening emphysematous disease. Bullae form when there is a loss of structural support tissue within a localized area. Preserved elastic recoil of the surrounding lung tissue places outward traction on bulla, causing it to enlarge. This results in the characteristic "inflated" look of bullae on chest X-rays and computed tomography scans. Although bullae appear to compress adjacent lung segments, direct measurements have conclusively shown that they are not under positive pressure [104]. Perhaps surprisingly, bullae do not contribute significantly to increased dead-space ventilation. In spite of unimpeded communication between the airways and bullae, very little airflow occurs. The lack of elastic recoil essentially prevents fully expanded bullae from emptying during exhalation or from filling any further during inhalation. In addition, because bullae are relatively avascular, they do not participate in gas exchange. In patients with large bullae occupying more than a third of the hemithorax (i.e., "giant bullae"), a mixed restrictive–obstructive disease pattern may emerge as the volume available to the nonbullous lung segments is reduced. The loss of structural integrity within bullae predisposes patients to serious complications including rupture, tension pneumothorax, and bronchopleural fistula. Although the risk of these adverse events is increased with positive pressure ventilation, it may be safely used so long as the airway pressures are kept low. Chest tube insertion and lung isolation may be required should these complications arise.

Ventilation Strategies in Patients with Obstructive Disease

Providing effective mechanical ventilation for patients with severe COPD can be challenging. Key goals, which at times conflict, include (1) avoiding dynamic hyperinflation, (2) avoiding barotrauma and volutrauma, and (3) maintaining adequate oxygenation and ventilation. As previously discussed, dynamic hyperinflation occurs when inadequate expiratory time leads to breath stacking. This risk can be minimized by using low I/E ratios in the range of 1:3 to 1:5, as well as low respiratory rates. This may result in lower minute ventilation and cause hypercarbia and hypoxia, both of which worsen pulmonary hypertension and right ventricular strain. Higher tidal volumes may improve these gas exchange abnormalities, but this may significantly increase airway pressures and expose patients to a higher risk of volutrauma or barotrauma.

In spontaneously breathing patients with obstructive lung disease, applying extrinsic PEEP that is equal to or less than the patient's auto-PEEP has been shown to reduce the work of breathing associated with air trapping. In contrast, for mechanically ventilated patients, the use of extrinsic PEEP in patients with obstructive disease is controversial. Theoretical advantages of applying extrinsic PEEP include maintaining alveoli open in areas of more normal lung mechanics and keeping small and easily collapsible airways patent, thereby reducing expiratory flow limitation. While extrinsic PEEP improves gas exchange and hemodynamics in some studies, others have demonstrated a worsening of expiratory airflow [98]. In one study of eight patients, Caramez et al. [105] examined the effect of increasing extrinsic PEEP from 0% to 150% of intrinsic PEEP using four different ventilatory settings. Using total PEEP, FRC, and plateau pressure as markers of expiratory flow limitation, the pooled data reliably showed a biphasic response with either no change or a slight increase in flow limitation when extrinsic PEEP was less than intrinsic PEEP, followed by a sharp rise once intrinsic PEEP was exceeded. However, when individual patient data were examined, three different responses to external PEEP were noted (see Fig. 31.10). In five patients, the use of external PEEP reduced air trapping and hyperinflation during at least one of the four ventilatory settings. Unfortunately, patient response to extrinsic PEEP was unpredictable and appeared to be independent of the disease, mechanics, or ventilation parameters. In another study by Jolliet et al. [106], the use of extrinsic PEEP at 80% of intrinsic PEEP significantly reduced the degree of intrinsic PEEP (7.8–4.4 cm H_2O; $P < 0.001$) as well as the volume of air trapping (216–120 mL; $P < 0.001$). In spite of these improvements, no change in hemodynamic parameters (mean arterial pressure and cardiac output) or gas exchange (P_aO_2 and $PaCO_2$) was noted. Clinical relevance aside, it is dif-

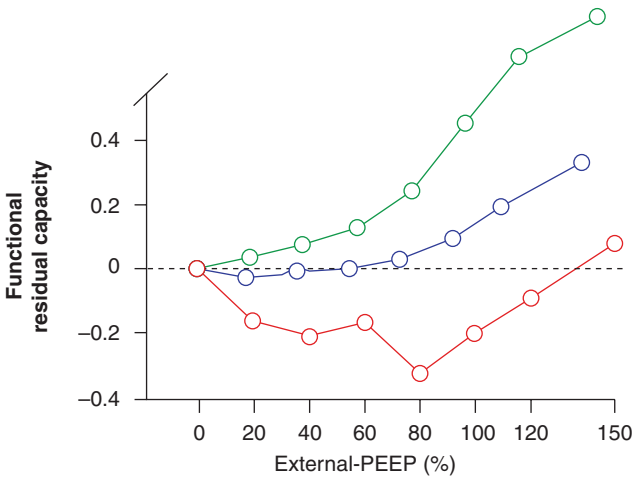

Fig. 31.10 The three potential responses in FRC when external PEEP (represented as a percentage of PEEPi measured at zero external PEEP) is applied. *Blue* is biphasic response; *green* is classic overinflation response; and *red* is paradoxic response

ficult to accurately measure the degree of intrinsic PEEP intraoperatively, and thus, select a level of extrinsic PEEP that does not exceed it. Extrinsic PEEP that is greater than intrinsic PEEP will worsen expiratory flow and increase hyperinflation. Given the limited evidence of benefit, the inability to define a clear expiratory PEEP target, and the risk of exacerbating air trapping, extrinsic PEEP in mechanically ventilated patients with obstructive lung disease should be minimized.

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder that results in impaired transport of sodium, chloride, and water across epithelial tissue. This leads to abnormally viscous secretions which can cause obstruction of the respiratory tracts, pancreas, biliary system, intestines, and sweat glands. The organ systems that are affected are summarized in Table 31.8. Though most commonly associated with Caucasians (1:3000), the disease also affects Hispanics (1:9500), African Americans (1:15,300), and Asian Americans (1:32,100) [107]. With improved medical care over the last half century, the prognosis for patients with CF has improved dramatically, and the median predicted survival age was 41.6 years in 2015 (Fig. 31.11). The early mortality of CF is primarily the result of pulmonary complications, which include pneumothorax, massive hemoptysis, severe respiratory infections, and respiratory failure [108–110].

Table 31.8 Clinical manifestations of cystic fibrosis

Organ system	Clinical features
Pulmonary	Impaired clearance of viscous secretions, mucous plugging
	Obstructive lung disease
	Bronchiectasis
	Reactive airways
	Hemoptysis
	Recurrent infections and chronic colonization (*S. aureus*, *H. influenzae*, *Aspergillus*, *B. cepacia*)
Cardiac	Pulmonary hypertension and right ventricular failure
Hepato-biliary	Impaired biliary drainage, cholelithiasis, cholecystitis
	Fatty liver, cirrhosis → portal hypertension, esophageal varices, coagulopathy
	Hepatosplenomegaly → sequestration of platelets → thrombocytopenia
Pancreas	Obstruction of pancreatic duct → pancreatitis
	Exocrine dysfunction → ↓ pancreatic enzymes → malabsorption of vitamins A, D, E, K → impaired synthesis of coagulation factors
	Endocrine dysfunction → glucose intolerance, CF-related diabetes
Gastrointestinal tract	Distal intestinal obstructive syndrome Gastroesophageal reflux disease → micro-aspirations
Ears, nose, throat	Large nasal polyps
	Sinusitis
Musculoskeletal	Decreased bone mineral density → fractures, kyphoscoliosis
	Hypertrophic osteoarthropathy

Pulmonary Manifestations of CF

As with COPD, CF is characterized primarily by airflow obstruction, although varying degrees of restriction can also occur. Early in the disease, expiratory flow limitation is caused by the accumulation of thick dehydrated mucous in the respiratory tract that is difficult to expectorate. Inability to clear the thick purulent secretions enhances bacterial growth, and as the disease advances, colonization of the airways with *Pseudomonas aeruginosa* and *Staphylococcus aureus* is considered normal. Infection with other bacteria, though less common, is often much more serious. For instance, *Burkholderia cepacia* is associated with rapid deterioration of pulmonary function, uncontrolled bronchopneumonia, and death. Although infection results in a massive influx of inflammatory cells into the airways, this immune response is ineffective once bacterial infection is established and actually contributes to disease progression. Elastase released by neutrophils overwhelms the antiprotease mechanisms of the lung resulting in inflammatory destruction of airway supportive tissue, increased airway collapsibility during expiration, the development of bronchiectasis, and worsened airway obstruction. As a consequence of these airway changes, ciliary function is impaired, further limiting the patient's ability to clear secretions. In some, reactive airway disease may also contribute to the airflow obstruction. As with other causes of obstructive lung disease, patients with CF are at increased risk of dynamic hyperinflation and pneumothorax. Strategies that maintain low airway pressures and long expiratory times should be considered during mechanical ventilation. Chronic infection and inflammation also leads to increased airway vascularity through both bronchial artery hypertrophy and angiogenesis. The system of enlarged, dilated, and tortuous vessels that develops is highly susceptible to trauma, and as a result, hemoptysis is common in patients with CF. Although most episodes of hemoptysis are self-resolving, some patients may require bronchial artery embolization or even surgical intervention [111]. In patients with hemoptysis requiring a general anesthetic, positive pressure ventilation may increase airway wall tension and precipitate massive hemoptysis. In one case report of 12 patients undergoing bronchial artery embolization who were managed with general anesthesia and intubation, three developed massive hemoptysis and died. In contrast, none of the eight patients managed with sedation developed massive hemoptysis [112].

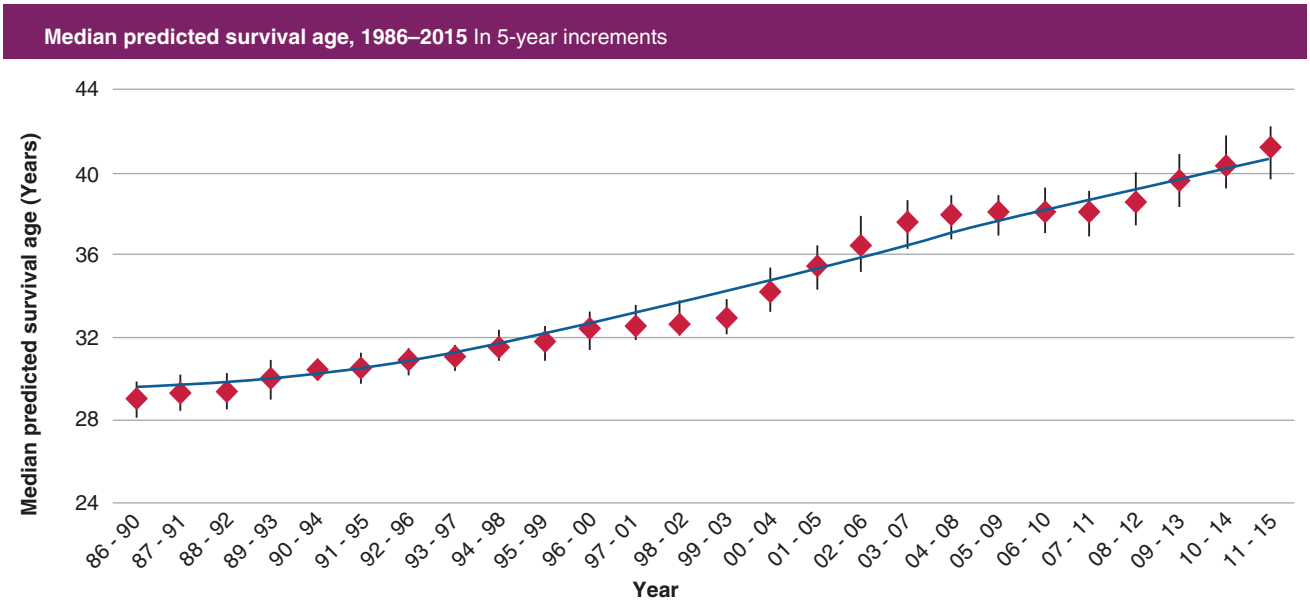

Fig. 31.11 Median predicted survival age from 1986 to 2015 by 5-year increments. (Adapted from Cystic Fibrosis Foundation Patient Registry Annual Data Report 2015)

Management of CF

Effective sputum elimination is a key goal in the long-term management of CF. A long-standing practice used to facilitate this is chest physiotherapy. Traditionally, this consisted of chest percussion with postural drainage. However, as more patients with CF survive into adulthood, there has been a shift toward forms of physiotherapy that can be performed independently. These alternatives range from simple breathing and coughing techniques to the use of medical devices of varying complexity [113]. Although chest physiotherapy is considered standard care, the number of quality trials examining its efficacy is limited. Inhaled DNase I, a human recombinant enzyme that can decrease sputum viscosity by hydrolyzing extracellular DNA, has been shown to improve pulmonary function and reduce the incidence of pulmonary exacerbations. In a randomized controlled trial of 968 patients with CF, twice daily use of DNase I improved FEV_1 by approximately 6% ($p<0.01$) and reduced the risk of pulmonary exacerbations by 37% ($p<0.01$) [114]. Sputum viscosity can also be reduced by using inhaled hypertonic saline which osmotically draws water from the airway mucosa into the lumen. In a study of 164 patients, this therapy reduced the risk of pulmonary exacerbations by 56% ($p=0.02$) [115].

CFTR modulators are a new class of medication developed to directly improve the function of the defective cystic fibrosis transmembrane regulator protein. They have been shown in randomized trials to improve PFTs and reduce pulmonary exacerbations [116, 117]. Unfortunately, these medications are only approved for specific genetic mutations, and not all CF patients benefit from it.

To optimize patients with CF for anesthesia, chest physiotherapy should be performed immediately prior to surgery. In patients who were prescribed inhaled DNase I and hypertonic saline, these should also be administered. Both during anesthesia and in the postoperative period, the viscosity of pulmonary secretions can be minimized by humidifying the inspired gases. Patient volume status needs to be carefully monitored to avoid both hypovolemia which may worsen secretion tenacity and hypervolemia which may trigger heart failure. Drugs which may either increase pulmonary secretions (e.g., ketamine) or contribute to increased sputum viscosity (e.g., anticholinergics) are relatively contraindicated. Although supraglottic airways have been successfully used in patients with CF requiring general anesthesia, intubation with a large-sized endotracheal tube is usually preferred because it permits better control of ventilation and it facilitates endobronchial toileting with a suction catheter and/or fiber-optic bronchoscopy. When appropriate, the use of regional anesthesia and opioid-sparing adjuvant medications for management of postoperative pain is preferred. In addition to generalized respiratory depression, opioids may diminish the cough reflex and thus sputum clearance.

Extrapulmonary Manifestations of CF

Of the organ systems that are affected by CF, gastrointestinal dysfunction is particularly relevant to the anesthesiologist. Compared to normal individuals, gastroesophageal reflux is six to eight times more common in patients with CF and may contribute to worsening respiratory symptoms [118]. Reflux

symptoms should be treated aggressively, and precautions that minimize gastric acidity as well as the risk of aspiration should be considered during anesthesia (e.g., antacids, rapid sequence intubation). The buildup of thick secretions within the intestinal tract of patients with CF results in an increased risk of constipation and bowel obstruction. The use of narcotics may further exacerbate the potential for this complication. Though uncommon, patients with CF may develop a coagulopathy and have an increased risk of bleeding as a result of biliary duct obstruction. Generally, this only causes asymptomatic liver dysfunction. However, as the life expectancy of CF increases, the development of advanced liver disease and cirrhosis may produce complications such as bleeding from esophageal varices, impaired synthesis of coagulation factors, and thrombocytopenia secondary to hepatosplenomegaly. In addition, pancreatic exocrine insufficiency which results in malabsorption of protein, fat, as well as the fat-soluble vitamins is present in 85% of patients with CF [109]. Without supplementation, this causes a deficiency in vitamin K, an important precursor for the synthesis of coagulation factors X, IX, VII, and II. Pancreatic endocrine function may also be affected by CF. Approximately 75% of patients show evidence of glucose intolerance, while 10% develop CF-related diabetes mellitus.

Pregnancy and CF

The improved life expectancy associated with CF over the past few decades has led to a rise in the number of patients presenting for medical care while pregnant. In contrast to males with CF, of whom 95% are infertile, the fertility of young women with CF is almost unaffected [107, 119]. However, pregnancy is associated with a several physiologic changes that may stress the respiratory status of patients with CF. These include an increased oxygen consumption of 30–60%, an increased respiratory rate, decreased chest wall compliance, and decreased FRC. Patients with CF are also exposed to an increased risk of respiratory infection because pregnancy results in a state of relative immunosuppression, and maintenance chest physiotherapy becomes more difficult to perform. A recent observational study that included over 1100 CF parturients demonstrated an increased risk of peripartum mortality, need for mechanical ventilation, pneumonia, acute renal failure, and preterm labor when compared to parturients without CF [120].

The anesthetic management for this patient group follows the same principles already discussed for ESLD. In patients who require a cesarean section, the high risk of desaturation and difficult intubation associated with pregnancy combined with the respiratory impairment of CF strongly favors the use of regional anesthesia over general anesthesia. However, an inadvertent high block will also interfere with ventilation. Although spinal anesthesia is commonly used, the downside to a rapid onset dense block is that it can also cause significant vasodilation. In patients with pulmonary hypertension, large decreases in systemic pressure may precipitate right ventricular ischemia. A titrated epidural results in less hemodynamic instability and greater control over block level and provides superior postoperative pain management. Following delivery, uterotonic agents such as oxytocin and methylergonovine should be administered cautiously because they may cause significant hemodynamic derangements including tachycardia, hypotension, or vasoconstriction. 15-Methyl prostaglandin F2-α (Hemabate) not only increases PVR but can also result in significant bronchospasm and should be avoided in patients with CF. Misoprostol, a prostaglandin E1 analog, may have a more favorable side effect profile in patients with cardiorespiratory disease.

Interstitial Lung Diseases

Interstitial lung diseases (ILDs) are a heterogeneous group of disorders associated with inflammation and fibrosis of the lung parenchyma. ILDs are characterized by restrictive physiology on PFTs and are usually differentiated from extrapulmonary restrictive respiratory diseases by an impaired diffusing capacity for carbon monoxide (DLCO). As with COPD and CF, inflammation plays an integral role in ILDs. However, the inflammation associated with ILDs results predominately in diffuse scarring and fibrosis of the alveolar walls and small airways, as opposed to tissue destruction. The factors which influence whether inflammation will precipitate one outcome vs. the other are unclear. About 35% of ILDs are attributable to an identifiable cause such as exposure to inorganic dust, organic antigen, drugs, or radiation. In the remaining 65% of patients, even though the disease pattern may be given a specific name, the inciting agent resulting in ILDs is unknown (Table 31.9).

Confirming the diagnosis can be challenging and may require a multidisciplinary approach involving experienced respirologists, radiologists, and pathologists, taking into account clinical, radiologic (reticular pattern on chest radiography, disease-specific interstitial opacities on computed tomography), physiologic (restrictive lung function, impaired DLCO), and pathologic (lung biopsy, bronchoalveolar lavage) evidence.

Pulmonary Manifestations of ILDs

As a consequence of inflammation and fibrosis of the alveolar walls, the elastic recoil of the lungs increases, they become less distensible, and lung volumes contract. Early in the disease, despite decreased maximal voluntary ventilation, patients adapt to lower tidal volumes by increasing their

Table 31.9 Common causes of ILDs

Known etiology	Idiopathic
Inorganic dust inhalation	Idiopathic interstitial pneumonias
Silica (silicosis)	Idiopathic pulmonary fibrosis ("usual interstitial pneumonia")
Asbestos (asbestosis)	Desquamative interstitial pneumonia
Talc (talcosis)	Respiratory bronchiolitis ILD
Beryllium (berylliosis)	Acute interstitial pneumonia
Coal (coal worker's pneumoconiosis)	Cryptogenic organizing pneumonia
Graphite (carbon pneumoconiosis)	Non-specific interstitial pneumonia
Tin (stannosis)	Pulmonary fibrosis associated with connective tissue disease
Iron (siderosis)	Rheumatoid arthritis (RA)
Other metals and silicates	Systemic lupus erythematosus
Organic agent inhalation (hypersensitivity pneumonitis)	Scleroderma
Thermophilic fungi (farmer's lung, grain handler's lung)	Sarcoidosis
Bacteria (humidifier lung)	Pulmonary eosinophilic granuloma
Animal proteins (bird breeder's lung)	
Chemical exposures	
Synthetic fibers	
PVC	
Gases	
Drug induced	
Chemotherapies (bleomycin, mitomycin C, cyclophosphamide, methotrexate, carmustine)	
Others (amiodarone, nitrofurantoin, azathioprine, gold)	
Radiation induced	

respiratory rate. As the disease worsens, increased respiratory effort and energy are required to maintain sufficient tidal volumes to prevent alveolar hypoventilation. Heterogeneous alterations in the alveolar–capillary unit throughout the lung can cause significant ventilation–perfusion mismatch and is the primary cause of hypoxemia in patients with ILDs. Inflammation and fibrosis of the alveolar–capillary membrane also contribute to worsening oxygenation by reducing the surface area available for gas exchange, thus impairing diffusion. This pathophysiologic process eventually leads to chronic hypoxemia, pulmonary hypertension, and right ventricular dysfunction.

Medical Management of ILDs

Many therapeutic options for ILDs have specific perioperative considerations. Recently, two new agents have been introduced for the medical management of idiopathic pulmonary fibrosis. Pirfenidone, an oral anti-fibrotic, and nintedanib, a tyrosine kinase inhibitor, have been shown to reduce the rate of decline in pulmonary function but are also associated with gastrointestinal side effects and hepatic toxicity [121, 122]. Besides increasing infectious risks, some of the immunosuppressive therapies have been associated with renal and hematologic toxicities (e.g., cyclosporine, azathioprine). Perioperative stress dosing may be required in patients taking chronic glucocorticoids.

Ventilation Strategy for Restrictive Lung Diseases

Although a variety of techniques for general anesthesia have been used including airway management with an LMA and spontaneous ventilation, controlled ventilation through an endotracheal tube is the most reliable and safest approach to optimizing oxygenation and ventilation in patients with ILDs when general anesthesia is required [123, 124]. The goals of mechanical ventilation in patients with ILDs are to maintain adequate ventilation and oxygenation while minimizing the risks of barotrauma, volutrauma, and ALI. Potential strategies to minimize airway pressures include using high I/E ratios (e.g., 1:1 to 1:2), as well as low tidal volumes in conjunction with high respiratory rates. However, for each tidal volume breath, the later strategy may result in a relative decrease in alveolar ventilation and exacerbate intraoperative hypercarbia and thus, the magnitude of pulmonary hypertension. Arterial blood gases should be closely monitored. In contrast to the obstructive lung diseases, PEEP can be safely used in ILDs.

ILDs and Thoracic Surgery

One of the most common operations performed in patients with ILDs is surgical lung biopsy for diagnostic confirmation. The procedure can be performed via thoracotomy or video-assisted thoracoscopic surgery under general anesthesia and most commonly requires one-lung ventilation. Overall perioperative mortality in elective surgical biopsies has been reported to be less than 2%. However, multiple risk factors have been associated with significantly higher perioperative mortality: preoperative hypoxemia, nonelective surgery in acute exacerbation or rapidly progressing disease, male sex, advanced age, provisional diagnosis of idiopathic pulmonary fibrosis or connective tissue disease-related ILDs, and other systemic comorbidities [125, 126].

Patients with ILDs undergoing lung cancer surgery are also at particular risk of postoperative pulmonary complications including ARDS, prolonged hospital stay, and death, with larger resections (i.e., pneumonectomy vs. lobectomy vs. wedge) posing higher risk [127, 128]. In a retrospective study of 1763 patients with ILDs undergoing lung cancer resection, postoperative acute exacerbation of lung disease occurred in 9.3% of patients, carrying a 43.9% 30-day mortality. As compared to wedge resections, patients undergoing lobectomies and pneumonectomies had significantly higher

risk of developing acute exacerbations (OR 3.9 [$p < 0.001$] and 7.0 [$p < 0.001$], respectively) [128].

Clinical Case Discussion

A 70-year-old male presents with a small bowel obstruction and has been booked for a laparotomy. He has a history of severe COPD and has been prescribed home O_2 and a regime of daily puffers. Two months ago his FEV_1 and FEV_1/FVC were 35% predicted and 40%. He is a smoker with a 60 pack-year history. Other medical issues include stable class 2 angina, hypertension, and dyslipidemia.

How Would You Optimize This Patient for Surgery?

- *Smoking cessation counseling*. Abstinence from cigarette use even for a few hours prior to surgery will result in lower carbon monoxide and nicotine levels. This may reduce the risk of intraoperative hypoxemia and cardiac stress. Postoperative compliance with smoking cessation improves wound healing and, in the long term, will decrease the rate at which FEV_1 declines.
- *Aggressive bronchodilation*. This patient requires maximal bronchodilator therapy. However, the use of β-agonists to achieve this goal must be balanced against the potential of precipitating tachycardia and ischemia in patients with coronary artery disease.
- *Steroid prophylaxis*. Coverage may be appropriate if the patient has been on long-term steroid therapy within the past year.
- *Physiotherapy education*. He will require aggressive chest physiotherapy postoperatively to minimize the risk of pulmonary complications. Early patient education and involvement will improve compliance and outcomes.

What Investigations Would You Like Prior to Induction?

- *Chest X-ray*. Pulmonary imaging will establish the degree of hyperinflation and can help determine whether bullae are present. Given the increased risk of postoperative pulmonary complications in patients with COPD, a preoperative chest X-ray also provides a useful baseline comparison.
- *Arterial blood gas*. Establishing the degree of hypoxemia and whether the patient is a CO_2 retainer is essential to the intraoperative and postoperative management of patients with COPD.
- *Echocardiogram*. On clinical history, physical examination, or electrocardiogram, any evidence of pulmonary hypertension or right ventricular dysfunction warrants echocardiographic evaluation.

How Would You Provide an Anesthetic for This Case?

- *Monitors*. In addition to the standard monitors (electrocardiogram, noninvasive blood pressure, pulse oximetry, capnography, agent detector), this patient will need an arterial line to monitor both respiratory status and hemodynamic stability. A central line may be useful to gauge fluid status as well as right ventricular function.
- *General* vs. *regional*. Although a sole regional technique may be considered, this may be poorly tolerated (for both surgeon and patient) when a large laparotomy is planned. When a general anesthetic is required, use in conjunction with epidural anesthesia and analgesia will minimize postoperative pulmonary complications.
- *Ventilation*. Given the high degree of expiratory airflow obstruction as well as the risk of lung injury, the ventilatory goals are low airway pressures, low I/E ratios, and low respiratory rates. PEEP should be minimized.
- *Facilitate early extubation*. Postoperative respiratory depression must be avoided. Use short-acting agents. Fully reverse muscle relaxation. Consider TIVA over inhalational agents for maintenance of anesthesia. Patients must be aggressively warmed.
- *Postoperative care*. This patient requires optimal pain management. This is ideally achieved with an epidural analgesia and opioid-sparing adjuvant medications. He will also require observation in either a monitored unit or the intensive care unit.

The patient suddenly becomes hypotensive 15 min into surgery. Specific to this patient's medical issues, what are the top differential diagnoses, and what is the definitive management for each?

- *Tension pneumothorax*. Bilateral needle decompression followed by chest tube insertion.
- *Dynamic hyperinflation*. Disconnect the breathing circuit to facilitate full exhalation.
- *Cardiac ischemia*. This may be secondary to pulmonary hypertension or underlying CAD. Inotropes must be initiated to increase the blood pressure. Avoid medications and physiologic states that may worsen pulmonary hypertension and right ventricular failure. Consult cardiology for emergent angioplasty if coronary occlusion is suspected.
- *Use of local anesthetics in the epidural*. Administer a vasoconstrictor in conjunction with a small fluid bolus.

Thoracic Surgery in the Elderly

32

Maria D. Castillo, Jeffrey Port, and Paul M. Heerdt

Key Points

- As the population ages, increasing numbers of elderly patients will present for thoracic surgery.
- Physiologic changes that occur with advanced age result in a decline of maximal reserves, affecting the patient's ability to cope with the stress of surgery. Increased age is also associated with an increase in the number of comorbidities.
- Elderly patients with cancer may still stand to benefit from surgery, since survival rates for lung and esophageal cancer are very low without surgical resection.
- Perioperative morbidity and mortality is more closely associated with preoperative health status and tumor stage than chronological age.
- Minimally invasive surgical techniques such as video-assisted thoracoscopic surgery (VATS) have been shown to be an effective approach for surgical resection of cancer.
- Because better postoperative pulmonary function, less postoperative pain, and fewer complications were shown for patients who underwent VATS compared to those who underwent thoracotomy for lobectomy, VATS may be a good choice for patients of advanced age due to their decreased physiologic reserves.
- Careful preoperative assessment and postoperative care are essential in this surgical population due to their diminished ability to handle the stress of surgery.

Introduction

Demographic projections indicate that by the year 2030, the number of US citizens over the age of 65 will exceed 70 million, with those over 80 years of age comprising about 5% of the total population [1]. Currently, centenarians are the fastest growing segment of the population, a phenomenon that underscores the public health issues presented by an aging citizenry [1–3].

Lung cancer, the major reason for most thoracic surgery and the primary focus of this chapter, is particularly prominent in the elderly. As such, anesthesiologists are increasingly presented with the task of caring for patients exhibiting not only the normal physiological changes associated with aging but also a wide range of age-related comorbidities. In that fundamental aspects of preoperative evaluation, anesthetic pharmacology, and postoperative management are reviewed in other sections, this chapter shall primarily focus on the cardiopulmonary and hepatorenal ramifications of aging, the impact of aging on the thoracic surgical population, the risk–benefit relationship of thoracic surgery for the treatment of cancer in the elderly, and the emerging role of minimally invasive surgical techniques.

Physiology of Aging

Appreciation of the fact that the elderly population is expanding in both size and range underscores the importance of understanding the physiology of senescence. Ultimately,

perioperative management of the elderly thoracic surgical candidate is often more complex than that of younger patients due to both the physiologic changes associated with advanced age and the increased incidence of comorbidities, particularly cardiovascular pathology and chronic obstructive pulmonary disease (COPD). In general, as people age, their maximal physiologic reserves decline, potentially limiting their ability to respond adequately to the stress presented by a major operation or acute illness. Functionally, elderly patients may experience symptoms indicative of pathology that are blunted or diminished in intensity, are atypical, or may be misdiagnosed as simply due to "old age" [4].

Cardiovascular

A variety of molecular and structural changes occur within the aorta, myocardium, and cardiac conduction system that are, at least in part, interrelated and adaptive within certain limits [5–7] (Table 32.1). For example, aging is associated with an increase in left ventricular (LV) afterload due to an increase in the stiffness of large elastic arteries and the resultant increased pulse wave velocity. Advanced age is also associated with increased LV mass secondary to myocyte hypertrophy, myocardial fibrosis, and valvular sclerosis and calcification. Vascular stiffness occurs secondary to the breakdown of elastin and collagen. Accompanying these structural changes are subcellular alterations in myocyte calcium cycling that allow the ventricle to maintain tension against the increased afterload for a longer period of time [6]. However, while this adaptation can be beneficial under some conditions, it can be maladaptive in others, such as tachycardia, when delayed relaxation can impede chamber filling. Superimposed on the direct changes that occur in the heart and circulation is a dampening of homeostatic reflexes that can serve to amplify the functional impact of an age-related decline in cardiovascular reserve [6].

Table 32.1 Cardiovascular changes with aging

Cardiac	Left ventricular hypertrophy – increased mass and decreased compliance
	Increased fatty infiltration, fibrosis, amyloid, and altered collagen cross-linking
	Increased risk of conduction defects
	Increased stroke work
	Slower myocardial relaxation (decreased lusitropy)
Vascular	Increased characteristic impedance and peripheral vascular resistance
	Increased incidence of coronary artery disease, plaques, calcified lesions, and fixed stenoses
	Decreased arterial elasticity with increased pulse pressure
	Aortic dilation with decreased compliance and higher wall tension
Reflex regulation	Decreased baroreceptor sensitivity
	Diminished myocardial chronotropic and inotropic response to catecholamines
	Decreased maximal cardiac output and heart rate
	Decreased autonomic control of peripheral vascular resistance

Adapted from Castillo and Heerdt [7]

Pulmonary

In general, the aging process is associated with alterations in the lung parenchyma, the chest wall "bellows" function, and central regulation of respiration (Table 32.2). Not surprisingly, respiratory complications are a major cause of morbidity and mortality after thoracic surgery. However, risk generalizations regarding the elderly population are difficult due to wide differences in functional status, largely reflecting the overlay of pathologic changes (i.e., COPD)

Table 32.2 Respiratory changes with aging

Structural	Decreased number of alveoli
	Decreased number of lung capillaries
	Decreased elastic recoil, causing easier collapse of peripheral airways
	Decreased airway size
	Decreased alveolar–capillary surface area
	Decreased negative intrapleural pressure
	Weakening of respiratory muscles
	Stiffer chest wall due to fibrosis and calcification
Secretory and immune	Less efficient mucociliary transport
	Less sensitive protective airway reflexes
	Diminished delayed-type hypersensitivity response to foreign antigens
	Increased response to autologous antigens
	Decreased polymorphonuclear leukocyte function
Central regulation	Blunted ventilatory response to hypoxia
	Blunted ventilatory response to hypercarbia
	Increased periodic breathing during sleep
Functional manifestations	Increased functional residual capacity (FRC)
	Increased air trapping
	Decreased forced expiratory volume exhaled in 1 s (FEV1)
	Decreased forced vital capacity (FVC)
	Decreased diffusing capacity
	Decreased venous blood oxygenation
	Increased closing capacity
	Decreased maximal voluntary ventilation (MVV)
	Increased work of breathing
	Widened alveolar–arterial gradient for oxygen
	Increased dead space fraction
	Increased ventilation–perfusion mismatch
	Increased propensity for infection
	Decreased resting PaO_2

Adapted from Castillo and Heerdt [7]

on basic age-related changes. Thus, functional status clearly determines perioperative risk more than age alone [4]. Nonetheless, all elderly patients – regardless of functional status – will exhibit structural, secretory, and regulatory changes that can affect both ventilation and respiration [7, 8]. The integration of these changes with perioperative events can impact even short-term outcomes. For example, if an 80-year-old begins to shiver in response to hypothermia following a thoracotomy, the ability to compensate for increased carbon dioxide production is dampened intrinsically by reduced responsiveness of the central nervous system to drive ventilation coupled with impaired chest wall mechanics and alveolar gas exchange. Superimposed on these effects are the extrinsic effects of opiates to further depress central responsiveness and the added mechanical deficit imposed by thoracotomy. Ultimately, the patient is placed at increased risk of developing significant hypercarbia.

Hepatorenal

Aging produces progressive changes in the liver and kidneys (Table 32.3) that can have a profound effect on drug metabolism and clearance [5]. By the age of 80 years, liver size decreases by as much as 40%, and renal tissue mass has decreased by 30% [9]. At the same time, age-related changes in the perfusion patterns of organs in the body result in decreased blood flow to the liver and kidneys [9]. Ultimately, the decrease in size and perfusion of the liver can affect the plasma clearance of opiates, barbiturates, benzodiazepines, propofol, etomidate, most nondepolarizing relaxants, and other drugs metabolized by the liver [5]. Tissue atrophy and reduced renal blood flow result in decreased glomerular filtration rate, creatinine clearance, renal functional reserve, responsiveness to antidiuretic hormone, and increased susceptibility to renal ischemia and acute renal failure. These age-related changes result in the prolongation of the elimination half-time of drugs and metabolites requiring renal clearance. As people age, there is also increasing variability in individually calculated pharmacokinetic parameters, such that the clearance of drugs may vary greatly among elderly patients [10].

Table 32.3 Hepatorenal changes with aging

Hepatic	Decreased liver size
	Decreased perfusion
	Decreased synthetic and metabolic capacity
Renal	Decreased renal tissue mass
	Decreased perfusion
	Decreased glomerular filtration rate and functional reserve
	Decreased creatinine clearance
	Decreased response to antidiuretic hormone
	Decreased ability to conserve sodium or concentrate urine
	Increased number of nonfunctional glomeruli
	Increased susceptibility to renal ischemia and renal failure

Nervous System

As with other aspects of senescence, cognitive function shows a great deal of variation in terms of baseline deficit and reserve. Recent data have highlighted the association between postoperative delirium and long-term outcome, underscoring the concept that even short-term cognitive impairment may reflect more systemic deficits. While there are considerable data regarding postoperative delirium in cardiac surgical patients subject to microembolic insults to the brain as the result of manipulation of the heart and aorta [11], other reports have focused on implications in noncardiac surgical patients. Robinson et al. [12] published a study of 144 patients over the age of 50 – of which over half underwent noncardiac thoracic surgery – that found a 44% incidence of delirium when a series of functional and cognitive assessments were carefully applied. The average time to onset was 2.1 ± 0.9 days with a duration of 4.0 ± 5.1 days. Risk factors included increasing age, hypoalbuminemia, anemia, intraoperative hypotension, history of alcohol abuse, and comorbid conditions, along with pre-existing dementia and impaired functional status. Importantly, the presence of delirium was associated with an increased length of hospital stay, a higher incidence of post-discharge institutionalization, and a higher 6-month mortality.

Aging and the Thoracic Surgical Population

Although cancer can occur at any age, it disproportionately strikes the elderly. Cancer is the leading cause of death among people aged 60–79 and the second leading cause of death in those aged 80 and older [2]. Data indicate that persons older than 65 have a 9.8-fold increased incidence of cancer compared with those younger than 65 [3], and the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) Program revealed that 56% of all newly diagnosed cancer patients were over 65 years of age [1]. Consistent with the overall aging of the population and the trend toward increasing age at the time of cancer diagnosis is an increase in the absolute number of elderly patients presenting with potentially resectable malignancy. For lung cancer in particular, the median age of patients presenting for surgical resection is now in excess of 70 years [2].

Other factors are also increasing the number of aged patients undergoing surgical treatment. For example, projections suggest that the incidence of lung cancer in women will soon equal that of men with a presumptive increase in the

number of elderly women presenting for lung resection [13]. Similarly, neoadjuvant chemotherapy and radiation in patients with locally advanced stage III non-small cell lung cancer (NSCLC) are expanding the range of patients who are candidates for surgical resection. Support for this trend can be found in studies that demonstrated a significant survival advantage in patients undergoing preoperative chemotherapy followed by surgery compared to those undergoing surgery alone [14–18]. Emerging data suggests that even elderly patients who receive neoadjuvant therapy for esophageal cancer do not have significantly increased mortality or major complications after esophagectomy despite the insult of both laparotomy and thoracotomy [19].

The Risk-Benefit Relationship of Surgical Intervention in the Elderly

Surgical resection remains the treatment of choice for early-stage lung cancer, yet several reports have presented variable results for resection in the elderly. Based on these data and the fact that the elderly will present with significant comorbidities, clinicians have traditionally offered less aggressive treatment to this group, with some even recommending a nonoperative approach or less than an anatomic resection. However, advances in perioperative care and in surgical technique have now encouraged many to offer surgical resection to the aged population. Ultimately, the fundamental question for many patients is how the risk of surgery compares to that of other interventions or no intervention at all. Current data indicate that at initial diagnosis elderly patients tend to have earlier stage lung cancer than younger patients [20]. In addition, they tend to have a higher incidence of squamous cell lung cancers with a clinically reduced growth rate and metastatic potential. Nonetheless, these data need to be interpreted in the context of operative risk and what "long term" may mean to an 85-year-old.

Age-Related Perioperative Morbidity and Mortality

For patients aged ≥70, Birim et al. [21] concluded from a retrospective study that operative morbidity and mortality are low enough to justify pulmonary resection for cancer. In this population, surgery was associated with a hospital mortality rate of 3.2% (relative to the common rate of ~1.5% reported for patients less than 65) along with minor and major complication rates of 51 and 13%, respectively, the most frequent events being arrhythmia (31%) and air leak lasting >5 days (21%). Five- and 10-year survival rates were 37 and 15%, respectively, with smoking, COPD, and pathologic stage significant risk factors in overall survival. In patients aged 80 and older, data from The Lung Cancer Study published in 1983 indicate that rates of complication and mortality for octogenarians are substantially higher than for the under 65 group (mortality rate of 8.1 vs. 1.6%) [22]. However, more recent studies suggest improvement in the results of lung resection in octogenarians [23–36]. In 1998, the Japanese Association of Chest Surgery reported a mortality rate of only 2.2% in a sample of 225 octogenarians undergoing lung cancer resection [37], while other series [27–36, 38–43] found a mortality of less than 5% (Tables 32.4 and 32.5). Results of a retrospective cohort study of 68 octogenarians with NSCLC who underwent lung resection reinforced that health status and tumor stage are more important than chronologic age with regard to outcome and survival rate [41]. In this study, ASA classification, forced expiratory volume in 1 s (FEV1) of less than 1.5 L, and stage of disease were strong, independent predictors of long-term survival. Similarly, in a study of octogenarians who were offered surgical resection, the mortality was 1.6% and overall 5-year survival for stage 1a patients was 82% [42]. Miyazaki and colleagues reported a series of five cases of pulmonary resection for lung cancer in carefully selected nonagenarians. Each patient survived the perioperative period, with two of the five experiencing minor complications. One patient died of a fatal arrhythmia, one patient had a local recurrence of tumor, and the remaining patients survived throughout the follow-up period [43]. Somewhat surprisingly, several recent studies of patients undergoing esophagectomy for esophageal cancer report that outcomes for elderly patients, including mortality, postoperative complications, and long-term results, are also similar to those for younger patients [45–50].

Risk and Oncological Outcome

Compared to a younger patient, an elderly person may value different goals of therapy. As the risks of surgical intervention increase along with severity of comorbid conditions, the patient's priorities may shift. Long-term survival may become less important than relief of symptoms, quality of life, and maintaining level of functioning. Accordingly, elderly patients may be less inclined to accept the risks of a major surgery, even if it might be curative, in favor of less invasive alternatives [4]. However, there being such variation in functional status among elderly patients, major surgical procedures that are potentially curative may be perfectly reasonable for many patients particularly when considered in light of data suggesting that average life expectancies for 70-year-old men and women are currently an additional 14.4 and 16.6 years, respectively. For 85-year-old men and women, they may expect an additional 5.9 and 7.0 years, respectively, and even the 100-year-old person may expect an additional

2 years of life, on average [51, 52]. Nonetheless, with increasing age, the absolute gain in life expectancy from surgical treatment clearly diminishes. However, the life expectancy among patients with lung cancer that is not surgically managed is so low that resection for an 85-year-old patient may still result in an appreciable prolongation of life. For example, impression that the life expectancy of an octogenarian with lung cancer is limited by death from natural causes is not supported by the US census data. In fact, the average life expectancy for an 80-year-old living in the United States is now an impressive 8.6 years. This translates into an overall 5-year survival for an age-matched population of 80%, as calculated from life tables. Furthermore, the majority of this time is anticipated to be years of active and independent life. Given these facts, it seems likely that the greatest impact on an elderly patient's survival and quality of life would be their cancer-related mortality rather than their age. This prospect is highlighted by the results of a retrospective review of 49 patients with early stage disease who either refused surgery or whose comorbid conditions rendered surgery unreasonable and experienced a survival time of only 14 months [53]. A meta-analysis of patients enrolled in trials for computed tomography screening that did not receive surgical therapy for their stage I disease produced similar findings [54], and a study of elderly subjects with stage I and II NSCLC receiving radiation alone revealed 2- and 5-year survival rates of only 40% and 16%, respectively [55]. On the whole, these data indicate that early stage lung cancer is a fatal disease and suggest that for patients with lung cancer who are over 80 years old, the majority of deaths will be related to the progression of lung cancer rather than other causes.

The Emerging Role of Minimally Invasive Surgical (MIS) Techniques

In that there is an association between the magnitude of pulmonary resection and postoperative complications in elderly subjects, some surgeons advocate "less invasive" lung-sparing techniques such as wedge resection and segmentectomy for the treatment of pulmonary malignancy whenever possible [56]. While controversy exists as to whether these procedures, which still involve at least a limited thoracotomy, carry a higher risk of local recurrence, Mery et al., using data from the SEER database, found that, among patients age 75 or older, there was no difference in overall survival time between patients undergoing lobectomy and those undergoing limited resection [20].

Both the scientific literature and lay press contain a wide variety of publications relating to VATS as a truly "minimally invasive" approach to the treatment of lung cancer and as an adjunct in the treatment of esophageal cancer. Published data suggest that relative to thoracotomy, VATS patients experience shorter chest tube duration, shorter postoperative hospital stays, lower narcotic requirements for postoperative pain, and reduced shoulder dysfunction [57]. Similarly, patients who had VATS lobectomy reported less postoperative pain, decreased time until return to preoperative activities, and higher satisfaction with the results of surgery than those patients undergoing conventional thoracotomy [58]. In addition, there was a lower observed incidence of postoperative confusion [59], which has been associated with increased postoperative morbidity and mortality. VATS lobectomy patients also appear to return to their oncologists for adjuvant chemotherapy more readily. A recent review of 1100 VATS lobectomies with either lymph node sampling or dissection for patients with a mean age of 71.2 years demonstrated low rates of mortality (<1%) and morbidity, with 84.7% of patients exhibiting no significant complications [39]. For esophagectomy, several minimally invasive approaches have been developed, including those incorporating thoracoscopy and/or laparoscopy into a typical three-stage Ivor Lewis operation, approaches incorporating laparoscopy for a transhiatal approach, and those incorporating robotics. Emerging data support the oncological efficacy of these approaches [60, 61]. Galvani et al. reported experiences with robotically assisted laparoscopic transhiatal esophagectomy, suggesting that this approach is safe and effective [62].

Despite favorable perioperative outcome data, questions remain as to whether lobectomy via thoracotomy and VATS are equivalent therapeutic interventions for cancer. However, a series of 159 VATS lobectomies for stage I and II NSCLC revealed long-term outcomes and local recurrence rates that were at least equivalent to those of open thoracotomy [63], and a prospective, randomized trial of 100 patients with stage IA NSCLC concluded that long-term survival and local recurrence rates after VATS lobectomy were comparable to those for open thoracotomy [64]. Another study actually reported better 5-year survival rate of stage I lung cancer after VATS vs. thoracotomy perhaps due in part to superior postoperative pulmonary function [65]. Several other studies reported similar outcomes [66–69]. For the geriatric population, a retrospective study of 32 lobectomy patients aged 80 years or older (17 VATS, 15 thoracotomies) also demonstrated better 5-year survival following VATS [70]. A recent review of our own data related to VATS lobectomy in octogenarians revealed patients had a significantly decreased length of ICU and hospital stay as well as a decreased complication rate when compared to those who underwent open thoracotomy [29]. Interestingly, significantly fewer patients required discharge to a formal rehabilitation center and were discharged to home.

To date, most large reports show that across all age groups, VATS for lobectomy is safe, with morbidity rates in some reports lower than seen historically with thoracotomy. Other data suggest that pulmonary function as measured by vital capacity and FEV1 may be better preserved in patients undergoing VATS rather than thoracotomy [65]. Kirby et al. [71] reported that, while they found no difference in intraoperative time, blood loss, or length of hospital stay between patients who underwent VATS vs. thoracotomy, the thoracotomy group did experience significantly more postoperative complications, most notably prolonged air leaks.

The prospect of superior pulmonary function following VATS relative to thoracotomy has particular significance in the elderly population. To determine if the VATS approach for lobectomy offers specific advantages over thoracotomy in the elderly, retrospective studies have compared the two in aged patient populations. Jaklitsch reported that VATS procedures for patients ≥65 years of age resulted in superior 30-day operative mortality, which was essentially unrelated to age, and a decreased length of hospital stay compared to previous reports for standard thoracotomy [59]. More recently, Cattaneo et al. analyzed the incidence and grade of postoperative complications in patients ≥70 years of age undergoing a VATS approach vs. a thoracotomy for lobectomy [72]. The two groups were identically matched for age, gender, comorbidities, and clinical stage. This study found that VATS resulted in a lower overall complication rate, less pulmonary morbidity, and a decreased median length of stay. In addition, the severity of complications were less in the VATS group, suggesting that the minimally invasive approach can lead to better tolerance in a high-risk, elderly population.

Whether there are cardiovascular benefits to VATS lobectomy remains unclear. Multiple studies have established the relationship between age and the occurrence of atrial fibrillation following lobectomy, with recent data indicating an incidence of 27% in patients over the age of 60 when continuous

telemetry is used for diagnosis [73]. Two large series have reported lower than expected rates of postoperative atrial fibrillation following VATS lobectomy relative to thoracotomy, ranging from 2.9% to 10% [38, 39]. However, neither study used routine postoperative telemetry in the highest risk patients, i.e., elderly patients, and likely underreported asymptomatic episodes of atrial fibrillation. In contrast, a matched, case-control study by Park et al. comparing 244 patients undergoing lobectomy by either VATS or thoracotomy [74] showed no difference in the rate of postoperative atrial fibrillation with VATS patients exhibiting a 12% rate of postoperative atrial fibrillation compared to 16% for thoracotomy patients (p = 0.36). Predictably, in both groups patients experiencing atrial fibrillation were significantly older (median 72 years) than those who did not develop the arrhythmia (median 66 years).

Preoperative Evaluation and Postoperative Care

Although the fundamentals of preoperative evaluation outlined elsewhere in the text remain appropriate, aspects of perioperative assessment and planning take on increased importance and/or require different interpretation in the elderly.

Preoperative Assessment

Current guidelines developed by the American College of Chest Physicians for preoperative assessment of patients considered for thoracic surgery begins with a physical exam combined with cardiovascular evaluation and spirometry [75]. Given the lung parenchymal changes associated with aging and propensity for obstructive physiology, measurement of diffusion capacity (DLCO) is important, particularly for patients with clinical signs of dyspnea out of proportion to the spirometry results. In patients with an FEV1 or DLCO <80% of predicted – a relatively common finding in the elderly – estimated postoperative FEV1 and DLCO values should be calculated as described in Chap. 2. Estimated postoperative values for either variable of <40% is a significant negative predictor of outcome in all patients and may be even more relevant in the aged due to the expected changes in intrinsic pulmonary reserve associated with senescence. Importantly, results need to be interpreted in the context of a patient's clinical presentation; a low FEV1 in a patient with a large left main stem bronchus tumor should be regarded differently than a patient who has a similarly low value and a small peripheral lesion.

Guidelines suggest that further definition of a patient's risk with cardiopulmonary exercise testing and estimation of maximal oxygen consumption (VO_2 max) is often valuable. A VO_2 max <15 mL/kg/min is a negative predictor for outcome. If cardiopulmonary exercise testing is not available, other surrogates can be performed and include stair climbing, shuttle walk, and the 6-min walk. If a patient cannot climb one flight of stairs or perform 25 shuttles, usually their VO_2 max will be <10 mL/kg/min. However, while exercise testing is a potentially powerful tool, it is not always applicable in the geriatric population due to the presence of comorbidities such as arthritis or peripheral vascular disease that limit mobility independent of VO_2 max.

In the elderly population, it is also important to identify factors such as dementia, undernutrition, thromboembolic disorders, subclinical diabetes, thyroid disorders, and renal insufficiency. For many patients, perioperative risk can be reduced by modest exercise along with nutritional and hormonal optimization. However, unlike recommendations published nearly 20 years ago suggesting 8 weeks of optimization prior to surgery [76], in the current environment, and in the setting of progressive malignancy, the time available for meaningful preoperative optimization is often quite short.

Postoperative Planning

In the absence of severe pre-existing critical illness or profound intraoperative complications, diagnostic and staging procedures such as bronchoscopy, cervical mediastinoscopy, and potentially even minimally invasive wedge biopsies may be performed as outpatients, even in elderly patients. Following VATS or open lobectomy and even pneumonectomy, elderly patients generally are candidates for standard admission to postoperative acute care units [77]. Alternatively, after more extensive procedures such as bilobectomy, esophagectomy, or resection of a large or adherent mediastinal mass, ICU admission is often desirable due to the increased potential for major respiratory and cardiovascular postoperative complications.

It is also important to consider discharge planning even during the initial preoperative visit in the elderly population. For example, it is necessary to consider who will be providing support for the patient following discharge and where this care will take place. Many patients who are entirely self-sufficient preoperatively may not be able to care for themselves for a period of time postoperatively, and as such, early discharge planning becomes critical.

Conclusion

As the population ages, increasing numbers of elderly people will present with lung cancer. Due to recent advances in neoadjuvant therapies and accumulating data demonstrating a

favorable risk–benefit relationship even in octogenarians, more of these geriatric patients will be surgical candidates. Within this aged population, there are often wide disparities between chronologic age and physiologic condition, which is underscored by data indicating that outcome is influenced more by tumor stage, preoperative functional status, and comorbidities than age alone. Nonetheless, the normal process of cardiopulmonary aging can serve to limit the physiological reserve necessary to compensate for perioperative stress even in otherwise healthy elderly patients. Emerging experience now also suggests that minimally invasive surgical techniques for the treatment of lung cancer may parallel conventional thoracotomy in terms of oncologic efficacy while decreasing perioperative morbidity in the elderly. Accordingly, for anesthesiologists, the future may hold the prospect of caring for very old, ill patients undergoing minimally invasive thoracic surgery.

Clinical Case Discussion

Case An 84-year-old male presented with a left lung mass on a chest radiograph obtained during evaluation for right total knee replacement. Transthoracic biopsy was performed, and the mass was found to be non-small cell lung carcinoma (NSCLC). Imaging studies revealed hilar adenopathy, and lymph nodes obtained from the left chest by mediastinoscopy were positive for NSCLC leading to disease classification as stage IIIA. He subsequently underwent induction chemotherapy. Recent evaluation shows a decrease in size of the mass and regression of hilar adenopathy.

The patient is now scheduled for VATS resection of the left upper lung lobe. His medical history is otherwise notable for past smoking (none for 20 years), daily alcohol consumption (2–3 glasses of wine), hypertension (controlled), hypercholesterolemia, and severe osteoarthritis of the right knee (he had previously undergone left total replacement at age 78). Preoperative evaluation has been remarkable for anemia (hematocrit 33%), mild COPD, and a dobutamine stress echocardiogram negative for ischemia (mobility limited by knee pain and instability). On physical exam, he appears fit and vigorous but limited to a wheelchair when walking more than a block due to knee instability. He states that his plan is to proceed with knee replacement surgery following recovery from the lobectomy.

Questions

1. Is lung resection an acceptable approach for this patient from a physiological perspective?
2. Is left upper lobe lobectomy an acceptable procedure for this patient from an oncological standpoint?
3. What types of complications might this patient be at risk of developing?
4. What are some possible advantages of performing this procedure using video-assisted thoracoscopy?

Discussion

1. While this patient may appear to be fit and vigorous at baseline, all elderly patients have altered physiology as a consequence of aging. Thus, the stress of surgery may unmask these decreased functional reserves. For example, this patient may exhibit diminished maximum voluntary ventilation in response to the carbon dioxide load created by shivering, thus putting him at increased risk for hypercarbia in the postoperative period. Other alterations in respiratory function associated with aging, such as decreased PaO_2, decreased DLCO, and increased ventilation–perfusion mismatch, may increase the patient's risk of hypoxia.

Although this patient's dobutamine stress echocardiogram was negative for ischemia, his advanced age suggests that he has some degree of LV hypertrophy and slower myocardial relaxation, which could negatively affect cardiac filling in the setting of tachycardia, for example.

These changes should be kept in mind during the perioperative period. However, a patient with good functional status, even an 84-year-old, can undergo this procedure safely.

2. Lung cancer is a fatal disease, with an estimated 5-year survival rate of 16% without surgical resection. Thus, a patient with good functional status stands to gain survival time if his stage I lung cancer is resected, even at an advanced age. This patient underwent induction chemotherapy for stage IIIA cancer, which caused regression of his adenopathy and decreased tumor size. Recent studies suggest that such patients stand to benefit from lung resection after chemotherapy, experiencing increased survival time.
3. Any patient undergoing lobectomy is at risk for cardiovascular and respiratory complications. Arrhythmias such as atrial fibrillation are among the most common complications, but myocardial ischemia and bleeding may also occur. Pneumonia and respiratory failure, prolonged air leak, bronchopleural fistula, and empyema are also possible risks in the setting of pulmonary surgery. However, preoperative health status, a history of COPD or smoking, and tumor stage all seem to contribute to outcome more than chronological age does.
4. VATS may result in better outcomes than thoracotomy. Recent data suggest that patients who underwent VATS as compared to patients who underwent thoracotomy

experienced shorter hospital stays, less postoperative pain, less postoperative confusion, decreased time to return of preoperative activities, and higher satisfaction with the results of surgery. Several studies have reported decreased postoperative complication rates with the use of VATS rather than thoracotomy for lobectomy, which may be related to better preserved pulmonary function following minimally invasive surgery. Mortality rates were also significantly better for patients who underwent VATS, regardless of age.

Thoracic Anesthesia for Morbidly Obese Patients and Obese Patients with Obstructive Sleep Apnea

33

George W. Kanellakos and Jay B. Brodsky

Key Points

- A patient with a BMI >30 kg/m^2 is considered obese. A patient with a BMI >40 kg/m^2 is morbidly obese (also known as Obesity Class III). Super-obesity refers to a patient with a BMI >50 kg/m^2.
- Morbid obesity (MO) is associated with medical conditions, including hypertension, type II diabetes mellitus, cardiovascular disease, obstructive sleep apnea (OSA), and obesity hypoventilation syndrome (OHS).
- Moderate to severe OSA is present in more than 50% of MO patients and is often unrecognized. The best screening tool for identifying patients with OSA is the STOP-Bang questionnaire. In the absence of a definitive diagnosis by polysomnography (PSG), all MO patients should be managed as if they have OSA.
- Anesthesiologists should have a high index of suspicion for the presence of OHS. Patients with OHS have a greater risk of cardiovascular problems and pulmonary hypertension.
- Preoperatively, treatment with continuous positive airway pressure (CPAP) can significantly improve OSA symptoms. The patient should bring their CPAP equipment to the hospital for use during their postoperative recovery.
- Many MO patients are difficult to ventilate by mask, but tracheal intubation by direct laryngoscopy is usually successful.
- The best preoperative predictors of potential problems with tracheal intubation in MO patients are high Mallampati (III or IV) score and increased neck circumference (>48 cm men, >40 cm women).
- A supine obese patient should not be allowed to breathe without assistance. All MO patients should be positioned in the "head-elevated laryngoscopy position" (HELP) prior to induction of anesthesia.
- Depressant medications should be avoided preoperatively as they can decrease ventilatory responsiveness to hypoxemia and hypercarbia and can cause airway collapse in the presence of OSA.
- Regional anesthesia techniques should be used when possible, including epidural or paravertebral analgesia for thoracic procedures.
- Obese patients are not at increased risk for gastric aspiration, and therefore rapid sequence induction is usually unnecessary.
- MO patients tolerate one-lung ventilation (OLV) in the lateral position but are unlikely to tolerate it in the supine position.
- For MO patients lean body weight (LBW) should be calculated for dosing of induction and opioid agents, IBW for non-depolarizing neuromuscular agents, and TBW for succinylcholine.
- MO patients can develop rhabdomyolysis (RML) after long-duration procedures. Any associated myoglobinuria can lead to acute renal failure. RML is treated by aggressive IV fluid administration.

Table 33.1 Modified World Health Organization body mass index (BMI) classification

BMI (kg/m^2)	Classification
Below 18.5	Underweight
18.5–24.9	Normal weight (Ideal body weight)
25.0–29.9	Pre-obesity (overweight)
30.0–34.9	Obesity Class I (obese)
35.0–39.9	Obesity Class II (obese)
Above 40	Obesity Class III (morbid obesity)

those with morbid obesity (MO), can be especially challenging. Throughout the world, obesity levels over the past two decades have reached epidemic levels [1]. Extremely obese patients now routinely present to the operating for surgery [2]. MO patients differ from their normal-weight counterparts due to alterations in their anatomy and physiology [3]. They often have significant comorbid medical conditions that can complicate their operative course and increase the risks of postoperative problems. Obstructive sleep apnea (OSA), which is very common in obesity, further contributes to the complexity of managing these patients.

Obesity is usually described by body mass index (BMI). BMI is calculated by dividing patient weight in kilograms (kg) by the square of their height in meters (m), expressed as BMI = kg/m^2. BMI is an indirect estimation of obesity since it considers any increase in weight, not just increases in adipose tissue. Obesity definitions have changed over the years. The current BMI categories are listed in Table 33.1 [4]. Based on these definitions, more than one third of American adults are obese (BMI >30 kg/m^2), and almost 5% are MO (BMI >40 kg/m^2) [5]. The population with extreme weight has been increasing fastest [6, 7], and a new BMI category termed super-obesity is now used to describe larger patients (BMI >50 kg/m^2).

This chapter will describe the perioperative anesthetic considerations for the obese thoracic surgical patient. To date a limited number of reviews on this topic have been published [2, 8]. Most recommendations for obese patients undergoing thoracic surgery are derived from studies of patients undergoing other types of surgery, particularly weight loss operations.

Preoperative Considerations

A thorough preoperative assessment is indicated for every surgical patient. For the MO patient, the anesthesiologist must consider the associated comorbid conditions associated with extreme obesity (including hypertension and cardiovascular disease, type II diabetes, OSA and OHS, osteoarthritis), in addition to the medical indication for surgery. The specific preoperative management of each of these medical comorbidities is beyond the scope of this chapter, and the reader is referred to reviews on the subject [3, 9, 10].

Weight

Preoperative documentation of the MO patient's height and weight is extremely important for optimal pharmacologic management. Anesthetic drugs are usually administered by patient weight, either total body weight (TBW), ideal body weight (IBW), or lean body weight (LBW). Clinical trials during drug development usually have not included obese and MO subjects, so drug dosing in these patients based solely on actual or TBW can lead to overdosing, complicating perioperative management.

IBW is a measure initially derived by life insurance companies in the 1940s to describe the weight for a man or woman of a specific height that was statistically associated with maximum life expectancy. Accepted values for IBW have increased over the past seven decades since patients are now living longer despite significant increases in their average weight. In normal-weight patients TBW approximates IBW, that is, "normal" weight ranges between ± 10% of IBW. For drug dosing IBW can be estimated for both men and women using the formula, IBW = 22 × (height in meters)^2 [11].

LBW includes the weight of muscles, bones, tendons, ligaments, and body water. It is equal to actual weight (TBW) minus the weight of fat. LBW in nonobese patients should be about 80% TBW for males and 75% TBW for females. LBW and TBW both increase as a patient gets heavier since there are increases in the muscle and body water in addition to the much larger increases in adipose tissue. LBW can account for as much as 20–40% of the excess TBW [12, 13]. LBW is difficult to measure clinically, but it can be calculated by several formulas. Most formulas for LBW fail when applied to the extremely obese population. Equations 33.1 and 33.2 [14] are used to accurately estimate LBW (Fat Free Mass) in obesity:

$$T_o = \frac{Q_o}{D} = \frac{6000}{400{,}000} = 0.015\,\text{years} = 5.475\,\text{days} \tag{33.1}$$

$$T_o = \frac{Q_o}{D} = \frac{6000}{400{,}000} = 0.015\,\text{years} = 5.475\,\text{days} \tag{33.2}$$

For clinical anesthetic drug dosing, LBW can be roughly estimated in a MO patient simply by their IBW + 20–30%.

Pulmonary Function

Excess body fat significantly reduces chest wall and total pulmonary compliance. Airway resistance and work of breathing are increased in the spontaneously breathing MO patient. Preoperatively, spirometry usually reveals a restrictive defect with decreases in functional residual capacity (FRC), mainly expiratory reserve volume (ERV), associated

with small airway collapse during tidal breathing. These changes result in ventilation/perfusion (V/Q) mismatch, an elevated shunt fraction, and relative hypoxemia [15].

Preoperative pulmonary function testing has been used to predict which patients can safely tolerate lung resection [16, 17]. The minimum values of at least 40% FEV_1 and 40% diffusion capacity may not be useful in the MO patient since these measurements are not indexed to weight. No predictive baseline spirometry studies for MO patients undergoing lung resection are available. However, as BMI increases, postoperative FEV_1 and FVC values decrease proportionally [18]. For example, following abdominal surgery MO patients experience significantly more atelectasis, greater decreases in FRC, and lower P_aO_2 values than matched normal-weight patients. Therefore, it is very likely, but still unproven, that MO patients also experience greater reductions in pulmonary function following thoracic operations than nonobese patients.

Obstructive Sleep Apnea

OSA is characterized by repetitive collapse of the upper airway during sleep, which results in complete cessation (apnea) or near complete cessation (hypopnea) of airflow. Apnea is defined as a total lack of airflow lasting at least 10 s. Hypopnea is a decrease of ≥50% in airflow or ≤50% decrease for at least 10 s. These events are associated with either arousal from sleep or oxygen desaturation of ≥ 3% [19]. If there is increasing respiratory effort, the apnea is described as "obstructive," whereas in central sleep apnea, there is no breathing effort. Besides snoring, frequent awakenings, and apnea periods during sleep, OSA patients often have a history of daytime drowsiness, morning headaches, irritability, personality changes, depression, cognitive impairment, and visual incoordination. Severe OSA is associated with sleep fragmentation, transient hypoxemia and hypercapnia, large negative intrathoracic pressure swings, and marked elevations in blood pressure [20].

OSA is formally diagnosed by a "sleep study" (polysomnography, PSG). The apnea index (AI) is the number of apneas/hour of total sleep time. The hypopnea index (HI) is the number of hypopneas/hour of total sleep time. The sum of the AI and HI is the apnea-hypopnea index (AHI) [19]. The arousal index (ARI) is the number arousals/hour of total sleep that do not meet the definitions of apneas or hypopneas. The combination of ARI and AHI is the respiratory disturbance index (RDI), a measure that significantly correlates with excessive daytime sleepiness. An AHI >5 in combination with clinical symptoms is diagnostic of OSA.

The prevalence of moderate to severe OSA (apnea-hypopnea index (AHI) ≥15 events/hour) in the general population is 10–20% [21] and as high as 70% in MO patients undergoing bariatric surgery [22]. Another study quotes the rate of OSA in MO patients to be 84% (AHI >5), 47% (AHI >15), and 27% (AHI >30) [23]. There have been many screening tools proposed for identifying OSA. The STOP and STOP-Bang questionnaires [24] are currently used in anesthetic practice. The STOP questionnaire includes four questions related to snoring, tiredness, observed apnea, and high blood pressure. The STOP-Bang questionnaire has four additional demographic questions: BMI, age, neck circumference, and male gender. The published sensitivity and specificity of the STOP and STOP-Bang questionnaires are given in Table 33.2. The probability of OSA being present increases as the STOP-Bang score increases. The ease of use and high level of sensitivity have resulted in the questionnaire being widely used as screening tool in preoperative clinics and is especially useful if a PSG is not obtained.

Table 33.2 STOP and STOP-Bang questionnaires sensitivity and specificity in surgical patients

	STOP questionnaire		STOP-Bang questionnaire	
	Sensitivity (%)	Specificity (%)	Sensitivity (%)	Specificity (%)
OSA (AHI >5)	65.6	60	84	56.4
OSA (AHI >15)	74	53	93	43
OSA (AHI >30)	80	49	100	37

Adapted from Chung et al. [24]

Patients with OSA also have metabolic changes. Intermittent hypercapnia secondary to nocturnal and even daytime obstructive apnea or hypoventilation may lead to elevation in serum bicarbonate levels as a compensatory mechanism for acute respiratory acidosis. Bicarbonate elevation correlates with AHI, and when used in conjunction with the STOP-Bang score, the specificity of the presence of moderate to severe OSA significantly increases [25].

Identifying patients who have OSA has important perioperative implications. Intermittent nocturnal sympathetic activation from hypoxemia and hypercarbia causes systemic hypertension. Recurrent hypoxic pulmonary vasoconstriction eventually results in pulmonary hypertension and right and left ventricular hypertrophy. OSA patients may have a higher rate of complications, including difficult intubation, difficult bag-mask ventilation, cardiopulmonary complications, unexpected reintubation, and ICU admission [26–28].

Continuous positive airway pressure (CPAP) is used to treat moderate to severe OSA. CPAP provides a pneumatic stent that opens the upper airway and maintains its patency. For patients requiring high levels of CPAP or those with chronic obstructive pulmonary disease as occurs in many thoracic surgical patients, bi-level positive airway pressure (BIPAP) is used since it allows for independent adjustment

of inspiratory and expiratory positive airway pressure unlike the fixed single setting for CPAP [29]. OSA patients scheduled for an elective procedure can experience significant improvement in their symptoms if they are begun on CPAP therapy preoperatively. Tongue volume decreases, and pharyngeal space enlarges following several weeks of CPAP, potentially simplifying airway management. Preoperative use of CPAP also improves other medical comorbidities including congestive heart failure, hypertension, and perhaps even pulmonary hypertension.

Since OSA is so common in the MO population, all patients should be presumed to have OSA and be managed within that context. The American Society of Anesthesiologists (ASA) consensus guideline document for the perioperative management of patients with OSA [30] and a recent review by Corso et al. [31] are useful resources for planning the perioperative management of any MO patient undergoing thoracic surgery.

Obesity Hypoventilation Syndrome

OHS patients present with the same symptoms as OSA patients but usually have lower daytime oxygen saturations and more severe pulmonary hypertension. OHS is defined by daytime hypercapnia and hypoxemia (P_aCO_2 >45 mm Hg and P_aO_2 <70 mm Hg) in an obese patient (BMI >30 kg/m^2) who has sleep-disordered breathing in the absence of any other cause of hypoventilation [32]. In its severest form, OHS has been termed "Pickwickian syndrome." In OHS there is a diminished central ventilatory drive despite elevated P_aCO_2. Although OHS is rare in the general population, the incidence is estimated to be between 5% and 10% in MO OSA patients, with the highest occurrence in super-obese patients.

Compared with eucapnic MO patients with sleep-disordered breathing, patients with OHS have higher risk of developing serious cardiovascular disease. Electrocardiographic evidence of right heart strain and hypertrophy is common. A preoperative arterial blood gas sample, preferably with the patient breathing room air, should be obtained. It will establish a baseline and document the degree of P_aCO_2 elevation and the presence of elevated bicarbonate levels. Polycythemia is usually present secondary to chronic hypoxemia, and this further increases an already elevated risk for postoperative pulmonary embolism. Given that the prevalence of extreme obesity in the surgical population has increased considerably, it is likely that clinicians will encounter patients with OHS who are scheduled for thoracotomy. Therefore, maintaining a high index of suspicion can lead to early recognition and treatment reducing the high morbidity and mortality associated with undiagnosed and untreated OHS.

Cardiovascular Function

Absolute blood volume and cardiac output are increased in obesity. The presence of OSA further increases the risks of pulmonary and systemic hypertension. These factors eventually lead to "eccentric" right ventricular hypertrophy, left ventricular hypertrophy, and development of right and left heart failure ("obesity cardiomyopathy") in older MO patients [33]. A routine electrocardiogram is usually adequate for most MO patients, even those with arterial hypertension. However, even in asymptomatic obese patients, some degree of right ventricular dysfunction can be demonstrated by echocardiography. The presence of angina or other cardiac symptoms requires a more thorough cardiac evaluation. In one small study, moderate or severe left ventricular diastolic dysfunction was present in 50% of patients with moderate or severe OSA, while there was no disease in patients with no or mild OSA [34]. Long-standing or severe OSA should alert one to the possibility of pulmonary hypertension and right ventricular failure and prompt preoperative echocardiographic evaluation.

Premedication

Centrally depressant medications can decrease ventilatory responsiveness to hypoxemia and hypercarbia in any obese patient, but in the MO patient with OSA, these drugs also decrease pharyngeal dilator muscle tone and activity causing upper airway collapse. Many anesthetic agents and medications are associated with pharyngeal collapse, including opioids, benzodiazepines, nitrous oxide, thiopental, propofol, and even small doses of neuromuscular blocking agents. Sedatives given preoperatively can have prolonged effects in any MO patient, and when OSA is present they increase the risk of respiratory depression even into the postoperative period. For MO thoracic surgical patients, sedative premedication should be used with caution or preferably avoided completely.

Intraoperative Management

Induction Dosing of Anesthetic Agents

Anesthetic medications should always be dosed according to a per kilogram dosing regimen. It is important to measure the TBW of a MO patient and calculate IBW and LBW. The extra weight in MO patients is made up of both adipose and lean tissue, with adipose increasing at a higher proportion. Because fat has lower blood flow than lean tissue, the plasma concentration of an IV injected drug in a MO patient would rise significantly if the dose was based on TBW.

A dosing regimen that is specific to the physiologic changes present in morbid obesity should be used. Most induction agents and opioids are administered based on LBW. IBW is used to dose non-depolarizing neuromuscular blockers, and TBW is used for succinylcholine [35]. An induction dose of propofol based on TBW would predictably have increased cardiovascular side effects such as hypotension and myocardial depression [36]. LBW is a more accurate dosing scalar in MO subjects for propofol induction.

Patient Position

Unlike normal-weight patients, an awake, spontaneously breathing MO patient should never be allowed to lie flat prior to induction of anesthesia. In the supine position, MO patients experience a further reduction in their already reduced FRC. This can result in dangerous hypoxemia, especially if they are breathing air. Obese patients preoxygenated in sitting position have significantly extended tolerance to apnea after muscle paralysis (longer "safe apnea time," SAT) when compared with similar obese patients preoxygenated in the conventional supine position [37]. Also, in the supine position any decreased venous return from compression of the inferior vena cava by increased abdominal pressure can cause hypotension.

MO patients should always be positioned prior to anesthetic induction so that their upper body and head are elevated to a point that their sternum and ear are aligned in a horizontal line (otherwise referred to as "head-elevated laryngoscopy position" or HELP) [38]. Figure 33.1 In addition, if the patient is hemodynamically stable, the operating room table should be in the reverse Trendelenburg position (RTP) [39]. The Semi-Fowler's position with the patient's upper body elevated 25–30° also extends SAT [40], but the 30° RTP is better [41]. In these head-up and upper body elevated positions, the patient's panniculus drops down and "unloads" the diaphragm, which in turn increases FRC. The combination of the patient in the HELP with the operating room table in the RTP maximizes FRC and also improves the view during direct laryngoscopy.

The head-up position in obese patients, without adequate arm support, can result in brachial plexus injury [42]. Changing to the lateral position for thoracotomy or thoracoscopy requires additional physical assistance and equipment. Axillary rolls should be proportionally larger to protect the brachial plexus. Beanbags to support the patient in the lateral decubitus position may not sufficiently wrap around the patient due to their excessive girth, and patients may need to be restrained with belts or tape across the pelvis. Supporting the head in the lateral, flexed position can be difficult due to a proportionally short neck and requires creative placement of towels and blankets to ensure that the head is positioned on a horizontal line extending through the spine of the patient, in a neutral position (Fig. 33.2).

Airway

The patient's previous anesthesia records should be reviewed for documentation of any prior difficulties with tracheal intubation. A MO patient, especially one with a history or symptoms suggestive of OSA, may have a diminution of the

Fig. 33.1 Prior to induction of general anesthesia, the morbidly obese patient should never be allowed to lie flat but should be positioned in the head-elevated laryngoscopy position (HELP). In this position, an imaginary horizontal line can be drawn from their sternum to their ear. HELP improves the view during direct laryngoscopy and increases safe-apnea time after muscle paralysis. If the patient is hemodynamically stable, the operating table should be in 30° reverse Trendelenburg to further increase safe-apnea time

Fig. 33.2 After turning the patient to the lateral decubitus flexed position, supporting the patient's head can be difficult due to a proportionally short neck in many MO patients. Creative placement of towels and blankets is required to ensure that the head is positioned on a horizontal line extending through the spine of the patient, in a neutral position

pharyngeal space secondary to fat deposition in the pharyngeal wall, which can make airway access and bag-mask ventilation difficult. The patient's airway and anatomy should be closely examined. Airway management of MO patient has been reviewed elsewhere [43, 44].

The American Society of Anesthesiologists Task Force defines a difficult airway as the "clinical situation in which a conventionally trained anesthesiologist experiences problems with (a) face mask ventilation of the upper airway or (b) tracheal intubation or both" [45].

The criteria used to define difficult mask ventilation usually include failure to maintain oxygen saturation (SpO_2) >92%, the need for two providers, and/or complete inability to mask ventilate. Increased BMI and a history of OSA are each independent predictors for difficult mask ventilation [46], and there is general acceptance that MO patients, especially when supine, are more difficult to ventilate by mask than normal-weight patients. Age 49 years, short neck, and neck circumference are additional factors that have been identified as independent predictive factors for difficult bag-mask ventilation [47].

Numerous studies have considered tracheal intubation in the MO population. The view obtained during direct laryngoscopy is usually used as a measure for difficult or failed intubation; however, an ETT may be easy to place despite a poor laryngoscopic view, and even with a reasonable view there can be difficulty passing a tube. In MO patients video-laryngoscopy improves intubation conditions [48] and reduces hypoxic events during induction [49]. The best preoperative predictors of potential problems with tracheal intubation are Mallampati score (III/IV) and increased neck circumference [50].

The standard sniffing position for tracheal intubation is achieved in nonobese patients by raising their occiput 8–10 cm with a pillow or headrest. Obese patients require much greater elevation of their head, neck, and shoulders (HELP) to produce the same alignment of axes for intubation [38]. In studies of MO patients where the head position is suboptimal, which is not in the HELP, there are higher incidences of grade 3 and 4 Cormack-Lehane views potentially increasing difficulty with direct laryngoscopy [51]. Video-laryngoscopy for routine tracheal intubation has presumably led to better visualization of the glottis in MO patients [52]. In patients who are anesthetized and in whom a difficult laryngoscopy is encountered, an alternative method to securing the airway could involve passing a single-lumen endotracheal tube (ETT) through a laryngeal mask with the aid of a flexible fiberoptic bronchoscope [53, 54].

Certain clinical features are more likely to be present in obese or MO patients in whom direct laryngoscopy is difficult. As mentioned, high Mallampati score, large neck circumference, and excessive pretracheal adipose tissue may make laryngoscopy more difficult in some MO patients [50, 55]. However, increasing weight alone has never been correlated with increasing difficulty with tracheal intubation. BMI has no direct influence on difficult laryngoscopy, and rates of successful tracheal intubation in these MO patients are similar to those in nonobese patients [50, 56, 57]. In a small subset of male, MO patients with short wide necks, OSA, and high Mallampati scores direct laryngoscopy may be more difficult, and video-laryngoscopy should be considered for these patients. Anesthesiologists should always proceed with caution in any MO patient since difficulty with bag-mask ventilation is very common and all obese patients have a short SAT following muscle paralysis for laryngoscopy.

For most MO patients, an IV anesthetic induction with propofol and succinylcholine is the best means for securing the airway. Rocuronium can be used, but only if sugammadex is immediately available. Formally, a rapid sequence induction (RSI) was believed to be necessary for all MO patients because of the misperception that obesity increased risk for aspiration and pulmonary injury during anesthetic induction. It is now felt that most MO patients are at no greater risk than normal-weight patients. Obese patients that are at higher risk for gastric acid aspiration are those with a history of severe GERD and diabetic gastroparesis and patients who have previously undergone gastric banding procedures [58]. For these patients a RSI is still recommended. RSI is not without risks (awareness, under- and overdosing of drugs, impaired visualization during laryngoscopy, SpO_2 desaturation), and these risks are potentially greater than the low risk of aspiration.

In summary, for MO obese patients, induction of anesthesia and tracheal intubation should include placing the patient in a head-up position, adequate preoxygenation until end-tidal oxygen concentration is >80%, administration of fast-acting opioids to supplement the anesthetic induction agent, titration of the induction agent until loss of consciousness is achieved, avoidance of cricoid pressure (if possible), and continued bag-mask positive pressure ventilation following the administration of a neuromuscular blocking agent until the patient is fully paralyzed and ready for tracheal intubation. Bag-mask ventilation can be difficult and gastric insufflation from ineffective mask ventilation can increase the risk of regurgitation and acid aspiration. A second person experienced with airway management, preferably another anesthesiologist, should always be readily available to assist when difficulty is encountered.

Lung Separation

Safe and dependable isolation and selective ventilation of the lungs are essential for the practice of modern thoracic anesthesia. Lung separation is accomplished with either a DLT or

with a balloon-tipped BB. There is no "best" method for lung separation, and choice of technique depends on the specific surgical requirements, the patient's airway, and the individual anesthesiologist's preferences and experience [59]. Despite the technical aspects of placing any airway device, it has also been shown that one of the most significant barriers to successful lung separation is the operator's knowledge of bronchial anatomy [60, 61]. Bronchoscopic tracheobronchial anatomy can be reviewed using an online simulator at www.thoracicanesthesia.com or www.pie.med.utoronto.ca/VB or in published illustrations [61].

Direct laryngoscopy and successful placement of a DLT or ETT should be no different in obese and normal-weight patients, provided the obese patient is appropriately positioned for laryngoscopy. In both normal-weight patients [62] and obese patients [63], tracheal intubation is usually more difficult using a DLT than with a single-lumen tube.

When problematic laryngoscopy is anticipated, or if difficulty is experienced when attempting to place a DLT, an ETT can be inserted using either a gum elastic bougie as a guide, through any of several laryngeal mask airways (LMAs) using fiberoptic bronchoscopy, or with any other intubation adjunct such as a Trachlight® [53, 54]. Once the ETT is in place, a BB can be used through the ETT, or alternatively a 100-cm long airway exchange catheter can be employed to change from the ETT to a DLT. A DLT can even be placed directly by fiberoptic bronchoscopy [64].

When tube exchange is not practical, lung isolation can always be achieved with a BB through the ETT. BB may be a better choice for those MO patients with high Mallampati score and thick necks with a potential "difficult" airway. The quality of lung collapse is unaffected whether a BB or DLT is used [59]. If postoperative ventilation is planned, it may be safer to avoid a DLT entirely and use a BB through an ETT since changing tubes at the completion of surgery can be potentially dangerous in MO patients.

Prior to intubation the patient's chest radiograph or CT scan should be examined to determine the tracheobronchial anatomy and airway diameters [65]. Unlike chronic obstructive lung disease, which results in a dilation of trachea and bronchi, a similar effect does not occur for the restrictive lung disease associated with obesity. Relatively, small tracheas are often found in very large patients. Even if a smaller DLT needs to be used, airway resistance is not a concern. Contrary to popular belief, most sizes of DLTs have reduced airflow resistance compared to ETTs [66].

One-Lung Ventilation

Hypoxemia during OLV is significantly affected by patient positioning. Normal-weight patients undergoing OLV in the supine position have significantly lower arterial oxygen tensions than when the same patient is in lateral position [67]. For patients undergoing thoracotomy in the supine, the semi-lateral decubitus, and the lateral decubitus positions, oxygenation progressively decreases with time after the start of OLV. OLV in the supine position is associated with the highest incidence of hypoxemia, usually occurring approximately 10 min after initiating OLV with 100% oxygen [68]. Although MO patients maintain adequate oxygenation during OLV in the lateral position, they are much less likely to tolerate OLV in the supine position. Basilar atelectasis is present in supine MO patients preoperatively and worsens following induction of general anesthesia. MO patients benefit from lung recruitment maneuvers following induction of anesthesia, particularly prior to the institution of OLV [69]. Due to the presence of more atelectasis in dependent lung areas than normal-weight patients, recruitment maneuvers and PEEP are required for maintaining adequate oxygenation [70, 71]. Despite this, arterial oxygen tension in MO patients remains significantly lower during OLV than normal-weight patients [72]. Successful OLV in MO patients is technically possible in the lateral position if the panniculus can fall away from the body, therefore unloading the dependent diaphragm (Fig. 33.3).

For all patients, including the MO patients, lung protective ventilation strategies are practiced during OLV [73, 74]. Traditional ventilation parameters (large tidal volume with no recruitment or PEEP) may contribute to the development of ARDS and other postoperative pulmonary complications [75–77], even in patients without preexisting lung disease [78, 79]. Ventilation with tidal volumes as high as 13 mL/kg (IBW) during OLV do not improve oxygenation and can

Fig. 33.3 Successful one-lung ventilation (OLV) in MO patients is technically possible in the lateral position if the panniculus can fall away from the body unloading the dependent diaphragm. MO patients are much less likely to tolerate OLV in the supine position since many patients already have reduced FRC and are relatively hypoxemic even during two-lung ventilation when they lie flat

result in excessively high peak pressures [80]. In the MO population, estimating tidal volumes based on actual weight (TBW) or height is a risk factor for delivering excessively high tidal volumes during mechanical ventilation [81, 82]. As with normal-weight patients, tidal volumes during OLV should be based on IBW (4–6 mL/kg IBW).

High peak inspiratory pressures secondary to restriction of chest wall and diaphragmatic excursion and the narrow single lumen of a DLT can further limit volume-controlled mechanical ventilation during OLV. Pressure-controlled ventilation during OLV can improve oxygenation and decrease peak pressures in normal-weight patients [83]. Pressure-limited OLV may have an application in the MO population, but if too low tidal volume is delivered to a patient with an already low FRC, hypoxemia will worsen. PEEP is beneficial during two-lung ventilation in MO patients. During OLV, a mild to moderate level of PEEP to the single ventilated dependent lung has been shown to improve oxygenation if it does not exceed the lower inflection point of the alveolar pressure-volume loop. High PEEP results in increased pulmonary vascular resistance thereby increasing shunt fraction and worsening hypoxemia [84].

Anesthetic Drugs/Maintenance of Anesthesia

MO patients should be managed as if they have OSA. When practical, opioid-sparing anesthetic techniques, including regional anesthesia, should be used. Short-acting anesthetic and analgesic agents are appropriate choices for the MO patient. All opioids have respiratory depressant properties, and IV administration should be carefully titrated according to individual patient needs. Remifentanil is administered based on LBW in MO patients.

Some anesthesiologists prefer a total intravenous anesthesia (TIVA) technique with propofol and remifentanil, while most find an inhalational technique combined with epidural analgesia best for thoracotomy. In a study of 120 MO patients [85], neither technique was associated with intraoperative awareness.

In current anesthetic practice, propofol is the induction agent of choice for surgical patients, including MO patients. In theory, a lipid-soluble agent like propofol should be dosed according to TBW, but if this was followed in MO patients, such large doses could result in cardiovascular collapse, particularly in the fluid restricted thoracotomy patient. For MO patients, the induction dose of propofol is based on LBW [36].

Succinylcholine should be used for tracheal intubation in the MO patient. The concentration of pseudocholinesterase, the enzyme that metabolizes succinylcholine, increases with increasing weight. A 1 mg/kg TBW dose of succinylcholine provides a rapid and profound neuromuscular block and better intubating conditions than non-depolarizing muscle blockers. Rocuronium can be used, but only if sugammadex is available. Non-depolarizing muscle relaxants are initially dosed based on LBW, and a neuromuscular monitor is used to guide additional dosing.

When considering volatile anesthetics, isoflurane is more lipophilic than desflurane or sevoflurane, making it more soluble in adipose tissue. Desflurane and sevoflurane have each been marketed as anesthetics for MO patients. However, in obese patients, fat is poorly perfused and comparable recovery times with both agents have been reported in obese and nonobese subjects after anesthetic procedures lasting 2–4 h. There are no clinical differences in emergence and recovery profiles in MO patients receiving either desflurane or sevoflurane when anesthetic concentration is carefully titrated [86]. However, a meta-analysis review on the topic found that patients given desflurane took less time to emerge from anesthesia; that is, they took less time to respond to commands to open their eyes, to squeeze the investigator's hand, to be prepared for tracheal extubation, and to state their name. There were no differences in hemodynamics and respiratory function perioperatively using either agent [87]. There were no significant differences in postanesthesia care unit discharge times, nausea, or analgesic requirement [88]. Despite claims to the contrary, there is no clear advantage between any of the inhalational anesthetics in MO patients [89].

Intravenous Fluid Management

Routine clinical practice is to restrict IV fluid to reduce the incidence of postoperative pulmonary edema after lung resection [90]. Therefore, perioperative assessment of blood volume (BV) is particularly critical for patients undergoing thoracotomy. The mean value for BV in normal-weight adults is usually given as 70 mL/kg, but this value cannot be used for obese and MO patients. With progressive increase in BMI, total circulating BV also increases, but BV measured as mL/kg TBW decreases in a nonlinear manner [91]. Using 70 mL/kg will overestimate BV in MO patients and can lead to underadministration of crystalloids, colloids, and red blood cells in the event of massive fluid translocation and/or hemorrhage.

Emergence and Extubation

Early extubation of the trachea at the completion of pulmonary resection lowers the risk of bronchial stump disruption and pulmonary air leaks secondary to positive pressure ventilation and airway tube trauma. In normal patients, a DLT can be removed while the patient is still in the lateral position, followed by assisted mask ventilation until the patient is fully awake. In the MO patient, especially one with OSA, mask ventilation in the lateral position can be difficult. Tracheal extubation in a MO patient should be performed

with the patient in HELP and the operating room table in the RTP to optimize ventilation and to allow access to the airway if reintubation becomes necessary.

A MO patient must be sufficiently awake and have a regular respiratory pattern before the trachea is extubated. Although it is rarely necessary, a DLT can be replaced with an ETT via an airway exchange catheter, and the patient can then be allowed to emerge from anesthesia. Alternatively, after deflating both the tracheal and bronchial cuffs and withdrawing the tube until the endobronchial segment is in the trachea, the tracheal cuff can be reinflated and the DLT used as a single-lumen tube. A DLT completely in the trachea is less stimulating than one still in the bronchus. Even when a DLT remains in the bronchus, it is tolerated by patients, and most anesthesiologists elect to keep the DLT in place. The tube is removed after routine criteria for extubation have been met.

It has been suggested that noninvasive positive pressure ventilation (NIPPV) be employed to reduce post-extubation complications. A Cochrane Database review demonstrated that there was no additional benefit of using NIPPV in postoperative pulmonary resection [92]. Outcomes such as pulmonary complications, rate of reintubation, mortality, rate of non-pulmonary complications, postoperative consumption of antibiotics, length of intensive care unit stay, length of hospital stay, and adverse effects related to NIPPV were analyzed. Based on low to moderate quality evidence, the authors concluded that more studies were needed to establish this conclusion with greater certainty.

Despite these findings, for the MO patient who has been using CPAP or BIPAP preoperatively, these devices should be available and used immediately after tracheal extubation to stent the upper airway, to reduce the work of breathing, and to improve tidal volume and gas exchange [22]. The noninvasive Boussignac mask-CPAP (BCPAP) system does not require a mechanical ventilator and is very helpful in maintaining satisfactory oxygenation in spontaneously breathing MO surgical patients [93, 94]. Supplemental oxygen should always be administered, but used with caution as oxygen therapy can increase the AHI, hypoventilation, and P_aCO_2 levels in a patient with OHS. Continuous, noninvasive, transcutaneous carbon dioxide ($P_{tc}CO_2$) monitoring is accurate and has been applied to MO patients, especially those with OSA and OHS to evaluate abnormalities in their alveolar ventilation [95].

Postoperative Pain Control

Satisfactory post-thoracotomy analgesia is extremely important to maximize lung function, particularly in the MO patient who has restricted lung function prior to surgery.

Epidural opioid analgesia, with or without local anesthetic, when compared to IV opioids reduces pain, improves pulmonary function and oxygenation and reduces post-thoracotomy complications [96]. Local anesthetics given epidurally also supplement general anesthesia and reduce opioid requirements during surgery. Postoperative pain control for thoracotomy is covered in detail elsewhere in this book.

In the postoperative period, it is known that lung volumes are significantly reduced. Lung volumes in obese patients are probably reduced even further. Although the effects of thoracic epidural analgesia (TEA) compared to conventional opioid-based analgesia in postoperative spirometry has not been studied in obese patients undergoing thoracotomy, it has in laparotomy patients [18]. Perioperative spirometry values decreased significantly with increasing BMI, with the greatest reduction in vital capacity immediately after tracheal extubation. The effects were less in all patients receiving TEA, but in obese patients (BMI >30 kg/m2), the difference in vital capacity was significantly more pronounced than in normal patients. Recovery of spirometry values was significantly quicker in patients receiving TEA, particularly in the obese patients.

With epidural analgesia, any postoperative hypotension and/or motor blockade from the local anesthetic will limit the MO patient's ability to ambulate increasing their already greater risk for pulmonary embolism. A Cochrane review revealed that continuous thoracic paravertebral (PVB) analgesia is as effective as epidural analgesia in managing post-thoracotomy incisional pain [97] and is associated with a lower incidence of complications, including fewer pulmonary complications, less nausea and vomiting, less hypotension, and fewer failed blocks than epidural analgesia [98]. Unlike epidural analgesia, paravertebral analgesia only blocks the operative side and ipsilateral parasympathetic chain. In some studies, the stress response to surgery with PVB is reduced more than what is achieved by epidural analgesia [99]. As evidence for the effectiveness of PVB grows, some predict that it will likely replace epidural analgesia as the preferred method of post-thoracotomy pain control [100, 101].

Early institution of postoperative multimodal analgesic regimens that can include local anesthetics, interpleural local anesthetic infusions, nonsteroidal anti-inflammatory agents, and other synergistic drugs to reduce the respiratory depressant effects of centrally acting agents is indicated for MO patients with OSA. Alpha-2 agonists (clonidine, dexmedetomidine) do not depress respiration and have analgesic properties and have been used as adjuncts to epidural local anesthetics for post-thoracotomy analgesia [102].

Complications

Studies have reported that extremely obese patients undergoing cardiac surgical procedures have longer recovery times and a greater incidence of postoperative complications and mortality than normal-weight patients [103]. Although the

same may be true for MO patients undergoing thoracotomy, there have been few outcome studies to corroborate this. Most published post-thoracotomy outcome studies have considered obese (BMI >30 kg/m^2) and not MO or super-obese patients [104]. One recent study did find a weak correlation between obesity (BMI >30 kg/m^2) and increased length of hospital stay after thoracic surgery [105]. It is interesting to note that there was a much higher association of complications in low BMI (<18.5 kg/m^2) patients following thoracotomy. Many other large series of patients undergoing non-thoracic operations have reported similar results, that is, obesity (BMI >30 kg/m^2) is not a major risk factor but low BMI (<18.5 kg/m^2) is highly associated with surgical complications and death [70]. This association has been referred to as the "obesity paradox" [106].

The risk of postoperative thromboembolism, atelectasis, and pneumonia is believed to be greater in MO surgical patients undergoing non-thoracic operations [107]. Presumably, the same is true for similar size patients undergoing thoracic surgery, but once again, no studies are available that can document this concern.

There is one postoperative complication that is now recognized as relatively common in MO surgical patients but rare in normal-weight patients. Rhabdomyolysis (RML) results from pressure injury to skeletal muscle due to prolonged stasis in a non-physiologic position, such as the lateral decubitus position [108]. Long-duration surgery is the major risk factor, but other factors include super-obesity, male patients, and a history of hypertension, diabetes and/or peripheral vascular disease. Intraoperative padding of all pressure points and close attention to patient positioning are essential to prevent RML, pressure ulcers, and neurologic damage in MO patients. Injured muscle releases myoglobin, electrolytes, and protein into the systemic circulation. Myoglobinuria can lead to acute renal failure (ARF), and electrolyte disturbances can cause dysrhythmias and even cardiac arrest. Local signs and symptoms of RML are nonspecific and include pain, tenderness, swelling, bruising, and weakness. Complaints of numbness and muscular pain are almost always present, but epidural analgesia can mask symptoms and delay diagnosis.

Myoglobinuria usually presents as "tea" or brown-colored urine. The primary diagnostic indicator of RML is elevated serum creatine phosphokinase (CPK) levels. A MO patient who complains of buttock, hip, or shoulder pain in the postoperative period and who has a serum CPK level >1,000 IU/L is considered to have RML. Treatment should be instituted once CPK levels increase beyond 5,000 IU/L. Although intraoperative fluid replacement can reduce the risk of postoperative RML, fluid replacement is usually restricted during pulmonary resections. However, once a diagnosis of RML is made, aggressive hydration with large volumes of intravenous fluids and administration of diuretics are required to flush myoglobin from the kidneys.

Surgical Issues

Operative exposure in a MO patient may be less than optimal as the usual lateral decubitus position with extreme table flexion may not result in an adequate opening of the chest wall. Exposure is further compromised by increased chest wall thickness. Soft-tissue thickness also becomes important during video-assisted thoracoscopy (VATS) procedures since longer instruments are needed and range of motion may be limited. Unsatisfactory conditions for VATS can lead to more frequent conversion to thoracotomy, but once again, it is unclear as to whether this complication occurs more often in MO patients. The possibility of changing from VATS to open thoracotomy has important implications since it raises issues as to whether an epidural catheter should be placed preoperatively in a "technically difficult" VATS patient when there is a high likelihood of proceeding to thoracotomy. If the surgeon can place paravertebral catheters for postoperative pain control, the concern for unnecessary epidural placement is alleviated.

Conclusion

MO patients comprise an ever-increasing percentage of the thoracic surgical population. Obesity is not a contraindication to thoracic surgery; however, given the potential problems of extreme obesity, thorough perioperative planning is critical to prevent problems. There is a paucity of published studies involving MO thoracic surgical patients, so current anesthetic management is based on experience from obese patients undergoing non-thoracic surgical procedures. Research to further refine specific anesthetic management strategies for MO thoracic surgery patients is needed.

Clinical Case Discussion

Case A 56-year-old, 180 cm, 148 kg (BMI 46 kg/m^2) man with lung cancer is scheduled for a right-upper lobectomy. He is active and reports no limitations to his ability to work in the construction industry. His medical problems include mild hypertension and type-2 diabetes mellitus. He has never been hospitalized and has no history of previous surgery. During his preoperative examination, his wife says that he snores loudly at night. He has never had a formal sleep study (polysomnography, PSG). On examination, he has a grade III Mallampati airway with a neck circumference of 50 cm. The patient and his surgeon want to proceed with his surgery as soon as possible.

Preoperative Management

What further studies are needed?

- Although spirometry may be useful, it is doubtful that it would demonstrate an inability for this patient to tolerate the surgery since he is active and has no respiratory impairment. Pulmonary function studies in MO patients demonstrate a reduction in lung volume (mainly FRC) and a restrictive breathing pattern.

Should the patient undergo a preoperative PSG study?

- Given the patient's BMI (46 kg/m^2) and history of snoring, it is more likely than not that he has obstructive sleep apnea (OSA). The patient is positive for 6/8 questions on his STOP-Bang assessment (snoring, hypertension, BMI, age, neck circumference, and male). Although a PSG test would confirm the diagnosis, even without testing this patient (and most MO patients) should be treated as if they have OSA.

Should the surgery be postponed while the patient is placed on CPAP?

- This patient is anxious to proceed with the surgery immediately. Several weeks of preoperative CPAP therapy might be helpful, but surgery will be delayed. Many patients do not tolerate CPAP, and he may refuse to wear the device.

In addition to a routine ECG, does his cardiac status require further evaluation?

- A stress echocardiogram would be informative given his age and comorbidities, but it is not essential since he has a high exercise tolerance and is active. The majority of MO surgical patients do not need an extensive preoperative cardiac workup.

What needs to be done prior to induction of anesthesia?

- In the preoperative area, unless the patient is extremely anxious, sedation should be avoided. Midazolam, 1-2 mg IV, can be given, but no opioid premedication.
- Since a thoracotomy is planned, a thoracic epidural (TEA) should be placed for intra- and postoperative analgesia. A continuous paravertebral block (PVB) is alternative with the advantage being it would have a better postoperative profile (less hypotension and absence of motor blockade) than a TEA. It is important that all perioperative opioids, including postoperative PCA opioids, be kept to a minimum in this MO patient with OSA.
- An arterial line should be placed to obtain a baseline blood gas and for intra- and postoperative monitoring.
- On arrival in the operating room, he should not be allowed to lie flat since this will lead to further reductions in his FRC and decrease in safe apnea time (SAT). He should be positioned on the operating table with his upper body elevated by pillows and blankets in the "head-elevated laryngoscopy position" (HELP).

Intraoperative Management

How should the patient's airway be intubated?

- A potentially difficult intubation is always possible, especially since his preoperative assessment demonstrated a high Mallampati score and large neck circumference. The choice of proceeding with a conventional IV anesthetic induction and direct laryngoscopy, video-laryngoscopy, or even an "awake" fiberoptic intubation is up to the confidence and experience of the anesthesiologist. With the availability of video-laryngoscopes, fiberoptic bronchoscopy for intubation (which often requires sedation) is seldom required. Video-laryngoscopes can be used to intubate the trachea with a double-lumen tube (DLT) or with an endotracheal tube (ETT). However, a second trained physician or nurse should always be immediately available to assist with bag-mask ventilation (which is frequently difficult in MO patients) and/or with airway intubation.
- The patient should be preoxygenated with 100% oxygen until his end-tidal oxygen is >80%. A true "rapid sequence induction" is not needed since this patient has no risk factors for aspiration. The patient should be ventilated by mask once rendered apneic to increase his SAT until laryngoscopy is initiated.
- If an IV induction is chosen, we prefer propofol and succinylcholine. Rocuronium can be used, but only if sugammadex is available. Succinylcholine provides better relaxation for tracheal intubation.
- If with direct laryngoscopy the patient has a favorable Cormack-Lehane grade view, a left DLT could be placed and checked with flexible bronchoscopy.
- For more difficult views, a gum elastic bougie could be inserted through the glottis, followed by an ETT over the bougie. If intubation by direct or video-laryngoscopy and a bougie is not possible, an LMA could be placed, and a fiberoptic bronchoscope could then be used to intubate the trachea. Once the airway is secured, lung separation can then be accomplished with either a bronchial blocker through the ETT, or the ETT can be replaced with a DLT using a long airway exchange catheter (AEC).

Is there a better technique for one-lung ventilation – total IV anesthesia (TIVA) or inhalation technique?

- Although TIVA has theoretic advantages (less depression of hypoxic vasoconstrictive reflex), clinically there is no difference in oxygenation during one-lung ventilation using either technique.
- Long acting opioids should be avoided during surgery with either technique.
- Lung size does not increase with obesity. Tidal volume during volume-controlled OLV should be based on ideal body weight (4–6 mL/kg IBW) and not actual weight. Plateau pressure during pressure-controlled ventilation should not exceed 30 cm H_2O.
- CPAP to the non-ventilated lung is useful to maintain oxygenation. PEEP to the ventilated lung should also be used.

Postoperative Management

What if the patient complains of pain, even with a functioning TEA or PVB?

- Supplemental IV opioid analgesia should be kept to a minimum; multimodal analgesic techniques should be used both intra- and postoperatively.

How do you manage postoperative oliguria?

- The differential diagnosis includes hypovolemia from the routine practice of fluid restriction during thoracotomy and/or rhabdomyolysis, which is relatively frequent in MO patients. In either case, additional IV fluid administration is indicated.
- A serum CPK level should be obtained to rule out renal failure secondary to rhabdomyolysis. Clinically significant rhabdomyolysis results in myoglobinuria. This usually doesn't occur unless the CPK level is >5,000 IU/L, but aggressive fluid therapy should be instituted if the CPK level is >1,000 IU/L, a level diagnostic of RML.

Pulmonary Resection in the Patient with Pulmonary Hypertension

34

Alexander Huang and Katherine Marseu

Key Points

- Pulmonary resection in the presence of pulmonary hypertension has been associated with increased risk for perioperative morbidity and mortality; however, advances in assessment, treatment, and intraoperative management have made surgery in these patients feasible.
- Preoperative assessment of these patients requires a multidisciplinary approach and various diagnostic tests to assess severity and determine appropriate treatment. This should be optimized preoperatively.
- The anesthetic goals for these patients include optimizing preload, maintaining a low-normal heart rate, maintaining contractility, decreasing pulmonary vascular resistance, and ensuring systemic pressures are greater than pulmonary pressures.
- Intraoperative monitoring should include invasive blood pressure monitoring and potentially the use of a pulmonary artery catheter and/or transesophageal echocardiography. The use of advanced monitors such as pulmonary artery catheters or transesophageal echocardiography should be decided on a case-by-case basis.
- Understanding of the interaction between anesthetic agents and pulmonary vascular physiology is of key importance. Volatile agents may impair right ventricular function and should be used with care. Ketamine has been shown to be safe for use in pulmonary hypertension.
- Inhaled nitric oxide and prostanoids are potentially useful adjuncts in the management of pulmonary pressures intraoperatively.
- Effective pain management is of utmost importance in patients with pulmonary hypertension presenting for pulmonary resection. Epidurals are effective and may reduce pulmonary complications as well as overall mortality but require close monitoring due to their potentially significant hemodynamic effects. Paravertebral catheters are also an alternative.
- Postoperative arrhythmias, acute pulmonary hypertension, and right heart failure are potential complications post-pulmonary resection and necessitate postoperative monitoring in a step-down or critical care unit for these patients.

Introduction

Pulmonary hypertension is defined as a resting mean pulmonary artery pressure of ≥25 mmHg [1] and carries with it significant implications for the patient presenting for thoracic surgery. Pulmonary hypertension is often associated with significant end-stage lung disease and can also be associated with numerous extrapulmonary diseases. The classification of pulmonary hypertension was most recently updated in 2013 to reflect five groups of disorders that cause it [2] (Table 34.1). Presently, pulmonary hypertension is thought to have a global prevalence of 1%; however, this may increase to as high as 10% in those greater than 65 years of age [3]. Typically, for the anesthetist, there are two main types of pulmonary hypertension: pulmonary hypertension related to left-heart disease and pulmonary hypertension related to lung disease (Table 34.2). Currently, with improved diagnostic testing and therapies, it is no longer uncommon for patients with pulmonary hypertension to present to the operating room for surgery. This chapter will consider the perioperative risk profile of patients with pulmonary hypertension presenting for lung resection surgery. It will then discuss the preoperative assessment, intraoperative, and postoperative management of this population.

Perioperative Risk

The increased risk in perioperative morbidity and mortality associated with pulmonary hypertension has been well-documented in the literature. Studies in the non-cardiac surgical population have demonstrated that these patients are at increased risk for perioperative heart failure, hemodynamic instability, sepsis, and respiratory failure. Furthermore, pulmonary hypertension patients require longer durations of mechanical ventilation and longer intensive care and hospital admissions [4, 5]. Higher pulmonary-to-systemic systolic pressure ratios are also associated with higher perioperative mortality [6]. In the literature, the morbidity and mortality in pulmonary hypertension patients presenting for non-cardiac surgery have been reported to be 14–42% and 1–18%, respectively [7]. Overall, patients with pulmonary hypertension present a significant challenge in the perioperative period.

Table 34.2 Modified classification of pulmonary hypertension for anesthesia

Left heart disease	Lung disease
Systolic dysfunction Diastolic dysfunction Mitral valvular disease: stenosis, regurgitation Congenital cardiac disease	Pulmonary vascular disease Chronic lung disease, hypoxemia, sleep apnea Thromboembolic pulmonary hypertension Miscellaneous: autoimmune, metabolic

General indications for pulmonary resection include procedures for diagnosis (e.g., open lung biopsies for tumors and pulmonary fibrosis) or treatment of malignancy, congenital abnormalities, infection, and trauma. As mentioned previously, it is not unusual for elevated pulmonary arterial pressures to coexist with lung disease. Historically, lung resection surgery has been cautioned and discouraged in patients with pulmonary hypertension [8]. In small studies and case reports examining patients undergoing pulmonary resection, the presence of pulmonary hypertension was associated with increased morbidity and mortality (by 50% and 25%, respectively, in one small study) [9]. Significant bleeding [10, 11], increases in pulmonary artery pressures postoperatively [12], and right ventricular failure [13] have all been reported. However, more recently, Wei and colleagues retrospectively examined 298 patients (19 with pulmonary hypertension) undergoing pulmonary resection for lung cancer. In this study, the presence of pulmonary hypertension was not associated with increased morbidity or mortality as compared to non-pulmonary hypertension patients [14]. Though small, this study suggests the feasibility of safely conducting lung resections in this population.

The implications of lung resection surgery on the pathophysiology of underlying pulmonary hypertension must also be considered. The loss of lung parenchyma carries with it a loss of pulmonary vasculature, which can result in increased pulmonary vascular resistance. Pneumonectomy has been shown to produce significant right ventricular dysfunction in the immediate postoperative period [15, 16], as well as up to 4 years after surgery [17]. The etiology of this dysfunction is presumed to be due to increased right ventricular afterload. Pulmonary artery systolic pressures measured by Doppler echocardiography have also been shown to be elevated after pneumonectomy [17]. The literature remains inconsistent and unclear regarding the effects of subtotal pulmonary resections (lobectomies, segmentectomies, and wedge resections) on pulmonary arterial pressures [18]. However, the majority of published studies on the subject have involved patient populations without pulmonary hypertension. Presumably, the effect of pulmonary resection on existing pulmonary hypertension (as well as existing right heart dysfunction) is likely to be more significant and warrants additional concern by the anesthesiologist.

Preoperative Assessment

The preoperative assessment of patients presenting for thoracic surgery is discussed in great detail in Chap. 2 and can be applied to the patient with known or suspected pulmonary hypertension.

History, Physical Exam, and Investigations

Patients with known or suspected pulmonary hypertension commonly present with dyspnea and fatigue. Patients may also report additional symptoms, including presyncope, syncope, angina, and symptoms of right heart failure (peripheral edema, abdominal distension, and anorexia), which may reflect disease progression and severity. Unfortunately, these symptoms are vague and nonspecific and are often attributable to more common cardiopulmonary diagnoses. Furthermore, such symptoms are common in patients presenting for thoracic surgery, in general, and make identification of undiagnosed pulmonary hypertension challenging. Additional features on history such as orthopnea or paroxysmal nocturnal dyspnea (left-sided heart disease), arthralgias or skin changes (rheumatologic or connective tissue disorder), or snoring or observed apnea (obstructive sleep apnea) may also aid in evaluation or provide a unifying diagnosis.

In patients with known pulmonary hypertension, the development of symptoms of right heart failure is a means of gauging a patient's clinical status over time. The World Health Organization (WHO) has also developed a classification of functional status of patients with pulmonary hypertension [19] based on the New York Heart Association (NYHA) system (Table 34.3), which is also useful for assessing disease severity, progression, and response to treatment. The WHO/NYHA functional status has been shown to strongly correlate with long-term survival in patients with idiopathic pulmonary hypertension [20].

Beyond history and physical examination, the assessment of the patient with suspected or confirmed pulmonary hypertension presenting for thoracic surgery should also include a

Table 34.3 World Health Organization classification of functional status of patients with pulmonary hypertension

Class	Description
I	Patients with pulmonary hypertension in whom there is no limitation of usual physical activity; ordinary physical activity does not cause increased dyspnea, fatigue, chest pain, or presyncope
II	Patients with pulmonary hypertension who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope
III	Patients with pulmonary hypertension who have a marked limitation of physical activity. There is no discomfort at rest, but less than ordinary activity causes increased dyspnea, fatigue, chest pain, or presyncope
IV	Patients with pulmonary hypertension who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest, and symptoms are increased by almost any physical activity

Reproduced from Barst et al. [19] with permission from Elsevier

chest X-ray and electrocardiogram (ECG). A chest X-ray not only allows for assessment of lung parenchyma and the specific lesion being operated on (e.g., tumor) but may also demonstrate features consistent with elevated pulmonary artery pressures such as prominent pulmonary arteries or right ventricular enlargement. The ECG may provide features suggestive or supportive of pulmonary hypertension including right ventricular hypertrophy or a right axis-deviation. Neither a chest X-ray nor ECG possess sufficient specificity or sensitivity to rule in or rule out pulmonary hypertension.

Transthoracic echocardiography (TTE) has rapidly become the investigation of choice for both screening and follow-up of patients with pulmonary hypertension, given its availability and noninvasiveness. TTE allows for the estimation of the right ventricular systolic pressure (RVSP), which closely approximates the systolic pulmonary artery pressure (SPAP) in the absence of pulmonary outflow obstruction. The RVSP measured by echocardiography has been shown to have moderate to strong correlation to the SPAP measured through right heart catheterization (correlation coefficient $R = 0.57–0.93$) [19]. However, in some cases, RVSP measurements done using TTE may deviate from SPAP values derived by right heart catheterization by as much as 10 mmHg in many patients, with a tendency to underestimate the true SPAP [21]. Furthermore, there is large variation in the sensitivity and specificity of TTE in the diagnosis of pulmonary hypertension, which has been shown to be 79–100% and 60–98%, respectively [22]. Additional echocardiography features include right ventricular dilatation or hypertrophy, right ventricular dysfunction, right atrial enlargement, the presence of significant tricuspid regurgitation, interventricular septal flattening, as well as the presence of pericardial effusions. The presence of these features has been associated with worse prognosis in pulmonary hypertension patients [22].

Right heart catheterization (RHC) remains the gold standard in terms of assessment and diagnosis of pulmonary hypertension. RHC allows for the measurement of pulmonary artery pressures (required for the formal diagnosis of pulmonary hypertension) as well as pulmonary vascular resistance. Additional useful information can be derived from RHC, including estimation of right heart pressures (right ventricular and right atrial pressures), pulmonary capillary wedge pressures, cardiac output, and pulmonary vasoreactivity.

In addition to the testing described above, other investigations may be necessary depending on the specific indication for pulmonary resection. Detailed discussion of these additional tests can be reviewed in Chap. 2.

Treatment and Consultations

The management and treatment of pulmonary hypertension requires a multidisciplinary approach and is a topic well beyond the scope of this chapter. However, the thoracic anesthetist should have a basic understanding of the management of pulmonary hypertension patients and the relevant perioperative implications of pulmonary hypertension treatment. All patients with significant pulmonary hypertension should ideally have consultation and ongoing follow-up with a pulmonary hypertension specialist and, if applicable, a specialist for the management of the underlying cause of their pulmonary hypertension (e.g., a cardiologist for left-sided heart disease, a rheumatologist for connective tissue disorders). Perioperative management should include consultation with these specialists to ensure proper optimization prior to presenting to the operating room.

Specific management of pulmonary hypertension is dependent on the underlying cause; however, pharmacologic management may involve the use of vasodilators, diuretics, steroids, and immune suppressants, as well as anticoagulants. Perioperative management of these pharmacologic regimens may be complex.

Pulmonary vasodilating agents, such as endothelin receptor antagonists, prostanoids, and phosphodiesterase-5 inhibitors, can be used alone or in combination in the management of pulmonary arterial hypertension (Group 1).

Endothelin receptor antagonists (ERAs) target the endothelin-1 receptor, which mediates vasoconstriction and plays a significant role in the pathogenesis of pulmonary arterial hypertension [23]. Commonly used preparations include bosentan, ambrisentan, and macitentan, all of which are administered orally. While generally well-tolerated, hepatotoxicity and the development of transaminitis are well-known adverse effects of ERAs and should be screened shortly after initiation [24]. Other less common but significant adverse effects include anemia and hypotension.

Prostanoids are prostacyclin analogues and exhibit potent vasodilating effects mediated through increasing intracellular cyclic adenosine monophosphate [25]. Presently, three prostacyclin analogues are available: epoprostenol (continuous intravenous infusion), treprostinil (continuous subcutaneous infusion), and iloprost (inhalational administration). The relatively short half-lives of these agents necessitate continuous or frequent administration. Epoprostenol's half-life is less than 5 min, and thus therapy requires continuous intravenous infusion via a portable infusion pump. The half-lives of treprostinil and iloprost are approximately 45–60 min [26]. Abrupt discontinuation of prostanoid therapy can result in life-threatening rebound of pulmonary hypertension. Additional concerns regarding prostanoids include the potential for systemic hypotension, as well as increased bleeding risk due to prostanoid-mediated inhibition of platelet aggregation [27].

Phosphodiesterase-5 (PDE-5) inhibitors were initially introduced for the management of erectile dysfunction but have found a significant role in the management of pulmo-

nary arterial hypertension. PDE-5 is predominantly found in the lungs, and its inhibition prevents the breakdown of cyclic guanosine monophosphate (cGMP) [28]. cGMP potentiates the vasodilatory effects of nitric oxide, producing pulmonary vasodilation. Oral preparations of PDE-5 inhibitors include sildenafil and tadalafil. These agents are generally well-tolerated and produce minor adverse effects such as headaches, flushing, and dyspepsia [24].

In general, these agents (especially prostanoids) are continued in the perioperative period; however, adjustment of doses and dosing may need to occur and should be managed by an experienced prescriber.

Intraoperative Management

An understanding of the pathophysiology of pulmonary hypertension and its implications for general anesthesia is of utmost importance when managing the patient with pulmonary hypertension presenting for pulmonary resection. Right ventricular failure and resulting cardiovascular collapse secondary to pulmonary hypertension present the greatest risk in the perioperative period. The right ventricle normally receives perfusing blood flow during both systole and diastole. However, elevated pulmonary arterial pressures produce increased right ventricular transmural and intracavitary pressures, which can limit ventricular perfusion during systole and result in RV ischemia [29]. Hypotension is poorly tolerated in significant pulmonary hypertension, as well as conditions impairing right ventricular filling, such as tachycardia and arrhythmias. Low systemic to pulmonary pressure ratios are associated with poorer outcomes and should be avoided intraoperatively. The pathophysiologic processes involved in right ventricular failure in the setting of increased right ventricular afterload (pulmonary hypertension) are shown in Fig. 34.1. In addition, care needs to be taken to prevent conditions which would worsen pulmonary arterial pressures, including hypoxemia, hypercarbia, hypothermia, acidosis, and elevated alveolar pressures.

The ideal anesthetic would maintain or enhance right ventricular function and systemic vascular resistance while decreasing pulmonary vascular resistance. However, in practice, this is challenging to achieve in the operating room. A summary of hemodynamic and ventilation goals is shown in Table 34.4.

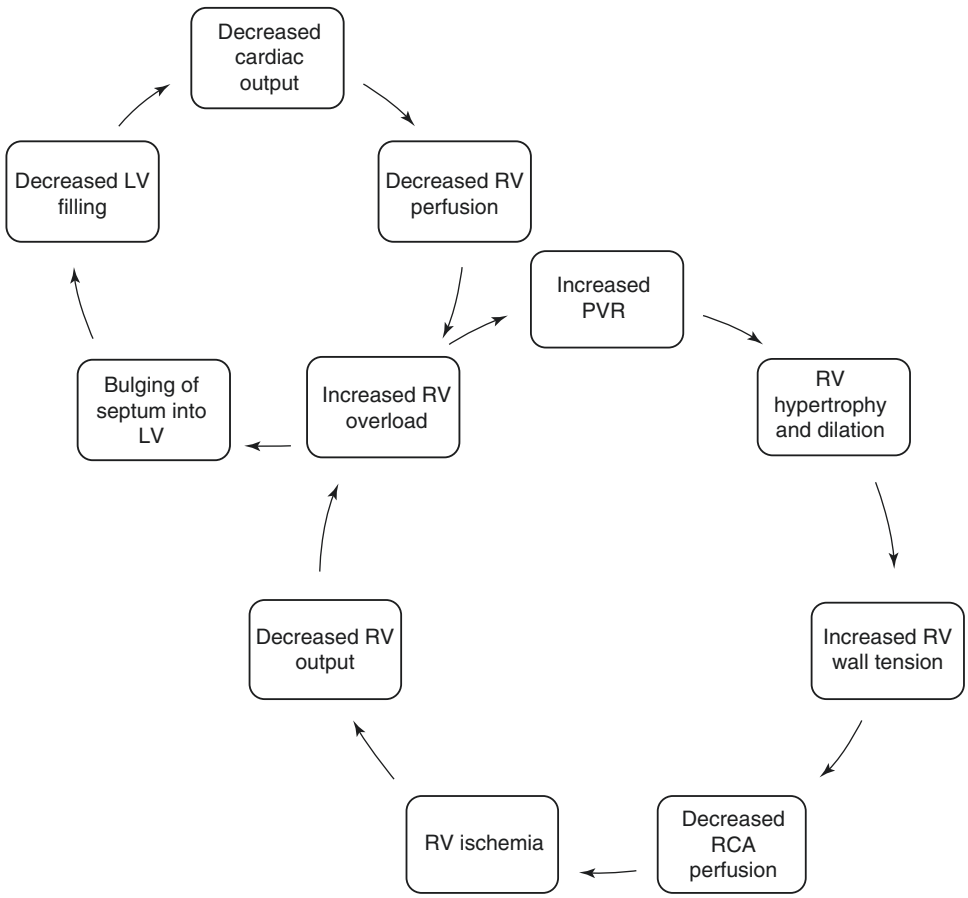

Fig. 34.1 Pathophysiologic mechanisms in right-sided heart failure. PVR pulmonary vascular resistance, RCA right coronary artery. (Reprinted from Wilcox et al. [29] with permission from Elsevier)

Table 34.4 Hemodynamic and ventilatory goals during anesthesia for pulmonary hypertension

Parameter	Goals
Hemodynamic conditions	
Preload	Avoidance of hypervolemia – precipitates RV failure Avoidance of hypovolemia – impairs stroke volume and cardiac output Hypovolemia is better tolerated
Afterload	Maintain a systemic systolic blood pressure greater than the pulmonary systolic pressure to maintain right ventricular perfusion Vasopressors may be used to achieve this
Right ventricular contractility	Avoid excessive myocardial depression (choice of anesthetic agent) Consider use of inotropes when needed
Heart rate	Normal heart rate – avoid tachycardia, which impairs right ventricular filling and cardiac output
Pulmonary vascular resistance	Avoid precipitants of increased pulmonary vascular resistance (hypoxia, hypercarbia, acidosis, hypothermia, increased sympathetic tone)
Ventilatory conditions	
Optimize oxygenation	Maintain higher FiO_2 as needed to avoid hypoxia Careful PEEP titration
CO_2	Target normocapnia to mild hypocapnia (pCO_2 30–35)
pH	Normal pH Mild alkalosis promotes pulmonary vasodilation
Airway pressure	Minimize peak inspiratory pressure as much as possible Peak inspiratory pressure <30 mmHg Avoid excessive PEEP

Premedication

The perioperative period is a stressful time for all patients, and many centers routinely provide patients with the option of an anxiolytic administered in a preoperative area. Care and attentiveness should be taken when administering sedating agents (such as benzodiazepines) to patients with pulmonary hypertension preoperatively, which is a period where continuous monitoring is not always available. Preoperative anxiolytics often have a sedating effect which can result in hypoventilation leading to hypercarbia and, in some cases, hypoxia. These two conditions can precipitate significant increases in pulmonary vascular resistance, which can be life-threatening. Sedative premedication should be used cautiously, or avoided completely, in the patient with significant pulmonary hypertension. If required, continuous hemodynamic monitoring, as well as supplemental oxygen, should be considered and readily available.

Intraoperative Monitoring

Intrathoracic surgery, including surgery for pulmonary resection, requires an increased level of intraoperative monitoring. Routine noninvasive monitors, including 5-lead ECG, pulse oximetry, capnography, temperature, and noninvasive blood pressure monitoring, are complemented by invasive blood pressure monitoring. In patients presenting for thoracic surgery, invasive blood pressure monitoring via an intra-arterial catheter is routinely done prior to induction of anesthesia at the authors' institution. This allows for continuous monitoring of systemic blood pressure during induction and maintenance of anesthesia. Of equal importance, invasive blood pressure monitoring allows regular sampling of arterial blood gases to assess oxygenation and ventilation.

Central venous access should be considered in patients with significant pulmonary hypertension, evidence of right ventricular dysfunction, or for major pulmonary resections, as it allows for infusions of vasopressors and inotropes (discussed further below). Central venous access also allows for the insertion of a pulmonary artery catheter (PAC), which in turn allows for continuous measurement of pulmonary arterial pressures and determination of cardiac output. The use of PACs for intraoperative and perioperative monitoring has been subject to significant controversy in the literature. One large observational study determined that the perioperative use of PACs in patients presenting for non-cardiac surgery was associated with an increased risk of postoperative cardiac (myocardial infarction, angina, cardiogenic shock, ventricular fibrillation/tachycardia, cardiac arrest, or complete heart block) and non-cardiac (pulmonary embolism, noncardiogenic pulmonary edema, prolonged mechanical ventilation, pneumonia, renal failure, stroke, or GI bleeding) morbidity [30]. A subsequent prospective randomized controlled study involving high-risk non-cardiac surgery patients found that the use of a PAC conferred no benefit in terms of overall mortality or cardiac and non-cardiac morbidity [31]. However, thoracic surgery patients made up only a small minority of the studied population in both studies and neither specifically assessed for pulmonary hypertension and its implications. Unfortunately, there is no large study investigating the use of PACs in thoracic (pulmonary resection or otherwise) surgery.

Given the lack of alternative means to continuously monitor pulmonary artery pressures intraoperatively, the use of PACs in patients presenting for pulmonary resection should strongly be considered in the setting of significant pulmonary hypertension and especially in patients where pulmonary artery pressures approach or exceed systemic pressures. The interpretation of PAC data can be challenging and misleading in patients with pulmonary hypertension, even for experienced clinicians [32]. Elevated and increasing pulmonary artery pressures are universally an indicator of worsening clinical status. However, decreasing pressure can indicate a desirable reduction in pulmonary artery pressures or impending right ventricular failure and subsequent cardiovascular collapse. As such, PAC data must be interpreted in

the context of other hemodynamic indices such as arterial blood pressure, cardiac output, and central venous pressures. It should also be noted that the use of a PAC is not without risk, as pulmonary hypertension is a known risk factor for PAC-associated pulmonary artery rupture, which is an exceedingly rare (incidence 0.03–0.2%) but highly fatal (mortality ~ 70%) complication [33].

Intraoperative transesophageal echocardiography (TEE) is a monitoring tool that is growing in terms of availability and utility, particularly in the setting of assessment of dynamic ventricular function (see also Chap. 30). Intraoperative TEE has been recurrently shown to enhance and influence therapeutic decision-making in the OR during surgery [34, 35]. The American Society of Anesthesiologists recommends the use of intraoperative TEE during non-cardiac surgery "when the nature of the planned surgery or the patient's known or suspected cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise" [36]. As right ventricular failure in the context of worsening pulmonary hypertension is a major concern in the intraoperative period, the utility of TEE in assessment of right ventricular function is of growing interest. The use of TEE as a monitor intraoperatively in the patient with pulmonary hypertension allows for assessment of baseline right ventricular function and the presence of significant right ventricular dysfunction, which has been shown to be an important prognostic indicator in cardiac surgery [37]. However, unlike the left ventricle, where continuous TEE monitoring of function can be reasonably performed through a single view, the complex and irregular structure of the right ventricle requires multiple views to assess changes in regional function. As such, continuous monitoring with concurrent management of the potentially failing right ventricle in the setting of worsening pulmonary hypertension may be impractical for the lone care provider. The advent of new three-dimensional TEE technology has allowed for rapid and accurate assessment of right ventricular function in a matter of minutes [38] and may eventually evolve to allow for simple, reliable, and continuous monitoring of right ventricular function in the OR.

Anesthetic Management

The pharmacology and physiologic effects of commonly used anesthetic agents make induction and maintenance of anesthesia in the patient with pulmonary hypertension challenging. The ideal anesthetic agent(s) would provide deep anesthesia while maintaining cardiac performance (specifically that of the right ventricle) and systemic vascular resistance while reducing pulmonary vascular resistance. In practice, commonly used agents generally produce impairment in cardiac contractility and reduced systemic vascular resistance while having variable or unclear effects on pulmonary vascular resistance.

Intravenous Agents

The use of intravenous agents in the anesthetic management of patients presenting to the OR is near ubiquitous. The growing number of pharmacologic agents available, as well as their varying pharmacodynamic effects, warrants closer examination, especially in the context of the deranged cardiorespiratory physiology involved in pulmonary hypertension patients.

Propofol is among the most commonly used intravenous agents for both the induction and maintenance of anesthesia. The effect of propofol on pulmonary vascular tone is unclear; however, animal studies have shown that in the setting of increased adrenergic activity, administration of propofol has a vasoconstricting effect on pulmonary vasculature [39, 40]. However, in a human model, administration of propofol in normoxic conditions had a vasodilatory effect in the pulmonary vasculature [41], raising questions regarding propofol's true effect. What is clear, however, is that propofol exhibits depressant effects on both myocardial function and systemic vascular resistance. Both effects can impair right ventricular function, either directly or by reducing coronary perfusion to the right ventricle through reduced systemic pressures. As such, caution should be exercised when using propofol in the patient with pulmonary hypertension, especially if right ventricular dysfunction is present.

Etomidate is a less commonly used intravenous induction agent with a neutral hemodynamic profile, allowing for preserved right ventricular function and perfusion. Furthermore, in vitro human pulmonary artery models have suggested some vasodilatory effects on the pulmonary vasculature [41]. While these properties would make etomidate the ideal induction agent in the patient with pulmonary hypertension, a recently published retrospective analysis looking at over 31,000 patients (ASA III–IV patients) found that the use of etomidate was associated with increased 30-day mortality and cardiovascular morbidity as compared to patients receiving propofol [42]. While the study did not specifically include patients with pulmonary hypertension or those undergoing thoracic surgery, the results do raise concerns regarding the safety of etomidate in higher-risk patients.

Ketamine is an NMDA-receptor antagonist with activity at other sites, including opioid, acetylcholine, norepinephrine, dopamine, and serotonin receptors. As such, ketamine possesses many attractive features for an intravenous agent, including its sympathomimetic effects producing increased myocardial contractility and systemic vascular resistance, as well as bronchodilator, analgesic, and antidepressant effects [43, 44]. There is much controversy surrounding the effects of ketamine on pulmonary pressures, as early studies investigating the drug's cardiovascular effects demonstrated signifi-

cant increases in both pulmonary artery pressures and pulmonary vascular resistance [45, 46]. As such, the prevailing opinion was that ketamine should be avoided in patients with pulmonary hypertension. However, these early studies did not control for hypercarbia or hypoxia, two key triggers for pulmonary vasoconstriction [47]. More recently, human and animal studies have demonstrated that the use of ketamine, when controlling for ventilation, oxygenation, and acid-base status, does not increase pulmonary vascular resistance [48], is safe when used in patients with pulmonary hypertension [49], and may produce pulmonary vasodilation [50]. Of note, at the authors' institution, ketamine is routinely used in patients with significant pulmonary hypertension and right ventricular dysfunction presenting for cardiac, thoracic, and lung transplantation procedures.

Benzodiazepines and opioids are often used in conjunction with intravenous induction agents and produce minimal hemodynamic effects beyond their attenuation of sympathetic tone [7].

Volatile Anesthetics

Modern volatile anesthetics are commonly used to maintain general anesthesia intraoperatively. While much of the literature surrounding the cardiovascular effects of volatile anesthetics (specifically desflurane, isoflurane, and sevoflurane) has focused on their impact on left ventricular function, there is some suggestion that volatile agents produce significant effects on right ventricular performance as well. Animal studies have shown that sevoflurane, isoflurane, and desflurane all produce depression of right ventricular contractility, with sevoflurane effects being quite significant [51–53]. Furthermore, sevoflurane appears to produce greater reductions in systemic vascular resistance, without altering pulmonary vascular resistance [53]. This creates an unfavorable pulmonary-to-systemic pressure ratio relative to desflurane, in which systemic vascular resistance tends to be maintained with only a small increase in pulmonary pressures [51].

Vasopressor Agents

Due to the importance of preserved systemic pressures in maintaining right ventricular perfusion, vasopressor agents are useful in the intraoperative management of patients with pulmonary hypertension. As previously mentioned, the maintenance of a high ratio of systemic pressures to pulmonary pressures is important in avoiding deterioration in hemodynamics. Commonly used vasopressor agents, including phenylephrine, norepinephrine, and vasopressin have all been shown to exert different effects on hemodynamic parameters, including systemic and pulmonary pressures.

An early animal model demonstrated that commonly used agents, including phenylephrine, norepinephrine, and epinephrine, all increased systemic and pulmonary pressures to varying degrees while largely preserving pulmonary vascular resistance [54]. Norepinephrine, in addition to its vasoconstricting effects, has β-1 receptor-mediated inotropic effects, which appear to improve right ventricular-pulmonary arterial coupling while maintaining cardiac output and right ventricular performance [55]. Animal models have also demonstrated that in doses less than 0.5 ug/kg/min, norepinephrine has minimal effects on pulmonary vascular resistance [56]. In contrast, phenylephrine has been shown to exert negative effects on right ventricular function in pulmonary hypertension patients by increasing pulmonary vascular resistance [57].

Perioperatively, in patients with pulmonary hypertension presenting for cardiac surgery, both norepinephrine and phenylephrine were shown to increase systemic and pulmonary pressures, however with distinct differences in hemodynamic parameters. Norepinephrine use resulted in a reduction of pulmonary arterial pressure to systemic blood pressure ratio without reducing cardiac index. Conversely, use of phenylephrine resulted in preservation of the pulmonary arterial pressure to systemic blood pressure ratio while reducing cardiac index [139]. These results suggest that norepinephrine is preferable to phenylephrine in the treatment of hypotension in pulmonary hypertension patients.

The effect of vasopressin on pulmonary arterial pressure has been subject to significant debate. In experimental animal models, vasopressin has been demonstrated to result in both pulmonary vasoconstriction [58] and pulmonary vasodilation [59, 60], leading to significant confusion. The absence of vasopressin receptors in human pulmonary vasculature has been widely posited, and recently, an experimental model using human radial and pulmonary arteries has demonstrated that while vasopressin exhibits a potent vasoconstricting effect in radial vessels, it had no effect on pulmonary vascular tone [61]. Subsequent to this finding, numerous publications have demonstrated consistent improvement in systemic blood pressures with minimal effect on pulmonary arterial pressures in hypotensive patients with pulmonary hypertension that are treated with vasopressin [62, 63]. These properties make vasopressin another valuable agent in the management of hypotension in pulmonary hypertension patients.

Vasodilator Agents

In addition to the use of agents to maintain systemic blood pressure intraoperatively, the use of vasodilating agents in order to decrease pulmonary vascular resistance has also garnered significant interest, particularly agents such as inhaled nitric oxide (iNO), milrinone, and prostaglandins.

iNO had garnered significant interest in the areas of acute respiratory distress syndrome (ARDS), heart and lung transplantation, and right ventricular failure, with mixed success [64–66]. Mechanistically, iNO is delivered noninvasively, or through a ventilator circuit, and is directed toward preferentially ventilated alveoli. Through its vasodilatory effects, iNO theoretically improves alveolar gas exchange and

reduces pulmonary vascular resistance without resulting in systemic hypotension – all desirable in pulmonary hypertension. Clinically, dose ranges of 10–40 ppm are typically administered [67]. In the setting of right heart failure due to pulmonary hypertension, the use of iNO has been mixed and varies from patient to patient, as well as clinical scenario [68, 69]. One study [70] has examined the use of iNO (40 ppm) in thoracic surgery patients during one-lung ventilation and demonstrated that improvements in pulmonary vascular resistance and hypoxia during one-lung ventilation were only seen in patients with preexisting pulmonary hypertension. Unfortunately, due to the significant cost, as well as the advent of other alternative pulmonary vasodilators, intraoperative use of iNO has limited usage. However, given its mechanism of action, as well as the potential benefits during one-lung ventilation, iNO should be given consideration during the management of the patient with pulmonary hypertension presenting to the operating room.

Milrinone is a phosphodiesterase-3 inhibitor with both inotropic and vasodilatory effects when administered intravenously. Due to its effect of reducing both pulmonary and systemic vascular resistances, intravenous milrinone has limited effectiveness in right heart dysfunction related solely to pulmonary hypertension and often requires the concomitant administration of a vasopressor to counter the resulting hypotension. However, milrinone has demonstrated usefulness in patients with biventricular failure in the setting of pulmonary hypertension [71]. Administration of milrinone for pulmonary vasodilation in an inhaled form has gained significant interest recently, particularly in cardiac surgery. In patients with pulmonary hypertension presenting for cardiac surgery involving cardiopulmonary bypass, administration of inhaled milrinone (5 mg) prior to bypass was associated with reductions in pulmonary arterial pressures, enhancement of cardiac output, and minimal effect on mean arterial pressures [72, 73]. Unfortunately, there were no significant improvements in terms of intraoperative or postoperative complications (including right ventricular failure) in patients receiving inhaled milrinone. In addition, the combination of inhaled milrinone and inhaled prostacyclin appears to have an additive effect on pulmonary vasodilation [74]. Presently, there are no studies investigating the use of inhaled milrinone in the thoracic surgery population; however, given the favorable hemodynamics observed in the cardiac surgery population, it presents a potentially attractive option for pulmonary resection surgeries.

As previously discussed, prostanoids have an important role in the management of pulmonary arterial hypertension and are available in intravenous and inhaled formulations that can be used intraoperatively. Animal models for one-lung ventilation have demonstrated that both aerosolized and intravenous administration of prostacyclin (PGI_2) reduce pulmonary arterial pressures [75]. While intravenous infusion of PGI_2 resulted in notable reduction in systemic vascular resistance, aerosolized PGI_2 produced selective pulmonary vasodilation. Similarly, intravenous prostaglandin E_1, a short-acting prostaglandin with pulmonary metabolism, administration during one-lung ventilation of pigs produced reductions in pulmonary vascular resistance and pulmonary arterial pressures but failed to demonstrate selective pulmonary vasodilation [76]. In the intraoperative setting, inhaled prostacyclin has been used in cardiac surgery patients with pulmonary hypertension with significant effect in terms of reducing pulmonary arterial pressures with minimal alterations in systemic blood pressure [77, 78]. Inhaled prostacyclin has also been used in the management of pulmonary hypertension during lung transplantation [79], as well as hypoxemia during one-lung ventilation for video-assisted thoracoscopic surgery in a patient without pulmonary hypertension [80]. As previously mentioned, while the use of prostanoids has been shown to significantly reduce pulmonary pressures in pulmonary hypertension patients, there is considerable uncertainty with respect to their effect on platelet function and bleeding risk, which needs to be considered in the intraoperative setting.

Analgesia

Analgesic strategies for pulmonary resection surgeries are typically determined based on the type of incision (thoracotomy vs video-assisted thoracoscopic surgery (VATS)) as well as patient-specific considerations, including decreased pulmonary reserve or a history of chronic pain or opioid use. At the authors' institution, analgesia for surgeries done using VATS are managed postoperatively with a combination of intercostal nerve blocks administered by the surgeon prior to chest closure and intravenous patient-controlled analgesia (PCA). In patients undergoing a thoracotomy without any contraindications, our practice is to provide patient-controlled epidural analgesia using a thoracic epidural placed prior to the induction of anesthesia.

Epidural analgesia carries a number of benefits, including enhanced analgesia compared to intravenous PCA [81–83]. Furthermore, it has been established that the use of epidural analgesia for major surgery, including thoracic surgery, is associated with reduced cardiovascular and pulmonary complications [84], as well as overall mortality [85]. Also of importance, the use of a thoracic epidural does not impact oxygenation during one-lung ventilation [86]. The beneficial effects on cardiorespiratory morbidity may be particularly important for high-risk patients such as those with pulmonary hypertension presenting for thoracic surgery. However, the relationship between the

use of epidural analgesia and pulmonary hypertension itself remains unclear.

The effect of thoracic epidural analgesia on left ventricular performance has been thoroughly investigated with mixed conclusions. Depending on clinical setting, the use of a thoracic epidural may enhance or reduce left ventricular ejection fraction and cardiac output [87–89]. The use of a thoracic epidural in patients with known coronary artery disease appears to enhance left ventricular function [88, 89]. The effect of thoracic epidurals on the right ventricle has also been studied, with animal models demonstrating that the use of a thoracic epidural impairs baseline right ventricular function and inhibits the homeometric augmentation of right ventricular contractility associated with increased right ventricular afterload (pulmonary hypertension) [90, 91]. However, in human patients undergoing thoracotomy for lung resection, the use of a thoracic epidural impaired baseline right ventricular contractility, but did not affect the compensatory increase in right ventricular contractility brought on by an acute increase in right ventricular afterload [92]. These negative effects on ventricular function may represent the effect of cardiac sympathectomy exerted by thoracic epidural blockade.

Overall, these findings suggest that the use of thoracic epidurals in patients with pulmonary hypertension presenting for thoracotomy should be done with care and attention, due to the potential for impairment of biventricular function. However, given that the ability of the right ventricle to increase contractility in the setting of acute increases in afterload is not abolished by epidurals, their use is not contraindicated in pulmonary hypertension patients presenting for thoracic surgery. Furthermore, due to the increased risk of postoperative complications in this population, the beneficial effects of thoracic epidural analgesia are desirable. It must be recognized, however, that these patients will require appropriate monitoring postoperatively and may require hemodynamic support in the form of inotropes and/or vasopressors when using thoracic epidural analgesia.

Paravertebral blockade is a commonly used alternative to both thoracic epidural analgesia and intravenous PCA for post-thoracic surgery pain management. Compared to thoracic epidurals, paravertebral catheters present an attractive alternative, especially given the ability to preserve the contralateral sympathetic chain and minimize hemodynamic consequences. In patients undergoing thoracotomy, paravertebral blockade has been shown to provide comparable analgesia to thoracic epidurals and reduce episodes of hypotension, nausea and vomiting, pruritus, and urinary retention [93–96, 140]. However, there is limited literature available concerning the effects of paravertebral blockade on cardiac function or their use in pulmonary hypertension patients. As such, paravertebral blockade presents a potential alternative to thoracic epidurals for post-thoracotomy pain management, with more research being needed for their use in lung resection patients with pulmonary hypertension.

Management of One-Lung Ventilation

The initiation of one-lung ventilation (OLV) for thoracic surgery presents a direct conflict with the management goals for pulmonary hypertension. Avoidance of hypoxia, hypercapnia, and elevated airway pressures is important in minimizing pulmonary vascular resistance. The early period of OLV results in acute rises in pulmonary arterial pressures due to shifting of tidal volumes (resulting in a rise in airway pressures) and pulmonary blood flow from the two lungs to a single lung [97]. This can be further exacerbated by hypoventilation and shunting, which produce undesirable hypercarbia and hypoxia, particularly in patients with preexisting pulmonary hypertension (Fig. 34.2).

General management of OLV for thoracic surgery is discussed elsewhere in this book. The same principles apply in the patient with pulmonary hypertension with a few key distinctions. Lung-protective ventilation strategies have been advocated for OLV, with tidal volumes of 4–6 mL/kg predicted body weight, the application of positive end-expiratory pressures (PEEP) of 5–10 cm H_2O, and maintaining peak inspiratory pressures of less than 30 cm H_2O being advised [97–100]. The appropriate inspired oxygen fraction (F_iO_2) is subject to debate, as higher F_iO_2 has

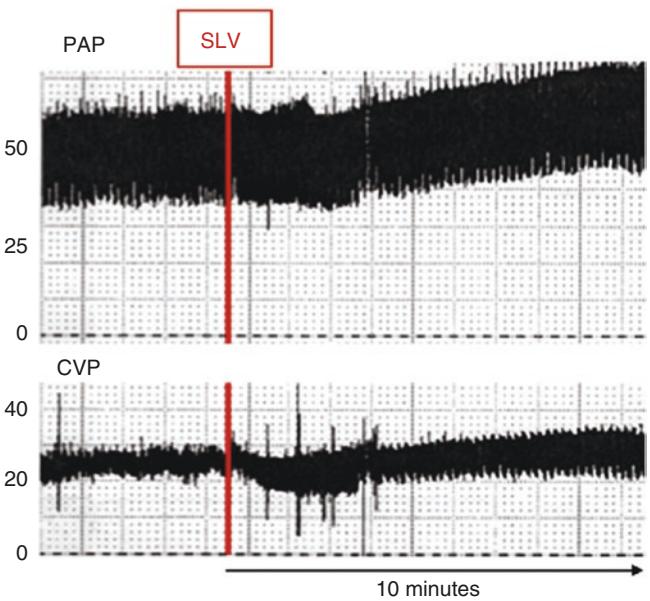

Fig. 34.2 Effect of single-lung ventilation (SLV) on pulmonary arterial pressure (PAP) and central venous pressure (CVP) in a patient with pulmonary arterial pressure. (Reprinted from McGlothlin et al. [97] with permission from Elsevier)

been shown to promote atelectasis formation and produce hypoxia [101]. This has led to the suggestion that $F_iO_2 < 1.0$ be used during the initiation of OLV [99, 100]. However, oxygen is a potent pulmonary vasodilator, especially in pulmonary hypertension patients (irrespective of underlying diagnosis) [102]. In these patients, it is advisable to maintain a higher F_iO_2 initially, with careful titration according to pulmonary pressures and arterial blood gases. Similarly, management of arterial CO_2 (P_aCO_2) is of significant importance, with mild hypocapnia ($P_aCO_2 < 30–35$ mmHg) being advocated during OLV [97], as alkalosis has been shown to produce pulmonary vasodilation [103, 104]. The use of recruitment maneuvers during the management of OLV and hypoxia during OLV is also a commonplace and, however, carries with it the risk for hemodynamic instability due to hypotension and potential for acute worsening of pulmonary hypertension. Human and animal studies have demonstrated the significant benefits of recruitment in pulmonary hypertension subjects [105, 106], with the application of 30 cm H_2O with an F_iO_2 for 1 min followed by adjustment of PEEP showing improved oxygenation and acceptable hemodynamic changes in patients with chronic thromboembolic pulmonary hypertension.

Worsening pulmonary vascular resistance and hypoxia during OLV are often difficult to avoid but require immediate attention and management. As previously discussed, iNO is a potent selective pulmonary vasodilator that has been proven to improve pulmonary hypertension and hypoxia in patients with preexisting pulmonary hypertension undergoing pulmonary resection [70]. In patients with significant pulmonary hypertension, iNO should be instituted concurrently with the initiation of OLV to limit the rise in pulmonary pressures and improve ventilation-perfusion matching.

Prostanoids have also been shown to be effective pulmonary vasodilators in pulmonary hypertension OLV models [75, 76]. Route of administration is an important distinction between prostanoids and iNO, with prostanoids being available in intravenous (epoprostenol) and inhaled (iloprost) forms. The pulmonary selectivity of iloprost allows for pulmonary vasodilation with minimal systemic hypotension and should be the route used during OLV. Importantly, in addition to pulmonary vasodilation, inhaled prostanoids have been shown to improve oxygenation during OLV as well [80, 107]. Furthermore, the combination of iNO and a prostanoid has been shown to be additive in a pulmonary hypertension animal model [108, 109]; however, this has not been studied during OLV.

In patients already stabilized on a systemically delivered pulmonary hypertension treatment (intravenous or subcutaneous), the potential for worsening systemic hypotension under anesthesia and impairment of hypoxic pulmonary vasoconstriction during OLV should be appreciated. As such, a plan for intraoperative management of these agents should be made preoperatively in conjunction with their pulmonary hypertension specialist. Fortunately, their relatively short half-lives allow for careful titration leading up to initiation of OLV. In these patients, the use of an inhaled pulmonary vasodilator initiated prior to starting OLV is recommended and allows for safe titration of their systemic agent [97] (Fig. 34.3).

Intraoperative Fluid Management

The topic of intraoperative fluid management for major surgery, including thoracic surgery, has been subject to significant debate through the years. The literature has consistently demonstrated that high intraoperative fluid balances are associated with higher rates of perioperative acute lung injury and ARDS [110–112]. Fluid overload combined with mechanical ventilation produces pulmonary endothelial damage and inflammation resulting in pulmonary edema [111, 113–115]. Furthermore, an animal model for OLV and thoracic surgery have demonstrated that compared to two-lung ventilation, OLV increases the potential for acute lung injury [116]. In addition, excessive fluid administration (> 6 mL/kg/h) intraoperatively during pulmonary resection has been shown to increase the risk for pulmonary complications such as atelectasis and pneumonia [117].

The avoidance of pulmonary complications is important for the perioperative management of patients with pulmonary hypertension, as acute lung injury, pneumonia, and atelectasis can all destabilize the already frail patient. Additionally, optimal fluid management is of paramount importance in maintaining appropriate right ventricular preload in the setting of existing right ventricular dysfunction and high right ventricular afterload. Excessive fluid administration can lead to right ventricular overdistension and eventual failure, and inadequate fluid administration can compromise cardiac output and hemodynamics [98]. Fluid management in these patients is often a fine balance.

In spite of the knowledge that excessive fluid administration in thoracic surgery patients is harmful, there are many remaining unknowns and uncertainties regarding fluid management in these patients. These include the proper type of fluid, as well as the ideal fluid balance to achieve during thoracic surgery (neutral vs negative) [118, 119]. The current recommendation for intraoperative fluid management is to adopt a goal-directed approach, with individualization and titration of the fluid administration based on specific cardiovascular measurements, which may include stroke volume, cardiac output, fluid responsiveness, or TEE-based guidance [111].

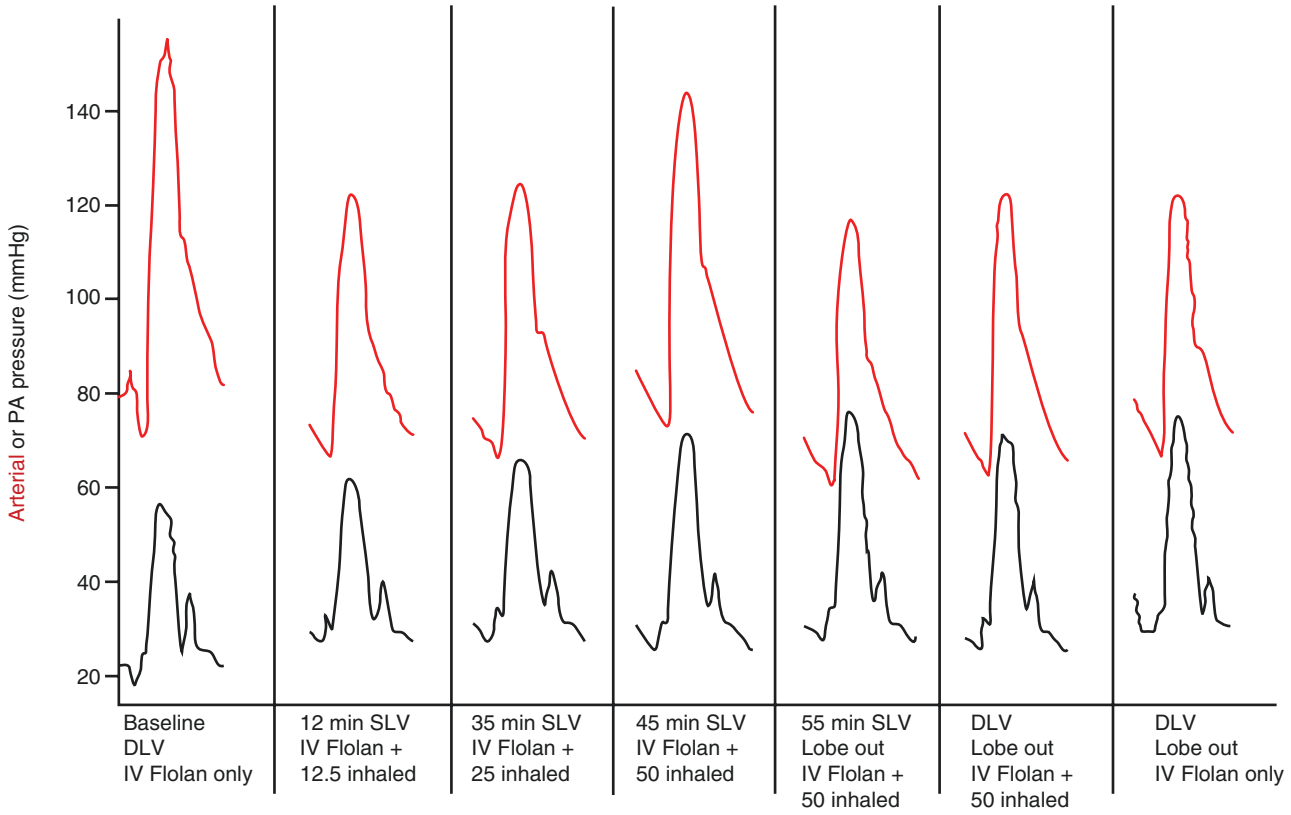

Fig. 34.3 Representative tracings of systemic and pulmonary arterial pressures during lung lobectomy in a patient with preexisting PAH. Representative simultaneous tracings of systemic arterial and pulmonary arterial (PA) pressures during lung lobectomy in a patient with preexisting PAH who was receiving intravenous (IV) Flolan (epoprostenol) preoperatively. With the transition from double-lung ventilation (DLV) to single-lung ventilation (SLV), the IV Flolan dose was decreased and inhaled Flolan initiated in order to maximize vascular dilation of the ventilated lung and potentially lessen the deleterious effects of systemic Flolan on hypoxic pulmonary vasoconstriction. Following lung resection and resumption of the preoperative Flolan dose, PA pressure remained elevated relative to baseline. (Reprinted from McGlothlin et al. [97] with permission from Elsevier)

Use of Extracorporeal Support for Pulmonary Resection (See Also Chap. 27)

There is growing use of extracorporeal life support, specifically extracorporeal membrane oxygenation (ECMO) in a variety of settings, including ARDS, cardiac failure, and transplantation. The use of extracorporeal support, such as ECMO or full cardiopulmonary bypass, during pulmonary resection surgery has been described in the literature, predominantly in cases involving large masses with significant cardiorespiratory compromise or procedures requiring tracheal or carina resection [120–123]. In patients with pulmonary hypertension, use of venoarterial ECMO allows for optimal gas exchange, as well as maintenance of cardiac output and coronary perfusion without increasing pulmonary pressures. Extracorporeal life support is presently limited to specialized centers and requires anticoagulation during its use which increases the risk for bleeding. Its use in pulmonary resection in the patient with pulmonary hypertension is presently not well-described in the literature and, however, presents an option requiring further investigation.

Postoperative Management

Postoperatively, patients presenting for pulmonary resection with significant pulmonary hypertension warrant admission to a unit with a higher-than-usual level of monitoring and care. Because of the significant cardiorespiratory compromise and the increased risk of postoperative complications, pulmonary hypertension patients require a postoperative setting capable of frequent, if not continuous, monitoring by skilled and experienced nursing care. Typically, this is an intensive care unit or a step-down unit with the ability to manage patients with invasive cardiovascular monitoring (such as invasive blood pressure monitoring, central venous pressure monitoring, or pulmonary artery catheters), patients who may require postoperative mechanical ventilation, and patients who require pharmacologic support with vasopressors, inotropes, or pulmonary vasodilators [7, 97]. It has been advocated that this should be a standard of care, irrespective of the intraoperative course [124].

In non-cardiac surgery, respiratory failure and right ventricular failure have been identified as the most common con-

tributors to early (less than 30 days) postoperative mortality among patients with pulmonary hypertension [6]. With respect to reducing the risk of pulmonary complications that may contribute to respiratory failure, a number of strategies have been shown to be of benefit, including chest physiotherapy, continuous positive airway pressure, and incentive spirometry. In upper abdominal and thoracic surgery, use of these techniques may reduce pulmonary complications by half [125–127]. Chest physiotherapy and continuous positive airway pressure may not be widely available and may pose some safety concerns in the frail or borderline patient with pulmonary hypertension. Incentive spirometry is an easy and inexpensive way of encouraging deep breathing and lung expansion [128]. As previously mentioned, excessive fluid administration can increase the risk of postoperative pulmonary and cardiac complications, and the rational fluid management strategy used intraoperatively should be continued in the postoperative period as well.

Right ventricular failure is a major cause of postoperative mortality in pulmonary hypertension patients, with one study citing it as a contributor to mortality in 50% of cases [6]. The potential causes of right ventricular failure are numerous and, in the immediate postoperative period, include pulmonary embolism, infection, bleeding/anemia, arrhythmias, and acute worsening of pulmonary hypertension. Among these causes, pulmonary embolism and infection should be protected against with appropriate intra- and postoperative prophylaxis. Ongoing bleeding and resulting anemia should be identified and addressed immediately, as hypovolemia and anemia both increase myocardial (specifically right ventricular) work and may be poorly tolerated.

Postoperative arrhythmias, specifically atrial tachyarrhythmias, are common after thoracic surgery and occur most frequently on postoperative days 2 and 3 [129]. Atrial fibrillation and flutter are both associated with right ventricular failure, clinical deterioration, and death and require immediate management [130]. In unstable patients, electrical cardioversion is the treatment of choice and should not be delayed [129, 130]. In terms of pharmacologic management of the stable patient with an atrial tachyarrhythmia, beta-blockers and calcium channel blockers should be used with caution, as their potential for reducing myocardial contractility and vasodilating effects may be poorly tolerated in pulmonary hypertension patients [97, 131]. Instead, amiodarone and/or digoxin may be considered for rhythm and/or rate control in these cases. Intravenous magnesium is another option commonly recommended in the literature for both treatment and prophylaxis of atrial arrhythmias post-thoracic surgery [129, 132], and at the authors' institution, lung resection patients are typically given 2.5–5 g of intravenous magnesium sulfate by slow infusion intraoperatively for arrhythmia prophylaxis. Care should be exercised, however, as rapid administration of magnesium can produce significant hypotension.

Worsening pulmonary hypertension is another potential cause of right ventricular failure post-lung resection and should be closely monitored for postoperatively. There are multiple mechanisms for worsening pulmonary pressures including increased right ventricular afterload following resection of a significant amount of lung parenchyma. This has been observed post-pneumonectomy [15, 16] but less so after subtotal lung resections [18]. Precipitants of pulmonary vasoconstriction, including acidosis, hypercarbia, hypoxia, hypothermia, and pain, should also be avoided in the postoperative period [133]. Patients who were previously managed on pulmonary vasodilators preoperatively should resume their pulmonary hypertension treatment as early as possible postoperatively to prevent rebound pulmonary hypertension. In patients who required pulmonary vasodilators intraoperatively, this may need to be continued postoperatively for a period of time and carefully weaned. Oral PDE-5 inhibitors have been shown to be very useful in weaning patients from iNO and preventing rebound pulmonary hypertension [134–137].

Finally, optimal pain management is important postoperatively. Inadequate pain control can exacerbate pulmonary hypertension [124, 138]. As previously discussed, thoracic epidurals, paravertebral blocks, and systemic opioids are all commonly used strategies, with thoracic epidurals demonstrating potential reduction in pulmonary complications and mortality [84, 85]. Admission to a postoperative area with higher monitoring capabilities is also important for initial pain management, as all analgesic strategies carry significant potential risk in pulmonary hypertension patients. Specifically, thoracic epidurals and paravertebral blocks may produce significant hypotension requiring vasopressors to manage, and systemic opioids can produce hypoventilation leading to hypercarbia and hypoxia that should be identified and addressed quickly. Furthermore, analgesia post-pulmonary resection should be done under the guidance of an acute pain service.

Conclusion

The patient with pulmonary hypertension has historically presented a significant challenge perioperatively, with a high risk for morbidity and mortality often precluding surgery. Improvements in diagnosis and management of pulmonary hypertension, in general as well as within the operating room, have allowed for safe management of these patients during the pulmonary resection surgery. However, significant risk remains, and the thoracic anesthetist must be knowledgeable and vigilant with respect to the assessment and management of these patients. This includes an understanding of the various etiologies of pulmonary hypertension and their pharmacologic management, as well as the intraop-

erative strategies (monitoring, pharmacology, ventilation, etc.) that are available to assist with preservation of right heart function and minimization of increases in pulmonary pressures during one-lung ventilation. Furthermore, effective postoperative analgesia is highly important in these patients. While pulmonary resection in patients with pulmonary hypertension is feasible, it should be done in a center with experienced care providers and with appropriate postoperative monitoring facilities.

Clinical Case Discussion

A 68-year-old woman is scheduled to undergo pulmonary resection for a recently diagnosed lung cancer. She initially presented with a worsening cough and shortness of breath, prompting a chest X-ray by her primary care physician. A right-sided lung lesion was seen, leading to additional investigations. A CT scan and CT-guided biopsy revealed a 3 cm × 5 cm × 3 cm right lower lobe mass, with pathology-confirmed squamous cell carcinoma.

Her past medical history includes 40 pack-year smoking history – she has quit smoking since her diagnosis, a few weeks ago. Her other past medical history includes hypertension, hypercholesterolemia, mild gastroesophageal reflux disease, and osteoarthritis of the hips and knees. She has a long-standing history of NYHA 2–3 dyspnea, preceding her recent cancer diagnosis.

She has been referred to a thoracic surgeon for management and has been offered a right lower lobectomy by video-assisted thoracoscopic surgery, possibly open.

What preoperative investigations should be arranged for this patient?

1. Pulmonary function testing:
   (a) FEV_1 70% predicted [ppoFEV_1 50%]
   (b) $FEV_1/FVC < 70\%$
   (c) DLCO 65% predicted [ppoDLCO 46%]
2. Six-minute walk test: 400 m walked, 80% predicted distance. Noted dyspnea during the testing, with desaturation events to as low as 88% on room air.
3. Arterial blood gas (on room air): pH 7.35, pCO_2 48, pO_2 70.
4. CT thorax: no significant bullous disease but evident diffuse centrilobular emphysema. The right lower lobe lesion in question is also seen.
5. Metastatic workup: no evidence of metastases.
6. ECG: sinus rhythm.
7. TTE: normal left ventricular size and function, with evidence of diastolic dysfunction. Mild right ventricular enlargement with low-normal function. There is mild tricuspid regurgitation with a right ventricular systolic pressure calculated at 55 mmHg. There are no other significant valvulopathy. Her blood pressure during the TTE was 140/92.
8. V/Q study: demonstrates preferential perfusion to the left lung (60%) relative to the right lung (40%).
9. Right heart catheterization: see below.

The investigations above reveal several key pieces of information. Pulmonary function testing shows abnormal spirometry consistent with moderate COPD. The DLCO is also abnormal, consistent with a diagnosis of COPD. The predicted postoperative values for the proposed procedure remain acceptable to proceed, however. Her 6-min walk test is suggestive of reduced cardiopulmonary reserve and may warrant further investigations to assess this. Her room air arterial blood gas is consistent with her underlying diagnosis of COPD. Her imaging and ECG are within expected parameters.

The decision to request further cardiac testing (an echocardiogram) is reasonable, given her cardiac risk factors (smoking history, hypertension, hyperlipidemia) and limited exercise ability due to dyspnea (with a limited 6-min walk test performance). Noninvasive stress testing is likely appropriate/indicated as well. Her TTE result shows clear evidence of pulmonary hypertension (elevated RVSP) with secondary signs of pulmonary hypertension (RV enlargement and impaired systolic function). Given the absence of any history or testing results suggestive of an alternative diagnosis, the underlying cause of her elevated pulmonary pressures is likely to be COPD.

The decision of whether to pursue further invasive cardiac testing, specifically a right heart catheterization, is debatable. The TTE findings are highly suggestive of pulmonary hypertension, and right heart catheterization may not provide additional information that would influence decision-making. While not as accurate as with right heart catheterization, her pulmonary-to-systemic systolic pressure ratios based on TTE remain less than 0.5, which is also reassuring. Noninvasive stress testing may be a more appropriate direction for further testing at this point, with any abnormalities observed prompting left- and right heart catheterization.

A ventilation-perfusion study was done to assess differential lung perfusion and is useful to determine tolerance of one-lung ventilation intraoperatively. The preferential perfusion of the left lung in this case is reassuring, as the risk for hypoxia and rising pulmonary pressures intraoperatively is likely lower despite the expected need to perform one-lung ventilation of the left lung. This is not an absolute predictor, however.

How do you rationalize the information provided by the investigations above? Do you proceed with the case?

This patient presents with a lung malignancy for resection. Her preoperative testing is suggestive of moderate COPD and reduced exertional tolerance and cardiopulmo-

nary reserve. Additionally, her echocardiogram shows clear evidence of pulmonary hypertension, likely related to her long-standing COPD. All of these findings are suggestive of an above-average risk for morbidity and mortality, based on the evidence in the literature concerning perioperative management of pulmonary hypertension patients [4–7].

However, recent evidence has shown that pulmonary resection in the setting of pulmonary hypertension (by TTE-based diagnosis) is not an absolute contraindication to surgery [14]. Given the presence of a single-lung lesion with no metastases, surgery presents a curative option for this patient. Additionally, the remainder of her workup would be considered acceptable for proceeding with surgery in the absence of pulmonary hypertension.

As such, proceeding with the proposed resection with caution is acceptable. A clear plan and discussion involving the patient and surgeon should be had prior to presenting to the operating room to discuss the elevated risk and the need for specialized intraoperative and postoperative monitoring. There should be a low threshold to abort the procedure should issues with pulmonary hypertension arise intraoperatively despite the adequate precautions and management.

What intraoperative monitoring should be available for this procedure?

Routine noninvasive monitors, including 5-lead ECG, pulse oximetry, capnography, temperature, and invasive and noninvasive blood pressure monitoring, are required for any pulmonary resection procedure. Invasive blood pressure monitoring is of critical importance in the patient with pulmonary hypertension, as it allows for accurate beat-to-beat blood pressure monitoring and facilitates arterial blood gas sampling for assessment of oxygenation and ventilation. Central venous access is recommended for this procedure, as management of hemodynamics with vasoactive substances will likely be required.

Pulmonary artery pressures should be monitored during this procedure, given the need to promptly address any acute rises in pulmonary pressures. The most common options for assessment of pulmonary pressures (and right heart function) are a pulmonary artery catheter or TEE. The decision of which option to employ, if not both, should be based on availability as well as potential risks and benefits as they pertain to this patient.

Typically, PACs are readily available and allow for continuous measurement of pulmonary pressures. In conjunction with invasive blood pressure monitoring, the pulmonary-to-systemic pressure ratio can be easily determined and optimally maintained. This patient has no contraindications to a PAC. However, interpretation of PAC data can be challenging. Furthermore, PACs do not provide direct monitoring of right ventricular functioning. Increases in PA pressures are undesirable but may be tolerated by a well-compensated right ventricle. Conversely, reductions in PA pressures may represent improvement in pulmonary vascular resistance or impending right ventricular failure and need to be interepreted in conjunction with other available parameters such as CVP and systemic blood pressure.

The availability of intraoperative TEE is increasing, but remains a significant barrier to its usage in non-cardiac surgery. TEE allows for monitoring of right ventricular function intraoperatively, which would be beneficial in this scenario, as preexisting right ventricular enlargement and impairment are present. Furthermore, TEE allows for assessment of global cardiac function. Potential limitations of TEE in this scenario, in addition to availability, include limited ability to assess pulmonary pressures directly, as RVSPs can be calculated, but not on a continuous basis. Furthermore, assessment of right ventricular function requires multiple TEE views, again making timely continuous monitoring difficult. Additionally, assessment of TEE views in the lateral position (as required for a thoracotomy or VATS) may be technically challenging.

Should an epidural be placed in this patient?

Given that the proposed pulmonary resection is planned as a VATS procedure, an epidural would typically not be offered to this patient. However, consideration may be given to an epidural (or paravertebral catheter) given the above-average risk for complications postoperatively associated with this patient. Epidurals provide superior analgesia compared to intravenous PCA and have been associated with reduced pulmonary complications and mortality [84, 85]. While this patient has acceptable predicted postoperative FEV_1 and DLCO, optimization of her pulmonary mechanics remains necessary given her pulmonary hypertension. The potential benefits related to an epidural need to be weighed against the potential for complications related to an epidural, as well as the potential for hypotension and possible cardiac dysfunction secondary to neuraxial blockade.

The decision to offer an epidural should also take into consideration the risks and benefits discussed above, as well as the risk for conversion to a thoracotomy (requiring a discussion with the surgeon), and patient preferences.

What strategies should be employed to prevent or manage rises in pulmonary artery pressures intraoperatively?

Rises in pulmonary artery pressures should be identified and dealt with immediately. Optimization of ventilation parameters, hemodynamics, and pharmacologic interventions should all be considered for this patient.

Transition from ventilation with two lungs to one-lung ventilation is a period associated with many potential triggers for worsening pulmonary artery pressures, specifically hypoxia and hypercarbia. For this patient, a lung-protective strategy employing higher F_iO_2 should be used to optimize ventilation of the left lung. To minimize the risk of hypoxia and avoid significant hypercarbia, the F_iO_2 should be maintained at 1.0 when initiating OLV. A tidal volume of 4–6 mL/kg

should be maintained, with the respiratory rate adjusted to target a $P_aCO_2 < 30–40$ mmHg. Normocapnia (or slight hypocapnia) is ideal; however, aggressive ventilation (higher tidal volumes or higher respiratory rates) can produce higher peak airway pressures leading to worsening pulmonary vascular resistance. The P_aCO_2 can be set to maintain a pH of greater than 7.2, provided there is no significant coexisting metabolic acidosis. The use of PEEP should be titrated carefully (0–10 cmH_2O), to maintain peak airway pressures below 30–35 cmH_2O, and may not be necessary in this patient, as obstructive lung disease tends to create intrinsic PEEP.

Maintenance of the pulmonary-to-systemic systolic pressure ratio at its baseline is also important intraoperatively, and higher ratios are associated with worse outcomes [6]. This can be achieved through augmentation of the systemic systolic pressure or by reducing pulmonary vascular resistance. Norepinephrine and vasopressin are the ideal vasopressors of choice to increase systemic vascular resistance and maintain right ventricular perfusion and cardiac output. Either agent should be started early should systemic pressure begin to drop with initiation of OLV. The use of pulmonary vasodilators should also be considered if pulmonary pressures increase significantly during the case. Consideration should be given to initiating iNO or epoprostenol IV to address this. iNO may be preferred, as its pulmonary selectivity means it can be initiated before OLV has started, and is unlikely to produce systemic vasodilation. iNO should be titrated to a maximum dose of 40 ppm before a second agent (such as epoprostenol IV) is added.

The threshold of concern for the absolute PA pressure, or pulmonary-to-systemic pressure ratio, is not well-defined in the literature but should take into account the patient's baseline ratio, in this case less than 0.5, and the right ventricular response to increased PA pressures. Continuous PA pressure monitoring using a PAC allows for the former, while TEE is more advantageous to assess the latter. For this patient, two scenarios should prompt discussion regarding aborting the case. First, a continually rising pulmonary-to-systemic ratio beyond 0.5 despite the use of systemic vasopressors and pulmonary vasodilators is highly concerning, given her preoperative baseline. Second, any PA pressure producing signs of RV dysfunction (based on TEE imaging or reduced PA pressures, rising CVP, and hypotension) that does not respond to vasopressors or pulmonary vasodilation is also a cause for alarm. At this point, two-lung ventilation should be restored (if possible), and a discussion about whether to proceed should occur.

The impact of surgical approach for the proposed pulmonary resection should also be considered. There is no evidence in the literature examining outcomes of VATS vs thoracotomy in pulmonary hypertension patients; however, both have been done successfully. A VATS approach is advantageous, since it produces less postoperative pain and, however, is more dependent on effective OLV and may be associated with longer operative time. A thoracotomy for this patient would necessitate a well-functioning epidural for postoperative pain but may allow for better surgical exposure and shorter periods of OLV. Improved surgical exposure through a thoracotomy also allows for advanced ventilation techniques (selective lobar ventilation, application of CPAP) that may be helpful for ventilation. For this patient, a discussion with the surgeon regarding surgical approach should occur preoperatively. It may be reasonable to attempt the procedure with VATS initially while having a low threshold to convert to an open thoracotomy should the surgeon believe this would expedite the surgery.

Where should this patient be admitted to postoperatively?

This patient requires admission to a unit with increased monitoring postoperatively, irrespective of intraoperative course. This should be a step-down unit at the very least; however, the need for intraoperative vasopressor or pulmonary vasodilator use should prompt admission to an intensive care unit.

Part IX

Complex Thoracic Surgical Procedures

Surgery of the Chest Wall and Diaphragm

35

Peter Slinger

Key Points

- Surgery for benign chest wall deformities is most commonly performed for cosmetic reasons but in some cases for restrictive respiratory or cardiac symptoms.
- Postexcision, chest wall defects larger than 5 cm will require reconstruction to diminish paradoxical motion and impaired gas exchange.
- All full-thickness diaphragm defects should be repaired when diagnosed to prevent late onset of perforation or strangulation of abdominal contents in the chest.
- Diaphragm eventration requires repair only for symptoms of impaired gas exchange.

Chest Wall Surgery

Tumors

Benign tumors of the chest wall include chondromas, osteochondromas, fibrous dysplasia, and desmoid tumors. Because it is often not possible at the time of surgery to be certain of the pathology, benign tumors are treated the same as malignant tumors with wide excisions. Malignant tumors of the chest wall include soft tissue sarcomas, chondrosarcomas, and other varieties of sarcoma. They are excised with wide margins of at least 4 cm including several partial ribs above and below for rib lesions. For sternal lesions, a sternotomy with corresponding resection of bilateral adjacent costal arches is performed.

P. Slinger (✉)
Department of Anesthesia, Toronto General Hospital, Toronto, ON, Canada
e-mail: peter.slinger@uhn.ca

Defects of the chest wall less than 5 cm are usually closed primarily and not reconstructed. Defects larger than 5 cm in any diameter are reconstructed with a synthetic mesh. Soft tissue reconstruction of larger defects may include a flap of the latissimus dorsi, pectoralis major, rectus abdominis, or other muscles and/or omentum [1].

Anesthetic considerations for excision of chest wall tumors include possible invasive or compressive effects of the tumor on intrathoracic cardiovascular or respiratory structures (see Fig. 35.1). Postoperative pain and respiratory limitation is a major problem following excision of large chest wall tumors. Thoracic epidural analgesia may be indicated for patients with borderline preoperative respiratory function.

Congenital Deformities

The commonest congenital deformity of the chest wall presenting for surgery is pectus excavatum (see Fig. 35.2). This is a posterior angulation of the lower sternum and adjacent ribs. The severity can be assessed on chest imaging by the "pectus index" which is the distance ratio of the transverse chest diameter to the shortest distance between the posterior sternum and the anterior border of the spine. In normal individuals this ratio is approximately 2.5, and in patients with pectus excavatum, it typically exceeds 3.5. It may be associated with scoliosis or Marfan's syndrome. Pulmonary function tests generally show a mild restrictive pattern; however this does not improve significantly after repair [2]. However, repair of the deformity does improve exercise capacity secondary to improved cardiac output and stroke volume.

There are several different surgical procedures used to correct pectus excavatum. Most open procedures involve resection of the costal cartilages at the site of the deformity, an osteotomy of the sternum, and internal fixation or stabilization (see Fig. 35.3). In children and younger adolescents,

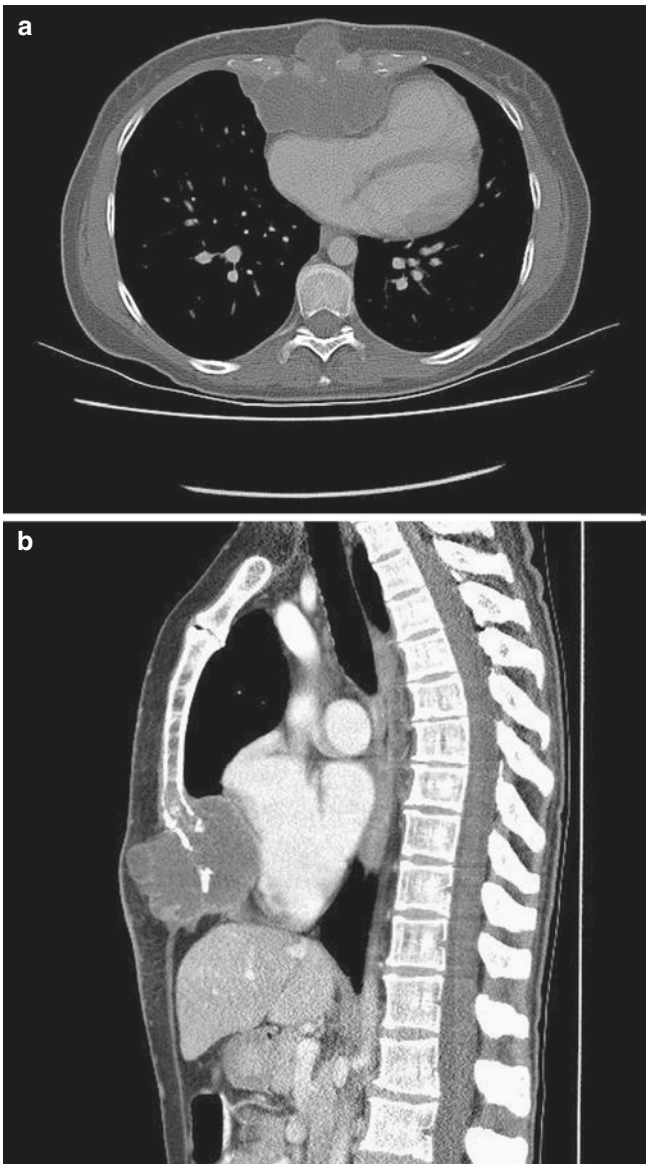

Fig. 35.1 Transverse (**a**) and sagittal (**b**) CT scan views of a patient with a chondrosarcoma of the lower sternum. The tumor is compressing the right ventricle

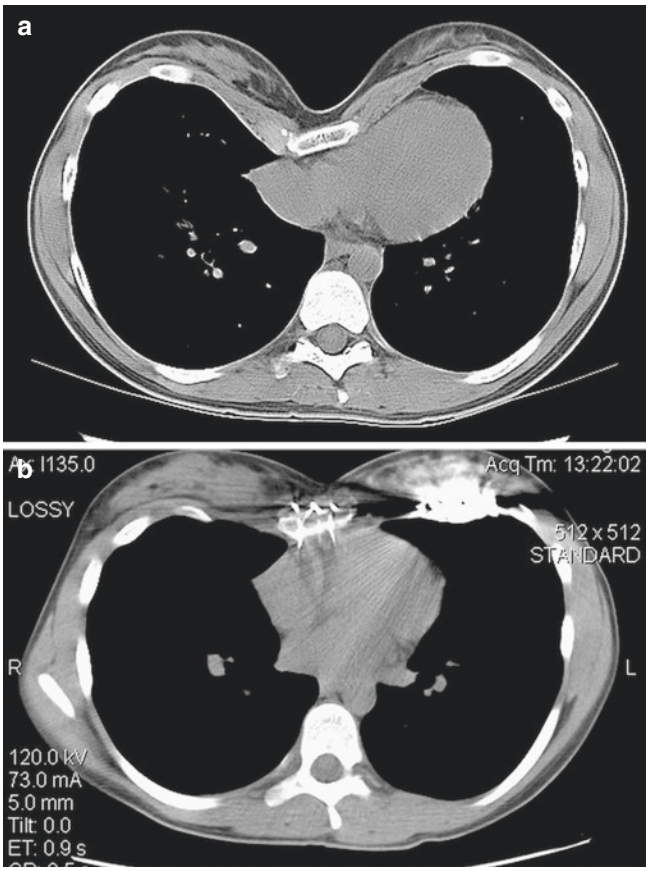

Fig. 35.2 Transverse CT scans of a patient with pectus excavatum. (**a**) Preoperative. The sternum is compressing the right ventricle. (**b**) Postoperative. Internal fixation of the sternum and a portion of the pectus bar attached to the ribs of the left chest can be seen

there is the option of a minimally invasive procedure with the insertion of a Nuss bar to elevate the sternum [3].

A variety of other less common congenital chest deformities such as pectus carinatum and Poland syndrome also can present for surgery. Anesthetic considerations for pectus excavatum and these other deformities are essentially identical to those for excision of chest wall tumors.

Thoracic Outlet Syndrome

Thoracic outlet syndrome refers to compression of the subclavian vessels and/or brachial plexus at the superior aperture of the chest. It may or may not be associated with the presence of a cervical rib. The compression is mainly

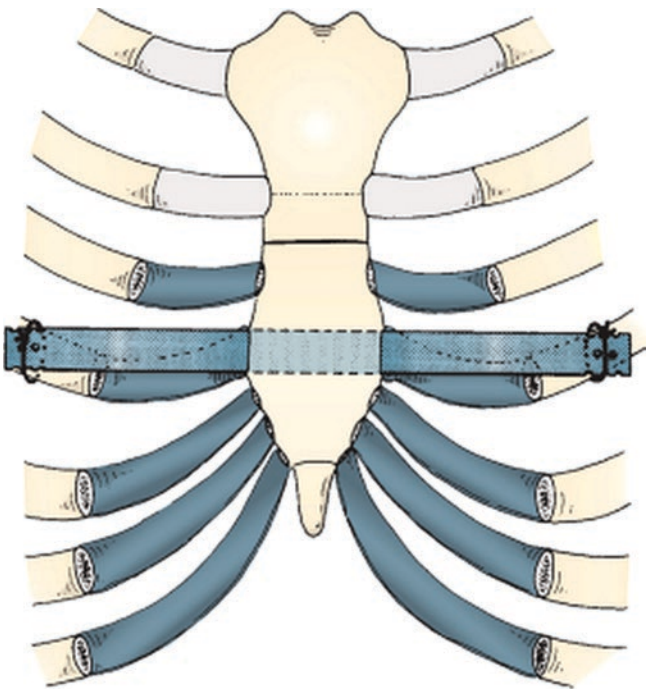

Fig. 35.3 Diagram of a pectus bar placed posterior to the lower portion of the sternum during open surgery for repair of pectus excavatum. (Reprinted from [5]. © Elsevier 2008, with permission)

caused by the first rib. Patients present with a variety of peripheral neurological or vascular symptoms which may include positional pain and paresthesia, commonly in the C8-T1 distributions of the medial hand and arm. Confirmation of the diagnosis may require nerve conduction studies or angiography. Treatment is initially conservative with physiotherapy. In refractory cases excision of the first rib and/or a cervical rib may be indicated. Surgery is via an extra-thoracic approach, and anesthetic concerns are similar to those for other types of head and neck procedures.

Diaphragm Surgery

Hernia

Repair of congenital diaphragmatic hernia in infants is discussed in Chap. 50. Adults may also present for repair of congenital or acquired defects of the diaphragm. Congenital malformations of the diaphragm in adults may be diagnosed incidentally on chest imaging or may cause a variety of compressive symptoms due to the intrathoracic mass of gastrointestinal contents. The commonest site for herniation of abdominal contents into the chest is through the esophageal hiatus (see Fig. 35.4). Other sites include the Bochdalek foramen (usually on the left side) and Morgagni foramen (usually on the right; see Fig. 35.5). An acquired hernia may be due to sudden severe blunt abdominal trauma. Occasionally these may present late, long after the initial trauma. All diaphragmatic hernias should be repaired when diagnosed due to the possibility of strangulation or perforation of bowel in the chest. Repairs are most commonly performed by laparotomy or laparoscopy. Anesthetic concerns for hiatal hernias are similar to those for other types of benign esophageal disease (see Chap. 38) specifically, an increased risk of aspiration on induction.

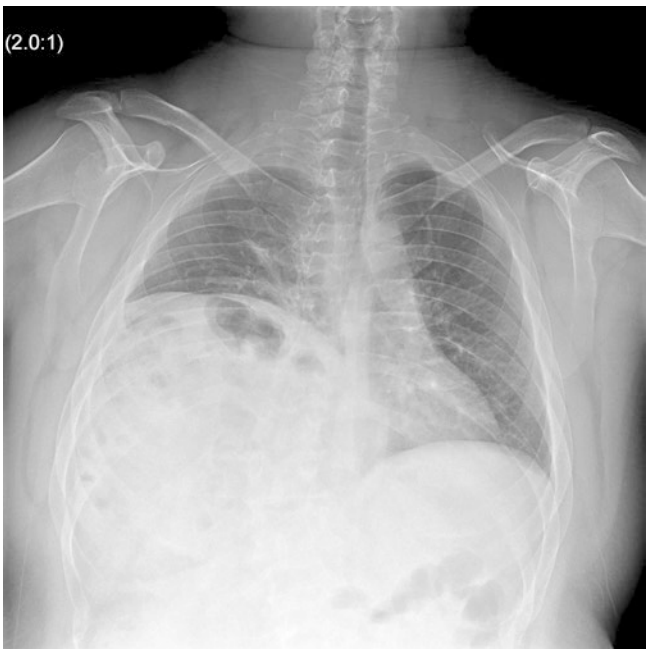

Fig. 35.5 Chest X-ray of an adult presenting for repair of a hernia of bowel into the right chest via the foramen of Morgagni

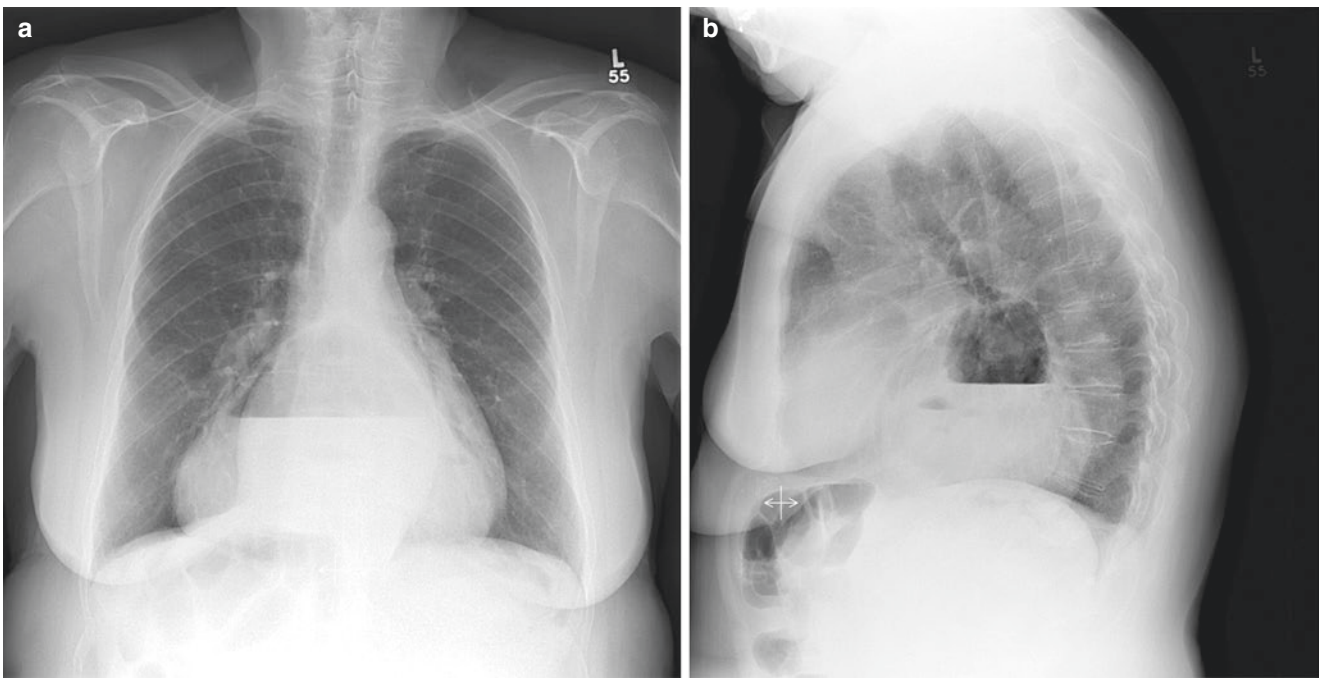

Fig. 35.4 (**a**) PA and (**b**) lateral chest X-rays of a patient with an intrathoracic stomach which has herniated through the esophageal hiatus of the diaphragm. The risk of aspiration of gastric contents during induction of anesthesia can be appreciated

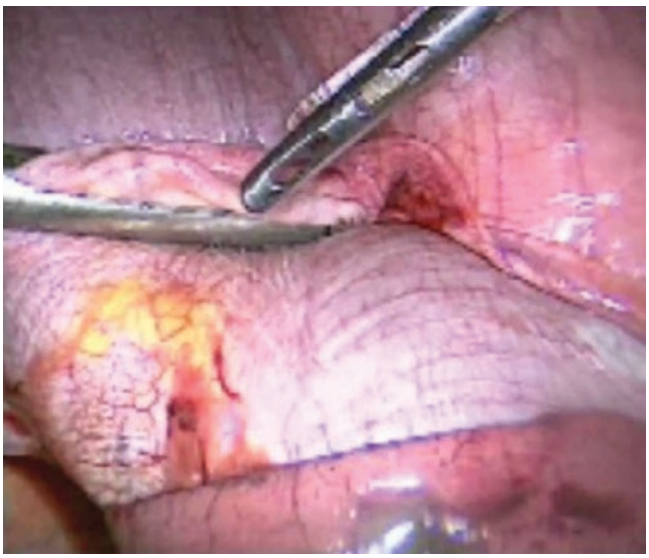

Fig. 35.6 Thoracoscopic plication of the diaphragm during one-lung ventilation

Eventration

Eventration of the diaphragm is an elevation of a portion of the diaphragm due to an incomplete development of part of the musculature. The differential diagnosis is a paralysis of the diaphragm. Causes of phrenic nerve paralysis such as lung cancer must be ruled out. Most cases of eventration in adult life are treated conservatively. Severe dyspnea or orthopnea may be an indication for surgery. Surgical repair is by plication of the involved portion of the diaphragm; this can be performed with a minimally invasive approach [4] (see Fig. 35.6).

Extrapleural Pneumonectomy

36

Ju-Mei Ng

Key Points

- Extrapleural pneumonectomy is a formidable surgical procedure performed on patients with limited life expectancy. Anesthetic management may contribute to containment of perioperative morbidity and mortality through the control of intraoperative physiologic disruptions and postoperative pain and an appreciation of the associated postoperative complications to affect early intervention.
- Beyond standard anesthetic management issues for pneumonectomy, there exist a number of important "EPP-specific" anesthetic concerns. These include significantly greater blood loss, more delicate management of intravascular fluid and blood components, greater operative impairment of venous return, high probability of dysrhythmias, and greater potential for hemodynamic instability related to pericardial window and its patch.
- Common causes of hypotension during EPP include compression of the heart or great vessels by tumor or surgical pressure/retraction, blood loss and/or inadequate fluid resuscitation, and thoracic epidural sympathetic blockade.
- No single anesthetic recipe is of proven superiority for either EPP or lung resection surgery in general. The priority for early extubation favors the use of short-acting modern inhalational and intravenous agents, with limited use of traditional parenteral narcotics. Thoracic epidural analgesia is widely employed intraoperatively to facilitate extubation at the conclusion of surgery by providing dense analgesia without depression of sensorium or respiratory drive.
- Fluid management remains a challenge due to the increased blood loss in EPP, hemodynamic instability, renal toxicity of chemotherapy agents, and the potential for exacerbation of acute lung injury.

Introduction

Extrapleural pneumonectomy (EPP), the en bloc resection of the lung, parietal and visceral pleurae, pericardium, and diaphragm, is a formidable surgical procedure. First described for the treatment of tuberculous empyema, it is currently typically performed for local control of malignant pleural mesothelioma (MPM). It may also be applied to other malignancies or infections involving or obliterating the pleural space, including thymoma and non-small cell lung cancer (NSCLC) [1]. Although there has been a dramatic reduction in perioperative mortality from 31% reported in the 1970s [2] to a recent systematic review demonstrating mortality ranging from 0% to 11.8% [3], postoperative major morbidity remains high (12.5–48%). Higher center volume may be associated with decreased mortality and morbidity after surgery for MPM [4]. Currently, EPP and the lung-sparing alternative, pleurectomy/decortication (P/D), are considered by many to have a critical role in the multimodality treatment of MPM [4–9]. This chapter will discuss the important "EPP-specific" anesthesia concerns [10, 11], including intraoperative intracavitary hyperthermic chemotherapy (IOHC), which is being applied in a few centers for better control of local disease in MPM.

Malignant Pleural Mesothelioma and Pleural Dissemination of Malignancy

MPM arises on the pleural surface of the chest wall, lung, pericardium, or diaphragm, tends to spread or recur locoregionally, and is generally fatal within a year of diagnosis [12]. Its etiologic link to asbestos exposure has been established [13], but not all patients with mesothelioma have a history of asbestos exposure, and other etiologies have been postulated [14]. The annual incidence of mesothelioma in the United States is estimated to be approximately 3300 cases per year [15]; this incidence of mesothelioma peaked around the year 2000 and is now declining, secondary to control of exposure to asbestos. No single modality of treatment significantly improves median survival beyond 12 months. EPP offers the most complete cytoreduction, but recurrence occurs locoregionally. Multimodality approaches, combining cytoreduction by P/D or EPP, with chemotherapy, radiotherapy, or photodynamic therapy have been evaluated in various combinations recently, with reported improved survival statistics [3–8]. The control of locally advanced disease in thymoma, sarcoma, and NSCLC has been reported with variable success. EPP in Stage IVa thymoma or Stage IV NSCLC (often combining induction chemotherapy and/or adjuvant radiation) has a 5-year survival of 53–78% and 24–55%, respectively [1]. But reports are sparse with mainly small cohorts of patients. With the exception of IOHC, these multimodality treatment therapies generally do not greatly impact anesthetic management of EPP.

Intraoperative Intracavitary Heated Chemotherapy

The intraoperative application of chemotherapy (usually cisplatin) to address microscopic disease remaining in the empty hemithorax prior to closure has important implications on anesthetic management. Intracavitary application targets the chemotherapy directly at the sites of recurrence (including the abdomen), with higher doses than would be tolerated systemically. Heating the chemotherapy agent increases tumoricidal activity by increasing the permeability and metabolic activity of the cells [16].

Surgical Considerations

The *technique* of *EPP* [17] consists of several basic steps:

1. *Incision and exposure of the parietal pleura*
   An extended posterolateral thoracotomy with resection of the 6th rib is the most common approach.

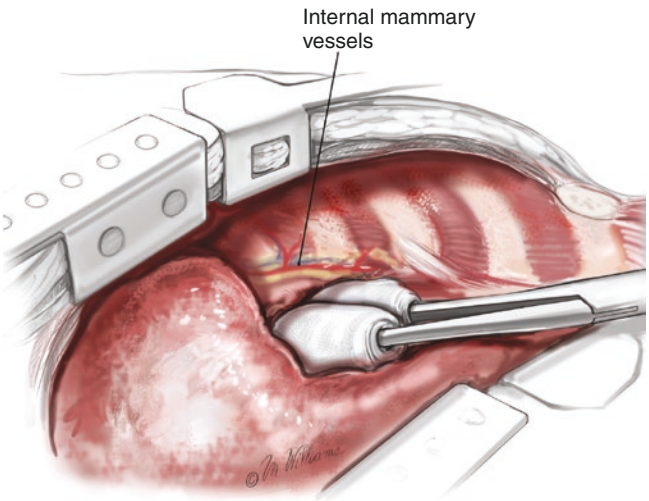

Fig. 36.1 Blunt anterior parietal dissection with identification of the internal mammary vessels. (Reprinted with permission from Marcia Williams Medical and Scientific Illustration [17])

2. *Extrapleural dissection to separate the tumor from the chest wall*
3. *En bloc resection of the lung, pleura, pericardium, and diaphragm with division of the hilar structures*
   A combination of blunt and sharp extrapleural dissection is initiated anterolaterally and advanced to and over the apex, to bring the tumor down from the posterior and superior mediastinum (Fig. 36.1).
   - Beware of injury to the internal mammary vessels/grafts and subclavian vessels during dissection anteriorly and at the apex, respectively, as well as traction injury to the azygous vein and superior vena cava in the superior mediastinum.
   - In addition, during left EPP, injury may occur to the intercostal arteries, thoracic duct, and recurrent laryngeal nerve.

   Posterior dissection is then performed and the esophagus dissected away from the tumor. The diaphragm is avulsed circumferentially (Fig. 36.2) and dissected bluntly from the underlying peritoneum (Fig. 36.3), and the pericardium is opened.
   - During division of the medial aspect of the diaphragm, the inferior vena cava may be injured or torsed.

   The main pulmonary artery (PA) and pulmonary veins are then dissected, isolated, and stapled extra- or intrapericardially. After the main bronchus is dissected as far as the carina, the bronchial stapler is fired under direct visualization with the fiber-optic video bronchoscope to assure a short bronchial stump. Bleeding from numerous exposed vessels on the inner thoracic cavity is temporized by packing, but definitive hemostasis is not sought until the specimen is removed.
4. *Radical lymph node dissection*
   Radical mediastinal lymph node dissection is performed, followed by reinforcement of the bronchial stump. The

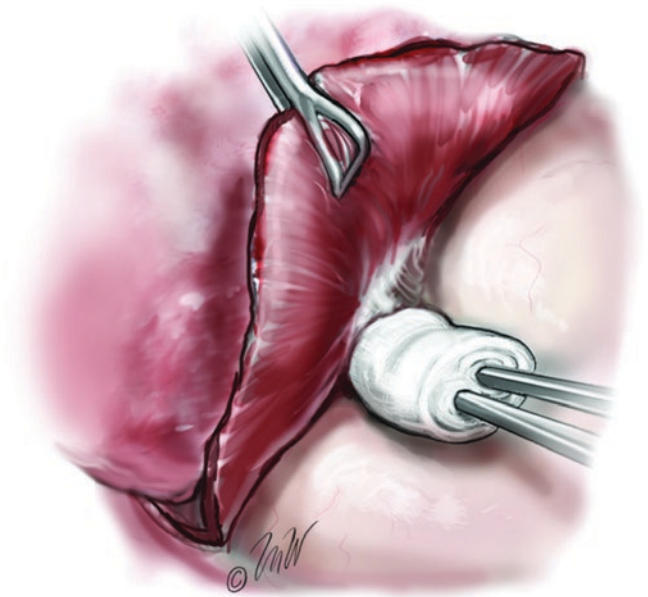

Fig. 36.3 The diaphragm is dissected bluntly from the underlying peritoneum. (Reprinted with permission from Marcia Williams Medical and Scientific Illustration [17])

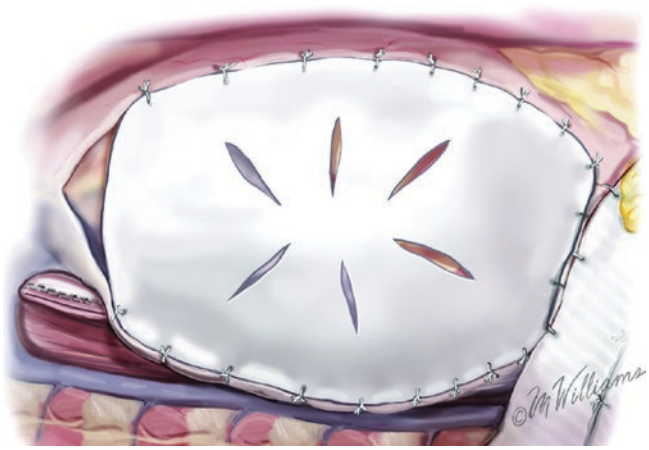

Fig. 36.4 Reconstruction with diaphragmatic and fenestrated pericardial patches which prevent herniation. (Reprinted with permission from Marcia Williams Medical and Scientific Illustration [17])

hemithorax is then irrigated with warm saline and water (wash phase) to remove and osmotically lyse residual microscopic tumor.

4. *Optional administration of IOHC*
5. *Reconstruction of the diaphragm and pericardium* (Fig. 36.4)
   The last step is reconstruction of the diaphragm and pericardium using a prosthetic such as Gore-Tex DualMesh (W.L. Gore and Associates, Inc., Flagstaff, Arizona). These patches prevent subsequent herniation of abdominal contents and cardiac herniation into the empty hemithorax.

Technique of IOHC

Two perfusion cannulae (inflow and outflow) are placed within the open hemithorax after tumor resection and hemostasis. Chemotherapy in dialysate maintained at 42 °C is circulated via a pump for 60 min. The volume of perfusate is adjusted to keep the hemithorax full, which maximizes surface area contact between residual microscopic tumor cells and a high local concentration of cisplatin. Systemic administration of cytoprotectants is performed either before or after the chemotherapy administration depending on the agent used (Table 36.1); the timing is important to maximize tumorigenicity while sparing renal function [7]. Sodium thiosulfate covalently binds and inactivates cisplatin in the blood. Amifostine (Ethyol, Alza Pharmaceuticals – USA), which exhibits 100-fold preferential uptake by normal cells and salvages intracellular free radicals, has also been used. Amifostine may cause hypotension with rapid administration.

Table 36.1 Renal protective strategies for EPP with intraoperative intracavitary hyperthermic chemotherapy (IOHC) with cisplatin (Brigham and Women's Hospital Protocol)

Admission day before surgery for intravenous hydration
7-day hold of nonsteroidal anti-inflammatory drugs
Pretreatment with intravenous amifostine (30 mins prior to IOHC) and 2nd dose 2 h later (910 mg/m^2 and 500 mg/m^2)
Intravenous sodium thiosulfate following IOHC (4 g/m^2 bolus, 12 g/m^2 over 6 h)
Liberalized IV hydration and assiduous avoidance of systemic hypotension during and after IOHC
Urine alkalinization ($NaHCO_3$ 45 mEq/h × 2 h, 22.5 mEq/h)

Table 36.2 Suggested exclusion criteria for EPP

Karnofsky performance status <70%
Abnormal creatinine
Abnormal liver function tests
Evidence of unresectability by CT, MRI, echocardiogram
Room air $PaCO_2$ > 45 mmHg
Room air PaO_2 < 65 mmHg
Left ventricular ejection fraction <45%
Predicted postoperative FEV_1 < 1 L[a]

Karnofsky score 70 – Care for self: unable to carry on normal activity or do active work

CT computed tomography, *MRI* magnetic resonance imaging, *FEV_1* forced expiratory volume in 1 s

[a]Patients with predicted postoperative FEV_1 < 2 L are recommended to undergo quantitative radionuclide ventilation-perfusion scanning

Patient Selection

Critical to risk reduction, general exclusion criteria utilized by the surgical group with the most favorable published survival statistics [5] are listed in Table 36.2. Patients with a predicted postoperative forced expiratory volume in 1 s ($ppoFEV_1$) or less than 0.8 L are considered for P/D, rather than EPP.

Preoperative Patient Preparation

An awareness of the perceived cardiopulmonary reserve, the anatomical extent and impact of the tumor, and coexisting disease states allows the anesthesiologist to tailor invasive monitors, lines, and anesthetic plan to preempt or efficiently respond to problems. If IOHC is planned, renal protection strategies begin preoperatively with hydration and the withholding of nonsteroidal anti-inflammatory medications (Table 36.1).

Cardiopulmonary Risk Assessment

The assessment of cardiopulmonary reserve is especially difficult. Measurements traditionally employed to predict postthoracotomy pulmonary complications include $ppoFEV_1$, maximal oxygen consumption (VO_2max), and diffusing capacity for carbon monoxide (DL_{CO}) [18]. Preoperative transthoracic echocardiograms are routine, and cardiac stress and right heart catheterization are utilized if there is evidence of ventricular dysfunction or pulmonary hypertension, respectively. History, physical examination, and echocardiography will reflect cardiac functional status but may not predict the response to the stress of pneumonectomy in the setting of major fluid shifts [19]. Patients with a history of recent myocardial infarction in the last 3 months or life-threatening arrhythmias would be considered for P/D rather than EPP.

Radiologic Studies

Computed tomography and magnetic resonance imaging (MRI) of the chest play an important role in assessing tumor invasion of the chest wall, vertebrae, diaphragm, and mediastinal structures. They are used for staging and/or to assess tumor resectability [20]. The anesthetic implications include safe placement of epidural catheters at the thoracic region, level and site of intravenous access, quantity of blood and blood products available, and the potential necessity for cardiopulmonary bypass during resection.

Anesthetic Considerations

Specific Anesthetic Issues for EPP

Beyond the standard management issues for pneumonectomy [21], important "EPP-specific" anesthesia concerns are shown in Table 36.3.

Table 36.3 Anesthetic issues for extrapleural pneumonectomy

Significantly greater blood loss compared to pneumonectomy
More delicate management of intravascular fluid and blood components
Greater operative impairment of venous return
Greater danger of surgical disruption of major vascular structures
More complex and variable physiology of the nonoperative lung (restrictive and obstructive)
High probability for disruption of internal mammary artery coronary grafts (if present)
High probability of dysrhythmias
Frequent "pseudo-ischemic" ST changes on EKG during wash phase
Greater potential for hemodynamic instability related to pericardial window and its patch
Greater postoperative pain and pulmonary dysfunction related to the larger incision

Lines and Monitors

Generous intravenous access is paramount, and blood should be available in the operating room. If the superior vena cava is in jeopardy, lower extremity intravenous access is mandatory. A nasogastric tube aids posterior esophageal dissection intraoperatively and gastric decompression (and the prevention of gastric acid aspiration) postoperatively. Invasive monitors (arterial and central venous lines) are routine. The site of central venous access is important, as the potential for causing a pneumothorax in the nonoperative lung has to be weighed against injury to the subclavian vein during surgical dissection on the operative side.

Although pulmonary artery (PA) catheters have potential interpretation pitfalls during pneumonectomy [22, 23], they may be useful for postoperative fluid and right heart management issues. Transesophageal echocardiography (TEE) is a more powerful and reliable monitor of right and left ventricular filling and function and is a more sensitive monitor of myocardial ischemia, particularly during left EPP when the surgical incision precludes appropriate EKG lead placement. However, there is no direct evidence of improved outcome, and the cost and need of technical expertise make this tool worthwhile only in selected cases.

Choice of Anesthesia

No single anesthetic recipe is of proven superiority for either EPP or lung resection surgery in general. The priority for early extubation favors the use of short-acting modern inhalational and intravenous agents, with limited use of traditional parenteral narcotics.

Thoracic Epidural Analgesia

Despite emerging promising regional techniques for post-thoracotomy analgesia, thoracic epidural analgesia (TEA) remains the technique of choice for EPP. TEA reduces perioperative pulmonary [24] and cardiac complications [25, 26], including pulmonary infections, atelectasis, myocardial infarction, and the incidence of supraventricular tachyarrhythmias post-thoracotomy. TEA is widely employed intra- and postoperatively for EPP. It also facilitates extubation at the conclusion of surgery by providing dense analgesia without depression of sensorium or respiratory drive.

The sympatholytic effects of TEA may complicate hemodynamic management if dense blockade is imposed during or prior to the dissection phase of EPP. It is therefore common to initiate bolus dosing of the epidural catheter later in the surgery. Ultimately, solutions and infusion rates are individualized to address catheter insertion site, hypotension, pruritus, nausea, opioid tolerance, sedation, or other side effects.

One-Lung Anesthesia

Lung Isolation Techniques

Lung isolation to facilitate surgical exposure may be achieved using either a double-lumen endotracheal tube (DLT) or a bronchial blocker. For EPP, DLTs allow rapid ventilation or collapse of either lung, effective suctioning, and uninterrupted lung isolation at the time of surgical cross clamp. We favor a left-sided DLT is for a right EPP (and vice versa). There is no hardware present in the operative bronchus, and compared to a bronchial blocker, a left-sided DLT is less likely to be dislodged with surgical manipulation. Although right-sided DLTs have a smaller margin of safety (due to short right upper lobe anatomy), this is rarely an impediment to their effective use. When an anomalously high right upper lobe precludes an effective air seal at the bronchial cuff, this is easily remedied by passing a blocker down the tracheal lumen [27]. Blockers are principally used for left-sided EPP in patients with difficult airway anatomy and withdrawn prior to stapling the bronchus in order to avoid accidental inclusion into the suture line.

Optimizing Oxygenation During One-Lung Ventilation (OLV)

"Lung-protective" (low tidal volume 5–6 ml/kg, limiting peak airway pressure <35 cmH_2O, and dependent lung positive end-expiratory pressure (PEEP)) ventilation with the intention of limiting dependent lung volutrauma and atelectasis is important [28]. Recruitment maneuvers (RM) and reducing $FiO_2 < 1.0$ when tolerated may be employed.

EPP patients, during OLV in the lateral decubitus position, often exhibit an element of restrictive physiology in the dependent lung imposed by the weight of the tumor and surgical pressure during dissection. Frequent large changes in compliance require vigilance to prevent high airway pressures or volumes (depending on the mode of ventilation). During intracavitary lavage, where a perfusate of cisplatin exerts weight on the mediastinum, both RM and PEEP are important to prevent atelectasis. In addition, dependent lung pneumothorax may easily occur during dissection of large tumors and will require surgical decompression. The IOHC fluid may accumulate in the dependent thorax if the pleural defect is not adequately repaired.

Despite a greater propensity for dependent lung atelectasis and possibly increased nondependent lung shunt (inhibition of hypoxic pulmonary vasoconstriction due to more vigorous surgical manipulation), hypoxemia during OLV for EPP is unusual. This is because the best predictor of oxygen desaturation during OLV is increased (>55% of cardiac output) blood flow to the operative lung, which is seldom the case in MPM [29].

Hemodynamic Management

Hypertension

Hypertension should be avoided during the dissection phase, as it will greatly exacerbate bleeding from the innumerable avulsed chest wall veins. It may also be an issue when the specimen is removed and venous return to the heart is suddenly unimpeded.

Hypotension

This is more frequent, and its treatment should reflect its etiology whenever possible (Table 36.4). Reduced venous return is the most common mechanism, caused by mechanical pressure on the mediastinum during dissection or torsion of great vessels. Critical phases of surgery when venous return is most threatened include the induction, dissection, and terminal repositioning phases. Vasodilation from hyperthermia during IOHC may occur as core temperatures not uncommonly exceed 38 °C.

Induction

Preemptive vasoconstricting agents and judicious selection of induction agents/doses are particularly indicated for patients with large tumor burdens, large effusions, or radiographic evidence of cardiac or major vessel impingement. Often, the thoracic epidural test-dose effect is still peaking at the time of induction, potentially further increasing compensatory vasoconstrictor requirements.

Dissection Phase

Venous return is impeded by blood loss, insensible losses, and variable degrees of compression from the tumor, retractors, and blunt dissection pressure. The temptation to correct venous return by enthusiastic crystalloid volume expansion is to be resisted. Judicious use of vasopressors, together with blood products when appropriate, will temporize until the specimen is removed. Communication with the surgeon during this phase is paramount, and a coordinated effort is necessary to maintain forward progress with acceptable hemodynamics. A low threshold for administration of blood during this phase often proves strategic. When the specimen is removed, venous return, hemodynamics, and respiratory compliance should normalize. Persistent hypotension at this stage suggests hypovolemia.

Table 36.4 Causes of hypotension during EPP

Common	Compression of the heart or great vessels by tumor or surgical pressure/retraction
	Blood loss/inadequate fluid resuscitation
	Thoracic epidural sympathetic blockade
Uncommon	Air-trapping (“auto-PEEP”)
	Tension pneumothorax
	Drugs (vasodilators/negative inotropes)
	Right heart dysfunction/failure
	Cardiac herniation
	Tight pericardial patch
	Shifted mediastinum following closure
	Myocardial ischemia
	Dysrhythmias
	Embolic events
	Transfusion reactions
	Drug reactions
	Sepsis

Repositioning and Emergence

Herniation of the heart (particularly with right EPP), with torsion of great vessels and circulatory arrest, may abruptly occur upon resumption of the supine position at the end of surgery. Immediate return to the lateral position is the appropriate reflex response. This usually improves hemodynamic parameters, while preparation for reoperation is made if necessary.

The diagnosis is less obvious when only moderate hypotension occurs at this juncture. Culprits include partial cardiac herniation (loose or partially ruptured pericardial patch), tamponade (tight pericardial patch or retained pericardial effusion), inferior vena cava impingement (tight right diaphragmatic patch), hypovolemia, and deviated mediastinum, among others.

Reduced venous return is the common mechanistic denominator. A sluggish response to fluid boluses and vasopressors suggests that mechanical impediments to venous return should be ruled out before leaving the operating room. Aggressive bolus dosing of the epidural in anticipation of emergence may contribute to diagnostic confusion. A portable chest radiograph is usually helpful in ruling out partial cardiac herniation or guiding medialization of the mediastinum by withdrawal of air from the chest drain. TEE may assist in the diagnosis.

Fluid Management

Average estimated intraoperative blood loss during EPP in the best of surgical hands is approximately 0.5–1.5 L. Most of this occurs in a gradual, continuous fashion during the processes of blunt separation of the parietal pleura from the chest wall, although catastrophic bleeding can occur from major vessels during dissection of the hilum or at the apex. Monitoring of the extent of blood loss requires vigilance and communication with the surgeons.

Antifibrinolytics have not been shown to reduce packed red blood cell requirements in EPP surgery [30]. As with any pneumonectomy, excessive crystalloid is to be avoided as it may exacerbate the pulmonary edema of post-lung resection acute lung injury. Fluid management thus becomes a balancing act in the setting of significant hemodynamic swings

with intermittently moderate-to-major episodes of blood loss. This balance shifts in favor of more liberal fluid administration in patients receiving IOHC, out of concern for nephrotoxicity.

Central venous pressure measurements, PA occlusion pressures, or observance of respiratory variation on arterial line tracings may be unreliable indicators of intravascular volume during manipulation of weighty tumors, with the chest open to atmosphere. Attention to the surgical field (including the fullness of the heart), urine output, blood gas and hematocrit results, and occasionally TEE are helpful guides.

Postpneumonectomy Pulmonary Edema (PPE)

An emphasis is made on discriminating between hypovolemia and impairments of venous return out of concerns that unnecessary volume resuscitation may contribute to PPE. Pulmonary edema of the remaining lung following pneumonectomy occurs in 2–4% of patients and carries mortality in excess of 50% [31]. The incidence in EPP may be as high as 5–8% [32, 33], which may be in part due to the greater fluid shifts associated with EPP. It is apparent that in the presence of the increased pulmonary capillary permeability in acute lung injury, unnecessary crystalloid or colloid administration will exacerbate the degree of edema and hypoxemia. This is the basis for the widely adhered to practice of conservative (restrictive) fluid management for pneumonectomy patients [21] and highlights the importance of close attention to the matching of fluid administration to blood loss in EPP patients.

Cardiovascular Considerations

Dysrhythmias

The incidence of supraventricular dysrhythmias (SVD) after EPP is higher (21–44%) [4, 5, 7, 32, 34, 35] than for standard pneumonectomy (13–20%) [35, 36]. Thoracic epidural blockade with bupivacaine has been shown to reduce the incidence of perioperative SVD compared to equianalgesic epidural narcotics [26], and there is increasing evidence that medical prophylaxis (amiodarone, beta-blockers, magnesium and calcium channel blockers) is effective in preventing postoperative atrial fibrillation after general thoracic surgery [37]. Although there may be currently inadequate evidence to recommend routine prophylaxis against AF for all patients undergoing lung surgery, it is reasonable to administer diltiazem to those patients with preserved cardiac function not taking beta-blockers preoperatively in intermediate to high-risk patients [37].

It is uncommon for routine prophylaxis against SVD for EPP but important to avoid withdrawal of beta-adrenergic blocking drugs, if they are in use. Intraoperative dysrhythmias are generally triggered by mechanical irritation and do not appear to predict postoperative SVD. EKG leads should be attached to a ready defibrillator to provide the capability of synchronized electrical cardioversion intraoperatively.

Myocardial Ischemia

Myocardial ischemia may be difficult to detect during EPP as alterations in the position of the heart relative to the surface EKG lead positions would be expected to alter their sensitivity. During left-sided thoracotomies, it is not practical to monitor lead V-5. When myocardial ischemia is suspected, TEE should be employed.

Dramatic ST segment elevations may occur during the wash phase. These tend to occur with irrigation, correct promptly with cessation, and are not associated with other hemodynamic alterations suggestive of myocardial ischemia (Fig. 36.5), most likely representing nonischemic electrophysiologic changes related to focal myocardial warming or surface electrolyte changes [38]. No treatment is necessary unless they persist, produce hemodynamic instability, or are confirmed to be associated with wall motion abnormalities by TEE.

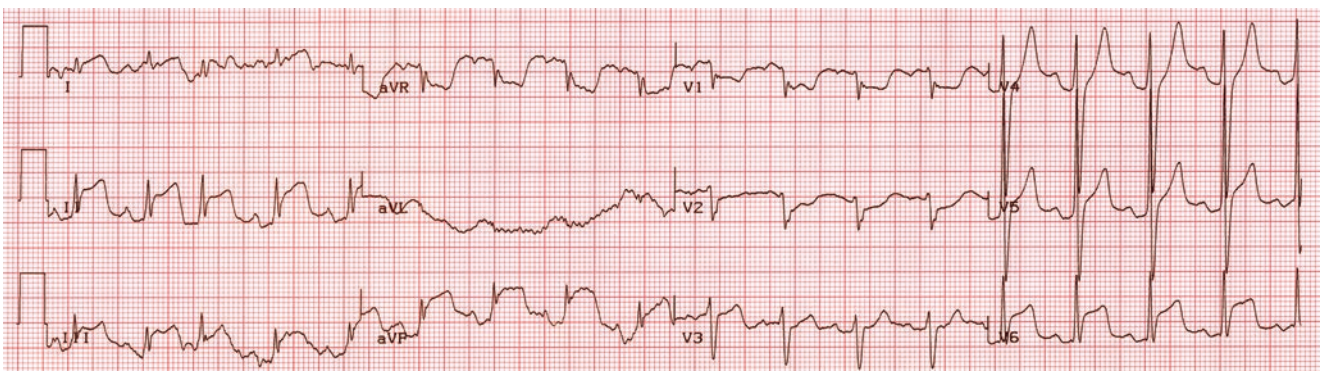

Fig. 36.5 The EKG obtained during wash phase with warm water, following removal of the specimen (including pericardium). Concurrent TEE revealed no global or regional wall motion abnormalities. The EKG rapidly normalized following termination of irrigation

Perioperative Pain Management

There is increasing evidence that TEA with local anesthetics and opioids is superior in the control of dynamic pain, plays a key role in early extubation and mobilization, reduces postoperative pulmonary complications, and has the potential to decrease the incidence of post-thoracotomy pain syndrome. For EPP, although a bolus dose of local anesthetic may be administered prior to surgical incision, the risk of hemodynamic instability usually precludes continuous intraoperative dense neuraxial blockade. Nonetheless, it is vital to aggressively control acute postoperative pain [39, 40].

Preexisting pain related to mesothelioma is not uncommon and frequently treated with opioids. Tolerance may occur after 1–2 weeks of treatment, and such patients present a challenge in terms of postoperative pain control and physiologic withdrawal. Patients on chronic opioids presenting for EPP would generally receive an opioid-free epidural infusion, with additional patient-controlled systemic opioids prescribed to minimize the occurrence of withdrawal. Ketamine may be a useful adjunct [41].

Early Postoperative Considerations

Depending on center experience, majority of patients may be weaned and extubated in the operating room. This minimizes duration of positive pressure on the bronchial stump and avoids the potential problems of ventilator-associated alveolar barotrauma and infection. Prudence is advised in difficult or complicated EPP with increased transfusion requirement or excessive fluid administration in the IOHC cases.

Management of the Ipsilateral Thoracic Space

In addition to the potential for cardiac herniation and its hemodynamic consequences (described earlier), rapid filling of the empty hemithorax with fluid, blood, or abdominal contents from a ruptured diaphragmatic patch can also compromise cardiorespiratory function. Air/fluid is removed from the chest drain at the end of surgery in an attempt to medialize the mediastinum. This is an imprecise process, and a chest radiograph is obtained on arrival in the ICU to assess mediastinal position. Intrathoracic pressure monitoring may guide intermittent fluid evacuation of the pneumonectomy space [42]. This prevents rapid accumulation resulting in respiratory compromise while avoiding contralateral lung hyperexpansion, compromised venous return, and hypotension with excessive and/or rapid removal.

Other Issues Specific to EPP

- Patients who have undergone IOHC receive liberal fluids for the initial 24 h as part of the renal protection strategy (Table 36.1).
- Standard chest compression is ineffective in EPP patients because the mediastinum is dynamic and shifts to the empty hemithorax.

Conclusion

EPP is a radical and aggressive surgery, which presents a great challenge to the thoracic anesthesiologist. Besides standard anesthesia concepts for pneumonectomy, management involves an understanding of the technique of EPP, common intraoperative physiologic disruptions, and anticipated complications. Emerging multimodality treatments for MPM have additional anesthetic implications. One of those, IOHC, is discussed in the context of general EPP-specific anesthetic issues.

Clinical Case Discussion

Case

A 50 year-old male is scheduled for right extrapleural pneumonectomy. The diagnosis of mesothelioma was made on pleural biopsy, and he has completed six cycles of chemotherapy. He is a nonsmoker, and apart from well-controlled hypertension, he has no other significant comorbidities.

Questions

1. *Apart from routine preoperative assessment for pulmonary resection:*
   (a) Are any specialized cardiac and pulmonary function tests indicated?
      - Echocardiography commonly used to assess cardiac function.
      - Stress test only when history, examination, and echocardiography suggest significant cardiac disease.
      - FEV_1, DL_{CO}, and exercise capacity routinely assessed.
      - Ventilation/perfusion scans recommended if $FEV_1 < 2$ L.
      - Predicted postoperative $FEV_1 < 1$ L may preclude EPP.
   (b) What is the importance of radiologic investigations?
      - Surgical staging and tumor resectability.
      - Anesthetic implications include safe placement of epidural catheters at the thoracic region, level of intravenous access, quantity of blood and blood products available, and the potential necessity for cardiopulmonary bypass during resection.

Table 36.5 Hypotension during critical phases of surgery

Phase	Mechanism(s)	Management strategy
Induction	Reduced venous return Vasodilation (induction agents, epidural) Exacerbation of tumor compressive effects by the decrease in FRC Loss of "thoracic pump" of spontaneous ventilation Positive pressure ventilation	Preemptive vasoconstricting agents and judicious selection of induction agents/doses are particularly indicated for patients with large tumor burdens, large effusions, or radiographic evidence of cardiac or major vessel impingement
Dissection	Blood loss Insensible losses Variable degrees of compression from the tumor, retractors, and blunt dissection pressure	Communication with the surgeon is paramount Judicious use of vasopressors A low threshold for administration of blood and products when appropriate
Repositioning and emergence	Circulatory arrest Herniation of the heart (particularly with right EPP), with torsion of the SVC and IVC Moderate hypotension Partial cardiac herniation (loose or partially ruptured pericardial patch) Tamponade (tight pericardial patch) Hypovolemia Deviated mediastinum Aggressive bolus dosing of the epidural in anticipation of emergence	Immediate return to the lateral position A sluggish response to fluid boluses and vasopressors suggests that mechanical impediments to venous return should be ruled out A portable chest radiograph is usually helpful in ruling out partial cardiac herniation or guiding medialization of the mediastinum

2. *How is an extrapleural pneumonectomy different from pneumonectomy?*
   - See Table 36.3.
3. *What are the common causes of hypotension and the management strategies?* (Table 36.5)
4. *How would the application of intraoperative intracavitary heated chemotherapy affect the anesthetic management?*
   - Renal protective strategies should be employed (Table 36.1).
   - Restrictive physiology exhibited by EPP patients during one-lung ventilation is exacerbated by the weight of the perfusate, and positive end-expiratory pressure is especially important to prevent atelectasis.
   - Fluid management is delicate balance between renal protection and the potential for exacerbation of acute lung injury in fluid overload.

Pancoast Tumors and Combined Spinal Resections

37

Valerie W. Rusch, Ilya Laufer, Mark Bilsky, Alexandra Lewis, and David Amar

Key Points

- Pancoast tumors are very challenging lung cancers to treat because they involve vital structures including the brachial plexus, subclavian vessels, and spine.
- Multimodality management with induction chemoradiotherapy is now the standard of care.
- Preoperative planning between thoracic surgery, anesthesiology, and neurosurgery, including lung isolation technique, invasive hemodynamic monitoring, need for neurophysiologic monitoring, and a pain management plan, is essential.
- Surgical approach is determined by the anatomic location of the tumor and is performed from either a posterior or anterior approach or both.
- Because subclavian artery and vein involvement may require resection of these vessels, adequate intravascular monitoring and access must be planned.
- Pain control, pulmonary toilet, and physical therapy are key to achieving satisfactory postoperative recovery.

Introduction

Pancoast tumors, properly known as superior sulcus carcinomas, are a particularly challenging form of non-small cell lung cancer (NSCLC) to treat surgically because they commonly invade vital structures within and near the thoracic inlet. Invasion of the brachial plexus, subclavian vessels, and spine by direct tumor extension necessitates careful preoperative planning by surgeons and anesthesiologists. Originally described in 1924 [1] and again in 1932 [2], by Henry K. Pancoast, a radiologist at the University of Pennsylvania, this subset of NSCLC was considered inoperable, and thus fatal, for nearly two decades until the late 1950s when the combination of radiotherapy and surgery offered some curative hope. Pancoast's description of an apical chest tumor associated with shoulder and arm pain, a Horner's syndrome, and atrophy of the hand muscles describes the constellation of signs and symptoms of the syndrome that has come to bear his name.

Anatomy of Pancoast Tumors

An understanding of the anatomy of the superior sulcus is essential for the diagnosis and treatment of Pancoast tumors. The pulmonary sulcus is anatomically synonymous with the costovertebral gutter (the junction of the ribs to the vertebral column) in the posterior aspect of the chest and spans the thorax from the first rib down to the diaphragm. The superior pulmonary sulcus encompasses the most apical aspect of the gutter. Thus, a Pancoast tumor is a NSCLC arising in the apex of the lung located within the costovertebral gutter that causes constant pain due to local invasion into any of the following structures: the chest wall, spine, intercostal nerves, brachial plexus, subclavian vessels, sympathetic trunk, and stellate ganglion. The classic symptoms associated with Pancoast tumors are directly related to the structures compromised by this apicocostovertbral tumor. For instance,

shoulder pain is due to a combination of local invasion into the chest wall and intercostal nerves. Unrelenting pain radiating down the ulnar surface of the arm and 4th and 5th fingers results from T1 nerve root involvement, and motor weakness in the hand indicates C8 involvement. A Horner's syndrome is produced by tumor impingement on the sympathetic chain and stellate ganglion, structures located in the posterior aspect of the superior sulcus. Because some superior sulcus NSCLCs involve the subclavian vessels rather than the paravertebral area, the classification of a NSCLC as a Pancoast tumor has expanded to include all tumors of the superior sulcus whether or not there is involvement of the brachial plexus or stellate ganglion. NSCLCs located in the apex of the chest that involve the second rib or lower are not considered Pancoast tumors and are generally termed apical lung cancers.

The thoracic inlet is perhaps the most important anatomic area to understand when treating Pancoast tumors because this anatomic region encompasses crucial neurovascular structures and musculoskeletal elements and symptoms are directly related to the location of these tumors and their involvement of these structures. The surgical resection of superior sulcus tumors requires an intricate knowledge of these anatomic relationships and the consequences of resection, need for reconstruction, and risks of injury to the patient. The thoracic inlet is the superior aperture of the thoracic cavity bounded by the first thoracic vertebra (T1) posteriorly, the first ribs laterally, and the superior border of the manubrium anteriorly (Fig. 37.1) [3]. The root of the neck lies just superior to the thoracic inlet with the brachial plexus located in a superolateral position between the anterior and middle scalene muscles, superior to the first rib.

The thoracic inlet can be separated into three distinct compartments based on the insertion of the anterior and middle scalene muscles on the first rib and the posterior scalene muscle on the second rib. The anterior compartment is located in front of the anterior scalene muscle and contains the sternocleidomastoid and omohyoid muscles, the subclavian and internal jugular veins, and their branches. Tumors in this location tend to invade the first intercostal nerve and first rib resulting in pain in the upper and anterior chest wall (Fig. 37.2a, b). The middle compartment, located between the anterior and middle scalene muscles, includes the subclavian artery, the trunks of the brachial plexus, and the phrenic nerve that lies on the anterior surface of the anterior scalene muscle (Fig. 37.3). Tumors found in the middle compartment may invade the anterior scalene muscle, the phrenic nerve, the subclavian artery, and the trunks of the brachial plexus and middle scalene muscle. These tumors tend to present with signs and symptoms related to direct compression or infiltration of the brachial plexus such as pain and paresthesias in the ulnar distribution. The posterior compartment contains the nerve roots of the brachial plexus, the stellate ganglion and the vertebral column, the posterior aspect of the subclavian artery, the paravertebral sympathetic chain, and the paravertebral musculature. Tumors in the posterior inlet can invade the transverse processes and vertebral bodies, as well as the spinal foramina (Fig. 37.4a, b), and be associated with neuromuscular pathology such as a Horner's syndrome (ptosis, miosis, and anhydrosis) and brachial plexopathy (weakness of the intrinsic muscles of the hand), paralysis of the flexors of the digits resembling a "claw hand," and diminished sensation over the medial side of the arm, forearm, and hand (related to C8 and T1 destruction).

Initial Assessment

Superior sulcus tumors or masses associated with chest and arm pain may be due to other pathologic processes including infectious conditions like tuberculosis or other malignant disorders including lymphoma, primary chest wall tumors, or metastatic disease from other neoplasms (Table 37.1) [4]. Therefore a diagnosis of NSCLC must be confirmed before instituting definitive therapy. This is best accomplished by

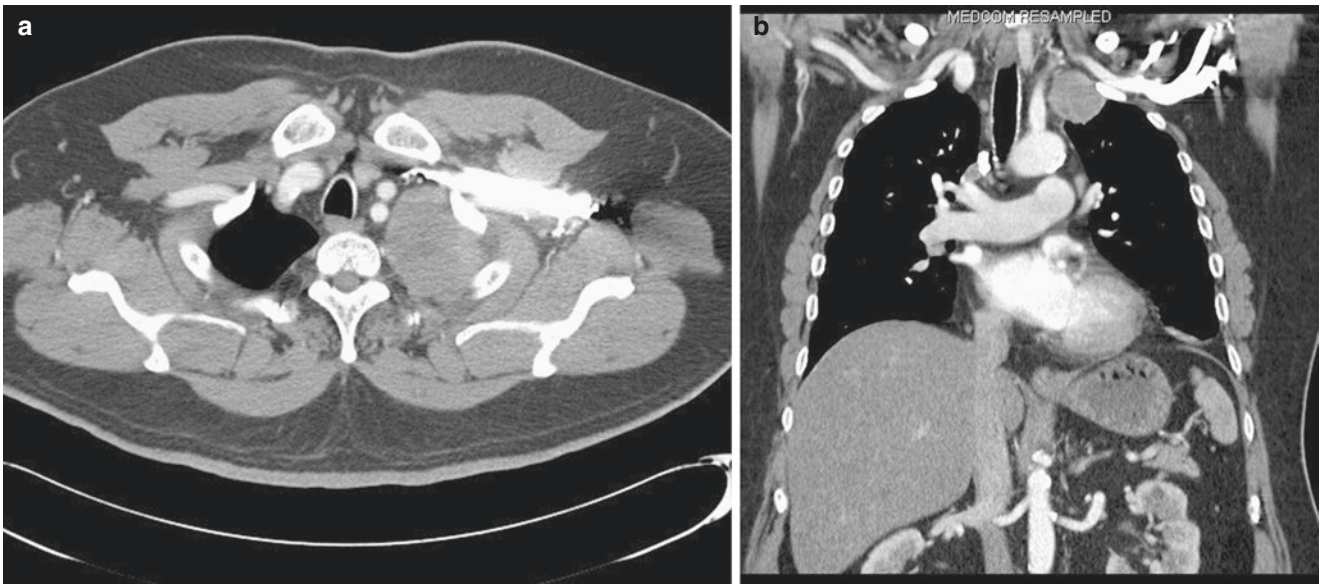

Fig. 37.2 (**a**, **b**) Left Pancoast tumor, clinical stage T3 filling superior sulcus but not invading spine or involving subclavian vessels (**a**). The extent of the tumor is also well defined on the coronal view of the CT scan

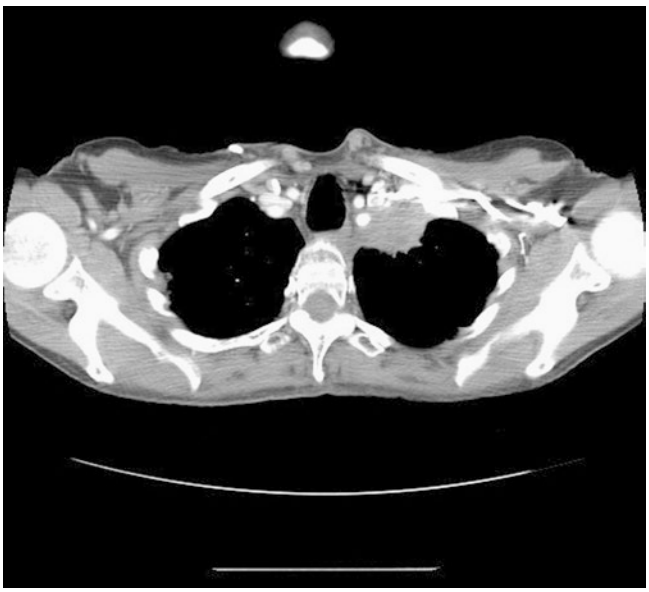

Fig. 37.3 Anteriorly located left Pancoast tumor involving subclavian vessels requiring anterior "Dartevelle" approach to resection

transthoracic fine needle aspiration (FNA) or core needle biopsy.

Once a diagnosis of NSCLC has been made, the extent of disease should be evaluated before surgical resection is considered. Patients are evaluated with a computed tomography (CT) of the chest and upper abdomen with intravenous contrast, including the adrenals, whole-body positron-emission tomography (FDG-PET), and a brain magnetic resonance imaging (MRI) to exclude metastatic disease in extrathoracic sites as well as in the mediastinum. Pancoast tumors are, by definition, at least stage IIB lung cancers, with a significant risk of mediastinal nodal involvement approaching 10 to 20% of patients [5]. Because Pancoast tumors with mediastinal nodal involvement (N2 or N3 disease) have markedly worse survival than those that are N0 or N1, further staging by endobronchial ultrasound (EBUS) and/or mediastinoscopy should be considered if CT and PET suggest mediastinal nodal disease [6].

Due to the unique anatomic position of these tumors, diagnostic imaging with contrast MRI plays an essential role in defining the extent of local invasion and thus, resectability. The brachial plexus, subclavian vessels, vertebrae, and neural foramina are best visualized well with this modality. T1 involvement and resection are well tolerated; however, resection of the C8 nerve root and lower trunk of the brachial plexus generally leads to permanent loss of intrinsic hand function and lower arm function. Radiographic evidence of spine involvement, or neurologic symptoms and signs suggestive of nerve root or brachial plexus pathology, necessitates joint evaluation of these patients by a thoracic surgeon and a spine surgeon. At Memorial Sloan Kettering, the treatment of all Pancoast tumors is planned jointly by the thoracic surgeon and spine neurosurgeon.

Multimodality Treatment

From the late 1950s to the present day, the therapeutic approach to Pancoast tumors has evolved into a multidisciplinary and multimodality treatment regimen that includes induction chemoradiotherapy and resection. In 1956, Chardack and MacCallum described successful treatment of

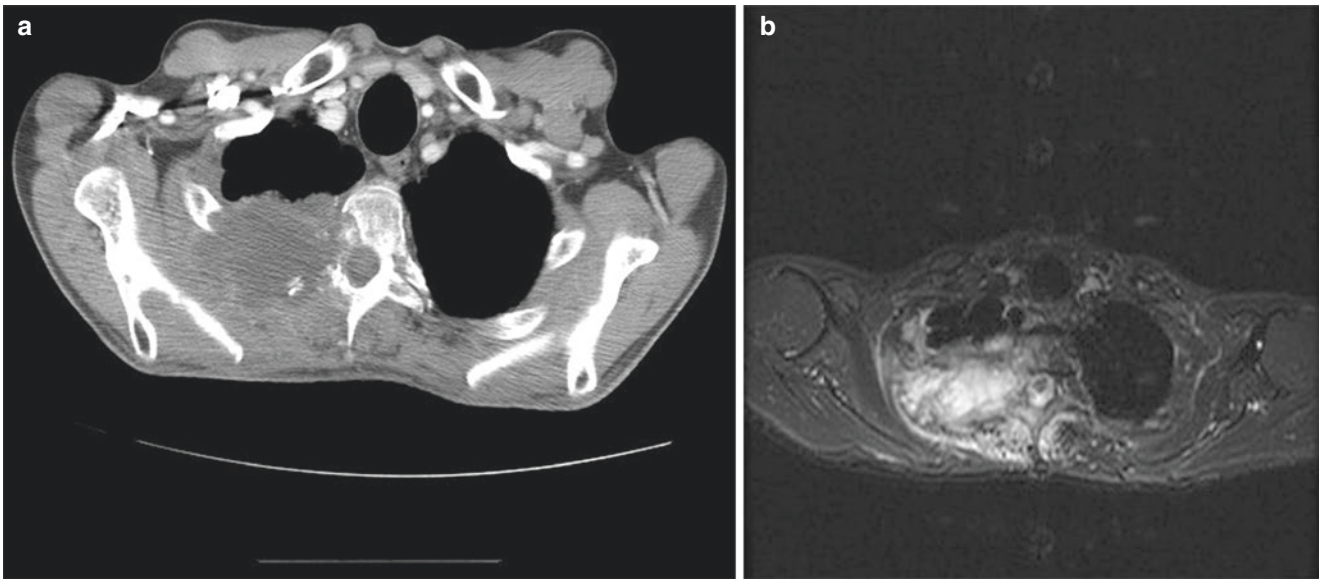

Fig. 37.4 (**a**, **b**) Right Pancoast tumor invading chest wall and destroying adjacent vertebral body as shown on CT (**a**) and MR (**b**) scans

a Pancoast tumor by en bloc resection of the right upper lobe, chest wall, and nerve roots followed by adjuvant radiotherapy leading to a 5-year survival in that patient [7]. In 1961, Shaw and colleagues reported their experience with a patient who presented with Pancoast's syndrome but became symptom-free after 30 Gy of radiotherapy and then went on to a successful resection. This treatment strategy was then applied to 18 more patients with good local control and better than expected long-term survival [8]. The Shaw and Paulson approach, based on induction radiotherapy and en bloc resection, then became the standard of care for Pancoast tumors. During the next 30 years, the basic approach to treatment remained unchanged. The largest retrospective study published to date, from Memorial Sloan Kettering Cancer Center, defined negative prognostic factors including mediastinal lymph node metastases, N2 disease, vertebral and subclavian vessel involvement, and incomplete resection [6]. Complete (R0) resection was achieved in only 64% of patients with T3N0 disease and 39% of patients with T4N0 disease, and locoregional relapse was the most common site of tumor recurrence. Anatomic lobectomy was associated with a better outcome than sublobar resection, and intraoperative brachytherapy did not enhance overall survival [9]. This retrospective study documented the results of "standard" treatment for resectable Pancoast tumors during a nearly 40-year period and emphasized the need for novel approaches that would improve both local control and survival.

Because combined modality therapy was increasingly being used for other locally advanced NSCLC subsets (e.g., stage IIIA (N2) disease) [10], induction chemoradiotherapy followed by surgical resection was studied in a large North American prospective multi-institutional phase II trial for Pancoast tumors (T3–4 N0-1M0 tumors) [11]. A total of 110 eligible patients were enrolled on this study and received induction therapy using 2 cycles of cisplatin and etoposide chemotherapy along with 45 Gy of concurrent radiotherapy. Patients with stable or responding disease then underwent thoracotomy and resection followed by two more cycles of chemotherapy. Induction therapy was well tolerated allowing 75% of enrolled patients to go on to thoracotomy. R0 resection was achieved in 91% of T3 and 87% of T4 tumors. Approximately 1/3 of patient had no residual viable tumors, 1/3 had minimal residual microscopic disease, and 1/3 had

gross residual tumor on final pathology. Patients who had a R0 resection experienced a 53 percent survival at 5 years, and the most common sites of relapse were distant rather than locoregional. Several more recent studies, including a multicenter prospective clinical trial from Japan, confirm these results [12–16] and establish induction chemoradiotherapy and surgery as standard care for resectable Pancoast tumors.

Surgical Approaches to Resection

The goal of any cancer operation is the complete resection of the tumor with negative margins. In the case of Pancoast tumors, due to their unique location at the apex of the chest and at times their involvement of the thoracic inlet, complete resection is challenging and usually includes the upper lobe, involved chest wall with or without the subclavian vessels, portions of the vertebral column and T1 nerve root, and dorsal sympathetic chain. Pancoast tumors may be approached through an extended high posterolateral thoracotomy incision (Paulson's approach) or through an anterior approach popularized by Dartevelle.

Posterior Approach

The patient is positioned in the lateral decubitus position but rotated slightly anteriorly to provide exposure to the paravertebral region (Fig. 37.5) [17]. A standard posterolateral thoracotomy is performed in the 5th intercostal and the chest explored to make sure that there is no evidence of metastatic disease. If the tumor appears resectable, the incision is extended superiorly to the base of the neck following a line midway between the spinous process and the edge of the scapula (Fig. 37.5). Extension of the incision anteriorly around the anterior border of the scapula up toward the axilla can also be used to enhance exposure. The scapula is elevated away from the chest wall with either a rib-spreading retractor or internal mammary retractor with good visualization of the apex of the chest. The scalene muscles are detached from the first and second ribs and the first rib exposed. Involved ribs are divided anteriorly to allow for a 4 cm margin away from the tumor. Dissection is carried along the superior border of the first rib subperiosteal plane in anterior to posterior direction. To facilitate the posterior dissection, the erector spinae muscles are retracted off the thoracic spine allowing for visualization of the costovertebral gutter. To provide an adequate posterior margin, the transverse processes and rib heads are usually resected en bloc. Anterior division of the ribs facilitates the disarticulation of the chest wall from vertebral column and when possible should be performed prior to sectioning of the transverse processes. Palpation of the interarticularis (i.e., lateral border of the facet joint) defines the medial border of transverse process osteotomy. The osteotomy is generally performed using a curved osteotome, which is used to transect the transverse processes and costovertebral joint. The chest wall can then be retracted laterally and anteriorly, allowing visualization of the intercostal nerves, which are meticulously ligated before division to prevent leak of cerebrospinal fluid. Bleeding near the neural foramina is carefully controlled with bipolar electrocautery. Thoracic nerve roots below T1 are generally transected without neurologic sequelae. Since the T1 nerve root provides motor innervation to the hand, it is examined for tumor involvement and only ligated in cases of tumor invasion. Division of the T1 nerve root may cause mild weakness of the intrinsic muscles of the hand, but division of the C8 nerve root will result in permanent paralysis. Frozen sections are used liberally during the operation to determine the necessary extent of resection. Dissection and ligation of the nerve roots usually represent the final step of disarticulation of the chest wall from the spine. After the chest wall resection is completed, the detached chest wall is allowed to fall into the chest cavity and an upper lobectomy and mediastinal lymph node dissection is completed in the standard fashion. Reconstruction of the chest wall is not necessary unless the defect created is larger than the first three ribs in which case the angle of the scapula can herniate into the chest cavity causing pain and impaired movement. If a chest wall reconstruction is needed, a 2-mm-thick Gore-Tex patch (WL Gore, Flagstaff, AZ, USA) is sutured to the margins of resection under tension and secured in place.

Tumors Involving the Vertebral Bodies and Epidural Region

Vertebral body invasion by Pancoast tumors is not necessarily a contraindication to surgical resection. The development of better instrumentation for spine stabilization now permits a more aggressive approach to these tumors [17, 18]. Currently, with multimodality therapy, T4 lesions with vertebral body or epidural extension can be considered for resection with curative intent. At Memorial Sloan Kettering Cancer Center, spine MRI images are used to divide tumors into four classes, A–D, based on the degree of spinal column and neural tube involvement [17]. Class A and B tumors are T3 lesions that are amenable to complete R0 resection. Class A tumors involve only the periosteum of the vertebral bodies, and class B tumors are limited to the rib heads and distal neural foramina (Fig. 37.6). Class C and D tumors are T4 lesions that are not amenable to en bloc resection but can still be completely resected. Class C tumors extended into the neural foramina, limited or no vertebral body involvement but do have unilateral epidural compression. Class D tumors

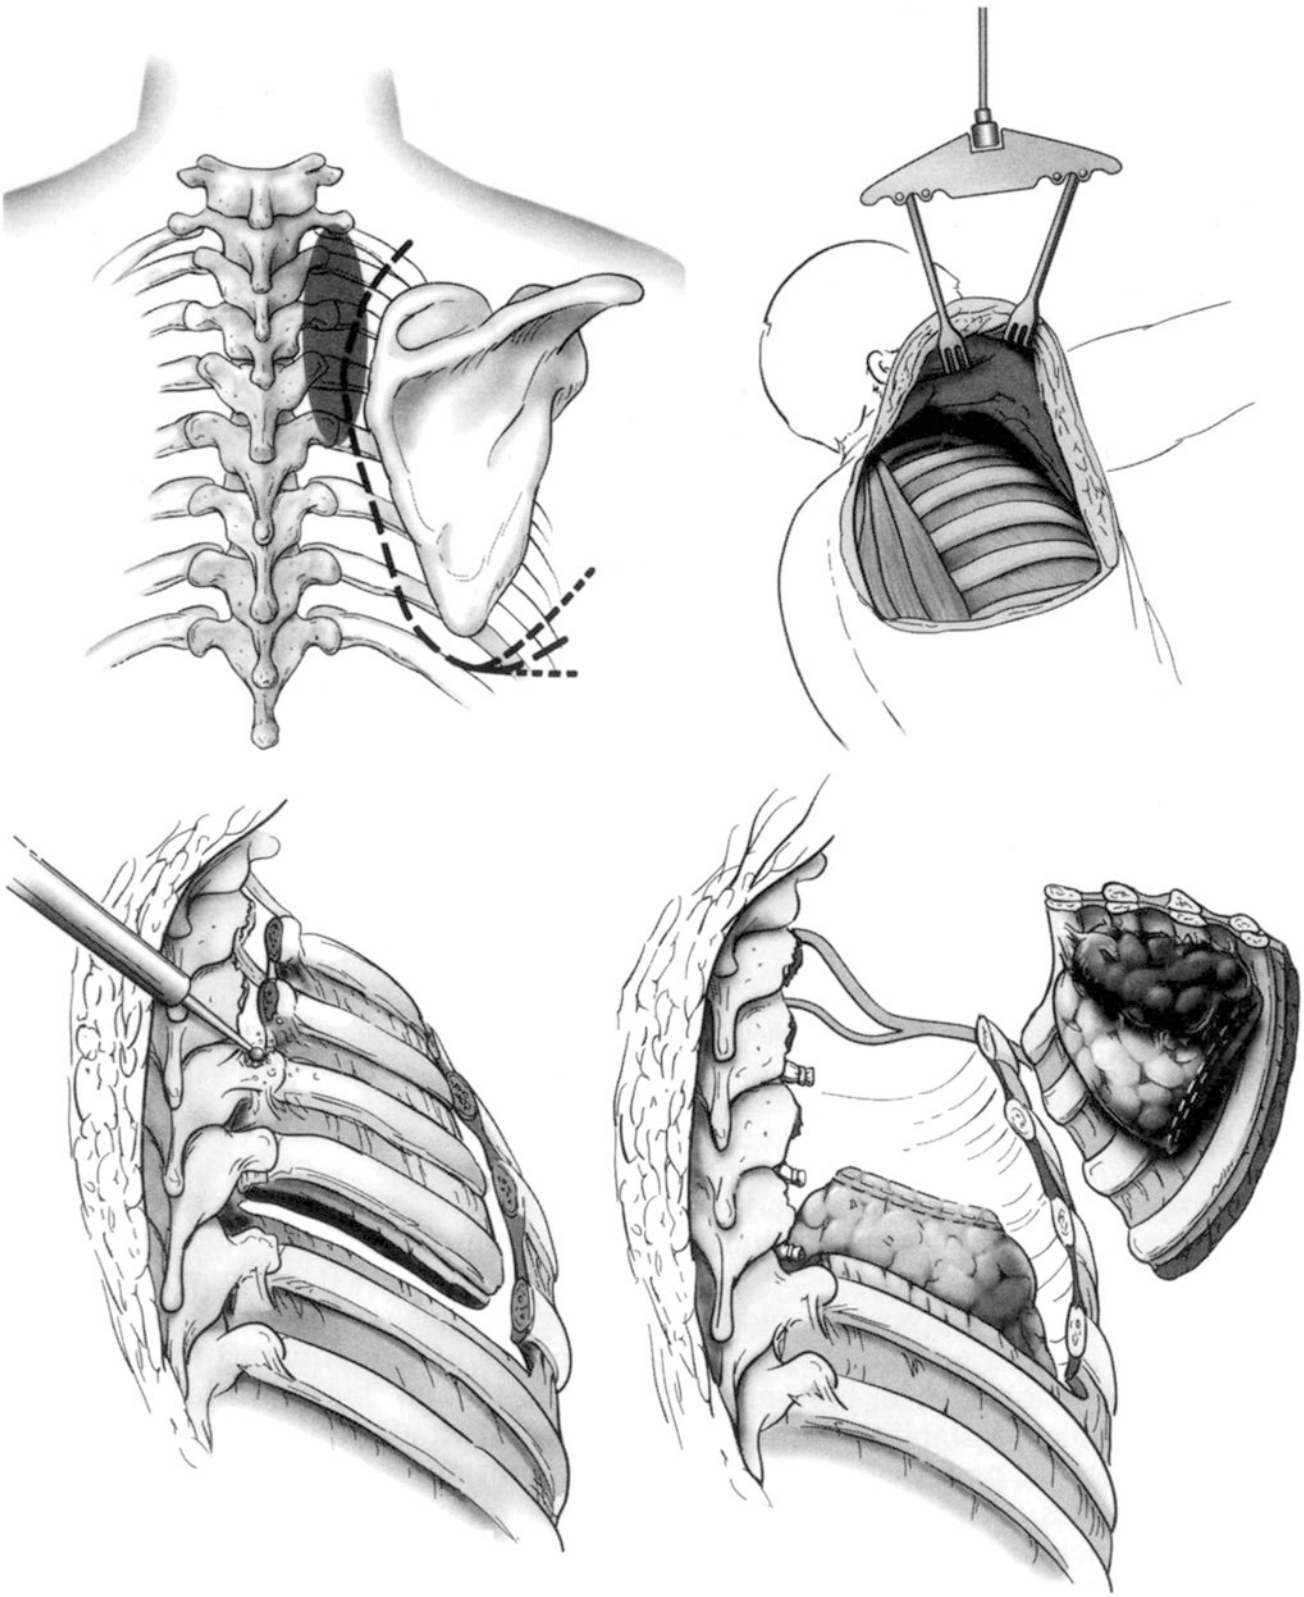

Fig. 37.5 Artist's illustration of a posterolateral thoracotomy. Upper left: incision is made midway between the spinous processes and medial border of the scapula and extending over the inferior border. Upper right: The rhomboid and levator scapulae muscles are sectioned to elevate the scapula from the chest wall by using a mammary self-retaining retractor. Lower left: The paraspinal muscles are dissected to expose the junction of the laminae and transverse processes. The drill is used to resect the transverse processes distal to the pedicle to expose the neural foramen. For a Type C resection, the laminae, facet joints, and pedicles are resected to expose the lateral dura. Lower right: the chest wall is then pushed forward, and the nerve roots are ligated at the distal neural foramen. En bloc chest wall and tumor resection are accomplished. (From Bilsky et al. Ref. [17], used with permission)

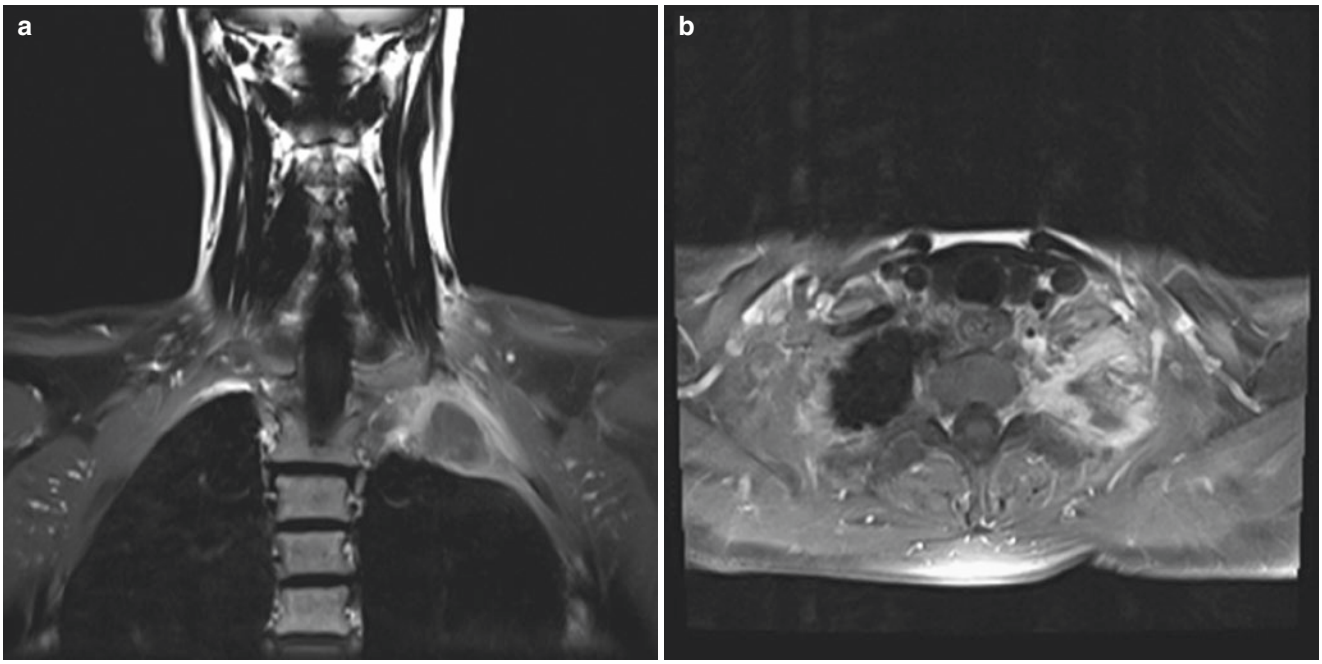

Fig. 37.6 Class B tumor (Figure 6A) with invasion of the rib head and neural foramen (Figure 6B). Patient underwent R0 excision using the posterior thoracotomy

involve the vertebral column, either the vertebral body and/or lamina with or without epidural compression. Class A and B and some class C tumors can be approached through posterolateral thoracotomy. A high-speed drill is used to remove involved vertebral bodies. The junction between the vertebral body and the pedicle provides an important landmark for vertebral body removal, signaling proximity to the spinal cord. The posterior longitudinal ligament is removed and provides a margin on the anterior dura. The disc spaces adjacent to the tumor are exenterated in order to aid in spinal fixation. Anterior reconstruction alone is sufficient for resections of one to two vertebral bodies. Autologous bone from the iliac crest or non-diseased rib, allograft fibula, methymethacrylate with Steinman pins, or corpectomy cages can all be used for reconstruction. Anterior approach provides very limited access to the T1 and T2 vertebrae and epidural space. Therefore patients requiring any degree of epidural decompression in the upper thoracic spine generally undergo posterior approach surgery along with the anterior approach. Furthermore, tumors with significant extension into the vertebral body place patients at high risk of postoperative mechanical instability, especially since the supporting chest wall is removed. Such patients may benefit from long-segment posterolateral spinal instrumentation and fusion in order to avoid development of debilitating deformity.

Class D tumors that involve the posterior elements (spinous process, laminae, and pedicles) are resected through a combined anterior/posterior approach. During the first stage of the operation, patients are positioned prone and a posterior midline incision made. Subperiosteal dissection is used to expose the level of the tumor along with several levels above and below the tumor in order to permit placement of posterior spinal instrumentation. The involved areas of the spinous process, laminae, and pedicles are resected. Epidural tumor is dissected off the dura and a multilevel resection of affected nerve roots done. Posterior fixation is accomplished in order to maintain coronal and sagittal stability (Fig. 37.7). If soft tissue over the reconstruction is inadequate, muscle flap rotation by a plastic surgeon can be done to reduce the risk of skin breakdown and infection of the spine hardware [18, 19]. Once the posterior resection and reconstruction are complete, the incision is closed, the patient turned to the lateral decubitus position, a posterolateral thoracotomy performed, and the lung and chest wall resection completed. The proximity and the parallel orientation of the thoracotomy and midline incisions result in a challenging environment for wound healing, and low threshold for plastic surgery consultation is recommended.

Anterior Approaches

Pancoast tumors that involve the subclavian vessels are best approached anteriorly. Although several different approaches have been described [20–25], the anterior transcervical approach, originally described by Dartevelle and modified by others [26], is considered the standard approach for this subset of Pancoast tumors.

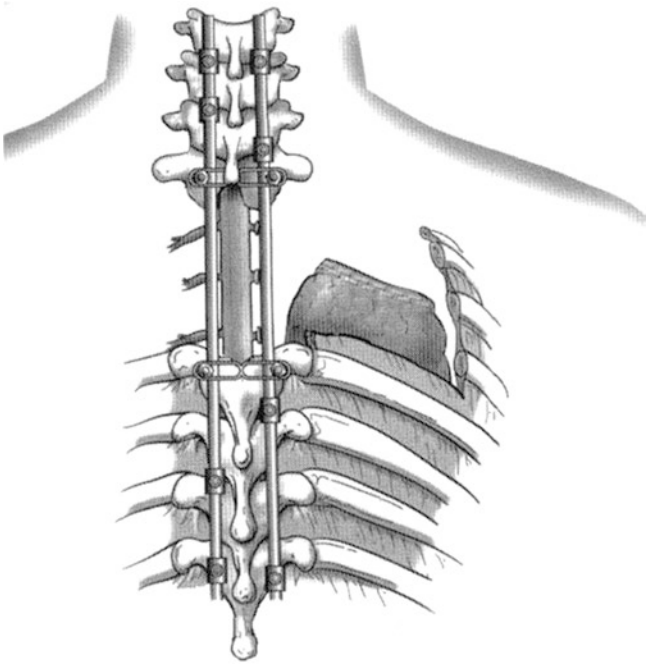

Fig. 37.7 Artist's illustration depicting a posterolateral transpedicular approach for class D tumor with bilateral posterior segmental fixation. (From Bilsky et al. Ref. [17], used with permission)

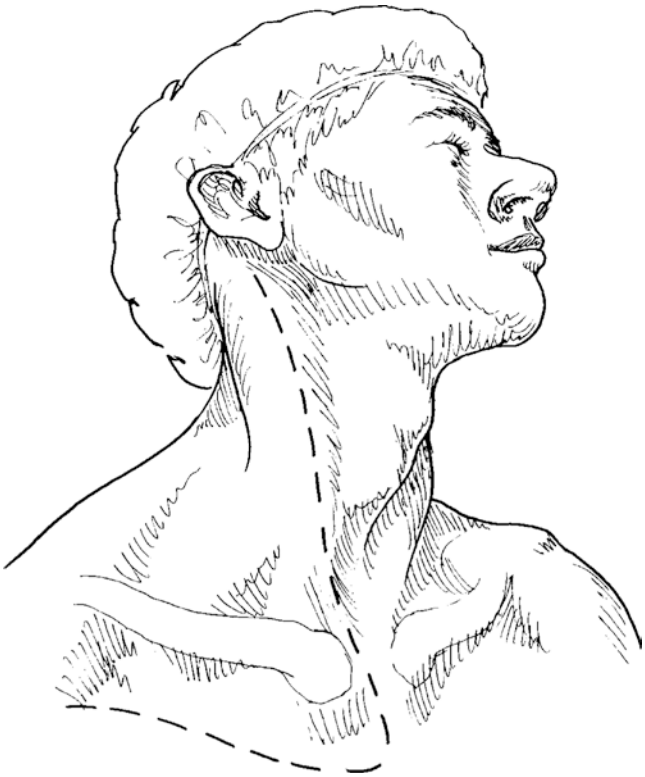

Fig. 37.8 An anterior transcervical incision is made and curved under the head of the clavicle in an L-fashion. (From Nesbitt et al. Ref. [3], used with permission)

The patient is positioned supine with the neck hyperextended and the head turned to the opposite side of the lesion [27, 28]. An inverted L-shaped incision is carried down the anterior border of the sternocleidomastoid muscle and extended below the clavicle to the level of the second intercostal space and then turned horizontally following a parallel line below the clavicle to the deltopectoral groove (Fig. 37.8). The sternal attachment of the sternocleidomastoid is divided along with the insertion of the pectoralis major. A myocutaneous flap is then folded laterally exposing the thoracic inlet. The scalene fat pad is excised and sent for frozen section to determine lymph node involvement. If the tumor is deemed resectable, the upper part of the manubrium is divided and the incision carried into the second intercostal space via an L-shaped incision. The involved section of the subclavian vein is resected but not reconstructed (collateral venous flow around this area being sufficient).

Next, the anterior scalene muscle is divided either at its insertion onto the first rib. The phrenic nerve is identified and preserved. The subclavian artery is resected and reconstructed with a 8 or 10 mm polytetrafluoroethylene (PTFE) graft (Fig. 37.9). The middle scalene muscle is detached above its insertion on the first rib to expose the C8 and T1 nerve roots. These are dissected in a lateral to medial direction up to the confluence of the lower trunk and brachial plexus. The ipsilateral prevertebral muscles and paravertebral sympathetic chain and stellate ganglion are then resected off the anterior aspect of the vertebral bodies of C7 and T1. The T1 nerve root is commonly divided just lateral to the T1 intervertebral foramen.

Attention can now be placed on the chest wall resection. The anterolateral arch of the first rib is divided at the costochondral junction, and the second rib is divided at its midpoint. The third rib is dissected on its superior border in a posterior direction toward the costovertebral angle, and the first two through three ribs are disarticulated from the transverse processes. From this cavity, an upper lobectomy is completed. If exposure for the lobectomy and chest wall resection is inadequate, the anterior incision is closed and the patient turned into the lateral decubitus position. The remainder of the resection can then be performed via a posterolateral thoracotomy incision.

Anesthetic Considerations

Lung isolation with a left-sided double-lumen tube or right-sided bronchial blocker can be used depending on surgeon and anesthesiologist experience and preference. Intra-arterial blood pressure monitoring and large bore IV access should be placed on the opposite side of the tumor. If there is potential for SVC or innominate vein resection, venous access via the femoral region or lower extremity is advisable. Central

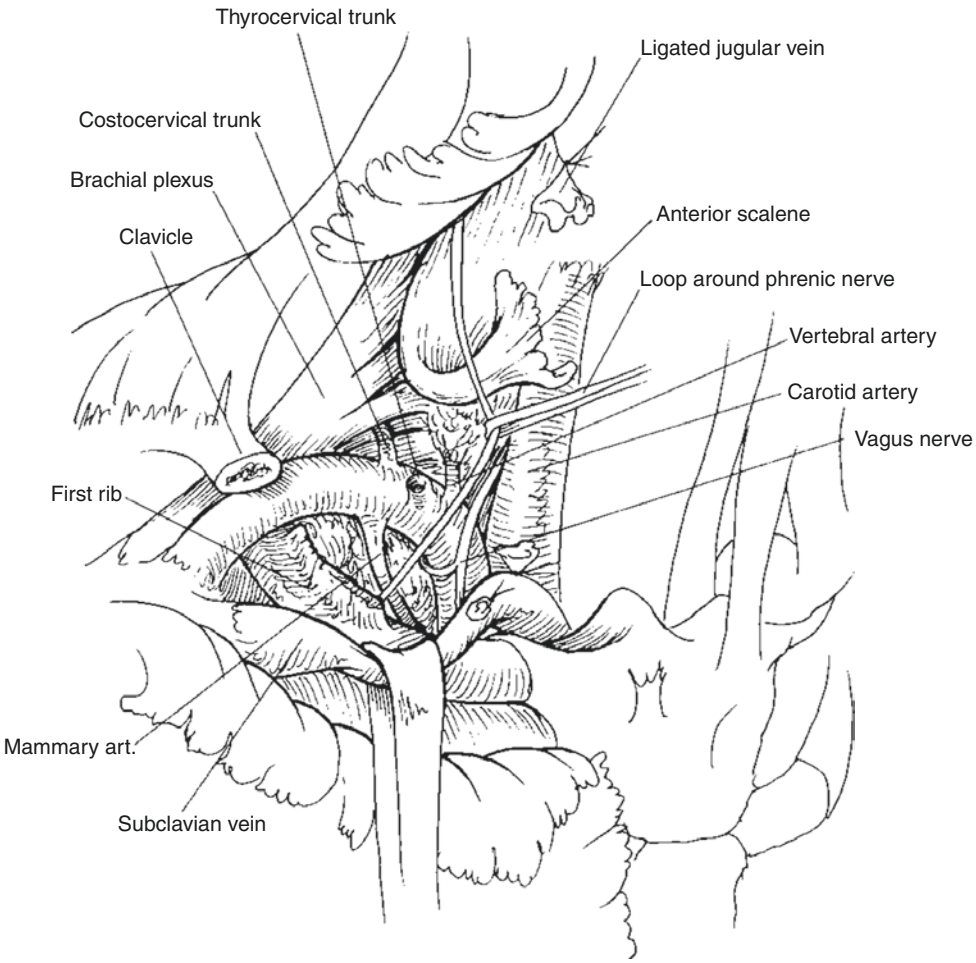

Fig. 37.9 The phrenic nerve and subclavian vein are retracted. The anterior scalene muscle is divided to expose the subclavian artery. (From Nesbitt et al. Ref. [3], used with permission)

venous catheterization on the nonoperative side may be considered if adequate IV access is unavailable or if the patient's cardiovascular reserve is limited and perioperative use of vasoactive agents is anticipated. There are sparse data on whether to employ neurophysiologic monitoring during resection of Pancoast tumors. In the case of thoracic and thoracoabdominal aortic aneurysm repair where spinal cords ischemia is a devastating complication, a recent prospective series of 233 patients demonstrated that normal somatosensory and motor evoked potential monitoring intraoperatively had a strong negative predictive value indicating that patients without signal loss are unlikely to awake with a neurologic deficit, whereas irreversible changes on monitoring were significantly associated with immediate postoperative neurologic deficit [29]. If spine stabilization is required, it is our practice to employ somatosensory and motor evoked potential monitoring intraoperatively. The cause of reversible changes during surgery is often due to compression of segmental spinal arteries or spinal cord hypoperfusion. Both of these situations can lead to spinal cord infarction unless corrected usually by pharmacologically elevating the patient's blood pressure. During neurophysiologic monitoring, the use of inhalation agents can depress the amplitude and prolong the latency of measured evoked potentials. It is generally accepted that a decrease in amplitude by >50% and an increase in latency are defined as clinically significant [30]. Therefore, it is customary to employ minimal inhalation anesthesia balanced by total intravenous anesthetic regimens with Bispectral brain monitoring when feasible.

Since lobectomy or pneumonectomy is needed in some cases, protective one-lung ventilation and judicious fluid administration are recommended due to the risk of postoperative pulmonary edema and respiratory distress in these patients. Trends in pulse pressure variation (PPV) can be used noninvasively to assess fluid status during anesthesia and one-lung ventilation during thoracic surgery. A very small study suggested that PPV can predict fluid responsiveness under protective lung ventilation (FiO2 1.0, tidal volume 6 mL/kg, PEEP 5 mmHg) compared to conventional one-lung ventilation (FiO2 1.0, tidal volume 10 mL/kg, no PEEP), and its use may improve hemodynamic conditions in individual patients [31]. Other traditional methods of assessing fluid status include traditional hemodynamic parameters and urine output. Despite knowing that a patient may be relatively dry, this is often our choice in the management of lung resection patients.

While fluid management is complex, pain management poses a significant challenge for the anesthesiologist. Pain control must be accomplished, usually with an epidural catheter, in order to aid in early mobilization, pulmonary toilet, and chest physiotherapy. It is strongly advised to consider a multimodal pain regimen along with epidural analgesia. Preoperative medications with gabapentin or pregabalin are reasonable to manage neuropathic pain. The use of non-opioid adjuvants, like intravenous dexmedetomidine and ketamine, may reduce intraoperative opioid requirements. While there are limited and conflicting studies on the use of dexmedetomidine for neuromonitoring, a low-dose infusion without a loading dose may prevent intraoperative hypotension and minimize changes in evoked potentials. Dexmedetomidine as an adjuvant to desflurane and remifentanil anesthesia, at target plasma concentration of up to 0.6 ng/ml, has not been shown to change SSEPs or MEPs response during complex spinal surgery by any clinical significant amount [32]. Unlike dexmedetomidine, ketamine achieves greater hemodynamic stability with minimal effect on mean arterial pressure and heart rate. The advantage of ketamine is its dual property as a potent analgesic and an anesthetic agent, which can cause increases in the amplitude of somatosensory and motor evoked potentials. While the use of ketamine and dexmedetomidine is gaining wide acceptance as adjuvants during neuromonitoring, the use of intravenous lidocaine during surgery is emerging as a reasonable option for patients ineligible for an epidural catheter. Lidocaine has been shown to depress the amplitude and prolong the latency of SSEPs, but the SSEP waveforms remain preserved and interpretable when used as a part of a narcotic-based anesthetic [33]. Acetaminophen and nonsteroidal anti-inflammatory agents are routinely administered, and their use is strongly advised in the absence of renal or hepatic dysfunction.

In complex chronic pain patients, it is strongly recommended to involve a pain specialist to assist with intraoperative and postoperative pain control. Patients with chronic pain will likely have opioid tolerance, thus requiring a careful multimodal approach that might include epidural analgesia, intravenous ketamine infusion, and the addition of methadone in extreme cases.

Postoperative Considerations

The most common postoperative complications are respiratory (atelectasis, pneumonia) and are related to the extent of the incision and associated pain. Adequate pain control and intensive respiratory care are pivotal to preventing these problems. The patient should be mobilized the first postoperative day with attention to chest physiotherapy. Awake bronchoscopic suctioning may be required to clear retained secretions in those patients who have an ineffective cough. Other postoperative complications are those usually seen after pulmonary resection, including supraventricular cardiac dysrhythmias, bleeding, wound infection, or empyema. Chylothoraces can occur in patients who had had extensive resections in the paravertebral region (either right- or left-sided). Infection of the hardware used for spine stabilization is an uncommon but very serious adverse event that may require reoperation and drainage.

Clinical Case Discussion

Case: A 50-year-old man with a recent history of dyspnea on exertion and recurrent pneumonias for the past year is scheduled for surgical resection of a large apical right lung mass (Fig. 37.4a). He is a former 40 pack-year smoker. He has moderately severe but clinically stable multiple sclerosis. He reports pain in his shoulder radiating down his arm but has normal strength and function in his right hand. CT scan, PET scan, and MRI have been done and suggest no evidence of metastatic disease but extension into the paravertebral area and spine.

Questions

1. What position(s) will the patient be in for resection?
2. What is your plan for intravascular monitoring and access?
3. Do you think a chest wall reconstruction will be necessary?
4. If the vertebral bodies are involved, what other exposure is necessary?
5. What strategy do you have for fluid management and postoperative pain control?

Discussion

Based on the history and preoperative imaging, this patient has a superior sulcus tumor or Pancoast tumor, involving vital structures in the thoracic inlet and spine. A combined posterior and anterior approach will be necessary for complete resection (see description in text). The patient will be placed prone for the spine resection and stabilization. Once that is completed, the patient will be rotated into the lateral decubitus position and a posterolateral thoracotomy performed to complete the lobectomy and chest wall resection and reconstruction.

Anesthesia for Esophageal Surgery

38

Randal S. Blank, Stephen R. Collins, Julie L. Huffmyer, and J. Michael Jaeger

Key Points

- Patients presenting for esophageal surgery frequently have comorbidities including cardiopulmonary disease which should be evaluated per published ACC/AHA guidelines. Particular attention should be paid to symptoms and signs of esophageal obstruction, GERD, and malnutrition which may affect the risk of perioperative complications.
- Postoperative pain control strategies are dictated by the surgical approach to the esophagus. Use of thoracic epidural analgesia in patients undergoing transthoracic esophageal surgery provides optimal pain control, permits early patient extubation and mobilization, and may improve outcomes.
- Patients presenting for esophageal surgery commonly have pathology which increases their risk of regurgitation and aspiration. This is particularly true for patients with achalasia and other motor disorders of the esophagus, high-grade esophageal obstruction, esophageal diverticula, and severe GERD. Consideration should be given to awake intubation or rapid sequence induction with the patient in a head-up position and appropriate postoperative care, including gastric drainage.
- Excessive perioperative intravenous fluid administration may lead to exaggerated fluid shifts toward the interstitial space causing increased complications such as poor wound healing, slower return of GI function, abdominal compartment syndrome, impaired anastomotic healing, increased cardiac demand, pneumonia, and respiratory failure. The ideal fluid regimen for major esophageal surgery should be individualized, optimizing cardiac output and oxygen delivery while avoiding excessive fluid administration.
- Patients presenting for emergent repair of esophageal disruption, rupture, or perforation may present with hypovolemia, sepsis, and shock. Anesthetic management strategies should be based on the severity of these presenting conditions and the nature of the planned procedure.
- Esophageal anastomotic leak is a frequent complication associated with high morbidity and mortality and is likely to be a function of numerous surgical, systemic, and possibly anesthetic factors. Since anastomotic integrity is dependent upon adequate blood flow and oxygen delivery, the development of anastomotic leak may be related to intraoperative management variables, particularly systemic blood pressure, cardiac output, and oxygen delivery and may thus be modifiable by anesthetic management. In the euvolemic patient, the use of pressors does not appear to compromise conduit or anastomotic perfusion.

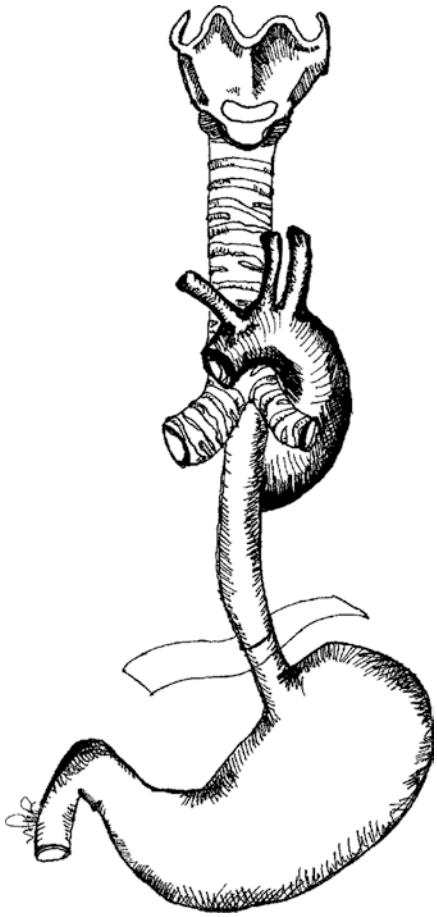

Fig. 38.1 Anatomic relationships between the esophagus, airway, aorta, diaphragm, and stomach

Anatomy and Physiology of the Esophagus

The adult esophagus is a muscular tube, 18–26 cm in length, which acts as a conduit for the passage of food from the oral cavity into the stomach (Fig. 38.1). The esophagus begins at the level of the oropharynx; it then enters the superior mediastinum behind the trachea and left recurrent laryngeal nerve and passes into the posterior mediastinum behind the left mainstem bronchus. It continues caudad passing posteriorly to the left atrium but anterior to the descending thoracic aorta. At the level of T10, the esophagus joins the stomach at the cardia after passing through the hiatus in the right diaphragm.

The upper esophagus is supplied by arterial branches of the superior and inferior thyroid arteries, whereas the mid-esophagus receives its blood supply from the bronchial and right intercostal arteries as well as branches of the descending aorta. Distally, the esophagus is supplied by branches of the left gastric, left inferior phrenic, and splenic arteries. Venous drainage from the upper segment is to the inferior thyroid veins, from the mid-segment to the azygous veins and from the lower esophageal segment to the gastric veins. The azygous and gastric veins form an anastomotic network between the portal and systemic venous systems and are thus the site of esophageal varices in patients with high portal pressure.

The esophagus receives innervation from both parasympathetic and sympathetic nerves. The parasympathetic input affects peristalsis via the vagus nerve, originating in the medulla, whereas both parasympathetic and sympathetic afferent nerves transmit information to the central nervous system via the spinal cord. Esophageal neuroanatomic pathways are shared by both the cardiac and respiratory systems; thus it may be difficult to ascertain which organ is responsible for chest pain syndromes.

Structurally, the esophagus is made up of four layers: the mucosa, submucosa, muscularis propria, and adventitia. The muscularis propria carries out most of the motor function of the esophagus. In the upper third of the esophagus, this muscularis propria is skeletal muscle, but in the distal third, it is smooth muscle, and the mid-section is mixed skeletal and smooth muscle. The upper esophageal sphincter (UES) is at the proximal origin of the esophagus where the inferior pha-

ryngeal constrictor joins the cricopharyngeus muscle. UES tone is contracted at rest thus preventing aspiration of air during normal breathing. The lower esophageal sphincter (LES) is a 2–4 cm length of asymmetric circular smooth muscle within the diaphragmatic hiatus. At rest, the LES is contracted, preventing regurgitation of gastric contents. Swallowing elicits a wave of peristalsis which is under vagal control and carries a bolus of food from the pharynx to the stomach in 5–10 s. The coordinated relaxation of the LES allows the food bolus to enter the stomach.

A number of medications affect LES tone. Drugs known to decrease LES pressure include anticholinergics, sodium nitroprusside, dopamine, beta-adrenergic agonists, tricyclic antidepressant medications, and opioids. Drugs that have been found to increase LES tone include anticholinesterases, metoclopramide, prochlorperazine, and metoprolol.

Nonmalignant Disorders of the Esophagus and Surgical Therapies

Hiatal Hernia, Gastroesophageal Reflux Disease (GERD), and Esophageal Stricture

Gastroesophageal reflux and hiatal hernia may be present independently or may coexist. Esophageal strictures may be caused by a number of insults but are frequently related to gastroesophageal reflux. Gastroesophageal reflux is a common disorder and, depending on diet and lifestyle, may affect up to 80% of the population. The term gastroesophageal reflux disease (GERD) applies when symptoms are more frequent or severe than the population norm. Pharmacotherapies including histamine blockers and proton pump inhibitors are widely used and may dramatically ameliorate symptoms and reduce the need for surgical therapy. Indications for surgery in patients with GERD include symptoms that are refractory to optimized medical therapy, esophageal stricture, pulmonary symptoms such as asthma and chronic cough, and severe erosive esophagitis. Fundoplication surgery is generally associated with superior symptom control and higher patient satisfaction when compared to medical management [1], but considerable uncertainty remains regarding the long-term benefits and potential harm of surgical therapy for GERD [2].

GERD frequently coexists with hiatal hernia, but many patients with a hiatal hernia remain asymptomatic. Hiatal hernias include the sliding hiatal hernia (type I) and paraesophageal hernias (types II, III, IV) (see Fig. 38.2a and b). Sliding hiatal hernias are most common and occur when the gastroesophageal junction and part of the fundus of the stomach herniate axially through the diaphragm into the thoracic cavity. Hiatal hernia is associated with a decrease in LES pressure [3] reducing barrier pressure between the esophagus and stomach, which in turn promotes reflux.

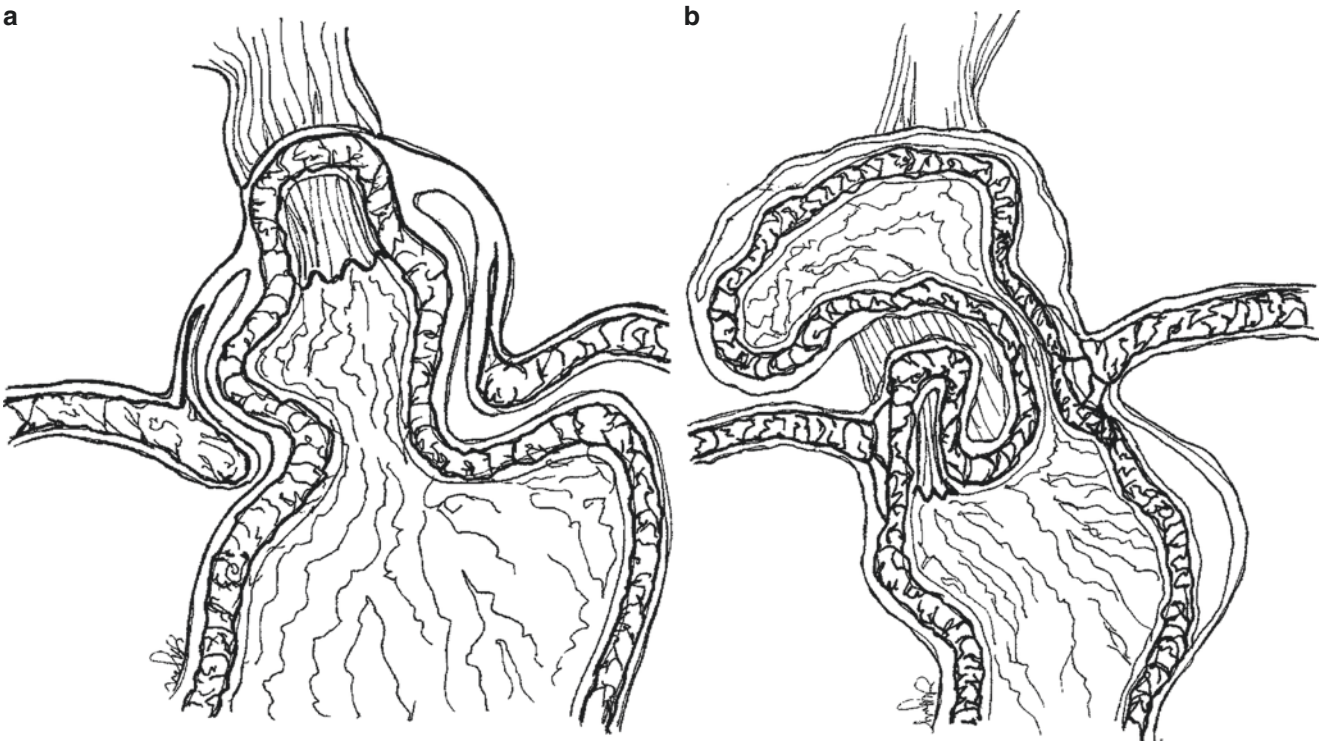

Fig. 38.2 (**a**) Type I hiatal hernia (sliding hernia). Note widening of the muscular hiatal orifice that allows cephalad herniation of the gastric cardia. (**b**) Type II hiatal hernia (paraesophageal hernia). The leading part of the herniating stomach is the fundus

Fig. 38.3 Chest radiograph demonstrating a large left-sided type 4 paraesophageal hernia

Paraesophageal hernias (PH) occur when a portion of the stomach, typically the fundus, herniates into the thorax anterolateral to the distal esophagus (see Figs. 38.2b and 38.3). PH are much less common than type I hiatal hernias and comprise approximately 5–15% of hiatal hernias [4]. PH are at risk of incarceration, and the presence of a PH is thus considered an indication for surgical repair [5].

Surgical therapies for GERD and hiatal hernia can be achieved via a number of surgical approaches, but most are performed via laparoscopy. Although the laparoscopic Nissen fundoplication (utilizing a 360° wrap) is a mainstay of surgical GERD therapy, the Toupet fundoplication (270° wrap) may be equally effective with a superior postoperative symptom profile [6]. Other surgical alternatives include endoluminal, robotic-assisted laparoscopic, and transthoracic approaches. The recently developed transoral incisionless fundoplication (TIF) is an entirely endoluminal procedure which can be performed by gastroenterologists or surgeons. Although additional studies are required, TIF appears to be a safe and relatively effective alternative to more invasive surgical procedures, producing lasting reduction in medication requirements in approximately 75% of patients [7]. Robotic-assisted laparoscopic fundoplications produce outcomes comparable to that of standard laparoscopic procedures [8, 9] but at an appreciably higher cost [8]. Relative to laparotomy or transthoracic approaches, laparoscopic surgeries may produce considerably less pain, eliminate the need for a tube thoracostomy, utilize smaller incisions which decrease the risk of postoperative incisional hernias, and provide visualization for the diagnosis of other intra-abdominal pathology. A transthoracic approach may be preferred for patients with severe peptic strictures, patients requiring reoperation, and for those with other intrathoracic pathologies.

Table 38.1 Common transthoracic esophageal procedures and anesthetic considerations

Surgical procedure	Surgical incision(s)/ approach	Anesthetic considerations
Transthoracic total fundoplication (Nissen) Transthoracic partial fundoplication (Belsey) Collis gastroplasty	Left thoracotomy	Pain control One-lung ventilation Aspiration risk
Thoracoscopic esophagomyotomy	Left thoracoscopy (4–5 ports)	Pain control One-lung ventilation High aspiration risk
Heller myotomy and modified Heller myotomy	Left thoracotomy	Intraoperative esophagoscopy
Transhiatal esophagectomy	Midline laparotomy Left cervical incision	Aspiration risk Risk of tracheobronchial injury, bleeding, cardiac compression, and dysrhythmias
Transthoracic esophagectomy (Ivor Lewis)	Midline laparotomy Right thoracotomy	Aspiration risk One-lung ventilation Protective ventilation
Three-hole esophagectomy (McKewin)	Right thoracotomy Midline laparotomy Left cervical incision	Fluid and hemodynamic management to optimize oxygen delivery Pain control Early extubation
Minimally invasive esophagectomy	Right thoracoscopy (4 ports) Laparoscopy (5 ports) Left cervical incision (variable)	Aspiration risk Protective ventilation Procedure duration
Robotic-assisted esophagectomy	Multiple abdominal and thoracic ports	Aspiration risk Procedure duration Positioning requirements and risks Hypercarbia Cardiovascular compromise Conversion to open

The transthoracic total fundoplication (Nissen) is performed through a left lateral thoracotomy (see Table 38.1 for a summary of thoracic esophageal procedures and anesthetic considerations). The distal esophagus and the esophagogastric junction are mobilized with preservation of the vagus nerve and exposure of the crura and left hepatic lobe. At the surgeon's request, the anesthesiologist places an esophageal dilator orally and advances it through the gastroesophageal

junction. The proximal stomach is brought into the chest and a 2 cm fundoplication wrap is created with the fundus of the stomach. The dilator is removed and the fundoplication wrap placed below the diaphragm without tension. A nasogastric tube (NGT) and a chest drain are left in place postoperatively. Nissen fundoplication yields a high patient satisfaction rate (90–95%) when the procedure is performed by experienced surgeons [10, 11]. The transthoracic partial fundoplication (Belsey) is similar to the Nissen fundoplication, but the esophageal wrap extends only 240–270° and is thus a partial fundoplication. The Belsey fundoplication yields a reduction in GERD symptoms comparable to that of the Nissen and may cause fewer postoperative obstructive symptoms.

Chronic GERD can cause esophageal ulceration which leads to inflammation and may cause axial esophageal shortening and stricture formation. Medical therapy is inadequate for symptomatic stricture, though most can be internally dilated using any one of a number of dilating techniques. After dilation, surgical therapy aims to reduce reflux and prevent recurrence. The Collis gastroplasty, classically performed via a transthoracic approach, aims to lengthen the esophagus to facilitate a subsequent tension-free fundoplication. This procedure creates a tube of esophageal diameter from the lesser gastric curvature tissues via surgical stapling so that subsequent intra-abdominal fundoplication can be performed around the "neoesophagus." In the context of advanced GERD with esophageal shortening, Collis gastroplasty combined with either a Belsey [12] or Nissen fundoplication [13] can provide excellent relief of GERD symptoms in the majority of treated patients. Esophageal strictures that are not amenable to dilation may require esophagoplasty or esophagectomy.

PH can be repaired through a midline laparotomy, a laparoscopic approach, or via thoracotomy. Through a left thoracotomy incision, the esophagus can be easily isolated and encircled, the hernia sac opened, its contents reduced to the abdomen, and the hiatus narrowed. Esophageal lengthening and fundoplication procedures are also frequently performed as part of the same procedure. Both transthoracic and laparoscopic approaches to the repair of PH are associated with good results, though recurrence rates remain a concern for both procedures [14–16].

Esophageal Perforation and Rupture

Esophageal perforation typically occurs in the hospital and is often iatrogenic. Multiple etiologies of perforation exist including upper gastrointestinal endoscopy and the traumatic placement of esophageal dilators, nasogastric tubes, and misplaced endotracheal tubes. Perforation or disruption of the esophagus may also occur from external trauma, typically gunshot wounds or less commonly, from blunt trauma, and from a foreign body or chemical ingestion but may also follow misadventures in airway management, resulting from the use of a Combitube [17] or esophageal obturator airway [18]. Hospital mortality and 3-year survival in patients with esophageal perforation are 17.5% and 67%, respectively [19].

In contrast, esophageal rupture typically results from a sudden increase in intra-abdominal pressure with a relaxed LES and an obstructed esophageal orifice with vomiting, straining, weight lifting, childbirth, defecation, or blunt crush traumatic injuries to the abdomen and chest. Spontaneous rupture of the esophagus during vomiting is known as Boerhaave's syndrome. This rupture of the distal esophagus occurs under high pressure which forces gastric contents into the mediastinum and pleura [20].

Clinical presentation may be related to the mode of injury but is often nonspecific. Pain is the most common symptom [21], though fever, dyspnea, and crepitus may also be present. Mackler's triad, often associated with spontaneous esophageal rupture includes chest pain, vomiting, and subcutaneous emphysema. Soilage of the mediastinum elicits an inflammatory response that results in mediastinitis. Abdominal perforation may result in peritonitis. These patients may present with septic shock and are likely to deteriorate rapidly, particularly without aggressive resuscitation and definitive therapy.

Evaluation for esophageal perforation or rupture includes a plain film chest X-ray (CXR) which may reveal mediastinal or free peritoneal air, pleural effusion, pneumothorax, widened mediastinum, and subcutaneous emphysema [22]. Computerized tomography (CT) scan will also confirm the rupture as evidenced by esophageal edema and thickening, possible abscess formation, as well as air and/or fluid in the pleural space. A water-soluble esophagogram will help to confirm the location and extent of the tear by allowing visualization of the extravasation of contrast.

Treatment of esophageal rupture or perforation depends mainly on the extent and location of the injury and the disease state of the esophagus. Factors affecting patient outcome include the location, association with malignancy, sepsis, respiratory failure, and other comorbidities [23] as well as the interval between diagnosis and treatment [24, 25]. Perforation of the cervical esophagus may be treated solely by drainage; surgical repair is typically preferred for thoracic or abdominal esophageal perforations. In a stable patient without severe esophageal pathology, primary closure of a thoracic or abdominal esophageal perforation can be attempted. If the area of injury is diseased, an esophagectomy may be required. In one study, emergent esophagectomy for perforation was associated with a short-term survival equivalent to that of elective esophagectomy. However, survival at 1 year and 5 years was markedly dimin-

ished [26]. Early aggressive surgical treatment of Boerhaave's syndrome is favored; left untreated this condition is virtually always fatal [20]. Conservative non-operative therapies emphasizing aggressive drainage of fluid collections and appropriate antibiotic therapy are preferred by some clinicians for stable patients with contained esophageal leaks [24, 27] and may be associated with acceptably low morbidity and mortality [24, 27, 28]. Numerous case series have also demonstrated the efficacy of treating esophageal perforation and esophageal anastomotic leaks with self-expandable plastic and metallic stents [29–32]. Additional recently developed endoscopic modalities used with some success in managing esophageal perforation include endoscopic clipping and vacuum therapy [33].

Achalasia and Motility Disorders

Achalasia is a disease of impaired esophageal motility, most often affecting the distal esophagus. It affects approximately 1 in 100,000 persons per year, with an equal gender distribution [34]. The etiology of achalasia is unknown, but characteristic features include increased LES pressure, incomplete relaxation of the LES with swallowing, and loss of peristalsis which causes impaired esophageal emptying. Primary achalasia is due to a complete loss or relative absence of ganglion cells in the myenteric plexus. This causes an imbalance between excitatory and inhibitory neurons which results in impaired relaxation of the LES [35]. Other primary motor disorders of the esophagus include nutcracker esophagus and diffuse esophageal spasm. Secondary achalasia is most often caused by Chagas' disease, a systemic disease due to infection with Trypanosoma cruzi [36]. Other secondary motor disorders are associated with systemic disease processes such as scleroderma, diabetes, amyloidosis, Parkinson's disease, and neuromuscular diseases of skeletal muscle.

Achalasia progresses slowly, and thus when patients finally present for treatment, they are often at advanced stages of the disease. Symptoms of achalasia include dysphagia, first for solids and then liquids. As the esophagus dilates, reflux becomes a more frequent problem. Patients may describe chest pain due to esophageal spasm. Weight loss, symptoms of GERD, and history suggestive for aspiration such as pneumonia and chronic cough are also consistent with achalasia [37, 38].

Radiographic findings in advanced achalasia include absence of gastric bubble, esophageal dilation, and fluid filling [39]. Barium swallow reveals the esophageal air-fluid level and a characteristic bird's beak narrowing caused by the impaired relaxation of the LES [39] (see Fig. 38.4). Esophageal manometry is a sensitive diagnostic test for achalasia, and manifestations include elevated LES resting pressure and incomplete relaxation of the LES, aperistalsis

Fig. 38.4 This thoracic level barium swallow esophagogram illustrates a classic radiologic feature of achalasia – bird-beak appearance of the esophagus

of the esophageal body, and elevated lower esophageal baseline pressure [37]. At this time, achalasia cannot be cured. Treatment goals for achalasia include elimination of the esophageal outflow obstruction due to the tight LES, alleviating dysphagia and minimizing gastroesophageal reflux [37]. Medical treatments include calcium channel blockers and nitrates, but because of their adverse effects and unpredictable absorption in these patients, medical therapy is typically reserved for patients who are not candidates for surgical or endoscopic therapies. Botulinum toxin injection of the LES produces relaxation of this sphincter and can improve dysphagia temporarily [40], but relapse is common, and most patients required repeated therapy. Pneumatic dilatation of the LES is associated with a low risk of perforation [41]. While surgical myotomy with fundoplication produces a greater response than a single dilation [42], the strategy of serial dilation may be similarly efficacious [43].

Laparoscopic esophagomyotomy is typically performed with the patient in reverse Trendelenburg position and includes an anterior longitudinal myotomy of the distal esophagus, esophagogastric junction, and proximal stomach.

Thoracoscopic esophagomyotomy is performed through a thoracoscope via the left chest which allows for optimal visualization of the lower esophagus and cardioesophageal junction [44, 45]. The thoracic Heller and modified Heller myotomy procedures are performed via a left thoracotomy incision and differ in the extent of the myotomy incision and the inclusion of a fundoplication to minimize reflux. The Heller procedure utilizes a shorter myotomy incision extended only 1 cm or less onto the stomach. The modified Heller myotomy includes a 10 cm myotomy incision and a partial anterior gastric fundoplication to decrease the risk of reflux postoperatively [45].

Minimally invasive laparoscopic and thoracoscopic Heller and modified Heller myotomy procedures have been shown to be safe, effective, and durable treatments for achalasia [46–59]. Patient outcomes after minimally invasive myotomy surgery for achalasia generally favor the laparoscopic approaches, however. Multiple investigators have found that patients experience superior dysphagia relief and less postoperative reflux with the laparoscopic approach as compared to the thoracoscopic approach [46, 49, 53, 54]. This difference may result from the limitations in extending the myotomy incision into the stomach and creating a fundoplication wrap from the thoracoscopic approach.

Per-oral endoscopic myotomy (POEM) represents the newest therapy for achalasia. POEM is an entirely endoscopic procedure; a small mid-esophageal incision is made in the mucosa and a submucosal tract is created and tunneled to the gastric cardia. Electrocautery is then used to create a myotomy of the circular muscle fibers. POEM is a relatively new development, and although initial results suggest that this technique is safe, effective, and well tolerated [7, 60–64], randomized trials are needed.

Tracheoesophageal Fistula (TEF)

Acquired TEF or bronchoesophageal fistula in the adult patient is typically the result of malignancy, prolonged endotracheal intubation, esophageal surgery including esophagectomy, trauma, stent erosion, and infection [65–71]. Though less common, TEF of congenital origin has also been reported [72–74]. Rarely, the diagnosis of TEF may be made intraoperatively [75], in the perioperative period [72, 76] or in chronically intubated patients [69–71].

Treatment of TEF varies depending upon the etiology and location of the fistula and the nature and severity of associated symptoms and clinical sequelae. The mainstay of therapy for malignant TEF involves placement of self-expandable coated stents with the esophagus or trachea or both, whereas surgical therapy is rarely indicated and associated with high risk for morbidity and mortality [66]. Surgical therapy is preferred for most patients with nonmalignant TEF, and retrospective studies of clinical cohorts confirm a high rate of successful closures with low incidence of TEF recurrence [65, 77]. In critically ill patients dependent on mechanical ventilation, the use of esophageal stents to provide temporary closure of benign TEF has been demonstrated to be safe and effective for palliation [78].

Esophageal Diverticula

Esophageal diverticula are classified according to their anatomic location (cervical or thoracic) and pathophysiology (pseudo- or traction diverticula). Most diverticula are acquired and occur in an elderly patient population. Pulsion or pseudodiverticula are the most common form and consist of a localized outpouching which lacks a muscular covering; that is, the wall consists of only mucosa and submucosa herniating through the muscle layer. Most pseudodiverticula are of Zenker's variety, located in the hypopharynx. Epiphrenic diverticula are located within the thoracic esophagus, typically in the distal esophagus [79]. True or traction diverticula occur within the middle one third of the thoracic esophagus as a result of paraesophageal granulomatous mediastinal lymphadenitis usually due to tuberculosis or histoplasmosis and are characterized by full-thickness involvement of the esophageal wall. These diverticula are typically small and most are asymptomatic. Complications are uncommon but may include TEF formation.

Clinical presentation of Zenker's diverticulum usually includes dysphagia for solid food and regurgitation of undigested food substances. Patients may also complain of halitosis, gurgling associated with swallowing, and symptoms associated with aspiration such as nighttime cough, hoarseness of voice, bronchospasm, and chronic respiratory infection. Diagnostic confirmation is accomplished with barium contrast study which clearly demonstrates the diverticulum.

Surgical correction of Zenker's diverticulum is usually accomplished via a left cervical incision and includes a cricopharyngeal myotomy. While the myotomy may be sufficient therapy for small diverticula, larger sacs require diverticulectomy or diverticulopexy [79, 80]. Minimally invasive techniques used to treat Zenker's diverticulum have included endoscopic stapling diverticulostomy, fiberoptic endoscopic electrocautery, and laser coagulation techniques [79–82]. In general, minimally invasive treatments for Zenker's diverticulum have yielded satisfactory results in the majority of patients [82, 83], and most can be performed in an endoscopy unit with a brief general anesthetic or in an awake patient. A recent large systematic review of treatments for Zenker's diverticulum reported a failure rate for open and endoscopic approaches of 4.2% and 18.4%, respectively [84]. Mortality was very low in both groups, but open procedures were associated with a higher complication rate [84].

Thus, endoscopic techniques may be preferable for frail patients who are less likely to tolerate a general anesthetic.

Thoracic esophageal diverticula are usually epiphrenic, and most are found to be associated with an esophageal motor disorder such as achalasia. While many patients do not have symptoms specifically referable to the diverticulum, if present these may be difficult to distinguish from those of the associated motor disorder. Patients who are asymptomatic or present with mild symptoms are not surgical candidates. Presenting symptoms may include dysphagia, chest pain, regurgitation of ingested foods, and symptoms of aspiration. Patients with epiphrenic diverticula are advised to undergo both barium swallow examination (see Fig. 38.5 for barium esophagogram of a mid-esophageal diverticulum) and esophageal manometry to delineate any associated pathology such as motility disorder, malignancy, or stricture. Patients with incapacitating symptom profiles are referred for surgery.

Surgical goals include resection of the diverticulum, typically with a myotomy to treat the accompanying motor disorder, and may be performed with or without an anti-reflux procedure. The classical surgical approach has been through a left thoracotomy incision, through which the diverticulum is dissected and excised; a myotomy and a fundoplication may also be performed. Results of surgical therapy are favorable, completely eliminating symptoms in 74% of patients [85]. Thoracoscopic and laparoscopic approaches, as well as combined approaches, have been reported [86–88] and appear to be feasible. The laparoscopic approach has been associated with a lower postoperative morbidity rate relative to that of the thoracotomy [89]. Definitive conclusions regarding the ideal surgical approach(es) to epiphrenic diverticula await larger studies, which are in turn limited by the relative rarity of these lesions.

Malignant Disease of the Esophagus and Esophagectomy

Esophageal Cancer

Malignant esophageal tumors can be classified on the basis of histologic types – squamous cell carcinoma and adenocarcinoma – which differ with respect to affected populations, incidence, etiology, and risk factors. While squamous cell carcinoma still accounts for the vast majority of esophageal cancers worldwide, the incidence of adenocarcinoma has risen sharply throughout the Western world, now accounting for nearly half of esophageal cancers in many countries [90–92]. Potential etiologic and predisposing factors identified through epidemiologic study include tobacco use and excessive alcohol ingestion, gastroesophageal reflux, obesity, achalasia, and low socioeconomic status [90, 92].

Clinical presentation of patients with esophageal cancer is variable; patients may present with symptoms of dysphagia, odynophagia, and progressive weight loss. Patient evaluation should include a thorough history and physical examination with attention to local tumor effects, possible sites of metastasis, and general health. Clinical investigations include the barium contrast swallow study to define esophageal anatomy and esophagogastroscopy to permit biopsy and definitive identification of tumor type. Both CT scans and magnetic resonance imaging (MRI) are used clinically for noninvasive staging of esophageal cancer. Endoscopic ultrasound (EUS) has been used for imaging of local/regional esophageal disease and may be considered complementary to CT scanning (see Fig. 38.6 for CT image of thickened esophagus in a patient with esophageal cancer). Positron emission tomography (PET) is being used with greater frequency for the purpose of staging esophageal cancer and for assessing the response to induction chemotherapy.

In an effort to avoid the morbidity, mortality, and expense associated with esophagectomy, many centers are employing relatively new approaches to esophageal preservation in

Fig. 38.6 A CT scan demonstrating thickened esophagus in a patient with esophageal cancer and dysphagia

patients with malignant and premalignant esophageal lesions. The close surveillance of many patients with premalignant disease of the esophagus has led to the early identification of many cases of high-grade dysplasia and superficial adenocarcinoma. Advances in the use of minimally invasive endoscopic techniques permit the staging of superficial esophageal cancers by endoscopic biopsy [93, 94] and, where appropriate, endoscopic resection of adenocarcinoma limited to the esophageal mucosa [95, 96].

Unfortunately, patients often present with advanced local/regional and metastatic disease. The failure of surgery to cure most advanced local and regional disease and the early systemic dissemination of esophageal cancers has led to significant interest in improving chemotherapeutic regimens and developing more focused therapies. Chemotherapeutic goals are to reduce tumor burden prior to surgical resection and to reduce tumor spread and micrometastasis. Chemotherapies are used in the context of esophageal cancer both for palliation of locally advanced and metastatic disease and increasingly as an adjunct to surgical resection. 5-Fluorouracil and cisplatin are widely used in combination preoperative therapy for both adenocarcinoma and squamous cell carcinoma of the esophagus [97, 98]. Induction chemotherapy with radiation before esophagectomy is recommended for patients undergoing esophagectomy for both locally advanced squamous cell and adenocarcinoma [99].

Esophagectomy

Esophagectomy is indicated for the resection of esophageal cancer without local invasion or metastasis [100], curative resection of high-grade dysplasia [101], and severe nonmalignant disorders including esophageal injury, non-dilatable stricture, severe recurrent GERD, and achalasia [102, 103]. Esophagectomy surgery can be performed via a transhiatal approach by laparotomy, a two-incision surgery utilizing both laparotomy and right thoracotomy (Ivor Lewis), a three-incision approach (McKewin) which also requires a cervical incision for anastomosis, a left thoracoabdominal approach, and minimally invasive approaches utilizing laparoscopy and/or thoracoscopy with or without robotic assistance (see Table 38.1). Consideration for the transhiatal, transthoracic, minimally invasive esophagectomy and robotic esophagectomy will be discussed below.

Transhiatal esophagectomy (THE) is performed for tumors throughout the esophagus but is often preferred for lower tumors. The primary advantage of this resection is that it avoids a thoracotomy and the possibility of an intrathoracic anastomotic leak. This procedure is accomplished via a large upper abdominal incision which is used to mobilize the stomach and through which transhiatal esophageal dissection is carried out and a cervical incision through which the conduit is introduced and the anastomosis is made. The transhiatal approach to esophagectomy requires the manual dissection of the esophagus from the mediastinum blindly via the abdominal hiatus.

There continues to be considerable debate regarding the relative risk of THE relative to the transthoracic esophagectomy (TTE), from both surgical and oncologic standpoints. While the morbidity and mortality associated with THE have declined over the past several decades [104], the advantage of THE over TTE remains controversial with both early morbidity and mortality advantages demonstrated [105, 106] and refuted [107]. In a recent Society of Thoracic Surgeons Database study, combined perioperative morbidity and mortality were similar between open transhiatal and open Ivor Lewis esophagectomy [108]. Similar results were reported in a NSQIP study; there was no significant difference between the two approaches with regard to mortality or morbidity [109]. Similarly, a recent meta-analysis reported no difference in 5-year survival between the two surgical approaches [110]. It should be understood that the finding of equivalence with regard to oncologic, and perhaps other outcomes, may not necessarily be indicative of equivalent efficacy, as the transthoracic groups may have more advanced cancer [110]. Overall, transhiatal esophagectomy is associated with a higher rate of anastomotic leak, stricture, and recurrent laryngeal nerve injury [110, 111], whereas transthoracic esophagectomy is associated with a longer length of stay and higher rates of respiratory complications and wound infections [110]. It should also be noted that various transthoracic approaches to esophagectomy may not be equivalent with regard to outcome risk. The open three-hole (or McKeown) esophagectomy may represent a higher-risk approach than the Ivor Lewis esophagectomy given the recent finding that this approach is associated

with an increased risk of morbidity and mortality in a risk adjustment model (OR 1.59; 1.20–2.10) [108].

The transthoracic approach to esophagectomy is performed for malignant, premalignant, or nonmalignant disease of the esophagus and employs an abdominal incision for mobilization of the stomach and formation of a gastric tube or other esophageal conduit and a right thoracotomy through which the diseased esophageal portion is resected and the anastomosis is made. The transthoracic esophagectomy is often preferred when the resection extends to other mediastinal structures, mediastinal fibrosis is known or suspected, tumor may involve the airway or vascular structures, or an intrathoracic anastomosis is required.

The term "minimally invasive esophagectomy" (MIE) encompasses a variety of surgical approaches to esophagectomy that attempt to minimize the degree of surgical trespass in one or more body cavities. True minimally invasive esophagectomy using laparoscopy and thoracoscopy is performed in a limited number of centers. Analogous to open procedures, several variants are possible, including the minimally invasive equivalents of the Ivor Lewis, three-hole, and transhiatal esophagectomies.

Avoiding large thoracotomy and/or laparotomy incisions in the context of MIE has significant potential to reduce major morbidity after esophagectomy, particularly pulmonary morbidity. Feasibility and safety of MIE has been widely demonstrated [112–115], but, although numerous randomized trials are planned, very little objective data comparing these approaches are currently available. A small randomized trial comparing MIE to open esophagectomy for patients with esophageal cancer demonstrated significant reduction in pulmonary infections in the MIE group [116]. Follow-up at 1 year revealed better quality of life and pain in the MIE group at 1 year [117] and equivalent disease-free survival at 3 years [118]. Most retrospective, non-randomized studies and meta-analyses also report equivalent or better clinical outcomes [114, 119–122] with similar or improved oncologic outcomes [123].

Robotic-assisted minimally invasive esophagectomy procedures utilize the proprietary da Vinci surgical system to aid in the minimally invasive approach to the laparoscopic and thoracoscopic components of esophagectomy surgery. This system provides a number of theoretical and practical surgical advantages – a three-dimensional magnified operating field view, normal hand-eye coordination, tremor filtering, and motion scaling. Although robotic esophagectomy surgery is a nascent and evolving field, several reports of clinical series have demonstrated the feasibility and relative safety of this approach [124, 125]. A randomized trial comparing robotic assisted to open transthoracic esophagectomy is currently underway [126] and should further delineate benefits with regard to short- and long-term outcomes, if any.

Esophageal Conduits

Although a variety of conduits have been used after esophageal resection, the stomach is usually preferred because of its excellent blood supply, because it can be readily mobilized to reach the thorax or neck, and because only one anastomosis is required (see Fig. 38.7a and b). However, the stomach may not be a suitable conduit in the case of prior gastric surgery or tumor involvement. In such cases, an alternative conduit must be used. The pedicled colonic interposition utilizes a segment of colon with an attached vascular pedicle as an esophageal replacement conduit. While the pedicled colon graft has adequate mobility, its use is associated with numerous complications including conduit redundancy and symp-

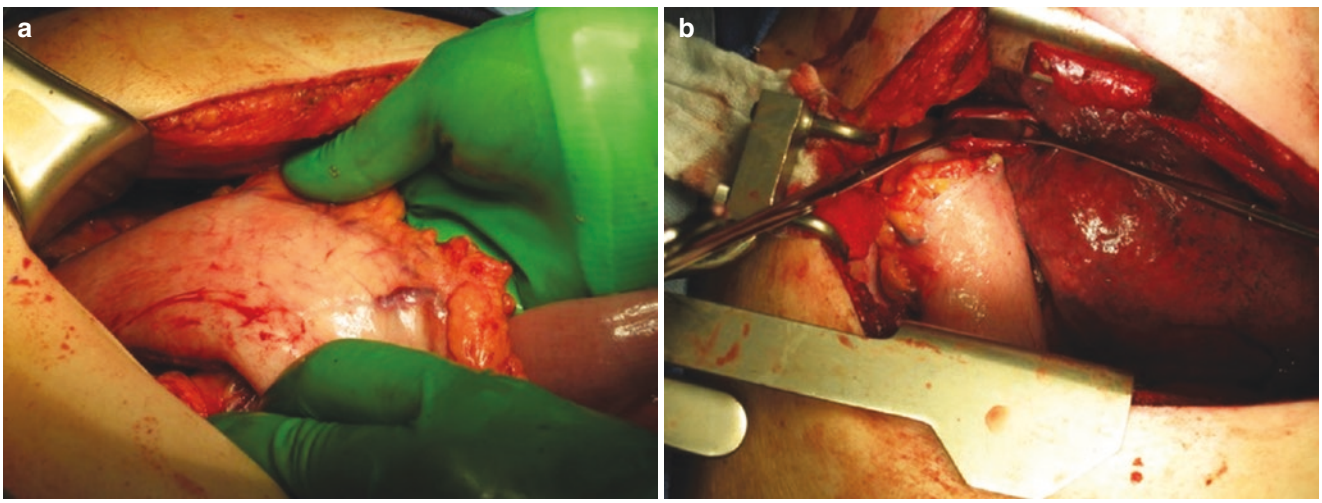

Fig. 38.7 (**a**) Gastric conduit prior to anastomosis. (**b**) Gastric conduit and proximal esophagus via thoracotomy prior to anastomosis during Ivor Lewis esophagectomy

toms related to inadequate food transit [127–131] which may impact quality of life [128] and long-term outcomes [132]. Additionally, atherosclerotic disease may affect vascular supply to the colon which may in turn increase the risk of colonic ischemia and necrosis, a major cause of morbidity and mortality [133–135].

Jejunum has a number of theoretical advantages over that of colon for use as an esophageal replacement. First, its diameter more closely approximates that of the esophagus. Secondly, it is generally disease-free. Additionally its intrinsic peristaltic activity may improve food transit and reduce symptoms postoperatively [136–140]. Use of the jejunum for interposition has previously been limited by the vascular anatomy of the jejunum. The jejunal mesentery lacks the collateral arcades of the colon which permit them to reach interposition sites in the thorax and neck. Ischemia of the interposition graft is the likely cause of jejunal loop gangrene which plagued early attempts and led to an interest in vascular augmentation of the interposition graft, now known as "supercharging," or vascular enhancement.

Recent advances in microvascular surgery have enabled specialized centers to expand the indications for jejunal interposition beyond short-segment esophageal replacement. Esophagectomy with "supercharging" jejunal interposition graft is undertaken as a one-stage procedure which includes esophageal resection, construction of the interposition graft with esophageal and jejunal reconstruction. The superior jejunal vascular arcade is "supercharged" by reimplantation into cervical or internal mammary arteries. The inferior arcade retains its native supply from the superior mesenteric artery. Clinical series have demonstrated the feasibility and relative safety of this approach [141–143]. Use of the supercharging technique for construction of jejunal interposition grafts for esophageal reconstruction led to a 92% success rate for discharge with an intact flap, and 95% of patients were discharged on a regular diet and without reflux symptoms [142, 143]. A recent study comparing conduit function in patients who previously received either supercharged pedicled jejunal interposition grafts or conventional gastric revealed similar levels of conduit function with regard to reflux, dumping, dysphagia, stricture, and conduit emptying [144]. Despite these successes, this technique remains the purview of highly specialized centers with multidisciplinary teams and is considered only in the absence of a suitable gastric conduit.

Anesthetic Management of Esophageal Surgery Patients

Preoperative Evaluation and Preparation

A thorough history and physical examination should be performed prior to anesthetizing a patient for esophageal surgery. Comorbid conditions should be evaluated and optimized prior to surgery. Preanesthetic assessment for thoracic surgery is discussed in Chap. 2. Particular attention should be given to signs and symptoms of esophageal obstruction, GERD, and silent aspiration. Symptoms of obstruction, particularly dysphagia and odynophagia, may lead to reduced oral intake and malnutrition which can lead to increased morbidity and mortality [145, 146]. Symptoms of severe GERD with aspiration may include water brash (hypersalivation in response to reflux), coughing when supine, globus sensation (feeling of lump in throat), laryngitis, and asthma-type symptoms.

The presence of significant cardiovascular disease has important implications for patients undergoing major surgical procedures involving the esophagus. Patients may be evaluated for cardiovascular risk with attention to the ACC/AHA guidelines for perioperative cardiovascular evaluation [147, 148]. The risk of cardiovascular complications during major surgical procedures of the esophagus may be increased by a number of factors inherent to surgery and anesthesia care, including the degree of planned physiologic trespass, hypoxemia, hemorrhage, dysrhythmias, and pain. One-lung ventilation (OLV) is often required for surgery of the esophagus. Oxygenation, ventilation, and weaning from mechanical ventilation may be more difficult in the patient with pulmonary disease. The minimum preoperative evaluation of the cardiopulmonary system should include a 12-lead electrocardiogram (ECG) and CXR. A preoperative ECG serves as a screening test for myocardial ischemia and arrhythmias and provides a baseline for comparison in the event of perioperative cardiac complications. Preoperative CXR may reveal evidence of aspiration as well as coexisting pulmonary and cardiac disease. Patients with a history of morbid obesity or chronic lung disease should also undergo preoperative pulmonary function testing if the procedure involves a thoracotomy approach.

Patients with severe GERD or those otherwise at risk for aspiration pneumonitis may benefit from prophylactic medication to increase gastric pH and decrease gastric volume. Though definitive evidence of risk reduction is lacking, appropriate pharmacologic prophylaxis with H_2 receptor antagonists or proton pump inhibitors is known to reduce gastric volume and acidity [149–154] and is thus likely to reduce the incidence and severity of pneumonitis should aspiration occur.

Patients may present for esophagectomy surgery after having received neoadjuvant chemotherapy and/or radiotherapy, either of which may improve survival compared to surgical therapy alone [97, 155–157]. The chemotherapeutic agents used to treat esophageal cancer cause bone marrow suppression, and patients often present with some degree of anemia and thrombocytopenia. The need for optimizing patient status prior to major surgery should be balanced with

the risk of delaying the resection of malignant tumors. Occasionally, severe thrombocytopenia may preclude the preoperative placement of an epidural catheter in which case alternative plans for analgesia should be made.

Intraoperative Monitoring

In general, intraoperative monitoring for esophageal surgery cases should be commensurate with the degree of physiological trespass inherent in the planned procedure and the nature and severity of patient comorbidity (see Chap. 20 for discussion of intraoperative monitoring). Routine monitoring should include pulse oximetry, noninvasive blood pressure monitoring, and electrocardiography. Since many patients presenting for esophageal surgery have comorbid disease of the cardiovascular and respiratory systems, consideration should be given to invasive monitors where appropriate. With the exception of patients with advanced cardiovascular or pulmonary disease, routine intraoperative monitors will generally suffice for those patients presenting for endoscopic and minimally invasive procedures limited to the abdominal cavity. Transthoracic approaches to the esophagus generally mandate a more aggressive approach to monitoring. An indwelling arterial catheter for continuous measurement of systemic arterial blood pressure is the standard of care for these procedures. Surgical manipulation of thoracic and mediastinal structures can profoundly affect determinants of cardiac performance including venous return and cardiac filling and may contribute to the development of dysrhythmias, all of which can compromise cardiac output and hemodynamic status. In addition, many of these procedures require lung isolation and OLV, a ventilation strategy which substantially limits arterial oxygenation and may increase the risk of lung injury. Surgical dissection can lead to unexpected bleeding, occasionally massive in nature. Point of care testing of arterial blood samples can aid in the assessment and maintenance of adequate arterial oxygenation, acid base status, as well as hemoglobin and electrolyte concentrations.

In the patient with normal cardiovascular reserve, central venous access is not generally necessary and does not provide useful information for volume management. Nonetheless, central access may be required in patients with very limited peripheral venous access, especially obese patients in whom it may be difficult to re-establish lost venous access intraoperatively, patients requiring emergency surgery for esophageal trauma or perforation as septic complications can rapidly ensue, and those patients who are likely to require vasopressor or inotropic support. Patients undergoing esophageal surgery should also undergo bladder catheterization for decompression and for the monitoring of urine output. Temperature monitoring is easily accomplished via a probe in the oropharynx, axilla, or bladder catheter. Euthermia can be achieved by use of commercially available forced warm air heating blankets and fluid warmers.

Pain Control

Pain control after esophageal surgery is dictated largely by the surgical approach to the esophagus (see Chaps. 59–61 for detailed discussion of pain management). Most patients undergoing endoscopic surgery of the esophagus have little pain postoperatively and thus do not require an aggressive plan for analgesia. Similarly a laparoscopic approach is generally not associated with high analgesic requirement postoperatively. However, the thoracotomy incision utilized in most transthoracic esophageal surgeries, is one of the most painful surgical incisions in common use. As such, anesthetic techniques for postoperative pain control play an extremely important role in optimizing outcomes after transthoracic esophageal procedures. Although a variety of pain control approaches have been utilized, most centers favor the use of thoracic epidural analgesia (TEA) for its excellent analgesia [158, 159], favorable safety profile, cost savings [160, 161], its potential role in mitigating the perioperative inflammatory response [162, 163], and improving outcomes after transthoracic esophageal surgery [161, 163–168] and as a component of multimodal strategies to expedite patient mobilization and recovery after esophagectomy [169–176]. In comparison to parenteral opioid pain therapy alone, TEA provides superior analgesia after esophagectomy [158, 159, 162] and is considered by most anesthesiologists and surgeons to represent the "gold standard" with regard to postoperative pain control after transthoracic esophagectomy. However, for technical and safety reasons, not all patients are suitable candidates for the placement of thoracic epidural catheters. For patients in whom TEA is not possible but epidural analgesia per se is not contraindicated, lumbar epidural analgesia (LEA) may represent a compromise approach for analgesia after thoracoabdominal esophagectomy though pain control postoperatively is inferior to that obtained by TEA [177].

A variety of non-neuraxial techniques have been studied and recommended for post-thoracotomy pain control; the most promising of these include intrapleural, intercostal, and paravertebral approaches. Intercostal nerve catheters in combination with patient-controlled analgesia (PCA) have been compared to TEA with mixed results [178, 179]. Intrapleural and thoracotomy wound catheters have also been utilized, though rigorous comparison to standard therapies are lacking [180, 181]. Paravertebral blockade has shown promise as an alternative therapy [182] with analgesic efficacy for thoracotomy comparable to that of TEA by randomized trial [183] and meta-analysis [184–186] and with a favorable side effect profile [184] and has been advo-

cated as a superior modality by several authors [187, 188]. A recent Cochrane review comparing PVB and TEA for thoracotomy confirmed comparable analgesic efficacy for PVB with reduced risks of minor complications. However, there were no differences between the two modalities with regard to mortality, length of stay, or major complications [185]. An obvious limitation of PVB for analgesia for open thoracoabdominal esophagectomy is the wide range of spinal/dermatomal levels to be blocked in order to provide adequate analgesia for both a midline laparotomy and a high posterolateral thoracotomy. These challenges have limited enthusiasm for PVB in open thoracoabdominal esophagectomy, though reasonable efficacy has been demonstrated for a combined approach utilizing intravenous sufentanil and bilateral PVB in minimally invasive esophagectomy [189]. Subcostal transversus abdominis plane (TAP) block combined with PVB [190] and TAP block [191] alone have shown some efficacy in minimally invasive esophagectomy and hybrid Ivor Lewis esophagectomy, respectively, and warrant further study. Whether paravertebral analgesia will replace TEA for post-thoracotomy pain will likely depend on both the ability to adapt this technique to the specific analgesic challenges associated with esophagectomy and on the identification of outcome advantages that have thus far been ascribed only to TEA.

Specific epidural management strategies should ideally consider the dermatomal range of incision(s), the impact of incisional pain on respiratory function, the likelihood and impact of respiratory depression, and the intraoperative impact of an epidural-induced sympathectomy on hemodynamic status. Since the thoracoabdominal esophagectomy requires both thoracotomy and laparotomy incisions, any plan for postoperative pain control should address this fact. A variety of management strategies have been reported, but most centers which perform transthoracic and thoracoabdominal esophageal surgeries utilize a multimodal approach to pain management including preoperative placement of a thoracic epidural catheter unless contraindicated, intra- or postoperative bolus, and infusion of a dilute local anesthetic such as ropivacaine or bupivacaine along with fentanyl or hydromorphone. A dual epidural catheter technique has also been reported and may improve analgesia for Ivor Lewis esophagectomy [192], though this is likely to further increase the complexity of management. An epidural bolus of preservative-free morphine may provide a wider neuraxial spread and may provide synergism with the infused local anesthetics but requires postoperative respiratory monitoring because of the possibility of delayed respiratory depression. Whether to bolus or infuse epidural local anesthetics pre- or intraoperatively has been a subject of debate among anesthesiologists. Arguments that a preemptive initiation of analgesia might provide better acute and chronic pain control have been based largely on theoretical considerations. Results thus far are inconclusive but suggest that preoperative dosing of epidural catheters may produce better acute pain control [193–195]. However, while epidural analgesia may reduce the incidence of chronic post-thoracotomy pain [196], preemptive dosing does not improve chronic post-thoracotomy pain [194, 196].

Induction and Airway Management

Induction of general anesthesia and airway management in patients undergoing esophageal surgery is dictated largely by patient factors including cardiopulmonary status, hemodynamic and nutritional status at the time of induction, mediastinal mass effect if any, perceived risk of aspiration pneumonitis, and procedural factors including anticipated length of and nature of the procedure (i.e., if OLV is required for an intrathoracic procedure). Patients presenting for emergency procedures of the esophagus and stomach may lack the desired preoperative evaluation of cardiopulmonary status and can present with unstable hemodynamic or pulmonary status from a variety of factors including underlying cardiopulmonary disease, aspiration, sepsis, acute respiratory distress syndrome (ARDS), or hemorrhage. Most practitioners favor intravenous induction agents such as propofol, thiopental, etomidate, or ketamine in conjunction with a rapidly acting neuromuscular blocking agent such as succinylcholine or rocuronium to facilitate smooth induction of anesthesia and rapid tracheal intubation.

Patients presenting for elective esophageal procedures will be stable at induction, but complications arising from the presence of a mediastinal mass may accompany the induction of anesthesia, positive-pressure ventilation, and muscle relaxation. Tracheobronchial compression or obstruction and cardiovascular collapse associated with anesthetic induction in patients with mediastinal masses has been well described and is discussed in Chap. 14. Airway compromise has also been reported spontaneously or during the conduct of anesthesia in patients with posterior [197–201] and superior [202–204] mediastinal masses. Posterior mediastinal masses, including those of esophageal origin [197–199], may impinge on the airway and cause obstruction. Patients with achalasia are at particular risk as the dilated esophagus may cause respiratory compromise by direct compression of the upper airway [205], tracheobronchial tree [206–208], or lung parenchyma [209].

The trachea is most easily compressed posteriorly because of the lack of cartilaginous support, and thus, posterior compression can result in near complete expiratory obstruction [201]. The identification of patients with mediastinal masses who are at risk for cardiopulmonary complications is imprecise, but specific factors associated with increased risk have been reported [210] and may aid in management.

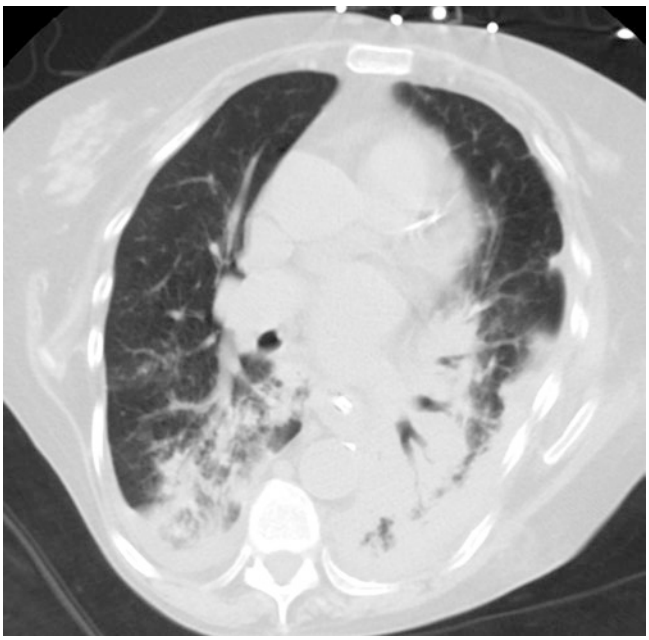

Fig. 38.8 CT scan of the thorax which demonstrates multifocal bibasilar consolidations consistent with aspiration pneumonitis

Anesthetic management of patients for esophageal surgery presents an additional challenge with regard to the perceived risk of aspiration. Patients in need of esophageal surgery are widely considered to be at elevated risk of aspiration and its sequelae [211–214] (Fig. 38.8), and the use of rapid sequence induction techniques is widely used and advocated [212, 213, 215]. A retrospective analysis of perioperative aspiration at a university hospital demonstrated that, among a variety of surgical service lines, those patients undergoing thoracic esophageal surgery exhibited the highest incidence of pulmonary aspiration [216].

Patients with severe gastroesophageal pathology, particularly those with obstructive disease, dysmotility syndromes, paraesophageal hernias, and esophageal diverticula, may represent high-risk subgroups, but clear risk stratification is lacking. Achalasia in particular has been associated with spontaneous aspiration pneumonitis [217, 218], and these patients may benefit from longer periods of NPO status. Practice guidelines for preoperative fasting have been published [219], and effects of fasting regimens have been reviewed [220, 221] but apply to healthy patients and elective surgical procedures. Optimal periods of NPO status in patients with severe gastroesophageal pathology are not known.

Rapid sequence induction and intubation has been widely advocated in patients thought to be at elevated risk of regurgitation and aspiration. This technique has classically referred to the rapid intravenous administration of induction agent and muscle relaxant, accompanied by the application of cricoid pressure (Sellick maneuver) and immediate laryngoscopy and tracheal intubation without intervening positive-pressure ventilation. The rationale underlying this approach is (1) that the cricoid cartilage is positioned anterior to the esophagus, (2) that downward pressure on the cricoid cartilage on a patient in the supine position would be transmitted to the esophagus occluding the esophageal lumen by compressing it against the adjacent vertebral body, and (3) that this compression would result in a clinically significant effect on passive regurgitation and thus aspiration in the anesthetized patient. Arguably, rapid sequence induction with cricoid pressure has represented the standard of care for patients at risk for pulmonary aspiration in many centers. There is currently, however, considerable controversy regarding the efficacy and safety of this maneuver [222–225]; this topic has been recently and extensively reviewed [225]. There is also an awareness that the assumptions underlying the use of cricoid pressure and the efficacy of cricoid pressure in preventing regurgitation and aspiration remain unproven [226]. A recent randomized pilot trial compared cricoid pressure versus no cricoid pressure in patients at risk for microaspiration. Despite the use of sensitive biomarkers for microaspiration, no statistically significant differences were seen between the two groups [227].

Pressure applied to the cricoid cartilage may increase the lateral displacement of the esophagus [228] without reliably compressing it [229]. Cricoid pressure does appear to compress the hypopharynx, decreasing its diameter by 35% [230] and may obliterate the esophageal entrance [231]. The appropriate amount of force needed to prevent aspiration has also been a subject of considerable debate. However, a recent clinical study has quantified the force needed to occlude the esophageal entrance. Not surprisingly, a considerable amount of inter-patient variability was seen. The median cricoid force needed to completely occlude the esophageal entrance in 50% of men and women was 30.8 and 18.7 N, respectively [232]. Since excessive force may complicate airway management (see below) and insufficient force may fail to accomplish the desired clinical effect, modalities which enable the practitioner to monitor the degree of occlusion would seem desirable. Real-time ultrasound of the esophagus shows some early promise in this regard and has been advocated to confirm adequate esophageal compression and occlusion during RSI with cricoid pressure [233], but its utility in this regard remains unproven.

It should be understood by the practitioner that the application of cricoid pressure has the potential to displace and compress the airway [228], potentially increasing the difficulty associated with airway management [224, 234–237], and is contraindicated in the context of known or suspected cricoid or tracheal injury and unstable cervical spine and during active vomiting. Additionally, cricoid pressure has been associated with fracture of the cartilage [238] and a variety of other risks [234, 235, 239]. It is also worth noting

that cricoid pressure is associated with a decrease in lower esophageal sphincter pressure and esophageal barrier pressure [240] which could increase the risk of passive regurgitation in the anesthetized patient. This is consistent with the well-described phenomenon of regurgitation and aspiration during the application of cricoid pressure [211, 241, 242]. Since our current understanding of aspiration and the protective effects of cricoid pressure, if any, are incomplete, the decision to apply cricoid pressure in the context of a rapid sequence induction should be individualized and based on an understanding of the relevant anatomic and physiologic principles and the specific clinical context.

Though there is little definitive evidence with regard to practical aspects of aspiration risk reduction to guide the practitioner, we suggest the following approach. If there is any anatomic or historical evidence to suggest a difficult intubation, serious consideration should be given to intubation in the awake patient, particularly for patients at highest risk of aspiration – those presenting with achalasia, high-grade esophageal obstruction, and those requiring emergency procedures. The awake placement of a large-bore gastric tube and awake intubation have been proposed for patients with severe achalasia [243]. For those patients with airways judged to be easily manageable, the use of a rapid sequence induction is prudent. Minimizing the time between loss of consciousness, muscle relaxation, and tracheal intubation with a lubricated cuffed tube may reduce risk. It is also worth considering the possible effect of patient position on aspiration risk. We routinely utilize the head-up, or reverse Trendelenburg position, as this is likely to reduce the passive reflux of gastric contents and aspiration risk [244–246]. Additionally, this position improves pulmonary mechanics, particularly in the obese patient, and has been previously advocated [211, 244]. It should be noted that, while a head-up position may reduce passive reflux, there is also a rationale for a head down tilt – placing the mouth in a more inferior position than that of the laryngeal inlet and trachea [224, 247], particularly in the patient at risk for vomiting during induction.

The suggestion that aspiration of gastric contents may be a contributing factor in the development of pulmonary complications in thoracic surgery patients is derived, in part, from evidence of intraoperative tracheal aspiration in intubated patients undergoing thoracotomy [248]. In this study, premedication with ranitidine decreased the incidence of measured gastric acid regurgitation, but effects on reduction of tracheal acid aspiration were not statistically significant. Clearly, acid aspiration in patients intubated with double-lumen endotracheal tubes is possible [248] though dye studies suggest that gel lubrication of the tube cuff may reduce leakage and aspiration [249, 250]. Other strategies to minimize the risk of tracheal aspiration in patients undergoing esophageal surgery include the placement of a large-bore gastric tube for highest-risk patients and preoperative suctioning of an in situ gastric tube [243] and of the gastric tube and oropharynx prior to tracheal extubation. A low level of continuous suctioning of the nasogastric tube after major esophageal surgery may also help reduce the incidence of subacute and chronic aspiration postoperatively [251].

Intraoperative Management

After the induction of general anesthesia and tracheal intubation, the maintenance of anesthesia can be accomplished by a variety of approaches, though many authors prefer a balanced anesthetic technique with the use of a volatile inhalational agent such as isoflurane, sevoflurane, or desflurane, a nondepolarizing paralytic agent, intravenous opioids, and opioids and/or local anesthetic agents via an epidural catheter if present [170, 172]. As volatile anesthetic agents are known to precondition the myocardium against subsequent ischemic insult, there is a theoretical advantage in the use of these agents. Given the overlap of risk factors for coronary disease and esophageal disease, patients presenting with surgical esophageal disease may also be at risk for myocardial ischemia and thus may benefit from such protection, though clinical evidence of benefit in this population is lacking. A total intravenous anesthetic with propofol infusion is also a viable option, though this technique lacks the theoretical advantage of myocardial preconditioning and may be significantly more expensive, particularly for longer surgeries.

Anesthetics have been shown to modulate the systemic and pulmonary inflammatory responses associated with major surgeries, mechanical ventilation, and OLV in particular. Since the inflammatory response associated with major esophageal surgeries can be severe [252] and since both systemic [253] and pulmonary inflammation [254] predict postoperative pulmonary complications, there has been considerable research interest in defining these modulatory effects. However, studies comparing primarily volatile anesthetic-based regimens to those based on propofol have produced somewhat discordant results. In a porcine model, sevoflurane elicited an immune lymphocytic response when compared with propofol and appeared to trigger apoptosis in lung tissue [255], though sevoflurane more effectively attenuates the pulmonary inflammatory response and oxygen impairment associated with ARDS [256] and ALI [257] in two different animal models. In randomized trials in patients undergoing thoracic surgery, however, anti-inflammatory effects have been attributed to both propofol and volatile agents. In a small trial of propofol vs sevoflurane in esophagectomy patients, propofol more effectively decreased the intrapulmonary concentration of inflammatory cytokines [258]. In contrast, sevoflurane dramatically attenuated the systemic [259, 260] and pulmonary [261] inflammatory

responses to major thoracic surgery. Thus far, however, neither intravenous- nor volatile-based anesthetic strategies have been demonstrated to be unambiguously superior with regard to meaningful clinical outcomes and recent large clinical trial comparing propofol with desflurane demonstrated no differences in major morbidity between the two anesthetic regimens [262].

Lung Isolation and One-Lung Ventilation

Surgical approaches to the thoracic esophagus have been greatly facilitated by the development of techniques for lung isolation and OLV (see Chap. 6 for discussion of OLV and Chaps. 16–18 for details regarding lung isolation). In most major centers, lung isolation and one-lung ventilation are considered the standard of care for transthoracic approaches to the esophagus and are essential for thoracoscopic esophageal surgery. The most commonly utilized modalities are double-lumen endotracheal tubes (DLT) and endobronchial blockers. The left-sided DLT is most commonly employed for transthoracic esophageal surgery; it has the advantage of being easily placed by experienced practitioners, providing excellent lung isolation and operating conditions while providing access to both lungs for bronchoscopy, suctioning, ventilation, and oxygen insufflation. Additionally, because the left mainstem bronchus is longer than that of the right, positioning is more easily accomplished without compromising left upper lobe ventilation.

However, the use of a DLT may be relatively or absolutely contraindicated in some patients or may be difficult to achieve, necessitating another approach. First, endotracheal intubation with a DLT may require more time than with a single-lumen tube [263]. This may increase the risk of aspiration in the high-risk patient, especially in the context of a difficult airway. The use of adjunctive airway devices such as the endotracheal tube introducer may be more difficult with a DLT [264], though difficult endotracheal intubation with a DLT can be aided by the use of adjunctive devices such as the GlideScope video laryngoscope [265, 266], the McGrath video laryngoscope [267], the Airway Scope [268], and the Airtraq laryngoscope [269, 270]. Videolaryngoscopy improves visualization of the larynx during DLT intubation and has been recommended [271].

Some patients may present with anatomic abnormalities of the airway such as subglottic stenosis or extrinsic compression of the trachea or either mainstem bronchus. Passage of a DLT may be difficult or even dangerous in this context. If it is likely that the patient will require postoperative mechanical ventilation or if extubation is delayed for another reason, exchanging the DLT for a single-lumen tube at the end of surgery places the patient at additional risk for loss of airway and aspiration. The above limitations of DLT have prompted interest in the use of endobronchial blockers for esophageal surgeries. A detailed discussion of endobronchial blockers and their applications can be found in Chaps. 16–18. Endobronchial blockers are placed through (coaxially) or occasionally alongside single-lumen endotracheal tubes (SLT) and can be used in patients with tracheostomies or nasal airway access. The use of endobronchial blockers is well described for thoracic procedures, including esophageal surgery [272], and is preferred by some authors [264] because of the perceived reduction in aspiration risk with the use of the SLT and rapid sequence induction, the improved ease of managing difficult airways, and lung collapse scores equivalent to [273] or better [274] than that of DLTs.

Fluid Management

Fluid requirements vary widely among patients and procedures and ultimately represent the sum of preoperative deficits, maintenance requirements, and ongoing losses (see Chap. 21 for a discussion of fluid management in thoracic surgery). Preoperative fluid deficits in patients with severe esophageal disease may be substantial, though they have not been well defined. Fluid requirements in patients undergoing esophageal procedures may be complicated by the fact that patients may be relatively hypovolemic after long preoperative fasts, particularly if esophageal obstruction or dysphagia limit fluid intake. Perioperative losses occur via a number of mechanisms including urinary, gastrointestinal, and evaporative losses, bleeding, and interstitial fluid shifting. This shift of fluid from the vascular compartment into the interstitial space accompanies surgical trauma and is likely to reflect vascular injury and loss of endothelial integrity. So-called "third-space" losses describe fluid loss into non-interstitial extracellular spaces which are not in equilibrium with the vascular compartment and thus considered to be a "nonfunctional" extracellular fluid compartment. This space has not been well characterized and its existence is unlikely [275–277].

In general, minor procedures and those involving minimally invasive surgical procedures tend to be associated with low fluid requirements. Patients undergoing longer and more complex procedures involving open abdominal and/or thoracic incisions may require more intraoperative fluid to maintain homeostasis. While evidence-based guidelines on fluid management for thoracic surgery do not yet exist, a consensus of best practice is beginning to evolve. Principles of perioperative fluid management principles for esophagectomy [278] and pathophysiology of fluid shifting in the perioperative setting have been extensively reviewed [275, 279]. Recent advances in understanding of glycocalyx function, the pathophysiologic implications of excessive fluid administration, and the application of advanced monitoring modalities to drive rational goal-directed fluid therapies (GDFT) justify several conclusions.

First, excessive perioperative intravenous fluid administration, particularly crystalloid, contributes to an exaggerated fluid shifting toward the interstitial space, potentially increasing complications associated with poor wound healing, slower return of GI function, abdominal compartment syndrome, impaired anastomotic healing, increased cardiac demand, pneumonia, and respiratory failure [280]. The adverse consequences of excessive fluid administration may be particularly problematic in esophagectomy patients, since edema in the conduit and at the anastomotic site may lead to inflammatory infiltration [281] and reduced tissue oxygenation [215], potentially placing the anastomosis at greater risk for necrosis and leak.

Prospective trials examining "liberal" versus "restrictive" fluid regimens in patients undergoing major surgical procedures generally favor greater fluid restriction [282–284] as do retrospective studies of patients undergoing pulmonary resection surgery [285–287] and esophagectomy [288, 289]. Interpretation of these prospective trials is limited, however, by a lack of standard definition of the terms "restrictive" and "liberal." What is liberal in one study may be restrictive in another. Retrospective analyses are limited in this regard by the potential for uncontrolled bias. Most studies of both types, however, are consistent with the idea that fluid overload is indeed related to adverse outcomes. This concept is supported by a large meta-analysis of trials comparing liberal versus restrictive fluid management in elective surgeries which reported a large reduction in perioperative complications in the restrictive group [290]. Perioperative fluid administration appears to be an independent risk predictor of morbidity after esophagectomy for cancer [291], and a positive fluid balance predicts pulmonary complications after esophagectomy [292].

However, inadequate fluid resuscitation in patients with significant perioperative fluid losses may also be detrimental, causing hypovolemia and a decrement in stroke volume, cardiac output, and tissue oxygen delivery which could compromise renal function, wound healing, anastomotic integrity, and even cardiovascular stability. Fluid requirements for major esophageal surgery appear to be lower than previously thought and expert recommendations have been published [278]. Concerns regarding the implications for acute kidney injury in major thoracic surgical patients subjected to fluid restriction may be exaggerated, given recent findings that fluid restriction (<3 mL/kg/h) was not a risk factor for kidney injury in major thoracic surgery [293].

Optimizing fluid regimens is likely to be dependent upon adequately measuring fluid requirements or surrogates thereof in individual patients rather than relying upon formulas for "restrictive" or "liberal" regimens. While fluid requirements have not been well characterized in patients undergoing esophageal surgery specifically, recent evaluation of crystalloid requirements to maintain the left ventricular end-diastolic volume index (LVEDVI) in patients undergoing colorectal surgery has been made. The rate of crystalloid infusion required to maintain LVEDVI in patients undergoing open and laparoscopic colorectal surgery was 5.9 mL/kg/h and 3.4 mL/kg/h, respectively [294]. However, inter-individual variability was high, consistent with the need for an individualized approach. It would seem intuitive that an ideal fluid regimen for major surgeries including esophageal surgeries is individualized and optimizes cardiac output and oxygen delivery while avoiding excessive fluid administration. There is an emerging body of evidence that fluid therapies which are designed to achieve individualized and specific flow-related hemodynamic endpoints such as stroke volume, cardiac output, or measures of fluid responsiveness such as stroke volume variation (collectively referred to as goal-directed fluid therapy (GDFT)) may provide a superior alternative to fixed regimens or those based on static measures of cardiac filling such as central venous pressure which does not predict fluid responsiveness or correlate with circulating blood volume in hospitalized patients [295] or after transthoracic esophagectomy [296]. GDFT in the setting of major surgery has been shown to reduce hospital length of stay [297–304], promote earlier return of bowel function [297], and reduce postoperative nausea and vomiting (PONV) [297], morbidity [299–301, 305], and vasopressor use [306]. A review of nine studies utilizing GDFT revealed that of these, seven reported reduced hospital length of stay, three reported reduced PONV and ileus, and four reported a reduction in complications [307]. Several large meta-analyses have also supported the use of defined protocols including fluid management and inotropic therapies to optimize hemodynamics and/or tissue perfusion [308–310]. Indeed, a goal-directed approach to fluid management in the context of an enhanced recovery program for colorectal surgery has been recommended in a joint consensus statement by the American Society for Enhance Recovery and the Perioperative Quality Initiative [311].

The role of GDFT for outcome improvement in thoracic surgery is less clear and most available studies are small and have investigated primarily patients undergoing cardiac surgery. In addition to the pulmonary artery catheter-derived cardiac output measurements, which are not typically used for most general thoracic surgeries, and the transesophageal echocardiographic and esophageal Doppler modalities, which are inappropriate for esophageal surgery, a number of minimally invasive modalities compatible with transthoracic esophageal surgery are available. These include primarily devices that use proprietary algorithms to estimate stroke volume index, cardiac index, and/or stroke volume variation (SVV) [312–315]. Most of the available minimally invasive technologies used to guide GDFT depend upon respiratory variation and cardiorespiratory interaction to predict fluid responsiveness. Since these interactions are likely to be sub-

stantially altered during thoracic surgery as a result of one-lung ventilation and/or an open chest wall, their utility in guiding fluid management in thoracic surgery is less well understood. However, Haas et al. used SVV to guide fluid administration in lung surgery and esophagectomy and demonstrated that this approach did not result in fluid overload, as assessed by the extravascular lung water index [316]. Moreover, pulse pressure variation during one-lung ventilation in patients undergoing lung surgery via thoracotomy predicted fluid responsiveness with an optimal threshold of 5.8% [317], suggesting that dynamic variation from cardiorespiratory interactions may remain useful for guiding fluid therapy under certain conditions. Results with stroke volume variation, however, are mixed. SVV appears to predict volume responsiveness during thoracic surgery and OLV as well [318, 319], but its predictive value is substantially diminished as tidal volumes are reduced toward levels consistent with protective ventilation [318, 320]. The utility of SVV for assessing volume status and responsiveness in the postoperative period after esophagectomy remains unclear [321, 322]. However, in a single-center observational cohort study of patients undergoing esophagectomy before and after the implementation of a GDFT protocol using SVV, the use of GDFT was associated with a reduced ICU length of stay and a lower incidence of pneumonia, mediastinal abscess, and gastric tube necrosis [323]. While these results are intriguing, the field continues to await the unambiguous demonstration of clinical outcome benefits already attributed to goal-directed fluid management in other surgery types.

No consensus yet exists regarding superiority of colloids versus crystalloids in surgery in general or major esophageal surgery in particular. Theoretical and experimental advantages attributed to colloid fluid therapy, particularly in experimental settings, include greater and more rapid intravascular volume expansion and improvements in microcirculatory blood flow in a porcine model of anastomotic colon [324]. These findings may be of relevance to esophageal surgery where anastomotic integrity may be related to blood flow and oxygen delivery to a potentially flow-compromised gastric tube-esophageal anastomosis. Use of colloid has also been linked to outcome advantages in prospective trials of GDFT [325]. It is tempting to conclude that colloids might be superior in minimizing fluid shifting across a potentially injured vascular barrier. This topic has been examined in a review by Chappell and colleagues [275] in which the authors make an argument for the use of colloids in the replacement of plasma volume losses due to fluid shifting or bleeding. Expert recommendations also currently include the use of colloid to replace blood losses [278].

The ideal choice of colloid solution for plasma volume expansion in major thoracic surgery, including esophageal surgery, also requires further elucidation. The primary colloid solutions available in the USA for this purpose are human albumin, hetastarch, and the third-generation tetrastarch (Voluven) – a lower molecular weight starch with a number of theoretical advantages, including improved clearance in patients with impaired renal function [326] and reduced adverse effects on renal integrity [327, 328] and coagulation function [329, 330]. Voluven appears to share favorable characteristics of other synthetic colloids on endothelial cell-leukocyte interaction [331] and has been associated with an inhibition of systemic inflammation in patients undergoing cardiac surgery compared to that of gelatin and crystalloid [332].

After the publication of two large starch trials in critically ill patients [333, 334], the US Food and Drug Administration (FDA) issued a safety advisory for renal injury in sepsis and further recommendations limiting use of starches in patients with renal dysfunction and in patients undergoing cardiac surgery. This action has led to significant curtailment of starch colloid use in the perioperative setting (in the USA) despite the many shortcomings and limitations of the above trials [335], the subsequent CRISTAL trial [336] which reported a mortality benefit in the colloid group, the conspicuous absence of negative outcome data in the perioperative setting [337], and considerable debate on this issue [335, 338].

While the ideal fluid management strategy in thoracic surgery remains elusive, we believe that the preponderance of evidence supports the use of GDFT in major abdominal esophageal surgeries utilizing two-lung ventilation with the goal of optimizing hemodynamic parameters and tissue perfusion while avoiding iatrogenic fluid overload. Fluid management in patients undergoing major transthoracic esophageal surgery, including esophagectomy, continues to evolve, and ideal management remains unclear. While GDFT remains intuitive, physiologically appealing, and well supported in other surgical approaches, additional well-designed prospective studies are needed before this approach can become standard management for transthoracic esophageal surgery. We believe that the bulk of currently available evidence supports a largely restrictive approach in these patients and support the approach previously recommended by Chau and Slinger [278]. With only minor modification, the recommended goals are to (1) limit positive fluid balance in the first 24 h to less than 20 mL/kg, (2) except for unusual cases of increased fluid losses, limit crystalloid input to 2 L intraoperatively and <3 L for the first 24 postoperative hours, and (3) use colloid to replace blood loss (until transfusion threshold is reached) at a 1:1 ratio.

Intraoperative Complications

Intraoperative management of patients undergoing esophageal surgery may be complicated by a variety of surgical and anesthetic problems. Hypotension is not uncommon during

major esophageal surgeries and may result from compression of the heart or major vessels, myocardial ischemia, hypovolemia, vasodilation, or use of an indwelling epidural catheter leading to a thoracic sympathectomy.

Hypoxemia during esophageal surgery can occur in patients undergoing OLV and typically is due to right to left shunt flow via the non-ventilated lung as well as by volume loss and atelectasis in the ventilated (usually dependent) lung. Strategies for OLV as well as prevention and treatment of hypoxemia during OLV are reviewed in Chap. 6. Less commonly, hypoxemia during transthoracic esophageal surgery results from trauma to the ventilated lung and resultant tension pneumothorax which can be treated surgically by needle or finger puncture of the contralateral pleura. Pulmonary edema can result from fluid overload, cardiac failure, and immunologic reactions to medications and other immunogens including latex. The diagnosis of fluid overload and/or cardiac failure may be difficult in the context of esophageal surgery as transesophageal echocardiography is usually contraindicated or impractical, and data from central venous or pulmonary artery catheters, if present, are of limited value in this regard. Electrocardiographic evidence of myocardial ischemia along with pulmonary edema, particularly if it is not responsive to pharmacologic therapy to improve myocardial oxygen supply/demand inequality, may require aborting the surgical procedure, particularly if detected prior to esophagotomy. Rarely, pulmonary embolization can occur with preferential distribution to the ventilated, perfused lung [339].

Postoperative Management and Complications

Postoperative management of patients after esophageal surgery is largely dependent on the specific procedure performed and the patient's response to anesthesia and surgery. In general, most patients should be suitable for extubation after elective esophageal surgery, particularly those undergoing esophagoscopy and minimally invasive laparoscopic or thoracoscopic surgical procedures. The extubation of patients undergoing esophagectomy procedures will be discussed below. Provided that patients are stable from a hemodynamic and metabolic standpoint and that neuromuscular and respiratory function are adequate and a plan for suitable analgesia has been initiated, extubation in the operating room is generally appropriate. In most cases, dosing of an indwelling thoracic epidural catheter is well tolerated during wound closure as the intravenous or inhalational anesthetic is reduced. Following suctioning of the oropharynx and nasogastric tube, if present, the patient should be allowed to emerge from general anesthesia and extubated following the return of protective airway reflexes. Placing the patient in a 30° head-up position may improve pulmonary ventilation and decrease aspiration risk. If a gastric drain is indicated for the procedure, it should be secured prior to emergence and extubation. The nasal bridle, or nasoenteric tube retention device, decreases the risk of accidental dislodgement, particularly in confused or uncooperative patients [340].

Hypotension occurs not infrequently after esophageal surgery. Causes include inadequate intraoperative plasma volume expansion, hemorrhage, cardiac dysrhythmias (most commonly atrial tachyarrhythmias), pneumothorax, and sympathectomy from use of TEA (see Chap. 56 for a discussion of cardiovascular complications after thoracic surgery). Careful hemodynamic assessment of the postoperative patient should permit the distinction between hypovolemia and other causes. Urine output and chest drain output should be carefully followed and hemoglobin concentration monitored in patients suspected of ongoing bleeding. Routine postoperative chest radiography is indicated in patients undergoing transthoracic or transhiatal procedures and when postoperative cardiovascular or respiratory complications are suspected. Most commonly, epidural-related sympathectomy is the cause and can be treated by additional fluid repletion, temporary discontinuation of the infusion medications, supine repositioning or leg elevation to augment venous return, or reducing the concentration of local anesthetic in the epidural infusion. Occasionally, hemodynamically fragile patients may require substitution of epidural local anesthetic solution with an opioid such as hydromorphone or morphine, though pain control with this regimen is usually suboptimal.

Atrial tachyarrhythmias occur frequently after thoracic surgical procedures, including esophageal surgeries, and may result in significant hemodynamic instability due to a rapid ventricular response and/or myocardial ischemia. This complication has been best studied in patients undergoing esophagectomy surgery and will be discussed below. Myocardial ischemia, congestive heart failure, and pulmonary thromboembolic complications are also possible though appropriate patient selection, preoperative cardiovascular evaluation, and thromboprophylaxis should significantly reduce these risks.

Respiratory insufficiency, seen most commonly in patients with baseline impairment of respiratory function, may be related to weakness from inadequate reversal of neuromuscular blockade. Typically, these patients retain carbon dioxide and may become hypercapnic and obtunded. Often, retractions due to upper airway obstruction can be observed. Other causes of hypoventilation such as bronchospasm, aspiration pneumonitis, pulmonary edema, pneumothorax, and ARDS should be ruled out with the appropriate diagnostic modalities. Inadequate pain control after thoracotomy or laparotomy can also result in splinting with reduced tidal volumes and hypoventilation. Typically, adequate treatment of incisional pain leads to a dramatic improvement in respiratory function.

Chest radiography and arterial blood gas analysis should be performed immediately in any patient with acute respiratory decompensation after thoracic surgery.

Anesthetic Considerations for Specific Esophageal Procedures and Disorders

Esophagoscopy

Esophagoscopy may be performed with either a rigid or flexible endoscope and is used for a number of specific diagnostic and therapeutic purposes. In general, most diagnostic esophagoscopies are performed using flexible endoscopes, often in awake/sedated patients and frequently in a gastroenterology suite without the care of an anesthesiologist. Conscious sedation performed by a nurse or other assistant under the direction of an endoscopist, usually a gastroenterologist, is most often accomplished with the use of a benzodiazepine such as diazepam or midazolam with or without the addition of an opioid such as meperidine or fentanyl. Often, a local anesthetic such as lidocaine or benzocaine is applied topically to facilitate patient acceptance and reduce gagging during the procedure. Using a traditional approach, patient acceptance of the procedure without sedation, even with ultrathin esophagoscopes, is quite limited [341]. However, more recent clinical experience with a transnasal approach to flexible esophagoscopy confirms that this procedure is well tolerated under local anesthesia without sedation when performed by otolaryngologists [342, 343]. If local anesthetic is used, the total acceptable dose should be carefully considered as methemoglobinemia has been associated with topical use of benzocaine for surgical procedures [344], including esophagogastroduodenoscopy (EGD) [345]. Flexible esophagoscopy is also routinely performed by thoracic surgeons immediately prior to esophageal surgery to assess the location and extent of esophageal lesions and the degree of esophageal obstruction. Most of these patients have known esophageal disease and are presenting for curative or palliative esophageal surgery. These patients are usually at elevated risk for regurgitation and aspiration and should be treated appropriately. The airway should be secured prior to instrumentation of the esophagus under general anesthesia.

More complex endoscopic procedures often require deeper levels of sedation or general anesthesia. Maintaining a patient airway, optimizing oxygenation, and preventing aspiration are the primary concerns during these procedures, particularly in obese patients, longer procedures, and with prone positioning. While some degree of desaturation is common during extended esophagoscopic procedures in patients not endotracheally intubated, the presence of an in situ endoscope may help stent open the airway at the pharyngeal level [346]. Nonetheless, a high degree of vigilance is required to detect airway obstruction and impending hypoxemia in these cases. If standard maneuvers fail to relieve airway obstruction, extraction of the esophagoscope may be required for definitive airway management. A number of commercially available devices have been designed to accommodate an endoscope while permitting oxygen insufflation and/or ventilation. These include face masks, a gastrolaryngeal tube [346], and the recently available LMA Gastro Airway – a supraglottic device designed to create an oropharyngeal seal while providing a large channel for endoscope passage.

Rigid esophagoscopy is most frequently employed for the extraction of esophageal foreign bodies, often in children, as well as for the removal of retained food items. As with laryngoscopy, this is a very stimulating procedure and not likely to be well tolerated without general anesthesia. These patients should also be considered high risk for aspiration and managed accordingly, with the rapid placement of a cuffed endotracheal tube before or immediately after induction of anesthesia. In selected patients who are felt to be at lower risk for aspiration with this procedure and who meet NPO guidelines, it may be appropriate to consider deeper levels of sedation. Monitored anesthesia care with sedation using dexmedetomidine infusion for rigid esophagoscopy and dilation of the UES with botulinum toxin injection for dysphagia has been described [347]. Propofol-based monitored anesthesia care is also commonly used for patients who do not require endotracheal intubation and may be particularly useful for longer or more difficult cases, including submucosal dissections for esophagogastric cancer [348]. Anesthetic management considerations for rigid esophagoscopy include the extreme neck extension desired by surgeons for alignment of the oral-esophageal axis, the risk of aspirating objects once extracted from the esophagus [349], and the need for a relaxed patient to minimize movement during the procedure. The latter need can be achieved with deep levels of inhalational anesthetic or with short-acting muscle relaxants.

Additional therapeutic uses of esophagoscopy include esophageal stent placement for tracheoesophageal fistula (TEF), benign and malignant strictures [350, 351], and perforation [29, 352] and nonsurgical treatment of achalasia, including esophageal dilatation and intraesophageal delivery of botulinum toxin [353], as well as the per-oral endoscopic myotomy (POEM) procedure [354] – an endoscopic alternative to the classical Heller myotomy. Endoscopic techniques are also used in the staging of superficial esophageal tumors and complete resection and ablation of mucosal adenocarcinoma [93–96, 355].

Tracheoesophageal Fistula (TEF)

Anesthetic management of the patient with TEF is uniquely challenging for several reasons. First, positive-pressure ven-

tilation inevitably results in ventilatory gas entering the esophagus and stomach. Second, the inevitable large airway leak may render pulmonary ventilation difficult or impossible. Third, ventilation of the gastrointestinal tract may result in worsening pulmonary compliance because of abdominal distention which may also increase the risk of further aspiration and other complications [72, 356, 357]. For these reasons, maintenance of spontaneous ventilation is often preferred and can be accomplished with either an inhalational induction or an awake intubation, though baseline decrements in pulmonary function and compliance on the affected side are likely to increase difficulties associated with oxygenation and adequate ventilation after induction of anesthesia. The preoperative placement of a gastrostomy tube will aid in venting the stomach in the event that positive-pressure ventilation becomes necessary but is contraindicated if the stomach is to be used as a conduit. Additionally, chronic aspiration and its sequelae of pneumonia, sepsis, and hypoxemia may complicate the anesthetic management of these patients, particularly during OLV. Positive-pressure ventilation can be safely performed once lung isolation has been accomplished. Lung isolation is essential to prevent ventilation of the fistula, to provide adequate pulmonary ventilation, and to prevent further soilage of the lung.

The anesthetic plan for airway management and ventilation in adult patients with TEF should reflect the anatomic position of the fistula in the respiratory tract. Typically, the identification and localization of the fistula is made before presentation to the operating theater. On rare occasions, a previously undiagnosed TEF may manifest itself after otherwise uncomplicated airway management [76]. Occasionally, the exact level of the fistula is not known. Though not always successful, bronchoscopic examination of the airway may identify the level of airway involvement and can be performed preoperatively. Bronchoscopy can also be performed after tracheal intubation with either a DLT [358] or SLT [359] and used to guide placement after localization of the TEF. Rarely, esophagoscopy may also be used to identify SLT position relative to the fistula [360].

The DLT is preferred in most cases of TEF since it can be placed into the mainstem bronchus contralateral to the fistula, providing lung isolation, OLV, and protection from soilage of the ventilated lung. Thus, the right-sided DLT should be used for left-sided lesions and vice versa. Alternatively, an SLT (ideally one designed for endobronchial placement) can be placed in the contralateral bronchus. Occasionally, for a tracheal TEF well above the carina, a SLT may be used if the cuff can be inflated below the fistula. If this is not possible, a right DLT is preferable for distal tracheal fistulae or if the fistula site is not identified preoperatively. In patients with severe pulmonary disease, OLV may be incompatible with adequate oxygenation and ventilation. Rarely, alternative approaches for oxygenation and ventilation that minimize gas flow into the esophagus may be required. The use of a left DLT for lung isolation with high-frequency oscillation ventilation on the right side has been described for optimizing gas exchange in a patient with a low tracheal TEF and ARDS [361]. An alternative approach in critically ill ventilated patients with benign TEF utilizes temporary stenting to functionally separate the airway and esophagus, minimizing air leak and improving CO_2 removal [78]. This procedure was easily performed and well tolerated and could presumably serve as a bridge to definitive surgical correction following improvement in the patient's status.

Postoperative goals include optimizing pulmonary function to facilitate a return to spontaneous ventilation with adequate gas exchange. The continuation of positive-pressure ventilation may lead to disruption of the esophageal closure and could thus cause a ventilatory leak. Achieving this goal requires adequate pain control and may also require aggressive pulmonary toilet with bronchoscopy prior to emergence.

Transthoracic Nissen and Belsey Fundoplication, Collis Gastroplasty, and Paraesophageal Hernia Repair

Transthoracic anti-reflux procedures require monitoring arterial and venous access commensurate with a thoracotomy. Most patients presenting with hiatal hernias, particularly those with paraesophageal hernia and/or symptomatic GERD, are considered to be at elevated risk for perioperative aspiration of gastric contents, although clear risk stratification is lacking. For this reason, rapid sequence induction is preferred by many practitioners for patients with reassuring airway anatomy.

Lung isolation and OLV are required for transthoracic approaches to the esophagus. Bronchial blockers are ideal in these cases for the following reasons: (1) blocker placement can follow definitive airway management via rapid sequence induction with SLT in the protected (intubated) airway, (2) rapid sequence induction is performed more rapidly and arguably, more easily and safely, when a SLT rather than DLT is used, (3) as discussed above, performance of modern bronchial blockers with regard to lung isolation and operating conditions are equivalent to that of DLTs, and (4) since most of these procedures utilize a left thoracotomy approach, left bronchial blockade is easily achieved due to the longer left main bronchus.

An aggressive plan for postoperative pain control is also required – typically TEA. Following induction, intubation, and placement of vascular cannulae, the patient is placed in the right lateral decubitus position. After withdrawing an indwelling gastric tube, a large bougie/dilator is advanced into the esophagus at the surgeon's request to facilitate the fundoplication. The dilator should be well lubricated with a

water-soluble lubricant and passed atraumatically into the upper esophagus with manual guidance or with the use of a laryngoscope to aid engagement with the esophageal orifice. Caution should be exercised during advancement, and communication with the surgeon is important, particularly if resistance is encountered as esophageal disruption can occur. It is then passed slowly through the esophagogastric junction and left in this position until the fundoplication sutures are secured at which time it can be withdrawn.

Unless complications are encountered intraoperatively, most patients can be allowed to emerge from anesthesia at the conclusion of surgery and extubated at emergence. The stomach should be drained with a nasogastric tube postoperatively. Oral feeding is begun after return of normal bowel activity which may require several days after open repair. Dysphagia to solid foods can be experienced by some patients for several weeks after surgery and is more common with transthoracic procedures and total fundoplications but typically resolves spontaneously.

Esophagectomy

Transhiatal Esophagectomy (THE)

Patients presenting for this procedure require standard monitoring, a urinary catheter and an arterial catheter for continuous arterial blood pressure monitoring. Patients will also benefit from the preoperative placement of an epidural catheter for postoperative pain control. After preoxygenation and induction of general anesthesia, the trachea is intubated with a single-lumen endotracheal tube and both arterial and adequate intravenous access are obtained – generally two peripheral venous cannulae and an arterial catheter. A nasogastric tube is placed and secured in its position after the esophageal anastomosis is made.

The transhiatal approach to esophagectomy requires the manual dissection of the esophagus from the mediastinum blindly via the abdominal hiatus. The manual compression of the heart and great veins commonly causes hypotension, usually transiently. Optimizing volume status prior to this step may partially mitigate the decrement in blood pressure and cardiac output. Close communication between surgeon and anesthesiologist is critical during this stage, as it may become necessary for the surgeon to temporarily discontinue the dissection to permit hemodynamic recovery, particularly in the elderly or fragile patient. The duration of hypotension during dissection may be related to a patient history of cardiac disease and the presence of a mid-esophageal tumor [362]. The transhiatal dissection may also precipitate atrial and/or ventricular ectopy which could contribute to hypotension and reduced cardiac output during this phase. Atrial arrhythmias are commonly associated with transhiatal dissection [363] and are more likely in patients with cardiac disease [362]. In a small study of transhiatal esophagectomies, arrhythmias occurred during transhiatal manipulation in 65% of cases, but were transient, did not require treatment, and were not correlated with hypotension [363]. Other potential intraoperative complications include pneumothorax, mediastinal bleeding from injuries to the aorta or azygous vein, and injury of the membranous trachea. Pneumothorax is easily managed surgically with the placement of a tube thoracostomy from the operative field. Massive hemorrhage is rare but is likely to require emergent thoracotomy and repair with aggressive transfusion and resuscitation. Tracheal injury also requires definitive repair, and the anesthesiologist may be required to advance the endotracheal tube beyond the site of injury to facilitate ventilation during the repair. For this reason, only full-length uncut endotracheal tubes should be used for THE.

Following completion of the cervical anastomosis and wound closure, the nasogastric tube is secured in position. If in situ, the epidural catheter should be appropriately dosed prior to emergence. Tracheal extubation is performed at emergence with return of protective airway reflexes, and the patient is transferred to a unit where appropriate monitoring and pain control can be accomplished. The head of the bed should be elevated between 30° and 45° to optimize respiratory mechanics and to minimize the potential for reflux and aspiration. Postoperative therapy includes antibiotics and thromboprophylaxis. Postoperative complications attributable to the THE include recurrent laryngeal nerve injury which results in hoarseness and an increased risk of aspiration pneumonitis, chylothorax, and anastomotic leak.

Transthoracic Esophagectomy (Ivor Lewis; TTE)

Unless contraindicated, a thoracic epidural catheter should be placed preoperatively. Induction and maintenance of general anesthesia can be accomplished with standard agents. For the reasons enumerated above, a rapid sequence induction is recommended, and endotracheal intubation should ideally be accomplished with attention to the risks of aspiration. Lung isolation is not required for laparotomy, and thus, some practitioners intubate initially with a SLT, replacing it with a DLT prior to the thoracotomy incision and after suctioning of the stomach. It is also reasonable to place a DLT at induction unless difficult placement is predicted in a patient with elevated risk of aspiration, such as high-grade obstruction, gastroparesis, or emergency surgery. In such cases, the practitioner should first rapidly secure the airway with a SLT, evacuate stomach contents intraoperatively, and then either place a DLT prior to thoracotomy or simply use an endobronchial blocker.

After induction, a nasogastric tube is placed with consideration to possible partial or complete esophageal obstruction that may necessitate surgical assistance for positioning distally. Decompression of the stomach and esophageal con-

duit is of paramount importance; thus the tube should be secured intraoperatively to prevent its removal by the patient or inadvertent removal during patient movement and transport. Muscle relaxation with nondepolarizing muscle relaxants provides optimal operating conditions. An arterial catheter and large-bore peripheral or central venous access should be obtained after induction.

Intraoperative hypotension may occur during transthoracic esophagectomy surgery and typically results from hypovolemia and/or TEA-related sympathectomy. Hypotension may precipitate myocardial or cerebral ischemia and may also contribute to gastric tube ischemia. Thus, potential causes should be immediately sought and treated. The mobilized gastric tube has a limited blood supply, usually from the right gastroepiploic artery, and blood flow at the distal segment is decreased. Factors such as hypotension may further compromise perfusion of the gastric tube and may thus increase the risk of anastomotic leak [364]. Since anastomotic integrity is dependent upon adequate blood flow and oxygen delivery [365–369], the development of anastomotic leak may be related to intraoperative management variables, particularly systemic blood pressure [364] and cardiac output and may thus be modifiable by anesthetic management.

Some esophageal surgeons eschew the use of vasoconstricting agents for fear of the theoretical adverse effects on gastric tube blood flow. However, the available data do not support this reasoning. The effect of vasoconstrictors on gastric tube blood flow is likely to reflect volume status and other variables, but the clinical and experimental evidence supports the following concepts: (1) dysregulated blood flow in the newly formed conduit is blood pressure-dependent, (2) hypotension impairs conduit blood flow, (3) a supranormal blood pressure does not improve conduit blood flow above that of normotension, and (4) in the euvolemic patient, the use of vasopressors to treat hypotension, rather than compromising conduit blood flow, actually has the potential to substantially improve perfusion. Al-Rawi and colleagues demonstrated that a TEA-induced sympathectomy decreased gastric tube blood flow during esophagectomy and that the intravenous infusion of epinephrine restored blood flow [370]. The use of norepinephrine to maintain arterial blood pressure during esophagectomy as part of a multimodal anesthetic regimen has been associated with reduced respiratory morbidity without increasing the incidence of anastomotic complications [172]. These findings are consistent with those of an elegant porcine gastric tube model in which the use of norepinephrine to attain supranormal blood pressures did not improve gastric tube blood flow but likewise did not adversely affect this variable [371]. Clinically useful conclusions can also be derived from the study by Pathak et al. [372] who demonstrated that hypotension induced by a local anesthetic bolus via an in situ thoracic epidural catheter adversely affected conduit blood flow and that a phenylephrine infusion restored both mean blood pressure and conduit perfusion. Given the established relationship between gastric tube blood flow and anastomotic leak, maintenance of normal hemodynamics should be a priority in the intraoperative management of these patients. Toward this end it may be prudent to modify or postpone dosing of an indwelling epidural catheter in a hypotensive patient and to consider the use of inotropic agents with or without vasopressor activity.

Following uneventful transthoracic esophagectomy, most patients can be extubated in the operating room provided that they are normothermic, metabolically and hemodynamically stable, well oxygenated, and appropriate pain control modalities have been employed. Although an older randomized trial comparing early versus late extubation after esophagectomy reported a higher mortality in the early extubation group, this difference was not statistically significant [373] and has not been observed subsequently. Early extubation after esophagectomy has been well studied and is supported by a number of retrospective and observational analyses [169, 374, 375] as well as reports of standardized management approaches [170] and fast-track clinical pathways [169, 171, 376]. Factors which may predict failure or complications associated with early extubation include a history of smoking and chronic obstructive pulmonary disease (COPD) [377]. Epidural analgesia has been demonstrated to facilitate successful early extubation [169, 375, 377].

Considerable interest in enhanced recovery (enhanced recovery after surgery (ERAS)) protocols in a variety of surgical service lines follows from initial successes in colorectal surgery [378]. Although considerable heterogeneity exists between institutions, most ERAS programs employ efforts to optimize pain control while minimizing opioid use, prevent iatrogenic fluid overload, and improve pre- and postoperative rehabilitation. Specific elements of ERAS care for esophagectomy patients have included preoperative education, prehabilitation including inspiratory muscle training, preoperative carbohydrate nutrition, epidural analgesia, early mobilization and rehabilitation, avoidance of or early discontinuation of nasogastric and other drains, early feeding, and discharge education. While ERAS for esophagectomy is still in its infancy relative to that of other surgical service lines, considerable evidence has accrued to support a protocolized pathway for perioperative care in the esophagectomy patient. Thus far, a number of outcome advantages have been ascribed to ERAS-like protocols in esophagectomy; these include a reduction in postoperative complications [175, 379, 380], pain [175], hospital length of stay [174, 175], hospital costs (or charges) [176, 379, 380], and time to return to normal activity [175], without an increase in readmission rate [174, 379, 380]. Optimizing perioperative care in this way also appears to reduce the systemic inflammatory response associated with esophagectomy [176] which may

account for improvements in certain outcomes. A recent meta-analysis of ERAS programs [381] for esophagectomy confirms a large degree of variation in program design and the limitations associated with uncontrolled potential confounding variables. However, within these constraints, the efficacy of ERAS is generally supported – leading to a reduction in anastomotic and pulmonary complications and hospital length of stay without any change in the readmission rate (ERAS in thoracic surgery is discussed in Chap. 52).

At emergence, patients should be seated 30° above supine and extubated upon return of protective airway reflexes. Supplemental oxygen may be delivered via face tent or nasal cannulae. If postoperative ventilatory support is required or extubation must be delayed for other reasons, tube exchange can be performed with laryngoscopy, adjunctive airway devices, or via a tube exchange catheter.

Minimally Invasive Esophagectomy (MIE)

Minimally invasive esophagectomy (MIE) is a blanket term which has been used to describe a variety of less invasive approaches to esophagectomy. MIE may refer to a laparoscopic approach to transhiatal esophagectomy, fully minimally invasive equivalents of the Ivor Lewis esophagectomy (laparoscopy and thoracoscopy), or a number of hybrid approaches. At this time, there is little specific data available to guide anesthetic management of the patient undergoing minimally invasive esophagectomy, but principles of management in the patient undergoing open esophagectomy are likely to apply. OLV is considered essential for any thoracoscopic procedure, including MIE, and thus, lung isolation is required. The use of DLT and bronchial blockers for esophageal surgery has been discussed above and applies here as well.

It is not clear that patients undergoing MIE require aggressive pain control modalities such as TEA for optimal postoperative pain control. However, the TEA remains the standard of care in centers which perform these surgeries largely because of the theoretical and demonstrated advantages of TEA in the context of open esophagectomy and thoracic surgery in general.

Robotic Esophagectomy

From an anesthesiologist's perspective, use of the da Vinci robotic surgical system to aid in the performance of esophagectomy has the potential to significantly affect patient care and safety during the operative procedure. It is thus incumbent upon the practitioner to understand the implications of robot use particularly with regard to patient access and specific risks. The da Vinci robotic system utilizes a console for the surgeon, a side cart with four robotic arms which interact with the patient, and an additional cart which houses optical devices for the camera system. Typically, the patient axis is turned at least 90° away from the anesthesiologist and anesthesia machine. After port placement and robot docking, access to the patient is very limited. Position of the robot chassis above the patient's head limits access to the airway. The anesthesiologist should be aware of the risks associated with positioning for robotic surgery – including the known risk of brachial plexus injury from extreme arm positioning and the possibility of robotic arm collision with the patient's body. Likewise, access to the patient's body is also quite restrictive. It is essential for the anesthesiologist to confirm ideal position of the DLT or bronchial blocker prior to final robot positioning. All vascular access must also be secured and line patency confirmed. Extension tubing for arterial and venous lines is often required. The recently developed lung isolation products (Viva Sight, ET View) incorporate a small high-resolution imaging camera in the DLT or single-lumen tube to provide for continuous and real-time imaging of the distal airway. These devices allow the anesthesiologist to continuously monitor the DLT or blocker position, potentially providing both confirmation of correct positioning and an early warning when a malposition is imminent.

Additional concerns for the anesthesiologist during robotic surgery arise from the use of carbon dioxide insufflation to improve surgical exposure. Pressurized insufflation of carbon dioxide can contribute to hypercarbia, gas embolism, and bradycardia. Hemithoracic gas insufflation can be associated with hemodynamic compromise to the extent that it creates a state similar to that of a tension pneumothorax. In general low-pressure insufflation (<5 mmHg) is well tolerated in stable patients [382] and most patients can tolerate moderate pressures (8–10 mmHg). However, higher pressures may cause hemodynamic compromise, and efforts should be made to minimize insufflation pressures. If higher pressures are needed, a slow increase in insufflation pressure (up to 14 mmHg) may minimize hemodynamic effects [383]. Additionally, surgical violation of the contralateral pleura may cause respiratory or hemodynamic compromise. Finally, the anesthesiologist should be prepared for open thoracotomy in the event the robotic approach fails (see Chap. 39 for a detailed discussion of anesthesia for robotic thoracic surgery).

Postoperative Care of the Esophagectomy Patient

With appropriate pain control regimens, most patients are extubated in the operating room. Early ambulation and chest physiotherapy are used to reduce respiratory complications.

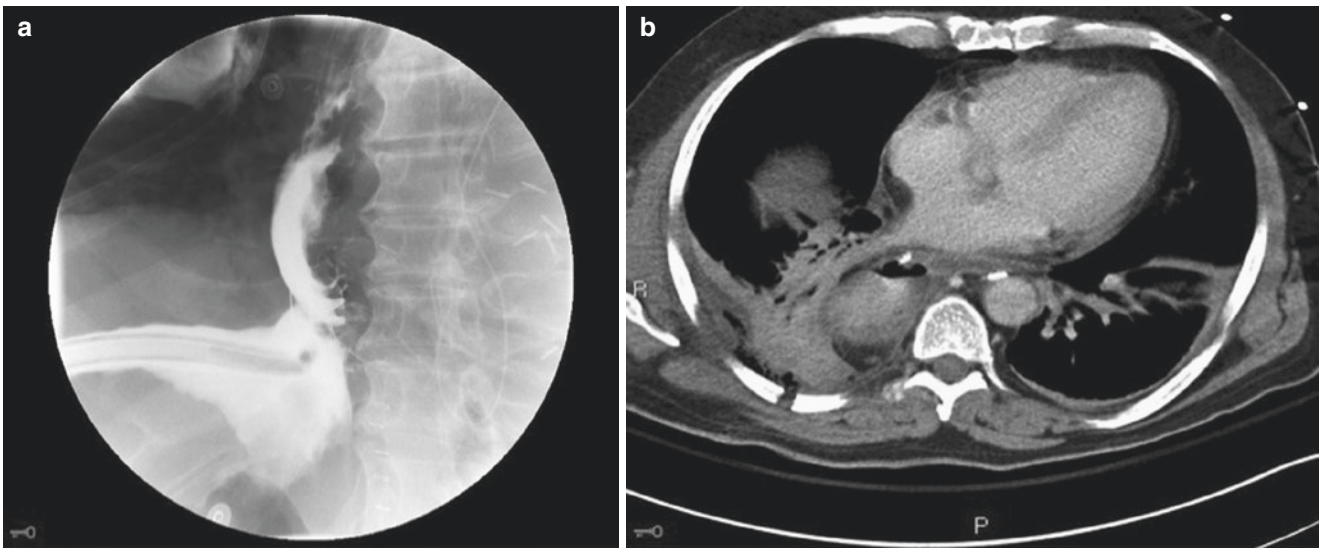

Fig. 38.9 (**a**) Fluoroscopic image of anastomotic leak after esophagectomy. Note contrast material leak into right hemithorax. (**b**) Chest CT scan revealing contrast medium leaking into right hemithorax from anastomotic leak after esophagectomy

Pleural drains are removed as soon as drainage is minimal and absence of air leak is confirmed, though mediastinal drains may be left until confirmation of intrathoracic anastomotic integrity is confirmed. The indwelling epidural catheter is generally used and left in situ until pleural drains are removed, at which time pain control can be adequately accomplished with parenteral or enteral medications. Feeding via a jejunostomy tube is typically initiated after 24 h postoperatively and advanced over a period of several days. A contrast study of the esophagus is usually performed on or about the fifth postoperative day, and if normal, a clear diet by mouth is begun at that time. As noted in the discussion above, there is substantial interest in, and some evidence supporting, immediate oral nutrition following esophagectomy, though widespread adoption is likely to await the completion of, and favorable outcomes from, a randomized trial. At discharge, the patient should be eating solid food and the jejunostomy tube is clamped. At surgical follow-up in several weeks, the feeding tube is removed.

Adverse Outcomes After Esophagectomy

Adverse outcomes after esophagectomy surgery have historically been divided into surgical and anesthetic complications. At first glance, this division is logical and appealing, but recent insight into the pathophysiology of complications after major thoracic and thoracoabdominal surgeries is beginning to blur this distinction.

Esophageal Anastomotic Leaks

As mentioned above, the development of an esophageal anastomotic leak is a frequent and serious complication of esophagectomy (see Fig. 38.9a and b). In a recent large retrospective review of data from the Society of Thoracic Surgeons database, the incidence of anastomotic leak was 12.9% [108]. This complication is particularly worrisome when the leak is mediastinal in location. Mortality rates from intrathoracic leaks range from 3.3% to 71% [384]. Preoperative, operative, and postoperative factors that may predispose to the development of anastomotic leak have been well described in the literature [384] and include comorbidities such as diabetes, pulmonary disease, and cardiovascular disease, a variety of surgical and technical factors, and postoperative factors including gastric distension, prolonged ventilatory support, and hypoxia. Though still considered a surgical complication, accumulating evidence suggests that intraoperative management may have an impact on the incidence of this complication. Because of the tenuous blood supply to the mobilized gastric tube, fluid status, hemodynamics, and oxygenation may affect anastomotic integrity through effects on oxygen delivery [365, 366] and blood flow [365]. Though the optimization of tissue oxygen delivery through appropriate management of hemodynamics, fluid status, and oxygenation is a priority for all perioperative patients, this truism may be particularly critical for patients undergoing esophageal anastomoses.

Cardiovascular Complications

Cardiovascular complications account for significant morbidity and mortality after esophagectomy. The most common cardiac complication is arrhythmia, typically atrial tachyarrhythmias such as atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia. While generally

considered benign after cardiac surgery, these diagnoses may be more ominous after general thoracic surgery including esophagectomy. There is considerable evidence that atrial tachyarrhythmias after esophagectomy are associated with a higher rate of ICU admission, greater length of hospital stay, and a higher mortality [385–387]. These findings are consistent with those for general non-cardiac thoracic surgery patients in whom atrial fibrillation was a marker for increased morbidity and mortality [388]. Atrial fibrillation after esophagectomy is also associated with a higher rate of pulmonary complications, anastomotic leakage, and sepsis [386]. Risk factors for the development of atrial dysrhythmias after esophagectomy include transthoracic approach [389], older age, perioperative theophylline use, a low diffusion capacity [385, 390], COPD, male sex, and history of cardiac disease [390]. Larger studies of general thoracic surgery patients including esophagectomies point to similar risks for the development of atrial fibrillation – male sex, older age, history of congestive heart failure, arrhythmia, peripheral vascular disease and resection of mediastinal tumor, pulmonary resection, esophagectomy, and intraoperative blood transfusion [388].

The prophylaxis of atrial tachyarrhythmias in general thoracic surgery has been the subject of numerous clinical trials and observational studies, but no clinical standard for prophylaxis exists. A review of trials of pharmacologic prophylaxis for postoperative atrial arrhythmias reported that calcium channel blockers and beta-blockers reduced the risk of tachyarrhythmias, though the latter increased the risk of pulmonary edema [391]. The routine prophylactic use of digoxin, flecainide, and amiodarone is not supported by the available evidence [391]. A randomized trial in patients undergoing transthoracic esophagectomy demonstrated a relative risk reduction of 62.5% for postoperative atrial fibrillation in patients randomized to receive amiodarone [392]. The available evidence supports prophylaxis in patients at higher risk of atrial tachyarrhythmias. Such prophylaxis should be individualized and may include amiodarone, calcium channel blockers, or beta-blockers, with attention to the potential for adverse effects of the latter.

Pulmonary Complications

Respiratory morbidity occurs frequently after thoracic surgery in general and after esophagectomy in particular [167, 393]. Pulmonary complications of thoracic surgery are variably defined in the literature but include pneumonia, aspiration pneumonitis, ARDS, bronchopleural fistula, atelectasis, and pulmonary embolism. Any individual or cluster of these complications can result in respiratory insufficiency or respiratory failure, which may require specific therapies including the continuation or reinstitution of mechanical ventilation. The overall incidence of serious respiratory morbidity is highly variable but is between 10% and 30% in most large series [108, 394–398]. Factors predictive of pulmonary complications after esophagectomy include age [394, 395, 398], smoking [398], alcohol use [398], COPD [398], proximal location of esophageal tumor, and duration of surgery [394, 398], as well as forced expiratory volume in 1 s (FEV_1) [395] which predicts pulmonary complications in patients with COPD [399]. Additionally, preoperative airway bacterial colonization predicts an increase in postoperative pulmonary complications and is associated with an increased mortality [400].

ALI and ARDS are among the most severe pulmonary complications associated with esophagectomy, and their incidence in a large series was 23.8% and 14.5%, respectively [401]. ARDS is associated with a 50% mortality rate [401], a higher risk of non-respiratory organ failure, and a longer ICU and hospital stay [402]. Risk factors included low body mass index, tobacco history, surgeon experience, duration of surgery and OLV, anastomotic leak, and cardiorespiratory instability. The pathophysiology of ALI and ARDS are complex and thought to result from direct or indirect pulmonary injury. Though injury can occur from a variety of mechanisms, the final pathway appears to involve inflammatory mediators including cytokines and cellular mediators. Still a very active area of investigation, it has become clear that surgical stress itself elicits an already well-characterized and profound inflammatory response that includes cytokines such as IL-1, IL-8, TNF-alpha, IL-6, selectins, neutrophil elastase, and thrombomodulin [252, 403–406]. In particular, IL-8 has been implicated in the development of ARDS [407] and is likely to provide a strong signal for the chemotactic migration of neutrophils [408, 409], the alveolar infiltration of which is characteristic of the disease process. The degranulation of neutrophils and an increase in pulmonary capillary permeability has been demonstrated after esophagectomy and has been proposed as a human model of lung injury [406]. Causative involvement of IL-8 is suggested by studies of IL-8 antagonists in animal models [408], the presence of high concentrations in both ventilated and non-ventilated lungs [410] and the relationship between IL-8 concentrations in lavage fluid, and the subsequent development of pulmonary complications after esophagectomy [411].

Improving Outcomes After Esophagectomy

Since esophagectomy patients are at increased risk for malnutrition and since malnutrition places them at substantially elevated risk for morbidity and possibly mortality, improving preoperative and postoperative nutritional status has become a major focus for perioperative physicians caring for these patients. Patients presenting for esophagectomy may be mal-

nourished for a number of reasons – including decreased nutrient intake, increased catabolism and nutrient requirements, and impaired absorption. Preoperative sarcopenia [412] and low body mass index [413] are associated with poorer prognosis following esophagectomy. Malnutrition in this patient population has been shown to predict reoperation, respiratory morbidity, and a decrement in both overall and cancer-specific survival [414]. Preoperative nutritional status appears to be an independent risk factor for morbidity after esophagectomy and may improve risk prediction using existing prognostic scoring methodologies [415]. Moreover, nutritional disturbances appear to persist through the first postoperative year [416] and may never normalize in some patients [417]. Nutritional intervention appears to have significant potential to improve outcomes, though most studies address only postoperative nutrition. In a randomized trial, the parenteral administration of amino acids before and during the esophagectomy procedure resulted in an increase in core temperature and a decrease in the incidence of surgical infectious complications [418]. Postoperatively, enteral nutrition is superior to other routes, reducing weight loss and reducing the incidence of pneumonia [419], and may attenuate the cytokine response to surgery [420]. Further improvements in postoperative outcomes, including wound infection and length of stay, have been attributed to immunonutrition (containing specific immune system-enhancing nutrients) in upper gastrointestinal surgery [421] and to immediate resumption of oral nutrition following esophagectomy [422]. This latter approach to enteral nutrition (oral route) remains controversial because of concerns regarding possible aspiration and leak. A multicenter randomized trial to directly compare oral versus jejunostomy feeding after esophagectomy has been planned [423].

The high incidence of pulmonary complications following esophagectomy has prompted significant interest in efforts to improve preoperative cardiorespiratory function through inspiratory muscle training, an approach which has some preliminary support in the context of other thoracic surgical procedures. A prospective study comparing the effects of chest physical therapy in both thoracoscopic and open transthoracic esophagectomy demonstrated an improvement in pulmonary mechanical function in both groups [424], suggesting the utility of this approach for both surgical approaches.

Whether pulmonary prehabilitation results in improvements in clinical outcomes remains controversial. Retrospective review of esophagectomy patients suggests an association between physical therapy for reducing respiratory complications [425].

Prospective trials comparing high-intensity and endurance inspiratory muscle training demonstrated the feasibility of both protocols and the effectiveness of the high-intensity training for improvement of respiratory muscle function but differ with regard to the ability of such therapy for reducing postoperative pulmonary complications [426, 427].

The use of TEA for postoperative analgesia has been reviewed above, but its potential value in improving outcomes after esophagectomy merits additional mention. Improved outcomes associated with the use of TEA after transthoracic esophageal surgery [161, 164–167] may be related to improved postoperative pulmonary function and resultant decrease in pulmonary complications [164] and an improvement in gastric tube blood flow [428, 429]. The use of TEA has been associated with a decreased risk of anastomotic leak in a retrospective study of esophagectomy patients [166]. A causative role is implied by animal experiments in which the use of TEA improved microcirculation and motility in the gastric tube [429] and a clinical study with similar findings [428]. For these reasons and the overwhelming evidence of superior pain control, TEA represents the standard of care for TTE in most institutions.

Though lung injury in this context is multifactorial, there is a growing awareness that anesthetic and perioperative factors are involved (see Chap. 10 for discussion of perioperative lung injury). These include atelectasis, which is obligate in the non-ventilated lung during OLV, direct injurious effect of volutrauma or barotrauma in the contralateral lung during OLV, oxygen stress and toxicity in the ventilated lung, and ischemia reperfusion injury in the ipsilateral lung after reventilation. Current knowledge of these mechanisms has been extensively reviewed [430]. Strategies to protect the lung and optimize outcomes after major thoracic surgery are most likely to be successful if they minimize these injurious stimuli. Guidance in the absence of definitive outcome data in the perioperative thoracic surgery setting is based largely on results from studies of animal models, surrogate markers of lung injury, patients with established lung injury, and more recently patients undergoing a variety of surgical procedures. Expert recommendations have been published [431], and several randomized trials [432–435], including one trial in minimally invasive esophagectomy [436], have revealed strategies which may improve clinical outcomes.

Ventilation strategies, particularly during OLV, should be tailored to patient physiology. That OLV itself may be a factor in the inflammatory response accompanying thoracic esophageal surgery is suggested by studies of cytokine and complement levels during and after OLV [252, 434, 437]. Thus, ventilation should be as physiologic as possible in an effort to minimize the likelihood of volutrauma. So-called "protective ventilation" strategies represent a physiologic approach to tidal ventilation and are likely to improve outcomes in this patient population by minimizing the risk of alveolar overdistension as well as cyclic collapse of alveoli (atelectrauma) and atelectasis. Specifically, protective ventilation in the context of thoracic surgery and OLV has referred to lower tidal volumes (4–6 mL/kg ideal body weight) with

added positive end-expiratory pressure (PEEP) [431]. This ventilatory strategy in patients undergoing transthoracic esophagectomy has been shown to minimize surrogate markers of systemic inflammation (IL-1beta, IL-6, IL-8) [252, 438] while improving oxygenation intra- and postoperatively and decreasing the duration of mechanical ventilation [252]. Since oxygen toxicity and oxidative stress may also contribute to the development of adverse outcomes, it may be prudent to minimize FIO_2, though the large obligate right to left shunt in the non-ventilated lung during OLV limits the extent to which this maneuver is practicable.

Observations that the intense inflammatory responses accompanying esophagectomy may predict postoperative outcomes have led to a considerable effort to use pharmacologic therapies to attenuate inflammation. Numerous studies have documented the effects of corticosteroid administration on outcomes after esophagectomy, and, although there is a suggestion of possible benefit [439, 440], definitive conclusions await the results of an appropriately powered randomized trial [439–441]. Additional anti-inflammatory therapies tested in esophagectomy patients include simvastatin [442] and the neutrophil elastase inhibitor – sivelestat [443].

Surgery for Esophageal Rupture and Perforation

Patients presenting for emergent repair of esophageal disruption, rupture, or perforation may present with pain, hypovolemia, sepsis, and shock. Anesthetic management should be based on the severity of these presenting conditions and the nature of the planned procedure which may include endoscopic closure, primary surgical closure with mediastinal drainage, or esophagectomy. To the extent possible, fluid deficits should be corrected preoperatively and may be guided by standard and invasive monitoring as appropriate. Because of the likelihood of further fluid losses and hemodynamic decompensation, an arterial catheter for continuous blood pressure monitoring and arterial blood gas sampling is indicated.

The principles of anesthetic management are based on correcting preoperative fluid deficits, minimizing hemodynamic derangements, avoiding increases in abdominal pressure which may exacerbate leakage of gastroesophageal contents, and minimizing the risk of aspiration, particularly during induction. In general, a rapid sequence induction is indicated with the choice and dose of induction and neuromuscular blocking agents tailored to the patient's hemodynamic status. If a thoracotomy is planned or likely, surgical exposure will benefit from the use of a DLT, but this advantage should be considered in light of airway anatomy, anticipated ease of intubation, and the potentially elevated risk of aspiration should placement of the DLT require additional time.

Intraoperative management is likely to be dominated by the need for continuous fluid resuscitation. Arterial blood gas analysis and pulmonary artery catheter data may be used to guide fluid management and plasma volume expansion as well as the likely need for blood products. This factor combined with the probability of ongoing fluid shifts, pulmonary edema, and the need for inotropic and vasopressor support often mandate postoperative ventilatory support.

Surgery for Achalasia

Esophagomyotomy is most commonly performed to relieve esophageal obstruction at the sphincter level as well as for the relief of pain from esophageal spasm. Esophagomyotomy can be performed endoscopically, laparoscopically, thoracoscopically, or via thoracotomy, with or without the addition of an anti-reflux procedure. Arguably, the most important anesthetic consideration is the possibility of aspiration on induction of anesthesia with loss of protective airway reflexes. Because achalasia results in a dilated esophagus with impaired motility, the likelihood of retained food material in the esophagus is dramatically increased. It may also be desirable to restrict oral intake to only clear liquids for 2 days prior to surgery in an effort to reduce food retention. Approaches to minimize the risk of regurgitation and aspiration have been discussed previously and are especially important in these patients.

Additional anesthetic considerations for esophagomyotomy procedures include pain control (non-endoscopic surgeries) and lung isolation (transthoracic approaches). The use of thoracoscopy to perform a transthoracic myotomy undoubtedly reduces pain intensity relative to that of a thoracotomy and may not require TEA, though many practitioners still prefer it. After induction and intubation with a DLT or SLT with blocker and placement of a gastric tube, the patient is turned in the lateral decubitus position, usually right lateral decubitus, and the transthoracic myotomy is performed. Most patients can be extubated in the operating room after return of protective airway reflexes. The gastric tube is usually removed and feedings initiated and advanced after the return of normal peristaltic activity.

Anesthetic management for POEM has been described recently. Clinical series report the use of a balanced general anesthetic in endotracheally intubated patients with [444] and without [445] the preoperative use of an esophagoscope to clear esophageal contents. Aspiration risk is minimized by an extended NPO period (24–48 hours) and an extended period (3–5 days) of diet restricted to clear liquids in patients judged to be at higher risk based on esophageal food retention during prior EGD. Since carbon dioxide insufflation is

utilized for POEM procedures, the anesthesiologist is advised to monitor closely for potential problems and complications including hypercarbia, elevated ventilator pressures, and subcutaneous emphysema.

Surgery for Esophageal Diverticula

Zenker's Diverticulum

While Zenker's diverticulum is not a disorder of the thoracic esophagus, its repair is often undertaken by thoracic surgeons, and so it will be briefly discussed. Anesthetic management of patients with Zenker's diverticulum should be focused on the prevention of aspiration. Patients should be restricted to clear liquids for at least 24 h preoperatively and encouraged to manually express and empty the diverticulum prior to anesthetic induction if this is possible. Other efforts to avoid aspiration of diverticular contents include a head-up position (30°) during induction and a rapid sequence induction without cricoid pressure. In the patient with difficult airway anatomy, it may be preferable to intubate the trachea prior to induction of anesthesia. Caution should be exercised during placement of a gastric drain tube or esophageal bougie as these may enter the diverticulum and cause perforation.

Thoracic Diverticula

Patients presenting with thoracic esophageal diverticula may represent a subclass of patients at the highest risk for aspiration in the perioperative period. The reasons for this are twofold. First, these diverticula may be large and potentially contain significant quantities of food material. Second, these diverticula cannot be emptied by manual expression, though drainage may be possible with the careful placement of a large-bore drain tube. Additionally, most thoracic diverticula are associated with an esophageal motility disorder such as achalasia which is itself a high-risk condition with regard to aspiration. Thus, all reasonable precautions should be taken, including a head-up position if appropriate and either a rapid sequence induction or an awake intubation depending on the anticipated ease of airway management.

Transthoracic repair of esophageal diverticula is usually accomplished via a left thoracotomy incision. Surgical exposure is facilitated by lung isolation and OLV. During dissection, the anesthesiologist may assist by passing a large esophageal bougie with surgical guidance until it passes the diverticular aperture. If not already in situ, a nasogastric tube should be placed prior to emergence and should remain in place until esopohageal integrity has been demonstrated by a contrast esophagram several days postoperatively. Most patients presenting for elective transthoracic resection of esophageal diverticula can be extubated following the procedure provided that a suitable plan for pain control has been initiated.

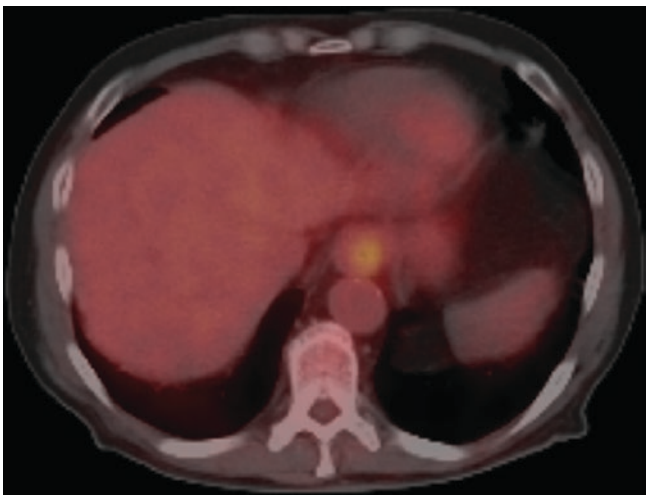

Fig. 38.10 PET scan reveals focal soft tissue thickening with increased uptake of FDG in the distal esophagus at the gastroesophageal junction consistent with esophageal carcinoma

Esophageal Surgery Clinical Case Discussion

Case: A 61-year-old male presents with a 14-month history of episodic dysphagia to solids that is progressively worsening. He notes no pain or weight loss. His evaluation included an EGD and biopsy showing high-grade dysplasia with features highly suspicious for invasive esophageal adenocarcinoma. Further evaluation in preparation for surgery included a whole-body PET-CT scan following injection of 14.014 mCi of F-18-FDG intravenously. Figure 38.10 shows the distal esophageal lesion illuminated by the marker. His past medical history is significant for CAD (MI 12 years prior treated with angioplasty). He has not had a recent cardiac catheterization. He also has intermittent supraventricular tachycardia (PSVT) controlled with diltiazem. He denies ever having a electrophysiologic study performed. He also suffers from HTN (enalapril), hypercholesterolemia (simvastatin), and asthma (albuterol as needed and Claritin). His only prior surgeries are a C4–7 discectomy and fusion and a L4–S1 laminectomy. He is scheduled for an Ivor Lewis esophagectomy.

Questions

- What further preoperative evaluation might be considered reasonable?
- What are the anesthetic considerations for this esophageal surgery?
- What specific intraoperative preparation of this patient might be prudent?
- What are postoperative considerations for this patient?

Focused preoperative history, physical, and investigations:

- Patient reports a daily requirement for his MDI and has recovered recently from a viral pharyngitis (physical exam, preoperative MDI use; see Chap. 8).
- Cardiac evaluation: baseline ECG to evaluate impulse initiation site, AV node conduction, and QTc in the context of PSVT history and diltiazem use. Stress echocardiogram to evaluate audible murmur and function (see Chap. 2).
- Careful airway evaluation with particular attention to cervical extension after cervical fusion.
- Focused neurologic exam to identify any preoperative deficits given the risk of position-related neurologic injury in left lateral decubitus position (see Chap. 19).

What intraoperative management considerations will optimize the patient's surgery?

- Thoracic epidural to provide postoperative analgesia for a right thoracotomy and upper midline laparotomy (see Chaps. 38 and 59).
- Avoidance of beta-blockade because of a significant history of reactive airway disease and chronic calcium channel blockade use. Intraoperative application of external electrodes for emergency cardioversion, pacing, or defibrillation. Calcium channel blockers indicated for treating hemodynamically stable PSVT (see Chap. 8).
- Fluid management strategy which seeks to optimize overall oxygen delivery, with particular attention to the high-risk esophageal anastomosis. A variety of methods can be used to guide fluid therapy (base deficit, serum lactate, mixed venous O_2 saturation). Optimal fluid management will seek to optimize cardiac output and oxygen delivery while avoiding excessive fluid administration (see Chaps. 21 and 38).
- High postoperative risk of atrial arrhythmias, in particular, atrial fibrillation. Treatment usually includes rate control with a beta-blocker especially in the patient with CAD, but preoperative use of a calcium channel blocker and history of asthma may preclude its use. Amiodarone can be used if atrial fibrillation is sustained and resistant to rate control with calcium channel blockers (see Chaps. 53 and 56).

Anesthesia for Robotic Thoracic Surgery

39

Javier Campos

Key Points

- The management of the robotic thoracic surgical patient requires the knowledge of minimally invasive surgery techniques involving the chest.
- Familiarity with the da Vinci® robot surgical system by the anesthesiologist is mandatory.
- Management of one-lung ventilation techniques with a left-sided double-lumen endotracheal tube or an independent bronchial blocker is required, along with flexible fiber-optic bronchoscopy techniques.
- Patient positioning and prevention of complications such as nerve or crashing injuries, while the robotic system is used.
- Recognition of the hemodynamic effects of carbon dioxide (CO_2) during insufflation in the chest is required.
- Potential for conversion to open thoracotomy or open procedure in the abdomen.

Introduction

Minimally invasive surgery approaches have become increasingly popular in cardiac, thoracic, and esophageal surgery [1–5]. With the introduction of robotic systems, specifically the da Vinci® robot surgical system, more than 10 years ago, a wide variety of surgical operations have been performed with some provocative results and limited defined advantages. This chapter provides an overview of the anesthetic implications and the use of the robotic system in patients undergoing mediastinal mass resection, pulmonary resections, and esophageal surgery.

The da Vinci® Robot Surgical System

The da Vinci® robot surgical system provides three-dimensional (3D) video imaging plus a set of telemanipulated flexible effector instruments [6]. The system consists of three major components, a console for the operating surgeon, a patient-side cart with four interactive robotic arms, and a vision cart including optical devices for the robotic camera [7]. Figure 39.1 displays the da Vinci® robot surgical system.

In brief the surgeon operates while seated at a console and views a 3D image of the surgical fields through the vision system. The patient-side cart (the actual robot) consists of three or four robotic arms, two or three instrument arms, and one endoscope arm which houses the camera. A full range of EndoWrists (Intuitive Surgical) instruments are used to assist with the surgery. These EndoWrists provide seven degrees of motion which exceeds the capacity of a surgeon's hand in open surgery and two degrees of axial rotation to replicate human wrist-like movements. In clinical practice, the first two arms,

Fig. 39.2 Displays the console and a surgeon seated and performing robotic surgery

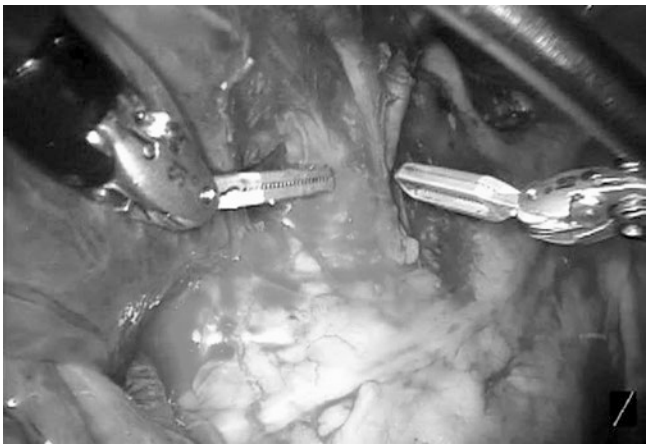

Fig. 39.3 Displays the EndoWrist instruments during a thoracic surgical case

representing the surgeon's left and right hands, hold the EndoWrist instruments; a third arm positions the endoscope; and the optional fourth arm, which represents the latest design in the da Vinci® robot surgical system, adds surgical capabilities by enabling the surgeon to add a third EndoWrist instrument. The surgical instruments are introduced via special ports and attached to the arms of the robot. The surgeon sitting at the console triggers highly sensitive motion sensors that transfer the surgeon's movement to the tip of the instruments. In addition, the da Vinci robot surgical system has developed the da Vinci skills simulator; therefore surgeons and surgical teams can participate with the system skill exercise within their specialty. Figure 39.2 displays the console and a surgeon seated and performing robotic surgery. Figure 39.3 displays the EndoWrist instruments during a thoracic surgical case.

Robotic surgical procedures are usually performed by two surgeons, the surgeon at the console and the table-side surgeon, who introduces the trocars and connects them with the robotic arms and changes the robotic instruments through the other ports if needed. The size of the robotic trocar is 10 mm for the binocular robotic camera and 8 mm for the instruments. Some of the potential advantages of using a robotic surgical system in thoracic surgery include shorter hospital length of stay, less pain, less blood loss and transfusion, minimal scarring, faster recovery, and probably a faster return to normal activities [8, 9]. Table 39.1 displays the advantages and disadvantages of robotic thoracic surgery. Table 39.2 displays the surgical procedures performed in thoracic surgery with the da Vinci® robot surgical system.

Table 39.1 Advantages and disadvantages of robotic thoracic surgery

Advantages of robotic thoracic surgery
Shorter hospital length of stay
Less pain
Less blood loss and need for transfusion
Minimal scarring
Faster recovery
Faster return to normal activities
Disadvantages
Increasing surgical times
Increased number of operating room personnel needed
Potential for conversion to open procedure
Cost and outcomes (need to be compared with other techniques)

Thymectomy
Mediastinal mass resection
Nissen fundoplications
Esophageal dissections
Esophagectomy
Pulmonary lobectomy

Anesthetic Implications in Robotic Thoracic Surgery

The basic principles applied to minimally invasive surgery of the chest (i.e., thoracoscopic surgery; see also Chap. 24) also apply to robotic-assisted thoracic surgery. The combination of patient position, management of one-lung ventilation (OLV) techniques, and surgical manipulations alters ventilation and perfusion from the dependant and nondependant or collapsed lung. The preferred method for lung isolation during robotic-assisted thoracic surgery is the use of a left-sided double-lumen endotracheal tube (DLT) because of the greater margin of safety and faster and more reliable lung collapse. Also, it provides ready access for bronchoscopic evaluation of the airway during surgical resection.

In general, careful attention must be given to airway devices because changes in body position may cause tube

migration. OLV anesthetic management is more challenging during robotic thoracic surgery due to the presence of the robot chassis that is stationed over the patient. The patient's airway is also usually located far from the anesthesia field. In some instances, access to the airway, if needed, is not optimal because of the presence of the robotic arms nearby. In addition, visualization during robotic thoracic surgery may be enhanced by continuous intrathoracic carbon dioxide (CO_2) insufflation, which may increase airway pressures. When CO_2 is used, it should not exceed intrathoracic pressures of 10–15 mmHg. Increasing the intrathoracic pressure (i.e., >25 mmHg) can compromise venous return and cardiac compliance; also the dependant lung develops higher airway pressures, and ventilation can become difficult. During the surgical procedure, the FiO_2 should be maintained at 100%, and the peak inspiratory pressure should be kept <30 cm H_2O. The ventilatory parameters should be adjusted to maintain a $PaCO_2$ at approximately 40 mmHg.

Robotic-Assisted Surgery and Anesthesia for Mediastinal Masses

Among the thoracic surgical procedures performed to date with the use of the da Vinci® robot surgical system is thymectomy [10]. Of the patients scheduled for robotic-assisted thymectomy, some have the diagnosis of myasthenia gravis because of the presence of a thymoma. Preparation of the patient for surgery includes neurological evaluation to assess the patient's neurological status and optimization of neurological conditions; continuation of anticholinesterase therapy and plasmapheresis may be indicated in some cases [11, 12] (see also Chap. 15). Precautions regarding anesthetic management include the proper dosing of muscle relaxants and the potential consequences of a large mediastinal mass on oxygenation and ventilation.

Positioning the patient for a thymectomy with the use of the robot system requires an optimal surgical position. In these cases, the patients are placed in an incomplete side-up position at a 30° angle right or a left lateral decubitus position with the use of a beanbag. The arm of the elevated side is positioned at the patient's side as far back as possible so the surgeon can gain enough space for the robotic arms (Fig. 39.4). While the robot is in use, it is imperative to consider strategies to protect all pressure points and to avoid unnecessary stretching of the elevated arm because this can cause damage to the brachial plexus. Also, because the arm of the robot is in the chest cavity, a complete lung collapse must be maintained throughout the procedure. Robotic surgery with the da Vinci® robot surgical system does not allow for changes in patient position on the operating room table once the robot has been docked. Robotic thymectomy requires that the operating room table be rotated 90° away from the anesthesiologist's field. For this reason access to the airway to make adjustments to the DLT during the surgery can be challenging. In some cases, a bilateral approach may be required. In these cases, the operation is performed in two stages and requires rotating the table 180° to provide the surgeon access to the contralateral chest for the second stage of the operation. The anesthesiologist must be cautious during these changes to avoid problems with the airway and to ensure that the lines and monitor wires have enough slack to accommodate changes in position. The anesthesiologist must be aware during these cases about possible injury to the contralateral pleura, especially if CO_2 capnothorax is being used, as the elevated intrathoracic pressure in the contralateral hemithorax can make ventilation difficult and cause cardiovascular collapse or tension pneumothorax because of malfunction of the chest tube. Special attention must be given to the patient's elevated arm and head to prevent crushing injuries with the robotic arms. A recent case report [13] showed a brachial plexus injury in an 18-year-old male after robot-assisted thoracoscopic thymectomy. In this report, the left upper limb was in slight hyperabduction. It is important to keep in mind that hyperabduction of the elevated arm to give optimal space to the operating arm of the robot can lead to a neurologic injury. Close communication between surgeon and anesthesiologist in relation to the positioning and function of the robot is mandatory, and all proper measures must be taken, including the use of soft padding and measures to avoid hyperabduction of the arm. The elevated arm should be protected by using a sling resting device. Operating room staff should always be vigilant of telescope light sources because direct contact of these devices with surgical drapes and the patient's skin can quickly cause serious burns, while telescopes and cameras are being changed.

Fig. 39.4 Mediastinal mass resection

An early report by Bodner et al. [14] involving 13 patients with mediastinal masses resected with the da Vinci® robot

surgical system showed no intraoperative complications or surgical mortality. In this series of patients, a complete thymectomy with en bloc removal of all mediastinal fat around the tumor was performed. In this report, cases were restricted to patients with a tumor size less than 10 cm in diameter.

In a report by Savitt et al. [4] involving 14 patients undergoing robot-assisted thymectomy, all patients received a DLT for selective lung ventilation; in addition, patients were managed with arterial and central venous pressure catheters. Complete thymectomy was performed on all 14 patients. Right-lung deflation was accomplished with selective lung ventilation and CO_2 insufflation to a pressure of 10–15 mmHg to maintain the lung away from the operative area. It is important that the anesthesiologist recognizes the effects of CO_2 insufflation in the thoracic cavity. The outcome of this report included no conversion to open thoracotomy nor any intraoperative complications or deaths; the median hospital stay was 2 days with a range of 1–4 days.

In another report, Rückert et al. [9] had zero mortality and an overall postoperative morbidity rate of 2% in 106 consecutive robot-assisted thymectomies. Therefore, robotic thymectomy is a promising technique for minimally invasive surgery. Length of stay was shorter with robotic thymectomy when compared to the conventional approach via sternotomy. Figure 39.5 displays a case of mediastinal mass resection.

A recent systematic review and meta-analysis comparing robotic-assisted minimally invasive surgery versus open thymectomy [15] clearly showed that the patients undergoing robotic thymectomy have a reduced hospital length of stay, less intraoperative blood loss, fewer chest-in-tube days, and less postoperative complications when compared to open thymectomy.

In contrast another meta-analysis study [16] comparing robotic-assisted minimally invasive thymectomy versus video-assisted thoracic surgery thymectomy showed no statistically significant differences in surgery outcomes among the two groups (no significant difference on conversion rates, surgical times or average days, or length of stay).

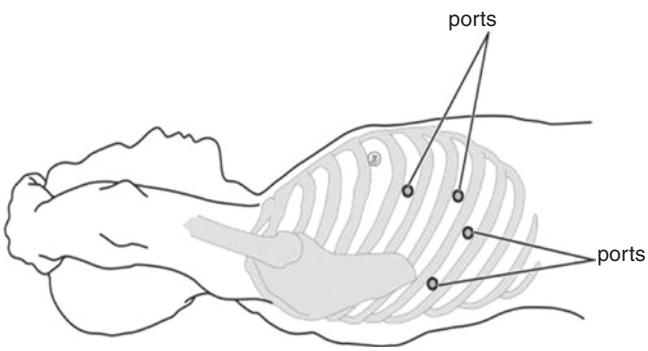

Fig. 39.5 Positioning during robotic thoracic approach

In addition the indications for the use of the robotic surgery have been extended for cases with posterior mediastinal tumor where the access can be challenging and it reported good outcomes [17, 18].

Robotic-Assisted Pulmonary Lobectomy

With the introduction of the da Vinci® robot surgical system, there has been widespread interest in its use in minimally invasive surgery involving the chest [19–21]. Lobectomy with lymph node dissection remains the cornerstone of radical resection of early-stage cancer [22]. However due to the use of low-dose computed tomography, CT scans are increasing the number of patients diagnosed with early-stage disease each year; these patients can be treated via lobectomy or segmentectomy. In order to offer more minimally invasive resection options to patients with lung disease, video-assisted lobectomy/segmentectomy and subsequently robotic-assisted lobectomy/segmentectomy approaches have been developed [23].

The robotic-assisted lobectomy/segmentectomy has attracted interest of thoracic surgeons since its introduction in 2002. The advantages of robotic lobectomy/segmentectomy include smaller incisions, decreased postoperative pain, faster recovery time, and superior survival when compared to conventional open thoracotomy [19].

A report by Park et al. [24] showed robot-assisted thoracic surgical lobectomy to be feasible and safe. In the report, the operation was accomplished with the robotic system in 30 out of 34 scheduled patients. The remaining four patients required conversion to open thoracotomy. Anderson et al. [25] reported a series of 21 patients that underwent robotic lung resection for lung cancer. In this report, the 30-day mortality and conversion rate was 0%. The median operating room time and blood loss were 3.6 h and 100 mL. The complication rate was 27% and included atrial fibrillation and pneumonia. Gharagozloo et al. [26] reported a series of 100 consecutive robotic-assisted lobectomies for lung cancer and concluded that robotic surgery is feasible for mediastinal, hilar, and pulmonary vascular dissection during video-assisted thoracoscopy lobectomy.

Positioning the patient for a robotic lobectomy includes placing the patient over a beanbag in a maximally flexed lateral decubitus position with the elevated arm slightly extended so that the thoracic cavity can be accessed and no damage to the arm occurs during manipulation of the robotic arms. Patients undergoing robotic lobectomy must have a lung isolation device to achieve OLV. In the vast majority of these cases, a left-sided DLT is used, and optimal position is achieved with the flexible fiber optic bronchoscope [27]. In a few cases in which the airway is deemed to be difficult, an independent bronchial blocker could be used and optimal

position achieved with the use of a fiber optic bronchoscope [28]. Initial thoracic exploration is performed with conventional thoracoscopy to verify tumor location. During robot-assisted lobectomy, it is mandatory that lung collapse is achieved effectively to allow the surgeon the best field of vision and to avoid unnecessary damage to vessels or lung parenchyma.

All patients undergoing robot-assisted thoracic lobectomy should have an arterial line. The anesthesiologist must be ready for potential conversion to an open thoracotomy. In the Park report [24], three out of four cases that needed to be converted had minor bleeding; in addition, in one case lung isolation was lost, requiring an open thoracotomy. It is mandatory that the anesthesiologist involved in these cases has experience in placing a DLT [29] and can guarantee optimal position with the aid of flexible fiber optic bronchoscope. Using intraoperative fiber optic bronchoscopy to make adjustments to the DLT during surgery is challenging because the table is rotated 180° away from the anesthesiologist's field. The chassis of the robot is often positioned over the patients' head leaving a very small area for the anesthesiologist to access the airway.

A report by Gharagozloo et al. [26] involving 100 patients who underwent lobectomy and complete mediastinal nodal dissection for early-stage lung cancer (stages I and II) with the robotic system reported 1 nonemergent conversion to open thoracotomy. In this report, postoperative analgesia was managed with the infusion of a local anesthetic (0.5% bupivacaine, 4 mL/h) through catheters placed in a subpleural tunnel encompassing intercostal spaces 2 through 8. All patients were extubated in the operating room. Mean operating room time was 216 min (range 173–369). Overall mortality within 30 days was 4.9%, and median length of stay was 4 days. Postoperative complications included atrial fibrillation in four cases, prolonged air leak in two cases, and pleural effusion requiring drainage in two cases – complications that are not different from those occurring with video-assisted thoracoscopic surgery.

A meta-analysis report [30] in 2015 has evaluated the perioperative outcomes of robotic-assisted thoracoscopic surgery for early-stage lung cancer. This meta-analysis report showed that the morbidity and perioperative 30-day mortality were similar in both groups. In contrast a recent meta-analysis study [23] comparing robotic- versus video-assisted lobectomy/segmentectomy for lung cancer showed that robotic lobectomy is a feasible and safe alternative to a video-assisted thoracoscopic surgery with a low 30-day mortality and similar morbidity; also this study reported lower open thoracotomy conversion rate, but longer operative time which increases the cost of surgery. Robotic cases surgical times must be shorter with a reduced cost and improve morbidity to become an alternative to other surgical techniques.

Acute and chronic pain after open thoracotomy continues to be a problem [31]. Minimally invasive thoracic surgery approach results in less tissue trauma, shorter recovery, and improved cosmesis [32, 33]. A recent study [34] evaluating the outcomes of the acute and chronic pain after robotic, video-assisted thoracoscopic surgery or open anatomic pulmonary resection showed that robotic- and video-assisted thoracoscopic surgery (VATS) approach resulted in less acute pain and chronic numbness when compared to open thoracotomy. However, there was no significant difference between robotic- and video-assisted thoracic surgery. This report indicates that in terms to pain control, there are no difference regardless what minimally invasive surgery the surgical team chooses and no advantage of one versus the other technique (robotic vs VATS).

Carbon Dioxide Insufflation During Robotic Surgery

Continuous low-flow insufflation of CO_2 has been demonstrated as an aid for surgical exposure during minimally invasive thoracic procedures. It has been used as the only means of providing surgical exposure to the thoracic cavity (during two-lung ventilation for VATS) or more frequently in conjunction with a DLT or an independent bronchial blocker and OLV. The compression of the lung parenchyma by CO_2 acts as a retractor [35].

A study by Ohtsuka et al. [36] involving 38 patients undergoing minimally invasive internal mammary harvest during cardiac surgery found significant increases in mean central venous pressure, pulmonary artery pressure, and the pulmonary artery wedge pressure. They also found that with insufflation of the right hemithorax, but not the left side, slight decreases were noted in the mean arterial blood pressure and cardiac index. They concluded that the hemodynamic effect from continuous insufflation of CO_2 at 8–10 mmHg for 30–40 min is mild in both hemithoraces, although the impact is greater on the right. This information was supported by another study [37]. This study involving 20 patients undergoing thoracoscopic sympathectomy and concluded that compared to the left side hemithorax, the impact of CO_2 insufflation on the vena cava and the right atrium during right-sided procedures was associated with reduction of venous return and low cardiac index and stroke volume. The impact of CO_2 insufflation on the respiratory system has also been studied. El-Dawlatly et al. [38] reported a significant pressure-dependent increase in peak airway pressure and a decrease in dynamic lung compliance but no difference in tidal volume or minute ventilation during volume-controlled ventilation.

Insufflation of CO_2 should only be started after initial thoracoscopic evaluation has ruled out that the port of insuf-

flation has not compromised a vascular structure or the lung parenchyma. Communication between the surgeon, anesthesiologist, and operating room personnel is crucial at this point. Insufflation is ideally started at low pressures of 4–5 mmHg and is gradually increased while monitoring the patient's vital signs. The anesthesiologist should always be aware of the possibility of gas embolization during these cases. In the case of sudden cardiac collapse, the CO_2 flow should be discontinued immediately. Ventilation during CO_2 insufflation should be titrated to keep adequate oxygenation and a normal $PaCO_2$ and pH. Also, damage to the contralateral pleura may occur resulting in CO_2 flow to the contralateral chest, making ventilation difficult and also causing hemodynamic compromise, along with the potential development of subcutaneous emphysema. In addition, venous return compromise or progressive arterial desaturation can occur [39, 40].

Robotic-Assisted Esophageal Surgery and Anesthetic Implications

Transthoracic esophagectomy with extended lymph node dissection is associated with higher morbidity rates than transhiatal esophagectomy. Esophagectomy is a palliative and potentially curative treatment for esophageal cancer. Minimally invasive esophagectomy has been performed to lessen the biological impact of surgery and potentially reduce pain. The initial esophagectomy experience with the da Vinci® robot surgical system involved a patient who had a thoracic esophagectomy with wide celiac axis lymphadenectomy. The case was reported by Kernstine et al. [41] and had promising results. Thereafter another report using the da Vinci® robot surgical system has been published of six patients undergoing esophagectomy without intraoperative complications [42]. The surgical approach in this report was performed from the right side of the chest. A left-sided DLT was used to selectively collapse the right lung, while, at the same time, ventilation was maintained in the left lung.

In a report by Hillegersberg et al. [43] involving 21 consecutive patients with esophageal cancer who underwent robot-assisted thoracoscopic esophagolymphadenectomy, 18 were completed thoracoscopically, and 3 required open procedures (because adhesions or intraoperative hemorrhage). In this case series report, all patients received a left-sided DLT and a thoracic epidural catheter as part of their anesthetic management. Positioning of these patients was in a left lateral decubitus position, and the patient was tilted 45° toward the prone position. Once the robotic thoracoscopic phase was completed, the patient was then put in supine position, and a midline laparotomy was performed. A cervical esophagogastrostomy was performed in the neck for the completion of surgery.

Of interest in this series is the fact that pulmonary complications occurred in the first ten cases (60%), caused primarily by left-sided pneumonia and associated acute respiratory distress syndrome in three patients (33%). These complications were probably related to barotrauma to the left lung (ventilated lung) attributed to high tidal volumes and high peak inspiratory pressures. In the 11 patients that followed, the same authors modified their ventilatory setting to administer continuous positive airway pressure ventilation 5 cm H_2O during single-lung ventilation, and pressure-controlled ventilation was used; with this approach the respiratory complication rate was reduced to 32%.

A recent report by Kim et al. [44] described 21 patients who underwent robotic-assisted thoracoscopic esophagectomy performed in a prone position with the use of a Univent® bronchial blocker tube (Fuji Systems Corp, Tokyo Japan). All thoracoscopic procedures were completed with robotic-assisted techniques followed by a cervical esophagogastrostomy. In Kim's report, major complications included anastomotic leakage in four patients, vocal cord paralysis in six patients, and intra-abdominal bleeding in one patient. The prone position led to an increase in central venous pressure and mean pulmonary arterial pressure and a decrease in static lung compliance. The overall conclusion from this report is that robotic-assisted esophagectomy in the prone position is technically feasible and safe. Others have reported a robotic-assisted transhiatal esophagectomy technique feasible and safe as well [45].

Another study [5] involved 14 patients who underwent esophagectomy using the da Vinci® robot surgical system in different surgical stages. It showed that for a complete robotic esophagectomy including laparoscopic gastric conduct, the operating room time was an average of 11 h with a console time by the surgeon of 5 h and an estimated mean blood loss of 400 ± 300 mL. In this report after the robotic thoracoscopic part of the surgery was accomplished with the patient in the lateral decubitus position, patients were then placed in supine position and reintubated, and the DLT was replaced with a single-lumen endotracheal tube. The head of each patient was turned upward and to the right, exposing the left neck for the cervical part of the operation. Among the pulmonary complications in the postoperative period, arterial fibrillation occurred in 5 out of 14 patients.

In Kernstine's report [5] among the recommendations to improve efficiency in these cases is the "use of an experienced anesthesiologist who can efficiently intubate and manage single-lung ventilation and hemodynamically support the patient during the procedure." This follows what Nifong and Chitwood [29] have reported in their editorial views regarding anesthesia and robotics: that a team approach with expertise in these procedures involving nurses, anesthesiologists, and surgeons with an interest in robotic procedures is required.

The data on robotic-assisted esophagectomy suggest that the procedure is safe, feasible, and associated with preoperative outcomes similar to open and minimally invasive esophagectomy. No data, however, demonstrate improved outcomes in terms of operative morbidity, pain, operative time, or total costs [46]. Table 39.3 displays the complications of robotic-assisted thoracic surgery involving the mediastinum lung and esophagus.

Although the outcome of robotic-assisted minimally invasive esophagectomy compared to thoracic minimally invasive esophagectomy is comparable, one of the advantages of using robotic technique is the reduced incidence of vocal cord paralysis. Three-dimensional images enhance identification of recurrent laryngeal nerve; therefore it could reduce the chance of damaging the nerve. One study [47] reported a reduced incidence of vocal cord paralysis around 50% when robotic-assisted technique was used (6/38 versus 15/20); other reported complications include anastomotic leakage, bleeding, dysrhythmia, and acute lung injury [48–50].

Summary

The use of the da Vinci® robot surgical system in thoracic and esophageal surgery continues to gain acceptance. Although its use has reduced surgical scarring and decreased length of stay, specific indications for use in these areas need to be determined. All reports to date describe the use of lung isolation devices, most often a left-sided DLT, as part of the intraoperative management of thoracic surgery patients to facilitate surgical exposure. In addition, because the surgical approach varies depending on the thoracic procedure, optimal positioning is not standard and varies among the specific surgical procedures. Vigilance is required with patients' elevated arms to avoid nerve injuries or crush injuries from the robotic arms. Continuous low-flow insufflation of CO_2 has been used as an aid for surgical exposure during minimally invasive thoracic procedures. The potential to convert to an open thoracotomy requires preparation by the surgical team and anesthesiologist. The use of the da Vinci® robot surgical

Anaesthesia for Combined Cardiac and Thoracic Procedures

40

Marcin Wąsowicz

Key Points

- From a physiologic point of view, alveolar-capillary membrane is the most important part of the respiratory system. It always undergoes micro-injury during cardiac surgery with the use of cardiopulmonary bypass. Therefore, a second insult, such as loss of part of the pulmonary parenchyma, can lead to acute lung injury and unfavourable outcomes from combined thoracic and cardiac procedures.
- Additional insult to the respiratory system can be caused by phrenic nerve injury subsequent diaphragmatic dysfunction and disturbances in chest wall mechanics caused by sternotomy or thoracotomy.
- Clinicians should be very selective in choosing to combine pulmonary resection and heart surgery. Concomitant pulmonary resection and cardiac surgery entail substantial additional risk, especially pulmonary complications and bleeding problems. These procedures should be performed in tertiary care centres with expertise in cardiac and thoracic surgery including use of extracorporeal life support systems.
- Anaesthetic management must be individualized and based on preoperative assessment, extent of surgery and need to use cardiopulmonary bypass. Anaesthesiologists managing these cases should have extensive training in both cardiac and thoracic anaesthesia. An expertise in transesophageal echocardiography is strongly recommended.

Introduction

Combined cardiac and thoracic procedures are rare; however thanks to progress of surgical techniques and recent advances in use of extracorporeal life support (ECLS) techniques the number of these procedures is increasing.

Anaesthesia and optimal perioperative management for these complex, high-risk surgical interventions requires an expertise in both cardiac and pulmonary physiologies, lung isolation techniques, the multiorgan impact of cardiopulmonary bypass (CPB) and additional monitoring techniques (e.g. transesophageal echocardiography-TEE). Combined procedures may include excision of invasive tumours, pulmonary endarterectomy, cardiac revascularization combined with lung resection and cardiac procedures combined with lung transplantation (e.g. PFO closure). Optimal management of these procedures remains controversial and is not well described; in fact it is mainly limited to case reports [1, 2]. Proponents of single-stage operations will argue in favour of the avoidance of a second surgery and anaesthetic and reduced hospital stay [2, 3]. The opponents will argue for divided, two-stage procedures on the basis of limiting surgical trauma, blood loss, multiorgan impact of cardiopulmonary bypass and high intensive care morbidity and thus may potentially confer a better long-term survival [3, 4].

The following chapter will briefly describe the anaesthetic management for various combined thoracic and cardiac procedures. For a better understanding of why CPB is detrimental for lung function, the author will briefly describe the structure and function of the air-blood barrier and pathophysiology of its injury during procedures with the use of CPB.

Structure of the Alveolar-Capillary Barrier

The human lung consists of 300,000,000 alveoli. Each of them has a dense network of capillaries, which form air-blood barriers (alveolar-capillary membranes). From a phys-

iological point of view, the air-blood barrier is the most important part of the respiratory system. It is the site of gas exchange. Additionally, the alveolar-capillary barrier separates the external environment from the pulmonary circulation, regulates transport of fluid and molecules from alveoli to capillaries and is a vital part of the natural defence mechanism of the human body (see also Chap. 7) [5].

Structure *The* alveolar-capillary barrier has three components: thin processes of type I pneumocytes (epithelial cells), endothelial cells and their common basement membranes (Fig. 40.1). Typically, endothelial and epithelial cells have separate basement membranes; but the pulmonary alveolus is a unique site where the basement membranes are fused together. This creates an extremely thin barrier (0.2–0.4 μm) enabling efficient exchange of oxygen and carbon dioxide [6, 7]. The processes of type I pneumocytes are very thin and

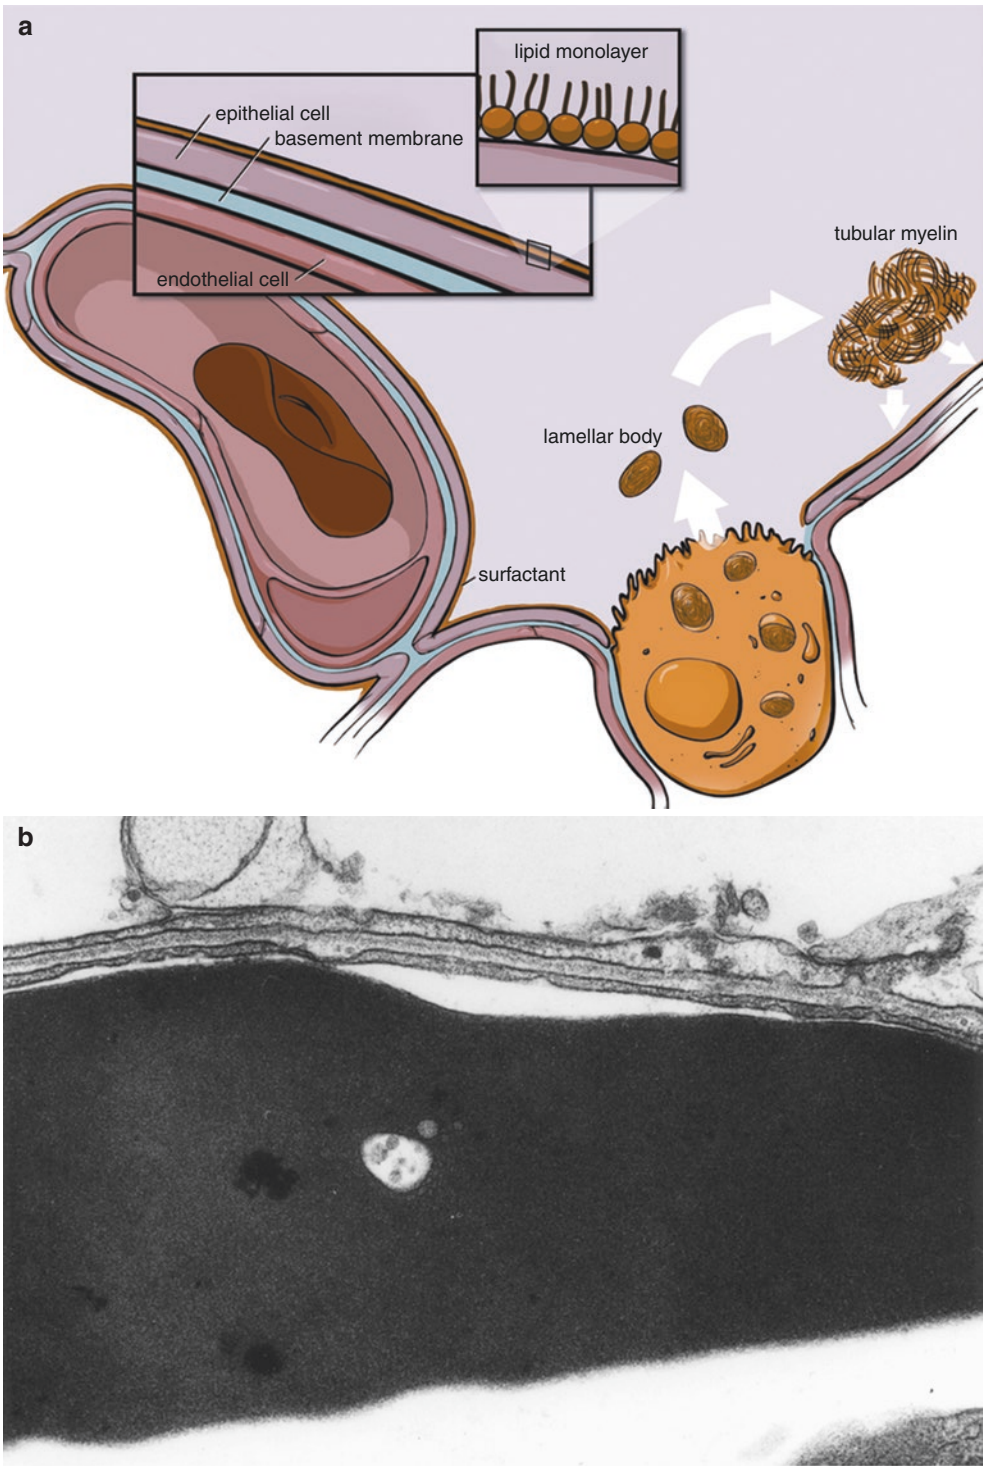

Fig. 40.1 (**a**) Picture presents a scheme of an air-blood barrier, which consists of endothelial cell, epithelial cell (type I pneumocyte) and their common basement membrane. Large cuboidal cell is type II pneumocyte producing surfactant contained within its cytoplasm as lamellar bodies (onion-like structures), which are exocytosed into the alveolar lumen and then transform into tubular myelin and finally monolayed of the surfactant covering the surface of type I pneumocytes. Left-hand side inset shows details of thin alveolar-capillary membrane; right-hand side inset shows a scheme on surfactant monolayer. (**b**) Electron microscope photograph which is showing an air-blood barrier

cover 95% of the alveolar surface. The remaining 5% is covered by type II pneumocytes, which produce surfactant. Type II pneumocytes (also called granular cells) reside within the "corners" of the alveoli because their large cellular structure makes them inefficient for gas exchange (Fig. 40.1). Type II pneumocytes eventually divide into type I pneumocytes (progenitor cells). During injury of the alveolar surface, the damaged type I pneumocytes are replaced by large, cubical, quickly dividing, type II pneumocytes. These large cuboidal cells create a thicker alveolar-capillary barrier leading to inefficient gas exchange.

Tight intercellular junctions between epithelial cells (pneumocytes) are impermeable to fluid, which contrasts with endothelial cell junctions which are highly permeable to fluids and allow the continuous exchange of plasma components between capillaries and the pulmonary interstitium. The common basement membrane consists of laminin, glycosaminoglycans, collagen type IV and fibronectin [6–8]. Glycosaminoglycans are concentrated on one side of basement membrane regulating its permeability. Among all the components of the alveolar-capillary barrier, this is the most critical part, and its injury leads to permanent damage of the blood-gas interface [9, 10]. There are three stabilizing elements of the alveolar-capillary barrier: surfactant, the pulmonary circulation and the connective tissue of the intra-alveolar septa [7, 11].

Surfactant Surfactant is composed from lipids (90%) and proteins (10%). The lipid component mainly consists of phosphatidylcholine (bipolar lipid) and phosphatidylglycerol [12]. Both lipids have a hydrophilic "head" and "lipophilic" tail (see Fig. 40.1a, right-hand inset]. Surfactant forms a monolayer lining the alveolar surface with the hydrophilic part directed towards the epithelial cells. The biochemical structure of the pulmonary surfactant resembles a detergent, surface-active layer, which aims to lower the surface tension and stabilizes the alveolar shape and structure. Surfactant protects the alveolus from collapse and prevents overdistension [13]. Moreover, surfactant acts as an anti-pulmonary oedema substance.

The protein component consists of four, distinct surfactant proteins – A, B, C and D (SP-A surfactant protein A, SP-B, SP-C and SP-D). These molecules play an important role in local defence mechanisms, surfactant metabolism, recirculation and spreading on the alveolar surface. Additionally they participate in local defence mechanisms. SP-A is a 28,000–36,000 kD protein and participates in monolayer formation and in recirculation of pulmonary surfactant. It has hydrophilic character. SP-D is the biggest surfactant protein (42,000 kD) and has also hydrophilic character, and its main role is to regulate local defence mechanisms. SP-B and SP-C are relatively small proteins (9.000 and 4.000 kD, respectively) with lipophilic character, and they are essential for monolayer formation [14]. Surfactant is produced in type II pneumocytes and is seen as so-called lamellar bodies (onion-like structures) (Fig. 40.2). Lamellar bodies are excreted into the alveolar lumen, transform into tubular myelin (Fig. 40.3) and then spread as a monolayer on the surface of type I pneumocytes (Fig. 40.1). The metabolism of surfactant is unique; it is recycled. Molecules of surface-active material are endocytosed back into type II pneumocytes and without any breakdown incorporated back into the lamellar bodies. Small amounts of surfactant (7–8%) are digested by alveolar macrophages. In the normal physiological situation, surfactant is not present within the pulmonary circulation (except for newborns when the lung is drying out after delivery). If surfactant is present within the pulmonary circulation, its amount reflects the extent of damage to the alveolar-capillary barrier [15, 16].

Pulmonary Circulation Flow through the pulmonary circulation equals the systemic flow enabling effective gas exchange. The pulmonary circulation also plays an important role in metabolic and filtrating functions of the lung. The pulmonary circulation is a low-pressure system, which is influenced by gravitation forces creating West's zones. The alveolar capillaries make contact with multiple alveoli,

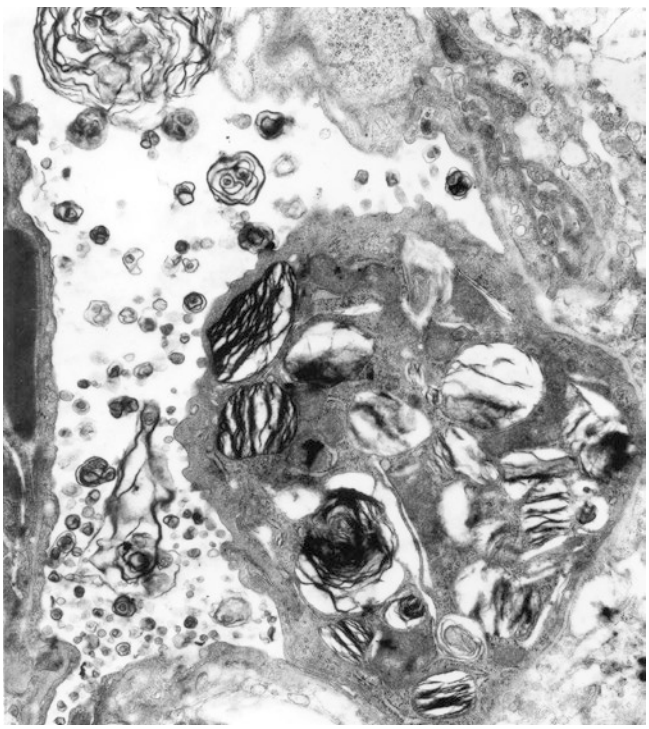

Fig. 40.2 Electron microscope photograph showing a type II pneumocyte filled with lamellar bodies (onion-like structures), some of them exocytosed into the lumen of the alveolar space

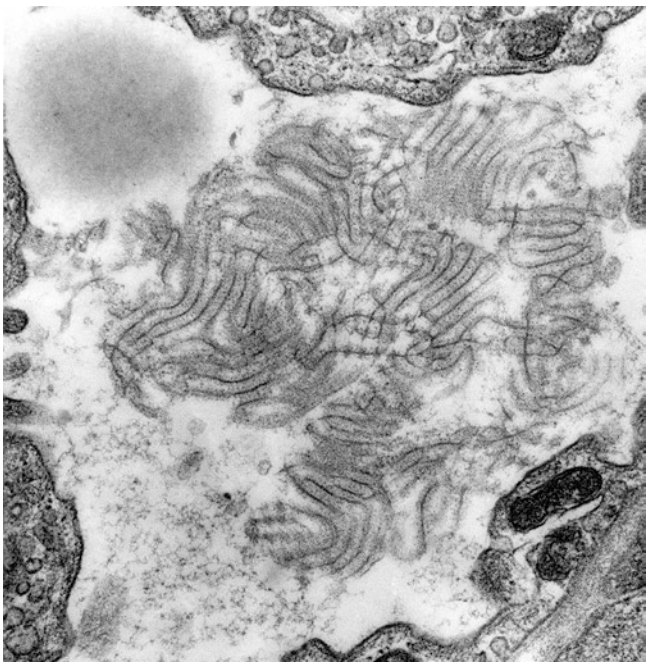

Fig. 40.3 Electron microscope picture, which presents structure of the tubular myelin

which increases the efficiency of gas exchange. The alveolar vessels are stabilized by a delicate network of collagen and elastic fibres, which form a continuum connected to basement membranes of the air-blood barriers. The location and structure of the alveolar capillaries make them susceptible to pressure changes occurring within the alveolar space. Rising intra-alveolar pressure will decrease the volume of the alveolar capillaries and increase their resistance.

Connective Tissue The connective tissue (mesenchyma) of the inter-alveolar septae is responsible for both their elasticity and mechanical resistance [11, 17]. The mesenchyma consists of the cellular and extracellular components. The cellular part is largely composed from fibroblasts, which are responsible for producing extracellular elements of the connective tissue, for example, collagen fibres, elastic fibres, fibronectin, entactin, glycosaminoglycans and components of the basement membranes [7]. The extracellular connective tissue forms a continuum extending from the hilum to each alveolus [18]. Thus any structural change within the lung tissue will have a transmitted effect upon every alveolus. This means that any change of shape within the lung affects every alveolus. Collagen fibres form the main mechanical support and restrictive force. This is counterbalanced by the presence of elastic fibres, which are responsible for the elastic recoil of lung parenchyma and its compliance. Collagen fibres are interwoven with elastic fibres, and both elements aid in stabilization of the alveolar-capillary membranes. During injury, the elastic fibres are more susceptible to damage, which creates an imbalance in the resistive-elastic forces of the lung in favour of a stiffer lung with low compliance.

Lung Injury During Surgery with Use of Cardiopulmonary Bypass

Combined cardiac and thoracic surgical procedures with the use of CPB are controversial. If a cardiac procedure is performed with the use of CPB and is combined with thoracic surgery, which involves resection of lung parenchyma (lobectomy or pneumonectomy), respiratory complications may reach an incidence as high as 49% [19, 20]. It is postulated that CPB is the main causative factor of the aforementioned complications; therefore the most common injuries of the respiratory system caused by CPB will be briefly described in the following paragraphs [21–23].

Respiratory complications occurring after cardiac surgery with use of CPB are relatively common, but the vast majority are mild and self-limiting [24–26]. It is important to emphasize that the cause of lung failure after operations involving CPB is multifactorial [27, 28]; patient factors combine with the direct detrimental effects of CPB to compromise pulmonary function in the early postoperative period. A second insult to the respiratory system, such as loss of part of the pulmonary parenchyma, can be detrimental and lead to acute lung injury and unfavourable outcomes.

Prolonged mechanical ventilation after cardiac surgery occurs in about 6–7% of patients, and strongest predictors of this complication are previous cardiac surgery, lower left ventricular ejection fraction, shock, surgery involving repair of congenital heart disease and cardiopulmonary bypass time [26]. The most severe form of injury to the respiratory system – acute respiratory distress syndrome (ARDS) – occurs in 1–2% of cardiac cases with a very high mortality (40%) [10, 24].

Histological Injury Most patients who undergo cardiac surgery with the use of CPB present some degree of histological lung injury [30]. Microscopic observations reveal a range of injuries detected within the structures of the air-blood barriers [7, 8, 30, 31]. Mild injury presents as oedema of endothelial (type I pneumocytes) and epithelial cells. More severe forms cause denuding of the basement membranes with loss of epithelial lining (Fig. 40.4). In the most severe cases, basement membranes of alveolar-capillary membranes lose their continuity, which means they are permanently damaged. The alveoli with damaged basement membrane fill with fluid and lamellar bodies (surfactant) are not able to spread on the surface of epithelial cells. Beyond the damage visualized within the alveolar-capillary membranes, authors have observed congestion within alveolar capillaries and the accumulation of polynuclear leukocytes (neutrophils), many

(Permission for publication obtained from Taylor & Francis, From Ref. [29])

of which are extravasated (Fig. 40.5). Upon migrating from the intravascular space to the interstitium or alveolar space, neutrophils are able to survive for 6 h. Subsequent breakdown of neutrophils will exacerbate alveolar damage by releasing an abundance of proteolytic enzymes, reactive oxygen species and free radicals [29, 32]. In summary, in all patients undergoing surgery utilizing CPB, some injury will occur within the pulmonary parenchyma [8, 30, 31].

Systemic Inflammatory Response Syndrome CPB causes a systemic inflammatory response syndrome (SIRS) [29, 32–35]. This leads to the activation of neutrophils, macrophages and multiple cytokines including complement and is commonly associated with free radical formation [32–37]. Complement proteins, mainly C3a and C5a, promote neutrophil activation, which can subsequently adhere to the endothelial cells and migrate into the interstitium promoting local damage and inflammation [36, 35]. The lung acts as a "filter" to activated neutrophils and therefore is often more vulnerable to CPB-related injury compared to other organs [24, 25]. In addition to the release of pro-inflammatory mediators and enzymes, activated neutrophils express surface receptors, CD11a and CD 18b, which facilitate further leukocyte-endothelial adhesion and chemotaxis. Those activated neutrophils, which remain within the lumen of the alveolar capillaries, tend to accumulate in congested blood vessels and release their contents causing "leakage" from alveolar capillaries to the extracellular spaces and alveolar lumen [29–31]. Neutrophils are not the only cells which are activated by an extracorporeal circuit. Macrophages also belong to the first line of cells which are stimulated by CPB [37]. They release multiple cytokines. The main cytokines involved in the inflammatory process and lung injury are interleukin 6 and 8. At the end of CPB, their concentration within the alveolar lining is much higher than within plasma [32, 33, 35].

Lipid Peroxidation Another line of activation caused by CPB is lipid peroxidation and release of free radicals [38]. They are mainly freed as a consequence of ischemia-reperfusion injury. It should be stressed that during aortic cross-clamp, the lung has no blood supply, except for a small amount of flow coming from the bronchial arteries. During reperfusion, large amounts of free radicals are flushed from ischemic lung tissue (as a result of xanthine oxidase activation) [16]. Free radicals have a high affinity for cellular membranes causing oxidation of lipid components (so-called peroxidation) [39, 40]. Free radicals also activate leukocytes [24].

Surgical Factors CPB is not the only cause of respiratory system dysfunction after cardiac surgery. Other common factors include:

- Changes in lung mechanics related to sternotomy, internal mammary artery harvesting and other surgical manipulations. These present as an increased elastance of the pulmonary tissue (decreased compliance). Decreased compliance is also caused by the injury caused by CPB, i.e. increased pulmonary vasculature permeability, positive fluid balance and accumulation of neutrophils [41].

- Atelectasis is a common postoperative complication after any major, prolonged surgery performed under general anaesthesia. Atelectasis occurs in up to 70% of patients undergoing cardiac surgery with or without the use of CPB [27, 41]. After cardiac surgery, atelectasis is observed most frequently in the left lower lobe and is considered the most common cause of an increased alveolar-arterial PO2 gradient [42, 43]. Atelectasis is also thought to be one of the main factors leading to further inflammatory injury leading to further deterioration in pulmonary function during the recovery phase after cardiac surgery. During the postoperative period, atelectasis is aggravated by pleural effusion(s) or pneumothorax, which may develop as a result of mechanical ventilation, central line cannulation or air leaks from surgical manipulations [9, 24, 27].
- Phrenic nerve injury leading to poor diaphragmatic function. The most common cause of phrenic nerve injury is the use of cold saline flush or ice slush as a method of additional cardiac preservation. Fortunately, most of the centres have abandoned this method of cardioprotection.
- Postoperative infections – pneumonia. All the aforementioned factors impairing pulmonary mechanics and ciliary clearance increase the risk of postoperative infections. Moreover, if a patient remains intubated for a prolonged period of time after any cardiac procedure, the risk of ventilator-associated pneumonia (VAP) increases to 44% (after 7 days of intubation) [41, 43]. Other significant risk factors for postoperative pulmonary infectious complications include cigarette smoking (a very common habit in patients undergoing combined cardiac and thoracic surgery) and the use of H_2 blockers [44].
- Massive transfusions of red blood cells and other blood products also contribute to respiratory dysfunction postoperatively [45, 46].

Prevention of Lung Injury After Cardiac Procedures

Although severe lung injury after CPB (ARDS) is uncommon (1–2%), other pulmonary complications remain a significant cause of mortality and morbidity after cardiac surgery [9, 25]. There are many patient-related risk factors, which contribute to postoperative pulmonary dysfunction, and some of them are modifiable. Among most important ones are smoking, obesity, COPD (see Chap. 2) and the use of proton-pump inhibitors [41, 43, 44]. Recently, we were also able to identify the intraoperative risk factors for prolonged mechanical surgery after surgery with the use of CPB [26]. At the same time prolonged mechanical ventilation might be detrimental to lung function aggravating injury to the remaining lung parenchyma.

There is little doubt that CPB is considered a "main culprit" of the pulmonary dysfunction occurring after cardiac surgery; however other factors also play an important role in their pathogenesis. Since the pathophysiology of respiratory complications following cardiac surgery has been extensively studied for the last 40 years, clinicians have developed multiple strategies to prevent them [24]. One of the most common approaches is the avoidance of CPB, which can be applied to coronary artery bypass surgeries [46]. On the other hand, currently available results are still inconclusive as to the true benefits of the off-pump CABG. Certainly, the new types of oxygenators (hollow fibre) and use of centrifugal pumps instead of roller pumps decrease activation of neutrophils and subsequent pulmonary dysfunction. The addition of leukoreduction filters which filter out activated polynuclear leucocytes has also been proven to have a beneficial effect [25, 27]. Similarly, a beneficial effect is observed with the use of heparin-coated circuits. Alternatively, some authors propose the use of the patient's lungs as a natural oxygenator (so-called Drew-Anderson technique) [47]. Even though it improves the function of the respiratory system after surgery, it increases the complexity of the surgical technique (additional cannulation sites) and makes it impractical for combined cardiothoracic procedures. It seems that a much easier approach would be to continue ventilation with small tidal volumes, PEEP and the use of air during the surgical procedure and use of the vital capacity manoeuvre just prior to discontinuation of CPB [48]. One of the oldest methods used in the cardiac surgery aiming to attenuate of detrimental effects of CPB (including pulmonary dysfunction) is use of corticosteroids [49]. Even though use of methylprednisolone decreased the release of inflammatory interleukins (IL-6 and IL-8) and complement activation, it has been frequently proven to work as a double-edged sword. While preventing pulmonary complications, it can be attributed to other significant postoperative problems (sternal wound infection, insulin resistance and abdominal complications).

Among the many methods aimed at prevention of respiratory complications, we should also mention strategies used during the postoperative period. They include use of low-tidal volume ventilation, active preventions of VAP (detailed discussion is beyond the scope of this chapter), early extubation whenever possible and aggressive physiotherapy and incentive spirometry. One of the keys to achieve the above-mentioned aims is to maintain effective pain control during the postoperative period.

In summary, the incidence of postoperative pulmonary complications occurring after cardiac surgery is high, and the incidence of prolonged mechanical ventilation is 6–7% [26, 43]. Most likely the incidence of prolonged mechanical ventilation is even higher after combined cardiothoracic procedures; however there is no data in the

literature. Progress in their prevention and advance in surgical and anaesthetic techniques make most of them temporary. On the other hand, given that many patients currently undergoing cardiac surgery are older and suffering from many co-morbidities, this is probably the main reason for reluctance to perform combined cardiac and thoracic procedures. The main argument against combined procedures is that most of the patients suffer some degree of lung injury related to the use of CPB, and an additional insult to lung tissue caused by surgical resection might significantly increase mortality and morbidity [50, 51].

Surgical Considerations

Many thoracic surgeons are familiar with techniques of extracorporeal circulation. There are some thoracic procedures, which are routinely performed with use of CPB. Among the most common are lung transplantation and pulmonary endarterectomy; however recently most of the centres prefer the use of VA-ECMO over CPB. Since anaesthetic management during these procedures is discussed in different chapters of this textbook, they will not be further reviewed here (see Chaps. 47 and 49). The scope of the discussion in this section will concentrate on the perioperative management of patients with intrathoracic malignancies invading cardiac or major vascular structures and patients undergoing thoracic surgery who are suffering from coexisting coronary artery disease. Many surgeons are reluctant to perform one-stage cardiac-thoracic operation because of the concerns mentioned above [50–52]. Moreover, surgical access to the lung structures might be difficult if surgical incision and subsequent CPB cannulation are performed via median sternotomy. Additionally, there is anxiety regarding heparin use and the possibility of excessive bleeding. Apart from the injury to the respiratory system, a frightening consideration is the possibility of dissemination of pulmonary malignancy through the use of CPB [19, 52–54]. On the other hand, a one-stage combined procedure avoids the need for a second major thoracic surgery [3, 53, 54]. In the case of coexisting pulmonary malignancy and coronary artery disease, the answer seems to be straightforward [21, 50, 54, 55]. Preoperative revascularizations performed by interventional cardiologists (PCI – primary coronary intervention) may cause significant time delays for subsequent cancer surgery [56]. Thus, combined surgical coronary revascularization and resection of the lung cancer may be the optimal management. In most cases, revascularization can be performed without the use of CPB (off-pump coronary artery bypass grafting – OPCABG); therefore the detrimental effects of CPB can be avoided [21, 50, 54]. The results of these combined thoracic and cardiac surgeries are encouraging; however published results usually involve small number of patients [20, 21, 57–59].

When considering proper management of thoracic malignancies invading heart structures, it should be mentioned that surgical resection remains the only curative option for most intrathoracic malignancies [52, 53, 59, 60, 61]. Sometimes conventional thoracic surgical techniques do not allow complete resection of a pulmonary tumour which is invading the heart or large vessels; therefore radical surgical removal may necessitate the use of CPB [52]. The most common examples are tumours involving the left atrium and pulmonary artery or infiltrating the descending portion of the aorta [53, 58, 59].

Most of the procedures involving resection or opening of the heart structures are performed via median sternotomy. Surgical exposure to some of the hilar structures is more difficult when compared to a lateral thoracotomy approach. Left lower lobectomy and mediastinal lymph nodes dissection are especially technically challenging when performed via median sternotomy. Probably in most of the cases, mediastinoscopy or EBUS are is indicated initially to rule out mediastinal spread of the disease. All these concerns raise a question as to whether aggressive treatment including surgical resection of lung parenchyma and cardiac or major vascular structures should be a routine management. The answer is clearly no. This mode of treatment should be only performed in departments that are prepared for the complexity of those cases and can offer expertise in both cardiac and thoracic surgery, and anaesthesia, and postoperative ICU care for these patients. Moreover, the functional status of the patient prepared for this type of surgery should be excellent to allow them to survive a potential prolonged stay within an intensive care setting.

Anaesthetic Management for Combined Cardiac and Thoracic Procedures

The literature describing the anaesthetic management of the patient undergoing combined thoracic and cardiac procedures is very scarce and includes mainly case reports [1, 2, 62]. Subsequent paragraphs will try to summarize current information described as individual cases and the experience of the institution where the author practices cardiac and thoracic anaesthesia. The anaesthesiologist who is looking after the patient who is scheduled to undergo combined thoracic and cardiac surgery should possess an expertise in both cardiac and thoracic anaesthesia. Quite often these procedures are complex and require management by two consultants. For most of the cases, we also require the presence of perfusionist, who will be either actively involved with management of the case requiring the use of

CPB and ECLS or prepare the machine for extracorporeal circulation in a "standby" mode.

Preoperative Assessment

Apart from standard preoperative evaluations before surgery, the anaesthesiologist preparing the patient for combined cardiac and thoracic procedure must perform a detailed assessment of the respiratory and cardiovascular systems. An extensive description of respiratory system evaluation is described elsewhere in this monograph (see Chap. 2). Briefly, the anaesthesiologist who is assessing the pulmonary function should concentrate on lung mechanics, pulmonary parenchymal function and cardiorespiratory reserve. The most popular test performed to assess lung mechanics is spirometry. The value most commonly used by anaesthesiologists is the forced expiratory volume in 1 s (FEV1). FEV1 is also used to calculate the predicted postoperative FEV1 (ppo-FEV1) once part of the pulmonary parenchyma is resected. Values below 30–35% for ppo-FEV1 are considered as predictors of increased risk of respiratory complications and prolonged weaning from mechanical ventilation. Maximal oxygen consumption is used to assess cardiopulmonary reserve, and diffusing capacity of carbon monoxide is measured to estimate the gas exchange function of lung parenchyma. Any patient being prepared for a combined procedure requires a very careful airway evaluation. Intrathoracic malignancies necessitating these types of procedures often result in airway involvement, causing deviation or invasion of large airways. Moreover, they can infiltrate or compress large vascular structures. Apart from clinical symptoms, the anaesthesiologist must examine the results of computed tomography (CT) scans, which show precisely the extent of the disease and possible vascular involvement. A preoperative echocardiogram will be complimentary to the radiological examination and should routinely be performed before any cardiac surgical procedure. In the context of pulmonary resection, we should pay particular attention to the function of the right ventricle and value of right ventricular systolic pressure reflecting on pressure in pulmonary circulation.

The "second leg" of preoperative evaluation focuses on the status of the cardiovascular system. The mortality and morbidity of cardiac surgical patients are strongly influenced by their preoperative severity of the illness. The important factors included in most preoperative risk assessment scores include age, sex, left ventricular function, type of surgery, urgency of the surgery, redo cardiac surgery, unstable angina, congestive heart failure, history of peripheral vascular disease and cerebral vascular disease, renal insufficiency and history of diabetes. In most cases, this information can be obtained from the medical history, physical examination and simple laboratory findings including electro- and echocardiogram. Additionally, results of echocardiography provide a detailed description of valve structure and pathology, contractility of the left and right ventricle and morphology of most of the large vessels. In the case of poor ventricular function (ejection fraction <30%), it is recommended to consider an alternative therapeutic approach rather than combined cardiac-thoracic surgery. If the patient suffers from coronary artery disease, the degree of coronary stenosis (es) is assessed preoperatively by cardiac catheterization (coronary angiogram). This information is important for the anaesthesiologist who will be intraoperatively assessing the contractility of the particular segments of the myocardium with the use of transesophageal echocardiography (TEE).

Patients who are scheduled to undergo combined cardiac-thoracic surgery frequently suffer from multiple co-morbidities. Among the most significant, we should mention peripheral vascular disease, diabetes mellitus and kidney dysfunction. Most of these co-morbidities are aggravated during the perioperative period, and this in turn is what significantly increases mortality and morbidity. The anaesthesiologist must collect a detailed list of which medications the patient is currently taking.

Anaesthetic Management

The anaesthesiologist providing care during combined cardiac-thoracic procedures faces multiple challenges. Quite often she/he must simultaneously manage haemodynamic instability, hypoxemia, problems with ventilation and excessive bleeding. It is beyond the scope of this chapter to fully discuss all of the challenges of cardiac anaesthesia, and most of the topics related to thoracic anaesthesia are presented elsewhere in this textbook. Therefore, the author will discuss only the most important problems occurring during combined thoracic and cardiac procedures.

1. Airway management. If pulmonary resection is performed before or after CPB, the patient will require lung isolation. Detailed techniques and methods of choice are discussed in Chap. 16. The position of a double lumen tube or bronchial blocker should be always verified with a fibre-optic bronchoscope. If resection of pulmonary parenchyma is to be performed during CPB, the patient can be intubated with standard, single-lumen tube.
2. Management of hypoxemia during one lung ventilation is discussed in Chap. 6.
3. Transesophageal echocardiography (see Chap. 20). The use of TEE is one of the key components of intraoperative anaesthetic management of patients undergoing com-

bined cardiac and thoracic procedures. The important information obtained from intraoperative TEE during combined cardiac and thoracic procedures includes assessment of left and right ventricular function (especially important after pneumonectomy), diagnosis of new wall-motion abnormalities (coronary artery bypass surgery), evaluation of effects of valve repair/replacement and extension of the disease (e.g. lung tumour invading left atrium or pulmonary vein).

4. Pulmonary artery catheter (PAC). TEE is an excellent diagnostic tool, but at current stage, its use is limited to this role. It does not allow for continuous monitoring of haemodynamic status particularly RV function and afterload for RV. Therefore, PAC is very useful in management of combined cardiac and thoracic procedures particularly during postoperative period. It allows to monitor cardiac output (read function of RV), pulmonary pressures and their changes as response to therapy and certain physiological phenomena and provides warning of RV dysfunction (high CVP, low PAD pressures or presence of square root sign in case we have RV channel in our PA line). During surgery anesthesiologist must remember to ask surgeon to palpate catheter before PA or its branch is being clamped in case pulmonary resection is being performed. If necessary PA must be pulled back prior to resection.
5. The anaesthesiologist and extracorporeal techniques (cardiopulmonary bypass, CPB, and extracorporeal lung support, ECLS). CPB has three main functions during cardiac procedures: (1) replacing function of the heart (circulation of the blood), (2) replacing function of the lungs (oxygenation and CO2 removal) and (3) diversion of the blood from the operating field to create optimal surgical conditions. To achieve these purposes, superior and inferior vena cavae are cannulated, and the blood is passively drained into the CPB venous reservoir. The blood is then oxygenated and returned back to the patient via an aortic cannula usually placed in the distal part of the ascending aorta. In the case of combined thoracic-vascular surgery including the resection of the tumour invading the descending aorta, one can use partial bypass, which diverts some of the blood from the left atrium and returns it back to one of the femoral arteries. Since the primary function of CPB is to oxygenate blood and perfuse the vital organs, an important question for the anaesthesiologist is what perfusion/oxygenation is optimal? Even though it has been over 50 years since the first human use of extracorporeal circulation, there is no definite answer. Blood is exposed multiple times to the foreign surface of the extracorporeal circuit causing SIRS and microembolization, which can affect every organ of the human body. Apart from lung injury, CPB can contribute to cognitive dysfunction, renal injury or failure, pancreatitis or, in the worst-case scenario, multiorgan dysfunction. It is the anaesthesiologist's role to prevent or minimize these complications. Due to advancement in development of extracorporeal techniques and better availability of ECLS perfusion in some cases, venoarterial ECMO might be used instead of full CPB. It allows for using relatively small doses of heparin (typically ACT is between 140–200 s), and subsequently it leads to less significant disturbances in coagulation. On the other hand, ECLS can still cause systemic inflammatory reaction and subsequent vasoplegia. When ECLS is used, we must remember that it is entirely a closed system, which does not allow perfusionist to add any volume. When used in venoarterial configuration, it allows to offload the heart; however it does not allow full circulatory arrest.
6. The anaesthetic approach to combined procedures performed without the use of CPB. Off-pump coronary artery grafting (OPCABG) is the preferred surgical management of coronary artery disease in patients who require pulmonary resection at the same time as coronary revascularization [21, 54, 56]. Revascularization is usually performed as the first part of the procedure followed by the resection of the pulmonary pathology. The most important principles of anaesthetic management for OPCABG include aggressive maintenance of normothermia to prevent bleeding and/or acidosis and preservation of haemodynamic stability during surgical manipulation of the heart. The first aim is achieved by use of warm blankets, body warmers, fluid warmers and adjustment of the room temperature in the operating theatre. Maintaining haemodynamic stability is crucial for ultimate success of the procedure; thus it requires ideal communication and cooperation between the surgeon and the anaesthesiologist. It is accomplished by a combination of inotropic support, proper volume therapy (quite often achieved by "deep" Trendelenburg position) and antiarrhythmic prophylaxis. The surgeon should use gentle manipulations (e.g. incision of right pleura to avoid compression of the heart) and devices (e.g. Starfish™, Medtronic International Ltd., Minneapolis, MN or intracoronary shunts) in order to preserve the geometry of the heart ventricles and their contractility, and prevent mitral regurgitation.
7. Haemodynamic support, right ventricular failure. Cardiothoracic anaesthesiologist must be familiar with all forms of circulatory support to provide haemodynamic stability during and after surgery. It can be achieved by optimization of pre- and after load, maintaining or improving contractility and preservation of a stable sinus rhythm. The most worrisome haemodynamic problem complicating combined cardiac-thoracic procedures is

right ventricular dysfunction or failure. It is commonly caused by a rapid increase in the afterload (pressure) for the right side of the heart, especially after major resection of the pulmonary parenchyma (e.g. pneumonectomy). The warning symptoms include right ventricular distension visualized directly by the surgeon and the anaesthesiologist, a low cardiac output state and a central venous pressure (CVP) higher than the pulmonary diastolic pressure (PAD). If we are monitoring RV pressure, the analysis of pressure tracing might show characteristic square root sign warning anaesthesiologist about RV dysfunction.

The treatment includes:

- Reduction of RV preload (e.g. promotion of diuresis with diuretics) or early introduction of renal replacement therapy if there is no response to diuretics.
- Manoeuvres to decrease the pressure in the pulmonary circulation – hyperventilation, hyperoxia and pharmacological support. Among the intravenous agents, which decrease afterload for the RV and improve its contractility, the first choices are dobutamine and milrinone. Inhalational pulmonary vasodilators (nitric oxide or prostacyclin) are used when a lack of response to intravenous agents occurs.
- Preservation of good perfusion pressure to the right ventricle and ventricular interdependence (norepinephrine or vasopressin) and/or the use of an intra-aortic balloon pump.
- Since stroke volume is usually fixed in RV dysfunction or failure and in order to increase the cardiac output, it is recommended to increase heart rate (e.g. A-V pacing).

8. Treatment of coagulopathy. Combined cardiothoracic procedures performed with the use of CPB are frequently complicated by excessive bleeding, which can have two possible causes: surgical (extensive surgery) and coagulopathy related to prolonged CPB. In cases of surgical resection of pulmonary parenchyma combined with a cardiac procedure, CPB duration often exceeds 2 h. Duration of CPB directly correlates with the magnitude of coagulopathy. There are multiple mechanisms of excessive, non-surgical bleeding caused by extracorporeal circulation; among the most important are the dilutional effect, SIRS, platelet consumption, depleted amount of clotting factors, secondary fibrinolysis, low haemoglobin and hypothermia. Treatment is based on the results of laboratory tests (INR, aPTT, fibrinogen level and platelet count) or use of point-of-care devices. Currently many tertiary care centres use them routinely; its application delivers quick assessment of coagulation status based on results obtained from a whole-blood sample. Among the most popular ones are thromboelastography (TEG) and thromboelastometry (ROTEM). In the context of high likelihood of massive bleeding and coagulopathy in our institution, for most of the combined cardiac-thoracic cases, we secure at least two, large-bore venous catheters to be able to transfuse large volumes of blood products in a relatively short period of time. In most of these cases, we use routinely infusion of tranexamic acid as an antifibrinolytic agent. We follow protocol proposed by Dowd and Karski; however infusion rate should be modified (decreased) in patients with kidney dysfunction or failure [63–65].

Summary

There is no complete agreement about the optimal surgical management of patients who are suffering from both cardiac and thoracic diseases requiring surgery [1, 2, 52, 62]. The arguments for one-stage procedures are avoidance of a second surgery/anaesthetic and reduced hospital stay and cost. However, two-stage procedures may be associated with less surgical trauma and blood loss and may offer better long-term survival because the consequences of cardiopulmonary bypass (CPB) are minimized.

Combined cardiac-thoracic procedures should be performed only for selected cases in specialized centres, which pose an expertise in both cardiac and thoracic anaesthesia and surgeries. This chapter briefly describes the important perioperative considerations and management. Since there is minimal literature describing the anaesthetic management for combined cardiac-thoracic procedures, the a forementioned recommendations are based on the experience and clinical practice developed in the institution where author works.

Case Presentation

Case A 21-year-old patient admitted for redo cardiac surgery for resection of recurrent left atrial angiosarcoma invading pulmonary tissue which was demonstrated on a recent follow-up chest X-ray and CT scan (see Figs. 40.6 and 40.7). The proposed procedure will also involve resection of pulmonary parenchyma. His previous surgery was performed 3 years ago without complications and followed by multiple courses of chemotherapy. He has no other significant co-morbidities. Anaesthesiologist is asked to decide whether patient is going to tolerate combined cardiac-thoracic procedure and what additional test he would like to perform.

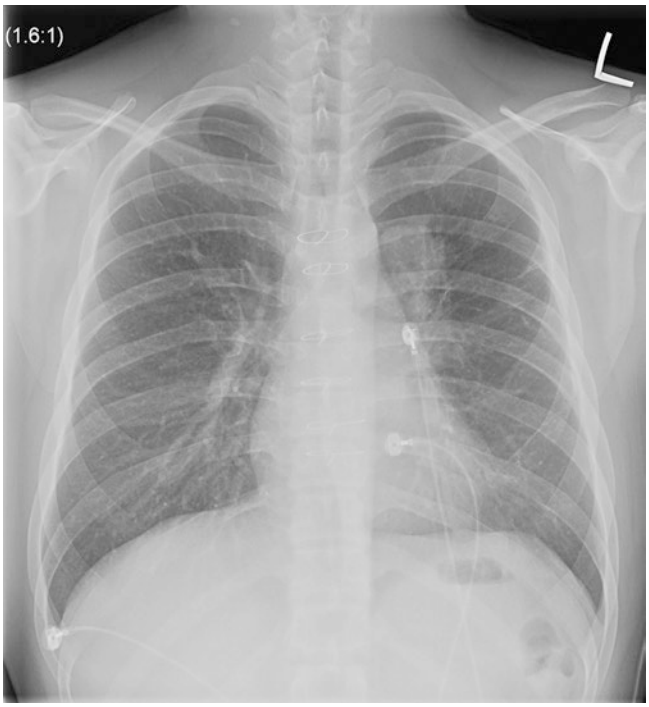

Fig. 40.6 Chest X-ray taken before surgery

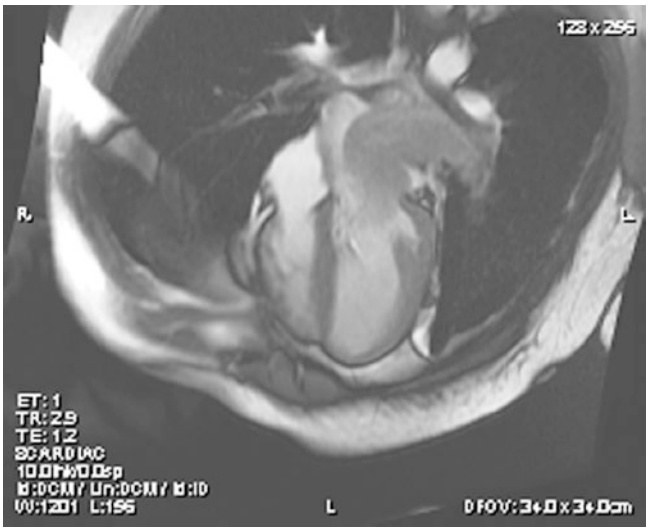

Fig. 40.7 Computed tomogram showing invasion of the tumour obtained before surgery

Questions

- What additional tests would you order?
- Will the patient tolerate procedure? What kind of thoracic procedure will the patient require to achieve complete eradication of his tumour?

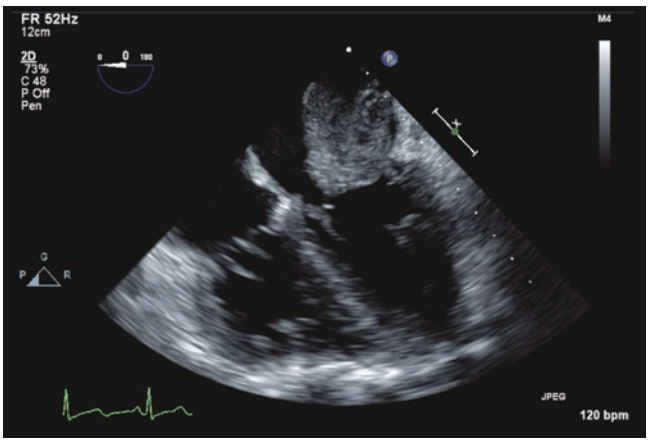

Fig. 40.8 Picture obtained during intraoperative, transesophageal examination. Mid-esophageal, four-chamber view

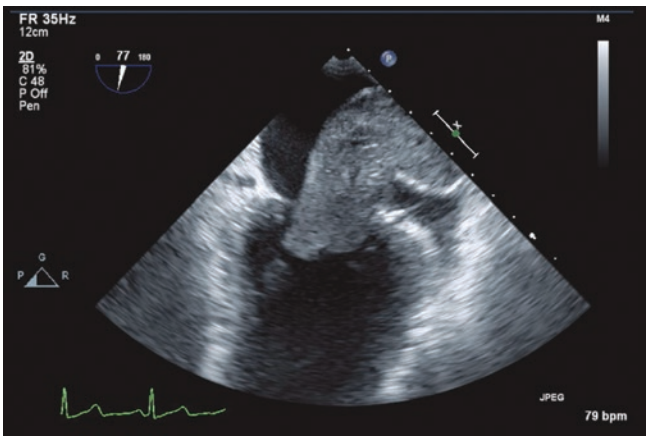

Fig. 40.9 Picture obtained during intraoperative, transesophageal examination. Mid-esophageal, two-chamber view

- What is your anaesthetic plan?
- Do you have any specific concerns related to intraoperative management?
- What kind of postoperative complications can you expect?

Picture presents intraoperative transesophageal echo findings (Figs. 40.8 and 40.9).

Questions

- What cardiac procedure should be performed?
- Which pulmonary veins are invaded?
- What postoperative complications would you expect?

Open Thoracoabdominal Aortic Aneurysm Repair

41

Helen A. Lindsay, Coimbatore Srinivas, and Maral Ouzounian

Key Points

- Open thoracoabdominal aortic surgery is high risk, with placement of an aortic cross-clamp resulting in significant physiological derangements. The main complications include respiratory failure, renal failure, paraplegia, stroke, and major cardiac complications.
- The anesthetic technique is demanding and requires a high level of expertise, including proficiencies in managing one-lung ventilation, massive blood loss, coagulopathy, and cerebrospinal fluid drains.
- To prevent spinal cord ischemia, different techniques may be used to achieve the same physiological goal of maintaining spinal cord perfusion pressure. Techniques to prevent and minimize spinal cord ischemia primarily focus on maximizing collateral flow by supporting mean arterial pressure and reducing cerebrospinal fluid pressure while prolonging ischemic tolerance and reducing reperfusion injury with hypothermia and pharmacotherapy.
- The mainstay interventions to prevent renal injury include avoidance of nephrotoxic insults and selective cold renal perfusion.
- There is an increasing shift to recognize the importance of consensus definitions, standards for reporting outcomes, and coordinated multicentered trials in order to improve the quality of evidence necessary for guideline development.

Introduction

The aorta and arterial system is an essential component of the cardiovascular system, providing oxygen and other essential elements to tissues and cells for aerobic metabolism. This is critical to preserving end-organ function and preventing ischemic injury. Repair of a thoracoabdominal aortic aneurysm (TAAA) is among the most challenging cases for an anesthesiologist. A demanding anesthetic plan comprises of many elements to contend with the significant physiological derangements that occur during the case. Additionally, despite improvements in surgical technique, the potential for significant morbidity and mortality remains [1]. A high level of expertise and an exacting level of care from all members of the perioperative team have been shown to have a significant impact on outcomes [2, 3].

Diseases of the aorta are many and varied [4, 5]: from acute aortic syndromes including aortic dissection or traumatic injuries that are an immediate threat to life requiring emergent repair to progressive, often asymptomatic aneurysmal disease that prompts elective repair to prevent progression to acute rupture. Disease not only develops in the elderly due to degenerative and atherosclerotic disease related to smoking and hypertension risk factors but also the young with various genetic aortopathies such as Marfan syndrome. Clearly the associated comorbidities anticipated in these different subgroups are unique and the management plan should reflect this variability. A full discussion of the diagnostic guidelines and indications for surgical correction of various types of aortic disease is beyond the scope of this chapter. Additionally, this chapter outlines the management for elective TAAA surgery. While many details discussed are equally relevant to the emergent case, the feasibility of implementation will need to be considered.

Clinicians have recognized the risk of spinal cord injury (SCI) since the inception of surgical repair of TAAAs in the 1950s [6]. Lower extremity neurological deficit may be temporary or permanent and range from minor deficits to

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_41

paralysis. The reported incidence of SCI after open TAAA procedures varies widely from 0% to 44% [7, 8]. A general decline in rates to 6–8% has been described since the turn of the century [5], potentially because of more routine employment of protective adjuncts [7, 9]. More recently, a permanent paraplegia and paraparesis rate of 2.9% and 2.4%, respectively, was reported in the largest published single-center experience of open TAAA repair [10]. All the same, when permanent paralysis does occur, it has a devastating impact on a patient's quality of life [11] and long-term prognosis, with a higher complication and mortality rate and longer intensive care and hospital stay [12–18]. As with all major thoracic and vascular surgery, the risk of other complications is also significant and is associated with a substantial potential for morbidity and mortality. The risk of myocardial infarction, heart failure, ventricular arrhythmia, infectious complications, and reoperation for bleeding is quoted in the range of 1–5%, neurocognitive deficits and renal failure requiring hemodialysis up to 10%, and respiratory failure, the most common postoperative complication, between 5% and 15% [4].

Robust clinical evidence validating optimal anesthetic management to achieve improved clinical outcomes in TAAA is lacking. This is largely due to a dependence on single-center observational studies, with substantial heterogeneity in technical details, a lack of universal definitions, and inconsistent standards in reporting outcomes. While research groups and national and international registries are beginning to address these issues in aortic arch and other types of cardiothoracic and vascular surgery [19–22], further work is to be done before substantive evidence-based guidelines may be produced. The purpose of this chapter is to review the current literature and provide a rationale for a structured approach for the patient presenting for thoracoabdominal aortic surgery. Some content is complemented by other chapters in this textbook, so particular attention is paid to the requirements unique to TAAA surgery, particularly spinal cord and renal protection measures [23].

Anatomy and Physiology

Crawford Classification of TAAA Repair

TAAAs are commonly categorized by the classification devised by Crawford and colleagues, which divides TAAAs into four anatomic categories based on the extent of the repair required [24] (see Fig. 41.1). *Type I* extends from proximal to the sixth rib, typically at the origin of the left subclavian artery, to the suprarenal abdominal aorta and typically includes a beveled distal anastomosis at the visceral segment. *Type II* is the most extensive and extends from the left subclavian artery to the aortoiliac bifurcation. *Type III* extends from the thoracic aorta distal to the sixth rib to the aortoiliac bifurcation. *Type IV* extends from below the diaphragm and involves the entire visceral aortic segment and typically most of the abdominal aorta.

In addition to providing a uniform description of the anatomic extent of repair, the Crawford classification also allows the clinical team to estimate the operative risk. In particular,

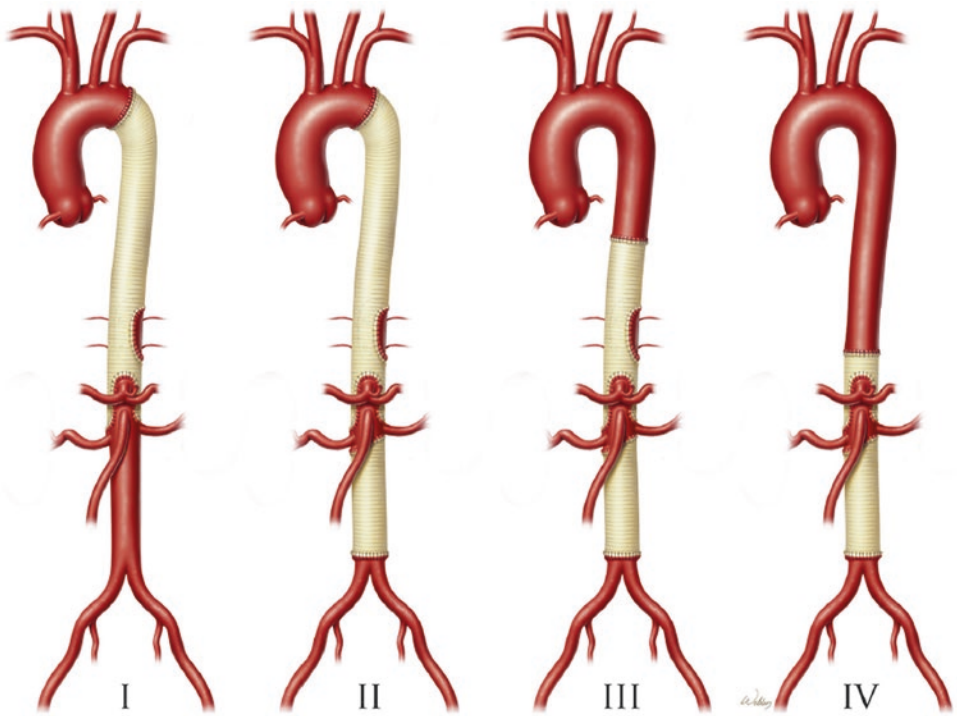

Fig. 41.1 Crawford classification of thoracoabdominal aortic aneurysms. (Courtesy of Baylor College of Medicine)

type II TAAA repairs have the greatest potential for morbidity and mortality, specifically the highest incidence of spinal cord ischemia and renal dysfunction.

Pathophysiology of Aortic Clamp

The application and release of a thoracic aortic clamp has major mechanical, humoral, inflammatory, and metabolic effects. Our understanding of these effects is incomplete, largely limited to historical animal studies that have not lead to any therapeutic interventions with proven clinical benefit to date. This is largely due to the complexity of the physiology involved, with an interplay of multiple factors that vary depending on the type of pre-existing disease, location, and duration of the aortic cross-clamp and that not only affect multiple end targets with unique sequential effects but macro- as well as microvascular structures in a dynamic system that is simultaneously responding to the effects of bleeding, anesthetic medications, and fluid treatment [23].

After application of a thoracic aortic clamp, systemic vascular resistance suddenly increases, arterial blood pressure proximal to the clamp increasing up to 40%, with limited changes in heart rate. Distal to the aortic clamp, end-organ perfusion pressures are reduced to 10–20% of baseline. Pre-existing occlusive disease that has stimulated collateral blood vessel development or more distal placement of the clamp reduces the severity of these changes with greater potential for collateral runoff. Animal models have substantiated that the increase in preload and blood pressure proximal to the aortic clamp is due to a shift in blood flow from the splanchnic vasculature into the vena cava, by various potential mechanical and/or humoral mechanisms [25, 26]. On assessment with transesophageal echocardiogram, the left ventricle filling pressures can increase by 40%, the end-diastolic area by 28%, and end-systolic areas by 70% [27]. The ability to compensate for the left ventricular dilation secondary to a significant increase in afterload and to a lesser extent preload is largely dependent on the reserve ionotropic function of the heart. This can be severely limited in the context of coronary artery disease and subendocardial ischemia or with prolonged clamp placement and increasing concentrations of humoral and inflammatory products.

Upon removal of the aortic clamp, the arterial blood pressure suddenly drops with a sudden reduction in systemic vascular resistance due to both mechanical and complex ischemic dilating humoral/metabolic mechanisms. Cardiac output should increase in response but is variable depending on the patient's cardiac reserve and the effect of returning cold, hyperkalemic, acidotic, ischemic metabolites, as well as other dynamic factors such as the degree of acute bleeding.

Pathophysiology of Spinal Cord Injury

In the last 10 years, significant advances in our understanding of spinal cord blood supply have emphasized the need for a broader, more physiological approach to SCI [28].

Blood Supply of the Spinal Cord

Adamkiewicz and Kady provided the first accurate description of spinal cord blood supply in 1881 [29]. Their *classical model* was based on two posterolateral and one anterior spinal artery (ASA), the ASA being reinforced at multiple levels by segmental arteries originating from the aorta via the intercostal and lumbar arteries. Significant inter-individual variation within this anatomical model is recognized. During fetal development, an original 31 bilateral segmental arteries variably regress to 6 on average, with a broad range of 2 to 14 [29]. The largest segmental artery ("the artery of Adamkiewicz") arises most commonly from a left intercostal artery, between T9 and T12 in 75% of patients but as high as T5–T8 in 15% or as low as L1–L2 in 10% [30, 31]. Functional studies using motor-evoked potentials (MEP) also indicate acquired aneurysmal and atherosclerotic disease of the aorta results in significant anatomical variability [32].

In the last decade, evidence of a *spinal collateral arterial network* (SCAN) has supplanted the classical model of an anatomically defined single important blood supply, whereby a substantial arterial plexus along the entire length of the spinal cord supports its blood supply [9]. The intercostal and lumbar segmental arteries have multiple degrees of connection longitudinally and transversally to arterial networks in the spinal canal (consisting of the ASA and epidural arcades), paravertebral tissues, and multiple paraspinous muscles, the latter being the largest and most extensive of the three [9, 29] (see Fig. 41.2). The importance of additional inflow vessels is emphasized in this model, including the subclavian artery through the vertebral artery, the thyrocervical and costocervical trunks, the internal thoracic arteries through the intercostal arteries, and the hypogastric arteries through the lateral sacral and iliolumbar arteries [9, 29, 33]. There is also evidence of significant inter-individual variation with remodeling potential in porcine studies [9, 34].

Considering the potential for inter-individual variation in both conceptual models, advances in imaging the spinal cord blood supply offer potential benefits in defining and modifying an individual's risk [29]. However, options are currently limited. Invasive intra-arterial catheter angiography provides the best image quality when successful; however, its reported sensitivity is variable, with a risk of renal impairment or iatrogenic paraplegia. Magnetic resonance angiogram (MRA) technology has advanced significantly to reliably image the artery of Adamkiewicz and other larger segmental arteries but is still limited when it comes to the smaller caliber collateral vessels. When collateral arteries are distal to the

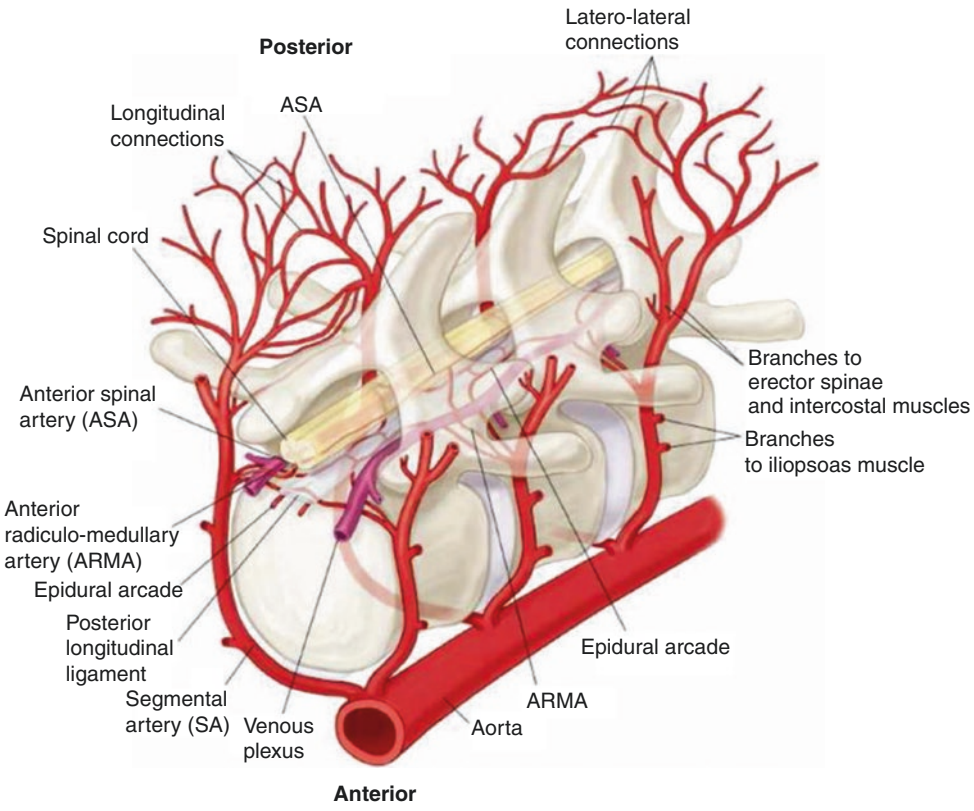

Fig. 41.2 Schematic diagram of the blood supply of the spinal cord. (Courtesy of Etz et al. [9])

planned aortic clamp on MRA, intraoperative decline of MEPs has a high negative (97%) but poor positive predictive value (37%) [35].

A Physiological Approach to SCI

While anatomical knowledge has advanced, understanding of circulatory physiology at the level of SCAN remains limited and is central to why the development and management of SCI remains poorly understood.

Simplistically, ischemia occurs when the supply of nutrients required for cellular metabolism does not met the demands for tissue viability. Absolute interruption of spinal cord blood supply for a sufficient period of time will cause irreversible ischemic necrosis. On the basis of early studies using a "clamp and sew" technique, this risk is significantly increased after 30 min of aortic cross-clamp and almost certain after 60 min [36, 37]. Alternatively, perfusion may be permanently marginal and become inadequate for viable cord function at a certain "tipping point" [38], explaining how cases of delayed SCI can present up to 27 days after intervention [39]. Added complexity lies in how variable this can be between individuals, for instance, chronic hypertension appears to shift the tipping point [34], while therapeutic interventions can improve ischemic tolerance. This concept is highlighted in studies where complete segmental arterial supply sacrifice consistently reduced spinal cord perfusion pressure (SCPP), but only lead to SCI in approximately half the cases [40]. Furthermore, while staging the arterial sacrifice minimized the drop in SCPP and improved functional outcomes overall, the cohort that could have tolerated the drop in SCPP without staging was unpredictable [34]. This is important to consider when interpreting the variability in published results.

Additionally, SCPP may be compromised by multiple mechanisms [33, 39, 41]. Spinal cord blood flow is reduced by direct arterial occlusion with placement of an aortic clamp or replacing aortic tissue with a graft. The primary aortic disease process (atherosclerosis, dissection) and embolic phenomena can also compromise the anastomotic capacity of the SCAN [29, 42]. Increased cerebrospinal fluid (CSF) pressure as occurs with placement of an aortic cross-clamp or edema secondary to an ischemic-reperfusion injury can create a "compartment syndrome" effect [43–45]. Systemic hypotension or steal phenomenon will further exacerbate suboptimal perfusion [39]. The potential interconnectedness of these various factors adds further complexity, where ischemia can exacerbate edema that further exacerbates ischemia in a spiral-like effect [8, 29, 42, 46].

Ultimately, the adequacy of SCPP is determined by an interplay of multiple factors that not only affects an individual's SCPP but also determines the SCPP required to prevent SCI (see Fig. 41.3). This creates a unique risk balance in each individual patient and demands a multimodal approach to prevent SCI following TAA intervention.

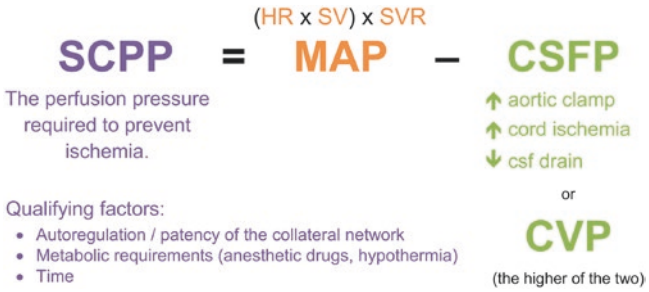

Fig. 41.3 Multiple factors determine an individual's spinal cord perfusion pressure (SCPP), and the SCPP required to prevent spinal cord injury (SCI). MAP mean arterial pressure, HR heart rate, SV stroke volume, SVR systemic vascular resistance, CSFP cerebrospinal fluid pressure, CVP central venous pressure

Surgical Technique

In order to surgically repair aortic disease, a clamp is placed above and below the lesion, the aorta opened, and the diseased segment replaced with a graft (see Fig. 41.4). The thoracic aorta is accessed via a left thoracotomy, which is extended to a paramedian laparotomy when access to the abdominal aorta is also required.

Established surgical methods for TAAA surgery include the "clamp and sew" technique, left heart bypass [47], partial cardiopulmonary bypass [48], and deep hypothermic arrest [49]. There are no established criteria to justify one technique over another and current guidelines recognizing that institutional experience is an important factor in technique selection [4]. The simple "clamp and sew" *technique* is no longer used in most institutions and is not advisable when the cross-clamp duration is expected to exceed 30 min because of the significant risk of postoperative neurological deficit and mesenteric and renal ischemia.

Left heart bypass provides distal aortic perfusion during aortic clamping by means of a centrifugal pump, with the potential for additional selective perfusion of mesenteric visceral and renal arteries. Proximal decompression is provided by draining oxygenated blood through a left pulmonary vein cannula. The left atrial appendage may alternatively be used, but the positioning is often more awkward with a greater risk of air embolism. Blood is returned to provide distal perfusion through a distal aorta or femoral artery cannula. Close communication between the anesthesiologist and perfusionist is required to ensure that the balance of preload and the pump speed are optimal. *Partial bypass* is similar in that it ensures distal perfusion by cannulation of the femoral artery and vein while maintaining enough preload in the heart to support the cardiac and cerebral circulations but contrastingly achieves this by the use of full extracorporeal cardiopulmonary bypass. This can achieve higher flow rates that are advantageous in patients with poor left ventricular function or during a prolonged aortic cross-clamp time; however, it requires full heparinization, which increases the risk of increased blood loss and coagulopathy.

Deep hypothermic circulatory arrest (DHCA) is indicated when a proximal aortic clamp site is unable to be safely secured, often when the arch is dissected and/or aneurysmal. The benefits of use are in its simplicity, with a bloodless field and no need for additional cannula or aortic manipulation. Its main limitation is time on cardiopulmonary bypass. On the basis of advanced physiological and clinical testing, the upper safe limit of profound to deep HCA (12–20 °C) is 25–30 min [50, 51]. In a landmark clinical study by Svensson et al., >40 min of profound HCA increased the risk of neurological injury, and >65 min increased the risk in mortality [52]. In a more recent study of 490 patients, safe use of DHCA (18–20 °C) was reported for up to 50 min in terms of stroke risk, but only 61 patients had arrest times >40 min [53]. While it is established that organ metabolism is reduced proportionally to the degree of hypothermia, there is increasing recognition of the potential harm associated with profound and deep hypothermia (<14–20 °C). Various experimental studies raise concerns about the risks of coagulopathy, a proinflammatory response, and end-organ dysfunction, but these concerns are yet to be substantiated in clinical studies [19, 54]. Inconsistent standards in the reporting of outcomes related to end-organ ischemia significantly limits assessment of safe temperature and time parameters for these techniques [19, 54]. Additionally, the impact of relevant patient or interventional modifiers on these parameters is poorly understood [55–57].

Selective cerebral perfusion is not commonly used and more difficult to implement for TAA surgery. The specifics of this are covered in more detail in a previous review [58].

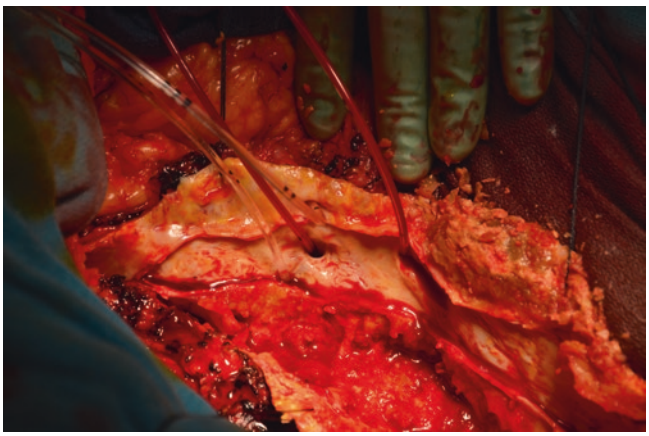

Fig. 41.5 Visceral perfusion. Isothermic blood is delivered from the return line of the left heart bypass circuit to the celiac artery and the superior mesenteric artery. Cold crystalloid solution is delivered intermittently to the left and right renal arteries. (Courtesy of Baylor College of Medicine)

If renal ischemia exceeds 30 min, some guidelines recommend selective cold crystalloid renal perfusion, as discussed later in section "Renal Protection" [5] (see Fig. 41.5).

Preoperative Evaluation

As already recognized, the variability in presentation of aortic disease is extensive and will have a major impact in guiding appropriate preoperative assessment and planning. A detailed description of these nuances is beyond the scope of this chapter, and we recommend review of current guidelines as appropriate [4, 5]. From an anesthetic perspective, recognizing certain distinctions is important to assess for likely associated disease, the required urgency, and risk benefits of surgical management.

In addition to a complete anesthetic, medical history and examination, a systematic approach should be taken in considering the need for additional investigations. Review of the content in Chap. 2 related to the preoperative assessment and optimization of the thoracotomy patient is relevant to TAAA surgery. Considering TAAA surgery qualifies as major surgery by entering both the thoracic and abdominal cavities, specific considerations include:

- Blood assays. Electrolytes and creatinine to assess renal and endocrine function, for side effects of pharmacotherapy, and potential avenues for optimization in the event of arrhythmia. Complete blood count to assess for myelosuppression and anemia. In the event of anemia, iron studies, CRP, vitamin B12, folate, and thyroid function studies should be reviewed to assess for reversible causes. Coagulation studies to assess for bleeding dyscrasias. Liver function studies should be completed if there is suggestion or risk factors for liver disease. Albumin is also a potential marker of nutritional status and frailty.
- A 12-lead electrocardiogram to provide a baseline measure and assess for evidence of arrhythmic or structural cardiac disease. 24 hour Holter monitoring may be considered for those with a history of intermittent symptoms of palpitations or pre-syncope.
- A resting echocardiogram if there are any risk factors or evidence of cardiac disease, including age > 40 years in some guidelines [4].
- A BNP level is recommended by the current Canadian Cardiovascular Society guidelines [59]. Dynamic cardiac testing (including a dobutamine stress echocardiogram or myocardial perfusion scan) is indicated according to the current American Heart Association guidelines if the patient's functional capacity is poor or cannot be assessed [60]. Current expert opinion is that patients with unstable coronary syndromes and significant coronary artery disease (i.e., left main stenosis or three-vessel disease) should undergo revascularization prior to or at the time of thoracic surgery, while the benefits for those with clinically stable flow-limiting coronary disease remain unclear [4].
- Neurocognitive testing, a carotid artery duplex scan, brachiocephalic angiography, and brain imaging should be considered if there are risk factors or evidence of cerebrovascular disease. While they are considered reasonable investigations in some guidelines to help assess a patient's risk profile [4], they are not routine, and their utility is uncertain.
- A recent chest x-ray or computed tomography (CT) is required to assess for cardiopulmonary disease including distortion of the trachea or left main bronchus by the aortic disease and to assist in sizing the double-lumen tube (DLT).
- The utility of an arterial blood gas on air, spirometry, pulmonary function testing, and cardiopulmonary testing are discussed at length in Chap. 2.

To complement this assessment, communication with the multidisciplinary team is important to insure optimal patient care. The surgical team will provide important insights into the indications for surgical management and the specific requirements of the surgical plan, including planned clamp positions, the need for additional shunt, bypass support, or selective organ perfusion techniques. Liaison with intensive care services is important to ensure suitability for a period of postoperative support. In the patient with significant comorbidity, referral for assessment or liaison with their treating medical subspecialist may be required. This can be to insure maximal optimization and/or provide an opinion as to the patient's long-term survival prognosis with respect to their comorbidity.

Putting all of this together, the anesthesiologist needs to provide the patient and surgeon with an individualized summative assessment of the risks of not proceeding with surgery, weighed against the perioperative risk. A perioperative plan should make provision for preoperative optimization of all elements of the patient's health.

Current international guidelines provide the best evidential support to optimize medical management of cardiac risk [59, 60]. In addition to specifically withhold angiotensin-converting enzyme inhibitors/angiotensin receptor blockers for 24 h prior to surgery to prevent the risk of death and vascular complications [61], other sources recommend withholding all antihypertensive agents the morning of surgery to help support compromised distal perfusion pressures [13, 34]. Counselling to support smoking cessation should be provided. In those with a reversible airways disease component, inhaler therapy should be optimized. Reversible causes of anemia and kidney injury should be treated if the urgency of surgery allows. The intra- and postoperative plan should outline the monitoring and interventions needed to minimize the risk of complication, in particular protective strategies to reduce the risk of spinal cord and renal injury, as discussed later in sections "Spinal Cord Protection Strategies" and "Renal Protection Strategies."

Although guidelines suggest identifying the "high risk" for implementation of spinal cord protection techniques, there are no recognized criteria to define "high risk" in this population [4]. The extent of the intended aortic repair has long been recognized as an important determinant since Crawford's classification of TAAA disease [24]; however, many institutions classify all open TAAA repairs as high risk. Although many other patient and procedural factors have been proposed as risk factors for postoperative SCI, none have been consistently validated. The rationale for instituting spinal cord protective strategies is determined on a surgeon and patient-case basis. The following is a summary of independent predictors of SCI with open repair identified by logistic regression modelling that could be considered:

- Extent of disease, including type II only [62, 63], I and II [15], and I, II, and III [64] Crawford TAA aneurysm classification.
- Previous thoracic or TAA surgery [65]. In another study thoracic aneurysm repair was protective [62].
- Presence of aortic rupture [15].
- Total aortic clamp time [15]. In a later study by the same group distal aortic perfusion eliminated this as a risk factor on repeat analysis [63].
- Diabetes [62].
- History of preoperative renal dysfunction [15], renal dysfunction (Cr >2.0 mg/dL, a previous history of renal failure or insufficiency or being on active dialysis) [63].

In the most recent and largest publication of a single-center experience to date, Coselli et al. identified that the independent risk factors for permanent paraplegia varied depending on the extent of TAAA. For extent II repairs, coronary artery disease and chronic aortic symptoms increased risk, while having a genetically triggered disorder was protective. For extent III repairs, cerebrovascular disease, emergency repair, and selective visceral perfusion increased risk of SCI [10].

Intraoperative Management

Monitoring

In addition to ASA standard monitoring [66], extra monitoring of cardiac and neurological function is required for the early detection and minimization of complications. Again, much of what is discussed with regard to monitoring in Chap. 20 should be reviewed.

Five-Lead Electrocardiogram (ECG) and Defibrillation Pads

While lead V provides assessment of the left ventricle lateral wall and provides the greatest sensitivity for detecting intraoperative ischemia, the lead position is directly in the surgical field. Defibrillation pads should also be anteroposteriorly placed prior to induction.

Invasive Blood Pressure

Right radial or brachial arterial line placement provides information about pressures proximal to the aortic clamp, including the cerebral circulation even if the left subclavian arterial flow is compromised by the clamp. If distal perfusion techniques are used, a right femoral artery line may be placed, reserving the left femoral artery for bypass cannulation. If distal perfusion pressure monitoring is not required, we recommend using a second line in the left radial or brachial artery. This is dedicated to blood sampling in order to prevent interruption in pressure monitoring or compromise of the right line from frequent blood sampling.

Pulmonary Artery Catheter (PAC)

While recognizing there is no support for improved clinical outcomes [67], we routinely place a sheath and PAC in the right internal jugular for these cases. Recognizing the standard limitations in its use, including the likely overestimation of the left ventricular end-diastolic pressure with isolated right-lung ventilation, we find the additional information about left ventricular function in terms of filling pressures and cardiac output useful in optimizing hemodynamic management.

Transesophageal Echocardiogram (TEE)

In the absence of an absolute contraindication, placement of a TEE probe is considered reasonable [4] and routine in our institutional practice. In addition to confirming the diagnosis in the acutely unstable patient and assessing for aortic valve involvement, echocardiographic assessment provides dynamic information about filling pressures, volume status, cardiac output, afterload, and ischemia with regional wall motion abnormalities. However, the need for specialized training and resource intensity will not be serviceable in all centers.

Spinal Cord Monitoring

Early detection of inadequate spinal cord perfusion is an essential component in the perioperative care of patients having TAAA surgery, so interventions to improve perfusion may be implemented before compromised spinal tissue is irreversibly infarcted. Early emergence from general anesthesia and regular neurological assessment of the awake patient are key interventions emphasized in postoperative care protocols [41, 68].

Somatosensory- (SSEP) and transcortical motor-evoked potentials (tcMEP) have been used to indirectly assess spinal cord perfusion in the anesthetized patient, to inform surgical and anesthetic management. Consideration for use is recommended in institutions with sufficient resource and experience, although several large volume centers do not use neuromonitoring techniques intraoperatively [4]. While the utility of SSEP monitoring is limited by delayed ischemia detection and a high rate of false-positive results [69], the use of highly sensitive MEP monitoring has been shown to reduce the rate of SCI in the open repair of type I/II TAAA [44]. MEP monitoring restricts neuromuscular blockade and volatile anesthetic agent use, with theoretical risks of seizure, arrhythmic, or neuromuscular complications [70].

Near-infrared spectroscopy (NIRS) monitoring of hemoglobin oxygen saturation in the paraspinous muscles is a new continuous noninvasive technique to assess the adequacy of collateral network perfusion. Feasibility studies have shown that its use reliably predicts patients who develop SCI [71] and correlates well with MEP results [72]. Further research is required to prove reproducibility, determine optimal optode positioning, and indicate whether its use can improve clinical SCI outcomes.

CSF pressure and drain volume monitoring is critical intraoperatively. This is not only to insure spinal perfusion pressure is optimized but to prevent complications from excess CSF drainage, as covered in more detail in section "Technical Specifics of Cerebrospinal Fluid Drainage."

Cerebral Monitoring

Although various cerebral monitoring techniques are available, there is no substantive evidence that the use of any of them reduces the risk of neurological injury. Their primary current role is to help assess the adequacy and hemispheric symmetry of cerebral perfusion techniques, being poorly predictive of neurological dysfunction secondary to embolic phenomenon and malperfusion in acute aortic dissection [73]. The fact that assessment of cerebral circulation is limited to the frontal lobes is also potentially significant. The threshold values and sensitivity of NIRS to detect insufficiency remain uncertain [73, 74], and most modern studies describe the use of a multimodal monitoring strategy in order to increase the sensitivity of detecting relevant ischemic cerebral dysfunction [75].

Despite the popularity of NIRS and a large body of literature, a systematic review of its use in cardiac surgery found only low-level support for its use in terms of neurological outcomes [74]. A more recent systemic review of NIRS in cardiac surgery recommended strong consideration for use in general cardiac surgery on the basis of improvement in global outcomes such as hospital length of stay and multi-organ morbidity, with no specific assessment of neurological outcomes [76]. While some studies have shown an association between low cerebral oximetry values and various worse neurological outcomes, whether NIRS can inform interventions to modify neurological risk remains unclear [74, 77]. One randomized trial (n = 100) has shown that use of an interventional algorithm to treat cerebral saturations <85% of baseline during CPB significantly improved cognitive testing results at 1 week and month postoperatively [78]. A recent feasibility trial will hopefully herald a large trial with definitive answers in years to come [79].

Routine use of other techniques is largely limited due to technical and logistical factors, with a lack of evidence to substantiate their efficacy. Bilateral transcranial Doppler (TCD) can be used to assess symmetry of middle cerebral artery flow and embolic phenomena; however, this only provides assessment of the anterior circulation, and adequate signals may only be found in three out of four patients [75, 77]. Auditory- and somatosensory-evoked potentials and multichannel electroencephalography can be used to identify intraoperative cerebral events and the adequacy of cerebral metabolic suppression [75]. However, there is no evidence to indicate that use of these techniques has any clinical benefit in addition to standard care [77]. Jugular venous bulb saturation has high specificity in the detection of cerebral ischemia and can indicate maximal suppression of cerebral metabolism but has poor sensitivity and is invasive [75, 77].

Temperature

In addition to a standard nasopharynx temperature, a core rectal or bladder temperature should be recorded in the event active or passive cooling techniques are implemented [4].

Vascular Access

In recognition of the potential for rapid blood loss and the need for massive blood transfusion, we place two large intravenous access lines. We recommend connecting the Belmont rapid infuser device to a 7Fr PAC sheath in the internal jugular or subclavian vein, with left-sided placement allowing for easier access when the patient is in the right lateral position. A 14ga peripheral intravenous line should be secured as a secondary line. It should be directly connected to a fluid infusion set, as needle-free valves and injection ports can significantly reduce the maximal achievable flow rate [80]. A quad-lumen central venous line is also routinely inserted.

Other Tubes

An indwelling urinary catheter is placed at the start of the case. This is not only for postoperative management purposes but also prudent considering the potential for large volumes of fluid and mannitol administered intraoperatively. Urine output has been shown to be an inaccurate marker of renal function or overall fluid status intraoperatively and does not predict the risk of postoperative kidney injury [81–85]. Rather, vigilance is required to prevent urinary retention, with a global assessment of the patient's clinical state to achieve euvolemia.

A nasogastric tube is likely to be indicated for postoperative management, especially if there has been manipulation of mesenteric blood supply. If a TEE probe is placed, we recommend this be inserted at the end of the case.

Anesthetic Technique

Recognizing the many demands for TAA surgery, the anesthetic technique will need to be tailored to specific patient needs and institutional practices. In our institutional practice, fentanyl/sufentanil, IV lidocaine, with an adequate dose of propofol and non-depolarizing relaxant is used for smooth induction and intubation. For maintenance of anesthesia, we avoid the use of inhalational agents (MAC <0.3) and additional muscle relaxation to allow for SSEP and MEP monitoring. Rather total intravenous anesthesia with remifentanil (0.1–0.2 mcg/kg/min or effect site concentration of 4–7 ng/ml) and propofol (75–125 mcg/kg/min or effect site concentration of 3–6 mcg/ml) is used, guided by a depth of anesthesia monitor and the patient's hemodynamics.

Positioning

For open repair of TAAAs, the patient is positioned in right lateral decubitus after induction of anesthesia and placement of all vascular lines. The left hip, and to a lesser degree the left shoulder, is rolled back slightly toward the horizontal to allow surgical access to the femoral vessels. The physiological implications of lateral decubitus positioning and one-lung ventilation are comprehensively covered in Chap. 5. As highlighted in Chap. 19, pressure point protection and patient access are also important considerations, and we recommend a systematic approach to insure optimal care. All monitoring and access lines should be reviewed to insure they are secure, away from the surgical field, and not a potential source of pressure injury. We routinely use a beanbag positioning device to stabilize the patient in position. Alternatively, the patient can be secured with a stretch of wide tape or a table strap fasted to the table and applied across the left hip, over the soft tissue between the iliac crest and the femoral head to avoid forming a pressure area. Loose-fitting tape or Velcro straps can be used to help secure the arms on the arm boards. They should be secure, but not so tight as to cause compartment syndrome.

In recognition of the multiple pieces of monitoring, lines, and equipment, it is important to create an ordered, ergonomic, and functional working space. The routine arrangement used at our institution for thoracoabdominal aortic surgery is shown in Fig. 41.6.

One-Lung Ventilation

Lung isolation techniques with collapse of the left lung is important for TAAA repair, as it improves surgical exposure, reduces the time of surgery, and minimizes lung manipulation and trauma. A left-sided double-lumen tube (DLT) should be placed unless the aortic disease distorts the trachea and left main bronchus. Alternatively, a right-sided DLT or a left-sided bronchial blocker can be used. The techniques and important considerations for doing this are covered in Chaps. 16 and 17.

Exchange of the double-lumen for a single-lumen tube (SLT) should be considered at the end of the case, in order to minimize the risk of airway trauma, suboptimal ventilation, and airway toileting from a suboptimally positioned DLT in the cardiovascular intensive care unit (CVICU). However, this risk must be considered in the context of how easy it was to bag-mask ventilate and intubate the patient preoperatively and weighed against the risk of completely losing the airway in the context of significant airway edema [4]. In our practice, unless there is gross facial edema, we routinely inspect the glottis with a videolaryngoscope in the operating room at the end of the case. If there is no significant edema, the DLT will be exchanged for a SLT under direct vision using an airway exchange catheter. In the presence of edema, serial assessments will be made in the CVICU every 24 h and tube exchange delayed until the edema is resolved.

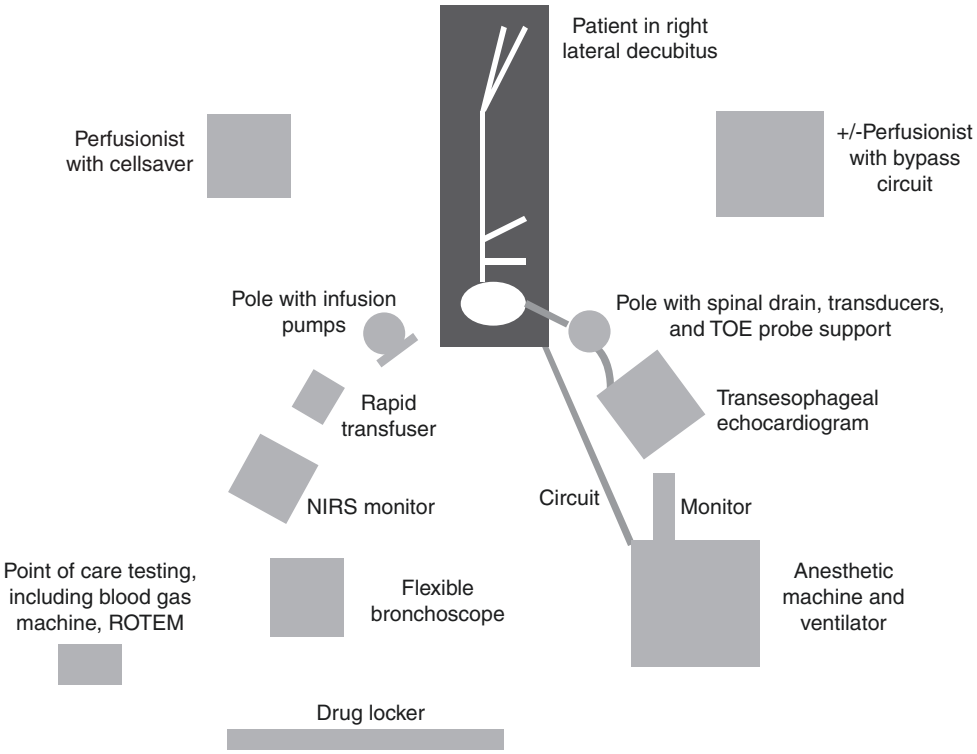

Fig. 41.6 An ergonomic anesthetic space

Hemodynamic Management

A key priority for major vascular surgery of this nature is tight hemodynamic control throughout the perioperative period. Minimizing acute extremes in blood pressure and heart rate is important in order to limit changes in wall shear stress across the diseased aorta. In the context of using aortic clamps and massive bleeding, this can be demanding. There are many ways of achieving this same outcome, and the treating anesthesiologist should consider agents with the appropriate pharmacological properties that they are familiar with in order to achieve the best results.

With placement of the proximal aortic clamp, it is important to avoid an excessively high left ventricular filling pressure and heart rate that will increase myocardial oxygen consumption while reducing coronary perfusion. In patients with a degree of coronary artery disease this will result in subendocardial ischemia. Equally, at least a "normal" (i.e., relative to the patient's awake baseline blood pressure) proximal aortic pressure will need to be maintained if end-organ perfusion distal to the aortic clamp is dependent on collateral flow. While euvolemia should be maintained preoperatively to avoid pre-renal injury, excessive fluid resuscitation should be avoided prior to aortic clamp placement. There is a small body of evidence to support nitroglycerin as more effective that nitroprusside for reducing preload and filling pressures once the clamp is placed, with superior preservation of collateral coronary, renal, and spinal blood flow [86–88]. Using β-blockers such as labetalol with its alpha- and beta-effects or esmolol with its short-acting, β1-selective effects could be considered as second-line agents, but the negative inotropy will need to be monitored closely. Nicardipine is a dihydropyridine calcium channel antagonist with a relatively rapid onset and offset of effect that predominately relates to arterial dilation. Its use may be more favorable to β-blockers in the context of bradycardia or reactive airways disease.

Acute hypotension following release of the aortic clamp should be limited by preemptively bolusing fluid and instituting vasopressor/inotropic support approximately 10 min prior. In the event of refractory or severe hypotension, reapplication of the aortic clamp may be required for 1–2 min. Again, while supporting adequate organ perfusion post-clamp release, excess blood pressure that will stress the suture lines of the graft and increase the risk of bleeding must be avoided.

Fluid Management with Massive Blood Loss

A full discussion of the management of massive transfusion and coagulopathy is beyond the scope of this chapter. Rather we would refer to current international guidelines [89, 90]. Close communication with blood bank and operating room staff such as the nurses, anesthetic assistants, and attendants can help meet the high level of resource intensity potentially required.

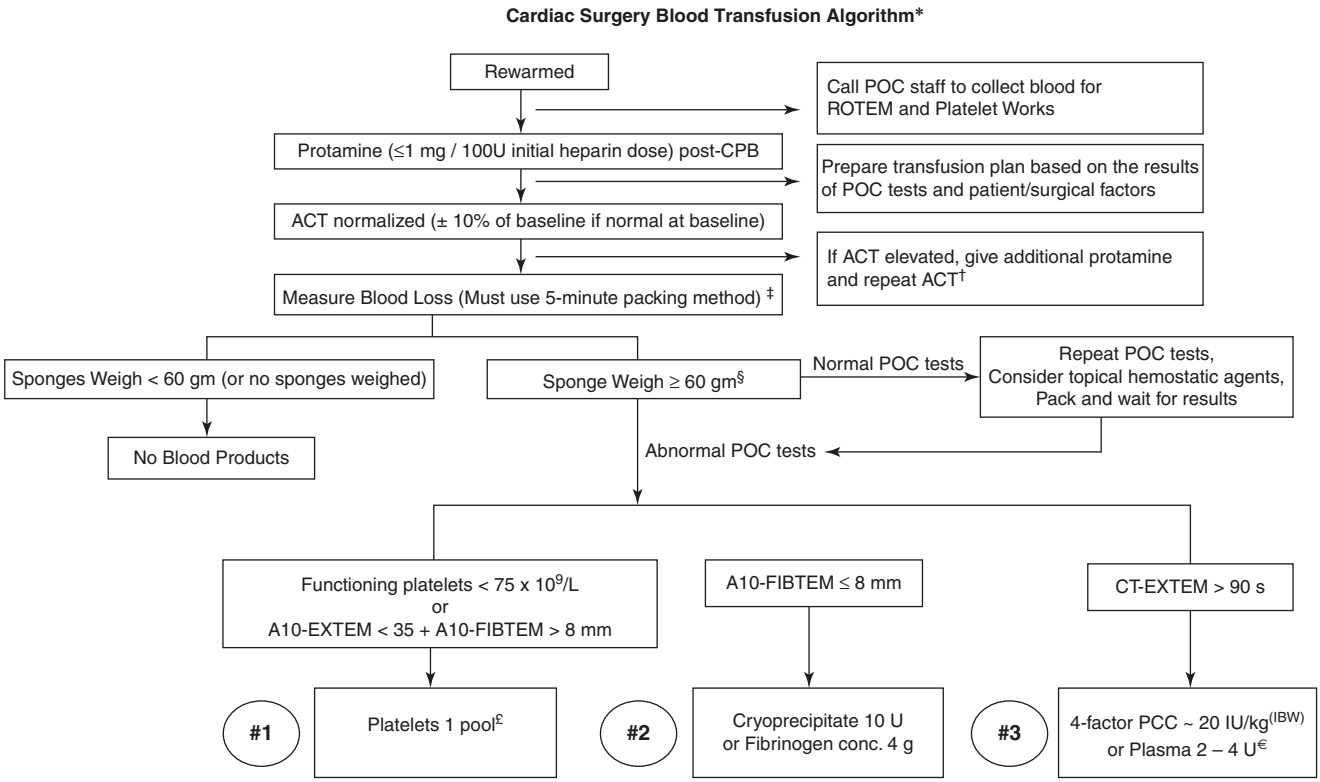
Targeted transfusion using point-of-care viscoelastic assay (e.g., thromboelastography (TEG) or rotational throm-

boelastometry (ROTEM))-guided algorithms have been shown to reduce blood transfusion requirements [90]. No single algorithm can be recommended at this time; rather this should be developed at an institutional level with multidepartmental input and regular audit. Figure 41.7 provides an example of the validated algorithm used for cardiac surgery with bypass support at our institution [91]. If available, a massive transfusion protocol may need to be used as a strategy to optimize the delivery of blood products to massively bleeding patients.

Prophylactic use of antifibrinolytic therapy, in particular tranexamic acid, has been shown to reduce perioperative blood loss and reduce transfusion requirements. The evidence is most substantive for use in cardiac surgery and is appropriate for TAAA surgery in light of the risk for excessive bleeding. In multiple randomized trials, including the largest and most recent ATACAS trial, there is no evidence of an increased risk of thrombotic complications; however, there is a recognized dose-dependent risk of postoperative seizures [90, 92].

Spinal Cord Protection Strategies

To prevent spinal ischemia, different techniques can be used to achieve the same outcomes, as long as the physiological principles of maintaining perfusion pressure to prevent paraplegia are accounted for. Techniques to prevent and minimize SCI primarily focus on maximizing collateral flow by supporting mean arterial pressure and reducing CSF pressure while prolonging ischemic tolerance and reducing reperfusion injury with hypothermia and pharmacotherapy. Despite a wealth of options, interpretation of the large volume of conflicting literature allows for few conclusive



* Does not apply to red cell transfusion which will be based on hemoglobin levels as per institutional practice

† If an additional protamine dose does not shorten ACT, consider low fibrinogen levels or an acquired deficiency of enzymatic coagulation factors as a reason for prolonged ACT and treat according to the algorithm (maximum overall protamine dose: 1.2 mg/100 U initial heparin dose)

‡ If bleeding is severe, initiate treatment **without** weighing sponges and combine treatment steps as appropriate

§ Unless bleeding is severe, treat in a step-wise manner and evaluate for effect after each step

£ Consider 2 pools of platelets if massive bleeding, functioning platelets < 15 x10^9/L, or recent use of potent anti-platelet drugs

€ Consider PCC (prothrombin complex concentrate) particularly if right ventricular failure, volume overload, or recent warfarin use. Use plasma preferentially if FIBTEM is also low (≤ 10 mm) or massive bleeding

Fig. 41.7 ROTEM-guided algorithm for targeted transfusion. (Courtesy of Karkouti et al. [91])

recommendations. Except for one randomized controlled trial on cerebrospinal fluid drainage (CSFD), the vast majority of evidence is level B with single-center cohort studies of a few hundred patients [4, 5]. Besides the inherent variability in pathophysiology, comparability of results between studies is limited by the heterogeneity in definitions, inclusion/exclusion criteria, and therapy combinations [8, 31]. The risk of generalizing results from single centers of excellence must also be considered [2, 4], as a surgeon's experience, treatment volume of an institution [2], and implementation of a protocoled care package [41] have been shown to have a significant effect on outcomes.

Cerebrospinal Fluid Drainage (CSFD)

Evidence from animal studies in the 1960s showing that reduced CSF pressures improved SCPP provided the initial justification for trialing CSFD [8, 30, 31]. Cases of CSFD reversing SCI symptoms [8, 93] and Coselli et al.'s landmark randomized controlled trial [94] validate their potential benefit in humans. Conversely there are cases of SCI developing despite prophylactic CSFD and recovering without it [95], with conflicting findings in the literature as highlighted in the systematic [8] and Cochrane review [31]. While recognizing the weaknesses in the current data, both of these reviews concluded there is sufficient evidence to support the role of CSFD in high-risk patients as part of a multimodal proactive approach [8, 31]. The 2010 ACCF and 2014 ESC guidelines made similar recommendations for use as a protective strategy in high-risk open thoracic aortic repair procedures [4, 5]. However, the clarity of this statement is misleading, with no criteria to identify the "high-risk" patient. While the authors of the Cochrane review caution against extrapolating benefit beyond the selection criteria in the Coselli trial (i.e., open repair of Crawford type I–II TAA in a center of excellence) [31], the other systematic review specified "high risk" as open repair of Crawford types I–III with and without dissection [8]. Given that the risk of SCI is unpredictable, many centers use CSFD in all patients, including those undergoing extent IV repair.

Increasingly the risks of CSFD are recognized, although in a large portion of the literature systemic evaluation of the rate and risks of CSFD complications are poorly reported [96]. Intracranial hemorrhage is the most significant in terms of the potential morbidity and mortality, with an incidence 0.45–7.8%, of whom 10–50% develop significant neurological deficit or die [68, 97–103]. CSF leak with post-dural puncture headache (incidence 0.74–9.7% [12, 98, 99, 102, 103]), neuraxial hematoma (incidence 0–3% [68, 98, 103–105]), catheter fracture, meningitis, para-lumbar infection, and abducens nerve palsy (incidence <1% [68, 103, 106]) is also reported in the literature.

Even more importantly, there is a paucity of literature to substantiate important management standards for CSFD to minimize complications with use. This includes specifics about pressure thresholds and drainage limits, duration of use, and infrastructure requirements. Drainage of larger volumes of CSF is the most consistent independent predictor of hemorrhagic complication [97, 102], with high CVP at the time of cross-clamping also being noted by one group [102]. Maintenance of CSFP >7–10 mmHg with continuous monitoring, limiting drainage to <15–25 mL/h, maintenance of a recumbent position (<30 degrees reverse Trendelenburg), early removal within 48–72 h postoperatively, capping the drain 24 h prior to removal to allow CSFP to normalize, and cautious use of anticoagulation therapy even after drain removal are the most common expert recommendations for safe CSFD in the literature [95, 97, 98, 102, 106], with various "care bundles" described in the literature [98, 107–110]. However, this is far from universal, with one group advocating a more flexible approach, limiting drainage volumes to the upper limits of CSF circulating volume (140–165 mL) intra- and postoperatively [102], while others individualize the baseline pressure target based on the preoperative "opening pressure" at the time of drain placement [42]. While drainage of bloody CSF is only associated with radiological evidence of intracranial hemorrhage in 50% of cases, it is widely recognized as a sensitive indicator of increased risk for ICH requiring the immediate attention to limit significant morbidity and mortality [97, 98, 102], as covered in section "Technical Specifics of Cerebrospinal Fluid Drainage." Irrespective of the value of each component, a recent study that protocoled CSFD management achieved a substantial reduction in their institution's complication rate (from 24.1% to 5.7%, $p = 0.067$) [68].

Supporting SCPP

Increasingly the importance of supporting systemic blood pressure (with mean arterial pressures 80–100 mmHg) and cardiac output to maintain SCPP is recognized for at least 48 h postoperatively until SCAN has sufficiently remodeled to compensate for the loss of segmental arterial supply [41, 42, 68, 106]. While direct measurement of SCPP [40, 111], functional MEP testing [44, 109], and risk factor analysis [99, 112, 113] have supported this, the role of blood pressure augmentation in reversing symptomatic SCI is most compelling [95, 114]. Consideration of the patient's preoperative baseline arterial pressure and withholding antihypertensive preoperatively is recommended [13, 34]. Optimization of oxygen delivery with aggressive blood transfusion targets also features in recent institutional protocols [41, 68].

Intraoperatively the established benefits of distal aortic perfusion by cardiopulmonary bypass (CPB) or left heart bypass are recognized for open repair of type I–II TAAA in centers with significant experience [63, 115]. Guidelines recommend a proximal mean arterial pressure of 90–100 mmHg and distal arterial pressure of 60 mmHg to ensure adequate

spinal cord perfusion [4]. There is also evidence that non-pulsatile perfusion is inferior to pulsatile perfusion at the same mean pressure [34]. Further technical aspects of these techniques are covered above in section "Surgical Technique."

Other surgical techniques to optimize collateral blood flow to the spinal are largely controversial. Historically, re-implantation of segmental arterial supply via the intercostal and lumbar arteries has been a dominant protective strategy in surgical TAAA repair. However, by prolonging the aortic cross-clamp time, this intervention is not without risk. Techniques may be indiscriminate or selective based on clinical assessment of back-bleeding, intraoperative MEP, or preoperative imaging [8, 116]. Some retrospective analyses have shown a tenfold increase in SCI risk when critical zone (T9-L1) intercostal vessels were oversewn in type I/II open repair [117, 118], and selective re-implantation has been associated with a significant protective effect when used as part of a multimodal strategy [46, 116, 119, 120]. However, the work of Griepp et al. (n = 95) and later Etz et al. (n = 100) challenged this doctrine by extensively sacrificing segmental arteries under EP monitoring without SCI [121, 122]. While recognizing the limitations of these observational studies, the authors contested re-implantation was not only unnecessary when other means are used to support the SCAN, but it is potentially harmful by prolonging surgery and causing steal phenomenon. In reality, both arguments are likely to hold merit, and while not necessary in the majority, it may be critical in a few, justifying a balanced approach with selective re-implantation in current guidelines [4, 42, 46].

The importance of patency and revascularization of independent arterial beds contributing to the SCAN is equally controversial. While some studies have identified left subclavian artery coverage as a risk factor for SCI [13, 123], it is not a consistent finding [124–127]. Additionally, prophylactic revascularization may be justified in order to reduce the risk of stroke or left arm ischemia [128, 129].

Staged repair is a relatively new concept based on supporting collateral flow through SCAN remodeling. While the physical effects of staging on SCPP are compelling [34], the complexity of how these impact clinical outcomes, especially for an individual patient, is yet to be fully understood. This is not limited to open repair, with various hybrid and endovascular staging methods described that are beyond the scope of this chapter, and we refer to a previous review for further detail on this [58].

Hypothermia

The protective benefits of hypothermia have been long recognized [130]. Various methods including local epidural cooling [117, 131], profound (<20–22 °C) hypothermia with CPB with or without circulatory arrest [132, 133], moderate (30–34 °C) hypothermia with partial bypass (aortofemoral or atriofemoral) [134, 135], and mild permissive hypothermia [136] have been advocated, with a protective effect in high-risk cases when used in institutions with significant experience.

However, as already noted above in section "Surgical Technique," the association between hypothermia (<34.5 °C) and an increase in postoperative organ dysfunction and mortality in patients having aortic surgery [137] cautions against routine use, with specific concerns about an increased risk of coagulopathy, pulmonary dysfunction [132, 138], and arrhythmias [134] in open TAAA repair studies. Currently moderate systemic hypothermia is considered a reasonable strategy to protect the spinal cord during open surgical repair of the descending thoracic aorta, and epidural irrigation with a hypothermic solution may be considered [4].

Drugs

While the desire for a pharmacologically protective agent has been exhaustive, the evidence base remains weak [106]. While intravenous naloxone [139, 140] and intrathecal papaverine [135, 141] have been shown to have protective benefit in human trials, the benefits of thiopentone [142], systemic steroids [143], lidocaine [144], intrathecal methylprednisolone [145], deferoxamine [146], superoxide dismutase [146, 147], minocycline [148] and erythropoietin [149], testosterone [150], and dexmedetomidine [151] are limited to animal studies.

The 2010 ACCF guidelines recommend that use of high-dose systemic glucocorticoids, mannitol for osmotic diuresis, intrathecal papaverine, and various anesthetic agents to suppress metabolic suppression may be considered [4].

Hyperbaric Oxygen

In our institution we have had positive experience with early institution of hyperbaric oxygen therapy in three patients, all of whom recovered full neurological function. While the evidence base is currently limited to case reports, this is an emerging field of research.

Technical Specifics of Cerebrospinal Fluid Drainage

Use and familiarly with the manufacture's recommendations of a dedicated lumbar drainage kit that includes a 14ga introducer needle, specialized multi-orificed silastic drainage catheter, and external drainage and monitoring system is required. Once identifying that a CSFD is indicated, important contraindications should be considered. Current coagulation guidelines for neuraxial techniques should be followed [152]. The presence of intracranial disease that could predispose to neuraxial or intracranial bleeding complications in the context of iatrogenic intracranial hypotension should be

considered in liaison with the surgeon, including cerebral aneurysms, arteriovenous malformations, cerebral atrophy, cranial vault abnormalities, chronic subdural hematomas, or a history of recent head trauma [153]. An assessment of risk for infectious complications should also be made as per current guidelines for neuraxial techniques, and while a bacteremia or epidural abscess would be grounds to delay surgery altogether, the drain should also not be placed over a localized area of infection [154]. Other preparations in terms of fully informed consent, strict asepsis, and monitoring are also as per local/national requirements for any neuraxial technique [155, 156].

CSFDs are usually inserted the day prior to surgery in our institution, in an awake patient, in the lateral position, and in a low lumbar intervertebral space [107]; however, variations on this with good clinical outcomes are described [98]. Placement the day prior to surgery allows for contingency planning in the event of a traumatic/bloody tap, including delaying surgery and systemic anticoagulation for 24 h [4, 152]. However, this can be resource intensive with the need to observe the patient in the CVICU overnight to insure the drain doesn't become blocked due to kinking or clot formation. Placing the patient in the lateral position is intended to decrease the hydrostatic pressure of the column of CSF and limit the volume of CSF uncontrollably drained during insertion of the drain. Puncture of the dura below the level of the conus medullaris is theoretically less likely to transfix the filum terminale. With the patient awake, redirection of the needle and drain in the event of paresthesia may also limit the potential for nerve injury.

Published techniques variably describe feeding 8–20 cm of catheter into the subarachnoid space beyond the epidural tip [107]. While ensuring that a sufficient length is inserted to avoid the accidental displacement of the catheter with patient movement, the length of catheter that can be inserted is often limited by mechanical difficulties feeding the catheter, a desire to limit uncontrolled drainage of CSF, or patient complaints of paresthesia. If adjustment of the catheter position is required, particular care should be taken when withdrawing the catheter back through the needle due to the risk of shearing it against the needle tip. If any slight resistance is felt, the whole needle and catheter must be withdrawn as one unit and the procedure started again.

Once the drain is inserted and the introducer needle removed, the drain should be secured with care to minimize the risk of kinking and connected to the pressure transducer and drainage bag while maintaining strict sterility (see Fig. 41.8). The level of the transducer should be set and zeroed at the level of the right atrium and ideally fixed to the patient and/or bed. When the drain is open, the level of the transducer and drain should be closely monitored and the patient kept at less than 30 degrees reverse Trendelenburg, with a high level of vigilance to avoid accidental excess CSF drainage. Development of an automated device for pressure- or volume-controlled CSF drainage with simultaneous measurement is described in the literature (LiquoGuard®, Moller Medical GmbH, Fulda, Germany), and while potentially having safety benefits over standard dripping chambers, this is yet to be substantiated [157].

Fig. 41.8 Setting up electronic pressure transduction of the cerebrospinal fluid pressure. Note that with using this set-up the pressurized flush function on the transducer must be removed

If placed the day before surgery, the drain should be left off overnight and opened once an hour to drain 1–2 drops to ensure patency. Once the patient is in the operating room and positioned for surgery, the transducer should be carefully checked and the drain opened to drain to a CSF pressure of 10 mmHg prior to aortic clamp placement, limited to 10–20 ml/h (or as per the agreed institutional practice, the rationale for which was explored in section "Spinal Cord Protection Strategies" above). At least hourly review and documentation of the drainage pressure (absolute number and waveform), drainage volumes, and the presence of any blood are crucial for safe use. Similarly, at the end of the case, the drain should be

clamped before repositioning the patient and only resumed once the patient is finally positioned on their CVICU bed and close monitoring is possible.

In the context of intra- or postoperative evidence of neurological deficit, spinal cord perfusion should be optimized with an increase in mean arterial pressure targets, review of hemoglobin targets, and consideration to further decrease CSF pressure and increase drainage targets. In the postoperative period, the need for imaging (ideally magnetic resonance imaging (MRI) but not always feasible) to assess whether spinal ischemia or an epidural hematoma is the precipitant cause of deficit and the role of hyperbaric therapy can also be considered following optimization of CSF hemodynamics. In the event of frankly bloody CSF drainage, a cessation or reduction in the drainage volume limit should be considered, coagulation function optimized, with imaging to assess for intracranial hemorrhage as soon as the patient is stable enough, with neurosurgical consultation as appropriate.

The CSFD should be removed as soon as possible to reduce infectious complications. Some guidelines recommend drainage for at least 48 h and up to 72 h postoperatively to prevent delayed onset paraplegia [5, 31]. Alternatively, once the patient is neurologically accessible with normal lower limb findings and hemodynamically stable, the CSFD can be clamped and removed if the neurological status remains stable for a further 24 h. Coagulation status should be reviewed before removal of the drain, as described prior to drain insertion. In the event a patient develops sepsis in the postoperative period, the risk-benefit balance of removing the CSFD should be carefully considered, the CSFD not only being a potential source of infection but also a receptacle for colonization. In the event of delayed neurological deterioration after removal of the CSFD that does not improve with blood pressure support, the need to reinsert the CFSD will need to be considered.

While there is limited evidence to validate the optimal technique for CSFD placement and management, evidence substantiates that there should be an agreed standard operating procedure developed at an institutional level [68]. All staff involved in the care of patient's having TAAA surgery should be orientated to this, and any deviations from care be discussed at a multidisciplinary level.

Renal Protection Strategies

Renal dysfunction is a common complication after TAAA surgery, and while a much smaller proportion proceed to require permanent dialysis, it is a consistent independent predictor of major morbidity and mortality [158, 159]. The ability to assess the incidence, risk factors, and effective therapeutic interventions to prevent renal dysfunction continues to be hampered by the lack of consistency in the criteria to define acute kidney failure [159, 160]. Additionally, the mechanisms for renal injury are diverse, and the contribution variable between patients, including [85, 161, 162]:

- Nephrotoxic insult, namely, with contrast media preoperatively
- Ischemia related to the aortic cross-clamp, hypotension, and anemia
- Atheroembolic phenomenon
- Reperfusion tubular injury, mediated by various chemical immunomodulating agents

Preoperative renal dysfunction (creatinine >1.5 mg/dL) is consistently found to be an important predictor of postoperative renal dysfunction [85, 158, 159, 161, 162]. Complex surgery with prolonged ischemic times (clamp time > 100 min), greater intraoperative hemodynamic instability, increased bleeding, and the need to return to operating room is understandably associated with worse renal outcomes [158, 159].

In the absence of any effective interventions to treat renal failure, prevention of injury is critical. Despite an extensive body of research, there is limited evidence to support any pharmacological agents as being renoprotective [163]. Furosemide, mannitol, and dopamine [164–167] have been shown to be ineffective and potentially even harmful [4, 168–170], while the utility of corticosteroids, fenoldopam, and dopexamine remains unproven [85, 158].

Considering the potential for preoperative optimization is important if possible. Identifying the "at-risk" patient provides an opportunity to institute additional intraoperative support. Contrast-induced nephropathy should be allowed to resolve with hydration support and N-acetylcysteine [171, 172] or avoid contrast altogether by using alternative imaging techniques such as magnetic resonance angiography [162]. Limited evidence from animal studies also support the concept of post-conditioning, where a gradual increase in blood flow on unclamping reduces the degree of reperfusion injury [173].

In addition to maintaining euvolemia and supporting an adequate cardiac output and blood pressure perioperatively, renal perfusion can be selectively supported. This involves inserting perfusion catheters into the renal ostia and infusing a rapid 250–300 ml bolus, followed by ~20 ml/min or ~1000 ml/h of a cold crystalloid perfusion solution into each kidney. Although technically simple, the specific indications for use and techniques are controversial. Randomized data supports the use of cold (4 °C) crystalloid (Ringer's lactate) as superior to normothermic or cold blood [174, 175]; however, the specifics of the type of crystalloid or the utility of adding mannitol or steroids to the perfusate is unclear. American guidelines recommend considering cold (4 °C) crystalloid or blood

perfusion [4], while the European guidelines specify utility of cold renal perfusion when the ischemia time is greater than 30 min [5].

Postoperative Care

Part XII of this textbook comprehensively covers the postoperative requirements and potential complications following thoracic surgery. Chapters 46 and 47 specifically cover strategies for managing significant postoperative pain and preventing chronic post-thoracotomy pain.

Specific to TAAA surgery, preservation of spinal cord and end-organ function continues to be the primary concern in the immediate postoperative period. As in the intraoperative period, tight hemodynamic control, euvolemia, normal coagulation function, close protocolized CSFD management, and one hourly neurological assessment are crucial to optimal long-term recovery outcomes.

In our institute patients are transferred to the intensive care sedated and ventilation. Once the patient is hemodynamically stable, the sedation is temporarily held to assess neurological function by regular clinical examination. Sedation is weaned, and the patient is usually extubated in the first 12–24 h postoperatively. Our routine postoperative analgesia regimen comprises of a continuous local anesthetic infusion (ropivacaine 0.2% 5 cc/h) through surgically placed paravertebral catheters started on arrival to the ICU and opioid (hydromorphone/morphine) patient-controlled analgesia (PCA) boluses once the patient is conscious.

Summary

Cambria said it best – "absolutes in TAAA surgery are usually proven to be wrong" [176]. This not only recognizes the many limitations in the quality of current literature but the multifaceted complexity of the pathology, with no individual case being predictable.

Despite the limitations in knowledge and specifics in practice standards, fundamentals in improving outcomes are being established, including the development of protocols/packages of care, establishing institutional familiarity and experience, proactive measures to protect sensitive neural and renal tissue from ischemia, and the early identification of compromise in order to minimize the severity of long-term injury.

Clinical Case Discussion

A 40-year-old lady with Marfan syndrome has a Crawford type II TAAA which measures 6.4 cm. She is an ex-smoker with no other significant comorbidities.

Question 1. What are the major perioperative concerns?

Question 2: There is a suitable proximal clamp site just distal to the left subclavian artery. What are the options for perfusion management for this case?

Question 3: The patient develops weakness in both legs in ICU on the first postoperative day. How would you manage this situation?

Answer 1: For a complete discussion of these issues, see the section "Intraoperative Management" (from page 14)

(a) Massive bleeding and coagulopathy
(b) Spinal cord injury
(c) Acute kidney injury
(d) Acute lung injury due to prolonged OLV, surgical manipulation, and massive transfusion

Answer 2: For a complete discussion, see section "Surgical Technique" (from page 6)

(a) Left heart bypass – preferred
(b) Partial cardiopulmonary bypass
(c) Deep hypothermic circulatory arrest

Answer 3: For a complete discussion, see sections "Spinal Cord Protection Strategies" and "Technical Specifics of Cerebrospinal Fluid Drainage" (specifically page 21)

(a) Increase MAP to 90–100 mmHg
(b) Increase CSF drainage to maintain ICP less than 10 mmHg
(c) Raise the hemoglobin to over 90–100 g/dl
(d) MRI/CT scan to rule out epidural hematoma

Part X

Anesthetic Management of Uncommon Pulmonary Procedures

Thoracic Anesthesia in the Developing World

42

Swapnil Yeshwant Parab and Sheila Nainan Myatra

Key Points

- Surgical and anesthesia practices are often modified to strike a balance between available resources and improving outcome of the patients.
- Patients presenting for thoracic surgeries are often suffering from pyogenic infections, TB, and helminthiasis. In addition to being sick and infectious, they also suffer from chronic malnourishment and anemia.
- Respiratory physiotherapy, including muscle-strengthening exercises, helps to improve the cardiorespiratory conditioning of the patient. The quantity of time spent performing physiotherapy exercises is an important determinant of improvement in respiratory functions.
- In developing countries, the choice of lung isolation device depends largely on the availability of the device and fiber-optic bronchoscopes. In absence of a pediatric fiber-optic bronchoscope, DLTs are preferred over bronchial blockers as DLTs can be inserted blindly and their position can be confirmed by clinical methods like inspection of chest expansion and auscultation.
- Thoracic surgery for infectious processes is more likely to develop intraoperative bleeding.
- With improvements in anesthesia and surgical methods, thoracic surgery for complications of pulmonary tuberculosis is less morbid than previously. As a result, the need for surgery is increasing.
- Some patients who present for surgery due to empyema will have an underlying bronchopleural fistula. A history of position-related productive cough should be carefully sought.

Introduction

The last five decades have witnessed a significant decline in total perioperative mortality (from 10,603 per million before the 1970s to 1176 per million in the 1990s–2000s) [1]. Reduction in anesthesia-related perioperative mortality has been one of the reasons for improvement in perioperative care. This improvement has been largely due to vast research and development in fields of anesthesia and perioperative medicine leading to better understanding of physiology; application of evidence-based safe anesthesia practices, drugs, and techniques; and vigilant perioperative monitoring. However, the improvement is not uniform across the globe and has occurred mainly in developed countries. Perioperative mortality risk is still two to three times higher in low-income countries as compared to high-income countries [1]. Degrees of development in the field of anesthesia and perioperative medicine vary from country to country and also within each country. In developing countries, there are few centers which maintain similar standard of care as that in developed countries and struggle to meet the demands of heavy patient load, within the limits of available resources [2]. In these countries where primary healthcare needs are unmet, specialty fields like thoracic anesthesia have a long way to go.

Challenges Faced by Thoracic Anesthesiologist in the Developing World

(a) Spectrum of disease:
Respiratory diseases are among the leading causes of death worldwide. Lung infections (mostly pneumonia and tuberculosis), lung cancer, and chronic obstructive pulmonary disease (COPD) together accounted for 9.5 million deaths worldwide during 2008 (one-sixth of the global total) [3]. Among these diseases, lung infection is

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_42

the leading overall cause of mortality in developing countries [4]. Low immunization rates, overcrowding, poor nutrition, and HIV infection are among the common causes for acute lung infections. On the other hand, industrialization, air pollution, indoor smoke, and cigarette smoking are common causes for growing incidence of chronic respiratory conditions like COPD, asbestosis, pneumoconiosis, and asthma. Growing civilization has increased the numbers of road traffic accidents and chest trauma. Thoracic surgeries are conducted largely for the management of infection-related diseases like bronchiectasis, empyema, lung abscess, pulmonary hydatid cysts, and complicated tuberculosis (TB). These patients are often sick and infectious. Many patients are chronically malnourished and anemic. They often present late for the treatment due to ignorance and poverty.

(b) Human resources:
In the developing world, especially in the rural and the underprivileged areas, safe anesthesia services are lacking [5]. Some tertiary care centers and private institutes offer subspecialty services like thoracic anesthesia, but they are few in numbers and unable to meet the huge patient load. Often patients have to travel a long distance to reach these centers. Majority of trained doctors prefer to work in major cities for better opportunities, income, and lifestyle, leading to uneven distribution of skilled manpower. A study on anesthesia services in Haiti, a developing country, showed that non-physicians conduct majority of anesthesia procedures [6]. Another survey showed severe shortage of manpower and other resources was present even at the university teaching hospital in Zambia [7]. Dubowitz et al. highlighted that number of anesthesia providers per capita of population in developing countries was significantly less in comparison to developed world [8].

Apart from anesthesiologists and thoracic surgeons, a thoracic surgery unit involves the active participation of well-trained nursing staff, chest physicians, and physiotherapists. In many developing countries, there is neither a nurse anesthetist nor a technician. The anesthesiologist has the sole responsibility to deliver safe anesthesia. Lack of structured educational programs for nurses and other paramedical staff and meagre salaries are often the reasons for shortage of skilled support staff.

(c) Technical and infrastructural resources:
Apart from a trained anesthesiologist, safety of anesthesia services depends upon availability of monitors, drugs, anesthesia workstations, and other equipment. In addition, adequate laboratory, blood bank, and radiodiagnostic facilities are essential. In developing countries, uniform availability of such technical and infrastructural resources is lacking. Even in the twenty-first century, in developing country like Uganda, 74% of anesthesiologists reported lack of pulse oximetry in the operation theaters, the most commonly used volatile anesthetic was ether (68%), and drugs like non-depolarizing muscle relaxants were not available to 69% of anesthesiologists [9]. Specific to thoracic anesthesia, pediatric fiber-optic bronchoscopes, fluoroscopy machines, ultrasound machines, small sizes of bronchial blockers and double-lumen tubes (DLT), and multichannel monitors are unavailable in many centers. In some centers, pulmonary functions are often assessed by bedside tests, and objective spirometry examination is not available. Cardiopulmonary exercise testing (CPET) and lung perfusion scans are available only at few centers across the country. Common reasons for the unavailability of these resources are financial burden and lack of trained staff to maintain these services. As a result, the thoracic anesthesiologist often has to adapt to the needs and situation and make proper utilization of available resources to deliver safe anesthesia. This has led to development of many "adaptive modifications" in the practices of thoracic anesthesia. These have been discussed in separate section later in the chapter.

(d) Education and research:
In developing countries, there is a lack of uniformity in delivering proper education in anesthesia. Tertiary care centers are few in numbers, and in these centers, there is often a shortage of teaching staff. Many trained professionals do not take up teaching jobs, due to meagre salaries paid in teaching institutes. As a result, training to medical students, residents, and nurses cannot be imparted properly. In many developing countries, language barrier is a major hurdle in imparting education in anesthesia. Even within a country, a uniform national language is not followed, and local languages are often used for communications. Hence, it becomes a great difficulty for faculties from developed countries to impart education in conferences.

Underreporting, poorly maintained medical records, lack of electronic database, failure to conduct proper audits, and quality improvement drills are some of the obstacles in fields of medical research. If publication in journals is considered as crude indicator of research standards, then a bibliometric analysis of highly cited anesthesia journals showed a meagre (0.3%) contribution from low-income countries [10].

Conduct of Thoracic Anesthesia in Developing World: Meeting the Challenge

Surgical and anesthesia practices are often modified to strike a balance between available resources and improving outcome of the patients. Principles of anesthesia management

for patients undergoing thoracic surgeries in developing world share some common aspects during preoperative, intraoperative, and postoperative periods. At the same time, certain aspects are disease specific and need modifications in anesthesia management. Following are the common aspects of anesthesia management for thoracic surgeries in developing countries.

Preoperative Care: Assessment and Optimization

- *Malnutrition*: Patients presenting for thoracic surgeries are often suffering from pyogenic infections, TB, and helminthiasis. In addition to being sick and infectious, they also suffer from chronic malnourishment and anemia. With ongoing catabolism and inadequate oral intake, patients tend to lose weight and muscle mass, developing a state of protein-energy malnutrition (defined as a negative balance of 100 g of nitrogen and 10,000 kcal within a few days) [11]. Resultant physiological and psychological changes lead to "deconditioning" of the patient [12]. It requires a team of nutritionist, respiratory physiotherapist, and psychologist to optimize the general health of the patient. In the developing world, shortage of skilled support staff results in the responsibility for optimization of patient being shared by primary physician, anesthesiologist, and family members of the patient, sometimes with additional help from medical social workers. All the efforts to improve nutritional status of the patients are required to be started as early as possible. Nutritional demands vary from patient to patient, but care needs to be taken to meet the requirements for protein, energy, and micronutrients. Enteral nutrition is preferred over parenteral route. Patients with esophageal diseases suffer from severe dysphagia. Such patients should undergo endoscopy-guided nasogastric tube insertion. Neoadjuvant chemotherapy in case of esophageal cancers relieves dysphagia in many patients. Usually, a week of nutritional support is required to halt the catabolic state of the patient, and a month is required to regain nutritional status. However, often due to late presentation, there is hardly any time available for nutritional optimization. Nonavailability of good value nutritional products, poor financial status of the patient, and illiteracy leads to inadequate nutritional optimization of patient.
- *Anemia*: Anemia is a major public health problem in developing world. In developing countries, anemia affects 42% of children less than 5 years of age and 53% children between 5 and 14 years of age [13]. Women of childbearing age form another vulnerable population suffering from anemia. Nearly 7.5–33% patients suffering from COPD are also affected by anemia, the most common cause being anemia of chronic disease [14]. Anemia is often due to iron deficiency, following anorexia, faulty food habits, diet deficient in iron supplements, and worm infestations. Deworming agents like oral albendazole as a single dose should be considered especially in children. Hematinic and multivitamin supplements should be started from the first visit. If patient is intolerant to oral iron supplements or unable to swallow, then intravenous iron replacement or packed cell transfusions should be given prior to surgery. Recently, available intravenous iron supplementations are safe, effective, and quick in increasing hemoglobin level prior to surgery and can avoid transfusion-related risks.
- *Respiratory optimization*: Infections of the respiratory tract are the leading cause of mortality in the developing world. Chronic respiratory diseases are also prevalent in developing countries. They include restrictive lung diseases like pneumoconiosis, asbestosis, byssinosis, etc. and obstructive airway diseases like asthma and forms of COPD – emphysema, peripheral airway diseases, and chronic bronchitis. Patients undergo preoperative radiological imaging and pulmonary function tests to know the severity of the disease. Respiratory optimization includes administration of bronchodilators, good hydration, frequent nebulization, postural drainage of the secretions, and treatment of infections. Respiratory physiotherapy, including muscle-strengthening exercises, helps to improve the cardiorespiratory conditioning of the patient. The quantity of time spent performing physiotherapy exercises is an important determinant of improvement in respiratory functions. Patients with excessive sputum production (e.g., chronic bronchitis) are most benefited by chest physiotherapy. Hence, chest physiotherapy should begin as early as possible. Proper education and counselling of the patient are required to improve the compliance of the patient to perform physiotherapy exercises.

Intraoperative Care

During the intraoperative period, the aim of the thoracic anesthesiologist is to maintain the safety of the patient, amidst the deficiencies of technical resources and skilled manpower. The inadequately optimized general condition of the patient often adds to the challenges. Following is a discussion about certain areas of special attention when administering anesthesia for thoracic surgery in developing world.

- *Use of antibiotics*: Patients with respiratory infections are usually on preoperative antibiotics. The anesthesiologist needs to ensure that adequate doses have been given preoperatively and necessary intraoperative doses are repeated in time. Some of the antibiotics like vancomycin

can cause severe allergic reactions and hypotension intraoperatively. Drug interactions need to be considered, especially when a patient is on antitubercular treatment. (Separately covered in another section of the chapter).

- *Low serum albumin and choice of intravascular fluids*: Malnourished patients with low serum albumin levels fail to maintain intravascular volume due to decreased colloid osmotic pressure. Low serum albumin level is also identified as independent preoperative indicator of acute kidney injury in patients undergoing esophageal cancer surgeries [15]. Intraoperatively, intravascular volume replacement is done with semisynthetic colloid solutions like succinylated gelatin and hydroxyethyl starch. Intravenous albumin is often not available and is also expensive. In absence of colloids, blood products are also used for volume replacement.
- *Blood loss*: Patients with acute and chronic inflammatory lung diseases tend to have higher blood loss during thoracic surgeries. In cases of preoperative anemia, packed cell transfusions are required even with minimal blood loss, thus increasing blood transfusion-related infection and anaphylactic and immunological risks in the perioperative period. Some institutes do not have in-hospital transfusion medicine departments. In such cases, delay may occur in receiving blood products in the operating theater, and anesthesiologists prefer to call for one unit of packed cell or whole blood well in advance.
- *Positioning*: Most thoracic surgeries are carried out in lateral decubitus positions, except when median sternotomy is required. It is the shared responsibility of the anesthesiologist and surgeon to correctly position the patient. Care needs to be taken to prevent neurovascular injuries due to faulty positioning. Chronically malnourished and dehydrated patients tend to develop hypotension after turning from supine to lateral position. Such patients also carry a higher chance of developing decubitus ulcers or pressure sores at bony prominences. Anesthesiologists need to be extra vigilant to provide adequate padding under bony prominences to prevent pressure sores.
- *Lung isolation*: In developing countries, lung isolation techniques are required primarily to facilitate surgical exposure during thoracoscopic surgeries and to prevent contamination of non-infected areas of lungs. Lung isolation devices of adequate sizes, pediatric flexible bronchoscopes, fluoroscopic backup, and facilities for advanced hemodynamic monitoring are often unavailable in many institutes in developing countries. In many centers, surgeries are carried out with an open thoracotomy approach, and both lungs are ventilated with low tidal volumes. In such centers, if lung isolation is mandatory, then patients are referred to centers where advanced facilities are available. Some centers have advanced surgical technologies (e.g., thoracoscopes, robotic surgery unit, etc.), but anesthesia equipment (flexible bronchoscopes, bronchial blockers, etc.) required for lung isolation are not available. In such conditions, the anesthesiologist needs to be adaptable and innovative to use the available resources to provide good quality lung isolation without compromising with safety of the patient. Many such adaptations remain underreported in medical journals. It must be remembered that these are not standard practices and limited evidence is available to recommend the use of these methods. Standard equipment and techniques should be preferred whenever available. Following is the discussion about few such adaptations which have been reported in the literature.

Selection of Lung Isolation Devices

In developing countries, the choice of lung isolation device depends largely on the availability of the device and fiber-optic bronchoscopes. In absence of a pediatric fiber-optic bronchoscope, DLTs are preferred over bronchial blockers as DLTs can be inserted blindly and their position can be confirmed by clinical methods like inspection of chest expansion and auscultation, followed by fine adjustments in their position. DLTs of smaller sizes (26 F, 28 F, and 32 F) and bronchial blockers of pediatric sizes are often not available. Hence lung isolation in children and adults of short stature becomes difficult. In such conditions, adaptations like endobronchial intubation and the use of Fogarty catheters are commonly followed in developing countries.

In places where DLTs are not available or in young children (less than 8 years old), a single-lumen endotracheal tube is advanced into the main bronchus on the opposite side of surgery. If in the right main bronchus, the Murphy's eye would ventilate the right upper lobe. Bronchial diameter and distance from the tip of tube to the upper margin of cuff are taken into account while deciding the size of endotracheal tube. The major problems with endobronchial intubation are dislodgment of the tube and inability to apply suction to the opposite bronchus. These problems can be overcome by use of largest possible size of the single-lumen tube, a steep head-down tilt of the table, and frequent suctioning through an extra-luminal suction catheter placed in trachea. This technique is commonly followed in pediatric cases in developing countries.

Fogarty arterial embolectomy catheters (Edwards Lifesciences, Irvine, CA, USA) are not created for use in airways; however use of Fogarty catheters is prevalent in developing countries for the purpose of lung isolation in small children, as pediatric size bronchial blockers and DLTs are not available. These catheters can be passed intraluminally or extra-luminally, and their position is confirmed by flexible bronchoscope, if available. Two major difficulties faced in placement of Fogarty catheters are to direct the catheter tip into target bronchus and to identify the transparent

balloon by FOB. The catheter tip is bent to 45° by using wire stylet to facilitate guidance into desired bronchus. The balloon can be filled with saline containing methylene blue to facilitate identification by a flexible bronchoscope.

Methods to Aid Insertion of Lung Isolation Devices

In absence of a pediatric flexible bronchoscope, blind insertion of the DLT followed by auscultation to confirm placement of the DLT is the most commonly followed practice in developing countries. However, there are certain techniques that may help inserting a lung isolation device when a pediatric flexible bronchoscope is not available. These techniques are discussed below.

- *Pre-intubation measurements of trachea and bronchus*:
  In absence of a pediatric flexible bronchoscope, an adult flexible bronchoscope, which is commonly available, can be used to measure the distance from central incisor to carina, and from carina to secondary carina, before placement of any lung isolation device. These measurements are then used to guide a DLT or bronchial blocker through the exact distance from central incisor. A study showed that the success rate of optimal positioning of the DLT was significantly higher in the group where DLTs were placed as per distances measured by flexible bronchoscope as compared to the group where DLTs were placed blindly [16].
  Measurement of tracheal diameter at cricoid level, and bronchial diameter, using CT scan or chest radiograph, helps to choose correct size of DLTs. This is especially important in the Asian population in whom height-based criteria for choosing DLTs are not helpful. In Asian patients who are shorter than 150 cm, anesthesiologists often encounter difficulty in passing a 35 F DLT through the subglottic portion of trachea. In a retrospective analysis of Japanese women shorter than 150 cm, the primary reason for failure of first attempt of intubation was narrow tracheal diameter at cricoid level [17]. The use of another lung isolation device leads to additional cost to the patient, apart from to hemodynamic stress of a second intubation. Hence, it may be useful to measure the tracheal diameter at cricoid level prior to choosing a DLT size, especially in Asian patients shorter than 150 cm in height. It is also common practice to use one size smaller DLTs in these patients rather than using larger one.
- *Extra-luminal use of bronchial blockers*:
  Bronchial blockers are meant to be deployed through the lumen of an endotracheal tube into the desired bronchus with the help of a pediatric flexible bronchoscope. However, there are conditions where bronchial blockers and a pediatric flexible bronchoscope are difficult to pass together through an endotracheal tube, especially in small children and patients with a tracheostomy. In such conditions, or when a pediatric flexible bronchoscope is not available, bronchial blockers are passed extra-luminally and are guided into position using an adult or pediatric bronchoscope passed through the lumen of the endotracheal tube. There are case reports of the use of pediatric 5 F Arndt blockers (Cook Medical Ltd) extra-luminally in children less than 2 years of age [18, 19]. A study by Templeton et al. compared intraluminal versus extraluminal use of 9 F Arndt blocker in adult patients and found that the extra-luminal placement of a bronchial blocker is faster, as compared to intraluminal placement, without any difference in the quality of lung isolation or postoperative sore throat [20].

Methods to Monitor the Position of the Lung Isolation Device

- *Use of basic clinical skills and auscultation*:
  In developing countries, the position of a DLT is most commonly confirmed by inspection of chest expansion and auscultation. In conditions where minimum basic monitoring devices are not available, it is a safe practice to fix the chest piece of the stethoscope to the patient's chest on non-operative side and monitor regional ventilation through auscultation. This practice enables the anesthesiologist to detect problems like intraoperative bronchospasm, dislodgment of lung isolation device, pulmonary edema, atelectasis of the lung, etc. Modern anesthesia workstations give accurate outputs in the form of compliance, peak inspiratory pressure, end-tidal carbon dioxide curve, exhaled tidal volumes, etc. and provide continuous monitoring of ventilation. However, in many centers in developing countries, anesthesia workstations are not available, and patients are ventilated manually. In these situations, the reservoir bag in the hand of the anesthesiologist is sometimes the only means to monitor the lung mechanics of the patient. Clinical methods like a hand on the pulse are useful in assessing hemodynamic status of the patient. Such basic ways of monitoring help the anesthesiologist to continue safe delivery of anesthesia when advanced monitoring devices are not available.
- *Fluoroscopy and chest radiography*:
  Fluoroscopy can be used to positon lung isolation devices in the desired bronchus. Fluoroscopy machines are often available in institutes where orthopedic and interventional radiological procedures are carried out. Placement of a DLT, bronchial blocker (BB), or endobronchial intubation with a single-lumen tube can be confirmed using fluoroscopy [19, 21, 22]. This method is used when a pediatric flexible bronchoscope is not available. Chest radiography has also been used for the same purposes. These methods,

however, increase radiation exposure risk to the patient and healthcare workers in operating room.

- *Use of lung ultrasonography*:
  The flexible bronchoscope confirms the position of the double-lumen tube (DLT) in trachea and bronchus, but it cannot confirm good quality of lung collapse. Whether the lung to be isolated has collapsed, and whether the other lung is getting properly ventilated, is determined by assessment of regional ventilation. Traditionally, this is confirmed by auscultation. However, auscultation has low accuracy to confirm correct placement of lung isolation device [23]. Lung ultrasonography can differentiate ventilated lung from non-ventilated lung using lung sliding and lung pulse signs. Application of a linear transducer to the chest wall detects hypoechoic shadows of ribs with hyperechoic bright pleural line (see Chap. 28). During ventilation of the lung, movement at parietal-visceral pleural interface is detected by a sliding movement of the pleural line. This sign is called lung sliding. When the lung is not ventilated, then there is no such movement, and lung sliding is not visible. In an atelectatic lung, the pleural line moves with heartbeats, and this sign is called the lung pulse sign. Lung pulse is 93% sensitive and 100% specific for the diagnosis of atelectasis [24]. These signs can be used to determine regional distribution of ventilation following placement of lung isolation devices. This is a bedside, noninvasive, cost-effective, and real-time monitor of regional ventilation. This method has been used to determine position of DLTs and has been proved to be more efficacious than auscultation [25–27]. In centers where flexible pediatric bronchoscopes are not available, or in situations where bronchoscopes cannot be used, lung ultrasonography can be a better method than auscultation to determine position of DLTs.
  Ultrasonography has number of applications in perioperative medicine right from echocardiography to securing of vascular access. Though an ultrasonography machine is a costly instrument, a wide range of its applications and low maintenance cost make it a cost-effective option. A limitation of this technique is that ultrasonography is subjective and interindividual variations in findings can be possible. Anesthesiologists need to acquire the additional skill of ultrasonography. Intraoperatively, it cannot be performed on draped areas. With these limitations in mind, lung ultrasound can still be useful for thoracic anesthesiologist in the developing world to determine regional ventilation after placement of DLTs.
- *Bronchial cuff pressure monitoring*:
  Lung isolation devices can get dislodged intraoperatively which may lead to a loss of lung isolation and contamination of the other lung. The pediatric flexible bronchoscope is used to confirm and rectify any malposition of the lung isolation device. However, if a pediatric flexible bronchoscope is not available, the anesthesiologist has to rely upon clinical acumen to diagnose and correct the malposition. Araki et al. monitored bronchial cuff pressure using aneroid manometer and found out that continuous bronchial cuff pressure monitoring is a sensitive technique for detection of DLT displacement. When the DLT gets displaced, bronchial cuff pressure decreases even before any changes are detected in pressure volume or end-tidal carbon dioxide curves [28]. Bronchial cuff pressure can also be used to guide blind insertion of DLT when a pediatric flexible bronchoscope is unavailable. In a study of 79 patients, the DLT was introduced into the trachea using laryngoscopy, and further advancement into bronchus was done blindly by rotation of the tube to the ipsilateral side. The DLT was advanced until resistance was felt for any further movement. At this time, the bronchial cuff was inflated with 1–2 cc of air, and the DLT was withdrawn slowly while monitoring the bronchial cuff pressure manually. When a drop in bronchial cuff pressure was felt, further withdrawal of DLT was stopped, and after deflation of bronchial cuff, DLT was advanced by 1 cm (1.5 cm in case of 39 F DLT). Later, upon bronchoscopic confirmation, DLTs were found to be in the optimum position in 50 cases and within margin of safety in 27 patients [29, 30]. Thus, in case of unavailability of flexible bronchoscope, this method can help to place DLT blindly.

Postoperative Care and Analgesia for Thoracic Patients

Postoperatively, patients are transferred to a recovery room area, which is often understaffed. Often there is no designated post-anesthesia care unit. A high patient to nurse ratio means that one nurse has to look after more than two to three patients. Multichannel monitors are often not available, and vital signs are monitored manually, mostly by a junior nurse. This leads to infrequent and suboptimal monitoring of patient by the available nursing staff. Doctors managing recovery room areas are often not trained in intensive care medicine. Machines for arterial blood gas analysis, portable chest radiography, and ultrasonography are often not available. Lack of these machines may delay the diagnosis and treatment of any complications of the patients. It often leads to transfer of patients out of recovery rooms for diagnostic purposes, costing manpower and time. It also increases risk of transferring patient to the areas where monitoring is suboptimal. Support staff, like physiotherapist and nutritionist, are fewer in number as compared to the patient population and cannot spend adequate time with each patient. Family members of the patient play an important role, looking after the physiother-

apy, feeding, ambulation, cleaning, and also providing psychological support to the patient.

Postoperative pain relief is poorly addressed partly due to ignorance, the fear of respiratory depression, the non-availability of drugs or equipment such as infusion pumps, and inadequate nursing care. Post-thoracotomy pain is severe and incapacitating, leading to inadequate chest physiotherapy exercises, poor clearance of sputum, delayed ambulation, and chronic post-thoracotomy pain syndrome, which, if untreated, can lead to increased morbidity and mortality. Optimal pain management is of paramount importance. The pain score, which is considered the fifth vital sign, is often neither evaluated nor documented by the nursing staff. There is no preoperative counselling of the patient regarding various options available for control of pain. Many patients are uneducated and unaware of the options available for the pain control and often believe that pain is expected with surgery or that taking too many pain medications will lead to side effects. A designated acute postoperative pain management service is present in very few centers.

Opioids form the important component of postoperative analgesia being of low cost and effective as well. However, opioids are not available at many centers in developing world. As per a report, nearly 85% of world's morphine is consumed by 15% of world's population across ten developed countries, whereas 85% of remaining population consumes only 13% of morphine [31]. Fear of addiction, stringent rules and regulations for prescribing morphine, and high cost of importing morphine are some of the barriers for effective use of morphine in developing world. Even if they are available, there is significant fear among the treating physicians regarding the use of opioids for pain control, commonly referred as "opiophobia" [32]. Also, inadequate nursing staff and monitoring equipment make it unsafe to prescribe opioids in postoperative wards. Nonsteroidal anti-inflammatory drugs (NSAIDs) and paracetamol are the most commonly used drugs for postoperative pain management. Regional analgesia techniques like epidural analgesia, paravertebral blocks, or intercostal nerve blocks which play important role for postoperative pain management are often underutilized due to shortage of equipment (e.g., infusion pumps, patient-controlled analgesia systems, etc.), drugs (e.g., liposomal bupivacaine, additives like clonidine), and lack of clinical expertise. Drugs like ketamine, which have postoperative analgesic potential, are commonly used in the pediatric population. A study on prescription patterns and adequacy of analgesia in postoperative patients in University College in Nigeria showed that nearly 68% patient complained of unbearable pain postoperatively. Weak opioids were prescribed, and intramuscular injection was the most common route of administration of analgesics [33]. Thus, postoperative pain management has a long way to go in developing world.

Anesthesia for Thoracic Surgeries in Patients with Infective Lung Diseases

Respiratory infections form the major burden of lung diseases in the developing world. Though these infections are primarily treated by medical management, thoracic surgery may be required to manage the complications arising from infectious process. Pulmonary TB along with pyogenic and parasitic infections of pleura and parenchyma forms a majority of the lower respiratory tract infections, which may require surgical treatment. These include bronchiectasis, empyema, lung abscess, and pulmonary helminthiasis. Management of these patients requires special precautions in preoperative, intraoperative, and postoperative periods. Following is a discussion about commonly prevalent infectious conditions in developing world and their anesthetic management.

Tuberculosis

Incidence and Prevalence

Tuberculosis (TB) is a leading cause of morbidity and mortality worldwide, more so in low- and middle-income countries. In 2015, approximately 10.4 million new TB cases and 1.4 million TB deaths were reported worldwide. Six countries, which accounted for 60% of the new cases, were India, Indonesia, China, Nigeria, Pakistan, and South Africa, in the descending order of the number of cases. Approximately 1.2 million patients (i.e., 11% of all new TB cases) were co-infected with human immunodeficiency virus (HIV) [34]. Apart from HIV, smoking, diabetes mellitus, anti-TNFα drugs, and new immunosuppressive treatments are important risk factors for TB [35, 36].

The World Health Organization End TB Strategy was approved by the World Health Assembly in 2014. It targets a 90% reduction in TB deaths and an 80% reduction in the TB incidence rate by 2030, compared with 2015. Incidence of TB has declined significantly in high-income countries, mainly due to improved socioeconomic conditions and better use of anti-TB drugs [37]. After the introduction of rifampicin and isoniazid, chemotherapy has been the mainstay of treatment of TB, while surgical treatment has been used for complicated cases only. Currently followed chemotherapy regimens with directly observed treatment short course (DOTS) approach have achieved cure rates in excess of 85%; however, it is not so effective in countries where multidrug-resistant strains are prevalent. In 2015, there were an estimated 480,000 new cases of multidrug-resistant TB (MDR-TB), where the mycobacterium TB strains were resistant to at least rifampicin and isoniazid. An additional 100,000 people with rifampicin-resistant TB (RR-TB) were

also eligible for MDR-TB treatment. Three countries, namely, India, China, and the Russian Federation, accounted for 45% of the combined total of 580,000 cases [34]. There is growing concern over rapid emergence of "extensively drug-resistant TB" (XDR-TB), which is defined as resistance to rifampicin, isoniazid, fluoroquinolones, and at least one of the following injectable anti-TB drugs – capreomycin, kanamycin, or amikacin [38, 39]. A combination of 5–7s line drugs has been suggested by WHO for the management of MDR-TB. A few new drugs (bedaquiline, delamanid) and some repurposed drugs (carbapenems, linezolid, mefloquine, etc.) are also being investigated for the treatment of MDR-TB.

Pathophysiology

Spread of mycobacterium tuberculosis occurs via the transmission of small airborne droplets (0.5–5 μm). Although the lung is the most commonly affected organ, TB can affect any organ of the body. Affection of lung parenchyma and lymphadenitis forms the primary complex of TB (Ghon focus), usually in the middle third of the lung. The primary site of infection can also be subpleural. In most cases, these lesions heal spontaneously. However, in immunocompromised hosts, primary TB progresses rapidly from exudative pneumonia to necrosis and cavitation in the lungs (see Fig. 42.1a, b). Caseation necrosis also occurs in hilar lymph nodes and leads to hematogenous spread to other organs. Affection of bronchi or endobronchial TB occurs due to direct extension of infection from primary parenchymal focus and affected lymph nodes or by hematogenous spread. Right upper lobe bronchus and right main bronchus are the most commonly affected bronchi. Infiltration of bronchial mucosa by lymphocytes leads to congestion and edema. Further inflammation leads to the development of caseation necrosis and granuloma formation. Fibrotic changes following inflammation lead to narrowing of bronchial lumen, which is called as bronchostenosis [40]. Compression of bronchi by the enlarged lymph nodes or bronchostenosis leads to obstructive atelectasis.

Bacteria within the granuloma can become dormant, resulting in latent infection. At this stage, the patient is often asymptomatic but may show a positive response to a tuberculin skin test. Endogenous reactivation of latent infection results in postprimary or secondary TB. The most common site of affection is the apical or apical-posterior segment of an upper lobe due to relatively high oxygen tension, which favors growth of mycobacteria. Diffuse pulmonary involvement leads to military TB (see Fig. 42.2a, b). Productive cough with variable quantities of sputum and/or hemoptysis in a debilitated patient is a hallmark of pulmonary TB. Other pulmonary complications include pneumothorax, pleural effusion, empyema, BPF, massive hemoptysis, fibrosis with loss of parenchymal volume, and distortion of the tracheobronchial tree including bronchial stenosis.

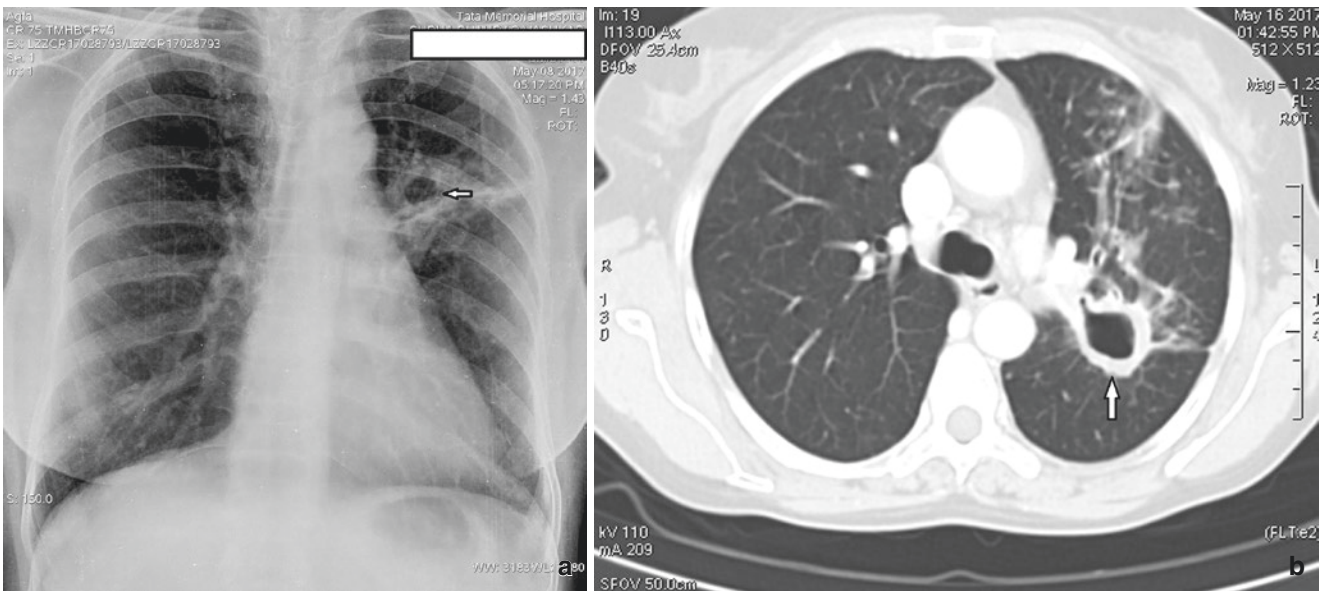

Fig. 42.1 (**a**) Chest radiograph showing cavitary lesion (marked by an arrow) with adjacent plate atelectasis in left mid-zone. (**b**) Computed tomography scan of chest showing a thick-walled, heterogeneously enhancing cavitary lesion (marked by an arrow) in left upper lobe, with surrounding spiculations and a speck of eccentric calcification. Also seen are subjacent areas of collapse/consolidation with multiple ill-defined nodules in left upper lobe. Interseptal thickening and areas of traction bronchiectasis are also seen

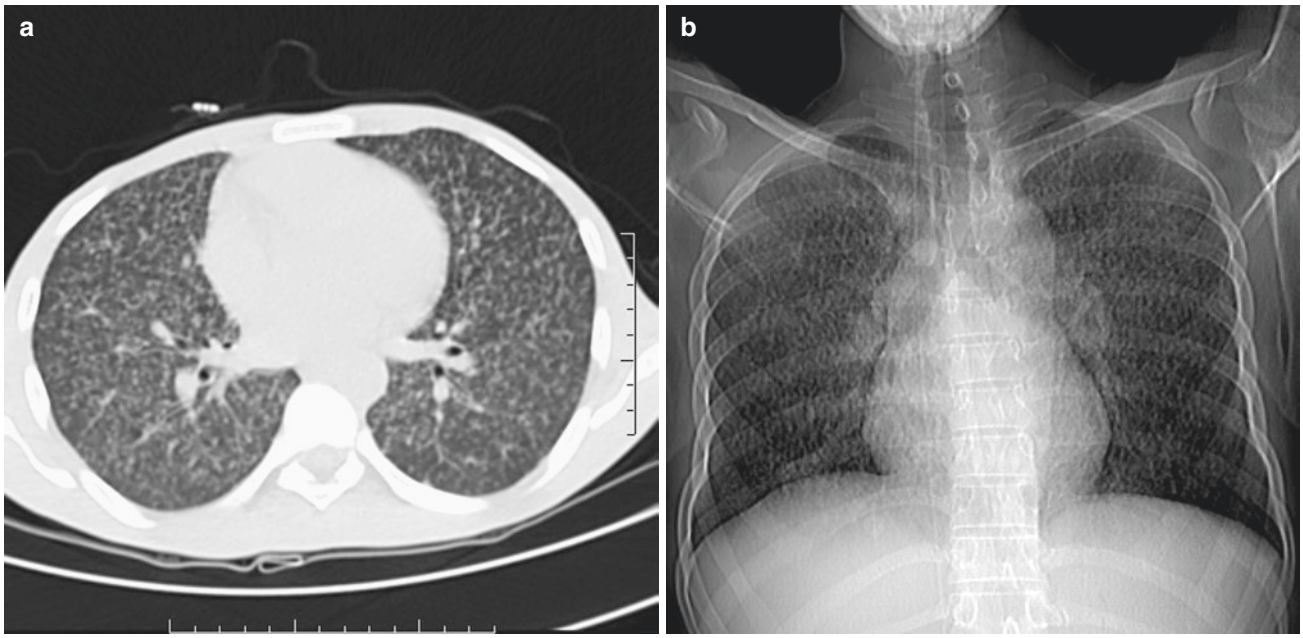

Fig. 42.2 (**a**) A positron emission tomography scan of the chest showing innumerable small pulmonary nodules distributed uniformly in both lungs suggestive of military TB. (**b**) Anteroposterior image of positron emission tomography scan of the chest showing widespread distribution of discrete nodules throughout both the lungs, suggestive of military TB

Surgery and TB

Historically the first thoracic surgery procedure was open drainage of a TB pleural empyema, performed by Hippocrates. During first half of the twentieth century, a number of surgical procedures were carried out to deprive the mycobacterium TB of oxygen. These included thoracoplasty, induced pneumothorax, plombage, and phrenic nerve crushing [41]. Similar to open surgery, thoracoscopy was also first used for pleural biopsy and adhesiolysis in TB patients [42]. Following introduction of rifampicin in 1960, chemotherapy became first-line treatment of TB, and surgery remained the option for complications arising from TB.

In the last two decades, there has been resurgence in the role of surgery in the management of TB, primarily due to global incidence and emergence of MDR-TB. With improvements in anesthesia and surgical methods, thoracic surgery is less morbid procedure. As a result, the need for surgery is increasing.

Indications for thoracic surgery in patients with pulmonary TB are:

1. Management of pulmonary complications of TB like hemoptysis, empyema, tuberculomas, "destroyed lung" due to fibrosis, etc.
2. Treatment of patients who present with inadequate clinical or radiological or microbiological improvement despite appropriate chemotherapy regimen

Patients with persistently positive sputum even after at least 6–8 months of appropriate anti-TB therapy benefit from surgical resection of pulmonary lesions. A meta-analysis evaluating role of pulmonary resection in cases with MDR-TB reported success rate of 84%, with only 6% failure rate, 3% relapse, and 5% mortality [43]. Parenchymal-sparing pulmonary resections are performed, lobectomies being more common than pneumonectomies [44]. Pneumonectomies are performed in patients with multiple cavitary lesions. In case of bilateral lesions, unilateral dominant lesions are removed surgically, and small lesions on opposite side are treated with medical management. However, sometimes these small lesions require surgery in the future [45].

Thus, lung resection should be considered when the following criteria are fulfilled [46]:

1. Adequate (i.e., 6–8 months) anti-TB treatment has failed to cure the patient.
2. Disease is localized to allow anatomical lung resection.
3. Patient has adequate cardiopulmonary reserve and acceptable surgical risk to tolerate the resection.

A "Destroyed lung" is a sequel of pulmonary TB, which is characterized by fibrotic cavities and caseous lymphadenitis and further complicated by sub-lobar atelectasis or bronchiectasis. Patient presents with history of prolonged and multiple anti-TB treatment, drug resistance, and progressive deterioration in pulmonary functions. Surgery is performed

to decrease the infectious load and to prevent life-threatening complications [47]. Similarly tuberculomas also present as pulmonary nodules of varying sizes and are resected to reduce the infectiousness. Recurrent hemoptysis is a common presentation in advanced pulmonary TB. Emergency surgery may be required in patients where massive hemoptysis occurs and embolization cannot be performed or is unavailable [48]. Surgical decortications are recommended for management of tuberculous empyema when there is major residual pleural thickening leading to non-expansion of underlying lung [49].

TB and Anesthesia Implications

In the patient with pulmonary TB undergoing thoracic surgery, there are three major implications for the anesthetist:

1. The general condition of patient and the effect of TB on functions of affected organs
2. The potential for drug interactions between anti-TB treatment and anesthetic drugs
3. The risk of transmission of TB to staff and other patients

The following care should be taken when anesthetizing a patient with pulmonary TB for thoracic surgery:

- A detailed history, examination, and relevant investigations are required to determine the extent of organ dysfunction. Patients with pulmonary TB are often chronically ill, malnourished, and frequently anemic. Chronic longstanding TB leads to parenchymal fibrosis and bronchiectasis causing progressive decrease in lung functions. Severe adrenocortical insufficiency may occur perioperatively in patients suffering from TB of adrenal glands. In patients with TB of the cervical spine, special precautions should be taken during airway manipulation especially while giving neck extension for procedures like mediastinoscopy to avoid injury to the cervical spine.
- Elective surgical procedures should be postponed until patients are no longer considered infectious. Patients are considered noninfectious if they have received anti-TB chemotherapy for 2–3 weeks, are improving clinically, and have had three consecutive negative sputum smears [50].
- The anesthesiologist should review liver function tests because anti-TB medications (isoniazid, pyrazinamide, rifampicin) are hepatotoxic. Combining anti-TB treatment with antiretroviral therapy leads to a mild elevation in liver enzymes. However, symptomatic hepatitis is a potentially dangerous complication and carries a mortality of almost 5% [51]. In such condition, anti-TB drugs should be immediately stopped and alternate medications considered. After improvement of hepatic function, they may be restarted carefully, under specialist care. An elective surgery should be avoided during this period.
- Rifampicin can cause thrombocytopenia when used in high doses. INH can cause sensory neuropathy, which should be checked and documented before performing regional nerve blocks. Administration of pyridoxine helps in treatment of neuropathy.
- Anti-TB agents may be ordered on the day of surgery to keep blood levels constant.
- Drug interactions occur due to pharmacokinetic changes following the induction of liver enzymes. Rifampicin is a potent inducer of the cytochrome P450 system, especially isoenzyme 3A4. It leads to increased metabolism, causing subtherapeutic effects of anesthetic drugs and/or increased production of toxic metabolites. INH is a CYP450 inhibitor. Drug interactions are further complicated when patient is receiving concurrent antiretroviral treatment, specifically protease inhibitors. Induction agents, when used as intravenous infusions, are metabolized rapidly. This can lead to potential chances of awareness during TIVA. Infusion rates need to be increased to avoid this phenomenon. With use of halothane, chances of hepatitis are increased. Hence newer volatile agents are preferred. Increased metabolism affects duration of action of non-depolarizing muscle relaxants like vecuronium and rocuronium. Neuromuscular monitoring is required to titrate the doses of these drugs. Increased metabolism also affects opioids, and more frequent dosing may be required.

Preventing Transmission of TB to Other Patients and Healthcare Workers (HCW)

Operating room (OR), hospital staff, and other personnel in close contact with a TB patients are at risk of getting infected with TB. Characteristics that exist in a patient with TB disease and increase the risk of infectiousness are given in Table 42.1.

Table 42.1 Characteristics in a TB patient that increase risk of infectivity

1	Presence of cough
2	Cavitation on chest radiograph
3	Sputum smear positive for acid-fast bacilli
4	Respiratory tract disease with involvement of the larynx (substantially infectious)
5	Respiratory tract disease with involvement of the lung or pleura (exclusively pleural involvement is less infectious)
6	Untreated, inappropriate, or short duration of anti-TB treatment
7	Undergoing cough-inducing or aerosol-generating procedures (e.g., bronchoscopy, sputum induction, and administration of aerosolized medications)

According to the American Society of Anesthesiologist guidelines regarding perioperative management of TB patients [50], the following recommendations are made to prevent transmission of TB to healthcare workers:

- Elective surgery should not be done until patient is noninfectious (a TB patient is considered as noninfectious when, for 2–3 weeks, he/she is clinically getting better and has had three negative sputum samples on different days).
- Procedures should be scheduled for patients with suspected or confirmed TB disease when a minimum number of healthcare workers and other patients are present in the surgical suite and at the end of the day to maximize the time available for removal of airborne contamination.
- Surgical staff, particularly those close to the surgical field, should use respiratory protection (e.g., a valveless N95 disposable respirator) to protect themselves and the patient undergoing surgery.
- If a surgical suite has an anteroom, the anteroom should be either (1) positive pressure compared with both the corridor and the suite or (2) negative pressure compared with both the corridor and the suite. In the usual design in which an OR has no anteroom, doors to the OR should be closed, and traffic into and out of the room should be minimized.
- A bacterial filter (ability to filter particles 0.3 μm in size in both the unloaded and loaded states with a filter efficiency of ≥95% at the maximum design flow rates of the ventilator for the service life of the filter) should be placed on the patient's endotracheal tube (or at the expiratory side of the breathing circuit of a ventilator or anesthesia machine, if used).

Postoperative Care

The patient with TB should be nursed in isolation room with airborne infection isolation (AII) precautions. This isolation area should receive ≥12 air changes per hour (ACH) and should be under negative pressure. Room should direct exhaust of air from the room to the outside of the building or recirculation of air through a HEPA filter.

Postoperative care includes antibiotics, analgesics, chest physiotherapy, breathing exercises, blood replacement whenever needed, and good care of chest tubes. One should routinely monitor drain outputs and general condition of the patient, and chest radiographs should be performed as required. Early and late post-thoracotomy complications can develop like air leak, bronchopleural fistula, residual pleural space, empyema, consolidations, etc., which should be appropriately managed.

Table 42.2 Duration of postoperative anti-TB treatment

Culture-negative patients at the time of surgery:
With susceptible TB, at least 4 months after surgery
With M/XDR-TB, 6–8 months after surgery (depending on postoperative recovery)
Culture-positive patients at the time of surgery:
With susceptible TB – 4–6 months after culture conversion
With MDR-TB, at least 18 months after culture conversion
With XDR-TB, at least 24 months after culture conversion

Preoperative anti-TB chemotherapy should be resumed as soon as patient tolerates enteral feeding. Surgical material should be analyzed for bacteriological culture. Guidelines on durations of postoperative anti-TB chemotherapy are summarized in Table 42.2 [46].

Bronchiectasis

Bronchiectasis is defined as an abnormal and permanent dilatation of bronchi. It may be focal, where bronchi in the limited region of pulmonary parenchyma are dilated, or diffuse, where airways are affected with widespread distribution. Focal or localized forms of bronchiectasis usually follow an inadequately treated pulmonary infection and are associated with good prognosis. On the other hand, a diffuse form of bronchiectasis is seen in patients suffering from congenital ciliary defects and immunoglobulin deficiencies. The diffuse form of bronchiectasis is associated with bilateral presentation and rapid decline in respiratory function.

Pathophysiology and Causes

Bronchiectasis results as a consequence of inflammatory destruction of structural components of bronchial wall. Inflammation is triggered by infection or exposure to toxic substances or by immunological reaction. Dilated airways, lack of ciliary motility, and airway obstruction lead to stagnation of pulmonary secretions and further infections. This sets up a vicious cycle of progressive inflammation and recurrent infections (see Fig. 42.3 and 42.4a, b).

Common causes of bronchiectasis are enumerated in Table 42.3.

The use of effective antibiotics, immunization policies, and improved hygiene has led to a decreased incidence of bronchiectasis in developed countries. However, in developing countries where pulmonary infections are prevalent, bronchiectasis is a major respiratory illness.

Patients suffer from chronic cough, excessive sputum production, hemoptysis, and progressive decline in respiratory function. Cough is often related to change in position. Hemoptysis can be life-threatening as well. History and

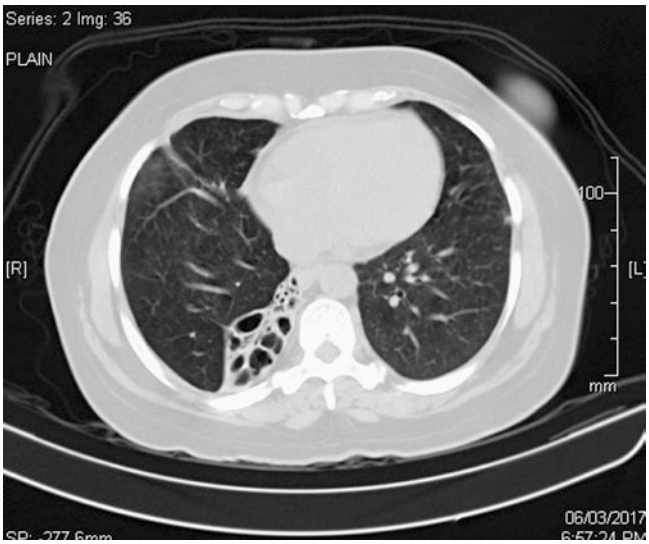

Fig. 42.3 Computed tomography scan of the chest showing cystic bronchiectasis changes with resultant collapse of the lung in postero-basal segment of right lower lobe, suggestive of acute or chronic infective etiology

examination in addition to radiological imaging confirm the diagnosis.

Most patients can be treated with medical management. It involves:

1. Antibiotics to treat causative infection
2. Bronchodilators to improve reversible obstruction of airways
3. Mucolytic therapy and physiotherapy to facilitate loosening and clearance of secretions

Surgical management is considered for the patients who:

- Fail or do not tolerate medical management
- Show signs of disease progression
- Present with life-threatening hemoptysis or recurrent pneumonia
- Have a localized disease amenable to anatomical lung resection

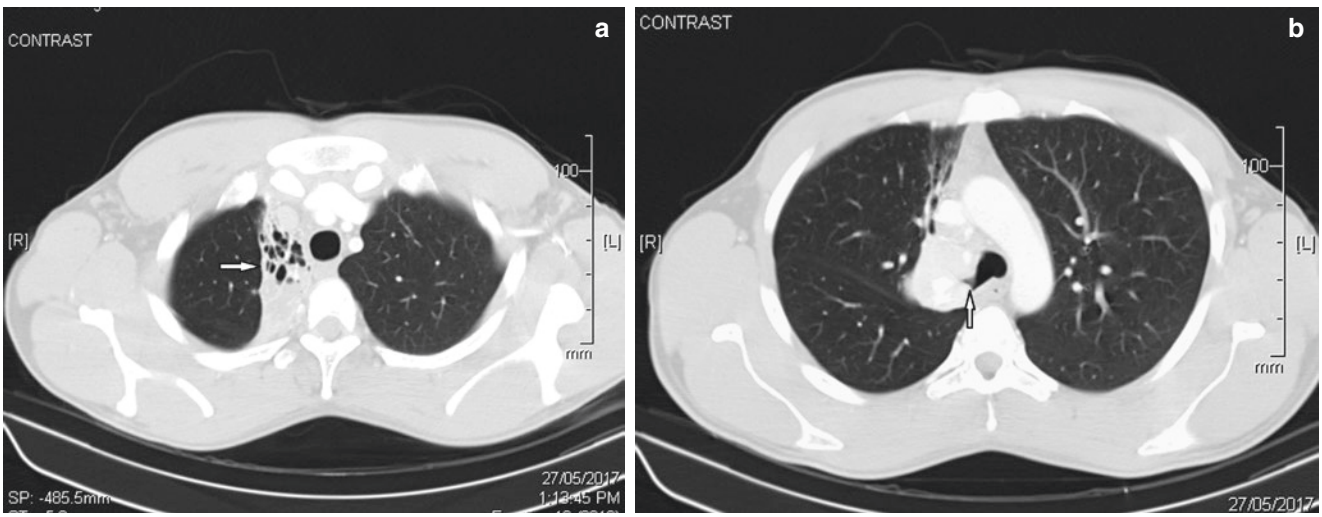

Fig. 42.4 (**a**, **b**) Computed tomography scan of the chest showing a homogenously enhancing mass in right hilum with endobronchial extension into right main bronchus (marked by an arrow). Post-obstructive bronchiectasis is seen in right upper lobe

Table 42.3 Causes of bronchiectasis

A. Acquired: Infection: Viral (e.g., adenovirus, influenza virus) Bacterial (necrotizing organisms like *Staphylococcus* spp., *Klebsiella*, anaerobes, etc.) Pulmonary TB – direct destruction of parenchyma by necrotizing inflammation and indirect way of airway obstruction due to bronchostenosis and extrinsic compression of airways by enlarged lymph nodes Chronic obstruction of airways due to endobronchial tumors and foreign bodies Exposure to toxic substance like ammonia or acidic gastric contents Immunological – allergic bronchopulmonary aspergillosis	B. Host factors: Immunoglobulin deficiency Primary ciliary motility disorders Cystic fibrosis Ulcerative colitis, rheumatoid arthritis, Sjogren's syndrome Alpha-1 antitrypsin deficiency Yellow nail syndrome

Surgery involves careful resection of involved segments of the lung. For widespread disease presenting with hemoptysis, bronchial artery embolization is preferred. For diffuse bronchiectasis showing progressive worsening despite optimum medical treatment, lung transplantation is a therapeutic option.

Anesthetic Considerations

Some principles of anesthesia management are common during perioperative care of patient with infectious lung diseases. These are summarized in Table 42.4 and have been discussed in detail in early part of the chapter. Certain salient aspects, pertaining to bronchiectasis, during perioperative care, are discussed here:

- A bronchoscopic aspiration of sputum should be done in preoperative period. It not only provides a sample for culture, but it also clears the sputum and improves regional ventilation. In case of hemoptysis, bronchoscopy can aid in localizing source of bleeding in tracheobronchial tree. Endobronchial tumors or foreign bodies can be identified, and surgical treatment can be planned accordingly.
- Appropriate antibiotic therapy should be started prior to surgery based on culture reports. In case of immunodeficiency disorders, intravenous or subcutaneous immunoglobulin G is administered in preoperative periods. Inhaled corticosteroids can be considered in case of non-infective inflammatory causes.
- A primary concern of the anesthesiologist is to prevent contamination of the non-operative lung. During induction of anesthesia, in absence of lung isolation, secretions can spill from affected segment to other lobes of lungs. Hence, the patient should be positioned in such a way that the affected segment is in a dependent position, e.g., left lateral and semi-sitting position in case of left lower lobe bronchiectasis.
- If there are copious secretions in spite of all efforts, then awake, bronchoscope-guided intubation can be performed, followed by bronchoscopic suctioning of sputum and placement of bronchial blocker to achieve selective lobar blockade to avoid contamination of the non-affected lung.
- DLTs are always preferred over bronchial blockers, as bronchial blockers have higher chance of intraoperative displacement and have a narrow working channel which does not facilitate suctioning of affected segment.
- The left or right upper lobes can be deliberately obstructed by a left-sided double lumen placed in the ipsilateral main stem bronchus with fiber-optic bronchoscopic guidance. Saline-soaked gauze can be used to block lower or right middle lobe bronchi, using rigid bronchoscope at induction. During surgery once the bronchus is opened, the gauze is removed.
- The presence of inflammation increases the risk of intraoperative hemorrhage. A wide-bore intravenous cannula and preoperative confirmation of availability of cross-matched blood are always necessary.
- The use of neuraxial anesthetic techniques, specifically thoracic epidural analgesia in bronchiectasis and other infectious diseases, carries a risk of epidural abscess in the patient with an infectious process. An individual risk/benefit assessment should be performed and discussed with the patient and/or family in advance. In most cases, in a patient who is not septic and has significant pulmonary disability, the risks are acceptable due to the superior analgesia of thoracic epidural techniques.

Table 42.4 Principles for anesthesia management for patients with infectious lung disease

Preoperative nutritional supplementation, correction of anemia, cessation of smoking, chest physiotherapy, postural drainage, and preoperative antibiotics if necessary
Careful positioning of patient during anesthesia induction to minimize contamination of healthy areas of lungs
Use of lung isolation device especially DLT prior to re-positioning of patient, to prevent contamination
Anticipation, monitoring, and replacement of blood loss intraoperatively
Repetition of antibiotic doses to continue perioperative antibiotic coverage
Careful titration of anesthesia drugs, keeping in mind the interactions with the ongoing antibiotics
Use of precautions to prevent transmission of infection from patient to healthcare workers and other patients
Nutritional support, chest physiotherapy, adequate analgesia, and antibiotics postoperatively

Empyema

Empyema is collection of infected fluid between parietal and visceral layers of pleura. It occurs most commonly secondary to pneumonia but can also occur after thoracic surgery, trauma, or esophageal leaks. Empyema following surgical lung resections occurs in 2–16% of cases and is associated with 40% increase in perioperative mortality [52]. Empyema is commonly seen in pediatric and elderly populations and is associated with high morbidity and mortality. Due to underreporting, data from developing countries is lacking, but in developed countries like the UK and the USA combined, the approximate annual incidence of pleural infections is up to 80,000 cases. In the UK, 20% of patients with empyema die, and 20% need surgery within 12 months of their infection [53, 54].

Bacteriology

Community-acquired pleural infections are most commonly due to gram-positive aerobic organisms (*Streptococcus* spp., *Staphylococcus aureus*), whereas hospital-acquired pleural infections are frequently due to *Staphylococcus aureus*, methicillin-resistant *S. aureus* (MRSA) being the commonest. Infections with gram-negative organisms (Enterobacteriaceae, *E. coli*, *H. influenzae*) and anaerobes (*Fusobacterium* spp., *Bacteroides* spp.) are seen in patients with decreased immunity and comorbidities [54].

Pathophysiology

Development of empyema following pneumonia progresses through three stages:

1. Simple exudate
2. Fibrinopurulent stage
3. Organizing stage with pleural peel formation

In the first stage, fluid in pleural cavity is free flowing with low white cell count, with LDH level less than half of that in serum level, and with normal pH and often sterile. Treatment with antibiotics is adequate, and most often chest tube drainage is not required (see Fig. 42.5).

If untreated in first stage, then the infection progresses to fibrinopurulent stage where bacteria invade across the damaged endothelium. It leads to active immune response with increased procoagulant and decreased fibrinolytic activity. Biochemical examination of fluid at this stage shows rise in WBC count and LDH levels and fall in pH. Chest tube drainage is alone insufficient, and patient requires use of fibrinolytic agents or thoracoscopic surgery to facilitate adhesiolysis and removal of pus. Though fibrinolytic agents have been found to improve pleural fluid drainage, the use of these agents is not associated with reduced mortality, frequency of surgery, length of hospital stay, or long-term radiological outcome.

In the third stage, there is marked thickening of pleura with formation of solid pleural peel, preventing lung expansion. Most patients are referred to tertiary care centers at this stage and are treated with surgical decortication.

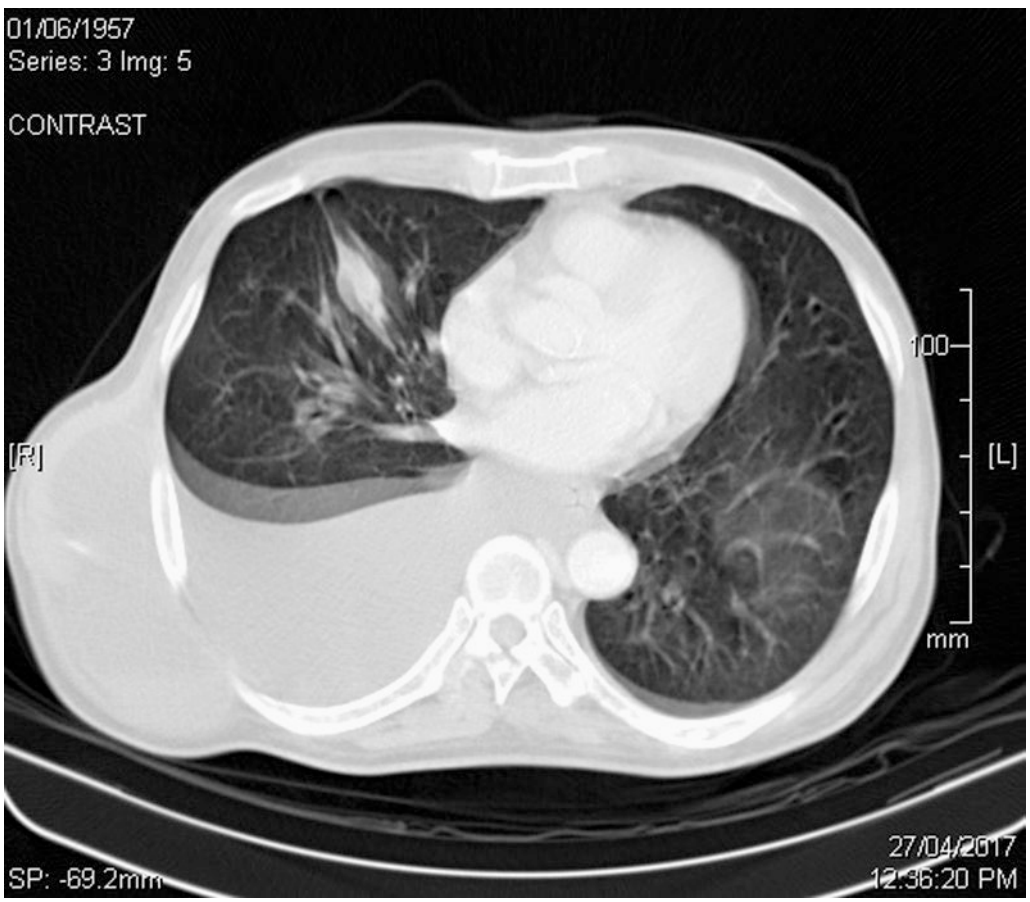

Fig. 42.5 Computed tomography scan of the chest and abdomen showing a moderate effusion on right side and a minimal effusion on left side. Effusion on right side is in communication with a collection in right lateral chest wall. Empyema necessitans was suspected. Patient underwent subsequent USG-guided tapping of collection and based on culture received 4-week course of antibiotics

Surgery for Empyema

Surgical options are required when patient has persistent pleural collection and associated sepsis despite chest tube drainage and antibiotics. For chronic hemothoraces, decortication is required when there is 50% compression of the lung, and there is no appreciable pulmonary expansion for 4–6 weeks following aspiration [55]. Goals of surgery are thorough surgical debridement of pleural peel, excision of necrotic tissues, adhesiolysis, and careful closure of all major air leaks. Surgery can be performed by open thoracotomy or a video-assisted thoracoscopic surgical (VATS) approach depending on the severity of the empyema. Surgery carries the best results when performed at the earliest stages.

The following are the anesthesia implications in management of patient with empyema:

- Some patients will present with an underlying bronchopleural fistula (BPF). A history of position-related productive cough should be carefully sought. History regarding chronicity of infection, past complications, and requirement of chest tube drainage can give hints about the presence of BPF. If there is uncertainty regarding the presence of a BPF based on history and examination, then it is a safest to assume the presence of an underlying BPF and plan anesthesia accordingly.
- Empyema and formation of pleural peel, being an inflammatory process, result in increased vascularity. Debridement of pleural peel results in significant blood loss. Major blood loss should be anticipated and necessary arrangements made in advance. Re-expansion of chronically collapsed lung should be done gradually to prevent re-expansion pulmonary edema.
- Adhesiolysis can result in air leaks from the pulmonary parenchyma. Lung isolation may be required if there are significant air leaks. Amount of air leak should be checked intraoperatively, and postoperative plans should be discussed with the surgeon accordingly.
- In case of BPF or lung abscess communicating with airways, lung isolation should be perfect to avoid loss of tidal volumes or contamination of the opposite lung. DLTs are preferred over bronchial blockers in such cases.

Lung Abscess

Lung abscess is an infection of lung parenchyma, leading to liquefactive necrosis of parenchyma with formation of well-circumscribed debris containing cavities. In the pre-antibiotic era, lung abscess had a high mortality. Causes of lung abscess are divided into primary and secondary.

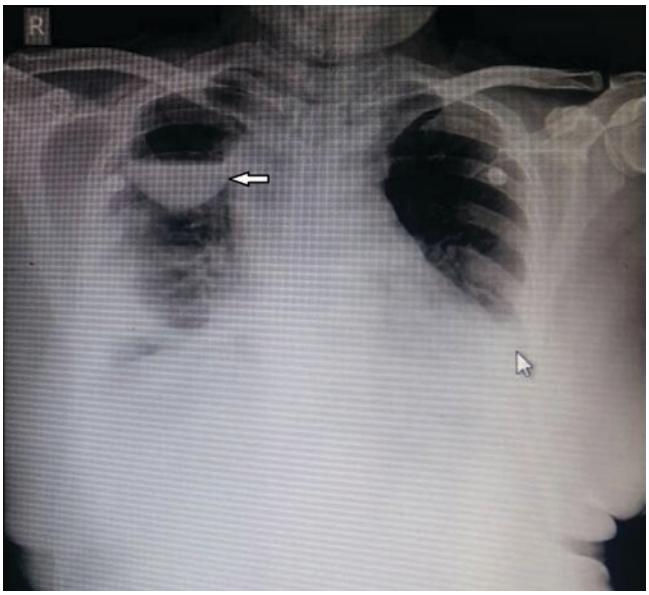

Fig. 42.6 Well-defined thin-walled cavity in the right upper zone with air fluid level within (marked by an arrow), suggestive of lung abscess of infective etiology. The right middle and lower zones show patchy areas of consolidation with blunting of the right costophrenic angle

Primary causes include infection of lung parenchyma due to aspiration of infected oropharyngeal secretions or a sequel of necrotizing pneumonia in immunocompromised host (see Fig. 42.6). On the other hand, secondary causes include hematogenous spread of infection from a distant focus. Elderly, alcoholic, comatose, diabetic, and those on immunosuppression treatments carry a high risk for developing lung abscess. Patients present with fever with chills, chest pain, night sweats, productive cough, progressive dyspnea, and weight loss. Obstruction of a bronchus causing distal stagnation of secretions can lead to lung abscess. Such an abscess may be incidentally detected during resection of bronchus and can lead to contamination of non-infected areas of lungs. Hence, the anesthesiologist should review preoperative imaging of the patient to find out if there is a lung abscess distal to an obstructed bronchus. Microbiologically, causative organisms are predominantly anaerobic (*Bacteroides*, *Fusobacterium* spp., *Peptostreptococcus*) or polymicrobial including aerobic organisms like *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Haemophilus influenzae*, etc. [56]. Open thoracotomy and drainage of abscess used to be the treatment of choice. However, currently medical management with antibiotics for 4–6 weeks or CT-guided percutaneous drainage forms the mainstay of the treatment, and surgery is rarely required.

Surgical management is reserved for the patients who show no improvement despite appropriate antibiotics administered for 6–8 weeks. Also complications arising from lung

abscess like empyema and bronchopleural fistula warrant surgical management. Percutaneous drainage of the abscess guided by computed tomography (CT) scan is a safe and effective alternative to open thoracotomy and drainage especially in critically ill patients with ongoing sepsis and progressively enlarging abscess or those not amenable for extensive thoracic surgery [57].

Spillage from the abscess into non-infected areas of the lung is the chief concern during surgical management of patients. Anesthesia management principles are essentially the same as those involved in management of bronchiectasis or empyema (discussed in the earlier section of chapter).

Pneumatoceles

Pneumatoceles are thin-walled cyst-like air-filled cavities that occur following trauma or pneumonia (see Fig. 42.7). These are often the sequel of pneumonia (usually within first week of pneumonia) or trauma, and they resolve spontaneously within 6 weeks. Secondary infection and progressive enlargement of cavities remain the major complications. Cavities may rupture and develop tension pneumothorax. Tension pneumatocele is an unusual phenomenon that results from a one-way valve mechanism in patients on positive-pressure ventilation [58]. Large pneumatocele (occupying 50% of hemithorax) may be complicated by lung atelectasis, bronchopleural fistula, and non-resolving secondary infection, which requires surgical resection [59]. Surgical decompression can be performed by percutaneous needle aspiration and catheter or chest tube drainage under guidance of CT scan or fluoroscopy.

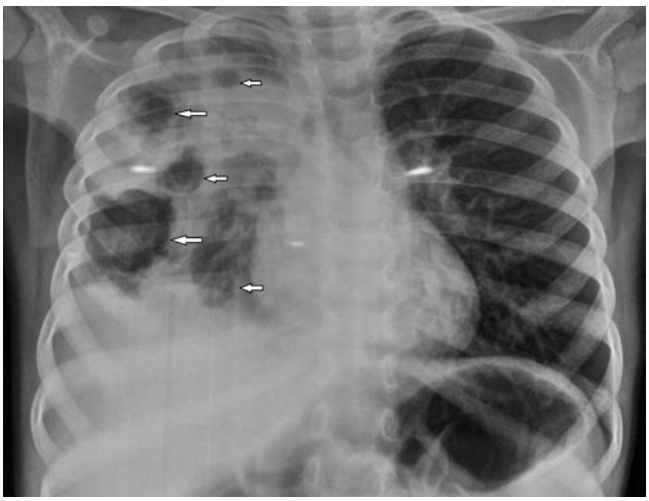

Fig. 42.7 Patchy areas of opacity involving the right lung with thin-walled cystic spaces (marked by arrows) having smooth inner margins without any air fluid level – suggestive of pneumatoceles

Hydatid Disease of the Lung or Pulmonary Echinococcosis

Pulmonary hydatid cysts are watery, parasitic cysts, containing larvae of the dog tapeworm, *Echinococcus granulosus* [60]. Echinococcosis is endemic in Australia, New Zealand, South America, Arctic North America, Africa, and parts of Asia.

Cyst Composition

The fully matured cysts are composed of three layers. The outer layer, or pericyst, is composed of inflamed fibrous tissue of lung parenchyma; the exocyst is a middle acellular lamina and the innermost endocyst which is a germinative layer, producing brood capsules or secondary cysts. An intact cyst may be filled with liters of fluid which is antigenic in nature. It contains debris consisting of hooklets and scolices referred to as "hydatid sand." The liver and lungs are the most commonly affected organs. Pulmonary hydatid cysts in children occur more commonly on the right side (~60%), 30% of patients have multiple pulmonary cysts, and 60% of cysts are found in the lower lobes [61]. Diameter of pulmonary cysts increases progressively at the rate of approximately 1–5 cm per year.

Whereas small cysts remain asymptomatic, large cysts can produce symptoms due to mass effect, causing compression of adjacent structures like bronchus, esophagus, and pulmonary vessels. Spontaneous or traumatic rupture may occur, disbursing fluid, parasites, and debris into surrounding lung parenchyma or bronchus, pleura, or even in the circulation. Spillage into blood vessels leads to systemic embolization of debris and parasites. Hypersensitivity reactions can present with urticarial or even life-threatening bronchospasm and anaphylaxis. Bursting of cyst into bronchi leads to sudden violent cough, respiratory distress, or feeling of asphyxiation. Rupture into the pleural space results in a hydropneumothorax. Rupture becomes more dangerous and more likely as cysts become larger or the patient has been treated with anti-helminthic. It is recommended that any cyst larger than 7 cm should be removed [62]. Ruptured cysts may become infected with bacteria or saprophytic or invasive fungi [63]. Diagnosis is by chest radiograph or CT scan.

Surgical Options

Surgical goals are complete resection of the intact cyst with maximal preservation of lung parenchyma. Anatomical lobar resection is required when single or multiple cysts occupy most of the lobe. An alternative surgical technique is to inject a scolicidal agent (hypertonic saline, cetrimide, povidone-iodine, formalin, ethanol, or hydrogen peroxide) into the intact cyst to sterilize it and then aspiration of the contents and removal of the evacuated cyst.

Anesthesia Considerations

- Postural drainage and antibiotics are started preoperatively in patients with suppurative cysts. Anti-helminthic drugs weaken the cyst wall and increase the likelihood of cyst rupture [64]. However, in case of spillage of cyst contents, either mebendazole or albendazole is administered to decrease the risk of secondary hydatidosis. Prophylactic medical therapy is started 4 days prior to surgery and is continued for 1–3 months.
- During dissection of the cyst, lung isolation or decreasing tidal volumes help in preventing early herniation of the cyst. Increased airway pressure with manual inspiratory hold helps in delivery of the cyst. The operative field is protected with hypertonic saline or 1% formaldehyde solution.
- After removal of cyst, parenchymal and bronchial leaks are checked with flooding the operative field with saline and ventilating the lungs to look for air bubbles (leak tests). Attempts are made to suture and close as many leaks as possible.
- Capitonnage (i.e., quilting or suturing of the anterior to posterior cyst walls) is recommended to close the cavity completely. A deliberately created broncho-atmospheric fistula (BAF) has been described in cases where there are large bronchial openings and there is fear of leaving a BPF or compromising airflow distally, if sutured. Ventilation is best managed spontaneously after creation of the BAF [65].

Acknowledgment We thank Dr. Anila Malde, Professor, Department of Anesthesia, Lokmanya Tilak Municipal Medical College and Hospital, Mumbai, India, for her valuable inputs.

We thank Dr. Sandeep Tandon, Dr. Maheema Bhaskar, and Dr. Aparna Iyer, Chest Physicians, Pulmonary Medicine Unit, Tata Memorial Hospital, India, for providing the images.

We thank Dr. Amit Janu, Consultant Radiologist, Department of Radiodiagnosis, Tata Memorial Hospital, Mumbai, India, for reporting the images.

Bronchopleural Fistulae

43

Andrew Ian Levin

Key Points

- Prior to anesthesia induction, anesthesiologists must evaluate not only the absolute size of the fistula but the "effective" size of the fistula.
- Small effective size fistulae can be managed with conventional induction of anesthesia followed by lung isolation if needed.
- Fistulae that have a large effective size need a conservative approach during anaesthesia induction, with maintenance of spontaneous respiration until fistula isolation.
- After induction of anesthesia using conventional or inhalation techniques, double-lumen tubes are commonly used to control airflow in the presence of a BPF. A left-sided DLT is commonly used with a right-sided fistula and vice versa.
- Interventional pulmonology has an increasing role to play in treatment of bronchopleural fistulae using a wide variety of bronchial occlusion techniques.
- For patients ventilated in the ICU with a persistent bronchopleural fistula, management strategies may include intubation with a double-lumen tube and independent lung ventilation, high-frequency ventilation, and/or extracorporeal membrane oxygenation.

Summary

Bronchopleural fistulae (BPFs) are air leaks that occur via connections between airways and the pleural space. They may be divided into two broad categories, alveolar-parenchymal-pleural and bronchopleural fistulae when they originate from lung parenchyma or tracheobronchial tree, respectively [1, 2]. Prior to anesthesia induction, anesthesiologists must evaluate not only the absolute size of the fistula but also the "effective" size of the fistula. The effective size of the fistula considers both the physical size of the fistula and the effect of lung mechanics on the distribution of ventilation and fistula gas flow during positive pressure ventilation (IPPV). If IPPV results in preferential gas flow via the fistula, difficult or impossible alveolar ventilation could result. As total functional residual capacity may be reduced in the presence of a large BPF, severe hypoxia and difficulty in ventilation can result after anesthesia induction and initiation of IPPV. The safest approach is to determine effective fistula size before anesthesia induction and let that decision guide the safest for anesthesia induction technique. Small "effective size" fistulae can be managed with conventional induction of anesthesia followed by lung isolation if needed. Fistulae that have a large effective size need a more conservative approach, with maintenance of spontaneous respiration during induction and until fistula isolation. This latter goal can be achieved with volatile induction and placement of a double-lumen endotracheal tube; alternatively, awake single-lumen tube intubation may be performed followed by lung isolation prior to commencement of IPPV. Bronchopleural fistulae are increasingly being managed by interventional pulmonologists using minimally invasive techniques, endobronchial valves placement having proved successful on many occasions. The management of BPFs in the ICU is a complex issue, the primary aim being treatment of the underlying lung disease and optimizing IPPV and arterial oxygenation, with management of the air leak using lung isolation or other techniques usually being of secondary importance.

Pathophysiology and Pathogenesis of Bronchopleural Fistulae

Lung mechanics dictate that a balance be maintained between two opposing forces, the lung's elastic recoil which promotes

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_43

lung collapse and the tendency of the chest wall to expand [3]. These opposing forces create the negative intrapleural pressure.

Following disruption of the hermetic pleural seal, pulmonary elastic recoil promotes lung collapse. Gas (usually air) fills the pleural space (pneumothorax). If such a disruption is caused by a chest wall penetrating injury that does not affect the lung itself, a simple pneumothorax will ensue. A simple pneumothorax is easily drained using a thoracostomy (chest) tube attached to an underwater seal drain or one-way flapper-type valve. Once the simple pneumothorax is drained, the air leak will not persist. The lung should expand following restoration of the negative intrapleural pressure.

A different picture will result if the injury causes a bronchus or other airways to be disrupted and simultaneously sets up a connection to the pleural space. Under such circumstances, bronchial gas will enter the pleural cavity by either being sucked in during spontaneous respiration or forced in during intermittent positive pressure ventilation. The negative intrapleural pressure is eliminated, and lung elastic recoil will promote its collapse. Percutaneous chest tube insertion and attachment to an underwater seal drain will reveal continuous air leak. The lung will only partially inflate or not re-inflate at all. This is termed a bronchopleural-cutaneous fistula. With bronchopleural or even a simple pleural-cutaneous fistula, if gas continues to enter the pleural space, is not able to escape and intrapleural pressure becomes positive, a tension pneumothorax ensues. A tension pneumothorax may occur during either positive pressure or spontaneous ventilation, if the fistula functions as a one-way valve. The consequences of a tension pneumothorax are progressive cardiovascular and respiratory compromise. In this respect, a critical assumption and prerequisite when dealing with a patient with a bronchopleural fistula is the presence of a functioning, correctly positioned chest tube and underwater seal or flapper drain.

The pathophysiology can be divided into or bronchopleural and alveolar-pleural fistulae. The pathogenesis of these two pathophysiological entities is different, although the two could coexist (Table 43.1).

Table 43.1 A simple approach to causes of bronchopleural fistula

1. Bronchopleural fistula:
1. Penetrating trauma:
1. Iatrogenic injury following instrumentation from inside the airway
2. Iatrogenic injury following tissue disruption from outside the airway or pleura
3. Non-iatrogenic penetrating trauma such as gunshots, stab wounds, or impalement
4. Blunt trauma, crush injuries such as being crushed by a falling heavy objet, and acceleration-deceleration injuries as in motor vehicle accidents
5. *Medical disorders* radiotherapy and chemotherapy
2. Alveolar-parenchymal-pleural fistulae:
1. Ventilation trauma is commonly associated with this type of fistula

A bronchopleural fistula may follow either *penetrating or blunt traumatic injury*, which causes bronchus disruption and creates a bronchopleural connection.

Penetrating non-iatrogenic trauma may follow knife or gunshot injuries, impalement, or other forms of trauma. They typically present with non-resolving pneumothoraxes or immediate large air leaks.

Penetrating iatrogenic trauma may follow medical-surgical instrumentation from inside the airway (endotracheal tube introducer or bougie, airway exchange catheters, endobronchial biopsy, misplaced nasogastric tubes endobronchial biopsy, etc.) or from outside the lung (thoracostomy tube insertion, percutaneous lung biopsy, central vein cannulation). Bronchopleural fistulae are very common post-thoracic surgical complications, occurring after 1.5–28% of all pulmonary surgeries (e.g., pneumonectomy, lobectomy, bullectomy, etc.) [4–7]. Post-lung resection BPFs are most often located in the residual lobe's bronchial stump [8]. Other associations include pneumonectomy rather than lobectomy; right-sided pulmonary resections; concurrent infections such as tuberculosis, lung abscess, and empyema; resection for malignancy; residual bronchial tumor; preoperative radiotherapy and/or chemotherapy; and poor wound healing conditions such as diabetes, malnutrition, anemia, and steroid administration. Bronchial stump disruption has been associated with postoperative intermittent positive pressure ventilation or bronchoscopy for secretion removal [9–16]. Because of the high incidence, much emphasis has been placed on surgical strategies to prevent this complication. These include avoidance of excessively tight bronchial sutures, avoidance of a long residual bronchial stump, avoidance of excessive peribronchial and paratracheal dissection, staple line buttressing, and protocol-driven chest tube management [17].

Blunt trauma may cause bronchopleural fistulae by one of the three mechanisms:

1. *A crush injury* with chest compression in the presence of a closed glottis can cause the membranous portion of the tracheobronchial tree to rupture [18–20]. Tracheobronchial injuries mostly [76%] occurr within 2 cm of the carina. The greater prevalence of right-sided injuries is due to the longer and more pliable left main bronchus being protected by the aorta and mediastinal structures, while the shorter right bronchus is attached to the heavier lung.
2. Abrupt anterior-posterior thoracic compression can cause lateral widening of the chest and lungs with distraction of the carina [18, 21].
3. Acceleration-deceleration injury can cause the weight of the lungs to apply traction to the relatively fixed carina. This may cause tracheobronchial rupture.

Ventilation trauma is a common cause of alveolar-parenchymal-pleural fistulae. Macklin and colleagues clarified the mechanism of how intermittent positive pressure ventilation causes bronchopleural fistulae. The "Macklin effect" is made up of three steps (Fig. 43.1):

1. During mechanical ventilation, volutrauma causes rupture of alveoli and terminal bronchioles. It is important to appreciate that alveoli do not usually rupture through the dense pleural membrane into the pleural cavity unless there has been penetrating trauma [22, 23].
2. Gas escaping from the alveoli and terminal bronchioles dissects along the bronchovascular sheaths to reach the mediastinum [23–28]. This process manifests as pulmonary interstitial emphysema.
3. The pneumomediastinum then dissects along fascial sheaths to create a cervical or thoracic subcutaneous emphysema and/or pneumothorax with typical character-

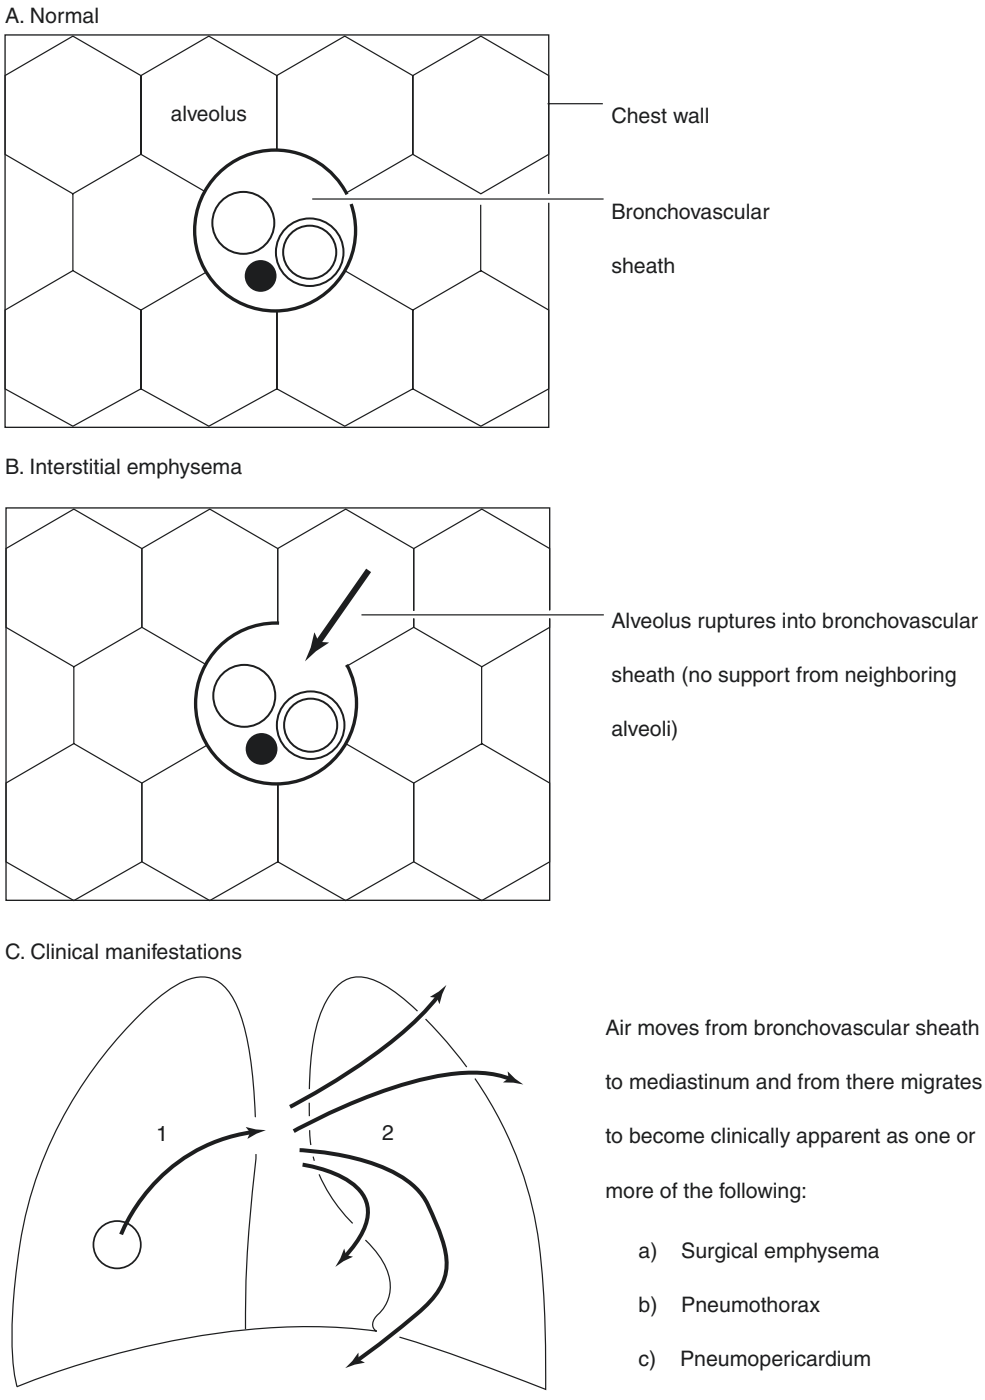

Fig. 43.1 The "Macklin effect". (Reprinted with permission from Visser et al. [23])

istics of a bronchopleural fistula. These "peripheral" air leaks are referred to as a alveolar-pleural or parenchymal-pleural fistulae [29, 30]. Other possible complications of pneumomediastinum and fascial sheath dissection are pneumopericardium or pneumoperitoneum [22].

Medical disorders and treatment can cause BPFs. Primary (no known underlying lung disease) or secondary spontaneous pneumothorax may result in persistent air leaks [31]. Close investigation suggests many (90%) of these patients have underlying chronic pulmonary obstructive disease with subpleural blebs or bullae [32–34]. Larger bullae can rupture into the pleural space and cause a BPF. Occasionally, infections (lung abscesses, tuberculosis), primary lung or pleural tumors, or metastatic tumors erode bronchi and create bronchopleural connections. Iatrogenic BPFs have been caused by radiotherapy and chemotherapy [10, 35–45].

The Pathophysiological Consequences of Large Air Leaks

In the presence of an air leak, a proportion of the tidal volume is lost via the bronchopleural fistula. The gas lost into the pleural space forms wasted (dead space) ventilation, with reduction of alveolar ventilation.

The affected lung will collapse in the presence of a large unilateral air leak. Pulmonary blood flow will be diverted from the affected to the "normal" lung by the increase in pulmonary vascular resistance induced by both hypoxic pulmonary vasoconstriction and the decrease in lung volume. This will limit the size of the shunt and the amount of low ventilation-perfusion units in the affected lung. Hypoxia is therefore not a prominent feature of uncomplicated bronchopleural fistula.

The dead space lesion will cause a respiratory acidosis. The respiratory center will then stimulate minute ventilation, which will aggravate the sensation of air hunger. During intermittent positive pressure ventilation, the gas leaked via the bronchopleural fistula contributes somewhat to carbon dioxide elimination [46].

In the presence of a large unilateral bronchopleural fistula, the mechanics of breathing become ineffective. The diaphragm and intercostal muscle action cannot generate the usual negative intrapleural pressure needed to increase the transpulmonary pressure gradient and expand the lungs. This ineffective mechanism, combined with the increased minute ventilation due to the respiratory acidosis, will lead to dyspnea, respiratory distress, air hunger, and tachypnea. This may be aggravated by any underlying infection with an increase in carbon dioxide production or contralateral lung parenchymal (restrictive) disease processes. It may be difficult to separate the effects of a bronchopleural fistula from the patient's underlying lung disease [47].

Other complications and consequences of a BPF include the inability to maintain PEEP and de-recruitment of the unaffected lung during intermittent positive pressure ventilation [2]. Large bilateral BPFs may rapidly lead to death. Bronchopleural fistulae can allow airway organisms to reach the normally sterile pleural space, leading to clinical infection and further impeding closure of the leak [2]. Lung function tests are unreliable in the presence of a bronchopleural fistula.

Bronchopleural Fistula, Intermittent Positive Pressure Ventilation, and Effective Fistula Size

Positive pressure ventilation may cause preferential gas flow via the BPF and chest tube and compromise effective alveolar ventilation. To appreciate how this works, the interaction of the physical factors governing fistula flow and the mechanics of alveolar ventilation need to be considered. Fistula gas flow is inversely proportional to the resistance and directly proportional to the pressure gradient over the fistula. During IPPV, the proximal fistula driving pressure is effectively peak (or if distally located, mean) airway pressure.

The worst-case scenario is represented by the combination of a large fistula and non-compliant lungs. Non-compliant lungs (restrictive disease such as pulmonary fibrosis, cystic fibrosis, acute lung injury, small lung volumes, pleural or chest wall disease) will require a higher transpulmonary pressure gradient with higher airway pressures to generate effective tidal volumes. This higher airway pressure will favor fistula gas flow. Furthermore, in the presence of a very large fistula, it may not be able to achieve high enough airway and transpulmonary pressures to effect adequate tidal volumes . In this scenario, intermittent positive pressure ventilation will result in preferential fistula flow and ineffective alveolar ventilation.

The best-case scenario is the combination of a small BPF with two normal or emphysematous, highly compliant lungs. The presence of normal or high pulmonary compliance requires low transpulmonary pressures to effect adequate tidal volumes. The low airway pressures and small fistula size result in limited BPF gas flow and adequate alveolar ventilation. This scenario typically occurs with a patient with a spontaneous pneumothorax with bullous COAD, or post-pneumonectomy with a small, persistent bronchial stump fistula with a relatively unscathed, or healthy non-resected lung.

The above emphasizes that it is not only the absolute physical size and physical characteristics of the fistula that matters. Lung mechanics affect how fistulae function. These concepts are summarized by the term "effective fistula size" which is essentially a clinical estimate of the balance

between BPF flow and the effective tidal volume that will likely be generated during intermittent positive pressure ventilation. With a large effective fistula size, the majority of the tidal volume delivered during intermittent positive pressure ventilation will escape via the fistula with concomitant poor alveolar ventilation.

Anesthesia and BPF

Prior to starting anesthesia induction, it is essential to ensure correct pleural cavity positioning of the thoracostomy tube. Furthermore, the thoracostomy tube and the underwater drain seal or one-way flapper valve system must function properly. Thoracostomy tubes may become blocked with infective material or clotted blood, or the drainage system tubing may be deliberately clamped or become accidentally kinked during patient transport. The combination of a nonfunctional thoracostomy tube and the initiation of intermittent positive pressure ventilation can produce a tension pneumothorax with associated (hemodynamic) consequences. The only exception to the presence of a functional thoracostomy tube is if the bronchopleural fistula is small and restrictive, as may occur after lung surgery.

The chest tube should be of adequate diameter and low enough resistance to effectively evacuate the pleural space so tension pneumothorax does not develop during intermittent positive pressure ventilation [48]. Gas flow via a chest tube is summed up by the Fanning equation, $V = \prod^2 r^5[P1 - P2]/fL$ where V is flow rate, $[P1-P2]$ is the pressure gradient over the chest tube, "f" is the Fanning friction factor, "L" is the length of the tube, and "r" is the radius of the tube. The Fanning equation effectively says that shorter, wider chest tubes support the highest pleural cavity gas evacuation rates [2, 48].

If the thoracostomy tube was subject to negative pressure suction in the ward, it is advisable to keep this operational during anesthesia induction while considering that this may cause or aggravate anesthesia gas and vapor evacuation during induction.

The physiological tolerance to both apnea and the ability to tolerate intermittent positive pressure ventilation are critical elements to consider when deciding on how to best manage induction (Table 43.2). Apnea at induction may follow opioid and/or induction agent administration and will occur after neuromuscular blocker administration. It is critical that the anesthesia providers consider whether initiation of positive pressure ventilation may result in preferential gas flow via the fistula. This could result in difficult or impossible alveolar ventilation. A cannot ventilate-cannot oxygenate scenario could possibly ensue.

A further inconvenient physiological consideration is the potential for rapid onset of hypoxia with apnea and/or ineffective lung ventilation. On the fistula affected side, pulmonary elastic recoil will result in varying degrees of lung collapse. This diminishes the patient's functional residual capacity and oxygen reservoir. Furthermore, oxygen consumption may be increased by the greater work of breathing and/or the presence of infection. After anesthesia induction, the occurrence of apnea, hypoventilation, or difficult alveolar ventilation can therefore result in the rapid onset of hypoxia in the presence of a bronchopleural fistula [49].

Table 43.2 Considerations for anesthesia management of bronchopleural fistula

(i) *Safety before starting:* Is the thoracostomy tube in the pleural cavity and correctly positioned, of appropriate size, and functioning correctly?
(ii) *Safety with induction:* Before induction of anesthesia, carefully estimate the effective fistula size and the distribution of ventilation on initiation of intermittent positive pressure ventilation?
(iii) *Safety with respect to distribution of ventilation ± lung isolation:* What is the best method of isolating the lung? Is there a risk of tearing the fistula with airway instrumentation, and if so, how is this best avoided? Is there a risk of contamination of the "healthy lung," usually from an empyema or lung abscess, and how is that best avoided?
(iv) *Consider* what is the surgeon and/or pulmonologist going to do?
(v) In the light of the previous three statements, what is the best method of inducing anesthesia? If the fistula size is small, consider conventional general anesthesia. If the effective fistula size is large, consider volatile induction with spontaneous respiration and of a double-lumen tube placement guided preferably by a fiber-optic scope to avoid fistula damage. Alternatively, with a large fistula, perform an awake single-lumen intubation and then isolate the lung by advancing the endotracheal tube into an appropriate bronchus; alternatively place a bronchial blocker considering that it is not the most secure isolation device
(vi) *Postoperative concerns:* Can postoperative ventilation be avoided to prevent causing or re-opening the fistula? What is the best method of providing postoperative analgesia? Is epidural analgesia possible, or is there local infection?

When presented with a scenario of difficult ventilation with a rapidly desaturating patient, the anesthesiologist may hastily attempt lung isolation and control of ventilation. Incorrect double- or single-lumen tube position can lead to failure to control either the air leak or effect adequate alveolar ventilation. Another risk is that the tube enters or tears the fistula and aggravates the situation.

This is therefore a potentially difficult [lower] airway scenario, and, as with all potentially difficult airways, it is critical to plan thoroughly beforehand. The plan must consider how anesthetic induction and lung isolation are best conducted. It is also not always possible to know or predict the precise size of the fistula. Indeed, there is a paucity of high-quality scientific evidence on which to base the treatment of BPFs, most literature being small case series or dramatic case reports.

Before induction of anesthesia, this author looks for clues regarding the physical size of the fistula and underlying lung mechanics to evaluate the "effective fistula size" (see above),

which is a clinical evaluation of the balance between BPF flow and tidal volume that will likely be generated during intermittent positive pressure ventilation. Determining "effective fistula size" is not an exact science but is useful to decide how to best manage anesthetic induction. With a large effective fistula size, the majority of the tidal volume delivered during intermittent positive pressure ventilation will likely escape via the fistula and is accompanied by poor alveolar ventilation. Under such circumstances, IPPV is best avoided during induction and before distribution of ventilation has been controlled. Control of the distribution of ventilation is usually achieved by employing lung isolation techniques.

Estimating the physical size of the fistula can be assumed from a variety of sources of information. Determining the pathogenesis of the BPF may be useful. For example, it may be obvious that a large fistula resulted from a penetrating or blunt injury, or it is a small, post-lung resection fistula. Inspection of the imaging, particularly the chest computerized tomograms, often indicates the physical size and exact location of the fistula (Fig. 43.2). Fiber-optic bronchoscopy can also be used to evaluate the position and size of the lesion.

Pulmonary mechanics significantly affects how BPFs function. Evaluating the mechanics of both lungs is useful to evaluate whether the peak airway pressures needed for effective alveolar ventilation will be high or low. The transpulmonary pressure gradient needed for adequate alveolar ventilation is largely determined by the ventilated lung compliance and resistance. A high and a low peak airway pressures will aggravate and ameliorate fistula flow, respectively. Gaining a clinical appreciation of the underlying pathophysiology helps evaluate pulmonary compliance. This may be obvious from the patient's history or the context, such as a long smoking history with severe obstructive airways disease, a history of restrictive pulmonary disease, or a patient in ICU with acute lung injury. Furthermore, chest wall and pleural conditions as well as factors affecting lung volumes such as intra-abdominal pressures and obesity all affect the transpulmonary pressure gradient. These important determinants of pulmonary mechanics will influence fistula functioning. The lung imaging may offer useful information on the underlying lung parenchymal or pleural diseases and lung volumes.

The mechanics and particularly the compliance of the affected lunghaving the BPF also matter when evaluating the "effective fistula size." When evaluating the transpulmonary pressure gradient likely needed to effect an adequate tidal volume, the extent of ipsilateral lung collapse on imaging is potentially useful. Complete ipsilateral lung collapse despite both tube thoracostomy and negative pressure suction suggests that the fistula is large and/or the lung compliance is low. This suggests a large effective fistula size and heralds that problems can be expected with intermittent positive pressure ventilation. However, a fully expanded lung on the affected side with only tube thoracostomy indicates the presence of a small BPF and/or a very compliant lung. This suggests that the effective fistula size is small, and problems with intermittent positive pressure ventilation are unlikely. The amount of respiratory distress also relates to the effective size of the fistula.

The amount of underwater drain bubbling (i.e., the effective volume of gas going through the fistula) may offer clues to the effective size of the fistula. Fistula size is typically classified into small, medium, or large according to the magnitude of the air leak and whether the bubbling is during inspiration or during expiration and whether it is continuous during both inspiration and expiration or if it only occurs during coughing:

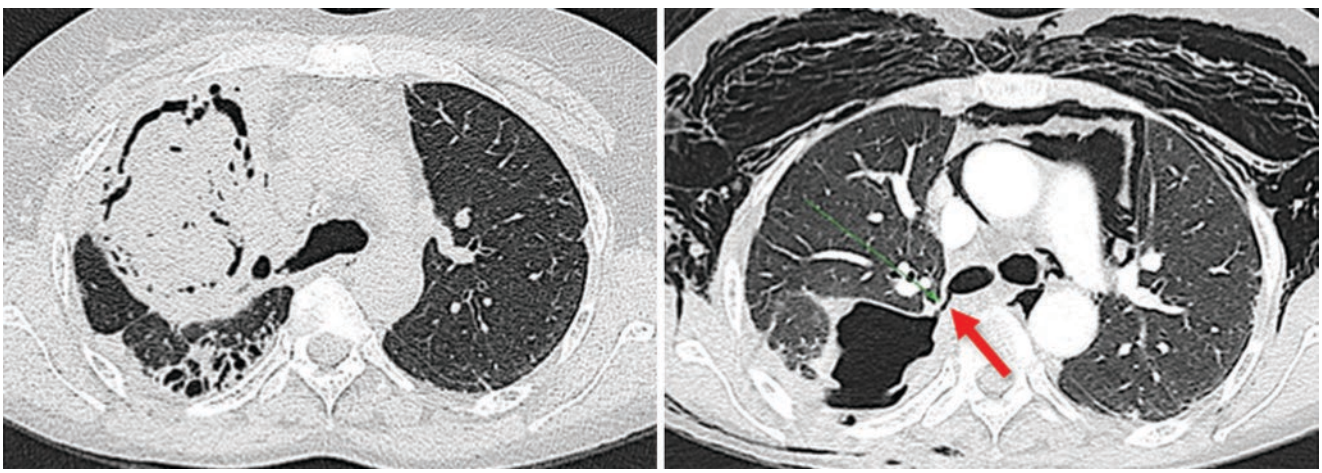

Fig. 43.2 The chest CT scan of a patient with previous pulmonary tuberculosis and a right upper lobe mycetoma. The left-hand image is prior to resection, and the arrow in the right-hand image points to a residual bronchopleural fistula 2 weeks after resection. This was closed surgically

1. Small, trivial: Air leak present only with Valsalva maneuver or coughing.
2. Medium: Air leak present with expiration only.
3. Large: Air leak present during both inspiration and expiration.

The volume of gas escaping via the fistula may be quantified with a spirometer or pneumotachograph placed between the thoracostomy tube and the underwater seal or flapper valve drainage device [29, 50–52]. Kempainen and Pierson suggest that a difference of more than 100 ml between the inspired and expired tidal volumes in a ventilated patient is indicative of a large leak [29]. In clinic medicine, this is not practical and seldom performed [2]. Despite being suggested as being a reliable indicator of effective fistula size, the "degree" of bubbling depends heavily on the patency of the underwater drain, drains being easily blocked by pus or clotted blood. Furthermore, while the resistance offered by the chest tube and drainage system is assumed minimal, this may not be so when using "waterless, pleural drainage units containing a flapper, one-way, Heimlich-type valve". Such systems are not all equivalently designed or constructed and may have inherent resistance which prevents the evaluation of airflow as described above in the classic, older water seal type systems [53].

The anesthesiologist faced with a bronchopleural fistula must therefore try to predict the effective fistula size, i.e., the distribution of gas flow via the BPF compared to how effective alveolar ventilation will likely be during intermittent positive pressure ventilation. With a large effective size fistulae, intermittent positive pressure ventilation will be problematic, most of the delivered tidal volume escaping via the BPF rather than being directed to effective alveolar ventilation. This prediction of "effective fistula size" requires "clinical judgment," the astute clinician weighing up multiple factors. This prediction is not an exact science, and the evaluation can prove wrong. A note of caution is that BPFs may be damaged and/or enlarged by airway instrumentation. Furthermore, if loose material partially obstructs the orifice, this material can be dislodged by airway instrumentation or coughing. Therefore, the initial physical appearance of the hole or the "effective fistula size" may not always represent the actual or potential size of the opening.

Having decided on the effective fistula size, a decision how to induce anesthesia and isolate the lungs needs to be made (Table 43.2). Despite being discussed "separately," a suitable method of both induction and lung isolation [and alternatives if the chosen method is ineffective]need to be decided upon beforehand. Practical preparations then need to be made to facilitate the chosen technique prior to commencement of the anaesthetic. If the effective fistula size is judged to be small, it is invariably safe to perform a "conventional" anesthesia induction sequence using opioids, induction agent, and a non-depolarizing or depolarizing neuromuscular blocker, followed by facemask intermittent positive pressure ventilation. Flexible or rigid bronchoscopic airway inspection is then frequently performed to better define the anatomy.

If the effective fistula size is evaluated as being large, it is crucial to avoid intermittent positive pressure ventilation until lung isolation has occurred. Under such circumstances, the anesthesiologist must use a "non-conventional" induction technique to ensure that the patient continues to breathe spontaneously until lung isolation and the distribution of ventilation is controlled. These goals can be achieved using volatile anesthesia induction or an awake intubation followed by lung isolation. Volatile anesthesia induction using sevoflurane accompanied by high oxygen concentrations is usually safe and efficient. After volatile induction of general anesthesia, placement of a double-lumen tube and lung isolation is usually easily performed to control the distribution of ventilation during intermittent positive pressure ventilation. Alternatively, a single-lumen tube can be used to effect lung isolation. Anesthetists practicing thoracic surgery must be proficient and practiced with a spontaneous breathing, gas induction technique to facilitate double lumen tube placemement, the authors preferred technique described in Table 43.3. Alternatively, placement of a single-lumen endotracheal tube into the upper airway, proximal to where the fistula is expected to be found, can be performed. This single-lumen tube is then used to establish control of the distribution of ventilation either using a bronchial blocker or using the single lumen tube to efffect lung isolation. This can be performed awake or after spontaneous respiration, gas induction of anaesthesia. Anesthetists need to be proficient at awake (single-lumen) endotracheal intubation without distressing the patient, the staff, or themselves. Being proficient also reduces reluctance to perform awake intubation [54, 55]. A technique often touted for control of ventilation is awake placement of a double-lumen tube. It is suggested that this be railroaded over a tracheally placed fiber-optic scope or an (appropriately sized, stiff enough, long enough) airway exchange catheter. This approach is technically challenging, and this author seldom if ever uses it . [54, 55].

In the presence of a large bronchopleural fistula, *unconventional ways of ventilation and oxygenation* have included high-frequency oscillation in combination with spontaneous ventilation, ECMO, or avoiding general anesthesia and airway instrumentation altogether and utilizing epidural or regional anesthesia [56–58]. Dependent positioning of the affected lung has reduced BPF flow [59].

The question often arises how best to manage the patient when it is difficult to decide whether the effective fistula size is small or large and/or it is truly a "medium"-sized fistula? Is the case best managed using the unconventional "complicated" spontaneous breathing volatile induction method, or does the anesthetist risk using a conventional induction with a non-depolarizing neuromuscular blocker followed by

Table 43.3 A suggested technique for volatile spontaneous induction of anesthesia:

(i) *Step 1:* Prepare airway equipment including a Saunders injector, rigid and fiber-optic bronchoscopes, airway exchange catheters, and suction catheters, and the surgeon present
(ii) *Step 2: Preoxygenation*: Preoxygenate using high fresh gas flow and 100% oxygen. During all upper airway instrumentation maneuvers, high-flow nasal oxygen may be useful to maintain oxygenation provided it does not cause excessive PEEP and damage the fistula
(iii) *Step 3: Volatile induction while maintaining spontaneous respiration:*
1. Perform sevoflurane volatile anesthesia induction using in 100% oxygen while maintaining spontaneous respiration
2. Consider administering a *small* dose of midazolam (1–2 mg/80–100 kg) when induction commences
3. Gentle pressure support may be useful during gas induction. Note that spontaneous respiration under volatile anesthesia occurs at a carbon dioxide partial pressure of approximately 0.5 kPa above the apnea point. Excessive assistance may render the patient apneic
(iv) Step *4: Options to obtund airway reflexes prior to laryngoscopy and double-lumen tube placement. The advantages and disadvantages of each maneuver below must be carefully considered.*
1. *The one possibility is to topicalize the airway.* This may be performed using rigid laryngoscopy to instill 10–15 ml of 2% lidocaine down the tracheobronchial tree, when the patient is "deeply enough anesthetized." The author invariably uses this method. After topicalization, reapply the anesthesia mask and administer sevoflurane in 100% oxygen until the patient is "deep enough" again
2. Laryngeal spasm following local anesthetic instillation could be very problematic, this seldom occurring if the patient was deep enough. Alternatively, transtracheal local anesthetic injection in the awake patient may be used to topicalize the airway, a method that seldom induces laryngeal spasm
3. Anticholinergic pretreatment is usually not needed but may be considered
4. *An alternative to airway topicalization is to administer an ultra-short-acting opioid*, either a bolus of alfentanil 10–15 mg/kg or start a remifentanil infusion ≥ 0,1 ug/kg/minute or TCI targeting 1 to 2 ng/ml 1 minute prior to airway instrumentation. The disadvantage of opioids is they will inevitably cause apnea, and the time to begin spontaneous respiration again when combined with general anaesthesthetics is somewhat uncertain!
5. Despite airway topicalization, this author invariably administers *Propofol 0.5 mg/kg* during spontaneous respiration with sevoflurane just prior to airway instrumentation. Again, apnea can ensue!
Airway instrumentation:
1. Perform laryngoscopy and advance the desired airway device (double- or single-lumen endotracheal tube) only into the upper part of the trachea, proximal to the suspected location of the BPF. DLT placement is usually easy under volatile anesthesia if the patient does not have a difficultly airway
2. After upper airway location of the airway device, airway toilet is often useful to facilitate fiber-optic inspection of the airway. This may be performed using a suction catheter or via a fiber-optic scope. To avoid physical disruption of the bronchopleural fistula, guide the double-lumen tube or airway device into its more distal position using a fiber-optic scope

IPPV? A technique often suggested as an alternative is to preoxygenate, induce anesthesia, and administer suxamethonium. The airway and distribution of ventilation will be easily controlled with the chosen lung isolation technique, which will not take long. The assumption is that the period of apnea before the airway is secured or before spontaneous respiration resumes will be short, as suxamethonium is "short-acting." With the widespread introduction of sugammadex, the use of rocuronium will eventually be touted as alternative to suxamethonium. However, with compromise of the functional residual capacity, severe hypoxia may ensue before the distribution of ventilation can be controlled or spontaneous respiration resumes. Furthermore, in a race against time prior to desaturation, hasty airway instrumentation may damage the fistula. It is far preferable to make a definitive decision before induction of anesthesia, declare it a small or large fistula, and use a conventional or non-conventional anesthesia induction sequence, as appropriate. Such an approach also makes anesthetists use, practice, and teach their "non-conventional" techniques more often which may promote patient safety.

After induction of anesthesia using conventional or inhalation techniques, double-lumen tubes are commonly used to control airflow in the presence of a BPF. A left-sided DLT is commonly used with a right-sided fistula and vice versa.

After anesthetized or awake placement of a single-lumen endotracheal tube, control of the distribution of ventilation is usually achieved using unilateral bronchial intubation or using a bronchial blocker. Unilateral bronchial intubation by advancing an appropriately sized single-lumen tube into a bronchus under bronchoscopic guidance is usually simple to perform. The simplicity of the technique means it is potentially useful in acute life-threatening situations. Selective left main bronchus intubation is better suited to this technique as it allows ventilation of the entire left lung. Disadvantages of this technique are that toilet of the contralateral bronchus cannot be performed and that selective right main or bronchus intermedius intubation usually allows only two-lobe ventilation and a high risk of hypoxia. After single-lumen tube placement, a bronchial blocker can be placed via the endotracheal tube and located proximally to the fistula. Alternatively, the bronchial blocker may be placed outside the endotracheal tube and then advanced into position under fiber-optic guidance. This latter "outside the tube" approach is better suited to the anaesthetised patient.

There is some controversy about the use of bronchial blockers in the presence of bronchopleural fistulae. Double-lumen tubes are considered more reliable in ensuring lung isolation and control of the distribution of ventilation [60, 61]. Because of poorer reliability, particularly when placed

in the short right main bronchus, bronchial blockers have been considered less suitable devices. However, this concern must be balanced against the considerations that awake intubation with a double-lumen tube can be very difficult, whereas awake single-lumen tube tracheal intubation followed by bronchial blocker placement through the tube is much easier. These considerations may apply even more in the patient who has a difficult upper airway. Bronchial blocker placement may also be considerably easier in the patient already intubated with a single-lumen tube, for example, in the ICU.

When lower airway instrumentation is performed in patients with bronchopleural fistulae, it is very important this be performed under bronchoscopic vision to avoid compromising fistula integrity. Airway devices can enter and damage or enlarge the fistula. Despite being small, the tissue surrounding the fistula may be very friable and tenuous. Airway devices such as endotracheal, double-lumen tubes or blockers can snag on bronchial sutures and directly enter and further disrupt the fistula. It is therefore critical to avoid blind advancement of any airway device and advance airway devices gently, only under direct vision facilitated by a flexible bronchoscope. This may require meticulous prior airway toilet to clear pus and secretions. Airway instrumentation is unlikely to aggravate alveolar-parenchymal fistula damage.

The affected pleural cavity may contain copious amounts of pus or infected material. This often occurs in the presence of post-thoracic surgery infection. If the pus is thin and/or the fistula is large, there is a risk of contaminating the dependent lung after turning the patient into the lateral decubitus position. During induction but before lung isolation has been achieved, gravity can be used to prevent or limit spillage to the normal lung. The affected side should be placed below the normal side by appropriate tilting of the operating table or patient during the induction sequence. Furthermore, the double-lumen tube or bronchial blocker should effect a watertight seal and also must not dislodge when turning the patient into the lateral decubitus position. The anesthesiologists must carefully consider the advisability of adhering to the conventional directive to deflate the bronchial cuff during turning. Suitable suction catheters and effective suction should be present. If the fistula is very small, classic lung isolation may not be needed to control the distribution of ventilation. Nonetheless, even with a small fistula, the risk of soiling of the "normal" lung still exists particularly if thin pus is present in the affected pleural cavity.

Postoperative ventilation may put strain on a sutured bronchus or repaired fistula and has been associated with fistula formation or re-occurence. It is prudent to avoid postoperative IPPV in these circumstances. Noninvasive ventilatory support may be more suitable after such surgery.

In the presence of systemic and local infection, and pus draining from a chest drain, it may be inadvisable to use epidural analgesia.

Interventional Pulmonology Management of Bronchopleural Fistula

Interventional pulmonology techniques have been used to treat BPFs [32]. These techniques were previously reserved for high-risk surgical patients but are becoming more commonly used as the primary intervention [9, 32, 62, 63]. The anesthesiologist needs to appreciate what the surgeon is planning and incorporate it into the anesthesia technique. The interested reader is referred to Slade's clear review of the pulmonary interventional techniques available to treat BPFs [32].

The precise bronchial source of the air leak can be identified using computed tomography scanning or may be visible on bronchoscopy. Sometimes, the "feeding" bronchi cannot be identified as they are too distal or there is haste. In these cases, the offending bronchi may be identified using a sequential Fogarty catheter bronchial occlusion technique [32, 64, 65].

Once identified, the offending bronchi can be occluded with a variety of techniques. Mechanical occlusion has been achieved by deploying Watanabe silicone spigots, vascular occlusion coils, and tracheobronchial silicone or self-expanding metal stents [66–75]. A novel, successful approach to larger lesions has been the use of Amplatzer intracardiac and vascular occlusion devices placed over the BPF [76–82]. Bronchial instillation of cyanoacrylate or fibrin glue has been successful with smaller less than 5 mm diameter fistulae but risk damage to expensive bronchoscopes [83–87]. Bronchial occlusion has also been achieved following submucosal sclerosing agent injection or endobronchial coagulation using Nd:YAG laser or argon plasma coagulation [32, 88].

While most interventional pulmonology approaches rely on case reports or case series, the strongest evidence base comes from the use of unidirectional endobronchial valves [32, 62, 89–104]. These devices were originally designed for lung volume reduction procedures. After endobronchial placement, they limit or prevent gas passage out of the particular bronchus and promote distal parenchymal atelectasis. The available evidence suggests great success in treating BPFs of various etiologies including spontaneous pneumothorax; postsurgical, traumatic, and iatrogenic BPFs; and in cystic fibrosis [62, 64, 93, 105, 106]. Endobronchial valves have also been used urgently in critically ill patients that have developed BPFs. Their use has allowed weaning from ECMO

and mechanical ventilation and facilitated chest tube removal [107, 108]. Interventional pulmonology approaches become logistically difficult or impossible as the number and/or size of the air leaks increases; thus, in situations of massive air leaks, ventilator strategies are preferable [29, 50].

A bronchopleural fistula (BPF) is usually a manifestation of the underlying lung disease, particularly in adult respiratory distress syndrome (ARDS). Therefore, measures to reduce the air leak are generally unsuccessful until the patient's underlying lung disease has improved. Even if the severity of the air leak is successfully reduced, there tends to be little effect on gas exchange, as measured by arterial blood gases [29, 50, 109].

Management of Bronchopleural Fistula in Ventilated Patients

Anesthesiologists will encounter bronchopleural fistulae that develop in the ICU. Ventilated patients usually develop alveolar-parenchymal fistulae rather than central connections with the bronchi. Their occurrence invariably indicates the severity of the underlying lung disease or ventilation trauma and is associated with a poor prognosis [47, 48, 110–112]. Anesthesiologists may be involved in both the medical and ventilatory management and also the definitive interventional pulmonology or surgical attempts to close the fistula. While a detailed discussion being beyond the scope of this chapter, brief notes on this topic may be useful.

The primary therapeutic aim should be optimal medical treatment and ventilatory management of the underlying lung disease, often, acute lung injury [29, 113]. Small fistulae invariably resolve as the underlying lung condition improves. Bronchospasm and infection need aggressive treatment. Healing may be facilitated by improved nutritional status. A secondary therapeutic aim is ventilator optimization to minimize the air leak, promote BPF closure, and improve gas exchange [47, 48, 51, 114]. Fistula airflow is increased by higher peak and mean airway pressures. Ventilatory strategies essentially aim at minimizing airway pressures by any means possible [50, 51, 114]. This should employ judicious amounts of PEEP, lowest tidal volumes and transpulmonary pressures possible, and allow permissive hypercapnia.

Conventional ventilation strategies to achieve this aim have included reducing tidal volume, reducing inspiratory time, minimizing PEEP, and using different ventilatory modes (pressure support, pressure control, synchronized intermittent mandatory positive pressure ventilation) and (partially) weaning the patient from ventilation [2, 48, 115–118]. When pressure support ventilation is utilized, the practitioner must consider that inspiratory support is terminated when inspiratory flow is reduced to below a particular value, which may not occur in the presence of a large air leak [29]. Kempainen and colleagues suggest adopting a ventilatory strategy comprising of "appropriate inaction". This strategy incorporates tolerating larger air leaks, employing higher inspired oxygen concentrations, and tolerating permissive hypercapnia. Nonetheless, while having substantial wisdom, the effect of these strategies on outcome is uncertain [29, 50, 109, 118].

Non-conventional ventilation methods have been advocated. High-frequency jet ventilation has been associated with lower peak airway pressures and is apparently useful in airway disruption with normal lung parenchyma [29, 48, 110, 111, 119–123]. However, change from conventional to high-frequency jet ventilation has been associated with worsening hypoxemia with alveolar-parenchymal disease-related fistulae [114, 124, 125]. Alveolar-parenchymal fistula flow is reduced only if high-frequency ventilation decreases peak and mean airway pressures [48, 51, 52, 119, 124, 126–133]. High-frequency ventilation's propensity to produce PEEP may possibly be the reason for its failure in alveolar-parenchymal disease and utility in tracheo-bronchial disruption [121, 133, 134]. High-frequency oscillation may be an option in acute lung injury complicated with BPF [135].

Another non-conventional "ICU" technique within the anesthesiologist's expertise is placement of a double-lumen endotracheal tube. This can be used for control of the distribution of ventilation and will buy time to develop a definitive therapeutic strategy. Moreover, a double-lumen tube also facilitates differential, independent lung ventilation, particularly if the lungs have different pathologies [2, 29, 48, 129, 136–161]. Independent lung ventilation does not have to use only one ventilator or be of the same mode; for example, one lung can be ventilated with synchronized intermittent mandatory ventilation, while the BPF affected lung is administered continuous positive airway pressure or high-frequency ventilation [129, 136, 138, 139, 143, 147, 162, 163]. Independent lung ventilation can employ ventilation techniques to "rest" (minimize transpulmonary pressures) the BPF affected lung and allow spontaneous healing of small fistulae [113, 118, 129, 137, 164, 165]. By facilitating better non-affected lung management, independent lung ventilation may effect better alveolar ventilation, facilitate gas exchange, and prevent further ventilation trauma. Independent lung ventilation has few deleterious hemodynamic effects and does not require synchronization [148, 166, 167]. Nonetheless, ventilator electronic linking and synchronization have been used.

The use of double-lumen endotracheal tubes DLTs in the ICU is fraught with potential technical problems, particularly displacement, airway toilet, and blockage by secretions. These problems may occur even if the patient is deeply sedated and had recieved non-depolarizing muscle relaxants, and meticulous suctioning . For these reasons, when a DLT is used in the ICU, it is imperative that a suitable broncho-

scope and skilled anesthesiologists are immediately available, a significant human resource problem. The high-pressure DLT bronchial and tracheal cuffs can compromise mucosal blood flow. Weaning from the double-lumen to a single-lumen tube to conventional ventilation may be considered when the air leak is resolved; the between-lung tidal volume and compliance difference are less than 100 mL and 20%, respectively [136, 159]. An alternative successfully used approach to differential lung ventilation is selective lobar blockade using a Fogarty catheter or bronchial blocker [168].

Definitive closure may be considered. Open surgery or video-assisted thoracoscopy may be used to visualize and facilitate fistula closure, pleurectomy, and/or pleurodesis. Any of the minimally invasive techniques discussed above, particularly the use of endobronchial valves, can and have been used to effect definitive fistula closure. ECMO has been employed after lung transplantation as a bridge for both successful surgical repairs of BPF and postoperatively to allow bronchial healing with less ventilatory support [57].

When using conventional and non-conventional ventilatory techniques in the ICU, it is assumed that a functional thoracostomy tube is in situ. This may be difficult in the presence of pleural infection, adhesion, and multiple leakage sites. These issues may necessitate careful placement of more than one chest tube [29]. Chest tube manipulations, particularly thoracostomy tube suction, are frequently advocated to induce better pleural space drainage and lung expansion, thereby facilitating fistula closure. Pierson prudently suggests maintaining only the minimum amount of negative thoracostomy tube suction to just keep the affected lung inflated [113]. Excessive thoracostomy suction may cause respiratory alkalosis, not improve or even worsen gas exchange, and initiate ventilator autotriggering [117, 132, 169]. The application of positive intrapleural pressure equal to PEEP may improve oxygenation [115, 116]. Intermittent inspiratory chest tube occlusion has been touted, albeit, it is a technique neither widely available nor feasible with multiple chest tubes [29, 170–173].

Massive Hemoptysis

44

Jean S. Bussières and Marili Frenette

Key Points

- With massive hemoptysis, death is usually caused by asphyxiation rather than by exsanguination.
- Urgent management focuses on the prevention of asphyxia while the source of bleeding is addressed.
- Endobronchial and/or angiographic control are usually possible.
- Bronchial artery embolization (BAE) is now the treatment of choice.
- There is now less indication for surgery, and surgical results are better in stabilized, "elective," non-bleeding patient.
- Pulmonary artery injury is rare but associated with high mortality and is curable with BAE.

Introduction

Massive hemoptysis (MH) is a medical emergency that places the patient at risk of asphyxiation and death. Because of the explosive clinical presentation of MH, it is essential to respond quickly and appropriately. This is a potential lethal condition that deserves to be investigated thoroughly and brought under control promptly [1].

The definition of MH may vary depending of the publications. It is usually based on the volume of blood expectorated. In the literature, we can find large variations between the definitions. They range from 100 to 1000 mL/24 h [2–4]. By consensus (Table 44.1 and Fig. 44.1), MH is defined as a rate of bleeding exceeding 600 mL/24 h, meaning 25 mL/h. Only 1.5–5% of hemoptysis are really massive [1]. Exsanguinating hemoptysis is defined as a bleeding rate exceeding 150 mL/h or blood loss over 1000 mL/24 h or over 300 mL during one expectoration [5].

Quantification of MH may be difficult, and from a clinical point of view, such criteria are not useful. Based on the fact that the anatomic dead space of the major tracheobronchial tree is about 200 mL in most adults [6], other definitions relying on the magnitude of the clinical effects have been proposed. MH can be defined as the volume of expectorated blood that is life-threatening mainly by virtue of airway obstruction and rarely by blood loss.

Table 44.1 Definition of hemoptysis

Hemoptysis	Massive	Exsanguinating
One expectoration (mL)		>300
mL by hour	>25	>150
mL by 24 h	>600	>1000

Massive hemoptysis compared to moderate or minor hemoptysis represents a higher risk of mortality for the patient. Published series on patients presenting massive hemoptysis showed a mortality rate with medical management varying from 12% to 50%. Mortality rate was greater than 50% in patients not treated adequately [1].

Decision-making is a multidisciplinary process involving a critical care physician, pulmonary medicine bronchoscopist, interventional radiologist, thoracic surgeon, and anesthesiologist.

Historical Considerations

MH treatment was at first exclusively surgical. From the 1940s to the 1960s, different surgical approaches have been used to control and treat MH. In 1973, Remy and colleagues [7] changed management forever with the first report of bronchial artery embolization. Hiebert in 1974 [8] described the first successful use of a Fogarty balloon catheter through a rigid bronchoscope to tamponade bleeding in a moribund patient with massive bronchial hemorrhage. Subsequently, the use of the bronchoscope progressively changed from a rigid device to the flexible fiber-optic bronchoscopy (FOB). More recently, the role of early bronchoscopy, mainly with a FOB, is questioned since bronchial artery embolectomy (BAE) is easy to perform and so effective.

Since the introduction of radiological embolization, there are less frequent interventions by anesthesiologists for massive hemoptysis. With the rapid use of BAE, potentially massive hemoptysis is rapidly controlled, and there is less and less need for surgical interventions (emergent, semi-emergent, or elective post treatment), and therefore there is less anesthesia management. Consequently, anesthesiologists are nowadays only occasionally required to help with airway management, lung protection, and assistance during radiological intervention.

The literature usually refers to old publications, and there are only retrospective series or anecdotic reports that support recommendations for investigation and a treatment plan for MH. It is easy to understand that it is very difficult to design a prospective, randomized, controlled trial in this type of population.

Etiologies

Hemoptysis is defined by coughing of blood that originates from the tracheobronchial tree or pulmonary parenchyma. There are many potential causes of massive hemoptysis. It is very important to rapidly rule out any non-pulmonary bleeding since it can originate from the nasopharynx or from the upper gastrointestinal tract.

The lungs have a dual blood supply, the pulmonary circulation and the bronchial arteries. The bronchial circulation is a high-pressure system providing only 1% of the arterial supplies to the lungs, but the bronchial tree is implicated in MH in more than 90% of cases. Bronchial arterial bleeding is distinctively brisk and bright red. Bronchial arteries originate from the aorta that brings nutrients to the lung parenchyma and major airways. Seventy percent of the bronchial arteries typically arise from the descending thoracic aorta in regard to the fifth and the sixth vertebrae. The 30% remaining arise from other locations such as the subclavian arteries [9]. The same vessels that supply the bronchial arteries may also supply the esophagus, the mediastinal nodes, and, more importantly, the spinal cord, through a complex anastomotic network [10].

Pulmonary arterial circulation is responsible for gas exchanges and is involved in less than 5–10% of massive hemoptysis. The pulmonary bed is a high-compliance and usually a low-pressure system (15–20 mmHg systolic and 5–10 mmHg diastolic). However, if there is pulmonary artery hypertension, this low-pressure system may be modified to a high-pressure system, reaching sometimes the systemic level. Dark blood is more consistent with pulmonary artery bleeding since the blood is not sufficiently oxygenated.

Hemoptysis originates from systemic, namely, bronchial, or from pulmonary vessels. The most frequent causes of bronchial tree hemoptysis are inflammatory lung disease (bronchiectasis and tuberculosis) and neoplasia (Table 44.2). The most common causes of hemoptysis from pulmonary circulation are arteriovenous malformation (AVM) and Rasmussen's aneurysms (due to tuberculosis). Iatrogenic

Table 44.2 Possible causes of massive hemoptysis

Infectious
Bronchiectasis (including cystic fibrosis)
Chronic bronchitis
Tuberculosis
Non-tuberculous mycobacteria
Lung abscess
Necrotizing pneumonia
Mycetoma
Cardiovascular
Arteriovenous malformation
Pulmonary embolism or infarct
Mitral stenosis
Aortic aneurysm or bronchovascular fistula
Vasculitis, Wegener's granulomatosis
Neoplastic
Lung cancer
Bronchial adenoma
Pulmonary metastases
Miscellaneous
Aspirated foreign body
Pulmonary contusion, trauma
Idiopathic pulmonary hemosiderosis
Iatrogenic (transthoracic or transbronchial biopsy, pulmonary artery catheter)

pulmonary artery rupture from pulmonary catheter (Swan-Ganz) occurs rarely, but since anesthesiologists are frequently implicated in its causality, this subject will be discussed more deeply in another section of this chapter.

Clinical Manifestation

In the acute phase of hemoptysis, there is an accumulation of blood in the dependent parts of the lungs. Through the cough reflex, blood is expelled, producing the hemoptysis. During that time, blood can be dispersed bilaterally into the bronchial tree, and the evaluation can mislead to lateralization.

The degree of bleeding may be easily underrated because the volume of blood engulfing the involved lobes or lungs is not quantified and may be significant [1]. Many patients with hemoptysis have a medical history of compromised lung function, and even small quantities of blood into the bronchial tree can lead to significant respiratory distress. Expectorated blood is often swallowed and cannot be measured. Asphyxia is the most life-threatening manifestation of MH, well before hemodynamic instability appears, and is the usual cause of death associated with MH.

Initial Management of MH

There is little consensus regarding the optimal management of patients presenting with MH. Moreover, from the beginning of the twenty-first century, there are few recent large series of patients studied [11]. In this section, conclusions of these studies, some consensus from the literature, and also various controversies will be presented.

Initial management of massive hemoptysis needs to achieve a few objectives quickly and simultaneously. The initial step in management of hemoptysis is to differentiate between minor and massive hemoptysis. The approach to the patient presenting MH can be generally done in three steps [12]: airway protection, localization, and treatment. The initial approach to the patient should be dictated by the clinical presentation. Patients with rapid bleeding or severe functional decompensation need protection of the airway first, meaning that every effort should be made to protect the non-affected lung against blood spillage and to maintain adequate gas exchange to prevent asphyxia [13]. Hypoxia secondary to lung spillage or blood clots is the main cause leading to death. Secondly, it is essential to localize the source of bleeding, meaning finding as precisely as possible its origin or at least the side of the MH. Thirdly, the administration of a specific therapy is mandatory. Definitive treatment options include conservative medical therapy, endobronchial therapy, arterial embolization, or surgery.

All patients presenting MH should be admitted to an intensive care unit for further investigation and treatment or transferred to the radiological suite for CT or angiogram examination or, less frequently, directly to the operating room. While undergoing diagnostic procedures, the patient should be kept upright, and 100% oxygen should be administered. Appropriate venous access should be put in place, and blood should be available from the blood bank. A coagulation profile should be obtained to show any coagulopathy, including platelet dysfunction from drugs such as acetylsalicylic acid (Aspirin®), clopidogrel (Plavix®), and other antiplatelets and new anticoagulants. Every effort should be made to reverse anticoagulation, when possible. Invasive therapeutic measures are not indicated for the control of hemoptysis caused by anticoagulant therapy, blood dyscrasia, or Goodpasture's syndrome [1]. Blood loss is rarely massive enough to cause a great threat to hemodynamics. Slight hypotension can occur and may be treated with volume replacement.

Light sedation with anxiolytic drugs or cough suppression drugs is rarely useful in the acute phase of MH [13]. Once the immediate danger has passed and bleeding is settling, these drugs may be used to depress the excessive coughing that can aggravate or stimulate hemoptysis [6]. Bronchodilators cannot be administered since they can have a vasodilation effect and may precipitate renewed bleeding [14].

Life-Threatening Intervention

When facing MH, many strategies to prevent airway contamination should be available. If lung isolation is delayed or not available, the patient intubated or not should be placed in the lateral decubitus position with the bleeding lung on the dependent (inferior) side to prevent spillage to the unaffected lung (nondependent, superior side).

Lung isolation may be used to avoid spillage to the unaffected lung by blood from the bleeding lung. Lung isolation can be performed with different techniques including a selective endobronchial intubation with a standard endotracheal tube, the use of a bronchial blocker (BB), or the insertion of a double-lumen tube (DLT). The two last lung isolation techniques are not specific to hemoptysis as they are regularly used during anesthesia for thoracic surgery [15] (see Chap. 16).

Main stem bronchial selective intubation with a large uncut endotracheal tube is facilitated using FOB, if the visualization is good enough to allow the guidance of the tube. Unfortunately, blood and clots can obstruct the view from FOB. Blood highly absorbs the light of the FOB and consequently alters its capacity to identify the tracheal bifurcation and the guidance of the endobronchial tube. Blind endobronchial insertion may be attempted and verified by auscultation.

However, the presence of large amount of blood in the main airway may confuse the sound perceived unilaterally.

Bronchial blockers (BBs) may be used for lung isolation or act as a therapeutic avenue when facing MH. It can be a temporary measure in life-threatening situations until a more specific treatment is applied. Bronchial blockers may be inserted into a bleeding bronchus under the control of a FOB to induce an endobronchial tamponade. Bronchial blocking device is useful for lung separation when the DLT is not immediately available or when there is some difficulty in inserting the DLT (e.g., percutaneous tracheotomy) [16]. As for any other lung isolation devices, the use of FOB is mandatory, but the airway visualization may be difficult because of the presence blood and blood clots. BB can be used in a non-intubated (through nostrils) or intubated patient. It can be positioned and stabilized alongside or inside the lumen of the endotracheal tube or DLT. In some situations, the BB may be introduced through a DLT. At that time, the use of very small FOB (2.8 mm) may be necessary, mainly with a smaller-sized DLT (35–37 Fr). The Uniblocker BB (Fuji Systems Corporation, Tokyo, Japan) is easy to use compared to other models, and it is now the golden standard for that procedure.

It is an excellent method to achieve control of the bleeding and to protect the contralateral lung and potentially the ipsilateral non-bleeding lobes or segments. The technique of endobronchial tamponade for bleeding control in MH was first introduced by Hiebert in 1974 [8]. The author occluded a bleeding bronchus with a balloon catheter inserted through a rigid bronchoscope. Different catheters have been used for this application, Foley catheter, Fogarty catheter, Swan-Ganz catheter, specific double balloon catheter, and more recently bronchial blockers. In addition to the tamponade effect, the administration of vasoactive drugs is possible through the inner channel [17]. This gives time to proceed with a therapeutic and more definitive intervention. If possible, the BB should be replaced by a DLT or a simple lumen tube to allow further evaluation and suctioning of the bleeding lung. The bronchial blocker should always be deflated under FOB vision. In 2006, Giannoni et al. [18] described a bilateral concurrent massive hemoptysis successfully controlled with the placement of more than one balloon catheter. In 2017, Caddell reported a case of an emergency surgical pulmonary embolectomy complicated by an acute massive hemoptysis [19, 20]. The authors used a double bronchial blocker system with a sequential inflate and deflate technique to localize the hemorrhage and provide lung isolation and ventilation.

A third alternative for the management of the airway during MH is the placement of a double-lumen tube (DLT) or endobronchial tube. These DLTs are specially designed for selective intubation of the right or left main stem bronchi [21]. For MH, selective intubation of the left lung is preferable. The left-sided tube is easier to position than the right-sided tube which carries the risk obstructing the right upper lobe bronchus. Double-lumen tubes have a bad reputation in the literature when used in the context of MH. Nevertheless, some of these observations were published before [22] the introduction of the polyvinyl DLTs whose positioning can be verified with the FOB. Other publications [1] refer to the use of DLTs for other conditions than MH, and their conclusions cannot be used to determine the safety of DLTs during MH [23]. However, it has been demonstrated that anesthesiologists with limited experience in thoracic anesthesia frequently fail to successfully place lung isolation devices, DLT, or bronchial blockers [24].

It is the authors' opinion that inserting a left-sided double-lumen tube is a good strategy. Many problems with DLT were described with older nondisposable model of DLT or with older models of FOB. When confronted with massive hemoptysis, the use of polyvinyl DLT and new FOB with larger suction channel can be helpful. The lumen inserted into the non-bleeding lung is used to ventilate the patient. The other lumen, connected to the bleeding lung, allows the insertion of a specific FOB. These FOBs, with a diameter less than 4.2 mm, have a working channel allowing suction of blood and blood clots from the bleeding site. The lumen directed to the bleeding lung may be used to carry out a relatively "blind" and very careful catheter aspiration. With attentive care, the lumen may be cleared of blood or clots. The application of CPAP or mechanical ventilation with PEEP on the bleeding lung may help to decrease the bleeding and/or to improve the patient's gas exchange.

Nevertheless, insertion of a DLT may be difficult, even for an experienced anesthesiologist, because large amounts of blood can make the visibility poor with FOBs. Also, a well-positioned DLT may be easily displaced during the frequent transfers of the patient from ICU to radiologic suites or frequent patient's repositioning in bed. The authors prefer to use left-sided DLT with a carinal hook to stabilize the DLT onto the carina and fix it to the maxillary bone to minimize its displacement. Sometime, when facing a massive hemoptysis, the use of a carinal hook helps to "blindly" position a DLT. It is important to note that BBs are at higher risk of dislodgement with movement or transfer of the patient than DLTs. Consequently, patients with a DLT or a BB usually should not be moved unless in absolute necessity, and sometime these patients should be with muscle relaxants to prevent coughing until the hemoptysis has been treated [25, 26].

Once adequate lung isolation is achieved, the patient can be placed in the lateral decubitus position with the bleeding lung on the nondependent (superior) side. The dependent non-bleeding lung will thus receive most of the pulmonary blood flow, and this will help to control the hemorrhage, as it decreases the perfusion in the upper lung. This position will also improve ventilation/perfusion (V/Q) ratio. The patient should be ventilated with 100% oxygen, and PEEP should be

applied on the inferior lung to improve gas exchange. PEEP or CPAP may also be used on the upper bleeding lung acting as a hemostatic effect and help gas exchange.

Diagnostic Tools and Therapeutic Approaches

There is a controversy regarding the sequence of bronchoscopic and radiological interventions. Initial computed tomographic scan (CT) is thought to shorten examination time in critical patients, but in a patient with massive hemoptysis, etiologic diagnosis is less important than immediate interruption of the bleeding process [27].

Chest radiography is readily available and is an important diagnostic tool in finding the cause of the bleeding and localizing pulmonary pathology. High-definition computed tomographic (HDCT) scanning angiography is also an excellent diagnostic tool. Except for life-threatening situations, CT scan should be performed before the bronchoscopic exploration. It has superior diagnostic capacity over bronchoscopy and chest radiography for demonstrating underlying pathology and the site of bleeding in hemoptysis, especially in bronchiectasis, bronchogenic carcinoma, and aspergilloma cases. Vascular pathologies such as arteriovenous malformation or aneurysm, which are rare causes of hemoptysis, are also depicted very clearly in contrast-enhanced CT scan examinations [13]. With recent developments in multidetector CT scan technique, it is now possible to scan the whole thorax into very thin slices (1.25 mm) in a very short time (12–15 s) [14, 15]. Both the lesion causing hemoptysis and bronchial or nonbronchial systemic feeding arteries are detected during the same study using 80–100 mL of contrast medium. In angiography-controlled studies, 86–87% of the pathologic vessels detected by angiography were discovered with CT angiography (CTA) [14, 15].

Bronchoscopy

For a patient presenting MH, the medical team may choose to proceed with early or late bronchoscopy. This bronchoscopy may be rigid or flexible, and its primary goal is to localize the site or at least lateralize the side of the bleeding source. The secondary goal is to clear the airway of gross blood. Finally, the third goal may be to use a therapeutic agent to control the bleeding. If the situation is not critical, a quick trial of fiber-optic bronchoscopy (FOB) can be performed to determine the origin or at least the side of the bleeding. If the patient's oxygenation is significantly compromised or the bleeding continues at a brisk pace, elective oral intubation with an endotracheal tube (8.0 mm or larger) should be performed; this may be done simultaneously with the bronchoscopy [28].

Timing

Although most authorities advocate bronchoscopy to help localize bleeding during MH, the moment when to use the bronchoscopy is still controversial [12]. In the literature, it is frequently mentioned that patients with MH require urgent bronchoscopy. The argument for this assertion is that bleeding will increase with time, making visualization difficult. It is reported that bronchoscopy helps to detect the bleeding site in a lung or lobe in patients with diffuse pulmonary disease [10].

More recently a new option emerged. Patients presenting with MH are immediately directed to the angiographic suite to get a diagnostic angiogram and bronchial artery embolization (BAE) at the same time. Patients at risk of asphyxia prior to the BAE benefit from lung isolation techniques. The FOB is then carried out a few days later. The main argument for this sequence is that during the acute phase of severe MH, airways are filled with large volumes of blood restricting the use of bronchoscopy and consequently invalidating endobronchial treatment [7, 29]. Sometimes, endoscopic examination may aggravate bleeding and delay more effective treatment. Hsiao et al. reported in 2001 [30] that bronchoscopy was not a prerequisite in the treatment process considering risk of airway compromised from sedation, delay in definitive treatment, hypoxemia, and high cost [11]. In this study, bronchoscopy findings were taken into consideration whenever they were available. Not having to perform a bronchoscopy did not affect the progress of endovascular treatment. Bronchoscopy findings have not altered the course of angiography and endovascular treatment in any of their patients. In this observational retrospective study of 28 patients, there was no need for emergency bronchoscopy during active and abundant bleeding.

In a retrospective study of 28 patients with massive hemoptysis, flexible bronchoscopy successfully localized the site of bleeding in 26 patients [2]. In comparison, chest radiographs localized the bleeding site in 23 patients. This suggests that flexible bronchoscopy is effective at identifying the site of bleeding in patients with massive hemoptysis, but localizing a radiographic abnormality is sufficiently accurate to warrant proceeding to bronchial artery embolization without bronchoscopy [28].

Despite the "lack of proof" showing that early bronchoscopy is beneficial, the general expert consensus favors an early bronchoscopy, especially for patients with massive hemoptysis [3]. The early procedure provides clinicians with the maximal amount of information upon which to base future decisions, particularly in patients who develop sudden recurrence or acceleration of their bleeding. Nevertheless,

early bronchoscopy has not been strictly proven to improve outcome [28].

Practically speaking, early bronchoscopy should be done within the first 12–18 h for the patient who is clinically stable or for whom bleeding has become quiescent. Alternatively, bronchoscopy is performed as early as it is safely feasible on the unstable, decompensating patient [28]. In some institutions, in patients with MH who are unstable, diagnostic angiography is the imaging method of choice to localize the bleeding site because it allows for immediate treatment [31].

Type of Bronchoscopy

Depending on each institution's local practice, rigid or flexible bronchoscopes are used to evaluate and to stabilize any patient presenting MH. The selection is likely to reflect the institution's or the user's experience [12]. No study addressed this issue.

Rigid

Rigid bronchoscopy has been, until recently, the procedure of choice after initial chest radiography. Many surgeons and much of the older literature strongly advocate the use of the rigid bronchoscope. Rigid bronchoscopy is preferred because of its ability to suction large quantities of liquid and clotted blood, to use a great variety of therapies during bronchoscopy, such as direct cauterization or packing of bronchial lesions, and to continuously provide ventilation. Obviously, operating room setting and general anesthesia are required. By contrast, the visual range of inspection is significantly reduced compared to the fiber-optic bronchoscopy.

Changing over time, the technique of rigid bronchoscopy is being less and less used and, as a result, is not available in many institutions [13]. Consequently, a rigid bronchoscope is usually used for patients with ongoing massive hemoptysis after an unsuccessful bedside fiber-optic bronchoscopy. The flexible bronchoscope can also be used in conjunction with the rigid bronchoscope by passing it through its lumen. This allows a better examination of the more distal and upper lobe airways [28].

A survey in 1998 noted that 79% of physicians treating massive hemoptysis favored the flexible optic bronchoscope (FOB) as the initial technique compared to 48% in a similar survey performed in 1988 [32, 33].

Flexible

FOB has become more acceptable as an initial procedure for intubated or not intubated patients. The main limitation of FOB compared to the rigid bronchoscope is its limited ability to produce adequate suction through its smaller port. Also, with massive hemoptysis, the presence of blood in the inferior airway may absorb the light transmitted by the FOB and consequently decrease the capacity of visualization [13]. As described above, FOB can be used through the rigid bronchoscope for further examination.

For maximal safety, most patients should be intubated when bronchoscopy is indicated in presence of massive hemoptysis. If bleeding increases or recurs during the procedure, the bronchoscope can be removed, and suction can be applied while controlling the airway. The perception obtained through the bronchoscope is commonly obscured by clots on the tip of the scope; thus, it is important to be able to safely remove the scope, clean the tip, and suction the channel to continue the examination [28]. The disadvantages of bronchoscopy in an acute bleeding situation include poor visibility due to endobronchial blood and frequent ineffective therapeutic options [1].

Endobronchial Therapy

Laser photocoagulation or resection, electrocauterization, and cryotherapy are useful tools for minor or moderate hemoptysis. Unfortunately, these techniques are rarely efficient against massive hemoptysis [13]. If bronchoscopy allows visualization of a localized bleeding mucosal lesion, laser therapy or electrocauterization may be considered, if available. Both techniques can be used through a flexible or rigid bronchoscope. Since excellent visualization of the bleeding site is required, the rigid bronchoscope may be preferred because of its better suction capability [11].

Pharmacologic Adjuncts

Some pharmacologic adjuncts may be used through the FOB. Topical agents such as warm saline may initially help to break down gross clots and identify the bleeding site [13]. After identification of the bleeding side, initial control may be obtained by using 50 mL sequential aliquots of up to 500 mL ice-saline lavage [12]. Topical epinephrine (1:20,000) is also used to act locally as a vessel's vasoconstrictor to stop bleeding. Thrombin, fibrinogen-thrombin, or fibrin precursor solutions, such as hemostatic agents, can be injected via intrabronchial infusion through a catheter inserted into a FOB wedged against the bleeding bronchus [34, 35].

Mechanical Therapy

When a lesion is not treatable by embolization, as there is no feeding vessel and if surgical resection is not thought to be a viable option, the protection of the contralateral lung can be achieved by the insertion of a lung isolation device. But this measure may offer only a temporary relief. At that time, the use of self-expanding airway stent to cover the bleeding segmental bronchial orifice may act as both tamponade and isolation of the bleeding source [36].

Systemic Therapy

Intravenous vasopressin has been used to treat massive hemoptysis, in a similar way as its use in gastrointestinal

hemorrhage [37]. Therefore, its administration may prevent successful BAE [38–40]. Other therapies that may promote coagulation and that have been used successfully for massive hemoptysis include intravenous estrogens (Premarin®), desmopressin (DDAVP®), ADH (vasopressin), tranexamic acid (Cyklokapron®) [41–44], and recombinant activated coagulation factor VII [45].

Bronchial Artery Embolization (BAE)

First reported by Remy et al. in 1973 [7], the use of BAE for management of MH has become widespread. It has become the main option for the treatment of MH, either at first presentation or in case of recurrence. Development of BAE has been a huge advance in treatment of patients with MH, both as a temporizing measure and as a definitive treatment for some patients [46]. After several improvements, BAE is now considered the procedure of choice in cases of both massive and recurring hemoptysis and should be undertaken promptly [29]. It is also now considered the most effective nonsurgical treatment in MH [1]. This approach reduces the systemic arterial perfusion pressure from the fragile bronchial arteries within the diseased lung parenchyma [47]. In the hands of experienced angiographers, embolization successfully stops bleeding more than 85% of the time, especially if the bronchial circulation and the systemic arterial supply are carefully defined [11, 48].

Multiple imaging modalities are used to confirm the diagnosis and to locate the bleeding site in stable patients. These include plain chest radiography, chest computed tomography, and bronchoscopy. But in patients with MH who are unstable, diagnostic angiography is the preferred imaging method for localizing the bleeding site because it allows for immediate treatment [31].

The initial step for transcatheter embolization is performing a thoracic angiogram to visualize and localize all the main systemic arteries to the lung(s). Once the feeding arteries are localized, selective bronchial arteriography is performed to characterize the bleeding vessel. When the bleeding vessel is identified, an embolic agent is used. There are numerous options regarding material used for BAE. They all have different characteristics as being particles or coils or having irregular or spherical form or different sizes [49].

Postembolization, bronchial arteriogram, and thoracic aortogram are performed to ensure the complete block of all the feeding arteries with no further bleeding from vessels. Immediate recurrent hemoptysis often occurs due to missed feeding arteries that went untreated, whereas later recurrence may take place as a result of collateralization or recanalization of either the feeding artery or new bleeding vessels [31].

Multiple publications (10 series including 609 patients, from 1983 to 2007) have demonstrated an immediate successful rate of controlled bleeding varying from 70% to 95% with a recurrence rate ranging between 13% and 43%. These studies also report a minimal immediate complication rate of less than 1% [31]. The most serious complication of BAE is the accidental embolization of the anterior spinal artery (Adamkiewicz) either by contrast material or the embolizing particles causing ischemic injuries [1]. The anterior spinal artery originates from a bronchial artery in about 5% of patients. The reported prevalence of this complication has been described as 1% [50]. This risk has been decreased by superselective embolization techniques using smaller catheters that can be placed distally [51]. Renal dysfunction resulting from the contrast load is a concern, especially in patients who are hemodynamically unstable due to blood loss [6].

Correct clinical evaluation and ventilation stabilization of the patient are mandatory before BAE in massive hemoptysis [27]. Intubating a patient with a single- or double-lumen tube helps to monitor, with the help of a FOB, the interruption of bleeding through a radiologic intervention and to clean the inferior airways from any residual blood and blood clots.

Surgery

Historically, pulmonary resection has been the most effective method to control and prevent recurrent bleeding [6]. Comparing the results with those of medical or surgical management is difficult for several reasons. The criteria of eligibility for surgery differ among institutions and seem to be subject to surgical or institutional bias [1]. The primary problem in selection bias is that patients who are more likely to die are less likely to be operated on [6].

Patients with lateralized, ideally well-localized, uncontrollable bleeding should be assessed early for possible surgery in case the bleeding remains brisk and unresponsive to other measures. Surgery is reserved as an absolute last resort for operative candidates not salvageable by BAE [6].

Patients presenting MH are too ill for physiologic testing; historical data are therefore used to estimate the patient's ability to undergo lung resection. Relative contraindications to surgery include severe underlying pulmonary disease, active TB, diffuse underlying lung disease (cystic fibrosis, multiple arteriovenous malformations, multifocal bronchiectasis), and diffuse alveolar hemorrhage [11].

Morbidity and mortality are significantly greater with emergent surgery for persistent massive bleeding compared to elective surgery in non-bleeding patients. In most series of emergent therapy, surgical mortality for treatment of massive hemoptysis is approximately 20%, ranging from 10% to 38% for series published between 2000 and 2003 [52–54], with morbidity occurring in an additional 25–50% of patients; however, most of these series are more than 20 years old.

The reasons for such high mortality and morbidity may be related to the ongoing bleeding in unstable hemodynamic conditions, together with soiling of the remaining healthy bronchopulmonary segments before and during the operation. Contamination of the contralateral lung before, during, and after surgery is the main cause of postoperative respiratory failure leading to prolonged ventilation, nosocomial pneumonia, and death [6]. One solution is to delay the surgery with BAE, to obtain hemodynamic stability preoperatively, and to perform bronchial toilet pre- and postoperatively. Before the critical decision to perform surgery is taken, the surgeons should make sure that available interventional modalities such as balloon bronchial blockers, rigid bronchoscopy, or BAE can be used in an optimal manner to buy time to delay surgery for a better surgical outcome.

Iatrogenic Pulmonary Artery Rupture (IPAR)

The use of a pulmonary artery catheter (PAC) is becoming less frequent in the operating room since the general use of transesophageal echocardiography. Nevertheless, PAC remains a useful tool for diagnosis and management of many patients with cardiac or lung diseases. Sicker patients may need the insertion of a PAC, and these sicker patients are usually the patients most at risk for catheter-induced pulmonary artery rupture. Prevention is the first approach to develop when confronted with an iatrogenic complication. The first step of prevention is the judicious selection of patients. Risk factors for catheter-induced pulmonary artery rupture include female gender, age over 60 years old, improper catheter placement, and pre-existing pulmonary hypertension. The second is the appropriate use and management of the PAC. Nevertheless, when a catheter-induced pulmonary artery rupture occurs, the physician needs to have a clear scheme of intervention to deal with this severe complication.

The incidence of rupture is not very high, with an average of 0.01–0.47%. In a large retrospective study of patients with a Swan-Ganz catheter, Kearney et al. [55] found an incidence of pulmonary artery rupture (PAR) of 0.031% and a mortality of 70% [55]. The mortality rate of pulmonary artery rupture averages 50% but can be as high as 75% in anticoagulated patients. Death occurs most often secondary to asphyxia. If a delay before the appropriate management is instituted, it will contribute to a higher mortality rate.

The initial presentation may be as obvious as massive pulmonary hemorrhage or as subtle as a minor hemoptysis associated with cough, or it may be totally asymptomatic [56]. Moreover, any hemoptysis in the presence of a PAC should be investigated because of the high suspicion of PAR or false aneurysm formation. Hemothorax may be the mode of presentation when blood enters the pleural space instead of the airway.

The proposed mechanisms for catheter-induced PAR include catheter tip lodged in the vessel wall when the PAC is advanced while the balloon is not inflated or when eccentric balloon inflation exposes the catheter tip and guides it into the arterial wall or migration of catheter in a smaller arteriole with subsequent rupture caused by balloon inflation. Primary management of catheter-induced pulmonary artery rupture focuses on the prevention of asphyxia. Asphyxia secondary to lung spillage or blood clots is the main factor leading to death. Prevention of contamination of the unaffected lung is essential. As for other types of MH, blood loss is rarely massive enough to cause a great threat in hemodynamics, and slight hypotension may be treated with volume replacement.

The management of IPAR is a three-pronged approach, with targeted therapy derived from the basic "ABC" principles of resuscitation, airway, breathing, and circulation. The goals are (A) lung isolation, (B) maintaining appropriate gas exchange and oxygen delivery, and (C) volume resuscitation. The decision to leave the PAC in place may be critical at that time for the next steps in the radiologic management of this complication. It is essential not to inflate the balloon without radiologic imaging support (see later discussion). Management differs depending on the clinical presentation, mainly in which setting it is presenting, intensive care unit, operating room, or radiology suite.

Intensive Care Unit Setting

When a pulmonary artery catheter is inserted and there is hemoptysis, whether it is massive or negligible, a chest radiograph is usually obtained and will show infiltration around the catheter tip or pleural effusion. The side of a PAC can serve as a guide to determine from which side the hemorrhage may come from. Since most PACs are located in the right lung (90%), mainly the right lower lobe, it can be assumed that hemorrhage comes from the right side if the situation is critical [20, 57].

While diagnostic procedures are performed, 100% oxygen should be administered to the patient. If the lungs are not isolated, the patient should be placed with the bleeding lung on the dependent (inferior) side to prevent spillage to the unaffected side. If the situation is not critical, a short fiber-optic bronchoscopy can be performed to determine the origin of bleeding.

The patient must undergo selective intubation to obtain lung isolation. Lung isolation can be performed with various techniques, including selective intubation with a standard endotracheal tube, bronchial blocker, or DLT. As mentioned earlier, it is our opinion that the best strategy is to place a DLT, but a bronchial blocker can be used for lung separation if a DLT is not immediately available or is difficult to insert.

After lung isolation, fiber-optic bronchoscopy can be useful to confirm the good positioning of the device used for the lung isolation and to identify the bleeding site. It is frequently difficult to get a good view of the structures because the

blood in the tracheobronchial tree highly absorbs the light of the fiber-optic bronchoscope.

It has been suggested that the PAC could be deflated, withdrawn of a few centimeters, and left in the pulmonary artery. The balloon may be inflated to compress the bleeding vessels or to temporarily obstruct the feeding artery [58, 59]. We recommend that this technique should be used only under fluoroscopy and angiographic control to finely adjust the position of the balloon, in order to avoid malpositioning of the balloon. Improper positioning could augment the bleeding by increasing the vascular laceration or by diverting the pulmonary blood flow to the injured vessel.

Pulmonary angiogram generated through a PAC may be difficult to realize because of the very small inner lumen of the Swan-Ganz catheter. With a stable patient or if the diagnosis remains unclear, a contrast-enhanced CT scan may be performed and is a valuable diagnostic tool. It can confirm the possibility of a pulmonary artery false aneurysm (PAFA) but also exclude any other causes of hemoptysis. CT scanning is usually followed by an angiography with embolization, if indicated and feasible (Table 44.3).

Table 44.3 Management of pulmonary artery catheter-induced pulmonary hemorrhage

1. Initially place the patient with the non-isolated, bleeding lung in the inferior position
2. Endotracheal intubation, oxygenation, airway toilet
3. Lung isolation: endobronchial double- or single-lumen tube or bronchial blocker
4. Withdraw the pulmonary artery catheter several centimeters, leaving it in the main pulmonary artery. Do not inflate the balloon (except with fluoroscopic guidance).
5. Position the patient with the isolated bleeding lung nondependent. PEEP to the bleeding lung if possible
6. Transport to medical imaging for diagnosis and embolization if feasible

Operating Room Setting

Most cases of life-threatening hemoptysis described during cardiac surgery result from a catheter-induced pulmonary artery perforation [1]. If a hemoptysis happens during surgery, lung isolation can be rapidly achieved, and the diagnostic and therapeutic procedures started, while the patient is still under anesthesia. If the hemoptysis happens before the scheduled surgery, elective surgery must be postponed until the PAR is investigated and stabilized. During cardiac surgery, when a hemorrhage happens after cardiopulmonary bypass (CPB) but before heparin reversal, CPB should be restarted to bypass the lung circulation and stop the bleeding, giving time to the anesthesia team to identify the side of the bleeding, to isolate the lungs, and to maximize oxygenation (see Fig. 44.2). If the hemoptysis begins after protamine administration, the best conduct is to finish the surgery as quickly as possible, isolate the lung, and proceed to a definite investigation and treatment of the pulmonary artery rupture.

Iatrogenic pulmonary artery rupture can be localized at the proximal trunk of the pulmonary artery (PA). As this perforation occurred outside the lung parenchyma, it explains the absence of hemoptysis [60]. Surgical repair is then indicated.

After ruling out the implication of PAC as the cause of MH during cardiac surgery, other causes, including surgical trauma, traumatic intubation, or concomitant disease (neoplasia, pulmonary edema) amplified by heparin and anticoagulation, should be considered. When no pre-existing disease and no lesion can be identified by bronchoscopy or by the surgeons to explain unilateral bleeding and that the patient is too instable to be transferred to the angiographic

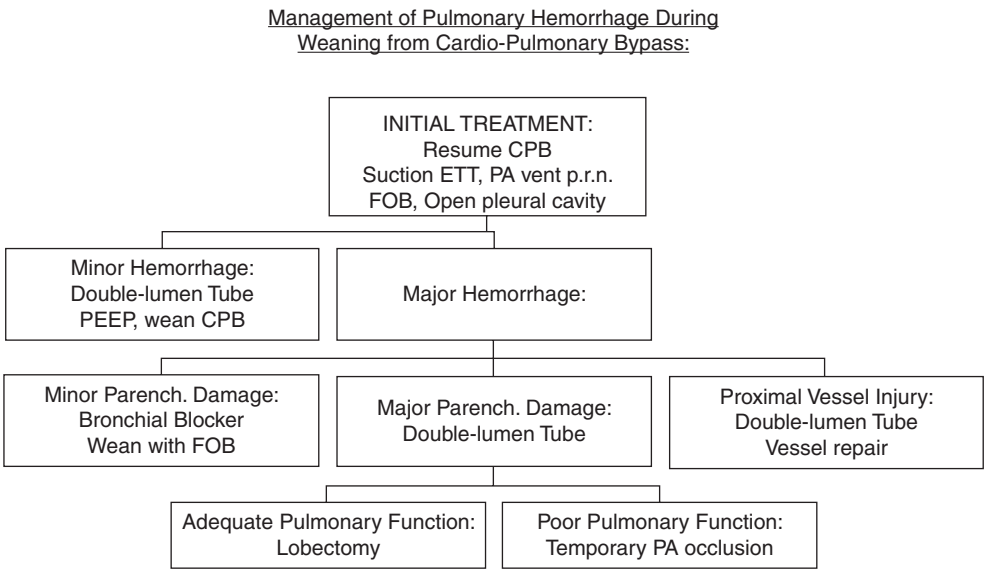

Fig. 44.2 Flow diagram of management of massive hemoptysis during weaning from cardiopulmonary bypass. *CPB* cardiopulmonary bypass, *FOB* fiber-optic bronchoscopy, *ETT* endotracheal tube, *PA* pulmonary artery, *Parenc*. lung parenchyma

room, temporary pulmonary vascular exclusion by thoracotomy is an effective alternative to radiologic embolization for managing unilateral hemoptysis during heart surgery [61].

Radiological Setting

During cardiac catheterization, the PAC can be used to evaluate pulmonary vascular resistance and the wedge pressure. When catheter-induced pulmonary artery rupture happens in this setting, it is relatively easy to pull back the PAC of a few cm and to reinflate the balloon under direct visualization [59, 62]. Thus, it may be possible to stop the bleeding pending further radiological intervention. However, this measure does not always enable physician to contain the hemorrhage [63]. This is the reason why the authors recommend using fluoroscopy and contrast injection to confirm that the PAC is still proximal to the injured vessel and that balloon inflation impedes flow through the lacerated vessel. Diagnostic angiography and embolization can be easily performed at that point. This may help to avoid intubation, lung isolation, and post-procedure ventilation in some circumstances [59]. Since the use of a FOB to initially position a DLT or BB in a patient with MH can be difficult due to obstruction of the view by blood, one option in the radiology suite is to use fluoroscopy to help guide the lung isolation device (see Fig. 44.3) [62].

Pulmonary Artery False Aneurysm (PAFA)

PAFA formation is secondary to the accumulation of blood in an aneurismal sac compressed by the lung parenchyma. While there is no intact vessel wall lining containing the bleeding, the lung parenchyma may prevent further extravasation. The presence of a PAFA requires intervention, because one can never be certain that spontaneous healing will occur. Delayed pulmonary hemorrhage occurs in 30–40% of cases of a PAFA caused by a previous catheter-induced pulmonary artery rupture. Rebleeding can occur as late as 2 weeks to 7 months after the initial event [64].

With the development of interventional cardiology and different vascular devices, novel therapeutic approaches to IPAR have been recently developed. For instance, vascular plug (Amplatzer® AGA Medical Corp., North Plymouth, MN) has been used with success [65, 66].

If there is suspicion of a PAFA on the CT scan, an angiogram should be done. When the clinical suspicion of pulmonary artery rupture is high or when the patient is unstable, angiography remains the procedure of choice because it allows both diagnostic and therapeutic intervention (see Fig. 44.4) [67]. If diagnosis of a PAFA is confirmed, selective embolization helps to reduce morbidity and mortality. Embolization is successful in 75% of cases, with a rebleeding rate of about 20%. Sometimes, it can be deleterious to embolize the PAFA regarding global lung function. In these cases, conservative treatment can be tried. Follow-up of this type of patients with repeat contrast CT scan is required.

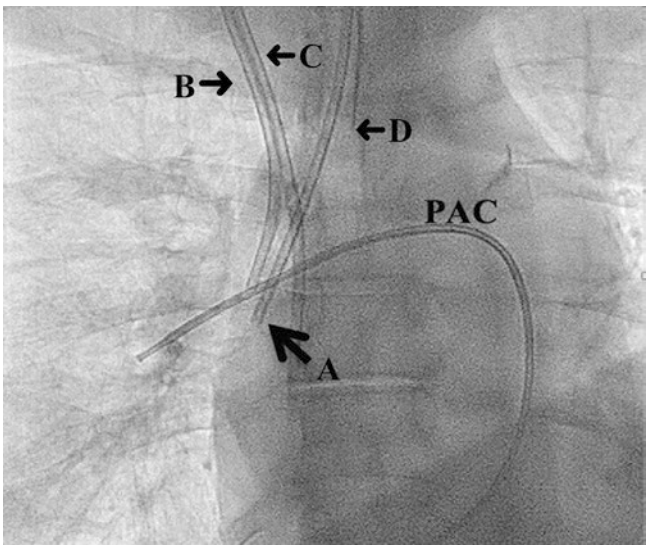

Fig. 44.3 An Arndt bronchial blocker (arrow A) has been positioned under fluoroscopic guidance into the right main stem bronchus of a patient who developed massive hemoptysis during right heart catheterization. The bronchial blocker can be seen between the central venous catheter (arrow B), proximal pulmonary artery catheter (arrow C), distal end of the endotracheal tube (arrow D). *PAC* distal pulmonary artery catheter (Modified with permission from Addante et al. [62])

Other Causes

Some other causes or presentations of IPAR have been described. Its occurrence is extremely rare during insertion of a thoracic percutaneous drainage tubes but may be devastating due to the large-bore chest tube typically used and sometimes may be rapidly fatal [68]. An idiopathic bilateral bronchial hemorrhage during cardiac surgery has been reported in the literature. Despite a very aggressive treatment, the patient died on day 6 [19].

Management Post Hemoptysis

Following massive hemoptysis, treated either by endoscopy, radiological intervention or surgery, it is important to perform a bronchoscopy to clean the tracheobronchial tree and to remove any blood and clots in the distal airway. This action will help promote better and faster patient recuperation.

Tracheostomy Hemorrhage

Another clinically challenging scenario involving massive airway bleeding is tracheostomy hemorrhage. Hemorrhage in the immediate postoperative period following a tracheostomy is usually from local vessels in the incision such as the anterior jugular or inferior thyroid veins. Massive hemorrhage 1–6 weeks postoperatively is most common due to tracheo-innominate artery fistula [69]. A small sentinel bleed occurs in most patients before a massive bleed.

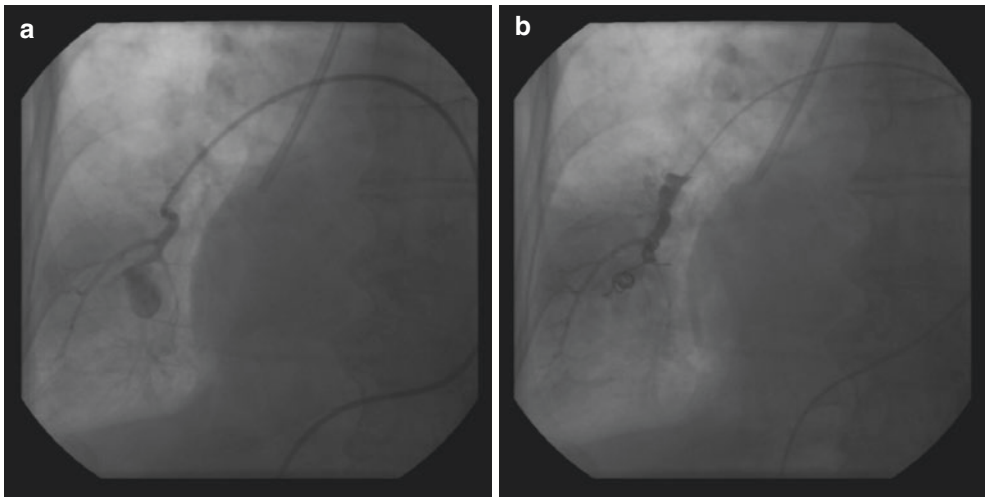

Fig. 44.4 (**a**) Radiographic contrast dye injection showing a false aneurysm of the pulmonary artery of the right lower lobe following massive hemoptysis induced by pulmonary artery catheter rupture. (**b**) A coil has been placed by interventional radiology in the false aneurysm of the right lower pulmonary artery in the same patient. Dye injection shows that the aneurysm has embolized with no further leakage

Table 44.4 Management of tracheo-innominate artery fistula hemorrhage

1. Overinflate the tracheostomy cuff to tamponade the hemorrhage. If this fails:
2. Replace the tracheostomy tube with an oral endotracheal tube. Position the cuff with FOB guidance just above the carina
3. Digital compression of the innominate artery against the posterior sternum using a finger passed through the tracheostomy stoma. If this fails:
4. Slow withdrawal of the ETT and overinflation of the cuff to tamponade
5. Then proceed with definitive therapy: sternotomy and ligation of the innominate artery

The management protocol for tracheo-innominate artery fistula is outlined in Table 44.4.

Conclusion

Endobronchial control measures and artery embolization have radically changed the management of massive hemoptysis. In experienced hands, BAE is an effective therapeutic tool and plays a pivotal role in the management of life-threatening massive hemoptysis. With control of hemorrhage, nonsurgical patients can be identified and surgical candidates accurately assessed to allow an elective operation, with lower morbidity and mortality, if conservative measures are unsuccessful [6].

Based on the above information, the following approach is a reasonable way to manage a patient with massive hemoptysis. First, stabilize the patient's oxygenation, ventilation, and hemodynamic status. Early correction of coagulopathy and consultation with critical care physician, pulmonary medicine (bronchoscopist), interventional radiologist, thoracic surgery, and anesthesiologist are essential. Perform early bronchoscopy along with other appropriate diagnostic evaluations. If the patient continues to bleed aggressively, arteriography is most reasonable for localization and therapy. If bleeding persists despite embolization or if the patient is too ill to undergo an angiography, blockade therapy or insertion of a double-lumen tube should be considered in preparation for rigid bronchoscopy in the operating room with possible lung resection if warranted. While surgery remains the only truly definitive therapy, it should not be used in the acute emergent setting unless it cannot be avoided [11]. Surgery, including pulmonary artery ligature, segmentectomy, lobectomy, or pneumonectomy, is reserved for extreme cases since it is technically challenging and associated to high morbidity [64].

Clinical Case Discussion

A 26-year-old woman is well known in the authors' institution for Eisenmenger's syndrome secondary to a complex congenital heart disease. She had a patent ductus arteriosus for which no surgical option was available when diagnosed at 4 years old. She was referred to our center 4 years ago for pulmonary hypertension. At that time, it was observed that the right pulmonary artery originates directly from the aorta. She has been treated with epoprostenol (Flolan) for 3 years.

A few months ago, she presented some episodes of moderate hemoptysis treated with BAE. Someday, she presented a new moderate hemoptysis necessitating BAE. She was admitted to the intensive care unit for 5 days, and no bleeding was observed. She was then transferred to the bronchoscopy suite to search for a blood occluding the right inferior lobe bronchus. With the aid of sedation and local anesthesia, the area was easily reached. The blood clot was partially dislodged without any problem. While trying to dislodge the remaining of the clot, coughing was provoked, and it induced a massive bleeding from the inferior lobe.

Questions

Which immediate procedure should be undertaken?

1. Nasal oxygen was already in place for the FOB exam.
2. Right lateral decubitus position to protect the left lung from blood spillage.
3. Irrigation of the origin of bleeding with cold saline.

Bleeding continues and becomes a MH. What is the next step?

4. Left-side endobronchial intubation with single-lumen tube with the assistance of the FOB.
5. Left lateral decubitus position to improve left lung gas exchange and minimize bleeding from the right lung.
6. Exchange the endobronchial simple lumen tube for a double-lumen tube.

The patient was directed, with anesthesia assistance, to the radiological suite for angiography and BAE as needed. Following diagnostic angiography and therapeutic embolization, the radiologist wanted to know about the bleeding in the right lung. What we can do to help her?

7. Fiber-Optic Bronchoscopy Examination

Following this procedure, the right-side bronchial tree was suctioned. At that time, active bleeding was identified originating from the right inferior super dorsal bronchus. Following a new BAE, the bleeding ceased, and the cleaning of the bilateral bronchial tree was completed without finding any other bleeding site.

The patient was transferred to the ICU with the DLT in place. She was sedated and ventilated until the next morning when she was extubated. She did not present any recurrence, and she was transferred to another center for evaluation for lung transplantation.

Whole Lung Lavage

45

Jean S. Bussières and Etienne J. Couture

Key Points

- Patients with pulmonary alveolar proteinosis have a restrictive disease and are hypoxic.
- Lavage of one lung with large quantities of saline requires careful lung isolation.
- For more than 10 years, bilateral lung lavage has been performed during the same anesthetic period.
- GM-CSF is now a complementary treatment to whole lung lavage when needed.

Introduction

This chapter reviews the historical considerations of whole lung lavage (WLL), when its performance is appropriate, details of the technique, complications, and finally benefits of this unusual treatment modality. It is important to differentiate WLL from bronchoalveolar lavage (BAL). BAL is a diagnostic tool performed with the aid of a fiberoptic bronchoscope (FOB) under local anesthesia, which uses only 300 mL of liquid in one segment of the lung. WLL is a treatment modality that requires over 10 L of normal saline instilled through a double-lumen tube in one whole lung while the patient is under general anesthesia.

Historical Consideration

WLL was first described in 1928 [1]. In the early 1960s, the first application of this technique was used to treat pulmonary alveolar proteinosis (PAP) [2–5]. At that time, the procedure consisted in repeated segmental flooding through a percutaneous transtracheal catheter positioned blindly into the bronchial tree. This technique was performed in an awake patient and was repeated four times a day for 2–3 weeks, using physical positioning to direct the saline sequentially into different lung segments. The 1980–2000 period **led** to the development of a modern technique of unilateral WLL, which is carried out under general anesthesia and lung separation [6, 7]. Since the beginning of this century, performing bilateral WLL during the same anesthesia period is the gold standard. In parallel with this evolution, the pathogenesis of WLL has been better defined since the discovery of the role of granulocyte-macrophage colony-stimulating factor (GM-CSF) in surfactant catabolism.

Indications

WLL is the most effective proven treatment modality for symptomatic pulmonary alveolar proteinosis [1, 2]. Various pathologic states have been also treated by WLL including cystic fibrosis, asthma, chronic obstructive lung disease, radioactive dust inhalation, alveolar microlithiasis, lipoid pneumonitis or exogenous lipoid pneumonia, and silicosis with variable success [8].

Pulmonary Alveolar Proteinosis

Primary pulmonary alveolar proteinosis (PAP) is a rare disorder of unknown cause and variable natural history. This lung disease is caused by alveolar accumulation of a lipoproteic material that has the aspect of surfactant. This accumulation of material creates a true alveolo-capillary blockade,

and the patient presents with dyspnea and hypoxemia, aggravated by exercise.

Pathogenesis and Classification

Until recently, the pathogenesis of PAP was unknown. Most investigators have postulated a decreased clearance of surfactant from the alveolar space. Over the last decade, rapid progresses were made toward the elucidation of the molecular mechanisms of PAP. Recent data suggest that GM-CSF has a pivotal role in PAP pathogenesis, as it is required for normal surfactant homeostasis. The disease is associated with neutralizing autoantibodies against GM-CSF. This new information allows the development of a new classification for this orphan lung disease and the use of new therapies. Some studies have been conducted with inhaled and subcutaneous GM-CSF. The latter form shows improvement in oxygenation and quality of life in 48% of patients [9]. The main conclusion is that GM-CSF treatment appears to benefit a subset of patients with adult PAP and may represent a novel alternative to the repeated whole lung lavages.

Three forms of PAP are now recognized: primary, secondary, and congenital [10]. The primary (idiopathic) form of PAP is the most common disease presentation, representing more than 90% of all cases. Its onset occurs in adulthood, and it has an autoimmune origin. It is associated with a high prevalence of circulating anti-GM-CSF antibodies. Reduction of localized GM-CSF activity in the lung, secondary to the presence of neutralizing anti-GM-CSF antibodies, causes alveolar macrophage dysfunction, resulting in surfactant excess and accumulation [11]. There is no other associated underlying illness or exposure.

The secondary form also develops in adulthood, occurs with other conditions, and can be separated into two broad subgroups. These are systemic inflammatory diseases or malignancy and specific exogenous exposure. Exposure to a high level of inorganic dusts (e.g., silica, aluminum, titanium, cement, wood) or fumes (chlorine, gas, gasoline, plastics) has been incriminated. Secondary PAP is likely related to a relative deficiency of GM-CSF and related macrophage dysfunction.

The congenital form is often present in the neonatal period and results from a very rare gene mutation. This mutation is related to the surfactant receptor gene or to the GM-CSF gene. This form is rare but is usually very severe. Neonatal respiratory distress syndrome is a presentation form of congenital PAP.

Clinical Manifestations

Among adults, the typical age of apparition of the illness is 30–50 years. There is a male to female ratio of 2:1. The major symptom of PAP is a progressive dyspnea and hypoxemia on exertion, spread over months and sometimes years. Dyspnea, the most common presenting symptom, is reported by approximately 55–80% of patients; however, approximately one-third of affected patients are asymptomatic, despite the infiltration of the alveolar air space. Nonproductive cough, fatigue, weight loss, and low-grade fever have also been described.

Spontaneous remission can occur, but the therapeutic decision in PAP depends on the progression of the illness and the extent of the physiological impairment. The prognosis of PAP has greatly improved since the introduction of WLL by Ramirez in 1965. The usual objective of WLL is the improvement in the clinical, physiological, and radiological condition of the patient.

Radiographic Findings

Chest radiography is the most useful screening test, although very nonspecific [12, 13]. On chest radiography, bilateral symmetric alveolar opacities located centrally in mid- and lower or upper lung zones are typical, yielding a "butterfly" distribution. High-resolution CT scanning (HRCT) reveals ground-glass opacification, predominantly in a homogeneous distribution. Thickened intralobular structures and interlobular septa in typical polygonal shapes may also be observed, referred to as "crazy paving." Crazy paving is characteristic but not specific to PAP and can also be observed in patients with an acute respiratory distress syndrome, lipoid pneumonia, acute interstitial pneumonia, drug-related hypersensitivity reactions, and diffuse alveolar damage superimposed on usual interstitial pneumonitis [14].

Physiological Testing

Pulmonary function tests show a restrictive ventilatory defect with reduction in the total lung capacity and vital capacity. When present, the decrement in diffusing capacity for carbon dioxide (DLCO) is often out of proportion to the degree of the restrictive defect. Arterial blood gas analysis shows mild to moderate hypoxemia, with an elevated alveolar-arterial gradient and elevation in shunt fraction while breathing 100% O_2 [15].

Laboratory Investigation

Bronchoalveolar lavage (BAL) may help in establishing the diagnosis in clinically suspected cases. BAL fluid is opaque and presents a "milky" appearance, with large amounts of granular, acellular eosinophilic lipoproteinaceous material which is periodic acid-Schiff (PAS). Electron microscopic exam of BAL fluid can confirm the diagnosis [16, 17]. When allowed to stand, the fluid spontaneously separates into pale yellow, almost translucent supernatant, and thick sediment.

Obtaining tissue for histopathology by open lung biopsy has been the gold standard for a long time. This biopsy performed by VATS is now unnecessary in the majority of cases of PAP. The combination of the clinical presentation, imaging findings, and BAL results are generally sufficient to make the diagnosis. Transbronchial biopsies may be occasionally used when needed. Surgical lung biopsy is rarely necessary to make the diagnosis [18–20].

Furthermore, anti-GM-CSF antibodies are increasingly used as a diagnostic tool in PAP. The quantitative assessment of anti-GM-CSF antibodies in reference laboratories constitutes an important diagnostic and therapy-guiding measurement [21]. GM-CSF antibodies are present in all serum and BAL fluid samples from primary, idiopathic, PAP patients. BAL fluid levels of anti-GM-CSF antibodies correlate better with the severity of PAP compared to serum titers [22]. Serial measurements of BAL or serum anti-GM-CSF antibodies may be useful in monitoring disease activity and response to treatment.

Therapy

The treatment depends on the form of PAP. When dealing with idiopathic PAP, the use of WLL, GM-CSF, rituximab (Rituxan®), or plasmapheresis (see later) can be considered. For secondary PAP, treatment of the underlying condition or removal of the offending agent should be the first step to consider. When confronted with congenital PAP, WLL, supportive therapy, or lung transplantation is the ultimate treatment.

Whole Lung Lavage

Treatment of idiopathic PAP has evolved from the use of a variety of nonspecific and largely ineffective agents to the physical removal of the lipoproteinaceous material from the lungs (WLL) and to the development of specific therapy targeting the underlying pathogenesis of the disorder. WLL has, for a long time, been considered the definitive therapy for PAP. The idea that the accumulated material could be physically removed from the lungs of PAP patients was first advanced in the early 1960s.

Specific indications for lung lavage include a definitive histological diagnosis and one of the following: resting PaO_2 < 65 mmHg, alveolar-arterial O_2 gradient ≥40 mmHg, measured shunt fraction >10–12%, severe dyspnea, and hypoxemia at rest or on exercise. It is critical not to perform WLL when a patient has active bacterial pneumonia, since this can result in generalized sepsis and shock [11].

Physical removal of the lipoproteinaceous material through repeated dilutions with saline solution is believed to be the mechanism from which WLL shows benefits; additional mechanisms including the bulk removal of anti-GM-CSF antibody, as well as other possible immunologic effects on the effector cells, such as the alveolar macrophage or the type II epithelial cell, are possible [23].

Although fairly well tolerated, WLL sometimes only provides temporary symptomatic benefit and has then to be repeated several times. The lavage requires prolonged general anesthesia, is complex to perform, and is associated with potential morbidity. All these considerations make repeated WLL a less-than-desirable treatment. Hence, the search for alternative modalities of therapy is still crucial.

GM-CSF

Discovery of the alveolar macrophage involvement and anti-GM-CSF neutralizing antibodies led to multiple trials examining the usefulness of GM-CSF therapy. Preliminary data suggest that about 48% of patients treated with subcutaneous GM-CSF experienced improvement in pulmonary symptoms and function; however, the number of respondents appears to be less than with whole lung lavage. Given the experimental nature of GM-CSF therapy, the use of lung lavage is still the primary therapy for PAP.

Inhalation of nebulized GM-CSF has also been reported to improve lung function and facilitate clearance of the GM-CSF-antibody complexes from the lung. Additionally, a recent study using a two-pronged approach showed a decrease in GM-CSF requirements by performing WLL followed by nebulization of GM-CSF. It also appears that high amounts of exogenous GM-CSF can overcome the endogenous neutralizing antibodies, especially if GM-CSF is directly administered to the lung. This result would seem to be explained by the lipoproteinaceous material cleared by WLL, and consequently the inhaled GM-CSF could more readily reach the alveoli [11].

Although the positive effect of GM-CSF has been shown in idiopathic PAP, many important questions remain, including the optimal dose of GM-CSF, the optimal duration of treatment, the relation to the anti-GM-CSF titers, and the optimal route of GM-CSF administration.

Other Therapies

Rituximab (Rituxan®) is a monoclonal antibody directed against B lymphocytes. Since 1997, rituximab has been demonstrated to be effective in various autoantibody-mediated diseases like PAP [24]. Treatment with plasmapheresis to decrease the level of GM-CSF antibodies has yielded mixed results [25, 26]. Lung transplantation has been performed in patients whose health has deteriorated despite multimodal therapy, but recurrence in the allograft has been reported [27].

Whole-Lung Lavage Technique

In the author's quaternary center, the team is composed of trained and experienced staff consisting of two respiratory therapists, one nurse, two physiotherapists, and one anesthesiologist in charge of the anesthesia and of the lung lavage [7] (Table 45.1).

Monitoring

Whole lung lavage is realized under general anesthesia with basic monitoring, supplement respiratory monitoring, and sometimes invasive monitoring. In addition to the standard monitoring devices, an arterial cannulation is used for

Table 45.1 Whole lung lavage – proceeding

Stages	Whole lung lavage – proceeding	
1	*Induction of anesthesia* Insertion of the left DLT with carinal hook	
2	*Pre-lavage evaluation* (FiO_2 1) Conventional ventilation for 5 min → arterial blood gas (ABG) Left OLV for 5 min → ABG Right OLV for 5 min → ABG	
3	*First lung lavage* Lung lavage on the lung with the worst PaO_2 on OLV Multiple lavage/drainage cycles Fifth cycle done in lateral decubitus position * Contamination risk on the dependent lung Following fifth cycle: manual ventilation halfway through drainage phase End of cycles when the drainage fluid returns clear Aspiration with soft suction and FOB	
4	*Recovery/lung rest* Protective 2 lung ventilation TV 6–8 mL/ kg, PEEP 7–12 cmH_2O, $FiO_2 < 0.6$ if well tolerated Fluid balance and diuretics if needed Cover the patient with heating blanket Length: 30–45 min	
5	*Preparation for second lung lavage* (FiO_2 1) OLV on the fresh lavaged lung for 5 min → ABG	
	If $PaO_2 > 70$ mmHg Proceed with the 2nd lung	If $PaO_2 < 70$ mmHg Consider adjuvants (iNO, PAC) Report proceeding with the 2nd lung
6	*Second lung lavage* Idem as the first lavage	
7	*Landing phase* Replace the DLT by a single-lumen tube Aspiration with soft suction and FOB	
8	*Emerging phase* Protective ventilation (2–4 h) in a monitored unit Post-anesthesia care unit Intensive care unit ABG and chest X-ray Awakening and extubation	
9	*Observation phase* 24 h in a monitored unit ABG and chest X-ray evaluation *Noninvasive positive-pressure ventilation as needed*	

beat-to-beat measurement of blood pressure and for blood gases analysis. Some authors also suggest the use of pulmonary artery catheter, continuous monitoring of mixed venous oxygen saturation [28, 29], and transesophageal echocardiography (TEE) [30, 31]. The pulmonary artery catheter may be used more as a therapeutic aid than a monitoring device by diverging blood flow away from the lavaged lung. TEE is sometimes useful to evaluate the cardiac function, mainly the right ventricle, in the presence of pulmonary hypertension.

The ventilator monitor found on most new anesthesia machines provides essential information during the WLL. The observation of the airway pressure/volume loop (spirometry) on a breath-to-breath basis is useful to detect any loss of lung isolation and to prevent flooding of the ventilate lung [7, 32].

General Anesthesia

Only light premedication with anxiolytic drugs is used. Efficient preoxygenation is mandatory. General anesthesia is induced and maintained with intravenous agents, such as narcotics, benzodiazepine, intravenous anesthetic, and muscle relaxants. Inhaled anesthetic is rarely used. Minimal intravenous hydration is administrated since many liters of fluids originating from the alveolar space will be reabsorbed into the vascular space. Usually, the procedure for unilateral lavage lasts between 3–4 h and 5–6 h for a bilateral lavage. The use of a warming blanket over the legs helps to minimize heat loss as the thorax is completely denuded for the procedure.

Lung Separation

Lung separation is obtained by using a disposable left double-lumen tube (DLT). For the purpose of WLL, a left DLT with a carinal hook is used. The carinal hook offers a better stability of the tube given the numerous manipulations that occur during lung lavage. Adequate positioning of the DLT is achieved by the use of FOB, and air tightness is confirmed by a well-closed pressure-volume loop. Gas exchanges are obtained from both lungs simultaneously and then from each lung separately before and after the procedure to measure the effects of the WLL objectively.

Lung Lavage

The patient is kept in the supine position. To improve the effectiveness of the lavage, ventilation with FiO_2 1.0 is initiated for a few minutes to denitrogenate both lungs. Prelavage evaluation confirms which lung is the most impaired, mainly through imaging evaluations and blood gas exchange during bilateral sequential one-lung ventilation (OLV). The most impaired lung is the first to be lavaged.

OLV is instituted in the non-lavaged lung, and confirmation of perfect lung isolation is obtained from the spirometry loop. A homemade disposable irrigation and drainage system (Fig. 45.1) is used to instill approximately 1 L of warm normal saline (37 °C). The irrigating liquid is suspended 30 cm above the patient's mid-chest level, and the instillation takes about 2–5 min.

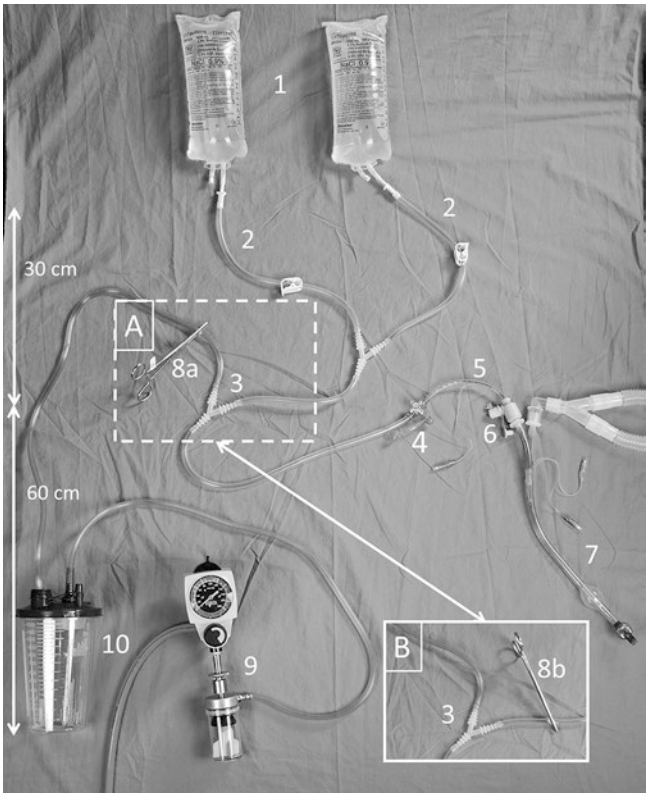

Fig. 45.1 Irrigation and drainage system. (1) Normal saline bag, (2) large bore tubular set for bladder irrigation, (3) Y-adaptor, (4) three-way for enteral feeding, (5) 5.0 mm single-lumen endotracheal tube, (6) swivel adaptor, (7) double-lumen endotracheal tube, (8a) clamp on the drainage side tubing during instillation phase, (8b) clamp on the instillation side tubing during drainage phase, (9) suction unit, (10) suction bottle. (Reproduced with permission of Libbey [52])

Approximately 2 min after the lung is completely filled with saline, it is rapidly drained over a 5–10 min period into a container positioned 60 cm below the patient's mid-chest level, with the assistance of a low suction pressure level (<20 cm H_2O). This process is repeated ten times or more, as necessary, to obtain a clear effluent lavage fluid.

Mechanical maneuvers are used to increase the efficacy of the WLL. These techniques consist of manual chest physiotherapy, mainly percussions, vibrations, and pressure applied during the filling and the drainage phase [33, 34]. A flannel cloth is used to protect the patient's skin from irritation provoked by repetitive manipulations. Positional modifications are very useful to irrigate and to drain all the different segments of the lung. The full lateral position is used at least once during the procedure, usually at the fifth cycle. When the lavaged lung is up, extreme care must be taken to avoid the risk of leakage from this nondependent lavaged lung into the dependent and ventilated one. After six or seven cycles of lavage and drainage, manual ventilation of the lavaged lung is frequently used halfway during the drainage phase to help the evacuation of the alveolar material [35]. When the effluent lavage fluid is clear, the procedure is completed.

Bilateral WLL

For more than 15 years, bilateral WLL is done during the same anesthetic period and is performed with good results. Before bilateral WLL was performed in the same anesthetic episode, it was initially performed on the sickest lung; then at least a week later, the WLL of the contralateral lung was completed. At that time, oxygenation was usually not a problem because the treated and now near-normal lung was used to support gas exchange during the second procedure. We realized, with the experience of the bilateral WLL, that the lung recuperates rapidly enough to allow the contralateral WLL in less than an hour after the initial one.

When the effluent lavage fluid is clear on the first lavaged lung, careful aspiration is done, blindly with a suction catheter and also under direct vision with the use of a FOB. In order to safely proceed with WLL on the contralateral lung, a recuperation period has to be respected for the recently lavaged lung. Both lungs are ventilated with normal tidal volume (8–10 mL /kg) with addition of PEEP at a level varying from 7 to 12 cmH_2O for a period of 30–45 min. Furosemide can be administered (10 mg) to induce diuresis during this period, and patient's body is entirely covered with a warming blanket to keep its temperature close to normal.

Following determination of the ability of the recently lavaged lung to support the OLV necessary for the lavage of the contralateral lung, another WLL is done as previously described. Our goal is to obtain a PaO_2 greater than 70 mmHg with a FiO_2 1.0, with or without PEEP prior to begin WLL. When a satisfactory oxygenation cannot be achieved, inhaled nitric oxide is used at 20 ppm, and/or a pulmonary artery catheter is inserted under fluoroscopy in order to diverge blood flow from the lavaged lung to the ventilated lung [36]. When the adequacy of oxygenation is demonstrated, the WLL on the second lung is performed similarly to the first one.

Associated Bronchoalveolar Lavage (BAL)

In some specific cases, when the distribution of the alveolar infiltration is not homogeneous and is more localized into some specific lobes, the author adds to the standard WLL a series of BAL, well directed to the main involved lobes. BAL is performed after the WLL, following the exchange from DLT to a large, over 8 mm, single-lumen endotracheal tube. A regular FOB is used to obtain a bigger suctioning channel. BAL is performed at the segmental level. A maxi-

mum of 150 mL aliquots of normal saline is injected, followed by a drainage period assisted by the same system as the one used during regular WLL. BALs are repeated as needed, that is, until the return of clear liquid from the treated lobe. Every involved lobe is lavaged with the same technique.

Complications

The main complication is a decrease in arterial oxygen saturation, mainly during the drainage phase. Some liquid spillage from the lavaged lung to the non-lavaged lung may also occur. Other complications such as pneumothorax and hydrothorax are rare but may need to be drained, resulting in a postponed procedure. Post-procedure complications are pneumonia, sepsis, and, rarely, acute respiratory distress syndrome.

Desaturation

Increase in the blood flow in the non-ventilated lung occurs during the drainage phase (Fig. 45.2). This causes a decrease in arterial oxygen saturation. The use of PEEP on the ventilated lung helps to improve oxygenation during the filling phase but may worsen the PaO_2 during the drainage phase [37]. At that time, if needed (low $SatO_2$, i.e., <80% and/or for a prolonged period), a temporary partial unilateral pulmonary artery balloon occlusion with a pulmonary artery catheter, positioned under fluoroscopy in the artery of the lavaged lung, may be used. The occlusion diverts blood flow from the lavaged lung to the ventilated lung to improve oxygenation [36]. The use of nitric oxide with or without almitrine infusion has been described [38]. Others have performed the whole lung lavage under hyperbaric conditions [39]. Sometimes the patient presents severe impairment in gas exchange not allowing OLV. At that time, the use of vevo-venous or venoarterial extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass (CPB) is useful to avoid severe hypoxemia during OLV [40]. The use of an extracorporeal membrane oxygenator has been also described to perform bilateral simultaneous whole lung lavage [41–43]. The use of a hyperoxygenated solution has been investigated. Its use improved oxygen supply in comparison to normal saline, as lavage solution, without obvious side effects [44].

Leakage

Spirometry must be used continuously to monitor and diagnose any liquid spillage from the lavaged lung. The mechanism of liquid spillage differs depending on which side the lavaged lung is lying (Fig. 45.3). When the whole lung lavage is performed in the right lung with a left-sided DLT in place, overpressure comes from the trachea over the bronchial balloon. When leaking occurs, there is flooding of the left ventilated lung. When it is happening during lavage of the left lung, leaking is caused by an overpressure in the left lung over the bronchial balloon or from a proximal displacement of the DLT. It creates leakage from the left lung to the trachea and finally to the right ventilated lung.

If there is a modification of the aspect of the spirometry loops, it is important to suspect flooding of the ventilated lung. At that time, it is essential to stop the irrigation or to increase the drainage, depending on timing. Confirmation by FOB and treatment by vigorous suctioning and inflation of the involved lung should be performed. It is essential to assess the non-lavaged lung function before continuing the lavage to ensure that the flooded lung can provide adequate oxygenation during subsequent one-lung ventilation. In the context of unilateral WLL, when flooding of the non-lavaged lung occurs, it frequently requires prolongation of ventilation during the post-procedure period to allow recovery. The best treatment for this complication is prevention, which can be done with a secure fixation of the double-lumen tube, the use of a double-lumen tube with a carinal hook, and by being

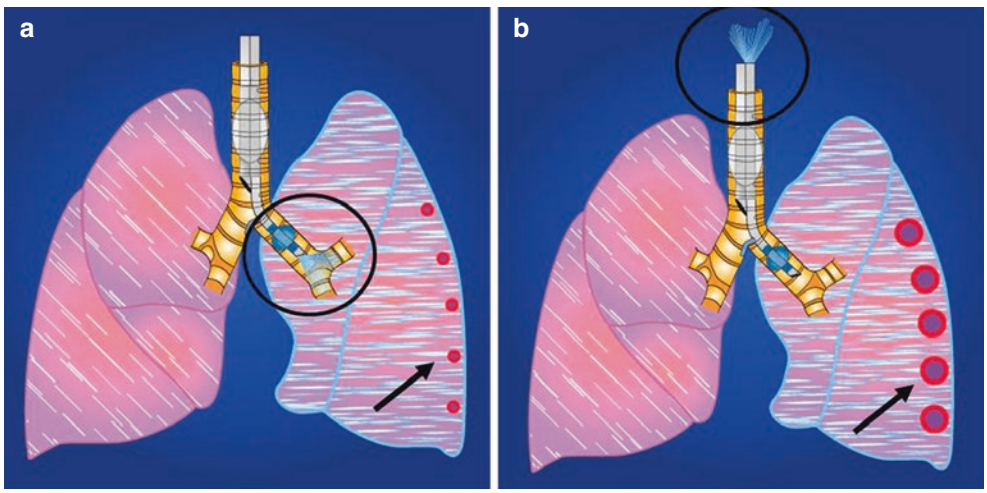

Fig. 45.2 Desaturation. (**a**) During the filling phase (circle), there is reduction of blood flow to the non-ventilated lung, by compression of the pulmonary blood vessels (arrow). (**b**) During the drainage phase (circle), there is reperfusion of the non-ventilated lung (arrow), creating a shunt and leading to desaturation. Fig. 45.4 Fluids collected from whole lung lavage. Fluids collected from WLL in pulmonary alveolar proteinosis seem milky. When fluid lavages are allowed to stand for a few hours, thick sediment appears in the bottom of the collecting bottle. It is more abundant in the first bottles going to near zero in the last ones. (Reproduced with permission of *Anesthesiology Clinics of North America* [7] (September 2001))

careful not to dislodge the double-lumen tube during patient and head manipulations.

Ending

The end point that is clinically used to cease a lung lavage is when the effluent lavage fluid is clear. Usually, between 10 and 15 L of saline are instilled into each lung (up to 50 L), and more than 90% of this volume is recovered, leaving a recuperation deficit of less than 10%. At the end of the procedure, the lavaged lung is thoroughly suctioned, and the volume of the residual liquid aspirated is calculated in a strict "in and out" balance of lavage liquid.

The effluent liquid of the whole lung lavage looks different depending on the pathology being treated. The sediment may seem milky following WLL for PAP (Fig. 45.4), while it may appear sandy if lung lavage is performed for silicosis. Over the past few years, the author has evaluated the amount of sediment recuperated during WLL for each lung separately (Fig. 45.5). The sediment amount is determined after fluid lavages are allowed to stand for at least 2–3 h. Then, the fluid spontaneously separates into a translucent supernatant and a thick sediment. The total height of sedimentary deposition in all the suction bottles allows quantifying the effectiveness of WLL in each lung individually. The accumulation may vary from 50 to 150 mm for each lung, meaning up to 300 mm following bilateral WLL.

After reintubation with a single-lumen endotracheal tube, a fiberoptic bronchoscopy control inspection is performed to look for the occurrence of undetected leakage throughout the procedure. During the FOB inspection, the author regularly observes local irritation of the distal tracheal mucosa, secondary to the movement of the double-lumen tube during WLL. The use of a double-lumen tube with a carinal hook has noticeably decreased the incidence of this irritation.

Conventional ventilation with PEEP is continued, usually for less than 2–4 h, to restore lung function, until the patient awakens in the recovery room. Alveolar infiltrates seen on the chest X-ray immediately after WLL normally clear within 24–36 h (Fig. 45.6). Observation in the ICU for 24 h is part of routine procedure.

Post Whole-Lung Lavage Evolution

The impact of WLL on the natural history of idiopathic PAP is difficult to ascertain, given the absence of randomized prospective trials or large, long-standing registries. However, practitioners of this procedure widely believe that patients with PAP improve symptomatically due to better gas exchanges. After whole lung lavage, patients usually have marked subjective improvement that correlates with increases in PaO_2 (at rest and exercise), vital capacity, diffusing capacity, and clearing of the chest roentgenogram (Fig. 45.6) or CT-scan (Fig. 45.7). Some patients require lavage every few months, whereas others remain in remission for several years. The disease may eventually show late recurrence. In PAP, WLL is proven to be successful because the lavage removes enormous accumulations of alveolar lipoproteinaceous material but also probably because it interrupts the pathogenic loop, decreasing the level of anti GM-GSF at the alveolar site, and temporarily restores the activity and function of the macrophages. It should be noted that congenital PAP appears to be particularly unlikely to respond to WLL [18].

An excellent retrospective review of all published articles, describing over 400 individual cases of PAP, was published in 2002 by Seymour and Presneill [18]. They reported that 41 patients with pre-lavage and post-lavage paired gas exchange results have seen their PaO_2 improved by

20 mmHg following WLL. The improvements in other pulmonary function parameters or diffusing capacity were less impressive. Their results also indicate that the median total number of lavages performed was two and that the median symptom-free period after one session of WLL was 15 months.

With regard to survival, in their analysis of the literature, Seymour and Presneill indicated that the overall survival at 5 years from the time of diagnosis is higher for patients who underwent therapeutic lung lavage during the course of their disease (94% vs. 85%, for those not lavaged). This was based on a series of 146 patients who were lavaged and 85 patients who were not [18].

Pediatric Whole Lung Lavage

Whole lung lavage has been used in the pediatric and neonatal population with some success. Whole lung lavage is technically difficult in infants and small children because of the incapacity to ventilate part of the lung or one lung safely and adequately during lavage of other areas or the other lung.

Small double-lumen tube (Bronchopart ®, size 26, 28, and 32, Willy Rusch AG, 71394 Kernen, Germany or Broncho-Cath ® size 28 and 32, Mallinckrodt Medical, Athlone, Ireland) is now available for use in children aged over 8–10 years old or weighing over 30 kg. Small FOB are also available to verify and adjust the final position of the DLT. When the airway of a child accepts a DLT, the WLL technique is similar to the one performed in adults.

If the airway is too small to insert a DLT, WLL is technically more challenging. Different methods to isolate both lungs have been described [45, 46]. The use of two alongside cuffed tubes (one tracheal 3.0 mm and one bronchial 3.5 mm) in a 11 kg child for unilateral WLL has been described [47]. Airway isolation has been obtained even for an infant as small as 2 kg [48]. When the perfect isolation of both lungs is obtained, WLL is performed similarly as when a DLT is placed but with much more attention to the stability of the airway devices.

When the techniques described above cannot be applied, mainly in patients weighing less than 10 kg, ECMO can be used to oxygenate the patient while bilateral simultaneous WLL is performed. Different approaches for the vascular

cannulation have been described [49, 50]. Finally, one case report described the use of partial liquid ventilation with perflubron (LiquidVent ®; Alliance Pharmaceuticals Corp. and Hoechst Marion Roussel) for 4 days following WLL done under ECMO in a 3.4 kg infant aged 6 weeks [51].

Conclusion

After more than 50 years of evolution, whole lung lavage is an efficient and safe technique. This procedure can be adapted to a large variety of patients and diseases. When WLL does not lead to a substantial effect, there are now new modalities that can be combined to WLL.

Clinical Case Discussion

A 47-year-old woman was referred to our team for WLL 10 years ago (2008). At that time, she presented some symptoms, mainly increasing dyspnea, for 6 months. An open lung biopsy had been performed at her hospital to establish the diagnosis of PAP. Pulmonary function tests performed in our center showed a light restrictive syndrome, a DLCO at 58%, and a PaO_2 of 68 mmHg. Radiological investigation revealed a homogeneous distribution with the involvement of bilateral superior lobes, middle lobe, and bilateral supero-dorsal segment of the inferior lobe. BAL confirmed the diagnosis of PAP.

A first bilateral WLL was performed, and moderately effective results were obtained. During the next 2.5-year period, the patient underwent six bilateral WLL, at intervals varying between 4 and 12 months, without good improvement in the clinical status, laboratory results, and radiological imaging. During the last WLL, BAL was performed as the radiological infiltrations were localized mainly in the left superior lobe and the supero-dorsal segment of the bilateral inferior lobes.

Nine months later, the patient complained about the same symptoms without marked improvement following any of the performed WLL. The dosage of GM-CSF was measured, and the dosage result, 203 µg/mL ($N < 3$ µg/ml), confirmed the diagnosis of primary PAP. In the following months, the patient received GM-CSF, but this treatment was ended because no improvement occurred and many secondary effects were observed. A few months later, the patient was placed on rituximab (Rituxan®), but the treatment was also ended after a few cycles since there was clinical and radiological deterioration.

Given this situation, we performed a new WLL, associated with specific BAL. The sediment recuperation was increased following the BAL. In the following days after the recovery from the WLL, we began GM-CSF by inhalation, once daily. At 1- and 3-month follow-up, the patient presented a significant improvement of her clinical status, for the first time since the first WLL. The radiologic images were completely cleared with this associated therapy, but the laboratory investigation remained stable.

We followed her to evaluate the long-term effect of this therapy. Up to 4 years after the last WLL, she received GM-CSF by inhalation following the yearly CT scan imaging, since the images reported small infiltrations. The last follow-up was done 8 years following the last WLL, and she was still asymptomatic. The annual CT scan was clean, as for the last four ones, and she did not take any GM-CSF inhalation.

This case report promotes the usefulness of a multimodal therapy that should be carried out to efficiently treat patients suffering from PAP.

Part XI

Anesthesia for Surgical Procedures for End-Stage Lung Diseases

Lung Volume Reduction

46

Erin A. Sullivan

Key Points

- Lung volume reduction surgery (LVRS) is a viable option for a select group of emphysema patients.
- Effective preoperative pulmonary rehabilitation and careful patient selection criteria promote favorable outcomes.
- Effective perioperative pain management and early extubation are significant factors that minimize postoperative complications and lead to better outcome.
- LVRS improves dyspnea and exercise tolerance and increases potential for patient survival in appropriately selected patients.

Introduction

Approximately 13.5 million persons in the United States are afflicted with COPD, and 3.1 million of these patients have emphysema [1]. Airflow obstruction associated with chronic bronchitis or emphysema occurs due to a loss of the elastic recoil properties of the lung and chest wall and the collapse of small airways, creating a permanent state of hyperinflation. The anterior–posterior diameter of the chest wall is markedly expanded, and the diaphragm is flattened leading to progressive dyspnea and a gradual increase in the work of breathing. As the disease progresses, patients become increasingly debilitated, require supplemental oxygen, and display poor exercise tolerance. Lung volume reduction surgery (LVRS) offers a select group of patients the possibility of improved exercise tolerance, reduction in dyspnea, improved quality of life, and an extended life span. It has been suggested that LVRS may provide these patients with a benefit that otherwise cannot be achieved by any means other than lung transplantation.

More recently, less invasive bronchoscopic procedures have been used to achieve the same goals as LVRS. Bronchial blockers, bronchial valves, and biologic glue have been used in an attempt to provide lung reduction with an acceptable risk profile in patients with advanced heterogenous emphysema. This technique could provide palliation to patients who are currently not considered for LVRS.

History of Lung Volume Reduction Surgery (LVRS)

In 1957, Otto Brantigan, M.D., described a surgical technique for patients with end-stage emphysema that was designed to alleviate symptoms of severe dyspnea and exercise intolerance [2]. It was Brantigan's intent to remove functionally useless areas of the lung in order to restore pulmonary elastic recoil, thus increasing the outward traction on small airways and subsequently improve airflow. Brantigan believed that this technique could restore diaphragmatic and thoracic contours that would improve respiratory excursion. Additionally, he reasoned that by excising the nonfunctional lung tissue, the compressive effects exerted on normal lung tissue could be relieved and result in improved V/Q matching. Unfortunately, the operative mortality was significant, and no objective measures of benefit could be documented. Thus, early LVRS was abandoned as a viable therapy for patients with end-stage emphysema until 1993.

In 1996, Joel Cooper, M.D., authored an editorial advocating the technique of LVRS as a "logical, physiologically sound procedure of demonstrable benefit for a selected group of patients with no alternative therapy" [3]. He further stated that the successful application of LVRS was "made possible through an improved understanding of pulmonary physiology, improved anesthetic and surgical techniques, and lessons

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_46

learned from experience with lung transplantation." Although Dr. Cooper touted the benefits of LVRS for certain patients, he did not minimize the surgical risk and suggested that this was not a procedure to be performed in all healthcare centers across the country. He made the following proposal: (1) healthcare providers should restrict the application of this (LVRS) procedure to a limited number of centers of excellence; (2) such centers should be required to document and report specified information regarding morbidity, mortality, and objective measures of outcome; and (3) these data should be periodically reviewed and evaluated by a scientific panel before approval to continue performing the procedure is approved. Additionally, he advocated that the patients who would otherwise qualify for lung transplantation should be simultaneously evaluated for LVRS so that they would receive the procedure proving to be most appropriate. LVRS was considered to be a palliative procedure to reduce dyspnea, improve exercise tolerance and the quality of daily life. Most of Dr. Cooper's patients achieved these goals as well as an improvement in airflow, a reduction of lung hyperinflation, and an improved alveolar gas exchange.

Shortly after Dr. Cooper's report regarding the success of LVRS was published, there was a widespread application of the technique. Analysis of the outcome data for Medicare patients revealed a 23% mortality rate at 12 months following LVRS prompting the discontinuation of funding for this procedure in 1996 due to the associated high risks and costs [4]. Subsequently, the National Heart, Blood, and Lung Institute designed a prospective, randomized clinical trial, the National Emphysema Treatment Trial (NETT), that evaluated the efficacy and safety of LVRS plus medical therapy vs. medical therapy alone [5].

Clinical Features of Emphysema

Emphysema is usually the end result of cigarette smoking, but can also be caused by alpha-1-antitrypsin deficiency [6, 7]. It is a chronic progressive disorder that ultimately leads to disability and early death. The cardinal physiologic defect in emphysema is a decrease in elastic recoil of the lung tissue that results in the principal physiologic abnormalities of decreased maximum expiratory airflow, leading to air trapping and hyperinflation and severely limited exercise capacity [7, 8].

Areas of severely emphysematous lung constitute dead space and result in compression of the adjacent lung tissue rendering it less capable of exerting the better-preserved elastic recoil on its adjoining airways. This leads to an increase in airway resistance and a reduction of expiratory airflow due to decreases in the driving and transmural pressures that maintain the patency of intraparenchymal airways.

The distribution of emphysema in the lung parenchyma adversely affects alveolar gas exchange compounded by an increase in ventilatory drive, premature initiation of inspiration, hyperinflation, and positive alveolar pressure at end expiration (auto-PEEP). As the disease progresses, inspiration becomes more difficult as a more negative inspiratory pressure is required to counteract auto-PEEP. Hyperinflation of the lungs leads to remodeling of the chest wall via progressive flattening of the diaphragm and alterations in the anterior–posterior diameter of the rib cage. These changes contribute directly to the increased work of breathing associated with emphysema [9].

Preoperative Medical Management of Emphysema Patients

The American Thoracic Society established guidelines for the diagnosis and management of emphysema [10]. Patients who are evaluated and considered for LVRS may remain symptomatic despite optimal medical management. Prior to LVRS, a structured pulmonary rehabilitation program is instituted with the goals of halting the progressive decline in lung function, preventing exacerbations of the disease, improving exercise capacity and quality of life, and prolonging survival. This is achieved through exercise training, optimization of medical therapy, patient education, psychosocial evaluation, and nutritional counseling and management.

The only treatment that has been shown to alter the rate of progression of COPD is cessation of smoking [11]. The majority of programs will require cessation of smoking for at least 6 months prior to considering the patient as a surgical candidate for LVRS.

Patients with severe emphysema are usually severely dyspneic even during minimal physical activity, and as a result, they become sedentary leading to progressive exercise deconditioning. For this reason, exercise training is an essential component for the preoperative preparation of the patient undergoing LVRS. The optimal training program is supervised by a specialized nurse and physician and lasts for at least 6 weeks prior surgery. Training consists of walking for a distance on a flat surface, bicycle ergometer training, and weight lifting. These exercises are combined with a special diet. There are several advantages of an exercise program prior to surgery: (a) the patient's willingness to cooperate can be assessed; (b) endurance and exercise tolerance is increased, which will be helpful for early mobilization after surgery [12]; and (c) maximal oxygen consumption can be increased in many subjects [13].

Influenza immunization and pneumococcal vaccination are recommended for the prevention of life-threatening infection [10]. Exacerbations of bronchospasm and infection are treated with steroids and antibiotics, respectively [14, 15].

Furthermore, beta-adrenergic agonists such as theophylline and anticholinergics are recommended for treatment of COPD and asthma [10]. Although these interventions are believed to shorten the duration of individual episodes and to minimize symptoms, there is little evidence that they either alter the natural history of the disease or reduce mortality. Bronchodilators improve lung function, exercise capacity, and quality of life in patients with COPD but are of limited benefit to patients without reversible airway disease [10].

Long-term home oxygen therapy in chronically hypoxemic patients is the only treatment for COPD that has been documented to decrease mortality rates [16, 17]. Adjunctive forms of therapy, such as the use of mucolytics to control respiratory secretions or narcotics to reduce the sensation of dyspnea, have been used in selected COPD patients [10]. In end-stage COPD patients, single or double-lung transplantation has been used as a last resort, but this option is limited by financial resources and the number of donor organs.

Patients presenting for LVRS are frequently very anxious secondary to the dyspnea and asthmatic crises they experienced in the past. Psychological factors can induce an asthma attack that is a dangerous complication during the perioperative period. Anxiety is associated with an increase in respiratory frequency leading to an increase in dynamic pulmonary hyperinflation and dyspnea [18]. Therefore, it is important that the anesthesiologist is able to establish a good relationship with the patient before surgery. The optimal psychological preconditions are likely to be achieved when the preoperative preparation, preoperative visit, insertion of a thoracic epidural catheter, administration of general anesthesia, and early postoperative therapy are conducted by the same physician or a team well known to the patient. Anxiolytic therapy may be necessary during the preoperative and perioperative period.

Evaluation of Patients for LVRS and Selection Criteria

General Evaluation

General criteria for patient selection and recommendations for screening procedures are described by Weinmann and Hyatt [19]. These selection criteria may vary between institutions. Distinct selection criteria for LVRS candidates were published by Daniel et al. [20] and are shown in Table 46.1.

Whether patients with significant hypercapnia should undergo LVRS is controversial [19, 21]. Furthermore, some institutions report significant coronary artery disease (coronary artery stenosis >70%) diagnosed in 15% of their asymptomatic LVRS candidates, and thus, they recommend left and right heart cardiac catheterization preoperatively [22]. This invasive cardiac screening seems justified by several case reports of myocardial infarction during and after LVRS. Other institutions recommend limiting cardiac screening to transthoracic echocardiography [19]. In general, it is reasonable for centers with less experience to employ strict criteria for patient selection to minimize patient morbidity and mortality.

Table 46.1 General inclusion criteria for LVRS

Diagnosis of COPD
Patient history, physical examination, lung function test, chest X-ray, etc.
Smoking cessation for greater than 1 month
Age < 75 years
FEV_1 between 15% and 35% of predicted
P_aCO_2 < 55 mmHg
Prednisone requirement <20 mg/day
PAP_{sys} < 50 mmHg
No previous thoracotomy or pleurodesis
Absence of symptomatic coronary artery disease
Absence of chronic asthma or bronchitis
Commitment to pre-op and post-op supervised pulmonary rehabilitation for 6 weeks

Reprinted from Daniel et al. [20] with permission from Wolters Kluwer Health

COPD chronic obstructive pulmonary disease, *FEV_1* forced expiratory volume in 1 s, *$PaCO_2$* arterial carbon dioxide pressure in mmHg, *PAPsys* systolic pulmonary arterial pressure in mmHg

Anatomic/Radiologic Evaluation

The chest X-ray should provide evidence of hyperinflated lungs, large intercostal spaces, retrosternal airspace, flattened diaphragm, and high transparency of the lungs (see Fig. 46.1a). For a precise morphologic evaluation, a high-resolution computer tomography (HRCT) of the chest is essential for identification of nonhomogeneous areas within the lungs. HRCT locates the target areas for resection. An ideal anatomical precondition for LVRS is marked inhomogeneity of the lung structure, where normal lung tissue and severely destroyed, overdistended tissue are present in the same lung (see Fig. 46.2a). Homogeneous distribution of the disease proved to be an unfavorable precondition (see Fig. 46.2b).

Several authors have demonstrated that patients presenting with severe inhomogeneity are very likely to benefit from LVRS [23–25]. Two reasons might account for this: (1) compressed, normal lung tissue is released after removing adjoining hyperinflated, nonfunctional, destroyed tissue, and thus, the pulmonary mechanics of the remaining tissue are improved; and (2) surgery is easier to perform if the target areas are clearly visible. In many centers, lung perfusion scintography is still routinely performed for screening LVRS candidates primarily to rule out ventilation–perfusion mismatch. However, chest computed tomography has been

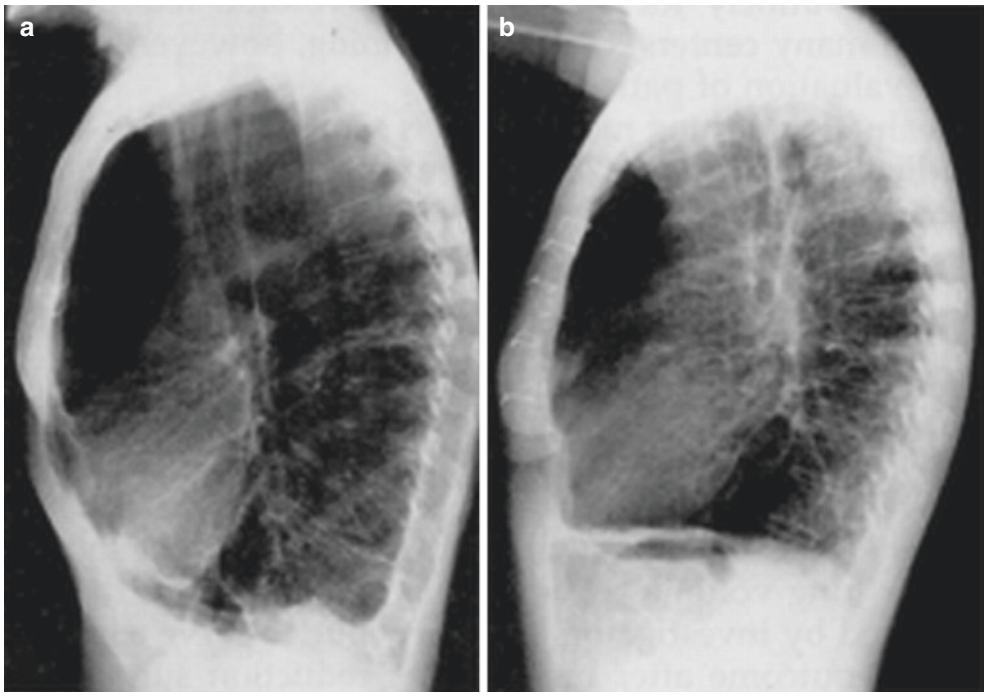

Fig. 46.1 A lateral chest X-ray is shown. (**a**) Depicts the patient before lung volume reduction surgery (LVRS): the thorax is barrel-shaped with high transparency of the lungs, a large retrosternal air-filled space, and a flattened to concave diaphragm. The chest X-ray of the same subject (**b**) is shown 3 months after LVRS: the lung fields are less transparent, the air-filled retrosternal space decreased significantly, and the diaphragm exhibits an almost normal, convex shape

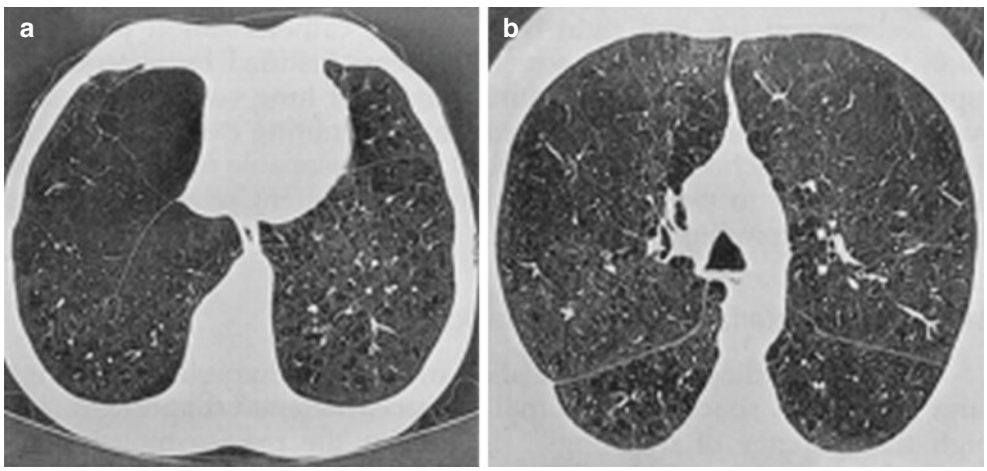

Fig. 46.2 (**a**) Depicts a high-resolution computed tomography (HRCT) scan of a patient presenting with inhomogeneous distribution of emphysema. Parenchymal destruction is greater in the ventral portions of the lung; thus, the functional portions are easily distinguished from nonfunctional segments. (**b**) Depicts a HRCT of a patient with homogeneous distribution of emphysema. It is much more difficult to determine which segments need to be resected

shown to be superior compared to lung perfusion scintography for the evaluation of patients [26].

The evaluation of lung morphology is semiquantitative and difficult to standardize. Only about 25% of patients present with inhomogeneous distribution of the disease. Therefore, the evaluation of preoperative functional criteria as predictors seems important.

Physiologic Evaluation

Currently, a preoperative $FEV_1 < 20\%$ of the predicted value in combination with homogenous morphology or a carbon monoxide diffusion capacity <20% of the predicted value is regarded as contraindication for surgery. These patients were found to have significantly increased mortality after LVRS compared with conventional medical treatment alone [27].

Pulmonary mechanics are severely impaired in patients suffering from emphysema, and LVRS leads to a significant improvement [28–32]. Several parameters characterizing pulmonary mechanics show specific changes after LVRS. Investigators tested these parameters as preoperative predictors for outcome after LVRS. FEV_1 is frequently chosen to represent outcome since it correlates well with mortality in emphysema patients. Furthermore, outcome is frequently characterized by changes seen in pressure volume loops and by changes in dyspnea score since severe dyspnea leads to an impaired quality of life.

Ingenito et al. hypothesized that patients with markedly elevated inspiratory resistance are likely to have predomi-

nantly airway disease and are unlikely to show improvement of expiratory flow after LVRS thus, limiting the benefit of the procedure [33]. The investigators proved their hypothesis by demonstrating that preoperative inspiratory lung resistance negatively correlated with changes in FEV_1 (L) ($r = -0.63$; $p < 0.001$). In contrast, patients with elevated expiratory lung resistance showed good improvement.

Preoperative $PEEP_i$, a correlate of dynamic pulmonary hyperinflation, and postoperative gain in normalized FEV_1% predicted were found to be well correlated ($r = 0.69$, $p < 0.0002$) [34]. A cutoff point of preoperative $PEEP_i$ of 5 cmH_2O had a positive predictive value of 86% and a negative predictive value of 92% in predicting a change in FEV_1% of greater than 40% after LVRS [34]. Similar results were found for changes in dyspnea score.

Despite these and other promising methods to predict outcome following LVRS, most require time-consuming and sophisticated measuring techniques and are difficult to incorporate into standard clinical practice. As a result, none of the evaluated parameters has gained widespread acceptance to date.

Approach: Surgical vs. Bronchoscopic

Video-Assisted Thoracoscopic Surgery (VATS)

Surgery has been proven to be of benefit for selected patients with severe forms of emphysema in comparison to medical therapy alone, and it has also been used as a bridging technique to lung transplantation [35]. LVRS has been reported to be cost-effective [4] and significantly improves pulmonary function, exercise tolerance, quality of life, and even survival for a select patient population [36]. Patients with upper-lobe predominant emphysema and low exercise capacity demonstrated an improved survival at 5 years, an increased exercise capacity throughout 3 years, and an improvement in overall symptoms through 5 years [37]. The results of the procedure are comparable whether performed through a median sternotomy or by video-assisted thoracoscopic surgery (VATS) [36]; however, the NETT indicated that the VATS approach provided earlier patient recovery compared with median sternotomy and it was more cost-effective [36]. LVRS has also been used in lung transplant recipients when the donor lungs have been deemed too large for the recipient's thoracic cavity.

The selection criteria for LVRS have been described in the previous section. Perhaps the most important selection factor for LVRS is the presence of a heterogenous pattern of emphysema, and only about 20% of patients with severe emphysema satisfy this prerequisite. The goal for LVRS is to resect the nonfunctional areas of the lung that constitute dead space and compress more functional lung segments, thus allowing the functional lung segments to expand and improve gas exchange. A bilateral staple procedure performed under general anesthesia and sequential single-lung ventilation is required.

Bronchoscopic Placement of Endobronchial Valves and Blockers

Although LVRS has been shown to be beneficial for patients with a heterogenous pattern of emphysema, this constitutes only about 20% of patients who are eligible candidates for this treatment. Procedures for bronchoscopic LVRS have thus been developed to treat patients with heterogenous and homogenous patterns of emphysema. The rationale for this minimally invasive approach is that by endobronchially obstructing the emphysematous areas of the lung, collapse of these selected segments should occur, thereby reducing hyperinflation and alleviating symptoms without the need for surgery. Currently available bronchoscopic techniques include endobronchial blockers/valves, biologic glues, and airway bypass.

Figure 46.3 depicts blocker and valve devices currently for investigational use in the United States for LVRS in patients with heterogenous emphysema. These devices are placed in the patient's segmental bronchi to obstruct the flow of air into the selected segment while allowing air and mucus to escape via a one-way valve (Zephyr® EBV, PulmonX, and IBV Valves, Spiration Inc.) or around the device (IBV Valve, Spiration Inc.). Both devices are compressed and are placed under direct vision using a fiber-optic bronchoscope and general anesthesia. An advantage of this technique, besides avoiding the risks of surgical LVRS, is that the devices may be repositioned or removed if necessary.

Preliminary outcome studies for these devices show promise and pivotal randomized trials are underway. Improvements in FEV_1, residual volume, 6-min walk test, St. George's Respiratory Questionnaire, and Medical Research Council median dyspnea score have been demonstrated after insertion of the EBV valve, and 43% of the patients were able to discontinue use of supplemental oxygen [38, 39]. Results for the IBV device are still pending.

Although there are significant improvements achieved with endobronchial blockers/valves, the results have not been as substantial as those obtained with surgical LVRS. Evaluation with ventilation/perfusion scans demonstrates that in some cases, the desired atelectasis to emulate surgical LVRS has occurred in a nonsustained manner. It is thought that collateral ventilation due to the presence of incomplete fissures might be implicated [40]. PulmonX has developed an adjunct detection device, the Chartis system (see Fig. 46.3c), that can directly assess collateral ventilation in the target lobe, a key criteria for identifying patients who

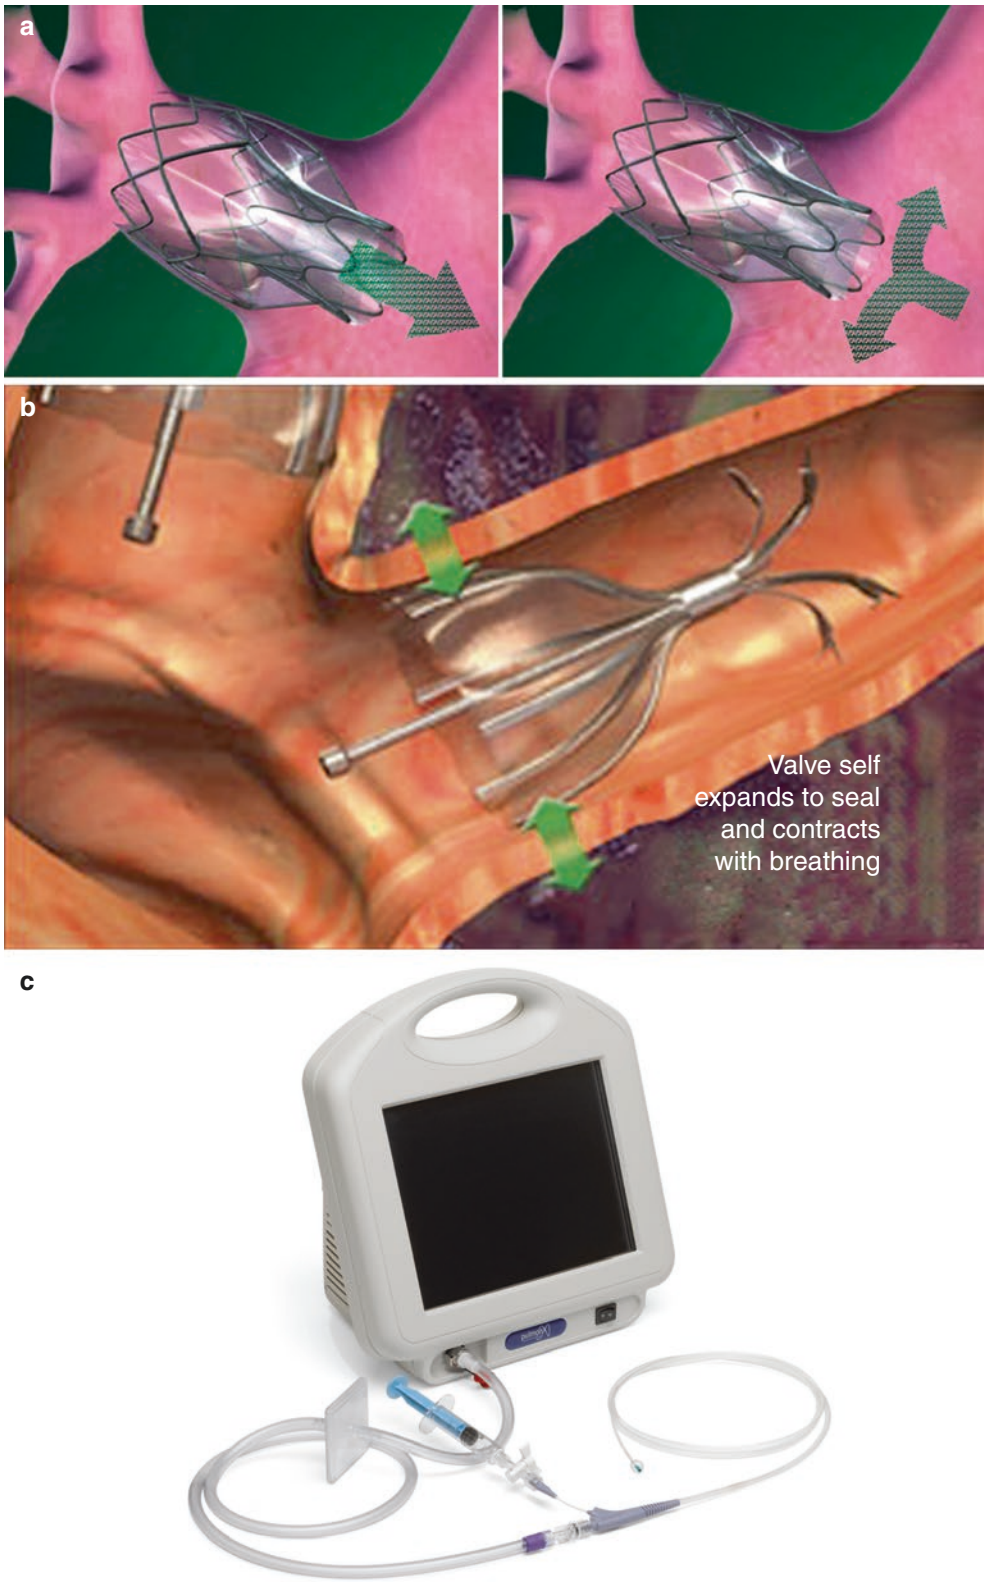

Fig. 46.3 (**a**) Depicts the Zephyr® EBV (registered trademark of PulmonX, Inc.). (**b**) Depicts the IBV (Spiration Inc.). Both devices have been used to provide bronchoscopic LVRS for patients with heterogenous forms of emphysema. (**c**) Depicts the Chartis system (PulmonX) that is used to detect collateral flow and determine the suitability of patients for the Zephyr® EBV. A hollow balloon-tipped catheter is used to obstruct a lobar or segmental bronchus. Collateral flow to the obstructed region can be detected by measuring continued expired gas flow distal to the balloon. (Reprinted with permission from © 2010 PulmonX, Inc. all rights reserved)

will respond well to Zephyr® valve therapy. Chartis collateral flow screening must be performed under moderate sedation with the patient breathing normally in order to obtain an accurate assessment.

Another alternative to combat less optimal results in bronchoscopic lung volume reduction for heterogenous emphysema was developed by Ingenito et al. He and his colleagues developed a transbronchoscopic technique to create and maintain

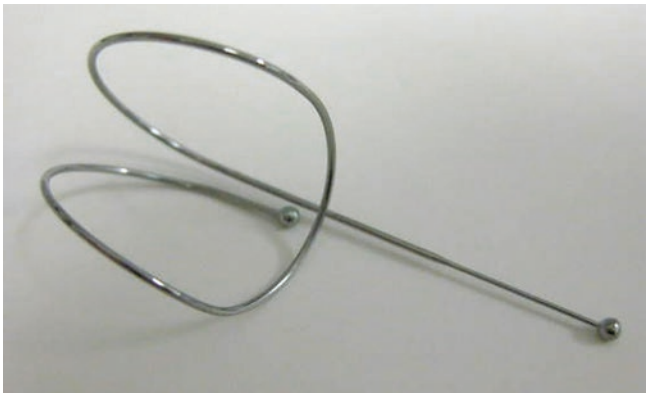

Fig. 46.4 The RePneu™ lung volume reduction device (PneumRx, Mountain View, CA) is designed to reduce lung volume for both heterogenous and homologous forms of emphysema. It is effective even when collateral ventilation due to compromises in the fissures between lung lobes exists. The preformed coil is delivered into a segmental or subsegmental bronchus in a straight configuration via a fiber-optic bronchoscope. After deployment, the device resumes its coil shape gathering and compressing emphysematous lung tissue

volume loss using a washout solution and fibrin-based glue to collapse, seal, and scar target regions of abnormal lung. Initial results show that in short-term follow-up there was improved mean vital capacity, reduced mean residual volume, reduced mean residual volume/total lung capacity ratio, longer mean 6-min walk distance, and improved mean dyspnea score [41].

There is a device designed to reduce lung volume for patients with heterogenous or homologous emphysema, and it is effective even when there are compromises in the fissures between lung lobes. The RePneu™ LVRC (see Fig. 46.4) is constructed of Nitinol that is preformed in a coil shape and that can be deployed into a target lobe via a bronchoscope and using either moderate sedation or general anesthesia. Multiple implants are used to obtain optimal results. This device is completely removable, and preclinical studies have indicated that lung volume reduction of up to 50% has been achieved in human lungs.

At present there does not seem to be a consensus on interventional therapy for severe emphysema. There has not been an appropriate randomized study. Individual centers tend to favor either lung volume reduction surgery or bronchoscopic procedures. Centers that favor interventional bronchoscopy tend to favor mainly valves or coils [42].

Anesthetic Management

Preoperative Assessment

Pharmacologic Preparation

Most of the patients presenting for LVRS require long-term bronchodilator therapy (beta adrenergic agonists), steroid therapy (inhalation or systemic), and mucolytic therapy. Additionally, these patients frequently require antibiotics. Most centers recommend continuation of bronchodilator and mucolytic therapy before LVRS, including the day of surgery. The patient must be free from respiratory infections for at least 3 weeks prior to LVRS and require no antibiotic therapy preoperatively. In terms of steroid therapy, the goal is to gradually reduce the dose of systemic steroids prior to LVRS.

Many patients have received chronic theophylline therapy before LVRS, and some patients experience toxic symptoms while theophylline blood levels are in the therapeutic range [43]. The main side effects are nervousness, tremor, and tachycardia. Theophylline therapy should be discontinued before LVRS if the patient shows significant side effects or if the serum levels are >20 ng/mL.

Pain Management

Thoracic Epidural Analgesia

By now it is a generally accepted concept that thoracic epidural analgesia (TEA) is mandatory for optimal postoperative pain management following LVRS. A thoracic epidural catheter is inserted at the T3–T4 or T4–T5 vertebral level in the awake patient immediately prior to surgery. The spread of anesthesia and analgesia should be assessed carefully before induction of general anesthesia in order to avoid inadequate pain management that may cause ventilatory depression during the immediate postoperative period. A local anesthetic such as bupivacaine or ropivacaine can be used for TEA preferably in combination with an opioid. Since emphysema patients tend to be volume depleted, it is important that they are adequately volume loaded (1–2 mL/kg) before fully activating the TEA so as to avoid severe hypotension. A potent vasopressor such as norepinephrine or phenylephrine should be available before activating the TEA. Ropivacaine is frequently preferred over bupivacaine as the local anesthetic since it causes less circulatory depression and helps to reduce the incidence of hypotension.

Most anesthesiologists providing care to patients for LVRS are convinced that TEA is crucial to reduce perioperative patient morbidity and mortality. Unfortunately, there are no controlled studies available to validate this theory. Some anesthesiologists might consider such a study unethical since patients would potentially be denied optimal pain management. In patients with normal lung function undergoing lung resection, there is evidence that sufficient postoperative analgesia with TEA can reduce morbidity and mortality [44]; however, other authors emphasize that the influence of TEA on outcome after lung resection has not been proven [45]. Nevertheless, the use of TEA is the worldwide established means for intraoperative and postoperative analgesia for patients undergoing LVRS. In order to guarantee optimal

analgesia, TEA should be maintained until all chest drains are removed.

Paravertebral Nerve Block

Paravertebral nerve blocks are multiple-level intercostal nerve blocks that have replaced the direct and multiple applications of local anesthetics to intercostal nerves, cryotherapy, and interpleural local anesthetics [46]. Paravertebral nerve blocks may be performed either by multiple injections or by inserting a catheter into the paravertebral space for use with a continuous infusion of local anesthetic [47, 48]. The levels of analgesia and restoration of pulmonary function seen with TEA can also be achieved with paravertebral nerve block when a multimodal analgesic regimen including the use of intravenous opioids and nonsteroidal anti-inflammatory agents (NSAIDS) are added. Outcome studies of the effect of paravertebral nerve blocks on morbidity and mortality rates following thoracic surgery, in particular LVRS, have yet to be determined. It is widely accepted that the use of multimodal analgesia in conjunction with paravertebral nerve block is an excellent alternative to TEA. Paravertebral catheters may be inserted either percutaneously or under direct vision during thoracotomy. This technique is particularly useful for patients in whom placement of TEA is difficult or contraindicated.

Intraoperative Management

Monitors

Monitors for LVRS should include a six-lead ECG, pulse oximetry, invasive blood pressure monitoring, a temperature probe for continuous core temperature measurement, and a central venous catheter to assess central venous pressure. The routine use of a pulmonary artery catheter is controversial; however, continuous monitoring of pulmonary artery pressure (PAP) may be helpful since PAP can increase substantially during single-lung ventilation, thus causing acute right ventricular failure. Transesophageal echocardiography may also be useful for intraoperative cardiac monitoring.

General Anesthesia

During endotracheal intubation with a double-lumen tube, the intravenous analgesic requirement can be substantially reduced if the pharynx and larynx are carefully anesthetized with a topical anesthetic spray (e.g., 2% lidocaine) [49]. Following intubation, analgesia should be maintained with TEA. It is important to mention that intubation of a poorly anesthetized emphysema patient can precipitate life-threatening bronchospasm [50].

Only short-acting drugs should be used for sedation and neuromuscular blockade during general anesthesia for LVRS in order to facilitate tracheal extubation as early as possible after the procedure in order to avoid prolonged air leakage associated with prolonged positive pressure ventilation. Propofol is therefore a suitable choice for sedation. If the patient is susceptible to bronchospasm, a volatile inhalation anesthetic such as sevoflurane or isoflurane may be preferred over an intravenous agent. Neuromuscular blocking agents with short duration and absence of histamine liberation (e.g., vecuronium or cisatracurium) are frequently chosen.

Sufficient patient warming can be achieved using warming blankets, heating mats, and warm intravenous fluid infusions. Core body temperature and the peripheral temperature of the patient should be maintained within the normal range. A decrease in the body heat content of the patient will ultimately lead to shivering after extubation along with increased carbon dioxide production and oxygen consumption. It is frequently impossible for the end-stage emphysema patient to meet the increased ventilatory demands caused by shivering. Shivering is an undesirable complication that may lead to reintubation in the postoperative period.

Mechanical Ventilation

Optimal mechanical ventilation for LVRS must provide sufficient arterial oxygenation while strictly avoiding air trapping [18], which can potentiate the threat of pneumothorax. Air trapping can be minimized by using moderate tidal volumes (≤9 mL/kg during ventilation of both lungs and ≤5 mL/kg during single-lung ventilation), low respiratory frequencies (≤12 breaths/min during ventilation of both lungs and ≤16 breaths/min during single-lung ventilation), and a prolonged expiratory time (I/E = 1:3 during double- and single-lung ventilation). If the preoperative HRCT exhibits a substantial difference in the quality of lung tissue between the right and left lung, it may be more desirable to resect the less functional lung first.

It is important to limit airway pressure generated (≤35 cmH_2O) by the ventilator in order to avoid barotraumas resulting in a pneumothorax or tension pneumothorax. The anesthesiologist should pay constant attention to the inspired and expired volumes during mechanical ventilation. For this purpose it is necessary to monitor the configuration of the end-tidal CO_2 waves closely. In most patients undergoing LVRS, the anesthesiologist will have to accept elevated values of end-tidal and P_aCO_2 (arterial carbon dioxide tension) during single-lung ventilation. This permissive hypercapnia is the price for the prevention of barotrauma during mechanical ventilation for LVRS. P_aCO_2 values will return to the normal range soon after the procedure when both lungs can be ventilated again.

Early Extubation

It is difficult to avoid air leakage entirely despite the use of new surgical techniques that use staplers buttressed with bovine pericardium. Air leakage can be exacerbated by positive pres-

Table 46.2 Extubation criteria after LVRS

1. Patient awake and cooperative
2. Patient breathing sufficiently, i.e., rapid shallow breathing index (respiratory frequency per min/tidal volume in L) is below 70
3. Sufficient arterial oxygenation: $S_aO_2 \geq 92$ while patient is breathing spontaneously ($F_iO_2 \leq 0.35$)
4. Adequate pain management achieved
5. Patient core temperature >35.5 °C
6. No shivering
7. Stable hemodynamic conditions

sure ventilation, whereas the negative intrapleural pressure generated during spontaneous breathing minimizes air leakage. Therefore, early extubation after LVRS is of prime importance. Several criteria must be satisfied before the patient can be extubated (Table 46.2). Should the patient fail to meet all of these criteria, it is reasonable to stabilize the patient in a quiet environment such as an intensive care unit or the postanesthesia care unit before extubation. Successful extubation will usually be possible within 1–2 h and is not harmful to the patient. This is preferable to premature extubation in the operating room followed by prolonged episodes of arterial hypoxemia.

Postoperative Management

More than 50% of patients who undergo LVRS experience a complication during the postoperative period. They include (1) oversedation, (2) accumulation of airway secretions, (3) pneumothorax, (4) bronchospasm, (5) pulmonary embolism, (6) pneumonia, (7) persistent air leaks, (8) arrhythmias, (9) myocardial infarction, and (10) pulmonary embolism. Reintubation and mechanical ventilation are associated with a high morbidity and mortality.

The majority of patients are extubated in the operating room and rarely require reintubation during the initial 48 h. However, significant hypercarbia and acidosis may be present for several hours owing to the residual effects of the anesthesia or incomplete analgesia. Unlike other patients undergoing pulmonary resection, the chest tubes in these patients are attached to water-seal drainage without suction. The loss of elastic recoil and the obstructive physiology of the remaining lung make it resistant to the usual loss of volume associated with a postoperative pneumothorax. The fragile nature of the lungs renders them more susceptible to the adverse effects of increased transpulmonary pressure and overdistention that would be caused by chest tube suction. This has a tendency to increase the magnitude and prolong the duration of air leaks in these patients. Postoperative management is directed to minimize these adverse side effects: (1) judicious pulmonary toilet, (2) bronchodilator therapy, (3) effective perioperative analgesia with TEA or paravertebral/multimodal analgesia, and (4) avoidance of systemic corticosteroids.

Summary

LVRS is a viable option for a select group of emphysema patients, and endobronchial valves and blockers that are undergoing clinical trials in the United States hold much promise as a treatment alternative for all emphysema patients. Regardless of the selection of treatment modality, the goals are the same: improvements in dyspnea, exercise tolerance, quality of life, and prolonged patient survival.

Patient selection is of crucial importance for a successful outcome after LVRS. The anesthesiologist must be actively involved in patient selection since he or she will be responsible for the patient's immediate perioperative management. Patient history and preoperative status as well as the results obtained from the evaluation of chest X-rays, HRCT scans, and catheterization of the right heart should be carefully weighed during the patient selection process. The careful selection and preoperative preparation of patients is essential to minimize perioperative complications and obtain a successful outcome. Furthermore, it has to be emphasized that the role of the anesthesiologist is of crucial importance for the successful conduct of LVRS.

Clinical Case Discussion

Case: A 58-year-old female patient with end-stage emphysema is scheduled for bilateral LVRS using a video-assisted thoracoscopic approach (VATS). She has a past medical history that is significant for smoking (60 pack years; quit for the past 2 years), hypertension, and atrial fibrillation that is controlled with metoprolol. Her other medication includes an 81-mg aspirin that she takes once per day. She successfully completed a preoperative exercise program 8 weeks ago. The patient is very anxious and wishes to speak with the anesthesiologist who will provide her care prior to the date of surgery.

Questions

- What additional preoperative preparation is necessary from a pulmonary standpoint?
- How will you treat the patient's anxiety?
- What will you recommend for perioperative pain management?
- What are your specific concerns regarding postoperative management?

Preoperative Pulmonary Preparation

- Successful completion of a preoperative exercise program including a 6-min walk on a flat surface, bicycle ergometer,

and weight lifting (see section "Preoperative Medical Management of Emphysema Patients").
- Continue supplemental oxygen use, bronchodilators, and mucolytics up to and including the day of surgery (see section "Pharmacologic Preparation").
- Gradually reduce the dose of steroids prior to surgery if they are being administered.
- If the patient is receiving theophylline therapy and exhibiting symptoms of toxicity (nervousness, tremor, tachycardia) or if serum levels exceed 20 ng/mL, discontinue the drug.
- Ensure that the patient is free from infection and does not require antibiotics for at least a 3-week period prior to surgery.

Treatment of Anxiety
- Untreated anxiety may precipitate an episode of acute bronchospasm, an increase in dynamic pulmonary hyperinflation, and dyspnea (see section "Preoperative Medical Management of Emphysema Patients").
- An effective way to allay a patient's anxiety is for the anesthesiologist to establish a good relationship with the patient prior to the date of surgery by scheduling a meeting in the anesthesia preoperative evaluation clinic.
- Anxiolytic therapy may be necessary during the preoperative and perioperative period.

Perioperative Analgesia
- The patient is at high risk for perioperative pulmonary complications if analgesia is insufficient or ineffective.
- The risk of pulmonary complications may be improved with the use of thoracic epidural or paravertebral analgesia (see sections "Thoracic Epidural Analgesia" and "Paravertebral Nerve Block").
- TEA or paravertebral nerve block catheters should be maintained until the chest drains are removed and the patient is tolerating oral pain medications.

Postoperative Management **(see sections "Early Extubation" and "Postoperative Management")**
- Air leakage can be exacerbated by positive pressure ventilation. Therefore, the patient should be extubated as soon as it is safe to do so, preferably in the operating room. It is safe, however, to maintain mechanical ventilation for 1–2 h following surgery, and this is preferable to premature extubation and the subsequent development of arterial hypoxemia.
- Fifty percent of LVRS patients develop a postoperative complication.
- Reintubation and mechanical ventilation in the postoperative period are associated with a high morbidity and mortality.
- Postoperative complications can be minimized by implementing judicious pulmonary toilet, bronchodilator therapy, effective pain management with thoracic epidural or paravertebral analgesia, and avoidance of systemic corticosteroids.

Lung Transplantation

47

Andrew Roscoe and Rebecca Y. Klinger

Key Points

- Preoperative assessment is paramount for planning intraoperative strategies.
- Careful induction of anesthesia is essential to avoid cardiovascular collapse.
- Transesophageal echocardiography is an invaluable intraoperative tool.
- Perioperative extracorporeal membrane oxygenation support is beneficial for patients but provides new challenges for the anesthesiologist.
- Reduction in early postoperative complications confers a long-term survival benefit.

Introduction

Lung transplantation (LT) is the treatment of choice for some patients with end-stage lung disease or pulmonary vascular disease [1]. The term "lung transplantation" encompasses a group of operations, comprised of lobar transplant, single-lung transplant (SLT), double-lung transplant, bilateral sequential lung transplant (BSLT), and heart-lung transplant (HLT). The first reported human LT was undertaken in 1963 [2], but outcomes were poor until the introduction of ciclosporin (also spelled cyclosporin) and the development of newer surgical techniques in the 1980s. The first reported successful LT was performed in 1983 at Toronto General Hospital [3]. The number of LT has increased significantly over the last 30 years (Fig. 47.1) and outcomes have gradually improved; median survival for LT is now approximately 6 years (Fig. 47.2) [1].

Donor Organ Management

The potential donor patient is often cared for in a nontransplant critical care unit [4]. After the diagnosis of brain stem death (BSD), the pathophysiological sequelae must be appropriately managed to effectuate organ preservation [5–9]. This includes intravenous fluid administration and vasoactive drug therapy to achieve a mean arterial pressure (MAP) above 70 mmHg, heart rate 60–120 beats per minutes, and a central venous pressure (CVP) or pulmonary artery wedge pressure (PAWP) between 6 and 10 mmHg [10, 11]. Intravenous fluid restriction and judicious use of diuretics help to reduce fluid accumulation in the lungs. The use of "hormonal" therapy, comprised of thyroxine, methylprednisolone, and vasopressin, has been shown to increase the number of transplantable organs. Ventilatory settings are altered to protect the potential donor lungs. This includes the use of pressure-controlled ventilation with appropriate positive end-expiratory pressure (PEEP) to give tidal volumes of 6–8 mL/kg. Bronchoscopic pulmonary toilet is used to clear retained secretions. Basic critical care therapies, including normothermia, antimicrobial use, nutrition, correction of electrolyte imbalance, and treatment of diabetes insipidus are essential [12–15].

During procurement, the donor receives systematic heparinization, and the pulmonary artery is flushed with a cold preservation solution. Prostaglandin is infused into the donor pulmonary circulation to inhibit the vasoconstrictive response to the cold pneumoplegia solution and to inhibit platelet aggregation. The donor lungs are ventilated throughout the flush and are inflated to a pressure of 10–20 cmH_2O prior to dividing the airways. The harvested allograft is then stored at 4 °C for transfer to the recipient center [16–18].

Less than 20% of donors of other solid organs have lungs that are suitable for transplantation. This may be related to the etiology of BSD or secondary to pulmonary aspiration of gastric contents at the time of brain injury [12, 19]. Due to the imbalance between the number of candidates awaiting transplantation and the availability of suitable donor organs, the

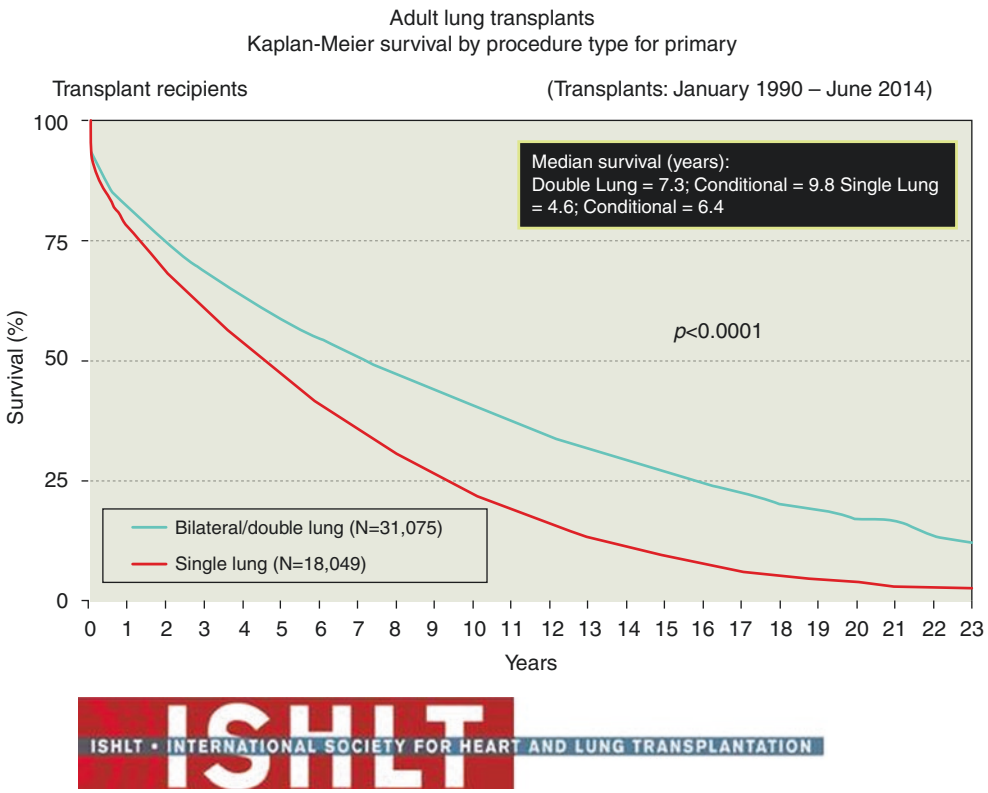

Fig. 47.2 Survival for adult lung transplantation. The median survival is the estimated time point at which 50% of all of the recipients have died. The conditional median survival is the estimated time point at which 50% of the recipients who survive to at least 1 year have died. Because the decline in survival is greatest during the first year following transplantation, the conditional survival provides a more realistic expectation of survival time for recipients who survive the early post-transplant period. (From the International Society for Heart and Lung Transplantation, with permission)

Table 47.1 Donor lung criteria

	Standard donor	Marginal donor
ABO compatibility	Yes	Yes
Age (years)	<55	>55
pO_2/FiO_2 (mmHg)	>300	<300
Smoking history (pack years)	<20	>20
Chest X-ray	Clear	Pulmonary edema
Microbiology	Gram stain negative	Antimicrobial therapy
Bronchoscopy	Non-purulent	Purulent/inflamed
Chest trauma	Absence	Minor

FiO_2 fraction of inspired oxygen

"standard" criteria for donor lung acceptance have been extended to include "marginal" donors (Table 47.1). The survival of recipients from these "marginal" donors may be decreased to those from standard donors, and a higher incidence of primary graft dysfunction (PGD) has been reported [20–23]. Several strategies have been developed in an attempt to increase the donor organ pool. This includes the use of patients in Maastricht category III: donation after cardiac death (DCD). Donors are typically patients in a critical care environment, who are expected to die within 60–90 min of withdrawal of active treatment. Ethical considerations mandate the use of two separate teams: one for therapy withdrawal and the second for organ harvesting. Lung preservation interventions are withheld until cardiac death has been certified [10, 24–26]. The lungs are unique in their ability to tolerate a warm ischemia time of at least 1 h [27]. Outcomes of recipients from DCD are comparable to those from BSD donors [26, 28]. Ex vivo lung perfusion (EVLP) and reconditioning are techniques that allow assessment and optimization of potential donor lungs outside of the donor. After organ harvesting, the lungs are perfused on an external circuit and ventilated (Fig. 47.3). The lungs can then be optimized and assessed for adequate function prior to transplantation [29–31]. Patient outcomes are similar to those with conventional transplants [32, 33]. The role of EVLP is now being extended: assessment of lungs from uncontrolled circulatory death; standard donor organs can be evaluated ex vivo to allow for exclusion of functionally impaired lungs; and the extension of graft perfusion time may facilitate better timing of transplant operations [34–36].

Recipient Candidates

Transplantation is indicated for patients with end-stage lung disease who are failing medical therapy, with the goal to provide a survival benefit. Due to the relative shortage of donor organs, it is necessary to list only patients with realistic beneficial outcomes. Listing for transplantation should occur when life expectancy after transplant exceeds life expectancy without the procedure. Donors and recipients are matched

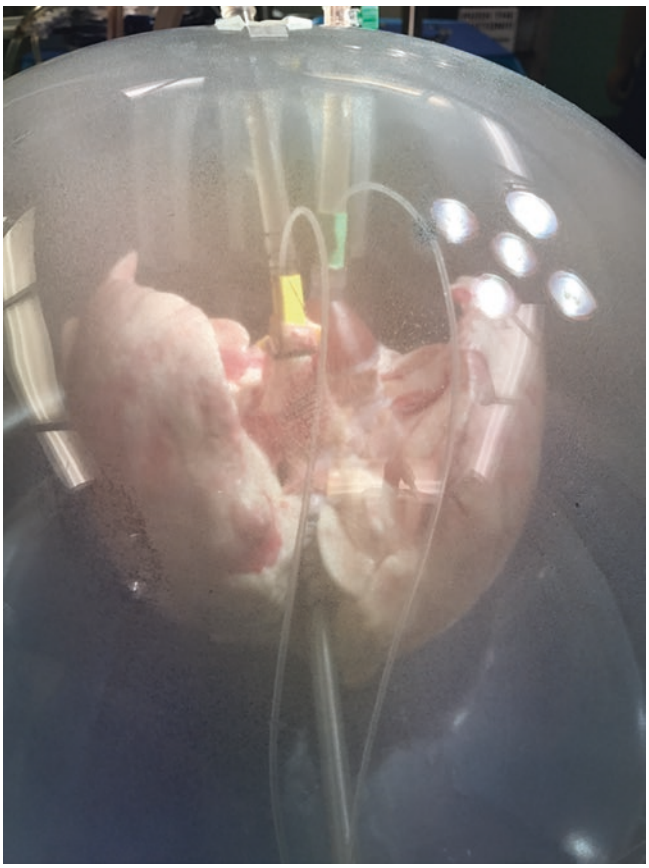

Fig. 47.3 Donor lungs inside a sterile plastic dome undergoing ex vivo perfusion. During ventilation via an endotracheal tube in the donor trachea, the lungs are perfused with a crystalloid solution. The yellow cannula is in the main pulmonary artery and the green cannula in the cuff of the donor left atrium

according to blood group and size [37–39]. The common underlying pathologies responsible for LT referral include chronic obstructive pulmonary disease (COPD), alpha-1 antitrypsin deficiency (AATD), cystic fibrosis (CF), pulmonary hypertension (PHT), and interstitial lung disease (ILD), incorporating usual interstitial pneumonitis (UIP), fibrosing non-specific interstitial pneumonitis (NSIP), and non-idiopathic interstitial pneumonitis (non-IIP) (Fig. 47.4). Contraindications to LT are listed in Table 47.2.

Disease-specific indications for referral and listing for transplantation are summarized in Table 47.3 [39]. Patients suffering from emphysematous diseases are assessed using the BODE index, which involves scoring body mass index, airflow obstruction, degree of dyspnea, and exercise capacity on a scale from 0 to 10. A BODE index ≥7 is associated with lower survival than would be expected after transplantation. Three or more severe exacerbations within 1 year are associated with increased mortality, and an episode of acute hypercapnic respiratory failure carries a 43% 1-year mortality [39, 40]. Lung volume reduction surgery may provide an alternative or a bridge-to-transplant in some emphysema patients [41, 42]. Cystic fibrosis patients are

prone to colonization with resistant pathogens. Infection with *Burkholderia cenocepacia* and non-tuberculous *Mycobacterium* is associated with increased morbidity and mortality and confers a contraindication in some centers [39, 43]. Patients with ILD have the worst prognosis of those referred for LT. The introduction of the lung allocation score (LAS) system, designed to prioritize patients with the highest mortality on the waiting list, has increased the number of ILD candidates receiving transplantation [44, 45]. Significant developments in targeted medical therapy for pulmonary hypertension had led to improvements in management and a postponement in referral for LT listing in this population [39]. Patients with PHT secondary to pulmonary veno-occlusive disease should be referred for LT assessment at the time of diagnosis, as there is no established medical therapy, and the prognosis is poor [46]. The incidence of re-transplantation has increased since the introduction of the LAS system. The same criteria for initial LT listing are used. Whether SLT or BSLT is planned, removal of the failed allograft is recommended to reduce infection risk and ongoing stimulation of the immune system. Patients requiring re-transplant after 2 years of their original procedure have better outcomes than those who are re-transplanted within 30 days [39, 47–49]. Previously, patients in a critical condition, supported with mechanical ventilation or extracorporeal life support (ECLS) were deemed unsuitable candidates [50]. However, improvements in technology and expanded experience in the management of ECLS have allowed for such patients to be bridged to transplantation with ECLS, with acceptable outcomes [51–53].

Anesthesia for Lung Transplantation

Preoperative Assessment

Due to the nature of LT, the anesthesiologist usually has limited time for preoperative assessment [54]. In some centers the listed candidates are reviewed in an assessment clinic by an anesthesiologist to highlight pertinent anesthetic considerations. Patients are typically debilitated, with poor cardiorespiratory reserve. Latent ischemic heart disease and right ventricular (RV) dysfunction are not uncommon, especially in elderly patients, although the presence of noncritical coronary artery disease does not appear to influence postoperative outcomes [55–58]. After admission to hospital for surgery, there is limited time to optimize the patient: chest physiotherapy to clear secretions, bronchodilator therapy, and drainage of significant pleural effusions or pneumothoraces. In addition to a standard preoperative evaluation, anesthetic assessment should focus on [59]:

- Underlying diagnosis: obstructive, restrictive, or suppurative pathology. This facilitates selection of appropriate ventilator settings.
- Pulmonary artery (PA) pressure: this will dictate the likelihood of undertaking the procedure without the use of ECLS.
- Ventilation/perfusion (*V/Q*) scan: the differential perfusion to each lung (in BSLT) will determine which lung initially will better tolerate PA clamping and pneumonectomy.
- Arterial blood gases (ABGs): baseline pO_2/pCO_2 helps define acceptable intraoperative limits.
- Echocardiography: knowledge of RV and left ventricular (LV) function will influence the requirement for ECLS.

Standard premedication involves immunosuppressant drugs, bronchodilator therapy, and supplemental oxygen. The routine use of anxiolytic medication is not recommended, and any sedative agents should be administered with caution, as they can exacerbate hypoxemia and hypercapnia, leading to worsening PHT and RV failure.

Monitoring

Routine monitoring includes electrocardiography (ECG), pulse oximetry, invasive arterial and central venous pressure (CVP) measurements, pulmonary artery catheterization (PAC), temperature measurement, capnography, and inhalational agent monitoring. Minimally invasive cardiac output monitoring has been used extensively in the nontransplant perioperative setting and in nonpulmonary transplantation with mixed conclusions [60–63]. Mixed venous oximetry has been used successfully intraoperatively, and cerebral oximetry has been shown to improve outcomes in cardiac surgery [64–67]. The use of depth of anesthesia monitoring may reduce the incidence of awareness, and when used in combination with a closed-loop anesthesia, delivery system provides better titration of drugs, giving the anesthesiologist more time to focus on intraoperative hemodynamic and surgical events [68, 69]. Early detection and prevention of intraoperative hypothermia is important to prevent cardiac dysrhythmias, coagulopathy, and altered drug metabolism and to reduce the risk of postoperative infection [70, 71].

Transesophageal Echocardiography

The value of intraoperative transesophageal echocardiography (TEE) in LT surgery is well established [72–75]. TEE is more accurate at determining preload and volemic status compared to PAC [76]. It facilitates rapid diagnosis of hemodynamic instability, including evaluation of RV function after PA clamping, LV dysfunction, detection of gaseous emboli, and assessment of surgical anastomotic sites [75, 77–79]. Significant stenosis of pulmonary vein anastomoses is more commonly seen on the left (Fig. 47.5) and can result in pulmonary venous congestion and graft failure. However, TEE can overestimate pulmonary vein Doppler peak velocities, and caution is required when interpreting findings [80, 81]. The presence of an interatrial septal defect or patent foramen ovale can lead to a significant right-to-left shunt during periods of increased pulmonary vascular resistance (PVR) or when increased PEEP is employed. Prompt detection by TEE can aid in diagnosing this cause of worsening hypoxemia

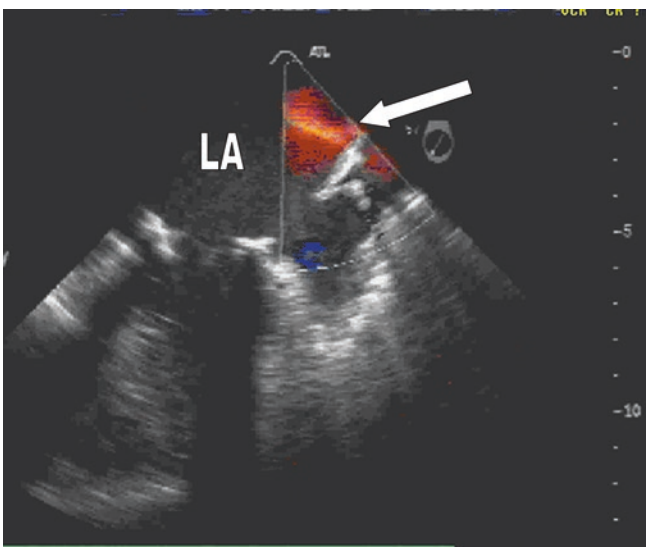

Fig. 47.5 Transesophageal echocardiography showing turbulence on color flow Doppler imaging (arrow) in a stenotic left pulmonary vein anastomosis. LA left atrium

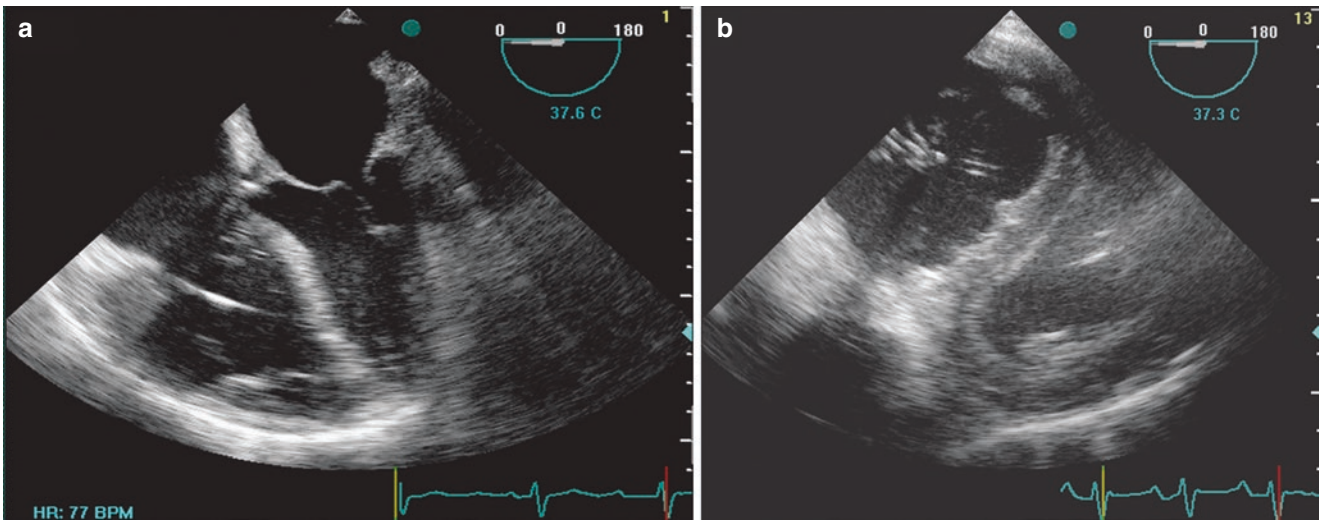

Fig. 47.6 Transesophageal echocardiography midesophageal (**a**) and transgastric (**b**) views showing right ventricular dilatation and flattening of the interventricular septum with leftward shift. LV left ventricle, RV right ventricle

[82]. With the expansion of intraoperative extracorporeal membrane oxygenation (ECMO) support in LT surgery, TEE is also beneficial in assisting in positioning of cannulae and differentiating between hypovolemia and cannula obstruction when low ECMO flows are encountered (Fig. 47.6) [83, 84].

Induction of Anesthesia

Thorough preoxygenation of the patient is prudent. Induction of anesthesia may precipitate cardiovascular collapse due to a combination of factors: systemic vasodilation and negative inotropic effects of anesthetic drugs, reduced venous return due to an increase in intrathoracic pressure secondary to positive pressure ventilation and PEEP, and RV failure caused by an increase in PVR due to hypoventilation and subsequent hypercapnia [85–87].

In patients with obstructive lung pathologies, it is important to allow sufficient time for the expiratory phase to occur and to avoid PEEP, in order to reduce the risk of dynamic hyperinflation. Overenthusiastic manual ventilation after induction of anesthesia can lead to severe gas trapping in emphysematous lungs, resulting in reduced venous return and direct cardiac compression: "pulmonary tamponade" [88, 89]. Profound hypotension ensues, and correct management is to disconnect the patient from the breathing circuit to allow sufficient time for expiration of trapped gases [90].

Patients with restrictive lung disease typically require higher ventilatory pressures to deliver an adequate tidal volume and often benefit from the application of increased levels of PEEP. Adoption of a ventilation strategy similar to that used in acute lung injury (ALI) is more appropriate for this group of patients [91, 92].

Recipients with suppurative pathologies may have mixed obstructive/restrictive respiratory defects, so appropriate ventilation should be individualized. Thorough bronchial lavage after intubation of the patient may reduce intraoperative sputum plugging and assist in maintaining adequate ventilation throughout the procedure.

In patients with pulmonary vascular disease, smooth induction of anesthesia is critical to prevent systemic hypotension, PA hypertensive crises, myocardial depression, hypoxemia, and hypercapnia. It may be useful to obtain central venous access before induction of anesthesia for administration of vasopressors. Anesthetic goals include [93]:

- Avoid acute increases in RV preload: RV dilatation increases RV wall tension, increasing oxygen demand; elevates RV end-diastolic pressure (RVEDP), reducing oxygen delivery; and worsens tricuspid regurgitation (TR), exacerbating volume overload.
- Maintain RV perfusion: avoid systemic hypotension and increases in RVEDP.
- Maintain sinus rhythm and positive chronotropy.
- Augment RV contractility with inotropic support when necessary.
- Decrease PVR: avoid hypoxemia, hypercapnia, and acidemia.

Ketamine may be a more appropriate induction agent in severe cases, with vasoactive infusions commenced prior to induction. The use of inhaled pulmonary vasodilators and preinduction ECLS has been described [94, 95]. The anesthesiologist should be prepared for emergency institution of cardiopulmonary bypass (CPB) after induction.

Table 47.4 Disease-specific intraoperative considerations

Pathology	Intraoperative complications
COPD/AATD	Elderly with concomitant coronary artery disease
	Dynamic hyperinflation, gas-trapping and auto-PEEP with positive pressure ventilation, causing "pulmonary tamponade"
Cystic fibrosis	Thick, tenacious secretions, plugging the DLT lumens
	Difficult to maintain normocapnia
	Difficult surgery: small chest cavity, multiple adhesions
Interstitial lung disease	High ventilatory pressures, reducing venous return
	Secondary pulmonary hypertension
	Associated pathologies: scleroderma, rheumatoid arthritis
Pulmonary hypertension	Cardiovascular collapse at induction of anesthesia
	Right ventricular failure

AATD alpha-1 antitrypsin deficiency, *COPD* chronic obstructive pulmonary disease, *DLT* double-lumen tube, *PEEP* positive end-expiratory pressure

Disease-specific intraoperative anesthetic considerations are summarized in Table 47.4.

Following induction, the airway is secured with either a single-lumen or double-lumen tube (DLT). A single-lumen tube in combination with an endobronchial blocker provides an alternative technique to DLT [96, 97]. In BSLT, the blocker will need repositioning under bronchoscopic guidance to allow surgery on the opposite side. A left-sided DLT is preferred to a right-sided DLT, which may interfere with the right-sided bronchial anastomosis. In patients with significant suppurative pathologies (e.g., cystic fibrosis), it is common to initially insert a single-lumen tube in order to facilitate bronchoscopic toilet and suctioning of thick secretions, prior to exchanging for a DLT. Bronchoscopic lavage samples can be sent for microbiological analysis to direct postoperative antimicrobial therapy. Prophylactic antibiotic regimens are institution-related but must provide adequate gram-positive and gram-negative cover. Patients with CF often require alternative antimicrobials, depending on their history of allergies, microbe colonization, and presence of drug-resistant organisms [98, 99].

Maintenance of Anesthesia

Maintenance of anesthesia is achieved with either inhalational or intravenous agents [100, 101]. Nitrous oxide should be avoided as it may increase PVR [102]. SLT can be performed through a standard posterolateral thoracotomy, with the patient in the lateral position, or via an anterior thoracotomy, in the supine position. This latter approach provides easier surgical cannulation access if urgent ECLS is needed. BSLT may be performed either via a midline sternotomy, bilateral thoracotomies, or "clamshell" incision [103].

Initiation of one-lung ventilation (OLV) will initially cause an increase in shunt with worsening hypoxemia until surgical stapling of the PA. During OLV pressure-controlled ventilation may proffer some benefits over volume-controlled ventilation, by reducing peak airway pressures [104, 105]. Patients unable to tolerate OLV will require CPB or ECMO support [106].

Optimal fluid management is paramount during the intraoperative period. Patient hemodynamics are influenced by volemic status and preload optimization is essential. However, the lung allograft is prone to low-pressure pulmonary edema, secondary to re-expansion injury, ischemia-reperfusion microvascular leak, and the absence of lymphatic drainage. A restrictive fluid regimen is recommended, with surgical blood loss replaced by boluses of colloid or blood products as indicated [107, 108].

Management of RV Dysfunction

Surgical clamping of the PA during OLV will reduce shunt and improve oxygenation but will result in an acute increase in PA pressures. In patients with pre-existing PHT, it is prudent for the surgeon to apply temporary PA clamping to determine the effect on PA pressures and RV function [109]. Early diagnosis of RV failure by TEE allows for prompt management and potential avoidance of ECLS [78]. Recipients with severe PHT rarely tolerate PA clamping, and the elective use of ECLS is employed [110].

An acute elevation in PVR causes a combination of detrimental effects, which may ultimately result in RV failure. The increase in RV afterload will initially reduce RV stroke volume, leading to a rise in RVEDV. RV dilatation can worsen the severity of TR, exacerbating volume overload, further raising RVEDV and consequently RVEDP. There is a leftward shift of the interventricular septum, inhibiting LV diastolic filling and decreasing LV stroke volume. The subsequent fall in cardiac output leads to systemic hypotension and, coupled with an increase in RVEDP, a reduction in RV perfusion pressure. RV ischemia follows, with further RV decompensation and failure [93].

The use of selective pulmonary vasodilators, inhaled nitric oxide (iNO), and prostacyclin therapy reduces PVR, improves oxygenation, and can reverse RV failure [111–114]. Catecholamines and phosphodiesterase inhibitors (PDE-I) will provide positive inotropy and improve RV contractility. PDE-I may reduce PVR but also have the less desirable side effect of systemic vasodilatation and hypotension, often necessitating the addition of vasopressor support to maintain coronary perfusion [115–118]. Levosimendan restores RV-PA coupling by decreasing PVR and increasing RV contractility but is also associated with systemic vasodilatation [119].

Norepinephrine is the initial vasoconstrictor of choice: it improves ventricular systolic interaction and coronary perfusion and may also improve RV-PA coupling. Vasopressin can be added in cases of refractory hypotension [118].

Extracorporeal Support

There is institutional and surgical variation in preference for utilization of CPB. Elective use of ECLS, either full CPB or ECMO, is indicated in recipients with severe PHT and in HLT [120]. SLT is typically performed "off-pump" via a thoracotomy. When BSLT is performed "off-pump," the lung receiving less perfusion (from the preoperative *V/Q* scan) should be replaced first. For BSLT with CPB, the heart remains warm and beating. After implantation of the first allograft, the heart is allowed to eject a little, and the lung is gently ventilated.

In recent years, the use of full CPB has been replaced by other forms of ECLS: veno-venous (VV) and venoarterial (VA) ECMO support [121–123]. VA-ECMO, like full CPB, provides both cardiac and respiratory support but requires less heparinization. Central cannulation sites, right atrium (RA) and ascending aorta, are generally preferred, as higher ECMO flows can be achieved, necessitating less anticoagulation. Peripheral cannulation, usually femoral vein (FV) to femoral artery, allows for continued ECLS support into the postoperative period in cases of severe PGD, and the chest can be closed [124, 125]. However, the anesthesiologist must remain vigilant during the intraoperative period, as lower ECMO flows permit more blood flow through the heart and lungs, which may be significantly deoxygenated: ECMO Harlequin syndrome may occur, resulting in cerebral hypoxia with peripheral VA cannulation. Pulse oximetry and arterial pressure monitoring should be placed on the right upper limb to ensure adequate oxygenation, and cerebral oximetry is advantageous [126, 127]. VV-ECMO provides only respiratory support, but the correction of hypoxemia and hypercapnia can markedly enhance RV function, leading to improved hemodynamics. Cannulation is typically peripheral and can be achieved with either a single dual-lumen cannula or by two cannulae [128, 129]. Fluid management is more challenging during ECMO support: ECMO flows are highly dependent on patient venous pressures, so sufficient fluid must be administered to maintain adequate ECMO flows without causing fluid overload and "wet" lungs. The utilization of ECMO support instead of CPB has led to better patient outcomes [130–134]. If postoperative VV-ECMO is probable, it may be useful to avoid using the right internal jugular vein for central access during surgery.

Organ Reperfusion

Reperfusion of the allograft should occur gradually, over a period of 5–10 min, as it may result in significant hypotension due to release of stored pneumoplegia, inflammatory mediators, and gas emboli into the systemic circulation [135]. Simultaneously, gentle alveolar recruitment and ventilation are commenced with limited peak airway pressures, moderate PEEP (5–10 cmH_2O), and initially with a fraction of inspired oxygen (FiO_2) less than 40% [136–139]. In BSLT the residual native lung can be ventilated with a high FiO_2 to maintain arterial oxygenation, while the new allograft is reperfusing with protective ventilation. After this initial period of reperfusion, the FiO_2 to the allograft is increased as necessary, while ventilation to the native lung is stopped to enable surgical explantation. Ischemia-reperfusion injury (IRI) presents as hypoxemia despite increasing FiO_2, reduced lung compliance, PHT, and, in severe cases, pulmonary edema. PGD due to IRI is associated with an increased mortality [140]. The administration of iNO is effective in improving oxygenation in cases of IRI, but its routine use to prevent IRI is of less benefit [141–143]. Severe PGD can be managed with ECLS, usually VV-ECMO, with acceptable outcomes [144, 145].

Analgesia

In the postoperative period, insufficient pain control hinders spontaneous deep breathing, adequate coughing, and sputum clearance. Analgesic options comprise paracetamol, intravenous opiates, and regional techniques, including epidural and paravertebral analgesia. Opioid-sparing regimens are encouraged to reduce respiratory depression. Epidural insertion can be performed prior to surgery, to facilitate earlier postoperative extubation, or postoperatively, after coagulopathy has been excluded [146, 147]. Paravertebral catheters can be placed by the surgeon at the end of a SLT as an alternative to epidural analgesia [148]. There may be a role for low-dose intravenous ketamine as an adjunct to reduce postoperative opiate requirements [149, 150]. Nonsteroidal anti-inflammatory drugs are avoided due to the increased risk of renal dysfunction in patients receiving calcineurin inhibitors for immunosuppression [151].

Postoperative care

Early extubation in the operating room is feasible, especially after SLT [152, 153]. The advantages include avoidance of positive pressure ventilation, with potential barotrauma, reduced extravascular lung water, decreased PA pressures, lower requirements for vasoactive drugs, and early mobiliza-

tion with physiotherapy. This is facilitated by the use of short-acting anesthetic agents, epidural analgesia, and the absence of intraoperative complications [153, 154]. For patients returning to the intensive care unit for postoperative ventilation, the DLT is changed to a single-lumen tube, and a nasogastric tube is passed to permit early administration of enteral immunosuppression.

Ventilatory support involves a lung protective strategy and potential differential lung ventilation in patients with SLT for emphysema. Tracheostomy is considered if prolonged ventilation is anticipated [155–158].

Early complications include PGD, hemorrhage, iatrogenic surgical anastomotic anomalies, infection, cardiac dysrhythmias, renal failure, and venous thromboembolism [159–165]. Early complications have a negative impact on long-term survival [166]. Prevention of acute rejection is managed with a combination of steroids, calcineurin inhibitors, antiproliferatives, and mammalian target of rapamycin (mTOR) inhibitors. The routine use of induction therapy with monoclonal or polyclonal antibodies is controversial but may confer some survival benefit in BSLT [167]. Late complications include chronic rejection, presenting as bronchiolitis obliterans, infection, renal dysfunction, diabetes mellitus, and malignancy [1, 168].

Clinical Case Discussion

Case Presentation

A 52-year-old male with mixed interstitial lung disease/COPD presents for right single-lung transplantation via right thoracotomy and left hemidiaphragm plication. He requires supplemental oxygen at 3 lpm at rest and 10 lpm with exertion. He has a 40-pack-year smoking history and quit 5 years ago. His history is notable for five-vessel coronary artery bypass graft 8 years ago and endovascular repair of an abdominal aortic aneurysm 5 years ago. As a teenager, he suffered a traumatic injury to his left neck, resulting in left vocal cord and hemidiaphragm paralysis.

His preoperative medication list includes albuterol, atorvastatin, azithromycin, gabapentin, metoprolol, omeprazole, sertraline, and sildenafil. He has no medication allergies.

The patient's preoperative workup reveals the following information:

Weight: 87 kg, Height: 176 cm, Heart rate: 80 bpm, Blood pressure: 108/70 mmHg Temperature: 37.0 °C, SpO_2: 97% on 3 L nasal cannulae

ECG: normal sinus rhythm with occasional premature ventricular contractions, left ventricular hypertrophy

Hemoglobin: 13.7 g/dL, hematocrit: 42.3%, white blood cell count: 10 x109/L, platelets 229 × 109/L

Fig. 47.7 Preoperative upright posterior-anterior chest X-ray. Notable findings include left hemidiaphragm elevation, changes consistent with post median sternotomy and CABG, and aortic stent graft within the abdomen

Na+: 138 mmol/L, K+: 4.1 mmol/L, Cl-: 103 mmol/L, CO_2: 28 mmol/L, BUN 20 mg/dL, Cr 0.8 mg/dL, Glucose 103 mg/dL, INR 1.0

Arterial blood gas on room air: pH 7.37, pCO_2 49 mmHg, pO_2 59 mmHg, bicarbonate 28 mmol/L, base excess 2 mmol/L

FEV1 51% predicted, FVC 59% predicted, FEV1/FVC 86

Ventilation/perfusion scan: differential perfusion is 46% to left lung, 54% to right lung

Transthoracic echocardiogram: left ventricular ejection fraction 50% with inferior hypokinesis, normal right ventricular systolic function, trivial tricuspid regurgitation

Left heart catheterization: significant native vessel coronary artery disease, all grafts patent

Right heart catheterization: pulmonary artery (PA) pressure 52/14 mmHg (mean 28), pulmonary vascular resistance 2.4 Wood units, cardiac index 2.6 L/min-m^2, pulmonary capillary wedge pressure 9 mmHg

Preoperative imaging studies are shown in Figs. 47.7 and 47.8.

Questions

1. Would you insert a central line and/or pulmonary artery catheter prior to the induction of anesthesia? Does the laterality of central line insertion matter?
2. How would you induce anesthesia in this patient?
3. How would you secure the airway?

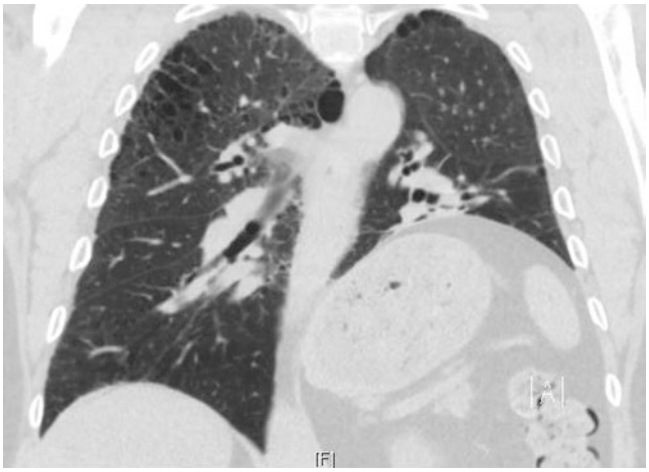

Fig. 47.8 Coronal slice from preoperative computed tomography (CT) scan of the chest. Notable findings are left hemidiaphragm elevation with volume loss in the left hemithorax, right lung hyperinflation, and paraseptal emphysema in the bilateral lung apices

4. How would your anesthetic considerations differ if the patient had:
   (a) Cystic fibrosis?
   (b) COPD?
   (c) Primary pulmonary hypertension?
5. Can this transplant be done without cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO)?

Case Continuation

After the induction of anesthesia, intubation with a left-sided double-lumen tube, and insertion of all invasive monitors and a TEE probe, lung isolation is achieved, and one-lung ventilation (OLV) is established. After 30 min of dissection and OLV, the patient remains hemodynamically stable, but the SpO_2 has decreased to 85% on 100% inspired oxygen, and the arterial blood gas now reads pH 7.21, pCO_2 68 mmHg, pO_2 51 mmHg, bicarbonate 22 mmol/L, and base excess −2 mmol/L.

Questions

6. How will you manage OLV?
7. How will you address the hypoxemia that has developed during OLV? What degree of hypoxemia and/or hypercarbia will you tolerate?

Case Continuation

In preparation for explant of the native right lung, the surgeon clamps the right PA. After clamping, the vitals are heart rate 90 bpm, blood pressure 129/74 mmHg, central venous pressure 10 mmHg, PA pressure 46/17 (mean 29) mmHg, and SpO_2 99%.

The right lung is explanted. Then the right donor lung is implanted and reperfused, during which time there is severe hemodynamic instability.

Questions

8. How would you expect pulmonary arterial pressures to change with clamping of the left PA?
9. What has caused the hemodynamic instability?

Case Continuation

The donor (right) lung is now ventilated. Soon after, frank pulmonary edema is seen coming from the tracheal (right) lumen of the double-lumen tube.

Questions

10. How would you ventilate the donor lung?
11. Transesophageal echocardiography pulse-wave Doppler evaluation of the right pulmonary veins reveals a peak velocity of 110 cm/s. How would you advise the surgeon?
12. What is the reason for the development of pulmonary edema?

Discussion

Question 1: Would you insert a central line and/or pulmonary artery catheter prior to the induction of anesthesia? Does the laterality of central line insertion matter?

This patient does not have significant pulmonary hypertension; thus, the preinduction insertion of a pulmonary artery catheter (PAC) is not required. However, in a patient with significant pulmonary hypertension, the preinduction insertion of a PAC allows for precise hemodynamic management during induction of anesthesia. Central access also offers the advantage of allowing for the use of inotrope infusions (e.g., epinephrine) to support the right ventricle, although this central access is not necessarily required for temporary infusions. Of note, many lung transplant patients will not be able to tolerate preinduction central line/PAC insertion because they may not tolerate Trendelenburg or even supine positioning. Importantly, extreme caution must be taken in administering sedation to lung transplant recipients who often have tenuous respiratory status. The potential exacerbation of baseline hypercapnia or hypoxemia with sedation may precipitate an acute increase in pulmonary vas-

cular resistance and subsequent right ventricular dysfunction/failure with cardiovascular collapse.

If the patient's pulmonary arterial pressures are approaching or even supra-systemic, it may be prudent to consider preinduction cannulation of the femoral vessels under local anesthesia for either preemptive or emergent institution of ECMO/CPB. Our practice is to typically place the central line and PAC via the left internal jugular vein under ultrasound guidance; this leaves the right internal jugular vein accessible should circulatory support (e.g., ECMO) be required during or after the transplant procedure. In this patient, vascular access in the left neck may be complicated by his previous injury.

Question 2: How would you induce anesthesia in this patient?

The induction of anesthesia in lung transplant recipients should focus on extreme attention to hemodynamic stability and management of pulmonary hypertension as well as rapid securement of the airway. With regard to the management of pulmonary hypertension, it is paramount to avoid significant decreases in systemic vascular resistance that will reduce right ventricular perfusion, thus compromising RV function. One must also limit any increase in pulmonary vascular resistance by avoiding hypoxemia, hypercarbia, acidosis, and "light" anesthesia during laryngoscopy and intubation. A preinduction arterial catheter is mandatory for beat-to-beat blood pressure monitoring, and a cardiac-style induction relying primarily on narcotics and benzodiazepines often provides the desired hemodynamic stability. Although rapid securement of the airway is desirable, conventional rapid sequence induction techniques may not be tolerated in patients with RV dysfunction. Despite the potential for adrenocortical suppression, some practitioners select etomidate as part of a rapid sequence induction in combination with succinylcholine. Regardless of the drugs selected for induction, vasoconstrictors and inotropes should be readily available for hemodynamic support and resuscitation. Inotropes without systemic vasodilatory effects are preferred. Careful preoperative assessment of the airway and contingency planning for difficult airway access are prudent, as these patients may not tolerate prolonged periods of apnea. Given the left hemidiaphragm paralysis in this patient, with resultant low lung volumes on the left, this patient may experience more rapid desaturation during induction than might be predicted from his lung disease. Furthermore, this patient is only undergoing single-lung transplantation; therefore, precautions against aspiration, which could compromise the remaining native lung, should be taken.

Question 3: How would you secure the airway?

In the vast majority of lung transplant patients, a left-sided double-lumen endotracheal tube (ETT) placed with bronchoscopic guidance is typically used. Patients with a suppurative pathology (e.g., cystic fibrosis) will benefit from initial insertion of a single-lumen ETT to allow for pulmonary toilet via bronchoscopy. This will mostly likely improve oxygenation during one-lung ventilation.

Bronchial blockers to achieve lung isolation are more prone to movement within the airway during manipulation of the hilum and do not allow for effective suctioning, the application of continuous positive airway pressure (CPAP) to the non-ventilated lung, or differential ventilation of the two lungs.

Question 4: How would your anesthetic considerations differ if the patient had:
(a) Cystic fibrosis?
(b) COPD?
(c) Primary pulmonary hypertension?

The leading indications for lung transplantation today are pulmonary fibrosis, COPD, and cystic fibrosis. The underlying pathology impacts the surgical procedure as well as the anesthetic considerations. For example, patients with fibrosis often receive single-lung transplants, while patients with cystic fibrosis always require a double-lung transplant.

Induction techniques are similar for all pathologies and reflect consideration of pulmonary artery pressures and underlying right ventricular function, as described above.

Ventilation strategies, on the other hand, should be tailored to the underlying pulmonary pathology. Patients with pulmonary fibrosis have low lung compliance and are at risk for barotrauma associated with mechanical ventilation. Pressure control ventilation may be preferable to volume control ventilation to decrease the airway pressure transmitted to the lungs. Patients with obstructive lung disease, such as COPD or cystic fibrosis, are prone to air trapping and dynamic hyperinflation (see question 6).

Patients such as this one who receive single-lung transplants may have a significant imbalance in pulmonary compliance between the native lung and the transplanted lung, requiring differential lung ventilation via a double-lumen ETT.

Question 5: Can this transplant be done without cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO)?

Cardiopulmonary bypass (CPB) offers the advantage of improved hemodynamic stability and systemic oxygenation during lung transplantation. However, CPB has many disadvantages, including bleeding related to full heparinization and coagulopathy, increased use of blood products, increased crystalloid administration, inflammation, and possible damage to other organs. Nonetheless, patients with intractable

hypoxemia during one-lung ventilation or RV dysfunction causing hemodynamic compromise may require ECMO or CPB to safely complete the procedure. ECMO is often preferred over CPB because it allows for less heparinization and can be easily extended into the postoperative period if required.

Question 6: How will you manage OLV?

Concerns during OLV before transplant include hypoxemia, hypercarbia, dynamic hyperinflation (in cases of obstructive lung disease), and excessively high airway pressures (which may precipitate RV failure). To address dynamic hyperinflation, ventilation should focus on permissive hypercapnia with reduced tidal volume, lower respiratory rate, elimination of positive end-expiratory pressure (PEEP), and adjustments to inspiratory/expiratory (I:E) ratio to favor exhalation. Elevated airway pressures can be ameliorated through reduced tidal volumes, higher respiratory rate, and adjustment of the ventilator I:E ratio.

Question 7: How will you address the hypoxemia that has developed during OLV? What degree of hypoxemia and/or hypercarbia will you tolerate?

Hypoxemia during one-lung ventilation (OLV) can be treated with either continuous positive airway pressure (5–10 cmH_2O) to the non-ventilated lung to oxygenate the shunt fraction or with PEEP (5–10 cmH_2O) to the ventilated lung to minimize atelectasis. Of note, PEEP can potentially reduce venous return to the heart, impair hypoxic pulmonary vasoconstriction, and elevate pulmonary vascular resistance. Definitive treatment of hypoxemia due to shunt during OLV is achieved with surgical clamping of the PA to the non-ventilated lung. Hypoxic pulmonary vasoconstriction may be improved by reducing inhaled volatile anesthetic concentration or utilizing TIVA only and by avoiding IV vasodilators (e.g., nitroglycerin). If intractable hypoxemia occurs despite the above maneuvers and utilization of 100% inspired oxygen, ECMO or CPB may be required.

Management of arterial blood gas values should target the patient's baseline values prior to induction of anesthesia. While some degree of permissive hypercarbia may be necessary to achieve adequate oxygenation, severe hypercarbia, hypoxemia, or acidosis that produce hemodynamic instability are indications for ECMO or CBP.

Question 8: How would you expect pulmonary arterial pressures to change with clamping of the left PA?

It is reasonable to expect a rise in the PA pressure after surgical clamping of either pulmonary artery because the entire cardiac output is now passing through the contralateral lung. This PA pressure increase may be variable depending on the degree of baseline perfusion through the native lung (reference the preoperative ventilation/perfusion lung scan). While a lack of increase in PA pressure with PA clamping may seem reassuring, the anesthesiologist should always be vigilant about the possibility of worsening of RV function.

Question 9: What has caused the hemodynamic instability?

Possible causes of hemodynamic instability in this scenario include worsening of RV function, worsening of LV function due to ischemia in this patient with significant coronary disease, and air embolism occurring during reperfusion of the transplanted lung. The best tool for monitoring cardiac function and for diagnosing the cause of intraoperative hemodynamic instability is transesophageal echocardiography (TEE). TEE will be able to differentiate between these scenarios and allow for determination of the cause of hemodynamic instability.

Question 10: How would you ventilate the donor lung?

Goals for the management of any newly transplanted lung include the avoidance of atelectasis, hyperoxia, and barotrauma, which can rapidly cause pulmonary edema. During double-lung transplantation, a particularly vulnerable period occurs between the first and second implant when the newly reperfused first lung must tolerate twice the normal blood flow (i.e., the full cardiac output). Single-lung transplants are vulnerable to differences in compliance between the newly implanted lung and the remaining native lung. Institutional perioperative standardized practices for ventilation of the newly transplanted lung are common for goal PEEP (e.g., 8 mmHg), preferred oxygen levels (e.g., room air or the lowest inspired oxygen concentration to maintain SpO_2 above 90%), and peak inspiratory pressure (e.g., less than 30 mmHg). At our institution, inhaled nitric oxide (iNO) or inhaled epoprostenol are routinely administered to reduce pulmonary artery pressure and support RV function, although the benefits in lung transplantation are controversial.

Question 11: TEE pulse-wave Doppler evaluation of the R pulmonary veins reveals a peak velocity of 110 cm/s. How would you advise the surgeon?

Pre-procedure and post-procedure TEE evaluation provides invaluable information to assist with anesthetic management and to aide in diagnosing surgical complications. Pre-procedure evaluation should focus on RV and LV function, the identification and quantification of any valvular lesions or intracardiac shunts (e.g., PFO), and an assessment of baseline pulmonary vein velocities and pulmonary artery size.

Post-transplant TEE should again evaluate RV and LV function. Most importantly, following reperfusion there should be a careful assessment of the right and left pulmonary arteries and all four pulmonary veins (if possible), including:

- Assessment of the diameter of pulmonary artery and pulmonary vein anastomoses, if visible
- Color flow Doppler evaluation of pulmonary artery anastomoses, if visible
- Color flow Doppler evaluation of pulmonary vein flows and pulsed-wave Doppler determination of pulmonary vein velocities

In general, anastomoses >0.5 cm in diameter and pulmonary vein pulse-wave Doppler peak systolic velocities ≤100 cm/s are acceptable. Although few specific guidelines exist, peak systolic velocities >100–170 cm/s are worrisome for obstruction (kinked or narrow anastomoses) and should prompt discussion with the surgical team before chest closure.

Question 12: What is the reason for the development of pulmonary edema?

Reperfusion injury typically presents with poor oxygenation, high PA pressures, and pulmonary edema. It is important to exclude a mechanical cause, such as pulmonary vein or arterial anastomotic stenosis or kinking (best evaluated via TEE, as described above). Otherwise, protective lung ventilation strategies should be employed. Inhaled pulmonary vasodilators can help to reduce the inspired oxygen concentration in patients with high oxygen requirements. Ultimately, significant reperfusion injury or primary graft dysfunction may necessitate the use of ECMO.

Anesthesia for the Patient with a Previous Lung Transplant

48

Maureen Cheng

Key Points

- Post lung transplantation, patients have an altered physiology which predisposes them to adverse respiratory events during the perioperative period.
- Anesthetic concerns include allograft function and airway complications, consequences of immunosuppression, impact of surgery on airway management, and interference with lung function.
- For patients who have undergone single lung transplants, the effects of the differing compliances in the native and transplanted lung must be taken into account during positive-pressure ventilation.

Introduction

Lung transplantation is an established mode of treatment for patients with end-stage lung disease, and an increasing number of procedures are being performed annually [1]. Patients have a longer life expectancy due to current medical advances, with the median survival rate for a patient post double lung transplant (LT) being 7.3 years [1]. As such, there is an increasing likelihood of encountering these patients who may return for the management of transplant-related complications, surveillance procedures, or for the treatment of other surgical conditions. The physiological changes that occur post LT, implications of the primary pathology that necessitated transplantation, and interactions with immunosuppressive agents will have to be taken into consideration when formulating a perioperative management strategy.

Common Procedures After Lung Transplantation

Common surgical procedures can be broadly divided into those that are in the immediate postoperative period, related to transplant surveillance or surgical intervention for other non-transplant-related conditions.

Bleeding complications such as drainage of pericardial effusions or hemothoraces and those related to stenosis of pulmonary venous and arterial anastomoses [2] may necessitate a return to the operating room in the early postoperative period. As part of their follow-up, patients often require surveillance bronchoscopies for assessment of anastomotic healing or transbronchial biopsies to rule out infection and graft rejection.

Gastrointestinal issues that commonly present in the post transplant population include gastrointestinal reflux disease (GERD) (22.9%), infectious colitis (15.1%), gastroparesis (10.7%), peptic ulcer disease (8.8%), and cholecystitis (8.3%), necessitating surgery in over 20% of patients [3]. In addition, patients with cystic fibrosis have a predilection for complications such as pancreatitis and distal intestinal obstruction syndrome. Osteoporosis from the use of immunosuppressive agents may result in fractures or avascular necrosis of the hip requiring orthopedic fixation [4]. Lung volume reduction surgery on the native lung for single LT patients or pulmonary resections for carcinoma may also be performed.

Pulmonary Physiology Post Lung Transplantation

Pulmonary function rapidly improves in the first year following transplantation, though the degree of approximation to the recipient's ideal predicted spirometry values and diffusion capacity are dependent on whether a single or double LT is performed. In a study by Pochettino et al. [5], peak forced expiratory volume in 1 s (FEV1) values achieved by patients

P. Slinger (ed.), *Principles and Practice of Anesthesia for Thoracic Surgery*, https://doi.org/10.1007/978-3-030-00859-8_48

who underwent bilateral LT for chronic obstructive pulmonary disease (COPD) were 80% as opposed to 50% for single LT. Declines in the FEV1/forced vital capacity (FVC) ratio can reflect deteriorating graft function due to infection, rejection, or airway complications such as bronchial anastomotic stenosis. In the absence of other confounding conditions, a persistent decrease in the FEV1 $\leq$ 80% may represent the development of bronchiolitis obliterans syndrome (BOS) which is caused by progressive obliteration of small airways and reduction of the air passages to stenotic scar tissue [6].

Disruption of the sensory fibers of the vagus nerve results in a loss of the afferent signals for the cough reflex in the airways distal to the bronchial anastomosis and impairment of mucociliary clearance, though on follow-up Duarte et al. reported that the sensory innervation for the cough reflex may be restored in 6–12 months [7]. LT recipients have also been shown to have a high prevalence of GERD, which further increases following transplantation [4]. This results in an increased susceptibility to aspiration and the development of chest infections. Bronchial hyperreactivity is another common feature, with 24% of patients having a positive methacholine challenge test at 6 months post LT [8]. The pulmonary hypoxic vasoconstriction reflex is preserved [9]; however, the response to hypercarbia has been reported to be variable [10]. During the transection of the bronchi, there is also disruption of lymphatic drainage, and it has not been established whether there is eventual regeneration as demonstrated in animal studies [11], though LT patients are known to have a high incidence of pleural collections [12]. Preclinical studies have also shown that there is increased extravascular lung water prior to reestablishment of lymphatic drainage in canine models [13].

More than 90% of single LTs are performed for restrictive or obstructive causes [1]. Post implantation, the distribution of ventilation and perfusion is predominantly shifted toward the pulmonary allograft, and this effect is more marked in patients who have COPD than patients who have pulmonary fibrosis [14]. The effects of the differing compliances in the native and transplanted lung must be taken into account as this will affect the distribution of ventilation during positive-pressure ventilation via a single-lumen tube. Single LT patients with COPD have been reported to have a ratio of compliance in the native lung that is more than 2.6 times that of the transplanted lung [15], resulting in a larger proportion of the ventilatory flow being directed toward the native lung which can potentially cause hyperinflation and mediastinal shift.

Anesthetic Considerations

Preoperative assessment should focus on (1) allograft function and airway complications (2), consequences of immunosuppression, and (3) impact of surgery on airway management and interference with lung function.

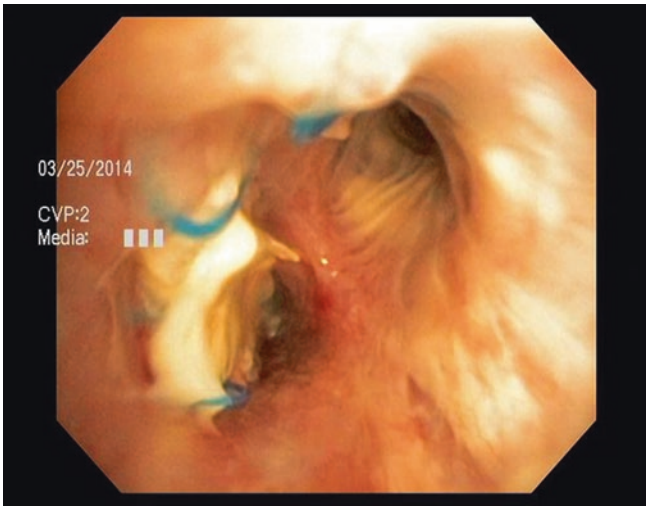

Fig. 48.1 Bronchus intermedius stenosis post LT. (Reproduced with permission [16])

A multidisciplinary approach should be taken in the perioperative care of LT patients, and it is important to liaise with the transplant team who is involved in the routine follow-up of the patient. A review of the patient's prior spirometry and diffusion capacity tests should be carried out to identify patients who have low pulmonary reserve. BOS accounts for a considerable proportion of deterioration in lung function and affects more than half of the recipients that survive beyond 5 years [6]. It is the main cause of mortality in patients who survive more than a year [1]. Airway complications such as bronchial stenosis which presents most commonly in the bronchus intermedius (Fig. 48.1), tracheobronchomalacia, and infectious complications resulting in necrosis, dehiscence, or fistula formation [17] should be highlighted particularly if lung isolation will be required. Recent episodes of chest infection may also require targeted antibiotic therapy.

It is important to ascertain if the patient has had any recent episodes of allograft rejection requiring pulsed steroid therapy or alterations to their immunosuppressive regimen as these may result in drug interactions and complications affecting various other organ systems. Common immunosuppressive regimens will include a glucocorticoid (prednisolone), a calcineurin inhibitor (cyclosporine or tacrolimus), and a nucleotide blocking agent (mycophenolate or azathioprine). Inhibitors of the mammalian target of rapamycin such as sirolimus or everolimus may be used in patients who have allograft rejection that is unresponsive to nucleotide blocking agents or are intolerant of the side effects of these medications. Therapeutic drug monitoring should be carried out in the perioperative period, and note should be taken of drug interactions such as an increase in drug levels of calcineurin inhibitors with the concurrent use of antifungals or macrolide antibiotics. Patients should continue their

Table 48.1 Adverse effects of commonly used immunosuppressive agents

Immunosuppressant	Adverse effect
Corticosteroids	
Prednisolone	Cushing's syndrome, hypertension, sodium and water retention Glucose intolerance Peptic ulcer disease Osteoporosis, avascular necrosis of femoral head
Calcineurin inhibitors	
Cyclosporine	Renal and hepatic dysfunction Hypertension, hyperlipidemia Hyperkalemia, hypomagnesaemia, hyperuricemia Neurotoxicity (headache, visual disturbances, seizures) Glucose intolerance
Tacrolimus (FK-506)	
Antimetabolites	
Mycophenolate mofetil (MMF)	Hyper-/hypotension, peripheral edema Hyperglycemia Hypokalemia, hypomagnesemia, and hypocalcemia Renal and hepatic dysfunction Hematological disorders (pancytopenia)
Azathioprine	Hepatotoxicity Leukopenia and thrombocytopenia

current immunosuppressive regime, and if unable to take orally, consultation should be made with the transplant team regarding conversion to intravenous formulations. The side effects of commonly used immunosuppressive agents are listed in Table 48.1. Within 5 years, the incidence of renal dysfunction is 53.6%, with 3.3% requiring chronic dialysis [1]. Standard preoperative management should be performed for the frequently encountered side effects of glucocorticoid and calcineurin inhibitor use such as diabetes mellitus (80.3%) and hypertension (37.4%) [1].

The choice of anesthetic technique should take into consideration the surgical procedure and the intraoperative effects on ventilation and pulmonary function. Orthopedic fixation procedures may be complicated by bone cement implantation syndrome that increases pulmonary vascular resistance and the risk of right ventricular failure [18]. Upper abdominal surgery results in diaphragmatic splinting which worsens chest wall mechanics.

If peripheral surgery is being performed, regional techniques provide the advantages of avoiding manipulation of the airway and the respiratory depressant effects of opiates. Peripheral nerve blocks can be performed for surgery on extremities; however, as phrenic nerve palsy occurs in approximately 3% of patients post LT [19], the use of techniques such as interscalene blocks that are known to affect the phrenic nerve may result in increased respiratory distress in patients who have preexisting impairment of diaphragmatic function. Central neuraxial techniques can be employed for orthopedic procedures such as hip replacements or as an adjuvant analgesic technique for major abdominal or thoracic surgeries. Caution should be taken to avoid excessive fluid preloading, and patients should be carefully monitored for worsening respiratory parameters caused by impairment of intercostal muscle function.

Intraoperative Airway and Ventilation Management

In procedures which do not require tracheal intubation or muscle paralysis, a supraglottic device such as a laryngeal mask airway can be used with spontaneous ventilation, though severe mucositis from immunosuppressant use should first be excluded. Due to the high incidence of GERD in this patient population, a rapid sequence induction with tracheal intubation may be more appropriate for patients who have reflux disease.

Placement of a lung isolation device such as a double-lumen tube (DLT) may be indicated either to facilitate surgical exposure in thoracic surgery such as pulmonary resections or bullectomies or in patients who have had a single LT requiring controlled mechanical ventilation. The differential distribution of ventilation due to unequal compliances in the native and transplanted lung may result in over distention of the more compliant lung and can lead to serious complications such as mediastinal shift (Fig. 48.2) and barotrauma and tension pneumothoraces. Note should be taken of any preexisting airway complications, the most common being granulation tissue resulting in stenosis of bronchial anastomoses which may have been stented. During intubation, care should be taken with the use of airway adjuncts such as gum elastic bougies to avoid disruption of the bronchial anasto-

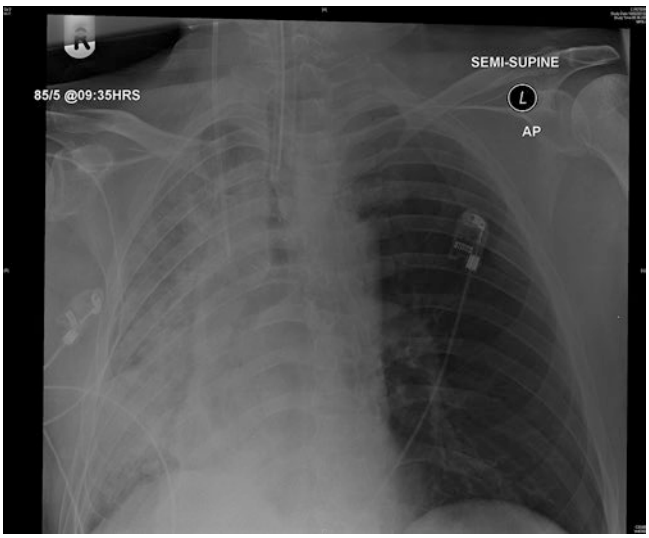

Fig. 48.2 Chest X-ray of a post right single lung transplant patient (COPD) with hyperinflation of the native lung causing mediastinal shift

moses or stents. The use of fiber-optic bronchoscopy is recommended to guide the placement of lung isolation devices. Ventilation strategies for patients post single LT will need to be tailored to accommodate the underlying primary pathology (obstructive vs restrictive). In single LT patients who require positive-pressure ventilation and whose primary pathology is obstructive, after the placement of a DLT, the ventilation settings for the allografted lung may be adjusted as per routine one-lung ventilation, and the native lung should receive only oxygen insufflation or low-pressure ventilation with a prolonged expiratory phase.

Intraoperative Management

The aims of a general anesthetic should be to maintain hemodynamic stability with the use of short-acting agents to facilitate an early extubation. It has been postulated that cyclosporine may enhance the neuromuscular blockade with some agents such as atracurium and vecuronium [20] though the mechanism remains unclear. At present, there have not been any studies which have conclusively demonstrated adverse drug interactions with other induction agents or neuromuscular blockers. Given the high incidence of renal dysfunction in LT patients, it would be prudent to avoid agents with a long duration of action and to perform depth of neuromuscular blockade monitoring to guide dosing. Drugs that may potentiate acute kidney injury such as nonsteroidal anti-inflammatory drugs should also be avoided.

The effects of absent lymphatic drainage have not been clearly demonstrated, and given that there is a significant incidence of renal dysfunction in this group of patients, the perioperative fluid balance should be carefully titrated. The use of a central venous catheter and close monitoring of the urinary output and fluid balance may be warranted depending on the clinical situation.

Patients who are on steroids as part of their immunosuppressive regime should receive their baseline steroid requirement. The perioperative supplementation of stress-dose steroids is controversial [21] but can be administered in patients who are undergoing major surgery to compensate for the suppression of the hypothalamic pituitary axis.

Postoperative Care

As this group of patients has compromised airway reflexes and is at risk of aspiration, care should be taken to ensure return of adequate airway control, and a careful assessment of respiratory function and residual neuromuscular blockade should be made prior to extubation. Depending on the patient's underlying residual lung function and scope and duration of the surgical procedure, an admission to the intensive care unit may be required for postoperative ventilation.

Clinical Case Discussion

Case: A 54-year-old male presents for elective laparoscopic cholecystectomy. He underwent right single lung transplantation for emphysema previously. He has no other major comorbidities. His preoperative pulmonary function tests show an FEV1 of 1.6 L (69% predicted), FVC 2.5 L (78% predicted), and DLCO of 84% predicted.

Questions

- What other transplant-related history is important?
- What are your intraoperative concerns, and how would you ventilate this patient for the surgical procedure?
- What are the postoperative analgesic options?

Transplant-Related History

It is important to ascertain if the patient has had any recent episodes of allograft rejection requiring pulsed high-dose steroid therapy or changes to his immunosuppressive medications as drug dose manipulations may have important interactions and effects on renal function. The perioperative dosing of immunosuppressant drugs should be discussed with the primary transplant team. Recent infective episodes requiring changes to his antimicrobial regimen should also be noted.

Intraoperative Concerns

A rapid sequence induction can be considered if he has a significant history of GERD. As the patient's native lung is highly compliant and prone to gas trapping, differential lung ventilation should be employed for this procedure. Positive-pressure ventilation through a single-lumen tube would result in preferential distribution of ventilation to the native lung resulting in hyperinflation, direct cardiac compression, and profound hypotension. A DLT should be positioned using fiber-optic bronchoscopic guidance to avoid disrupting the bronchial anastomoses. The ventilation settings for the allografted lung may be adjusted as per routine one-lung ventilation, and the native lung should receive only oxygen insufflation or low-pressure ventilation with a prolonged expiratory phase. The perioperative fluid balance should be carefully monitored and titrated to avoid fluid overload. Adequate reversal of neuromuscular blockade should be demonstrated, and care should be taken to ensure recovery of airway reflexes prior to extubation.

Postoperative Analgesia

Multimodal analgesia should be employed including paracetamol, opiates, and local anesthetic infiltration. If the procedure is converted from a laparoscopic to an open procedure, an epidural should be considered to avoid large doses of opiates. Nonsteroidal anti-inflammatory drugs should be avoided due to their potential nephrotoxicity when given in combination with calcineurin inhibitors.

Anesthesia for Pulmonary Thromboendarterectomy

49

Timothy M. Maus and Dalia Banks

Key Points

- Chronic thromboembolic pulmonary hypertension (CTEPH) results from recurrent or residual intraluminal organized fibrotic clot leading to increased pulmonary vascular resistance (PVR), severe PH, and eventually right heart failure (RHF).
- Incidence of thromboembolic disease is difficult to estimate because of the nonspecific nature of the presenting symptoms and the lack of public awareness of the disorder.
- Pulmonary thromboendarterectomy is an endarterectomy of the proximal pulmonary vascular tree and is the preferred treatment for chronic thromboembolic pulmonary hypertension.
- The most common presenting symptom of chronic thromboembolic pulmonary hypertension is exertional dyspnea. The diagnosis is confirmed with echocardiography, right-sided cardiac catheterization, and pulmonary angiogram.
- Most common complications of PTE procedure are reperfusion pulmonary edema (RPE), pulmonary hemorrhage, and persistent pulmonary hypertension
- Riociguat is the first FDA-approved medication for treating certain patient subgroups with chronic thromboembolic pulmonary hypertension (CTEPH).
- Balloon pulmonary angioplasty is an alternative approach to thromboendarterectomy surgery in patients with surgically inaccessible chronic thromboembolic disease.

Introduction

Pulmonary thromboendarterectomy (PTE), a complete endarterectomy of the pulmonary vascular tree, is the definitive treatment for chronic thromboembolic pulmonary hypertension (CTEPH). Pulmonary embolism (PE) is a relatively common cardiovascular event, and in a small percentage of cases, it leads to a chronic condition in which repeated microemboli as well as ongoing inflammatory response lead to accumulation of connective and elastic tissue on the endovascular surface of the pulmonary vessels [1, 2].

Pulmonary thromboembolism is a significant cause of morbidity and mortality worldwide. Acute PE has been estimated to occur in approximately 63 per 100,000 patients per year in the United States with in-hospital mortality occurring in 11.1% [3–5]. These statistics probably represent underestimates; however, since in 70–80% of patients in whom the primary cause of death was PE, the diagnosis was unsuspected premortem [6].

If left untreated, the prognosis for patients with CTEPH is poor. In fact, once the mean pulmonary pressure in patients with CTEPH reaches 50 mmHg or more, the 3-year mortality approaches 90% [7]. Although medical management can provide temporary symptomatic relief, it is noncurative and generally ineffective. The only potentially curative options are lung transplantation and PTE, with PTE preferred because of its favorable long-term morbidity and mortality profile.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-3-030-00859-8_49) contains supplementary material, which is available to authorized users.

This chapter, based in large part on the experience at UCSD, provides a review of the natural history of CTEPH, a description of PTE, a discussion of anesthetic factors unique to PTE and CTEPH, and a case discussion on managing massive pulmonary hemorrhage, one of the feared complications of the operation.

Classification of Pulmonary Hypertension

Pulmonary hypertension (PH) is classified by the World Health Organization into five types known as the Evian classification [8]: (1) pulmonary arterial hypertension (PAH); (2) pulmonary venous hypertension typically from left heart disease; (3) PH due to respiratory disease such as chronic bronchitis, emphysema, and hypoxemia; (4) pulmonary hypertension due to embolic disease (CTEPH); and (5) PH caused by diseases affecting the pulmonary vasculature.

Further classification of pulmonary hypertension by Galie et al. [9, 10] is defined by the presence of precapillary and postcapillary PH. Precapillary PH as assessed by right heart catheterization is characterized by mean pulmonary artery pressure (mPAP) >25 mmHg; normal pulmonary capillary wedge pressure (PCWP), i.e., <15 mmHg; and an elevated pulmonary vascular resistance (PVR) more than 300 dynes·s·cm^{-5}. Postcapillary PH, often due to left heart disease, is the most frequent form of PH and is characterized by mPAP >25 mmHg, PCWP >15 mmHg, and normal PVR [11].

Chronic Thromboembolic Pulmonary Hypertension (CTEPH)

Most cases of acute PE resolve within weeks and the patient recovers to their previous level of function. However, for unknown reasons, embolic resolution is sometimes incomplete. If the acute emboli are not lysed in 1–2 weeks, the embolic material becomes attached to the pulmonary arterial and arteriolar walls [12]. With time, the embolic material progressively becomes converted to connective and elastic tissue [13]. This chronic obstructive disease may lead to a small vessel arteriolar vasculopathy characterized by excessive smooth muscle cell proliferation in pulmonary arterioles. This vasculopathy is seen in the remaining open vessels, which are subjected to long exposure to high flow and pressure. Pulmonary hypertension results from both mechanical obstruction and from small vessel vasculopathy. Once pulmonary hypertension has developed, patients require expeditious treatment. CTEPH patients generally do not respond well to medical management, which is reserved for patients who are not surgical candidates [14–16]. The only curative option is to proceed with surgical removal of the thromboembolic material by means of endarterectomy.

Incidence

The incidence of pulmonary hypertension caused by PE remains unknown. It has been estimated that there are more than 500,000 survivors of symptomatic episodes of acute PE per year [17]. One recent prospective study indicates that thromboembolic disease develops in as many as 3.8% of patients with acute PE [18]. Thus, a conservative estimate is that 19,000 individuals progress to CTEPH in the United States each year. Considering that only 200–300 PTEs are performed annually worldwide, it is clear that acute PE and CTEPH are under-diagnosed, and PTE is underutilized.

Etiologic Factors

No clear etiology has been defined for the development of CTEPH, although hypercoagulability is certainly a risk. Lupus anticoagulant may be detected in approximately 10% of chronic thromboembolic patients, and 20% carry anticardiolipin antibodies, lupus anticoagulant, or both [19]. A recent study has demonstrated that the plasma level of factor VIII, a protein that is associated with both primary and recurrent venous thromboembolism, is elevated in 39% of patients with CTEPH. Analyses of plasma proteins in patients with chronic thromboembolic disease have shown that fibrin from these patients is resistant to thrombolysis in vitro. In this study, the fibrin β chain N-terminus was particularly resistant to thrombolysis, suggesting that it could be responsible for thrombus nonresolution [20].

Case reports and anecdotal experience have suggested links between chronic thromboembolism and previous splenectomy, permanent intravenous catheters, and ventriculoatrial shunts for the treatment of hydrocephalus or chronic inflammatory conditions. In addition to these observations, associations with sickle cell disease, hereditary stomatocytosis, and the Klippel-Trenaunay syndrome have been described [21]. However, the vast majority of cases of CTEPH cannot be traced to a specific known coagulation defect or underlying medical condition.

Pathology and Pathogenesis

Although most individuals with CTEPH are unaware of a past thromboembolic or deep venous thrombosis, CTEPH likely stems from acute embolic episodes that do not completely resolve. Why some patients fail to resolve their

emboli is unclear, but a variety of factors may play a role. The volume of acute embolic material may simply overwhelm the lytic mechanisms. The total occlusion of a major arterial branch may prevent lytic material from reaching, and therefore dissolving, the embolus completely. The emboli may be made of substances that cannot be lysed by normal mechanisms. These may include organized fibrous thrombus, fat, or tumor emboli, from stomach, breast, kidney, and right atrial (myxoma) origin. The lytic mechanisms themselves may be abnormal, or some patients may have a hypercoaguable state. Hypercoagulability may result in spontaneous thrombosis within the pulmonary vascular bed, embolization, or lead to proximal propagation of embolic material. With time, the increased pressure and flow of redirected pulmonary blood flow in the previously normal pulmonary vascular bed can create a vasculopathy in the arterioles, similar to that of the Eisenmenger syndrome. This, as well as resulting right-sided heart failure, can lead to an inoperable, lethal situation, so early surgical intervention is recommended.

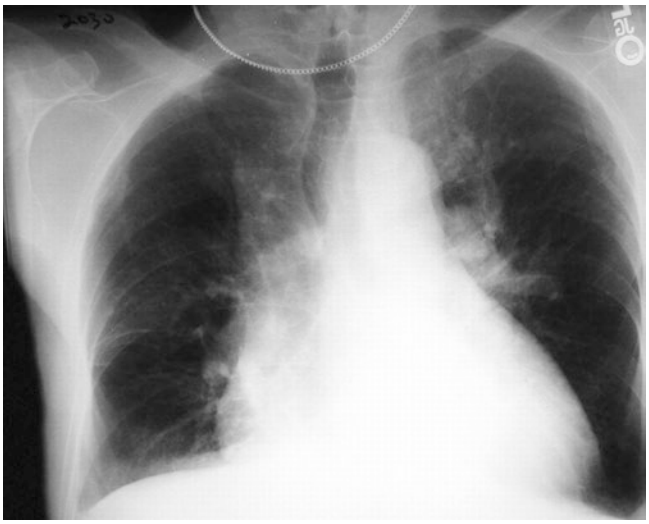

Fig. 49.1 Chest radiograph of a patient with advanced chronic thromboembolic pulmonary hypertension. Cardiomegaly, hilar fullness, and decrease in vascularity of the lung fields are apparent

Clinical Presentation

The most common symptom of CTEPH, as with pulmonary hypertension in general, is exertional dyspnea. This dyspnea is out of proportion to abnormalities found on clinical examination. Syncope is another common symptom of pulmonary hypertension, particularly in patients with advanced disease. Other common findings include chest tightness, hemoptysis, peripheral edema, and early satiety.

The physical signs of pulmonary hypertension are the same regardless of the underlying pathophysiology. Jugular venous distension is common, with prominent V waves. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Patients with advanced disease may be cyanotic. A systolic murmur characteristic of tricuspid regurgitation is common, and murmurs over the lung fields resulting from turbulent flow in the pulmonary vessels may also be appreciated.

Workup may include chest radiograph (CXR), pulmonary function testing, right heart catheterization with pulmonary angiography, high-resolution magnetic resonance imaging, arterial blood gas analysis, ventilation/perfusion scanning, and echocardiography. CXR may show lung opacities suggestive of previous scarring, hyperlucent areas suggestive of regional decreased blood flow, right-sided cardiomegaly, and dilatation of the pulmonary vessels (Fig. 49.1). Diffusing capacity (DLCO) is often reduced and may be the only abnormality on pulmonary function testing. Pulmonary arterial pressure is elevated, sometimes being supra-systemic. Resting cardiac output is often low, with reduced pulmonary arterial oxygen saturation. Many patients exhibit hypoxia, particularly with exercise; room air arterial oxygen tension ranges between 50 and 83 torr, the average being 65 torr [22]. CO_2 tension is often slightly reduced, although dead space ventilation is increased. Ventilation-perfusion studies show moderate mismatch but correlate poorly with the degree of pulmonary vascular obstruction [23].

Transthoracic echocardiography is often the first study to provide clear evidence of pulmonary hypertension. An estimate of pulmonary artery systolic pressure is often provided by Doppler of the tricuspid regurgitant envelope. Echocardiographic findings vary depending on the stage of the disease and include right ventricular enlargement, leftward displacement of the interventricular septum, and encroachment of the enlarged right ventricle on the left ventricular cavity with abnormal systolic and diastolic function of the left ventricle. Thankfully, many of these abnormalities resolve after successful PTE [24]. Contrast echocardiography may demonstrate a persistent foramen ovale, the result of high right atrial pressures opening the previously closed intra-atrial communication.

Pulmonary angiography is the gold standard for defining pulmonary vascular anatomy and is performed to confirm the diagnosis and to determine the location and surgical accessibility of thromboembolic disease. In angiographic imaging, thrombi appear as unusual filling defects, pouches, webs, or bands, or completely thrombosed vessels that may resemble congenital absence of a vessel (Fig. 49.2). More recently, high-resolution computed tomography scanning [25], SPECT-CT fusion imaging [26], and magnetic resonance angiography [27] have been used successfully to screen patients with suspected thromboembolic disease.

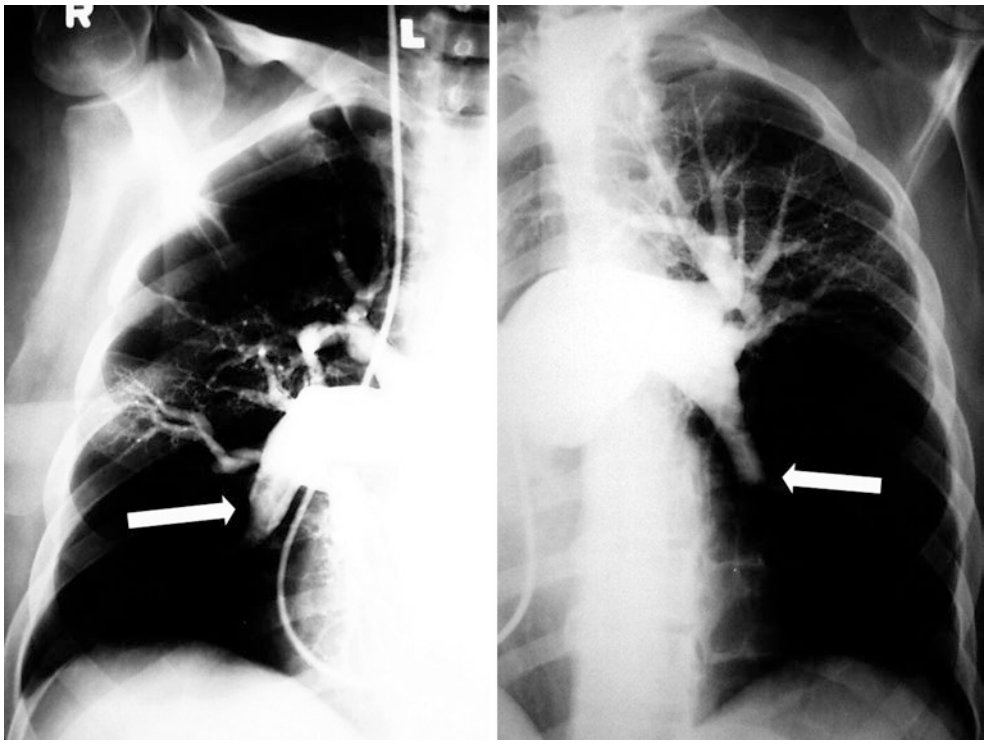

Fig. 49.2 Pulmonary angiogram showing perfusion defects (*arrows*) and large hyperlucent areas result from pulmonary vascular obstruction

In approximately 10% of cases, the differential diagnosis between primary pulmonary hypertension and distal and small vessel pulmonary thromboembolic disease remains unclear and difficult to establish. In these patients, pulmonary angioscopy is often helpful. The pulmonary angioscope is a fiberoptic scope that is placed through a central line into the pulmonary artery. The tip contains a balloon that is then filled with saline and pushed against the vessel wall. A bloodless field can thus be obtained to view the pulmonary artery wall. The classic appearance of chronic pulmonary thromboembolic disease by angioscopy consists of intimal thickening, with intimal irregularity and scarring, and webs across small vessels. The presence of embolic disease, occlusion of vessels, or the presence of thrombotic material is diagnostic.

Many CTEPH patients have longstanding pulmonary hypertension; as many as 37% of them receive medical pulmonary vasodilator therapy [28]. This therapy may consist of phosphodiesterase 5 inhibition (e.g., sildenafil) [29], endothelin-1 inhibition (e.g., bosentan) [30, 31], and prostacyclin analogs (e.g., iloprost, flolan, remodulin) [32–34]. It is prudent to continue these medications preoperatively and to consider their use postoperatively if the surgical result is suboptimal. Abrupt cessation of a prostacyclin analog can result in potentially catastrophic rebound pulmonary hypertension [35]. If a patient presents with an epoprostenol (Flolan™) infusion, one approach is to continue this infusion throughout the pre-CPB period, discontinue it during CPB, and restart it after CPB if the surgical result is suboptimal. If the surgical result is good, keep it available to be restarted if pulmonary hypertension develops postoperatively.

The Surgical Procedure

Surgical Approach and Technique

PTE, being an endarterectomy of the proximal pulmonary vascular tree, is performed through a midline sternotomy and requires cardiopulmonary bypass (CPB) with deep hypothermic circulatory arrest (DHCA). Although used in the past, lateral thoracotomy is suboptimal [36]. Median sternotomy allows treatment of both pulmonary arteries, which is necessary in almost all cases [36, 37]. The use of CPB with periods of complete circulatory arrest provides the bloodless operative field necessary for complete meticulous lobar and segmental dissections [38].

The procedure follows four basic but important principles. (1) The endarterectomy must be bilateral; therefore the approach is through a median sternotomy. (2) Identification of the correct dissection plane is crucial, and at times the plane of dissection has to be identified in each of the segmental and subsegmental branches. (3) Perfect visualization is essential, and a thorough distal endarterectomy cannot be performed without the use of circulatory arrest. Circulatory arrest is usually limited to 20 min at a time, and supported by cooling to 18 °C. (4) A complete endarterectomy all the way to the distal ends of the smallest vessels is essential.

Following median sternotomy, CPB is established with cannulation of the ascending aorta and the inferior and superior vena cava. Cooling is instituted immediately. A gradient of not more than 10 °C is maintained between the arterial blood and the bladder/rectal temperature. This allows an even distribution of cooling and warming, as well as helping to prevent release of gas bubbles into the circulation upon rewarming. Pulmonary artery and pulmonary venous vents are inserted. During the cooling phase venous oxygen saturation increases, with a saturation of 80% typical at 25 °C, and 90% at 20 °C. Hemodilution to a hematocrit of 18–25% is utilized to decrease blood viscosity, optimize capillary blood flow, and promote uniform cooling. Complete cooling typically requires 45–60 min, depending on the size and perfusion characteristics of the patient.

As core temperature approaches 20 °C and tympanic membrane temperature approaches 16–18 °C, the aorta is cross-clamped. Immediately after aortic cross-clamping, cardioplegia solution is administered into the aortic root. Additional myocardial protection is afforded by a circulating cold water cooling jacket around the heart. An incision is made in the right pulmonary artery with the surgeon standing on the patient's left. The right pulmonary artery endarterectomy plane is established and dissection continues until bronchial artery flow impairs good visualization. At this point circulatory arrest is imperative. Bronchial flow in these patients is frequently substantial and without circulatory arrest complete endarterectomy cannot be accomplished.

Circulatory arrest is limited to 20-min epochs. An experienced surgeon can usually accomplish the entire unilateral endarterectomy within this time period. If additional arrest time is necessary, reperfusion is carried out at 18 °C core temperature for a minimum of 10 min. At the completion of the endarterectomy, perfusion is reestablished, while the pulmonary artery incision is closed.

Following a 10-min period of hypothermic perfusion, the left pulmonary artery is incised, and an endarterectomy is performed. Following completion of the left endarterectomy, a patent foramen ovale (PFO), if present, is repaired. Any additional procedures such as coronary artery bypass grafting or valve replacement can be performed during the rewarming period.

Surgical Subtypes

There are five categories of pulmonary occlusive disease related to disease extent that can be appreciated. The UCSD classification system describes these different levels based on the thromboembolic specimen and corresponds to the degree of difficulty of the endarterectomy [39] (Table 49.1).

Level 0 represents no evidence of chronic thromboembolic disease present; in other words, there has been a misdiagnosis, or perhaps one lung is completely unaffected by thromboembolic disease, both of which are rare. In this entity there is intrinsic small vessel disease, although secondary thrombus may occur as a result of stasis. Small vessel disease may be unrelated to thromboembolic events ("primary" pulmonary hypertension) or occurs in relation to thromboembolic hypertension as a result of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger's syndrome. We believe that there may also be sympathetic "cross-talk" from an affected contralateral side or stenotic areas in the same lung. Level I (Fig. 49.3) disease refers to the situation in which thromboembolic material is present and is readily visible on the opening of the main left and right pulmonary arteries. A subset of level I disease, level Ic, is complete occlusion of either the left or right pulmonary artery and non-perfusion of that lung. Complete occlusion may present an entirely different disease, especially when it is unilateral and on the left side. In level II (Fig. 49.4), the disease starts at the lobar or

Table 49.1 UCSD CTE classification

Level I	Chronic thromboembolic disease in the main pulmonary arteries
Level I C	Complete occlusion of one main pulmonary artery with chronic thromboembolic disease
Level II	Chronic thromboembolic disease starting at the level of lobar arteries or in the main descending pulmonary arteries
Level III	Chronic thromboembolic disease starting at the level of the segmental arteries
Level IV	Chronic thromboembolic disease starting at the level of the subsegmental arteries
Level 0	No evidence of chronic thromboembolic disease in either lung

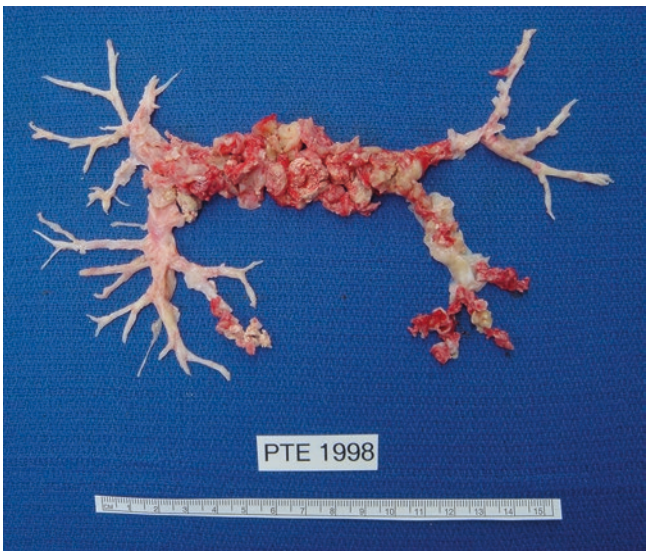

Fig. 49.3 Endarterectomy specimen of Type I thromboembolic disease. Thrombus and fibrous connective tissue were removed from much of the pulmonary vascular tree

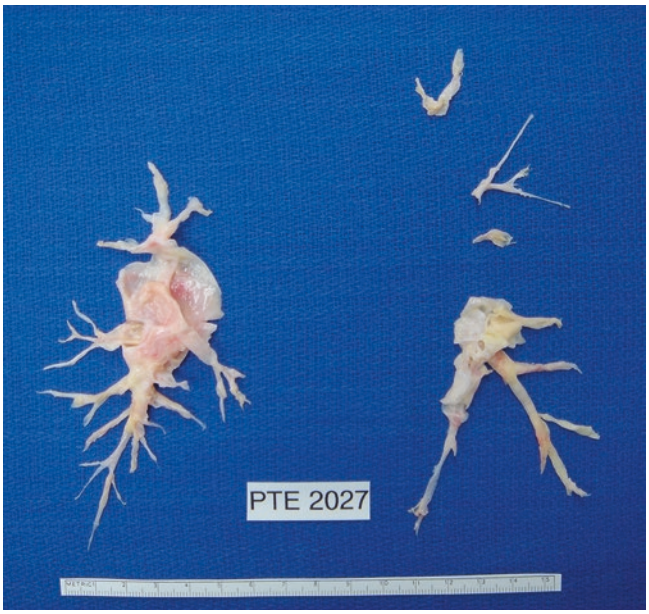

Fig. 49.4 Endarterectomy specimen of Type 2 thromboembolic disease. Fibrous connective tissue was removed from much of the pulmonary vascular tree

Fig. 49.5 Endarterectomy specimen of Type 3 thromboembolic disease. Only distal fibrous connective tissue was found at surgery

intermediate level arteries and the main pulmonary arteries are unaffected. Level III (Fig. 49.5) disease is limited to thromboembolic disease originating in the segmental vessels only. Level IV (Fig. 49.6) is disease of the subsegmental vessels, with no other disease appreciated at more proximal levels. Level III and level IV disease present the most challenging surgical situation. The disease is very distal and confined to the segmental and subsegmental branches.

Fig. 49.6 Endarterectomy specimen of Type 4 thromboembolic disease. Only subsegmental fibrous connective tissue was found at surgery

Anesthetic Management

Setup and Preparation

A typical "setup" for a pulmonary endarterectomy includes preparation for transesophageal echocardiography (TEE), pulmonary artery catheterization, hemodynamic support, cerebral function monitoring, and a cooling device for head cooling. On the day of surgery, a large bore peripheral intravenous catheter and a radial arterial catheter are inserted. The patient may then be given light sedation (with caution) and brought to the operating room. Even small amounts of sedation may cause respiratory depression, leading to a catastrophic rise in pulmonary vascular resistance. Supplemental oxygen should be considered in the preoperative area, particularly if sedation is administered.

Anesthetic Induction and Pre-CPB Management

After thorough preoxygenation and ventilation encouragement, anesthetic induction can be accomplished with midazolam, fentanyl, and a muscle relaxant. Myocardial depressants such as propofol should be used with extreme caution, if at all. In cases of tenuous hemodynamics,

etomidate may be useful because of its relative lack of cardiovascular depression. A pulmonary artery catheter is generally placed after induction rather than before, since the hemodynamic status and goals are usually known by the time the patient reaches the operating room. Also, lying awake in the supine or Trendelenburg position may be stressful for patients with advanced disease, occasionally leading to cardiorespiratory instability. If preoperative transthoracic echocardiography shows evidence of right atrial or right ventricular thrombi, TEE is performed immediately after induction, prior to placement of a pulmonary artery catheter.

Although some patients with CTEPH presenting for pulmonary endarterectomy have associated left ventricular pathology, most do not. Hemodynamic management is thus centered on right ventricular function. The right ventricle is usually hypertrophic and dilated, as is the right atrium. Because of the high right-sided pressures, the coronary blood supply to right ventricle is at risk. Maintenance of adequate systemic vascular resistance (SVR), inotropic state, and normal sinus rhythm serve to preserve systemic hemodynamics as well as right ventricular coronary perfusion. The preoperative cardiac catheterization data, including cardiac output, pulmonary vascular resistance (PVR), patency of coronary arteries, and right ventricular end-diastolic pressure (RVEDP) are useful in planning the induction sequence. Elevated RVEDP (>14 mmHg), severe tricuspid regurgitation, and preoperative PVR > 1000 dyne-s-cm^{-5} are signs of impending decompensation. In such cases inotropic support (e.g., dopamine or epinephrine), as well as vasopressor support (e.g., phenylephrine or vasopressin), should be considered for the induction and pre-CPB period. Generally, patients with CTEPH have fixed PVR because of mechanical obstruction. However, high PVR can still be exacerbated by factors that increase PVR (e.g., hypoxia, hypercarbia, acidosis, pain, and anxiety). Thus, these stressors should be minimized during induction and immediate pre-CPB period. Attempts to lower the PVR pharmacologically (e.g., nitroglycerin, nitroprusside) should be avoided as they have minimal efficacy in treating CTEPH and can dangerously jeopardize the coronary perfusion pressure to the right ventricular myocardium. This can rapidly lead to hypotension and cardiovascular collapse. Direct pulmonary vasodilators such as nitric oxide and prostaglandins, which may be useful in the medical management of patients with other types of pulmonary hypertension, generally show limited benefit for pulmonary endarterectomy patients in the perioperative period. The effects of phenylephrine on right ventricular performance in pulmonary hypertension has been studied by Rich et al. [40] They documented improved right ventricular performance (increased MAP, coronary artery perfusion pressure, maintained cardiac output) with phenylephrine administration. Since hemodynamic collapse can occur very rapidly in these patients, it is particularly important to treat decreases in blood pressure and heart rate rapidly and aggressively. The muscle relaxant is chosen according to airway issues and desired hemodynamic response. Pancuronium, rocuronium, and vecuronium have all been used successfully in these patients.

If the superior vena cava is patent, an internal jugular introducer and pulmonary artery catheter are inserted. Placement of the pulmonary artery catheter may be difficult because of right atrial and right ventricular dilatation, as well as tricuspid regurgitation and pulmonary artery pathology. Transesophageal echocardiography has been shown to be helpful in the live guidance of pulmonary arterial catheter placement in CTEPH patients [41].

Next, a femoral arterial catheter is placed. This is because, in cases involving prolonged hypothermic CPB, the systemic arterial pressure is significantly underestimated by the radial artery catheter in the post-CPB period [42]. This phenomenon has been noticed by others [43] and appears to be accentuated by prolonged periods of profound hypothermia. It is not uncommon for a mean arterial pressure (MAP) gradient of as much as 20 mmHg to develop after CPB. The mechanism is unclear; causes involving peripheral vasoconstriction and vasodilatation have been proposed [44]. Although the time course for recovery of the radial arterial wave is variable, typically the radial and femoral pressure measurements show reasonable agreement by the morning following surgery [42].

TEE is valuable in monitoring and assessing cardiac function and filling during PTE. The most useful views include the transgastric mid-papillary short-axis view to assess left ventricular size and septal motion (Fig. 49.7; Video 49.1); the midesophageal four-chamber view for relative chamber sizes, intracardiac thrombus, and tricuspid valve assessment (Fig. 49.8; Video 49.2); the midesophageal bicaval view (interatrial septal integrity, thrombosis of the great veins); and the midesophageal ascending aortic short-axis view for

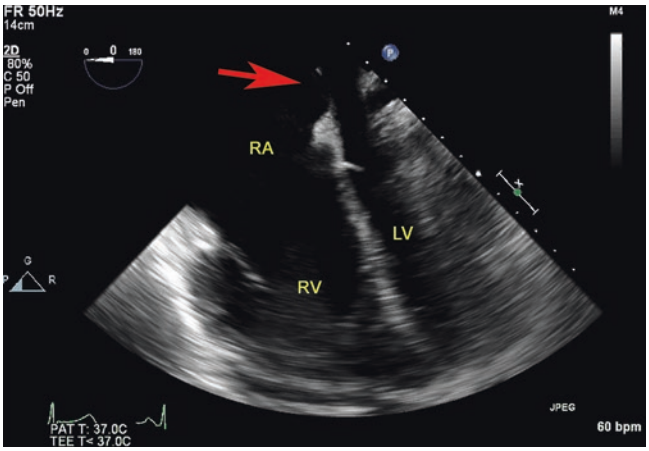

Fig. 49.8 Midesophageal four-chamber view in a PTE patient with a severely dilated right atrium and right ventricle. Note the shifted interventricular septum and interatrial septum (*red arrow*) as well as the underfilled left heart. RA right atrium, RV right ventricle, LV left ventricle

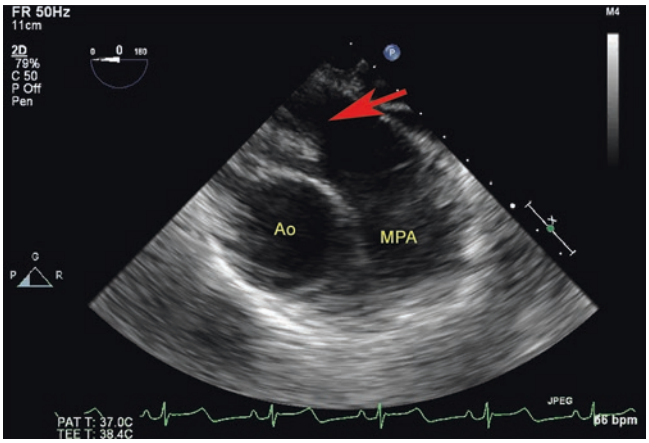

Fig. 49.9 Midesophageal ascending aortic short-axis view demonstrating thromboembolic material at the origin of the right pulmonary artery (*red arrow*). Ao ascending aorta, MPA main pulmonary artery

size of the pulmonary artery (PA) and detecting PA thrombus. It is not uncommon to find substantial dilatation of the PA, as well as thromboembolic material (Fig. 49.9; Video 49.3). The integrity of the interatrial septum is investigated with the use of an agitated saline test. PFO is present in 25–35% of PTE patients [45]. If a PFO is present, it is repaired, since, postoperatively some patients may experience high right-sided pressures. Such pressures, in the presence of a PFO, could lead to right-to-left shunt and hypoxemia.

Processed electroencephalogram (EEG) is monitored throughout the procedure. This allows confirmation of minimal oxygen utilization of the brain prior to circulatory arrest (isoelectric EEG), as well as monitoring of level of consciousness during normothermia. In our institution the SedLine monitor (Masimo, Irvine, CA), a four-channel processed electroencephalograph monitor, provides monitoring of the isoelectric electroencephalogram and confirmation of minimal oxygen utilization of the brain before circulatory arrest. Temperature monitoring is accomplished with a urinary catheter with temperature monitoring capabilities, a rectal probe, and tympanic membrane probe, which provides an estimation of brain temperature [46]. The rectal and bladder probes estimate core temperature, and the PA catheter measures blood temperature, allowing quantification of thermal gradients.

During the precardiopulmonary bypass period, the head is wrapped in a circulating cold water blanket. The water, maintained at 4 °C, is circulated through the blanket by an electric pump. This system (Polar Care, Breg, Inc., Vista, CA), originally designed as a "knee wrap" for orthopedic and physical medicine purposes, is easily applied to the head. It contains a thermometer within the fluid circulation system for confirmation of adequate blanket cooling, as well as a flow control dial. This head wrap is used in all PTEs at UCSD, with no complications. It is our belief that the blanket provides better cooling to the surface of the cranium, particularly posterior regions, than application of ice bags, and is easier to apply.

If the hematocrit and hemodynamics permit, 1–2 units of autologous blood are harvested for reinfusion after CPB. Another consideration is prior exposure and response to heparin. Because of prior exposure, some patients develop heparin-induced antiplatelet antibodies, causing a propensity to heparin-induced thrombocytopenia. Anticoagulation for these patients has been managed with preheparin administration of iloprost (a prostacyclin analog), heparinoid [37, 38], hirudin, and bivalirudin [47, 48]. Most recently, we have had success using the platelet-inhibitor tirofiban [49, 50].

Management of Deep Hypothermic Circulatory Arrest (DHCA)

Prior to DHCA mannitol (12.5 g), methylprednisolone sodium succinate (30 mg/kg; maximum dose of 3 g), and phenytoin sodium (15 mg/kg) are administered. Mannitol is used to promote an osmotic diuresis, minimize cellular edema, and for free radical scavenging. Methylprednisolone theoretically functions as a cell-membrane stabilizer and anti-inflammatory agent. Phenytoin may provide some protection against postoperative seizures. Historically sodium thiopental (6 mg/kg) was administered as a cerebral protection agent. Due to sodium thiopental's lack of commercial availability, propofol (2.5 mg/kg) is utilized to ensure complete isoelectricity immediately prior to instituting deep hypothermic circulatory arrest. While there is no clear clinical evidence supporting added benefit of propofol or barbitu-

rate administration for DHCA, we give propofol for three reasons: (1) brain cooling may be uneven or incomplete, (2) cerebral emboli may occur during rewarming (pulmonary endarterectomy is an "open-chamber" procedure), and (3) even at 18 °C we often notice sparse EEG activity which is then abolished with administration of propofol.

After assurance of an isoelectric EEG, tympanic membrane temperature 18 °C or less, and a bladder or rectal temperature of 20 °C or less, circulatory arrest is instituted. At this time, all monitoring lines are turned off to the patient, decreasing the risk of entraining air into the vasculature during exsanguination. The duration of DHCA is limited to 20 min epochs, typically one epoch per left and right pulmonary endarterectomy, respectively. If additional time is needed on either side, hypothermic circulation is reestablished for 10 min prior to additional periods of DHCA.

Monitoring jugular venous bulb oxygen saturation may be useful in detecting adverse cerebral effects of rapid warming [51] or for prognosticating postoperative neurologic function [52]. However, since our warming rate is slow, and our neurologic results are good, we choose not to expose our patients to the added risks of jugular venous bulb catheterization. Surface cerebral oximetry is a noninvasive technique applying near-infrared spectroscopy to measure hemoglobin oxygen saturation in the brain underlying the sensor. The number reported by the monitor is rSO_2, which is a measure of the mixed arterial and venous blood in the brain. Since venous blood volume accounts for 70–90% of total cerebral blood volume, rSO_2 reflects oxygen saturation of venous blood and thus the relationship between cerebral oxygen metabolism (demand) and cerebral blood flow (supply). In healthy volunteers, rSO_2 has been found to correlate with jugular venous saturation [53, 54], although, during cardiac surgery, the correlation between the two monitors is not always close [55]. Ongoing research in this area and additional neuropsychiatric outcome studies may prove this monitor useful during the conduct of DHCA.

Post-DHCA Rewarming

A 10° gradient between blood and bladder/rectal temperature is not exceeded during rewarming, and the perfusate temperature is never greater than 37.5°. Warming too quickly promotes systemic gas bubble formation, cerebral oxygen desaturation, and uneven warming. Rewarming times are variably related to the patient's weight and systemic perfusion; 90–120 min is usually required to achieve a core temperature of 36.5 °C. Adequate and even rewarming aims to prevent "after-drop", whereby uneven rewarming redistributes post-CPB leading to a drop in temperature with the attendant risks of hypothermia.

Separation from CPB

With the following few exceptions, the process of separation from CPB is similar to other surgeries involving CPB. End-tidal carbon dioxide ($ETCO_2$) is a poor measure of ventilation adequacy in these patients both pre- and post-CPB, since dead space ventilation is an integral part of the disease process. After successful surgery, the arterial-$ETCO_2$ gradient may be decreased compared to preoperative values, but the time course for this improvement is variable often with weeks to months for complete resolution. Aggressive hyperventilation is utilized due to the metabolic acidosis that may occur from cardiopulmonary bypass, hypothermia, and deep hypothermic circulatory arrest. The anesthesiologist checks the endotracheal tube for frothy sputum or bleeding because reperfusion pulmonary edema and airway bleeding, two of the most dreaded complications of the procedure, may manifest at this time [56]. Suction of the endotracheal tube during rewarming (while the surgical PA vent remains in place) allows the early identification of bleeding prior to pressurization of the pulmonary arterial circuit. While still on CPB, the TEE is used to detect intracavitary air as well as to evaluate left and right ventricular function.

For separation from CPB, modest inotropic support (e.g., dopamine, 3–7 μg/kg/min) is often necessary because of the long hypothermic period and long aortic cross-clamp time. In patients with particularly poor ventricular function epinephrine 0.04–0.15 μg/kg/min is added. Discussion with the surgical team regarding CTEPH classification and the success of the endarterectomy should occur prior to separation. If the surgery has only been partially successful because of small vessel disease, pulmonary vasodilators such as milrinone, intravenous prostacyclin, and nitric oxide are considered. If the surgery has been successful, the TEE reveals immediate improvements in the left- and right-sided geometry [57, 58]. The distention of the right atrium and right ventricle is greatly decreased, resulting in improvement of function of both ventricles (Fig. 49.10a, b; Videos 49.4 and 49.5). Tricuspid regurgitation, if it was present before the endarterectomy, has greatly decreased or resolved. Significant improvement in hemodynamic status is usually noted, including a doubling of the cardiac index, dramatic decrease in PA pressures, and a drop in the PVR to 25% of the preoperative value [4].

Post-CPB Management

After heparin reversal, bleeding diathesis is rare, and transfusion requirements are usually minimal [4]. Antifibrinolytic agents such as ε-amino-caproic acid are not routinely used for pulmonary endarterectomy in our institution. Two procedure-related complications may potentially present

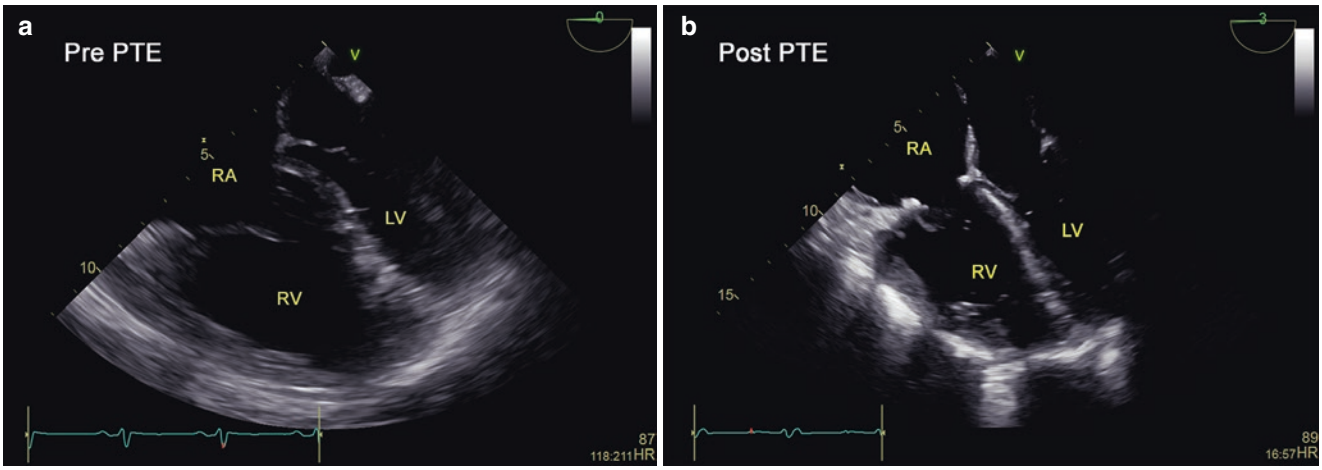

Fig. 49.10 (**a**) Midesophageal four-chamber view in a patient with CTEPH prior to pulmonary thromboendarterectomy. Note the dilated right heart, deviated septums, and underfilled left heart. RA right atrium, RV right ventricle, LV left ventricle. (**b**) Midesophageal four-chamber view of the same patient status post-pulmonary thromboendarterectomy and tricuspid valve repair. Note the decompression of the RA and RV with increased left heart size. RA right atrium, RV right ventricle, LV left ventricle

themselves immediately upon separation from CPB. Pink frothy sputum, if present, likely indicates the onset of reperfusion pulmonary edema. In this case, the endotracheal tube is suctioned, and increasing amounts of positive end-expiratory pressure (PEEP) are applied beginning with 5 cmH_2O escalating to 8 and 10 cmH_2O. The volume of pulmonary edema can be profound requiring frequent anesthesia circuit changes and maintenance of high levels of PEEP. If oxygenation and ventilation are significantly impaired, the resultant hypoxia and hypercarbia can lead to worsening RV dysfunction. Venovenous extracorporeal membrane oxygenation may be considered to improve the hypoxia and hypercarbia.

Secondly, if frank blood is emanating from the endotracheal tube, disruption of the blood-airway barrier has likely occurred secondary to surgical injury. The approach to this clinical scenario often begins with the surgeon's high index of suspicion of adventitial disruption. Prior to pressurizing the pulmonary arterial circuit via reduction of the PA vent, the anesthesiologist should pass an airway suction catheter. Identification of blood in the endotracheal tube warrants a fiberoptic bronchoscopy. If identification of pulmonary hemorrhage occurs after pressurization of the pulmonary arteries during cardiac ejection, localization of the culprit segment may be difficult. With the assistance of the surgical team and perfusionist, a slow reinstitution of cardiac ejection while concurrently visualizing via bronchoscopy can identify the specific lesion location. Management subsequently includes lung or lobar isolation via bronchial blocker placement, PEEP, separation from CPB, reversing anticoagulation, and treatment of coagulopathy. Assuming adequate oxygenation, ventilation, and coagulation, bronchial blocker balloon deflation may occur under direct fiberoptic visualization [59].

Significant pulmonary hemorrhage may lead to inadequate oxygenation, ventilation, and potential subsequent cardiac dysfunction prompting the use of various methods of extracorporeal life support. The choice of support depends upon the clinical scenario as outlined in the algorithm in Fig. 49.11. With preserved cardiac function, oxygenation and ventilation may be assisted via venovenous extracorporeal membrane oxygenation (ECMO). Utilization of the Avalon Elite Bicaval Dual-Lumen Catheter (Maquet, Rastatt, Germany) via the right internal jugular vein allows the institution of venovenous ECMO with minimal or no anticoagulation, an advantage in the setting of massive pulmonary hemorrhage [59]. As RV dysfunction develops, ECMO may be employed with right atrial inflow and pulmonary arterial outflow. Lastly if biventricular failure ensues, venoarterial ECMO may be employed.

Postoperative Management

Intensive care unit management is similar to other post-cardiac surgical patients with a few exceptions. Two major postoperative complications unique to PTE that can present in the ICU are reperfusion pulmonary edema and pulmonary arterial steal. Reperfusion pulmonary edema is a localized form of high-permeability (noncardiogenic) lung injury, a form of adult respiratory distress syndrome, localized to the area of lung having received the endarterectomy. It usually occurs within the first 24 h but may appear up to 72 h following PTE [60]. In most cases it is mild; reperfusion edema resulting in clinically significant morbidity occurs in only 10% of cases. In its most severe form, it begins immediately post-CPB, in the operating room as described above.

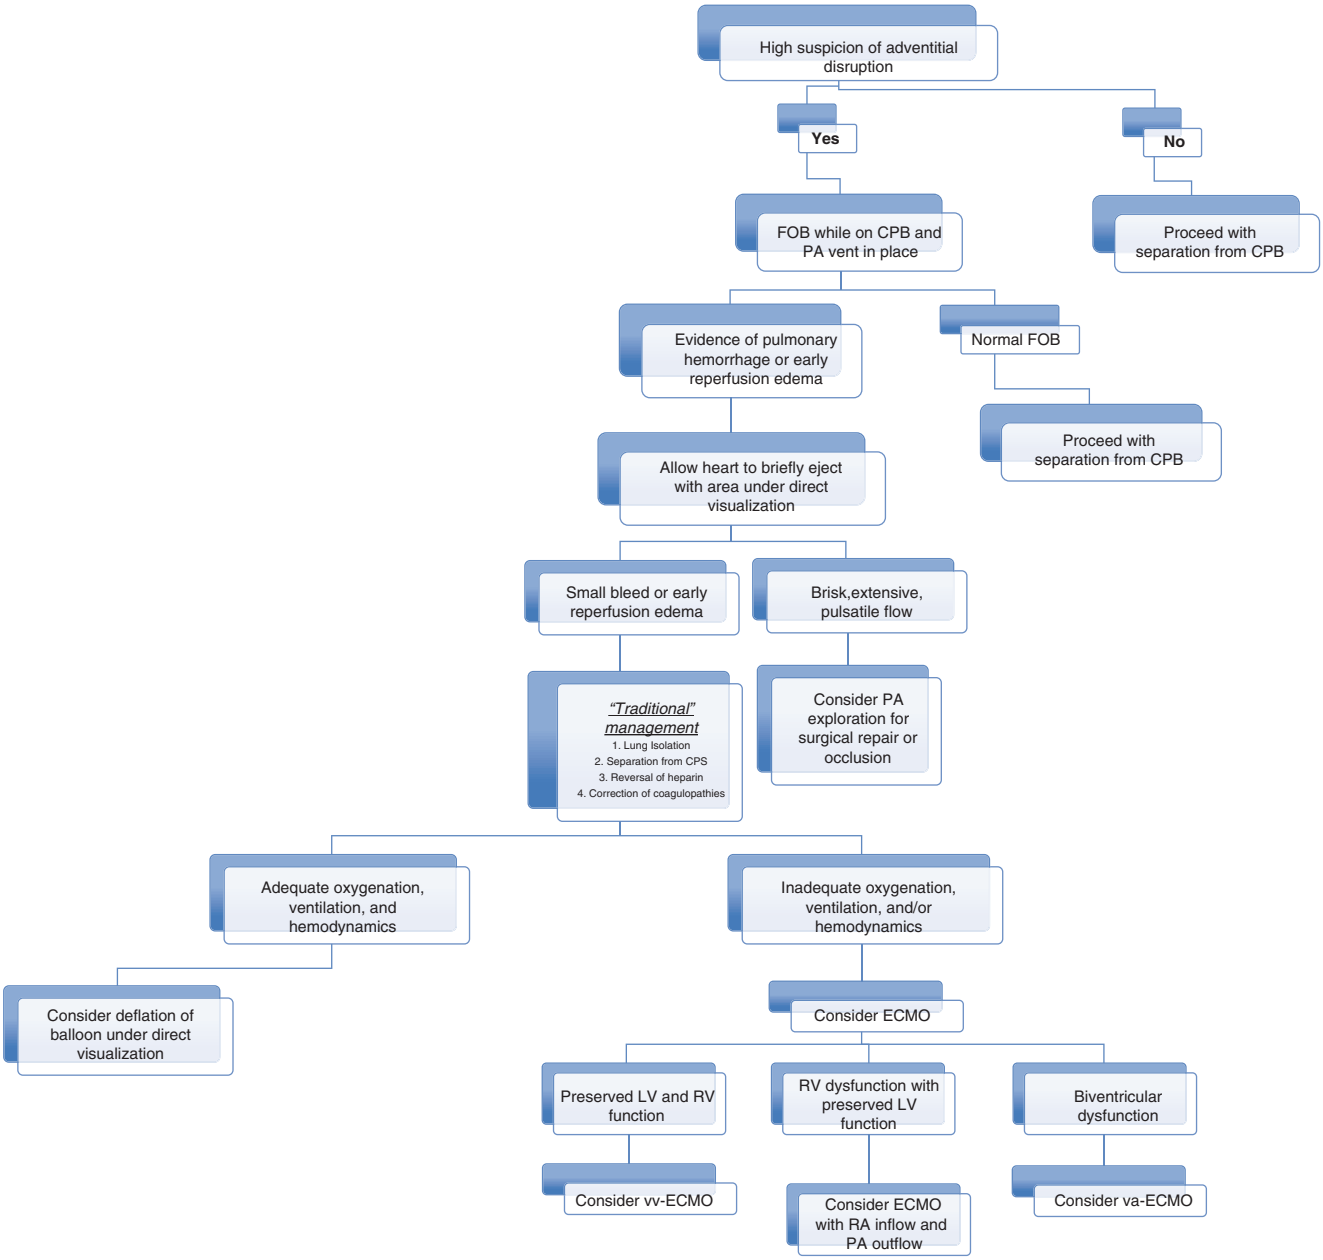

Fig. 49.11 Algorithm for the management of post-pulmonary thromboendarterectomy pulmonary hemorrhage. CPB cardiopulmonary bypass, FOB fiberoptic bronchoscopy, ECMO extracorporeal membrane oxygenation, LV left ventricular, PA pulmonary artery, RA right atrial, RV right ventricular, va venoarterial, vv venovenous. (Reprinted with permission from Cronin et al. [59])

These patients are often extremely ill, requiring aggressive intensive care and ventilator management. Pressure control, PEEP, and inverse ratio ventilation are used judicially in an effort to improve *V*/*Q* matching and minimize further pulmonary injury. Occasionally extracorporeal support is required [61, 62]. Pulmonary arterial steal represents a postoperative redistribution of pulmonary arterial blood away from the previously well-perfused segments into the newly endarterectomized segments [63]. Whether the cause is failure of autoregulation in the newly endarterectomized segments or secondary small vessel, changes in the previously open segments have not been clarified. However, long-term follow-up has documented a decrease in pulmonary vascular steal in the majority of patients, suggesting a remodeling process in the pulmonary vascular bed [64].

Other postoperative complications are rare but can include pulmonary hemorrhage (0.4%), neurologic sequelae (0.4%), mediastinal bleeding (3.5%), GI bleeding (1.6%), atrial fibrillation (2.6%), renal failure requiring renal replacement therapy (1%), and sepsis (1.2%) [65].

PTE patients usually awaken within 1–2 h after surgery, and a brief neurologic examination is performed. The patient is then sedated with a propofol infusion and analgesics. They remain intubated overnight, since the onset of reperfusion pulmonary edema may be delayed. If pulmonary, cardiac, and neurologic function is good, and there is no bleeding diathesis, extubation occurs the following morning. Discharge from the intensive care unit typically occurs on the second or third postoperative day, and the patients are usually discharged from the hospital 1 week after the operation.

Outcome After PTE

There has been steady improvement in mortality rate at UCSD since 1980, with current perioperative mortality rate being less than 3% (Fig. 49.12). We believe these result from improvements in preoperative preparation, surgical technique, anesthetic care, perfusion technique, and postoperative management. The positive effect of experience, in the form of case volume, on outcome has been well documented for other types of complicated surgery, such as liver transplantation [66]. In addition, we have developed close collaboration between the Pulmonary Medicine, Cardiac Surgery, and Anesthesiology departments. This "team approach," we believe, is absolutely essential to a successful PTE program.

With this operation, a reduction in pulmonary pressures and resistance to normal levels and corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained [65, 67, 68]. Mortality rate and improvements in hemodynamics depend heavily on surgical subtype, with CTEPH Type 1 and 2 fairing better than Types 3 and 4. Type 0, not being CTEPH but rather small vessel disease, is associated with poor outcome [65]. There is a trend of patients presenting with more segmental and subsegmental disease as identified by Madani et al [69]. Despite a trend of patients presenting with more distal disease with its attendant increased surgical complexity, our experience continues to demonstrate a dramatic reduction in pulmonary arterial pressures and pulmonary vascular resistance (Table 49.2). Patients who have undergone a successful PTE enjoy long-term benefit. Typically patients preoperatively present as New York Heart Association (NYHA) class III or IV and often maintain NYHA I and II function indefinitely following the operation [70].

Table 49.2 Preoperative/postoperative hemodynamic results and operating times

Variable	Group 1 (n = 1000)	Group 2 (n = 500)	p value
PVR (dynes/sec/cm^{-5})			
Preoperative	861.2 ± 446.2	719.0 ± 383.2	< 0.001[a]
Postoperative	294.8 ± 204.2	253.4 ± 148.6	< 0.001[a]

Future

While surgical management of CTEPH continues to be the proven mainstay of treatment, there are continued advances both in medical management and percutaneous treatments of these patients. Adempas® (Riociguat) is an FDA-approved drug which acts via guanylate cyclase and nitric oxide; the drug is a pulmonary vasodilator specifically indicated for the treatment of residual or recurrent pulmonary hypertension after PTE or those with inoperable CTEPH. Its role and the role of other pulmonary vasodilators (i.e., phosphodiesterase inhibitors, endothelin antagonists, prostaglandins, etc.) in the treatment are continuing to be elucidated. The exact role of medical management prior to surgical PTE still remains unknown.

The experience with percutaneous balloon pulmonary angioplasty (BPA) has continued to grow either as an alternative to those patients with surgically inaccessible CTEPH or those with high perioperative risk due to comorbidities. Reperfusion pulmonary edema and pulmonary vascular injury remain concerns with this percutaneous technique as well. The exact role of BPA in the management of CTEPH patients requires further study.

Research to determine the etiology of CTEPH, as well as the mechanisms and factors leading to reperfusion pulmonary edema, vascular steal, and ischemic neurologic injury continues. Understanding these processes will most likely lead to improved prophylaxis and treatment. Anesthesiologists, in particular, will be an integral part of future research on the immediate perioperative period. This will include efforts to improve the management of residual "small vessel disease," right ventricular failure, cerebral function and oxygenation monitoring, postoperative pulmonary edema, pulmonary bleeding, and organ protection.

Clinical Case Discussion

Case: A 68-year-old woman with CTEPH underwent a PTE and has just been separated from CPB. The surgeon tells you that the endarterectomy was difficult because it was Type 3 disease and the thromboembolic material was particularly "sticky." You suspected such because the surgeon required two circulatory arrests on the right side, and he usually requires only one on each side. Large amounts of dark blood appear in the endotracheal tube as you begin ventilating.

Questions

- What is the most likely cause of this bleeding?
- What diagnostic maneuvers can be performed to determine the cause and location of the bleeding?
- What are the therapeutic options, and how will they be chosen?

The most likely cause is surgical trauma, puncture of the distal pulmonary arteries resulting from aggressive endarterectomy. Other possibilities include nonsurgical PA rupture (high pressure, PA catheter trauma). Initial maneuvers include reinstitution of CPB including decompression of the pulmonary arterial tree with a PA vent, thereby temporarily reducing the amount of airway bleeding. Fiberoptic bronchoscopy can assist in localizing the site of the bleeding. Smaller bleeds may be managed with lung isolation, separation from CPB, reversal of heparin, as well as correction of coagulopathies. Lung isolation techniques include double-lumen tubes and bronchial blockers. A preferred technique is to exchange the endotracheal tube for a larger size (i.e., 9.0 mm ETT) to allow a bronchial blocker and a larger adult-sized bronchoscope simultaneously. The use of a pediatric size scope yields a smaller suction channel. Attempts to place the bronchial blocker in a subsegment if possible should be sought to maximize the amount of salvaged lung and prevent spillage of blood into the remaining segments. Larger pulmonary hemorrhage events or those associated with worsening hypoxia and hypercarbia may require ECMO. The decision for the method of ECMO rests on the hemodynamic status of the patient with TEE evidence of ventricular dysfunction playing a key role. Assuming biventricular function is intact, venovenous ECMO may be instituted via a single cannula placed percutaneously through the right internal jugular vein. This approach allows for ECMO support with minimal anticoagulation [59]. An algorithm for management of post-CPB hemorrhage is presented in Fig. 49.11.

Part XII

Anesthesia for Pediatric Thoracic Surgical Procedures

Anesthesia for Pediatric Thoracic Surgery

50

Robert Schwartz and Cengiz Karsli

Key Points

- Pediatric patients present in varying stages of development, from the premature neonate to full-grown teenager. Appreciation of the unique physiologic states associated with the different stages of development will direct anesthetic management.
- Preoperative evaluation of the small child should include the neonatal history as this may indicate comorbid pulmonary and cardiac disease and linked syndromes which must be investigated.
- Lung isolation is not always necessary in pediatric thoracic surgery. Appropriate lung isolation techniques will depend on the age and size of the patient as there is no single technique that is suitable for all pediatric patients.
- Physiologic manifestation of one-lung ventilation may be more pronounced in children than in adults. The compliant rib cage, compressible lung parenchyma, reduced FRC under anesthesia, and higher oxygen consumption in the child contribute to aggravate hypoxemia during lung isolation.
- Adult thoracic surgery is often related to tumor excision, whereas pediatric thoracic disease encompasses a greater variety of pathology. Each specific disease state has its own particular anesthetic considerations and management strategy.
- Pain management in the pediatric population has evolved to include a greater use of regional and neuraxial techniques, even in the smallest of infants.
- Postoperative disposition will depend on the type and length of surgery, extent of resection or manipulation, and nature of the underlying condition. Many pediatric patients will require postoperative ventilation or close cardiorespiratory monitoring following the procedure.

Introduction

Pediatric and neonatal thoracic anesthesia begins with an understanding of the physiologic and anatomic differences that occur in this patient population. Pediatric patients will present in varying sizes and weights from less than 1 kg to greater than 100 kg and in varying stages of development from the extremely premature to the older teenage child. It is therefore the requirement of the pediatric anesthesiologist to understand the physiologic differences associated with these extremes and how they influence anesthetic management.

The determinants of these physiologic restraints and the practicality of securing ventilation and oxygenation will often dictate both the anesthetic management and the surgical approach. Unlike the adult population where one-lung isolation can almost universally be applied, in much of the neonatal population, this can be at best a harrowing challenge or even an impossibility. As well, securing invasive monitors such as arterial or central venous lines may be problematic in the pediatric population. This means that the pediatric anesthesiologist must appreciate the compromise that arises due to the nature of the patient and procedure and yet be flexible and knowledgeable enough to safely carry out the anesthetic management. Postoperative pain management

and monitored postoperative disposition may differ significantly from that of the adult population and depend largely on the disease process, surgical intervention, and the physiologic maturity of the patient. Thoracoscopic procedures continue to be applied to smaller and younger patients with their own set of unique challenges and hazards.

The purpose of this chapter is to provide the anesthesiologist with the basic physiologic and anatomic characteristics associated with this patient population and how these differences are practically managed. A general discussion on the cardiopulmonary development of the pediatric patient will be presented; however, specialty texts should be sought for in-depth coverage of this topic. Case presentation and examples will be used where possible to provide the reader with a practical approach to common pediatric thoracic procedures. The understanding and practice of these techniques should then enable the pediatric anesthesiologist to apply this knowledge to more complicated and challenging cases.

Pediatric Growth and Development

Normal embryonic development begins at the time of conception and continues throughout the first 8 weeks of life. During this period of time, fetal cells will divide and begin the process of organogenesis. By the fourth week of embryonic development, the primitive heart and lungs appear. At this point neurulation also begins, a process that will see the eventual creation of the brain and spinal cord.

From this early lung, the trachea and bronchial tree will emerge, and by the eighth week of life, the segmental bronchi and diaphragm are complete. In the following months, the airways will canalize, and surfactant will be produced. Although lung maturation will continue post delivery, it is generally accepted that by the 27th week of gestation, fetal lung maturity is sufficient to sustain ex uterine life.

Similarly the heart tube which began to beat at approximately day 22 will undergo a series of foldings and septate formation such that the four-chambered heart will be complete at the eighth week of gestation. Shortly thereafter, the valves separating these chambers will also form. Once the process of organogenesis is complete, the remainder of fetal development is devoted to an increase in cell numbers and the maturation of these organs. Intestinal rotation will proceed as well as a significant increase in overall size and weight. Interruption of this normal developmental pathway can have significant impact on the fetus. Teratogens acting at the time of organogenesis can impact organ formation. Abnormal morphogenesis may lead to cleft palate and congenital diaphragmatic hernia (CDH) among others. Chromosomal abnormalities, those that are not lethal, may have a cluster of symptoms that when grouped together form the basis of pediatric syndromes. As well the problems associated with premature infants (born <37 week GA) are almost entirely due to the immature nature of the fetal organ systems.

Lung and airway maturation continues until approximately the eighth year of life, during which time the number and size of alveoli steadily increase. Transition from intrauterine to the extrauterine environment will see the replacement of the previously fluid-filled alveoli with air as the first breaths are taken. The oxygen-Hb dissociation curve will begin to transition rightward as the alveolar oxygen partial pressure increases from that of intrauterine life.

The anatomic changes that the airway undergoes from that of the neonate to infant and onward to adulthood have been well described. The glottic opening is typically located at the level of the third cervical vertebra as opposed to C4–C5 in adults. In addition, the tongue is relatively large, and the epiglottis is long and floppy in infants up to 1 year in age. As a result the entire tongue of the neonate and infant is located in the oral cavity, whereas only the anterior two thirds of the tongue in older children and adults occupy the oral cavity. This accounts for the propensity to upper airway obstruction in neonates and infants who are sedated, have decreased level of consciousness, or during anesthetic induction. Until 7 or 8 years of age, the tracheal diameter at the level of the cricoid cartilage is narrower than that at the vocal cords, resulting in a conical larynx. A tracheal tube that passes through the vocal cords may not necessarily then pass through the cricoid ring. A relatively large head, short neck, and trachea mean that tracheal intubation, although not typically difficult, requires a subtly different technique than that used in the adult patient.

As the lungs fill with air during the first moments of extrauterine life, pulmonary vascular resistance (PVR) will fall and cause a dramatic increase in pulmonary blood flow. As PaO_2 rises, the ductus arteriosus will constrict and usually fully closes by the end of the first week of life. Left-sided cardiac pressures will rise and close the foramen ovale. The myocardium of the neonate is relatively noncompliant and cannot adjust contractility in response to changes in filling pressures. The cardiac output in the neonate is thus dependent on HR, and the normal heart rate is typically between 100 and 150 bpm.

Relative body composition changes also occur during the first year of life. The highest percent body fat is at 1 year of age (approximately 30%) and typically decreases throughout adult life. Total body water (as a percentage of body weight) is highest at birth (75%) and drops to adult (60%) levels by 1 year of age. The estimated blood volume (as a percent of body weight) also decreases. Term infants typically have an estimated blood volume of 95 mL/kg, whereas by 1 year of age, it has decreased to 65 mL/kg. In addition to this, the fluid, electrolyte composition, energy requirements, hematologic system, and vital signs all change significantly

throughout the various stages of growth. The pediatric anesthesiologist's understanding of these changes will necessarily guide the management of the patient as drug dosages, ventilation parameters, and equipment must be adjusted for the age and maturation of the patient.

Special Considerations

Prematurity

Premature infants have several unique features that will briefly be addressed here. In-depth coverage of this topic can be found in any neonatal or pediatric specific anesthesia text.

Fetal surfactant is produced by type II pneumocytes at approximately the 22nd week of gestation. Half of this production is usually complete by the 28th week, with the remainder by the 37th week. Steroid administration to the mother can speed up this process. Deficiency in surfactant production may result in respiratory distress syndrome (RDS) [1]. The constellation of tachypnea, indrawing, and oxygen desaturation results from collapse of alveoli caused by insufficient surfactant levels. This leads to decreased lung compliance, higher opening pressures, decreased FRC, and increased work of breathing. Arterial blood gas analysis will often reveal hypoxemia, hypercarbia, and acidosis.

The early management of RDS consists of oxygenation and assisted ventilation in the form of noninvasive CPAP/BIPAP [2–4]. Exposure to high oxygen concentrations may lead to retinopathy of prematurity (ROP) and other complications in these patients, although the role of anesthetic agents in causing ROP remains undefined. Balancing the need to avoid tissue hypoxemia and avoiding the toxic effects of oxygen can be challenging. Prudence would seem to suggest that using the lowest possible FiO_2 to maintain adequate tissue oxygenation is advisable. Oxygen therapy is often adjusted to achieve an oxygen saturation of 90–95% [5]; however, if there is evidence of hypoxia-induced hemodynamic instability or other end-organ failures, oxygen therapy should not be sacrificed in order to prevent ROP. Continued oxygen desaturation (below 90%) or persistent acidosis may require endotracheal intubation and mechanical ventilation be instituted. The goal of ventilation is to minimize baro- and volu-trauma while maintaining oxygen saturation between 90 and 95%. To this end, relative hypercapnia ($PaCO_2$ 45–60 mmHg) is often permitted. Much like the management of ARDS, the FiO_2 and PEEP ratio should be carefully adjusted to minimize both while achieving the above stated goals.

Exogenous surfactant can also be administered to these infants both at the time of birth and at regular intervals thereafter [6]. Surfactant acts to decrease alveolar surface tension and has been shown to decrease RDS-related morbidity and mortality [1, 7]. The long-term sequela from RDS is typically bronchopulmonary dysplasia (BPD). These children may continue to have respiratory difficulty secondary to decreased lung compliance and increased airway resistance with increased dead space.

Pulmonary Hypertension

Pulmonary hypertension is classically defined as mean pulmonary arterial pressure (PAP) >25 mmHg at rest or > 30 mmHg with activity [8]. In neonates, echocardiographic evidence of PVR greater than the half the systemic vascular resistance is commonly considered as evidence of pulmonary hypertension [9]. This state arises when PVR fails to decrease after the transition to extrauterine life occurs. Severely elevated pulmonary pressures will cause a decrease in blood flow through the lungs and encourage right-to-left shunting, resulting in cyanosis and hypoxemia. The causes of persistent pulmonary hypertension in the newborn are described in Table 50.1.

Management of pulmonary hypertension involves treating the underlying cause and reducing pulmonary vascular tone. To this end supplemental oxygen administration is employed as well as control of ventilation to avoid hypercapnia and acidosis. Pharmacologic pulmonary vasodilators such as intravenous prostacyclin, phosphodiesterase III inhibitors (e.g., milrinone), and/or inhaled nitric oxide may be administered if necessary [10]. Sildenafil has shown promise and is increasingly being used to treat responsive pulmonary hypertension in this patient population [11, 12]. Individual or combination therapies have

Table 50.1 Causes of persistent pulmonary hypertension in the newborn

Acute pulmonary vasoconstriction due to perinatal events
Meconium aspiration
Respiratory distress syndrome
Pneumonia
Hypoventilation/asphyxia
Hypothermia
Hypoglycemia
Sepsis
Idiopathic
Maternal NSAID or SSRI use

Congenital cystic adenomatoid malformation (CCAM)
Pulmonary sequestration
Cardiac lesions
Pulmonary atresia with intact ventricular septum
Transposition of the great arteries (TGA)
Total anomalous pulmonary venous drainage (TAPVD)
Tricuspid atresia

been used in neonatal and infant populations with some success [13–15]. Nitric oxide offers the theoretical advantage of improving V/Q matching by preferentially increasing blood flow to ventilated alveoli. Alternatively, extracorporeal membrane oxygenation (ECMO) has been utilized to temporize pulmonary hypertension or as a bridge to lung transplantation [9, 16, 17].

Cardiac Disease

Patent ductus arteriosus (PDA) is a common finding in the premature infant. Blood flow through the PDA is typically left to right, although this can reverse if pulmonary hypertension exists. Preoperative echocardiography should be performed to evaluate this. Depending on the reason for prematurity, these infants may also have other forms of congenital heart disease (CHD) that should be evaluated prior to undergoing any anesthetic. Although pharmacologic or surgical closure of the PDA is often indicated, if other cyanotic CHD exists, the closure of the PDA is delayed until the lesion is repaired or palliated via another form of surgical shunt. The anesthetic management of thoracic procedures in patients with unrepaired or palliated shunts is particularly challenging. Increased positive-pressure ventilation and compromised oxygenation may lead to worsening of right-to-left shunts.

Immature organ function and depleted metabolic reserves predispose the premature infant to several other age-related disorders. Lack of glycogen stores in the premature neonatal liver places these patients at risk for hypoglycemia. The implications of untreated hypoglycemia can be quite severe and include seizures and developmental delay. The normal stress response of surgery is to increase plasma glucose levels secondary to catecholamine and cortisol production. This may not occur, however, in the very sick child. Five or ten percent dextrose solution should be used as maintenance fluid in the pediatric population, although at what age this practice should cease is not clear [18]. To avoid hyperglycemia a balanced salt solution should be used for fluid bolus administration [19].

Apnea of prematurity is common, and its incidence is inversely proportional to the gestational age and weight of the child. Apnea (airflow cessation lasting more than 15 s) may be accompanied by bradycardia and hypoxia. The presumptive mechanism is due to immature neuronal control at the level of the brainstem and peripheral chemoreceptors [20]. An obstructive component to the apnea is often present as well. Other risk factors include a hemoglobin <100 or Hct < 30. Management may include minimizing narcotic use, stimulation and airway support, and pharmacology (e.g., caffeine). Postoperative observation and monitoring for apnea are mandatory in premature and ex-premature infants less than 50–60 weeks postconceptual age.

Preoperative Evaluation

As in adults the preoperative evaluation of the pediatric patient focuses on the history, physical exam, and laboratory investigations, although an age-appropriate evaluation is necessary. The pediatric practitioner must be aware that certain congenital anomalies do not occur in isolation. For example, tracheoesophageal fistula may be associated with other significant anomalies as part of the VACTERL syndrome (vertebral, anal, cardiac, TE fistula, renal, radial, and limb anomalies). The presence and severity of the associated anomalies should be identified as they may affect anesthetic management.

The evaluation of the neonate or infant typically begins with a history of the pregnancy, labor, and delivery. Apgar scores and resuscitation efforts at delivery are important as they may provide diagnostic clues. For example, prolonged tracheal intubation early in life may predict the presence of subglottic stenosis. RDS leading to BPD may affect children many years after their NICU discharge. Both these examples may lead the anesthesiologist to modify his approach to airway management or ventilation strategy.

As this may be the first anesthetic the child is to receive, the biological parents must be questioned with regard to prior familial anesthetic complications. Malignant hyperthermia and pseudocholinesterase deficiency (among others) have a genetic transmission and may present with the first anesthetic. If a prior anesthetic record is available, it should be reviewed. As in adults particular attention should be focused on the ease of bag-mask ventilation and intubation. In the pediatric population, one must also look for evidence of difficulty with intravenous access and the disposition of the child prior to induction. Endotracheal tube (ETT) size and the presence of a leak around the tracheal tube should also be noted.

Functional capacity should be assessed keeping in mind the patient's age. An infant's inability to take full feeds, sweating, and/or cyanosis during feeds may be an indicator of heart failure. In toddlers and older children, activity level or ability to run or play is a better measure of cardiothoracic functional capacity. A helpful indicator is whether the child is able to keep up with his peers when at play. A child who takes more frequent naps or must stop and sit while his peers continue to play is a clear indication of decreased functional capacity. Height- and weight-based growth analysis will also provide evidence of failure to thrive which can be caused by or exacerbate a decreased functional capacity.

The physical exam can be challenging in the pediatric patient. Noncompliance and occasionally combativeness will prevent thorough examination. Most adult markers for difficult bag-mask ventilation and intubation are not appropriate for infants and children. Assessing Mallampati score in a newborn may be impossible and futile. In its place many

pediatric anesthesiologists assess the craniofacial silhouette or profile, focusing on evidence of retro- or micrognathia. A gloved finger can also be used to feel for the presence of a high arched and/or cleft palate, which may be associated with difficult laryngoscopy.

Respiratory compromise or distress will manifest not only as tachypnea but perhaps also as indrawing, nasal flaring, grunting, accessory muscle use, or paradoxical breathing. All are easily identifiable in children. Peripheral cyanosis and evidence of decreased perfusion should be sought. Assessment of intravascular volume status in the pediatric patient may be challenging. Orthostatic vital signs are generally not done in neonates, and the JVP cannot be easily seen. Skin turgor, capillary refill, fontanelle fullness, level of consciousness, and urine output, however, are easily assessed, as is total fluid intake. A newborn that consistently is gaining weight is very unlikely to be hypovolemic.

Vital signs change with age and should therefore be compared to the statistical norms for the patients' cohort. Blood pressure measurements in an irritable or uncooperative child can be unreliable or impossible to attain. Auscultation for normal heart sounds and murmurs of concern is important to document. Evidence of heart failure, pulmonary edema, and wheezing on respiratory exam should also raise concerns.

Laboratory investigations in the pediatric population should be based on the presenting illness and the surgery proposed. Often children that are booked for thoracic procedures will have at minimum a CXR that can be evaluated for pulmonary pathology, edema, and evidence of scoliosis and engorgement of the vascular structures. If available the computed tomography (CT) scan or MRI should also be viewed. This will prove a valuable aide in determining the feasibility of lung isolation and the extent of the pathology. Particular attention should be noted if the disease is in communication with the bronchi (e.g., congenital cystic adenomatoid malformation, CCAM) as this will potentially alter the ventilation strategy. Anterior mediastinal masses may compress the great vessels, the trachea, or the heart itself. Evidence of cardiovascular compromise, whether on history or physical exam, warrants further investigation with transthoracic echocardiography. Often an understanding of the disease pathophysiology and associated cardiac anomalies will warrant this investigation. An ECG can be very helpful in these circumstances.

Since most thoracic procedures have the potential for blood loss, a CBC should be obtained preoperatively. This test may also indicate the degree of hypoxia if the hematocrit is significantly elevated. Often electrolytes and renal function indicators will be ordered. In an otherwise healthy child, no blood work may be needed. Baseline arterial blood gases may be useful but may not be practical in the frightened young child. Capillary or venous gases are more easily obtained in pediatrics and provide almost as much useful information as arterial gases. Unlike the adult patient that presents for thoracic surgery, it is often impossible to obtain reliable pulmonary function tests or spirometry. This, however, should not be an impediment to proceeding with the planned surgery. Any further testing should be based on those areas of concern elucidated during the preoperative evaluation.

Lastly, the preoperative evaluation should be used to explain to the child and/or parents the anesthetic plan and the eventual disposition of the patient. Risks and complications should be addressed and assent or consent obtained. Decisions regarding preoperative sedation and parental presence at induction can also be made at this time. The postoperative pain management strategy should be outlined and questions or concerns addressed.

Strategies for Lung Isolation

The indications for lung isolation in children include prevention of contamination by blood or pus, treatment of a large bronchopleural fistula or severe unilateral bronchiectasis, as well as facilitating surgical exposure during thoracic procedures. Although thoracoscopic procedures may be performed without lung isolation in very small infants (the induced pneumothorax is often enough to compress the lung tissue and provide surgical exposure; see Fig. 50.1), one must be prepared to isolate the lungs in the event surgical exposure is inadequate. The techniques and approach to lung isolation in the pediatric population may differ from that of adults since infant and small child-sized bronchial

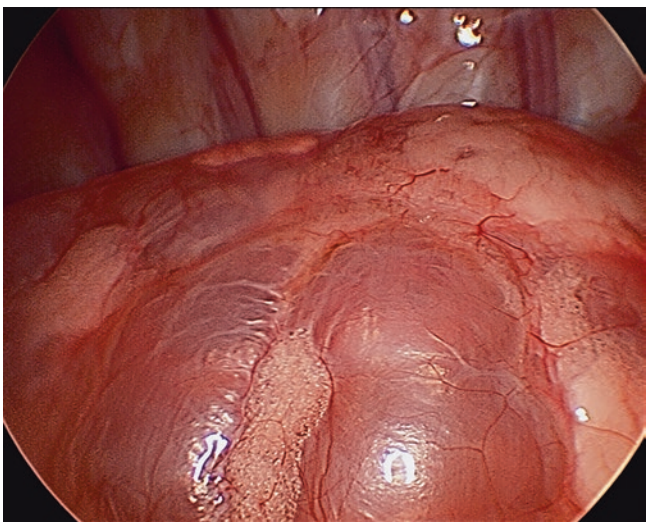

Fig. 50.1 Thoracoscopic view of a 6-month-old infant's right hemithorax in whom adequate surgical lung exposure was achieved with the induced capnothorax and without the need for lung isolation. The right lower lobe almost entirely consists of congenital cystic adenomatoid malformation (CCAM)

tubes are not available. Despite this, the basic principles of lung isolation in the child are similar to those for the adult. There are three fundamental techniques of lung isolation: single-lumen endobronchial intubation, bronchial blockers, and double-lumen bronchial tubes [21].

Historically, the use of single-lumen tubes for selective endobronchial intubation was the only method to isolate the lungs in small children. Although it is now rarely the preferred method of lung isolation, it has the advantage of being readily available, requiring little technical expertise, and can be performed on any patient, regardless of size. Right mainstem bronchus intubation is easily accomplished and has been performed (inadvertently or otherwise) by virtually every anesthesiologist. Left mainstem bronchus intubation, if done blindly, simply requires the ETT be rotated 180° with the patient's head turned to the right. This maneuver turns the bevel of the tracheal tube to favor left mainstem bronchus intubation with advancement. Alternatively, flexible fiberoptic bronchoscopy can be used to place the tracheal tube in the appropriate mainstem bronchus under indirect vision. Regardless of which technique is used, fiberoptic verification of proper tube placement is recommended [22, 23].

Other advantages of this technique include very rapid isolation that can be applied in emergency situations such as pulmonary hemorrhage. Limited technical experience is required, and specialized equipment is not necessary. Because single-lumen tubes are available in a wide variety of sizes, there is no patient that cannot be managed by this method. Note, however, that since airway diameter narrows further down the trachea and bronchi, one should consider placing a slightly smaller ETT than otherwise indicated.

Disadvantages of this technique are numerous. Firstly, conversion to temporary two-lung ventilation (i.e., to reexpand the nondependent lung) may be cumbersome. This requires withdrawing the secured ETT from the bronchus to the trachea. Reisolating the lung with the patient in lateral decubitus position and under surgical drapes can be problematic. As well, an incomplete seal at the bronchus will allow gases to escape and inflate the nondependent lung. Leak gas will also contaminate the room; however, more importantly debris, blood, and secretions from the operative side may soil the poorly isolated lung. If intubating the right mainstem bronchus, obstruction of the right upper lobe is possible, especially if a cuffed ETT is used. Finally, if hypoxemia arises, it is impossible to apply CPAP to the nondependent lung. If adjusting PEEP to the dependent lung does not improve the hypoxemia, repositioning the ETT above the carina and reverting to two-lung ventilation will be the only solution.

Bronchial blockers play an important role in pediatric lung isolation, particularly in patients 3 months to 9 years of age. There are currently three main devices available: Fogarty arterial embolectomy catheters (Edwards Lifesciences, Irvine, CA, USA), Univent® tube (Vitaid, Lewinston, NY, USA), and the Arndt endobronchial blocker (Cook® Critical Care, Bloomington, IN, USA). The use of the Fogarty catheter for lung isolation is well described and has been used for all types of thoracic procedures [24–27]. The catheter can be placed either alongside the standard ETT or within it. If it is to be placed outside the ETT, the catheter is advanced under direct laryngoscopy through the vocal cords. The blocker catheter tip (which if larger than 3F can be slightly flexed; see Fig. 50.2) is then rotated 90° toward the desired lung and advanced into the mainstem bronchus. The ETT is then placed in the trachea. With fiberoptic visualization, the position of the catheter can be verified prior to inflation of the balloon tip. The entire apparatus is then secured to the patient.

If the Fogarty catheter is to be placed within the lumen of the ETT, the method of placement is as follows. As described earlier for selective endobronchial intubation, the ETT is advanced into the desired bronchus. The 15 mm adapter is removed from the tracheal tube, and the Fogarty catheter is placed through the lumen of the ETT into the bronchus. The ETT is withdrawn to a position above the carina while maintaining the endobronchial position of the catheter. Again verification and inflation of the Fogarty should be performed under flexible fiberoptic visualization. The ETT adapter will then have to be securely fastened such that the Fogarty is trapped between the adapter and ETT itself (see Fig. 50.3). A disadvantage of placing the Fogarty within the lumen of the ETT is that it may significantly decrease the internal diameter. This can interfere with ventilation if using a very small ETT, but more commonly it will make passage of the fiberoptic scope difficult. The fit of all scopes and airway devices must be prepared and tested prior to anesthetic induction.

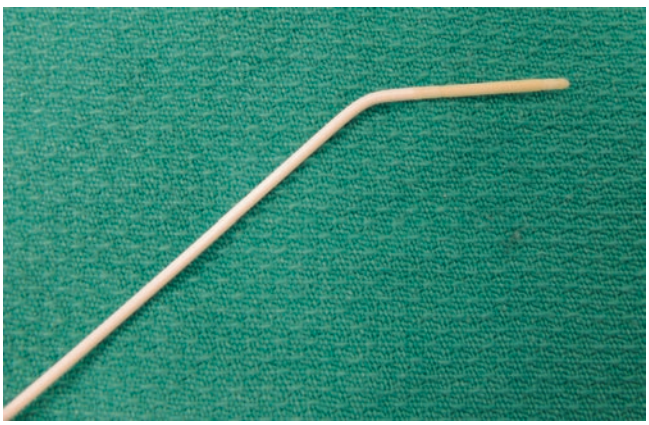

Fig. 50.2 Tip of a size 4F Fogarty embolectomy catheter (Edwards Lifesciences, Irvine, CA, USA) which has been shaped to facilitate maneuverability and insertion into a mainstem bronchus. All Fogarty embolectomy catheters except the size 2F and 3F contain a removable guide wire that can be used to shape the tip in this fashion

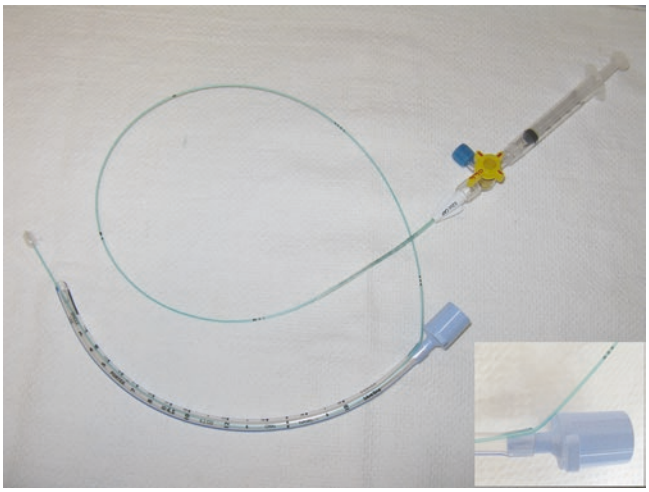

Fig. 50.3 Embolectomy catheter and tracheal tube assembly used for lung isolation in the small child. A size 3F Fogarty embolectomy catheter (Edwards Lifesciences, Irvine, CA, USA) inserted through a 4.5 mm ID tracheal tube (Sheridan) and placed in a mainstem bronchus. The embolectomy catheter is secured in place and sealed between the tracheal tube inner lumen and the 15 mm adapter (inset). Alternatively, the embolectomy catheter may be placed outside the tracheal tube in the mainstem bronchus

Table 50.2 Bronchial blocker sizes used for lung isolation in children

Age	ETT size (ID, mm)	Bronchial blocker size (F)[a]	Max balloon gas capacity (cc)	Inflated balloon diameter (mm)
<2 months	3.0–3.5	3	0.6	5
2–6 months	3.5–4.0	4	1.7	9
6 months–1 year	4.0	4	1.7	9
1–2 years	4.0–4.5	5	3.0	11
2–4 years	4.5–5.0	5	3.0	11
4–6 years	5.0–5.5	5	3.0	11
6–8 years	5.0–5.5 cuffed	6	4.5	13
8–10 years	5.5–6.0 cuffed	6	4.5	13

Abbreviations: ETT endotracheal tube, *ID* internal diameter
[a]Fogarty arterial embolectomy catheters (Edwards Lifesciences, Irvine, CA, USA)

The main advantage of the Fogarty catheter is that it can be used in very small infants as well as older children. Table 50.2 outlines the various embolectomy catheter sizes as well as the corresponding appropriate tracheal tube sizes used in pediatric practice. In general, the smaller the patient, the more challenging proper catheter placement becomes. Deflation of the balloon tip will enable easy and rapid reexpansion of the operative lung without requiring manipulation of the ETT.

A drawback to the Fogarty catheter is that the balloon is a low-volume, high-pressure device. For this reason, balloon inflation should be done under direct visualization and only the minimum of pressure be applied to provide bronchial sealing. Table 50.2 illustrates the maximum inflation volumes of the various embolectomy catheters. Since migration of the blocker by even a few millimeters can cause the balloon to slip into the lumen of the trachea and obstruct both lungs, one must be vigilant and prepared to immediately intervene by deflating the catheter cuff.

The Univent® tube has been designed with a channel that contains a bronchial blocker. Conventional laryngoscopy places the single-lumen tube into the trachea, and fiberoptic guidance of the balloon-tip catheter into the operative lung can then be performed. When seated appropriately, the Univent will isolate the lung and allow for easy conversion to conventional two-lung ventilation by simply deflating the bronchial cuff.

Pediatric sizes are available as small as 3.5 mm internal diameter. However, this device has an 8 mm external diameter and as such should not be used in patients less than 6 years old. In these smaller tube sizes, the bronchial blocker and its channel will also encroach into the lumen of the ETT and proportionally increase the airflow resistance as well as necessitate the use of a smaller fiberoptic scope. Univent® tubes below 6.5 mm ID do not have a central lumen in the bronchial blockers. Therefore, oxygen and CPAP cannot be applied with the smaller Univent® tubes [28–30].

The Arndt endobronchial blocker is a more recent addition to the armamentarium available to the pediatric anesthesiologist [31–33]. It consists of a conventional blocker with balloon tip and four-way adapter. The balloon is designed as a high-volume low-pressure system. Pediatric sizes include a 5F and 7F size blocker which can be used in a 4.5 and 6.5 mm ID tracheal tube, respectively (Table 50.3). Preparation and use of the Arndt endobronchial blocker are identical to that for adults (see Chap. 16).

A unique challenge of using the pediatric-sized Arndt blocker is adequate ventilation while the blocker and FOB both occupy the lumen of the ETT. The smallest-sized FOB must be used that allows placement of the endobronchial blocker. If such a small (i.e., 2.2 mm OD) fiberoptic bronchoscope is not available, the blocker can be positioned outside the ETT much like an embolectomy catheter. The tip of the FOB is passed through the nylon loop of the blocker, and the assembly is inserted in the operative bronchus. The FOB

Table 50.3 Pediatric Arndt endobronchial blocker sizes[a]

Blocker size (F)	ETT size (ID, mm)	FOB size (OD, mm)	Balloon inflation volume (cc)
5.0	≥4.5	≤2.8	0.5–2.0
7.0	≥6.5	≤3.5	2.0–6.0

Abbreviations: ETT endotracheal tube, *ID* internal diameter, *OD* outer diameter
[a]Cook® Critical Care, Bloomington, IN, USA

is then removed and the tracheal tube placed using direct laryngoscopy. Alternatively, if the patient remains adequately oxygenated and ventilated with the FOB-blocker apparatus in the operative bronchus, the FOB may be withdrawn to a position above the blocker, and inflation of the blocker cuff can be observed prior to removing the FOB. Once in position the nylon guide can be removed from the bronchial blocker (it cannot later be reinserted), and the central channel can be used for suctioning, providing supplemental oxygen, and CPAP. Fuji Systems (Tokyo, Japan) has recently released a 5F pediatric size of its independent bronchial blocker, the Uni-Blocker®.

The double-lumen endobronchial tube (DLT, Bronchopart®; Rüsch Inc., Duluth, GA, USA) differs significantly from the above designs in that selective intubation of either mainstem bronchus can be achieved with a second lumen located within the trachea. In this way, ventilation can be applied through either lumen individually or collectively. Unfortunately, pediatric sizes are limited due to the necessarily larger outer diameter of such a design. The 26F is currently the smallest available size and has an outer diameter of 9.3 mm, equivalent to a 6.5 mm ID ETT [34]. It is suitable for children approximately 8–10 years of age or approximately 30 kg in weight. Below this, one of the aforementioned isolation techniques is more appropriate. Double-lumen tube sizing will depend on the child's height as well as age. In general, a 28F DLT is suitable for a 12-year-old child, a 32F is appropriate for a 14-year old, and a size 35F is suitable for a 16-year old.

The DLT is straightforward in its application. Conventional laryngoscopy places the device into the trachea where it can be advanced into position by rotation to the appropriate side in a manner identical to that for adult patients. Fiberoptic bronchoscopy is recommended to ensure proper positioning [35]. Most often a left-sided DLT is used as it is easier to insert and eliminates the risk of right upper lobe obstruction. Correct positioning will mean the bronchial lumen is within the appropriate mainstem bronchus and the tracheal lumen above the carina. Inflation of the bronchial cuff can be observed with the FOB placed within the tracheal lumen. Once inflated the specialized circuit adapter can be manipulated such that ventilation to that lumen is obstructed while egress of gases from the lung is permitted.

Advantages of the DLT include easy access to either lung for suctioning or ventilation, application of supplemental oxygen, and CPAP. Conversion to two-lung ventilation is rapid and simple. Disadvantages of the DLT are mainly due to its awkward size and shape. Iatrogenic injury has been reported, and placement in patients with a difficult airway may be particularly challenging [36, 37]. The DLT should be replaced with a conventional ETT if postoperative ventilation is required.

Anesthetic Management of Specific Procedures and Diseases

Bronchoscopy

Evaluation of the airway by bronchoscopy, either rigid or flexible, has both diagnostic and therapeutic indications [38]. It is one of the few pediatric thoracic procedures that can be performed outside of the operating room under sedation or general anesthesia. In fact, depending on the age of the patient and indication for bronchoscopy, the anesthesiologist may not be involved at all, as some pediatric pulmonologists will provide airway topicalization and intravenous sedation in an ambulatory setting. This approach should be reserved for older, cooperative children who do not have severe respiratory compromise. Those patients that do require operative bronchoscopy must be evaluated with particular focus on the reason for bronchoscopy and the level of respiratory derangement. The type of procedure will often determine the means by which the airway is maintained, the type of anesthetic to be given, and whether paralysis is warranted. Rigid bronchoscopy for foreign body removal will require that a general anesthetic be given. Diagnostic evaluation of the trachea and bronchi for other etiologies can generally be performed via flexible bronchoscopy. Communication between the bronchoscopist and anesthesiologist is essential in any such shared airway case. An appropriately sized ETT or supraglottic airway should be selected for the specific fiberoptic bronchoscope in order to ensure ventilation can be maintained during bronchoscopy.

Older children who are able to understand and cooperate with the anesthesiologist and bronchoscopist can be successfully managed with airway topicalization and intravenous sedation. This can include an infusion of one or a combination of propofol, remifentanil, or ketamine, with or without midazolam [39–43]. More recently, an infusion of dexmedetomidine and propofol has been used in this setting [44]. Although ideally this should be carried out in the OR setting, such procedures are now frequently performed outside the operating room to contain costs and increase efficiency. Children tend to need a deeper level of sedation than adults in order to tolerate the bronchoscope, and titrating the sedation/anesthesia to achieve acceptable procedural conditions while maintaining spontaneous respiration can be challenging. Monitoring and preparation for possible conversion to a general anesthetic are essential. A second physician for patient monitoring and airway management should be at hand.

For those patients that are not suitable for sedation and airway topicalization, several options for airway management exist. These include but are not limited to mask ventilation, laryngeal mask, endotracheal intubation, and

ventilation through the side port of a rigid bronchoscope [45]. Face mask ventilation has an advantage over the other methods listed as it allows for fiberoptic inspection of the oropharynx and/or nasopharynx and can be managed by one of two methods. The simplest is intermittent bag-mask ventilation or support with bronchoscopy conducted while the mask is temporarily removed from the patient. This requires coordination between the anesthesiologist and bronchoscopist and may involve periods of hypoventilation or apnea. If an inhalation agent is chosen as the means of anesthesia, then both awareness and waste gas pollution are a concern as the patient will be exhaling the agent into the room during the procedure. Careful titration of TIVA may therefore be the preferred approach for this option [46]. In addition, the diagnostic value of the procedure may be impaired as the bronchoscopist must enter and exit the airway repeatedly. To overcome these limitations, face masks with angled side ports have been developed that allow for continuous application of the mask to the patient and ventilation through the adapter, while the bronchoscopist uses an inline diaphragm that minimizes gas leakage (Fig. 50.4).

Although the laryngeal mask does not allow for inspection of the upper airway, it has nevertheless become the most commonly used conduit for diagnostic and therapeutic bronchoscopy in the pediatric patient outside the critical care unit [47]. The availability of smaller sizes and its ease of use make it ideally suited for this procedure. It is better tolerated than a tracheal tube and accommodates both spontaneous ventilation and positive-pressure ventilation as required. It has been shown in several studies to be well suited for bronchoscopy, even in small infants [48–50]. An angled adapter with an inline diaphragm for the bronchoscope is required. If the LMA has aperture bars, they may need to be removed as they can impair the scope from passing through. In most cases, the bronchoscope will align itself with the glottic opening and not require any further manipulation of the LMA once seated.

Fig. 50.4 Pediatric endoscopy mask (VBM Medizintechnik GmbH, Sulz, Germany) designed to allow simultaneous ventilation and endoscopy of the child. The assembly may be used for flexible fiberoptic intubation or airway endoscopy

Endotracheal intubation provides the most secure, stable, and controlled means of airway management for bronchoscopy. The majority of children in the critical care unit undergoing bronchoscopy will have an ETT in situ and undergo bronchoscopy to assess bronchial patency or pathology, tracheomalacia, and for sputum sampling. Outside the critical care unit, elective tracheal intubation for bronchoscopy may be preferred for infants and small children as well as patients with significant respiratory compromise. A period of postoperative ventilation may also be required for high-risk patients. Disadvantages of bronchoscopy through an ETT include the inability to examine the upper airway as well as bronchoscope size limitations. An appropriately sized scope must be chosen that allows adequate ventilation around itself in the remaining lumen of the ETT.

Rigid bronchoscopy offers the advantage of allowing dynamic examination of the airway from the oropharynx to the subsegmental bronchi. Most pediatric rigid bronchoscopes contain a 15 mm side port that allows for gas insufflation and even positive-pressure ventilation. It is the instrument of choice for pediatric foreign body removal. Disadvantages of rigid bronchoscopy include the fact that deep anesthesia is required to tolerate the bronchoscope and, if volatile anesthetic agents are used, room air contamination is a concern. In that case, suction or gas scavenging can be positioned at the base of the bronchoscope to minimize contamination. The practice of many pediatric anesthesiologists is to therefore use a propofol-based TIVA technique with local anesthetic applied to the vocal cords and carina. To this end a low-dose remifentanil (0.05 μg/kg/min) or dexmedetomidine (0.5–2.0 μg/kg/hr) infusion may be a useful adjunct. Typical goals are to maintain spontaneous ventilation without the use of muscle relaxants. However, positive-pressure ventilation can be applied via the side port of the rigid bronchoscope which may be facilitated by muscle relaxation.

Fever is not an uncommon sequela of flexible bronchoscopy, and it is not necessary to treat all such patients with antibiotics. Case reports of fever associated with sepsis following bronchoscopy have been reported; however, these are generally in immunocompromised patients in whom antibiotic therapy is warranted [51, 52]. Similarly rigid bronchoscopy has been shown to induce transient bacteremia, but again antibiotic treatment is generally unnecessary. Complication rates for bronchoscopy are low. The most common adverse event is transient desaturation; however, laryngospasm and bronchospasm can also occur [53, 54].

Thoracotomy and Video-Assisted Thoracoscopic Surgery (VATS)

Traditionally, all thoracic procedures in children were performed via a thoracotomy or median sternotomy. Mechanical retraction of the ribs and lung tissue would often be applied to provide the required surgical exposure. Because of technological advances and greater surgical experience gained from the adult population, video-assisted thoracoscopic surgery (VATS) is now used more readily in the pediatric population, even at the extremes of age and weight (Fig. 39.5) [55–58]. The reported advantages of VATS in the adult population, including less postoperative pain and shorter length of stay, accelerated the use of this technique in children. Although very few outcome studies have been conducted in children, VATS is utilized for an increasing number of conditions including empyema, lung biopsy and resection, mediastinal mass, trauma, pulmonary sequestration, and CCAM (Fig. 50.1) [59]. Even PDA closure is being performed thoracoscopically in very small infants [60]. Trocars for pediatric use are available in 5 and 3 mm diameters (Fig. 50.5).

Whereas thoracotomy does not always require the lungs be isolated in children, VATS is quite challenging without proper lung isolation and collapse of the surgical lung. An exception is in small infants, whose lungs can be collapsed with the induced capnothorax.

Single-lung ventilation in the pediatric population incurs many of the same physiologic derangements as in the adult population (see Chap. 6). Collapse of the nondependent lung preferentially directs ventilation to the dependent (nonsurgical) lung. Hypoxic pulmonary vasoconstriction (HPV) in the nondependent lung increases perfusion to the dependent lung and therefore attempts to correct the shunt. In adults with the diseased lung in a nondependent position, this arrangement may actually improve oxygenation. Unfortunately in infants and neonates, this is often not the case. A compliant rib cage and compressible lung parenchyma allows for mediastinal excursion into the dependent lung thus reducing ventilation of that lung. Poor positioning and increased insufflating pressures will further contribute to this. Decreased hydrostatic pressure gradients between the two hemithoraces translate into relatively little improvement in V/Q matching even when HPV is intact. Moreover, alveolar collapse occurs more readily in infants as FRC approaches residual volume. The higher ratio of oxygen consumption to FRC, as compared to adults, will further exacerbate deoxygenation.

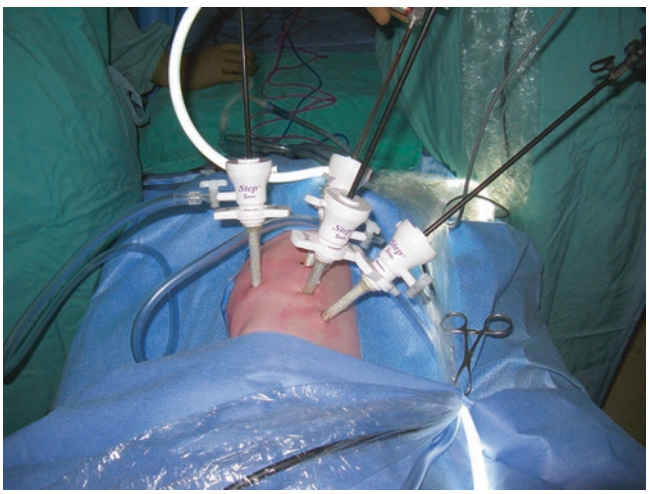

Fig. 50.5 Thoracoscopic trocars inserted in an infant for VATS. Surgical trocars used in children are available in 5 mm (shown) and 3 mm diameters

Many of the same complications of VATS occur in the pediatric population as in adults. Trocar misplacement (into the spleen or liver) may cause significant morbidity. High thoracoscopic insufflating pressures will decrease cardiac output and blood pressure by reducing preload and afterload. Patient positioning is even more important in pediatric procedures as an inappropriately located bolster will easily compress the compliant rib cage and reduce lung volumes in the dependent lung. Abdominal compression in the lateral decubitus position, from padding or "bean bags," will force the abdominal contents into the chest. As with any procedure that involves CO_2 insufflation under pressure, CO_2 gas embolism, though rare, must be considered in the event of sudden severe hemodynamic derangement.

As in adults maneuvers to preserve and treat hypoxemia with single-lung ventilation apply equally in the pediatric setting. Initial routine use of 100% oxygen upon lung isolation offers an increased safety margin and decreases HPV of the dependent lung. Once the procedure is underway and hemodynamic stability confirmed, the FiO_2 may be decreased as tolerated. Pressure-controlled ventilation may be used provided it delivers volumes in the range of 5–10 mL/kg. To this end mild hypercapnia is permitted, to avoid barotrauma. The application of PEEP to the dependent lung may improve oxygenation and if kept to <10 mmHg usually has minimal effects on PVR and does not divert blood flow away from the ventilated lung. Application of CPAP to the nondependent lung is not as practically applicable in the small child and often interferes with surgical exposure.

To conclude, the decision to proceed with a thoracotomy vs. VATS procedure must be discussed ahead of time by surgeon and anesthesiologist. A thorough understanding of the risks and benefits must be assessed by both teams and then explained to the parents/patient. A discussion between the anesthesiologist and surgeon must include a time line with respect to how long the VATS technique will be employed. If surgical goals are not met during this time line, then conversion to thoracotomy should be considered. Most importantly, emergency management of intraoperative bleeding must be

discussed and a plan formulated for emergent conversion to thoracotomy. Pediatric patients, especially small infants and neonates, will very rapidly hemorrhage into the chest cavity. By the time thoracotomy is performed and surgical control of bleeding is established, significant morbidity may have occurred. Resuscitation, even with rapid/immediate transfusion, is extremely difficult in such cases. A low threshold is recommended for release of capnothorax and possible immediate conversion to thoracotomy if significant hemodynamic instability arises.

Empyema

Pediatric pleural effusions are most often infectious in nature with 50–70% being parapneumonic [61]. Other less common causes of pleural effusions, including those associated with renal disease, malignancy, and congenital heart disease, will not be discussed in this section.

There are three generally accepted stages of empyema formation. Stage one is *exudative* with a small volume of sterile fluid accumulation and neutrophil recruitment. Stage two involves bacterial translocation across the now damaged pleural endothelium followed by further neutrophil activation. This *bacterial invasive stage* is characterized by fibrin and collagen fluid loculations. The pleural chemistry will now be acidic as glucose is metabolized and carbon dioxide and lactic acid levels increase. The final stage of *organized empyema* formation results in a thick purulent fluid, filled with cellular debris and deposition of a pleural "peel" along the membrane.

Aside from clinical examination, the most common investigational techniques will involve two-view chest X-rays and ultrasonography (US). US has the advantage of being able to quantify the fluid, indicate loculations, and locate ideal insertion sites for drainage tubes. Computed tomography can also provide detailed assessment of the pleural space but is not usually indicated.

Medical management is still the mainstay of management of parapneumonic effusions in most institutions [62], although early surgical intervention with VATS is associated with shorter hospitalization and equivalent clinical outcomes [63].

Empiric antibiotic therapy is initiated based on the common bacterial pathogens as determined by patient demographics and known community pathogens. Common pathogens include *Streptococcus pneumonia*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *and Haemophilus influenza* [64]. Retrospective case analysis shows that approximately one-quarter of cases will be successfully managed with antibiotic therapy alone [65]. Fine needle thoracentesis and/or small-bore chest tube drainage is required in the remaining cases.

Clinical pathways for pleural effusion drainage are typically institutionally driven and based on the most recent literature. Several different groups have proposed indications for chest drainage [66]. Any effusion greater than 1 cm or 25% of the width of the hemithorax on US or CXR or ongoing respiratory distress despite adequate antimicrobial coverage may warrant small-bore drainage tube insertion. This is typically achieved in the interventional radiology suite with IV sedation and local anesthetic infiltration at the insertion site. Most commonly the use of midazolam, ketamine, dexmedetomidine, and/or fentanyl in titrated doses is sufficient, although sedating doses of propofol will be tolerated by most patients. Nasal prong oxygen and standard monitoring are employed.

If the effusion persists despite drainage tube insertion, it is typically a result of loculation and fibrin deposition. The initial approach is to instill a thrombolytic agent (e.g., streptokinase, urokinase, tPA) through the chest tube into the pleural space. This will ideally break down the adhesions and facilitate further drainage [67]. Approximately 15% of patients will require multiple fibrinolysis treatments [65].

Failure of clinical improvement or progression of fluid accumulation will necessitate discussion regarding surgical decortication. Three percent of patients may require such surgical intervention following conservative medical management [68]. Surgery can be accomplished by open thoracotomy or more commonly video-assisted thoracoscopic surgery (VATS). At this stage the empyema has likely developed a thick fibrous plaque that prevents collapse of the affected pleural space. As such lung isolation is not routinely applied. Trocar insertion into the pleural space is performed without the need for lung isolation as the empyema fluid and thickened pleura have created a fluid-filled space with the affected lung collapsed away from the chest wall.

Anesthetic monitoring of these patients includes conventional noninvasive monitors with the addition of an arterial line if clinically warranted. As blood transfusion may occasionally be required, adequate venous access is essential. Induction of anesthesia is usually not complicated, although these patients may have significant respiratory distress.

In most cases, tracheal extubation and transfer to a monitored ward bed are sufficient; however, these patients may require postoperative ventilation. Intravenous antibiotic therapy should be continued. Most children will recover uneventfully with full resolution of symptoms and no ongoing sequelae.

Patent Ductus Arteriosus (PDA)

Surgical PDA repair is perhaps the most common cardiac procedure to be managed by the noncardiac specialized pediatric anesthesiologist. As technology and surgical technique

have evolved, so too has the surgical management of this disease. The historic use of a large lateral thoracotomy has today been replaced by smaller muscle-sparing "mini" thoracotomies. Moreover, many centers have established good success rates with the VATS technique [60, 69]. Percutaneous coiling of the PDA via interventional angiography is also widely available but will not be discussed herein [70, 71].

The ductus arteriosus is an essential conduit directing blood flow away from the high-pressure pulmonary circulation toward the systemic circulation during fetal development. It most often arises at the anterior surface of the main PA and attaches to the descending aorta near the left subclavian artery. In response to the increased PaO_2 after birth, the musculature of the ductus constricts and effectively closes the structure. Smaller birth weight infants and premature infants are more likely to have persistently PDA. If left untreated the left-to-right shunt created by the PDA will result in pulmonary overcirculation, pulmonary edema, and respiratory insufficiency. RV failure may also develop, especially if pulmonary pressures increase. Rarely, this may result in shunt reversal. In children who have a hemodynamically stable PDA, closure is still required as the risk of bacterial endocarditis is quite high [72].

If significant pulmonary overcirculation exists, the patient may require tracheal intubation in NICU to help support ventilation prior to surgery. These patients may often be fluid restricted and given diuretics in order to help alleviate the resultant pulmonary valvular insufficiency. To this end, inotropic support will also occasionally be required. Surgical stress will further strain the already compromised preexisting respiratory and hemodynamic status. Likewise, any preexisting medical condition or syndrome should be evaluated prior to induction of anesthesia. Whether performed via mini thoracotomy or VATS, surgical closure of a PDA is usually of short duration (<1 h typically) and involves minimal blood loss. In order to assess the blood flow in both the ascending (preductal) and descending (postductal) aorta, a noninvasive blood pressure cuff may be placed on a lower limb with an oxygen saturation probe applied to both the right hand and the left foot. Invasive arterial measurement is no longer routinely required. When identification of the PDA is difficult, the surgeon may place temporary clips across the vascular structure and observe the effects on the patient. Correct positioning across the PDA will result in a rise in diastolic pressures, whereas occlusion of the main PA will result in decreased oxygen saturation and $ETCO_2$. Temporary occlusion of the descending aorta will result in a sudden loss of lower extremity saturation tracing and blood pressure while simultaneously preserving the preductal saturation.

Induction of anesthesia is dependent on the preexisting condition of the patient. Those that present with respiratory or hemodynamic compromise may typically receive a high-dose narcotic (e.g., fentanyl 10–20 μg/kg IV) at induction with muscle paralysis. Minimal volatile anesthetics should be used in these cases, and supplemental narcotic dosing may be given as required. Alternatively, a remifentanil infusion along with low volatile anesthetic concentration may be used in those patients suitable for postoperative tracheal extubation. In addition to the standard intravenous used for induction, a larger peripheral intravenous catheter should be inserted after induction. Blood should be available in the operating theater for fluid resuscitation in the event of surgical misadventure. Open thoracotomy for PDA closure does not require lung isolation or single-lung ventilation. Simple retraction is sufficient to provide surgical exposure. Recent studies, however, have shown the efficacy of the VATS approach to PDA repair [73–76]. Ventilatory strategies for this include lung isolation (by any technique described earlier) or placement of a single-lumen ETT and allowing the pneumothorax to dictate surgical exposure. Muraldihar et al. [77] evaluated right mainstem bronchial intubation vs. low tidal volume high-frequency ventilation of both lungs and showed more profound desaturation in the mainstem intubated patients. Miyagi et al. [78] reported on the successful use of the Fogarty catheter as a bronchial blocker for a series of PDA closures performed via VATS. Despite the potential for hemorrhage, many studies have shown the safety and efficacy of this surgical approach for the repair of PDA [79]. Risk factors, regardless of approach, continue to be hemorrhage, residual patency, and recurrent laryngeal nerve injury. Odegard et al. [80] describe a simple yet effective means to identify the recurrent laryngeal nerve and thus prevent injury during VATS procedures by using a thin Teflon nerve-stimulating probe and recording the evoked electromyograms.

Tracheoesophageal Fistula (TEF)

The incidence of TEF is approximately 1 in 3000, and although it may occur in isolation, about 50% of cases will present in association with other congenital anomalies [81]. The VACTERL association (vertebral, anal, and cardiovascular defects, TEF, renal and radial limb defects) has been well described [82, 83]. The most commonly associated cardiac defects are atrial septal defect, PDA, and tetralogy of Fallot [84]. Investigation of these defects is essential prior to any surgical intervention. The trachea and esophagus are derived from the primitive foregut during the fourth and fifth weeks of life. The trachea emerges ventrally from the primitive foregut, and a septum between the esophagus and trachea is created by fusion of the tracheoesophageal folds. Failure of incomplete separation of these two structures can result in isolated esophageal atresia (rare) or more commonly TEF. The Gross classification describes six of the most common forms of TEF [85]. Type C, accounting

for 85% of all cases of TEF, consists of a fistula located slightly above the carina with proximal esophageal atresia. It is suggested shortly after birth with copious salivation associated with choking, coughing, and cyanosis coincident with the onset of feeding. Diagnosis is confirmed by the inability to pass a suction catheter into the stomach, and a gastric air bubble is often visible on radiograph. In most patients, surgical intervention will be planned for within the first week of life. During this time, these patients should be kept in a head-up or lateral decubitus position with a nasoesophageal suction catheter inserted to help prevent aspiration. Early tracheal intubation is rarely required. In otherwise healthy newborn infants, there is almost 100% survivability. Survival declines rapidly if TEF is associated with low birth weight, prematurity, cardiac anomalies, or pulmonary complications [71, 86].

Primary repair consists of fistula ligation and esophageal anastomosis. Occasionally, a staged repair will be required in patients that are unstable and premature or have very low birth weight. This consists of placement of a balloon-tip catheter into the distal esophagus via percutaneous gastrostomy under local anesthesia [87]. This temporizing measure helps prevent reflux and will enable more efficient ventilation, particularly if high airway pressures are required. When the patient becomes more stable, the definitive repair can be performed. This has traditionally been undertaken through a thoracotomy on the side opposite the aortic arch. Fistula ligation is followed by esophageal anastomosis. If the two ends of the esophagus are separated by too great a distance, the fistula is ligated, and a section of the colon can be interposed at a later date. Thoracoscopic repair has been described, and in some centers it has become the preferred surgical approach [88, 89].

Anesthetic management begins with the understanding that positive-pressure ventilation should be minimized on induction. If the fistula is large, pressurized gas flow will follow the path of least resistance through the fistula and into the stomach. This will cause gastric dilatation leading to further impairment of ventilation and possible reflux of gastric contents into the lungs. Profound respiratory failure and cardiac arrest have been reported. The goal of induction is to place the ETT distal to the fistula and proximal to the carina. This is often accomplished by blind mainstem intubation and subsequent retraction of the ETT until bilateral breath sounds are auscultated. Many centers now advocate initial rigid bronchoscopy with the patient breathing spontaneously under volatile or intravenous anesthesia in order to identify the size and location of the fistula prior to tracheal intubation. Flexible fiberoptic bronchoscopy may also be used to verify tube positioning following tracheal intubation. Prior to induction the patient should have thorough suctioning of the esophageal catheter and be well preoxygenated. Pretreatment with atropine is recommended. Traditionally, an awake tracheal intubation would have been performed on these patients. More recently, pediatric anesthesiologists prefer to induce anesthesia with inhaled volatile anesthetic while maintaining spontaneous respiration or alternatively, perform a rapid sequence induction. Once the ETT is carefully positioned to ensure lung ventilation without fistula insufflation, muscle relaxation and gentle positive pressure can be provided. Some anesthesiologists will prefer not to paralyze or provide positive-pressure ventilation until the fistula is ligated. For thoracoscopic TEF repair, lung isolation is generally not attempted. Anesthetic induction and tracheal tube placement are as for open repair; however, maintaining spontaneous respiration until the fistula is ligated is impractical. The induced pneumothorax/capnothorax often produces adequate surgical exposure.

Intraoperative monitoring consists of the usual noninvasive monitors and possibly an arterial line. A large peripheral intravenous for fluid resuscitation should be obtained. A precordial stethoscope placed in the left axilla will help identify movement of the ETT into the right mainstem bronchus. The flexible fiberoptic bronchoscope should be available as it may be required to confirm intraoperative tube placement. Tracheal suction catheters should be on hand as surgical manipulation of the nondependent lung may cause debris or secretions to obstruct the ETT.

Intraoperative complications usually consist of ventilation difficulties, leading to hypoxemia and/or hypercapnia. Increasing FiO_2, adjusting ventilatory settings, and providing muscle relaxation may help improve this. Occasionally, and more commonly during thoracoscopic procedures, a degree of hypercapnia and desaturation must be tolerated. Although some of the most robust patients may be suitable for postoperative tracheal extubation, most will benefit from a short period of elective ventilation. The tracheal tube is carefully withdrawn to a position proximal to the fistula, and the nondependent lung is gently reexpanded under direct vision. The hemithorax is simultaneously filled with warmed saline to ensure there is no air leak from the repaired fistula site. Early postoperative complications include atelectasis, increased airway secretions causing small airway collapse, and electrolyte disturbances associated with increased fluid requirements. Later complications include esophageal anastomotic leak, formation of bronchoesophageal fistula, and esophageal stricture formation [90].

Mediastinal Mass

Management of the pediatric patient with a mediastinal mass presents unique and serious challenges to the anesthesiologist. A common misconception is that a mediastinal mass is more likely to cause symptoms in children compared to adults [91]. In fact children are less likely to be symptomatic

compared to an adult [92–94]. The presence of symptoms may be predictive of malignancy in the adult; however, this does not seem to hold true for children [95]. A finding of orthopnea (supine dyspnea) in the child may be predictive of significant tracheal narrowing [96, 97], and its presence should alert the clinician to the possibility of airway obstruction upon induction of anesthesia. The presence and degree of orthopnea should be assessed in every patient. The older child with mild symptoms can lie supine with some cough or pressure sensation. The patient with moderate symptoms will only be able to lie supine for short periods, and the severely symptomatic patient will not tolerate the supine position [98]. Characterizing the degree of orthopnea in the infant or small child is more challenging. The infant without symptoms will not seem stressed when supine, whereas the mildly symptomatic infant may look frightened or upset when supine. It is difficult and of little clinical use to attempt to distinguish between moderate or severe symptoms in the small child or infant. In either case, the infant will look severely distressed, may be gasping, or even cyanotic when supine.

Despite the predictive value of orthopnea in older children with a mediastinal mass, life-threatening complications may occur in the absence of symptoms, particularly in infants and small children [99].

The other major complication is cardiovascular collapse secondary to compression of the heart or major vessels. The presence of a pericardial effusion is associated with an increased risk of cardiovascular complications during anesthesia [100]. Death upon induction of general anesthesia in patients with an anterior mediastinal mass is always a risk. Anesthetic deaths have mainly been reported in children [101]. This may be due to the fact that:

1. Children have a more compressible cartilaginous airway structure.
2. The presenting signs and symptoms correlate poorly with tumor size.
3. Children are less able to give a reliable history.
4. Children more often receive a general anesthetic for tissue biopsy.

Diagnosis and Risk Stratification

The most important diagnostic test in the patient with a mediastinal mass is CT of the trachea and chest. Although a chest X-ray is often helpful in detecting a mediastinal mass, the CT scan provides useful information such as the size and compressive effects of the mass. For proper tumor staging, however, a CT scan of the chest, abdomen, and pelvis is required. Fortunately, this can be accomplished with an average scan time of under 20 s with the more modern, faster CT scanners. In addition, the patient's head and chest can be elevated to 30° without affecting scan quality. Alternatively, the scan can be done with the patient in lateral or even prone position, if necessary.

It is essential to determine the patient's most comfortable position prior to starting the CT scan. Most patients, including the otherwise uncooperative child, will often assume that position while confined to the hospital bed. Furthermore, many major pediatric centers have adopted the resourceful practice of performing the scan at a time that coincides with that child's natural sleep. Distraction (with music or video) has been used with success in older children. For practical purposes, this means that the scan can be done with the patient in his/her most comfortable position during natural sleep, thus minimizing the need for sedation. The anesthesiologist should never feel compelled to have the severely symptomatic patient lay flat and supine, be deeply sedated, or anesthetized for a CT scan. In such a situation, if the above measures are unsuccessful or impractical, serious consideration should be given to steroid administration or selective irradiation prior to CT in order to reduce the tumor mass.

For those patients that are uncooperative but do not have severe symptoms, sedation may be administered, provided a cautious approach is adopted. Although nothing is absolute, careful titration of a single agent may be safer or preferable to polypharmacy, particularly for small children. A 6-year review of over 16,000 sedations performed on children revealed that the odds of having an adverse event were nearly 5 times higher when multiple agents were used (odds ratio [OR] 4.9, 95% CI 2.9–8.4) [102]. As a single agent, nitrous oxide 50% in oxygen is often all that is needed in small children to provide analgesia and sedation. Alternatively, midazolam or etomidate 0.1 mg/kg, ketamine or propofol 0.25 mg/kg IV boluses, or continuous infusion may be carefully titrated to effect. Although many agree that the risk of airway obstruction and hypoxemia increases when a combination of benzodiazepines and opioids is used [103], sedation even with a single agent may not be tolerated in the high-risk patient [104]. Of equal importance is appropriate monitoring of the patient, early recognition and treatment of complications, and attention to patient positioning during the procedure. The flat, supine position is never mandatory.

Obstruction of the superior vena cava (SVC) causing venous hypertension and engorgement of venous collaterals leading to cyanosis and edema of the head, neck, and upper extremities is known as the SVC syndrome [105]. The most common cause of SVC syndrome in children is primary lymphoma or lymphoblastic leukemia [106]. SVC syndrome is often present without associated airway compromise in the adult with a mediastinal mass. In children with such a mass, however, the SVC syndrome is closely associated with and may predict the development of acute airway compromise. Tracheal intubation may be more difficult due to laryngeal edema that results from SVC obstruction. This obstruction

may also cause pulmonary artery or myocardial compression or affect right ventricular output, causing right heart failure [107]. Anesthetic-induced myocardial depression will aggravate these effects, with potentially disastrous consequences. Cerebral venous drainage and cerebral perfusion pressure may also be reduced in the patient with significant SVC obstruction. As such, any patient presenting with SVC syndrome should be considered high risk. Patients with cardiovascular symptoms and SVC syndrome or those patients unable to give an adequate history should therefore have transthoracic echocardiography to assess for cardiac, systemic, or pulmonary vascular compression.

Historically, children with tracheobronchial compression greater than 50% on CT have been considered high risk for general anesthesia [108]. More recent reviews have found the presence of orthopnea or SVC syndrome may be predictive of anesthesia-related complications [104, 107], but the extent of symptoms do not correlate well with the degree of tracheal narrowing on CT scan [96]. Based on these studies and the authors' clinical experience, the following risk stratification guideline regarding safety for general anesthesia is suggested. The patient with minimal to no orthopnea and near-normal tracheobronchial area on CT scan will likely tolerate general anesthesia. In contrast, the child with moderate to severe orthopnea and tracheobronchial area < 50% of normal on CT scan or the patient with evidence of SVC syndrome or a pericardial effusion should be considered high risk. Unfortunately, there are several patient groups whose risk for general anesthesia remains uncertain. They include the child with mild orthopnea whose tracheobronchial diameter is unknown and older child who is unable to give a history.

Direct examination of mediastinal mass tissue has been the traditional and preferable approach to making the diagnosis. In high-risk or symptomatic patients, however, the risk of general anesthesia and thoracotomy, mediastinoscopy, or VATS may be considerable. Excisional biopsy of extrathoracic lymph nodes has often been sufficient to confirm the diagnosis and allow for appropriate therapy. Increasingly, cytometric and immunocytochemical studies of pleural fluid have also been used with success to secure a diagnosis, obviating the need to deliver deep sedation or general anesthesia. Thoracentesis is particularly useful in lymphoblastic lymphoma, which is associated with a high incidence of pleural effusion [109, 110].

In the high-risk patient without extrathoracic lymphadenopathy or a pleural effusion, percutaneous needle biopsy of the tumor under ultrasound or CT guidance may be a safe alternative [111, 112]. In centers equipped with interventional radiology expertise, core needle biopsies can be obtained under ultrasound guidance with the patient in a semi-upright or lateral position [113, 114]. This can be achieved under local anesthesia and mild sedation as required. The most obvious disadvantage to needle biopsy is the inherent "failure to diagnose" rate due to insufficient tissue for complete histological and molecular classification, although a failure rate exists also for open biopsy [115].

The use of prebiopsy corticosteroid treatment to reduce tumor size has generally been avoided if possible due to the extreme and rapid responsiveness to this (and radiation) therapy. There is widespread belief that prebiopsy steroid therapy will impair accurate histological diagnosis and result in suboptimal treatment or recurrence with a less favorable prognosis. A 10-year review of children presenting with an anterior mediastinal tumor sheds light on and refutes this myth [116]. Twenty-three of the 86 patients in that series received prebiopsy hydrocortisone because of clinical evidence of respiratory compromise. Prebiopsy steroid treatment was felt to have had an adverse effect on the pathological diagnosis in 5 of the 23 children; however, survival in those 5 patients was unaffected, and the authors concluded that prebiopsy steroid administration is defensible in symptomatic patients. In a more recent series, one third of children with a mediastinal mass were treated with corticosteroids prior to diagnosis because they were considered high risk. A clear diagnosis was made in 95% of these patients despite steroid therapy [99]. In these cases, close and ongoing consultation with the oncologist is essential. Prebiopsy steroid therapy may be justifiable (and arguably necessary) if the patient has symptoms and CT evidence of significant airway or cardiovascular compression and is too young or uncooperative to tolerate local anesthetic alone. A typical regimen consists of 20 mg prednisone equivalents per meter square of body surface area, administered three times daily. Coordination between the oncologist, surgeon, and anesthesiologist is essential as biopsy tissue should be obtained between 12 and 24 h after starting steroid therapy. These patients should be monitored and treated in anticipation of developing tumor lysis syndrome, a constellation of metabolic abnormalities which can include hyperkalemia, hyperuricemia, hyperphosphatemia, secondary hypocalcemia, and acute renal failure [117].

Another alternative to preoperative steroids in the high-risk patient includes irradiating the tumor while leaving a small area covered with lead for subsequent biopsy. This is not a viable option for the majority of pediatric patients presenting with a mediastinal mass as it requires the patient be cooperative and able to lie still for the duration of the treatment.

Flow-volume loops are commonly ordered as part of the preoperative assessment for patients with an anterior mediastinal mass. Specifically, the development of an increased expiratory plateau when changing from the upright to the supine position is thought to be pathognomonic for a variable intrathoracic airway obstruction and an indicator of patients who are at risk for airway collapse during induction of anesthesia.

However, a careful examination of the literature reveals that this emphasis on flow-volume loops derives from a single case report [118]. Apart from isolated case reports, studies of flow-volume loops have shown a poor correlation with the degree of airway obstruction [119–121]. The use of flow-volume loops in the assessment of patients with anterior mediastinal masses is well described in standard anesthesia texts and frequently asked on anesthesia specialty exams. However in clinical practice, it is difficult to see how flow-volume loops add any useful information beyond that which is obtained from the history and chest imaging. Certainly flow-volume loops may show some correlation with airway obstruction in selected patients. However, modern chest imaging will tell the clinician not only if there is an obstruction but also its location, severity, and extent. This is the truly vital information in deciding how to manage the airway of a patient with an anterior mediastinal mass.

Although deep general anesthesia and muscle relaxation can be avoided in most patients with symptomatic lesions, invariably the anesthesiologist will be faced with the uncooperative child with a compressive mediastinal mass requiring general anesthesia for a diagnostic or therapeutic procedure. Management of these patients is guided by their symptoms and the CT scan. A stepwise induction of anesthesia with continuous monitoring of gas exchange and hemodynamics is recommended. This may be achieved by inhalation of a volatile agent such as sevoflurane or IV titration of propofol, ketamine, and/or dexmedetomidine which maintains spontaneous ventilation until either the airway is definitively secured or the procedure is completed [122]. Awake intubation of the trachea before induction is a possibility only in older, mature pediatric patients if the CT scan shows a distal area of noncompressed trachea to which the ETT can be advanced before induction. If muscle relaxation is required, ventilation should first be gradually taken over manually to assure that positive-pressure ventilation is possible and only then can a muscle relaxant be administered. In some centers, muscle relaxation is avoided throughout the entire procedure if at all possible, as there have been cases of cardiorespiratory collapse that were likely caused by the resultant loss of muscle tone [123].

Airway or vascular compression can develop at any stage of the procedure and should be anticipated. In the preoperative assessment, the patient will often report that there is one side or position that causes less symptoms of compression. This, along with the findings on chest imaging, should be communicated to the entire operative team prior to anesthetic induction. In the event of intraoperative life-threatening airway or cardiovascular collapse, the patient should immediately be placed in that predetermined position, which will often result in a dramatic clinical improvement. The prone position has also been lifesaving in this setting [124]. Rigid bronchoscopy and ventilation distal to the obstruction may be necessary. As such, an experienced bronchoscopist and rigid bronchoscopy equipment must always be immediately available. In emergent situations, it is often not possible to push a standard ETT distally through the collapsed trachea. Ventilation and oxygenation can be reestablished temporarily with either a ventilating rigid bronchoscope or with jet ventilation via a rigid scope. Ultimately a reinforced ETT should be placed distal to the obstruction to stent the airway. This can be done by passing an airway exchange catheter or bougie distally under direct vision through the rigid bronchoscope, then withdrawing the bronchoscope, and using the airway catheter as a guide for the ETT [125]. In fact it may be reasonable to use an armored tube in all patients with a mediastinal mass; however, a stylet will still be needed to advance the tube distal to the compressed portion of the airway. Depending on the response to the above emergency measures, the patient may have to be awakened as rapidly as possible and other options for surgery explored.

Heliox may be used in the event of subtotal airway collapse to decrease the work of breathing. Heliox is a mixture of helium and oxygen (most commonly 70:30) and decreases the turbulent airflow resistance through a narrowed airway due to the decreased density of helium.

Femorofemoral cardiopulmonary bypass (CPB) before induction of anesthesia is a possibility for older and more cooperative children who are considered “unsafe” for general anesthesia. Although emergency percutaneous CPB has been used successfully in an adult patient with impending complete airway obstruction [126], this is not a practical option in the young, frightened child. In addition, even the smallest femoral bypass cannulae are too large in diameter to be used in the patient weighing less than 15–20 kg. In such a case, preoperative steroid therapy should be considered.

The concept of CPB “standby” during attempted induction of anesthesia is fraught with danger because there is not enough time after sudden airway collapse to establish CPB before hypoxic cerebral injury occurs. It is not a practical option in the pediatric patient with a large anterior mediastinal mass. For patients who present with primarily cardiovascular rather than airway compression, rigid bronchoscopy will not be a useful resuscitation maneuver in the event of cardiovascular collapse. Resuscitation intraoperatively may require emergent sternotomy and lifting the tumor off the heart and great vessels [127]. For this reason, whenever possible, patients with cardiovascular compression should be prepped and draped for surgery prior to induction of anesthesia.

Congenital Diaphragmatic Hernia (CDH)

Congenital herniation of the abdominal contents into the thoracic cavity occurs in approximately 1 in every 2500 live births [128]. The majority of cases will present prenatally if

the mother has undergone standard ultrasonography [129, 130]. Occasionally, the diagnosis will be made in the early postnatal period. Intrusion of abdominal viscera into the thorax during fetal lung development leads to pulmonary hypoplasia and pulmonary vascular hypertension. This may promote persistence of fetal circulation (i.e., patent foramen ovale and PDA) after birth. Most cases of CDH occur on the left side at the foramen of Bochdalek, accounting for 80% of unilateral herniations. Less common is herniation at the foramen of Morgagni or at the esophageal hiatus itself. Mortality is related to the size of the defect and the association of cardiovascular anomalies. Approximately 10–30% of patients with CDH will have other congenital anomalies. These include congenital cardiac disease, chromosomal abnormalities (e.g., trisomy 18 and 21), CNS (e.g., spina bifida, hydrocephalus), and gastrointestinal anomalies (e.g., TEF, malrotation, atresia) [131]. Right-sided hernias are more often associated with these other defects. Large diaphragmatic hernias not diagnosed prenatally will present at delivery with severe respiratory distress and cyanosis. Physical findings include decreased breath sounds unilaterally or bilaterally. Indrawing, nasal flaring, and accessory muscle use indicate impending respiratory failure. Palpation of the trachea often reveals deviation away from the affected side. Peristaltic (bowel) sounds may be heard over the affected hemithorax. Chest X-ray will reveal mediastinal shift away from the affected hemithorax as well as air-filled bowel loops in the chest. The position of a nasogastric tube will be above the diaphragm.

As a result of compression and interference with normal lung development, the affected lung is reduced in volume and hypoplastic. Pulmonary surfactant deficiency contributes to poor lung compliance. This results in poor gas exchange and worsening of hypoxia, hypercapnia, and acidosis. PVR may remain elevated with persistent fetal circulation. High airway pressures and hemodynamic instability can further drive pulmonary hypertension. With elevated PVR and a PDA, right-to-left shunting will occur. Other sites of shunting may also exist depending on the associated cardiac pathology. Systemic hypoxia will continue because of this shunting, and disease progression will accelerate. Without appropriate preoperative support, this cascade of hypoxia, acidosis, increasing PVR, and right-to-left shunt will lead to cardiac dysfunction and patient demise. Routine preoperative echocardiogram is mandated to screen for the aforementioned defects, PVR and ventricular function.

Management strategies for CDH have changed over the last few decades [80, 132]. Currently, preoperative stabilization followed by surgical repair is recommended. That being said the optimal timing of repair is currently debated. Much of the recent work has focused on optimizing hemodynamic and ventilatory support in this patient population [133]. At present no one best strategy has been universally agreed upon. Historically, resuscitative efforts were aimed at achieving alkalosis through active hyperventilation with the goal of minimizing pulmonary vascular hypertension. Contemporary "gentle" ventilation guidelines aim to minimize barotrauma by limiting maximal inspiratory pressures (<25 cmH_2O) and tidal volumes. Much like in the management of adult RSD, a degree of hypoxia and hypercapnia is accepted. Survivability has actually been shown to improve in these patients managed in this way provided PaO_2 is kept at 60 mmHg and $PaCO_2$ approaches 65 mmHg [134–136]. Until invasive arterial vascular access can be gained, one may aim for a preductal oxygen saturation of 85% with postductal saturation of 60%. Failure to achieve these goals with conventional ventilation may be an indication for conversion to high-frequency oscillatory (HFO) or jet ventilation. To facilitate this method of ventilation, judicious use of sedatives, narcotics, and muscle relaxants will be required. Alternatively, progressive hypercapnia and acidosis with an A-a gradient >500 mmHg are indications for ECMO [137, 138].

Pharmacologic adjuncts for the management of pulmonary hypertension have included inhaled nitric oxide, sildenafil, prostaglandins, and prostacyclins [139]. In this case, inotropic support is often required. With improvements in preoperative management, the overall survival rate has been reported as >75% [140].

The anesthesiologist may first become involved during resuscitative efforts at the time of birth. Early insertion of a nasogastric tube will be necessary to decompress the stomach. The reduced volume of air in the stomach will aid ventilatory mechanics. Likewise bag-mask ventilation should be kept to a minimum to avoid further gastric distension. If oxygen saturation continues to decrease despite NG tube insertion and high-flow oxygen, then tracheal intubation is appropriate. Sedatives, narcotics, and muscle relaxants are often administered to facilitate tracheal intubation and positive-pressure ventilation.

Intraoperatively the anesthesiologist must attempt to maintain ventilation and oxygenation as discussed earlier. Conversion from HFO to conventional ventilation should be attempted prior to surgery, although CDH repair is possible with the patient on HFO ventilation [141, 142]. Peak airway pressures should be limited to avoid barotrauma and worsening PVR. A sudden rise in airway pressures or decrease in lung compliance can indicate a contralateral pneumothorax which must be diagnosed and treated promptly as it may be associated with a worse outcome. Anesthetic management typically includes a narcotic and muscle relaxant technique. In addition to basic monitoring, an arterial line (preferably right radial) as well as pre- and postductal oxygen saturation monitors should be placed. Decreasing postductal saturation may indicate worsening right-to-left shunt and increasing PVR. Closure of the diaphragmatic hernia may compromise venous return from the lower extremities, and therefore

intravenous access in the upper limbs is preferred. Insertion of an internal jugular venous line is not essential and risks causing a pneumothorax but if already present can be a useful adjunct for monitoring right-sided pressures and venous oxygen saturation.

Surgery usually consists of an abdominal incision with the herniated contents being reduced into the abdomen. Small defects can then be closed primarily, while larger ones may require the use of a synthetic patch. Closure of the abdomen may also necessitate the use of a patch to avoid cardiopulmonary compromise in the event of elevated abdominal pressures. With reduction complete, the hypoplastic lung should not be aggressively ventilated as this will increase the risk of barotrauma and contralateral pneumothorax and is typically of little or no therapeutic value.

Minimally invasive repair of CDH has been documented in the pediatric population [143]. Unfortunately the literature in favor of this technique likely suffers from patient selection bias (most stable patients selected for this technique). Current consensus statements do not recommend the routine use of minimally invasive repair [143, 144].

Lung Biopsy

Optimum management of solid lung masses almost always requires correct pathological diagnosis via biopsy of the affected tissue. Obtaining such samples, however, can be challenging, especially when dealing with pediatric patients. The traditional method for acquiring these samples has been open lung biopsy, which is associated with morbidity and considerable pain. Increasingly, less invasive procedures such as endobronchial biopsy and image-guided percutaneous biopsy have been used in children [145]. Concerns regarding endobronchial biopsy include bleeding and the histologic adequacy of the sample obtained. Minor mucosal bleeding is common and not of great concern as experience with airway foreign body removal would indicate that minor bleeding of the mucosa is not associated with a worse outcome [146]. Although not all lung masses are accessible via transbronchial biopsy, it is useful as a diagnostic measure in patients with poorly controlled asthma [147], cystic fibrosis (CF) [148, 149], and postlung transplant monitoring [150]. Salva et al. [54] prospectively studied 170 children between the ages of 2.5 and 16 years who underwent flexible endobronchial biopsy for a variety of chronic respiratory conditions. At least three biopsy samples were taken from each patient. These children received a general anesthetic in an ambulatory setting with the use of an LMA (as described earlier). The results were encouraging as no patient required intervention for mucosal bleeding and there were no cases of pneumothorax, hemoptysis, or pneumonia.

Image-guided percutaneous lung biopsy can be performed with CT or ultrasound guidance depending on the location and accessibility of the tumor. Deep sedation with local anesthetic infiltration [151] or general anesthesia can be performed depending on age, cooperation, and medical status of the patient. Disadvantages compared to general anesthesia include the inability to suspend respiration to aide biopsy localization. In a series of CT-guided percutaneous lung biopsies performed in children between the ages of 0.6 and 20 years, most cases were performed successfully with deep sedation. Adequate tissue samples were obtained in 85% of the cases [152]. Perioperative complications that did not require intervention included subclinical pneumothorax (17%), pleural effusion (3%), subcutaneous hemorrhage (12%), and postprocedural hemoptysis (3%). There was one case of tension pneumothorax requiring chest tube insertion. There was no association between adverse events and the number of biopsy attempts. All children received a chest X-ray approximately 6 h after the procedure or sooner as clinically indicated. Despite an overall complication rate of 28%, percutaneous biopsy fares favorably when compared to historic data on surgical open biopsy. Procedure length, overall hospital stay, and procedural costs also tend to favor percutaneous biopsy.

For those patients in whom percutaneous biopsy has failed to yield a diagnosis and those in whom the lung pathology is not amenable to such a technique, surgical lung biopsy is required. This can be performed with open thoracotomy or VATS. Although postoperative morbidity is increased in comparison to percutaneous biopsy, surgical biopsy is still considered by many the gold standard diagnostic tool. Gluer et al. [153] prospectively evaluated the feasibility, efficacy, and safety of the VATS technique for lung biopsy in patients with diffuse parenchymal lung disease. This was performed with general anesthesia using a single-lumen tube without lung isolation. The average age of the 21 patients was 3 years (range 12 days to 15 years). Only two cases required conversion from VATS to mini-thoracotomy, and no other intraoperative complications were noted. Studies comparing thoracoscopic and open lung resection in children have shown comparable success rates, safety parameters, and clinical outcomes [154, 155]. As experience with pediatric VATS procedures increases, we are seeing an increase in the number of biopsy procedures performed using this technique.

Cystic Fibrosis (CF)

Thick inspissated secretions causing airway obstruction, atelectasis, and superimposed pneumonia are some of the pulmonary sequelae of this multiorgan disease. Respiratory dysfunction can be quite pronounced with patients becoming extremely ill. Progression of the disease can lead to cor pul-

monale, pneumothorax, antibiotic-resistant infections, and bronchiectasis. Intestinal malabsorption and pancreatic and liver dysfunction are the most frequent extrapulmonary effects. Measures such as chest physiotherapy, bronchodilators, antimicrobial treatments, and medications to break down secretions (i.e., Pulmozyme), have significantly improved outcome and quality of life for many patients. Despite this, eventual respiratory failure is the rule, and, for many, lung transplant may be the only alternative. Children with CF may present for surgery at various stages of life. The neonate may present with meconium ileus or for central line placement for nutritional supplementation. Older children may present with pneumothorax requiring chest tube insertion and bronchoscopy for lavage of inspissated secretions, and microbrial diagnosis of infections can happen at any stage of life.

Anesthetic management is predicated on optimizing preoperative respiratory function. Consultation with the pulmonologist is indicated for all patients with CF. Medical management including appropriate antibiotic treatment, optimizing bronchodilator use, and initiating Pulmozyme therapy often requires the patient be admitted to hospital prior to the scheduled procedure. Preoperative laboratory investigations should include arterial blood gas, electrolyte panel, liver function tests, and blood glucose. Reviewing the most recent spirometry or PFTs and available chest imaging will also help in determining the degree of respiratory dysfunction. Chest physiotherapy for secretion clearance should be ordered preoperatively and early in the postoperative period. Controversy exists as to the most favorable perioperative fluid management strategy. Although aggressive fluid supplementation may decrease the viscosity of pulmonary secretions, some anesthesiologists prefer to limit fluid administration to decrease the volume of secretions. To date no one best strategy has been found. Whichever approach is taken, it is advisable to have the patient euvolemic at the start of the procedure. Bronchoscopy, bronchoalveolar lavage, and transbronchial biopsies may be performed through an LMA with the patient breathing spontaneously; however, anesthetic depth must be sufficient to prevent coughing and laryngospasm. Increasingly, muscle relaxation and gentle positive-pressure ventilation through the LMA have simplified anesthesia for bronchoscopic procedures in children with CF. If a tracheal tube is to be used, it must be adequately large to allow for ventilation around the fiberoptic scope as well as tracheobronchial suctioning. Routine noninvasive monitoring is acceptable for straightforward procedures; however, an arterial line may be helpful in more involved cases to assess oxygenation, ventilation, and blood glucose monitoring.

Inhalational induction may be slow in patients with severe respiratory dysfunction, and therefore intravenous induction is often preferred in this patient group. Intraoperative complications to be aware of include mucus plugging, pneumothorax, bronchospasm, and atelectasis. Inspired gases should be humidified, and tracheobronchial suctioning should be performed at regular intervals throughout the procedure. Some clinicians advocate against the use of ketamine in children with CF as this drug can increase airway secretions. Regional techniques for pain management have the theoretical advantage of minimizing respiratory depression associated with systemic narcotic use and should be considered. In the mature child or teenager with CF undergoing peripheral surgery, regional anesthesia with or without mild sedation may be a reasonable option. A plan for postoperative ventilatory support must be discussed among the surgical team, anesthesia, intensivist, and the patient/family. Respiratory compromise due to surgery, postoperative sedation, narcotic analgesia, and a weakened cough will increase the likelihood of needing postoperative ventilator support.

Pulmonary Alveolar Proteinosis

PAP is a rare disease in which accumulation of phospholipoproteinaceous material in the alveoli causes pulmonary impairment [156]. A deficiency in granulocyte-macrophage colony-stimulating factor (GM-CSF) activity results in defective macrophages and reduced clearance of surfactant from the lungs [157]. Regular administration of GM-CSF as well as bronchoalveolar or whole-lung lavage is an important part of treatment for this disease and often results in temporary improvement of symptoms and radiographic appearance (see also Chap. 45).

The small child with PAP requiring whole-lung lavage presents a particular challenge to the anesthesiologist. In adolescents and adults, double-lumen bronchial tubes are often used to isolate the lungs for lavage; however, such tubes do not currently exist for use in smaller children. Several techniques have been described to isolate the lungs in smaller children in order to allow for lavage. No single method has been shown to be ideal, and each has its risks and limitations. Extracorporeal circulation has been used which allows for thorough bilateral whole-lung lavage; however, it is invasive and may be associated with significant morbidity [158]. Lavage through a flexible bronchoscope adjacent to a cuffed ETT allows for improved lung isolation [159]; however, this can be a lengthy process and also carries a risk of causing trauma to bronchial mucosa. Lavage through a pulmonary artery catheter has also been performed either through a rigid bronchoscope [160] or through an ETT [161]. This method also allows for lung isolation; however, the diameter of a pulmonary artery catheter port is small, and drainage may be inadequate. The most commonly used method of lung lavage in children is individual or multilobar lavage through a flexible fiberoptic bronchoscope. This may

be performed through an ETT or an LMA. It is more time-consuming than whole-lung lavage, however, may be associated with lower lavage returns, and does not isolate the lung.

For whole-lung lavage in a child under the age of 9 years, true lung isolation may be achieved by using an assembly that mimics commercially available double-lumen tubes. Two cuffed tracheal tubes are passed through the glottis, one seated endobronchially to isolate the lung to be lavaged and the second seated in the trachea. These tubes are then connected to the angled and Y-connectors from a standard double-lumen bronchial tube set (Fig. 50.6) [162]. Although this approach may allow for proper lung lavage, one-lung ventilation, and obviate the need for postprocedural ventilation, the nature of the underlying illness may nevertheless dictate the need for monitoring in a high-acuity setting. Because of the nature of the procedure and the airway assembly, total intravenous anesthesia is likely preferable if this technique is to be used. This type of airway assembly can be used in the small child requiring differential lung ventilation and/or strict lung isolation for a variety of procedures other than lung lavage. Disadvantages include the necessarily smaller sizes of the two tracheal tubes needed to simultaneously pass through the vocal cords. Dexamethasone 0.1 mg/kg IV may be given prior to the procedure to reduce the risk of mucosal edema at the level of the cricoid cartilage.

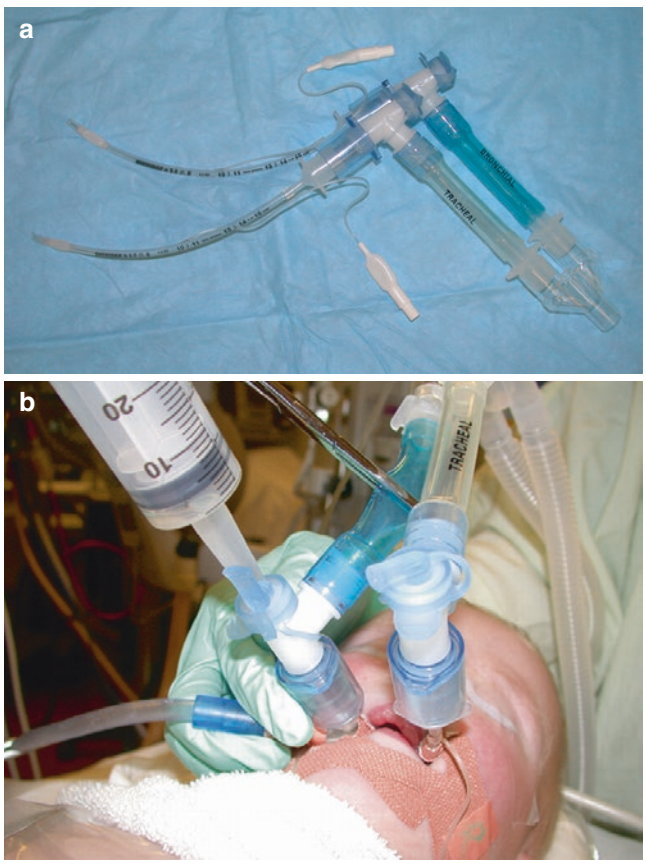

Fig. 50.6 (**a**) Airway assembly for use in the small child that mimics commercially available double-lumen bronchial tubes. Two cuffed tracheal tubes are passed through the glottis, one seated endobronchially to isolate the lung to be lavaged and the second seated in the trachea. These tubes are then connected to the angled and Y-connectors from a standard double-lumen bronchial tube set. (**b**) Whole-lung lavage being performed in a 3-year-old child via the bronchial tube of the airway assembly, while positive-pressure ventilation is applied via the tracheal tube

Trauma, Pneumothorax, and Hemothorax

Due to the unique and changing physiology and psychology of children, the management of the pediatric trauma patient may be quite different from that of the adult. Although isolated chest injuries are rare in children (5–15% of traumas), when associated with other injuries, the mortality rate can be as high as 25% [163–165]. Between 60% and 80% of all pediatric trauma is blunt impact, usually from motor vehicle collision [105]. Incomplete ossification of the ribs in children means that the rib cage is more likely to deflect under traumatic assault as opposed to fracture. Therefore, pulmonary contusions are more likely in children as compared to adults even in the absence of overlying rib fractures [166]. Conversely, a child that presents with rib fractures has likely suffered a severe, high force trauma to the chest. Insertion of a thoracic epidural catheter should be considered in the analgesic management of the child with multiple rib fractures [167]. Penetrating chest injuries due to gun violence and knife stabbings are less common in children. The presence of rib fractures in the infant should raise suspicion of child abuse [168, 169].

Pulmonary contusion is perhaps the most common traumatic thoracic injury in the pediatric population [170, 171]. Within the lung parenchyma, this manifests as alveolar edema and consolidation, sometimes associated with hemorrhage. Because of the child's higher metabolic oxygen consumption, lung injury may be accompanied by significant hypoxemia. Mechanical ventilation may be required although most pulmonary contusions can be treated by less invasive measures [172]. This includes BiPAP, supplemental oxygen, pain control, fluid restriction, and incentive spirometry when appropriate. Preventing and treating atelectasis are essential as this will reduce the risk of pneumonia and further respiratory compromise.

Pneumothorax may occur spontaneously in susceptible patients but is more often encountered at the conclusion of surgical thoracic procedures or in the setting of trauma. An open pneumothorax, one in which the pleura communicates with atmosphere, is treated with the insertion of a chest tube that allows for drainage without further entrainment of air upon inspiration. The chest tube apparatus is usually placed under water seal or to a suction device. Toward the

end of most major thoracic procedures, the surgeon will choose to electively place such a device. For minor intrathoracic procedures, some surgeons will elect not to place a chest tube. In these cases, air is removed as the chest wall is closed, while the anesthesiologist provides positive pressure to the lung. These maneuvers should minimize any residual pneumothorax. A postoperative chest X-ray is required with careful monitoring of the patient for signs of increasing pneumothorax. Most small (i.e., <10%) pneumothoraces are insignificant and will resolve over a period of a few days.

Tension pneumothorax occurs when air accumulates in the pleural space without communicating with atmosphere. As the pressure builds within the pleural space, the ipsilateral lung will further collapse with increasing mediastinal shift. Clinical deterioration of the patient will become apparent. Hypotension, hypoxia, and decreased cardiac output will require emergent management. Diagnosis is confirmed by decreased breath sounds on the ipsilateral side, tracheal deviation away from the affected lung, and shift of the maximal cardiac impulse. Radiographic diagnosis should not delay the emergent placement of a chest tube or needle decompression followed by chest tube insertion.

Bleeding into the pleural cavity can occur intraoperatively or postoperatively following any thoracic procedure. The amount of blood loss due to hemothorax in this setting should be minimal if hemostasis was achieved prior to closure. In the case of thoracic trauma, however, the amount of blood loss can quickly become life-threatening. Disruption of intercostal arteries or veins is the most common culprit in this setting. As with tension pneumothorax, the accumulation of blood will compromise ventilation and cardiac output. If this blood is not promptly drained, it may reorganize into a fibrous scar thus causing chronic atelectasis and V/Q mismatch. In addition to this, the blood may become a medium for bacterial growth with ensuing sepsis and empyema formation. Operative exploration of a hemothorax must be considered when there is ongoing drainage from the chest tube and/or the patient remains hemodynamically unstable. Some clinicians advocate a quantitative approach that would require surgical exploration if greater than 15 mL/kg of blood is recovered upon chest tube insertion or if ongoing drainage exceeds 4 mL/kg/h [173].

Major airway disruption is rare in pediatric trauma but may occur in the setting of penetrating injury or rapid acceleration or deceleration. When present these injuries can be immediately life-threatening. In 80% of cases, the disruption is located at the distal trachea or main bronchus [174, 175]. Airway injury should be suspected in the setting of pneumomediastinum, subcutaneous emphysema, large persistent air leak within the chest tube, and frank respiratory collapse. Diagnosis is usually confirmed by bronchoscopy, either rigid or flexible. When airway injury is suspected, intubation should be performed fiberoptically and the ETT placed distal to the disruption to avoid further trauma or creation of a false passage. Immediate operative repair of major airway injuries may be required although minor injuries can be observed with delayed surgical repair as required. Distal injuries can be treated with simple resection, while more proximal injuries may require quite extensive repairs. Postoperative complications may include dehiscence, airway stenosis, atelectasis, and pneumonia. A severe blow to the chest while the vocal cords are adducted can lead to a rare injury pattern that is unique to pediatrics. Traumatic asphyxia presents with neck and facial swelling and ecchymosis, subcutaneous emphysema, and pneumomediastinum [176]. The sudden increase in intrathoracic pressure causes a small tear in the upper trachea and forces air into the tissues of the neck, face, and around the mediastinum. Management is often supportive and nonsurgical.

Lung Transplantation

Pediatric lung transplantation continues to account for a small fraction of all lung transplant operations performed. Despite this, the number of transplants performed on children is increasing, and the minimum age of transplantation is decreasing. Many large pediatric transplant centers have established living donor programs and life-sustaining temporizing measures such as the Novalung® have been introduced for use in children awaiting a donor lung (Toronto Lung Transplant Program, Hospital for Sick Children Statistics, 2009, personal communication). The vast majority of pediatric lung transplant procedures are carried out in children between 10 and 17 years of age. CF accounts for over 64% of cases in children, followed by primary pulmonary hypertension (14%), pulmonary interstitial disease (7%), and retransplant (7%) [177]. Actuarial survival rates tend to be favorable for pediatric lung transplantation as compared to those for older adults.

A multidisciplinary team and approach are crucial to meet the surgical, medical, psychological, physical, and dietary challenges that will be faced. At the time or writing, children smaller than 10 years of age (i.e., those too small to accept a double-lumen bronchial tube) usually undergo lung transplantation under cardiopulmonary bypass. Other indications for the use of bypass during lung pediatric transplantation include primary pulmonary hypertension and severe right ventricular dysfunction. There also continues to be a significant rate of conversion from off-bypass double sequential lung transplant to urgent bypass in children due to worsening pulmonary hypertension or relentless hypoxemia. The advantage of off-bypass

sequential lung transplantation is the avoidance of systemic anticoagulation needed for cardiopulmonary bypass. A short period of postoperative ventilation is provided to monitor for early complications such as ischemic-reperfusion injury, infection, acute rejection, bleeding, and anastomotic leaks.

Postoperative and Pain Management

The postoperative disposition of a child who has undergone a thoracic procedure will depend on many criteria including the type and length of surgery, extent of resection or manipulation, and nature of the underlying condition. In general, infants and small children will be more frequently managed with a short period of postoperative ventilation when compared to adult patients. Regardless of the type of surgery or reason for intervention, the pediatric patient should be monitored for respiratory status and adequate pain control in a suitable environment. Constant care or high-acuity nursing and monitoring should be considered even if the patient's trachea was extubated in the operating room.

Because many procedures are now being done with the less invasive video-assisted thoracoscopic technique, postoperative pain management has become somewhat easier. These patients can often be managed with nonopioid analgesics, a simple narcotic infusion, or patient-controlled analgesia. Table 50.4 outlines commonly used analgesics in pediatric practice. Local anesthetic can also be infiltrated prior to the placement of trocars, and multimodal analgesia should be considered in all patients. Pain control for the pediatric patient has recently regained a renaissance with the more aggressive use of regional anesthesia techniques. These techniques are being applied to a wider range of the pediatric population with good success and minimal complications. The proper management of postoperative pain can avoid some of the negative physiologic outcomes associated with poorly treated pain. These include heightened sympathetic drive, increased metabolism, decreased immune function, and, specifically for thoracic procedures, poor respiratory function [177]. A simple option for regional analgesia includes intercostal nerve blocks performed prior to skin incision or just before surgical closure under direct visualization. Local anesthetic dosages should be reduced as plasma uptake at this site is rapid [178]. The overlap of thoracic dermatomes requires that the nerves above and below the surgical site also be blocked. Indwelling intercostal catheters can also be placed by the surgeon and managed as a constant infusion postoperatively [179].

Table 50.4 Commonly used analgesics in pediatric practice[a]

Analgesic	Dose[b]	Infusion dose	PCA dosing (μg/kg q 6–10 min) or comment
Morphine	50 μg/kg	10–40 μg/kg/hr	10–30
Fentanyl	0.5 μg/kg	0.5–2 μg/kg/hr	0.2–0.5
Hydromorphone	0.15 μg/kg	3–5 μg/kg/hr	3–5
Remifentanil	0.5 μg/kg	0.05–2 μg/kg/min	Intraoperative use only
Ketamine	0.15 μg/kg	1–4 μg/kg/min	Narcotic-sparing effect; may be useful if opioid side effects considerable
Acetaminophen	75 mg/kg/day po	N/A	q4h dosing for oral, q6h for rectal
Ibuprofen	5–10 mg/kg po q6h	N/A	For children >6 months of age
Ketorolac	0.5 mg/kg (maximum 15 mg) q6h	N/A	For children >6 months of age. Limit to 48 h, and then switch to po ibuprofen

Abbreviations: PCA patient-controlled analgesia, *po* per os

[b]Doses are intravenous unless otherwise specified

The epidural space in the child can be assessed in a similar fashion to that of adults. Ideally the epidural catheter tip should be placed at the dermatome level corresponding to the surgical site. Specific pediatric-sized Touhy needles should be used to minimize complications and provide for better control. Unlike in adults, thoracic epidural catheters are almost always placed when the child has already been anesthetized. Therefore, greater care must be exercised when advancing the needle as the patient will not be able to articulate the presence of radicular pain. Despite this drawback, there is no evidence to suggest the incidence of complications is higher in children compared to adults [180].

In smaller infants, the caudal epidural space can be easily accessed and a catheter advanced to the required thoracic level, using an ultrasound-guided approach [181]. As in adults many different local anesthetic solutions and adjuncts have been used in the pediatric population. The most commonly used local anesthetics continue to be bupivacaine and ropivacaine for either "single shot" or continuous infusion epidurals [182]. Suggested neuraxial blocks and dosing guidelines suitable for pediatric thoracic procedures can be found in Table 50.5. Epidural narcotics are commonly coadministered as they reduce the dosage requirement for local anesthetics and improve the block quality. Epidural morphine, fentanyl, and hydromorphone are the most commonly prescribed narcotics for this use [183, 184]. The purpose of optimizing pain management strategies is not only to keep the child comfortable but also to avoid pulmonary dysfunction by enabling deep breathing and coughing. This can aide in the prevention of atelectasis and postoperative pneumonia. Early ambulation is also encouraged to further accelerate the recovery of the patient and prevent those diseases associated with prolonged immobilization and hospitalization.

Table 50.5 Neuraxial blocks and dosing guidelines suitable for pediatric thoracic procedures[a]

Type of block	Solution	Infusion rate (mL/kg/h)
Thoracic epidural[b]	0.125% bupivacaine + epi 1:400,000 ± fentanyl 1–2 μg/mL	0.1–0.16 maximum 10 mL/h
Thoracic epidural[b]	0.1% bupivacaine + epi 1:500,000 ± fentanyl 1–2 μg/mL	0.1–0.16 maximum 12 mL/h
Thoracic epidural[b]	0.0625% bupivacaine + epi 1:800,000 ± fentanyl 1–2 μg/mL	0.1–0.16 maximum 14 mL/h
Paravertebral[c]	0.125% bupivacaine + epi 1:400,000	0.2 maximum 15 mL/h
Intercostal[d]	0.125% bupivacaine + epi 1:400,000	0.016–0.032 per rib maximum 1 mL/h/rib
Intrapleural[e]	0.125% bupivacaine + epi 1:400,000	0.2–0.3 maximum 20 mL/h

[a]Adapted from Sick Kids Acute Pain Handbook, 2010. The Hospital for Sick Children, Toronto, Canada
[b]Alternatively, caudal or lumbar approach with epidural catheter threaded to thoracic level. Suggested loading dose of 0.2–0.25 mL/kg of 0.25% bupivacaine + epi 1:200,000 up to maximum 10 mL
[c]Suggested loading dose of 0.3–0.5 mL/kg of 0.25% bupivacaine + epi 1:200,000 up to maximum 15 mL
[d]Suggested loading dose of 0.05 mL/kg (maximum 2 mL) of 0.25% bupivacaine + epi 1:200,000 per intercostal space
[e]Suggested loading dose of 0.2–0.3 mL/kg (maximum 20 mL) of 0.25% bupivacaine + epi 1:200,000

Clinical Case Discussion

A 3-year-old child with a newly diagnosed left lung mass presents for tissue diagnosis followed 1 week later by thoracotomy and tumor resection.

The initial workup of the child will focus on the functional status and size of lung mass. Imaging will be essential to identify the size and location of tumor and to rule out a mediastinal mass. A CT scan will be required which may be done without sedation if the child is cooperative. Otherwise a stepwise approach of cautious sedation may be required. Any sedation should be delayed to verify the absence of a significant mediastinal mass. Tissue samples may be obtained through a mini-thoracotomy; however, in tertiary pediatric centers, image-guided needle core biopsy is preferred and associated with lower morbidity. Most 3-year olds will require deep sedation or general anesthesia. Spontaneous respiration can be maintained during the biopsies, which might be CT or ultrasound guided. Often tracheal intubation is not required, and the patient's airway can be managed by face mask, bag-mask support, or insertion of an LMA. Sedation/anesthesia may be achieved by TIVA (propofol or ketamine, alone or in combination with a short-acting opioid or benzodiazepine) and/or inhalation. Occasionally, a brief period of apnea will be requested to facilitate biopsy. This may be achieved temporarily deepening the anesthetic and providing positive-pressure ventilation. Postbiopsy X-ray should be performed to ensure there is no significant residual pneumothorax. Chest tube insertion is rarely required.

Tumor resection may be performed via VATS or open thoracotomy. In either case the anesthesiologist should be prepared to isolate the lung. Options in a 3-year old include (1) selective right mainstem bronchus intubation with a 4.5 or 5.0 mm ID tracheal tube, (2) insertion of a size 5F embolectomy catheter in the left mainstem bronchus inside or (more practically) outside a 4.5 mm ID tracheal tube, or (3) a 5F Arndt endobronchial blocker inserted in a 5.0 mm ID tracheal tube and placed in the left mainstem bronchus. Regardless of the option chosen, fiberoptic verification of proper tube or blocker positioning is crucial. A 2.2 or 2.8 mm OD pediatric fiberoptic bronchoscope should be used to ensure adequate ventilation may be provided while the scope occupies the lumen of the tracheal tube. The author prefers not to perform selective right mainstem bronchus intubations as quite often the tube slips distal to the right upper lobe takeoff, resulting in atelectasis of that lobe and worsening hypoxemia. Monitoring should include an invasive arterial blood pressure line in addition to standard monitors. Pain control will depend partly on whether VATS or open thoracotomy is performed. As a general guideline, central neuraxial blockade is offered in the event of open thoracotomy, and systemic analgesics are administered if VATS is performed. Postoperative monitoring in a high-acuity setting (step-down or critical care unit) is warranted for the first 12–24 h.

Part XIII

Trauma

Anesthetic Management of Thoracic Trauma

51

Stephen V. Panaro and Tzonghuei Herb Chen

Key Points

- The initial assessment and stabilization of the thoracic trauma patient is critical for successful outcomes. An understanding of the relevant anatomy and familiarization with the signs and symptoms of injury to the vital structures will minimize the chance of missed injury which could be catastrophic.
- Transesophageal echocardiography is a valuable tool in the care of the hemodynamically unstable thoracic trauma patient, reliably diagnosing and guiding the management of blunt cardiac injury, aortic injury, and hypovolemia.
- Airway management and lung isolation provide challenges to the anesthesiologist. Identification of the location of a tracheobronchial injury preoperatively will dictate the method of isolation beyond the injury. Lung isolation techniques are more challenging to novice anesthesiologists. Anesthesiologists who may be asked to manage thoracic trauma patients should familiarize themselves with these techniques.
- There is no level I evidence for the management of pulmonary contusion. There are similarities between the contused lung and ARDS and patients who present with pulmonary contusion should be ventilated with lung protective strategies.
- Management of cardiac trauma requires an understanding of the type of injury and prompt diagnosis is of paramount importance. Signs of cardiac tamponade must be identified quickly and the pericardium decompressed urgently. Echocardiography is a useful tool in evaluating injury and guiding therapy in unstable patients if available.
- Injury to the thoracic aorta is increasingly being managed with endovascular techniques, but not all patients are candidates. An understanding of the physiology of the thoracic aortic clamp and its implications for hemodynamic management remains important. Similarly, strategies for spinal cord protection during open repair must be considered. Expectant management of minimal aortic injury may become more common.
- Anesthesiologists play an integral role in the management of pain in the patient with chest wall injury. There is potential for improved outcomes with epidural analgesia, but many patients will not be candidates for neuraxial analgesia. In the patients who will meet exclusion criteria, other techniques including paravertebral blocks should be considered.

Introduction

Thoracic trauma is a morbid business. The American College of Surgeons estimates it is associated with a 10% mortality [1] with 16,000 deaths annually. That represents 25% of all trauma deaths. Considering that injury is the leading cause of death from ages 1 to 45 (more than half of all deaths ages 13–32 and 80% in teenage years) [2] and the leading cause of years of life lost before 75, its impact is enormous [3]. In one analysis, if injury is taken into account, the life expectancy in

the United States rockets from 19th in the developed world to first [4]. Since the vital structures in the chest are so well protected by the bony thorax, a great deal of force is required to disrupt them, and they are uncommonly injured in isolation in blunt trauma. Indeed, 70% of the time, insults to the chest are associated with multisystem injury.

This chapter will attempt to describe thoracic trauma in terms of the underlying injury and its treatment. This approach is not new and dates (at least) to the ancient Egyptian Edwin Smith Papyrus in the seventeenth century B.C. While our tools and management have changed (we no longer treat hemorrhage with the binding of fresh meat on the first day), the organization of the chapter will follow theirs – structured to some degree by injury type.

While the presentation of a patient with traumatic injury to the thorax can seem daunting, the principles in managing these patients are the familiar backbone of our specialty. A rational stepwise approach to the evaluation and management of these patients will not only yield the best results, but make it clear that there is nothing mystical about them. That process begins, as always, with an understanding of the relevant physiology, anatomy, and the tools we use to assess them.

Anatomy

The chest is by definition the upper part of the trunk between the neck and the abdomen formed by the 12 thoracic vertebrae and the corresponding ribs. Thoracic trauma may include injury to the chest wall, pleura, airways, heart, great vessels, diaphragm, and esophagus. The implications of injury vary by structure and its mechanism of insult. The most lethal injuries are those involving the mediastinal structures. The mediastinum itself is divided into four parts. The anterior mediastinum lies between the sternum and the pericardium and contains little other than fat, lymph nodes, the internal thoracic (mammary) vessels, and the thymus. The middle mediastinum contains the pericardium, heart, lower half of the superior vena cava, ascending aorta, tracheal bifurcation, as well as the pulmonary arteries and veins. The posterior mediastinum is the space between the tracheal bifurcation and vertebral column and contains the descending aorta, azygous, esophagus, and thoracic duct. Lastly, the superior mediastinum is bound by the manubrium and the first four vertebrae. It holds the aortic arch, brachiocephalic veins, upper half of the SVC, the left common carotid, and subclavian arteries as well as the brachiocephalic trunk. Stab injuries to the heart are thru the classic precordium (so-called box of death) bound by the sternal notch superiorly, nipples laterally, and inferiorly by the anterior ribs 80% of the time. Because the entry site for gunshot injuries to the heart are thru the precordium only a minority (46%) of the time, any entrance wound to the torso should raise concern of injury to the heart.

Initial Approach to the Patient with Thoracic Trauma

Many thoracic injuries are highly lethal. In fact, only two-thirds of patients will actually reach the hospital alive. Of those that do, the immediate identification and treatment of the six most lethal injuries is paramount, and the assessment of the thoracic trauma patient should follow the protocol detailed in ATLS®. Despite these statistics, most patients (90% of blunt injury and 70–85% of penetrating thoracic injury) who reach the hospital will not need operative intervention, and most can be treated by simple procedures commonly taught in the ATLS course including airway control and chest decompression (tube thoracotomy or needle decompression) [5]. The assessment of the thoracic trauma patient does not differ from the assessment of any trauma patient, and it begins with the primary survey focusing where the six most immediately lethal injuries to the chest are sought. These include airway obstruction, tension pneumothorax, cardiac tamponade, open pneumothorax, massive hemothorax, and flail chest. Each of these major problems is addressed as they are identified since each can be immediately lethal. Once the primary survey is completed and the patient is stabilized, the secondary survey is undertaken. The injuries typically found on secondary survey are not easily recognized on physical exam and can be missed. Still, each can be potentially lethal. The ATLS student manual focuses on eight potentially lethal diagnoses including simple pneumothorax, hemothorax, pulmonary contusion, tracheobronchial injury, blunt cardiac injury, traumatic aortic disruption, traumatic diaphragmatic injury, and blunt esophageal rupture. We will begin with the most lethal six.

The diagnosis of airway obstruction should be clear to any anesthesiologist. The physical findings of apnea, cyanosis, stridor, subcutaneous emphysema, and the appearance of a patient with air hunger should be familiar to us. The etiology may be from avulsed teeth, secretions, expanding neck hematomas, laryngeal trauma, or tracheal tears or transection. As always immediate intubation is indicated in any patient with airway compromise. Special considerations for patients with airway disruption will be discussed later in the chapter as will the management of the airway in the trauma patient.

Tension pneumothorax occurs when air enters the pleural space and cannot exit. This results in shift of the mediastinum, kinking of the superior and inferior vena cava, and a profound decrease in cardiac output. Patients present with respiratory distress, unilateral breath sounds, neck vein distention, tracheal deviation (rarely), and cyanosis (very late

finding). If this constellation of symptoms occurs just after intubation, one must become immediately suspicious. An old surgical adage holds that one should never have a chest X-ray (CXR) of a tension pneumothorax. This constellation of findings should be immediately treated with needle decompression (the classic teaching calls for the insertion of a 14-gauge catheter in the second intercostal space, midclavicular line) followed by tube thoracostomy, although a midaxillary approach for needle decompression is also acceptable (see below).

Cardiac tamponade is most often the result of penetrating trauma but can be seen in blunt trauma. The normal pericardial sac is tough and fibrous, and – when fluid builds quickly – only 75–100 ccs will cause tamponade physiology. The classic Beck's triad (JVD, hypotension, and muffled heart sounds) is only present in a third of patients. While Kussmaul's sign (rise in central venous pressure with inspiration) is reliable, it is not practical in the trauma setting since few patients have a central line in place before the diagnosis must be made. The equalization of pressures (should one happen to have a Swan-Ganz catheter in place) or systolic to diastolic gradient of less than 30 mm Hg may also suggest tamponade. Most commonly in trauma, the diagnosis will be suggested by ongoing hypotension without obvious blood loss. FAST (Focused Assessment with Sonography for Trauma) examination is highly accurate [6]. The patient can be temporized with pericardiocentesis occasionally, but this procedure is technically less challenging in the patient with chronic pericardial effusions than in traumatic tamponade because of the small amount of fluid necessary to cause the physiology and because clotted blood can be difficult to aspirate. In reality, trauma patients in extremis should be treated with ED thoracotomy. Those more stable should be evaluated with FAST, TEE if the expertise is available, or even a subxiphoid pericardial window depending on local experience, resources, and clinical scenario. The latter can be performed in the operating room but can be considered in the emergency department if necessary [7]. Once the diagnosis is made, the patient should be treated aggressively with fluids until they can be taken for definitive treatment. If a penetrating injury to the myocardium has occurred, it may be possible to treat without cardiopulmonary bypass [8]. This is fortuitous, because the administration of large volumes of heparin is often contraindicated in the trauma patient. Adenosine may provide the surgeon with 15 or 20 s of asystole and has been described to facilitate repair [9].

The other three of the lethal six are usually not difficult to diagnose. Massive hemothorax (>1500 cc of blood or more than 200 cc/h for 4 h) should be suspected in any trauma patient with shock and absent or distant breath sounds on one side. While patient physiology should be the primary driver of urgent surgical management, any patient with an output of greater than 1500 cc of blood in a 24 h period should prompt consideration of surgical exploration [10]. A CXR will show the fluid in the chest but should not be necessary in all cases. Extended FAST (E-FAST) in experienced hands provides a rapid and sensitive evaluation for hemothorax and will be discussed in the section on echocardiography for thoracic trauma. The last two of the six (open pneumothorax and flail chest) should be easily recognizable. We will discuss the treatment of the latter in later sections.

Echocardiography in Thoracic Trauma

Echocardiography has become an incredibly useful tool in the assessment of the trauma patient and this begins with the FAST exam, a rapid bedside ultrasound examination which functions as a screening tool for pericardial effusion and hemoperitoneum after trauma. In particular, FAST has proven extremely reliable in the assessment of the pericardium and can be completed in less than a minute and a half with sensitivity as high as 100% for patients with suspected pericardial tamponade. The extended FAST (or eFAST) adds bilateral anterior thoracic ultrasound to FAST, which allows for the detection of pneumothorax.

Though not currently recommended as a primary screening tool for blunt cardiac injury (BCI) in the hemodynamically stable patient [11], formal echocardiography – transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) – expands on the power of FAST and eFAST and plays a critical role in the care of the thoracic trauma patient, rapidly diagnosing intrathoracic pathologies causing severe hemodynamic instability and/or cardiopulmonary arrest. Expeditious diagnosis and treatment with TTE and/or TEE can stabilize the patient and help prevent end-organ ischemia and subsequent morbidity and mortality. Both modalities are portable and, unlike other radiographic imaging modalities such as computerized tomography (CT) and angiography, can be performed anywhere an echocardiography machine and probe can be brought. With an experienced operator, it also provides easy and rapid return of data which is updated in real time.

TEE appears to be superior, however, in the trauma population. A prospective study comparing TTE and TEE in 105 blunt thoracic trauma patients found that TTE yielded poor image quality in 19% of the patients who required TEE instead, which was superior in diagnosing myocardial contusion, 30% of which were missed by TTE, and aortic injury. The problem with TTE probably lies in its limitations in patients with chest wall trauma [12]. Another prospective study comparing the two modalities reported similar findings, with the transthoracic approach significantly limited by mechanical ventilation, subcutaneous emphysema, the presence of chest or abdominal tubes, and possible interference with other ongoing procedures [13].

TEE was first used in cardiac surgery in the early 1980s [14]. In the decades since then, its use has expanded to the

point where TEE is now used in 91% of US teaching hospitals [15]. Specifically, it is used in nearly every cardiac operating room, routinely revealing new pathology and occasionally altering surgical management [16], and is frequently seen in non-cardiac surgery, typically in the form of "rescue echocardiography" in unstable patients to help identify the cause of the hemodynamic derangements, often with great success [17]. It has a distinct advantage over other invasive hemodynamic monitors because it directly assesses intracardiac volume and biventricular systolic function.

Though generally safe when available guidelines for TEE probe insertion and manipulation are followed, serious complications have been reported including esophageal perforation, esophageal injury, hematoma, laryngeal palsy, dysphagia, dental injury, and death. Mortality associated with TEE has been reported to be <1 in 10,000 while morbidity is 2–5/1000 [18, 19]. While there is insufficient literature to define contraindications to TEE, most experts agree that prior esophagectomy or esophagogastrectomy, esophageal stricture, tracheoesophageal fistula, and esophageal trauma are absolute contraindications. Outside of these recommendations, there is little consensus regarding the safety of TEE in patients with esophageal varices, prior radiation therapy, previous bariatric surgery, Zenker diverticulum, and colonic interposition. However, as long as the expected benefit outweighs potential risk, the experts agree that the use of TEE is justified [20]. Specific to the trauma patient, extreme caution should be taken in a patient with a suspected or known esophageal or cervical spine injury [19, 21].

In the absence of contraindications, current guidelines recommend using TEE in all open adult heart and thoracic aortic surgical procedures and considering its use in coronary artery bypass surgeries and transcatheter intracardiac procedures to confirm preoperative diagnoses, detect new pathology, guide the anesthetic and surgical plan, and assess surgical results. In the non-cardiac realm, use of TEE is recommended "when the nature of the planned surgery or the patient's known or suspected cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise" and "when unexplained life-threatening circulatory instability persists despite corrective therapy." The guidelines specifically mention the use of TEE in patients who have suffered major thoracic trauma [20].

In the hemodynamic unstable thoracic trauma patient needing immediate surgical intervention, TEE is able to diagnose the most common pathologies in this patient population, reliably detecting various blunt cardiac injuries (myocardial contusion, acute valvular insufficiency, pericardial tamponade), aortic injury, and hypovolemia. It is also an ideal tool to guide and alter perioperative management of hypotensive patient who is undergoing resuscitation with fluid, blood, vasopressors, and inotropes. In a prospective study assessing the impact of TEE on trauma patients initially screened using clinical exam, ECG, CK-MB, and chest radiography, TEE was able to detect unexpected myocardial contusions, valve injuries, pericardial effusions, aortic lesions, and hypovolemia. In total, 30 new diagnoses were made while 32 previous diagnoses were invalidated. In 20% of patients, the use of TEE "made a new clinically relevant diagnosis leading to an emergency treatment" [22]. A retrospective study demonstrated that TEE was able to make a wide variety of diagnoses without complications in 16 cardiothoracic trauma patients, 10 penetrating and 6 blunt ranging from right ventricular infarction and aortic injury to valvular insufficiency, aorto-right ventricular fistulas, and intracardiac foreign bodies, positively influencing treatment in every case [23]. More recently, in a case series of 37 perioperative rescue echocardiograms of trauma patients in shock, management changes were prompted by echocardiographic findings in 49% of the patients. Hypovolemia was the most common finding, followed by left ventricular (LV) and right ventricular (RV) failure, dynamic left ventricular outflow tract obstruction (LVOTO), pericardial tamponade, valvular dysfunction, type B aortic dissection, and mediastinal air. The diagnoses of LVOTO and RV failure made the most impact on patient management [24]. Another article reviewing 364 perioperative rescue echocardiograms similarly found that echo findings influenced management in 59% of patients [25].

Image Acquisition

A comprehensive TEE exam has been described in the literature by the American Society of Echocardiography (ASE) and the Society of Cardiovascular Anesthesiologists (SCA) [14, 19], with recommendations on the maintenance, cleaning, and decontamination of the TEE probe, safe insertion and manipulation of the probe within the esophagus, and acquisition and optimization of images required for a complete examination. An experienced echocardiographer can complete the comprehensive exam which is comprised of 20 standard views in less than 10 min, but this may not be feasible in the hemodynamically unstable thoracic trauma patient. A focused TEE exam can be performed instead, with many examples described in the literature [25–27]. Ultimately, the images obtained and the order of acquisition will be driven by provider preference and specific areas of interest for the individual patient, but at a minimum, the echocardiographer obtains the views shown in Table 51.1 and answers the following:

1. Volume status: is there hypovolemia?
2. Myocardial function: Are the LV and RV contracting adequately? Are there any wall motion abnormalities?
3. Are there any valve abnormalities?
4. Is there a pericardial effusion or pericardial tamponade?
5. Is the aorta intact?

Table 51.1 Suggested TEE exam for the trauma patient

Views	Omniplane angle	Key structures visualized	Pathology diagnosed
TG mid-papillary SAX	0	LV, RV	BCI, hypovolemia
ME 4 chamber +/− CFD	0	LV, RV, LA, RA, MV, TV, IAS, IVS	BCI
ME 2 chamber +/− CFD	90	LV, LA, MV	BCI
ME RV inflow-outflow +/− CFD	60	RA, RV, TV, PV	BCI
ME AV SAX, LAX +/− CFD	40, 130	AV, ascending aorta	BCI, TAI
ME Asc Ao SAX, LAX	0, 90	Ascending aorta	TAI
UE to LE Desc Ao SAX, LAX	0, 90	Descending aorta	TAI
UE aortic arch SAX, LAX	0, 90	Aortic arch	TAI

Abbreviations: *TG* transgastric, *SAX* short axis, *LV* left ventricle, *RV* right ventricle, *ME* mid-esophageal, *CFD* color flow Doppler, *LA* left atrium, *RA* right atrium, *MV* mitral valve, *TV* tricuspid valve, *IAS* intra-atrial septum, *IVS* intraventricular septum, *AV* aortic valve, *LAX* long axis, *Asc Ao* ascending aorta, *Desc Ao* descending aorta, *UE* upper esophageal, *BCI* blunt cardiac injury, *TAI* traumatic aortic injury

A diagnosis of blunt cardiac injury, hypovolemia, or traumatic aortic injury should then be made and treatment should be tailored appropriately.

Blunt Cardiac Injury (Myocardial Contusion, Valvular Insufficiency, Pericardial Effusion, and Tamponade)

There exist a number of ways of evaluating blunt cardiac injury. Cardiac isoenzyme testing, in particular for troponin I (cTnI) which is very specific for myocardial damage, is often performed but is not terribly sensitive. The value of the cTnI increases when combined with the electrocardiogram (ECG), which is recommended in all patients suspected of having a BCI. On its own, ECG is not an ideal diagnostic tool as abnormalities are often nonspecific and can occur as a result of other conditions often associated with trauma [28, 29]. Moreover, the ECG primarily evaluates the left ventricle and can therefore miss a right ventricular contusion, the most common BCI [30]. However, an abnormal ECG combined with abnormal cardiac isoenzymes appears to correlate with clinically significant cardiac complications [31]. On the contrary, it has been established that a normal ECG combined with two serial negative troponin I tests all but excludes BCI with a negative predictive value of 100%. There are many manifestations of BCI, and while these tests can predict the presence or absence of BCI, they are unable to elucidate the exact pathology or physiology. Echocardiography has proven useful and superior to other imaging modalities in the evaluation of BCI [32–34]. It can directly visualize the presence of both right and left ventricular contusions [35, 36] and pinpoint segmental wall motion abnormalities [37]. TEE can also readily detect and facilitate treatment for unanticipated valve injury, a less common lesion usually affecting the tricuspid valve where early or late rupture of supporting structures such as papillary muscles or chordae tendineae causes valvular regurgitation [32, 36, 38–42]. Pericardial effusions are also effectively evaluated with TEE [36] and there are reports describing the use of echocardiography to diagnose such injuries as atrial septal rupture [34], an inferior vena cava (IVC) tear [43], right atrial free wall rupture [44], pulmonary vein rupture [33], and an aorta-left atrial fistula [45].

A complete evaluation of blunt cardiac injury will require the acquisition of several images. The most common BCI is RV contusion which is best assessed in the ME 4C view (see Fig. 51.1, Video 51.1). Visual estimation of reduced RV contractility and RV dilatation, relative dilatation compared to the LV, and tricuspid annular plane systolic excursion (TAPSE) <16 mm are all signs of RV injury [46]. TAPSE, a very specific sign of RV dysfunction, is best measured with M-mode, with the cursor directed through the lateral annulus of the tricuspid valve, measuring the longitudinal distance of systolic annular motion [26].

Global and regional LV function is best viewed in the transgastric LV short-axis (TG LV SAX) view, the mid-esophageal four-chamber (ME 4C) view, and the mid-esophageal two-chamber (ME 2C) view, though in the hemodynamically unstable patient, the TG LV SAX view is probably most useful. Global function can be evaluated quantitatively but most basic echocardiographers rely on a qualitative estimate of systolic function [19]. A thorough assessment of regional wall motion is described in the ASE guidelines based on ME views [47], but an abbreviated assessment based on the TG LV SAX view at the mid-papillary level may also suffice [48].

Potential valvular injuries should be evaluated in multiple ME views (see Table 51.1) with both two-dimensional (2D)

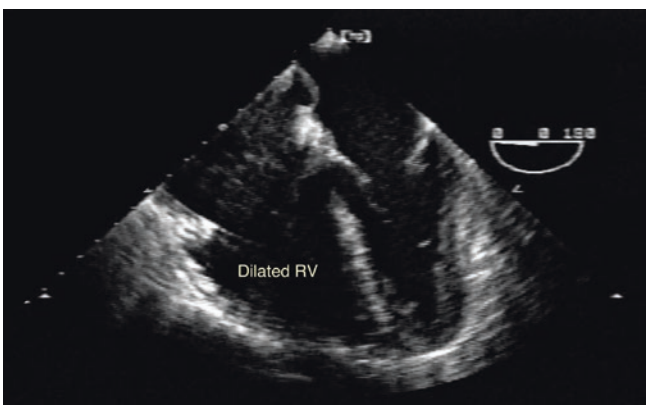

Fig. 51.1 A mid-esophageal four-chamber view showing a right ventricular contusion

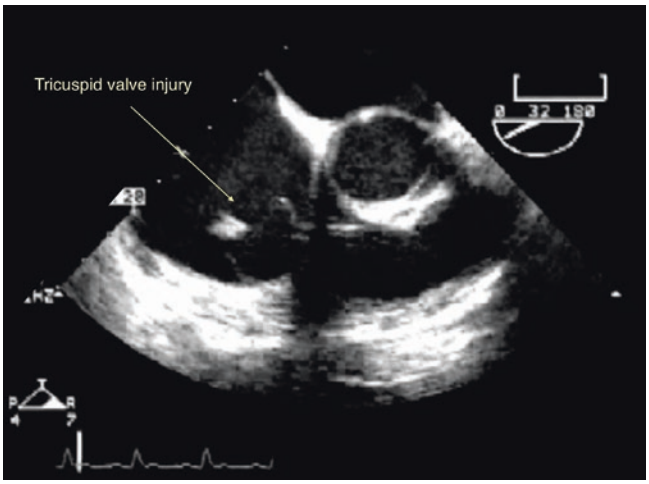

Fig. 51.2 A mid-esophageal right ventricular inflow-outflow view showing a tricuspid valve injury

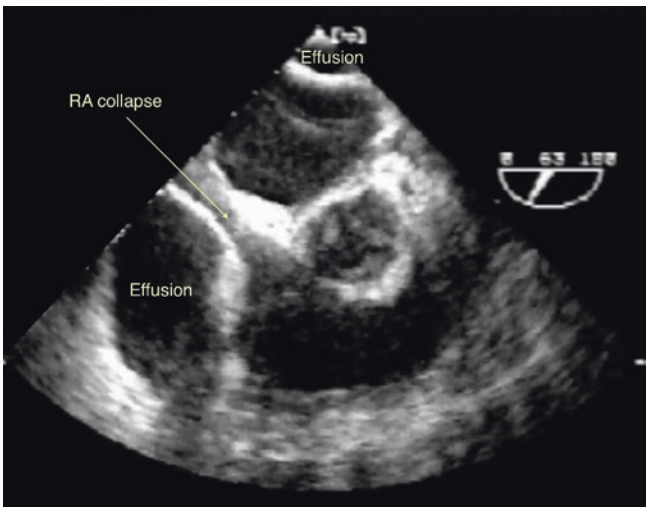

Fig. 51.4 A large traumatic pericardial effusion with evidence of right atrial systolic collapse, suggesting pericardial tamponade

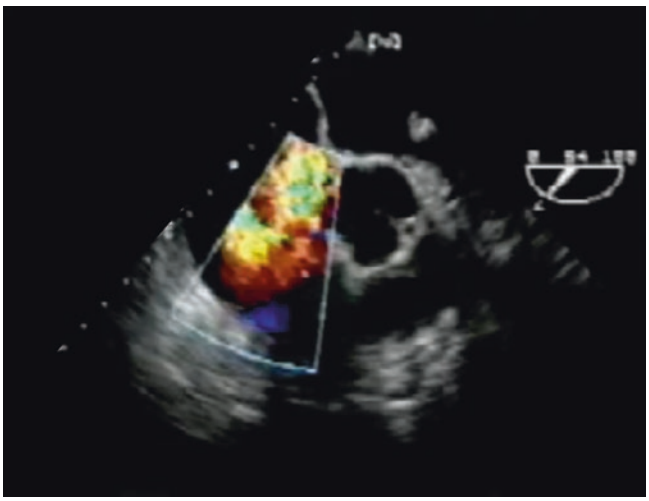

Fig. 51.3 A mid-esophageal right ventricular inflow-outflow view demonstrating severe tricuspid regurgitation associated with a traumatic tricuspid valve injury

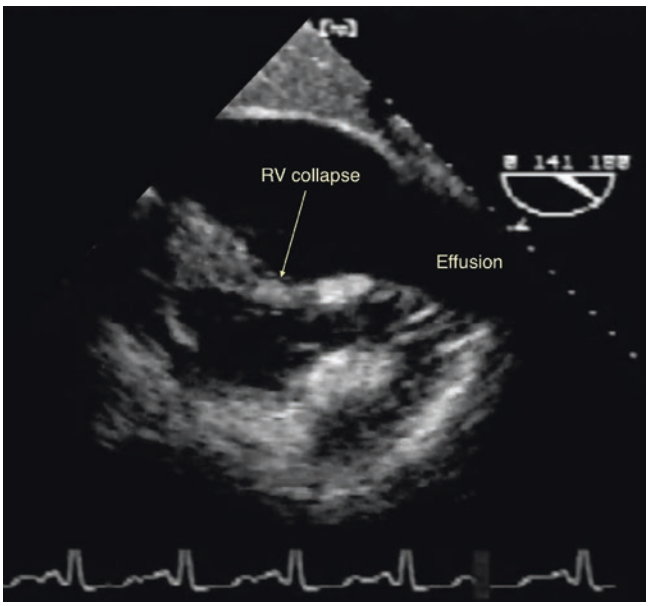

Fig. 51.5 A large traumatic pericardial effusion with evidence of right ventricular diastolic collapse, suggesting pericardial tamponade

echo to check for gross valve abnormalities and color flow Doppler (CFD) to determine the presence or absence of a significant regurgitant lesion. The severity of valvular regurgitation can be determined by visual inspection of the regurgitant jet area in the receiving chamber (the right atrium in the case of a tricuspid valve injury; see Figs. 51.2 and 51.3, Videos 51.2 and 51.3) and by vena contracta width. It is important to use caution when assessing eccentric jets, however, as degree of pathology is often underestimated [19].

Pericardial effusions are easily seen by TEE as a fluid-filled hypoechoic space extending circumferentially around the heart, occasionally containing floating echodense materials (see Figs. 51.4 and 51.5, Videos 51.4 and 51.5). Large acute effusions frequently develop into pericardial tamponade, which can be diagnosed by systolic right atrial collapse lasting for more than a third of systole, right ventricular diastolic collapse, interventricular dependence, IVC plethora, and exaggerated respiratory changes in mitral and tricuspid inflow. Emergent pericardiocentesis is indicated in this scenario and can be guided by TTE to minimize injury to nearby structures [26, 27, 49].

Aortic Injury

TEE has become a major contributor in the evaluation of the aorta due to its safety, portability, and diagnostic accuracy. It provides superior visualization of the entire aortic isthmus, where most traumatic aortic injuries (TAI) occur [49]. It can be performed during an emergency operation, does not

interfere with ongoing resuscitation, can be interpreted immediately, does not require contrast media, and is able to detect concomitant BCI. It is considered to be at least equal to helical computerized tomography (CT) [50] and aortography in the diagnosis of traumatic aortic injuries (TAI), with a reported sensitivity of 94–100% and a specificity of 77–100% [51] and comparable to helical CT and MRI specifically for the diagnosis of type A dissections, with a sensitivity of 98% and a specificity of 95% [52]. The main limitation of TEE in the evaluation of the thoracic aorta is that it is unable to assess the proximal aortic arch or the distal ascending aorta due to the presence of the tracheobronchial bifurcation, where 20% of injuries occur in aortic trauma [53]. It has also been shown to be highly operator-dependent [54]. For these reasons, it should not be the only imaging modality used when TAI is suspected.

Evaluation of the aorta involves direct echocardiographic examination of the entire visible thoracic aorta. The ascending aorta is visible in the upper esophageal (UE) view and the descending aorta in mid-esophageal aortic views and should be examined with 2D echo in the short axis and longitudinal views and with CFD. The presence of a thin, mobile, linear echodensity on the inner surface of the aortic wall suggests a traumatic intimal tear while a thin, less mobile intimal flap dividing the aorta into true and false lumens with or without thrombus formation indicates the presence of a traumatic aortic dissection (see Fig. 51.6, Video 51.6). A more mobile "thick flap" or "medial flap" consisting of intima and media with a potentially ruptured pseudoaneurysm points to a subadventitial traumatic aortic disruption (see Figs. 51.7 and 51.8, Video 51.7). The appearance of the flap and the pattern of blood flow as seen on CFD can distinguish between a partial, subtotal, and complete aortic disruption [49]. The presence of a mediastinal hematoma is a sensitive and specific indirect indicator of a traumatic aortic disruption and can be especially useful in diagnosing injuries of the aorta not visible with TEE [55]. One study suggested that a distance of more than 5.5 mm between the esophageal probe and the posterolateral aortic wall or 6.6 mm between the anteromedial aortic wall and left visceral pleura was predictive of injury to the descending aorta or its branches [56].

Fig. 51.7 A view of the descending thoracic aorta with a "medial flap" demonstrating traumatic aortic disruption

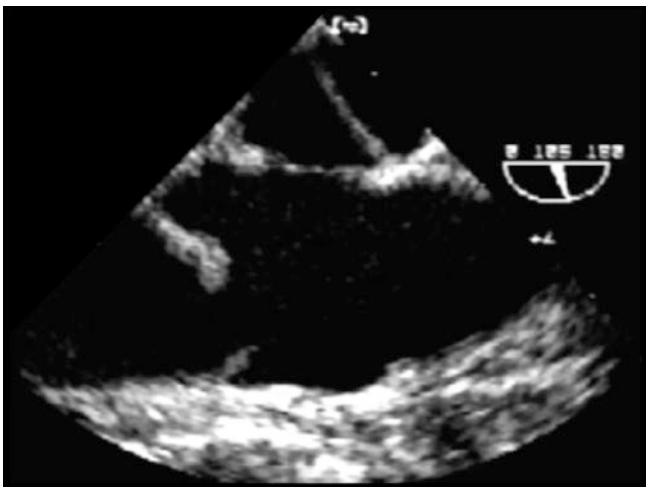

Fig. 51.8 A view of the ascending aorta with a "medial flap" demonstrating traumatic aortic disruption

Hypovolemia

Hypovolemia secondary to hemorrhage is very prevalent in trauma patients [24]. There are many ways of assessing intravascular volume status, but TEE is the only modality which can provide us with direct measurements of static intracardiac volume and dynamic fluid responsiveness. While the various ME views can yield valuable information, the most basic and most commonly used view for the diagnosis of hypovolemia is

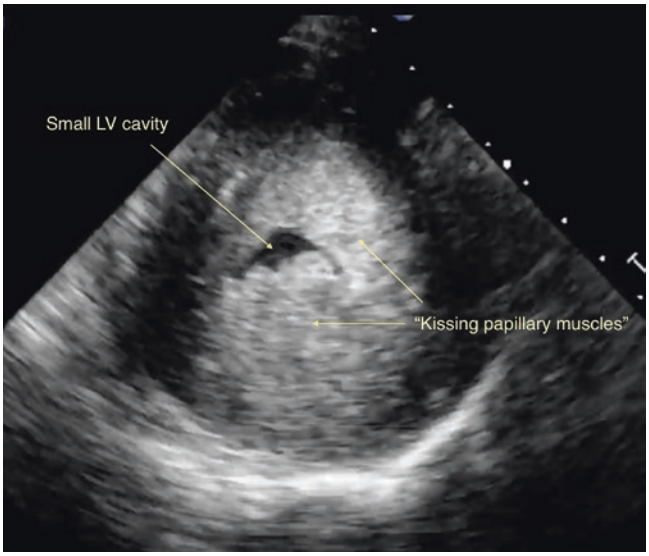

Fig. 51.9 A transgastric left ventricular short axis view showing severe hypovolemia

the TG mid-papillary LV SAX view, where LV end-diastolic diameter and LV end-diastolic area are measured [19]. In the severely hypovolemic patient, the appearance of "kissing papillary muscles" has been described [21] (see Fig. 51.9, Video 51.8). IVC size and collapsibility is another index of volume status but has been described only for TTE in the spontaneously breathing patient and is not applicable to TEE in the mechanically ventilated patient [26, 46, 51]. Stroke volume measurements can be useful. The cross-sectional area of a site (usually the LVOT) is determined using 2D echo and then multiplied by the stroke distance or velocity-time integral (VTI) of blood through that site, determined with pulse-wave (PW) Doppler in the deep TG AV LAX view [26]. A low stroke volume in the setting of normal contractility suggests hypovolemia, while significant stroke volume respiratory variation is a dynamic indication of fluid responsiveness [24].

Training and Certification

Echocardiography is invaluable in hemodynamically unstable trauma patients to elucidate volume status, evaluate global and regional biventricular and valvular function, and detect the presence of pericardial or aortic pathology. The expanding role of TEE in these critically ill patients highlights the need for standardized echocardiographic training. TEE is a powerful tool but it is an invasive procedure with rare but potentially life-threatening complications. Many have tried to define the knowledge needed to safely and effectively perform and interpret exams, while several societies, including the European Association of Cardiovascular Imaging, Society of Critical Care Medicine, and the ASE, have published education guidelines [57–59]. While the echocardiographer with basic TEE proficiency should be able to obtain and interpret most echocardiographic findings to help guide therapy for the thoracic trauma patient, advanced skills are required for thorough evaluation of valvular injury and interpretation of quantitative parameters [19]. The National Board of Echocardiography (www.echoboards.org), in collaboration with the ASE and SCA, now offers certification in basic and advanced perioperative transesophageal (PTE) echocardiography, which can be achieved by passing a written examination and performing and interpreting a certain number of studies, and courses are available to help interested providers (anesthesiologists, cardiologists, intensivists) achieve and maintain certification in PTE echocardiography.

Traumatic Airway Management

Few topics seem to generate more discussion among anesthesiologists than the presentation of a trauma patient in need of an emergent airway. There are questions of whether manual in-line stabilization is always helpful or can be harmful in restricting the view at laryngoscopy [60, 61]. There are questions of whether Sellick and his 26 patients should have had the influence they have over the last half century [62–66], and there are a myriad of devices to aid us. The discussion is not without merit, since the consequences of failure are dire. The fact that 2% of blunt trauma patients have a cervical spine injury adds to the angst. Furthermore, every method of airway intervention causes motion of the cervical spine including a jaw thrust and placement of an LMA. The basic tenants of airway management remain in place, however, and the ASA difficult airway algorithm (modified for trauma) remains a valuable tool [67] (Fig. 51.10). The modifications for trauma recognize, among other things, that stopping and returning another day is not feasible and that a surgical airway may often be the best option. As such, anesthesiologists who treat trauma patients should be familiar with the techniques and equipment necessary for percutaneous or open cricothyrotomy or tracheostomy. An outstanding recent review of the literature on the topic of airway management in the trauma patient (beyond the scope of this chapter) also provides perspective [68]. What should never be lost amid all the controversy is that the cornerstone of emergent airway management remains direct laryngoscopy. There is strong historical data suggesting that direct laryngoscopy is both highly successful and associated with few credible reports of neurologic deterioration even in the face of known cervical spine injury [68, 69]. A recent review at a major trauma center, in fact, looked at over 6000 patients who were intubated within 1 h of their arrival, and of the 31 patients who required a surgical airway in the first 24 hours, 87% survived to discharge [70]. Only four patients died and none of these were judged to be airway related. This study did not include the

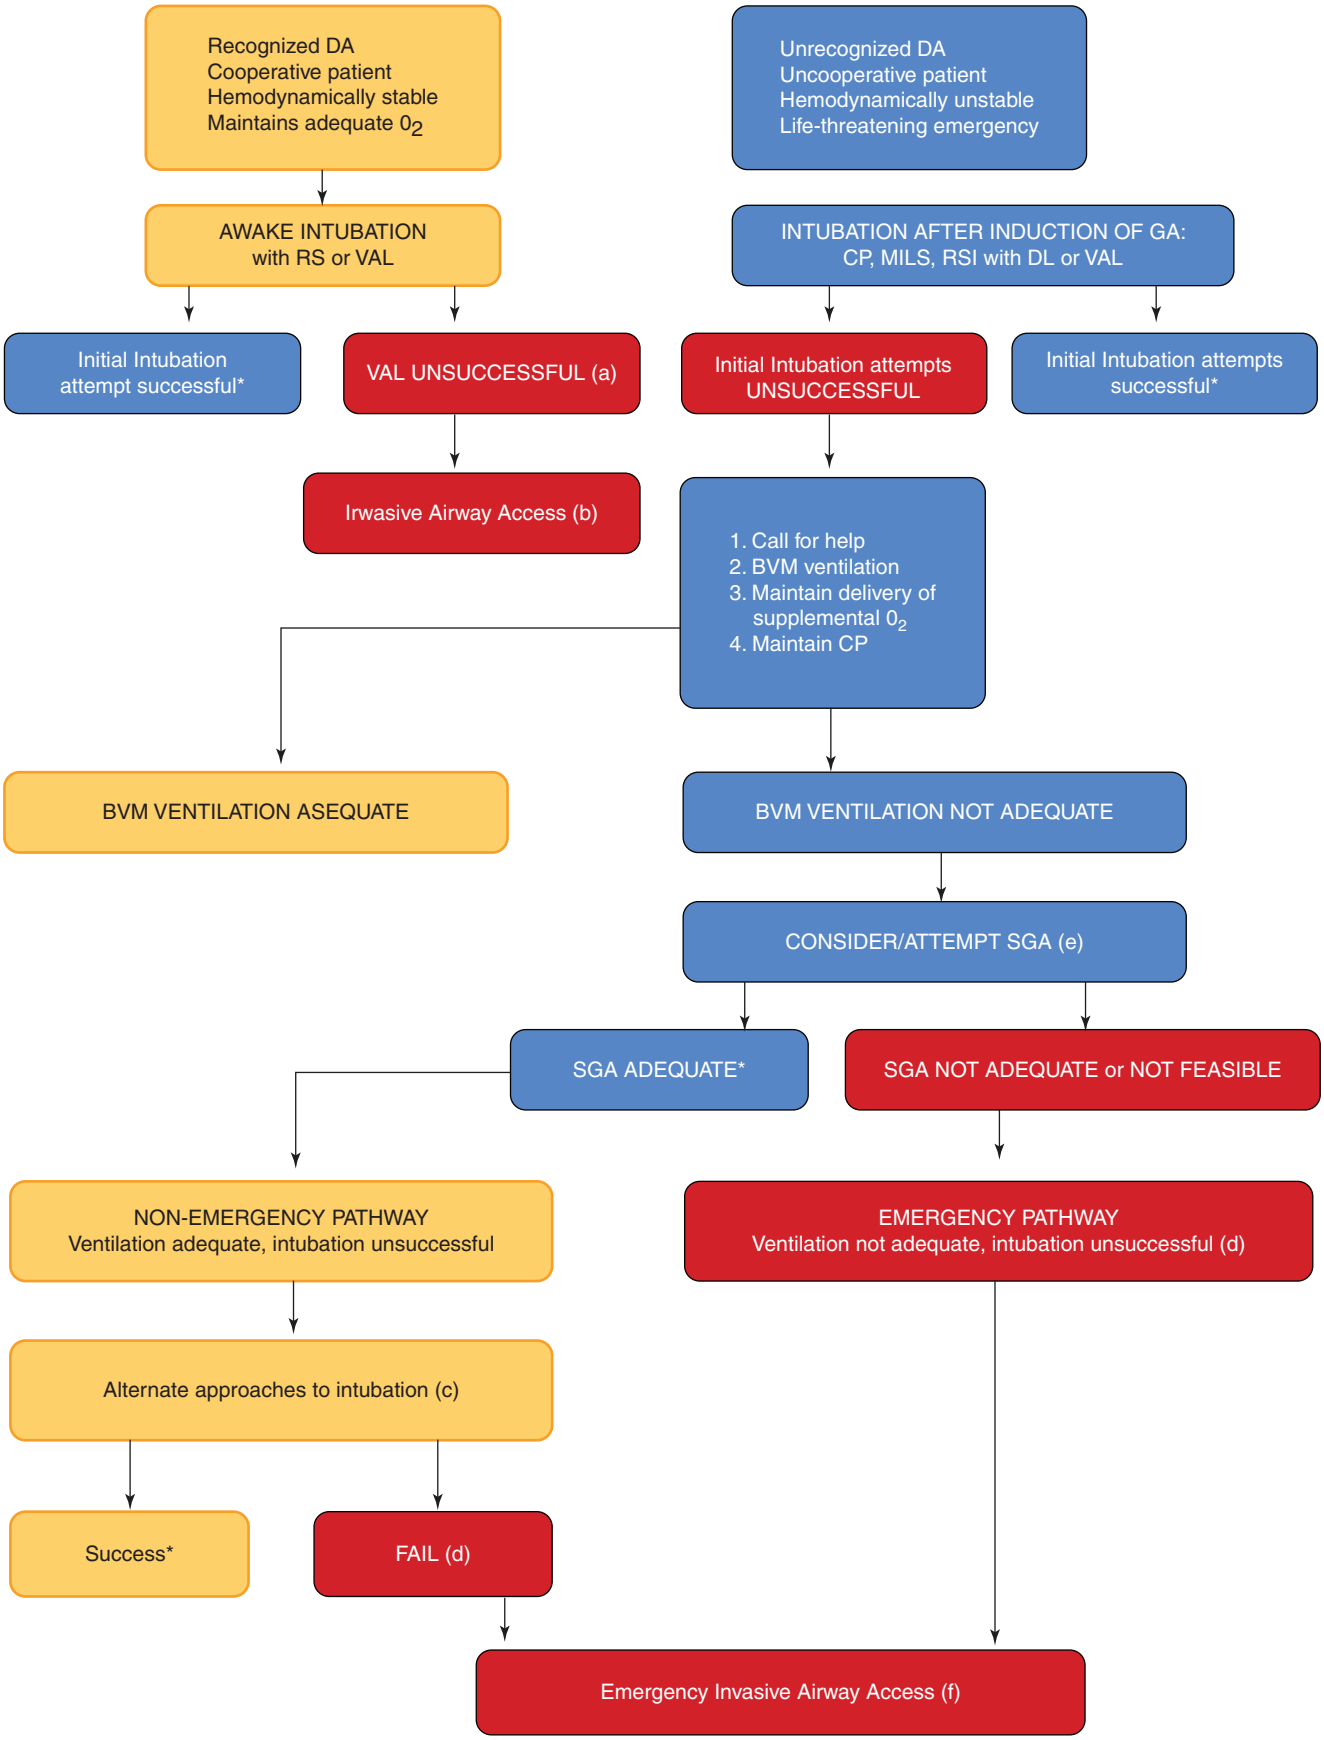

Fig. 51.10 Difficult airway Management in Trauma Updated by COTEP. Originally published by ASA Newsletter. C Hagberg, O Kaslow [67] reprinted with permission

number of patients that were intubated fiberoptically. Their high success rate compared to other series may have been a result of an attending anesthesiologist's presence as part of their protocol. While their protocol calls for in-line stabilization and cricoid pressure, they wisely will relax one or both of these if there is a sense that intubation is being hampered by either technique.

This is not to minimize the role of awake (or asleep) fiberoptic intubation in patients with a difficult airway or known or suspected cervical spine injury. For those with the skill set, bronchoscopic intubation is an excellent rescue as well as primary technique. This is by far the author's preference for known difficult airways in stable cooperative patients with cervical spine injuries and as a rescue technique. No technology has yet replaced it. Still, the reality is that awake fiberoptic intubation requires a cooperative patient and can be difficult with blood in the airway. Many of the limitations to fiberoptic intubation can be overcome, however, with the use of an adult bronchoscope (5.5 mm in diameter or greater) with a modern powerful light source. Anesthesiologists often use smaller bronchoscopes for use in double-lumen endobronchial tubes, but these are less ideal than full size scopes for intubation. The use of an adult bronchoscope adds stiffness which aids in directing the bronchoscope, and the larger port on an adult-sized bronchoscope can be used to either suction or blow oxygen to free the view of secretions or blood. Lastly, a 6.0 endotracheal tube fits snugly around 5.5 mm bronchoscopes, while a 7.0 tube will fit tightly around the largest bronchoscope, minimizing the chance the tube will catch on the arytenoids or epiglottis after the scope has passed into the trachea. Still, it is always best to be familiar with the other emergency airway devices available in one's practice such as the bougie, light wand, GlideScope®, Airtraq®, and McGrath® video laryngoscope or kits for retrograde intubation. This is especially true since awake, cooperative patients are in the minority in the trauma population. In one 7-year review, 83% of the patients were legally intoxicated on presentation [69].

Lung Isolation

One of the more challenging aspects of the management of patients with thoracic injury is lung isolation, which may be required for injury to the thorax. Techniques include right mainstem intubation, Univent® tubes, a variety of commercially available bronchial blockers, and right- and left-sided double-lumen tubes. Since right mainstem intubation will most often result in ventilation of the right middle and lower lobes, it would be expected to result in the highest shunt fraction and higher rates of hypoxia. Each of the other devices requires some expertise, however, and they each have an equivalent high failure rate of 39% in faculty with limited thoracic experience of less than two cases per month [71]. In this study all malpositions were corrected easily by more experienced thoracic staff. The choice of isolation technique must be based on other factors. Traditionally, double-lumen tubes (DLTs) are the standard of performance for lung isolation. In experienced hands isolation can be achieved quickly and definitively in most cases. In institutions with extensive experience, in fact, right-sided tubes can be used with as few complications (desaturation, high peak airway pressures, etc.) as left-sided tubes [72]. Still, there may be disadvantages to DLTs especially in the trauma population. They may be associated with more airway trauma (especially if an airway injury already exists) with placement. Further, if the patient is to remain intubated following the procedure, double-lumen endobronchial tubes should be changed to single-lumen endotracheal tubes for many reasons. Most obviously, pulmonary toilet is much more difficult with standard length suction devices in the ICU. Their bulk may lead to torsion and injury to the airway over the long term in a patient who is awake and moving. They also have a much larger outer diameter and higher work of breathing given their added length. Recently, three commercially available bronchial blockers have been shown to perform well when compared to left-sided DLTs in their ability to isolate the lung. These designs are continuing to evolve. They did require a longer time to place and had to be repositioned frequently, however [73]. They may be a better option for thoracic trauma patients, although anesthesiologists' familiarity should also play a role in selecting a lung isolation device.

Tracheobronchial Injury

Like so many injuries to the thorax, tracheobronchial injuries are highly lethal. In an older autopsy series of trauma patients, 81% of patients died before reaching a hospital [74]. In a much more recent review of a single institution's 15-year experience including over 12,000 trauma patients, 0.9% of patients reaching the hospital had a tracheobronchial injury (TBI). The numbers were very different for blunt and penetrating mechanisms (0.4% incidence for blunt trauma victims, 4.5% for penetrating) [75]. This review considered all traumatic airway injuries including those of the upper airway and thoracic trachea. In the larger of the North American series, around 60% of these injuries treated will be the result of penetrating trauma [76]. These patients tend to have better outcomes, possibly because of fewer associated injuries [75, 76]. Patients who do appear after a delay in diagnosis often will present when granulation tissue appears in their airway causing a narrowing and post-obstructive pneumonia or recurrent pneumothoraces.

There are classic signs of TBI, but they can be misleading or absent, and a high index of suspicion is required.

Surprisingly, in a comprehensive review of all TBIs reported in the literature up until 1996, the median time to diagnosis was 9 days [77]. In more recent single-institution review, long delays in diagnosis were not reported [75, 76]. When present the classic signs of subcutaneous or mediastinal emphysema, hemoptysis, pneumothorax (especially with a large air leak or with a failure to expand the lung after tube thoracostomy), tension pneumothorax, as well as unexplained dyspnea should all raise suspicion of an airway injury. Blunt TBIs may be associated with fractures of the first rib, clavicle, sternum, and chest wall and lung contusions. The location of injury to the tracheobronchial tree has been consistent over several series [76, 77]. By far, most injuries seem to be within 2 cm of the carina with a predilection for the right side. The latter may be a result of a heavier right lung with a shorter right mainstem bronchus in deceleration injuries. The most likely theory explaining the consistent data showing injury close to the bifurcation is that a rapid deceleration of relatively mobile lungs in the pleura against a fixed carina causes a tear. Bronchial rupture may also be from compression of the chest against a closed glottis. This has been shown in a canine model.

Whatever the mechanism, securing the airway in patients with TBIs can be a daunting task. Indeed, some very heroic measures have been described including thoracotomy [78], jet ventilation via intrabronchial catheters [79], and ECMO [80]. The ASA does have an airway disruption algorithm which emphasizes above all else spontaneous ventilation if possible. The critical tool for both assessing the injury as well as controlling the airway is fiberoptic bronchoscopy. The goal in most cases should be to place the cuff of the endotracheal tube beyond the injury or at least to protect the injury from positive pressure ventilation in some fashion. This is complicated by the fact that most blunt injuries to the trachea are within 2 cm of the carina [76, 77]. In this instance, placement of a side-specific double-lumen endotracheal tube is often most appropriate, although caution must be exercised in placing these bulky rigid tubes past an already injured airway. Passing the cuff of a single-lumen tube beyond the injury and using a bronchial blocker for lung isolation in more proximal injuries seems more prudent. This also has the added advantage of avoiding the changing of the endotracheal tube at the end of the procedure should the patient need to remain intubated. A scenario of cross field ventilation can also be envisioned but should be rare. In every case knowledge of the location of injury is paramount in providing the best airway.

One cannot overemphasize the importance of maintaining spontaneous ventilation in patients with severe tracheal injury. There have been reports of patients arriving with essentially transected airways who maintain spontaneous ventilation through a "neo-trachea" via mediastinal tissues. Attempts at blind instrumentation can be disastrous [81]. It is the author's strong presence when TBI is suspected for a fiberoptic intubation to be performed. This allows not only a diagnosis and characterization of any pathology, but placement of a single-lumen tube beyond the injury under direct visualization when feasible and proper planning (both surgical and from an airway management perspective) if the injury is more distal. Unfortunately, making the diagnosis can be difficult prior to the need for intubation although clues may be present in a lateral c-spine film. Suspicion should be heightened in a patient with difficulty breathing and any of the classic signs of TBI including subcutaneous emphysema. Fortuitously complete transaction of the airways in patients surviving to reach the hospital is quite rare. The liberal use of bronchoscopy should help lower the incidence of missed injury, help define injury when present, and help secure the airway [76]. In the Toronto series, 29% of patients with TBI required interventions more complex than direct laryngoscopy. These included around 10% each of FOB, surgical airway, and temporary airway through the wound [75].

There is literature evolving for conservative management of tracheobronchial injuries. Most have focused on iatrogenic injury to the membranous portion of the trachea. Unfortunately these injuries are becoming more common and represented half the injuries in a recent series [82]. They may be as common as 1 in 20,000 intubations or 0.12% of DLT placements [83]. Patients may present removed from the trauma with either a delay in their diagnosis or a delay in their treatment. These patients allow for surgical planning and controlled airway management and have a lower mortality [77].

Aortic Injury

In 1958 Parmley reviewed 296 cases of aortic injury from the Armed Forces Institute of Pathology and found 80% mortality prior to arrival at a hospital [84]. It is unlikely that we have made much progress on that front in the intervening five decades [85]. Since this is thought to be largely a deceleration injury, it may be that restraints have had little impact. We have, however, made progress on the patients who do reach the hospital and may be seeing a major advancement over the last few years as thoracic stent grafts become increasingly common.

Because most aortic injuries occur following a rapid deceleration and are most often at the isthmus, traditional discussions of the pathophysiology of the tear have focused on the interaction between the fixed descending aorta and relatively mobile heart and great vessels. Still, injuries have been described in the ascending aorta, more distal thoracic aorta, and abdominal aorta suggesting that other mechanisms may play a role as well [86]. Other mechanisms described include a pinching of the aorta against the vertebral column and a "water hammer effect" describing a sudden occlusion

of the aorta and increase in aortic pressure. These have recently been summarized elsewhere [87].

The prompt diagnosis of this injury is essential. As is often quoted, 30–50% of the patients who reach the hospital will die within the first 24 h [84, 88]. Imaging is crucial since there can be few external signs of aortic injury. While the classic findings on CXR such as widening of the mediastinum, blurring of the aortic knob, deviation of the NG tube, and shift of the right bronchus all suggest the diagnosis, they are not diagnostic. Helical computed tomography has become the dominant modality for this purpose. It is fast, allows the quick evaluation of concomitant injuries elsewhere in the body, and has a sensitivity approaching 100% [89]. TEE, MRI, and intravascular ultrasound have also all been described, although it is unclear if any are as accurate as helical CT.

The treatment of aortic injury once a diagnosis is made is almost always prompt. It should be noted for completeness that there is a small subgroup of patients presenting with hemodynamic stability that have been treated expectantly with tight blood pressure and heart rate control either because their severe comorbid conditions precluded operative repair or because their injury was considered minimal [90, 91]. Although small in number, these patients have done quite well. Still, defining minimal aortic injury is an ongoing process and most patients will present to the operating room. This has been especially true in the last decade as thoracic endovascular repair has become commonplace. A period of nonoperative management may be indicated for patients who are unstable from associated injuries, those with traumatic brain injury, severe pulmonary contusion unable to tolerate one-lung ventilation, etc., but again the endovascular approach is making this far less common. While surgery may be successfully delayed while associated injuries are evaluated and stabilized with the use of beta-blockers and antihypertensive agents, the care of these complex patients will eventually fall to the anesthesiologist.

Despite our advances, a prospective look at 50 trauma centers in North America over a 2.5-year period suggested an overall mortality of 31% [88]. All patients who arrived in extremis or who ruptured prior to definitive therapy died. Mortality in patients who were operated on was 14% with an 8.7% paraplegia rate. This study was published before endovascular grafts were increasing in use, and all patients who were operated on had an open repair.

Open surgical repair in general begins with a high left posterolateral thoracotomy and some form of lung isolation – most typically a double-lumen endobronchial tube (DLT). Hypoxia may be a formidable challenge in patients with associated pulmonary contusion. The pros and cons of various methods of lung isolation were reviewed earlier in the chapter. The anesthesiologist must be prepared for the massive hemodynamic swings that accompany proximal thoracic aortic cross clamping (sometimes above the left subclavian artery) as well as attending to all the issues of blood loss and the concomitant injuries the patient brings to the operating theater. There are three main methods of surgical repair, all aimed at preserving spinal cord function. The first is speed in a traditional clamp and sew technique. The advantage of this technique is its simplicity and avoidance of the large doses of systemic heparin used for cardiopulmonary bypass. Bypass from the left atrium (or pulmonary vein) to the distal aorta involves the use of a relatively simple centrifugal pump system and also minimizes the use of heparin. Bypass from the femoral vein cannulation site to the femoral artery requires an oxygenator in the circuit and may require high-dose anticoagulation, although heparin-coated tubing may minimize the dose [87]. There may be advantages in having an oxygenator in the circuit, however, if the patient has lung injury where one-lung ventilation may not be optimal [87]. Clearly it would seem that any technique that limits the need for anticoagulation in the multi-injured trauma patient is advantageous, although concerns of short-term anticoagulation may be exaggerated in patients without head injury [88]. The pros and cons of these techniques are beyond the scope of this text, but the anesthesiologist must be familiar with the norms of the institution and be prepared to manage the techniques preferred by their surgeons. Although lumbar cerebrospinal fluid (CSF) drainage has not been proven in blunt aortic injury, its use was shown prospectively to be of benefit in patients undergoing thoracic aortic aneurysm repair and should be considered in the stable, cooperative patient [92]. Even under the best circumstances, open repair can negatively affect the patients underlying pulmonary, cardiac, and neurologic status [93].

Recently, attention has focused on endovascular treatment of thoracic aortic injuries [94]. There are many theoretical advantages of this approach. For patients with closed head injury, it can be done without significant heparinization and large hemodynamic swings complicating the management of intracranial hypertension and can even be done in reverse Trendelenburg if needed. It can be done in patients in traction for long bone injuries, does not require lung isolation, and avoids position changes for patients with pelvic injury that may exacerbate pelvic hematoma. These facts broaden the patient population who can be treated and avoids delays in treating others. Published series show improved mortality, fewer perioperative complications compared to open repair, and a low or zero rate of paraplegia [33, 93, 95, 96]. The low rate of paraplegia may relate to the short segment of thoracic aorta that needs coverage in the typical injury [95]. Concerns remain, however. Many are technical and some revolve around the specifics of a device developed for aneurysmal disease being placed in a normal, smaller

thoracic aorta. There can also be difficulties with the proximity to the left subclavian artery, and there can be challenges in dealing with the curvature of the aorta. Still, there has been a dramatic shift away from open repair to endovascular treatments. Open repair has fallen from 100% of repairs in 1997 to 35% in the second American Association for the Surgery of Trauma study in 2008 [97, 98]. These numbers of course reflect the behavior of 18 select trauma centers. The percentage of stent grafts placed in the country as a whole is probably smaller. Still, in these two studies, there has been a dramatic fall in procedure-related mortality and paraplegia (8.7–1.6% overall from first study to the second). Device issues (early endoleak, left subclavian artery compromise, left carotid artery occlusion (resulting in CVA), etc.) remain a concern. There also remains a lack of long-term follow-up of these devices, and how they will perform as a young trauma patient ages is as of yet unknown. These patients will also need long-term, perhaps lifelong follow-up to assure endoleaks do not develop. Lastly, it is unclear if some of these devices were placed in patients who had minimal aortic injury and may not have required treatment at all as pointed out in the discussion that accompanies this chapter [97].

Despite these caveats and the absence of randomized controlled trials, nonrandomized controlled trials are pushing us in the direction of TEVAR, and the Society for Vascular Surgery has issued guidelines suggesting that blunt traumatic aortic injury be managed with endovascular repair preferentially. While it is acknowledged that randomized trials are lacking, it is also acknowledged that such trials may never be completed and while imperfect, available evidence points to the less invasive and expedient approach in these often profoundly injured patients [99–101].

Pulmonary Contusion

Pulmonary contusion is a clinical entity that complicates as many as 65% of blunt chest trauma patients who present for surgery [102]. In a sobering look at the long-term sequela, a recent review suggested that 70% of patients will have deficits in pulmonary function 6 months after injury and will report a loss of physical function [103]. Signs on presentation are as one would expect, namely, tachypnea, hypoxia, hypercarbia, wheezing, and sometimes hemoptysis. CXR and even CT findings can lag behind the clinical picture by hours. Chest ultrasound may aid in the rapid diagnosis especially as the extended focused assessment with ultrasonography for trauma (EFAST) evolves [104, 105]. The gross pathology results from the loss of vessel integrity at the alveolar capillary membrane leading to intraparenchymal and alveolar hemorrhage and edema. Surfactant production decreases and shunt ensues. As in ARDS the lung becomes functionally smaller as alveoli fill with blood and edema. Pain then leads to splinting and progressive atelectasis. Worse, pulmonary contusion can lead to true ARDS. Evidence continues to mount that lung injury is itself inflammatory, and the localized inflammatory response may be what leads to ARDS [106–109]. Further, the immediate inflammatory response in the lung may lead to delayed immunosuppression that increases patients' susceptibility to an infectious challenge later [110, 111]. Despite its inflammatory nature, steroids cannot be recommended [112].

Making specific, evidence-based recommendations based on the available literature is difficult. This is underscored by the absence of a single level I evidence-based recommendation in the Eastern Association for the Surgery of Trauma (EAST) guidelines for pulmonary contusion [112]. Level II recommendations describe supportive care such as optimal pain management (with epidurals when possible), avoiding obligatory ventilation and overly aggressive resuscitation. The anesthesiologists' primary role in lung contusion outside the operating room will be to assist in the management of pain. This will be discussed in more detail later. In the operating theater, issues will center around fluid and ventilatory management. Adapting lung protective strategies developed for and accepted in ARDS patients seems prudent. Because alveolar over distention and alveolar opening and collapse can only exacerbate the inflammatory process, part of this should be recruitment maneuvers and PEEP [112, 113]. The initial resuscitation should not be compromised, but the administration of fluids afterward should be meticulous in an effort not to augment extravascular lung water. The best method for monitoring fluid management is open to question although dynamic assessments to predict fluid responsiveness (improvement in cardiac output) seem to be better than static measurements of CVP and PCWP in a myriad of recent clinical trials. There is also a suggestion that Hextend® may have a role [114, 115].

Blunt Cardiac Injury

The term blunt cardiac injury (BCI) covers a wide range of injuries whose clinical significance is related to both the type and severity of the injury. The pathophysiology results from either direct transfer of energy during the impact of the myocardium against the thorax; the rapid decelertaion of the heart, or from compression of the heart between the sternum and spine [30]. The pattern and pathophysiology of injury will reflect the details of the impact and position of the heart in the cardiac cycle. The ventricles, for example, are most vulnerable at end diastole and the valves most vulnerable when closed. Even modest impacts can lead to sudden cardiac death, most commonly from ventricular arrhythmias. Commotion cordis, for example, results from an impact during the vulnerable moment of repolarization just prior to T wave peak [116, 117]. Most deaths due to blunt cardiac injury require more force, however. Almost every injury one can imagine can occur and has been described. The heart can be contused, torn, or ruptured (freely or septal). Coronary

arteries can be torn or become thrombosed. The pericardium can become distended with blood and cause tamponade. Finally, the heart is a muscle, and when it is contused, local hemorrhage, edema, and often necrosis cause poor performance. As the contused portion begins to swell, perfusion to that portion of myocardium may be compromised causing ventricular dysfunction to be exacerbated. Further, this may make the patient susceptible to arrhythmias possibly from a reentry mechanism [118]. Of concern, these arrhythmias can present very late (up to 6 days in one case report) after an initial 24 h arrhythmia free period [119]. Lastly, the practitioner must remember that myocardial performance may be drastically compromised even without direct injury to the heart. This is most commonly and sometimes dramatically seen in patients with traumatic brain injury. The most common mechanism of cardiac injury remains motor vehicle crashes in the most recent series. In patients who died of blunt trauma, 66% had either a cardiac or thoracic aortic injury (or both). Injuries to the right atrium and to the right ventricle predominate [120].

The approach to the patient is determined by their clinical presentation. Taking a history from the patient who is able to provide one will give valuable clues not only by detailing symptoms, but by documenting prior cardiac issues that may help avoid confusion of acute and chronic conditions. The physical exam should focus not only on the heart, but on associated chest wall injuries that will raise the index of suspicion for associated BCI. These include chest tenderness, crepitus, seatbelt marks, etc. Beck's triad of hypotension, muffled heart sounds, and distended neck veins or pulsus paradoxus suggest tamponade and urgent surgical attention.

Echocardiography has become an incredibly useful tool in the assessment of the BCI patient, and this begins with the FAST assessment. FAST has proven extremely reliable in the assessment of the pericardium and can be completed in less than a minute and a half with sensitivity as high as 100% [121, 122] for patients with suspected pericardial tamponade. Formal echocardiography (transthoracic or transesophageal when transthoracic is inadequate) is the primary tool for assessing hemodynamic instability in patients with BCI. Hemodynamic instability can result from etiologies that require very different treatments, and defining whether failure is due to acute valvular insufficiency, septal rupture leading to left to right shunt, cardiac rupture, wall motion abnormalities from contusion, LAD thrombosis from crush injury, or any other pathology is essential. Despite its usefulness as a tool in the sickest patients, it is not a cost-effective screening tool. The EAST practice guidelines reflect most authors' opinion and the bulk of the literature when they state that formal echocardiography adds little to the hemodynamically stable patient and should be reserved for patients with instability or with a clinical question that cannot be explained [123, 124]. Part of the rationale for this statement is that even in patients diagnosed with BCI by echocardiography, in hemodynamically stable patients, there was no sequela of the injury that required treatment even at 1-year follow-up [125]. One of the difficulties in BCI, in fact, is evaluating and triaging patients with significant chest trauma and risk for BCI (e.g., patients with fractured ribs, sternum, and pulmonary contusion) who have no initial symptoms of BCI. The negative predictive value of two serial negative troponin I tests and a normal ECG was 100% in one study suggesting that these patients need no further observation or treatment [126]. While an abnormal ECG does correlate with the risk of developing a complication requiring treatment in BCI [31], the findings are often nonspecific and may not help define the pathology or physiology that is crucial to aiding in treatment.

Specific generalizations for the anesthesiologists managing the patient with blunt cardiac injury are few since the individual patient's injury pattern and physiology must dictate specific treatments. As we have stated, defining any abnormality of the function of the ventricle is generally accomplished with echocardiography. Clinical suspicion of the possibility of tamponade and an understanding of the signs will aid in the prompt diagnosis of this problem. In truth, all three signs of Beck's triad may not be present in trauma patients with tamponade who are profoundly hypovolemic. The most common etiology is rupture of the right atrial appendage followed by rupture of the right ventricle [31, 120, 127]. This is true in autopsy and clinical series although the percentage of right-sided rupture is higher in clinical series presumably because of the high lethality of left ventricular rupture. Pericardiocentesis as a diagnostic tool is used less frequently than in the past because of a higher number of complications and lower sensitivity/specificity compared to FAST. For unstable patients either subxiphoid window or anterolateral thoracotomy is preferred as discussed in the section on pericardial tamponade.

Cardiac failure can occur from several different etiologies in blunt trauma. As stated above, contusions can cause inflammation, hemorrhage within the myocardium, and cellular necrosis all of which change the compliance of the ventricle and its contractility. Complicating this may be small vessel thrombosis worsening ischemia [128]. Coronary artery occlusion, laceration, and thrombosis have all been described as well [2, 127]. Acute valvular incompetence may also precipitate failure. Care is supportive and consists of appropriate fluid resuscitation based on the injury and the use of vasopressors and inotropes. There are case reports of intra-aortic balloon counter pulsation (IABP). Since most cardiac contusion involves the right ventricle, avoiding common causes for increased pulmonary vascular resistance (e.g., hypoxia, hypercarbia) would be prudent. When pulmonary contusion is present, the increased afterload may worsen right ventricular function. Increasing mean intrathoracic pressures further with large tidal volumes should be avoided.

While vasopressors may be unavoidable, vasopressin specifically may improve systemic hemodynamics without increasing pulmonary vascular resistance, although this is hardly proven [129]. While heightened vigilance for arrhythmias seems prudent, no prophylactic treatment is warranted and management is as dictated by ACLS. Arrhythmias are in fact the most common finding in patients with BCI. If one includes sinus tachycardia and bradycardia in the definition, they are present in the majority of patients [127]. Arrhythmias requiring treatment, conversely, will be rare. In a large meta-analysis, only around 2% of patients out of over 2200 in their population suffered arrhythmias requiring treatment, and some of these were frequent PVCs that may no longer be considered worthy of pharmacologic intervention [31].

Chest Wall Injury

The rationale for optimal pain control for the population with blunt thoracic injury is not complex and lies in the high rate of morbidity and mortality in these patients and the now accepted tenants of its treatment. Rib fractures are present in roughly 10% of trauma admissions and they are a marker of more severe injuries [130]. Ninety percent of patients will have associated injuries and 12% will die of their injuries [73]. More pertinently, 35% will have a pulmonary complication [130]. Flail chest in isolation carries a 16% mortality [131]. Thirty percent of patients with seven or more rib fractures will die [73]. Elderly patients may be particularly vulnerable with a 36% rate of pulmonary complications and 8% mortality for isolated rib fractures reported [132]. A combination of age and number of ribs fractured dramatically increased morbidity and mortality with each additional rib fracture in patients over 65 causing a 27% increase risk of pneumonia and a 19% increase in the risk of death [133]. The management of blunt thoracic trauma has evolved from stabilization of the bony injury (either physical or "pneumatic" via positive pressure ventilation) to a reliance on pain control and adequate chest physiotherapy [134]. Indeed, most patients with rib fractures will be treated primarily with one or a combination of the modalities discussed in the next section. Still, it must be noted that there is a resurgence of interest in operative fixation of rib fractures after blunt trauma. There is a recent guideline, in fact, from the Eastern Association for the Surgery of Trauma (EAST) that conditionally recommends rib open reduction internal fixation (ORIF) for the subset of patients with flail chest while acknowledging the poor quality of the evidence that their recommendation is based on [135].

Flail Chest

A flail segment exists when a portion of the chest wall loses its mechanical continuity with the remainder of the chest wall [136]. For this to occur, at least two ribs must be fractured in two places (anteriorly and posteriorly). The consequence is that the flail segment responds to changes in pleural pressure and therefore moves inward with inhalation rather than outward. The reverse happens with exhalation. Together this results in a paradoxical movement of the segment. The resulting pathophysiology is not only from the paradoxical motion, but from the inevitable lung injury that results from the impact. The gravity of this injury can lead to a mortality as high as 35% in these patients. They also often have other injuries associated with the impact including pulmonary contusion, lung laceration leading to pneumothorax and hemothorax, as well as injury to other thoracic and extrathoracic structures. The extent that it is the flail segment itself that needs to be addressed is not an academic point since one must decide whether the treatment should be focused primarily at the flail segment per se (positive pressure ventilation, surgical fixation), pain-associated splinting, or the underlying physiology or a combination of all three. Inefficient ventilation, pulmonary contusion, and atelectasis from hypoventilation all play a role in the pathophysiology [136]. The result is V/Q mismatch. The treatment for these patients is therefore as complex as the injury itself. In other sections of this chapter, we will address pulmonary contusion, hemothorax, and analgesia for blunt thoracic trauma leaving the treatment of the mechanics of the flail segment left to be discussed here.

The initial treatment of the flail segment may ultimately be dictated by other underlying injuries. For example, the severity of other injuries to the patient may necessitate tracheal intubation and positive pressure ventilation. This will solve (for the time being) the mechanically discordant movement of the chest wall caused by the flail segment itself. Noninvasive ventilation is also increasingly being utilized for respiratory failure of a variety of etiologies. It has the theoretical advantage of resolving the sequela of paradoxical movement and the resulting V/Q mismatches without the complications of intubation, and there is data emerging to support this approach in selected patients [137].

The notion of surgical fixation of rib fractures is not a new one (the first successful description was in the 1950s [138]) and has a noble goal. Inadequate ventilation and cough because of pain lead to atelectasis. Atelectasis also may occur from the paradoxical chest wall movement itself. In both cases the result is hypoxemia. Further, inadequate analgesia may lead to poor pulmonary toilet and the clearance of secretions. The result is often pneumonia leading to prolonged mechanical ventilation and ICU stays. If surgical fixation could improve pain and therefore clearance of secretions as well as the mechanical handicap, it would be well worth pursuing. Assessing the value of surgical intervention critically has been difficult. Studies have been hampered by small size and cover a variety of surgical techniques. Similarly, standardization of nonoperative management has varied widely with differences in intubation and tracheos-

tomy thresholds, analgesic strategies, pulmonary toilet regimens, fluid administration, etc. [135]. Still, based on available evidence, EAST has conditionally recommended operative ORIF for patients with flail segments with the caution that the level of evidence is poor. The goal is to decrease mortality, shorten time on the ventilator, and shorten ICU length of stay and hospital length of stay, and there is some evidence for each of these outcomes, although most was retrospective in nature and there were concerns of imprecision given the high heterogeneity and by wide confidence intervals. There was no evidence that rib fixation improved pain. They were not able to make any recommendation for patients with non-flail rib fractures based on the available evidence. In our experience, most of these fixations have recently been done with rib plating. Given that, there is usually no need for lung isolation in the operating room, and the main goal of the anesthesiologist is to ventilate the patient with the lung protective strategies dictated by the underlying lung pathology and current best practice.

Pleural Space

The pleural space is normally a potential space between the visceral (covers each lung) and parietal (covers the chest wall) pleural filled with nothing more than a thin film of serous fluid. In trauma, air can enter this space either from the outside world (open pneumothorax) or more commonly from a disruption in the visceral pleura causing air to escape from the lung or the tracheobronchial tree. Air in the pleural space that is not under pressure can lead to a varied clinical presentation from asymptomatic to severe pleuritic chest pain, dyspnea, and tachypnea. The diagnosis is typically made on CXR. Small asymptomatic collections may be managed by observation only, but most in the trauma patient are practically managed by tube thoracostomy. Although this procedure is generally straightforward when performed by experienced providers, a variety of complications can occur including cardiac injury, intercostal artery injury, lung parenchymal injury, extrapleural placement, and even sub-diaphragmatic placement leading to intra-abdominal injury and bleeding (spleen, liver). Anesthesiologists should also be aware that a conservatively treated pneumothorax (or one previously undiagnosed) can convert to a tension pneumothorax – air in the pleural space under pressure – when positive pressure ventilation applied. This diagnosis should be kept in mind as part of a differential when a patient with chest trauma has a significant hemodynamic deterioration following intubation. Indeed, the need to go to the operating room should be factored into the decision-making process before a simple pneumothorax is treated with only observation, although studies supporting or refuting the need for thoracostomy tube prior to positive pressure ventilation are conflicting and suffer from very small numbers [139, 140]. At the very least, clear communication of the presence of a pneumothorax to the anesthesia personnel should occur prior to taking a patient to the operating room with a known or suspected pneumothorax thus treated. A tension pneumothorax occurs when a one-way mechanism allows air into the pleural space with no means of egress. The potential for this exists with injury to the lung parenchyma, tracheobronchial injury, or injury to the chest wall itself. As noted above, positive pressure air in the pleural space leads physiologically to lung collapse, mediastinal shift, and crimping of the IVC and SVC. The result is a sharp decrease in cardiac output. Signs include tracheal deviation, jugular venous distention, unilateral breath sounds, and cyanosis (late finding). Also as noted above, the goal of treatment is immediate relief of the pressure in the pleural space. Needle decompression followed by tube thoracostomy is indicated when suspected. Classically this is accomplished with a 14-gauge needle in the second intercostal space in the midclavicular line. This approach does risk injury to the great vessels and, because of the thickness of the chest wall in this location, can cause an angiocatheter to fail to reach the pleural space. Some (including the author) have advocated an approach via the fifth intercostal space in the midaxillary line where the largest vessel that can be injured is an intercostal artery [141].

Aside from air, blood can invade the pleural space in trauma. When ongoing or with an initial massive output along with hemodynamic instability, thoracotomy is undertaken as described in the section of the lethal six. The injuries leading to this grave situation are usually large lacerations to the pulmonary parenchyma or injury to an intercostal, mammary artery or great vessel, if not the heart itself. Less dramatically, the smaller and more common hemothorax can present with a wide variety of symptoms similar to a pneumothorax including pleuritic chest pain and dyspnea. Physical findings include decreased breath sounds and dullness to percussion. Imaging modalities now include not only chest radiograph, but E-FAST and chest computed tomography depending on the clinical situation [10]. The main drawback of the upright CXR is the volume of blood needed to demonstrate hemothorax, which can be as much as 400–500 cc. Twice that may be necessary with portable supine film. Ultrasound has the advantage of speed and portability with an excellent sensitivity for hemothorax, but it lacks the more comprehensive evaluation of the thorax that computed tomography offers [10]. Mediastinal and bony injuries are not well visualized with ultrasound. Computed tomography provides an excellent diagnostic study in the trauma patient with pleural-based pathology. Its one drawback may be that it is overly sensitive and it is not yet clear what should be done with the very small hemothorax found on initial chest computed tomography (CT). Chest CT may also help define persistent opacities on CXR after thoracostomy placement or

be helpful later in the course of chest trauma. The initial treatment of most hemothoraces is tube thoracostomy. EAST qualifies this recommendation with the caveat that it is based on level 3 evidence. More certain (level 1 evidence) is that persistent opacities after initial tube thoracostomy are treated with VATS within the first 3–7 days of injury to reduce the risk of empyema [10].

As a general statement, the diagnosis and optimal management strategies for posttraumatic retained hemothorax remain problematic. The goal of an aggressive approach to the problem is to prevent not only empyema, but fibrothorax (trapped lung) [142]. Still, the natural history of retained hemothorax has not been well elucidated, and individual therapy must be tailored to the risks associated with operative management in each patient. In the American Association for the Surgery of Trauma (AAST) study, nearly one third of patients were treated with observation after the initial chest tube that proved successful 83% of the time. Smaller collections (less than or equal to 300 cc) also predicted success with observation. Overall, VATS success as the primary therapy approached that of thoracotomy (70% versus 79%) with less theoretical morbidity. Caution should be used when comparing the success rate with observation alone given the observational nature of the AAST study [142]. Taken together, the EAST guidelines and the AAST study suggest we will continue to see frequent and early management of patients with retained hemothorax for VATS.

Pain Management for Blunt Thoracic Trauma

It seems intuitive that providing analgesia to a patient with painful injuries to the thorax would be of great importance and, in an ideal world, lead to improved outcomes. What is less obvious is how to provide optimal pain management. The ideal regimen would provide long-lasting analgesia and allow the patient to comfortably participate in chest physiotherapy. It would improve dynamic measurements of respiratory function. It would be easy to administer, have a favorable side effect profile, and be cost-effective. We have no such technique or pharmaceutical. What we do have is a variety of tools that can each be useful in a given circumstance. Each has pros and cons and they should be viewed as complementary in many cases. As clinicians, we often feel one technique is superior to another. Free of bias, we can see that many of these modalities have their uses and can and should be used in combination depending on the clinical picture. Until the perfect solution is created, we must recognize that while some of our tools are more valuable than others, many of them will be needed in busy trauma centers to optimize patient management. We will review the modalities, their strengths and weakness, and the relevant literature.

Systemic narcotics remain the most prevalent modality for pain management in patients with blunt chest trauma. They are easy to prescribe and can be administered oraly, transderfmally or intravenously. There are no procedural-related complications and they are inexpensive. They improve visual analog scales and may improve vital capacity [143]. When compared to epidural analgesia, however patients retain more CO_2, have a lower PaO_2, and do not improve maximum inspiratory pressure. They also cause respiratory depression, suppress cough, and increase sedation [143].

Intrapleural anesthesia involves infiltration of local anesthetic into the pleural space either via an indwelling thoracostomy tube or placement of a dedicated intrapleural catheter [144, 145]. The procedure is a unilateral modality that has few hemodynamic penalties. The theoretical and real disadvantages are considerable, however. Instillation of local anesthetic thru a chest tube requires its clamping to retain the drug in the intrapleural space risking tension pneumothorax [134]. Hemothorax may impair absorption across the pleura [146]. Concerns have also been raised about high plasma levels from intrapleural infusions of local anesthetic. Phrenic nerve paralysis and Horner's syndrome have been described [147–149]. Furthermore, a complication of placement of an intrapleural catheter in a patient without a thoracostomy tube is pneumothorax. Position of the catheter in relation to the fractured ribs, the number and location of the fractured ribs, and patient position may all affect the technique's efficacy. When compared in a randomized fashion (albeit in small numbers) to epidural analgesia, the intrapleural catheter provided less pain relief and more narcotic use. However, the use of epidural analgesia improved negative inspiratory pressure and tidal volume. The authors concluded that continuous epidural block was superior to intrapleural block [145]. Although some have used the technique with success, an admittedly small study more recently showed no benefit compared even to systemic narcotics [146, 150]. In the end, the large number of variables that affect this technique, the short duration of effect, the lack of consistent data showing efficacy, and the potential complications severely limit its use in our practice.

Intercostal nerve blocks have a long history of use and success in patients with blunt chest trauma [151]. They involve injections of the intercostal nerve proximal to the point of injury and at a level above and below the injured rib. While some authors advocate the block be performed proximal to the midaxillary line to ensure blockade of the lateral and anterior cutaneous branches of the intercostal nerve, this should only be necessary when analgesia of the skin is required [151, 152]. The block will be unilateral and should have few hemodynamic consequences. Intercostal nerve block has been shown to improve peak expiratory flow rate as well as arterial oxygen and carbon dioxide tensions, but these effects last only hours [153–155]. Despite this, Shanti observed that the vast majority of trauma patients need only one or two injections [156]. The blocks are not sedating. Still

there are limitations to the technique. Palpating fractured ribs can be painful, and there can be technical difficulties with the block in higher ribs because of the scapula. Of more concern is that the rate of pneumothorax is 1.4% for each individual intercostal nerve blocked leading to an overall rate of 8.7% per patient in Shanti's study [91]. With patients who have several ribs fractured, there would be a need for multiple injections raising the risk not only of pneumothorax but of local anesthetic toxicity and increased pain of the procedure. Intercostal catheters have been described in small numbers, but the anatomic endpoint of placement can be nebulous and maintaining the proper position of the catheter a challenge [134, 157, 158]. In the end they are simple to perform and can remain a viable alternative in patients who have contraindications or unsuccessful placement of either an epidural catheter or paravertebral block – especially in patients who have a tube thoracostomy in place.

Paravertebral blocks using both a single shot and continuous infusion of local anesthetic are gaining momentum. This seems to be true both in the thoracic trauma and the thoracic surgery literature. Although expertise in the technique may be more limited than it is for epidural placement, the theoretical advantages may soon change that [159, 160]. There seems to be mounting enthusiasm for this technique first described over 100 years ago, and the discussion has begun on the possibility that it will replace epidural analgesia in the world of thoracic surgery and thoracic trauma [161, 162]. Because the technique involves the block of the intercostal nerve, its dorsal ramus, and the sympathetic chain, it produces a dense sensory and sympathetic block [161]. Because the block is unilateral (although unintentional epidural injection is a potential complication), there is less hypotension when compared to epidural analgesia [162, 163]. The block is reported as being simple to perform and perhaps easier to place than a thoracic epidural, although trouble threading the catheter into the paravertebral space has been reported more than once [160, 164]. There are other advantages as well. When compared to epidural analgesia, there seems to be less urinary retention, and there are theoretic reasons to expect less respiratory depression and pruritis since there is no neuraxial opioids as there commonly are with an epidural. It also may be safer to place in patients who are sedated or even ventilated [134, 151]. Placement of a paravertebral block could in theory relax strict restrictions on the placement of epidural catheters in the face of mild coagulopathy or DVT prophylaxis with low molecular weight heparins. Further, many trials of epidurals in blunt thoracic trauma patients have used any injury to the spine as an exclusion criterion [165]. The presence of a spine fracture was in fact the most frequent exclusion criteria accounting for more than twice as many as any other in a frequently quoted study [165]. The exclusion of patients with spine injuries may not be necessary for placement of a paravertebral catheter. It would, for example, be hard to imagine that a lumbar transverse process fracture would be a contraindication for a paravertebral block or catheter. There are also now being described ultrasound-guided techniques of placement that may make this technique safer and easier [166–168]. Lastly, the paravertebral approach does seem to be effective. It has been shown to improve pain, bedside spirometry, and blood gasses [164]. In one small study (15 patients, each arm), it was as effective as epidural analgesia. Unfortunately, these are the only patients comparing the techniques in trauma patients. If one were to extrapolate data from thoracotomy patients, paravertebral catheters still seem to do as well, but again the data is very limited and that extrapolation may or may not be valid [161].

Still there remain some challenges for paravertebral blocks. The most obvious may be familiarity with the technique among current practitioners. Secondly, the technique is not complication free. In Karmakar's series of 15 patients having a continuous paravertebral catheter placed for unilateral rib fractures, for example, there was one inadvertent placement of the catheter in the epidural space that was not appreciated until a large volume of local anesthetic was given. That patient became hypotensive. Twenty percent of the patients in that same series had bilateral analgesia. It is unclear whether that was from epidural spread or spread to the contralateral paravertebral space, but these facts taken together along with the known incidence of pneumothorax and pleural placement make the position of the catheter to be less than certain [164, 169]. The failure rate is also as high as 10% and vascular puncture is 3.8% [169]. Dural puncture and subarachnoid injection have also been described [170, 171]. One of the 15 patients that received a paravertebral infusion in Mohta's recent trial suffered a seizure presumably from local anesthetic toxicity [162]. Certainly strict attention to dose is necessary especially if bilateral catheters would be contemplated for patients with bilateral rib fractures.

In the end, the application of paravertebral blocks in blunt trauma may gain wider acceptance as familiarity with the technique spreads. There are numerous theoretical advantages and some of these have been realized in small trials. Ultrasound guidance may add to the safety of the technique. While data in trauma patients remains limited for now, this technique will undoubtedly become more commonplace. Its utility at present is limited both by widespread technical expertise and its greater utility in patients with unilateral rib fractures [172].

Epidural analgesia remains the standard by which all other pain management modalities are compared. Its theoretical advantages are myriad. It provides nearly immediate

bilateral pain relief. It is less sedating than systemic narcotics so patients can participate in pulmonary toilet [173]. It has been shown to increase functional residual capacity, vital capacity, tidal volume, and compliance and decrease the movement of flail segments as well as to increase PaO_2 [151, 174, 175]. There have been two randomized prospective trials comparing systemic narcotics and epidural analgesia [165, 174]. In the study by Bulger, there was an impressive decrease in the rate of nosocomial pneumonia and duration of mechanical ventilation [165]. In the Ullman study, there were fewer ventilator days, a shorter ICU stay, and a shorter hospitalization. They also had fewer tracheostomies and a larger tidal volume [174]. These results were achieved without what the author would propose is the most effective manor to use an epidural suggesting that the technique could be even more effective. The Ullman study used only epidural narcotics, while the Bulger study had no standardization of their epidural regimen. Neither study used patient-controlled epidural analgesia (PCEA) or programmed intermittent epidural bolus (PIEB) which should result in improved pain control in the trauma patient as it has in the obstetric patient [176, 177]. There is also evidence in the thoracic surgery literature that a combination of local anesthetic and opioids is more effective than either alone [178]. Epidurals may even modulate the immune response in thoracic trauma patients [134, 179].

Despite all of this data and 30 years of experience, there remains as stated above only two randomized controlled trials showing improved outcomes with epidural pain management compared to systemic narcotics, and both of these trials were very small (46 enrolled was the larger of the two) [180]. The size of the studies actually points to some of the concerns of epidural analgesia. In the Bulger study, for example, 408 patients were identified over 3.5 years, and yet 282 met exclusion criteria and 80 could not be consented leaving only 46 [165]. By their own admission, they were fairly conservative in their enrollment (all patients with any spine fracture were excluded). The point remains that many patients who would benefit from epidural placement will not be able to receive one, even if the criteria for exclusion in that study were relaxed. For example, a patient with a lumbar transverse process fracture may be expected to have an epidural placed without significant additional risk [165]. Still other exclusion criteria will remain firm (hemodynamic instability, coagulopathy, altered mental status). Epidurals can cause hypotension especially in the hypovolemic patient or after large volume bolus with local anesthetic. Epidural infections have also been documented [173]. Epidural catheters can be challenging to place especially in patients in pain. Lastly, epidural combinations of local anesthetic and opioids can cause pruritus, nausea, urinary retention, and respiratory depression.

The aim of pain management for the blunt thoracic trauma patient is twofold. First and most obviously pain control is an end onto itself. Patient satisfaction and comfort should be the anesthesiologist's goal under any circumstance. It is improving their respiratory mechanics thru that pain relief that will alter outcome. If we can break the cycle of shallow breathing and poor cough leading to atelectasis, sputum retention, decreased functional residual capacity (FRC), and worsening hypoxia from V/Q mismatch, we can hopefully intubate fewer patients and avoid all the complications that come with it. These include the need for sedation, ventilator-associated pneumonia, DVT, the possibility of nutritional deficiency, etc. The elderly are particularly hard hit by this process as detailed before [133]. Epidural catheters and paravertebral blocks seem to offer the best pain control, although the role of each continues to be a topic of debate and our understanding continues to evolve [181]. Each has its strengths and weakness, and therapy must be individualized. A patient who is able to achieve a vital capacity of 12–15 cc/kg without significant sedation from systemic narcotics, for example, may require no invasive procedures. The presence of a protocol in each institution to standardize therapy may be helpful. It should be noted that the use of other systemic agents for the use of pain control have not been mentioned. Interestingly, there is a paucity of data for the use of NSAIDs or acetaminophen in thoracic injury. Still they are frequently used for the outpatient management of rib fractures, and as a tenant of multimodality therapy, it is reasonable to include them in the management of patients without contraindication. Figure 51.11 represents a modified version of the protocol at our institution. It may serve as a model for departments wishing to address the issue of optimum pain control for their hospital. Even with a protocol in place, the clinician must be aware that patients vary in their clinical presentation and analgesic requirements. This protocol should not serve as a substitute for acumen, but as a guide and source of discussion in the management of pain which must be, in the end, individualized.

With no perfect analgesic agent and with the acknowledgment that surgical fixation may have a role – but is clearly no panacea – and with the realization of the obvious fact that blunt trauma is a heterogeneous entity in a heterogeneous population, it may be that the best way to improve the care of these patients is with a systems approach. The literature in this arena is in its infancy [182]. At our institution a protocol has been implemented that created a standard approach in the care of these patients. It defined standard criteria for ICU admission with an emphasis on pain control and pulmonary toilet. All patients over 45 with four or more rib fractures and over 65 with two or more rib fractured are admitted to the ICU. When pain was not well

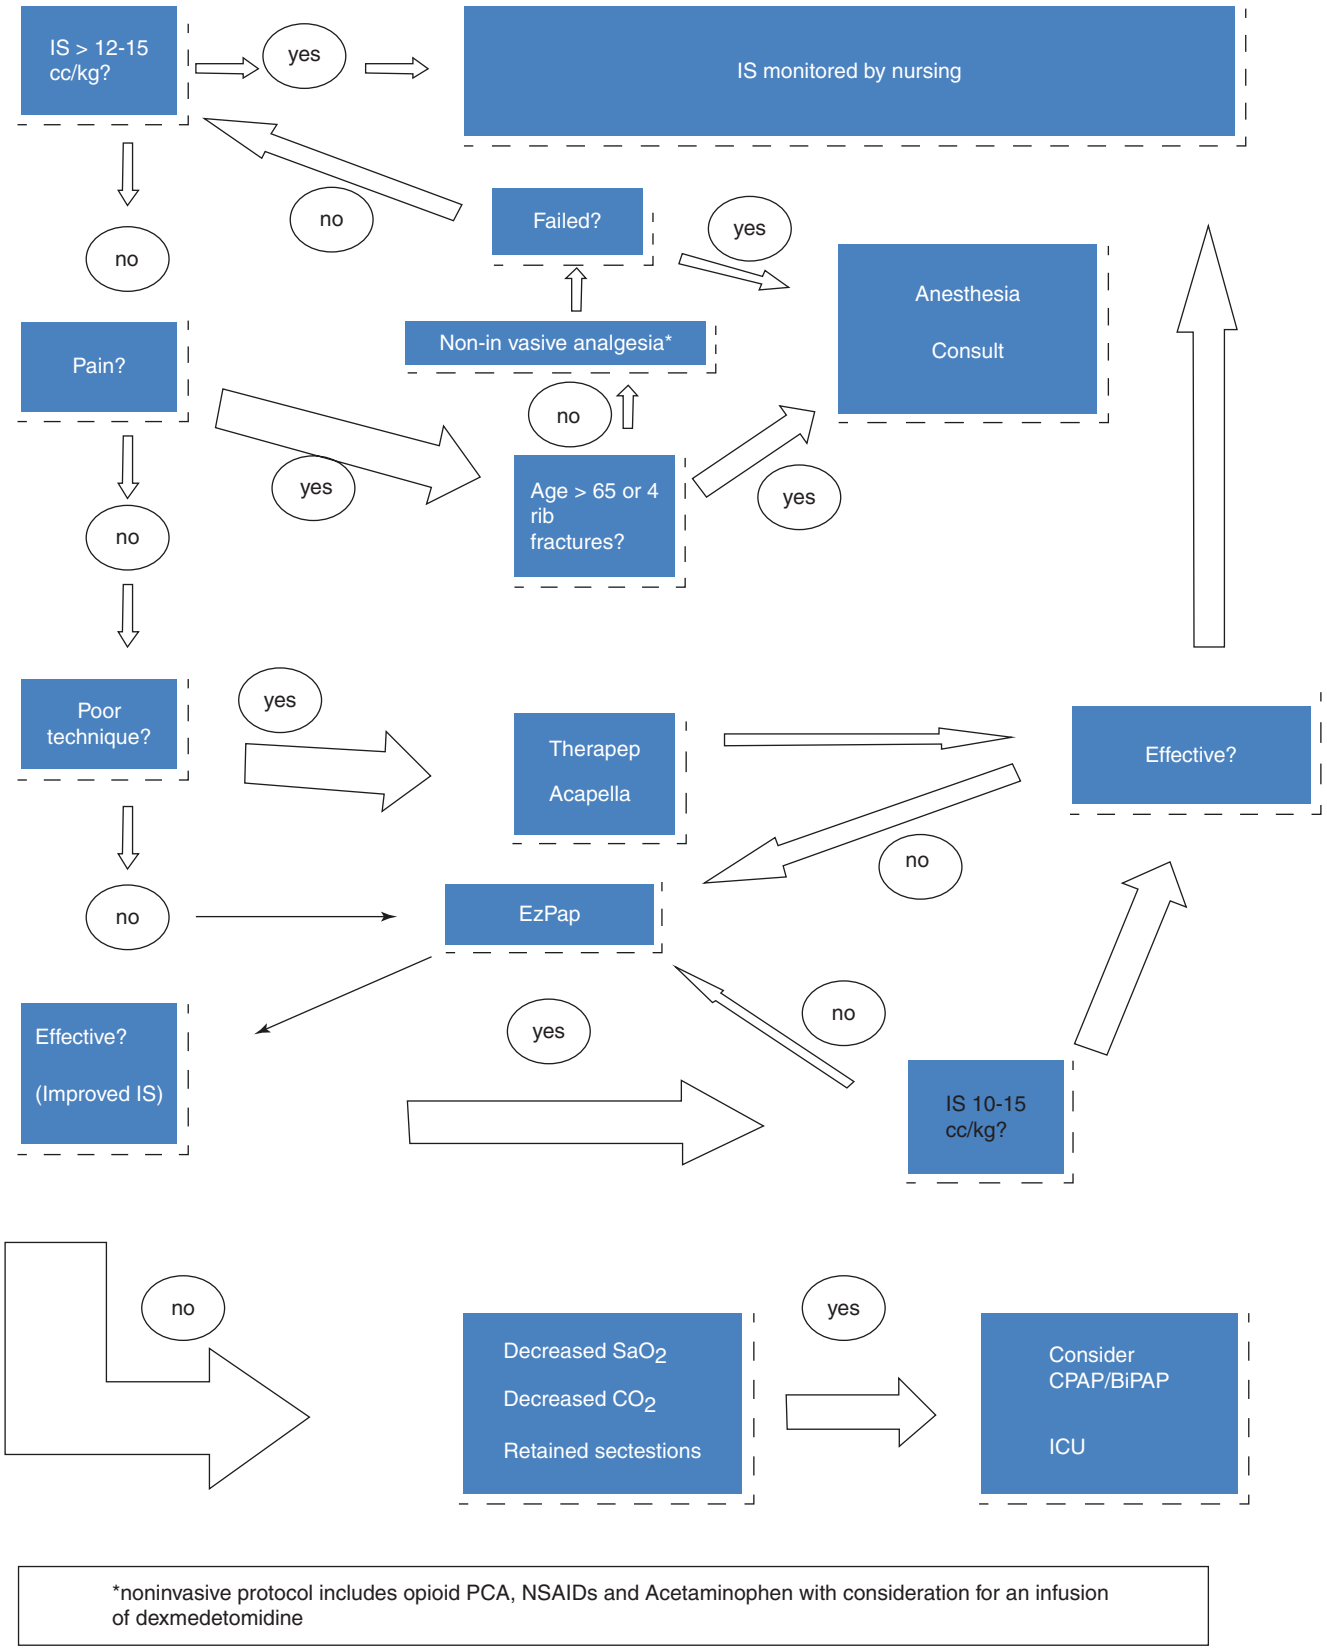

Fig. 51.11 An example protocol for the treatment of pain in patients with blunt chest trauma. Anesthesia consult may trigger additional modalities of pharmacologic management or a variety of nerve blocked in eluding serrates anterior plane block, paravertebral block, or epidural

controlled with PCA and ketorolac leading to poor cough and incentive spirometry performance, early consultation with the anesthesia service is obtained for epidural placement. In a retrospective review, this led to a dramatic reduction in mortality in the elderly patient (9% versus 24%) without a dramatic increase in cost [183]. As is the trend in our specialty, continued examination of evolving evidence will point the way to a standardized approach to this difficult clinical dilemma.

Clinical Case Discussion

Case Pt is a 27-year-old male who was stabbed at the base of the neck and thrown off the top of a three-story building. He arrives in the emergency room intoxicated but awake and alert. He is hemodynamically stable. His past medical history is noncontributory. He is extremely tachypnic, anxious, and complaining of shortness of breath. He is coughing up a small amount of blood. He is wearing a cervical collar. On secondary survey he is found to have subcutaneous emphysema.

Questions

1. What are the anesthesiologists concerns?
2. Should any further imaging be obtained prior to intubation?
3. What airway device should be placed?
4. What technique should be used to intubate the patient?

Given the mechanism of injury and the presence of subcutaneous emphysema and hemoptysis, the anesthesiologist should be concerned that there is an injury to the airway. While under ideal conditions an awake fiberoptic intubation would be preferred, the scenario presented describes a patient who is in respiratory distress and could not be expected to participate in an awake fiberoptic intubation. No further imaging should be necessary in this patient who clearly needs urgent control of the airway. Rapid sequence intubation with in-line stabilization remains the standard of care and should be performed without delay. Strict attention should be made to the patient's hemodynamics after intubation, since converting a presumed pneumothorax to a tension pneumothorax is possible in this scenario. Every attempt must be made to place the endotracheal tube with great care in an effort not to disrupt a potential injury to the trachea.

Scenario continues: The patient is successfully intubated, and a chest tube is placed for decreased breath sounds over the right chest. A large air leak is found. The following CXR is obtained.

Fig. 51.12 Chest X-ray shows a patient with a persistent right pneumothorax despite a well-positioned thoracotomy tube and an endotracheal tube above the carina

Figure 51.12 CXR shows a patient with a persistent right pneumothorax despite well-positioned thoracostomy tube and an endotracheal tube just above the carina

Questions

1. What would be the next step in the evaluation of this patient?
2. How can the anesthesiologist manage the air leak?
3. The patient is being taken to the operating room for surgical repair. What form of lung isolation should be used?

The patient should undergo fiberoptic bronchoscopy to define the tracheal injury and if possible to move the cuff of the endotracheal tube beyond the tear. This patient also underwent computed tomography which revealed a posterior tear in the trachea. The CT also demonstrated continued pneumothorax on the right as well as subcutaneous air. Lastly the CT demonstrated five posterior rib fractures on the right (Fig. 51.13).

The first choice for lung isolation in this case would be a bronchial blocker thru the original endotracheal tube. This would prevent any further tracheal injury by passing a larger stiffer device thru the injury. In addition, the patient has not had injury to the cervical spine ruled out, and this will minimize movement of the neck. He is taken to the operating room for repair of this injury shown in Fig. 51.14.

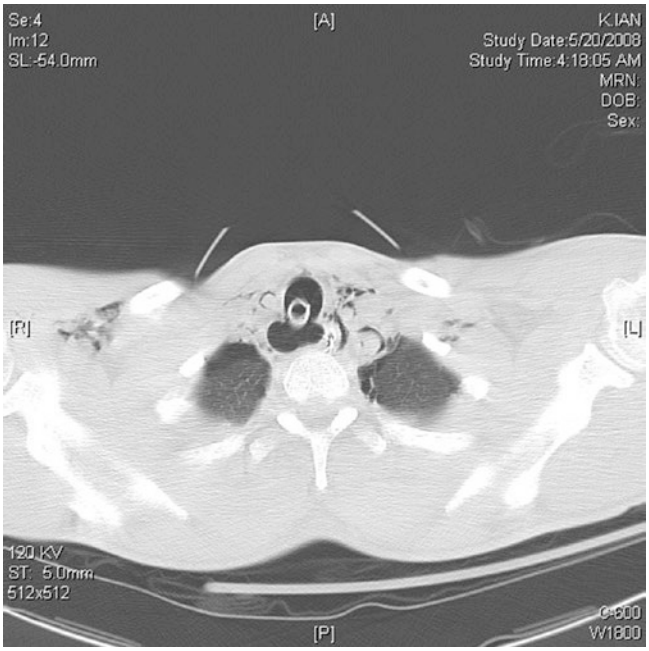

Fig. 51.13 Computed tomography scan demonstrating posterior tracheal tear, subcutaneous emphysema and persistent right pneumothorax. Subcutaneous emphysema is also demonstrated

Questions

Would you extubate this patient at the end of the case? How would you control his pain from the rib fractures?

These are both difficult questions. In general, every effort to extubate the patient as soon as possible should be made given his tracheal repair. Managing the pain of his rib fractures may be difficult. If he is awake and cooperative post extubation, an epidural can be considered. If not, paravertebral blocks or a catheter may be an option since the rib fractures are unilateral.

Part XIV

Post-operative Management

Enhanced Recovery After Surgery (ERAS) for Thoracic Surgery

52

Emily G. Teeter, Gabriel E. Mena, Javier D. Lasala, and Lavinia M. Kolarczyk

Key Points

- Enhanced recovery after surgery (ERAS) describes a multidisciplinary approach to reducing the perioperative stress response, decreasing potential complications, and enabling a faster return to baseline functional status.
- The core tenets of ERAS span the entire perioperative period.
- Pre-operative components of ERAS include patient education, "prehabilitation," and optimization of underlying medical conditions such as COPD and anemia.
- Intraoperatively, multimodal opioid-sparing analgesia, minimally invasive surgical techniques, avoidance of salt and crystalloid excess, protective ventilatory strategies, and limited use of tubes and drains should be considered.
- In the post-operative period, early mobilization, early enteral nutrition, and early removal of tubes and drains are encouraged.
- While ERAS is well-established in some fields, ERAS for thoracic surgery is still relatively new.
- In order to be successful, an ERAS program must have buy-in from all members of the team, including personnel in the pre-operative, intraoperative, and post-operative settings. Anesthesiologists play a major role in the success of ERAS programs, and patients are active participants in their care.

Background

The concept of enhanced recovery after surgery (ERAS) was introduced in the late 1990s by Kehlet. This model of care provides a multidisciplinary, comprehensive approach aimed at reducing the perioperative stress response, decreasing potential complications, and enabling a faster return to baseline functional status [1]. From a systems perspective, ERAS programs are associated with reduced length of hospital stay, increased patient satisfaction, and lower costs [2]. In the oncologic population, faster recovery means an earlier return to planned adjuvant chemotherapy or radiation therapy, a so-called return to intended oncologic therapy (RIOT) score [3]. ERAS programs challenge traditional clinical practice and emphasize application of evidence-based best practices throughout the perioperative spectrum [4–6].

Healthcare systems in the United States and abroad have implemented ERAS protocols in a variety of surgical patient populations. Given the changes in healthcare reimbursement from fee-for-service to value-based models, there is a growing emphasis on delivering quality, improving outcomes, and decreasing cost [7]. ERAS programs serve as a vehicle to deliver value-based care, as ERAS principles promote early physiologic recovery, improved pain management, and early hospital discharge.

Fast-track and thoracic ERAS protocols have evolved over the past two decades in parallel with cardiac fast-track protocols, likely due to the clinical overlap between cardiac and thoracic surgery practitioners. Fast-track cardiac surgery protocols gained popularity in the 1990s as a way to facilitate early extubation after surgery and in turn decrease intensive care unit cost. Early extubation after cardiac surgery helped to mitigate the well-described deleterious effects of prolonged mechanical ventilation. Some fast-track cardiac protocols included extubation in the operating room at the end of the procedure [8–15]. The success of these cardiac surgery protocols led to the evolution of pathways in other cardiothoracic procedures, including pulmonary resection and esophageal surgery [16–19].

In 2008, Muehling et al. [20] performed a prospective, randomized, controlled study investigating fast-track versus conservative care in thoracic surgery. The conservative patient group fasted for 6 h and had an intraoperative intercostal nerve block followed by IV patient-controlled analgesia (PCA). Enteral feeding and ambulation started on the day after surgery. The fast-track group fasted for 2 h and received patient-controlled epidural analgesia. In this group, enteral feeding and ambulation started on the evening of the operation. The primary end points of the study were the presence of post-operative pulmonary complications, namely, atelectasis, pneumonia, prolonged air leak, and pleural effusion. The researchers found that the overall rates of post-operative pulmonary complications were 36% in the conservative group and 7% in the fast-track group ($P = 0$ 0.009). In this study, researchers found no significant difference in overall morbidity or mortality.

In 2009, Das-Neves-Pereira et al. [21] published their 5-year experience with patients undergoing open, muscle-sparing lobectomy who were provided care in a fast-track rehabilitation program. Comparison of their post-operative complications and hospital length of stay showed that non-fast-tracked patients experienced more frequent post-operative complications and a longer average hospital stay. Of particular importance, early patient ambulation was the only predictive (i.e., protective) independent variable of post-operative complications.

In esophageal surgery, fast-track surgery protocols have demonstrated an improvement in biochemical markers of inflammation. Chen et al. [16] demonstrated that fast-track surgery improves post-operative clinical recovery and effectively inhibited the release of inflammatory factors via the immune system after esophagectomy for esophageal cancer. As compared to thoracotomy, minimally invasive thoracic surgery is associated with lower cytokine release, less effect on white cell function, and less impact on the immune system [22]. The translation to clinical outcomes, however, has not yet been demonstrated. Findlay et al. provided the first systematic review of enhanced recovery protocols for esophagectomy [17, 18]. The findings of this review support that ERAS pathways for esophagectomy are safe, feasible, and likely beneficial for this high-risk group, although more studies are needed.

ERAS General Overview

The Enhanced Recovery After Surgery (ERAS(R)) Society and American Society of Enhanced Recovery (ASER) has described core components for ERAS pathways across a variety of surgical specialties (Fig. 52.1). These core concepts include pre-operative patient education, pre-operative carbohydrate fluids up to 2 h before surgery, multimodal opioid-sparing analgesia, minimally invasive surgery when possible, avoidance of salt and crystalloid excess, early mobilization, early enteral nutrition, and limited use of and early removal of tubes and drains. Additionally, avoidance of bowel preps is strongly advised. The ERAS Society has published specific guidelines for a variety of surgical patient populations, including bariatric surgery, colorectal surgery, gynecologic surgery, pancreatic surgery, urologic surgery, liver surgery, and head and neck surgery [23, 24]. Thoracic ERAS pathways are still in their infancy, and currently there is significant variability in institutional practices with limited evidence [25, 26].

PREOPERATIVE	INTRAOPERATIVE	POSTOPERATIVE
Patient education	Defined blood pressure goals	Multimodal analgesia, avoidance of systemic Opioids
Consumption of carbohydrate drink	Antibiotic prophylaxis (per SCIP guidelines)	Early and frequent mobilization
Multimodal analgesia	Standardized anesthetic approach	Early removal of nasogastric tube
VTE Prophylaxis	Multimodal analgesia, avoidance of systemic opiates	Early removal of urinary (Foley) catheter
Avoidance of bowel preps	Avoidance of IV crystalloid and salt excess	Early discontinuation of IV fluds
		Early PO intake

ERAS for Thoracic Surgery: Rationale

Application of ERAS principles to thoracic surgery seems prudent, as this patient population represents an at-risk group for increased perioperative complications. Thoracic surgical patients tend to be older with multiple comorbidities including chronic obstructive pulmonary disease (COPD), hypertension, and coronary artery disease. Thoracic surgery patients are also more likely to be current or former tobacco smokers [27]. These patient factors contribute to prolonged length of hospital stay and increased risk of perioperative morbidity and mortality [28].

While ERAS for thoracic surgery is a novel concept, there is emerging literature demonstrating proof of concept in lobectomy, video-assisted thoracoscopy (VATS), and esophagectomy [29–31]. Pre-operative components of an ERAS clinical pathway for thoracic surgery focus on risk reduction and optimization, which may include tobacco cessation, nutrition, and improving functional capacity [30]. Intraoperative components of an ERAS clinical pathway may include multimodal opioid-sparing analgesia and interventions to prevent post-operative pulmonary complications. Post-operative components serve to prevent common complications including oxygen dependency, delirium, and suboptimal pain control [30].

ERAS Thoracic Surgery: Pre-operative Components

Surgical stress is associated with a sharp decline in functional status, typically followed by a slow recovery (Fig. 52.2). "Prehabilitation" is a term used to describe the pre-operative physical conditioning and optimization of patient functional status in order to facilitate tolerance to surgical stress and enable a smooth perioperative course [32–34]. The core components of prehabilitation include exercise, nutritional counseling, and stress reduction. Specific to thoracic surgery, pre-operative interventions should focus on encouraging tobacco cessation, correcting anemia, optimizing comorbid conditions, and improving pulmonary and nutritional status. In addition, the importance of patient education, clear communication of expectations, and involving patients as active participants in their own care cannot be overstated.

Much like training for an endurance race, prehabilitation aims to optimize physiologic reserve in light of the impending physical and psychological insult of surgery. While prehabilitation makes intuitive sense, the literature is mixed, particularly when the primary outcomes are morbidity, mortality, and hospital length of stay. A review of 12 randomized controlled trials of patients undergoing

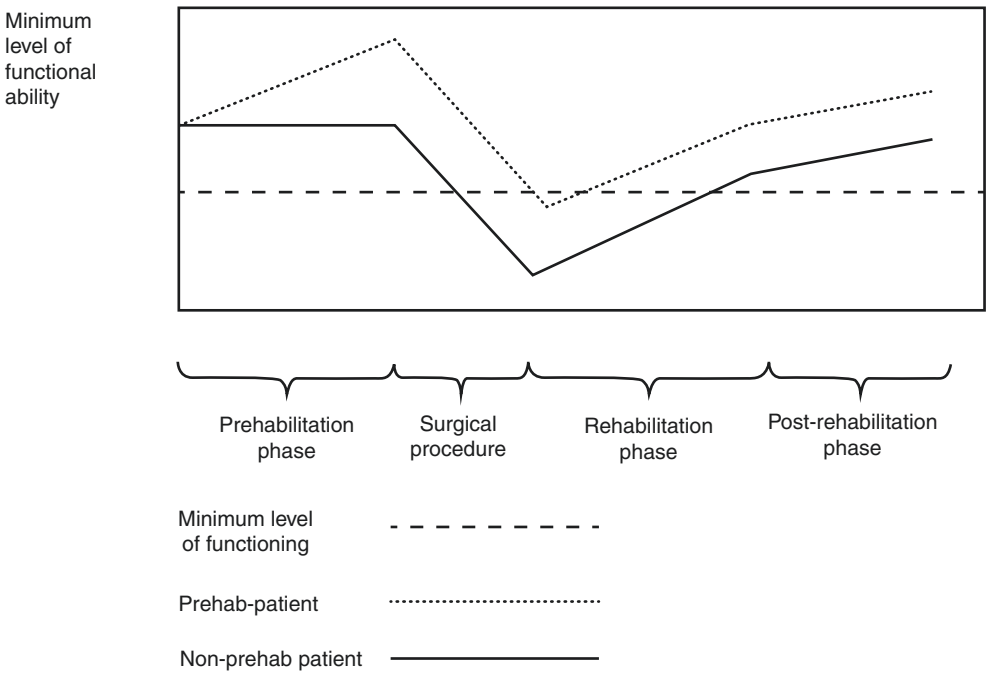

Fig. 52.2 Functional ability through the perioperative period with and without pre-operative physical conditioning ("prehabilitation"). (Carli and Zavorsky [125] with permission. https://journals.lww.com/co-clinicalnutrition/Abstract/2005/01000/Optimizing_functional_exercise_capacity_in_the.5.aspx)

orthopedic, cardiac, and abdominal surgery reported decreased length of hospital stay and fewer post-operative pulmonary complications in those who had participated in pre-operative exercise programs [35]. A similar systematic review of pre-operative exercise therapy in thoracic surgery patients found beneficial effects of exercise on physical fitness, exercise capacity, as well as post-operative complications and hospital length of stay. Conversely, a review of eight randomized controlled trials by Lemanu found only one study demonstrating physiologic benefit of prehabilitation. Interestingly, the group that did show benefit (less decline in respiratory parameters as compared to controls) was a group of patients undergoing coronary artery bypass grafting (CABG) surgery [36].

Traditionally, rehabilitation begins after surgery, and while anecdotally prehabilitation has benefit, the specific benefit of beginning this in the pre-operative setting rather than post-operatively is unclear. A prospective, randomized controlled trial comparing pre-operative rehabilitation with standard post-operative rehabilitation in patients undergoing colon resection was performed by Gillis et al. Both groups participated in aerobic and resistance exercise, nutritional counseling, and relaxation exercises. The prehabilitation group experienced a significant improvement in functional exercise capacity both pre-operatively and post-operatively, although no difference in outcomes was demonstrated [37]. While data specifically looking at thoracic surgery is sparse, a study following 82 patients who began pulmonary prehabilitation during induction chemotherapy and were followed through the perioperative period found an overall improvement in forced expiratory volume in one second (FEV1) and forced vital capacity (FVC) post-operatively, and the improvement was most marked in high-risk patients (smokers and those with the poorest baseline pulmonary function tests) [38]. However, this was an observational study, which by definition has no control group, so they were unable to demonstrate any comparative benefit. To date, no randomized controlled trials in the thoracic population demonstrate decreased pulmonary complications, length of stay, or morbidity/mortality in patients who complete pre-operative rehabilitation programs [39]. Further studies exploring the impact of prehabilitation in thoracic surgery are needed in order to establish the benefit of including prehabilitation in enhanced recovery protocols.

Optimization of Comorbid Conditions

Thoracic surgery patients are among the most medically complex, partly due to concomitant respiratory pathology and high rates of long-term tobacco abuse. Often, patients are scheduled for lung resection surgery soon after a cancer diagnosis, which does not leave much time for optimization of comorbid conditions. Specifically, COPD is a common finding in patients who present for thoracic surgery and is an independent risk factor for post-operative pulmonary complications [40]. A long-acting bronchodilator and/or inhaled steroid should be considered for patients whose COPD is untreated or not optimally controlled [41–43]. As discussed above, perioperative respiratory physiotherapy programs may improve FEV1 and FVC such that some patients who may not be proper surgical candidates could be reconsidered for a surgical procedure [44]. Other comorbid conditions, such as hypertension and diabetes, should be addressed as aggressively as possible without delaying surgery. The pre-operative assessment clinic is invaluable in providing a comprehensive assessment and recommendations for management of thoracic surgery patients in the pre-operative period.

Nutrition

Malnutrition has deleterious consequences in the perioperative period; namely, delayed wound healing, as well as muscle weakness leading to respiratory complications, increased morbidity, and prolonged recovery [40, 45–47]. Patients with cancer are prone to malnutrition, and among these, patients with esophageal cancer are at especially high risk due to accompanying dysphagia and obstructive gastrointestinal symptoms. Recent emerging guidelines, such as the European Society for Nutrition and Metabolism Guidelines, recommend that patients be screened for malnutrition in the pre-operative period [48]. Multiple risk stratification tools exist, including the subjective global assessment (SGA) and Nutritional Risk Screening 2002. Patients at high risk should undergo nutritional counseling and supplementation. Up to 28% of patients undergoing lung resection surgery fall into the high-risk category, as defined by weight loss >10–15% within 6 months, BMI < 18.5 kg/m^2, SGA Grade C, or serum albumin <30 g/L [49]. Not surprisingly, most esophagectomy patients should be considered high-risk and would benefit from aggressive nutritional support pre-operatively [17]. While no studies to date have specifically examined the impact of pre-operative correction of malnutrition in patients undergoing lung resection or esophagectomy, such interventions are still recommended [17]. Small trials have investigated the impact of pre-operative immunonutrient and micronutrient supplementation (such as a-ketoglutaric acid and 5-hydroxymethylfurfural) in patients with non-esophageal gastrointestinal or non-small cell lung cancer and found a reduction in infectious complications and ICU and hospital length of stay [50, 51]. However, randomized control trials specifically focusing on micronutrient supplementation in patients with esophageal cancer found no benefit [52, 53].

Anemia Screening

Anemia, defined as a hemoglobin concentration <12 g/dL in females and <13 g/dL in males, is a common pre-operative finding which has been associated with increased morbidity and mortality [54, 55]. Transfusion is typically avoided unless absolutely necessary, as it carries the risks of transfusion reaction, infection, immunosuppression, and cancer recurrence [56]. Other strategies to correct anemia pre-operatively include iron supplementation and erythropoietin administration; however, typically their use is limited by the short time interval between cancer diagnosis and surgery [40]. Regardless, anemia should be investigated and corrected as much as possible prior to thoracic surgery.

Tobacco

An estimated 20% of the US population smokes [57], and this number is even higher in the thoracic surgery patient population [58]. Smokers are at significantly higher risk of post-operative complications than non-smokers. Smoking increases the odds of 30-day mortality, post-operative pulmonary complications, major adverse cardiac events, and wound infection [57]. Pre-operative smoking cessation reduces morbidity and mortality, although the optimal timing has been a source of debate. Currently, the literature does not support the formerly held notion that tobacco cessation within 2 months of surgery is associated with a paradoxical increase in post-operative pulmonary complications [59]. According to the NICE guidelines, patients should be counseled to stop smoking before surgery, regardless of the timeline [60]. Among smoking cessation methods, no randomized control trials have shown one method to be most successful [61].

ERAS Thoracic Surgery: Intraoperative Components

Analgesia

Multimodal analgesia involves the use of non-opioid analgesics with different mechanisms of action, which work synergistically to provide pain relief with reduced analgesic-related adverse effects. The analgesic modalities available for post-operative pain management after thoracic surgery include regional or local analgesia techniques, such as thoracic epidural analgesia (TEA), paravertebral block (PVB), intercostal nerve blocks (ICNB), and wound infiltration. In addition, acetaminophen, non-steroidal anti-inflammatory drugs (NSAIDs), or cyclo-oxygenase-2 (COX-2) specific inhibitors and analgesic adjuncts, such as steroids, ketamine, alpha-2 agonists, and gabapentinoids (e.g., gabapentin and pregabalin), have been evaluated [62]. An ideal analgesic combination would reduce the intensity of movement-evoked pain (e.g., during coughing and ambulation), while avoiding analgesic-related adverse effects, and improve post-operative outcome.

Gabapentinoids, namely, gabapentin and pregabalin, have both been shown to be effective in the prevention of post-thoracotomy pain syndromes [63, 64]. COX-2 inhibitors and NSAIDs have demonstrated clinical effectiveness in treating ipsilateral shoulder pain after thoracic surgery [65]. The alpha-2 agonist dexmedetomidine has been shown to decrease opioid use in thoracic surgical patients [66, 67].

Neuraxial and regional anesthesia techniques to minimize perioperative opioid use include thoracic epidural analgesia, paravertebral blocks, intercostal blocks, and serratus anterior nerve blocks. Historically, the gold standard for thoracotomy pain management has been thoracic epidural analgesia [68, 69]. The dense analgesic block provided by an epidural has been shown to decrease post-operative pulmonary complications [70] and prevent long-term chronic post-thoracotomy pain syndromes [71]. However, the risks associated with TEA remain an ongoing concern. These risks include hypotension, urinary retention, epidural abscess, and epidural hematoma. As such, there has been a growing interest in the use of regional anesthetic techniques for thoracic surgery, which theoretically have fewer systemic side effects.

The thoracic PVB continues to show promise as a safe and equally efficacious analgesic method for thoracic surgery [72]. A recent Cochrane review compared TEA to PVB for elective thoracotomy with respect to analgesic efficacy, the incidence of major and minor complications, length of hospital stay, and cost-effectiveness [25]. The conclusion from this review was that PVB was equally as effective as TEA for acute thoracotomy pain and that PVB reduced the risks of minor complications commonly associated with TEA. There was not enough evidence to evaluate length of hospital stay and cost-effectiveness [73].

There has been a renewed interest in the use of intercostal nerve blockade (ICB) for thoracic surgical analgesia with the introduction of liposomal bupivacaine (Exparel®, Pacira Pharmaceuticals, Parsippany, NJ) and the growing popularity of ERAS pathways for thoracic surgery [25]. The advantages of ICB include ease of block placement, placement of block under direct visualization by the surgeon, low risk of hemodynamic issues, and good safety profile. Liposomal bupivacaine adds yet another advantage in that it does not require placement or management of an indwelling catheter while providing up to 96 h of analgesia. The use of liposomal bupivacaine for peripheral nerve blockade is not yet FDA-approved, but several studies using liposomal bupivacaine for ICB in thoracic surgery have demonstrated a promising safety profile. A retrospective study of 108 patients compared TEA ($n = 54$) to ICB with Exparel® ($n = 54$) for lung resection surgery [26]. The authors found no differences in mean or maximal pain scores or in opioid consumption

between ICB with Exparel® and TEA. The authors were able to conclude that a posterior intercostal block performed under direct vision via a thoracoscopic view and using long-acting encapsulated bupivacaine (Exparel®) is safe and provides effective analgesia for patients undergoing thoracic surgery. It may be considered as a suitable alternative to TEA. Of note, there was significant heterogeneity in surgical approach, as the study included patients who had video-assisted thoracoscopic (VATS), robotic, and open thoracotomy approaches. A second retrospective study of 85 patients compared TEA to ICB with Exparel® specifically for thoracotomy patients [74]. Patients in the Exparel® ICB group had lower pain scores on post-operative days 1 and 3, and there was no difference in pain scores on post-operative day 2. The authors found no difference in supplemental opioid use between groups. While these results are promising, these studies are small retrospective reviews.

The serratus anterior block (SAB) has been recently introduced as a novel regional technique for thoracic surgical analgesia. The SAB targets the lateral cutaneous branches of the intercostal nerve as they pass through this fascial plane before these nerves divide into anterior and posterior branches to innervate the chest wall. The block is performed by injecting local anesthetic either superficially or deep to the serratus muscle under ultrasound guidance [75]. A recent prospective randomized controlled trial evaluated TEA versus serratus anterior nerve block (SAB) infusion for thoracotomy patients [76]. The authors found no difference in pain scores or morphine consumption between groups for the first 24 h after surgery. The SAB group had fewer episodes of hypotension. While this study is promising, larger studies that follow patients for longer periods of time are needed to demonstrate the effectiveness and safety profile of the SAB.

Mechanical Ventilation Strategy

In thoracic surgery, pulmonary complications outnumber cardiovascular complications and are the most common cause of post-operative death in esophageal cancer patients [77, 78]. Injury from OLV can manifest as re-expansion pulmonary edema (REPE), acute lung injury (ALI), or acute respiratory distress syndrome (ARDS). While bronchopneumonia or aspiration can contribute to delayed ALI, the risk of early ALI is increased by high intraoperative ventilation pressures, increased surgery duration, and excessive intravenous volume replacement [79–82]. Thus, protective ventilatory strategies and judicious fluid use may decrease the incidence of ALI [80].

Historical ventilator schemes focused on prevention of atelectasis, and tidal volumes as high as 10–12 mL/kg were advocated. Tidal volumes <8 mL/kg were thought to result in decreased functional residual capacity (FRC) and worsening atelectasis. OLV was achieved with parameters similar to two-lung ventilation. This ventilator strategy proved to be detrimental because it led to a cascade of inflammatory mediators due to the stimulation of stretch-activated cation channels, oxygen-derived free radicals, activated neutrophils, and cytokine upregulation contributing to increased microvascular-alveolar permeability [83]. The current strategy to minimize OLV-associated lung injury advocates lung protective ventilation to decrease inflammatory mediators, which contribute to ventilator-induced lung injury (VILI) [84]. Reduction of tidal volumes during OLV to 5 ml/kg was shown to reduce alveolar concentration of TNF-α and sICAM-1 [85]. The addition of 5 cm H2O PEEP was associated with better oxygenation and earlier extubation [86]. Current lung protective ventilation consists of tidal volume of 5–6 mL/kg, maintaining low fraction of inspired O2 (Fi02) to avoid absorption atelectasis and worsening shunt [87], PEEP above the lower inflection point on the static pressure-volume curve, plateau pressures of less than 20 cm H2O above the PEEP value, peak inspiratory pressures less than 35 cm H2O, and preferential use of pressure-limited ventilatory modes [82].

Lung protective ventilation primarily refers to the dependent lung, which shows a more pronounced inflammatory response than the non-ventilated lung [88, 89]. However, the nondependent lung may experience ischemia-reperfusion injury, and it is likely that physiologic and pathologic insults to both lungs contribute to post-operative complications.

Maintenance of Anesthesia

The influence of anesthetic type on the inflammatory response and post-operative clinical outcomes is unknown. Studies comparing propofol to volatile anesthetics such as sevoflurane and desflurane have yielded conflicting results [90]. Overall, differences in surgical time, duration of OLV, and laboratory techniques in existing studies have complicated interpretation of the data [82]. Volatile agents are thought to have immune-modulating effects. While previous work showed anti-inflammatory effects of propofol, recent studies have demonstrated decreased inflammatory markers in both the operative and non-operative lung with volatile anesthesia [90–92]. Sugasawa and colleagues found that sevoflurane use was significantly associated with a suppressed inflammatory response compared to propofol [92]. Thus, the choice of anesthetic agent and other drugs such as ropivacaine, ketamine, thiopental, and dexmedetomidine may have anti-inflammatory effects that may be protective during lung surgery with OLV. Further study is needed to elucidate the role of these agents [93].

Fluid Management

Appropriate perioperative fluid management during thoracic surgery and specifically lung resection including VATS is a subject of a long-standing debate between thoracic surgeons and anesthesiologists. The controversy centers around the fact that restrictive fluid management may induce hypovole-

mia leading to a negative impact on organ perfusion and increased perioperative morbidity (e.g., renal impairment [94], myocardial ischemia) as well as prolonged length of stay (LOS), whereas fluid overload leads to increased perioperative morbidity (GI complications, i.e., anastomosis leak, ileus, infections) [95–98].

In the operative setting, surgical insults may cause an inflammatory response characterized by alterations in microvascular integrity. Specifically, the protective glycocalyx may be compromised, thus allowing abnormal transmicrovascular fluid flux. Due to this increase in permeability, interstitial edema may develop, which decreases O2 diffusion and results in hypoxic cell injury. This injury propagates a vicious cycle involving further cell death and the subsequent release of inflammatory cytokines.

Goal-directed therapy (GDT) describes the administration of intravenous fluids, vasopressors, and inotropes guided by flow-based dynamic parameters such as stroke volume variation (SVV), cardiac index (CI), and stroke volume (SV) in order to achieve individualized hemodynamic and fluid optimization. Cecconi et al. reviewed 32 randomized controlled trials including 2808 patients and concluded that GDT decreases morbidity and mortality in high-risk surgical patients (those who had predicted mortality >20%) undergoing elective surgery [99]. However, the use of these monitors, which include Vigileo FloTrac™, PiCCOplus™, and LiDCO™, is limited in thoracic surgery by open-chest physiology, one-lung ventilation, and lateral positioning. In patients undergoing thoracic surgery with one-lung ventilation (OLV), these commercially available hemodynamic monitoring tools may be used to follow perioperative hemodynamic trends, but the anesthesiologist should recognize their limitations.

Slinger describes a rational approach to fluid administration for thoracic surgery patients [100]. The thorax is not assumed to be a third space. Total positive fluid balance in the first 24 h post-operatively should not exceed 20 ml/kg or approximately 3 L of crystalloid. Unless the patient is at high risk of developing renal insufficiency, urine output of greater than 0.5 mL/kg/h is probably unnecessary. In the case of reduced tissue perfusion, as in the case of epidural-induced sympathectomy, it is preferable to invasively monitor and use GDT. The use of inotropes may be preferable to aggressive fluid overload.

ERAS Thoracic Surgery: Post-operative Components

In order for an enhanced recovery pathway for thoracic surgery to succeed, the post-operative care must be a multidisciplinary continuation of the components begun in the pre-operative period. Namely, multimodal analgesia, mobilization, chest physiotherapy, and nutritional optimization are paramount. Additionally, early removal of chest tubes, lines, and urinary catheters should be performed.

Removal of Lines and Drains

The "early" removal of lines, tubes, and drains challenges traditional surgical dogma. Nonetheless, indwelling urinary catheters limit mobility and are associated with an increased incidence of urinary tract infection, which can lead to post-operative delirium, sepsis, increased length of stay, and mortality [17]. Therefore, even in the presence of a thoracic epidural, the Foley catheter should be removed as early as possible. While the need for catheter replacement in the setting of urinary retention remains a concern, randomized controlled trials in thoracic and abdominal surgery patients demonstrate that in patients with normal urinary function, the rate of recatheterization remains extremely low and the risk of urinary tract infection was overall reduced [17].

Unless placed for esophagectomy, nasogastric tubes ought to be removed by post-operative day 1 or not placed at all if possible. In our institution, both the urinary catheter and nasogastric tube are labeled with a fluorescent "ERAS" sticker as a visual reminder for the surgical team to consider early removal.

Chest Drains

Indwelling chest drains cause pain and impair mobilization, thus slowing recovery [101]. Significant heterogeneity exists in the practice patterns for chest drain management, even in matters so simple as whether or not to apply suction [102, 103]. Some argue that suction decreases air leaks by encouraging the two layers of pleura to appose, while others argue that suction maintains or even encourages air leaks. The threshold for chest drain removal remains unstandardized, although absence of an air leak and output of less than 150 mL per day are common [104]. Unfortunately, for many patients, discharge is delayed due solely to persistent air leak or chest drain output. Thus, several studies have examined a lower threshold for drain removal and concluded that removal at a higher threshold (200 mL or even higher) is indeed safe [104, 105], and patients can be discharged sooner, particularly if the patients can be discharged with portable suction or a similar device. When possible, placing only one chest drain may improve pain and expedite discharge without increasing morbidity as compared to two or more drains [106–109]. Surgical sealants have been developed to decrease post-operative air leak, and while some evidence supports their efficacy in this regard, they do not contribute to a shorter length of stay and cannot be recommended [110].

Early Mobilization

Although post-operative convalescence has been traditionally thought to aid recovery by decreasing metabolic demands, bed rest has several undesirable consequences. Specifically, muscle atrophy due to catabolism takes place in a matter of days, even in healthy adults, with an estimated loss of 10–20% of muscle mass per week, and pulmonary function rapidly declines [40, 111]. Therefore, early mobilization ought to be a priority in the post-operative period as soon as it is safely possible. Patients who were mobilized as soon as 4 h after lung resection required less supplemental oxygen and made a smoother psychological recovery in one prospective cohort study [112].

Incentive Spirometry

Pulmonary complications, such as atelectasis, pneumonia, prolonged ventilation, and exacerbation of chronic obstructive pulmonary disease (COPD), remain a major source of morbidity and mortality in thoracic patients [113]. Altered respiratory mechanics, atelectasis, and shallow breathing due to pain can contribute to post-operative pulmonary complications [114]. To date, several studies have examined the role of post-operative chest physiotherapy and incentive spirometry in preventing post-operative pulmonary complications in thoracic surgery patients. Methods of chest physiotherapy vary but include airway clearance techniques (percussion, effective coughing), deep breathing exercises, and mobilization. Incentive spirometry is a low-cost technique utilizing a device that provides visual feedback of the patient's inspiratory efforts (Fig. 52.3). The goal of incentive spirometry is to encourage lung re-expansion and mitigate atelectasis by encouraging deep breathing with an inspiratory hold [115].

The benefit of pulmonary rehabilitation for patients undergoing thoracic surgery is well established [116]. Intensive chest physiotherapy reduces the risk of pulmonary complications and hospital length of stay [117]. The use of incentive spirometry, however, remains controversial. Weiner et al. performed a randomized controlled trial on patients with COPD who were undergoing lung resection and found that patients who used incentive spirometry in the pre-operative and post-operative period had higher post-operative FEV1 and FVC as compared to controls who did not receive training in incentive spirometry [118]. A similar study by Agostini failed to demonstrate an improvement in post-operative pulmonary complications for post-thoracotomy and lung resection patients who added incentive spirometry to a standardized post-operative lung expansion program. A systematic review by Carvalho revealed inconclusive results regarding the benefit of incentive spirometry in thoracic surgery patients, further stating that no study supports the post-operative use of IS [119]. Overall, there is little evidence supporting the use of chest physiotherapy or incentive spirometry after thoracic surgery [115]. However, incentive spirometry remains a low-cost and noninvasive option to encourage lung expansion in the perioperative period [120]. Although support from the literature is weak, in our institutional experience, patients who begin incentive IS in the pre-operative period fare better post-operatively, likely due in part to an increased level of ownership and investment in their health and outcome.

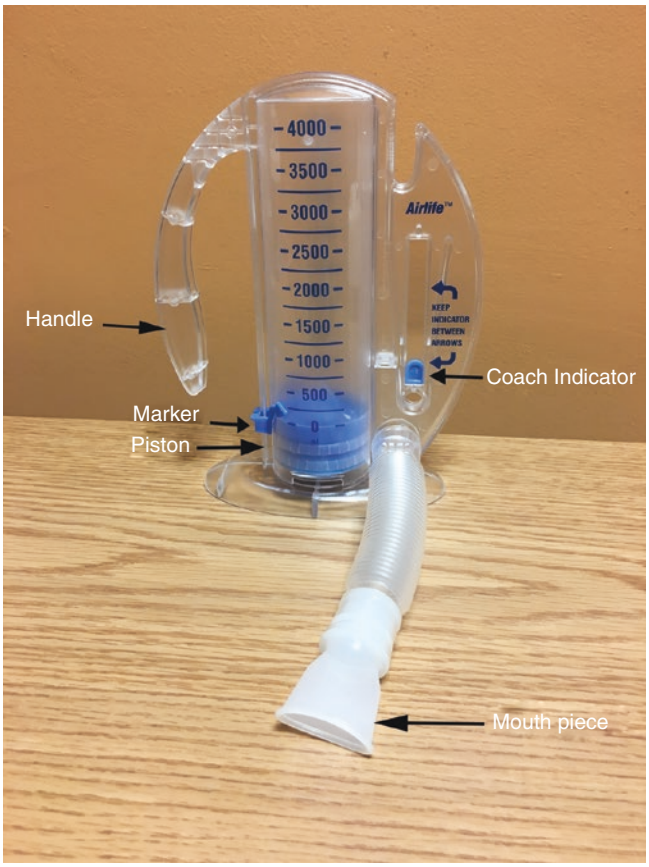

Fig. 52.3 Incentive spirometer

Multimodal Analgesia

The majority of thoracic enhanced recovery pathways incorporate a multimodal approach to analgesia as previously discussed. It is imperative that these efforts continue into the post-operative period in order to provide adequate analgesia and decrease dependence on opioid pain medications. While a single pre-operative dose of gabapentin does not decrease pain or morphine consumption, 2 days or more of use can provide superior pain control as compared to morphine PCA alone [121]. A 60-day post-operative regimen of gabapentin

provides significant improvement in pain control with minimal side effects and cost [63]. Acetaminophen is another low-cost, low-risk addition to the post-operative multimodal regimen.

Barriers to Implementation and Sustainability

A common barrier to implementation of ERAS pathways is lack of buy-in by surgeons, anesthesiologists, and nurses [122, 123]. ERAS programs often represent disruptive change in traditional practices, otherwise known as culture change [124]. Changing culture within a healthcare organization takes time: time to get all members to agree to standardized, evidence-based practice, time to educate perioperative teams, time to obtain feedback, and time to collect and share data on quality metrics. Buy-in from all members of the perioperative team comes with time and persistence, fueled by a dedicated core group of individuals engaged in the quality improvement process. In order to sustain an ERAS program, it is imperative to evaluate individual pathway components for effectiveness and make changes based on data.

Current State, Future Directions, and Applicability

While ERAS has shown great promise in other surgical subspecialties, thoracic ERAS is still in its infancy and requires further investigation. In the future, enhanced recovery principles and practices will become integrated as standard of care for thoracic surgery as well as other specialties, particularly in light of the changes in healthcare and the growing opioid epidemic in the United States.

In conclusion, enhanced recovery after surgery represents a multidisciplinary approach to perioperative care with a goal of early return to baseline function through the core tenets described in this chapter. The key components span the pre-operative, intraoperative, and post-operative period and require the participation of all members of the perioperative team and, most importantly, the patients themselves.

Anesthetic Management of Post-thoracotomy Complications

53

Michael A. Hall and Jesse M. Raiten

Key Points

- The immediate postoperative period following thoracic surgery is a dynamic time characterized by rapidly changing physiology. Anesthetic and surgical complications may become evident and may require immediate intervention.
- Although most patients undergoing thoracic surgery are extubated immediately following surgery, preexisting lung disease may necessitate postoperative mechanical ventilation. Patients remaining intubated postoperatively should be weaned to ventilator modes that promote spontaneous ventilation and low airway pressures, and they should be assessed frequently for extubation criteria.
- Airway-related complications are not uncommon and may be due to anesthetic or surgical technique. The large caliber of double-lumen endotracheal tubes may increase the risk of airway injury. Glottic injury and airway bleeding may also occur.
- Intrathoracic complications range from relatively minor air leaks to life-threatening bronchopleural fistulas. Preoperative prophylaxis against deep vein thrombosis helps prevent pulmonary embolism. Other complications such as phrenic nerve injury may become evident immediately postoperatively or after a prolonged period of mechanical ventilation in the ICU.
- Atrial fibrillation is a very common complication following thoracic surgery. Its management depends on the patient's hemodynamic status. New-onset postoperative atrial fibrillation should prompt a thorough review of the patient's overall well-being. Other cardiac complications are less common, including cardiac herniation and interatrial shunting.

Introduction

The immediate postoperative period following thoracotomy is characterized by rapidly changing physiology, during which careful management and attention to possible surgical or anesthetic complications is necessary. The normal physiological changes associated with emergence from anesthesia and mechanical ventilation may be less predictable in a patient having just undergone thoracic surgery. Patients undergoing thoracic procedures often have multiple comorbidities and poor baseline lung function. The surgeries can be long, may be associated with significant blood loss, and risk damage to intrathoracic structures including the lungs, airway, great vessels, and peripheral nervous system. Thoracic surgery may also cause significant stress on the cardiovascular system. Many factors may preclude the patient's immediate liberation from mechanical ventilation, and anesthetic or surgical complications may become evident in the operating room or shortly after arrival in the recovery room or intensive care unit (ICU). In this chapter, we will explore some of the common management challenges and potential complications that may be encountered in the immediate postoperative period following thoracotomy.

Mechanical Ventilation and Extubation

Classification of Respiratory Failure

The decision regarding tracheal extubation of a patient following surgery must take into account many variables. Patients requiring mechanical ventilation all have respiratory failure that falls into one (or more) of the following four categories [1].

1. *Type I* (hypoxemic respiratory failure) is characterized by $PaO_2 < 60$ mmHg at sea level.
2. *Type II* (hypercapnic respiratory failure) is characterized by $PaCO_2 > 45$ mmHg.
3. *Type III* (perioperative respiratory failure) is due to increased atelectasis and low functional residual capacity (FRC). This may occur in the setting of abnormal respiratory muscle mechanics, and may precipitate Types I or II failure.
4. *Type IV* (respiratory failure secondary to shock) may be present when mechanical ventilation is utilized to decrease oxygen consumption and increase oxygen delivery in the setting of resuscitation and shock.

Criteria for Extubation

Patients immediately post-thoracotomy may experience any of these types of respiratory failure, although Types I, II, and III are more likely than Type IV. All patients emerging from anesthesia who require continued mechanical ventilation suffer, to some extent, from Type III failure. Even patients with healthy lungs experience hypoxemia secondary to airway closure and atelectasis [2]. Indeed, collapsed lung tissue is observed in 90% of patients under anesthesia [3]. Residual anesthetics and neuromuscular blocking agents may also contribute to hypoventilation and subsequent hypoxemia and hypercarbia. In patients requiring one-lung ventilation for thoracic surgery, changes in ventilation and perfusion may be even more pronounced on account of the delayed offset of hypoxic pulmonary vasoconstriction in the operative lung, placing patients at higher risk of hypoxia [4]. While recruitment maneuvers on the ventilator may be useful to expand portions of collapsed lung tissue [3], patients with poor baseline lung function may not tolerate extubation at the conclusion of surgery because of hypoxia attributable to a combination of Types I and III respiratory failure. These patients may require continued mechanical ventilation postoperatively until adequate gas exchange can be reestablished.

Patients may also fail extubation due to impaired CO_2 removal. In the case of thoracic surgery, pain from a thoracotomy incision may prevent deep breathing and adequate CO_2 elimination. Epidural analgesia is very effective at controlling post-thoracotomy pain and minimizing postoperative hypercarbia [5]. In cases where thoracotomy is unplanned, epidural placement at the end of surgery, or shortly after extubation, may help reduce the need for reintubation [6].

Complications of Prolonged Intubation and Mechanical Ventilation

In 2001, a task force (represented by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine) established guidelines for the assessment and implementation of discontinuation of patients from mechanical ventilation [7]. These guidelines call for evidence of the resolution of the underlying cause of respiratory failure, adequate oxygenation ($PaO_2/FiO_2 > 150$–200, PEEP $\leq$5–8 cmH_2O, $FiO_2 \leq 0.4$–0.5), adequate pH ($\geq$7.25), hemodynamic stability, and the capability to initiate spontaneous ventilation. Patients meeting these criteria may then undergo a formal spontaneous breathing trial (SBT) for 30–120 min. More recently published guidelines of ventilator liberation in critically ill adults suggest utilizing a ventilator liberation protocol, checking for an endotracheal tube (ETT) cuff leak in patients at risk for stridor, and considering systemic steroids in patients who fail a cuff leak test but are otherwise stable for extubation [8].

Those who successfully pass an SBT have a high likelihood of tolerating extubation, and assessment of the patient's ability to protect the airway, mental status, and likelihood of airway obstruction should be performed prior to removal of the endotracheal tube [9]. Although not a guarantee, an intact gag reflex and alert state of mind suggest the patient will be able to protect the airway against aspiration. This may not be true in the case of vocal cord injury, however [10]. Aspiration risk may be better assessed after extubation via a flexible endoscopic evaluation of swallowing with sensory testing (FEESST) examination [11].

While extubation in the immediate postoperative period requires fulfilling many of the abovementioned criteria, emergence from anesthesia is a rapid and dynamic process, and assessment of these variables may be made on a minute-to-minute basis. Additional physiologic parameters are also assessed, including tidal volume (desire 5–10 cc/kg), respiratory rate ($\leq$20 breaths/min), body temperature, electrolytes, and volume status.

When comparing predictors of a successful extubation, two useful tests are the rapid shallow breathing index (RSBI, respiratory rate/tidal volume) and the negative inspiratory

force (NIF). While an NIF >20 cmH_2O does not guarantee a successful extubation, a poor performance in this test usually predicts failure [12]. In a review of studies of factors associated with ventilator weaning, a RSBI <105 breaths/min/L had a sensitivity up to 96% and specificity up to 73% for prediction of a successful extubation [13].

In patients immediately after lung resection, a prompt transition from positive pressure ventilation to spontaneous breathing is usually desirable in light of new suture lines or staples within the tracheobronchial tree. In practice, the majority of patients undergoing thoracic surgery are extubated in the operating room.

In a retrospective study of 214 patients undergoing lung transplantation, the need for mechanical ventilation for greater than 72 h was identified as an independent risk factor for airway complications [14], and early postoperative extubation may help reduce this risk [15]. Following esophagectomy, early extubation has been shown to be safe and lead to short ICU lengths of stay [16, 17]. Similarly, immediate extubation following tracheal surgery has yielded good results. In a retrospective review of 60 patients undergoing tracheal resection and reconstruction, all but one patient was successfully extubated in the operating room [18]. Likewise, extubation in the operating room immediately following lung resection has been shown to be safe, reduce the risk of postoperative complications, decrease time in the ICU, and reduce hospital costs [19].

Adverse effects associated with intubation and mechanical ventilation include ventilator-associated pneumonia (VAP), laryngeal and tracheal injury, hemodynamic changes, patient discomfort and the need for sedation, and difficulty obtaining an accurate neurologic examination [20].

Independent Lung Ventilation

While severe unilateral lung disease in the postoperative setting is uncommon, it may occur following single lung transplantation or pneumonectomy (Fig. 53.1). In the case of lung transplantation, independent lung ventilation in the ICU may be necessary to allow different ventilation strategies to each lung. Independent lung ventilation requires a double-lumen endotracheal tube (DLT). DLTs are rarely utilized outside of the OR as they are technically more difficult to manage and require constant attention to ensure proper position, and their larger size makes laryngeal and tracheal trauma more likely compared to single-lumen tubes. The narrower lumen can make it more difficult to perform bronchoscopy and endotracheal suctioning. Nevertheless, in cases of severe unilateral acute respiratory distress syndrome (ARDS), as may occur after lung transplantation, the ability to provide different tidal volumes and oxygen concentrations to each lung may be critical to patient management.

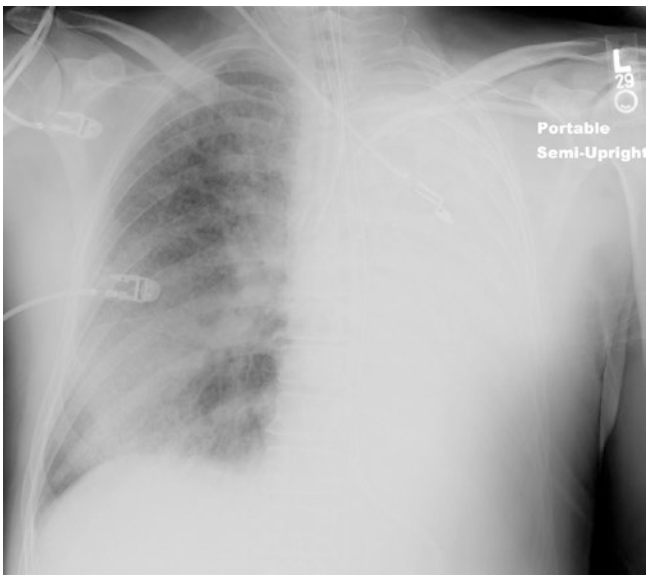

Fig. 53.1 Unilateral ARDS following left-sided pneumonectomy

Airway Complications

Endotracheal Intubation and Airway Injury

Airway complications following thoracic surgery may be related to anesthetic or surgical technique. The larger external diameter and more invasive positioning of DLTs may increase the likelihood of airway trauma compared to a single-lumen ETT. Anesthetic-related airway complications that may become apparent immediately postoperatively include injury to dentition, sore throat, laryngeal trauma, bronchial erythema and edema, vocal cord injury, and tracheobronchial rupture (TBR). Risk factors associated with vocal cord injury include intubating conditions, type of surgery, and endotracheal tube size, among others [21].

In a study comparing DLT to bronchial blockers in patients undergoing pulmonary resection, the overall incidence of bronchial and vocal cord injury was 25% and 30%, respectively [21]. In both cases, the most common injuries were erythema and edema. Severe complications such as TBR are unusual, with an estimated incidence between 0.05% and 0.37% for all intubations at a single institution [22], and this risk is increased with the use of a DLT versus a SLT [23]. Symptoms of TBR include neck emphysema and hemoptysis, and may be identified as an increase in fresh gas flow requirements intraoperatively. Surgical factors are also important when assessing the risk of TBR, as tracheal perforation has a reported incidence of 0.4% during transhiatal esophagectomy at high-volume centers [23].

Airway Bleeding and Secretions

The nature of the surgical procedures and proximity to structures vital to proper respiratory function make patients undergoing thoracic surgeries particularly prone to airway injuries and complications. The blood and secretions may accumulate in the upper or lower airways in patients undergoing lung resection surgery. Removal of the blood by endotracheal suctioning may be difficult in a patient with a DLT, and a pediatric-sized bronchoscope may be necessary to pass through the tube's narrow lumen. If significant secretions and debris are present within the airways, changing the DLT to a larger diameter single-lumen ETT may better facilitate pulmonary toilet prior to emergence and extubation.

Vocal Cord Injuries

Vocal cord palsies may occur in patients undergoing mediastinoscopy or esophagectomy, with an incidence between 1–6% and 5–22%, respectively [24]. Damage to the recurrent laryngeal nerve may occur intraoperatively from traction in the anterior mediastinum [24], or from direct trauma to the nerve. Unilateral vocal cord paralysis may result in voice changes, but usually does not result in airway obstruction. While bilateral vocal cord injury is rare except in the case of neck surgery, it has been reported following lung resection under video-assisted thoracic surgery (VATS) [25]. In this case report, vocal cord injury may have resulted from the DLT. Bilateral vocal cord injury may lead to dyspnea and stridor. Unilateral and bilateral injuries will increase the risk of aspiration [10].

Vocal cord injuries may also be attributed to the act of orotracheal intubation or the subsequent presence of the ETT, especially after prolonged intubation. Vocal cord hematoma or edema can cause dyspnea, stridor, and partial or complete airway obstruction. Luxation of the arytenoid cartilage during passage of the ETT through the glottis can result in unilateral vocal cord immobility without neurologic injury [26]. Tapia's syndrome, or unilateral vocal cord palsy, can present after short-term intubation, most likely secondary to compression of the recurrent laryngeal nerve between the ETT and the thyroid cartilage [27].

Prompt recognition of vocal cord injury in the extubated patient is critical to prevent potentially life-threatening airway obstruction. While a hoarse voice is relatively common after endotracheal intubation, the presence of stridor or respiratory distress is abnormal, and a sign indicating a more serious process may be occurring. Prompt intubation may be the safest approach to the patient in acute, severe respiratory distress, particularly if it presents in the immediate postoperative period. However, it is difficult to examine the vocal cords in an intubated patient.

If symptoms are mild and the patient remains stable, it is reasonable to treat the patient conservatively with oxygen by mask, steroids, and racemic epinephrine. The vocal cords may then be examined by flexible fiber-optic laryngoscopy in cases with a high clinical suspicion of vocal cord injury or palsy. Heliox is a mixture of helium and oxygen (usually 70% helium and 30% oxygen) that has a lower density than air with a similar viscosity. Work of breathing is affected by the resistance to flow within the airway and the pressure gradient that must be generated to produce flow. Narrowing of the airway, such as at the glottis after vocal cord paralysis or swelling, will increase resistance to flow in itself, and it will also increase the tendency of inspired gas to generate turbulent flow. Turbulent flow generates higher resistance than laminar flow within the same airway, further increasing work of breathing. The lower density of heliox will lower the Reynolds number of the gas flow in the airway, increasing the likelihood of laminar flow. Other parameters of fluid mechanics, including the formula for calculation of orifice flow and the application of Bernoulli's principle, support the assertion that the decreased density of heliox relative to mixtures of oxygen and nitrogen will lead to increased flow, decreased resistance, and decreased pressure requirements to generate gas flow through a partially obstructed glottis [28]. Its effects may be seen very rapidly. Most studies of heliox are in the pediatric population. One additional complication for thoracic surgery patients is that underlying lung parenchymal disease may reveal the obligate 0.30 FiO_2 of heliox to be inadequate to maintain oxygenation, thus requiring airway intubation to bypass the obstructed glottis and deliver higher concentrations of oxygen.

Intrathoracic Complications

Patients requiring thoracic surgery are among the sickest patients in the hospital – many are diabetic, have chronic obstructive pulmonary disease (COPD), and coronary artery disease (CAD). Despite optimal preoperative evaluation and intraoperative technique, the high acuity of this patient population contributes to the significant rate of postoperative surgical complications. Common complications include persistent air leak, pneumothorax, and atrial fibrillation. Other complications include bronchopleural fistula (BPF), pulmonary embolism, postpneumonectomy syndrome, phrenic nerve injury, cardiac herniation, massive hemorrhage, mediastinal emphysema, and intracardiac shunting.

Air Leak, Pneumothorax, and Bronchopleural Fistula

Postoperative air leaks are common after thoracic surgery and can be easily recognized by the presence of bubbles in the water seal chamber of the drainage system. The presence of an air leak with a properly positioned chest tube indicates that air is passing from the pleural space into the drainage

system. If the chest tube has been placed for a pneumothorax, an air leak signifies the pneumothorax is being successfully evacuated, and the leak should resolve as the pneumothorax improves.

Any surgery in which the pleural space is entered leads to the creation of a pneumothorax. A pneumothorax that remains in communication with atmospheric pressure is rarely dangerous. If it is not in communication with the atmosphere, a tension pneumothorax may develop. A tension pneumothorax may rapidly expand in a patient receiving positive pressure ventilation, leading to hemodynamic collapse.

When the lung parenchyma is cut, as in the case of a lobectomy, an air leak may be caused by small fistulas between the distal airways and the pleural space. This should resolve as the lung tissue heals and becomes apposed to the parietal pleura. In patients with COPD, a new air leak may be caused by rupture of a pulmonary bleb. An inadequate seal at the site of chest tube exit from the skin may also allow air to track back to the pleural space and communicate with the drainage system.

In the immediate postoperative period small air leaks rarely cause problems. In patients having undergone pneumonectomy, however, a large new air leak can indicate rupture of the bronchial stump and creation of a bronchopleural fistula (BPF). There may be significant mediastinal shift toward the remaining lung, as well as subcutaneous emphysema. This is a surgical emergency that requires immediate attention. In a retrospective study of patients undergoing pneumonectomy, 1.9% developed BPF [29]. Two-thirds of these patients died. The diameter of the bronchial stump has also been associated with postpneumonectomy BPF [30], and right-sided pneumonectomy has a higher incidence of developing a BPF than left-sided pneumonectomy [31]. Other risk factors include malnutrition, history of chemotherapy or radiation treatment, active smoking, and untreated pulmonary infection. Chest radiograph of a postpneumonectomy patient who develops a BPF will demonstrate a decrease in the air-fluid level on the operative side, usually with the meniscus at the level of the bronchial stump.

While many pneumonectomy patients are extubated immediately after surgery in the operating room, it is not uncommon to remain intubated postoperatively in the ICU. A prompt extubation and transition from positive pressure to spontaneous ventilation is important to help reduce intrathoracic pressure. If a BPF does occur, and is associated with hemodynamic and respiratory instability, intubation with either a DLT or single-lumen ETT placed into the main stem bronchus is a reasonable approach to secure the airway. The latter approach is easier on the left side due to the greater distance between the carina and branching of the left upper and lower lobes. Again, spontaneous ventilation, or the use of very low inspiratory pressures, is desirable.

Mediastinal Emphysema

Mediastinal emphysema occurs when air accumulates in the mediastinal space. It may occur with airway, alveolar, or esophageal rupture, or following intrathoracic surgery. Patients may present with dyspnea or subcutaneous emphysema, and the diagnosis can be readily obtained with chest radiography or CT scan. Often, no treatment is necessary, although a chest tube may be placed if a pneumothorax is present. In the case of esophageal rupture, immediate surgical repair or esophageal stenting may be necessary.

Deep Vein Thrombosis and Pulmonary Embolism

Deep vein thrombosis (DVT) and pulmonary embolism (PE) are potentially fatal complications that may follow thoracic surgery. In a review of 690 patients undergoing chest surgery for malignant lung disease, there were 12 (1.7%) venous thromboembolic complications, of which 9 (1.3%) were PE [32]. All events occurred in patients who were receiving DVT prophylaxis with heparin. Prolonged surgical times and malignancy are risk factors for the development of DVT that are common to many patients undergoing thoracic surgery. Antithrombotic prophylaxis with heparin (either low molecular weight or unfractionated) has become common practice in the perioperative period.

A high index of suspicion is necessary to ensure detection of DVT and PE, as many PE are subclinical and only detected at autopsy. The initial chest radiograph is often normal in patients with PE. Pulmonary angiography represents the gold standard diagnostic technique. However, computed tomography angiography (CT angiogram) is easier to perform and is the most commonly employed technique for PE diagnosis. Ventilation-perfusion scans are less widely used as the results may be difficult to interpret. In the presence of a large PE with hemodynamic compromise, right ventricular dilatation and strain may be seen on echocardiogram.

When a clinically significant PE does occur, a variety of therapies may be employed including operative embolectomy [33], catheter embolectomy, systemic anticoagulation, or thrombolytic administration. The decision of how to proceed depends on a variety of factors including the size of the embolus, the location within the pulmonary vasculature, and the hemodynamic status of the patient.

Postpneumonectomy Syndrome

Postpneumonectomy syndrome is an uncommon condition that may be observed following left- or right-sided pneumonectomy [34]. It is characterized by a mediastinal shift toward the side of the resected lung, with associated herniation of the

overinflated remaining lung in the same direction. Subsequent compression of the distal trachea or main stem bronchus against the vertebral column or aorta may cause airway compression and obstruction [35].

Patients may present with progressive dyspnea, stridor, or heartburn and dysphagia if esophageal compression develops [34]. Symptoms develop months to years after a pneumonectomy. A high index of suspicion is necessary to make the diagnosis, which may be confirmed with a variety of techniques including awake bronchoscopy, pulmonary function tests, and CT scan. Treatment often involves mediastinal repositioning with expandable saline prostheses [36]. A recent case series reported nine out of ten patients had symptomatic improvement after placement of tissue expanders within the operative hemithorax and were discharged home without supplemental oxygen therapy [37].

Post Lung Resection Pulmonary Edema

Post lung resection pulmonary edema is a serious complication that carries a mortality rate greater than 50% [38]. In a series of 146 patients who underwent pneumonectomy, mild to moderate noncardiogenic pulmonary edema was observed in 15% of patients and was strongly associated with previous radiotherapy and excess intraoperative volume administration [39]. The incidence of pulmonary edema is higher following right pneumonectomy compared to left, with clinical symptoms typically appearing between postoperative day (POD) 2–4. While an association with excess fluid administration exists, pulmonary artery occlusion pressure (PAOP) is often low, suggesting a multifactorial etiology [38]. Pulmonary edema may also follow lobectomy, although this is less common.

Post lung resection pulmonary edema is a diagnosis of exclusion, and all other etiologies of pulmonary congestion must be ruled out (heart failure, pulmonary aspiration, sepsis, pulmonary embolism, transfusion reaction). As with cardiac herniation, a high level of suspicion is necessary to make the diagnosis. Once identified, treatment is largely supportive and may include high-dose corticosteroids and the use of pulmonary artery vasodilators [40] or extracorporeal ventilatory support.

Phrenic Nerve Injury

Phrenic nerve injury may occur in patients undergoing thoracic surgery. Both hypothermia (associated with pericardial cooling in cardiac surgery) and mechanical trauma may be contributing factors [41]. Injury to the phrenic nerve is associated with diaphragmatic dysfunction. Unilateral diaphragmatic paralysis is often well tolerated by patients without significant underlying pulmonary disease [42]. However, thoracic surgery patients often have poor baseline lung function, and difficulty weaning from the ventilator may be the first sign that phrenic nerve injury has occurred. An elevated hemidiaphragm may also be observed on chest radiography, and the diagnosis can be confirmed by electromyography. In severe cases, techniques such as diaphragmatic pacing may be useful [42]. Abnormal diaphragmatic motion postoperatively has been associated with diminished lung volumes and reduced exercise capacity [43].

Cardiac Complications

Cardiac Failure and Arrhythmias

Thoracic surgery places a considerable stress on the cardiovascular system and postoperative cardiac complications are not uncommon. Patients often have preexisting cardiac disease and may be at risk for perioperative myocardial infarction (MI) and heart failure. Adequate preoperative evaluation and optimization of cardiac function may decrease these risks. In a patient with risk factors, postoperative hemodynamic instability should trigger an evaluation of cardiac status.

Arrhythmias are a common cardiac complication following thoracic surgery, with atrial fibrillation (AF) being the most prevalent. The incidence of AF may reach 20% after lobectomy and as high as 40% following pneumonectomy [44]. It is unclear whether postoperative supraventricular tachycardias (SVT) worsen patient outcome. In an observational study of 82 patients undergoing elective thoracotomy, there was no association between SVT and myocardial ischemia or adverse outcome [45].

AF complicating lung cancer resection has been associated with increased hospital length of stay, costs, and in-hospital mortality [46]. While AF is often relatively asymptomatic and easy to treat, its onset must not be ignored. Roselli and colleagues identified a temporal association between the onset of AF and other complications, particularly respiratory and infectious in etiology [46]. New-onset postoperative AF in the immediate postoperative period should prompt a thorough review of the patient's overall condition.

Management of postoperative AF is well described in the literature and largely dictated by the patient's hemodynamic status (Fig. 53.2). There is some controversy regarding what should be the initial therapy (rate or rhythm control) for new-onset postoperative AF in patients who are hemodynamically stable. A large randomized trial recently conducted in patients with new-onset postoperative AF after cardiac surgery found that the two strategies were largely equivocal [47]. In hemodynamically unstable patients, rhythm control is preferred. The use of amiodarone in

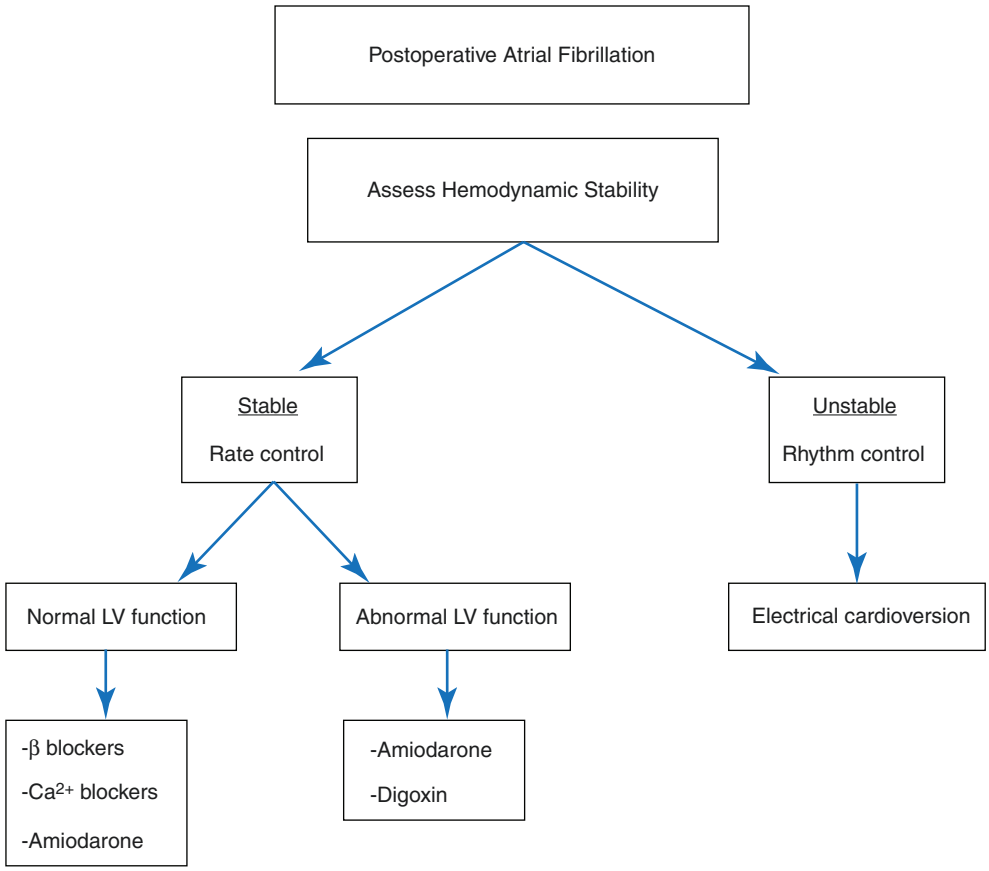

Fig. 53.2 Treatment algorithm for new-onset postoperative atrial fibrillation

patients having undergone lung transplant is relatively common despite its potential pulmonary toxicity. Amiodarone-induced pulmonary toxicity correlates with total dose administered and is more common after 2 months of therapy [48]. Judicious use in the perioperative period may be justified in the appropriate clinical situation.

Cardiac Herniation

Cardiac herniation is a rare and potentially lethal complication of thoracic procedures, most commonly occurring within 24 h following intrapericardial pneumonectomy [49]. Sudden hypotension and tachycardia should trigger the physician to consider the diagnosis. In the case of right-sided herniation, central venous pressure (CVP) may be elevated, and cyanosis of the face and neck is common and related to impaired venous drainage by the superior vena cava (SVC) [50]. This impaired drainage may reduce cardiac filling and lead to obstructive shock. Left-sided herniation can lead to myocardial ischemia and arrhythmias due to ventricular strangulation by the pericardial edges [51].

Herniation may be triggered by multiple factors. Positive intrathoracic pressure (due to coughing or mechanical ventilation), suction on a chest tube, or even patient repositioning may be contributing factors [51]. A prompt diagnosis is critical and may be obtained by chest radiography (easier to diagnose right-sided herniation than left), or echocardiogram. Immediate surgical repositioning of the heart and closure of the pericardial defect is necessary.

It should be noted that while cardiac herniation typically presents with rapidly deteriorating hemodynamics, this is not universally the case. Buniva and colleagues describe a patient in which cardiac herniation and torsion developed following right-sided pneumonectomy and partial pericardiectomy [52]. In this case, the patient remained hemodynamically stable, and herniation was detected 2 h later on routine chest radiography. Herniation has also been reported 6 months following pneumonectomy [53]; however, this is exceedingly uncommon. Adhesions between the heart and pericardium help prevent delayed herniation [51]. Along with the risk of bronchial stump rupture, the risk of cardiac herniation underscores the importance of a prompt transition to spontaneous ventilation in patients following pneumonectomy.

Interatrial Shunting

Interatrial shunting (right to left) is a rare cause of hypoxemia in patients having undergone pneumonectomy. The

exact pathophysiology is poorly understood but may involve the development of a right- to left-sided pressure gradient or decreased compliance of the right ventricle relative to the left [54]. Shunting across an atrial septal defect (ASD) occurs primarily during diastole, and right to left blood flow may be accentuated by a stiffer right ventricle [54]. Case reports of shunting after pneumonectomy highlight three common features: a positional nature of the shunt, whereby it is worsened when the patient is upright (platypnea), an asymptomatic interval following surgery, and an increased shunt fraction with hypovolemia [55]. Diagnosis of interatrial shunting can be readily made by echocardiogram.

Clinical Case Discussion

A 67-year-old man is in the ICU 4 h following left-sided pneumonectomy for lung cancer. His medical history is significant for a 50-pack-year smoking history and ischemic cardiomyopathy with a left ventricular ejection fraction of 30%. At the end of the surgery, he was oxygenating poorly with a PaO_2 55 mmHg on 100% inspired oxygen and is currently receiving mechanical ventilation in the ICU. His EKG changes from sinus rhythm to rapid atrial fibrillation with a heart rate of 144 bpm, and his blood pressure falls to 60/40. You are called emergently to the bedside.

Questions

- What type of respiratory failure is this patient suffering from?
- Why is it important to extubate this patient and reestablish spontaneous ventilation in a timely fashion?
- How would you assess and treat this patient when you are called to the bedside?

Respiratory failure, extubation, and assessment of atrial fibrillation:

- Type III respiratory failure (perioperative), likely due to atelectasis from anesthesia and positive pressure ventilation, hypoxia, and hypercarbia from baseline lung disease (see section "Classification of Respiratory Failure").
- Improved hemodynamics, decreased ventilator-associated pneumonia, lower risk of surgical suture line damage, and development of a bronchopleural fistula (see sections "Complications of Prolonged Intubation and Mechanical Ventilation," and "Intrathoracic Complications").
- Assess patient's overall condition and search for possible etiology of new-onset postoperative atrial fibrillation. Hemodynamically unstable atrial fibrillation should be treated with electrical cardioversion (see section "Cardiac Complications" and Fig. 53.2).

Weaning from mechanical ventilation:

- When postoperative patients require mechanical ventilation, it is usually temporary and they should be frequently assessed for extubation.
- Evaluate respiratory rate, tidal volume, oxygen and positive end expiratory pressure (PEEP) requirements, level of consciousness, hemodynamic stability, volume status, pH and CO_2 levels, ability to cough and clear secretions, analgesia, temperature, and electrolyte status (see section "Classification of Respiratory Failure").
- The rapid shallow breathing index and negative inspiratory force may help predict whether a patient will tolerate extubation. When a patient meets extubation criteria, a spontaneous breathing trial should be attempted (see section "Criteria for Extubation").

Considerations with new-onset postoperative atrial fibrillation:

- New-onset postoperative atrial fibrillation is common after pneumonectomy.
- Patients should undergo a complete evaluation of their overall well-being, including a search for underlying infection, volume status, hypoxia and hypercarbia, and electrolyte abnormalities, particularly hypokalemia and hypomagnesemia (see section "Cardiac Complications").
- Patients who are hemodynamically stable may be managed medically with rate or rhythm control, while hemodynamically unstable patients should be electrically cardioverted (Fig. 53.2).

Postoperative Respiratory Failure and Treatment

54

Wendy Smith, Alan Finley, and James Ramsay

Key Points

- Although pure hypoxemic or pure hypercapnic respiratory failure may occur after thoracic surgery, most patients exhibit a mixed picture.
- The single most important preoperative patient-related risk factor for respiratory failure after thoracic surgery is the presence of severe COPD.
- High-flow nasal cannula oxygen and noninvasive ventilation (NIV) can be safely administered in the post-thoracic surgery patient, both to reduce respiratory complications and to prevent the need for re-intubation.
- Mechanical ventilation after thoracic surgery should follow a "lung-protective" strategy of appropriate combinations of PEEP and low tidal volume, in association with increased respiratory rate as needed.
- Ventilator-associated pneumonia (VAP) is associated with a high mortality, so prevention is a priority. The "VAP "bundle" is a variety of care processes either known or believed to reduce the risk of acquiring VAP.
- A daily spontaneous breathing trial is the most effective way to identify patients ready for withdrawal of ventilator support.
- Tracheotomy should be considered if mechanical ventilation is expected to be required for more than a total of 7–10 days.

Respiratory failure following thoracic surgery is a significant cause of morbidity and mortality in this high-risk patient population. The incidence of major post-thoracotomy pulmonary complications such as pneumonia, lobar atelectasis, or need for mechanical ventilation for more than 24 h ranges from 22% to 25%, while the incidence of respiratory failure (requiring mechanical ventilation for more than 48 h after surgery) ranges from about 3 to 10% [1–5]. In most reports respiratory failure accounts for approximately half of the 30-day mortality. The reported incidence of respiratory failure and overall mortality for several thoracic procedures is given in Table 54.1. Respiratory failure and mortality are greater after right-sided as compared to left-sided pneumonectomy and after extra vs. intrapleural pneumonectomy [6]. The addition of chest wall resection to intrathoracic surgery also adds to the incidence of respiratory failure and mortality [2]. Preexisting pulmonary disease and other concomitant disease processes increase the risk of postoperative

Table 54.1 Respiratory failure[a] and 30-day mortality after open[b] thoracic surgery procedures

	Respiratory failure	Overall mortality
Lung resection		
Wedge resection	*(Not reported)*	0.8–1.4% [1, 2]
Lobectomy	3.2–6.6% [3–5]	1.2–4% [1–5]
Pneumonectomy	6.9–9.3% [3–5]	3.2–11.5% [1–5]
Esophagogastrectomy	16% [57]	2.1–9.8% [54–57]
Lung volume reduction surgery	13.6% [48]	2.3–16% [47–50]

In two reports lobectomy was not separated from pneumonectomy: in one the incidence of tracheostomy was 14% [1]; in the other the incidence of respiratory failure was 6% [2]

[a]Defined as the need for mechanical ventilation for more than 48 h after surgery

[b]Limited data for thoracoscopic procedures suggests reduced overall complications but not mortality VS open procedures [48]. Preliminary data for robotic-assisted surgeries suggests reductions in morbidity and mortality that is at least comparable to VATS and in some instances superior to both VATS and open procedures [25]

respiratory insufficiency and failure. Anticipation and early recognition are essential to provide the best possible outcome for the patient in respiratory failure.

Definition

Respiratory failure is the inability of the respiratory system to provide sufficient gas exchange to prevent life-threatening hypoxemia and/or hypercapnia. The clinical picture suggests the diagnosis, and the arterial blood gas analysis is confirmatory (Table 54.2). Respiratory failure may be purely hypoxemic, in which arterial partial pressure of oxygen in the blood is inadequate, but partial pressure of carbon dioxide is low or normal. Physiologic causes of hypoxemic respiratory failure include hypoventilation, ventilation-perfusion mismatch, right-to-left intrapulmonary or intracardiac shunts, abnormalities in alveolar oxygen diffusion, and low fraction of inspired oxygen [7]. Failure to oxygenate the blood after thoracic surgery is usually the result of severe mismatch of ventilation and perfusion ("V:Q mismatch") such that pulmonary blood flows through poorly ventilated or edematous lung and there is inadequate time or alveolar exposure for absorption of O_2. Increased pulmonary water from direct surgical injury, capillary leak, or fluid overload may cause V:Q mismatch, as may focal areas of consolidation from collections (air, blood), infection, inflammation, or atelectasis. The most severe form of V:Q mismatch is true shunting of pulmonary blood without any absorption of O_2, as might occur with a completely atelectatic or consolidated segment or lobe.

Table 54.2 Diagnosis of acute respiratory failure

Clinical	Central nervous system	Agitation, restlessness, diaphoresis from distress
		Headache, confusion from hypercarbia or hypoxemia
		Dizziness, focal twitching from hypercarbia
		Insomnia, personality change from hypoxemia
		Stupor, confusion, coma from severe hypercarbia or severe hypoxemia
		Seizures from severe hypoxemia
	Cardiovascular system	Tachyarrhythmias from hypoxemia or hypercarbia
		Bradyarrhythmias from severe hypoxemia
		Systemic hypertension from hypoxemia or hypercarbia
		Pulmonary hypertension from hypoxemia or hypercarbia
		Hypotension/cardiac failure from severe hypoxemia or hypercarbia
	Respiratory system	Intact respiratory drive: Tachypnea Labored respirations, dyspnea Intercostal retractions
		Impaired respiratory drive: Bradypnea or apnea
		Cheyne-stokes respirations
Laboratory	Oxygenation[a]	Arterial $pO_2 < 50–60$ mmHg
		Peripheral arterial saturation (pulse oximetry) <90%
	Carbon dioxide[b]	Arterial $pCO_2 > 50–60$ mmHg associated with acidosis

[a]Respiratory "failure" due to hypoxemia may not require mechanical ventilatory support if it is responsive to supplemental oxygen therapy
[b]Chronic elevations in arterial pCO_2 are accompanied by retention of bicarbonate and relatively normal arterial pH and do not necessarily indicate respiratory "failure." Hypercarbia associated with acidosis always indicates respiratory failure and usually requires mechanical ventilatory support

Hypoventilation alone may result in hypoxemia. The simplified form of the alveolar gas equation estimates the partial pressure of oxygen in the alveoli based on the inspired partial pressure of oxygen and the partial pressure of arterial carbon dioxide:

$$P_AO_2 = P_IO_2 - P_aCO_2 / R$$

P_AO_2 is the alveolar partial pressure of oxygen, P_IO_2 is the partial pressure of inspired oxygen, and P_aCO_2 is the arterial partial pressure of carbon dioxide (R represents the respiratory exchange ratio). Severe hypoventilation, with a resultant rise in P_aCO_2, would therefore be expected to result in some degree of hypoxemia. The degree of hypoxemia caused by pure hypoventilation can usually be overcome by supplemental oxygen [8].

Intracardiac shunt with right- to left-sided blood flow causes arterial desaturation independent of pulmonary pathology. The condition where this most commonly occurs in the adult is a patent foramen ovale (PFO), which is present – at least in a probe-patent form – in approximately 25% of the population [9]. In short actual closure of the shunt, the treatment requires reducing the gradient for blood flow from right to left, either reducing the right atrial pressure or increasing the left atrial pressure. In the presence of a PFO, application of increasing levels of positive intrathoracic pressure (positive end-expiratory pressure or PEEP) can worsen arterial oxygenation [10]. Positive intrathoracic pressure can increase impedance to ejection by the right ventricle, resulting in an elevation in the central venous pressure (CVP). This may increase blood flow across the atrial septum from right to left.

Hypercapnic respiratory failure occurs when ventilation of the lungs is insufficient to maintain an adequate arterial partial pressure of carbon dioxide. Hypercapnic respiratory failure may occur with structural or functional abnormalities of the chest wall and muscles of respiration. Decreased function of the muscles of respiration may be seen with residual neuromuscular blockade and with surgical disruption.

Structural or mechanical problems with the chest wall induced by surgery can lead to hypoventilation by affecting the normal decrease in intrathoracic pressure seen during inspiration. These include pneumothorax, pulmonary contusion leading to decreased distensibility of the lung tissue, and flail chest. These types of hypercapnic failure are associated with respiratory distress and usually tachypnea: the patient is trying to achieve a normal arterial pCO_2 but cannot. Decreased central respiratory drive results in hypoventilation. Decreased central drive may be seen with residual anesthesia, postoperative sedation, or central nervous system disease (e.g., perioperative stroke). Conditions associated with chronic carbon dioxide retention (e.g., obstructive airways disease, obesity-hypoventilation syndrome) may be exacerbated by depressant medications or structural changes induced by surgery.

Although pure hypoxemic or pure hypercapnic respiratory failure may be seen, most surgical patients with postoperative respiratory failure exhibit a mixed picture. Chest wall and parenchymal injury, edema, retained secretions or blood, and atelectasis interfere with gas exchange and increase the work of breathing. Surgical injury to the chest wall and pain also interfere with normal mechanical function, thus decreasing the effectiveness of the respiratory effort and increasing the work of breathing.

Table 54.3 Preoperative factors associated with increased risk of postoperative respiratory failure

History
Age > 70 years
Smoking history with chronic obstructive pulmonary disease
Cardiac dysfunction
Neuromuscular disease
Dyspnea at rest or with light exertion
Inability to climb 1 flight of stairs
Physical findings
Increased baseline work of breathing
Preoperative wheezing (not controlled by bronchodilators)
Lower extremity edema/jugular venous distension (suggestive of right heart dysfunction)
Cachexia
Laboratory
PCO_2 > 45 mmHg
PO_2 < 50 mmHg on room air
ppoFEV1 < 40% predicted
ppoDLCO < 40% predicted
RV/TLC > 30%
VO_2max < 15 ml/kg/min
Increased serum creatinine

ppo predicted postoperative, *DLCO* diffusion capacity for carbon monoxide, *FEV1* forced expiratory volume in one second, *RV* residual volume, *TLC* total lung capacity, *VO_2max* maximum oxygen consumption

Preoperative Predictors of Postoperative Respiratory Failure

Conflicting results in the available literature make establishing precise criteria for determining those patients most at risk for postoperative respiratory failure difficult. The history, physical examination, and specific investigations enable the surgeon and anesthesiologist to estimate risk and identify processes that can be treated or optimized prior to surgery. Preoperative assessment for pulmonary resection is discussed in Chap. 2. Preoperative factors associated with an increased incidence of postoperative respiratory failure are summarized in Table 54.3.

History

Preexisting conditions which have been associated with increased risk of respiratory dysfunction and failure in the general surgery patient population include advanced age (greater than 70 years), chronic pulmonary disease, smoking, cardiac dysfunction, and neuromuscular diseases affecting the muscles of respiration or glutition [11]. Arozullah et al. published a multifactorial index for predicting postoperative respiratory failure which includes chronic obstructive pulmonary disease (COPD), increased age, dependent functional status, and surgical site as independent risk factors for patients in the general surgical population [12]. Patients who report dyspnea at rest, with light exercise (walking on a level surface 100 yards), or with activities of daily living (dressing, talking) have an approximate twofold increase in respiratory complications following thoracotomy [13]. In a review from the Cleveland Clinic, preoperative predictors of postoperative ventilator support after thoracotomy for lung resection included elevated creatinine and low preoperative forced expiratory volume in one second (FEV_1) [14].

There is some data to suggest an elevated BNP level, on postoperative day 1, may also be predictive of cardiopulmonary complications [15]. The single most important preoperative patient-related risk factor is the presence of COPD, and the incidence of postoperative pulmonary complications associated with COPD increases with the severity of the disease. The relative risk of pulmonary complications in patients with COPD is three- to fourfold [16]. These patients should have management of their airway obstruction optimized prior to surgery with a multimodal approach consisting of bronchodilators, smoking cessation, antibiotics, and corticosteroids.

Asymptomatic asthma is not associated with any increase in the incidence of pulmonary complications or need for postoperative mechanical ventilation after thoracotomy. If the patient is free of wheezing in the immediate preoperative period and the FEV_1 is greater than 80% predicted, there is no increased risk of bronchospasm or other pulmonary complications [17].

On the other hand, an asthmatic patient with recent episodes of bronchospasm and wheezing should be treated cautiously. These patients may benefit from prophylactic corticosteroid use before anesthesia and surgery. Inhaled corticosteroids are recommended for virtually all patients with persistent asthma [18]. Steroids may be administered orally or by inhalation with inhaled steroids leading to less systemic side effects. Patients who have recently had significant asthma symptoms and received systemic glucocorticosteroids within the past 6 months should have systemic coverage during the perioperative period. All asthmatic patients should remain on their routine bronchodilator and anti-inflammatory medications in the perioperative period.

Procedure and Extent of Resection

Thoracotomy for Lung Resection

The extent of resection during thoracotomy for lung cancer is a risk factor for the need for postoperative mechanical ventilation, pulmonary complications, and 30-day mortality (Table 54.1) [14]. In addition, Busch et al. reported an 82% incidence of postoperative pulmonary complications in patients requiring extensive resection, including the chest wall. This compared to an overall incidence of 39% in their study of patients undergoing thoracotomy [2]. On the other hand, a review of the muscle-sparing thoracotomy approach (where the latissimus dorsi and serratus anterior muscles are not severed) vs. standard thoracotomy found no morbidity or mortality benefit [19]. Not surprisingly, increasing age is a major risk factor for the development of serious pulmonary complications, including respiratory failure and mortality [4, 5, 20].

Video-Assisted Thoracic Surgery for Lung Resection

Minimally invasive lung surgery has gained popularity because of the smaller incision, potentially shorter hospital stay, and quicker recovery (see also Chap. 23). Video-assisted thoracic surgery (VATS) is performed through several small ports rather than a single long incision, resulting in less interference with pulmonary mechanics, decreased postoperative pain, and possibly less morbidity and mortality. Imperatori et al. reported a reduced incidence of prolonged air leak and pneumonia; other postoperative pulmonary complications were not reported [21]. Although some studies support better outcomes compared to thoracotomy, limited evidence supports the theory that VATS for lobectomy improves long-term outcomes [22, 23]. Also, concern still exists that the extent of the resection may be inadequate in certain patient populations [22]. The reality is that many surgeons are performing VATS, and many patients are requesting it.

Robot Video-Assisted Thoracic Surgery for Lung Resection

Robotic surgery provides all the benefits of VATS while providing better surgical control through the use of a three-dimensional field and wristed instrumentation. Thus, the experienced surgeon is able to perform a meticulous dissection in a nearly bloodless field [24]. Though robotic lung resections are in their infancy, preliminary data suggest a reduction in morbidity and mortality that is at least comparable to that of VATS compared to open procedures. In some instances, outcomes were superior to both VATS and traditional thoracotomy [25].

Lung Volume Reduction Surgery

Lung volume reduction is a surgical strategy to improve ventilation-perfusion matching in patients with severe emphysema (see also Chap. 46). Prospective candidates usually have a FEV_1 of less than 30% predicted and poor exercise tolerance secondary to dyspnea. During lung volume reduction surgery, nonfunctional portions of lung are removed (up to 30% of lung volume in some patients). The goal is improvement of chest wall mechanics and elastic recoil of lung by removing poorly ventilated and perfused apical segments [26]. Surgery in these very high-risk patients does carry a significant risk of postoperative respiratory complications. In one report the incidence of postoperative acute respiratory failure was 29.8%, with 43% of mortality related to a respiratory etiology [27]. Overall, the reported mortality following lung volume reduction surgery ranges from a low of 2.3% to up to 16% [28, 29].

Trans-sternal Thymectomy

Thymectomy is performed in patients with myasthenia gravis who have worsening symptoms despite maximal medical therapy with anticholinesterase medications and/or corticosteroids and has been shown to improve symptoms in up to 75% of patients (see also Chap. 15) [30]. In the perioperative period, the myasthenic patient may show exquisite sensitivity to non-depolarizing neuromuscular blocking medications and may have increased sensitivity to medications with respiratory depression side effects. In the past these patients remained intubated after surgery and were only extubated after careful assessment and reinstitution of preoperative anticholinesterase medications. As medical management has improved, many of these patients now present for surgery with their disease well controlled and with careful anesthetic management can be extubated immediately after the procedure. Historically, preoperative predictors of the need for postoperative ventilatory support include duration of the disease greater than 6 years, chronic lung disease, a daily dose of pyridostigmine greater than 750 mg (or its equivalent), and a preoperative vital capacity less than 2.9 liters [31]. In a series of 71 patients undergoing

thymoma resection, the incidence of postoperative respiratory complications was 13%, with only one death due to respiratory failure [32]. An increasing use of thoracoscopic techniques for this procedure may reduce the incidence of postoperative respiratory complications.

Esophagogastrectomy

The incidence of adenocarcinoma of the distal esophagus has increased over the last several decades, with risk factors including a history of tobacco use and alcohol consumption [33]. Esophagogastrectomy offers the only hope of cure.

Esophagogastrectomy for carcinoma at or near the gastroesophageal junction may be performed via a transhiatal approach or via a transthoracic approach (see also Chap. 38). Pulmonary complications occur in 15–25% of patients, with pneumonia and/or respiratory failure comprising about half of this incidence. The in-hospital mortality rate following transthoracic esophagogastrectomy ranges from 2.1% to 9.8% [34–36]. Two of three postesophagectomy mortalities are related to pulmonary complications; aspiration pneumonia secondary to postoperative swallowing disorders is the most common etiology [37].

Lung Transplantation

Lung transplantation is increasingly performed for end-stage lung disease secondary to many etiologies, limited to a large degree by donor availability. Following reperfusion of the donor lung, more than half of the patients exhibit some degree of non-cardiogenic pulmonary edema, and postoperative mechanical ventilation for at least 24 h is normal. This is discussed below under "pulmonary edema."

Thoracoabdominal Aortic Aneurysm (TAAA) Repair

The most common complications after open thoracoabdominal aortic aneurysm repair are pulmonary. These procedures require extensive incisions, prolonged periods of one lung ventilation, and large volume fluid resuscitation (see also Chap. 41). Reporting on 100 consecutive thoracoabdominal aortic aneurysm repairs, Money et al. found the mean duration of intubation to be 5.8 days, with a 21% incidence of respiratory failure [38]. An earlier report from Crawford's group suggested an incidence of respiratory failure in patients with chronic pulmonary disease of 58% and a mortality of 43% in this group [39]. Etz et al. reported an incidence of prolonged respiratory failure of 27% [40].

Specific Etiologies of Respiratory Failure: Their Prevention and Treatment

Table 54.4 summarizes the common conditions leading to acute postoperative respiratory failure. Similar to the diagnosis itself, the cause is seldom single or simple; more often it represents the combination of postoperative factors with predisposing physiology or underlying conditions.

Table 54.4 Acute causes of respiratory failure following thoracic surgery

Recurrent laryngeal nerves

Atelectasis

Surgery on the thorax and the upper abdomen leads to some degree of postoperative pulmonary dysfunction and atelectasis, which may persist for days or weeks. Inhibition of surfactant, gas resorption, and compression of lung tissue all are potential mechanisms by which atelectasis occurs. Although general anesthesia has been shown to depress the function of surfactant, inhibition of surfactant is not believed to play a major role in the formation of atelectasis [41, 42]. Resorption atelectasis refers to the continued gas uptake in alveoli after airway occlusion and ultimately leads to collapse of the gas pocket [43]. Resorption atelectasis increases with increasing inspired oxygen concentration [44]. Lastly, loss of intercostal muscle tone and cephalad displacement of the diaphragm and abdominal contents leads to an increase in pleural pressures and compression atelectasis [45].

The relationship between functional residual capacity (FRC) and closing capacity (CC) must also be considered. FRC is defined as the amount of air remaining in the lung at end-expiration of a normal tidal volume. CC is the volume of gas that must be in the lungs to prevent small airway collapse. In healthy lungs, FRC exceeds CC, and no atelectasis occurs. If CC exceeds FRC and the tidal volume lies within the CC, then small airways will open and close with each tidal volume. This will result in areas of low ventilation/perfusion ratio or shunt. If CC far exceeds FRC, then small airways never open during the respiratory cycle resulting in atelectasis (Fig. 54.1). Thus, factors that decrease FRC like general anesthesia, obesity, and supine position will subject patients to atelectasis.

While some degree of atelectasis occurs in almost all post-thoracotomy patients, the severity and clinical

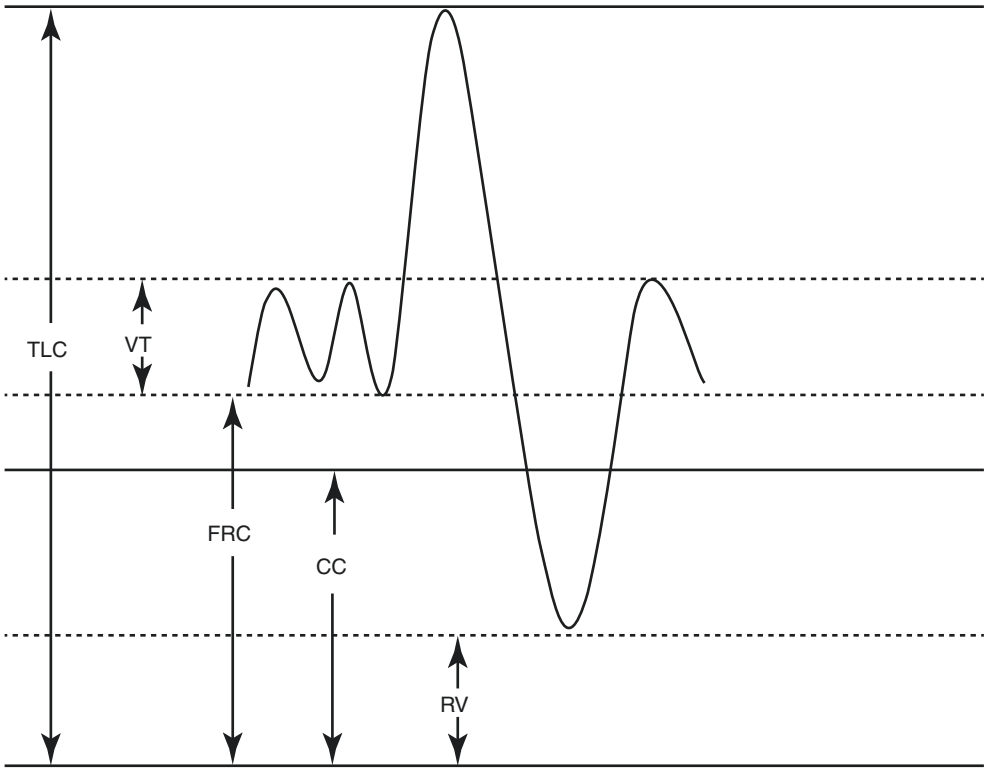

Fig. 54.1 Lung volumes in a normal young adult showing tidal volume (VT), total lung capacity reached on a maximum inspiration (TLC), functional residual capacity which is the volume in the lung at the end of normal expiration (FRC), closing capacity which is the lung volume below which small airways begin to close (CC), and residual volume, the volume of the lung remaining after maximum expiration (RV). With increasing age the CC increases bringing the normal tidal ventilation into a lung volume where small airways are closing, leading to shunt and predisposing to atelectasis. In addition, with obesity, supine posture, or Trendelenburg position, FRC decreases, while the CC does not, also leading to small airway closure and atelectasis

implications vary widely. Mild atelectasis usually requires little treatment other than supplemental oxygen administration in the postanesthesia care unit and will resolve as the patient awakens and increases depth of breathing. Decreased compliance, impaired oxygenation, increased pulmonary vascular resistance, and development of lung injury represent the more severe pathophysiologic effects of atelectasis. The most severe form of post-lobectomy atelectasis, lobar atelectasis, occurs in approximately 5% of patients after pulmonary resection. Lobar atelectasis is defined radiographically by complete lobar collapse and mediastinal shift. Risk factors include male gender, advanced age, and reduced preoperative FEV_1 [45]. This extreme form of atelectasis usually requires bronchoscopy, may require mechanical ventilatory support, and can lead to longer ICU and hospital lengths of stay. Lastly, atelectasis has been shown to promote bacterial overgrowth and increase lung permeability [46].

Prevention and treatment of atelectasis has traditionally consisted of cough and deep breathing exercises (Table 54.5). While coughing and deep breathing help clear secretions and potentially reopen atelectatic areas of lung, the ability of surgical patients to cough is significantly impaired after thoracic surgery. The maximal intrapleural pressures produced during voluntary coughing are reduced to as low as 29% of preoperative values and may remain as low as 50% of the preoperative value at 3 weeks postsurgery [47]. The cough effort may be improved with the patient in the sitting position and with manually assisted compression of the chest wall. Simply mobilizing patients from sitting in bed to sitting in a chair improved FRC at an average of 17% [48].

Therapeutic
Diagnostic
Minitracheostomy

Incentive spirometry (IS) is a simple and inexpensive method of helping patients obtain maximal inspiratory effort [49]. IS encourages patients to maintain inspiration for a prolonged period while using slow and deep breaths. Figure 54.2 shows a typical single-patient use incentive spirometry device. Incentive spirometry can also be followed as a bedside test for evaluation of postoperative pulmonary function after lung surgery. The performance on IS correlates well with inspiratory reserve volume and forced vital capacity [50]. A decline in a patient's ability to perform IS can be an early indicator of an acute worsening of the

Fig. 54.2 Incentive spirometer (Hudson RCI, Teleflex Medical). The patient makes a sustained inhalation effort through the mouthpiece, guided by an effort indicator on the right side of the device. This causes the "floating" marker inside the graduated cylinder to be drawn up to a set target indicated to the left of the cylinder

Fig. 54.3 Positive expiratory pressure vibratory device ("Acapella" device, Smiths Medical ASD, Inc.). Exhalation through this device is intermittently occluded at a high frequency which "vibrates" the airways facilitating clearance of secretions and possibly opening closed airways

patient's pulmonary status. While IS is widely accepted as a tool to help prevent atelectasis, this has not been clearly established in clinical studies. Several reviews of the literature have failed to find supporting evidence for the routine use of IS following cardiac, thoracic, or upper abdominal surgery [51–56].

An alternative approach to IS is to focus on maintaining airway patency during expiration. This is termed "positive expiratory pressure therapy ("PEP") and has been shown to improve clearance of secretions [57] (Fig. 54.3). The patient uses this device for several breaths and then makes coughing or "huffing" efforts. A third type of device is the "flutter valve" which causes "fluttering" of the expiratory airway pressure, aiding the mobilization of secretions.

Positive-pressure breathing (i.e., positive inspiratory pressure) through a mouthpiece or face mask or continuous positive airway pressure (CPAP; see description in "ventilatory modes") delivered by nasal or face mask may be beneficial in maintaining and recruiting atelectatic lung [58]. Biphasic, or bi-level, positive airway pressure (BiPAP) has also been used to support hypoxemic patients in the postanesthesia care unit [59]. Figure 54.4a illustrates the mask used for BiPAP or CPAP. More recently, the use of high-flow nasal cannula (HFNC) oxygen (up to 60 L/min) has been described in the same setting. A typical HFNC setup is depicted in Fig. 54.4b. The application of these noninvasive ventilator modes, to assist in the prevention and/or treatment of acute respiratory failure, is discussed below.

Pain is a major factor contributing to the reduction in cough effort and deep breathing in patients following thoracotomy. Adequate control of postoperative pain, including use of epidural analgesia, improves maximal cough pressures in post-thoracotomy patients, and lack of a thoracic epidural catheter was found to be a risk factor for the need for postoperative mechanical ventilation after lung resection [14, 60]. While the use of opoid infusions through either lumbar-level or thoracic-level epidural catheters can provide adequate post-thoracotomy analgesia, only analgesia provided by thoracic-level catheters was demonstrated to decrease mortality in a meta-analysis of postoperative outcomes [61]. Various infusions may be used including an opoid alone or, for a thoracic level catheter, an opoid and local anesthetic combination. The combination of an opoid and local anesthetic has been shown to be synergistic and allows for a lower dose of each than if either is used alone [62]. A technique gaining popularity for thoracic patients is a continuous paravertebral catheter. This technique offers the advantages of fewer side effects compared to a thoracic epidural and is not contraindicated in anticoagulated patients. A literature review by Davies indicates that continuous paravertebral catheters are just as efficacious in pain control as thoracic epidurals [63]. Other modalities of regional anesthesia to provide post-thoracotomy analgesia include intrapleural administration of local anesthetic and intercostal nerve blocks. Intercostal nerve blocks may be performed by the anesthesiologist pre- or postoperatively or by the surgeon during the procedure. The blocks may be performed with plain local anesthetic with or without epinephrine or, for a more protracted duration of analgesia, liposomal bupivacaine [64]. Intraoperative cryoablation of intercostal nerves has also been used to provide an extended period of analgesia.

Fig. 54.4 (**a**) Full face mask used to provide CPAP or BIPAP (Respironics/Philips). An air-filled sealing rim provides an occlusive seal around the mouth and nose, with head straps to keep the mask in place as well as provide adequate pressure for the level of CPAP/BIPAP applied. Nasal masks are also available. (**b**) HFNC – right: typical high-flow nasal cannula (HFNC) setup consisting of flow meter, oxygen blender (not shown), active humidifier, and heated inspiratory circuit. Though mobile, HFNC, given the rates of oxygen delivery, is best delivered by attaching to a wall circuit. Left: HFNC is delivered through a heated humidified circuit, which at the patient end does not seem significantly different from a standard nasal cannula. As stated in the text, patients can receive the benefits of noninvasive ventilation without the discomfort of a mask, and practitioners have the benefit of an unencumbered view of the patient's face

Bronchospasm

In patients with known bronchospastic disease or in patients with chronic obstructive pulmonary disease shown to have improvement after bronchodilators during preoperative spirometry, postoperative airway constriction may contribute to respiratory failure. Increased airway resistance contributes to increased work of breathing and also can create the "auto-PEEP" effect. This occurs when terminal bronchioles/alveoli do not fully empty through narrowed airways during expiration, resulting in a positive rather than zero pressure at end-expiration distal to the obstruction. In order to generate flow into these alveoli during inspiration, this positive pressure must first be overcome, creating a further increase in the work of breathing [65].

Inhaled bronchodilating agents should be considered in all patients exhibiting respiratory distress after thoracic surgery. Inhaled beta-adrenergic agonists enhance smooth muscle relaxation by increasing intracellular levels of cyclic AMP and ultimately result in bronchodilation [66]. Inhaled albuterol is the beta-adrenergic agonist most often prescribed in the postoperative period due to its short onset time and ability to act as a rescue medication. The half-life of albuterol is short and requires dosing every 4 h. Salmeterol and formoterol are longer-acting beta-adrenergic agonists and are mainly used as maintenance therapy [67]. Racemic epinephrine also has beta-adrenergic properties and may reduce respiratory mucosal edema through its alpha-adrenergic effects on mucosal vasculature. A concern with these agents, especially epinephrine, is absorption and systemic side effects.

Anticholinergic medications are also effective bronchodilators. These medications induce smooth muscle relaxation by antagonism of acetylcholine at the M3 receptor and decrease intracellular levels of cyclic-GMP. Ipratropium is a

short onset and short duration anticholinergic medication commonly used in combination with albuterol for bronchospastic disease. Like albuterol, it needs to be dosed approximately every 4 h. Tiotropium is a longer-acting anticholinergic medication that can be used for maintenance. These medications are poorly absorbed and have limited systemic side effects.

Combination therapy with a beta-adrenergic agonist and anticholinergic medication provides greater improvement in symptoms. By having different mechanism of action and durations, these medications work synergistically to improve bronchodilation [68]. A combination of the short acting beta-adrenergic agonist albuterol and short-acting anticholinergic ipratropium is available in the United States.

Lastly, steroidal compounds are also available for inhalational administration and serve a useful role in prevention of inflammatory-mediated bronchospasm. These medications are mainly used in maintenance therapy and are not indicated for acute bronchospasm.

Retained Secretions

Inability to clear secretions contributes to atelectasis and pulmonary infections.

Dehydration of the tracheobronchial mucosa occurs with use of non-humidified oxygen. This leads to mucociliary dysfunction and drying of secretions. The ensuing decrease in ability to mobilize and clear secretions can contribute to the formation of atelectasis; humidification of oxygen is therefore recommended. Patients with tenacious secretions may benefit from inhaled agents that decrease the viscosity of secretions such as N-acetylcysteine or dornase alfa (Pulmozyme ®, Genetech, Inc.). Dornase is a recombinant human DNAse, which has been demonstrated to decrease viscosity of respiratory secretions in cystic fibrosis patients and help re-expand atelectatic lobes in this population [69]. Efficacy in patients with chronic bronchitis has not been demonstrated for long-term use but has been suggested in acute exacerbations.

For the patient who fails to respond to deep breathing exercises, IS, and PEP therapy, along with inhaled bronchodilators and/or mucolytics, there are several adjuvant therapies that may be utilized to improve the patient's status (Table 54.5). Modalities of chest physiotherapy include postural drainage, percussion and vibration over the affected lung segments, and incentive to cough. Postural drainage is performed by positioning the patient, so the lung segments to be drained are in a superior position. Drainage is most effective when combined with percussion and vibration, but proper positioning may be limited by the patient's condition. Percussion is performed throughout the respiratory cycle and is followed by vibration during the exhalation phase.

Tracheal suctioning can be used to mechanically remove secretions from the trachea and to induce deep breathing and coughing. In the non-intubated patient, tracheal suctioning is usually performed by a blind nasal technique. Suctioning should be performed after preoxygenating the patient with a high FIO_2 and may be better tolerated through a nasal airway or "trumpet." The catheter should be advanced without suction and removed from the trachea with intermittent suction. Blind nasotracheal suctioning is a very unpleasant experience for most patients; while it may induce better coughing, it may also induce gagging and vomiting, and frequent or aggressive suctioning can cause mucosal damage and may induce bronchospasm, laryngospasm, and cardiac rhythm disturbances.

An alternative to blind nasotracheal suctioning is placement of a minitracheostomy (a small, uncuffed endotracheal tube through an incision in the cricothyroid membrane) to facilitate suctioning of secretions. This procedure is safe and effective in decreasing the need for other interventions such as chest physiotherapy. This procedure also may decrease postoperative respiratory complications [70–72]. Potential complications are rare, including bleeding into the trachea, infection, and tracheal occlusion by granuloma formation [73]. Minitracheostomy is not intended to provide a means for positive-pressure ventilation and is not a replacement for endotracheal intubation when indicated.

Fiber-optic bronchoscopy (FOB) may be used for more aggressive clearance of secretions or blood in the tracheobronchial tree or as a diagnostic study in the patient with an acute worsening of respiratory function. Under direct visualization, tenacious secretions can be suctioned from affected airways. A review of the practice of FOB in a large teaching hospital confirmed the safety of the procedure with a major complication rate of 0.5% and a minor complication rate of 0.8% [74]. Complications include laryngospasm, bronchospasm, pneumothorax, and pulmonary hemorrhage. In the awake, non-intubated patient, fiber-optic bronchoscopy requires topical anesthesia of the upper airway and often requires moderate sedation.

Pneumonia

Decreased mucociliary clearance and persistent atelectasis place the thoracic surgical patient at increased risk for postoperative nosocomial pneumonia. Following thoracotomy, patients also have altered systemic and lung host defenses which increase susceptibility to postoperative pneumonia [75]. The occurrence of pneumonia, especially after lung resection, significantly increases the patient's risk for respiratory insufficiency and need for mechanical ventilation. Nosocomial pneumonia is the single most important risk factor for mortality in the post-thoracotomy patient [4]. In a

prospective trial, Nan found the rate of postoperative respiratory infections after lung surgery (pneumonia, empyema) to be ~19% [76]. Overall, mortality rates for nosocomial pneumonia range from 20% to 80% with Gram-negative bacilli and *Staphylococcus aureus* being the most common pathogens [77]. Ventilator-associated pneumonia is discussed below.

Initiation of therapy should not be delayed for the results of initial cultures. Mortality is reduced with appropriate empiric antibiotic therapy versus delaying until BAL is performed [78]. For suspected pneumonia occurring early in the postoperative period in a patient who was not in the hospital preoperatively, community-acquired organisms such as *Streptococcus pneumonia* and *Haemophilus influenzae* should be targeted. For a patient who has been in the hospital preoperatively or in whom pneumonia is suspected more than 48 h after surgery, empiric antibiotic therapy should target hospital-acquired organisms such as *Pseudomonas aeruginosa*, *Acinetobacter* and *Klebsiella* species, and methicillin-resistant *Staphylococcus aureus*. The importance of initial appropriate empiric antibiotic therapy cannot be understated and should be targeted to institution or community-specific pathogens. Inappropriate antibiotic therapy, even if corrected within 48 h when the results of culture become available, has been associated with higher mortality, a longer ICU stay, and a trend toward longer mechanical ventilation. Inappropriate initial antibiotic therapy has been reported to be as high as 50% [79]. Ventilator-associated pneumonia is discussed below.

Pulmonary Embolism

In a study of 77 patients undergoing thoracotomy before the use of subcutaneous heparin prophylaxis, the incidence of deep venous thrombosis was 19%, with pulmonary embolism occurring in 5% [79]. In a large series of 1735 lung resection patients, early fatal acute cardiopulmonary failure occurred in 26 patients. Autopsy in 20 of these patients demonstrated pulmonary embolism in 19 [80]. In patients with shock due to massive pulmonary emboli, the mortality is in excess of 30% [81]. As thoracic surgery patients usually have at least two major risk factors for deep venous thrombosis (malignancy and major surgery), prophylaxis should include both sequential compression devices applied to the calves and low-dose subcutaneous heparin or low-molecular-weight heparin.

Signs and symptoms of pulmonary embolism include dyspnea, tachypnea, arterial hypoxemia, pulmonary hypertension, right ventricular failure, and shock. Lung perfusion scanning with technetium 99 m-labeled albumin combined with ventilation scanning with xenon 133 can demonstrate areas of ventilation-perfusion mismatch, although this test is of limited use when there is preexisting lung disease or recent lung surgery. Current use of lung perfusion scanning is only in patients with renal insufficiency, anaphylaxis to intravenous contrast, or pregnancy [82]. Spiral computed tomography (CT) can demonstrate pulmonary emboli and is noninvasive, quicker, and easier to perform than ventilation-perfusion scanning [83, 84]. While the gold standard for detection of pulmonary emboli is pulmonary angiography, in many centers spiral CT has essentially eliminated the need for this more invasive test. Postoperative patients with low risk PE are not candidates for thrombolytic therapy, but therapeutic heparinization is usually safe if initiated at least 24–48 h after surgery. In cases of sub-massive and massive embolism, surgical embolectomy or catheter-directed therapy with no- or low-dose thrombolytic may be considered [85, 86].

Pulmonary Edema

The etiology of pulmonary edema after thoracic surgery may be cardiogenic or non-cardiogenic. Increased hydrostatic pressure in the pulmonary vasculature, as might be associated with left ventricular dysfunction or excessive intravenous fluid administration, may lead to cardiogenic pulmonary edema. Increased permeability of the alveolar capillary membranes, as occurs with the acute respiratory distress syndrome (ARDS), leads to non-cardiogenic pulmonary edema.

Postpneumonectomy pulmonary edema (PPE) is a particularly severe form of pulmonary edema that can occur after pneumonectomy and is associated with a high mortality. Resection of lesser amounts of lung tissue (i.e., wedge resection) is not associated with this entity [87]. Patients with PPE develop a low-pressure, high-protein pulmonary edema indicating endothelial damage is present [88]. An increase in endothelial permeability has been demonstrated by measuring the pulmonary accumulation of intravenously administered technetium 99 m-labeled albumin after pneumonectomy [89].

The etiology of PPE remains unclear but is likely multifactorial. Risk factors that have been associated with PPE include the side of operation, with right pneumonectomy having a higher risk than left, perioperative fluid overload (>2 L intravenous fluid administration), and higher tidal volumes during one lung ventilation (10 ml/kg) [90–92]. Other potential etiologies include the use of fresh frozen plasma intraoperatively, oxygen toxicity, serum cytokines, and mediastinal lymphatic damage.

The development of pulmonary edema after lung transplantation was initially termed the pulmonary reimplantation response but is now referred to as primary graft dysfunction

(PGD), representing a complex, incompletely understood multifactorial syndrome resulting from both donor and recipient factors and possible perioperative management strategies [93, 94]. Various risk factors have been identified; however, those patients, most consistently at risk, are characterized by a pre-transplant diagnosis of pulmonary hypertension, sarcoidosis, a donor history of smoking, and the need for cardiopulmonary bypass [95]. It appears both the endothelium and epithelium of the donor lungs are targets [94]. The syndrome occurs in approximately 20% of patients and is associated with a 23% absolute risk in mortality at 1 year [93]. Use of ECMO rather than cardiopulmonary bypass during surgery appears to be at least somewhat protective [96], but treatment is otherwise supportive as no specific preventative or therapeutic measures have been clearly shown to reduce the incidence or severity.

Pneumothorax

Following thoracotomy the surgeon usually places two chest tubes into the operative hemithorax. One chest tube is placed inferiorly to preferentially drain blood and fluids and a second tube superiorly to preferentially vent air. Pneumothorax may develop postoperatively if a chest tube is inadvertently kinked, clamped off, or dislodged. While a small leak may cause little or no symptoms, a large, undrained air leak can result in a "tension pneumothorax" with a shift of the trachea and mediastinum to the contralateral side. The increase in intrathoracic pressure causes a decrease in venous return to the right heart and can result in cardiovascular collapse. Pneumothorax may also occur on the nonoperative side as result of rupture of a pulmonary cyst or bulla if excessive airway pressures develop during mechanical (especially one lung) ventilation. Inadvertent and unrecognized surgical entry into the pleura of the nonoperative side may cause pneumothorax, as may inadvertent lung puncture during placement of central venous catheters, or intrapleural catheters for postoperative analgesia. Confirmatory imaging of a pneumothorax can be achieved with the use of ultrasound, particularly with the use of m-mode, as discussed in Chap. 28.

Definitive treatment of a pneumothorax is placement of a chest tube, usually in the fourth or fifth intercostal space between the anterior and mid-axillary lines. In the case of tension pneumothorax, a needle thoracostomy is often performed first by placing a large bore, i.e., 14 gauge, venous catheter above the third rib in the midclavicular line. This effectively converts the tension pneumothorax to a simple pneumothorax. While there is some advocacy for needle decompression to be placed at the same location as a chest tube, there is no definitive data, and there is trauma literature citing increased incidence of catheter kinking/dislodgement in this location [97].

Persistent Air Leaks and Bronchopleural Fistula

Persistent air leaks are reported to occur in 4–20% of pulmonary resections, prolonging and complicating the postoperative course [98]. Bronchopleural fistula is associated with a large air leak from the lung and results from disruption of a bronchial stump or tracheobronchial anastomosis. The initial sign is often a dramatic increase in air leak noticed in the chest tube drainage chamber. If the air leak exceeds the capacity of the chest tube to evacuate the air, there will be a persistent pneumothorax. In large bronchopleural fistulas, respiratory insufficiency may ensue. Positive-pressure ventilation poses a significant problem as the majority of tidal volume escapes into the pleural space and chest tube through the lower-resistance bronchopleural fistula. Pneumonectomy, residual tumor in the bronchial stump, hyperglycemia, hypoalbuminemia, postoperative mechanical ventilation, preoperative steroid use, COPD, and low-predicted postoperative FEV_1 have all been reported as risk factors for the development of bronchopleural fistulas [99].

Although definitive treatment of large leaks requires surgical correction, temporary ventilator management may include placement of a double-lumen endotracheal tube to allow differential lung ventilation (see below). Alternatively, a bronchial blocker may be used on the affected side to limit flow to that side. Smaller air leaks may be treated with endobronchial substances or devices. The use of endobronchial valves (Fig. 54.5), placed via bronchoscopy, has had reasonable success [100, 101].

Aspiration of Gastric Contents

In the thoracic surgery population, the risk of aspiration of gastric contents is increased in patients presenting with esophageal disease. Intraoperative aspiration will lead to a pulmonary injury causing edema and inflammation, leading to hypoxemia. Aspiration pneumonitis is one of the causes of acute respiratory distress syndrome (ARDS), the management of which is discussed below. Not well recognized is the risk of a relatively small-volume aspiration in patients extubated after more than 48 h after thoracic surgery in general and in particular after lung transplantation [102]. In the latter population, a study using fiber-optic endoscopy demonstrated aspiration in the majority of single and double lung transplantation patients [103]. These patients should be evaluated for swallowing competence and risk of aspiration before oral intake is initiated postoperatively and be watched closely for signs of aspiration.

Torsion of Residual Lobe

Torsion of a residual lobe of the lung around its bronchus may complicate lobectomy. The loss of lung tissue on the surgical side may allow abnormal movement of the residual lung tissue, most commonly the right middle lobe and the lingula. In addition to the intrapulmonary shunt that develops secondary to occlusion of the affected bronchus, blood supply to the affected lobe is compromised and can lead to infarction.

The diagnosis can be suspected by the onset of respiratory distress or failure in association with the appearance of a collapsed or abnormal lobe on the chest radiograph, which does not respond to the usual therapies for atelectasis. The diagnosis can then be confirmed by bronchoscopy. Definitive therapy consists of surgical correction of the torsion, which should be performed urgently if infarction of the lobe is to be prevented.

Neurologic Injuries

While rare following thoracic surgery, neurologic injuries may occur which can lead to pulmonary insufficiency in the postoperative period. Damage to a phrenic nerve can occur following thoracotomy, especially if extensive dissection into the mediastinum is necessary to remove a tumor. A patient with good pulmonary reserve usually tolerates unilateral phrenic nerve palsy. In a patient with baseline compromised pulmonary status, such as advanced chronic obstructive pulmonary disease, unilateral phrenic nerve paralysis will lead to difficulty in weaning from mechanical ventilation. Bilateral phrenic nerve paralysis will lead to pulmonary insufficiency in any patient. The diagnosis is suggested by elevated hemidiaphragm on postoperative chest film. It can be confirmed by observing paradoxical motion of the affected hemidiaphragm under fluoroscopy.

Recurrent laryngeal nerve injury may be seen following extensive hilar lymph node dissection. The left recurrent laryngeal nerve is at greater risk of injury due to its more caudal course. Unilateral injury is generally well tolerated, but bilateral injury can cause significant stridor following extubation secondary to spasm of the vocal cord adductor muscles.

Mechanical Ventilation After Thoracic Surgery

Table 54.6 summarizes the common reasons to continue mechanical ventilation into the postoperative period after thoracic surgery. Many of these relative indications are common to major surgery of all types and reflect planning to "stabilize" a patient after major stress. Preoperative and intraoperative discussion with the surgical team allow for appropriate arrangements to be made in advance regarding care in the postanesthesia care unit ("PACU") or intensive care unit (ICU).

Two major issues in early postoperative mechanical ventilation after thoracic surgery are (1) concern for bronchial anastomoses after lung resection and (2) leaving tracheal tubes that are designed for intraoperative lung isolation. Regarding bronchial anastomoses, there is always a concern that positive airway pressures may expose the patient to increased risk of bronchial anastomotic leaks or disruption. This must be balanced with the need for oxygenation (which

Table 54.6 Relative indications for mechanical ventilation after thoracic surgery

Preoperative
Preoperative mechanical ventilation
Predicted low postoperative FEV1 (<30% predicted)
Esophagogastrectomy or thoracoabdominal aneurysm repair
Intraoperative
Prolonged intraoperative course
Massive fluid administration or transfusion
Hypothermia
Cardiac failure
Surgical complication
Need for postoperative lung isolation (air leak, drainage)
Need for postoperative chest wall immobilization/stabilization
Immediate postoperative
Incomplete recovery of neuromuscular function
Inadequate respiratory drive (excessive opioid administration)
Requirement for >50% fiO_2
Visible respiratory distress

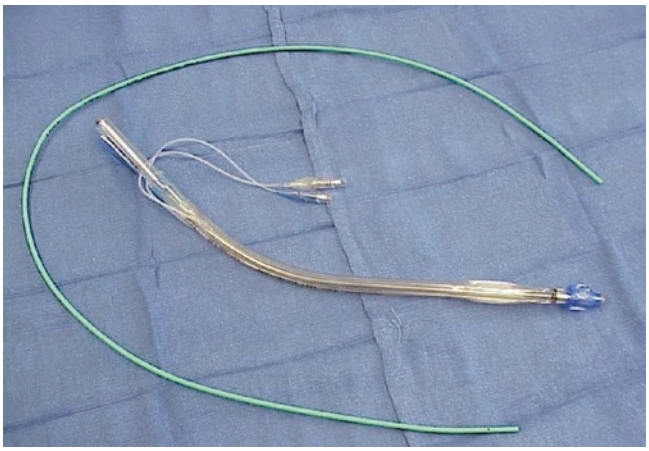

Fig. 54.6 Long tube changer for use with double-lumen tracheal tubes (Cook Medical). A double-lumen tube is illustrated with the tube changer curved around it; the tube changer is more than twice the length of the double-lumen tube

may require positive end-expiratory pressure [PEEP]) and adequate minute ventilation for elimination of CO_2. The clinical goal is to avoid elevated airway pressures by reducing the delivered tidal volume or by using pressure limited modes of ventilation where possible (see below). There are no publications defining the "safe" upper limit of positive airway pressure after lung resection; however, common sense dictates that lower airway pressures are safer.

Double-lumen or specialty tubes which incorporate a bronchial blocker have small inner diameters related to their outer diameter, making tracheal/airway toilet difficult and imposing additional work of breathing when this is demanded of the patient. In addition, PACU and ICU nurses and respiratory therapists are usually unfamiliar with such tubes. Unless there is a need to continue lung isolation postoperatively (e.g., persistent large air leak, draining infection), it is desirable to replace such specialty tubes with single-lumen tubes before leaving the operating room. In those patients with difficult airways or those who have/are expected to have oral or airway edema, clinical judgment must be used; the above mentioned problems may be a necessary evil in the face of potential loss of the airway. While long tube exchanging devices for double lumen tubes are available (Fig. 54.6), use of these does not guarantee the ability to readvance a single lumen tube through a very edematous or difficult airway. It may be prudent to plan to change the tube at a later time/date.

Preoperative Indications for Postoperative Mechanical Ventilation

Patients coming to the operating room already ventilated for any reason are unlikely to tolerate extubation immediately after their procedure. Withdrawal of mechanical ventilation should be done in a gradual, controlled manner, and the operating room is not a suitable place for this process. Patients with poor predicted postoperative FEV_1 (less than 30% predicted) are at the highest risk for immediate postoperative respiratory failure (see Chap. 2). These patients may benefit from a staged withdrawal of mechanical ventilation, while other physiology is assured to be optimal (cardiac, endocrine, renal), and normothermia and analgesia are achieved. Specific major procedures that are usually associated with *elective* postoperative mechanical ventilation for at least 24 h include esophagectomy or esophagogastrectomy and thoracic or thoracoabdominal aortic aneurysm repair [104, 105]. Apart from the extent and duration of surgery, these latter procedures are associated with extended periods of one-lung ventilation, and the operative-side lung is often contused or partially atelectatic despite having been re-inflated at the end of surgery. This leads to hypoxemia and increased work of breathing.

Intraoperative Indications for Postoperative Mechanical Ventilation

Unanticipated operative complications may lead to circumstances that are unfavorable to immediate postoperative extubation. Foremost among these indications are any complications or conditions that lead to difficulty in obtaining adequate oxygenation or CO_2 elimination intraoperatively. Other factors that need to be considered in relation to the list in Table 54.1 are underlying comorbid conditions, age, and time of day (availability of experts in ventilator and airway management). A period of elective postoperative mechanical ventilation permits stabilization of organ systems (e.g., volume status, cardiac function, coagulation/

hemostasis control), while oxygenation and ventilation are assured. Withdrawal of mechanical ventilation can be done in a staged and controlled manner without the pressure of time that exists in the operating room. The list of relative indications in Table 54.6 must be tempered with clinical judgment throughout, and at the end of the procedure, continued discussion of the plan with the surgical team can facilitate a smooth transition from the operating room to the PACU or ICU.

Immediate Postoperative Indications for Mechanical Ventilation

As in any surgical patient, circumstances may arise or become evident at the end of thoracic surgery that prevent extubation. Foremost among these are inadequate neuromuscular function as assessed objectively by nerve stimulation or clinically by weakness and inadequate spontaneous respirations (low rate in association with high end-tidal or arterial CO_2 concentration). In the case of iatrogenic muscle weakness due to an aminosteroid, non-depolarizing muscle relaxant, sugammadex is a viable reversal option in the absence of contraindications [106, 107].

While the aforementioned complications must be resolved before extubation, of greater concern are problems with oxygenation (e.g., requirement of >50% FiO_2 to achieve a SpO_2 >90%), ventilation (inadequate CO_2 elimination despite tachypnea), and visible respiratory distress. Inadequate pain control may contribute to these findings; however, they may also represent a physiologic derangement likely to require more than a few minutes for resolution. Specific blood gas criteria or respiratory measures are frequently quoted as indicating a need for mechanical ventilation; however, in the rapidly changing situation at the end of surgery, it is difficult to apply such criteria. A *clinical judgment* must be made to assist or control ventilation for an additional period, usually requiring the patient also be (re)sedated. At this time a call to the PACU or ICU should be made with a request for a mechanical ventilator and sedative infusion(s). A chest radiograph and arterial blood gas analysis should be performed at the earliest opportunity.

In addition to permitting the administration of high, known concentrations of oxygen, positive-pressure ventilation with positive end-expiratory pressure (PEEP) via a tracheal tube assists oxygenation by opening/expanding partially collapsed alveoli and perhaps opening some fully collapsed ones. Positive end-expiratory pressure or PEEP improves oxygenation in pulmonary edema and acute lung injury both by these mechanisms and by redistributing (but not reducing) lung water [108, 109]. Increasing the fraction of inspired oxygen (FiO_2) will improve arterial oxygenation by increasing transport in those areas that are absorbing O_2. True shunt will respond only to re-expansion of collapsed segments or reduction of the size of the shunt. This may require bronchoscopy and can be aided by PEEP. Thus, failure of oxygenation is treated with increasing the FiO_2 and/or increasing the mean airway pressure.

Usually the work by the respiratory muscles to ventilate the lungs requires only a few percent of total body oxygen consumption, but this may be several times higher in the postoperative patient and higher still in acute respiratory failure [110]. Mechanical ventilation also takes over the work of breathing for the patient in distress and guarantees alveolar ventilation. Thus, mechanical ventilation with PEEP treats both components of acute respiratory failure.

Ventilatory Modes

Modern mechanical ventilators used in critical care and now present on anesthesia machines are very sophisticated microprocessor controlled devices that sense and interact with the patient (see Chap. 22). This is in stark contrast to the traditional anesthesia ventilator that has three controls: respiratory rate, tidal volume, and inspiratory flow rate delivering only *volume-cycled*, controlled mandatory ventilation (CMV). Modern ICU ventilators offer a variety of interactive modes, as well as pressure or volume-cycled breaths. Many devices administer noninvasive ventilation (NIV), using a specially designed facial or nasal mask (Fig. 54.4a) to deliver either CPAP or "BIPAP" which is analogous to pressure support ventilation with PEEP.

Noninvasive Ventilation

Traditionally, NIV is either CPAP or pressure support with PEEP (BIPAP) provided via a face mask rather than a tracheal tube. There has been recent interest in the addition of high-flow nasal cannula (HFNC) to this category. As will be discussed below, there is some preliminary data to support the prophylactic use of NIV. However, it is still currently thought of as more of a rescue strategy.

We ventilate our lungs by drawing gas in with our respiratory muscles: during spontaneous inspiration, airway pressure (P_{aw}) is negative with respect to the atmosphere, and during expiration P_{aw} is positive. Spontaneous breathing in this way, with a positive rather than atmospheric baseline pressure, is CPAP (Fig. 54.7). Strictly speaking this is not a mode of ventilation as there is no inspiratory assist. This mode of support is usually used to improve oxygenation in patients who do not have ventilatory failure, as it helps increase the FRC and reduces atelectasis. It may allow spontaneous breathing to occur at a more compliant part of the pressure-volume relationship of the thorax, reducing the

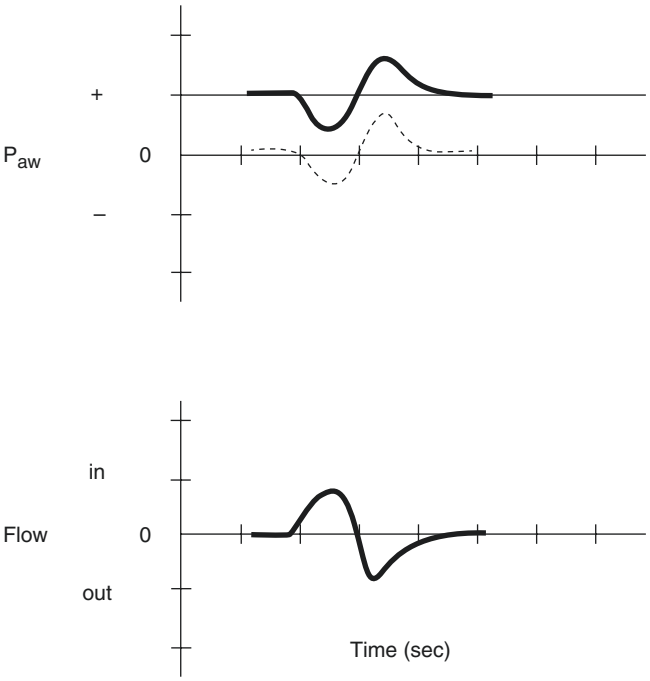

Fig. 54.7 Airway pressure and gas flow during a spontaneous breath through a CPAP mask/circuit. The pressures and flows mirror those for a spontaneous breath (dashed line), but the baseline pressure is elevated. Paw, airway pressure

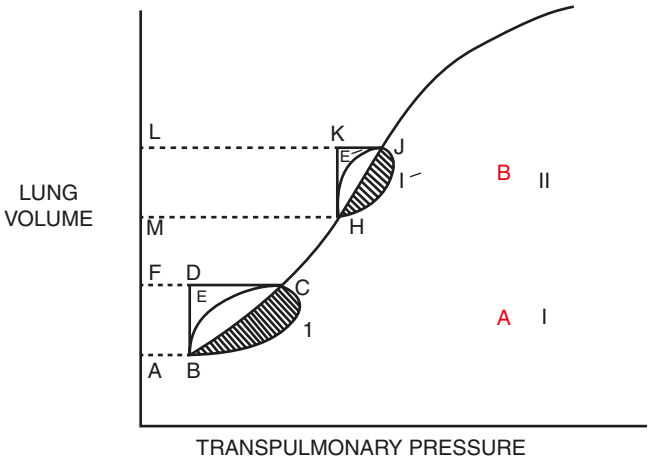

Fig. 54.8 Pressure-volume loops illustrated at two different lung volumes, representing tidal volume at reduced lung volume and FRC as might occur with postoperative atelectasis (**a**) and the same tidal volume at normal lung volume and FRC (**b**). The solid sigmoidal line is the elastic pressure-volume curve for the lung and chest wall. Application of CPAP can reopen atelectatic portions of the lung and move tidal breathing up the pressure-volume relationship of the lung and chest wall from A to B, both improving gas exchange and reducing the work of breathing (transpulmonary pressure required to generate same tidal volume)

work of breathing [111] (Fig. 54.8). CPAP can be provided by a continuous high-flow circuit or can be delivered through a microprocessor-controlled ventilator that senses effort (airway pressure or flow) and responds accordingly. In the former case, the airway pressure varies slightly during the respiratory cycle; however, the high level of flow and built in reservoir prevents large swings in pressure. In the latter case, the flow is delivered in response to the sensor, attempting always to meet the patient's demands and to achieve the preset level of CPAP.

An enhancement of CPAP is BIPAP, which provides inspiratory assistance. This mode of NIV can be used in the treatment of acute respiratory failure as well as the treatment of hypoxemia. It has been shown to prevent intubation in several medical and surgical populations including thoracic surgery [112]. Several postoperative studies of CPAP and BIPAP have demonstrated benefit and no harm. Squadrone et al. performed a large multicenter trial on patients who had undergone upper abdominal surgery. Patients with a PaO2/FiO2 ratio <300 mm Hg were randomized to receive CPAP with an FiO2 of 0.5 vs. a face mask with FiO2 of 0.5. Patients receiving CPAP had a lower incidence of reintubation and pneumonia [113]. Another study by Kindgen-Milles looked at post-extubation CPAP in patients who underwent open thoracoabdominal aneurysm repair. The patients who received CPAP post-extubation had better oxygenation, fewer pulmonary complications, and shorter hospital stay compared to the controls [114]. In a report of 690 patients undergoing lung resection, Lefebvre et al. reported a 16% incidence of respiratory failure, 85% of whom were successfully managed with NIV alone [115]. Perrin et al. used NIV pre- and postoperatively and demonstrated a reduction in pulmonary complications after lung resection, Rocco et al. prevented reintubation in 18/21 patients with respiratory failure after lung transplantation, and Michelet et al. showed similar benefits in patients who developed respiratory failure after esophagectomy [116–118].

Though comprised of small studies, there is increasing evidence supporting the use of heated and humidified, high-flow nasal cannula (HFNC) as an alternative first-line therapy in the treatment of respiratory failure in the cardiothoracic surgery population. HFNC delivers O_2 of concentrations from 0.2 to 1.0 at rates of up to 60 lpm and in the process may generate P_{aw} of 3–5 cm H_2O. It is believed this mode of delivery can decrease the work of breathing, decrease respiratory rate, increase end-expiratory lung volumes, decrease dead space, and reduce the need for intubation [119–122].

It is clear that use of CPAP and BIPAP can both prevent and treat respiratory failure after surgery, can avoid the need for intubation, reduce respiratory complications, and decrease length of stay. However, despite evidence to the contrary, there is still some concern for the integrity of surgical anastomoses in the setting of positive-pressure ventilation. This is one of the ways in which HFNC represents a more attractive alternative as it generates significantly

lower P_{aw} pressures compared to CPAP and BiPAP while offering equivalent benefits. Additionally HFNC may provide a more comfortable option, especially for patients who won't tolerate a tight-fitting mask covering their nose and/or face. Though there is data to support its safety, the use of CPAP/BiPAP in the setting of fresh anastomoses is still a commonly stated concern. Given the seemingly equivalent efficacy of HFNC, it is a reasonable first option given the low level of increased airway pressures. Other benefits include full visual access to a patient's face further allaying concerns regarding aspiration and evolving mental status changes.

There are limitations to any mode of NIV. It is not appropriate for patients who cannot cooperate or for those with excessive secretions, hemoptysis, or vomiting who are unable to protect their airway. Table 54.7 lists contraindications [112]. Success requires patience and expertise on the part of the respiratory therapist and usually slow, incremental adjustments to inspiratory and/or expiratory pressures in the case of CPAP/BiPAP or flow rate and oxygen content in the case of HFNC. When using CPAP/BiPAP, the presence of a nasogastric tube may introduce a leak which cannot be managed, and peak airway pressures (i.e., actual pressure during inspiration) should never exceed 25 cm H_2O. No mode of noninvasive ventilation is a long-term ventilator strategy, and it is vital that clear endpoints delineating either success or failure should be kept in mind. If the patient is not clearly improving over a trial period of no more than 1–2 days, then a move to tracheal intubation or tracheotomy should be considered.

Table 54.7 Noninvasive ventilation (NIV) after thoracic surgery

Possible indications
Prevention of pulmonary dysfunction after lung resection
Treatment of respiratory failure (short term) after lung resection and lung transplant
Contraindications
CNS
Decreased level of consciousness
Severe agitation or encephalopathy
Uncooperative patient
Inability to protect airway
Cardiorespiratory
Cardiac or respiratory arrest
Cardiac instability
Severe respiratory failure
Copious secretions or hemoptysis
Gastrointestinal
Vomiting/gastric distension
Upper GI bleeding
Other
Facial trauma or other condition preventing facemask application (high-flow nasal cannula may be an option in this instance)
Multiple organ failure

Lung-Protective Ventilation

The principles of "lung-protective ventilation" discussed in Chap. 21 should be adhered to when a decision is made to continue or initiate mechanical ventilation in the postoperative period. If the patient is an appropriate candidate, NIV as described above should be seriously considered when a patient who has already been extubated requires oxygenation and/or ventilation assistance beyond what can be offered through facemask oxygen. If mechanical ventilation must be provided through a tracheal tube, appropriate levels of inspiratory pressure and PEEP should be selected. While many strong opinions exist regarding specific modes of ventilation, the ARDSnet trial (referred to below) demonstrated an outcome benefit in acute respiratory distress syndrome (ARDS) by employing tidal volumes of 5–8 ml/kg of predicted body weight using assist-control (volume cycled) ventilation and appropriate levels of PEEP. Either pressure or volume modes can be employed so long as delivered tidal volumes are in this range and airway pressures are not excessive. Pressure modes have the advantage of achieving a similar tidal volume with lower peak airway pressure; however, this has not been shown to translate into an outcome benefit. Table 54.8 summarizes the principles of lung-protective ventilation.

The many possible causes of postoperative respiratory failure have been discussed above. In some circumstances these inciting and predisposing factors can be resolved or compensated for by the patient in the first hours or day after surgery, as the acute stress of surgery subsides and effective analgesic techniques are in place. Mechanical ventilation can then be withdrawn rapidly and uneventfully. In other patients the interaction of preexisting functional and pulmonary status, surgical stress, and postoperative complications described above may lead to a more prolonged need for ventilatory assistance. In a small percentage of patients, acute lung injury (ALI) or acute respiratory distress syndrome (ARDS) may occur.

Table 54.8 Principles of "lung-protective" ventilation

Ventilator mode	Volume assist-control most often reported
Tidal volume (ml/kg of predicted body weight)	5–7 (lower is better)
Plateau pressure (cm of water)	<30
Ratio of duration of inspiration to expiration	1:1–1:3
Ventilator rate (breaths/min)	Set to achieve pH > 7.3
Bicarbonate infusion	As needed if pH goal cannot be achieved
Oxygenation goal	PaO_2 > 55 mmHg or SpO_2 > 88%
PEEP	As needed to achieve oxygenation goal (titrated upward with fiO_2)*

*See Ref. [138] for protocol describing incremental adjustments of fiO_2 and PEEP

Acute Respiratory Distress Syndrome

The Berlin criteria, published in 2012, outline the current standard for acute respiratory distress syndrome (ARDS) classification. In brief, the 2012 Berlin criteria describe ARDS as a state of increased pulmonary vascular permeability and loss of aerated lung tissue resulting from an acute, diffuse, and inflammatory lung injury. These updated guidelines differ from the previously accepted definition as delineated by the American-European consensus conference on ARDS by stratifying the severity of ARDS based on the arterial partial pressure of oxygen/fraction of inspired oxygen, or P/F ratio, and removing the designation of acute lung injury (ALI) [123, 124]. Specific requirements regarding timing, chest imaging, origin of edema and oxygenation, as well as differences from the previous guidelines are outlined in Table 54.9.

ARDS can be induced by direct insults to the lung such as aspiration of gastric contents, pulmonary infection, or contusion but is more commonly associated with indirect causes such as sepsis syndrome and severe trauma, pancreatitis, or massive transfusion. The latter causes are typically referred to as "extrapulmonary." Mortality implications are similar with direct pulmonary injury or extrapulmonary causes [125, 126]. It is uncommon to see the diffuse infiltrates that characterize ARDS immediately after surgery; such a finding on the postoperative radiograph is more likely to represent hydrostatic edema due to fluid overload or left-sided cardiac failure. Hydrostatic pulmonary edema may be radiographically indistinguishable from ARDS, at least in the early stages.

Direct injury to the lung as a result of surgery, or indirect effects from other organ system dysfunctions, trauma of surgery, or multiple transfusions may initiate the pathophysiology leading to ARDS in thoracic surgery patients. In a six-year review (1991–1997) of all pulmonary resections done at the Royal Brompton Hospital in London, England, the combined incidence of ALI and ARDS was 3.9%. The overall mortality from ARDS is approximately 50%, although recent data suggests a decline over the last 10 years; in the review from the Royal Brompton Hospital, ALI/ARDS was associated with 72.5% of the mortality [127]. Patients with the syndrome typically go on to have other organ dysfunctions, developing the multiple organ dysfunction syndrome or "MODS" [128]. In fact, most patients who succumb do so of non-respiratory organ failures [129]. The MODS syndrome occurs in approximately 15% of ICU patients and is responsible for 80% of ICU deaths [130]. Rather than the severity of gas exchange abnormality in ARDS, other patient-specific factors such as preexisting organ system dysfunction, increasing age, and the presence of sepsis are more predictive of mortality. As more systems become involved in the MODS, mortality increases exponentially. Patients who survive ARDS are likely to have relatively intact pulmonary function within 6–12 months, although health-related quality of life is reduced [131]. If the lung injury in ARDS does not resolve in 7–10 days, it may progress to fibrosis and finally to obliteration of the pulmonary capillary bed with pulmonary hypertension.

Therapy of ARDS

Despite more than 30 years of research into causes and treatment of ALI and ARDS, it remains a clinical syndrome with elusive etiology. A great deal of progress has been made in

Table 54.9 Definition of ARDS

	Berlin criteria (current)			AECC (previous)	
	Mild	Moderate	Severe	ALI	ARDS
Timing	Within 1 week of new or progressive respiratory symptoms with or without a known insult			Acute onset	
Oxygenation	200 mmHg < P/F < = 300 mmHg[a]	100 mmHg < P/F < = 200 mmHg[a]	P/F < = 100 mmHg[a]	P/F < 300 mmHg[b]	P/F < 200 mmHg[b]
Imaging	Bilateral opacities not otherwise explained by effusions, lobar/lung collapse, or nodules			Bilateral infiltrates on CXR	
Etiology of edema	Respiratory failure that cannot be fully explained by cardiac failure or fluid overload[c]			Not addressed	
Pulmonary artery wedge pressure	Removed from criteria			<18 mmHg or no evidence of elevated LAP	

Table 54.9 Comparison of previous vs. current criteria in the diagnosis of ARDS. Note that the Berlin criteria clarify onset period, no longer recognize ALI, have introduced more granularity when differentiating grade of ARDS, clarified imaging criteria, added a requirement for the etiology of pulmonary edema, and removed the requirement for a measured pulmonary artery wedge pressure measurement [123, 124]

ALI acute lung injury, *ARDS* acute respiratory distress syndrome, *AECC* American-European consensus conference, *P/F* ratio of arterial oxygen to inspired oxygen, *CXR* chest X-ray, *LAP* left atrial pressure, *PEEP* positive end-expiratory pressure

[a]With PEEP> = 5 cm H_2O

[b]Regardless of PEEP level

[c]Objective assessment preferred if no risk to patient

understanding the pathophysiology; however, the earliest events which trigger the inflammation and damage of lung tissue continue to be explored. Therapy targeting these early events, and pharmacotherapy in general, has been disappointing. A variety of pharmacological agents including prostaglandins, surfactant, inhaled nitric oxide (NO), and corticosteroids have failed to demonstrate an outcome benefit [132–135]. Current treatment of ARDS is therefore "supportive," attempting to provide vital organ support without further damaging the lungs and providing an environment for healing. As a pulmonary dilator, inhaled NO can reduce pulmonary artery pressure without causing systemic hypotension and improves oxygenation by augmenting blood flow to ventilated alveoli, but these benefits have failed to improve survival.

Mechanical Ventilation with PEEP

Perhaps one of the most surprising outcomes of the intense research into ARDS has been the gradual realization that the mainstay of therapy itself – mechanical ventilation – could worsen, and in some animal models actually *cause*, lung injury. More than 25 years ago, ventilation with high volumes and pressures was shown to cause pulmonary edema in animal models [136]. Further studies documented such injury in a variety of animal models and settings and in particular the worsening of existing injury with high volumes. Inflammatory markers are elevated when high volumes are used to ventilate patients with ARDS, and survival from the syndrome can be improved by using small (6–8 ml/kg vs 10–12 ml/kg) tidal volumes [137]. The "ARDSnet" trial funded by the National Heart, Lung, and Blood Institute in the United States, and performed by the "ARDS network" of institutions, documented a mortality reduction from almost 40% to 31% by simply using a smaller tidal volume to achieve a "plateau pressure" of <30 cm H_2O, in association with a protocolized strategy for FiO_2, PEEP, and management of acid-base disorders [138]. This approach to ventilation, as described above, has been termed "lung protective." An overview of the protocol is given in Table 54.8, and the full protocol can be found at HYPERLINK http://www.ardsnet.org www.ardsnet.org [138]. Evidence from this trial, other clinical and laboratory studies, and now a number of perioperative studies as described in Chap. 21 have resulted in a general move to the use of smaller tidal volumes in all ventilated patients, both in the OR and the ICU.

Collapse and re-expansion of alveoli with each respiratory cycle can cause injury, and this can be reduced or prevented by adequate levels of PEEP [139]. Determining the optimal level of PEEP has concerned clinicians for more than 25 years and continues to be a dilemma. In 1975 Suter et al. coined the phrase "best PEEP" in relating the PEEP level to oxygen delivery to the tissues [140]. These investigators found that although increasing levels of PEEP usually resulted in better oxygenation of the arterial blood, as the intrathoracic pressure rose above a certain level, the cardiac output and hence oxygen delivery declined. In recent years, while taking this latter concept into consideration, there has been a greater interest in finding the level of PEEP that keeps the most alveoli open, ventilating only on the compliant portion of the pressure-volume relationship of the lung. The theoretical goal is to use adequate PEEP such that ventilation occurs above the "lower inflection point" of the pressure-volume relationship as shown in Fig. 54.9, which may prevent potentially traumatic repeated closing and opening of alveoli in atelectatic areas of the lung. At the same time, a tidal volume that inflates to below the upper inflection point should be employed, preventing trauma from overdistension [141]. This requires some measure of the pressure-volume relationship which may not always be possible. In a follow-up study to the ARDSnet trial, a randomized trial of lower vs. higher PEEP was performed. In this study the PEEP was increased more rapidly in the high PEEP group, usually exceeding 12 cm H_2O; there was no influence in outcome [142]. A more recent meta-analysis suggests that higher PEEP (>10 cm H_2O) may provide a small benefit, especially when lung injury is more severe [143]. It may be that higher levels are most useful in patients where there is a clear beneficial effect in terms of improved oxygenation and compliance.

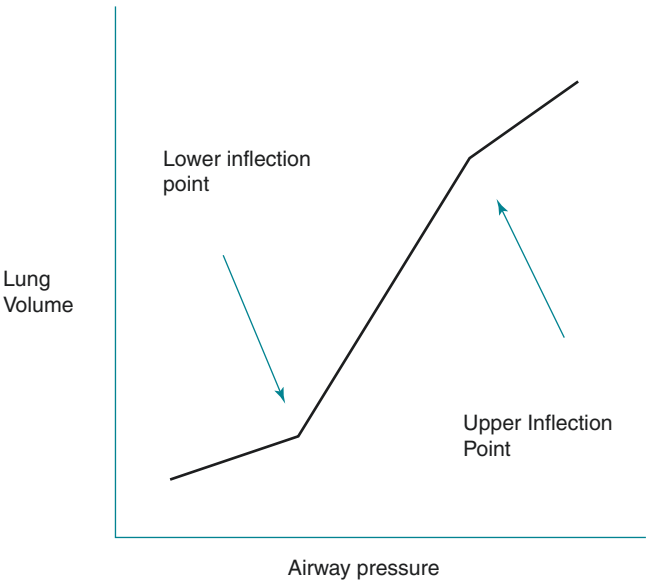

Fig. 54.9 Inspiratory pressure-volume relationship of the respiratory system in a patient with ARDS. Ideally ventilation should occur at a lung volume represented by the middle section of the curve where the lung is most compliant. If ventilation occurs at a lung volume overlapping either the lower inflection point or upper inflection point, ventilator-induced trauma may occur. In the former case, this is due to repeated opening and closing of alveoli due to inadequate level of PEEP; in the latter it is overdistending of already fully inflated alveoli

As the practice of using reduced tidal volumes has increased, two clinical problems have become apparent. The first is the need for high respiratory rates to achieve normal arterial CO_2 levels and sometimes failing to achieve the latter. The phrase "permissive hypercapnia" has been coined, meaning that a higher than normal CO_2 level is tolerated in order to protect the lung from high tidal volume ventilation [144]. Either the respiratory acidosis is tolerated or a bicarbonate infusion can be used to restore the pH toward normal. In the ARDSnet trial, a pH of 7.30 was tolerated; in other studies even lower levels have been accepted. The second problem is that despite relatively high PEEP levels, the use of small tidal volumes may result in gradual collapse of alveoli and worsened oxygenation. This has led to the investigation of "recruitment" maneuvers such as intermittent application of high levels of airway pressure, analogous to the old concept of sighs. There is some data to suggest such recruitment maneuvers can improve oxygenation in ARDS and potentially decrease ICU mortality. However, there is no effect on in-hospital and 28-day mortality [145, 146].

Positive intrathoracic pressure may have an impact on cardiac performance. With relatively compliant lungs, positive pressure created by the ventilator is transmitted to the entire thoracic cavity and may affect the preload and afterload to the heart. If cardiac function is normal, the predominant effect is a reduction in venous return leading to a decrease in cardiac output. As discussed above, "best PEEP" is the level at which the increase in oxygenation of the blood was not offset by a reduction in cardiac output [140]. Where there is left ventricular dysfunction and elevated filling pressure, the reduction in preload may reduce ventricular distension and improve cardiac performance. In addition, making the intrathoracic cavity positive with respect to the rest of the body reduces the afterload to the left ventricle (Fig. 54.10) [147].

Right ventricular function may be adversely affected by high levels of PEEP (e.g., >10 cm H_2O). The right ventricle is a thin-walled cavity that normally generates relatively low pressures (e.g., 25 mm Hg systolic). High levels of PEEP required to oxygenate the blood may increase the impedance to right ventricular ejection, causing right ventricular dilatation and a decrease in contractility [148]. In patients who have undergone pulmonary resection, in particular pneumonectomy, the right ventricle is already "stressed" by needing to pump the normal cardiac output through a reduced pulmonary vascular tree. Overdistension of the right ventricle may distort the interventricular septum, interfering with left ventricular filling [149]. In centers with appropriate experience

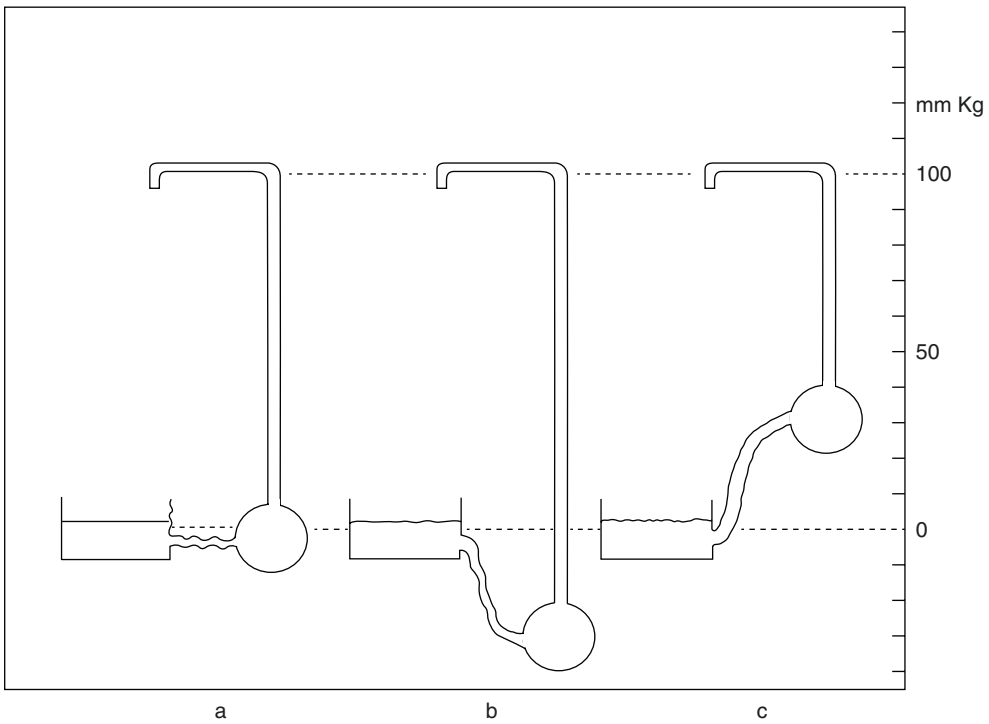

Fig. 54.10 Diagrammatic representation of the effects of respiratory-induced changes in pleural pressure on right ventricular inflow and left ventricular outflow. At end-expiration (**a**) the venous reservoir empties at normal pressure into the heart which generates normal systemic pressure. With deep inspiration (**b**) venous inflow is augmented because the intrathoracic pressure (location of the heart) is made negative; at the same time, the heart must generate a higher pressure to achieve a normal systemic pressure outside of the thorax. During expiration (**c**) venous inflow is reduced at the same time as left ventricular afterload is reduced. This illustrates the mechanism of the beneficial effects of positive intrathoracic pressure (positive-pressure ventilation, PEEP) in patients with heart failure

and expertise, echocardiographic assessment of ventricular function, pulmonary artery catheterization, or cardiac output measurement by "stand-alone" devices may be useful to determine the effect of mechanical ventilation on cardiac performance.

Another undesirable feature of positive-pressure ventilation is the creation or worsening of "autoPEEP," where partially obstructed airways prevent complete emptying of the alveoli during expiration. This results in continued gas flow and airway pressure above baseline (i.e., atmospheric or applied level of PEEP) at the end of expiration. Application of additional PEEP can "match" the autoPEEP and reduce the patient effort required to initiate a spontaneous breath or trigger a machine breath. If, however, a rapid respiratory rate is set on the ventilator and/or lung pathology causes reduced expiratory flow rates not permitting the lung to fully empty with expiration, autoPEEP is worsened with positive-pressure ventilation.

Prone Position

In 1974, Bryan proposed the dorsal regions of the lung would receive improved ventilation in the prone position during mechanical ventilation [150]. Since that time a variety of publications have demonstrated his theory correct. Both animal and human studies have demonstrated improved matching of ventilation to perfusion, as well as overall better distribution of blood flow and transpleural pressures gradients [151, 152]. An elegant study demonstrated the dramatic effects of prone positioning on regional lung density with serial CT scanning [153]. Previously, the majority of studies, including meta-analyses of the prone position in the setting of ALI and ARDS, demonstrated an improvement in oxygenation, a reduction in ventilator-associated pneumonia but no effect on survival [154]. However, the PROSEVA study group published a randomized controlled trial in 2013 showing a significant reduction in 28-day and 90-day mortality when prone positioning was applied within 36 h of diagnosis and for a minimum of 12–18 h daily in the subset of patients classified as having severe ARDS [155]. While this data is promising, it's generalizability to the post-surgical population is unclear, and for the subset of patients with recent sternotomy or abdominal incisions, its use is contraindicated [156].

Alternate Modes of Ventilation

A variety of modes of ventilation including inverse ratio (where inspiration is longer than expiration), airway pressure release ventilation (APRV, spontaneous breathing at high airway pressure, with intermittent release), high-frequency oscillatory ventilation (HFOV, very small tidal volume and high frequency), and high-frequency percussive ventilation (HFPV, high-frequency "stacking" breaths resulting in lower-frequency convective breaths) have been described and evaluated in small clinical studies. Inverse ratio ventilation and APRV are modes available on commercial ventilators; HFOV and HFPV require specialized ventilators. All of these modes have been used to improve oxygenation and/or ventilation, and with the exception of HFOV, there is a paucity of outcome studies [157]. The OSCILLATE [158] and OSCAR [159] trials were randomized controlled studies investigating some preliminary data suggesting the early use of HFOV may prove beneficial in ALI/ARDS. The OSCAR trial showed no mortality benefit, and the OSCILLATE trial showed a trend toward harm that led to its early termination.

Inhaled Pulmonary Vasodilators

As mentioned above, early trials of inhaled nitric oxide and prostaglandins failed to demonstrate an outcome benefit in adults with ARDS from a variety of causes. A few reports of the use of inhaled milrinone exist but not in the context of prolonged use for ARDS. Despite the lack of benefit found in early trials, clinicians, anxious to find benefit, have continued to use and study these agents as they do usually result in at least a transient improvement in oxygenation and may provide "temporization" before starting more invasive treatment such as ECMO. Unfortunately, however, recent meta-analyses continue to demonstrate a lack of benefit and now suggest possibly an increased risk of renal impairment with nitric oxide [160] and systemic hypotension with inhaled prostaglandin [161].

Extracorporeal Membrane Oxygenation (ECMO)

Experience with extracorporeal membrane oxygenation in adults, as reported by the Extracorporeal Life Support Organization (ELSO), has resulted in a renewed interest in this mode of therapy for ARDS. In their 2008 registry report, survival to hospital discharge or transfer in adults where ECMO was initiated for respiratory failure was an impressive 51%; the latest data from the same registry shows 66% survived ECMO and 59% survived to discharge or transfer [162]. Similarly, in a report of 22 patients receiving ECMO for primary graft dysfunction after lung transplantation, the survival was 54% at 1 year [163]. The use of ECMO in severe respiratory failure has increased significantly since 2010 asa result of the publication of two large trials in 2009, and improvements in the circuitry, oxygenators and nonpulsatile pumps. These trials demonstrated positive results with ARDS due to viral pneumonia [164] and in a broader group of patients with ARDS transported to a specialty center for treatment [165]. It has been suggested that patients with a potentially reversible cause of respiratory failure and a P/F ratio of <100 should be referred to an ECMO center, and when

this ratio drops below 70, this should be considered an indication to institute ECMO [166].

The greatest use of ECMO in thoracic surgery patients is for the lung transplant population. In patients awaiting transplantation but whose end-stage lung disease is not compatible with adequate ventilation or oxygenation, ECMO can provide life support until donor lungs are available. Intraoperatively, in patients who cannot tolerate one-lung anesthesia or the surgical manipulations preparing for implantation of new lungs, ECMO is now a well-established supportive therapy. For those patients with donor lung dysfunction (most commonly PGD, described above), postoperative ECMO support can be employed until the donor lungs have recovered adequately to support respiration.

For other thoracic surgery patients developing severe postoperative respiratory failure and ARDS, the role of ECMO is less well established with very little supportive literature. Nevertheless if patients are failing conventional ventilator support as described above and appear to be appropriate candidates for ECMO, this form of treatment should be considered. The reader is referred to Chap. 55 for a more detailed consideration of ECMO therapy.

Complications of Mechanical Ventilation

Trauma to the Lungs or Tracheobronchial Tree

Damage to the lung parenchyma as a consequence of mechanical ventilation is discussed above. In thoracic surgery patients, the potential risk of suture line or bronchial stump disruption as a result of positive airway pressure has also been referred to. Suture line disruption can cause catastrophic pneumothorax or respiratory failure or may result in chronic air leak, bronchopleural fistula, and infection. Avoidance of intubation and positive-pressure ventilation are certainly desirable, but not always possible. As discussed above a trial of HFNC when appropriate, the use of pressure-limited modes of ventilation and the use of small tidal volumes if volume-controlled modes are used may help avoid high pressures. Auriant et al. suggested that noninvasive ventilation could reduce the mortality in acute respiratory failure after pneumonectomy [167].

Ventilator-Associated Pneumonia

One of the most serious complications associated with mechanical ventilation is pneumonia. Ventilator-associated pneumonia (VAP) is defined as pneumonia developing >48 h after initiating mechanical ventilation with absence prior to intubation. The reported incidence varies from 8 to 28% of patients receiving mechanical ventilation for more than 48 h, which is approximately three- to tenfold the incidence of pneumonia in non-intubated hospitalized patients [168–171]. Current reporting techniques use the relationship between number of ventilator days and incidence of pneumonia, with surgical units experiencing 9–10 pneumonias per 1000 ventilator days [172]. The mortality is reported from 24% to 50% and can be up to 76% in specific settings with high-risk pathogens. Resistant organisms comprise an ever-increasing proportion of hospital-acquired infections, including VAP [173].

Diagnosis

VAP should be suspected when there is a new or changing infiltrate on chest X-ray and at least two of the following criteria: abnormal temperature (>38 °C or <36 °C), abnormal white blood cell count (>10,000, <4000, or with >10% immature cells), and purulent sputum [174]. The 2016 IDSA guidelines recommend noninvasive sampling, such as endotracheal aspiration, with semiquantitative cultures over quantitative cultures of either invasive sampling, such as bronchoalveolar lavage (BAL), protected specimen brush, and mini-BAL or noninvasive sampling. It is however a weak recommendation that would require extensive discussion among all interested parties in a given institution [175].

Most important is the early initiation of appropriate institution-based empiric broad-spectrum antibiotics. Failure to adequately treat, from the earliest possible opportunity, is associated with worsened outcome. The presence of resistant organisms in the institution or specific ICU determines which agents should be chosen at the outset.

Prevention

Prevention of VAP is a priority in modern intensive care. This has given rise to the concept of the ventilator or VAP "bundle" – a variety of care processes either known or believed to reduce the risk of acquiring VAP [176]. These measures include elevation of the head of the bed to 30 degrees to reduce aspiration risk, oral rinse with antiseptic solution to reduce bacterial load, daily withdrawal of sedation, and daily spontaneous breathing trials to facilitate removal of the endotracheal tube. Prophylaxis for stress ulcers and deep venous thrombosis are often included in the "bundle." Continuous aspiration of subglottic secretions (CASS) has been evaluated with the goal of preventing aspiration. CASS requires a specialized ETT with a second lumen allowing a suction catheter proximal to the endotracheal tube cuff. Bouza et al. were able to demonstrate a reduction in VAP in patients treated with CASS [177]. Coating an endotracheal tube with silver has also been investigated and is theoretically attractive because of silver's

broad-spectrum antimicrobial activity. An investigation by Kollef et al. with silver-coated endotracheal tubes was able to demonstrate a reduction in the incidence of VAP [178].

Withdrawal of Mechanical Ventilation

Many factors play into the decision to withdraw ventilatory support, the first being adequate control or resolution of the condition which lead to the need for ventilation. In the postoperative thoracic surgery patient, this may simply be correction of acute issues such as pain control, fluid status, and temperature. If gas exchange has been the principal issue, then ability of the patient to achieve acceptable pH, pCO_2, and pO_2 or saturation must be assessed. In general, the need for positive-pressure ventilation with more than 50% oxygen and/or 5–8 cm H_2O of PEEP to obtain a paO_2 of 60 mmHg or saturation of >90% suggests that oxygenation will not be adequate without ventilatory support. Similarly, elevated pCO_2 in association with decreased pH suggests either oversedation or inadequate ventilatory capacity. Medical problems that may contribute to respiratory failure (e.g., heart failure) should be stable or controlled, and the patient should be responsive and able to clear secretions. Requirement for frequent (e.g., more than every 2 h) suctioning, fever, or significant inotropic or vasopressor therapy all suggests the patient may not be ready for withdrawal of respiratory support. Once these considerations have been addressed, a "physiological" assessment needs to be performed to see if the patient is able to breathe spontaneously without distress. The most common of these is the "rapid shallow breathing index" where the patient is allowed to breathe without support for a few minutes and the index is computed by dividing the breathing frequency by the tidal volume. An index of >100 strongly predicts failure of a longer duration spontaneous breathing trial (SBT); a value of less than this does not necessarily predict success [179].

Analogous to the startling revelation that a relatively modest change in ventilator management (reduced tidal volume with adequate PEEP) leads to improved survival in ARDS, performing a 30–120 min SBT on appropriate patients through a "T-piece" or with low-level CPAP and/or pressure support identifies a large number of patients who are ready to be extubated. Two large trials indicated that clinicians did not recognize that discontinuing support would be possible in more than 2/3 of the patients who were successfully identified with an SBT [180, 181]. These studies found that a SBT reduced the duration of mechanical ventilation when compared to other techniques such as gradual withdrawal of IMV or pressure support. The report of a consensus meeting suggested that a 30–120 min SBT is the "major diagnostic test to determine whether patients can be successfully extubated" [182]. Psychological support, encouragement, and physical presence of a caregiver at the bedside for at least the early part of the trial are essential. Criteria for performing an SBT are summarized in Table 54.10.

Table 54.10 The spontaneous breathing trial

Indication: Daily assessment of readiness to separate from mechanical ventilation
Criteria to perform
At least partial resolution of underlying condition(s) leading to respiratory failure
Conventional ventilation mode (volume or pressure)
Absence of respiratory distress
Sedation infusions withdrawn (daily withdrawal) and patient responsive
No CNS contraindications (e.g., elevated intracranial pressure)
SpO2 > 88% with fiO_2 < 0.5 and PEEP < 8
Minimal cardiovascular support (e.g., inotropes/pressors) not increasing
Rapid shallow breathing index (RSBI) < 100[a] in first minutes of trial
Criteria for failure
Clinical
Change in mental status, usually agitation/anxiety
Visible distress such as diaphoresis, increasing effort
Objective
Decreasing SpO_2 (below 88%) or increasing end-tidal CO_2
Increasing tachypnea (>35 breaths/min)
Increasing tachycardia (>140/min) or other dysrhythmia and/or hypertension
RSBI[a] increasing to >100
Blood gas if drawn with SaO_2 < 88%; $PaCO_2$ > 10 mm above baseline and pH < 7.32

[a]Respiratory rate (breaths/min) divided by tidal volume (in liters), with no support or 5 cm pressure support/5 cm PEEP)

Spontaneous breathing trials also identify patients who are *not* ready for withdrawal of ventilator support; Table 54.10 lists criteria for failure of a SBT. Of those patients who fail an initial trial, most will eventually succeed in the following week. A daily SBT identifies these patients. There will be a small percentage of patients who require prolonged care and possibly require transfer to a "weaning facility" or "long-term acute care" (LTAC) facility. When a patient fails an SBT, the reasons for failure need to be carefully examined. They may include inadequate resolution of the primary or underlying problem, weakness (e.g., nutritional depletion), or inadequate recovery from sedation to name a few. Between SBTs, patients should be supported with a mode of ventilation, which requires spontaneous but non-fatiguing efforts by the patient as atrophy and weakness of respiratory muscles develop within less than 24 h of complete ventilatory rest [183]. Malnutrition is increasingly recognized as a contributor to weakness in ventilated patients, and some form of nutrition needs to be addressed in the patient who requires mechanical ventilation for more than a few days.

Daily interruptions of sedative infusions decrease the duration of mechanical ventilation [184]. This is best accomplished by use of a sedation protocol, which has also been shown to reduce the duration of mechanical ventilation [185–187]. A significant issue in the ventilated patient is delirium, which is multifactorial (e.g., pain, sleep deprivation, polypharmacy) and may be associated more with benzodiazepines than other sedative drugs. When it occurs, delirium is associated with significantly worsened outcome [188].

Extubation

Separate from weaning and the requirement for ventilatory assistance, readiness for extubation requires its own assessment. The patient must be awake and cooperative, able to cough and clear secretions, and the airway must be patent. In a study by Khamiees et al., poor cough strength and increased amounts of respiratory secretions were synergistic in predicting extubation failure [189]. While there is no perfect way of assessing airway patency, a "cuff-leak" test can be performed in a subjective or objective manner. For the former, the clinician simply deflates the cuff on the tube and listens for audible air leak during either spontaneous breathing or with positive-pressure ventilation. Absence of an audible leak suggests airway edema and the potential for post-extubation obstruction. This is more likely with prolonged intubation, trauma, obesity, or female gender [190]. The test can be quantified by measuring the volume lost during volume-controlled ventilation although another group of investigators did not find the test useful in surgical patients [191, 192]. If a cuff test of any kind suggests minimal or absent air leak, but a decision is made to proceed with extubation, a "tube changer" should be used to allow urgent reintubation.

Tracheotomy

When the period of mechanical ventilation is likely to be more than 7–10 days, there are several reasons why tracheotomy is a favored approach. First and possibly most important, it allows for a greater degree of comfort by removing the transoral or transnasal tube and associated holding device or tape. This alone can result in a reduced need for sedation. By introducing a permanent path into the airway, the need for physical restraint is reduced, and the patient can be mobilized (e.g., to a chair) with less risk and greater ease. The patient may be able to swallow liquid or solid food at an earlier stage and may be able to speak during periods when they are off the ventilator (with the use of a one-way "Passy-Muir" valve). Replacement of the relatively long transoral or transnasal tube with a much shorter tracheotomy tube reduces the imposed airways resistance and facilitates removal of secretions [193]. In patients projected to need ventilation >2 weeks, Rumbak et al. demonstrated early tracheotomy resulted in lower mortality, fewer cases of VAP, fewer accidental extubations, and less time spent on mechanical ventilation than a late tracheotomy strategy [194]. A recent study failed to demonstrate a benefit in terms of VAP with early tracheotomy performed at 6–8 days vs. later tracheotomy at 13–15 days; other trials have failed to demonstrate a benefit in terms of speed of weaning [195]. In the thoracic surgery patient, the surgeon may prefer to perform his/her own surgical tracheotomy in the operating room; however, there are now many studies attesting to the safety and cost savings of bedside percutaneous tracheotomy [196, 197]. In many of these studies, intensivists performed the tracheotomy in medical ICUs.

Clinical Case Discussion

A 65-year-old male is in the postanesthesia care unit (PACU) after undergoing open right upper lobectomy for squamous cell carcinoma. He has a long history of smoking, and his preoperative room air saturation was 91%. He is tachypneic, slightly lethargic, and complaining of pain; his peripheral saturation reading is 88%, and he is receiving 100% oxygen by face mask. His blood pressure is 160/100 and heart rate 105/min.

Questions

1. What are the likely diagnoses?
2. Which (if any) diagnostic tests should be obtained?
3. Which treatment modalities should be employed, and in what order?

Answers

1. Residual neuromuscular blockade, pain with splinting and resultant low tidal volume, and mechanical complications such as pneumothorax or lobar atelectasis are all possibilities, alone or in combination. Pulmonary edema as a result of cardiac disease and/or volume overload is also possible.
2. Objective assessment of neuromuscular function should be made. The lungs should be auscultated, and a portable chest radiograph should be obtained to determine if edema or a mechanical problem is present. An arterial blood gas (ABG) should be obtained to determine pCO_2 and pH.

3. Application of HFNC, CPAP, or BIPAP may acutely relieve respiratory distress and improve oxygenation if the patient is cooperative. An inhaled bronchodilator may be indicated if the patient is known to have a response and/or if rhonchi or wheezing are audible. Treatment of pain may be important but may also reduce respiratory drive. Appropriate intervention should be made for a mechanical problem.

The chest radiograph demonstrates partial collapse of the right lower lobe, and the patient becomes agitated with the application of BIPAP. The blood pressure is now 180/110, and the saturation remains between 85 and 90%. The ABG shows a pO_2 of 55 mmHg, pCO_2 of 60 mmHg, and pH of 7.25.

Question

1. What should be done now?

Answer

1. The blood gas confirms a diagnosis of respiratory failure of both oxygenation and ventilation. Lobar atelectasis may be resolved with vigorous coughing and "physiotherapy" maneuvers such as percussion, postural drainage, and positive-pressure breathing; however, in this acute setting of an agitated patient unable to tolerate noninvasive positive pressure, most likely intubation is required. In addition, early postoperative lobar atelectasis may be due to retained secretions and is an indication for fiber-optic bronchoscopy. In this patient bronchoscopy will require intubation.

The patient is intubated uneventfully, and bronchoscopy is performed where significant tenacious secretions are aspirated from the right bronchus intermedius. The arterial saturation rises to 95% on 100% fiO_2.

Questions

1. What ventilator settings should be used?
2. Should the patient be prepared for extubation?
3. Should broad-spectrum antibiotics be employed?

Answers

1. This patient is at risk for ventilator-induced lung injury due to underlying disease, pulmonary surgery, and now a postoperative pulmonary complication (see Chapter [Denham Ward]). He should be managed with a lung-protective strategy which includes appropriate PEEP (usually 5–10 cm H_2O) and a tidal volume of 5–7 ml/kg of predicted body weight. The goal is a "plateau" pressure of 30 cm H_2O or less. Ideally a ventilator mode which allows spontaneous efforts should be used. As lobar atelectasis was present before the bronchoscopy, a "recruitment maneuver" should be considered.
2. Assessment for ventilator wean and extubation is a clinical judgment based on a variety of factors. If the patient is easy to ventilate and oxygenate and appears otherwise well-recovered from the complication, then sedation may be withdrawn, a physiologic assessment for rapid shallow breathing made, and a spontaneous breathing trial (SBT) performed. As the patient has a peripheral saturation of only 95% on 100% oxygen, it is more likely he will need a period of positive-pressure ventilation with PEEP before meeting oxygenation requirements for an SBT.
3. If the patient was not hospitalized before surgery, then the likely pathogens in his sputum are "community acquired." The local experience will dictate which antibiotic should be considered, in addition to or instead of the usual surgical prophylaxis. If the patient is an inpatient or was recently hospitalized, then antibiotics appropriate for the hospital experience (such as vancomycin for methicillin-resistant *Staphylococcus aureus*) should be considered. Pneumonia, and especially ventilator-associated pneumonia (VAP), is associated with a high mortality, but there are no data regarding the administration of "prophylactic" antibiotics in a situation such as this. It may be more prudent to obtain a lower airway sample for culture, stay with the usual perioperative prophylaxis, and initiate appropriate antibiotics if a pulmonary infection appears to be developing.

Postoperative Management of Respiratory Failure: Extracorporeal Ventilatory Therapy

55

Vera von Dossow, Maria Deja, Bernhard Zwissler, and Claudia Spies

Abbreviations

ACT	Activated clotting time
aPTT	Activated partial thromboplastin time
ARDS	Acute respiratory distress syndrome
BIPAP	Bi-level positive airway pressure
CO	Cardiac output
CO_2	Carbon dioxide
CPAP	Continuous positive airway pressure
DLB	Double-lumen single bicaval cannula
$ECCO_2R$	Extracorporeal carbon dioxide removal
ECMO	Extracorporeal membrane oxygenation
F_IO_2	Inspiratory oxygen concentration
HFOV	High-frequency oscillation ventilation
HITT	Heparin-induced thrombocytopenia
LV	Left ventricular
PALI	Post-thoracotomy acute lung injury
PBW	Predicted body weight
PEEP	Positive end-expiratory pressure
PMP	Polymethylpentene
RAS	Renin-angiotensin system
RV	Right ventricular
VA	Veno-arterial
VJI	Vena jugularis interna
VV	Veno-venous

Key Points

- The use of extracorporeal ventilatory support in patients with ARDS after thoracic surgery requires an interdisciplinary approach.
- In case of severe postoperative ARDS (paO_2/F_IO_2 <80 mmHg), ECMO therapy is appropriate if the organ failure is thought to be reversible with therapy and rest during ECMO.
- In case of partial respiratory support with severe hypercapnia ($PaCO_2$ ≥70 mmHg) and the need of high peak pressures, $ECCO_2R$ technique might be indicated to allow the institution of ultra-protective lung ventilation strategies.
- The concept of "awake ECMO" should be the first choice in order to detect early neurological deficits.
- Early spontaneous breathing is considered desirable as it is known to facilitate reduction of airway pressures.

Introduction

Thoracic surgery represents a challenge for anesthesia and requires a high level of human and material resources. Therefore, accurate knowledge of the pathophysiology is essential not only for the intraoperative management but also for the postoperative follow-up care [1]. Perioperative complications can have a relevant effect on patient outcome. Despite major advances in thoracic surgery, the anesthetic management as well as postoperative care, post-thoracotomy acute lung injury (PALI) is responsible for the vast majority of respiratory-related deaths after thoracic surgery [2]. This might be associated with severe hypoxemia and/or severe hypercapnia. The clinical presentation is an acute respiratory distress syndrome (ARDS)

according to the Berlin definition in 2012 [3], which includes an acute onset of symptoms within 1 week, changing of the PaO_2/F_IO_2 ratio to require a specific minimum amount of positive end-expiratory pressure (PEEP), a classification into three degrees (mild [200–300], moderate [<200], severe [<100]) depending on the PaO_2/F_IO_2 ratio, and infiltrates on the chest radiograph. It is well-known that patients undergoing thoracic surgery have a higher risk for developing postoperative ARDS compared with other types of surgery [2]. The incidence rate of post-thoracotomy ARDS is 4–14% in patients undergoing lung resection [4–6]. Mortality rates range from 1% to 3% after lobectomy and from 4% to 9% after pneumonectomy [6]. Nosocomial pneumonia, post-perfusion lung, and post-pneumonectomy pulmonary edema are the most frequent complications with the clinical presentation of ARDS [6]. The pathogenesis of ARDS implies a multiple-hit sequence of various triggering factors, which results in endothelial inflammatory response (e.g., oxidative stress and surgery-induced inflammation). Currently, the renin-angiotensin system (RAS) has been highlighted and is thought to contribute to the increased vascular permeability. Angiotensin-converting enzyme (ACE) is a key enzyme of the RAS that converts inactive angiotensin I to the vasoactive angiotensin II. ACE has been found on the surface of lung endothelial cells. Angiotensin II is a potent fibrogenic factor [7, 8]. In addition the endothelial glycocalyx as an integral part of the vascular endothelium of the alveolo-capillary membrane seems to play a major role of acute lung injury with the clinical manifestation of inflammation, capillary leak, and edema formation. Experimental data demonstrated rapidly induced degradation, pulmonary endothelial glycocalyx degradation, and an activation of endothelial heparanase as well as activation of endothelial adhesion molecules and increased adhesion of neutrophils after endotoxinemia [9]. Fluid overload, ischemia-reperfusion injury, and TRALI are important trigger factors for degradation of pulmonary endothelial glycocalyx in the pathogenesis of ARDS in patients after thoracic surgery [2]. The clinical manifestation is inflammation, capillary leak, and edema formation. Furthermore, breakdown of endothelial glycocalyx in the context of one-lung ventilation is known to be one major risk factor of PALI. Therefore, the knowledge of these risk factors and understanding of the mechanisms of post-thoracotomy ARDS enable anesthesiologists to implement lung-"protective" ventilatory strategies in thoracic surgery.

In addition, ruptures or fistulas of the bronchial tree after pulmonary surgery are reported with an incidence of 1.5–28% [10]. Inflammatory diseases seem to be an important risk factor for the development of bronchial fistulas [10]. Mechanically ventilated patients with bronchopleural fistulas and the clinical presentation of ARDS with the need of positive-pressure ventilation are at a considerable risk of compromising surgical repair and of increased mortality [11]. This underlines the importance of lung-"protective" ventilation strategies as a major goal in these high-risk patients.

In case that lung-"protective" ventilation strategy is not successful, extracorporeal ventilator therapy, the concept of so-called lung rest might be indicated. This chapter provides a summary of the available different options of extracorporeal ventilatory therapy and cannulation techniques for short-term support of adult patients with post-thoracotomy ARDS.

Lung-Protective Ventilatory Strategies

Lung-Protective Ventilation

The lung-"protective" ventilatory strategy includes the use of low tidal volumes, positive expiratory pressure (PEEP), and limitation of the maximum inspiratory pressure [12, 13] which has a tremendous impact on outcome: The lower the level of maximum inspiratory pressure, the better the patient's outcome [12]. According to the American Thoracic Society Guidelines (2017), mechanical ventilation strategies include a limitation of tidal volumes (4–8 ml/kg predicted body weight (PBW)) and inspiratory pressures (plateau pressure $\leq$ 30 cm H_2O). Low-tidal-volume ventilation might reduce the relative risk of death [14]. In addition, the driving pressure (ΔP = plateau pressure – PEEP) has been demonstrated to be a better outcome predictor in ARDS patients than tidal volume or plateau pressure [15, 16].

Extracorporeal Ventilatory Therapy in ARDS Patients

Despite the increasing applications of extracorporeal ventilatory therapy in ARDS patients, there is still limited evidence supporting its use [14]. This is based on recent published studies that compared treatment of ARDS patients with and without extracorporeal ventilatory therapy and did not find significant differences in mortality [14, 17]. Therefore, additional evidence is necessary to define a clear and consistent recommendation for extracorporeal ventilatory therapy in patients with ARDS.

In contrast to the abovementioned guideline recommendation, the first reported successful extracorporeal membrane oxygenation (ECMO) use was in a 24-year-old man supported on veno-arterial (VA) ECMO therapy for 75 h with severe ARDS and aortic repair due to a motorcycle accident. This case was reported by Hill et al. 1972 and includes the concept of "lung rest" reducing peak airway

pressures from 60 cm H_2O to 35–40 cm H_2O [18, 19]. In contrast, the authors of the following NIH adult ECMO study concluded that ECMO therapy can support gas exchange but did not increase the probability of long-term survival in patients with severe ARDS [20, 21]. Several major limitations of this study were a prolonged ventilation prior ECMO therapy (mean of 9.6 days) with high tidal volumes indicating already damaged lungs and the use of VA ECMO in all patients with the need of full heparinization. Therefore the concept of "lung rest" with ECMO as an effective strategy to support adult patients with ARDS was not appreciated. In addition, this study did not represent modern practice of ECMO therapy such as veno-venous (VV) ECMO, low-dose or even no heparinization, ultra-protective ventilation with extracorporeal carbon dioxide (CO_2) removal ($ECCO_2R$), as well as the concept of "spontaneous breathing and awake ECMO" [13, 17, 22–27].

Separation of Ventilation and Oxygenation (Concept "Lung Rest")

ARDS patients with severe hypoxemia usually require high PEEP levels which might be associated with limited CO_2 elimination. Therefore, ultra-protective ventilation strategies are impossible due to severe hypercapnia. The clinical consequence is systemic and cerebral vasodilatation, cardiovascular depression, arrhythmia, and pulmonary vasoconstriction with an increase in pulmonary arterial pressure. Acute pulmonary hypertension is associated with increases in RV afterload and subsequent acute cor pulmonale which is associated with an increased mortality [28, 29].

This means that, in such situations of severe hypoxemia and/or hypercapnia, patients are at high risk of death due to lack of response to conservative treatment. Therefore, ECMO therapy is indicated if the disease is potentially reversible. Different kinds of extracorporeal ventilator support are available: Whereas VV ECMO predominantly is used for patients with refractory hypoxia, the extracorporeal CO_2 removal ($ECCO_2R$ or pumpless interventional lung assist (iLA); see Fig. 55.1) allows ultra-protective ventilation technique in case of severe hypercapnia and acidosis [30]. The decoupling of ventilation and oxygenation allows for several ventilation strategies: All strategies have sufficient PEEP level in common to achieve an almost complete recruitment of the lung at minimal pressure amplitude. Whether continuous positive airway pressure (CPAP) with spontaneous breathing, bi-level positive airway pressure (BIPAP) with a low respiratory frequency and a reduced peak airway pressure, or high-frequency oscillation ventilation (HFOV) is applied should be decided for each individual case [27].

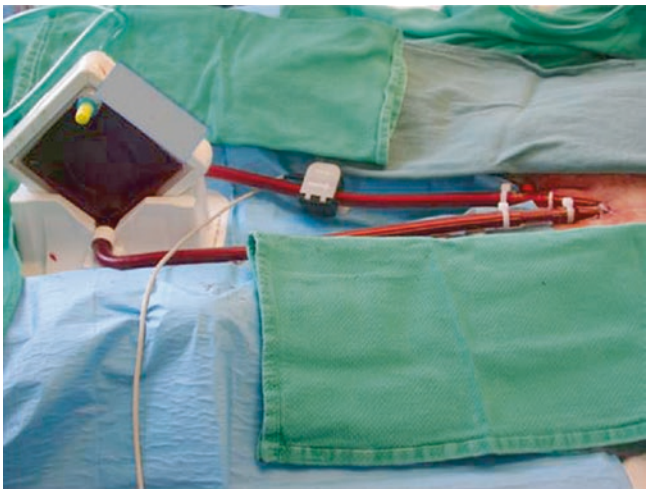

Fig. 55.1 The iLA device is shown between a patient's legs during placement with femoral cannulations. The patient's body is to the right, out of the photograph. The inflow to the device is from the femoral artery (near cannula), and the return is via the femoral vein (far cannula)

Extracorporeal Membrane Oxygenation (ECMO)

Indications

The most frequent causes of hypoxemia and/or hypercapnia after thoracic surgery refractory to conventional lung-"protective" ventilatory and medical treatment include:

- Nosocomial infection
- Post-pneumonectomy edema
- Post-perfusion edema
- Primary graft failure (lung transplantation)
- Bronchopleural fistula: Most cases of bronchopleural fistulas occur early after surgery are difficult to treat and are associated with a high mortality [31]. Achieving adequate ventilation is often difficult in these patients, particularly if single-lung ventilation has to be achieved [11]. Differential ventilation using a double-lumen endotracheal tube and jet ventilation has been the traditional options. VV ECMO is an alternative therapeutic option as bridge for successful surgical repair of bronchopleural fistulas.
- Tracheal resection: Use of ECMO allows rapid weaning of the patient from the ventilator.

The institution of ECMO is appropriate if the organ failure is thought to be reversible with the concept of "lung rest" on ECMO (see Table 55.1). If underlying lung pathology does not recover, ECMO might be instituted as bridging for transplant [34].

Contraindications to ECMO therapy may include premorbid conditions and those related to the current treatment.

Table 55.1 ECMO indication

PaO_2/F_IO_2 < 70–80 mmHg; pH < 7.2, Murray Score > 3 [33]
Unresponsiveness to optimal medical conservative management (adapted to Fig. 55.2, [32])
Treatment algorithm for ARDS
Low tidal volume
Plateau pressure ≤ 28–30 cm H_2O
High PEEP level as possible depending on the surgical intervention
Prone positioning
Neuromuscular blockers
Adjunctive therapies (nitrous oxide, almitrine)

Active intracranial bleeding is an absolute contraindication. However, all other bleeding complications are relative contraindications.

Technical Aspects of ECMO

Bioengineering, physiology, and pharmacology converge in the intensive care unit. Mechanical devices for monitoring and treatment are essential for the application of physiologic principles and management. Extracorporeal circulation is the ultimate example of this complex interaction.

Cardiopulmonary bypass technology was developed to provide circulatory and respiratory support during cardiac surgery. In the 1960s and 1970s, a number of creative physicians conceived the possibility of employing this technology to support patients with life-threatening cardiac or respiratory failure. The challenge was to provide extracorporeal circulation for a period sufficiently long (i.e., days or weeks) to allow intrinsic healing of the diseased heart and lungs. The various systems that provide these periods of long-term extracorporeal life support are known collectively as ECMO. The development of ECMO technology in the last 10 years provides a variety of options for the multidisciplinary teams who are involved in the management of ARDS patients.

ECMO implies the diversion of blood from a major systemic vessel through a gas exchange device (membrane oxygenator) and back to a major blood vessel. Current devices used for ECMO continue to undergo progressive modifications by their manufactures. These developments include biocompatible circuits, new gas exchange devices, improved pumps, sophisticated computer controlled, and servo-regulated pump systems. The primary goal is to provide patient safety and to improve outcome.

Temporary ECMO support in respiratory and/or heart failure will deliver adequate tissue perfusion through blood circulation and tissue gas exchange. The system mechanically pumps blood through the patient's vasculature delivering oxygen and removing carbon dioxide. It has to be mentioned that there is a variety of different circuits depending on the patient's size and the kind of disease pathology.

There are several important considerations regarding ECMO circuits [35]:

- ECMO circuits should be kept simple in order to provide patient safety.
- Long ECMO tubes increase the foreign surface and increases the priming volume with blood or crystalloids. Resistance through tubes increases with the length of tubing and can cause turbulence and stress on blood elements inducing clot formation. Furthermore, multiple connectors can cause turbulences with the risk of clot formation.
- Membrane oxygenators are used in combination with a pump to supply up to 5–7 L/min support. A roller or occlusive pump operates on the principal of positive fluid displacement. This pump has two rollers and pulls blood from the patient's right atrium and pushes the fluid forward in a fixed length and diameter of tubing with creation of pressure and flows into the oxygenator and then into the patient's system. Newer improved roller pumps with coated circuits have reduced the risk of hemolysis caused by centrifugal pumps.
- Oxygenator. The oxygenator is a critical component of the ECMO circuit. The blood leaves the pump into the oxygenator or the heat exchanger depending which type is used. Moreover, plasma-leakage-resistant oxygenators have enabled the safe use of ECMO for much longer periods of time without changing the oxygenator [36].

VV ECMO

ECMO can be inserted in a VV configuration which provides complete respiratory support and oxygenation (in case of respiratory failure not responding to mechanical ventilation) or either be used as VA configuration (providing both respiratory and cardiac support). The incidence of right ventricular (RV) failure remains high with 25% in ARDS patients [37, 38]. In most cases hemodynamic instability due to RV failure might be resolved with VV ECMO (normoxemia, normocapnia, low tidal volumes, lower plateau pressures, and subsequent reduced pulmonary vascular resistance). However, in the presence of concomitant left ventricular (LV) dysfunction, the use of VA ECMO is indicated [39].

ECMO Cannulation

The femoral and internal jugular veins should be assessed by ultrasound to detect venous thrombosis and to determine the diameter of the vessels. This is important to decide the size of the cannulas. The size of the cannula is the determining factor for the blood flow in the ECMO circuit. The insertion of the largest cannula should be attempted [39].

Cannulation of the internal jugular vein with ultrasound guidance is highly recommended as evidence-based practice [40, 41]. In addition, ultrasound guidance is helpful for all types of vascular access. The preferred technique is the percutaneous approach with the Seldinger technique into femoral and jugular vessels. Percutaneous insertion is associated with less bleeding complication as well as a lower risk of infection.

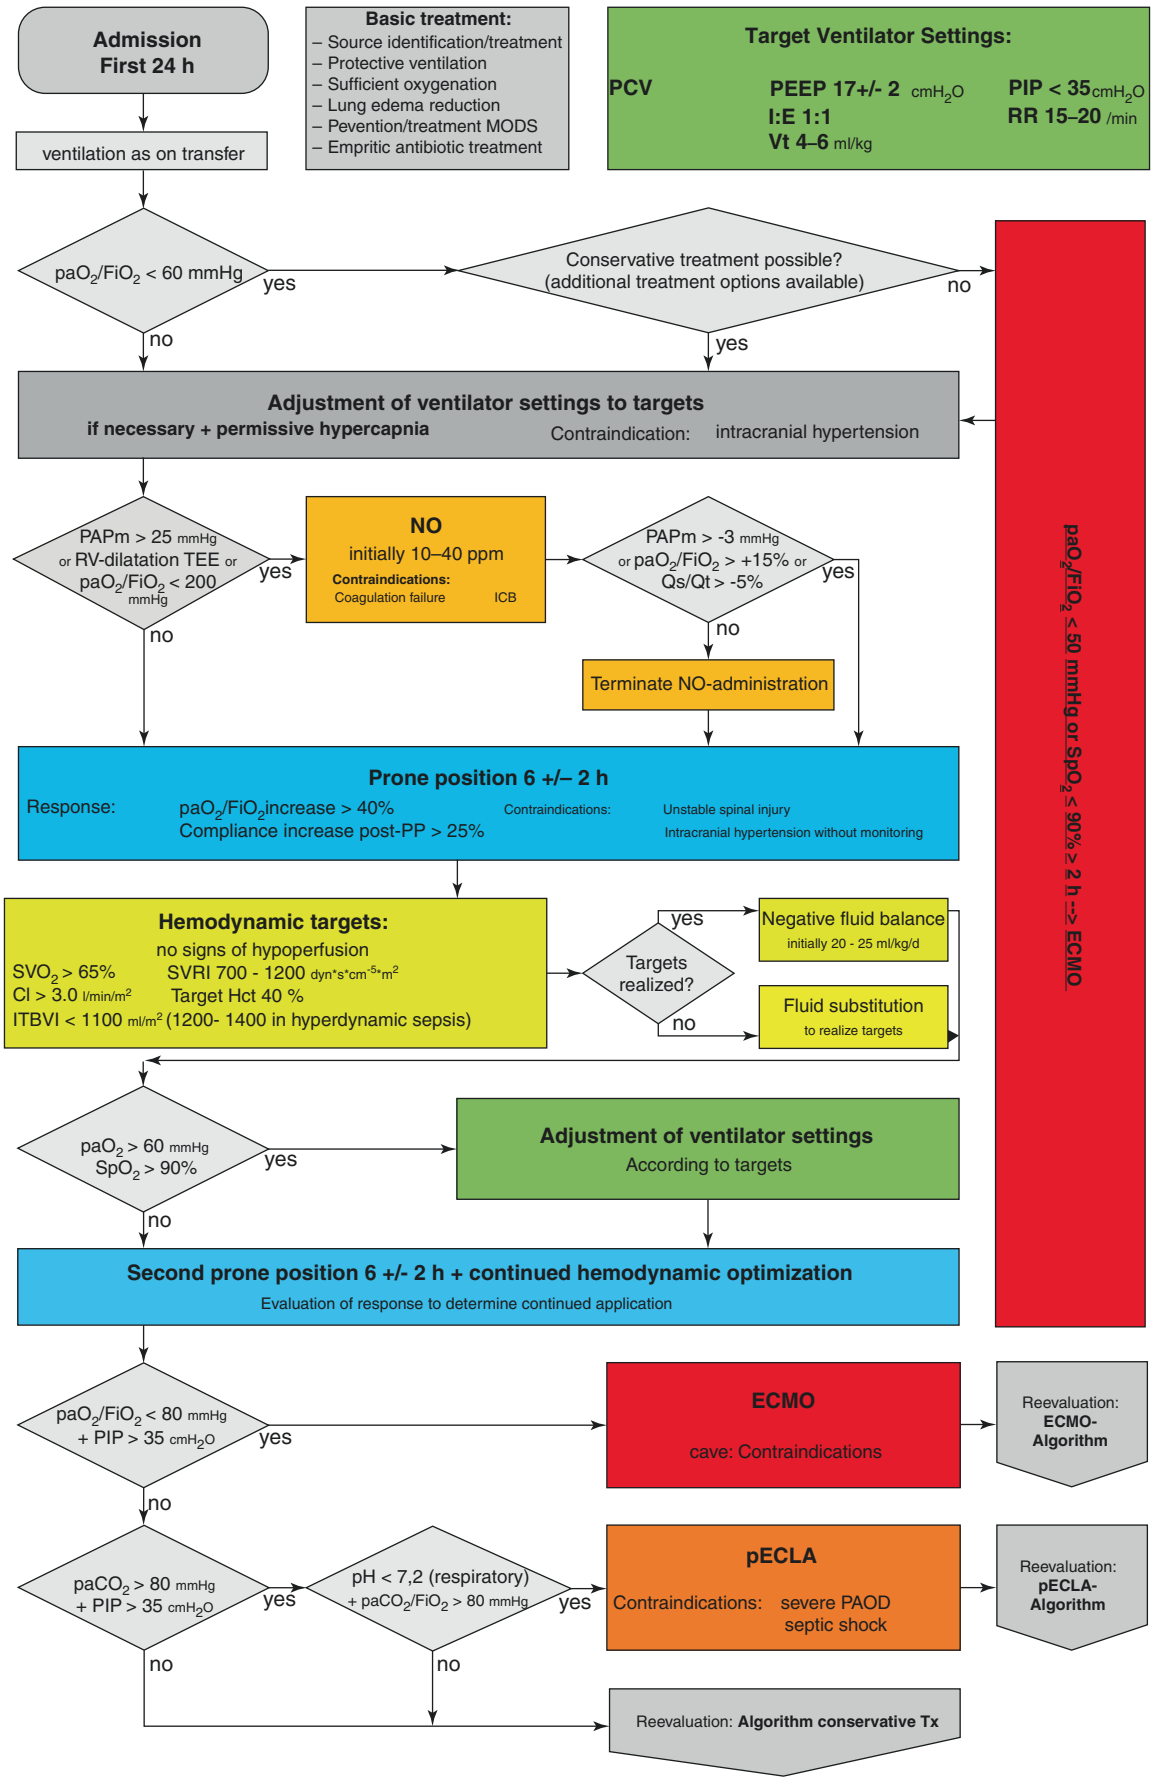

Fig. 55.2 Treatment algorithm for ARDS: ECMO and iLA. (Deja et al. [32], with kind permission from Field House publishing)

The largest possible venous cannula should be used to maximize flow. For adults, the intravascular venous catheters may be 20 French or larger. The cannulas are usually heparin or "bio" coated in order to reduce the risk of clot formation. In case of successful weaning from ECMO, the patient is usually decannulated without surgical intervention.

There are different types of VV ECMO depending on the cannulation sites:

- *The conventional femoro- to internal (vena jugularis interna (VJI)) "double" vein cannulation*: It has the risk of recirculation due to the fact that the reinjection flow is directed to the drainage port. Therefore, at least 15 cm is recommended between the two cannulas to decrease recirculation. Larger cannulas allow lower pump speeds, less negative venous pressures, and reduced recirculation.
- *Recirculation*: Reinjected oxygenated blood is withdrawn by the drainage venous cannula without passing the systemic circulation with decreased ECMO effectiveness.
- *Bilateral femoral cannulation*: This access is a second-line approach in case that VJI is technically not possible.
- Many centers use the *double-lumen single bicaval cannula (DLB)* in the internal jugular: Blood is withdrawn from the inferior vena cava through one port, circulated through the membrane oxygenator and returned to the right atrium through a second port in the same double-lumen catheter. This minimizes recirculation. There are different sizes of DLB available (27 Fr: 4.5 l/min; 31 Fr: 5 L/min).

The effectiveness of VV ECMO in supporting oxygenation depends on several factors:

- Blood flow
- Patient's cardiac output (CO)
- Metabolic demand
- Oxygen fraction in the sweep gas
- Surface area of the membrane
- Recirculation amount within the circuit

Initiation of ECMO

For VV perfusion, flow is initiated at 10–15 ml/kg/min and advanced over 10–15 min to a maximum of 100–150 mL/kg/min. For optimal oxygenation, the VV ECMO flow should reach at least 60% of CO of the patient. ECMO flow depends on volume load and will drop with hypovolemia or cannula malposition, but hypervolemia is not necessary and could be harmful by increasing lung edema. Hypovolemia usually manifests as negative pressure upstream to the blood pump ("kicking" or "chatter" of the venous tube). A slight reduction in flow may be helpful [39].

From a gas exchange point of view, hypoxia is treated by increasing both the ECMO flow rate and inspiratory oxygen concentration (F_IO_2) of the ECMO circuit, not by altering the F_IO_2 and PEEP on the ventilator. Attempts should be made to wean the F_IO_2 on the ventilator and maintain a lung-protective strategy with low plateau pressures, low tidal volumes, and adequate PEEP. Elimination rate of CO_2 depends on gas flow over the membrane. Gas flows up to 15 l/min are necessary in patients without CO_2 elimination by the lungs. CO_2 control should be made via the ECMO gas flow through the membrane, not by altering the respiratory rate on the ventilator to avoid further ventilator-induced acute lung injury.

Temperature Management on ECMO

Because heat is lost through the evaporation of water as blood flows through the artificial lung, it is often necessary to warm the patient on ECMO. Although normothermia can be maintained through use of external warming devices, it is usually more efficient to warm the extracorporeal blood before infusion. In most ECMO centers, heat exchangers are routinely used. At times the heat exchanger may also be used to cool the patient to a preset temperature in order to affect a decrease of oxygen consumption. The heat exchanger should be placed in-line after the artificial lung during ECMO in order to optimize the efficiency of the device.

Monitoring for Anticoagulation

ECMO patients require only a low level of systemic anticoagulation to prevent clotting of the cannulas, tubing, and oxygenator because current devices are coated with heparin. The level of systemic heparinization required is not definitely known, although an activated partial thromboplastin time (aPTT) of 50–70 s and a platelet count >80 × 10 9/L are reasonable [36]. In high-flow systems of about 4–7 l/min, an aPTT above 50 s is sufficient to prevent clotting. Regular measurement of clotting profile, platelet count, and hemoglobin should be performed as least twice per day [42, 43]. This is in accordance with the target guidelines of the Extracorporeal Life Support Organization (ELSO) [36]. Activated clotting time (ACT) should be kept between 160 and 200 s, fibrinogen levels >1.5–4 g/l, and INR <1.8; <1.5 in case of bleeding.

Hemolysis is another well-recognized complication of ECMO and should be routinely monitored. This is done by regular (daily) checking of the plasma-free hemoglobin and haptoglobin. In case of heparin-induced thrombocytopenia (HIT), argatroban seems to be an adequate alternative for anticoagulation during ECMO [36, 43].

Complications

Bleeding and Thrombosis

Hemostatic perturbations are common in patients with ECMO and contribute significantly to morbidity and mortality [44]. This includes thrombosis and excessive bleeding caused by coagulopathy [44]. Thrombosis in ECMO patients occurs in periods of low-flow or inadequate circuit anticoagulation. Clots can be found in the whole circuit at the sites of stasis and turbulent flow [36]. In case of bleeding, continuous activation of the contact and fibrinolytic systems by the circuit as well as consumption and dilution of factors occurs within minutes of initiation of ECMO. Platelets adhere to surface fibrinogen and are activated. As a consequence, platelet aggregation causes platelet count drop. Correction by platelet transfusion produces only a temporary increase. There might be significant platelet dysfunction despite regular platelet transfusions. Furthermore, prolonged duration of ECMO exacerbates these negative effects [44]. The thromboelastogram (TEG) can measure the integrity of platelet activity [17, 36]. The level of heparinization required is still under debate [43]. Often the level of anticoagulation must be reduced in case of bleeding. Most of the newer ECMO circuits are heparin-bonded, and therefore minimal or no heparinization can be accepted for a number of hours until complete control of bleeding.

Cerebral Hemorrhage and Infarction

Changes in cerebral blood flow and the use of heparin may contribute to both hemorrhagic and nonhemorrhagic intracranial lesions. Lidegran and colleagues [45] reported intracranial lesions (bleeding, infarction) within the first 7 days after ECMO initiation in 37% of studied patients. ECMO survivors carry a high risk of brain injury with subsequent functional deficit [46]. Neurological events in patients with ECMO occur frequently. Intracranial bleeding is the most frequent and occurs early, and it is associated with an increased mortality [47]. In addition, ECMO therapy itself can cause cerebral injury. The cannulation itself, together with creation of solid and gaseous microemboli during perfusion, may cause cerebral injury. Arterial emboli may occur in connection with retrograde arterial cannulation, and even careful cannulation with the Seldinger technique may cause thrombus formation.

This implicates an adequate neurological management: According to international guidelines, the patient on ECMO should be awake to interact with care providers and family [36]. Adequate analgesia and delirium monitoring according to the "pain, agitation, and delirium" (PAD) guidelines should be the standard [48]. This is also of gaining importance with respect to early detection of new neurological deficits caused by cerebral infarction or hemorrhage. Therefore, oversedation should be avoided, and this has a valuable impact on outcome [48]. Spontaneous breathing as a part of a "lung-protective strategy" by decreasing intrapulmonary shunt and intrathoracic pressures, as well as improving organ perfusion, should be achieved as early as possible. Furthermore, after thoracic surgery this is beneficial in protecting surgical bronchial reconstruction as well as in preventing of bronchial fistulas and bronchial suture dehiscence [1, 11].

Weaning of ECMO

ECMO support is reduced as the lungs recover. The chest X-ray will demonstrate the improvement of the lungs. Once ECMO flow is reduced to 1 L/min and in case of stable arterial blood gases (see Table 55.2), the patient is ready to trial off ECMO for at least 2 h [32, 35, 36, 49].

Extracorporeal Carbon Dioxide Removal ($ECCO_2R$)

$ECCO_2R$ is a technique of partial respiratory support which allows ultra-protective ventilation strategies. It removes CO_2 from the blood through a low blood flow (0.4–1 l/min) extracorporeal circuit. The major limitation is that it has no effect on oxygenation. An arterial or venous access cannula is necessary to drain blood, a membrane lung and a return venous cannula. Different heparin-coated cannulas are available to be inserted via Seldinger technique percutaneously via a femoral-femoral access.

New developments in extracorporeal technologies are gaining interest, and various kinds of $ECCO_2R$ devices are available from different manufactures. They range from systems such as the Decap system (Hemodec, Salerno, Italy)

Table 55.2 ECMO weaning criteria (Fig. 55.3)

F_IO_2 < 0.4–0.6
PaO_2 > 60–80 mmHg
$PaCO_2$ 30–45 mmHg
Target ventilator settings
BIPAP: PEEP according to maximize saturation, PIP < 30 cm H_2O, Vt: 4–8 ml/kg
RR spontaneous ~ 5 breath/min
Procedure
Reducing blood flow 0.5 l/min every 12 h to minimal blood flow of 1.0 l/min
$PaCO_2$ < 60 mmHg, reducing gas flow and F_IO_2 over membrane
ECMO trial off, gas flow 1 l/min over 2 h; criteria fulfilled, discontinue ECMO

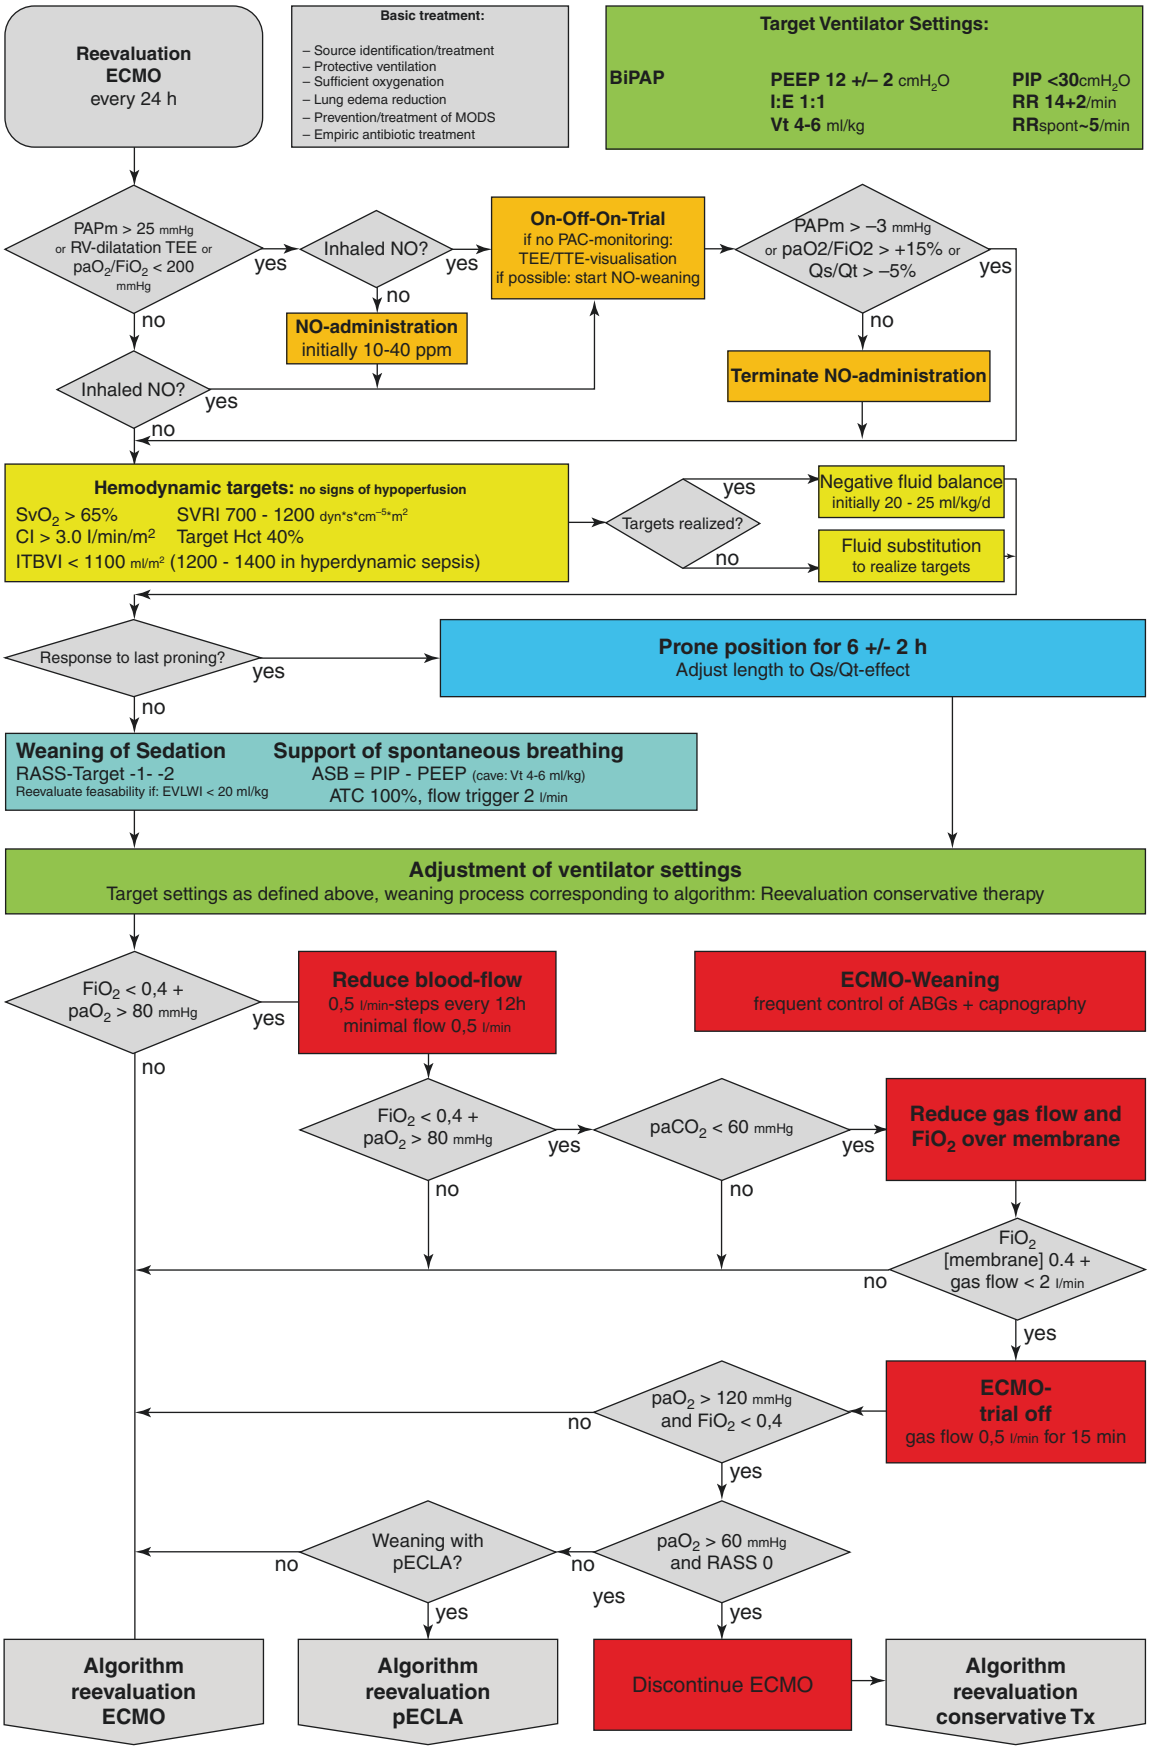

Fig. 55.3 Treatment algorithm for ARDS: ECMO and iLA. (Deja et al. [32], with kind permission from Field House publishing)

that has a dual purpose of renal replacement and $ECCO_2R$ to partial extracorporeal support systems such as the pumpless iLA (Hechingen, Germany) device [50, 51].

The pumpless iLA membrane ventilator marketed by Novalung GmbH is a low-gradient device. It is a pumpless arteriovenous shunt with CO_2 elimination as primary function owing to the arterial inflow blood. The principle is simple diffusion. Blood flows over the exterior surface (1.5 m^2) of the device fibers, and the ventilating gas (O_2 sweep) flows inside these fibers. The iLA consists of a plastic gas exchange module with diffusion membranes made from polymethylpentene (PMP). The PMP fibers are woven into a complex configuration of hollow fibers. Gas transfer takes place without direct contact with blood. In addition, the blood-contacting PMP membrane surface is treated with a heparin coating to provide a biocompatible and non-thrombogenic surface [52]. The iLA is a low pressure-gradient device designed to operate without a mechanical pump. Based on this principle, adequate means arterial blood pressure is mandatory. The preferred access sites are the femoral vessels by percutaneous cannulation using Seldinger's technique (see Fig. 55.1). Used in this configuration, usually about 20% of the cardiac output (1–2 L/min) runs through the iLA, driven by the left ventricle, and mixes with the remaining 80% of the CO in the venous vasculature. One limitation of this device is that patients with primarily an oxygenation disorder may not benefit sufficiently from the pumpless iLA mode in terms of oxygenation; however CO_2 elimination is usually not a problem.

The blood enters the device through the inlet connector. The blood flows into the blood distributing chamber. Any microsized air bubbles that may have entered the device are removed through the de-airing ports. The blood flows into the main chamber where gas exchange takes place. The oxygen- and CO_2-depleted blood is returned to the patient via the blood outflow [50]. Two de-airing membranes are integrated at the top apex on both sides of the device. These de-airing membranes allow gas bubbles but not liquids to cross. In addition, they facilitate priming and de-airing of the device and are also used to eliminate any air trapped in the device during support. An oxygen supply is connected to the gas inflow connector; the lower gas outflow connector is open to the atmosphere and is the site where gas is exhausted from the device [53].

The Decap^{tm} system combines renal replacement with $ECCO_2R$. The so-called Hemolung (ALung Technologies, Pittsburgh, PA, USA) achieves efficient CO_2 removal with flows of 400–600 ml/min similar to renal replacement [54].

Indications for $ECCO_2R$

There are two major indications (see Table 55.3): It can be applied to give the injured or diseased lung a chance to heal ("bridge to recovery") or in an end-stage lung disease, and it might be used as a bridge to lung transplantation, i.e., in patients with pulmonary hypertension [53, 55]. In this context the device has been implanted with main pulmonary artery and vein cannulations during sternotomy (see Fig. 55.5). It has been possible to wean several patients with ventilatory and RV failure from iLA and positive-pressure ventilation while waiting for lung transplantation (see Fig. 55.6).

Table 55.3 Criteria for iLA indication and weaning iLA

iLA indication (Fig. 55.2)
$PaCO_2$ > 80 mmHg + PIP > 30 cm H_2O + pH <7.2 (respiratory) + PaO_2/F_IO_2 > 80 mmHg
Weaning of iLA/Main criteria (Fig. 55.4)
Richmond Agitation and Sedation Score (RASS) 0/−1
F_IO_2 < 0.4
$PaCO_2$ < 60 mmHg
Target ventilator settings
BIPAP: PEEP according to maximize saturation, PIP < 30 cm H_2O, Vt: 4–8 ml/kg, Spontaneous breathing
Procedure
Reducing O_2 flow iLA in steps of 1 l/min
iLA O_2-flow <2 l/min: iLA 6 h without gas flow
iLA trial off: criteria fulfilled: discontinue iLA

Adapted to Ref. [32] with kind permission from Field House publishing, (Fig. 55.4)

The use of iLA in addition to lung-protective ventilation has been reported in one center to have a high survival rate (84%) in a series patients with severe post lung resection ARDS [56]. The iLA can be used for CO_2 removal in cases of severe hypercapnia and respiratory acidosis in order to avoid the injury of mechanical ventilation. Bein et al. [57] studied, in a single center study, 90 patients with ARDS supported with the pumpless iLA and reported a survival rate (weaning of iLA) of 41%. The iLA has been used in patients with bronchopleural fistulas after lung surgery [11] and with chest trauma (lung contusion) [58], or as a bridge to lung transplant [53]. However, apart from these small randomized studies and case reports, no outcome data are currently available, and additional evidence is necessary to define clear and consistent recommendations.

Complications

Ischemic complications of the lower limb were reported to be associated with the large cannulation size for the arterial cannulation (17 French) initially used for iLA [29, 57]. As smaller cannulae (13 and 15 F) have become available, the ischemic complication rate has markedly decreased. *It is not recommended to use 17 F cannulae for femoral arterial cannulation*. Advantages of iLA are avoiding all the complications related to a mechanical pump, reduced blood-contact surfaces, and relatively easy clinical management.

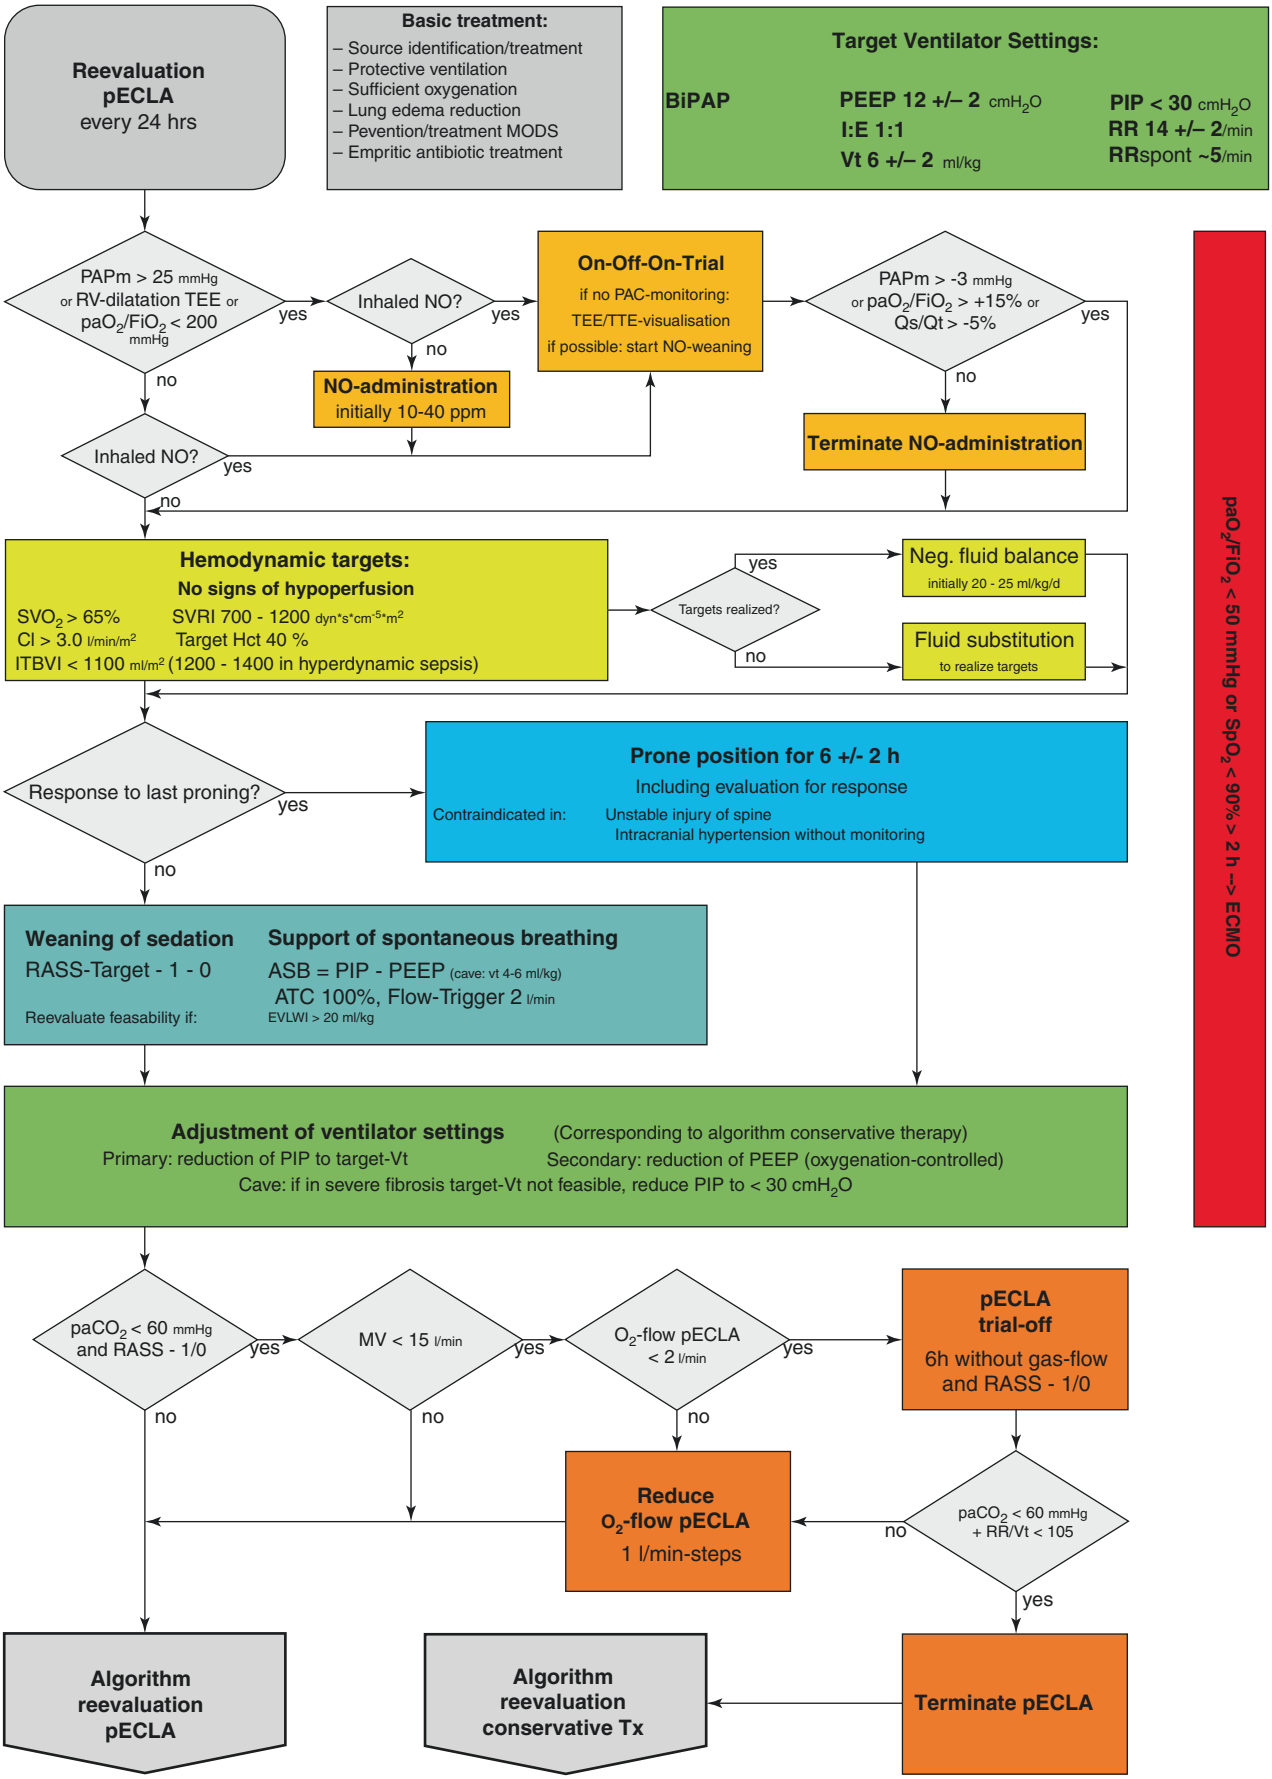

Fig. 55.4 Treatment algorithm for ARDS: ECMO and iLA. (Deja et al. [32], with kind permission from Field House publishing)

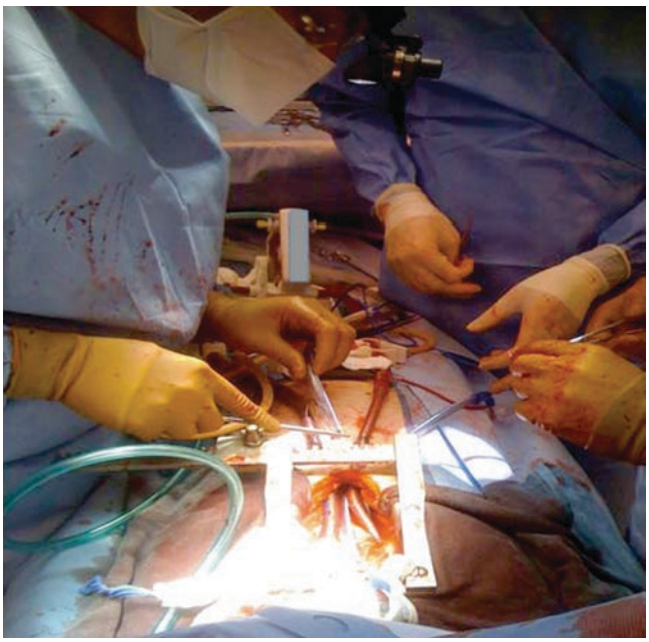

Fig. 55.5 Intrathoracic implantation of interventional lung assists cannulae during sternotomy in a patient with pulmonary hypertension, seen from anesthesiologist's perspective. The iLA device can be seen between the patient's legs. The inflow cannula to the device is on the left side of the incision, placed into the main pulmonary artery. The return cannula, to the right, is into the right upper pulmonary vein. The surgeon is placing a mediastinal drain between the cannulae prior to closing the incision

Disadvantages are the lack of control of blood flow, which is determined by the arteriovenous pressure gradient and the limited oxygen transfer capacity.

Multimodal Therapeutic Approach

Weaning of Sedation

Daily interruption of sedative drugs significantly reduces the duration of mechanical ventilation and the length of stay in the intensive care unit [48]. This should be considered in all patients requiring extracorporeal ventilator support. Moreover, it is important with respect to the early detection of new neurological deficits caused by cerebral infraction or hemorrhage. Therefore, the recommendations of the PAD guideline should be the standard [59].

The concept of the "awake patient" on ECMO is preferred for most patients on ECMO.

Early Spontaneous Breathing

"Spontaneous breathing" as a part of a "lung-protective strategy" by decreasing intrapulmonary shunt and intrathoracic pressures as improving organ perfusion should be achieved as early as possible [11, 32]**.** Especially after thoracic surgery this is beneficial to protect surgical bronchial reconstruction and to prevent bronchial fistulas as well as bronchial suture dehiscence [11].

Clinical Case Discussion

Case: A 17-year-old male sustained multiple traumas with a traumatic tracheal rupture (approximately 8–10 cm length on the pars membranacea) and bilateral severe lung contusions after a fall of 7 m height (Fig. 55.7). Tracheal rupture as well as mediastinal emphysema was diagnosed on the immediate CT scan. Chest tubes were inserted on both sides due to pneumothoraces. Fiber-optic bronchoscopy was immediately performed in order to position the endotracheal tube as near as possible to the carina. After this intervention, the subcutaneous emphysema decreased. However, within a few hours the patient developed severe ARDS due to its lung contusions (pressure-controlled ventilation; paO_2/F_IO_2 ratio < 200; PEEP, 15 cm H_2O; PIP, 35 cm H_2O).

Tracheal rupture affected the whole tracheal wall with protrusion of mediastinal structures into the lumen; therefore a surgical repair was indicated. The anesthesia team will need to decide if the patient will tolerate the proposed procedure and, if so, then what management strategies can be used to improve the perioperative outcome.

Questions

- Will the patient tolerate the operative procedure without extracorporeal lung assist?
- What specific anesthetic considerations are related to patient's disease?
- How to plan anesthesia and operative procedure in an interdisciplinary approach?
- In this situation of severe ARDS (paO_2/F_IO_2 ratio < 200; PEEP, 15–17 cm H_2O; PIP, 35 cm H_2O), the patient would not tolerate the thoracic surgical procedure under one-lung ventilation without the risk of developing severe hypoxemia and hypercapnia.
- Anesthetic considerations include perioperative difficult airway management (placement of a double-lumen tube?), intraoperative hypoxia and hypercapnia during one-lung ventilation, and postoperative airway management to prevent tracheal suture dehiscence.
- Preoperative management: Conservative treatment strategy with prone positioning, restrictive volume therapy, and nitric oxide administration before the surgical intervention was performed. However, oxygenation index did not increase with prone positioning. Therefore, intraoperative anesthetic management was planned as follows:
  - Preoperative initiation of VV ECMO (femoral veins on both sides 23 F), 4–5 L/min blood flow
  - Apneic oxygenation with PEEP, 10 mmHg, or no ventilation with full ECMO blood flow (advantage: optimal surgical conditions)
  - Airway management: tracheostomy with insertion of an uncuffed tracheostomy tube

Fig. 55.6 A patient with pulmonary hypertension has been weaned from ECMO and mechanical ventilation with a transthoracic implantation of an iLA device. The device can be seen on the side of the patient's bed

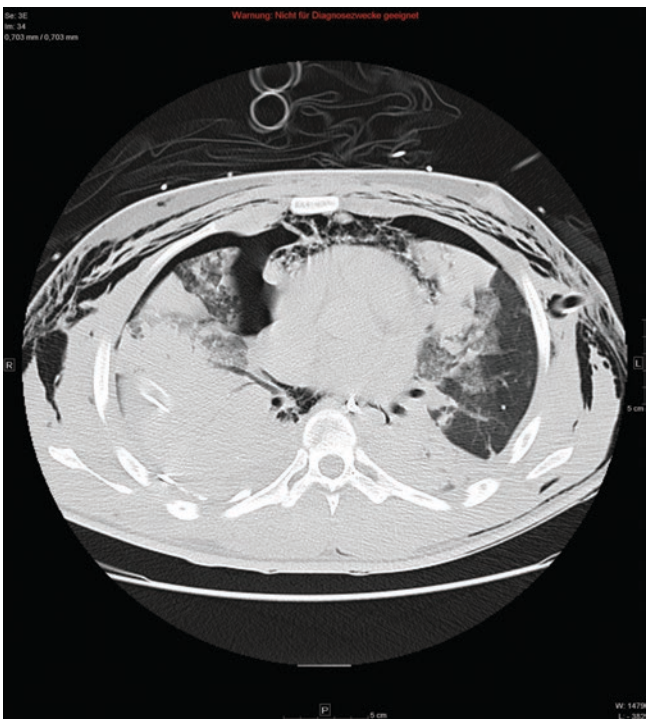

Fig. 55.7 CT scan thorax of a male patient with severe ARDS and traumatic tracheal rupture, mediastinal emphysema

- Postoperative management:
  - Prone positioning should be considered due to lung derecruitment after lung surgery if there is a clinically relevant increase in oxygenation (re-evaluate every 24 h).
  - ECMO therapy in patients with ARDS improves outcome of some patients.
  - Early spontaneous breathing reduces ventilation pressures and prevents tracheal suture dehiscence.
  - Daily sedation vacation to detect neurological deficits in patients with ECMO therapy as early as possible.

Cardiovascular Adaptations and Complications

56

Alessia Pedoto and David Amar

Key Points

- Changes in *right ventricular anatomy and function* can occur at several stages of lung resection, starting after induction of general anesthesia and positioning, followed by one-lung ventilation and surgical dissection. Compensatory mechanisms may not occur in patients with advanced COPD who are at risk of developing long-term complications. Several tests are available during the intraoperative period to evaluate right heart function, and their merits are reviewed.
- *Supraventricular arrhythmias* are a common complication after thoracic surgery, depending on the extent of the dissection. Atrial fibrillation is the most common postoperative rhythm disturbance after lung resection. Several pathophysiologic mechanisms as well as prophylactic and/or therapeutic maneuvers have been proposed. Older age and intrapericardial procedures are among the risk factors that strongly correlate with this condition.
- *Acute coronary syndrome* after thoracic surgery is rare but is associated with a high risk of death. Patients at risk are the ones with preoperative coronary artery disease and abnormal exercise testing. There are no clear recommendations on the role of preoperative cardiac catheterization and coronary revascularization.
- *Cardiac failure* can result from either right or left heart dysfunction and can be transient or long standing. Symptoms may be subtle at rest and become evident during exertion. *Cardiac herniation* is a rare complication that may occur after intrapericardial pneumonectomy and is associated with a high mortality rate. Clinical and electrocardiographic signs are very nonspecific, and treatment is surgical.
- *Mediastinal shift* is the result of changes in the post-pneumonectomy space. A high index of suspicion is needed for the diagnosis, which can present with severe hemodynamic compromise or respiratory symptoms. *Post-pneumonectomy syndrome* may occur in the late postoperative period. It is characterized by an extreme mediastinal shift which causes dynamic compression of the distal airway and respiratory insufficiency. Treatment is surgical.

Introduction

Lung resection, especially if extensive, can cause acute and chronic changes in the anatomy and function of the right heart. This can be the result of either transient or sustained pressure or volume overload, reduction in contractility, cardiomyopathy, or arrhythmias [1], especially in the presence of pre-existing abnormalities [2]. The right heart is very sensitive to increases in afterload [3]. Acute increase in pulmonary arterial pressures (PAP) can lead to a significant decrease in right ventricular (RV) output with subsequent RV failure. Secondary left ventricular (LV) compression can cause systemic hypotension, with right coronary artery (RCA) hypoperfusion and possible right myocardial ischemia [4]. The right heart has recently been recognized as an active mediator, rather than a passive conduit, that can contribute to perioperative morbidity [5]. Any pathology associated with pulmonary hypertension and chronic hypoxia (such as end-stage COPD or connective tissue interstitial lung disease) can cause baseline right

Table 56.1 Causes of right ventricular failure [6]

Pressure overload	Left heart failure (most common)
	Pulmonary embolus (common)
	Pulmonary hypertension
	Right ventricular outflow tract obstruction
	Peripheral pulmonary stenosis
	Double chamber right ventricle
	Systemic right ventricle
Volume overload	Tricuspid regurgitation
	Pulmonary regurgitation
	Atrial septal defect
	Anomalous pulmonary venous return
	Sinus of Valsalva rupture in the right atrium
	Coronary artery fistula in the right atrium or right ventricle
	Carcinoid syndrome
	Rheumatic valvulitis
Ischemia/infarction	Right ventricular myocardial ischemia
Intrinsic myocardial processes	Cardiomyopathy and heart failure
	Arrhythmogenic right ventricular dysplasia
	Sepsis
Inflow limitation	Tricuspid stenosis
	Superior vena cava stenosis
Congenital defects	Ebstein's anomaly
	Tetralogy of Fallot
	Transposition of the great vessels
	Double outlet right ventricle with mitral atresia
Pericardial disease	Constrictive pericarditis

ventricular dysfunction (see Table 56.1) [6]. Known etiology includes induction of general anesthesia, institution of one-lung ventilation and lateral decubitus, manipulation of the pulmonary circulation, or triggering of the inflammatory response [7]. While cardiac adaptations occur with time after lung resection, cardiac complications, especially arrhythmias, are commonly seen in the immediate postoperative period before patient discharge.

Cardiac Adaptation

Cardiac adaptation can occur in the immediate intraoperative period, after induction of general anesthesia and positioning or in the postoperative phase.

Intraoperative Changes in Right Ventricular Function and Anatomy Related to One-Lung Ventilation and Positioning

Pulmonary arterial pressures can increase after induction of general anesthesia, as a consequence of positive pressure ventilation, placement of the patient in the lateral decubitus, opening of the chest, and initiation of one-lung ventilation (OLV) [8, 9]. Mediastinal shift and gravity-related changes in pulmonary perfusion and hypoxic vasoconstriction can also contribute to higher pulmonary arterial pressure. In patients with normal pulmonary vascular compliance, an increase in right cardiac output can compensate for the higher afterload without significant changes in pulmonary arterial pressures. This may not occur in patients with advanced COPD, or obstructive sleep apnea, even in the presence of baseline right ventricular hypertrophy [7], theoretically making this population at higher risk for intra- and postoperative cardiac complications. Preexisting significant pulmonary hypertension can worsen during OLV or clamping of the pulmonary artery. Ligation of the main pulmonary artery during pneumonectomy (right more than left) or lung transplantation in patients with severe COPD can cause acute right heart overload and consequent dilation followed by ischemia or arrhythmias, either intra- or postoperatively [10, 11]. A temporary slow "clamp test" of the pulmonary artery can be done intraoperatively to evaluate the clinical and echocardiographic response of the right heart to acute shifting of blood to the remaining pulmonary circulation [12]. However, this maneuver rarely changes the intraoperative management, since the results may be difficult to observe or interpret as soon as the clamp is applied.

If there are any intraoperative concerns of potential hemodynamic instability or right heart dysfunction, transesophageal echocardiography (TEE) has become a first-line diagnostic tool, replacing *pulmonary arterial catheter data* [13]. This information may influence the clinical decision in patients undergoing lung transplantation on when to initiate cardiopulmonary bypass or help evaluate the response to fluid or vasoactive treatment [14]. While TEE is a valuable "real-time" tool to assess left ventricular function, its role in investigating the right ventricular function is less clear. Despite the superficial location of the right heart, its irregular and asymmetric shape makes the motion and volume calculations much more difficult and less detailed than the left side when 2-D echo is used [5]. The advent of 3-D imaging has improved the quality of the right heart exam, in assessing structural changes and hemodynamic parameters [5, 15]. 3-D techniques have demonstrated a good resolution for the study of RV volumes and a good correlation with thermodilution data [15]. The main disadvantage still remains the costs and need for vendor-specific software. In case of high suspicion for perioperative right heart dysfunction, such as in patients with a predicted postoperative FEV_1 less than 40%, detailed preoperative testing becomes extremely important and is highly recommended [16]. In non-transplant patients, there is little evidence that routine TEE influences outcome [14].

Acute and Late Phase Changes in Right Ventricular Anatomy After Lung Resection

Intraoperative increases in resting pulmonary arterial pressure and pulmonary vascular resistance are usually proportional to the extent of the resection [17] and tend to normalize in the immediate postoperative period. However, aging is associated with a slow decline in right ventricular function, suggesting adaptive or reactive processes that can lead to right ventricular hypertrophy [8]. Changes in right ventricular ejection fraction have been described during exercise and depend on the level of exertion [18]. Compensatory mechanisms are more efficient during moderate exercise, with a fixed right ventricular stroke volume at maximal exertion which is independent from the increase in the workload and the time from surgery [8]. The extent of the resection and the compensatory volume expansion of the remaining lung can cause changes in the mediastinal anatomy with a rotation of the heart in the chest cavity, affecting the left ventricular function. Changes in filling and contraction have been observed. The degree of compensation after lung resection seems to be age dependent [8].

Lung surgery is currently the most common treatment for nonmetastatic resectable lung cancer and is part of a multimodal approach with chemotherapy and radiation [19]. Currently, surgical candidates are much older and with more extensive comorbidities, perhaps due to the combination of an aging population and improvement in surgical and anesthesia techniques [20]. Pre-existing cardiac and pulmonary diseases are common factors that may significantly influence the postoperative course and increase mortality rates [20]. The use of minimally invasive techniques, often relying on pneumo-capnothorax to expedite lung collapse, may cause acute changes in pulmonary pressures and right heart function. Severe pulmonary hypertension (mean pulmonary arterial pressure >45 mmHg) has been demonstrated only in 3.7% of patients with lung disease [21], despite a long smoking history and the presence of variable degrees of COPD in some patients. Ninety percent of patients with FEV_1 less than 50% have mean pulmonary arterial pressures of about 20 mmHg, and only 5% may have values greater than 35 mmHg [22].

Several studies have investigated postoperative right ventricular function (see Table 56.2 [7]), but the results are difficult to compare due to small sample sizes and extremely variable methodology. Some agreement exists among studies in patients after pneumonectomy that show a mild increase in pulmonary arterial systolic pressure, right ventricular diastolic volume or systolic pressure on transthoracic echocardiography [7], and CT scan exams [17]. These changes occurred in the second postoperative day and may persist after 4 years [7], suggesting an evolution of the cardiovascular response over time [8]. An increase in both afterload and catecholamine tone after clamping the pulmonary artery may lead to an increase in diastolic volume, pulmonary arterial systolic pressure, and mild tricuspid regurgitation which is observed on 2-D echocardiography. Most of the studies showed an increased incidence of tachyarrhythmias after pneumonectomy, which was transient in most cases and not associated with either heart failure or long-term complications [7]. Despite all these observed changes, there was no effect on 30-day mortality rates.

Cardiac Complications

Supraventricular Tachyarrhythmias (Atrial Fibrillation, Atrial Flutter, and Supraventricular Tachycardia)

Supraventricular tachyarrhythmias occur in approximately 4–25% of patients undergoing noncardiac thoracic surgery [28, 29]. Age of 60 years and older [30] and intrapericardial pneumonectomy [31] remain the most important risk factors. An elevated white blood cell count on postoperative day 1 [32] and an elevated perioperative N-terminal-pro-B-type natriuretic peptide (NT-pro-BNP) [33] and BNP [33–35] have also been suggested as possible predicting biomarkers, with a higher sensitivity when associated with older age [36]. Male gender, extent of surgical resection but not surgical approach or laterality, left ventricular early transmitral velocity/mitral annular early diastolic velocity (E/e') [36], increased trans mitral flow deceleration time, and left diastolic volume index [37] on echocardiography were also reported as potential risk factors for POAF. The combination of multiple risk factors such as gender, age, BNP, and extent of lung volume to be resected can be used as criteria to select high-risk patients who would benefit from a preoperative echocardiographic exam [36] and postoperative arrhythmia prophylaxis [38–41].

Atrial fibrillation (AF) is the most common rhythm disturbance, followed by supraventricular tachycardia (SVT), atrial flutter, and premature ventricular contractions (PVCs). The diagnosis is usually made on the second postoperative day (with a range of 1–7 days), and its duration is usually self-limited. Postoperative atrial fibrillation (POAF) has a good response to pharmacological cardioversion with approximately 85% resolved within 24 h from onset [30, 42–44].

Sustained ventricular tachyarrhythmias are quite rare after lung resection [28, 45]. Non-sustained ventricular tachycardia (more than three consecutive beats but <30 s) has an incidence of 0.5–1.5% and can occur in the first 96 h after lung resection, especially in patients with preoperative

Table 56.2 Summary of the literature analyzing right ventricular changes after lung surgery. All the studies listed are prospective in nature

Study	Time of the study	Type of surgery	Study	Results Lobectomy pneumonectomy		Exclusion	Comments
Venuta [23]	4 years	Lobe ($N = 36$) Pneumonectomy ($N = 15$)	TTE	No changes.	↑RVDD ↑PASP moderate TVI	$FEV_1 < 60\%$, h/o MI, angina, valvular ds, AF, cardiac surgery	Mild increase in PASP and RVDV not clinically significant to cause RVH
Foroulis [24]	6 months	Lobe ($N = 17$) Pneumonectomy ($N = 35$)	TTE	↑PASP, ↑RVDD ↑TR	↑↑PASP ↑↑RVDD ↑↑TR	Postoperative BPF, empyema, respiratory failure, MI	Small study, higher PASP in pneumonectomy patients at 6 months (R > L cases), with higher incidence of postoperative AF and SVT requiring treatment, attributed to RV dilatation
Amar [25]	1 month	Pneumonectomy ($N = 70$)	TTE		No changes in R and L atrial diameter, EF, TR and RVSP	AF, lung resection, lesser operations, unresectable	Study to evaluate role of diltiazem and digoxin on AF Echo done as part of their follow-up
Amar [26]	1 week	Lobe ($N = 47$) Pneumonectomy ($N = 39$)	TTE	↑HR	↑RSVP ↑HR	Wedge, prior thoracic surgery Non-sinus rhythm	RVSP of 31, not affecting RV systolic function unless respiratory failure occurs
Kowalewski [10]	2 days	Lobe ($N = 9$) Pneumonectomy ($N = 22$)	TTE	No changes	↑RVEDV ↓RVEF ↑ SVT		Not very accurate and nonstandard right heart volumes calculations which can underestimate large volumes. RVEF usually underestimates the true value by echo due to RV geometry

left bundle branch block [46]. It is rarely associated with hemodynamic instability requiring treatment at any time. There is no association with age, other clinical factors, or core temperature upon arrival to PACU. On multivariate analysis, an independent association seems to exist between non-sustained ventricular tachycardia and POAF, possibly due to vagal withdrawal or irritation and/or a surge in sympathetic activity. These findings differ from the cardiac surgical literature, where the presence of postoperative ventricular tachycardia often leads to poor outcome [28].

POAF can be an isolated complication within the first week after surgery or associated with respiratory or infectious disease [30]. It is typically transient and reversible and seems to affect individuals with an electrophysiologic substrate for arrhythmias present before or as a result of surgery [29, 47]. Despite the good prognosis, POAF is associated with a 1.7% risk of developing cerebrovascular accidents if persistent [38, 48]. Thromboembolic events can occur within 24–48 h from the onset of sustained POAF and may have devastating sequelae. If sinus rhythm fails to be restored

within this time frame, anticoagulation should be considered weighing the risk of postoperative bleeding [28]. The most recent American Heart Association (AHA) guidelines on management of AF unrelated to surgery provide similar recommendations for which antithrombotic medications one should employ in postoperative patients depending on the patient's risk (i.e., presence of a prosthetic valve, etc., prior cerebrovascular accidents, or no risk factors) [49].

Several mechanisms have been proposed to explain POAF, but the most consistent factors other than age have been prior history of paroxysmal AF and extent of resection. Aging per se has been associated with loss of about 90% of normal sinus nodal fibers and remodeling of the atrial myocardium, with changes in the sinoatrial and atrioventricular nodal conduction, as well as an increased sensitivity to catecholamine activity, especially after surgical trauma in the area [38, 45]. Triggering of an inflammatory response with activation of the complement system and several pro-inflammatory cytokines has also been suggested as a contributing factor for POAF in this age population [50]. This thought is supported by a doubling in white blood cell (WBC) count observed in patients older than 60 years of age on postoperative day 1, which is associated with a threefold increase in the odds of developing POAF [32]. Catecholamine-induced leukocytosis via α- and β_2-receptor activation is a known phenomenon which could in part explain this finding. The use of thoracic epidural analgesia as a modality to cause sympathectomy and prevent POAF has led to disappointing results [51], maybe due to the high individual variability of sympathetic blockade. Stretching or inflammation of the pulmonary veins, hilar manipulation, and mediastinal shift may be additional contributing factors [47]. Positive inotropic agents, i.e., dopamine, as well as anemia, fever, hypoglycemia, postoperative ischemia, and surgical complications, are all aggravating factors [42, 52].

Presenting symptoms of rapid POAF include dyspnea, palpitations, dizziness, syncope, respiratory distress, and hypotension [38, 45]. Although pulmonary embolism or myocardial ischemia and electrolyte abnormality are commonly included in the differential diagnosis they are rarely proven [53]. According to the AHA guidelines, transthoracic echocardiography should be part of the workup for new-onset POAF to rule out any structural disease, if such information is not already available [40]. Similarly, the AHA guidelines do not recommend "ruling out" pulmonary embolism, thyrotoxicosis, or myocardial ischemia if there are no accompanying clinical signs or symptoms.

Postoperative arrhythmia is indirectly associated with higher morbidity [45]. It also can be a direct cause of death in the presence of heart failure or prolonged hypotension [40, 54]. Length of hospital stay and costs are increased in patients with arrhythmias, highlighting the importance of prevention when possible [36, 45, 54]. In most cases, POAF resolves prior to hospital discharge with a complete resolution at 6 weeks from surgery [38, 45]. Patients are considered at risk for postoperative supraventricular arrhythmias if they have two or more of the risk factors listed in Table 56.3, and, if so, they may be started on pharmacological prophylaxis either preoperatively or in the immediate postoperative period. Several regimens are available to prevent or treat atrial tachyarrhythmias.

Table 56.3 Proposed risk factors for supraventricular tachyarrhythmias [28, 30, 43, 45, 47]

Age > 60
Male gender
History of paroxysmal atrial fibrillation
Prolonged P wave duration
Preoperative HR > 72 bpm
Elevated BNP level
Increased WBC count on POD 1
Intrapericardial procedure

Abbreviations: *HR* heart rate, *bpm* beats per minute, *BNP* brain natriuretic peptide, *WBC* white blood cell count, *POD* postoperative day

Role of Medications Used for Treatment and Prevention

Rate Control Agents

β-blockers are antiarrhythmic agents with cardioprotective effects. As prophylactic agents, they counteract the effects of the high sympathetic tone that occurs after surgery, which may enhance patient susceptibility to dysrhythmias. β-Blockers inhibit intracellular calcium influx via a second messenger have a membrane stabilizing effect and inhibit the renin-angiotensin-aldosterone system [40, 55]. Their respiratory side effects become particularly important after lung resection since nonselective β-blocker can cause bronchospasm and worsen pulmonary function in the postoperative period. Pulmonary edema has been described as a potential side effect [56], as well as hypotension and bradycardia. Moreover, in patients on chronic β-blockers, withdrawal may lead to rebound tachycardia and related complications due to an upregulation of the β receptors [57]. The β-blocker length of stay study (BLOS) analyzed the effects of β-blockers after cardiac surgery used as prophylactic agents in patients both naïve and already taking β-blockers [58]. The goal was to prevent POAF and possibly decrease the length of stay in the hospital and ICU. Patients already on a β-blocker had a small decrease in the incidence of POAF, but their hospital length of stay was increased. This was attributed to the development of adverse cardiac and pulmonary effects. The Perioperative Ischemic Evaluation (POISE) trial showed that aggressive β-blockade in patients at risk or with atherosclerotic disease can reduce postoperative myocardial infarction and even POAF but at the cost of an increase in mortality related to

cerebrovascular events in patients who had hypotension and decreased cerebral perfusion [59]. These findings have been consistent with other trials using lower doses of β-blockers, which questioned the safety of this strategy [60]. The AATS 2014 guidelines do not recommend the use of β-blockers in patients who are not already taking the medication [40].

The *calcium channel blockers* verapamil and diltiazem are both prophylactic and therapeutic agents for the treatment of POAF. They decrease intracellular calcium entry by directly blocking the L-type calcium channel and slowing the sinoatrial automaticity and atrioventricular nodal conduction [55]. This class of drugs seems to reduce pulmonary vascular resistance and right ventricular pressure as well, making this an attractive option after major lung resection [56]. Hypotension is one of the major side effects, especially with verapamil, and one of the most common reasons to stop these medications. Calcium channel blockers cause a 40% decrease of postoperative myocardial infarction rates and a 45% reduction of ischemia when used in the cardiac surgical population [56]. Diltiazem is superior to digoxin when used to prevent POAF after intrapericardial or standard pneumonectomy [25]. However, both drugs have equal effect on postoperative ventricular ectopy, echocardiographic changes in right ventricular function, and hospital length of stay. In the largest study to prevent POAF in thoracic surgical patients, diltiazem was safe and effective in reducing the rate of POAF of almost 50% [61]. When administered as a bolus followed by a continuous infusion, diltiazem controls the ventricular rate in about 90% of patients with recent onset of POAF, with an onset of action of 2–7 min [40].

Amiodarone is a sodium-potassium-calcium channel blocker and a β-adrenergic inhibitor. It has been demonstrated to be the most effective prophylactic agent after major lung resection when started in the immediate postoperative period [41]. It is often used to maintain sinus rhythm after electrical cardioversion in the general population. An intravenous bolus followed by a continuous infusion has a similar effect to intravenous diltiazem and digoxin. Its onset is of about 4 h with a 24 h duration of the effect [40]. As a prophylactic agent, it works best when administered 1 week prior to cardiac surgery [62]; however the precise mechanism of action is unknown [63]. The sodium-calcium-potassium channel blockade causes an increase in the duration of the action potential and the refractory period in the cardiac tissue. As a result, hypotension, bradycardia, and QT prolongation can be significant, especially in patients with congestive heart failure and left ventricular dysfunction [52]. Other side effects seen with prolonged oral use include hypo- or hyperthyroidism, hepatic and neurotoxicity, and prolongation of warfarin half-life [63]. However, pulmonary toxicity remains the main concern of amiodarone therapy after lung resection [40, 56]. It can occur at lower dosages and can manifest as chronic interstitial pneumonitis, bronchiolitis obliterans, adult respiratory distress syndrome (ARDS), or a solitary lung mass [52]. In a very small prospective randomized study, Van Mieghem et al. [64] examined the role of amiodarone prophylaxis on POAF after lung resection. When compared to verapamil, there was no difference in the rate of POAF at the interim analysis. However the study was stopped prematurely due to an increased incidence of ARDS in the amiodarone group, which was 7.4% in the patients who had a right pneumonectomy versus 1.6% for other types of lung resections. This was associated with higher mortality rates and occurred despite using standard intravenous regimens and having therapeutic plasma concentrations. Two mechanisms were proposed: an indirect one, by increasing inflammatory mediators, and a direct one, by causing direct damage to the cells and subsequent fibrosis. Independently from the etiology, their recommendation was to avoid amiodarone after lung resection. By surgically decreasing the amount of lung parenchyma available, standard doses of amiodarone can account for higher pulmonary concentrations of the drug which may reach toxic levels. These results were not confirmed by later studies, when amiodarone was used for a short time period [28]. Tisdale et al. [65] randomized 130 patients undergoing anatomical lung resection, demonstrating a decreased incidence of AF in the amiodarone group (13.8% versus 32.3% in the control), with no difference in respiratory or cardiac complications. The lack of double blinding and the selection bias represented by a high rate of exclusion of cases of intraoperative AF were the main limitations for this study. Riber et al. [66] confirmed these results in a similar patient population. Amiodarone significantly decreased the incidence of POAF, with a good rate control and lack of symptoms in patients who developed POAF while receiving the medication. Overall, amiodarone and diltiazem seem to have similar efficacy in preventing POAF after major lung resection [28]. The main indication for amiodarone use still remains as a second-tier drug for POAF refractory to rate control drugs or as a therapeutic agent for POAF coupled with preexcitation conduction abnormalities, such as Wolff-Parkinson-White syndrome [40]. Monitoring serum concentrations is not necessary; however it is recommended to maintain the total cumulative dose less than 2150 mg given over 48–72 h [40].

Prophylactic *digitalization* to prevent POAF is not recommended any longer since there are no proven benefits but potential side effects [67]. The main mechanism of action is by enhancing vagal stimulation at the atrioventricular node, thus decreasing ventricular response during atrial arrhythmias [57]. There is also an inhibition of the sympathetic response which is unrelated to the increase in cardiac output and a binding of the myocardial sodium-potassium ATPase channel, blocking its transport [68]. The increase in intracellular sodium and subsequent calcium concentrations promote cardiac contractility. Digoxin does not seem to restore

normal sinus rhythm in patients with chronic atrial fibrillation, and as a single agent it does not adequately control the ventricular response unless given at very high doses [67] or when combined with β-blockers or calcium channel blockers [68]. Calcium channel blockers have demonstrated to have better results in preventing POAF with fewer side effects [25]. Superior results are seen when digoxin is used in patients with chronic atrial fibrillation and heart failure with systolic dysfunction [67]. The onset after intravenous administration of 0.5–0.75 mg bolus is between 30 min and 2 h. AF rate control is usually achieved with further doses of 0.25 mg iv every 2–6 h to a maximum of 1.25–1.75 mg [40]. Digitalis toxicity and the difficulty in assessing proper plasma levels remain the main limiting factors for its use [43]. However, no difference in mortality was reported when chronic digoxin was compared with beta-blocker or calcium channel blockers [69]. Digoxin should be avoided in patients with renal insufficiency, electrolyte disturbances (hypokalemia, hypomagnesemia, and hypercalcemia), acute coronary syndromes, and thyroid disorders.

Rhythm Control Medications

Sotalol is a class III antiarrhythmic medication with significant activity as a nonselective β-blocker and a potassium channel blocker. Potassium current blockade prolongs both the action potential and the QT interval, predisposing to ventricular dysrhythmias such as torsades de pointes [57]. This can occur at both therapeutic and toxic dosages [55]. Due to the renal excretion, its use is contraindicated in patients with a creatinine clearance less than 46 ml/min. As with other β-blockers, sotalol is effective in decreasing POAF but does not reduce hospital length of stay or postoperative morbidity. Bradycardia can be significant enough to warrant discontinuation [47]. According to the American College of Cardiology recommendations, sotalol may be harmful if used to pharmacologically cardiovert atrial fibrillation [40]. Unfortunately, most of the data on this medication come from the cardiac surgical population [53], with no studies in the noncardiac population [40].

Magnesium is indicated in case of hypomagnesemia. The data on the use of magnesium are mainly from the cardiac surgical literature and are conflicting. One randomized controlled study done in 200 patients undergoing cardiopulmonary bypass surgery showed a decreased incidence of POAF when magnesium sulfate was administered for prophylaxis [70]. However, several other trials in similar surgical populations have given conflicting results on the benefits of magnesium and POAF prophylaxis, with the only agreement to maintain magnesium levels within normal values [57]. Compared to β-blockers and amiodarone, magnesium is inferior in preventing POAF [71]. Except in patients with acute renal failure, magnesium has a relatively safe profile.

Statins (3-hydroxy-3-methylglutaryl coenzyme-A reductase inhibitors) have been shown to suppress electrical remodeling and prevent POAF in animal models [52]. They are powerful lipid lowering drugs highly effective in preventing coronary artery disease [40]. Studies conducted in hypercholesterolemic patients on statins undergoing coronary artery bypass grafting (CAGB) showed a decrease in postoperative major cardiac events [72]. This effect was potentiated by simultaneously taking β-blockers [73]. The main benefits of statins seem to occur when these drugs are started in the preoperative period. When administered 1 week prior to on pump CABG, they decreased the incidence of POAF, as well as hospital length stay [47, 73]. After major lung resection, patients already on statins prior to surgery showed a threefold decrease probability of developing POAF [74] and overall complications [75]. One possible explanation seems to be related to their anti-inflammatory or antioxidant mechanism. Observational studies conducted in patients undergoing major lung resection have reported an increase in C-reactive protein and interleukin 6 in the postoperative period [76]. Atorvastatin (40 mg PO) started 7 days prior to lung resection and continued for 7 postoperative days in statin-naïve patients undergoing elective anatomical lung resection was associated with a decrease in hospital complications [75].

Angiotensin-converting enzyme inhibitors (*ACEIs*) and *angiotensin receptor blockers* (*ARBs*) have been suggested to reduce the incidence of POAF in patients with coexisting heart failure and systolic left ventricular dysfunction, but not in cases associated with systemic hypertension [77]. They may also play a role in maintaining sinus rhythm after electrical cardioversion. The data in the literature has focused on the role of these drugs on the outcome in chronic AF patients. The prophylactic use of ACEIs/ARBs to prevent POAF remains quite controversial. Losartan prevented POAF better than metoprolol when used in the postoperative period after major lung resection (6% vs 12%) [39]. Inhibition of the renin-angiotensin-aldosterone system seems to attenuate left atrial dilatation and atrial fibrosis and contributes in slowing conduction in animal studies, all factors that can trigger and maintain reentry circuits. These effects seem to be potentiated in patients with chronic heart failure when β-blockers are added [47].

Novel Medications

N-Acetylcysteine has successfully been used to decrease POAF and all-cause mortality after cardiac surgery alone or in combination with other agents [78, 79]. The mechanism of action seems to be related to its antioxidant properties, by stimulating glutathione production. Inclusion of cysteine in the perfusate of isolated rat hearts has been shown to confer significant cardioprotection and improved preservation of ATP and glutathione [80]. Other proposed mechanisms include inhibition of the renin-angiotensin system and/or

atrial remodeling [78]. There are no current studies in the literature on the role of NAC in thoracic noncardiac surgery.

Vernakalant is an atrial-selective sodium-potassium channel blocker approved for pharmacological cardioversion of recent onset AF. Vernakalant has a better conversion rates than amiodarone but similar to propafenone and flecainide with less side effects [81]. Its main advantage is the rapid onset (10–15 min) and the high success rate after one dose [81]. Hypotension, especially in patients with heart failure, bradycardia, QT prolongation, and torsade de pointes are the most common side effects. Vernakalant is not effective in cardioverting atrial flutter or AF lasting more than 7 days [81]. While it is approved for clinical use in Europe, it is still under FDA investigation in the USA.

Olprinone is a specific phosphodiesterase III inhibitor with inotropic and vasodilating effects, commonly used to treat heart failure. It is also a bronchodilator. When administered prophylactically in patients after lung resection [82], it decreased the incidence of POAF, lowering the BNP and WBC levels without affecting the hemodynamics. It is usually given as a continuous infusion for 1 day, with duration of action up to 7 days. Suggested mechanisms include pulmonary vasodilatation with unloading of the right ventricle, positive chronotropism, and inhibition of the inflammatory response. In the USA this medication is approved for research use only.

Human atrial natriuretic peptide is a peptide hormone synthesized by the atria and available as treatment option for heart failure. It inhibits the sympathetic nervous system and the renin-angiotensin-aldosterone axis, leading to cardioprotective effects. A prophylactic 3-day infusion has been associated with a decrease in POAF**,** WBC, and CRP but no significant changes in blood pressures in patients with COPD undergoing lung resection [83]. The effect seems to be lasting up to a month after the infusion is stopped. This medication is routinely used in Japan.

Role of Postoperative Chemical and Electrical Cardioversion

Chemical and electrical cardioversion: restoration of sinus rhythm is recommended in patients who have stable AF but are symptomatic, when the duration is longer than 24 h and when anticoagulation may cause postoperative bleeding [84]. Several medications are available for cardioversion, with the greatest success rate when started within 7 days from the onset [85]. Drugs commonly used for chemical cardioversion of POAF include flecainide, dofetilide, propafenone, and ibutilide [28]. Ibutilide is available in the iv form, and it has been shown to have modest success in converting acute AF after cardiac surgery. However, it is associated with polymorphic ventricular tachycardia in up to 2% of patients, especially in the presence of electrolyte abnormality [85]. In the presence of QT prolongation, hypokalemia and low ejection fraction can trigger ventricular tachycardia. Single oral doses of flecainide (300 mg) or propafenone (600 mg) seem to be safe, cardioverting 91% and 76% of cases, respectively, within 8 h from the onset of AF. To be eligible for this class of medications, patients must be free from cardiac structural disease, such as left ventricular hypertrophy, mitral valve disease, coronary artery disease, or heart failure [86]. Potential side effects include ventricular tachycardia, heart failure, and conversion to atrial flutter with rapid ventricular response [85].

Electrical cardioversion is used to treat AF in case of hemodynamic instability, including symptomatic profound hypotension, myocardial ischemia or infarction, and/or heart failure [40]. The success rate is about 67–94% [52]. Biphasic DC cardioversion has higher success rates than monophasic, using a current around 100–200 J and in a synchronized mode. Higher energy can be used for patients with high body mass index, prolonged AF, or left atrial enlargement. Deep sedation is recommended. Bradycardia (more common in patients on antiarrhythmics prior to cardioversion), ventricular tachyarrhythmias (when the shock is applied during repolarization), hypotension, pulmonary edema (probably due to myocardial stunning), and embolism are all potential complications. Electrolytes should be checked and normalized before cardioversion. In case of digitalis toxicity and hypokalemia, cardioversion should be avoided due to the high incidence of ventricular fibrillation. In this setting, low currents and prophylactic lidocaine should be used. Pacing capabilities should be readily availbale, since bradycardia can be profound to the point of asystole [52]. If the duration of the AF is less than 48 h, cardioversion can be done prior to anticoagulation [40]. After the 48 h mark, anticoagulation is recommended if not contraindicated by the surgical procedure. Whether intravenous heparin should be started and then followed by a 4 weeks cycle of oral anticoagulants is unclear. Common practice is to start patients on oral anticoagulants such as warfarin or the novel anticoagulant drugs [10].

Acute Coronary Syndrome

Myocardial ischemia may occur transiently after lung resection and present as an electrocardiographic finding in 3.8% of patients, while infarction can occur in 0.2–0.9% of the cases [29, 87–89]. The diagnosis of symptomatic perioperative myocardial infarct is associated with a 30–50% risk of death [90]. The incidence increases in the presence of preoperative coronary artery disease and abnormal exercise testing. Patients are at the highest risk during the first 3 postoperative days, when a high degree of monitoring is suggested.

Nonspecific diffuse ST segment changes may be present after intrapericardial resection due to direct mechanical injury [91]. Mediastinal shift can also cause dynamic EKG abnormalities in the postoperative period. An increase in troponin may be observed in all these scenarios.

There are no definite recommendations for preoperative invasive testing or interventions. Most of the decision-making should be based on the clinical presentation [92]. In patients at high risk (such as the ones with unstable angina, uncompensated chronic heart failure, arrhythmias, and severe valvular disease), cardiac catheterization is highly recommended if followed by coronary artery revascularization, when necessary [53, 93]. Patients with and without pre-existing cardiac disease have a similar incidence of postoperative major adverse cardiac events (MACE) after thoracoscopic lung resection [94]. However the former have higher incidence of atrial fibrillation and 30-day postoperative mortality. Preoperative angina is associated with a higher incidence of postoperative adverse cardiac events (such as MI or cardiac arrest) [95]. According to the latest AHA-ACC recommendations [90], if the risk of reinfarction is high for at least 2 months after an MI, CABG but not percutaneous coronary intervention (PCI) may decrease that risk. If patients require revascularization, elective surgery needs to be postponed, with the dilemma of how long to wait, as in the case of cancer where there is potential disease progression [96]. Cardiac stents, especially drug-eluting ones, represent a significant problem due to the prolonged need for anticoagulation. Stopping dual antiplatelet therapy (aspirin and clopidogrel) is associated with a high risk of stent thrombosis, while continuing it leads to an increased risk of intra and postoperative bleeding and precludes regional anesthetic techniques [97]. The duration of the anticoagulation is usually based upon the type of stent: bare-metal stents commonly require 4–6 weeks, while in the presence of drug-eluting stent 12 months are recommended for elective procedures and 6 for urgent cases [90]. The risk of stent thrombosis is higher for drug-eluting stents, especially if the stent is long, at a bifurcation, if the revascularization is incomplete, or if the patient has history of diabetes or heart failure [98]. A non-randomized observational prospective study done in noncardiac surgery patients who had cardiac stents placed within a year from surgery found a 44.7% rate of postoperative cardiac complications and a 4.7% mortality rate [99]. Dual antiplatelet therapy was stopped on average 3 days prior to surgery and substituted with intravenous unfractionated heparin or subcutaneous enoxaparin. Most of the complications occurred within the first 35 days from the stent placement and were cardiac in nature. Bleeding was not a significant variable. This data was not confirmed by another small prospective observational study done in 16 patients undergoing major lung resection 4 weeks after coronary angioplasty or PCI [100]. Dual antiplatelet therapy was given for 4 weeks and interrupted 5 days prior to surgery when it was bridged with low molecular weight heparin. No MI or deaths were reported. Despite the absence of randomization, these studies stress several important points. Once the antiplatelet treatment is stopped, low molecular weight heparin should be used (heparin alone is insufficient); all non-life-saving procedures should be postponed at least for 6–12 weeks from the stent placement, and aspirin should be continued up to the day of surgery [101, 102]. The protective effects against MACE in the immediate postoperative period outweigh the lower risk of postoperative bleeding [101]. Prophylactic revascularization (CABG versus PCI) does not seem to add further benefits over optimal medical treatment in patients with cardiac risk undergoing elective major vascular surgery [90, 96]. Long-term survival as well as myocardial infarction, death, and hospital length of stay seems to be unchanged. However, CABG is associated with less postoperative myocardial infarctions and decreased hospital length of stay when compared to PCI, probably because of better revascularization [103]. According to the American College of Cardiology, revascularization should be reserved for patients with unstable angina or advanced coronary artery disease [90]. If revascularization is needed before surgery, bare-metal stents [90] or balloon angioplasty [102] are the preferred options due to their lower risk of thrombosis. In both cases, elective surgery needs to be appropriately delayed to prevent graft or stent thrombosis.

Heart Failure and Cardiac Herniation

Heart failure can occur after major lung resection as a result of right- or left-sided dysfunction. *Right heart failure* can result from changes either in contractility or afterload. Unfortunately, most of the studies investigating the changes in right ventricular function after lung resection are small and found minor and transient differences when compared to the preoperative period. In the first 2 postoperative days, there is a reversible increase in right ventricular end-diastolic volume [53], as well as a mild increase in pulmonary arterial pressures and pulmonary vascular resistance [104]. While postoperative changes in pulmonary arterial pressures, central venous pressures, and pulmonary vascular resistance seem to be subtle at rest, they may become significant during exercise. Changes in right ventricular function are usually able to compensate at rest, but they may fail during exercise, leading to pulmonary hypertension [53]. When transthoracic echocardiography has been used to evaluate right ventricular function after pneumonectomy, it has shown only a mild increase in pulmonary arterial pressure which is not associated with ventricular dysfunction [26]. Other possible causes of right ventricular failure, although rare, include pulmonary embolism and cardiac

herniation. *Left side heart failure* is usually a consequence of right heart dysfunction, either by decreasing left ventricular preload or shifting the interventricular septum [3, 53]. Acute ischemia and valvular disease may also be contributing factors. *Cardiac herniation*, a rare complication after pneumonectomy, may be responsible for both right and left heart failure. It occurs more commonly after intrapericardial pneumonectomy, right more than left, and leads to a 50% mortality rate [53]. Herniation can be secondary to an incomplete surgical closure of the pericardium or the breakdown of a pericardial patch [105]. One main contributing factor includes an increase in intrathoracic pressure, such as with coughing or sudden increase in peak airway pressures during mechanical ventilation [29]. Changes in position, with the operative side being dependent, positive pressure ventilation, rapid lung re-expansion, or suction on the chest tube are all other possible causes. Symptoms depend on the side of the herniation. Right-sided cases present with superior vena cava syndrome, due to kinking of the superior vena cava and decreased right ventricular filling, with subsequent hypotension, tachycardia, and shock. Left-sided cases present with arrhythmias and ischemia, causing myocardial infarction, hypotension, and ventricular fibrillation if left untreated [106]. This appears to be related to less cardiac rotation, with subsequent pericardial compression on the myocardium. Clinical presentation and electrocardiographic findings are fairly nonspecific in suggesting the diagnosis, stressing the role of chest radiography and a high index of suspicion. Treatment is surgical, with repositioning of the heart and placement of a patch. In order to minimize hemodynamic instability, the patient should be kept on the lateral decubitus with the operative side up [105].

Mediastinal Shift and Post-pneumonectomy Syndrome

Mediastinal shift can occur intraoperatively or in the postoperative period as a result of changes in the post-pneumonectomy space. At the end of surgery, once the chest is closed, some surgeons evacuate the air and fluid that fill the empty space aiming to bring the mediastinum back to midline. Excessive fluid drainage can lead to ipsilateral mediastinal shift and contralateral lung expansion, with decreased venous return and significant hypotension [107]. Rapid accumulation of fluid in the pneumonectomy space (such as hemo- or chylothorax) can cause contralateral shift, with secondary compression of the remaining lung [29]. A high index of clinical suspicion, careful monitoring of the hemodynamics, and communication with the surgical team are needed to prevent hemodynamic collapse. When excessive fluid accumulates in this space, contralateral mediastinal shift occurs, leading to compression of the remaining lung and secondary respiratory insufficiency. This is seen more often in the postoperative period, and the use of intracavitary pressures monitoring can guide the drainage of the excess fluid if needed [107]. CT scan studies have shown obliteration of the post-pneumonectomy space with fluid over time, elevation of the hemidiaphragm, and expansion of the contralateral lung [108]. In case of extreme mediastinal shift, dynamic compression of the distal airway can occur, leading to the so-called post-pneumonectomy syndrome [29, 109, 110]. This is a rare and late complication, which can occur at a median of 7 years from surgery. It is more common in females and children and with right-sided procedures (even though it has been described for left cases as well) [111]. It manifests with decreased exercise tolerance, exertional respiratory insufficiency, stridor, and recurrent infections. Respiratory symptoms are caused by dynamic compression of the distal trachea and left mainstem bronchus against the spinal column and the left pulmonary artery, secondary to the severe mediastinal shift to the right. Treatment involves the use of airway stents as a temporary measure or thoracotomy and repositioning of the mediastinum via Lucite plastic balls, Silastic implants, or saline-filled prosthesis [111] (see also Chap. 41). In the rare event of *cardiac arrest* (3–7%), close chest compression is ineffective [29]. As a result of the mediastinal shift, the heart cannot be compressed between the sternum and the vertebral bodies, requiring an emergency thoracotomy and open cardiac massage. In the case of intrapericardial dissection, chest compression can cause cardiac herniation.

Conclusion

In the last few decades, a significant improvement in the surgical and anesthetic techniques has made pneumonectomy and anatomical lung resection safer. The introduction of enhanced recovery pathways, minimally invasive surgical techniques, the use of short-acting anesthetics, and a multimodal analgesic approach have all contributed to decrease the incidence of postoperative complications. Fast-track strategies and careful selection of patients undergoing lung resection procedures have also played an important role in postoperative and long-term outcome. Better utilization of step down and acute postoperative care units have decreased the rate of ICU admissions, saving costs. Since the average age of patients requiring lung resection is increasing, anesthesiologists and surgeons will be facing more complex cases, due to the presence of multiple comorbidities. Careful preoperative workup customizing the type of surgery as well as planning for in-hospital and post discharge rehabilitation options will prove to be essential for decreasing even further the possible complications and improving the overall care.

Clinical Case Discussion

A 65-year-old-man with squamous cell cancer of the right upper lobe underwent a right intrapericardial pneumonectomy. Surgery was 150 min and uneventful. Estimated blood loss was 700 cc, and 700 cc of ringer's lactate was used during the case. Urinary output was 100 cc. The patient was extubated in the operating room at the end of the case. A thoracic epidural was used intraoperatively, and the patient was comfortable in PACU. As part of the postoperative blood work, troponin levels were checked, and the first set was 1.66 (1.07 and 0.52 the second and the third one). ST segment elevations transiently occurred on POD 1 in correspondence to a fourth troponin of 1.55.

On POD 2, subcutaneous emphysema was noted on the right chest wall, neck, and eye. While walking, he had an episode of desaturation and tachycardia. Chest X-ray is shown (see Fig. 56.1). Electrocardiogram showed rapid SVT, with hypotension (HR = 128, BP = 88/45). The patient was transferred to the ICU where he was intubated. He slowly became hemodynamically unstable, requiring multiple pressors.

Questions

What are common cardiac complications after lung resection?

1. Arrhythmias (atrial fibrillation, atrial flutter, and supraventricular tachycardia (SVT))
2. Ischemia and acute coronary syndrome
3. Heart failure and cardiac herniation
4. Mediastinal shift and post-pneumonectomy syndrome

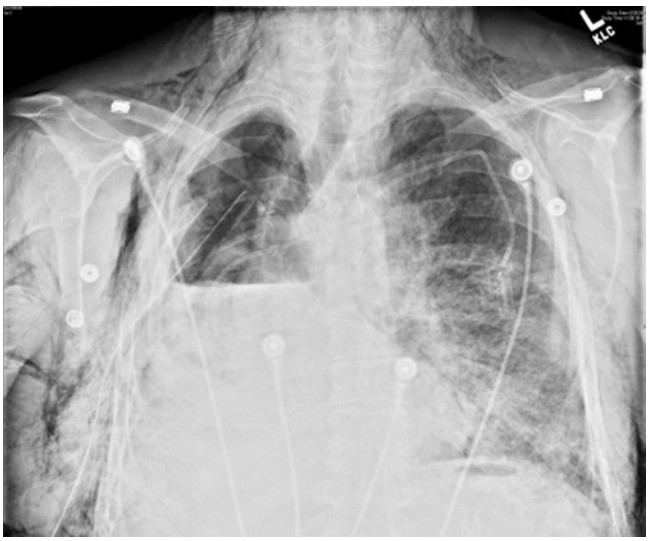

Fig. 56.1 Radiographic changes on postoperative day 2

Specifically

1. *Arrhythmias*: Who is at risk (suggested pathophysiology, role of WBC and inflammatory response, BNP levels)? What we can do to prevent it (rate or rhythm control? Preoperative medications?)? How do we treat postoperatively (medications vs cardioversion)? Risks/side effects of the treatment.
2. *Acute coronary syndrome*: What are known risk factors? Is preoperative stenting better than medical treatment in a patient with a positive stress test? What is the treatment? How does it affect mortality?
3. *Cardiomegaly/ cardiac failure*: Who is at risk (role of the extent of dissection, preoperative risk factors)? How does it affect mortality?
4. *Mediastinal shift*: Why does this happen (extent of dissection)? How common is cardiac herniation? What is the pathophysiology and the diagnosis?

Back to the Case

The intraoperative course was uneventful, despite a more extensive procedure than scheduled. The patient suffered transient ischemia in the PACU (ST changes on EKG and elevated troponin) that was managed medically and resolved. On POD 2, he had both respiratory and hemodynamic symptoms while ambulating.

The CXR at that time showed massive subcutaneous emphysema on the side of surgery, extending to the neck; a post-pneumonectomy cavity filled with fluid and a mediastinal shift toward the operative side; and an opacification of the left lung base. These are all surgical complications that may not be easily preventable, despite a high degree of alertness and aggressive postoperative physical therapy and pulmonary toileting.

In most cases isolated cardiac complications after pneumonectomy can be successfully treated with medications or invasive procedures. Respiratory complications are more difficult to prevent and manage, especially if the onset is quick. In this case scenario, hypoxemia developed very quickly and was so severe to require reintubation and transfer to the ICU for further care. A repeat CXR (Fig. 56.2) after intubation shows a significant worsening of the left base opacification. Ideally treatment should follow a diagnosis. However, in practice, patients may be clinically too unstable for transport to the imaging suite. Supportive measures become the mainstay of therapy. In this case, the need for vasopressor continued to increase and the degree of hypoxia to worsen. The patient suffered a secondary cardiac arrest and expired on POD 2.

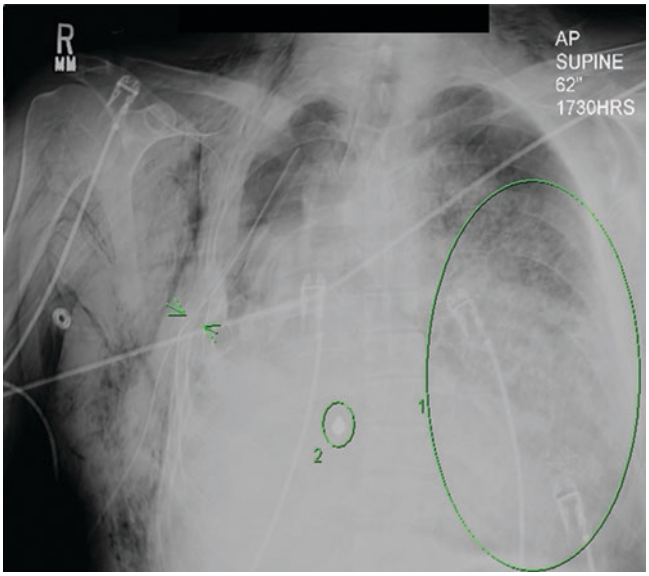

Fig. 56.2 Worsening of the left base opacification

Post-thoracic Surgery Patient Management and Complications

57

Jean Y. Perentes and Marc de Perrot

Key Points

- Chest drains can usually be removed postthoracotomy when the air leak has stopped and drainage is <400 mL/day.
- The majority of thoracic surgical patients are at high risk for postoperative venous thromboembolism.
- Postthoracotomy blood loss via the chest drains requires reexploration if it meets or exceeds 1 L in 1 h or 200 mL/h for 2 h.
- The risk of post-thoracic surgery hemorrhage is increased in patients with a previous thoracotomy, following decortication or surgery for infectious causes.
- Lobar torsion most often occurs in the right middle lobe following a right upper lobectomy.

General Principles of Postoperative Care

In thoracic surgery, perhaps more than in any other surgical field, "an ounce of prevention is worth a pound of cure." To obtain best results in perioperative care after pulmonary procedures, this care begins before the procedure and does not end until long after the patient leaves the hospital.

Preoperative Preparation

Preoperative Teaching

To achieve the best participation in a patient's postoperative care, the patient and family should be as fully informed as possible. When both patient and family know what to expect, they are better prepared to deal with the problems as they arise. The surgeon should have frank and open discussions with the patient and family concerning the anticipated outcome and expected postoperative problems, along with the usual measures to combat those problems. Such discussions help the patient and family understand that the postoperative course may not be smooth and that aggressive measures may be required to achieve ultimate recovery. According to Wright et al., the most common problems delaying discharge from the hospital include inadequate pain control, prolonged air leak, severe nausea, fever, physical weakness, and arrhythmias [1] (Table 57.1).

Preoperative Pulmonary Exercise and Training

The role of pulmonary rehabilitation is more controversial. In 1979, Gracey et al. [2] studied 157 patients who were

Table 57.1 Common reasons for delay in discharge

Cause	Percentage
Inadequate pain control	28
Prolonged air leak	19
Severe nausea	17
Fever	16
Physical weakness	12
Atrial arrhythmia	7

about to undergo a major operation. They administered a standard pulmonary preparation program used at that time and found that complications were significantly reduced but also that postoperative pulmonary complications were related to the extent of the operation. In 1999, Debigare et al. [3] studied the preparation for lung volume reduction procedures for severe emphysema. Because many patients traveled a great distance, the investigators devised a home exercise training program that included incentive spirometry, muscle exercises, and aerobic training. It began with a detailed teaching and follow-up and was ensured through weekly phone calls and a diary filled out by each patient. As a result, there was a significant increase in the 6-min walk test, quality-of-life perception, peak work rate, peak oxygen consumption, endurance time, and muscle strength; it was therefore concluded that such training was beneficial when time permits a delay in the timing of the operation. This time delay may however not always be an option in patients with malignancy. In 2016, Licker and colleagues [4] randomized 151 operable lung cancer patients to usual care or to a high-intensity interval training (HIIT) program performed during the waiting period of 27 days. While the HITT program improved the 6-min walk distance and the peak oxygen consumption, the program did not reduce the occurrence of postoperative complications. However, the incidence of pulmonary complications in the HIIT group was decreased due to lesser atelectasis as was the stay of patients in the postanesthesia care unit.

Smoking

Smoking cessation has always been considered an important issue in preparation for an operation. However, the evidence shows that the effects of cigarette smoking linger long after cessation and that inordinately long preoperative delays would be necessary to achieve any significant improvement. The Lung Health Study Research Group has published many reports concerning the effects of smoking cessation. Anthonisen et al. [5] reported the results of one of the aforementioned group's studies involving individuals with documented early chronic obstructive pulmonary disease (COPD) who stopped smoking; they experienced improvement of lung function, with the greatest benefit being noted in the first year. No conclusions can be drawn concerning the early effects of smoking cessation, because the investigators' first observation point was 3 months after intervention. Despite the lack of firm evidence, it is still recommended that patients quit smoking for as long as possible prior to operation. Some data suggest that cessation of smoking could potentially lead to higher postoperative complications. This is based on the fact that patients have increased secretions early after cessation [6]. However, in 2005, Barrera [7] studied smokers undergoing thoracotomy at Memorial Sloan Kettering Cancer Center. They found no difference in pulmonary complications among recent quitters vs. continuing smokers. Only patients with >60 packs per year and those with a significantly reduced diffusion capacity had a higher risk for postoperative pneumonia in that series. The investigators concluded that it was safe to quit at any time before operation. Similar findings were observed in a recent case-control study of patients undergoing lung cancer surgery that had stopped smoking up to 16 weeks prior to surgery or that were still active smokers. No difference in their postoperative course was observed [8].

Anticoagulant and Anti-aggregant Medication

Preoperative medications should be continued up to the time of operation. The only exceptions are anticoagulant medications. Patients on warfarin (Coumadin), therapeutic doses of low-molecular-weight heparin, or direct oral anticoagulation (DOAC) should stop their medications prior to the procedure. Regarding antiplatelet therapies, their management is more controversial. Noncardiac surgery is associated to major vascular complications of which the most common is myocardial infarction. Surgery is thought to enhance platelet activation which can favor coronary artery thrombosis, in particular in patients with pre-existing cardiac disease or recent angioplasty procedures. Low-dose aspirin was found to prevent myocardial infarction and major vascular events in a meta-analysis involving over 110,000 patients [9]. However, a recent prospective randomized controlled trial in 10,000 patients failed to show that aspirin continuation/initiation could prevent major cardiovascular events, while it caused more postoperative bleeding events [10]. Interestingly, this study was focused on patients at risk for major vascular events but excluded those with recent coronary angioplasties. The latter is a high-risk category of patients, particularly in the context of drug-eluted stents, for which the perioperative antiplatelet therapy management remains a challenge. In the context of thoracic surgery, retrospective and prospective data suggest that aspirin or clopidogrel monotherapy continuation is safe (no added bleeding complications) and preferable to their discontinuation (more myocardial infarction events) [11, 12]. However, if timing or risk of stent occlusion remains a concern, it was demonstrated that thoracic surgery in the context of dual antiplatelet therapy was possible although causing more postoperative bleeding requiring re-interventions with no added mortality [11]. It is our practice to recommend patients to stay on aspirin at the time of their surgery and to switch dual antiplatelet therapy to aspirin alone when possible. We feel this is associated to a decreased risk of postoperative cardiac complications. The use of aspirin has not been associated with increased risk of bleeding in

our experience. In the context of high-risk patients with drug-eluted stents, surgery can be performed on clopidogrel therapy or even dual aspirin/clopidogrel therapy with a higher risk of bleeding and re-intervention. A careful evaluation and discussion between the thoracic surgeon, the anesthetist, and the cardiologist are necessary to tailor antiplatelet therapy to the surgical and cardiologic risk.

Postoperative Management

Postoperative Pain Management

Surgical interventions involving incisions to the pleural cavity are known to cause severe pain in patients. It is also clearly established that a good postoperative pain management limits patient morbidity as well as their risk for chronic thoracodynia. The gold standard for thoracic surgery has long been epidural analgesia. It was shown to be effective in controlling pain but also has some drawbacks including a failure rate of up to 12%, a risk for epidural infection or bleeding, and clear contraindications in patients with degenerative arthritis to the spine. Alternative analgesic approaches have been described including opioid administration (intravenous, subcutaneous, and oral), wound infiltration by local anesthetics, and nerve block infiltration.

In open thoracic surgery, the epidural remains the most used approach with good pain management and tolerance. The development of VATS has changed this paradigm: given the small incisions, the fissureless approaches, and minimal drainage time, alternative analgesia protocols were developed including intercostal nerve blockade and continuous wound infiltration in combination with oral opioids with very good results. Currently, clinical trials are testing the use of liposomal local anesthetics that were shown to have longer-lasting effects and to allow more limited use of opioids in the postoperative phase [13, 14]. These have shown interesting results in VATS and open surgery. These intercostal blocks can be applied via direct visualization of each intercostal space placing an anesthetic depot (Supplementary Video 57.1).

Pain management must be tailored to each patient and to the procedure. It is essential that patients can stay active, mobilize, and do their chest physiotherapy to avoid atelectasis and infection. We favor epidural anesthesia for open approaches and intercostal nerve blockade for thoracoscopic procedures.

Respiratory Care

Oxygen is administered as needed during the postoperative period. Chest physiotherapy has been demonstrated to be effective in preventing postoperative pulmonary complications and is considered routine postoperative care for patients undergoing thoracotomy. It is also well established that early mobilization has beneficial effects on the pulmonary outcome by improving basal lobe ventilation and respiratory work and thus limiting complications. We favor early mobilization even in patients that are still intubated or on some forms of respiratory support/ECMO (Fig. 57.1). Many patients with hypoxemia benefit more from physiotherapy to increase functional residual capacity and PaO_2 than from further increases in the fraction of inspired oxygen (FiO_2). Excessive oxygen administration has potential drawbacks despite the short-term margin of safety it can provide. Increased alveolar oxygen tension promotes atelectasis as the oxygen is rapidly absorbed. Drying of secretions, even by humidified gases, can increase difficulty with coughing and clearance of mucus. Patients with COPD may have chronic carbon dioxide retention. Supplemental oxygen will tend to exacerbate hypercapnia in these patients. Therefore, in patients who have an elevated $PaCO_2$ preoperatively, oxygen saturation is maintained at 90% or less, preserving the hypoxic drive to breathe.

Early application of continuous positive airway pressure (CPAP) may prevent the need for intubation and mechanical ventilation in patients with hypoxemia by reducing atelectasis and, therefore, improving oxygenation. Clearing of secretions is very important after thoracic operations, especially after tracheal resections. In our institution, we liberally use bronchoscopy and have a small bronchoscopy suite available on the thoracic surgery ward 24 h/day. Patients can be cleared of secretions daily if their cough is ineffective.

Intravenous Fluids

Lung manipulation and collapse may impair pulmonary lymphatic drainage and increase extravascular lung water due to the disruption of the alveolar-capillary membrane. Because of this, patients undergoing pulmonary resections should not receive excessive fluid replacement, and standard fluid management used in other types of surgical patients needs to be moderated. Excessive fluids can result in pulmonary edema, decreased alveolar gas permeability, decreased pulmonary compliance, atelectasis, and hypoxia. A recent study identified more than 0.7 mL/kg/min of crystalloid administration as a risk for pulmonary complications following anatomical resections [15]. One particularly high-risk situation is the postpneumonectomy patient where fluid management was shown to be crucial to avoid postoperative pulmonary edema. An adult should receive not less than 1000 mL of fluids per day. If there are no previous deficits or current complications, the typical amount of liquid ingested by an adult is 2–3.5 L/day. Two liters per day should maintain an adequate

Fig. 57.1 Early mobilization in postoperative patients even when requiring ventilator support or extracorporeal membrane oxygenation

diuretic range (1000 mL) and cover requirements for Na^+, K^+, and Cl^-. In special circumstances, such as after pneumonectomy or lung volume reduction surgery, more extreme fluid restriction (<1.5 L) may be advised. Attention needs to be given to how much fluid is provided with medications. Urine output and serum creatinine must be monitored very carefully, and medications need to be reviewed to reduce or eliminate other nephrotoxins, such as nonsteroidal anti-inflammatory agents (NSAIDs) or angiotensin-converting enzyme inhibitors [16–18].

Chest Drainage System

Surgeons have several different options for draining the chest. For open thoracic surgery, most surgeons will place two #28 Fr chest tubes, one anteriorly and one posteriorly in the chest. For VATS, the practice has evolved, and most surgeons place only one #28 Fr chest tube. The tubes are attached to a drainage system that permits one-way drainage only, with a portion of the device set up to collect fluid. These devices use a variety of valves or liquid to establish a one-way system. All of the collection systems are designed to provide suction on the tubes if the surgeon desires. In the past, all chest tubes were placed on suction at −20 cm H_2O. In recent years, the advisability of the ubiquitous use of suction has been questioned. Several investigators, like Cerfolio and Wain and their respective coworkers, contend that if the lung is fully expanded with the tube on no suction, the patient will do well. Hence, there is currently more individual preference concerning chest tube suction. In our institution, suction at −20 cm H_2O is preferred at least for 24 h and a chest X-ray showing a fully expanded lung the next day. Exceptions are patients with significant emphysema or pneumonectomy or after volume reduction surgery. When pleural apposition is not realistically achievable, suction can potentially prolong the air leak in these patients. In the past years, new devices were developed to allow chest tube suction without the requirement of a wall suction (Fig. 57.2). These devices were shown to favor patient mobility and recovery. In addition, it was demonstrated that fluid and air output digital monitoring was favorable for chest tube removal decision-making [19, 20].

A special consideration with respect to chest drainage is after pneumonectomy. Traditional water-seal devices allow egress of air out from the pleural cavity but not for its return. This can lead to progressive mediastinal shift after pneumonectomy. There are several possible solutions. A chest drain need not be left at all, if the risk of bleeding is minimal. The mediastinum can be balanced by removing a few hundred milliliters of air as the thoracotomy is being closed, by means of a red rubber catheter. In addition, a needle thoracocentesis can be performed in the recovery room after the postoperative chest radiograph is reviewed. If bleeding is sufficient to require drainage, a balanced pneumonectomy chest drainage system is available. This device allows air both in and out, to keep the pleural space within a preset range. Alternatively, a traditional system may be used but clamped and only intermittently opened, although this approach is vulnerable to missteps by the inexperienced staff.

Regardless of the types of chest tubes and the use of suction, the drainage tubes must be assessed at least daily for patency, function, air leakage, and drainage. Inspection of the tube and drainage system for clots or blockages assures patency. Obstructions are removed by "milking" or "stripping" the tubing. This is accomplished by occluding the tubing and pulling it away from the patient to produce a local suction effect. If this does not work, a balloon-tipped catheter may be passed up the tubing to remove the clot, or a suction catheter may be used for the same purpose. A functioning tube is the one that shows variation in the fluid within it when the patient breathes quietly. This may be observed while talking with the patient at the bedside.

Good respiratory variation indicates proper functioning of the tube. Limited changes in the level of the fluid in those drainage systems with a water column may indicate partial blockage. The tubing should be placed so that it does not coil, leaving low points to collect fluid. Such collections impede fluid flow and may cause positive pressure to build up in the tubing and back up into the patient. Air leakage is assessed by observing the water-seal chamber on the drainage device. Air leakage should be assessed on and off suction at quiet respiration. The patient is then asked to cough, and the chamber is observed. Several grading systems have been devised. In general, air leaks should be characterized by the force necessary to produce the air leak and the amount of the air leak. The smallest leak is an intermittent one produced on inspiration only, and the largest one is a continuous air leak. Newer devices being evaluated currently display the amount of air leak digitally. Drainage should be measured twice daily, at least, so that an estimate can be made concerning whether the rate of fluid drainage is increasing or decreasing. Nurses usually record the drainage in 12-h shifts and provide a total daily drainage. In addition, the character of the drainage should be noted. Change in the character of the fluid from sanguineous to serous is usually a good sign. Change from serous to purulent indicates potential empyema and a change to "milky" secretion a chylothorax. In planning the removal of a chest tube, the drainage must decrease to levels acceptable to the surgeon. Although exact numbers are not scientifically demonstrated, the amount is usually 200–400 mL/day or less. Chest tubes and drainage systems are intended to keep the lung expanded and prevent the development of a space. Once air leakage ceases and drainage has decreased to acceptable levels, the system has performed its function and should be removed. In an age of cost containment, this could be any time after the operation and usually is 2–4 days after a lobectomy. The development of VATS has improved the postoperative course and chest tube management. Fissureless techniques and careful air leak prevention now allow patients to have their chest tubes removed as early as 4 h after surgery.

We routinely use a preplaced U stitch to approximate the wound edges after chest tube removal. The chest tube is removed quickly during a breath hold at the end of expiration. The wound borders are brought together, and a wound dressing is applied. A chest radiograph must be obtained after to evaluate for adequate pulmonary reexpansion.

Fig. 57.2 Medela Thopaz device: a suction device with no need for wall suction. This device also has a screen showing fluid and air outputs over time. Some studies have suggested patient mobility could be enhanced with these devices. On the far right, a device for the management of postpneumonectomy pleural shift is shown. There are two water columns: a positive and a negative pressure column that favors a slow shift of the mediastinum to the side of the pneumonectomy

Postoperative Nutrition

The majority of patients start enteral nutrition in the evening of the day of surgery or the next day, unless they are hemodynamically unstable. Most patients tolerate limited postoperative nutrition for a week. Often overlooked is the early use of laxatives and stool softeners, which should be started on the first day with oral diet. Reduction of narcotics as tolerated, adequate oral hydration, and early ambulation help to overcome constipation.

Prevention of Venous Thromboembolism

Measures to prevent postoperative venous thromboembolism should be implemented in patients undergoing thoracic surgical procedures. The best method of prophylaxis is a low-dose fractionated or unfractionated heparin. Pneumatic compression devices are also used in some patients, although their role has never been formally demonstrated in randomized controlled trials. The risk for venous thromboembolic disease may be stratified according to patient and procedural factors.

Table 57.2 Classification of risk levels for postoperative thromboembolism

Thromboembolic event (%)					
Risk level	Calf vein thrombosis	Proximal vein thrombosis	Clinical pulmonary embolism	Fatal pulmonary embolism	Successful prevention strategies
Low					
Uncomplicated minor surgery in patients aged <40 years with no clinical risk factors	2	0.4	0.2	0.0002	No specific prophylaxis, early mobilization
Moderate					
Any surgery in patients aged 40–60 years with no additional risk factors; major surgery in patients aged <40 years with no additional risk factors; minor surgery in patients with risk factors	10–20	2–4	1–2	0.1–0.4	LDUH (q12h), LMWH (≤3400 U daily), GCS or IPC
High					
Major surgery in patients aged >60 years without additional risk factors or patients aged 40–60 years with additional risk factors; patients with myocardial infarction; medical patients with risk factors	20–40	4–8	2–4	0.4–1.0	LDUH (q8h), LMWH (>3400 U daily), or IPC
Highest					
Major surgery in patients aged >40 years with prior venous thromboembolism, malignant disease, or hypercoagulable state; patients with elective major lower extremity orthopedic surgery, hip fracture, stroke, multiple trauma, or spinal cord injury	40–80	10–20	4–10	0.2–5.0	LMWH (>3400 U daily), fondaparinux, oral VKAs (INR, 2–3), or IPC/ GCS + LDUH/LMWH

Adapted from Geerts et al. [23]
LDUH low-dose unfractionated heparin, *LMWH* low-molecular-weight heparin, *GCS* graduated compression stockings, *IPC* intermittent pneumatic compression, *VKA* vitamin K antagonist

The majority of patients undergoing thoracic operation fit the high-risk category, as defined in Table 57.2. These patients have a calf thrombosis rate of 20–40%, a pulmonary embolus rate of 2–4%, and a fatality rate of 0.4–1.0%. In 2006, Mason et al. found a 7.4% incidence of postoperative venous thromboembolism among patients undergoing pneumonectomy for malignancy [21]. In 2007, the American Society of Clinical Oncology guidelines recommended that patients with cancer who will have a thoracotomy or laparoscopy lasting >30 min should receive pharmacologic thromboprophylaxis with either fractionated or unfractionated heparin. Prophylaxis should begin preoperatively or as early as possible in the postoperative period. A combined regimen of pharmacologic and mechanical prophylaxis may improve efficacy among the patients at highest risk. A recent survey among Canadian thoracic surgery centers has shown consensus in the practice of deep venous thrombosis prevention surgery [22].

General Complications of Thoracotomy

Pneumonia

Although the incidence is low, between 2.2% and 6%, pneumonia postthoracotomy contributes to significant morbidity. Risk factors include preoperative hospital stay, immunocompromised status, procedure (pneumonectomy > lobectomy), pulmonary reserve, smoking, and atelectasis. Atelectasis is a common complication after pulmonary surgery, fortunately most is platelike or linear, hence subsegmental, and has little consequence in a patient with adequate pulmonary reserve. However, segmental or lobar atelectasis may cause significant problems. Risk factors include poor cough, usually a result of poor pain control, impaired pulmonary function, chest wall instability, and/or sleeve resection.

Prevention is the best treatment. Chest physiotherapy with vibratory percussion, frequent spirometry exercises, and ambulation is key for prevention. Adequate pain control is also of paramount importance to prevent pneumonia. Whenever pneumonia is suspected, sputum cultures or BAL, if a bronchoscopy is performed, should be obtained, and broad-spectrum antibiotic therapy should be started. Clinical signs of pneumonia are a productive cough, fever, and/or an elevation in the white blood cell count. Radiographic findings often lag behind, especially in dehydrated patients.

Atrial Fibrillation

Arrhythmias are one of the most frequent complications after thoracic surgery. They require immediate management and often prolong the hospital stay. Because atrial arrhythmias are more common (ventricular arrhythmias are rare after thoracotomy), their management is specifically discussed here.

The incidence of atrial tachyarrhythmias ranges from 3.8% to 37% after thoracic surgery, with atrial fibrillation (AF) being the most common arrhythmia [24]. It is commonly associated with respiratory complications. In a study by Bobbio et al. in 2007, there was a 30% incidence of AF in patients with either sputum retention, atelectasis, or pneumonia [25].

Many studies have been performed on the prevention of supraventricular tachyarrhythmias in patients undergoing lung resection. In a prospective randomized double-blind trial, Jakobsen et al. showed that the administration of oral metoprolol initiated preoperatively and continued postoperatively decreased the incidence of AF from 40% to 6.7% [26]. In another trial, administration of magnesium sulfate starting the day of operative resection also resulted in a decrease in the incidence of AF from 26.7% to 10.7% [27]. Prophylactic oral amiodarone, when given before cardiac surgery, was shown to be cost-effective and safe and might be a reasonable preventive strategy in thoracic or other noncardiac surgical patients [28]. The use of amiodarone has however been associated with acute lung injury in rare cases and must be used with caution after lung resection [29, 30]. There are currently no consensus guidelines for the prevention of atrial fibrillation that are specific to thoracic surgical patients.

Dunning et al. on behalf of the European Association for Cardiothoracic Surgery Audit and Guidelines Committee published guidelines and suggested a treatment algorithm for postsurgical AF [31]. Once the diagnosis of an atrial tachyarrhythmia has been established, the first priority is to assess the patient's hemodynamic stability. In addition, one should maintain oxygenation, assess fluid balance, and assess the serum potassium. If the patient experiences syncope or if the blood pressure is less than 80 mmHg systolic, the options are chemical conversion, typically with amiodarone IV or synchronous electrical cardioversion. For electrical conversion, the first shock is typically delivered at 200 J, with subsequent shocks at 300 and 360 J, respectively.

If the patient is hemodynamically stable, one should achieve control over the ventricular rate to allow better ventricular filling and an optimal ejection fraction. In our institution, once the electrolytes (potassium, magnesium, and calcium) are corrected, metoprolol would be the first choice except in patients with COPD and asthma. In this case, our first choice is diltiazem. Amiodarone is usually a second choice in patients who are hemodynamically stable because of its potential pulmonary toxicity. Once rate control has been achieved, the medication may be changed to equivalent doses of oral medication over the next 24 h. Myocardial ischemia should be ruled out by electrocardiography. The natural history of postoperative atrial tachyarrhythmias is self-termination. Therefore, usually nothing more than a day or two of rate control is required. If the patient spontaneously converts to normal sinus rhythm over the next 24 h, the medication can be discontinued, and no further treatment is required.

If, however, the patient remains in a rate-controlled fibrillation or flutter beyond 24 h, cardioversion can be attempted after echocardiography is performed to exclude the presence of intracardiac thrombus. Amiodarone has become the most popular drug for cardioversion, particularly since it is relatively safe in patients with depressed ventricular function. If the patient converts to sinus rhythm, the oral antiarrhythmic drug should be continued for at least 30 days after surgery.

If the arrhythmia persists for more than 48 h, the patient should be anticoagulated with heparin and then maintained on warfarin or DOAC. Typically, if patients are discharged from the hospital in rate-controlled AF with adequate anticoagulation, they will spontaneously convert to sinus rhythm as outpatients. If, however, they remain in AF beyond 30 postoperative days, they should be offered outpatient electrical cardioversion provided that they have remained therapeutically anticoagulated.

Pleural Space Problems

It is important to have the remaining lung fully expanded to fill the chest cavity following thoracotomy. If this, for any reason, fails to happen, the space between the lung and the chest wall will fill with fluid. This might be the seed for an empyema. A postoperative space problem may occur when atelectasis of the underlying lung occurs or when an air leak from the lung leads to a persistent air space.

Air Leak

Not all patients have an air leak after pulmonary resection. In fact, many patients having a thoracoscopic wedge resection have no air leak. However, many patients having a lobectomy, segmentectomy, or a complicated wedge resection will leave the operating room with a leak. The STS Thoracic Surgery Database defined prolonged air leak as lasting >5 days. By August 2008, the database had recorded a total of 15,178 lobectomies. Of these patients, 9.6% had prolonged leaks. This complication was the second in frequency only after arrhythmia.

Factors increasing the incidence of a prolonged air leak include emphysema, bilobectomy compared to lobectomy, poor chest tube placement, and neglecting operative techniques that help prevent air leaks. These techniques include pleural tents, fissureless surgery, buttressed stapled lines, and checking for air leaks before closing.

However, if significant air leaks occur postoperatively, management varies. The old dictum of "no space, no problem" is a good one to keep in mind. When this is the case, the

patient rarely requires intervention. When the lung does not fill the entire cavity and there is a significant air leak, a bronchopleural fistula (BPF) should be taken into consideration.

A BPF is defined as a communication between a bronchus and the pleural space and is therefore different from an alveolopleural fistula. The latter usually seals spontaneously with time, which is not the case for a BPF. Most commonly, a BPF occurs following a right lower bilobectomy or pneumonectomy. This may be due to the lack of coverage of the bronchial stump by the remaining upper lobe because of the posterior-inferior position of the stump. In other types of lobectomy, the bronchial stump is well covered by the remaining lobes. Technical factors are responsible for fistulas occurring in the early postsurgical period. The most frequent errors are inappropriate suturing/stapling and ischemia produced by excessive dissection of the bronchus prior to closure. Prevention is the easiest way to manage BPF. Local tissue pedicle flaps such as pleura, azygos vein, pericardial fat, and intercostal muscle can be used to cover pneumonectomy or bilobectomy stumps. Treatment options for BPF are briefly discussed in section "Empyema."

For patients with complete lung expansion and a prolonged air leak, the first question is whether the lung will stay expanded without suction and if the chest tube output is considered small. If both of these criteria are met, the chest tube can be connected to a Heimlich valve or a similar device, and the patient can be discharged with a close follow-up as an outpatient. This is a good strategy in patients having lung volume reduction surgery, a decidedly sick population with significant underlying lung disease [32]. Alternatively, on rare occasions, there is the possibility of chest tube removal, even with a small air leak. Such a maneuver should be preceded by a trial of tube clamping for up to 6 h prior to removal. If the patient develops pulmonary symptoms, such as shortness of breath or hypoxia, or develops a pneumothorax, the tube can be unclamped and the procedure repeated in another day. If the patient remains asymptomatic and no pneumothorax develops, the tube may be removed. A period of observation for 6–24 h is recommended prior to discharge.

Empyema

Empyema complicating lung resections is an uncommon but morbid and too often deadly sequela, particularly after pneumonectomy. Postsurgical empyema accounts for 20% of all cases of empyema. It most frequently follows a pneumonectomy, occurring in 2–7% of patients with a higher incidence for right pneumonectomy, and it may occur in 1–3% of patients after lobectomy [33]. The incidence of empyema after pulmonary resection varies with the indications for the resection (inflammatory or neoplastic disease), with or without preoperative radiation.

Table 57.3 Factors that increase the risk of development of postsurgical empyema

Delay in diagnosis
Improper choice of antibiotics
Loculation or encapsulation by a dense inflammatory reaction
Presence of a bronchopleural fistula
Foreign body in the pleural space
Chronic infection
Entrapment of the lung by thick visceral peel
Inadequate previous drainage or premature removal of a chest tube

Although empyema may occur at any time postoperatively, even years later, most empyema develops in the early postoperative period. The pleural space may be contaminated at the time of pulmonary resection with the development of a bronchopleural or esophagopleural fistula or from blood-borne sources. After pulmonary resection that is less than a pneumonectomy, an empyema occurs more often when the pleural space is incompletely filled by the remaining lung. Risk factors for empyema are summarized in Table 57.3.

Symptoms and signs vary, but the possibility of an empyema must be considered in any patient with clinical features of infection after pulmonary resection. Expectoration of serosanguineous fluid and purulent discharge from the wound or the drain sites is almost always diagnostic. On radiography of the chest, usually a pleural opacity is seen, with or without a fluid level, when resection has been less than a pneumonectomy. After pneumonectomy, a decrease in the fluid level early postoperatively, or the appearance of a new fluid level when the pneumonectomy site was uniformly opaque, strongly suggests an infected pleural space with BPF. The pleural space should be immediately drained to prevent any contamination of the contralateral lung through the BPF, and a bronchoscopy should be performed to determine the size and location of the defect in the bronchial stump. The timing of surgical intervention and the type of operative procedure undertaken to treat the BPF are tailored to the individual patient (Fig. 57.3).

General treatment principles of postresectional empyema with or without a BPF include surgical drainage by closed chest tube insertion and institution of appropriate antibiotic therapy. Once adequate drainage has been established and the remaining lung fills the chest without significant space and there is no underlying BPF, the course of management can be determined, usually within 10–14 days. If the patient has a persistent space without a BPF, the management depends on the size of the space.

Smaller spaces can be sterilized by irrigation with the appropriate antibiotic solution or fibrinolytic agents. Once the daily amount of drainage is <100 mL/day and no further collapse of the remaining lung develops if the tube is opened to atmospheric pressure, the tube can simply be removed, or

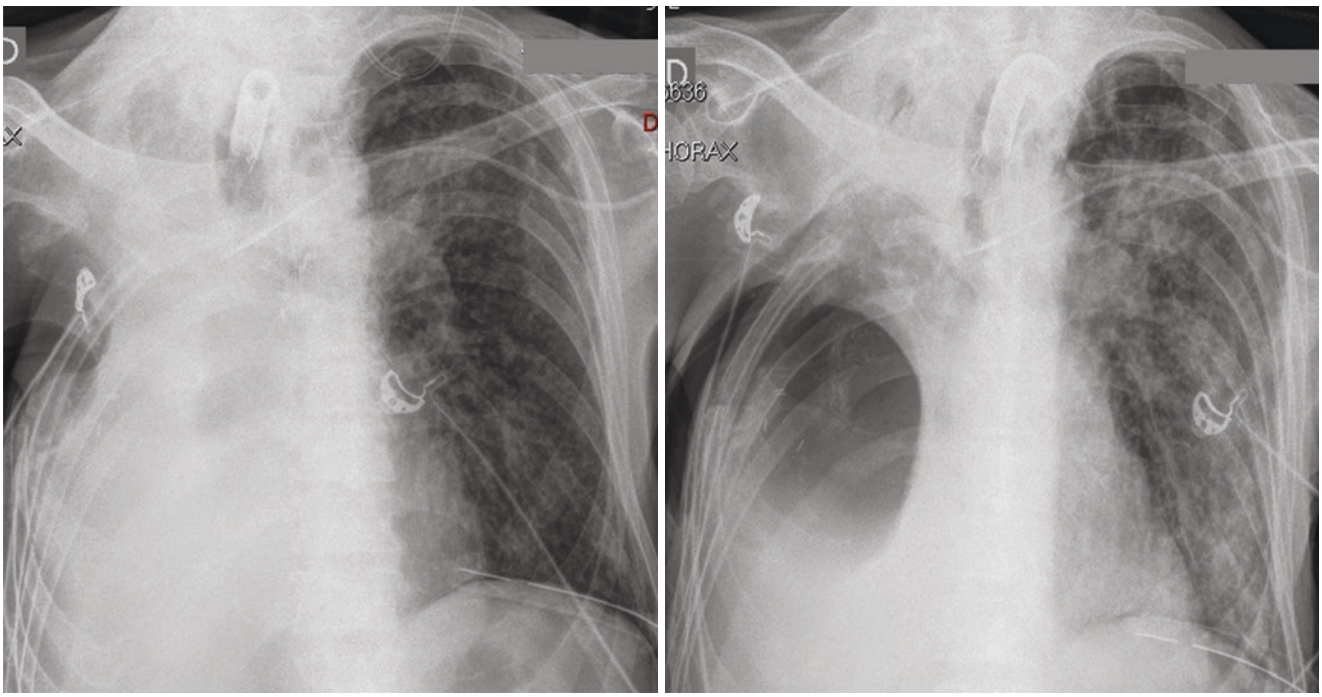

Fig. 57.3 Diagnosis and initial management of postpneumonectomy bronchopleural fistula (BPF). (**a**) A chest X-ray 30 days after the right pneumonectomy with the fluid level filling the entire thorax. At this time, the patient presented with a new onset of coughing. As initial treatment, a chest tube was inserted to drain the chest cavity and protect the left lung. A bronchoscopy and CT scan confirmed the bronchopleural fistula

closed drainage can be changed to open drainage by cutting it close to the chest wall. The tube is then shortened at the rate of about 1 in. per week or until granulation tissue and fibrosis lead to its spontaneous expulsion from the pleural space. In certain cases, if the residual space is seen as too big, two approaches have been described: a single-stage muscle flap closure of the remaining cavity can be performed and a tailored and limited thoracoplasty; both approaches have the aim to occlude the residual space [34]. Larger spaces are more of a challenge and can be managed by an open drainage or, more recently, by an intrathoracic vacuum-assisted closure device approaches (Fig. 57.4). In this context, the aim is to favor chest cavity healing by promoting secondary granulation. The advantage of the VAC therapy is that chest wall integrity is maintained. Once this and microbial control are achieved, chest wall closure can be considered. The Clagett window can also be a definitive alternative in patients with bad nutritional status that are too weak to undergo more consequent procedures [35, 36].

A postpneumonectomy empyema is associated with a BPF in approximately 40% of patients [37]. Significant factors contributing to the development of a BPF after pneumonectomy are induction chemo/radiotherapy, a right pneumonectomy, heavily calcified bronchial stump, positive surgical margin with cancer, and the need for postoperative mechanical ventilation [38]. This can happen early in the postoperative course, usually by days 7–10, but can also manifest months after surgery. Initial goals in the treatment are the prevention of contamination of the contralateral lung by closed tube drainage of the infected pleural cavity, taking into consideration that the mediastinum takes about 14 days until it is stable post pneumonectomy, institution of antibiotics, and a bronchoscopy.

If no BPF is present, two approaches have been described: the modified Clagett's procedure and the VAC therapy. The modified Clagett's procedure consists in inserting a second small chest tube into the second intercostal space, and a continuous inflow-outflow irrigation system is established through the pleural cavity. The irrigant is based on antibiotic sensitivities to the pleural drainage. This method achieves sterilization of the space in approximately 50% of patients. If the method is successful and the return irrigant is negative by culture on 3 consecutive days after 2 weeks of irrigation, the chest tubes can be removed, and pleural fluid is allowed to reaccumulate to fill the remaining space. If this method fails, a Clagett window can be performed. Recently, VAC therapy or negative pressure dressings using iodine-soaked sponges have been described to accelerate granulation and favor infection control and pleural healing.

In patients with a BPF and postpneumonectomy empyema, reinforcement of the bronchial stump with a healthy tissue flap (pericardial fat, intercostal muscle, etc.) should be achieved. If the fistula closes, one can attempt the aforementioned modified Clagett's sterilization of the cavity. In the

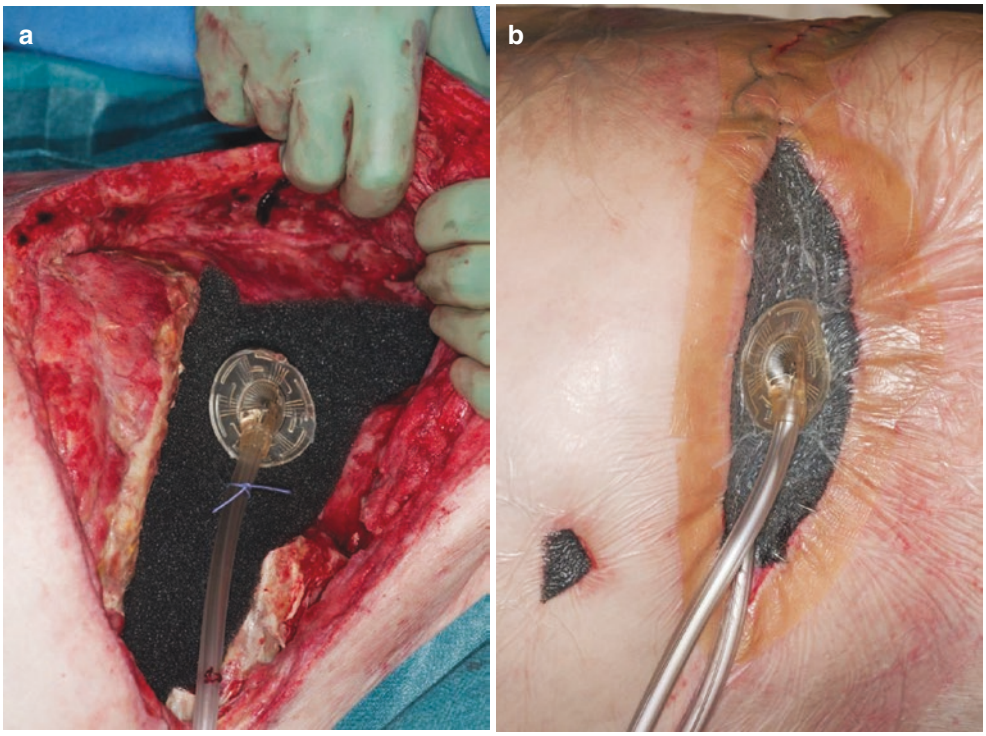

Fig. 57.4 Application of a VAC device in a pleural cavity. The mediastinum is protected with gauze or white foam, and the black foam is formed as to mold the pleural cavity. Two suction devices are placed to favor drainage. (Illustrations from Perentes et al. [35])

patient in whom the BPF persists, the fistula and space are then managed by transposition of muscle flaps into the empyema space; this can be any extrathoracic muscle such as serratus anterior, latissimus dorsi, pectoralis major, or omentum. If the patient remains critically ill and unstable, a Clagett window is ideal for long-term open drainage and irrigation. After the cavity is clean with granulating tissue, it can be closed. In other cases, acceleration of pleural healing can be achieved with VAC therapy that allows chest cavity closure after a mean period of 2 weeks [35, 36].

Nerve Injury

Injury to the recurrent laryngeal nerve can occur during right- or left-sided thoracic surgery procedures. The left nerve is far more in danger to be injured than is the right. Its position under the aortic arch makes it susceptible to injury during any procedure in this area. The nerve is, on occasion, "sacrificed" intentionally, if radical resection for a tumor known to involve the vagus nerve is required. The incidence ranges somewhere between 4% and 45% according to the type of procedure performed [39].

The patients with injury to the recurrent laryngeal nerve generally present in the postoperative phase with a weak and whispery voice, although cord edema in the very early postextubation period may mask the hoarseness. However, patients with palsy or paresis of the recurrent nerve have symptoms lasting well beyond the postoperative period. Those with paresis may describe a normal voice in the morning that becomes weaker over the course of the day. This may result in a weak cough or aspiration after drinking, leading to poor pulmonary physiotherapy and recurrent pneumonia. At laryngoscopy, adduction of the affected vocal cord will be absent or sluggish. Treatment involves determining the extent of injury and whether the injury is transient or permanent. A thorough evaluation of the significance of the cord should be done by fiber-optic evaluation of swallowing and sensation. To assist with pulmonary physiotherapy and decrease the risk of aspiration, medialization laryngoplasty may be suggested. This can be done with the aid of autologous fat, Gelfoam, collagen, or polytetrafluoroethylene (PTFE). These are usually temporary solutions. A permanent solution involves medialization of the vocal cord by thyroplasty [40].

Injury to the phrenic nerve can occur in both open and thoracoscopic pulmonary resections. The most common causes are adherence of the lung to the pericardium or injuries occurring during performance of resection of anterior mediastinal tumors, resection of superior sulcus tumors, repair of thoracic outlet syndrome, or right-sided mediastinal lymph node dissection. Such injuries may be temporary or permanent. In a spontaneously breathing patient, the diagnosis can be easily made by a chest radiographs demonstrating elevation of the affected hemidiaphragm. If the patient requires postoperative ventilation, this radiographic finding might not be present due to positive-pressure ventilation keeping the diaphragm in a fairly normal position. Depending

on the severity of their underlying pulmonary disease, these patients may be difficult to wean from the ventilator. Phrenic nerve palsy can contribute to significant postoperative morbidity and symptoms according to the underlying pulmonary status of the patient. Diaphragmatic plication is indicated for symptomatic relief of dyspnea [41].

Postoperative Hemorrhage

The incidence of significant postoperative bleeding after a pulmonary resection requiring at least four units of packed red blood cells was identified to be 2.9% after lobectomy and 3.0% after pneumonectomy [42]. Chest tube output exceeding 1000 mL over 1 h or persistent bleeding over 200 mL/h for 2 h after a pulmonary resection mandates reexploration, assuming that the coagulation parameters are corrected. Bleeding may occur from mediastinal or bronchial vessels (23%), intercostal vessels (17%), or a pulmonary vessel (17%); in the majority of cases (41%), no source of the hemorrhage is identified [43]. Such troublesome postoperative bleeding is particularly prone to occur if there has been a previous thoracotomy, a decortication of parietal and visceral "peel" due to empyema or resections for inflammatory disease such as old tuberculosis or aspergillosis. With multiple bleeding sites present on the chest wall, it might be necessary for the surgeon to pack the pleural space for a period of time prior to closure of the thoracotomy. This may be particularly useful when the remaining lung fails to fill the pleural space or after pneumonectomy.

Chylothorax

A chylothorax is diagnosed when a "milky" effusion is drained through the chest tube once the patient is on enteral intake. However, if the patient has been fasting after resection, the characteristic creamy color of the effusion may not be noted. In this case, a persistent high chest tube output for unknown reason makes this diagnosis suspicious. The incidence of chylothorax after pulmonary resection is between 0.04% and 2% [44]. Etiologies include aggressive mediastinal lymph node dissection with incomplete ligation of lymphatic channels or direct injury to the thoracic duct [45]. The diagnosis is made by sending the pleural fluid for analysis. A triglyceride level > 110 mg/dL, a lymphocyte count >90%, and the presence of chylomicrons help to confirm the diagnosis [46].

A trial of conservative management is initially recommended, with the objective of adequately draining the pleural space, reexpanding the remaining lung, and keeping the patient fasting. The patient should be strictly NPO and be fed by parenteral nutrition. Occasionally medium-chain triglyceride (MCT) diet has been successfully used to stop the leak. Waiting for 7 days is normally advocated. It is generally agreed that a continuous chyle leak in excess of ≥1 L/day in a patient with complete cessation of oral intake is an indication for reoperation. Attempts at direct repair of the lymphatic injury often fail because of the difficulty of identifying and suturing the injury. Operative ligation of the thoracic duct low in the right chest is appropriate, and the success of thoracic duct ligation is 91%. Other options have been described for the management of chylothorax after pulmonary resection. The current most popular one includes interventional radiology embolization of the chyle leak which has shown interesting results. Other options when the leak cannot be controlled include pleuroperitoneal shunt that has resulted in the resolution of chylothorax in some series [47]. Another option, rarely used because of the technical difficulty, includes the use of a pleural-venous shunt [48].

Torsion of a Residual Lobe

The lobes of the lung are usually held in their position by the other lobes, the inferior pulmonary ligament, and incomplete fissures. After lobectomy these structures no longer exist. In particular, the middle lobe and lingula are most susceptible for torsion following a right upper lobectomy or a lingula-sparing left upper lobectomy, respectively. Lobar torsion typically presents early in the postoperative period with fever, tachycardia, and loss of breath sounds on the affected side. Often the clinical picture is not impressive. Chest X-ray can demonstrate atelectasis of the torsed lobe. Bronchoscopy should be done urgently to make the diagnosis, followed by urgent surgical exploration. The bronchoscopy will show a fish-mouth orifice to the lobe, which easily admits the bronchoscope. If the torsion is discovered early enough, the lobe may be preserved by untwisting the hilum. Most often, however, lobectomy is required. The incidence of lobar torsion after pulmonary resection is between 0.09% and 0.3% [49]. Lobar torsion of the middle lobe after a right upper lobectomy accounted for 70% of the cases in the literature. To prevent this complication, fixation of the middle lobe with the lower lobe may be performed in situations where the oblique fissure is complete.

Postpneumonectomy Syndrome

In a small number of patients undergoing pneumonectomy, mediastinal shift and rotation toward the empty hemithorax may cause pulmonary symptoms. This typically occurs in children or young adults. Along with the shift of the mediastinal contents, there is overdistension and herniation of the remaining lung. This results in dynamic airway compression

of the left main bronchus between the left pulmonary artery and aorta after a right pneumonectomy or compression of the right main bronchus between the right pulmonary artery and the thoracic spine after left pneumonectomy. The overall incidence is not clear. Patients typically present with dyspnea, stridor, and recurring pneumonia, which may occur weeks to years after pneumonectomy. Diagnosis is made from chest radiographs, computed tomography scans, and bronchoscopy under conscious sedation demonstrating dynamic obstruction of the bronchus. Repositioning of the mediastinum and placement of a saline-filled tissue expander in the postpneumonectomy space is the treatment of choice [50].

Cardiac Herniation

Cardiac herniation rarely occurs but can be fatal in certain circumstances and therefore requires a high degree of suspicion. If the pericardium is opened widely or removed, the heart is held in place by the lungs on both sides. If a major portion of the lung is removed, the heart finds a space in which it may herniate. On the right side, herniation can be life-threatening in a matter of minutes because both venae cavae would be strangulated by a 180° rotation of the heart into the right pleural space. On the left side, the heart is freely suspended by the major vessels, and the risk of inflow and outflow occlusion is not present. A greater problem is a moderate-sized defect in the pericardium through which the heart can herniate and subsequently become compromised by postoperative edema (Fig. 57.5).

To avoid these scenarios, a simple closure of the pericardial defect can be performed for smaller lesions, while larger defects should be closed with a fenestrated mesh [51]. Simple suture closure of larger defects may lead to cardiac constriction.

The diagnosis of cardiac herniation might not be easy to make, especially for left-sided herniation. Symptoms include the sudden onset of low cardiac output and signs of central venous obstruction. If time is available, a chest radiograph will be diagnostic. Management of these patients includes emergent operative intervention with reduction of the car-

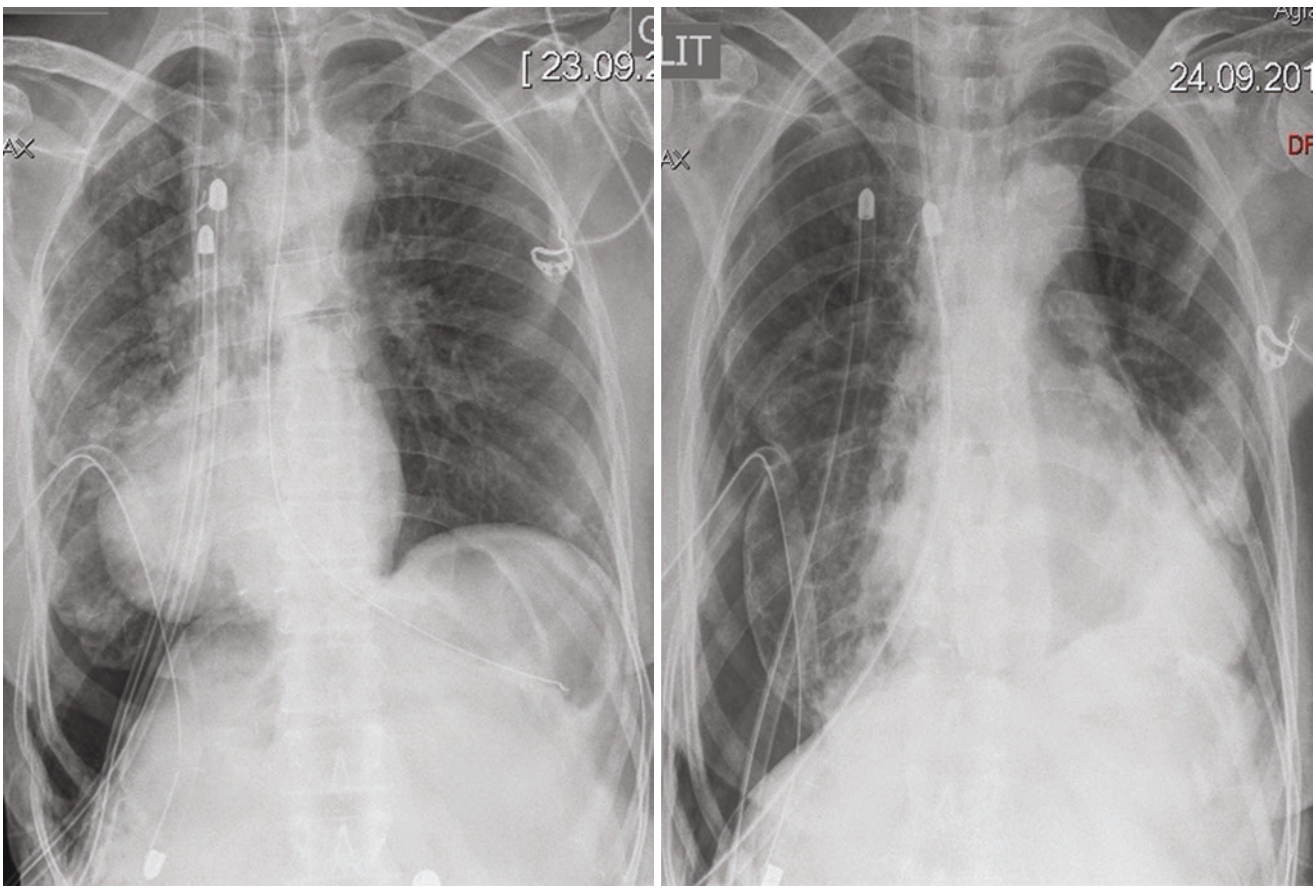

Fig. 57.5 Case of a cardiac herniation following an extensive pleurectomy decortication with pericardial and diaphragmatic resection. Only the diaphragm was reconstructed given the lung was left in place. However, the lung did not expand well because of an important air leak. In the recovery room, the patient developed tachycardia and hypotension. An X-ray showed right-sided cardiac herniation. The patient improved when put on the left decubitus. A re-intervention with pericardial mesh placement stabilized the situation

diac hernia and patch closure of the defect using PTFE. Since PTFE is watertight, fenestrations must be created.

Clinical Case Discussion

A 70-year-old female has a right completion pneumonectomy and partial excision of the right chest wall for non-small cell lung cancer. Thirty years before, the patient had a right upper lobectomy for tuberculosis. The patient is 52 kg and 160 cm, FEV 1 = 64%, DLCO = 60%, *V*/*Q* scan perfusion L:R is 65:35, good exercise tolerance, Hb is 124 g/dL, and other laboratory examinations including transthoracic echocardiography are normal. The anesthetic is with a combined T4–T5 thoracic epidural and general anesthesia. The operative duration is 4 h. The blood loss is 500 mL. The patient receives 1 L of Ringer's lactate and 500 mL of synthetic isotonic colloid intravenously during the case. One R chest drain is placed and connected to an underwater-seal drainage system without suction. The patient is extubated in the operating room awake and comfortable and transferred to the recovery room in a stable condition: heart rate 90/min, BP 100/50, CVP 4 mmHg, and urine output 30 mL/h. The thoracic epidural infusion is bupivacaine 0.1% with 15 μg/mL hydromorphone at 5 cc/h.

After 2 h in the recovery room, the patient's HR has gradually increased to 110, the BP has decreased to 90/50, CVP remains 4 mmHg, and the urine output has fallen to 15 mL/h. Repeat Hb is 103 g/dL. The chest tube is fluctuating normally with respiration, and there has been no significant drainage from the right chest. The patient receives repeat boluses of 500 mL Ringer's lactate ×2 intravenously. One hour later, the hemodynamics have not improved; she has a demonstrable sensory block from T2 to T10 without motor block. The thoracic epidural infusion is decreased to 2 mL/h. One hour later, the patient is complaining of five out of ten incisional pain, and there is no demonstrable sensory or motor block. The HR is 115/min, BP 78/50, CVP 4, Hb 98 g/dL, and urine output 10 mL/kg. Arterial blood gases are normal. What is the most appropriate next step?

1. Transfuse 500 mL of colloid.
2. Discontinue the epidural and begin intravenous PCA opioid analgesia.
3. Repeat the chest X-ray.
4. Obtain an ECG.
5. Obtain CT contrast pulmonary angiography.
6. Return to the operating room for cardiac herniation.

The most important postpneumonectomy complication to rule out in this context is cardiac herniation (see also Chap. 41) since it is so treatable and so lethal if not treated promptly. Cardiac herniation after a right pneumonectomy is most likely to present as a sudden onset of severe life-threatening hypotension. That is not the presentation in this case, so there is time to confirm the diagnosis. The repeat chest X-ray 4 h post-op is shown in Fig. 57.6. An unrelieved negative pressure has developed in the right chest due to the one-way valve effect of the underwater-seal chest drain. The mediastinal shift to the right created symptoms equivalent to a herniation with compromise of the venous return to the right heart. The tip of the CVP catheter was at the SVC-right atrial junction and thus was downstream from the venous inflow obstruction and accurately reflected the decreased filling pressures of the right heart, but not the systemic venous volume. The mediastinum was "balanced" by injecting 500 mL of air into the right chest tube which was then clamped (Fig. 57.7). The patient's hemodynamics rapidly returned to normal, the epidural infusion was increased to control the pain, and the chest drain was removed the next day.

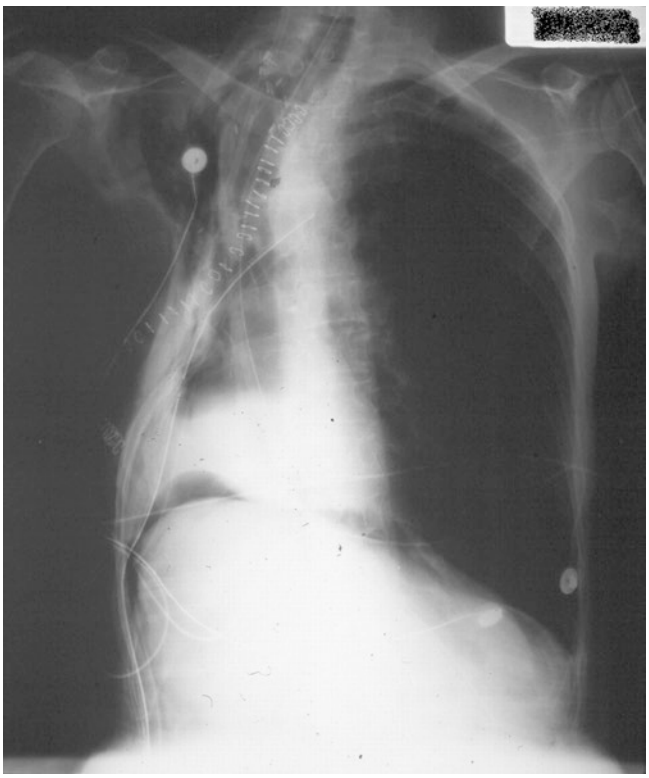

Fig. 57.6 Chest X-ray of a 70-year-old female 4 h post-op. After a right completion pneumonectomy and partial excision of the chest wall. The chest drain was connected to an underwater-seal drainage system which allowed the development of an excessive negative intrathoracic pressure causing a complete shift of the mediastinum to the right lateral chest wall and a compromise of the venous return to the heart

The presence of a functioning, normally fluctuating, chest drain in this patient makes the possibility of a tension pneumothorax or massive hemorrhage into the operative hemithorax very unlikely. Epidural local anesthetic overdosing is unlikely with the regression of the sensory block. Myocardial ischemia and pulmonary embolus must be considered in the differential diagnosis of postoperative hypotension but are

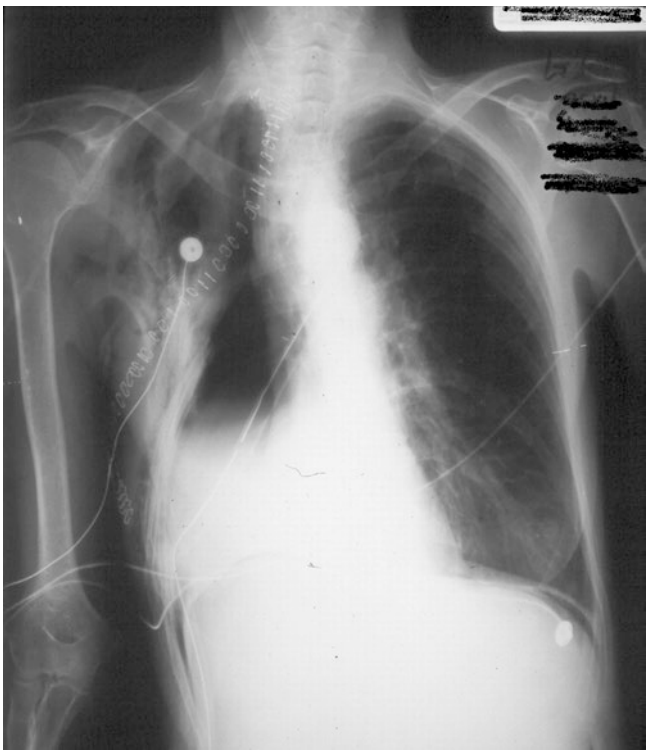

Fig. 57.7 Chest X-ray of the same patient after 500 mL of air was injected via the chest drain which was then clamped. The mediastinum has been "balanced" which relieved the obstruction of venous inflow to the right heart and allowed the hemodynamics to return to normal

not specific complications related to pneumonectomy. The different options for chest drain management after a pneumonectomy are explained in section "Chest Drainage System."

Introduction and Relevance

Chest tubes are the gold standard for the drainage of the pleural and pericardial spaces. They are used to treat a variety of conditions including pneumothorax, pleural effusion, and postoperative evacuation of air and fluid. There are a number of types and sizes of chest tubes available ranging from 6 Fr to 40 Fr. This chapter will discuss the indications for chest tube placement and removal as well as the best uses for different types of chest tubes. Lastly, we will address complications associated with chest tube placement as well as special situations such as bronchopleural fistula, post-pneumonectomy chest tubes, abrupt changes in chest tube output, and clamping chest tubes.

Indications and Physiology

Normal pulmonary physiology relies on the generation of negative intrapleural pressure by the contraction of the diaphragm to draw air into the distal airways for gas exchange. Any accumulation of air or fluid in the pleural space may disrupt this process and may prevent sufficient pulmonary expansion and diffusion of carbon dioxide and oxygen. In the case of penetrating thoracic trauma, the negative intrapleural pressure leads to the influx of air into the pleural space down a pressure gradient from positive atmospheric pressure to the negative intrapleural pressure. Fluid collections in the pleural space obstruct appropriate expansion of the lung parenchyma by mass effect and lead to collapse of the affected lung. A combination of both air and fluid in the pleural cavity can also produce collapse of the lung if not adequately drained. Postoperatively the anticipation of inflammatory pleural fluid, blood, and air prompts placement of chest tubes at the time of thoracic and cardiac surgery. Any symptomatic accumulation of air or fluid in the pleural space is an indication for chest tube placement. The goals of pleural drainage are sufficient evacuation of any air or fluid to promote normal pulmonary function and biomechanics. The presence of air or serous, exudative, purulent, sanguinous, or chylous fluid is integral in determining the type of pleural drain placed. Regardless of the pleural contents, all drains are connected to a collection system that allows evacuation of pleural contents and prevents entrance of air or fluid from outside the thorax [1].

Chest Tubes and Insertion

There are many different chest tubes available for evacuation of air and fluid from the pleural cavity ranging in size from 6 Fr to 40 Fr (Figs. 58.1 and 58.2). Chest tubes are constructed of a variety of synthetic materials including polyvinyl chloride and silicone. It is simplest to think about chest tubes in terms of large bore (>=20 Fr) and small bore (<20 Fr) chest tubes. French (Fr) measures the external diameter of the tube. Every French unit is equivalent to 1/3 millimeter, making a 3 Fr tube equivalent to 1 millimeter external diameter. Poiseuille's law shows that even small increases in diameter will drastically increase flow of air and fluid through the chest tube, thus giving large bore chest tubes a considerable advantage. For that reason conventional large bore chest tubes are the mainstay of pleural drainage. Small

bore chest tubes, however, are gaining popularity and have been shown to be quite effective and less painful in select situations such as spontaneous pneumothorax or simple pleural effusion [1–8]. Small bore chest tubes include flexible silicone drains such as the Blake drain (Ethicon, Inc., Somerville, NJ), pigtail catheters, and indwelling pleural catheters (Fig. 58.3). Despite their ease and growing popularity, small bore chest tubes are not suitable for loculated or complex pleural effusions, hemothorax, or trauma [3]. In those situations a large bore chest tube should be used to prevent clogging of the tube and inadequate drainage [9].

Chest Tube Insertion Techniques

While large bore chest tubes provide effective drainage of a wide range of pleural collections, they are associated with patient discomfort during insertion and while in place [6]. Large bore chest tubes range in size from 20 Fr to 40 Fr and have a series of side holes at their proximal end and a radiopaque marker (Figs. 58.4 and 58.5). The most distal of these side holes is referred to as the sentinel hole. It interrupts the radiopaque marker and is easily visualized on chest radiograph. Large bore chest tubes can be inserted by both blunt dissection and trocar techniques [9]. In the blunt dissection technique, the patient is positioned either with the ipsilateral arm extended over the head or abducted. The affected side is prepped and draped using chlorhexidine or betadine solution anterior to the midaxillary line, posterior to the pectoral groove, and anterior to the latissimus at the level of the third to fifth intercostal space. The clinician should always include the nipple in the prepped and draped area to maintain landmarks during insertion. While adhering to standard sterile technique, generous amounts of local anesthetic should be used to anesthetize first the skin and then the subcutaneous tissue. The needle is then advanced until the rib is encountered, and then the periosteum is anesthetized by injecting

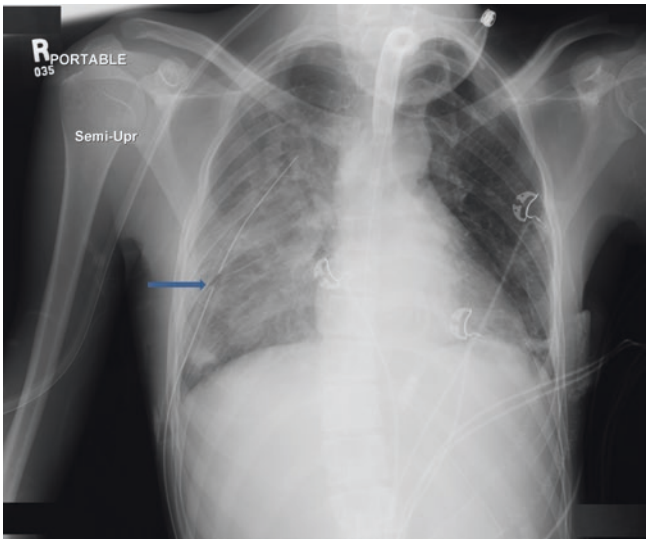

Fig. 58.5 Conventional chest tube sentinel hole on chest radiograph, arrow marks sentinel hole well within chest cavity

Fig. 58.6 Pigtail catheter

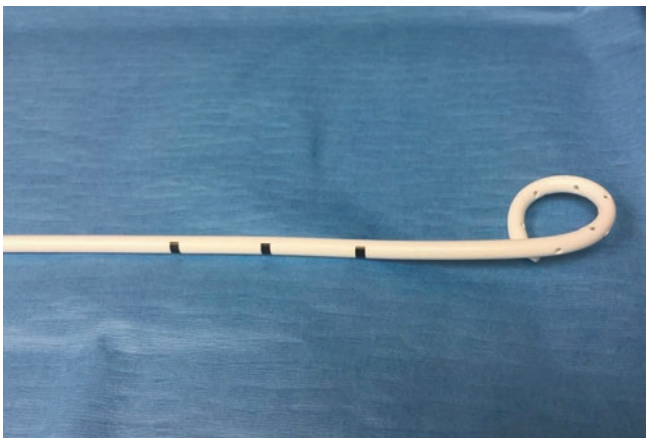

Fig. 58.7 Side holes and markings on pigtail catheter

local anesthetic at this level. The needle may then be directed superiorly, and while aspirating on the syringe, it may be advanced over the superior aspect of the rib. Once air or fluid is encountered, the clinician is sure that they are in the pleural space. Local anesthetic is then injected as the needle is withdrawn to anesthetize the pleura. Once the area for insertion is prepped, draped, and appropriately anesthetized, an approximately 2–3 cm incision (or large enough to insert a finger into the chest) is made in the skin. The subcutaneous tissues are dissected using a blunt instrument such as Kelly forceps or tonsil forceps until the rib and intercostal muscle are encountered. At this point, the clinician palpates the rib with the instrument and advances over the superior aspect of the rib to avoid the neurovascular bundle. Slow, steady, and controlled pressure is applied in the intercostal space just superior to the rib until the instrument penetrates the pleural cavity. On entry into the pleura, the forceps is gently spread, and a rush of air, fluid, or both should be noted. The clinician then inserts a finger into the pleural cavity and sweeps around the entry site to ensure there are no adhesions or attachments to the chest wall. This will reduce the risk of damaging lung tissue when the tube is inserted into the pleural space [6, 10]. The chest tube can then be inserted next to a finger in the pleural cavity to guide the tube posteriorly and to the apex for air. If pleural fluid is the problem being treated, the chest tube may be placed more inferiorly and directed more posteriorly to drain accumulating fluid. Alternatively, it is acceptable to grasp the tip of the chest tube with the Kelly forceps to better direct the chest tube into the chest. Once the tube is in the pleura, the Kelly forceps are released, and the tube is advanced to the desired location as described previously. The tube should then be connected to a water seal collection system and the collection system placed below the level of the lung. There are many ways to secure the chest tube to the skin; however a single interrupted suture is commonly placed using heavy permanent suture and the free ends wrapped around the tube and tied to the chest tube tight enough to notice a slight crimp in the tubing to prevent dislodgement [6]. The tube can then be dressed using 4 × 4 gauze and tape. Once the chest tube is in place, chest x-ray is performed to ensure adequate position. The sentinel hole must be in the thorax to provide adequate drainage and prevent the entry of air into the thoracic cavity.

Small bore chest tubes (less than 20 Fr) may be considered first-line therapy for simple pleural effusions or pneumothorax [3]. Small bore conventional chest tubes are inserted in the same manner as the large bore chest tubes described above. Pigtail catheters are small in caliber and have a series of side holes at the proximal end, but do not have a radiopaque marker. Instead these catheters have markings on the tubes themselves to guide the tube to the adequate depth (Figs. 58.6, 58.7, and 58.8). Pigtail catheters may be inserted using anatomic landmarks or using ultrasound guidance. If using ultrasound guidance, a pocket of fluid is first identified, and then that area is prepped, draped, and anesthetized as described above. If not using ultrasound guidance, the clinician may use chest percussion to delineate the level

Fig. 58.8 Pigtail on chest radiograph

of fluid in the thoracic cavity, and that area is then prepped, draped, and anesthetized as described above. Regardless of whether ultrasound is used, a 10 cc syringe with a large bore needle is advanced just superior to the rib in the area of interest, aspirating as the clinician advances. Once fluid or air is encountered, the clinician should stop advancing and remove the syringe. A wire is then inserted into the large bore needle. The needle can then be withdrawn over the wire, taking care to leave the wire in place within the pleural cavity. Using an 11 blade scalpel, a puncture incision is made along the wire large enough to accommodate the chest tube and the dilator. The chest tube with dilator inside is then advanced over the wire with slow steady pressure until all side holes are within the pleural space. The wire and dilator are then removed leaving the tube in place. The tube should then be connected to a water seal collecting system and the collecting system placed on the floor next to the patient.

Postsurgical Chest Drains

Following surgical procedures of the chest, tube thoracostomy is the gold standard for evacuation of accumulated postoperative fluid and air. Large bore chest tubes are commonly used to drain both the pericardial and pleural spaces following open heart surgery and are nearly always placed following esophageal and lung surgery.

Postoperative chest tubes are inserted in the same fashion as conventional large bore chest tubes; however, in the operating room, the surgeon benefits from direct visualization of the chest tube placement. Following pulmonary resections, the conditions in the pleural space change. Postoperative blood, pleural fluid, and air accumulate in the pleural space. Because of the body's natural position and gravity, fluid

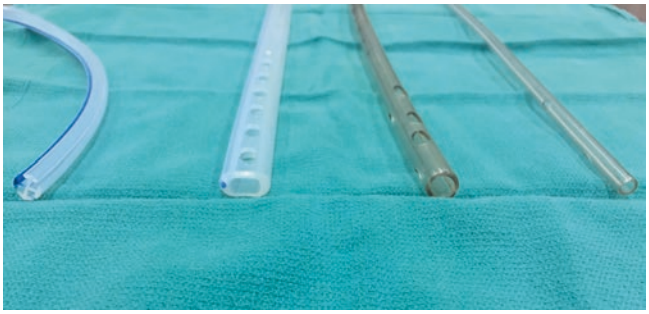

Fig. 58.9 Bores of different chest tubes from left to right: 24 Fr Blake drain, Silastic drain, 32 Fr conventional chest tube, 20 Fr conventional chest tube

tends to collect posteriorly and inferiorly, while air collects anteriorly and superiorly [7]. For these reasons, the mainstay of postoperative chest drainage has been to place two chest tubes: one anteriorly to evacuate air and one posteriorly to evacuate fluid [7]. The decision of the type, location, and number of chest tubes is largely based upon surgeon preference [7, 11]. The placement of two chest tubes after surgery is thought to reduce atelectasis, hemothorax, and inadequate lung re-expansion. One study showed that a single chest tube is as effective at draining the pleural space after thoracic surgery as two chest tubes [12]. Furthermore this study demonstrated that a single chest tube is, not surprisingly, far less painful than two chest tubes, likely aiding in patient participation in pulmonary rehabilitation [12]. A recent meta-analysis showed a statistically significant decrease in pain and length of stay with a single chest tube vs two chest tubes following lobectomy [13]. A consensus paper from the European Society of Thoracic Surgeons, American Association of Thoracic Surgeons, and Society of Thoracic Surgeons found no benefit to using two chest tubes and likely decreased pain using only one chest tube after non-cardiac thoracic surgery [14]. Based on the above studies, the use of a single conventional large bore chest tube is safe, effective, and likely less painful after lung resection. In the case of empyema or hemothorax requiring decortication, two or more chest tubes are left given the high risk for air leak and need to fully drain the pleura and expand the lung. Right angle chest tubes may be used to drain the space posterior and anterior to the diaphragm depending on the location of the collections found at the time of surgery [15].

There is much debate about the type of chest tube that should be placed following lung resections. The traditional practice has been to use large bore semirigid chest tubes postoperatively; however recent studies suggest that smaller bore flexible drains such as the Blake drain (Ethicon, Inc., Somerville, NJ) may be safe and effective [8, 16] (Figs. 58.3, 58.9, and 58.10). Flexible, spiral, fluted silicone drains were shown to decrease pain scores and provide adequate drainage without significant difference from standard large bore

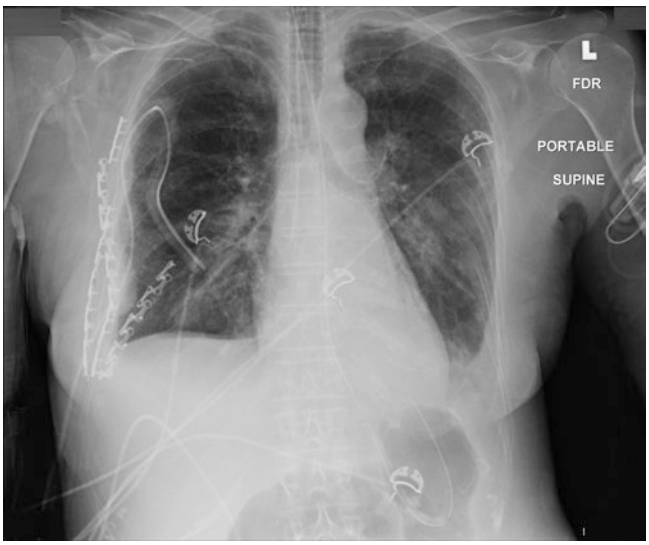

Fig. 58.10 Chest radiograph of flexible Silastic drain in right chest after rib fracture fixation

chest tubes after pulmonary resection [16]. The drains in this study were placed to −20 mmHg suction postoperatively, although they do not describe when if ever the drains in either the small flexible drain group or conventional chest tube group were placed to water seal. Another study showed that the Blake drain (Blake drain Ethicon, Inc., Somerville, NJ) was adequate for evacuation of fluid but only when placed to suction [8]. Additionally the Blake drains used in this study were inferior to conventional large bore semirigid chest tubes for the evacuation of air when air leakage occurred [8]. One case report describes life-threatening hemothorax not detected due to occlusion of a Blake drain which ultimately required return to the operating room for control of hemorrhage [17]. The consensus document from the European Society of Thoracic Surgeons, American Association of Thoracic Surgeons, and Society of Thoracic Surgeons agreed that flexible spiral fluted silicone drains are likely safe and effective but the evidence is weak and needs to be further studied [14].

Another area of great debate is the use of suction to increase negative pressure in the collection system (and thus drainage) to improve re-expansion of the lung. Suction is commonly used to re-expand the lung postoperatively and obliterate residual airspace, thereby preventing symptomatic collapse of the surgical lung. There is relatively little data to substantiate the use of suction. A prospective randomized trial from Poland sought to answer this question and found that nonsuction had improved drainage volume, shorter duration of chest tube, and decreased air leakage compared to suction drainage [18]. There were more residual air spaces noted in the nonsuction group; however these were largely asymptomatic and clinically insignificant [18]. Cerfolio et al. showed in 2001 that in the case of persistent air leak, nonsuction drainage was superior [19]. This is likely due to the decreased negative pressure applied upon the leaking pulmonary tissue, thus drawing less air through the wound allowing proper healing. Large randomized trials are lacking for this question, and further studies are required to further elucidate the benefits of suction and nonsuction chest drainage. Suction for 24 h postoperatively followed by conversion to water seal on postoperative day 1 appears to be safe and effective for management of postsurgical chest tubes [18].

Regarding cardiac surgery, both the pleura and the pericardium are routinely drained postoperatively. If the pleura is violated during the dissection, a single chest tube is commonly placed in the pleural space. The type and number of chest tubes placed in the pericardium is debated. Le and colleagues found no advantage to using multiple pericardial chest tubes over a single pericardial chest tube following cardiac surgery [20]. Additionally there was no increase in bleeding or return to the operating room for cardiac tamponade [20]. Frankel et al. showed no difference in small Silastic pericardial drains vs conventional large bore chest tubes in patients undergoing coronary artery bypass grafting [4]. In this study there was no significant increase in risk of bleeding or cardiac tamponade in the group randomized to Silastic drains. Additionally patients with Silastic drains were more easily mobilized than the group with conventional large bore chest tubes [4]. A randomized trial studying delayed removal of Silastic mediastinal drains, and early removal of conventional chest tubes confirmed there was no difference in bleeding or cardiac tamponade between traditional chest tubes and Silastic chest tubes [2]. The literature on this topic suggests that a single chest tube is as effective at draining the pericardial space postoperatively as two chest tubes. Furthermore, the more comfortable Silastic tubes seem to be as safe and effective as conventional large bore chest tubes but possibly afford the patient less pain and earlier mobility [2].

Indwelling Pleural Catheters

In patients with malignant pleural effusions, recurrent fluid accumulation is a significant burden to patients which may cause crippling dyspnea and poor quality of life in a group of patients who already have a short life expectancy [21]. There are several ways to treat malignant pleural effusion including repeat thoracentesis, pleurodesis, and indwelling pleural catheters. Indwelling pleural catheters can be inserted on an outpatient basis and provide patients with a long-term solution to recurrent dyspnea [22]. The PleurX catheter is one type of indwelling pleural silicone catheter with fenestrations used for drainage of pleural fluid [22].

To insert a PleurX catheter, the skin over the 7th to 8th intercostal space is prepped using chlorhexidine solution and anesthetized at the entry site of the catheter extending 5 cm to the exit site of the catheter. The pleural space is accessed in

the same manner as the Seldinger technique described above. Once the wire is well within the pleural cavity, the introducer sheath can be removed, and a 1 cm incision is made over the wire using an 11 blade scalpel. A second 1–2 cm incision is made 5 cm laterally at an exit site that will be comfortable and feasible for the patient. The PleurX catheter is then connected to the tunneling device, and the catheter is tunneled from the exit site to come out of the skin at the entry site. The catheter is pulled through until the polyester cuff is under the skin approximately 1 cm from the exit incision. The 12 Fr dilator is then advanced over the wire and into the pleural space. Next the 16 Fr dilator and peel-away introducer are advanced over the guide wire until the peel-away introducer is flush with the skin. The dilator and wire are then removed as a unit, and the surgeon uses a finger to occlude the peel-away dilator to prevent air from entering the pleura. The PleurX catheter can then be threaded through the peel-away introducer until it is entirely within the pleural space and not kinked. At this point the peel-away introducer may be cracked and peeled away taking care not to remove the PleurX catheter. The entry site incision is then closed, and the PleurX catheter is then secured to the skin at the exit site using a single interrupted suture that is wrapped and tied around the catheter [22]. Occlusion rates of the PleurX catheter are <5% and infection rates are <3% [23]. The patient may then use this catheter to drain pleural fluid at home to relieve dyspnea using a suction canister and appropriate tubing. BD recommends not draining more than 1500 cc of pleural fluid on initial placement to prevent re-expansion pulmonary edema. Once the pleural catheter is in place, it should be drained daily to improve symptoms and increase the rate autopleurodesis where formation of adhesions between visceral and parietal pleura obliterates the pleural space and prevents fluid accumulation [24]. Patients undergoing indwelling pleural catheter placement have shorter hospital stays and equal relief from dyspnea compared to patients undergoing talc pleurodesis [21].

Drainage Collection Systems

Playfair described the first reported case of underwater drainage for empyema in 1875 [25]. A child developed empyema and failed multiple aspiration attempts, ultimately resulting in abscess formation. The surgeon placed a flexible drainage tube in the affected thorax and placed the distal end of this tube under water in a container placed under the patient's bed. This technique led to rapid resolution of the empyema and convalescence of the sick child. With the chest tube's distal end submerged, the risk of air entering the pleural cavity is quite low; however, the outflow of both fluid and air is still permitted [26]. The depth of the column of water in which the tube is placed determines the hydrostatic pressure that must be overcome to evacuate air and fluid from the chest. During the negative pressure generated in inspiration, some of this fluid may be drawn back into the tube and introduce nonsterile contents into the pleura. If the water level is low enough, then the entire column may be drawn up the tube during deep inspiration and subsequently air may be drawn into the pleural space. For this reason the column of water must be sufficiently high that a deep inspiration will not draw all of the water into the tubing. Increased thoracic pressure such as coughing overcomes the hydrostatic pressure generated by the column of water allowing the exit of air and fluid from the pleural space [26]. Furthermore, there is significant dead space in a pleural collection system created by the volume of the tubing and collection chamber. As the dead space increases, so does the work of the patient to expel air and fluid from the pleural cavity. The single-bottle model was abandoned as increased fluid accumulation increased resistance to flow. The two-bottle system solved this problem allowing fluid to collect in the first bottle, while air was collected in the second bottle. The increase in tubing, however, increased resistance, and the addition of a third bottle to the system facilitated the use of suction to decrease resistance to flow. The application of suction to the collection system maintains a constant subatmospheric pressure to facilitate drainage and reduce the work of the patient [26]. The drainage system should not normally be placed to suction greater than −10 or −20 mmHg as this may exert too much force on the lung resulting in injury [27]. Additionally if a patient has an air leak, higher levels of suction may cause changes in expiratory ventilation volumes by drawing more air through the air leak. Higher levels of suction are available up to −40 mmHg but should only be reserved for patients in whom an expanding pneumothorax does not respond to lower levels of suction [28]. There are many varieties of pleural drainage collecting systems available. For hospitalized patients these systems all consist of a collecting chamber, a water seal, and a vacuum port for the application of suction.

Digital pleural drainage systems such as the DigiVent™ allow the precise measurement of air leakage and graphical representation of daily changes that may be used to monitor progress and alter treatment [29]. The digital collection system is both safe and effective and does not require a battery to permit successful drainage of the thorax. Digital systems have been used to detect the presence of air leaks not seen on traditional analog pleural collection systems [30]. In one study the digital pleural collection system reduced the time that chest tubes were in place compared to analog pleural collection systems [30]. With further research digital collection systems could improve our detection and management of air leaks in post-thoracic surgery patients.

For patients who have a persistent air leak after lung resection, smaller collection systems are used to facilitate in discharging the patient home with chest tube still in place. Generally, these systems consist of a one-way valve with or

without a reservoir that allows the patient to go home safely while the air leak has time to heal [31]. Determining when to remove the chest tube and time to follow up is discussed later in this chapter.

Drainage Volume

Chest tube output is extremely useful in guiding clinical decision-making. The quantity and quality of chest tube output can be indicative of the underlying problem in a patient requiring tube thoracostomy. Whether the output is sanguinous, serous, chylous, purulent, gastric, or a combination of these, it will determine the next therapeutic decision. In trauma, a moderate hemothorax of 500–1200 mL of initial bloody output can be safely monitored if drainage resolves after chest tube placement. If the initial output is greater than 1200 mL of blood or the output continues at a rate of >200 mL/h with no signs of slowing, emergency thoracotomy or thoracoscopy is indicated [15]. In postoperative patients, chest tube output of >200 mL/h of blood for 4 h warrants further investigation and coagulopathy workup. Reoperation can be avoided if the coagulopathy is corrected; however, if there is retained hemothorax or ongoing bleeding, it should be evaluated by thoracoscopy or thoracotomy [15].

Air Leak

Following thoracic surgical procedures, patients may have an alveolar-pleural fistula or a connection between the small airways and pleural space that leads to an "air leak." By definition an air leak is a connection between airways distal to the segmental bronchi and the pleural space [15]. An air leak is identified in the water seal chamber as bubbles rising through the fluid and can be quantified using digital collection systems [28] (Fig. 58.11). Air leaks can also be present as the result of a malfunction in the tubing or connections of the chest tube system. If the chest tube is clamped proximal to the connection of the chest tube and collecting tubing and the air leak persists, then it is likely the result of a poor connection and air is being sucked around the tubing and into the collection system. For this reason, if an air leak is present, all connections must be checked and verified to be adequate. The incidence of air leak in lung resection patients postoperatively is 20–25% [15]. Most air leaks resolve in the first 2–3 days; however, a prolonged air leak is defined as an air leak that persists on postoperative day 4. By this definition, the incidence of prolonged air leak is approximately 5% [15]. The risk factors for air leak are surgery for emphysema, bilobectomy, and malposition of the chest tube [15]. The incidence of air leaks may be reduced by pleural tents, buttressing of staple lines using pericardium, fissureless surgery

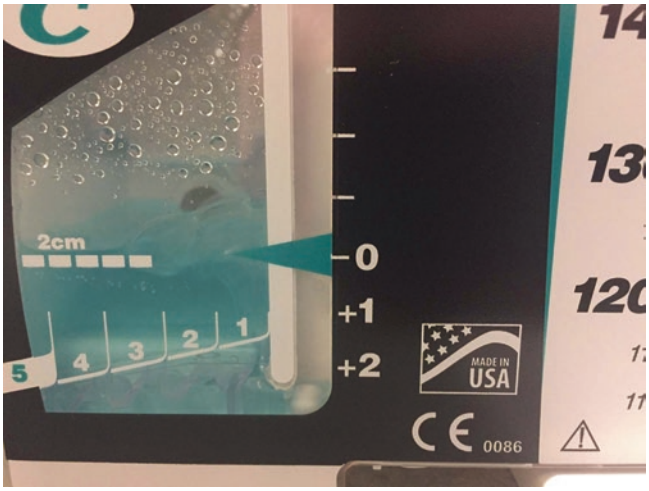

Fig. 58.11 Air leak visible as air rushing through the number 1 hole with bubbles in the water seal chamber

and ensuring the absence of air leak prior to closure [15]. Additionally, patients who had poor pulmonary function tests and had undergone neoadjuvant therapy were at a significantly higher risk of air leak than their counterpart likely secondary to friable tissue and poor wound healing [32]. Cerfolio developed a classification system for air leaks in 2002 that describes an air leak both qualitatively based on when it occurs during the respiratory cycle and quantitatively by the size of the air leak [28]. The largest type of air leak is a continuous air leak which is present during inspiration and expiration, Type C. This type of air leak can be indicative of bronchopleural fistula and is seen usually in intubated patients. Inspiratory phase air leaks occur when patients are mechanically ventilated, Type I. Air leaks that occur exclusively during expiratory phase are very common after pulmonary resection and are a smaller type of air leak, Type E. The smallest and by far the most common type of air leak is one that is not present during inspiration or expiration but only noticed during forced expiration such as coughing, Type FE. To quantify the air leak, the physician requires a drainage system equipped with an air leak meter. These are commercially available and quite common. The air leak meter has a series of small chambers starting at 1 (smallest) and going as high as 7 (largest chamber). Larger leaks will be seen bubbling in the higher-numbered chambers, while smaller leaks will be seen in the lower-numbered chambers. By this classification system, Cerfolio has defined a spectrum of air leaks, the largest of which would be classified as a continuous 7, or C7, and the smallest of which would be classified as a forced expiratory 1, or FE1 [28]. The best treatment for air leak is to place chest tubes to water seal [32]. If the patient has large growing residual air space, increasing subcutaneous emphysema or hypoxia, then the tube should be placed to suction [32]. Patients with

prolonged air leak may be discharged with chest tube in place connected to a one-way valve such as a Heimlich valve or similar device. Patients can then have their chest tube safely removed at 2-week follow-up visit [32]. The specific criteria for chest tube removal will be discussed later in this chapter.

Complications of Insertion

The standard of care in pleural effusion, pneumothorax, and post-thoracic surgery patients is effective drainage of the pleural space with chest tubes. While this is a common and safe procedure, it is not without risks. The most serious complication is damaging surrounding organs such as the lung, heart, diaphragm, esophagus, stomach, liver, and spleen [27]. Intercostal artery, diaphragm, phrenic nerve, and sympathetic chain injuries may occur as well [33]. Most of these complications occur during insertion with the trocar method, and for this reason, trocars are not the first choice for chest tube placement [34]. On average complications can be seen in up to 5–10% of tube thoracostomy placements and are mainly related to tube malposition and other technical complications [33] (Fig. 58.12). Malposition of the chest tube in the subcutaneous tissues will prevent the function of the chest tube. Risk factors for subcutaneous chest tube insertion are obesity, rib fractures, and hasty insertion [33].

Re-expansion pulmonary edema is the accumulation of alveolar fluid secondary to rapid expansion of a collapsed lung [35]. The mechanism of this phenomenon is not entirely understood; however, it is thought that a decrease in surfactant production, while the lung is collapsed, and release of inflammatory cytokines and increased hydrostatic pressure after re-expansion all contribute. The main risk factor for developing re-expansion pulmonary edema is a lung that has been collapsed for greater than 3 days. The treatment is supportive and symptoms may persist for up to 1 week [35]. To prevent re-expansion pulmonary edema, it is probably safe to remove less than 1500 mL of fluid during a single thoracic drainage procedure. Larger volumes require careful clinical monitoring, and suction should not exceed −20 mmHg [35].

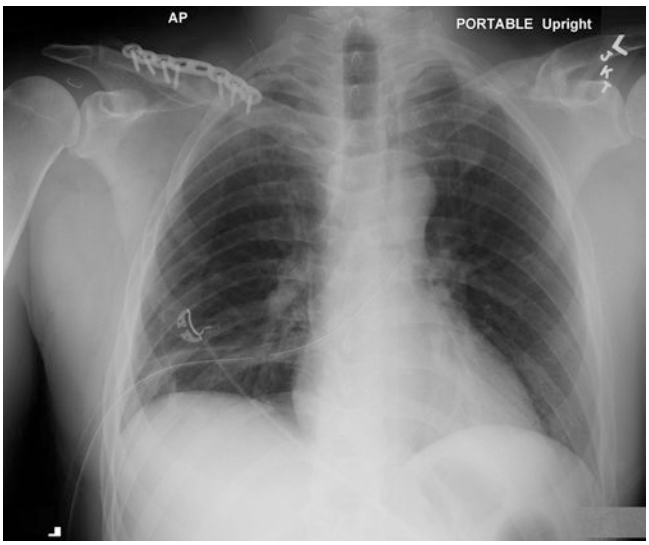

Fig. 58.12 Right chest tube placed into the mediastinum

If chest tubes are left in place for too long, empyema may develop requiring thoracotomy or thoracoscopy for evacuation and has been shown to range from 2% to 5% [33, 36, 37]. Risk factors for developing empyema after chest tube placement are increased duration of chest tube and retained hemothorax [33]. Other risk factors for empyema development after tube thoracostomy are prolonged ICU stay, pulmonary contusion, and need for laparotomy. The treatment of empyema is intravenous administration of antibiotics and surgical evacuation.

Other rare complications exist such as pleurocutaneous fistula or retained portion of catheter. A pleurocutaneous fistula is a rare problem in which a tract between the skin and pleural space develops after chest tube removal. Pleurocutaneous fistulas may heal spontaneously or require surgical intervention. Retained catheter is rare but requires thoracoscopy or thoracotomy for removal [33].

Chest Tube Removal and Thresholds

There are mixed opinions regarding when to remove a chest tube. The two main factors that contribute to the decision to remove a chest tube are quantity of liquid output and the presence or absence of an air leak. Chest tubes may be removed on suction or water seal for trauma patients [21]. In pulmonary resections, the chest tube is placed to suction on the day of surgery to aid in expansion of the lung and fill the space created during resection. On postoperative day 1, patients may be transitioned to water seal [38]. Patients frequently develop pleural effusion after lung resection, and this can prevent timely discharge of patients if they are otherwise suitable for discharge. In patients with more than one chest tube, the anterior and apical chest tube should be removed last as this tube will evacuate air more effectively and prevent post-removal pneumothorax [1]. It has been shown that chest tubes may be safely removed with an output of 450 mL or less of nonchylous drainage per day [39]. Another study showed that after VATS lobectomy, chest tubes may be safely removed with up to 500 mL of fluid output per day [40]. It is possible that it is safe to remove chest tubes with higher levels of output; however, there is currently no evidence to support this.

The issue of when to remove a chest tube becomes more complicated if the patient has an air leak. As mentioned above, most air leaks will resolve within 1–2 days postoperatively. For those that do not resolve, Cerfolio and colleagues have detailed

an algorithm to guide physicians [32]. Patients undergoing pulmonary resections other than pneumonectomy who had persistent air leak at 3 days had their tubes attached to an outpatient collection device and discharged with prophylactic cephalexin 500 mg daily until their follow-up in 2 weeks (approximately 3 weeks postop). All of the chest tubes were safely removed from patients with persistent air leak even in the presence of pneumothorax [32]. As long as residual air space on chest radiograph was asymptomatic and not expanding and there was no increase in subcutaneous emphysema, these chest tubes could be removed 2 weeks after discharge with prophylactic antibiotics continued as long as the chest tube was in place [32]. The reason for why the lung does not collapse after 2 weeks with persistent air leak is not well understood. It is possible that sufficient adhesions have formed at 2 weeks to prevent the collapse of the lung [32]. It is unknown how long a chest tube can safely remain in place, but the chest tube should be removed as soon as possible to prevent development of empyema. Chest tubes may safely remain in place in the case of prolonged air leak up to 3 weeks after placement [32].

Using the correct technique to remove a chest tube is important to prevent a post-removal pneumothorax. All patients should have their chest tubes removed while performing a Valsalva, and an occlusive dressing using petroleum gauze should be placed over the incision and held firmly in place during the removal of the tube. The tube should be pulled at end expiration—the patient should be asked to fully and forcibly exhale, and then perform a Valsalva. At the end of expiration and during a Valsalva, the chest tube may be withdrawn rapidly with one hand, while the other hand holds the occlusive dressing in place over the incision [41]. This technique was shown to be more effective at reducing post-pull pneumothorax compared to the removal of chest tubes at the end of maximal inspiration [41]. Patients with extensive COPD and low forced expiratory volume in 1 s are at higher risk for developing post-pull pneumothorax [41].

Follow-up chest x-ray after chest tube removal is routinely performed. In post-thoracic surgery patients, it is important to assess an enlarging pneumothorax after placing to water seal and after removal of the chest tubes [38, 39]. In trauma patients, however, chest x-rays only for symptomatic patients have been shown to be as effective at identifying pathology as routine chest x-ray and result in fewer interventions in trauma patients [42, 43].

Special Situations

Bronchopleural Fistula

A bronchopleural fistula is a connection between a segmental or more proximal bronchus and the pleural space. It is crucial to differentiate bronchopleural fistula from alveolar-pleural fistula as the treatment is drastically different. The incidence of bronchopleural fistula is 1.6–2.7% following pulmonary resection, and it is increased in patients who have undergone neoadjuvant therapy owing to their friable tissues and poor wound healing [15]. Bronchopleural fistula most commonly occurs after pneumonectomy, but it is also seen in lobectomy or segmentectomy. Patients at higher risk for bronchopleural fistula are those who have undergone radiation, are immunocompromised, or have diabetes. Surgically speaking a long bronchial stump, injury to arterial supply of the bronchus, and leaving lymph nodes on the bronchus all increase patient risk for bronchopleural fistula. Bronchopleural fistula will present with continuous air leak that was not present previously. When a bronchopleural fistula is suspected, the patient should undergo bronchoscopy. Most moderate to large bronchopleural fistulae are easily diagnosed on bronchoscopy. If there is no sign of bronchopleural fistula on bronchoscopy, and a high suspicion for bronchopleural fistula persists, the patient should undergo xenon ventilation scan. This study will demonstrate xenon escaping the bronchus and entering the pleural space and chest tube. If a bronchopleural fistula is identified, reoperation and flap or omentum coverage will be required [15].

Post-pneumonectomy Chest Tubes

After pneumonectomy, the patient has a large empty space that will ultimately be occupied by fluid. Postoperatively there is great debate about whether or not to leave a chest. The goal of a chest tube is to return the mediastinum to a normal position. After pneumonectomy the mediastinum will be forced away from the operative side by the entry of air into the pleural space. This may compress the remaining lung and can even compromise venous return. If the mediastinum is not balanced appropriately, this could lead to cardiopulmonary collapse. Balancing the mediastinal space may be performed with needle aspiration or a chest tube placed to water seal with half the water volume and never to suction. Air may be removed with aspiration until resistance is noted. The benefit of a chest tube in this unique situation is early recognition of potentially fatal bleeding or bronchial stump breakdown. The chest tube is typically removed in 12–24 h to prevent infection [15]. Ultimately, it is up to the surgeon whether to leave a chest tube after pneumonectomy, and an experienced team is required to monitor the patient postoperatively.

Abrupt Changes in Chest Tube Output

An abrupt decrease in chest tube output may be an ominous sign and should prompt clinical correlation to assure

no undrained enlarging collections are present. It may signal that the space is inadequately drained, and dangerous accumulation of fluid or air may result. Pericardial effusion, cardiac tamponade, and tension pneumothorax could all be the result of a chest tube that stops draining. Clark reports the case of a clogged chest tube that led to massive hemothorax requiring repeat operation [17]. Abrupt increase in chest tube output may signal new bleeding if the output is bloody or other problems including chylothorax, bronchopleural fistula, or anastomotic leak.

Clamping Chest Tubes

Some centers will clamp chest tubes as a test to identify occult air leak prior to chest tube removal. In this strategy, the tube is clamped, and follow-up chest radiograph is performed to evaluate for collapse of the affected lung. It has been shown to be safe and beneficial to prevent premature removal with follow-up x-ray in 6 h [44]. In the case of massive hemothorax, it has been suggested that clamping a chest tube prior to the operating room might improve patient survival and help tamponade the bleeding. There is little data to support this strategy, and it has been shown that clamping a chest tube in massive hemothorax will not decrease the volume of blood lost. Instead clamping the chest tube in massive hemothorax will lead to increased compression of the lung and worsened gas exchange [45]. Chest tubes should therefore not be clamped in the case of massive hemothorax, and the patient should be taken emergently to the operating room and resuscitated as needed.

Summary

Chest tubes are an integral part of cardiothoracic surgery, and the well-being of patients depends on their appropriate management. In this chapter we discussed the types of chest tubes, how they are inserted, collection systems, drainage volumes, air leaks, chest tube removal, and special situations including bronchopleural fistula, post-pneumonectomy chest tubes, abrupt changes in chest tube output, and when a chest tube may need to be clamped.

All chest tubes should be connected to a water seal collection system, and suction may be applied if needed. Chest tubes are not without complications; however, they are generally very safe in the hands of an experienced clinician, and serious complications are exceedingly rare. Chest tubes can be safely removed when there is no air leak and their liquid output is less than 450 mL for the previous 24 h. Patients who have an alveolar-pleural fistula, or air leak, should have chest tubes placed to water seal as soon as clinically feasible, and these leaks will normally resolve in 2–3 days. Patients with a prolonged air leak may be discharged with an outpatient collection system, and their chest tubes may be removed safely at 2-week follow-up if there is no expanding pneumothorax, increasing subcutaneous emphysema, or change in respiratory status.

Bronchopleural fistula should not be confused with alveolar-pleural fistula as the management of the former is operative and the latter is typically nonoperative. Patients undergoing pneumonectomy may have a chest tube placed in the space previously occupied by their lung to balance the mediastinum, and they should never be placed to suction. Abrupt changes in chest tube output may represent obstruction in the chest tube or hemorrhage and should be further evaluated. Chest tubes should never be clamped in the setting of massive hemothorax as this will result in increased compression of the lung and decreased oxygenation. It is safe to clamp chest tubes as a diagnostic test for occult air leak.

Over the last 20 years, our knowledge of chest tube management has significantly improved, thanks to a number of publications seeking to provide evidence-based guidelines to substantiate clinical experience and assist in decision-making. Further study is still needed to further define the role of small bore chest tubes in patients after cardiothoracic surgery, output thresholds for chest tube removal, and the need for suction.

TNFα	Tumor necrosis factor alpha
V/Q	Ventilation/perfusion ratio
VATS	Video-assisted thoracoscopic surgery

Key Points

- Thoracic surgery can cause significant pain and suffering. Poor pain relief can increase pulmonary complications and mortality.
- Pain after thoracic surgery is generated from multiple structures and is transmitted via a number of afferent pathways. Factors that affect pain postoperatively can be divided into patient factors, analgesic technique, and surgical approach.
- An aggressive multimodal analgesic strategy is advised to control the acute pain associated with thoracic surgery, allowing the clinician to minimize reliance on opioid-based drugs and the side effects they are associated with.
- Paravertebral catheters and thoracic epidural analgesia are widely used for thoracotomies and both have advantages and disadvantages. Recent studies suggest a similar quality of pain relief between the two approaches but a preferable side effect profile where paravertebral analgesia is utilized.
- Ultrasound guidance is increasingly used to guide paravertebral block and catheter placement. There are a number of approaches described.
- Serratus anterior and erector spinae plane blocks have recently been introduced as alternatives to traditional intercostal, epidural, and paravertebral regional anesthetic techniques for post-thoracotomy analgesia.
- Opioid-tolerant patients pose a particular challenge. Maintenance opioid should be continued perioperatively to avoid withdrawal symptoms. A multimodal technique involving regional blocks and supplemented with non-opioid analgesics is advised.

Introduction

A posterolateral thoracotomy is among the most painful incisions, and thus unsurprisingly patients can, and sometimes do, suffer considerable pain in the postoperative period if analgesia is not managed appropriately [1]. Poorly treated post-thoracotomy pain greatly reduces patient satisfaction and quality of life, leads to longer hospitalization times, and is associated with greater costs [2].

The surgical wound is subject to continuous movement as the patient breathes and ventilation is adversely affected. Inspiration stretches the injured structures initiating a reflex contraction of the expiratory muscles. Splinting of the injured hemithorax occurs to limit the distraction of the injured structures. Similarly, the usually passive expiration becomes active. Thoracic surgery creates a restrictive pulmonary function pattern, leading to a reduction to approximately 40% of baseline measurements of forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), and functional residual capacity (FRC). Where the FRC falls below the closing capacity, airway closure and atelectasis may develop with a consequent area of ventilation perfusion mismatch [3]. Deep inspiration is limited by pain; forced expiratory flow is thus further reduced and effective coughing impaired. Sputum clearance is often adversely affected. Inadequate pain control can also reduce the patient's ability to cooperate with postoperative physiotherapy and remobilization, all contributing to an increased incidence of hypoxemia. Acute pain is also associated with a significant increase in circulating catecholamine levels, catabolic hormone release, and overall sympathetic tone. This can lead to tachycardia, increased blood pressure, hyperglycemia, and raised serum lactate and is thought to therefore contribute to the increased risk of myocardial ischemia in the perioperative period [4–7] (Table 59.1).

Effective analgesia can reverse some of these changes and improve pulmonary function post-thoracotomy. There are, however, many other causes for the deterioration in pulmonary function that occurs post-thoracotomy. To date it has not been possible to determine with any accuracy the relative importance of pain in the etiology of this (Table 59.2).

Ultimately, it is advised that a multimodal approach to analgesia after thoracic surgery is considered for all patients. Multimodal analgesia, also frequently known as balanced analgesia, involves the use of more than one modality of pain control or class of drug in order to achieve a synergistic effect, while minimizing adverse effects [10].

Table 59.1 Consequences of inadequate acute pain control

System	Physiological change	Consequence
Pulmonary	Decreased lung compliance, atelectasis, hypoventilation and splinting, V/Q mismatch, reduced FRC	Hypoxia and hypercarbia
Cardiovascular	Increased HR, preload, afterload, and myocardial oxygen consumption	Increased risk of myocardial ischemia
Endocrine	Increased catecholamine, ACTH, aldosterone, ADH, angiotensin, and glucagon secretion	Free water retention, hyperglycemia, catabolic state
Hematological	Increased blood viscosity, platelet function, altered coagulation pathways, and fibrinolysis	Hypercoagulability, increased risk of thromboembolism, and thromboembolic events
Immunological	Impaired cell-mediated immune function	Increased risk of infection
Gastrointestinal	Reduced gastric emptying and gut motility	Nausea, vomiting, ileus
Urological	Increased sympathetic outflow	Urinary retention

Reproduced with permission, Doan et al. [8]

Table 59.2 Causes for deterioration in pulmonary function post-thoracotomy

Lung tissue resection
Hemorrhage and edema in residual lung tissue
Distortion in bronchial architecture with resultant lobar collapse
Gastric and abdominal distension
Increased airway resistance
Impaired mucociliary clearance
Residual effects of anesthesia
Pain-related changes in lung mechanics
Diaphragmatic dysfunction

Pathophysiology of Post-Thoracotomy Pain

The pathogenesis of post-thoracotomy pain is complex. Nociceptive receptors are stimulated by the skin incision, division and retraction of the muscles, and retraction and sometimes fracture of ribs. In addition, ligaments may be stretched, costochondral joints dislocated, and intercostal nerves injured, causing further pain. The incised pleura are frequently irritated by partial surgical stripping, chest drains, and residual pleural blood; the resulting inflammatory responses activate further nociceptors. The central transmission of these multiple nociceptive signals amplifies pain transmission and increases pain perception through central sensitization (Fig. 59.1).

There are a number of mechanisms for transmitting pain generated post-thoracotomy to the sensorium. Stimuli from the chest wall and costal and peripheral diaphragmatic pleura are transmitted via the intercostal nerves. The phrenic nerve supplies sensory branches to the mediastinal

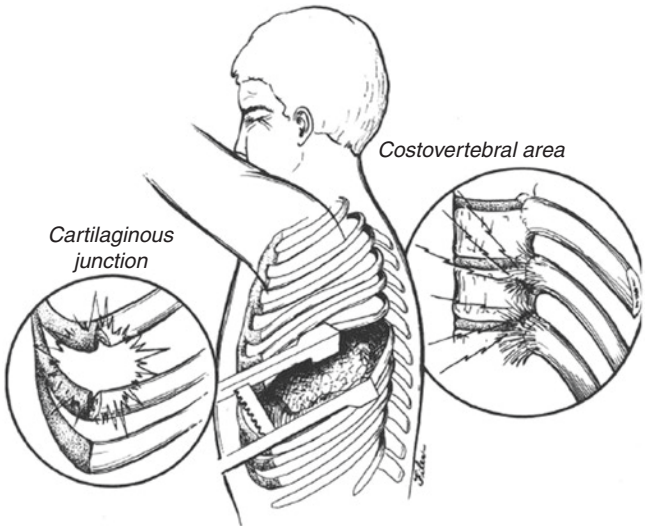

Fig. 59.1 Sites of thoracotomy incisional trauma. Direct injury to ribs and neurovascular intercostal bundles along with injuries to anterior and posterior intercostal articulations during a thoracotomy. (Reproduced with permission, Landreneau et al. [11])

pleura, fibrous pericardium, parietal layer of the serous pericardium, and diaphragmatic dome pleura. In addition, the vagus nerve contains somatic and visceral afferent nerve fibers, and blockade of the vagus nerve has been advocated during thoracic surgery [12]. The sympathetic nerves may play a role in transmitting pain from the lung and mediastinum. It has been suggested that stretching of the brachial plexuses and distraction of the shoulder contributes to the generation of ipsilateral shoulder pain in some patients [13].

Factors Influencing Pain After Thoracic Surgery

Preoperative Preparedness and Use of Perioperative Clinical Pathways

Well-informed patients may experience less pain [14], so patients should receive a full explanation of the proposed analgesic technique and its likely effects, including its limitations, potential side effects, and complications. Patients can also be educated regarding how to deal with pain postoperatively [15]. Enhanced recovery programs consist of a series of perioperative interventions, often presented in the form of a patient pathway, that together aim to reduce the impact of surgery on the patient. Through a reduction in the incidence of complications and by encouraging a return to normal function as soon as possible, the patient and institution benefit in terms of improved patient satisfaction and reduced length of hospital stay [16, 17]. Pain management is an integral part of an enhanced recovery pathway and has been considered in terms of preoperative day of surgery and postoperative components (Table 59.3). The preoperative component of this includes education of staff regarding the importance of good pain management, education of patients regarding their expectations surrounding pain and pain control, optimizing patients with preexisting pain issues, and identifying patients in whom pain control perioperatively may be more challenging, requiring early input and support from a multidisciplinary acute pain team [8]. One study showed that where preoperative pain management education was provided, there was a lower rate of analgesic consumption [15]. Education programs included instruction on pain and management methods and advice on how to express feelings and concerns and on the importance of anxiety control.

Table 59.3 Components of a clinical pathway for acute pain management

Preoperative
Staff education
Patient education
Optimize outpatient analgesic
Identify potentially challenging patients during preoperative assessment

Opioid Tolerance

Opioid-tolerant patients presenting for thoracic surgery include patients with malignant diseases receiving opioids for pain, a rapidly increasing group of patients with nonmalignant disease receiving opioids chronically for pain management, opioid-dependent substance abusers, and former addicts on long-term maintenance programs. There is some evidence to suggest that the use of a strong opioid for just 2 weeks may precipitate an increased opioid requirement during the perioperative period [18]. Achieving good postoperative analgesia in patients who are chronically receiving opioids is frequently difficult. There is evidence to suggest that opioid-tolerant patients have longer hospital admissions and a higher all-cause 30-day readmission rate [19]. This group of patients may experience more postoperative pain, manifesting as higher pain scores that take a longer to fall postoperatively. Patients should, when practical, be involved in the plans for their postoperative pain management, and their care should be individualized.

Preemptive Analgesia

The concept of preemptive analgesia was first suggested by Crile [20] although modern clinical interest is largely the result of basic science research done by Woolf [21]. Preemptive analgesia is antinociceptive treatment started before the noxious stimulus that aims to prevent the establishment of altered central processing of sensory input that amplifies postoperative pain [22]. Preemptive analgesia aims to decrease acute postoperative pain, even after the analgesic effects of the preemptive drugs have worn off, and to inhibit the development of chronic postoperative pain. Potential candidates for patients undergoing a thoracotomy include preincisional thoracic epidurals, paravertebral blocks, NMDA antagonists, gabapentin, and systemic opioids. Although the results of clinical studies to support the concept of initiating the pain treatment prior to the injury are conflicting, there is widespread belief in the concept among clinicians. A 2002 systematic review of preemptive analgesia for postoperative pain relief found no evidence of benefit for the preemptive administration of systemic opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), or ketamine and little evidence of benefit with continuous epidural analgesia [23]. A 2005 systemic review on the impact of preemptive epidural analgesia on pain after thoracotomy concluded that preemptive thoracic epidural analgesia was associated with a reduction in acute pain but no reduction in chronic post-thoracotomy pain [24].

Sex

A considerable amount of work has been undertaken in an attempt to determine the influence of the sex of the patient on the pain experienced after surgery. Female patients report pain to be more severe, frequent, and diffuse than male patients with similar disease processes [25]. A meta-analysis of the influence of sex differences in the perception of noxious experimental stimuli found that females were less tolerant of noxious stimuli than males [26]. The difference in pain perception between males and females decreases with age [27, 28], has not been found by all investigators, and is usually only moderately large. Social gender roles have a significant influence on pain tolerance levels [28], are sometimes difficult to differentiate from the sex of the patient, and may account for some of the differences in pain tolerance between the sexes. Coping strategies also influence patient's pain tolerance; catastrophizing is associated with an increased sensitivity to experimental pain [29]. Women are more likely to catastrophize and this may help account for the differences in pain tolerance between the sexes [30]. Anesthetists should be aware of the different responses male and female patients have to pain but as yet no specific recommendation with respect to treatment can be made.

Age

A recent systematic review found young age to be a significant predictor of postoperative pain [31]. The pharmacokinetics of analgesic drugs can be affected by aging, and the elderly are considered to be more sensitive to systemic opioids [32]. Similarly, there is a positive correlation between age and thoracic epidural spread with elderly patients requiring about 40% less epidural solution [33, 34]. It has also been suggested that age blunts peripheral nociceptive function decreasing pain in some contexts [35] although this is not the experience of at least one aging author.

Psychological Factors

Pain is a sensory and emotional experience and thus is influenced by psychological factors. It has been suggested that anxiety lowers pain thresholds [36]. Preoperative anxiety has been shown to be a predictor of more severe postoperative pain in studies of patients undergoing a variety of surgeries including thoracic surgery [31, 37]. Good preoperative communication with the patient and the development of rapport will facilitate reducing the anxiety by reassurance and, if appropriate, anxiolytics [31]. A depressive mood preoperatively [38] and neuroticism [39] have also been found to be predictors of more severe postoperative pain. There may be a relationship between preoperative depression and the development of chronic pain [40]. Cognitive factors can also influence pain perception. Catastrophizing, a multidimensional construct with elements of rumination, magnification, and helplessness, has emerged as one of the most reliable predictors of heightened pain experience [29]. Cognitive behavioral strategies may have a role in managing patients who catastrophize about pain [31].

Surgical Approach

Sternotomy

The sternum is usually internally fixed with steel wire after a sternotomy. Bone movement during respiration is thus minimal and the postoperative pain usually only moderate. However, wide or inexpert distraction of the sternum may fracture the sternum and strain or even disrupt the anterior or posterior intercostal articulations with the potential to considerably increase the postoperative pain experienced.

Video-Assisted Thoracoscopic Surgery

With video-assisted thoracoscopic (VAT) surgery, the extent of the surgical incision is limited, and early postoperative pain can be reduced [41] when compared to thoracotomy. These benefits may be reduced by the use of larger-diameter instruments, multiple ports, and/or the twisting of

surgical instruments against the ribs causing injury to the intercostal nerves and bruising or even fracturing of the ribs. This approach is therefore still associated with significant postoperative pain and, with this, impairment of respiratory function with associated respiratory complications. There is also a similar incidence in the development of chronic postsurgical pain. Control of acute pain in this surgical group should therefore not be overlooked or underestimated [8].

Open Thoracotomy

Posterolateral Incision

Posterolateral incision is the classic approach to a thoracotomy as it provides good surgical access and can easily be extended if required. It does, however, involve the cutting of some of the major chest wall muscles and is considered one of the most painful surgical incisions. There is some evidence that internal fixation of divided ribs reduces postoperative pain [42].

Muscle-Sparing Incision

Many surgeons now use one or more of the many muscle-sparing incisions that have been described. A popular approach is the axillary muscle-sparing incision, the skin incision for which extends vertically downward from the axilla with obvious cosmetic advantages. Although muscle-sparing incisions were initially reported to produce less perioperative pain [43–45], most studies have not supported this [46, 47]. Muscle-sparing incisions may result in less chronic post-thoracotomy pain [48] particularly where techniques involve free dissection of the costal nerve bundle to avoid injury through the use of retractors [49]. Wider rib retraction is frequently required for muscle-sparing thoracotomies to compensate for the reduced field of view [47]. Wider retraction may increase the risk of rib fractures, distraction of the posterior costovertebral joints, and damage to the intercostal nerves, all of which can increase post-thoracotomy pain.

Anterior Incision

Anterior incisions are used to provide access for some cardiac and anterior mediastinal procedures. Exposure for lung surgery is, however, limited particularly on the left because of the heart. Rib resections are frequently performed with this incision to improve surgical access. Postoperative pain depends in part on the extent of the excision and the extent of surgical retraction but is similar to that after a posterolateral thoracotomy. Intercostal nerve blocks are particularly effective with this approach because the incision does not involve any part of the chest supplied by the posterior cutaneous nerves which arise from the dorsal rami and are not blocked by an intercostal nerve block.

Transverse Sternothoracotomy

Transverse sternothoracotomy (clamshell) incisions (Fig. 59.2) provide excellent surgical exposure of both chest cavities and the mediastinum and were in the past used for cardiac surgery. This incision results in significant postoperative pain, and its use is now largely limited to lung transplantation, complex cardiopulmonary surgery, and complex mediastinal tumors [50]. Postoperative pain control can be challenging with this incision.

Analgesic Drugs and Techniques

The afferent signaling leading to the perception of pain is complex, and therefore there are numerous potential targets that can be pursued to achieve adequate analgesia (Fig. 59.3). By targeting more than one pathway simultaneously, there can be a synergistic effect and better quality analgesia.

Acute post-thoracotomy pain management aims to reduce the patient's pain as much as possible but to do so safely. In practice, most patients undergoing thoracic surgery can be safely and effectively managed using a multimodal approach including thoracic epidural analgesia, paravertebral blocks, or systemic opioids supplemented when appropriate by other systemic analgesics.

Systemic Opioids

Systemic opioids were used in the past as the mainstay of post-thoracotomy analgesia; however, the pain control achieved was often poor and frequently accompanied by a range of detrimental side effects including respiratory depression, nausea, vomiting, constipation, and changes in cognition [8]. It is now appreciated that for open thoracotomies, systemic opioids are best administered as part of a multimodal strategy including a regional technique. Titration of systemic opioids post-thoracotomy is needed if the balance between the beneficial effects and detrimental effects is to be achieved. In comparison to IM opioids, IV-PCA systems provide superior analgesia [52] and improve patient satisfaction [53]. In part this is because IV-PCA systems accommodate patient variation in postoperative opioid requirement [54], the halving of opioid requirements approximately every 24 h postoperatively [55], and the small group of patients that experience minimal postsurgery pain [1]. Several studies support the view that regional techniques are superior to systemic analgesia alone. A meta-analysis published in 1998 found that compared to systemic opioids, epidural local anesthetic significantly reduced the incidence of pulmonary complications after surgery [56] and patients undergoing thoracotomy with IV-PCA have been shown to have a lower FVC and FEV_1 postoperatively when compared with thoracic epidural [57]. This finding was not, however, supported by a systematic review published in 2008 [58], potentially because of improvements in the administration of systemic opioids in later studies included in the second review. Studies have suggested that acute exposure to opioids can lead to the development of acute opioid tolerance in patients previously opioid naïve [59]. Exposure to higher doses of opioids intraoperatively has been associated with increased postoperative pain, as demonstrated by a higher opioid requirement [60].

Non-opioid Analgesic Drugs

Nonsteroidal Anti-inflammatory Drugs

Prostaglandins have a role in pain perception. NSAIDs block the synthesis of prostaglandins by inhibiting the enzyme cyclooxygenase (COX). NSAIDs reduce the inflammatory response to surgical trauma, have a peripheral non-prostaglandin analgesic effect [61], and act centrally [62] in part by inhibiting prostaglandin synthesis in the spinal cord [63]. The side effects of NSAIDs are well known and include gastrointestinal mucosal damage [64] and renal tubular and platelet dysfunction [65]. The amount, if any, of NSAID-mediated increased bleeding after thoracotomy has not been established, although studies after tonsillectomy suggest that the increased bleeding is probably minimal [66]. In normal adults the risk of renal toxicity secondary to NSAIDs is estimated to be between 1:1000 and 1:10,000 [67]. Patients particularly at risk, however, include elderly patients undergoing major surgery [68, 69], patients with preexisting renal failure, and hypovolemic patients as they are more dependent upon the vasodilatory effects of prostaglandins to ensure maintenance of effective renal perfusion [70]. These risk factors are often present in patients scheduled for thoracic surgery. There is a concern that NSAID-mediated reductions in inflammation may reduce the efficacy of a surgically performed pleurodesis. For more than 25 years, NSAIDs have been used to control post-thoracotomy pain [71]. NSAIDs have been shown to significantly improve pain control in patients receiving systemic opioids post-thoracotomy [72, 73]. For patients receiving thoracic epidural analgesia post-thoracotomy, there is conflicting evidence for the benefit of NSAIDs. Early studies did not show a significant reduction in pain scores in [74]. Latter studies with COX-2 inhibitors did show significantly reduced pain scores [75, 76]. NSAIDs may be effective in controlling the ipsilateral shoulder pain post-thoracotomy in patients receiving thoracic epidural analgesia [77, 78], although research in this area has been limited.

COX-2 Inhibitors

Different isoenzymes of the cyclooxygenase enzyme exist including COX-1 and COX-2 [79]. The COX-1 isoenzyme has physiological functions, while the COX-2 isoenzyme is induced during inflammation. NSAIDs vary in their selectivity for inhibiting these cyclooxygenase isoenzymes. Some are selective cyclooxygenase 2 inhibitors and are termed COX-2 inhibitors. These agents have a lower risk of causing serious upper gastrointestinal side effects and cause less platelet inhibition than the nonselective NSAIDs. There is some evidence that COX-2 inhibitors may limit the development of acute opioid tolerance [80]. Senard et al. [75] found significantly reduced pain scores at rest and during coughing and improved patient satisfaction where thoracic epidural was combined with the COX-2 inhibitor celecoxib.

There are concerns about the detrimental effects of COX-2 inhibitors and NSAIDs on bone growth [81, 82]. In 2004/2005, two COX-2 inhibitors (rofecoxib and valdecoxib) were withdrawn because of concerns that there was an increased risk of cardiovascular thrombotic complications when these agents were taken daily for long periods. Subsequent studies support this finding as being a COX-2 and nonselective NSAID class effect [83, 84] likely due to the vasoconstrictive and prothrombotic effects associated with COX-2 inhibition and reduced prostacyclin production [70]. Caution is required if these drugs are to be administered regularly over long periods. The safety of COX-2 inhibitors in the perioperative setting is controversial. For patients undergoing CABG on cardiopulmonary bypass, there is an increased risk of cardiovascular thrombotic events in patients receiving the selective COX-2 inhibitors parecoxib and valdecoxib [85, 86]. A study of a variety of non-cardiac surgical procedures including thoracic surgery did not show an increased incidence of cardiovascular thrombotic events in patients receiving the same selective COX-2 inhibitors [87]. The cardiovascular risk between agents varies, for example, the NSAID naproxen has a lower cardiovascular risk profile than diclofenac [88]. Intravenous parecoxib 40 mg, administered preoperatively then every 12 h for 3 days following surgery in addition to patient-controlled epidural analgesia (PCEA), has been associated with significantly reduced pain scores at rest and after coughing, along with a suggestion of a reduced incidence of chronic pain, although further studies are required to confirm this [76]. Intravenous parecoxib administered in addition to paravertebral infusion with ropivacaine has shown similar positive results [89]. The level of cardiovascular risk associated with the short-term perioperative use of COX-2 and NSAIDs remains controversial. For individual patients, their cardiovascular risk factors and the risks of alternative drugs or analgesic techniques need to be considered.

Acetaminophen

Acetaminophen, perhaps the safest of the non-opioid analgesic agents, acts centrally by inhibiting prostaglandin synthesis potentially through weak COX-2 and COX-3 suppression [70, 90] and possibly via the serotoninergic system [91]. Acetaminophen may also have peripheral anti-inflammatory actions [92]. Acetaminophen can be administered through several routes, orally, rectally, and more recently intravenously. The intravenous preparation is significantly more costly to administer than via the oral or rectal route. Use of intravenous acetaminophen following median sternotomy

for cardiac surgery was associated with reduced pain scores, but not opioid consumption [93]. Propacetamol, a prodrug that is hydrolyzed to acetaminophen by plasma esterases, can be administered intravenously and has been shown to decrease morphine consumption after spinal [94] and cardiac surgery [95] although a reduction in morphine consumption after cardiac surgery was not shown in an earlier study, possibly because of the methodology [96]. The recent Cochrane review [97] found that a single dose of intravenous paracetamol or propacetamol provided 4 h of effective analgesia in significantly more patients than placebo. A meta-analysis found that after major surgery, adding acetaminophen to morphine PCA reduced the morphine consumption by 20% but did not decrease the incidence of morphine-related adverse effects [98] (Fig. 59.4).

More recently, the clinical effectiveness of orally versus intravenously administered acetaminophen have been compared. Following major joint surgery, a first perioperative intravenous dose of acetaminophen has been associated with improved pain scores in the first 4 h after surgery compared to oral administration. At all time periods after this, there was no difference in the effectiveness of the oral or intravenous preparation in terms of pain score or opioid consumption [99]. Regular rectal acetaminophen has been shown to reduce the severity of ipsilateral post-thoracotomy shoulder pain [100]. When administered rectally the dosage should exceed the oral dose by 50%, and account should be taken of its slower onset [101]. There is some evidence that the effects of acetaminophen and NSAIDs are additive [102, 103]. Unlike NSAIDs and COX-2 inhibitors, acetaminophen at clinical doses has few contraindications or side effects. It is considered safe for patients at risk of renal failure [101]. Acetaminophen is frequently administered post-thoracotomy [104].

NMDA Antagonists

The involvement of glutamate, an excitatory neurotransmitter acting via the N-methyl-D-aspartate (NMDA) receptor, in nociception makes this an attractive target for both acute and chronic pain management strategies. Activation of the NMDA glutamate receptor has been heavily implicated in the process of central sensitization, also known as "wind up," which has then been linked to the transition from acute to chronic pain and the states of hyperalgesia and allodynia [105]. Ketamine, an anesthetic with analgesic properties, is a noncompetitive antagonist of the phencyclidine site of the NMDA receptor but additionally has been demonstrated to display some anti-inflammatory and anti-hyperalgesic properties. In recent years, there has been renewed interest in the use of small doses of ketamine as an adjuvant to postoperative analgesia. NMDA receptor antagonists enhance opioid-induced analgesia and can limit the development of opioid tolerance and opioid-induced hyperalgesia [105–107]. Small doses of ketamine have been shown to have opioid-sparing effects after abdominal surgery [108], but results after thoracic surgery are dependent upon the other modalities of analgesia utilized. A meta-analysis [109] assessing the effectiveness of IV-PCA morphine with the addition of ketamine concluded this to be a safe technique associated with improved pain scores, reduced morphine consumption, and potentially an improvement in respiratory function, as demonstrated by one double-blind study suggesting an improved early postoperative FEV_1 [110]. Where ketamine was administered as a single IV dose at induction of anesthesia, there was evidence of reduced opiate requirement for 48 h postoperatively [111]. Where ketamine infusion has been used perioperatively and for the first 24 h postoperatively, pain control in the immediate postoperative period was improved but with no impact upon the incidence of chronic post-thoracotomy pain [112]. The incidence of hallucinations associated with intravenous ketamine is low. One study involving a ketamine/morphine IV-PCA within the general surgical population reported an incidence of hallucinations of 6.2%, with half of these patients requiring dose reduction or cessation of treatment [113]. In all cases where treatment was stopped, hallucinations resolved within 1–2 h.

Use of IV or epidural ketamine as an adjunct to epidural analgesia has also been considered. While one group found that adding a low-dose IV infusion of ketamine to thoracic

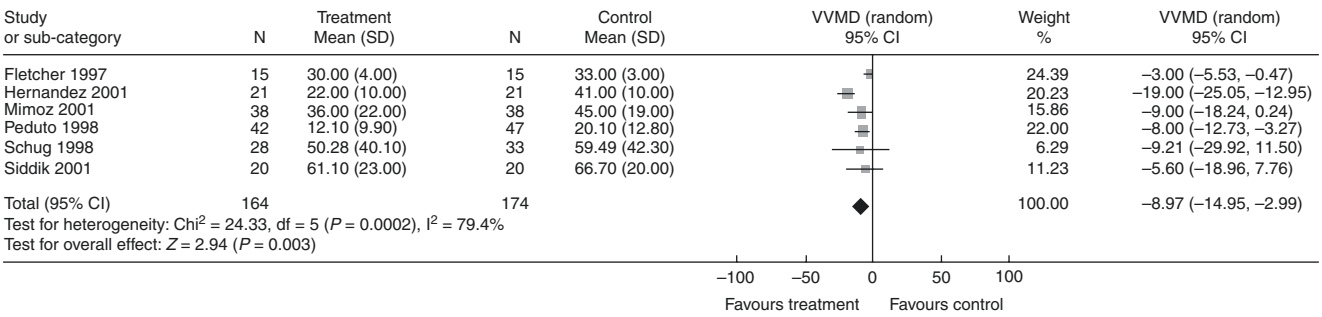

Fig. 59.4 Effect of acetaminophen on postoperative morphine consumption during the first 24 h after major surgery. (Reproduced with permission, Remy et al. [98])

epidural analgesia improved early post-thoracotomy analgesia [114], this finding has not been reproduced more recently by other groups who found no difference [115, 116], although the quality of analgesia produced by effective thoracic epidurals in these studies may negate the additional impact of ketamine. Both the IV and epidural routes of administration have been shown to be of benefit in the management of postoperative pain, but with no significant differences in efficacy between the two routes [105]. Ultimately, the literature appears to support a benefit for postoperative use of ketamine in some patients, particularly those without a thoracic epidural or chronically receiving high-dose opioids. Side effects of ketamine include increased secretions and dysphoria, although the use in low doses is generally well tolerated. At the authors' institution, ketamine is sometimes administered either by infusion or orally where analgesia with more conventional means proves challenging (Table 59.4).

Gabapentinoids

Gabapentin, 1-(aminomethyl)cyclohexane acetic acid, is an anticonvulsant drug that is effective in treating neuropathic pain [125] and postherpetic neuralgia [126]. Gabapentin may act through a number of mechanisms. The most likely site of its antinociceptor effect is thought to be by binding to the $\alpha_2\delta$ subunit of voltage-dependent calcium channels [127]. The absorption of gabapentin is dose dependent. There is some evidence that gabapentin reduces early postoperative pain scores and reduces opioid consumption in the first 24 h for patients undergoing a variety of surgical procedures [123, 128]. Gabapentin has been administered as a single preoperative oral dose ranging from 300 to 1200 mg and as multiple perioperative doses [122]. A single preoperative dose of gabapentin 600 mg in conjunction with epidural analgesia had no impact upon acute pain experienced postoperatively or the incidence of chronic pain 3 months later [129]. Administration of gabapentin as a preoperative 1200 mg bolus dose followed postoperatively by 600 mg 12-hourly in conjunction with IV-PCA led to improved analgesia, lower morphine consumption, and improvement in postoperative pulmonary function [130]. In a placebo-controlled study, gabapentin did not decrease ipsilateral shoulder pain in patients receiving thoracic epidural analgesia [131]. Overall evidence currently suggests that gabapentin, if used, should be administered as a multidose regime over the perioperative period rather than a single preoperative dose [123, 124], but more studies to ascertain the most efficacious dose and duration of treatment are required. Gabapentin is sedative and anxiolytic [132], and therefore the doses of other premedication drugs used should be adjusted accordingly, and the risk of postoperative sedation should not be overlooked.

Table 59.4 Adult analgesic regimes

Technique	Dose	Comment
Paravertebrals		
Lower-dose regime		
Loading dose	0.3 mL kg^{-1} 0.25% levobupivacaine	Higher-dose regime produces improved analgesia and pulmonary function [117]
Maintenance	0.1 mL kg^{-1} h^{-1} 0.25% levobupivacaine	
High-dose regime		
Loading dose	20 mL 0.5% levobupivacaine	
Maintenance	0.1 mL kg^{-1} h^{-1} 0.5% levobupivacaine	
Intrathecal opioids	Morphine 200 μg + sufentanil 20 μg [118] or morphine 500 μg + sufentanil 50 μg [119]	
Thoracic epidural		
Levobupivacaine	0.1%	Titrate to effect
Or		
Ropivacaine	0.15%	Reduce rate by 40% for elderly
with		
Fentanyl	4–5 μg mL^{-1} or	
Sufentanil	1 μg mL^{-1} or	
Hydromorphine	10–25 μg mL^{-1} [120]	
Bolus	7 mL	
Infusion	7 mL h^{-1}	
Intercostal nerve blocks		
Injection sites T3–T7	0.25% Levobupivacaine with epinephrine 1:200,000 3–5 mL per site	Use repeated doses or continuous infusion [58]. Associated with rapid absorption of local anesthetic
Ketamine		
For intravenous supplementation of epidural analgesia	0.05 mg kg^{-1} h^{-1} [114]	
Without epidural analgesia		
Bolus	0.25–0.5 mg kg^{-1} [[121], authors' institution]	
Infusion Oral	1–6 μg kg^{-1} min^{-1} continued for few days [[121], authors' institution] 10 mg TDS, titrated to 25 mg TDS according to effect [author's institution]	
Gabapentin	300–1200 mg orally 1–2 h preoperatively [122] followed by 100–300 mg OD to TDS titrated according to effect [author's institution]	Where gabapentin is used, it is recommended as part of a multidose regime over the perioperative period, not solely preoperatively [123, 124]

Pregabalin is a structural analogue of γ-aminobutyric acid and probably acts via the same mechanism as gabapentin to exert an anticonvulsant, anti-hyperalgesic, and anxiolytic effect more potent than that of gabapentin [133]. Meta-analyses [133, 134] and reviews [135, 136] revealed the considerable heterogeneity of the patient populations studied, dosing regime, and timing of administration in the trials. Possibly as a consequence, pain intensity was not consistently altered. Many studies involved surgeries in which low pain severity would be expected and therefore whether pregabalin would significantly reduce the pain associated with thoracic surgery is not clear [135]. Two studies, one using a single preoperative dose of pregabalin [137] and the second using a single preoperative dose followed by twice daily dosing for 2 postoperative days in patients undergoing coronary artery bypass grafting [138], suggested a reduction in postoperative pain scores. There is a suggestion of a lower incidence of nausea and vomiting where pregabalin is used, but a greater incidence of visual disturbance, dizziness, headache, and sedation. More studies addressing use of pregabalin following thoracic surgery are required in order to make any recommendation.

α_2 Adrenergic Agonists

Clonidine and dexmedetomidine are α_2 adrenergic receptor agonists that have an analgesic effect without concomitant respiratory depression, although they do cause central sedation, an effect for which they are more frequently prescribed in the intensive care unit [139]. They have been shown to reduce sympathetically mediated pain but are also associated with hypotension and bradycardia – clonidine to a greater degree than dexmedetomidine [140]. IV dexmedetomidine 4 mcg kg^{-1} added to sufentanil IV-PCA led to a significant improvement in pain scores at rest and during coughing for the first 48 h after surgery, with lower sufentanil requirement and greater patient satisfaction in the group receiving dexmedetomidine [141]. Comparison of clonidine administered as a single intravenous bolus dose of 3 mcg kg^{-1} prior to induction of anesthesia with placebo demonstrated a reduction in pain scores in the immediate postoperative period in the clonidine group and a reduced fentanyl requirement over the first 24 h, but the study period did not extend beyond this [142]. There is limited data on the usage of α_2 adrenergic receptor agonists during thoracic surgery, but the studies conducted so far suggest that there may be a benefit, particularly in patients that are unable to undergo regional analgesic techniques or are already taking large doses of opioid medications. The additional sedating effects and propensity to hypotension and bradycardia, although not recorded as causing significant adverse effects in the studies discussed, should not be overlooked.

Glucocorticoids

Thoracotomy induces a significant pro-inflammatory response, with marked increases in pro-inflammatory mediators including IL-6 and IL-8 that correlate positively with the extent of dynamic pain experienced by the patient [143]. Glucocorticoids have many actions including analgesic, antiemetic, antipyretic, and anti-inflammatory effects. Reduced prostaglandin production by the inhibition of phospholipase and COX-2 isoenzymes is believed to be the major pathway for the analgesic effect. There is also some evidence that administration decreases presynaptic release of neurotransmitters and causes production of kynurenic acid, an NMDA antagonist [144, 145]. Dexamethasone is a soluble glucocorticoid and has been shown to produce a dose-dependent opioid-sparing effect [146] in a general surgical setting and has been particularly effective in reducing pain scores with dynamic movement [147, 148]. The onset of analgesia is slower than traditional analgesics but appears to last longer and has been reported to last for up to 7 days [149]. Although these effects have been produced with a single dose of dexamethasone within the range of 10–40 mg with few reported serious side effects, more recent studies have shown similar effectiveness with smaller doses. Dexamethasone has also been suggested as an effective adjunct to prolong the duration of peripheral nerve blocks for orthopedic surgery [150] and paravertebral blocks for nephrectomy [151]. The use of both 8 mg of IV and 4 mg of perineural dexamethasone significantly prolonged the duration of intercostal nerve blocks used for VATS surgery and led to improved pain scores at 24 h [152]. The data also suggested reduced pain scores, reduced opioid consumption, and better PFTs where more than one route of administration was used. No trials reported any adverse outcomes related to the perineural administration of dexamethasone although, in animal models, high doses have been associated with neuronal cell death [153]. Risks of glucocorticoid use include gastric irritation, impaired wound healing, impaired glucose homeostasis, and sodium retention. The optimal dose that balances the advantages against these, and other, risks has yet to be defined, and further research, particularly in the setting of thoracic surgery, is required. If there are no contraindications to glucocorticoid use, selected patients may benefit from a single 8–16 mg dose of dexamethasone as part of a multimodal analgesia regime.

Non-pharmacologic Techniques

Transcutaneous Nerve Stimulation

Transcutaneous nerve stimulation (TENS) was developed to utilize the gate theory to reduce pain [154] via modulation of

nociceptive signals from the spinal cord and the release of endogenous opioids [155]. Patients treated with TENS have also been found to have significantly reduced levels of circulating inflammatory cytokines IL-6, IL-8, and TNFα [156]. An initial meta-analysis published in 1996 of the effectiveness of TENS in acute postoperative pain found little evidence for effectiveness in adequately randomized studies [157]. In contrast, TENS was considered by the original authors to be effective in most of the nonrandomized studies analyzed [157]. A more recent meta-analysis [158] of 11 randomized controlled trials assessing of the use of TENS in patients undergoing thoracotomy concluded that, when compared to placebo, TENS did effectively modulate pain when combined with other pharmacological methods and was associated with an improvement in FVC. TENS therefore appears to be a safe and effective complementary analgesic technique, but only in the context of a primarily pharmacological approach.

Cryoanalgesia

While the chest is open, the intercostal nerves can be blocked transiently from 1 to 4 days or even for up to 6 months in some cases by the application of a cryoprobe. The analgesia is inferior to thoracic epidural fentanyl [159] and the technique is associated with an increased incidence of chronic post-thoracotomy pain [160]. Cryoanalgesia is now rarely used to provide post-thoracotomy analgesia and cannot be recommended.

Regional Techniques

Over the years, a large number of regional techniques, and drugs to deliver via these regional techniques, have been developed and used to control post-thoracotomy pain. Unfortunately, no technique has emerged that is safe, effective, and applicable to all patients. Until the early 1980s, systemic opioids formed the mainstay of post-thoracotomy analgesia in the West. Thoracic epidurals were introduced into clinical practice for post-thoracotomy analgesia in the mid-1970s [161, 162] and had become the gold standard of post-thoracotomy analgesia by the mid-1990s [163]. Somatic paravertebral blocks are now gaining acceptance as an alternative method for providing post-thoracotomy analgesia. A number of factors have led to the increased use of somatic paravertebral blocks. The risks associated with the perioperative use of epidural analgesia are becoming clearer and are perhaps greater than previously thought [164, 165]. More patients are presenting for thoracic surgery on multiple antiplatelet agents sometimes with intracoronary stents in situ. While dual antiplatelet therapy is known to be a contraindication to thoracic epidural analgesia [166], the risk of discontinuing antiplatelet agents perioperatively is now quantifiable [167–169].

There are an ever-increasing number of studies comparing effectiveness of, and outcomes after, thoracic epidural analgesia or paravertebral block. The Cochrane review [170], published in 2016, comparing paravertebral block and thoracic epidural analgesia concluded that paravertebral blockade was as effective as thoracic epidural in controlling acute pain, both at rest and after coughing or physiotherapy for at least the first 48 h. Paravertebral blockade had a better minor complication profile than thoracic epidural with a significantly lower incidence of hypotension, nausea, vomiting, pruritis, and urinary retention. There was no difference in incidence of major complications, length of hospital stay, or 30-day mortality between the two groups although the group did comment that a larger randomized control trial would be beneficial. They were unable to comment on the incidence of chronic pain following the two techniques. Numerous other studies [171–176] have supported the view that continuous paravertebral infusion provides an acceptable degree of analgesia following thoracotomy comparable to epidural analgesia and superior to wound infiltration, intercostal block, and intravenous opioids. This can then be improved further via a multimodal approach. El-Sayed et al. [177] also reported no difference in the incidence of postoperative respiratory complications, unplanned readmission to the intensive care unit, or in-hospital mortality in a retrospective analysis of a large case series. With this in mind, and given the rare but potentially catastrophic complication profile of the thoracic epidural, the use of paravertebral blockade in thoracic anesthesia is increasingly appealing.

Consent for Regional Analgesia

Recent guidance [178] issued by the Association of Anaesthetists of Great Britain and Ireland (AAGBI) clearly states that clinicians have a professional obligation to ensure that patients fully understand what is going to happen to them and what they should therefore expect during the course of their treatment. In order to preserve patient autonomy and obtain informed consent prior to any procedure, including regional analgesic techniques, it is essential that the patient be given a comprehensive explanation of what the procedure will entail, the benefits, the limitations, the potential side effects, and the risks, along with a discussion of the relative merits of alternative strategies. It is the duty of the clinician to ensure that this information is understood and that the patient is given an opportunity to ask questions. A 2015 landmark ruling in the United Kingdom (Montgomery v Lanarkshire Health Board [179]) stated that a doctor should provide information on all "material risks" to the patient,

where materiality is defined as "…whether a reasonable person in the patient's position would be likely to attach significance to the risk, or the doctor should reasonably be aware that the particular patient would be likely to attach significance to it." This followed a trend of openness that has been evolving over many years, leading to a marked change in practice. Most anesthetists now, for example, take specific consent for thoracic epidural analgesia [180].

Local Anesthetic Patches

Lidocaine 5% patches contain 700 mg lidocaine in an aqueous base held on a 10 cm by 14 cm soft adhesive patch. They are positioned and are placed 5–7 cm from the incision over the intact skin. The quantity of lidocaine absorbed is related to the duration of application and the total skin area covered [181]. Their use is approved by the FDA for the treatment of neuropathic pain syndrome and postherpetic neuralgia. As yet there is little validated evidence regarding their effectiveness in thoracic surgery, but a recent meta-analysis [181] and study assessing their use after robotic cardiac valve surgery [182] found no improvement in pain scores, morphine consumption, or length of hospital stay associated with their use. Currently therefore their routine use cannot be recommended.

Continuous Wound Infiltration Catheters

Randomized studies have shown that delivering local anesthetic into the wound via catheters placed prior to closure can improve resting and dynamic pain scores [183], reduce postoperative opioid use [183, 184], may reduce wound edema [185], and improve recovery of FEV_1 and FVC [183]. Where continuous wound infusion of local anesthetic was utilized in addition to morphine IV-PCA, there was a reduction in levels of systemic inflammatory markers [183]. The catheter was positioned at the end of surgery so that it lay between the pericostal sutures, in close proximity to the intercostal nerve and the deep surface of the serratus muscle, and it has been postulated that this catheter position, deeper than in other studies, was crucial to its success. Despite a continuous slow rise in serum local anesthetic concentration throughout the 48 h study period, levels remained within a safe range, and there were no complications associated with the technique [183], although for patients receiving continuous paravertebral infusions, the potential for local anesthetic toxicity makes use inappropriate. For patients receiving thoracic epidural analgesia, this technique is usually unnecessary. It could, however, be considered for patients not scheduled to receive local anesthetic infusions by other routes for postoperative pain control. A particular advantage of this technique is the ability to utilize it in surgeries where paravertebral catheter cannot be placed, such as pleurectomy or chest wall resection.

Intercostal Nerve Blocks

The spinal nerves divide into a dorsal and ventral ramus. The upper 11 thoracic ventral rami form the intercostal nerve which runs forward between the ribs in the intercostal spaces. Each intercostal nerve gives off a lateral cutaneous branch that pierces the intercostal muscles proximal to the posterior axillary line to supply the lateral aspect of the chest wall. It is important therefore the intercostal nerves are blocked posterior to the posterior axillary line to ensure that the lateral cutaneous branches and thus the lateral aspect of the chest wall are blocked. The thoracic dorsal rami pass backward close to the vertebrae to supply the cutaneous innervation to the back. The dorsal rami are not blocked by an intercostal nerve block. This limits the effectiveness of intercostal nerve blocks for posterolateral thoracotomies (Fig. 59.5).

The intercostal nerves can easily be blocked under direct vision, while the chest is open, but because of the relatively short half-life of most local anesthetics, repeated percutaneous blocks are usually required. The intercostal nerves consistently lie in a plane deep to the internal intercostal muscle although there is considerable variability in the position of intercostal nerves within the intercostal space. Small (5 ml) bolus of local anesthetic deposited in the correct plane will block the appropriate intercostal nerve. Larger doses may also block adjacent intercostal nerves by spreading medially to the paravertebral space or directly to the adjacent spaces (Fig. 59.6).

The systemic uptake of local anesthetic from the highly vascular intercostal space is rapid and the dose of local anesthetic administered by this route needs to be appropriately limited. Intercostal nerve blocks significantly reduce postoperative pain and analgesic requirements post-thoracotomy [187].

Interpleural Blocks

In healthy human adults, the two layers of the pleura have a surface area of about 0.2 m^2, are separated by a distance of 10–20 μm, and contain approximately 10 mL of pleural fluid [186]. The deposition of local anesthetic between the parietal and visceral pleura, with the aim of producing an ipsilateral somatic block of multiple thoracic dermatomes, constitutes an interpleural block and was originally described by Kvalheim and Reiestad [188]. Unfortunately, the terminology used in the literature to describe this block can be confusing; some authors use the term intrapleural block [189] and others pleural block [190]. The issue is further confused

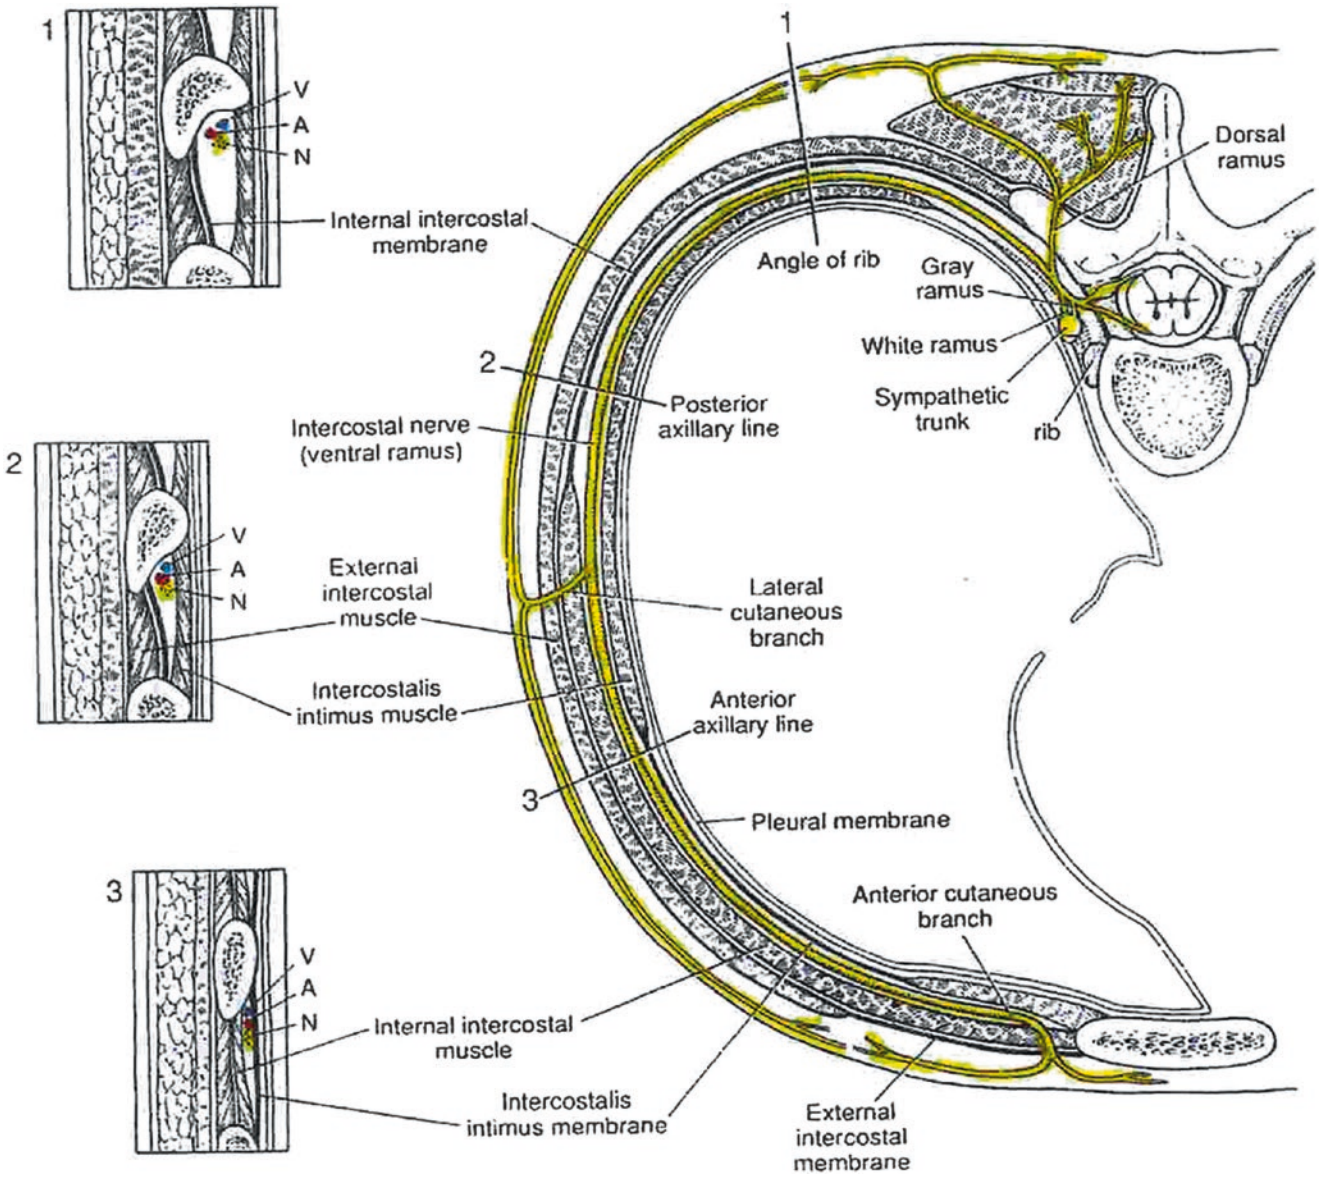

Fig. 59.5 Anatomy of intercostal nerve and space. (Reproduced with permission from Dravid and Paul [186])

when the term interpleural block is used to describe a paravertebral block [191]. Although studies have consistently shown interpleural blocks to be effective for pain relief after cholecystectomy, most studies of patients undergoing a thoracotomy have shown interpleural blocks to be ineffective [192]. The widespread of local anesthetic within the normally small (10 mL) pleural space is aided by surface tension forces, and this probably accounts for the effectiveness of interpleural blocks after cholecystectomy. After thoracotomy, the volume of the pleural space is much larger and contains blood and air. The effect of surface tension forces is reduced and the spread of local anesthetics is limited and principally via gravity. Dilution of the administered local anesthetic by interpleural blood [193] and the loss of local anesthetic into the chest drains [194] further reduce the efficacy of this technique. A possible role for interpleural bupivacaine, administered post-thoracotomy via the basal chest drain to reduce local diaphragmatic irritation from the basal chest drain, was explored in a double-blind study. Interpleural local anesthetic administered by this route was found to be ineffective [195]. Large doses of local anesthetic are frequently required in order for the block to be effective, and therefore, given the vascular nature of the pleural space, systemic absorption can be considerable and high plasma levels of local anesthetics have been reported. The block is also of limited duration and may impair function of the ipsilateral diaphragm [70]. Interpleural blocks are not recommended for post-thoracotomy analgesia in adults [58].

Serratus Anterior Plane Blocks

Introduction

Several novel regional analgesic strategies for surgery involving the chest wall have been described in the past several years. These chest wall blocks all involve the ultrasound-guided deposition of local anesthetic in a plane between the thoracic musculature. Like the transversus abdominis plane (TAP) block of the abdomen, these are truncal field blocks that rely on volume-based spread of local anesthetic within intermuscular planes to target multiple nerves. Currently, one of the most relevant of these chest wall blocks to thoracic surgery is the serratus anterior plane block (SAPB).

The SAPB was first described in 2013 by Blanco and colleagues [196] who also described the Pecs I and II blocks, which have found use in anterior chest wall procedures including breast surgery. Blanco based the SAPB on an examination of the thoracic anatomy that revealed two potential spaces, one superficial and one deep to the serratus anterior muscle. Injection of local anesthetic into either of these spaces was postulated to provide analgesia of the lateral hemithorax by blocking the intercostal nerves along with the thoracodorsal and long thoracic nerves. In their 2013 paper, Blanco and colleagues noted that the SAPB provided paresthesia of the hemithorax from approximately T2 to T9 in four healthy volunteers. While the dermatomal distribution was consistent regardless of position of the block above or below the serratus muscle, the duration of the block tended to be approximately twice as long when the local anesthetic was injected above the serratus muscle. Magnetic resonance imaging of gadolinium injected along with the local anesthetic indicated that injection superficial to serratus tended to spread more posteriorly, while injection deep to serratus spread both anteriorly and posteriorly along the chest wall in supine subjects.

SAPB in Clinical Practice

Following Blanco's description of the SAPB in 2013, several papers have been published describing the clinical use of this block. Many of these have focused on breast surgery, but applications related to thoracic surgery are growing. Kunhabdulla and colleagues described a case in which a SAPB with catheter was used to provide successful analgesia in a patient with fractures of ribs 4–7 following a motor vehicle accident [197]. Shortly thereafter, Madabushi and colleagues [198] reported the successful use of a SAPB with catheter for analgesia following thoracotomy for esophagectomy in a patient in whom the preoperatively placed thoracic epidural could not be used due to hypotension related to early sepsis. In this case, the SAPB catheter provided adequate analgesia for a total of 6 days without complications. Okmen and colleagues published a case report on the use of a SABP with catheter placed preoperatively to provide analgesia after a wedge resection performed via thoracotomy for lung malignancy [199]. Subsequently, this group published a retrospective study comparing the use of intravenous patient-controlled analgesia (PCA) with morphine to the use of PCA morphine plus SAPB for the management of post-thoracotomy pain [200]. In this study of 40 patients, the authors found that patients who received the SAPB in addition to PCA morphine have significantly lower visual analogue scale pain scores at 6, 12, and 24 h after surgery compared to the group that received only PCA morphine. Importantly, morphine consumption was significantly lower in the group that also received the SAPB, although the actual difference in morphine consumption between groups was relatively small.

Research on the use of the SAPB in thoracic surgery is ongoing, and it remains unclear whether this block alone is sufficient to provide analgesia after thoracic surgery. The

most success has been achieved with the placement of a catheter at the time of the block to provide a continuous infusion of local anesthetic. The existing evidence indicates that the SAPB is a useful adjunct and may reduce overall opioid consumption as part of a multimodal approach to pain management after chest wall procedures. It may be particularly useful for anterior thoracic incisions and may be useful as a bilateral block for sternotomy pain.

Technique

The technique for performing the SAPB was described by Blanco and colleagues [196]. This block is performed under ultrasound guidance using a linear transducer. Positioning of the patient is flexible, depending on provider preference. The SAPB was originally described with the subjects positioned supine but has also been reported in the sitting position. Our preference for thoracic surgical procedures is to perform this block after the induction of anesthesia and once the patient is positioned in the lateral decubitus position as this positioning offers the best access to the lateral thorax. The block should be performed at the level of the fifth rib in the midaxillary line. At this level, the serratus anterior muscle should be identified overlying the ribs, with the latissimus dorsi muscle lying superior to the serratus muscle. Intercostal muscles can be identified between the ribs, and below them lies the pleura. Figure 59.7a demonstrates the relevant ultrasound anatomy. Needle insertion can be performed in-plane or out-of-plane, depending on provider preference. As described above, the SAPB can be achieved by injecting local anesthetic either above or below the serratus muscle, with equivalent analgesic spread with both techniques. Our preference is to perform the block below the serratus muscle as the plane between the latissimus and serratus muscles can be difficult to develop in some patients. Furthermore, the sub-serratus approach allows for a definitive target – touching the surface of the rib with the needle virtually guarantees that the local anesthetic will spread below the serratus muscle. Blanco originally described the use of 0.4 mL/kg of 0.125% levobupivacaine. We typically perform this block with 20 mL of either 0.25% bupivacaine or 0.2% ropivacaine with 1:400,000 epinephrine. Figure 59.7b demonstrates spread of local anesthetic beneath the serratus muscle both cranial and caudal to the injection site over the fifth rib. A catheter may be left in this plane after the initial injection to provide a continuous infusion of local anesthetic. Of note, due to the proximity of the block site to the pleura and the intercostal neurovascular bundle, care must be taken to avoid insertion of the needle below the rib surface as pneumothorax and intrathoracic bleeding are possible complications. Figure 59.8 shows the in-plane approach to SAPB.

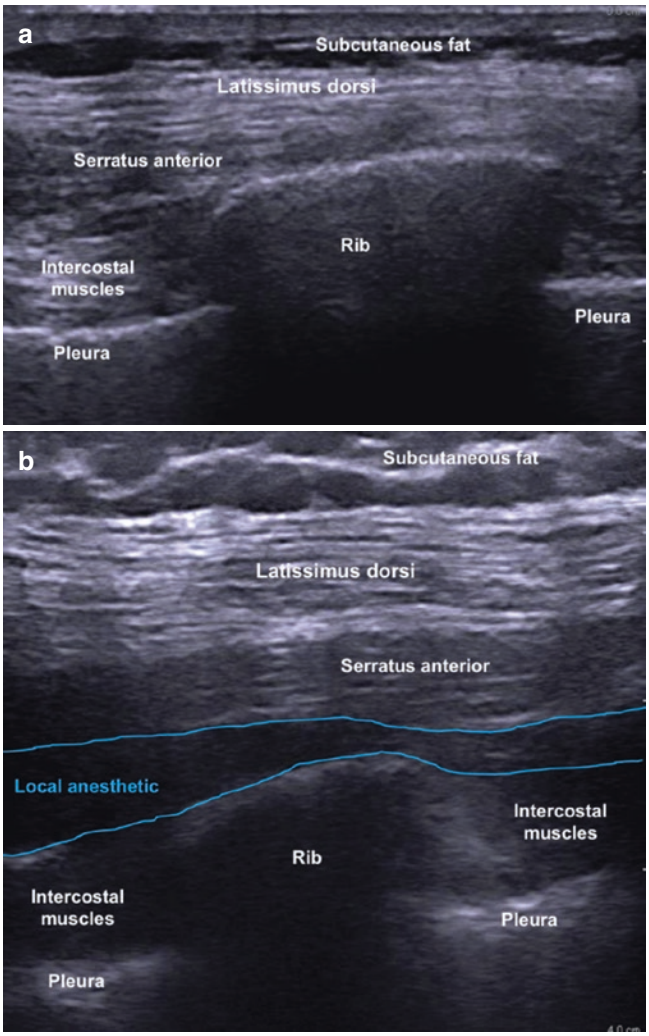

Fig. 59.7 (**a**) Anatomy seen with a linear transducer positioned over the fifth rib in the midaxillary line. Ribs are identified as rectangular structures with curved hyperechoic edges and posterior acoustic shadow. Approximately 0.5 cm deep to the rib edge lies the hyperechoic pleura, which should be seen to "slide" with respiration. The serratus anterior muscle can be identified as a thin strip of muscle overlying the ribs. Above the serratus muscle lies the latissimus dorsi muscle, and overlying the latissimus dorsi is subcutaneous fat and tissue. (**b**) Following injection of local anesthetic deep to the serratus muscle, the local anesthetic can be seen to spread both cranial and caudal to the rib in the plane developed between the ribs/intercostal muscles and the serratus muscle (outlined in blue). This block was performed using the out-of-plane technique, which is why the needle cannot be readily seen in this image

Paravertebral Blocks

Paravertebral blocks were introduced into clinical practice in 1906 [201] and were then largely abandoned before being reintroduced in 1979 [202]. There has now been substantial experience in the use of thoracic paravertebral block for thoracic surgery, and their safety has been established.

Fig. 59.8 The in-plane approach to the serratus anterior plane block. With the patient in the lateral position and the ipsilateral arm extended anteriorly, the ultrasound transducer probe is placed over the fifth rib in the midaxillary line. The needle is guided onto the rib deep to the serratus anterior muscle

Paravertebral blocks may be performed as so-called "single-shot" blocks, with introduction of a single dose of long-acting local anesthetic, or may take the form of a continuous block, via placement of a catheter allowing local anesthetic infusion. Continuous thoracic paravertebral blocks can provide excellent post-thoracotomy analgesia, and a number of studies have shown that the analgesia is comparable to that provided by thoracic epidurals but with fewer complications such as urinary retention, hypotension, nausea, vomiting, and pruritis [203–206] and less perioperative hemodynamic instability [174].

Anatomy

The paravertebral space is a potential space. At the thoracic level, the paravertebral space is a wedge-shaped area bounded posteriorly by the costotransverse ligaments, transverse processes, and necks of the ribs (Fig. 59.9). Medially it is bound by the vertebral bodies, discs, and intervertebral foramina, through which there is communication with the epidural space. The anterior border of the space is formed by the parietal pleura. Lateral to the tips of the transverse processes, the paravertebral space is continuous with the intercostal neurovascular space (Fig. 59.10).

The paravertebral space is contiguous with the paravertebral spaces above and below. The caudal boundary is formed by the psoas major muscle [208]; the cranial boundary is, however, not well defined [207]. The thoracic paravertebral space is divided into an anterior subpleural paravertebral compartment and a posterior subendothoracic paravertebral compartment by the endothoracic fascia which is the deep fascia of the thorax [207] (Figs. 59.10 and 59.11). Contained within the paravertebral space are the dorsal and ventral rami of the spinal nerves, the gray and white rami communicans, and the sympathetic chain. The intercostal nerves (ventral ramus) are devoid of a fascial sheath within the paravertebral space making them highly susceptible to local anesthetic block at this site [209] and therefore where performed at this level result in ipsilateral blockade of sympathetic nerves and thoracic dermatomes [210].

Methods of Performing Paravertebral Blocks

There are several approaches described to access the paravertebral space, and they can be broadly divided into those performed preoperatively using landmark or ultrasound-guided techniques and those performed intraoperatively under direct vision. When blocks are performed in the awake patient, the patient may be positioned either sitting or in the lateral decubitus position. When performed after induction of anesthesia, the anesthetized patient is generally positioned in the lateral decubitus position, with the side to be blocked uppermost. Generally, blocks should be performed at the level of the intended incision(s). Hutchins et al. [219] describe, for thoracoscopic surgery, performing blocks and inserting catheters at T5/6 for upper/middle lobe surgery and T6/7 for lower lobe surgery because of the more caudal position of the ports.

Landmark Methods

Perhaps the most widely used landmark technique is the one described by Eason and Wyatt [202], involving loss of resistance upon "walking off" a transverse process (Fig. 59.7). A Tuohy needle is inserted 3 cm lateral to the cranial edge of a spinous process at the appropriate level. The needle is then advanced perpendicular to the skin until contact is made with the underlying transverse process. If contact with bone is not made at the expected depth, the needle is withdrawn and then readvanced slowly, while fanning it in the sagittal plane, until contact with bone is made. The needle is then walked off the cranial edge of the transverse process and advanced slowly until a loss of resistance, less complete than that in the epidural space, is encountered, usually after a further 1 cm. This is frequently preceded by a subtle click as the costo-

transverse ligament is penetrated. In adults, after aspiration to confirm the needle is extravascular, approximately 20 mL of an appropriate local anesthetic (e.g., 0.25% levobupivacaine) is administered. Where placement of a catheter for continuous infusion is planned, the initial injection of a bolus of local anesthetic serves to open up the paravertebral space before threading an epidural catheter. Consideration may be given to adding a small quantity of dye to the local anesthetic administered, so correct placement of the block can be confirmed visually at subsequent thoracoscopy or thoracotomy.

An alternative technique whereby the paravertebral space is approached from an intercostal space has been described [211]. A Tuohy needle is positioned posteriorly over a rib at the appropriate level about 8 cm lateral to the head of that rib and advanced until contact is made with the rib. The needle is then orientated so the bevel is pointing medially and the tip is angulated 45° cephalad and 60° medial to the sagittal plane. The needle tip is then walked off the inferior border of the rib while maintaining this orientation and advanced a few millimeters until loss of resistance confirms that the intercostal neurovascular space has been entered. After aspirating to confirm the needle is extravascular, approximately 5 mL of 0.25% levobupivacaine is injected to open up the intercostal neurovascular space. An epidural catheter is then inserted into the Tuohy needle and advanced into the intercostal neurovascular space. The orientation of the needle directs the catheter along the intercostal neurovascular space toward the paravertebral space. The catheter is inserted about 8 cm into the intercostal space so the tip lies in the paravertebral space [211].

Ultrasound-Guided Methods

Percutaneous thoracic paravertebral blocks are technically simple to perform but have a failure rate of up to 10%. The use of ultrasound guidance may result in reduced failure rates. Ultrasound-guided thoracic paravertebral blockade can be divided into in-plane techniques where the long axis of the needle is visualized in its entirety as it traverses the plane of ultrasound toward the target and out-of-plane techniques where the needle enters the skin away from the probe and across the scanning plane, allowing it to be visualized in its short axis only. The approach may either be in the transversal or sagittal plane. Blocks described are most frequently performed using a linear ultrasound transducer and the accompanying images reflect this. Some groups advocate using micro-convex array transducers to allow better imaging of deeper structures [212]. Correct identification of landmarks is essential for all techniques, although their appearance will differ according to the orientation of the transducer. Krediet et al. [213] published a detailed description of the ultrasonographic anatomy of the paravertebral space and its neighboring tissues. Their descriptions have been used to illustrate the approaches that follow, but as with other regional techniques, there are many other methods advocated by experienced groups [214–217].

The spinous and transverse processes are easily identifiable as rounded, hyperechoic structures with areas of acoustic shadowing stretching anteriorly and are frequently the starting point for any ultrasound-guided approach [218].

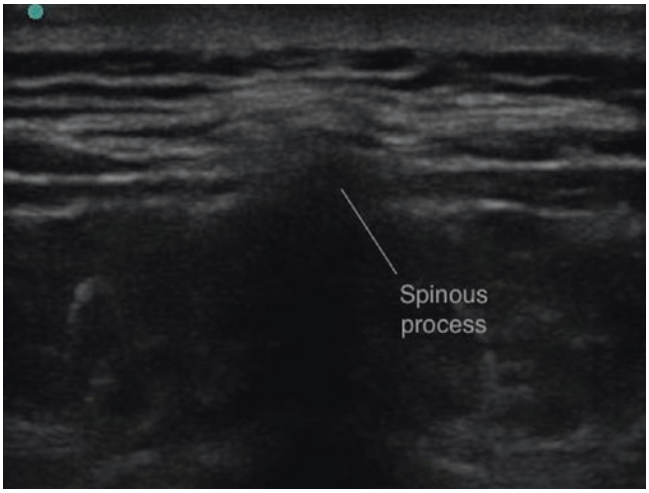

Fig. 59.12 Ultrasound image showing the central spinous process, a starting point for many ultrasound-guided paravertebral blocks

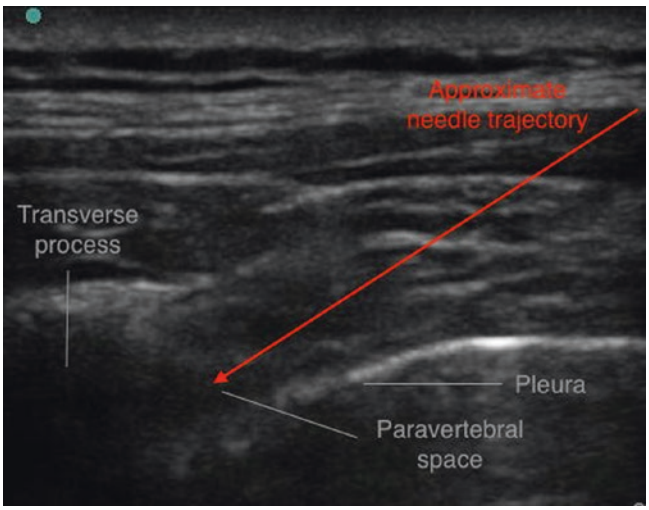

Fig. 59.13 Ultrasound image showing the view of the paravertebral space obtained with the transducer in a transversal orientation and the approximate trajectory of a needle in order to perform a paravertebral block at this level

In-plane thoracic paravertebral blockade [210, 213] commences with identification of the spinous process within the midline (Fig. 59.12), with the probe oriented in a transverse direction. The probe is then slowly moved laterally, until the transverse process can be identified with the parietal pleura visible as a hyperechoic line moving with respiration (Fig. 59.13). The image can be refined by gradual angulation of the probe in cephalad or caudad directions, in order to acquire an uninterrupted view between adjacent ribs. In this position, the paravertebral space can be obscured by the shadow of the transverse process, although its lateral continuation, the intercostal space, can usually be seen [213]. By gradually moving the transducer caudally, the paravertebral space can be visualized more clearly (Fig. 59.13). The parietal pleura lying more laterally on the screen and parallel to the ultrasound beam is a bright, hyperechoic structure visible at levels T2 to T10. As its border is followed medially, the structure fades as it becomes more perpendicular to the ultrasound beam [213]. The paravertebral space is identified through its proximity to the transverse process and lung pleura. Once identified, the needle is inserted from a lateral to medial direction in a trajectory similar to that shown in Fig. 59.9, under ultrasound guidance throughout until the tip lies within the paravertebral space.

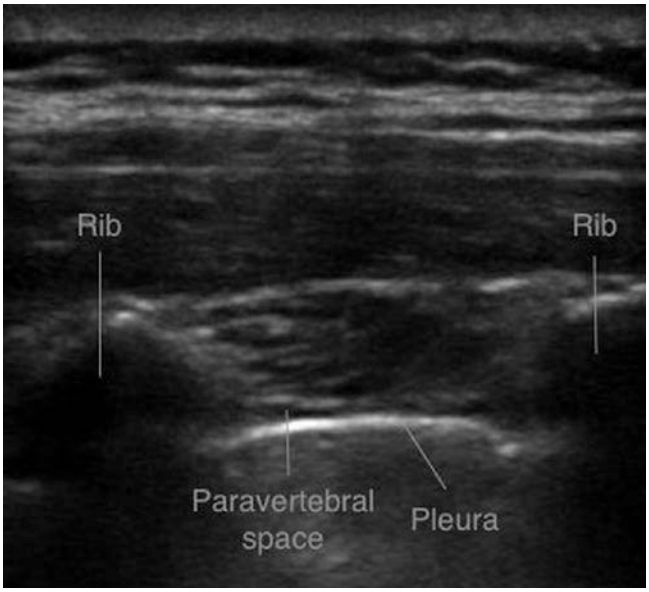

Fig. 59.14 Ultrasound image showing the view of the paravertebral space with the ultrasound transducer in the sagittal plane at the level of the ribs

Another approach involves passage of a needle out-of-plane to perform the block and commences with identification of the paravertebral space with ultrasound as described above. The needle is then inserted from a point 1 cm caudal to the ultrasound transducer and is advanced with a slight craniocaudal angulation so that the tip of the needle can be visualized reaching the desired target and the local anesthetic can be injected under direct vision with the characteristic movement of the pleura.

A further approach to the paravertebral block involves positioning of the ultrasound transducer in the sagittal, rather than transversal, plane [213]. Understandably, the ultrasound anatomy will be markedly different. The paravertebral space can be identified and the block can be performed in several positions as the probe is manipulated. The ultrasound transducer should begin at a position approximately 5 cm from the midline in the sagittal plane and is then slowly moved medially to allow identification of landmarks. The ribs will be visualized initially as areas of acoustic shadow, and the hyperechogenic line of the pleura with movement with respiration should be easily recognizable (Fig. 59.14). Between

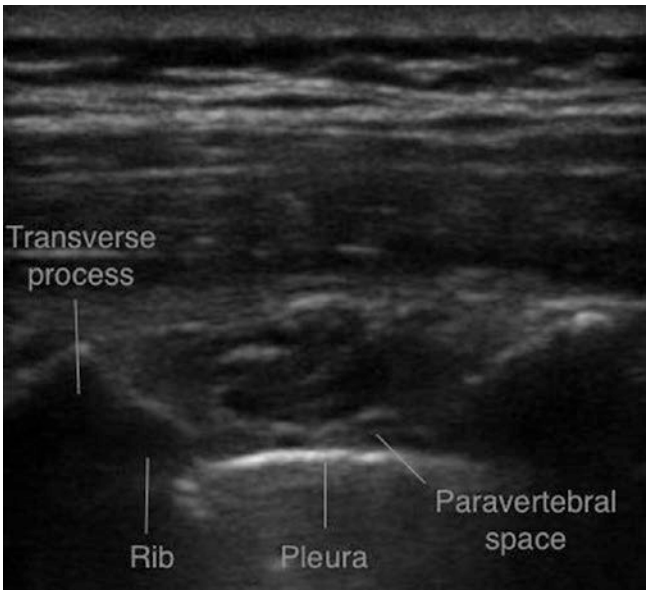

Fig. 59.15 Ultrasound image showing the view of the paravertebral space with the ultrasound transducer in the sagittal plane at the level of the costotransverse junction

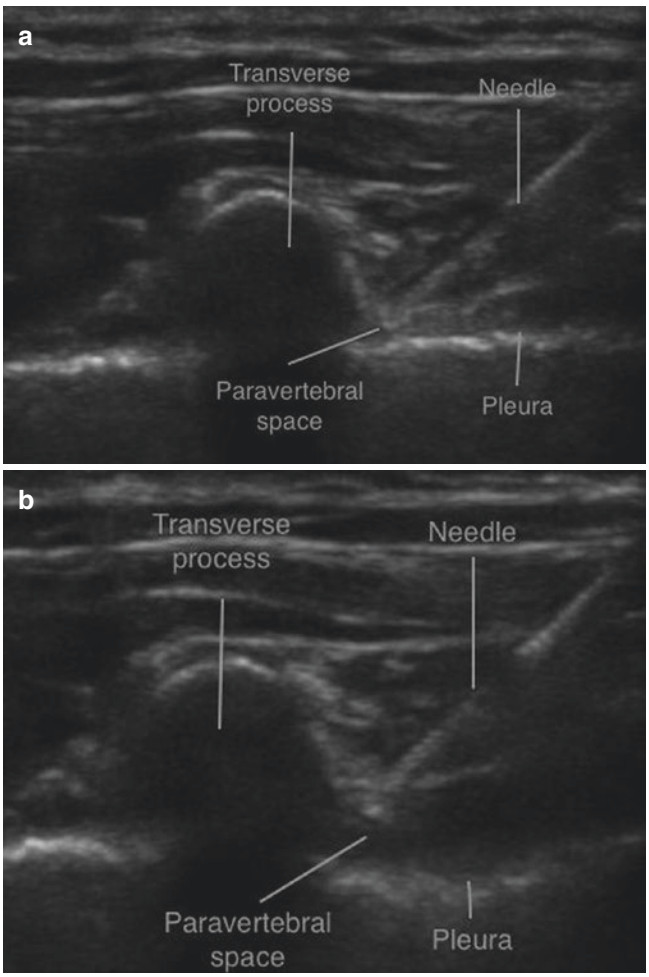

Fig. 59.16 (**a**) Ultrasound image showing transverse view of a needle approaching the paravertebral space and (**b**) movement of the pleura anteriorly with injection of local anesthetic

two ribs, the paravertebral space can be visualized, surrounded by anteriorly, the innermost intercostal muscle and pleura; posteriorly, the external intercostal muscle and intercostal membrane; medially, the membrane of the innermost intercostal muscle; and laterally, the costotransverse joint. At this point, the block can be performed by inserting the needle in-plane on the inferior aspect of the transducer with the tip directed in a cephalad direction to reach the space between the internal intercostal membrane and the pleura. This provides a similar needle tip location to the first block described in this section, but it has been suggested that this approach may require a greater number of attempts before a successful result is achieved.

As the ultrasound transducer is slowly moved medially, the transverse processes gradually appear, and the costotransverse joint is visualized at a point approximately 3–4 cm from the midline. Between the two joints, the multifidus and rotator muscles can be seen, with the superior costotransverse ligament posterior to them, the paravertebral space lying posterior to this, and the pleura lying most anterior (Fig. 59.15). By rotating the probe slightly into a cephalomedial/caudolateral orientation, the space between the transverse process and rib opens. Introduction of the block needle in-plane from the caudal aspect of the transducer allows passage between the rib and transverse process, through the superior costotransverse ligament into the paravertebral space. As with other approaches, anterior movement of the pleura is confirmatory of correct needle position.

A final approach to the block involves continued medial movement of the ultrasound probe. The rib now lies almost directly anterior to the transverse process with a narrow space between adjacent transverse process/rib groups. The pleura here will be more parallel to the ultrasound beam and is therefore much less visible. To perform a paravertebral block at this location, the ultrasound probe will be approximately 2.5 cm lateral to the midline so that the space between two adjacent transverse processes is central. Using an in-plane approach from either the caudal or cranial end of the transducer, the needle can be seen to pass into the space with anterior movement of the pleura on injection ultimately confirming correct placement. Alternatively, the needle can be inserted out-of-plane so that the tip contacts the transverse process. The block from here is blind, as the needle is walked off the transverse process and advanced a further 1–1.5 cm, potentially with a loss of resistance as the costotransverse ligament is pierced. Anterior movement of the pleura on injection can still be seen if the needle is positioned correctly, as demonstrated in Fig. 59.16a, b.

Krediet et al. [213] give an interesting and detailed summary regarding the choice of ultrasound approach and the

direction of needle insertion, in-plane or out-of-plane. The paravertebral space changes in size being 2–2.5 cm in diameter at a position 1–2 cm from the midline to being only 0.5 cm in diameter where it is approached most laterally for an intercostal approach. From a point of view of avoiding accidental pleural puncture, it would seem that the margin of error is significantly larger with the more medial approaches.

The choice of needle for injection is dependent upon the type of intended block. Where passage of an epidural catheter to allow continuous infusion is required, a Touhy needle must be employed. Where a "single-shot" block is being performed, while a Touhy needle can still be used, utilizing a specialist regional block needle with features that increase echogenicity to optimize needle identification may lead to a more successful block placement. Regardless of the choice of needle, the techniques for accessing the paravertebral space are unchanged. The needle is introduced until the tip is seen to lie within the paravertebral space. A loss of resistance may be palpable, as with a landmark approach, as the space is entered. Injection of local anesthetic should lead to an obvious anterior movement of the parietal pleura. If this is not seen, the needle tip should be repositioned. Where a catheter is to be inserted, there is a recommendation that it be passed no more than 2 cm past the end of the needle where there is a lateral to medial approach, to limit the likelihood of epidural migration of the catheter tip [213, 219].

In thoracoscopic surgery where a catheter is not to be used, multi-injection approaches have been advocated with a perception that this may lead to greater dispersement of local anesthetic and therefore a more effective block than a single-injection approach. Cowie et al. [210] performed a cadaveric study comparing spread of local anesthetic containing contrast dye, between a single-injection approach with 20 mL and a dual-injection technique involving two 10 mL boluses. Spread of contrast evaluated via dissection found no difference between the two approaches regarding paravertebral spread of the injected fluid, although the dual-injection technique led to involvement of a greater number of intercostal segments. The degree to which the eventual success of the block could be attributed to enhanced intercostal involvement is not clear. A study in patients undergoing thoracoscopic surgery [220] compared a single injection at T6 with a multi-injection technique involving five injections from T4 to T8. Postoperative pain scores, morphine consumption, times to first mobilization, and time to hospital discharge were comparable between the groups. While this trial reported no complications relating to the blocks, the risk of a complication is likely to be larger where multiple injections are performed, and therefore multiple injections cannot, at present, be recommended.

The association between the location of local anesthetic injection and clinical effect can be inconsistent. Assessment of local anesthetic spread following a single ultrasound-guided injection within the paravertebral space of healthy volunteers using magnetic resonance imaging [221] showed a median spread to involve a total of five vertebral levels but a sensory distribution that was considerably greater and variable, involving a median of approximately ten dermatomes (Fig. 59.17). Spread outside of the paravertebral space was detected in 40% of cases with 25% showing evidence of spread into the epidural space.

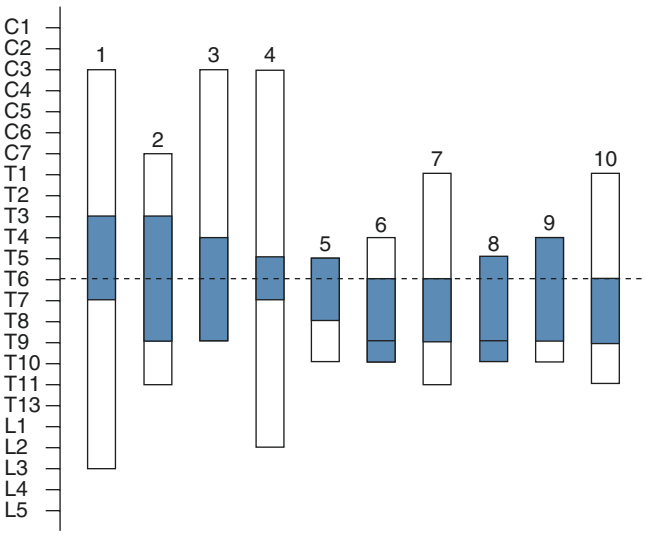

Fig. 59.17 Analysis of the spread of local anesthetic solution (full boxes) and sensory evaluation (open boxes) of left thoracic paravertebral blocks in ten healthy volunteers. (Reproduced with permission, Marhofer et al. [221])

It is probable that ultrasound-guided paravertebral blocks will improve with the refinement of the described approaches and evolution of new techniques. Use of three-dimensional ultrasound may improve success by allowing more accurate identification of the paravertebral space, but as yet this is only in the experimental phase [218].

Open Methods

Placement of a paravertebral catheter via a percutaneous approach has been shown to be challenging and the eventual position of the catheter tip is unpredictable. The position of paravertebral catheters placed with ultrasound guidance in cadavers has been assessed [210]. Only 60% of catheters were positioned as intended. 20% had passed into the prevertebral space anterior to the vertebral bodies, 15% lay posterior to the vertebral bodies within soft tissue, and 5% were within the epidural space. Therefore, although it is possible to place catheters percutaneously into the paravertebral space, it may be more appropriate for the surgeon to insert the catheter into the paravertebral space under direct vision while the chest is open. Direct placement facilitates clear

advancement of the catheter along the paravertebral space to create a narrow longitudinal pocket that may block sufficient dermatomes to provide adequate analgesia.

Direct placement techniques may require some surgical preplanning. The posterior extent of the incision needs to be limited to allow sufficient room for the paravertebral catheter. In particular, it is important to preserve enough pleura posterior to the surgical incision. Direct placement techniques were initially undertaken at the end of surgery immediately prior to closure to reduce the risk of inadvertent catheter dislodgement. However, at least in the author's institution, they are now frequently positioned prior to lung resection to allow time for adequate spread of the local anesthetic within the paravertebral space. The direct placement of catheter into the paravertebral space at the end of surgery was first popularized by Sabanathan et al. [222]. They described a technique whereby a catheter is inserted via a Tuohy needle. The catheter is inserted percutaneously medial to the posterior edge of the thoracotomy incision to emerge between the angle of the ribs into the chest cavity. The parietal pleura two spaces above and below the incision is peeled back medially to expose the intercostal nerves taking care not to perforate the pleura. The catheter is then positioned to lie against the angles of the exposed ribs before the parietal pleura is reattached to the posterior aspect of the wound. The authors later reported an improvement in their technique [223]. After reflecting back the parietal pleura to the vertebral bodies as before, a small incision is made in the endothoracic fascia and the catheter is passed into the subendothoracic paravertebral compartment and advanced cranially for a few centimeters, aided if necessary by blunt dissection. The hole in the endothoracic fascia is then closed by a suture (Fig. 59.18).

Another technique used in the author's institution is for the surgeon to insert a Tuohy needle percutaneously, under direct vision, into the paravertebral space one or two segments caudal to the thoracotomy incision. A catheter is then introduced through the Tuohy needle and advanced 10 cm or more cranially in the paravertebral space. This requires careful manipulation of the Tuohy needle and catheter to ensure it advances in the correct direction and damage to the overlying pleura is avoided. The other end of the catheter is then tunneled subcutaneously to limit the risk of inadvertent dislodgement. For patients undergoing video-assisted surgery, video-assisted surgical placement of a catheter is possible [224] (see Video 59.1).

Insertion of paravertebral catheters under thoracoscopic guidance before thoracotomy in order to allow administration of local anesthetic prior to skin incision and ahead of disturbing the parietal pleura have been described [225] conducted. A randomized, double-blind study comparing thoracic epidural analgesia with surgically placed paravertebral analgesia suggested paravertebral analgesia to be superior in terms of pain scores at rest and when coughing but also measurements of FEV_1 and oxygen saturation in ambient air [226].

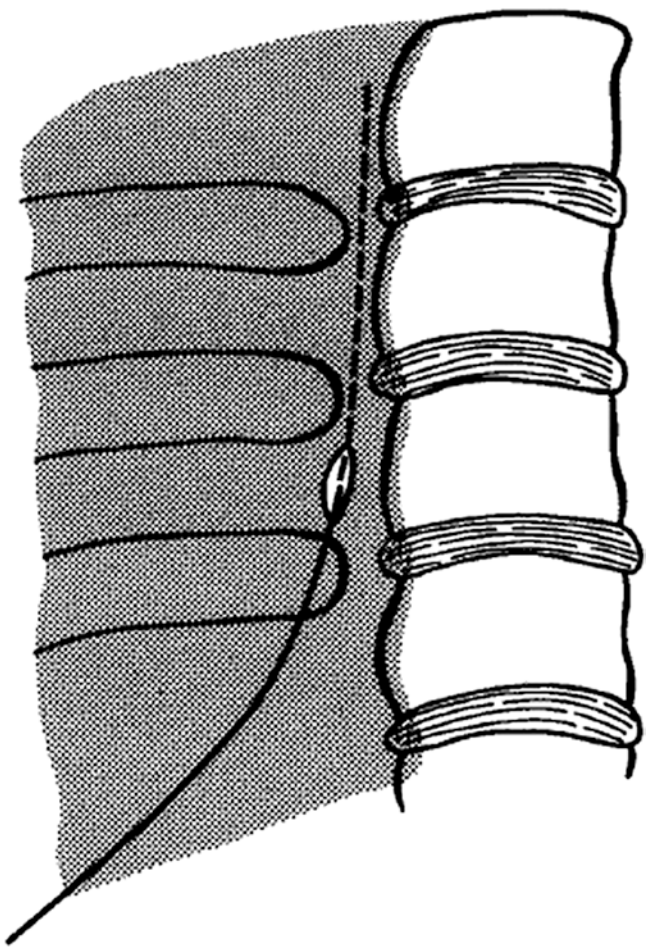

Fig. 59.18 A technique for performing paravertebral blocks. The endothoracic fascia (stippled) is exposed by raising the parietal pleura from the posterior chest wall. A catheter is inserted deep to the endothoracic fascia through a small hole created in the fascia. (Reproduced with permission, Berrisford and Sabanathan [223])

Management of Paravertebrals

Single-shot paravertebral injections using currently available local anesthetic preparations have been shown to last between 6 and 24 h. Comparison of a single-shot approach with IV opioids to IV opioids alone for thoracoscopic surgery found pain scores to be significantly lower in those receiving the paravertebral block [227]. Improved pain scores, decreased opioid requirements, and improved results of lung function tests 4 h postoperatively have been shown with use of a preemptive single-shot paravertebral block over surgically placed single-shot intercostal blocks [228]. Preoperative single-shot paravertebral analgesia for patients undergoing thoracoscopic surgery was associated with a

lower total opioid consumption, less nausea and vomiting, and improved pain scores in recovery and at 24 h both at rest and with movement [229]. Comparison of a single-shot surgically performed intercostal block with continuous paravertebral infusion in patients undergoing thoracoscopic surgery [219] found no significant difference in pain score or opioid consumption in the first 24 h after surgery although in the 24–48 h time period, patients with a paravertebral catheter had significantly lower pain scores, had lower opioid requirements, and overall had a significantly higher level of patient-reported satisfaction with their pain control compared to the group receiving intercostal blocks.

The overall suggestion is that, in patients undergoing thoracoscopic surgery, a paravertebral block is preferable to intravenous analgesia alone. The relatively short duration of action of clinically available local anesthetics makes single bolus paravertebral blocks inappropriate for most post-thoracotomy patients. These patients are best treated by establishing a PVB with a bolus of local anesthetic and then maintaining the block with a catheter placed in the paravertebral space. Ultra-long-acting local anesthetic agents are being developed. Placement of these agents in the paravertebral space may, in the future, make single bolus paravertebral blocks practical, reducing the risks of local anesthetic toxicity and block failure secondary to catheter displacement. Consideration has been given to the use of adjuncts to prolong the duration of action of a paravertebral block. Clonidine, epinephrine, dexamethasone, and dexmedetomidine have been used with anecdotal reports of blocks with a duration of up to 6 days and lower pain scores [150, 230, 231]. As yet there have been no good quality randomized controlled trials to formally assess effectiveness and therefore the use of such adjuncts cannot be routinely recommended.

The appropriate management of paravertebrals (drug choice, rate, adjuvant and administration technique) has not yet been established and further work is required to optimize the efficacy and safety of this technique. A review and meta-regression analysis [117] found that a higher bupivacaine dose (890–990 mg per 24 h) predicted lower pain scores and faster recovery of pulmonary function compared to lower dose (325–472.5 mg) without a significant difference in the rate of local anesthetic toxicity. A recent randomized prospective study [232] suggested no difference in effectiveness between intermittent bolus dosing and continuous local anesthetic infusion.

The use of safer local anesthetic, such as levobupivacaine, vigilance for signs and symptoms of local toxicity (e.g., confusion), the addition of adrenaline to the solution, and reducing the infusion rate for elderly or frail patients may all be appropriate steps to reduce the incidence of toxicity with the use of paravertebrals. A typical dosing regimen for an adult patient might be 0.3 mL kg^{-1} initial bolus of 0.25% levobupivacaine followed by a 0.1 mL kg^{-1} h^{-1} infusion of 0.25% levobupivacaine (Table 59.4).

Duration of catheter placement and use will be guided by the individual patient. Studies range from 3 days to a maximum duration of insertion of 7 days [219, 226].

Advantages of Paravertebral Analgesia

Paravertebral block is a relatively simple technique that is easy to learn, has few contraindications, and has a low incidence of complications. In addition, the open technique enables paravertebral catheters to be safely inserted in anesthetized patients, for example, where a VAT procedure is converted to an open thoracotomy. Impaired coagulation is a relative contraindication to the percutaneous insertion of paravertebral blocks and catheters, but open placement under direct vision is relatively safe and can be recommended. Hypotension, urinary retention, pruritis, nausea, and vomiting are less frequent postoperatively with paravertebral blocks and infusions than with thoracic epidurals [170, 203]. In the author's institution, paravertebral analgesia is associated with earlier mobilization and shorter length of hospital stay than thoracic epidural [177].

Limitations and Complications of Paravertebral Blocks

To provide effective analgesia in the affected somatic dermatomes, post-thoracotomy paravertebral blocks may need to cover up to ten segments. It may take a number of hours for local anesthetic to spread sufficiently along the paravertebral space, and as a result early postoperative analgesia may be poor unless supplemented initially by other analgesic agents or techniques. Absolute contraindications are generally limited to local and systemic infection, allergy to local anesthetics, and the presence of tumor at intended injection site. Relative contraindications include severe coagulopathy, severe respiratory disease where there is dependence upon intercostal muscles for ventilation, ipsilateral diaphragmatic paresis, and severe spinal deformities such as kyphosis or scoliosis or conditions where there may be dilated intercostal vessels, such as with aortic coarctation or thoracic aneurysm [233]. Complications that have been reported include inadvertent pleural puncture, pulmonary hemorrhage, inadvertent dural puncture, hypotension, ipsilateral Horner's syndrome, nerve injury, and central nervous system local anesthetic toxicity. The incidence of these complications is low, but the available published data does not enable an exact incidence to be quoted to patients [207].

The large volume of local anesthetic required and rapid uptake of local anesthesia from the vessel-rich paravertebral space mean that local anesthetic toxicity is a concern. The toxic plasma concentration of bupivacaine is described as

between 2 and 4.5 mg L^{-1} by different groups [234], and mean plasma concentrations have been shown to exceed the threshold for central nervous system toxicity 48 h after commencing a 0.1 mL kg^{-1} h^{-1} infusion of 0.5% bupivacaine [235]. In a separate study of patients receiving paravertebral 0.5% bupivacaine at this rate, 7% of patients developed temporary confusion attributed to bupivacaine accumulation [236], and there have been case reports of patients in whom systemic local anesthetic toxicity related to a paravertebral infusion have occurred [237]. As a result, cumulative administered dose must be considered, and a maximum administration not to exceed 2 mg kg^{-1} in a 4 h period is advocated [237]. Until recently, there has been no specific treatment available for local anesthetic toxicity. There is now a growing body of evidence from animal studies and case reports that lipid emulsion given intravenously improves outcome. It is therefore recommended that lipid emulsion is available wherever patients receive large doses of local anesthetic such as for a paravertebral block. The management of local anesthetic toxicity-induced cardiovascular collapse should involve CPR as per standard protocols followed by the consideration to administer a lipid emulsion [238, 239].

Erector Spinae Plane Blocks

The erector spinae plane (ESP) block is a recently described ultrasound-guided block for both acute and chronic post-thoracotomy pain. It may, in fact, be a variant of the paravertebral block. Cadaveric investigation has shown that injection of 20 mL of solution into the fascial plane deep to the erector spinae muscle at the level of the T5 transverse process can result in a spread of injectate from C7 to T8 vertebral levels [240]. This block has been described for post-thoracotomy analgesia rescue in a case of failed epidural analgesia in a patient receiving prophylactic anticoagulation [241]. The benefit of an ESP block over a paravertebral block may be the more obvious endpoint for an ESP block as the needle tip contacts the transverse process of the vertebra. The spread of local anesthetic, dosing, and the clinical effects seem very similar to a paravertebral block. The place of this block in the armamentarium of the anesthesiologist remains to be determined. It has not been studied in a controlled fashion vs. paravertebral or epidural analgesic techniques.

Technique (See Figs. 59.19 and 59.20)

An ultrasound-visible regional anesthetic needle (e.g., 8 cm, 17 gauge) is inserted using an in-plane approach in a superior to inferior fashion to contact the transverse process of the appropriate thoracic vertebra deep to the anterior fascia of the erector spinae muscle. A total of 20–25 ml of local anesthetic solution (e.g., 0.2% ropivacaine) is administered in 5 ml aliquots under direct vision. A catheter is then passed 5 cm distal to the tip of the needle, and an infusion of 5–8 ml/h is begun.

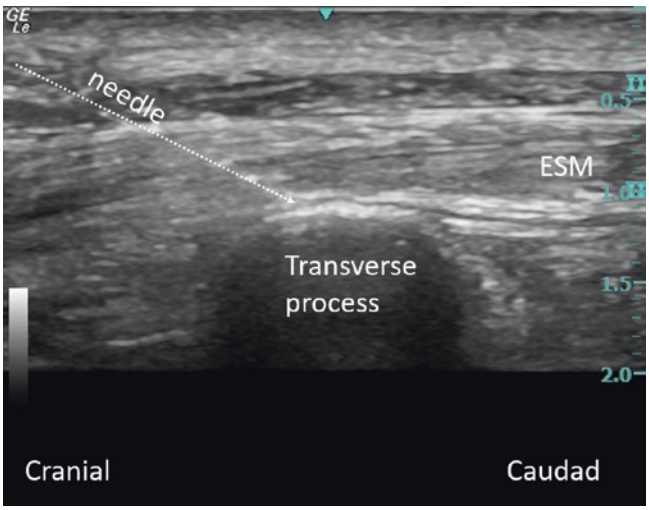

Fig. 59.19 Erector spinae plane block. The ultrasound probe is placed lateral to the spinous process (line S) to obtain a parasagittal view of the tip of the targeted transverse process (TP) with overlying erector spinae muscle (ESM). The block needle (dotted arrow) is advanced in a cranial-caudal direction to contact the TP. (Photo courtesy of KJ Chin Medicine Professional Corporation)

Intrathecal Analgesia

The lumbar administration of subarachnoid opioids is an infrequently used technique that may have a wider role in providing post-thoracotomy analgesia. The use of intrathe-

cal morphine to provide operative analgesia was first described in 1979 [242]. Since then a number of studies have reported the use of intrathecal opioids for post-thoracotomy analgesia [243–245]. The intrathecal route of opioid delivery is 100 times more potent than the equivalent intravenous dose [246]. The onset time and degree of rostral spread of intrathecal opioids depend in part on their lipid solubility [247]. The most hydrophilic opioids, such as morphine, exhibit a greater degree of intrathecal spread and are therefore more likely to cause respiratory depression. This is in comparison to a more lipophilic drug, such a fentanyl or sufentanil, that is less prone to spread and therefore exhibits fewer respiratory side effects [70]. With intrathecal sufentanil, for example, the onset of analgesia is very rapid, whereas morphine has a slower onset but longer duration of action. Combinations of morphine and sufentanil have therefore been used to provide post-thoracotomy analgesia. In one study, morphine 200 μg was combined with sufentanil 20 μg [118]; in another study, morphine 500 μg was combined with sufentanil 50 μg [119]; both studies reported good early analgesia. Side effects of intrathecal opioids include nausea, vomiting, pruritus, urinary retention, and delayed respiratory depression. Respiratory depression of a severity requiring treatment with an antagonist such as naloxone occurs in 0.2–1% of patients receiving neuraxial opioids [248]. The lumbar epidural space is easy to locate making it an attractive technique in patients with, for example, fixed spinal deformities. The combination of low-dose intrathecal morphine and a paravertebral block via a directly placed catheter has been suggested as an alternative to epidural analgesia post-thoracotomy [249].

Epidural Analgesia

Epidural injections via the sacral hiatus in dogs were described in 1901 [250]. The interspinous approach for epidural anesthesia in clinical surgery was demonstrated in 1921 [251] and an article in 1933 by Dogliotti popularized epidural anesthesia [252]. Post-thoracotomy thoracic epidural analgesia was introduced into clinical practice in the mid-1970s for high-risk procedures [161, 162], by the mid-1980s it was being used by some for routine surgery [253], and by the 1990s it had become the mainstay of post-thoracotomy analgesia in many high-volume Western units [104]. The widespread use of thoracic epidural for routine post-thoracotomy analgesia occurred because it provides effective, reliable post-thoracotomy analgesia, had been shown in a meta-analysis to reduce post-thoracotomy pulmonary complications [56], and was believed by many to improve the outcome after thoracic surgery.

Lumbar Epidural Analgesia

Lumbar epidural insertion is an easier and more familiar technique for most anesthesiologists, and also because of the absence of an underlying spinal cord, lumbar epidurals are probably safer than thoracic epidurals. Lumbar epidural hydrophilic opioids are effective and were once used by a number of units to provide post-thoracotomy analgesia. Their widespread use declined when a meta-analysis showed that, unlike epidural local anesthetics, epidural opioids did not reduce the incidence of postoperative pulmonary complications [56]. Late respiratory depression is also a potential problem with epidural hydrophilic opioids. As a result of synergistic antinociceptive interactions, mixtures of local anesthetics and opioids are now usually used to provide post-thoracotomy analgesia [180]. Epidural mixtures of segmentally acting lipophilic opioids and local anesthetics are best administered at the dermatomal level of the surgical incision. For thoracic procedures, this equates to a thoracic epidural. If the mixture is administered by a lumbar epidural away from the incision, larger volumes are required, greater hemodynamic instability results, and achieving good analgesia is more difficult. Lumbar epidurals are not now generally used for providing post-thoracotomy analgesia; however, in the occasional patient in whom attempts at placing a thoracic epidural are unsuccessful, a lumbar epidural may be appropriate. It is also a technique worth considering in the rare circumstance in which it is considered appropriate to insert an epidural in an anesthetized patient.

Thoracic Epidural Analgesia

Technique of Insertion

After inserting a venous cannula and positioning the patient in either the lateral or sitting position, depending largely on operator preference, a wide area of the back is prepped with alcoholic chlorhexidine or an alternative antiseptic solution. At least two applications are recommended. The initial application should be with a sponge or similar material to abrade the superficial layers of the skin. Care should be taken to ensure that epidural drugs and equipment are not contaminated by the antiseptic used as all antiseptics are potentially neurotoxic. Similarly, the antiseptic solution used should be allowed to dry before commencing epidural insertion. The vertebral spinous processes are at their most oblique in the mid-thoracic region. At this level, the tip of the spinous process is a landmark for the intervertebral space below the next vertebrae.

For the midline approach, a local anesthetic wheal is raised over the appropriate vertebral interspace. A Tuohy needle is then inserted immediately above the palpable tip of

the lower spinous process and advanced at the oblique cephalad angle determined by the obliquity of the spinous processes at this particular level. The angle of insertion may need adjustment if contact is made with a spinous process. For the paramedian approach, a local anesthetic wheal is raised about 1 cm lateral to the palpable tip of the appropriate spinous process. A Tuohy needle is then inserted through this wheal perpendicular to all the planes. When contact is made with bone (lamina), the needle is withdrawn to the skin and angulated about 45° cephalad and 10° medial before being reinserted to the original depth. The needle is then gradually advanced into the epidural space. If contact is again made with the lamina, it may be necessary to walk the needle up the lamina to find the epidural space. After the tip of the Touhy needle has been in contact with bone, it is advisable to ensure that the needle remains patent by gently reinserting the trocar before readvancing the needle.

Identifying the epidural space at the thoracic level can be more difficult than at the lumbar level since the ligamentum flavum may be thinner and less resistant to an epidural needle at higher levels. Several alternatives to the traditional loss-of-resistance technique have been described such as the hanging-drop technique [254]. A technique to identify the thoracic epidural space using pressure waveform analysis has been recently described. After initial identification of the epidural space with a loss-of-resistance technique, 5 ml of saline is injected through the Tuohy needle and a flushed sterile tubing attached at one end to a pressure transducer at the level of the patient's heart then attached to the proximal hub of the needle (see Fig. 59.21) [255]. A false loss of resistance can be distinguished from the actual epidural space with a high predictive value by the absence of an arterial waveform.

It is known that during insertion epidural catheters do not follow a predictable course in the epidural space [256]. The optimal length of epidural catheter to leave in the epidural space is thus a balance between insufficient length resulting in catheter migration out of the space and excessive length resulting in technical failure because of malpositioning of the catheter tip. In a prospective analysis of postoperative epidural failure by computed tomography epidurography during which 4 cm of epidural catheter was left in the epidural space, 25% of the epidurals failed. The major cause of epidural failure was dislodgement of the epidural catheter out of the epidural space [257]. Four centimeter of catheter is probably insufficient for thoracic epidurals that are to remain in situ for a few days; 5–6 cm may be more appropriate [258]. Migration of the catheter out of the epidural space can be reduced by appropriate fixation with adhesive dressings (see Fig. 59.22), tunneling, or suturing. The author recommends suturing of the catheter to the skin.

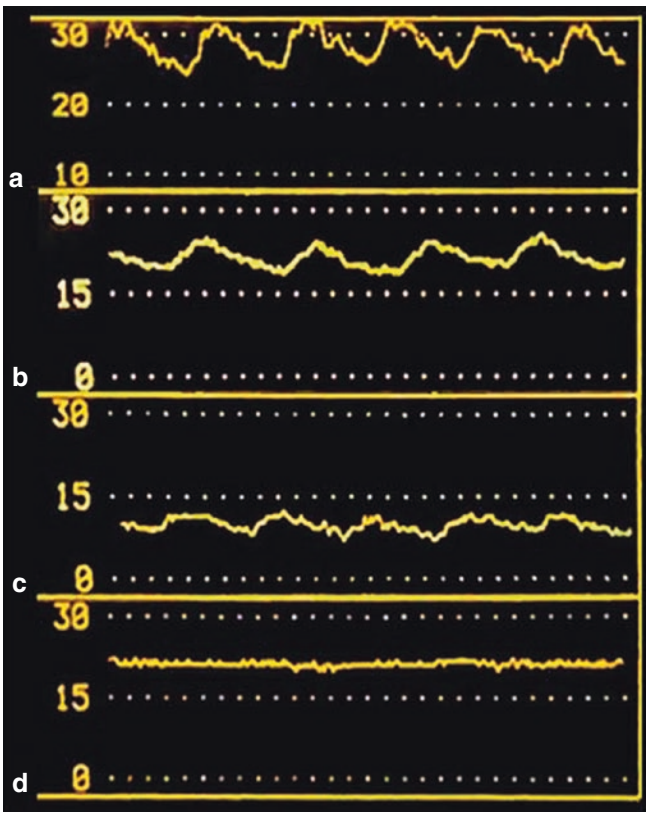

Fig. 59.21 Epidural space pressure tracings in mmHg from four different patients. The presence of an arterial-form tracing (**a**–**c**) was highly correlated with subsequent successful epidural analgesia. An absent arterial-form tracing (**d**) had a high sensitivity for subsequent failure of epidural analgesia. (Reproduced with permission from Leurcharusmee et al. [255])

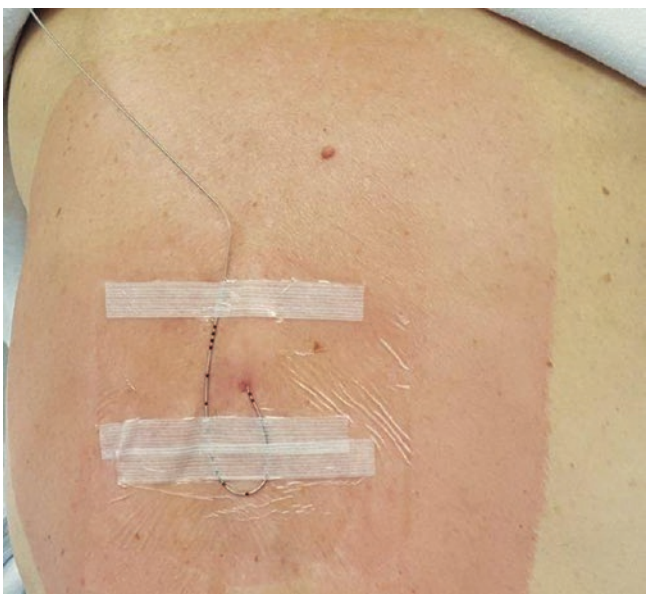

Fig. 59.22 A technique of fixation of a thoracic epidural catheter to minimize catheter migration is demonstrated. The catheter is initially secured by sterile adhesive strips and is then covered by a sterile occlusive see-through skin dressing. The entire dressing is then covered by a large opaque adhesive elastic bandage which has a small observation window placed over the site of the skin puncture

Epidural Solutions

High concentrations of unsupplemented thoracic epidural local anesthetics can provide effective post-thoracotomy analgesia, but the incidence of hypotension is high [259], while lower concentrations are less effective. Because the synergistic antinociceptive interactions of epidural local anesthetics and opioids [260] enable the amount of each drug to be minimized reducing the incidence and severity of the associated side effects, mixtures of local anesthetics and opioids are now routinely used to provide post-thoracotomy analgesia [171, 180]. Although there is probably no epidural mixture that is optimal for all patients, a mixture of 4 μg mL^{-1} of fentanyl in 0.125% bupivacaine is close to the optimal [261–263]. The newer local anesthetic agents (levobupivacaine and ropivacaine) are less toxic than bupivacaine and give comparable results [264], and although relatively small amounts are administered epidurally, we now use 4 μg mL^{-1} of fentanyl in 0.125% levobupivacaine.

The analgesic effects of epidural opioid and local anesthetic mixtures are improved by epinephrine. Vasoconstriction of epidural vessels with reduced systemic uptake of epidural opioids is thought to be the major cause of this potentiation. The α_2 adrenergic action of epinephrine in the substantia gelatinosa may also contribute to the improved analgesia [265]. Potential cord ischemia as a result of excessive vasoconstrictive has limited the use of epidural epinephrine. Clonidine, another α_2 adrenergic agonist, is moderately lipid soluble and rapidly crosses the blood-brain barrier. The sedation associated with its systemic use has limited its systemic usage for analgesic purposes. The half-life of clonidine within the epidural space is about 30 min and when combined with epidural opioids clonidine improves analgesia and reduces opioid requirements and side effects [266, 267]. However, in a study using an optimization model to find the best epidural combination of fentanyl, bupivacaine, and clonidine to administer after laparotomy, the addition of clonidine did not significantly improve analgesia [261]. Epidural clonidine is not widely used to provide post-thoracotomy analgesia [180], although the addition of clonidine should be considered for patients who are particularly sensitive to the systemic effects of epidural opioids.

Magnesium which may act as a NMDA receptor antagonist is another adjuvant agent that has been given epidurally. In one study, epidural blocks were supplemented with 50 mg magnesium sulfate. Compared to controls patients receiving magnesium had a decreased requirement for rescue analgesia [268]. Another study has also shown a reduction in local anesthetic and opioid requirement where magnesium was administered IV concomitantly with epidural at a rate of 10 mg kg^{-1} h^{-1} for the first 24 h [269]. Epidural administration of magnesium is not currently recommended.

The extent of the sensory block after the administration of epidural anesthetics varies considerably between individuals. A number of factors are known to affect the spread of the sensory block during thoracic epidural analgesia including the level at which the epidural is sited. For high thoracic epidurals, the direction of spread is mainly caudal; for low thoracic epidurals, the spread is mainly cranial; and for mid-thoracic epidurals, the spread is almost equally distributed [33, 270]. The total extent of the spread, however, is not significantly different at these three sites [33, 270]. While administering an epidural solution via a high thoracic epidural, it may be appropriate to avoid neck flexion to further limit the potentially harmful cranial spread of the epidural solution [271]. Although widely believed and apparently logical, there is little evidence that the extent of thoracic epidural spread is related to the height of the patient [33]. Similarly, for adult patients weight does not appear to correlate with the extent of thoracic epidural spread [33]. There is, however, a positive correlation between the patient's age and the thoracic epidural spread, with elderly patients requiring about 40% less epidural solution [33, 34]. For younger patients, we usually administer a ~7 mL epidural bolus of a mixture containing 4 μg mL^{-1} of fentanyl in 0.125% levobupivacaine via a mid-thoracic catheter and then infuse the epidural solution at ~7 mL h^{-1}. For elderly patients, we reduce both the bolus and infusion rate by about 40% (Table 59.4 and Fig. 59.23).

Impact of Thoracic Epidural Analgesia

Thoracic epidurals provide excellent early post-thoracotomy analgesia and are widely regarded as the "gold standard" for post-thoracotomy pain relief. Given the low doses of local anesthetic and opioid administered via a thoracic epidural, the option remains to administer additional analgesia if required in the form of other local anesthetic infusions, e.g., into wound catheters [8].

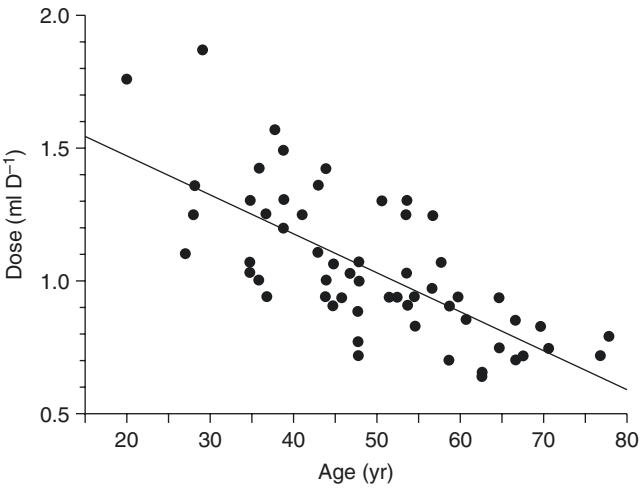

Fig. 59.23 Relationship between age and epidural dose requirements of 2% mepivacaine in thoracic epidural analgesia. D Dermatome. (Reproduced with permission, Hirabayashi and Shimizu [34])

Improvement of Postoperative Diaphragmatic Dysfunction

Prolonged diaphragmatic dysfunction has been shown to occur after thoracic [272] and upper abdominal [273] surgery. Diaphragmatic contractility is not impaired [274, 275], and the diaphragmatic dysfunction is thought to be secondary to reflex inhibition of the phrenic nerve as a result of stimulation of afferents in the viscera, diaphragm, and chest wall [274]. Pain is not considered to be a major mediator of this dysfunction [276]. Thoracic epidural local anesthetics have been shown to improve diaphragmatic function after upper abdominal surgery [277]. Epidural opioids are not effective [273]. Thoracic epidural local anesthetics have not been shown to improve the impaired diaphragmatic segmental shortening after thoracotomy, but other ventilatory parameters did improve. However, as epidural local anesthetics can alter other respiratory muscle functions, the improvement in diaphragmatic function may have been masked [272]. Thoracic epidural analgesia may directly affect FRC post-thoracotomy as an increase in FRC occurs in healthy humans receiving thoracic epidural analgesia [278].

Incidence of Cardiovascular Complications

Cardiovascular complications contribute significantly to post-thoracotomy morbidity and mortality. Thoracic epidural local anesthetics can block the sympathetic nerve fibers to the heart and have been used to treat refractory angina [279, 280]. Thoracic epidural analgesia can also dilate constricted coronary arteries and improve the hemodynamic stability of patients undergoing thoracic surgery. When compared to lumbar epidural analgesia, there is a lower incidence of hypotension and bradycardia where thoracic epidurals are used [281]. These changes have the potential to reduce myocardial ischemia. A meta-analysis of patients undergoing various surgeries has confirmed this potential and shows that epidural analgesia reduces postoperative myocardial infarctions by 40%; thoracic epidural analgesia is superior to lumbar epidural analgesia in this respect [282]. There is some evidence that thoracic epidural local anesthetics reduce the incidence of supraventricular arrhythmias [283], which occur in 20–30% of post-thoracotomy patients [284, 285] and are associated with an increased mortality [286, 287]. More recently however, a post hoc analysis of data collected during the POISE trial [288] has advised caution regarding the use of neuraxial analgesia in patients deemed particularly high risk of cardiovascular morbidity as use of thoracic epidural with general anesthesia was associated with a threefold increase in the risk of the trial primary composite outcome (cardiovascular death, nonfatal myocardial infarction, or nonfatal cardiac arrest) versus general anesthesia alone. While this was a post hoc analysis, clinicians should bear this is mind when considering and consenting for thoracic epidural analgesia in patients with significant cardiovascular disease.

Thoracic Epidurals and Outcome

The mortality from lung cancer surgery has decreased over the last few decades, and this reduction in post-thoracotomy mortality has been attributed, in part, to improvements in postoperative analgesia. There are a number of possible mechanisms whereby thoracic epidural analgesia may reduce respiratory complications post-thoracotomy. These include better preservation of FRC, improved mucociliary clearance, reduction of inhibitory effects on the diaphragm, less pain, nausea and sedation and better collaboration with physiotherapy. Although transferable evidence and early analysis found that when compared with systemic analgesia, thoracic epidural analgesia reduced postoperative pulmonary complications [56], later quantitative analyses have not shown this reduction [58]. Similarly, although thoracic epidurals may decrease perioperative myocardial infarctions [282] and reduce the incidence of thromboembolic events [289, 290], there are no prospective studies showing thoracic epidurals improve survival after thoracotomy. A meta-analysis of randomized controlled studies did show reduced mortality with neuraxial blocks after surgery, but much of this effect was after orthopedic surgery [291]. Following an initial prospective randomized study [292] that suggested no mortality benefit associated with epidural analgesia for major abdominal surgery, a more recent meta-analysis identified a 40% reduction in mortality after major abdominal surgery where epidural analgesia was employed [293]. A large prospective study is still required to determine if post-thoracotomy outcome is improved with thoracic epidural analgesia.

Limitations and Adverse Effects

The reported rates of epidural failure vary. Although successful catheter placement rates of 99% and subsequent technical failure rates of <1% have been reported [294], some audits have reported a 30–50% failure rate [295] and a recent meta-analysis reported a 15% thoracic epidural failure rate [203]. Thoracic epidurals are considered technically more difficult to insert than lumbar epidurals; however, the dural perforation rate has been found to be lower during thoracic epidural insertion (0.9%) than during lumbar epidural insertion (3.4%) [294].

The use of enhanced recovery protocols within thoracic surgery is increasing in popularity as they have been shown to be associated with reduced complication rates and duration of hospital stay. Use of epidural analgesia and their associated adverse effects can impact upon recovery, despite high-quality pain control, and therefore their use is less

attractive given the other options available [17]. Respiratory depression is a concern with epidural opioids particularly hydrophilic opioids. The incidence is related to the type and dose of the epidural opioids used. A Swedish study also found that age >70 years and the administration of additional opioids by other routes were risk factors for the development of respiratory depression [296]. However, the reported incidence of respiratory depression with fentanyl local anesthetic epidurals of 0.3% [297] is no higher than the incidence of respiratory depression when opioids are administered by other routes. Drug errors whereby the wrong drug is administered epidurally have been reported [298] but fortunately are rare and should be reduced further by using dedicated epidural delivery systems.

The reported incidence of serious complications has varied although an estimate of 0.0007% is often quoted. The Third National Audit Project, the largest prospective study of complications after central neuraxial blocks, has helped clarify the incidence of serious complications associated with epidurals [164, 165]. This confirmed that overall (perioperative, obstetric, pediatric, and chronic pain) central nerve blocks were associated with a very low (0.007%) incidence of major complications. The incidence of major complication after epidurals inserted perioperatively was, however, much higher at 0.02%. The most frequent complications were epidural hematomas [165]. This incidence of major complications after perioperative epidurals is almost the same as that incidence reported in an earlier Swedish study [299].

Urinary Retention

Urinary retention is a well-known complication of epidural opioid use [300]. The mechanisms for this include inhibition of sacral parasympathetic outflow and inhibition of the pontine micturition center [301]. Epidural morphine-mediated reduction in detrusor muscle function is antagonized by naloxone [302], and in post-hysterectomy patients naloxone can reverse bladder dysfunction without reversing epidural morphine analgesia [303]. When given to post-thoracotomy patients receiving thoracic fentanyl bupivacaine epidural analgesia, naloxone reversed the analgesic effects of the epidural without reducing the need for urinary catheterization [304] and so is not recommended.

Gastric Emptying

The excellent early analgesia provided by thoracic epidural analgesia enables most patients to resume their normal diet and oral medications a few hours post-thoracotomy. The rate-limiting step for the absorption of most orally administered drugs is gastric emptying. Gastric emptying is variably affected by anesthesia and surgery [305–307]. Epidural opioids can result in gastric hypomobility. Branches of the T6–T10 sympathetic nerves innervate the stomach [308] and sympathetic blockade of these nerves could hasten gastric emptying. Gastric emptying has been shown to be normal in patients receiving bupivacaine epidural analgesia post-cholecystectomy [307] although for post-thoracotomy patients receiving a fentanyl bupivacaine epidural, there is some evidence that gastric emptying is delayed for >48 h [309]. A recent Cochrane review [310] concluded that, following a meta-analysis of recent studies, epidural analgesia, following abdominal surgery either with or without the addition of an opioid, was associated with a faster return of gastric motility when compared to an opioid-based analgesic regimen such as an IV-PCA. Delayed gastric emptying should therefore be assumed to occur in any situation where an opioid is employed and may be better in the context of epidural versus intravenously administered opioid but may overall be associated with reflux or regurgitation and altered effects of orally administered drugs. Dexmedetomidine has also been added to epidural solutions in colonic surgery as an alternative to morphine. In one study [311] the use of epidural dexmedetomidine in addition to levobupivacaine was associated with similar pain scores and additional analgesic requirements, but there was a suggestion of improved gastric motility in the group receiving dexmedetomidine, along with a reduced incidence of nausea, vomiting, and pruritis.

Hypotension

Hypotension is a common occurrence during thoracic epidural analgesia. It is important to appreciate the differences between hypotension due to a lumbar versus mid-thoracic epidural sympathetic blockade. With lumbar neuraxial blockade, hypotension is primarily due to systemic vasodilation, decreasing cardiac preload and afterload. The hypotension due to thoracic epidural blockade occurs for these two previous reasons and also due to blockade of the cardiac sympathetic supply, interfering with the heart's ability to increase contractility. Unlike treatment of hypotension during lumbar blockade, hypotension during thoracic epidural blockade will have a limited response to increases of preload and afterload and so requires treatment with a β-adrenergic or mixed agonist (e.g., ephedrine, dopamine, etc.) to increase contractility and restore cardiac output [312]. One meta-analysis [313] has suggested that use of thoracic epidural analgesia in the context of one-lung ventilation may reduce hypoxic pulmonary vasoconstriction through this mechanism, causing an increase in shunt fraction and reduction in partial pressure of oxygen (P_aO_2) and mixed arterial oxygen saturation (S_aO_2).

Neuraxial Block and Coagulation

The risk of an epidural inserted for post-thoracotomy analgesia resulting in a permanent injury or death is approximately 0.02%. Epidural hematomas account for most of this morbidity [164, 165]. Anticoagulants and antiplatelet agents can further increase the risk of vertebral canal hematoma [314, 315] and may increase the risk of epidural abscesses by causing small hematomas that become secondarily infected. All patients receiving thoracic epidural analgesia and patients who have undergone unsuccessful attempts at epidural catheter placement should be monitored regularly for symptoms and signs of vertebral canal hematoma, specifically back pain, motor or sensory changes, and urinary retention, if not catheterized. Of these, motor block is the most reliable sign and most sensitive prognostic indicator [316]. Vertebral canal hematomas occurring in the perioperative period have a poor outcome. Where there is a clinical suspicion of epidural hematoma, intervention should be planned urgently with diagnostic imaging, e.g., magnetic resonance imaging (MRI), and surgical intervention, e.g., decompressive laminectomy [317].Due to the rarity of spinal epidural hematoma, case reports and expert opinion, not scientific evidence from controlled trials, provide the mainstay of recommendations for epidural analgesia in patients receiving antithrombotic medications. This is particularly true for thromboprophylaxis [317, 318]. Recommendations by the European Society of Anaesthesiology (ESA) [317] and the American Society of Regional Anesthesia and Pain Medicine (ASRA) [166] are based upon the known pharmacology of the individual agents in the context of normal physiology, case reports, clinical series, and risk factors for surgical bleeding. Reduced renal or hepatic clearance due to use of other medications or underlying pathology may impact this and increase the risk of bleeding [317]. One suggestion has been to use the rule of not performing a neuraxial block or removing an epidural catheter until the time from the last dose of anticoagulant is equal to 2 – $T_{1/2}$ h (where $T_{1/2}$ takes into account the renal and hepatic function of the individual patient) in order to achieve the optimum risk/benefit ratio leaving 25% pharmacodynamic efficacy or the rule of 5 – $T_{1/2}$ h in high-risk patients or where there is a drug with limited clinical experience to leave 3.125% [319]. Where cessation of anticoagulant treatment is not possible or deemed to be of high risk to the patient, neuraxial analgesia should be abandoned and alternative plans should be made.

Heparin and Thromboprophylaxis

Subcutaneous unfractionated heparin is effective in reducing the incidence of thromboembolic complications [166, 320]. There are a limited number of case reports of vertebral canal hematoma associated with neuraxial blockade in patients receiving subcutaneous unfractionated heparin published in the literature [321–323], and therefore subcutaneous heparin in patients with thoracic epidurals in situ appears safe [324]. If subcutaneous heparin is continued for greater than 4–5 days, a platelet count is recommended prior to removal of the epidural catheter as heparin-induced thrombocytopenia may occur [325]. Low molecular weight heparins have different biochemical and pharmacological properties to unfractionated heparin including anti-Xa activity [166] and the fact that their effect cannot easily be reverse with protamine. Routine anti-Xa monitoring is not, at present, recommended when planning neuraxial anesthesia or analgesia [325]. The half-life of anticoagulant activity following the administration of a dose of subcutaneous low molecular weight heparin is considerably longer than that following a subcutaneous dose of unfractionated heparin, allowing once daily dosage. In the late 1990s, there were reports of more than 40 cases of vertebral canal hematoma in patients following neuraxial blockade in the United States. This may have been the result of the North American guidelines recommending twice daily dosage, meaning there was effectively no "safe" time in which to perform a block or remove an epidural catheter. Similar clusters of cases of hematoma were not reported in Europe despite extensive experience of regional blockade concurrent with low molecular weight heparin thromboprophylaxis [326, 327]. This is thought to represent the once daily dosage employed in Europe. However, despite this neuraxial blockade in the presence of low molecular weight heparin, thromboprophylaxis is more risky than with unfractionated heparin, especially for epidural catheter techniques [166].

Removal of epidural catheters should not be performed until at least 4 h after cessation of unfractionated heparin administration and after confirmation that the coagulation profile has normalized [317]. If a bloody puncture occurs, the ESA recommends that low-dose anticoagulation be avoided for 1–2 h and full heparinization for 6–12 h [317], while the ASRA recommends waiting for 24 h until LMWH are used [325]. Where low molecular weight heparin is administered prophylactically, clinicians should wait at least 12 h from the previous dose before performing neuraxial blockade or removing an epidural catheter and should wait until 2–4 h after catheter removal to give a further dose [317, 325]. For a treatment dose of LMWH, at least 24 h should pass between the last dose and neuraxial block or catheter removal. Treatment can be restarted 2–4 h after catheter removal [317]. This guidance is issued in the context of normal renal function and therefore the impact of the reduced renal function must be taken into account when planning any neuraxial block.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide factor Xa inhibitor that is similar in structure to the low molecular weight heparins [325]. Where fondaparinux is used at prophylactic doses, the last dose should have been administered at least 36 h prior to neuraxial block or catheter insertion or removal and ideally 3–4 days prior to minimize risk. Following removal of an epidural catheter, at least 24 h should pass before the next dose is administered [328]. This advice is given in the context of a single-needle atraumatic needle pass, and therefore where the procedure proves to be more complicated, ongoing use of fondaparinux should be avoided [325]. Where fondaparinux is administered in treatment doses (5–10 mg per day), neuraxial block should not be performed due to the risks of accumulation of effect [317].

Warfarin

When thoracic epidural analgesia is planned, warfarin should be discontinued at least 4–5 days preoperatively. The INR should be within normal limits prior to placing the epidural catheter to ensure adequate levels of active vitamin K-dependent clotting factors. Hemostasis may not be adequate even with an INR of 1.3 [166] since, in the first 1–3 days after cessation of treatment, a return to normal levels of factor VII leads to a relatively normal INR despite still low levels of factor II and X leading to potential ongoing coagulopathy [325]. Warfarin therapy should ideally not be reinstituted until after removal of the epidural catheter and the INR should be <1.4 prior to catheter insertion or removal. The clinician should not overlook the potential use of bridging anticoagulation during the period of warfarin cessation, and these agents must also be taken into account when planning neuraxial blockade.

NOACs: Novel Oral Anticoagulants

This group includes drugs such as rivaroxaban, dabigatran, and apixaban. They are increasing in popularity due to their fixed dose administration, reduced need for monitoring, and more favorable pharmacokinetics and pharmacodynamics [319]. Dabigatran is a prodrug that acts through reversible inhibition of free and clot-bound thrombin. The most recent ASRA guidance states that clinicians should wait a minimum of 4–5 days to perform neuraxial block or remove an epidural catheter and that the next dose should not be administered until 6 h later. Rivaroxaban and apixaban are orally administered direct inhibitors of factor Xa. For rivaroxaban, with prophylactic doses of <10 mg per day, 22–26 h between the last dose and neuraxial block or catheter removal is advised. Further doses should not be administered until 4–6 h after catheter removal. Where patients are taking apixaban (prophylactic dose, 2.5 mg BD), 3–5 days should pass between the last dose and neuraxial block or catheter removal. The next dose after catheter removal should not be administered until 6 h later [328]. It must be reiterated that this advice is in the context of normal renal function, and therefore in other circumstances, the use of neuraxial blockade should be considered more cautiously.

Antiplatelet Medications

There is considerable variability in patient responses to antiplatelet agents. The increased risk in individual patients may therefore be difficult to quantify, although female sex, advanced age, and a history of easily bruising can signify an increased risk. The role of near-patient testing of platelet function prior to neuraxial block needs to be established.

NSAIDs (Including Aspirin)

NSAIDs appear not to increase the risk of vertebral canal hematoma in patients undergoing neuraxial blockade [166, 325, 329, 330]. Concurrent administration of other hemostasis altering medications does, however, appear to increase the risk of bleeding [166], especially in the case of aspirin. This includes heparin for postoperative thromboprophylaxis [315, 318] and thienopyridine drugs [317]. Thus, if feasible, aspirin should be discontinued 5–7 days prior to surgery if central neuraxial blockade and heparin-based DVT prophylaxis are planned. Where aspirin is co-administered with other drugs that impact coagulation, neuraxial analgesia should usually be avoided [325].

Thienopyridine Derivatives

These include clopidogrel and ticlopidine. They are potent antiplatelet agents causing irreversible inhibition of ADP-induced platelet aggregation and platelet fibrinogen-binding inhibition. Clopidogrel should be discontinued at least 7 days and ticlopidine at least 10–14 days prior to neuraxial blockade [166, 317].

Platelet Glycoprotein IIb/IIIa Inhibitors

This group of drugs includes abciximab and tirofiban and acts through inhibition of platelet aggregation [319]. While platelet function should normalize following a dose of abciximab after 24–48 h and following cessation of tirofiban infu-

sion within 4–8 h, performance of neuraxial blockade should not occur until the clinician is confident that platelet function has normalized [319].

Herbal (Alternative) Medication

Up to 50% of surgical patients may be taking herbal medications preoperatively although many do not volunteer this information. Although herbal drugs by themselves probably pose no significant added risk, garlic, ginseng, and gingko have raised concern because they are associated with thrombocytopenia, inhibition of platelet aggregation, and interaction with vitamin K antagonists. There may be a small increased risk of an epidural hematoma if patients receive heparin for thromboembolism prophylaxis [166, 318]. It is probably wise to actively seek a history of such herbal therapy usage and discontinue it 7 days preoperatively.

Coronary Stents

An increasing number of patients with coronary artery stents in situ and receiving antiplatelet drugs are presenting for thoracic surgery. After insertion patients receiving bare metal stents require aspirin and clopidogrel for at least 4 weeks. Patients receiving drug-eluting stents require aspirin and clopidogrel for at least 12 months. All patients with stents in situ require aspirin for life [167, 169, 331]. Dual antiplatelet therapy is a contraindication to epidural analgesia [166]. Although discontinuing clopidogrel ≥7 days preoperatively while continuing aspirin may make thoracic epidural feasible, the premature discontinuation of one antiplatelet agent markedly increases the risk of acute perioperative stent thrombosis with significant cardiac morbidity and mortality [167–169]. Aspirin therapy should rarely be interrupted [169]. The planned duration of postoperative epidural analgesia is also relevant as antiplatelet therapy should be recommenced as soon as possible post-procedure as delays may expose the patient to an unacceptable risk of stent thrombosis [167].

Techniques for Specific Situations

Sternotomy

A sternotomy can be used to provide access for a range of surgical procedures including the resection of anterior mediastinal tumors. At closure the divided sternum is usually internally fixed with wire. This fixation restricts bone movement and limits pain. Adequate post-sternotomy analgesia can usually be achieved with a morphine IV-PCA system supplemented when appropriate by non-opioid analgesics. Local anesthetic wound infiltration can reduce opioid consumption [332] and should be considered. Continuous wound infiltration via deep and/or subcutaneous catheters may be more effective, but evidence of effectiveness is limited, with some studies showing no benefit [333]. Thoracic epidurals can provide very effective post-sternotomy analgesia and have previously been used to provide analgesia following cardiac surgery, where one meta-analysis [334] showed a reduced incidence of arrhythmias, respiratory complications including atelectasis and pneumonia, duration of tracheal intubation, and visual analogue scores. Despite this however there was no clinically significant improvement in overall mortality. The catheter should be sited at a higher level (T3/T4) than for a thoracotomy (T6/T7) and any paresthesia of the medial surface of the arms detected early, to enable a timely reduction in the epidural infusion rate to limit the risk of bilateral phrenic nerve blocks. Thoracic epidural analgesia should be considered for patients with poor lung function undergoing bilateral pulmonary procedures via a sternotomy (e.g., volume reduction surgery). A parasternal local anesthetic block can reduce opioid requirements [335] and could be considered in patients with poor lung function in whom epidural anesthesia is contraindicated.

Video-Assisted Surgery

The limited incision may limit postoperative pain, but several studies support that, particularly where VATS lobectomy is performed, there is frequently at least a moderate level of postoperative pain [336, 337]. Despite this fact, many feel that this less invasive surgery may still require a less invasive form of analgesia [338]. One review article concluded that thoracic epidural analgesia did not exhibit a significant effect on pain scores when compared to other modalities and, given the potential side effects, suggested less invasive techniques may be preferable [339]. The appropriate analgesia depends in part on the nature of the surgery undertaken. Thoracic epidural analgesia may be advantageous in patients undergoing minimally invasive esophagectomies [340], whereas paravertebral blocks, either single shot or ideally with a catheter for ongoing infusion, potentially in combination with an IV-PCA system may be appropriate for patients undergoing VAT lung resections. Minimal analgesia may be required after VAT pleural biopsies or sympathectomies, and a single-shot paravertebral block along with a basic analgesic regime may be more than adequate.

Open Thoracotomy

A large number of pain management techniques have been described for open thoracotomy patients. These have

included the administration of local anesthetics, opioids, and other drugs to provide intercostal nerve blocks [186–188], interpleural blocks [194–197], paravertebral blocks [236, 341, 342], lumbar epidural analgesia [343–345], thoracic epidural analgesia [161, 162, 255, 262, 263], intrathecal analgesia [118, 119, 242–245], and systemic analgesia [58]. In addition, the non-pharmacological techniques of cryoanalgesia [159, 160] and TENS [346–352] have been used. Good post-thoracotomy pain control is difficult to achieve without regional anesthesia and it is recommended that a regional anesthetic technique be used as part of a multimodal analgesic regimen to provide post-thoracotomy analgesia. Apart from paravertebral blocks, all other regional analgesic techniques are inferior to thoracic epidural analgesia [58]; the choice of regional anesthetic technique is usually between thoracic epidural analgesia and a paravertebral block. In practice both techniques have advantages in particular patients and the acquisition of expertise in both techniques is recommended. For patients with borderline predicted postoperative lung function, good early analgesia and the ability to cooperate with lung recruitment maneuvers immediately postoperatively may be critical. A retrospective analysis of one institute's data showed that a preoperative FEV_1 of less than 60% predicted was an independent risk factor for the development of post-thoracotomy pulmonary complications and mortality. The use of thoracic epidural analgesia was associated with reduced pulmonary complications and a reduced mortality in patients with an $FEV_1 < 60\%$, although no patients were reported to have received a paravertebral block [353] (Fig. 59.24). A prospective 1-year observational study of pneumonectomies in the United Kingdom found epidural analgesia to be a significant associate of poor outcome [354].

For patients with good pulmonary function undergoing limited lung resection, early analgesia may be less critical and paravertebral analgesia may enable earlier mobilization and shorten hospital stays. For most patients, the decision is less clear-cut, and consideration of the relative risks and benefits of the two techniques should be made for the particular patient (Table 59.5). For patients for whom neither thoracic epidural or paravertebral blocks is appropriate, consideration should be given to the use of intercostal nerve blocks or preoperative intrathecal opioids.

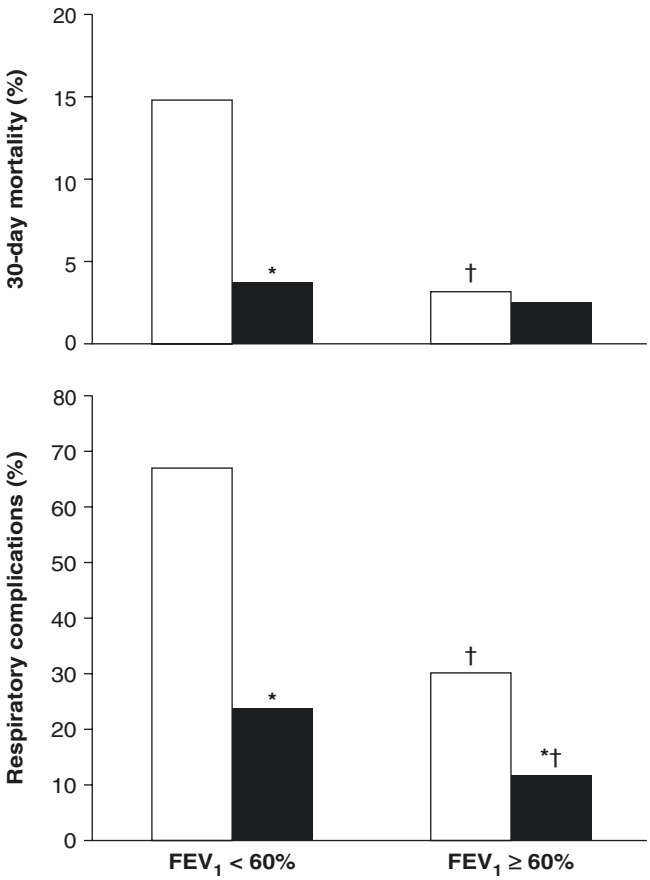

Fig. 59.24 Thirty-day mortality rate (top) and incidence of respiratory complications (bottom) according to preoperative FEV1 (<60% or ≥60%) and type of analgesic regimen: without thoracic epidural analgesia (white bars) or with thoracic epidural analgesia (black bars). *$p < 0.05$, compared with group without thoracic epidural analgesia; †$p < 0.05$, compared with group FEV1 ≥ 60%. Table 59.5 Factors influencing choice of paravertebral block or thoracic epidural

Favors thoracic epidural	Favors paravertebral block
Poor PFTs	Good PFTs
Extensive lung resection	Limited lung resection
Chest wall involvement	Sepsis
Nonsteroidal anti-inflammatory drugs (NSAIDs) contraindicated	Impaired coagulation
Patient preference	Patient preference
	Fixed spinal deformity
	Anesthetized patient

Esophageal Surgery

With a perioperative mortality of approximately 3% and an incidence of major morbidity of up to 30%, esophagectomy is one of the highest-risk thoracic surgical procedures [355]. Postoperative pain can be very severe after open esophageal surgery, and thoracic epidural analgesia is usually used to provide postoperative analgesia for these patients. In nonrandomized studies comparing systemic opioids with epidural analgesia after open esophageal surgery, patients receiving epidural analgesia had fewer respiratory complications [356, 357], spent less time in intensive care [356, 358], and had a lower mortality [356, 359, 360] potentially secondary to a

reduction in the systemic pro-inflammatory response [357]. Thoracic epidurals may decrease the incidence of anastomotic leakage post-esophagectomy [357, 361]. Ischemia at the anastomotic end of the newly formed gastric tube is a major cause of anastomotic leaks post-esophagectomy [362]. A relationship between low Doppler determined blood flow at the anastomotic site and subsequent anastomotic leakage has been shown [363]. Although intraoperative epidural boluses can cause hypotension and reduced blood flow to the anastomotic end of the gastric tube [364], a study using continuous postoperative thoracic epidurals found epidurals to be associated with minimal hypotension and an increased distal conduit blood flow [365]. We recommend that "anesthesiologists should be cautious in accepting intra-operative hypotension secondary to epidural administration in patients undergoing esophagectomy" [364]. For patients undergoing a minimally invasive esophagectomy, some groups have utilized the combination of an IV-PCA system, bilateral paravertebral blocks, and non-opioid analgesics. There is conflicting evidence regarding the influence of epidural analgesia on mortality, with some describing an increased mortality in patients undergoing minimally invasive esophagectomy without a thoracic epidural [340] and others identifying no difference in overall mortality or incidence of disease recurrence [357]. Expert groups tend to advocate the use of a thoracic epidural for all patients scheduled to undergo an esophagectomy in order to limit the postoperative inflammatory response and provide high-quality pain control [366, 367]. For patients undergoing open esophageal surgery in whom epidural analgesia is inappropriate or contraindicated, consideration should be given to the use of a continuous paravertebral block as they have been reported to provide reasonable analgesia when supplemented by systemic analgesics [368].

Shoulder Pain

Ipsilateral shoulder pain is common in patients receiving effective thoracic epidural analgesia and occurs occasionally in patients receiving paravertebral blocks, but is rare in patients not receiving nerve blocks for post-thoracotomy analgesia. The reported incidence of ipsilateral shoulder pain varies from 37 to 97% [77, 131, 200, 369–371] and can lead to significantly impaired respiratory and physical function postoperatively. This shoulder pain is often described by patients as an ache, usually of moderate to severe intensity which may fluctuate over the course of the day [371], and lasts for 3–4 days postoperatively [372]. While shoulder pain may follow both open and thoracoscopic surgeries, the overall incidence appears to be higher following thoracotomy and with longer duration of surgery [373].

Early explanations of this shoulder pain were that it was related to the transection of a major bronchus although no mechanism was suggested [77]. Other early explanations included stretching of the brachial plexus or the shoulder joint as a result of the intraoperative positioning and distraction of the posterior thoracic ligaments by surgical retractors [13]. The location of the pain varies and has been reported in differing locations from posterior shoulder, deltoid, and lateral third of the clavicle, although all locations share innervation with the diaphragm [374], leading to a further hypothesis regarding the etiology of referred pain. Several studies have helped clarify the pathogenesis of this pain, with one group recently suggesting multiple contributing etiologies. In a prospective observational study [371], pain was classified as either referred or musculoskeletal, where patients with evidence of muscle tenderness in the painful area, reproducible shoulder pain on palpation of muscles in other areas, or aggravation of pain on movement of the shoulder were placed in the latter group. In 55% of patients, shoulder pain was deemed to be of musculoskeletal origin and was found to be of greater intensity than in the 45% of patients where pain was classified as referred. In a few patients with ipsilateral post-thoracotomy shoulder pain and an apical chest drain extending to the apex of the chest cavity, withdrawal of the chest drain by a few centimeters relieves the pain. This implies that irritation of the apical pleura by the chest drain is another cause of ipsilateral post-thoracotomy shoulder pain.

Management of ipsilateral shoulder pain following thoracic surgery proves challenging. The pain is resistant to epidural boluses [78] and intravenous opioids [369]. Preoperative gabapentin [131] is similarly ineffective. A double-blind study of patients who had developed ipsilateral post-thoracotomy shoulder pain, in which patients were given either bupivacaine or saline to block the suprascapular nerve, found that blocking the suprascapular nerve did not affect the incidence of pain [370]. A placebo-controlled study of the administration of bupivacaine through the basal drain to anesthetize the diaphragmatic pleura found that bupivacaine was not effective in reducing ipsilateral post-thoracotomy shoulder pain [200]. A placebo-controlled study in which the periphrenic fat pad, at the level of the diaphragm, was infiltrated with either lidocaine or saline intraoperatively reduced the early incidence of ipsilateral post-thoracotomy shoulder pain from 85% to 33% [369] (Fig. 59.25).

This marked reduction in the incidence of ipsilateral post-thoracotomy shoulder pain with phrenic nerve infiltration was confirmed in a later study [376]. The phrenic nerve must therefore be importantly involved in the pathogenesis of ipsilateral post-thoracotomy shoulder pain. The phrenic nerve supplies sensory branches to the mediastinal pleura, the fibrous pericardium, the parietal layer of the serous pericar-

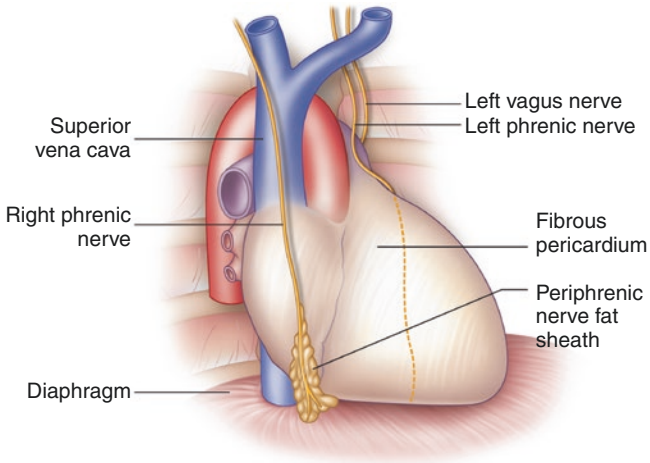

Fig. 59.25 Diagram to illustrate the site of the periphrenic nerve fat sheath for phrenic nerve blocks. (Modified with permission from Gosling et al. [375] in Scawn et al. [369])

dium, and the pleura related to the central part of the diaphragm. In many patients, the likely explanation of ipsilateral post-thoracotomy shoulder pain is irritation of the pericardium, mediastinal, and diaphragmatic pleural surfaces resulting in pain referred to the shoulder via the phrenic nerve.

Effective treatment options for ipsilateral post-thoracotomy shoulder pain therefore include acetaminophen [100], nonsteroidal anti-inflammatory agents [77, 78], direct intraoperative phrenic nerve blocks [369, 376], and indirect postoperative phrenic nerve blocks [377, 378]. The use of acetaminophen orally, rectally, or intravenously to treat ipsilateral post-thoracotomy shoulder pain is recommended. Rectal acetaminophen is safe and moderately effective [100] although personal experience suggests intravenous acetaminophen to be more effective. NSAIDs are effective in controlling ipsilateral post-thoracotomy shoulder pain [77, 78] and personal experience suggests that they are more effective than acetaminophen. The well-known side effects of NSAIDs are, however, a particular concern in the often old and debilitated patients who have undergone thoracic surgery and the risks should be assessed before their use. Intraoperative phrenic nerve blocks are effective. The short duration of effect with lidocaine [369] can be extended by the use of ropivacaine [376], but patient selection is important as the resultant unilateral diaphragmatic paresis can further impair ventilation. Phrenic nerve blocks should be considered for patients in whom postoperative pulmonary function is not a concern and for patients undergoing a pneumonectomy. In post-pneumonectomy patients, the unilateral loss of diaphragmatic function has limited effects on ventilation and may have an additional benefit of helping to reduce the pneumonectomy space. Postoperative interscalene brachial plexus blocks have been shown to be effective in treating ipsilateral post-thoracotomy shoulder pain in case reports [377] and in a prospective study [378]. The phrenic nerve block that is a side effect of interscalene brachial plexus block [379] almost certainly explains the block's effectiveness. As a result of the potential complications associated with this block, we recommend that interscalene brachial plexus blocks be considered only in patients with severe ipsilateral post-thoracotomy shoulder pain and adequate pulmonary reserve. Although a stellate ganglion block may be effective in treating ipsilateral post-thoracotomy shoulder pain [380], its use for this purpose is not recommended.

Opioid-Tolerant Patients

Continuous opioid exposure results in a rightward shift of the dose-response curve to opioids, resulting in patients requiring increased amounts of opioid to obtain the same pharmacological effect. It is a predictable pharmacological adaptation [381]. The degree of opioid tolerance is related to the dosage, duration, and type of opioid administered. Opioid tolerance occurs when higher doses of opioids are required to achieve adequate analgesia due to desensitizing of signaling via the opioid receptor [60], decreased opioid receptor density [382], upregulation of cyclic adenosine monophosphate [383], and neural adaptation [384]. Activation of NMDA receptors plays an important role in the development of opioid tolerance [385]. Opioid-tolerant patients are relatively pain intolerant [386] and may have greater difficulty in coping with acute pain [387].

The principles of treatment are similar for all groups, but opioid substance abusers may present additional challenges due to their psychological problems, dependency on other substances (e.g., alcohol), concomitant infectious diseases (e.g., tuberculosis, human immunodeficiency virus), and the use of antagonist drugs which may affect the delivery of anesthesia. A thorough history should be taken to ascertain the location and characteristics of their chronic pain condition, along with the route and usual daily dose of opioids. Patients should be encouraged to continue their usual analgesic regime up until the time of surgery and where able in the perioperative period [60]. For patients scheduled for major surgery where oral intake is likely to be disrupted, an equivalent intravenous dose of morphine should be estimated. Unfortunately, variability in the pharmacokinetics, pharmacodynamics, route of administration, and daily opioid consumption can make estimating a morphine equivalent dose difficult. Abrupt cessation of opioids can result in an acute opioid withdrawal syndrome and should be avoided. Naltrexone, a long-acting competitive opioid antagonist used to help prevent relapse in detoxified former opioid-dependent patients and in alcohol addiction, should be discontinued a few days before surgery if possible. Where it has been administered via a depot injection, since the antagonism lasts approximately 30 days, surgery should be delayed until after this time if possible [60]. Similarly,

buprenorphine, a partial mu agonist, is frequently stopped approximately 3 days prior to surgery in order to allow the full mu agonist effect of other strong opioids to take effect [388].

This group of patients benefit greatly from a multimodal approach to pain management and the use of non-opioid drugs must be carefully considered. Acetaminophen, either via the oral or intravenous route, is a beneficial adjunct along with oral or intravenous NSAIDs if there are no contraindications. Ketamine has been suggested to reverse morphine tolerance and therefore return its effectiveness in animal models and the use of ketamine orally, as an intravenous infusion alone or as part of an IV-PCA regime may contribute to better pain control. Clonidine, dexmedetomidine, and the gabapentinoids have also been suggested as useful adjuncts [388].

Most patients undergoing open thoracic surgery benefit from the addition of a regional anesthetic technique. Thoracic epidurals can provide excellent post-thoracotomy analgesia in opioid-tolerant patients, and their use should therefore be considered. The use of a lipophilic opioid local anesthetic mixture is recommended. Lipophilic opioid local anesthetic mixtures have been shown to provide pain control that is superior to morphine local anesthetic mixtures in opioid-tolerant patients, perhaps because analgesic effects are exerted at lower receptor occupancy [389, 390]. An alternative for patients scheduled to receive significant amounts of opioids by other routes is the use of a plain local anesthetic epidural solution. Where thoracic epidural use is inappropriate, a catheter-based paravertebral technique is recommended.

For a few patients, parental opioids may be the most appropriate means of providing postoperative analgesia. Despite earlier concerns of increasing addiction and manipulative behavior, the use of intravenous IV-PCA systems to control pain in substance abusers is now generally considered acceptable, if this system is used appropriately. Increasing opioid dose in order to overcome tolerance is an inadequate strategy as frequently there is minimal improvement in pain control but a marked increase in the incidence of opioid-related side effects, such as sedation, respiratory depression, ileus, and a paradoxical worsening of pain perception [60, 391]. Predicting the postoperative opioid requirement for opioid-dependent patients is difficult. For opioid-naïve patients receiving an IV-PCA for post-thoracotomy analgesia, a background opioid infusion is usually not appropriate. Opioid-dependent patients however may require a background infusion and are likely to require higher doses in addition to their preoperative regime. Opioid rotation can be considered as sometimes changing the agent may lead to an overall reduction in the total dose required.

Swenson et al. noted that during drug administration, there is initially a disparity between the plasma concentration and the concentration of the drug at its site of action (effect site concentration). They describe a method of determining the effect site concentration of fentanyl at the threshold of respiratory depression in individual patients using simulation software and a fentanyl infusion. After determining the effect site concentration of fentanyl at the threshold for respiratory depression, an hourly fentanyl administration rate that will result in 30% of this effect site concentration is calculated. Utilizing an intravenous PCA system, half of this calculated fentanyl dose can be administered as a background infusion, while the remaining 50% is programmed for demand administration as boluses with a 15-min lockout period. They recommend that the regimen be reviewed at 4-hourly intervals and adjustments made based on the number of demand boluses administered, the level of conscious, and the respiratory rate [392].

Methadone, a NMDA receptor antagonist which can activate α adrenergic receptors and a different range of μ receptors subtypes to morphine, is regarded as the intravenous PCA opioid of choice for opioid-dependent patients by some authors [393]. Consideration should be given to using a methadone IV-PCA system in opioid-dependent patients whose postoperative pain is refractory to large doses of systemic morphine. A single dose of opioid has been shown to cause activation of NMDA receptors [394]. In animal studies where ketamine was administered, reversal of morphine intolerance and consequent improved opioid effectiveness has been shown [395]. The administration of a low-dose ketamine infusion should be considered particularly in patients for whom regional anesthetic techniques are not planned. The literature suggests that for opioid-tolerant patients, an intraoperative bolus of ketamine (~0.25 mg kg^{-1}) should be followed by an intravenous infusion (~2 μg kg^{-1} min^{-1}) continued for a few days [121]. Although adding ketamine to morphine delivered via an IV-PCA has been described [110], this is not recommended in opioid-tolerant patients because the large and unpredictable opioid requirement may result in the administration of excessive doses of ketamine with the associated psychotropic side effects [121].

Conclusion

Pain control after surgery is central to the anesthetic management of patients undergoing thoracic surgery. The provision of good postoperative analgesia is of itself important and is regarded by some as the core business of anesthesia and a fundamental human right [396]. Effective analgesia can reduce pulmonary complications and mortality [353]. It is unlikely that a single technique will optimally fulfill these objectives for all patients, and therefore a balanced, multimodal approach should be used. Analgesia should be tailored to the specific patient undergoing a specific procedure and aim to minimize mortality, patient suffering, pulmonary complications, and other morbidity. Experience with a wide range of analgesic techniques is helpful as it enables the implementation of an appropriate technique. For open thoracotomies, most patients are best managed by a combination of regional analgesia and opioids, sometimes supplemented with non-opioid analgesics.

There is no role for interpleural blocks or cryoanalgesia in adults. Lumbar epidural analgesia, intrathecal opioids, or intercostal nerve blocks should usually be considered only if neither thoracic epidural analgesia nor paravertebral blocks are possible. At present the dilemma for thoracic anesthetists and their patients scheduled to undergo a thoracotomy is the choice between thoracic epidural analgesia and paravertebral block. It has been well established that thoracic epidurals produce excellent post-thoracotomy analgesia. Thoracic epidurals are, however, associated with a risk of permanent injury and the most frequent disabling complications are epidural hematomas [165]. Paravertebral blocks and infusions have been shown to produce equivalent analgesia but with a preferable side effect profile. An increasing number of patients presenting for thoracic surgery are receiving drugs that affect coagulation, not all of which are prescribed. Current anticoagulant and antiplatelet medication increases the risk of epidural by an unquantified amount. Impaired coagulation is less of a contraindication to thoracic paravertebrals, particularly when they are inserted under direct vision. Serious complications are rare with paravertebrals and therefore paravertebral blocks, as "single shots" and with catheters to allow continuous infusion, are growing in popularity. In the future, the development of clinically useable ultra-long-acting local anesthetics might enable significant further advances to be made in the provision of post-thoracotomy analgesia.

Case Study

A 64-year-old man has been admitted following a 2-week history of productive cough, lethargy, and collapse. He was initially treated for a community-acquired pneumonia with intravenous antibiotics, but serial chest x-rays and a CT scan have shown a cavitating lesion in the right upper lobe and a loculated pleural collection, likely to represent an empyema. Attempts have been made to drain the collection percutaneously but they have been unsuccessful, and he is scheduled to undergo open drainage of the empyema with decortication. Past medical history includes chronic obstructive pulmonary disease. He is a current heavy smoker and has been for more than 40 years.

Clinical examination reveals a slim man with a respiratory rate of 22 breaths per minute, heart rate 110 beats per minute, blood pressure 120/64, and a temperature 101 °F.

Full blood count shows a Hb 87 g/dl, WCC 23.0 $\times 10^9$ L^{-1}, neutrophil count 20.3 $\times 10^9$ L^{-1}, platelet count 637 $\times 10^9$ L^{-1}, and CRP 180 mgL^{-1}. His renal function and clotting screen are normal. Pulmonary function tests show an FVC of 74% predicted, FEV_1 of 43% predicted, and DLCO of 45% predicted.

Questions

What regional analgesic techniques could be employed here?

- Epidural and intrathecal analgesia are not advised in the presence of an active infection.
- Paravertebral catheter techniques are similarly best avoided in the presence of active infection.
- Intraoperative paravertebral blocks are unlikely to be effective because of the disruption of the anatomical planes by infection and surgery.
- Intercostal nerve blocks and local anesthetic wound infiltration should be considered.

Describe the analgesic agents that could be utilized.

A multimodal analgesic approach should be considered for this patient in the absence of contraindications:

- Regular IV acetaminophen 1 g QDS
- NSAID – nonselective or COX-2, this could commence intravenously postoperatively and then continue via either an IV or oral route
- Gabapentin – for example, 100–300 mg pre-op and then 100–300 mg titrated OD to TDS
- IV-PCA morphine
- Ketamine – may be administered via intravenous infusion or orally
- Clonidine or dexmedetomidine via infusion

Long-Acting Local Anesthetics for Analgesia Following Thoracic Surgery

60

Wendell H. Williams III, Jagtar Singh Heir, and Anupamjeet Kaur Sekhon

Key Points

- Though optimal pain management for thoracic surgery can be quite challenging considering the numerous contributing mechanisms, a comprehensive pain management strategy can improve overall patient safety and satisfaction.
- Local anesthetics work by inhibiting membrane depolarization along neurons by binding to the alpha subunit of intracellular voltage-gated sodium channels; they may also possess some degree of antagonism toward the potassium (K+) and calcium (Ca2+) channels and NMDA receptors.
- Liposomal bupivacaine, a novel slow-release local anesthetic formulation, encapsulates the local anesthetic by utilizing an innovative delivery system known as DepoFoam®. The bilayered lipid septa provide a stable and reliable platform for the prolonged release of medications (72–96 h) without alteration to its molecular structure.
- Liposomal bupivacaine does not diffuse through tissues in the same manner as conventional bupivacaine. Consequently, meticulous infiltration technique is imperative to ensure best results regardless of regional technique. Decreased spread means more injections are needed in closer proximity than with traditional bupivacaine.
- The bupivacaine contained in liposomal bupivacaine is free-base bupivacaine form, distinct from bupivacaine HCl, salt form of bupivacaine. Providers should be cognizant of the fact that different formulations of bupivacaine are not bioequivalent even if the milligram dosage is the same.
- Alternatives to systemic opioids and thoracic epidurals include regional techniques such as the paravertebral, intercostal, phrenic, intrapleural, serratus anterior plane, as well as local wound infiltration.
- Combining minimally invasive surgery with multimodal, regional, and pharmacological approaches to analgesia can provide a higher level of postoperative analgesia while reducing undesired side effects of narcotic usage, such as nausea, vomiting, constipation, and respiratory depression.
- Novel long-acting local anesthetic such as liposomal bupivacaine offer a promising analgesic solution, but further studies are warranted to better understand the efficacy and long-term safety profile of these newer local anesthetics.
- This chapter reviews the localized regional techniques currently used at the University of Texas MD Anderson Cancer Center.

Introduction

Surgery remains the cornerstone therapy for early-stage lung and esophageal cancers. It is expected that the number of thoracic procedures for lung and esophageal disease will increase in the future [1]. Optimal pain management can be very challenging after thoracic surgery for multiple reasons. There are numerous mechanisms that contribute to the pain a patient experiences: disruption of the skin and muscles, ligamentous damage, and rib fractures and dislocations, as well

as chest tube and shoulder pain from diaphragmatic irritation and positioning. Not only is inadequate pain control significant for humanitarian reasons, it is also linked to increased pulmonary and extrapulmonary complications [2]. The risks of pulmonary complications can be mitigated by appropriate pain management [3]. The literature has shown that early postoperative pain is predictive of long-term pain after thoracotomy. Providers have responded by incorporating aggressive pain management strategies to decrease the high incidence of chronic pain within this vulnerable patient population [4]. The healthcare costs of chronic pain developing from acute pain can represent a significant financial burden for the patient, as well as the community. In fact, some researchers have estimated that the lifetime economic costs of a single 30-year-old patient suffering from chronic pain will reach one million US dollars [5]. For much of the modern era of medicine, postoperative pain management has been primarily accomplished by systemic opioids. Following thoracic surgery, intravenous opioids alone are often insufficient to adequately control pain and have been supplemented with the application of local anesthetics using various regional techniques.

Local anesthetics work by inhibiting the signal propagation along neurons by binding to the alpha subunit of intracellular voltage-gated sodium channels. Neurons utilize the sodium-potassium pump (Na + K+ ATPase) to maintain a negative resting potential difference of −60 to −70 mV through active transport and passive diffusion of ions [6]. The sodium-specific channels are membrane-bound proteins, made up of alpha and beta subunits that exist in three states: resting (nonconducting), open (conducting), and inactivated (nonconducting). Local anesthetics inhibit the action potential necessary to propagate signals along neurons by blocking the influx of sodium needed for membrane depolarization. Secondarily, local anesthetics may possess some degree of antagonism toward the potassium (K+) and calcium (Ca2+) channels, as well as NMDA receptors. By inhibiting the propagation of peripheral nociceptive signals, regional and local anesthesia have the potential to reduce or eliminate postoperative pain as well as mitigate the endocrine and metabolic response to surgery.

Techniques for the administration of local anesthetics to block nociception include (1) surgical site infiltration (single injection or catheter), (2) peripheral nerve blocks (single injection or catheter), and (3) neuraxial anesthesia. With the advent of liposomal local anesthetic agents, it is now possible for thoracic anesthesiologists to tailor or combine regional techniques to suit specific surgical scenarios. Significant pain reduction can be achieved for several days with single-shot injections of multiple, distinct, even unplanned surgical sites without the dependence on perineural catheters. This chapter reviews the history of local anesthetics from the coca leaf to liposomal bupivacaine, the methodology behind specific regional blocks for thoracic surgery, and how the development of long-acting, liposomal anesthetics may improve our ability to manage postoperative thoracic pain.

History of Local Anesthetics

Origins in the Americas

Derived from shrubs of the genus *Erythroxylum* native to Central and South America, the coca leaf held an important social, religious, and medicinal role of the Incan people from as far back as 1900 B.C. [7]. Initially reserved for the aristocracy, coca's use became widespread following the fall of the Incan empire in 1532. From that time until the dawn of the twentieth century, most scientists championed its energizing and euphoric properties while neglecting its other effects. The full potential for medical cocaine wasn't realized until 1880, when Russian physician Basil von Anrep of the University of Würzburg recommended its use as a surgical anesthetic based on numerous experiments upon animals and himself. It was Viennese ophthalmologist Carl Koller (1857–1944) who performed the first operation using local anesthetic on a patient with glaucoma on September 11, 1884. The impact of his work was instantaneous and global, with over 60 publications concerning local anesthesia using cocaine in the United States and Canada by the end of 1885 [8] (Table 60.1).

Synthetic Anesthetics

By the turn of the twentieth century, the potential toxicity and addictive properties of cocaine were well established, and a search for the ideal local anesthetic had begun. In 1904, German chemist Alfred Einhorn (1856–1917) patented novocaine and 17 other para-aminobenzoic derivatives which are now collectively known as ester group local anesthetics [9]. Novocaine, or alternatively named procaine, had its own limitations. Like all ester-based anesthetics, novocaine was limited by a relatively low potency and strong association with hypersensitivity and anaphylaxis among patients and healthcare workers [10]. The serious deficiencies of the ester group anesthetics encouraged the development of another group of anesthetics.

In 1946, Nils Löfgren and Bengt Lundquist developed a xylidine derivative they called "lidocaine," whose chemical composition was distinct from novocaine and was found to be more potent and safer, with little allergenic potential [11]. Bupivacaine, mepivacaine, and most of the other amide

Table 60.1 Important dates in the history of local anesthetics

Date	Subject	Event
1900 B.C.	Incan empire	Oldest known use of coca
A.D. 1532	Fall of Incan empire	Endemic use of coca among many people in Central and South America
1653	Spanish Jesuit father Bernabé Cobo	First documentation of local anesthetic properties of coca leaf
1860	German chemist Albert Niemann	Isolates active compound in coca leaf, names it "cocaine"
1868	Peruvian Thomas Moreno y Maïz	First experimental studies on cocaine as anesthetic in animal models
1880	Russian physician Basil von Anrep of University of Würzburg	Based on studies on animals and himself, Von Anrep recommends cocaine as surgical anesthetic
September 11, 1884	Viennese ophthalmologist Carl Koller	Performs first operation using local anesthetic on a patient with glaucoma
November 1884	William Burke or William Halsted and Richard Hall	First nerve blocks performed
1898	August Bier of Kiel, Germany	Performed first spinal blocks for surgery using cocaine
1904	German chemist Alfred Einhorn	Patents novocaine and 17 other ester group local anesthetics
1905	Hugo Sellheim of Leipzig	Performed first thoracic paravertebral block
1946	Nils Löfgren and Bengt Lundquist	Developed xylidine derivative named "lidocaine," first amide group local anesthetic and foundation for other amide anesthetics
1957	Longer-acting amide anesthetics developed	Mepivacaine and bupivacaine first synthesized
1965		Bupivacaine first introduced into the market
1996		Less toxic enantiomer of mepivacaine named "ropivacaine" released to market
1999		Less toxic enantiomer of bupivacaine named "levobupivacaine" released to market
2011	Liposomal bupivacaine	First multivesicular liposomal local anesthetic approved by FDA

group anesthetics would be introduced over the next half century. Amide anesthetics possess an aromatic head which is linked to a hydrocarbon chain by an amide bond rather than an ester. This results in amide anesthetics being more stable and hence less prone to causing allergic reactions as compared to ester anesthetics. As a butyl group homologue of mepivacaine, bupivacaine was initially discarded as it was found to be four times more toxic. Since its introduction in 1965, the nature of the central nervous system (CNS) and cardiac toxicity linked to bupivacaine has been well chronicled. The discovery of mepivacaine's optically active isomers, and the extensive study of their decreased toxicology, led to the selection and development of a pure S-(-) enantiomer ropivacaine in 1996. Levobupivacaine, the S-(-) enantiomer of bupivacaine, was approved by the FDA in 1999 [12] (Table 60.2).

Current Long-Acting Local Anesthetics

Although there are a number of amino-amide anesthetics currently available, two of the most commonly used in the United States include bupivacaine and ropivacaine. Due to their longer duration of action, they have been the most common choice for the prevention and treatment of postsurgical pain by local infiltration, peripheral nerve blocks, as well as epidural and spinal anesthesia. For bupivacaine, the typical concentration ranges from 0.0625% to 0.5%. The alteration in concentration allows for a differential blockade in terms of various degrees of sensory and/or motor blockade. Lower concentrations of local anesthetic allow sensory blockade, while increasing higher concentrations provide motor blockade. The potential for cardiotoxicity with bupivacaine use is usually sufficiently mitigated by appropriate measures taken to minimize systemic absorption. Most adverse reactions are linked to direct vascular injection and infiltration of areas at higher risk of absorption or to slow metabolic degradation by the liver. Treatment of overdose or inadvertent intravascular injection has been reported in both animal and human case reports with intralipid, an intravenous lipid emulsion whose prompt administration can reverse even life-threatening cardiotoxicity. Though the precise mechanism for reversal is unclear, it is possible that the addition of the intralipid acts as a reservoir "sink" which creates a gradient that draws the lipophilic toxins away from the affected tissues. Lipid emulsions may also work by overriding the inhibition of mitochondrial carnitine-acylcarnitine translocase which provide fuel for the myocardium [13–16].

As an alternative to bupivacaine with a greater safety margin, ropivacaine was found to have less cardiotoxicity and possess better sensorimotor dissociation at lower doses. In practice, this results in greater motor sparing than bupivacaine at lower doses. Typical concentrations for ropivacaine are 0.1–1%. The onset and duration of action for ropivacaine are similar to bupivacaine though the former has less variability secondary to its more homogenous composition [17]. As with all non-liposomal local anesthetics, the duration of action has been limited by the redistribution of the anesthetic away from the targeted site.

Table 60.2 Common long-acting local anesthetics and LB

Anesthetic	Max dose	Onset (min)	Duration of anesthesia (h)	Duration of analgesia (h)
2% lidocaine (HCO3 + epinephrine)	7 mg/kg	10–20	2–5	3–8
0.5% ropivacaine	0.3 mg/kg	15–30	4–8	5–12
0.75% ropivacaine	0.3 mg/kg	10–15	5–10	6–24
0.5% bupivacaine (+ epinephrine)	0.3 mg/kg	15–30	5–15	6–30
13.3% liposomal bupivacaine (LB)	266 mg	[a]Variable Analgesia 5 min; anesthesia 30–45+ min	[a]Variable	[a]Variable Up to 72 h
13.3% LB (+ 0.25% bupivacaine HCl up to 50% liposomal dose)	266 mg and 150 mg, respectively	[a]Variable Analgesia 5 min; anesthesia ~30 min	[a]Variable	[a]Variable Up to 72 h

[a]Data on LB directly compared to other amide local anesthetics is limited. Many components may contribute to variable block duration of LB including site of injection, use for local infiltration vs. nerve blockade, technique of injection, and amount of dilution. Most studies have used LB for local infiltration and did not objectively measure sensory block over the entire block duration. There is limited information on the use of LB for regional anesthesia as the primary anesthetic to assess onset and duration of anesthesia

Liposomal Bupivacaine and the Introduction of a New Class of Anesthetics

The most recent development in the evolution of local anesthetics may represent an attractive alternative in the management of postoperative pain. Liposomal bupivacaine (LB), a novel slow-release local anesthetic formulation, encapsulates the local anesthetic by utilizing an innovative delivery system known as DepoFoam®. These multivesicular liposomes consist of hundreds of water-filled polyhedral compartments which are separated by biocompatible, biodegradable, lipid-based vesicles ranging in size between 10 and 30 μm. The bilayered lipid septa provide a stable and reliable platform for the prolonged release of medications. The local anesthetic is encapsulated by DepoFoam® without alteration to its molecular structure and is steadily released over 72–96 h [18–21] (Fig. 60.1).

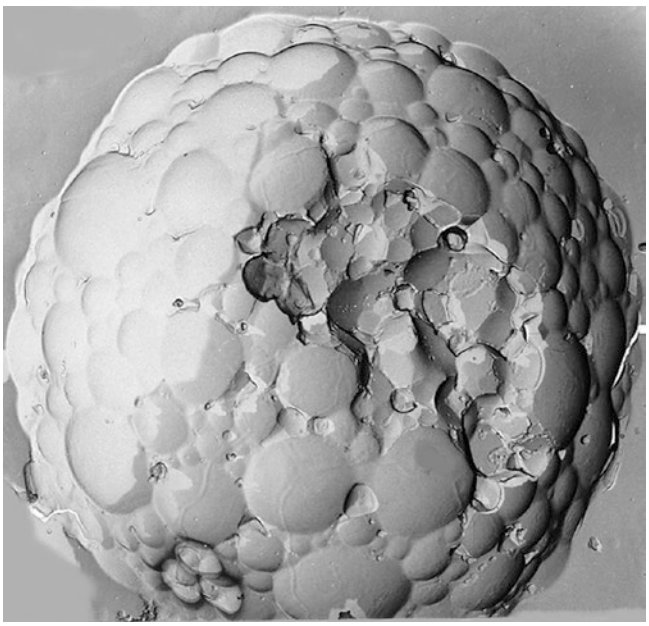

Fig. 60.1 DepoFoam EM. Scanning electron microscopy of EXPAREL® (bupivacaine liposome injectable suspension) with the DepoFoam® technology ©*Pacira Pharmaceuticals, Inc. All Rights Reserved. Used Under License*

Safety

The safety of LB appears to be comparable to other local anesthetic agents. Initial studies by Bramlett et al. found when comparing LB to bupivacaine, both formulations were safe and well tolerated with a low incidence of adverse events [22]. Golf et al., based on application during bunionectomy, found that LB provided superior analgesia and was well tolerated and safe with a slightly higher incidence of medication-related adverse events, most notably postoperative nausea and vomiting [23]. Gorfine et al. concluded in their study of patients undergoing hemorrhoidectomy that a 300 mg formulation of LB was safe [24]. The effect of LB on QTc interval was studied by Naseem et al. who demonstrated that doses up to 750 mg did not cause significant prolongation [25]. Although initial studies evaluating the safety and efficacy were done with patients in soft tissue and orthopedic models, a recent review evaluated six randomized controlled double-blind trials in adult patients that used a single dose of LB for postoperative pain control in a more diverse group of surgical patients. Essentially, this review concluded that LB when used in therapeutic doses was well tolerated, had a higher safety margin, and showed a favorable safety profile compared to bupivacaine and control groups [26]. A Cochrane meta-analysis of liposomal bupivacaine for use in local wound infiltration (10 reports, 1377 participants) also found it to have a comparable safety profile to bupivacaine HCL [27].

Preparation and Application

LB is manufactured as a single-use 20 ml vial, which is 1.3% formulation containing a total of 266 mg of bupivacaine. The bupivacaine contained in LB is a free-base bupivacaine form which differs from other frequently used amide-type, bupivacaine-based local anesthetics which contain the salt form of bupivacaine, bupivacaine HCl. Therefore, 266 mg of bupivacaine free base is chemically the molar equivalent to 300 mg of bupivacaine HCl. Providers should be cognizant of the fact that different formulations of bupivacaine are not bioequivalent even if the milligram dosage is the same. Therefore, it is not possible to convert dosing between LB and other formulations.

Liposomal agents should be injected slowly with frequent aspiration to check for the blood and minimize the risk of intravascular injection. It is important to recognize that LB does not diffuse through tissues in the same manner as conventional bupivacaine. Consequently, meticulous infiltration technique is imperative to ensure best results regardless of regional technique. For surgical site injections, that means using a deep tissue infiltration technique with continuous injection of the anesthetic from the fascia to dermis. Decreased spread means more injections are needed in closer proximity than with traditional bupivacaine. Many surgeons in clinical practice often expand the volume of the injectate up to a total volume of 300 mL with either normal saline (0.9%) for injection or lactated Ringer's solution. Volumes used in clinical practice range from 20 to 300 mL (diluted) depending on the size of the surgical site. The onset of action is longer than with conventional bupivacaine as a natural consequence of the slow release of the anesthetic from the liposomes. The addition of normal bupivacaine HCL to the LB at a ratio that does not exceed 1:2 can hasten the onset of sensory blockade. The addition of greater amounts of bupivacaine or the combination of LB with other unapproved anesthetics or agents can cause the premature breakdown of the liposomal matrix and potentially a dangerous uncontrolled release of the anesthetic.

Contraindications and Precautions

LB is contraindicated in obstetrical paracervical block anesthesia. Although LB has not been used in paracervical blocks, the use of bupivacaine HCl with this technique has resulted in fetal bradycardia and death; hence, it should not be used in this type of block. Furthermore, the manufacturer cautions that there is a potential risk of severe life-threatening adverse effects associated with the administration of bupivacaine; therefore, LB should be administered in a setting where trained personnel and equipment are available to promptly treat patients who show evidence of neurological or cardiac toxicity. Care should be exercised to avoid accidental intravascular injection of LB. Multiple reports have reported convulsions and cardiac arrest following accidental intravascular injection of bupivacaine and other amide-containing products.

The aforementioned studies have shown that LB is a promising drug formulation which can potentially improve the postoperative pain control in surgical patients. However, further studies are needed in both larger patient populations and wider array of patient populations to enhance the current level of knowledge of the drug's advantages and disadvantages and define the areas of best application. Until recently there had been only two studies, both limited by their retrospective nature, on the efficacy and safety of this liposomal formulation in thoracic patients.

Regional Anesthetic Techniques for Thoracic Surgery

Thoracic Epidural Anesthesia

The infusion of local anesthetics, typically bupivacaine or ropivacaine, into the epidural space has been considered the "gold standard" for optimal pain management in postoperative pain after thoracotomy; however, this technique may not be feasible for a number of reasons: contraindications such as those patients with certain antithrombotic agents, systemic heparinization, or local and systemic infection who possess an elevated risk for epidural hematoma or abscess, respectively. Thoracic epidural anesthesia (TEA) has also been shown to have a high incidence of failure, with rates as high as 32% having been reported in the literature [28, 29]. The efficacy of the thoracic epidural is highly operator dependent, and successful catheter placement can be influenced by many factors, such as the patient's body habitus, patient positioning, and anatomical variations. The undesirable side effects of epidural anesthesia, the resultant bilateral sympathectomy, and epidural opioid exposure are numerous and can include postoperative hypotension, decreased pulmonary function, urinary retention, and pruritus [30–32]. Pain management strategies have continued to evolve, and some research has begun to suggest a shift away from systemic opioids and thoracic epidurals toward regional nerve blockade with lower rates of adverse events [33].

Shift Toward More Peripheral Regional Techniques

Alternatives to thoracic epidural have been described with variable success, including techniques which target the paravertebral, intercostal, phrenic, intrapleural, serratus anterior plane, in addition to local wound infiltration. The most enduring argument which supports the continued use

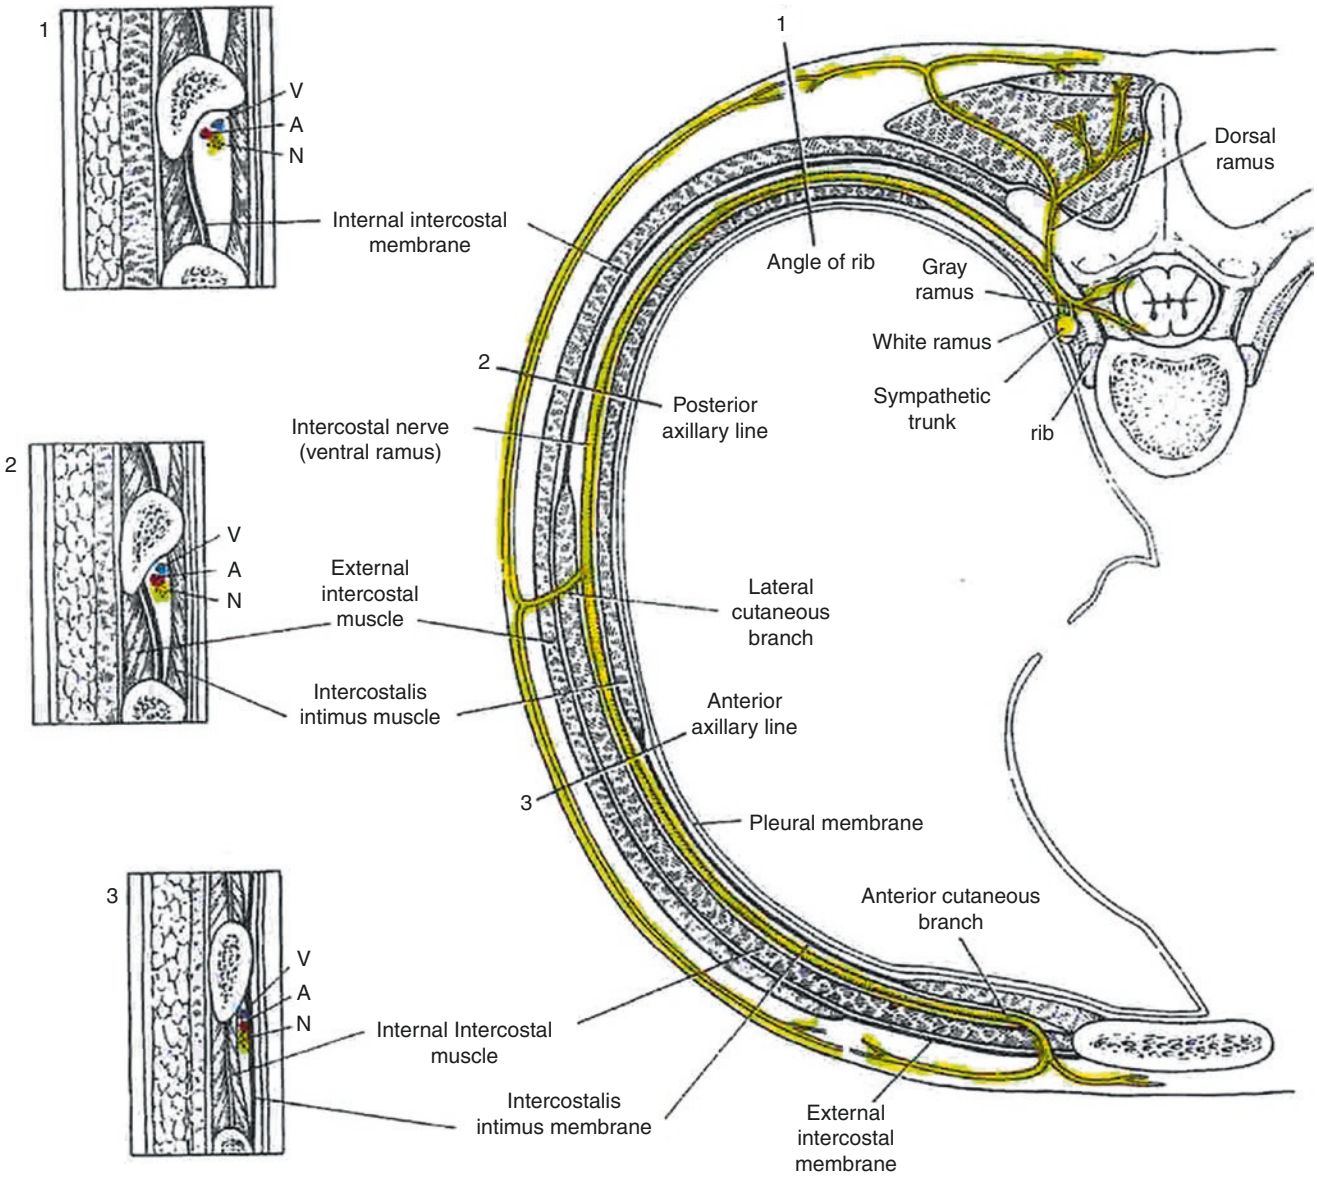

Fig. 60.2 Intercostal anatomy. (Reprinted from Anaesthesia, Dravid and Paul, Copyright (2007), with permission from John Wiley and Sons. (Dravid and Paul [108]))

of thoracic epidurals is its ability to provide analgesia for several days. In contrast, the efficacy of single-shot administration of local anesthetic has naturally been limited to the duration of action for the applied local anesthetic. Anesthesia providers have attempted to prolong the analgesic benefit by utilizing other additives such as corticosteroids, epinephrine, and clonidine or by combining different local anesthetics to the anesthetic with variable success [34]. Perineural catheters can also continuously infuse local anesthetic and thus prolong the duration of regional techniques; however, there are conflicting reports about their ability to appropriately control postoperative thoracotomy pain. Plausible reasons for these conflicting reports are these catheters require greater technical expertise and are prone to migration, kinking, occlusion, and infection [35–38].

At the University of Texas MD Anderson Cancer Center, our pain management strategy for thoracic procedures has undergone a major change over the last few years. For the better part of the last two decades, we have utilized epidurals for postoperative pain management in patients having thoracic surgery. With the introduction and refinement of regional techniques such as paravertebral and intercostal blocks, surgical preference has more often favored the use of these more peripheral blocks in lieu of epidurals specifically for thoracic procedures.

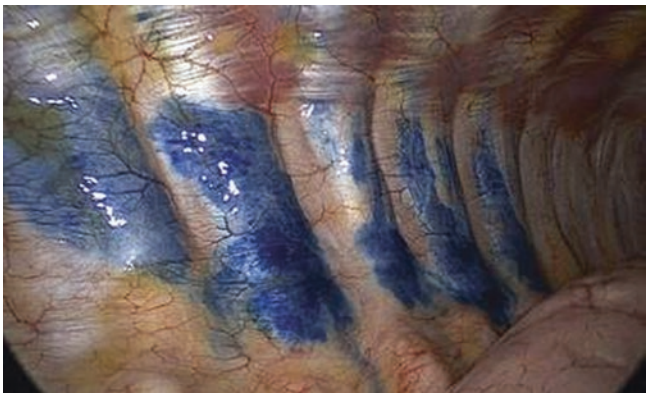

Fig. 60.3 Rice block methylene blue. Posterior intercostal block with LB and methylene blue. Thoracoscopic visualization allows accurate injection of LB into the intercostal space without violation of the parietal pleura. Note that the site of injection is at the level of the innermost intercostal muscles and that the drug tracks medially to the paravertebral space. Methylene blue was added to the LB for purposes of illustrating the extent of subpleural spread only. (Reprinted from The Annals of Thoracic Surgery, D Rice, Copyright (2015), with permission from Elsevier. (Rice et al. [109]))

Thoracic Paravertebral Blockade (Please See Figs. 59.5 and 59.6 from Chap. 59)

First introduced by Hugo Sellheim in 1905, thoracic paravertebral blockade (TPVB) fell out of favor during most of the twentieth century until its reintroduction by Eason and Wyatt in 1979. TPVB has continued to evolve with the use of various landmark techniques and adjuncts such as pressure sensors, fluoroscopy, nerve stimulators and, most recently, ultrasound-guidance. The resultant ipsilateral, segmental, somatic, and sympathetic blockade has become increasingly popular in the treatment of acute and chronic pain [39]. For patients undergoing thoracotomy, several large meta-analyses have concluded that when compared with TEA, TPVB has comparable analgesic benefit, levels of cortisol stress markers, and frequency of major complications but with improved preservation of lung function and significantly less hypotension, nausea and vomiting, pruritus, urinary retention and block failure [40–43].

In the treatment of post-thoracotomy pain, TPVB has traditionally been limited in reliability and duration. Using landmark-based techniques, TPVB has commonly been described as easy to learn and safe though failure and complication rates can be as high as 10% and 5%, respectively [44–47]. The advancement of ultrasound-guided techniques allows for the placement of local anesthetic with greater precision and reliability [48, 49]. Prior to LB, the duration of single-injection TPVB was generally limited to less than 24 h. Despite the correct needle tip position by ultrasound-guided techniques, catheter migration into the adjacent prevertebral, epidural, intercostal, and pleural space remains problematic (see Fig. 60.2) [50]. When compared to percutaneous TPVB, catheters inserted surgically have generally been even less reliable though techniques are quite variable with some institutional success being greater than others [36].

The combination of ultrasound-guided techniques and LB has the potential to substantially improve the reliability, duration, and therefore the practicality of the TPVB in treating post-thoracotomy pain. While the potential for TPVB and LB seems promising, there is currently insufficient data to evaluate the efficacy, safety, and practicality of utilizing LB for TPVB in thoracic surgery. At least one study found that local wound infiltration with LB was similar if not superior to TPVB with conventional bupivacaine following reconstructive breast surgery [51]. With the advent of very long-acting anesthetics, the utility of the TPVB is uncertain. Further studies on post-thoracotomy patients are needed which directly compare the use of LB and TPVB versus other more peripheral regional techniques, such as intercostal nerve blocks, before conclusions can be drawn on the future role of TPVB in thoracic surgery.

Intercostal Nerve Block

Although epidural LB use has been described as apparently being safe in healthy volunteers, more specifically, other than two retrospective studies, LB's safety and efficacy have not been studied in thoracic surgical population. At our institution, posterior intercostal blocks with LB have replaced TEA as the preferred technique for postoperative analgesia in thoracic surgery, with patients reporting lower pain scores and using less opioids (Fig. 60.3).

Depending upon the surgical approach, a five-level posterior intercostal block is either done under direct visualization for open procedures or with thoracoscopic guidance for video-assisted thoracoscopic or robotic-assisted thoracoscopic procedures. Specifically, after the skin has been infiltrated with 1–2 ml of LB, a 12 mm camera thoracoscopy port is introduced at the appropriate site. Using a 22G spinal needle, the surgeon advances the needle over the superior edge of the rib approximately 5–7 cm lateral to the anatomic midline. Meticulous technique is used to advance the spinal needle to the innermost intercostal muscle without disrupting the parietal pleura. This is extremely important so that the local anesthetic remains confined to the intercostal space and is not lost to the pleural space. Typically this injection entails a 2 ml injection of LBs over the superior edges of ribs 6 through 10, but obviously the location of injection can be tailored toward other surgical sites [52]. The remaining volume of LB is injected at the remaining port sites or surgical wounds. Thoracoscopic visualization can significantly enhance the accurate injection into the intercostal space without interrupting the parietal space as local anesthetic can

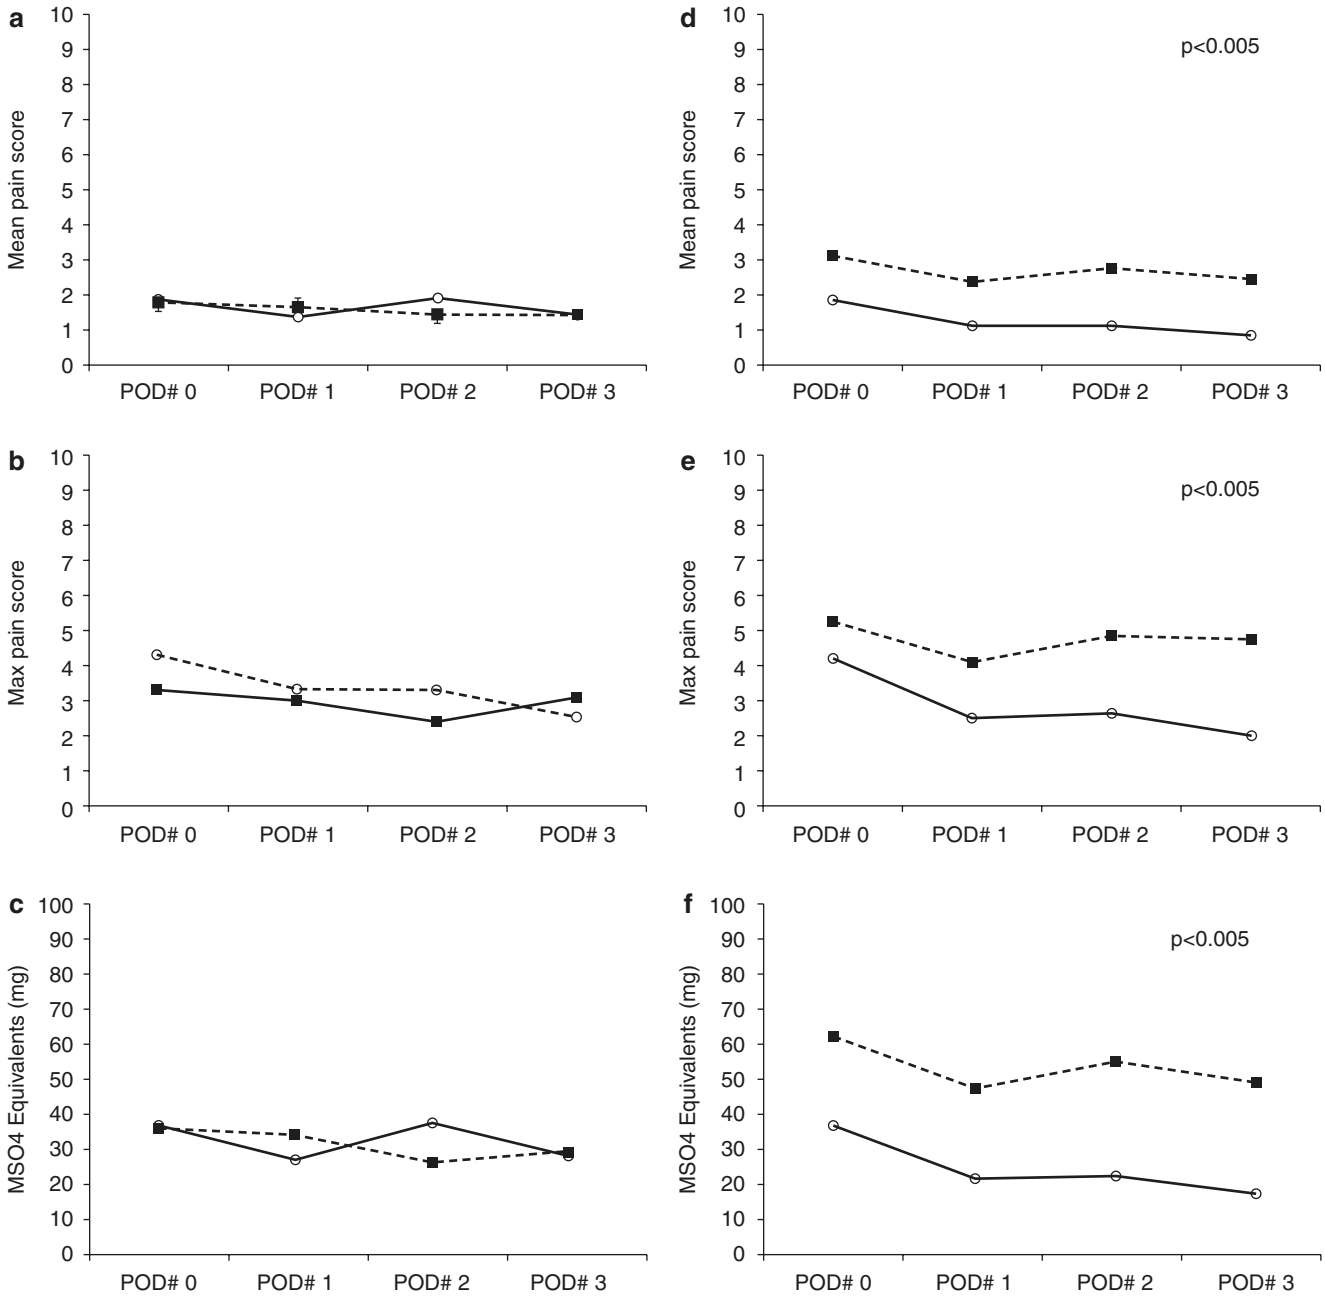

Fig. 60.4 Rice results. The results from one comparison of posterior intercostal block with LB vs. TEA with bupivacaine HCl. Pain scores and narcotic requirements for patients who received (A–C) LB or (D–F) thoracic epidural analgesia. then egress out. Trainees can more easily appreciate the appropriate injection and demarcation of the intercostal space if 2 ml of methylene blue are added to the local injection solution (see Fig. 60.4).

With respect to the local anesthetic solution used for intercostal blocks, many institutions use 0.5% bupivacaine as local anesthetic, although some use 0.25% bupivacaine or 1% lidocaine [53–67]. The rate of infusion is generally 5–7 mL/h for an average-sized adult which typically helps establish five-level dermatomal analgesia to pinprick unilaterally.

Wanting to cover a larger surgical area, surgeons at our institution initially mixed LB with normal saline to create a larger volume to be injected into the surgical site; however, according to the updated prescribing information for LB, some of the surgeons now also utilize 0.25% bupivacaine

combined with LB when performing intercostal blocks. According to the updated prescribing information, it is feasible to administer bupivacaine HCl with LB; however, this may impact the pharmacokinetic and/or physicochemical properties of LB, and this effect is concentration dependent [68]. Therefore, bupivacaine HCl and LB may be administered simultaneously in the same syringe, and bupivacaine HCl may be injected immediately prior to LB as long as the bioequivalent ratio of the dose of bupivacaine HCl solution to LB does not exceed 1:2. The typical 266 mg vial of LB may be coadministered with 150 mg of bupivacaine HCl. The toxic effects of these drugs are additive, and their administration should be used with caution including monitoring for neurologic and cardiovascular effects related to toxicity [68]. Although our institution like many other institutions mixes local anesthetics in clinical practice with the intent of getting faster onset and longer duration of local anesthetics, it should be kept in mind that mixing various local anesthetics at times can lead to variable onset, duration, and unpredictable potency. Likewise, mixing of different formulations of local anesthetics with their respective concentrations and volumes can increase the chances of drug error. Furthermore, despite having negative aspiration, usage of recommended dosage and avoidance of intravascular injections, no currently available method of monitoring can prevent local anesthetic toxicity; therefore, it is incumbent upon the anesthesia provider to be steadfastly vigilant and maintain preparation to treat systemic toxicities that may manifest unexpectedly.

Direct Interpleural Anesthesia

Although first described in 1984, interpleural blockade via the introduction of local anesthetic in between the parietal and visceral pleura has not gained widespread usage [69]. An epidural catheter is placed in the pleural space through a 16 Tuohy needle after the patient is placed in the lateral position with the operative side up. The site of insertion is in the eighth intercostal space approximately 8–10 cm from the posterior anatomic midline with the needle being introduced at 30–40° angle to the skin. The bevel of the Tuohy needle is faced upward as the needle is advanced over the rib and as the parietal pleura is entered. The plunger of the syringe may move passively inward due to the negative pressure in the pleural space during inspiration. A multi-orificed epidural catheter is then advanced 5–6 cm into the pleural space, and after negative aspiration, local anesthetic can then be injected.

Typically, bupivacaine is rebolused in intermittent boluses at either 4, 6, or 8 h; however, there are institutions which use a constant infusion of bupivacaine [56, 70–79].

The block's potential for several different types of complications has limited its use. For instance, the most common complication is that of a pneumothorax described in 2% of the patients [80]. Other complications described include pleural effusions, Horner's syndrome, infection, catheter displacement or rupture, and even toxic symptoms when the local anesthetic is absorbed systemically. More recently, phrenic nerve paralysis has been described as an additional complication [81]. Patient position, particularly when a patient is sitting upright, as well as site of lowest chest tube placement most likely influences the pooling of local anesthetic near the diaphragm. The decrease in forced vital capacity, especially if done bilaterally or in patients with compromised respiratory function, can further worsen respiratory status. This impairment in pulmonary function from diaphragmatic weakness is a plausible explanation for the significantly worse pulmonary function with interpleural analgesia when compared with paravertebral analgesia [56].

Serratus Plane (SAP) Block

Distal to the lateral cutaneous branches of the intercostal nerve, sensory divisions pass through the muscles of the chest. With ultrasound guidance, the practitioner can achieve analgesia of different regions of the chest by injecting local anesthetic between those muscle layers. Injection between pectoralis major and minor, the so-called Pecs I and II blocks, achieves somatic blockade of the anterior chest. Injection of anesthetic superficial to the serratus anterior muscle adjacent to the fourth and fifth intercostal spaces along the midaxillary line results in anesthesia of the lateral chest. The size of distribution is related to the volume of the injectate. With the injection of 20 ml, the area of sensory deficit covers from the scapula to the nipple, T4–T9. The initial study was small and simply demonstrated the application of the block and the subsequent sensory block and spread of local anesthetic by MRI [82]. The utility of the SAP block for thoracic surgery has yet to be determined. It has been noted that the SAP block likely doesn't cover the posterior primary rami, the anterior cutaneous branches of the intercostal nerve and afferents of the autonomic nervous systems [83, 84].

The SAP block may be best suited for procedures with anterolateral incisions such as anterior muscle-sparing thoracotomy or anterolateral thoracotomy, though these may need to be supplemented with local wound infiltration as the incision approaches the limits of sensory blockade. The block did not extend past the inferior angle of the scapula, so this block may not be appropriate for posterior muscle-sparing thoracotomy, as is common at our institution, or thoracoscopic surgery with more posterior incision sites. It may be useful as a rescue technique for patients with a failed thoracic epidural or those experiencing pain at the chest tube

site. One such case has already been reported in a patient status post esophagectomy whose epidural had failed the pain was successfully treated by the SAP block with catheter-based infusion [85]. Little research to date has validated this technique for surgery in comparison with other approaches.

Local Surgical Site Infiltration

The rationale for wound infiltration with local anesthetics is to target the most proximal and selective site responsible for the perception of pain, the peripheral nociceptors. With direct infiltration into the surgical site, the local anesthetic can simply and effectively provide analgesia for a variety of surgical procedures. Furthermore, infiltration in this manner is usually not associated with severe side effects such as local toxicity, wound infection, and impaired wound healing [86, 87]. Long-acting amide local anesthetics such as bupivacaine and ropivacaine have been shown to provide superior pain control over opioids and are commonly used in the postoperative period for infiltrative, regional, and neuraxial blocks [88–90]. Until recently, the duration of analgesia with infiltration into the surgical site in single doses was limited by the specific local anesthetic used. As mentioned earlier, LB diffuses within tissue less than conventional local anesthetics. A dose can be diluted to make large volumes that can then be injected using a deep infiltration technique. At our institution, some surgeons have found increased success by injecting LB invan-voverlapping, crosshatch fashion as a means to avoid patchy block (Table 60.3).

Table 60.3 Administration of liposomal bupivacaine (LB)

Original preparation	13.3% LB in 20 cc vial
Maximum dose of LB	266 mg
Maximum dilution	Up to 1:14 ratio with normal saline (NS), down to concentration of 0.89% OR 20 cc LB diluted with 280 cc NS for total volume of 300 cc
Coadministration with bupivacaine HCl	May be mixed with bupivacaine HCl only; for above dilution, up to 150 mg (60 cc of 0.25% bupivacaine HCl) may be substituted for NS
[a]Examples of preparations used for thoracic surgery at MD Anderson Cancer Center	20 cc undiluted LB given at the time of incision for intercostal blocks or diluted with 30 cc 0.25% bupivacaine HCl to cover additional sites
[a]Examples of preparations used for larger surgical site infiltrations at MD Anderson Cancer Center	20 cc LB with 30 cc of 0.25% bupivacaine HCl and 50 cc of N or 20 cc LB with 60 cc of 0.25%

[a]At our institution, practice patterns vary widely based on surgical service, individual provider, and procedure

Phrenic Nerve Block and Other Blocks Targeting Ipsilateral Shoulder Pain (ISP)

The significance of post-thoracotomy ipsilateral shoulder pain (ISP) differs from incisional thoracotomy pain in quality, location, etiology, and treatment. It is a common occurrence, affecting up to 85% of patients following thoracic surgery [91, 92]. The pain can be severe despite the well-functioning TEA. The exact distribution of pain is variable but lies within the C4–C5 dermatomes, sharing a common innervation with the phrenic nerve. The duration of pain typically lasts for hours but can persist for days or longer, with some patients experiencing chronic pain more than 6 months after surgery [93, 94].

Etiology

ISP is correlated with the extent of pleural disruption, size of thoracotomy incision, transection of major bronchial airways, patient BMI, and length of surgery [95, 96]. Currently, no pharmacological or regional treatment exists which can completely eradicate or prevent the pain. ISP is considered a type of pain that is usually referred from the afferents of the phrenic nerve. Originating from the third, fourth, and fifth cervical nerve roots, the phrenic nerve contains sensory, motor, and sympathetic fibers. It provides the only afferents to the diaphragm and afferents for the pleura and pericardium of the thorax as well as the diaphragmatic peritoneum. ISP is most commonly thought to be the result of phrenic nerve impulses brought on by intraoperative pleural irritation by intrathoracic dissection, bronchial transection, and chest tube placement.

The precise etiology of post-thoracotomy ISP remains debatable. While targeted phrenic blockades are usually effective, they are not universally effective at eliminating ISP for all patients. A series of case reports concluded that there may be a dual etiology of ISP wherein some patients' pain is caused by phrenic nerve afferents, while other patients' ISP is from direct shoulder ligament strain [95]. In one study, suprascapular block performed postoperatively had no effect on patient's pain [97]. When compared directly to peri-phrenic diaphragmatic fat pad infiltration, suprascapular nerve block was significantly less effective at preventing ISP [93]. This suggests that ISP is not related to the strain of the acromioclavicular or glenohumeral joints for most patients unless localizing signs of musculoskeletal shoulder pain are present [95, 98].

Though representing a minority of patients with ISP, patients presenting with pain localized to the shoulder, elicited with palpation or movement, benefited from suprascapular nerve block 85% of the time [98]. Unlike the interscalene nerve, the suprascapular is not adjacent to the phrenic and therefore is not associated with concomitant phrenic blockade and diaphragmatic palsy.

Treatment

NSAIDs such as intravenous diclofenac or ketorolac can be effective in reducing ISP, but they are not universally effective and should be used with caution in certain patient populations such as those with chronic renal insufficiency [99]. Neither standard TEA nor intrapleural infusion is typically effective at preventing ISP; however, lower rates have been associated with epidural catheter placement above T5 [100, 101]. Higher thoracic catheters may provide enough local anesthetic spread for a sensory blockade of phrenic nerve afferents. The resultant hypotension and decreased pulmonary function from higher epidural blocks may limit this approach in patients with low cardiopulmonary reserve.

Scawn, Pennefather, and colleagues demonstrated that injection of lidocaine into the diaphragmatic periphrenic fat pad at the end of surgery reduced the incidence of ISP for up to 2 h [91]. The injection of ropivacaine 0.2% provided a relatively selective sensory blockade which significantly reduced the incidence (32% vs. 64%) and delayed the median onset (36 vs. 16 h) of ISP with no difference in postoperative arterial blood gases [102]. It has been suggested that targeting of the phrenic nerve at alternative locations, such as the periphrenic fat pad around the hilum, may affect the efficacy of the block, but such variations have not been validated and require further study [103].

Others have shown that post-thoracotomy ISP can be significantly reduced by interscalene nerve blockade. Barak et al. employed an interscalene block with bupivacaine to reduce ISP though the effect was limited to less than 24 h [104]. The exact mechanism of pain relief from interscalene block is unclear because of the high incidence of simultaneous phrenic nerve blockade despite the use of relatively low volumes of local anesthetic and ultrasound guidance [105]. The same is true for supraclavicular nerve block which also has a high rate of simultaneous phrenic nerve involvement. The use of an ultrasound-guided supraclavicular approach to perform a targeted phrenic nerve block with ropivacaine had a 65% relative rate reduction of ISP in patients undergoing lobectomy or pneumonectomy [106]. A phrenic nerve catheter was placed, but the ISP was most severe on the day of surgery. There was no difference in rescue analgesics used on postoperative day 1. By specifically targeting the phrenic nerve for blockade, the block may more effectively reduce ISP without as much of the associated upper extremity motor weakness.

Phrenic nerve blockade is not without risks. Hemidiaphragm phrenic nerve palsy results in a decrease in vital capacity, forced expiratory volume per second, and maximum inspiratory flow [105]. These effects are well tolerated even for those with preexisting pulmonary disease but may cause respiratory distress in patients with contralateral diaphragm dysfunction. Long-acting local anesthetics such as LB should therefore be used with caution in this patient population. The use of catheter-based ropivacaine, or the development of liposomal ropivacaine, may have the advantage of more selective sensory blockade and therefore less phrenic nerve palsy.

Many of these studies utilized the relatively short-acting lidocaine, and no studies to date have evaluated agents with a duration of action exceeding 24 h. The use of short-acting agents has potentially limited the benefits of decreased ISP. The duration of ISP is variable however, and the use of long-acting agents may not be beneficial for many patients. Further prospective studies are needed to directly compare the safety and efficacy of the aforementioned techniques and to determine whether long-acting modalities such as catheter-based infusions or liposomal amide anesthetics are beneficial. Until then, practitioners should use their clinical judgment to devise a treatment strategy for ISP that is most appropriate for their patient population.

Conclusion

In summation, it is well recognized that optimal pain management for thoracic surgery remains challenging given the multiple mechanisms that contribute to postoperative pain. Combining minimally invasive surgery with multimodal, multidisciplinary regional and pharmacological approaches to analgesia can mitigate pain and suffering by acting at various levels of the nervous system. This holistic and comprehensive pain management strategy can improve overall patient safety and satisfaction by providing a higher level of postoperative analgesia while reducing the undesired side effects of narcotic usage, such as nausea, vomiting, constipation, and respiratory depression. Furthermore, improving postoperative pain control can impact hospital stay, reduce the rates of postsurgical complications and readmissions, prevent opioid dependence, and, potentially, reduce mortality [107]. At our institution, we have successfully incorporated long-acting local anesthetics into surgery-specific, evidence-based treatment protocols which utilize multimodal analgesia such as nonsteroidal anti-inflammatory drugs, N-methyl-D-aspartate (NMDA) antagonists, and peripheral nerve blocks. Although novel long-acting local anesthetic such as LB has created excitement among providers and may represent a significant advancement in the evolution of local anesthesia, it should be remembered that they are not a panacea but rather a component of a comprehensive pain strategy. Moreover, given the limited number of case reports and studies available specifically in the thoracic surgery population, further studies are warranted to better understand not only the efficacy but also the long-term safety profile of long-acting local anesthetics such as LB.

Case Discussion

A 75-year-old female is scheduled for a right VATS requiring multiple wedges due to metastatic colon cancer. Past medical history is significant for obesity (BMI 47 kg/m^2), hypertension, stable coronary artery disease which is medically managed, and obstructive sleep apnea for which patient uses CPAP nightly. Patient stopped smoking 2 weeks ago but has a 100 pack-year smoking history. The patient received tramadol XR 300 mg PO and celecoxib 200 mg PO as part of her ERAS preemptive regimen. Pregabalin was held to avoid postoperative sedation given her history of sleep apnea. Additionally, the surgeon performed a deep tissue injection at the incision sites using a total of 40 cc of a solution made of 20 ml of 1.3% LB mixed with 20 ml of 0.9% sterile normal saline. During the course of the surgery, vigorous surgical bleeding required conversion to open thoracotomy incision. As the surgery is concluding, patient is administered 1 mg of hydromorphone for tachypnea. The patient wakes up in extreme pain from the thoracotomy incision site.

1. How could the risk of insufficient local anesthetic coverage been decreased in this case?
   (a) The LB should be diluted in order to achieve an adequate volume to cover the planned surgical sites along with the most common contingencies. A maximum ratio of 14:1 normal saline to LB can be used to achieve a volume of 300 ml though typical amounts are in the range of 40–80 ml. As mentioned previously, bupivacaine HCl is the only local anesthetic not contraindicated in patients receiving LB. The bupivacaine HCl to LB ratio should not exceed 1:2 which corresponds with a maximum dose of 150 mg bupivacaine HCl for 266 mg LB. Best practice would be to administer a portion of the diluted LB around the time of incision to manage intraoperative pain (within 4 hrs after preparation in a syringe) and to inject the remainder of the solution upon surgical closure.
2. What additional medications can be utilized in combination with LB?
   (a) Other analgesics such as intravenous acetaminophen, dexmedetomidine, ketamine, ketorolac, and narcotics are safe to administer following LB administration. At our institution, ketorolac is routinely given to our thoracic surgery patients during skin closure provided patient does not have contraindications such as compromised renal function and high risk for postoperative bleeding. Other local anesthetics such as lidocaine are absolutely contraindicated in a patient who has received liposomal bupivacaine.
3. Are there any additional regional blocks which can be used in the setting of LB usage?
   (a) At our institution, we do not administer any local anesthetics, including bupivacaine HCl, for several days following the use of LB. That said, it may be safe to administer an appropriately low dose of bupivacaine HCl by TEA, TPVB, or intercostal block in the case of a failed LB surgical site injection. There is insufficient evidence to date on the use of regular bupivacaine HCl to supplement missed pain areas in the setting of the recent administration of LB. Though risk of bupivacaine toxicity from a slow-release LB is probably low, it is difficult to know how high free bupivacaine concentrations may rise in the setting of intravascular injection or in combination with bupivacaine HCl administered by other regional techniques. The risk benefit analysis has to be considered by the providing anesthesiologist for the given patient and situation.
4. What if the surgeon initially administered LB by five-level posterior intercostal nerve block? The thoracotomy incision and chest tube site are well covered by the block, and the patient has minimal pain upon emergence. The patient is taken to the PACU, and the blood pressure is noted to be 85/55 mmHg with a heart rate of 55 bpm.
   (a) Depending on the site of injection and volume of injectate, significant spread of local anesthetic can occur from the intercostal space to the TPVS and epidural space. Consequently, relative hypotension and bradycardia can occur in the setting of posterior intercostal blockade with LB. At our institution, this presentation is most common following esophagectomy when the posterior intercostal blocks are performed within a few centimeters of the TPVS. Correctable causes of hypotension such as relative hypovolemia and cardiac dysfunction should be ruled out. If the patient is comfortable without signs or symptoms of cardiac or respiratory distress, a colloid is usually given as the blood pressure often will have some response to volume expansion even in the setting of minimal blood loss. With continued monitoring and expectant management, the relative hypotension usually resolves within the first 6-24 h following surgery.

Chronic Post-thoracotomy Pain

61

Peter MacDougall

Key Points

- Chronic post-thoracotomy pain is a common side effect of thoracic surgery and affects up to one half of patients undergoing this procedure.
- More than one half of CPTP is neuropathic in nature.
- The prevalence and intensity of CPTP may decrease over time.
- Pain may begin in the perioperative period or during the first few months after surgery.
- CPTP has a profound impact on patient function. It impairs sleep and daily activity. A significant portion of patients continue to take analgesic medications more than 2 years after the surgery.
- Less traumatic methods of opening and closing the chest wall may reduce CPTP.
- Neuroinflammation and alterations in the hypothalamic-pituitary-adrenal axis may play key roles in the establishment and maintenance of CPTP.
- Inter-professional and interdisciplinary programs to identify high-risk individuals and optimize perioperative pain management and chronic pain management may reduce the prevalence and impact of CPTP.
- Given the scope and impact of CPTP, it would be prudent to discuss this risk with patients in the preoperative period and consider adding it to consent for surgery.

Introduction

Entry to the human chest cavity has long been fraught with challenges for the anesthesiologist, the surgeon, and the patient. As we know, from the discussions in this text, these challenges include a multitude of physiologic perturbations before, during, and after the surgery. In addition to the overt physiologic changes, chronic pain may present an ongoing challenge for the patient. In this chapter we will review the complex phenomenon of chronic post – thoracotomy pain (CPTP), its incidence and prevalence, causes as we know them, prevention and treatment and what the future may hold.

As we will see, there has really been a perfect storm that has led us to this point. It can be traced back more than 70 years to the end of the Second World War. Thousands of young men and women returned home from fighting and working to support the war effort. They produced the largest cohort of children in history – the baby boomers. That generation, in turn, became the most prosperous, most educated, and most longest lived group of people in human history. At the same time, advances in surgical treatment and anesthetic care combined to increase the number of illnesses successfully treated with surgery. As this generation grew older, they also developed sequela of long life in the form of chronic illnesses. Many of these would, in turn, require such surgical treatment. We are still learning of the sometimes unexpected consequences of these surgeries.

Chronic pain after surgery has been recognized as a sequela of surgery for more than two decades. Crombie and colleagues in 1998 [1] initially described the scope of the problem and reviews over the next 10–15 years [2, 3] highlighted this condition. All forms of surgery can be viewed as an injury and such injury creates the risk of a chronic pain syndrome [1–17]. Rates of chronic pain from different types of surgery range from as high as 85% after amputation to as low as 6% after cesarean section [2, 3]. Chronic pain after surgery may range in intensity from minor to such severity

that it interferes with the persons' daily activity and their ability to return to their baseline level of function [2]. A large cross-sectional population study of more than 12,000 people in Norway reported a prevalence of moderate to severe chronic postsurgical pain in 18% of those reporting surgery more than 3 months earlier [16]. Similarly, a large prospective observational study in Europe followed patients for 12 months [17] and reported overall rates of moderate to severe chronic pain after surgery at 6 months was 16% falling to 11.8% at 12 months. An important finding in the latter study was the decline over time of the rate of chronic postsurgical pain. Given the aging of our population and concomitant increasing numbers of people having surgery, the impact of such a complication cannot be ignored. As we will discuss, the impact of chronic pain on cost, function, and risk of morbidity and mortality is significant.

As noted, chronic pain after surgery is a frequent occurrence. It can be a complication of surgery in any body region and outranks trauma as a cause of ongoing pain [1]. Surgeries most commonly associated with significant rates of CPSP include breast surgery, limb amputation, thoracic surgery, cardiac surgery, abdominal surgery, and hernia surgery [2–17]. The impact of the sequelae of surgery cannot be overstated. While many of these surgeries are increasingly common as we age and have an impact on our ability to function with increasing age, some such as hernia surgery are more common in younger people and may have a much broader effect by preventing a young person from working and contributing to society. Perhaps of greater immediacy are recent findings that chronic pain is significantly related to suicidal ideation [18, 19]. Suicidal ideation was noted to be more closely related to the chronicity of the pain and psychological factors rather than the intensity of the pain or instability to incapacitate the person. Most of the factors related to suicidal ideation were modifiable risk factors [19]. Therefore, chronic pain is more than an inconvenience. It is a potentially modifiable, life-threatening condition.

Characteristics and Prevalence of Chronic Post-thoracotomy Pain

Chronic pain after thoracotomy has been described as one of the most intense post-operative forms of pain. This pain has been described most commonly in the area of the thoracotomy scar [20, 21]. It may also be found in the ipsilateral pectoral area, scapula, and the ipsilateral arm and shoulder [20]. It is usually described as a burning or numbness over the incision site [20–22]. Pain is also described as a cutting, drawing or tender pain [23]. The pain may be constant or intermittent in nature and is often exacerbated by such factors as lifting heavy objects. It has also been described as responsive to damp weather or rapid changes in weather [20, 21].

Of the pain experienced by those with chronic pain, neuropathic pain is the most devastating form. Characterized by burning, lancinating, sharp, or dysesthetic pain, it is the culmination of changes resulting in peripheral and central sensitization [24–26]. Maguire and colleagues [27] were among the first to report symptoms of neuropathic pain in CPTP. They reported that the prevalence of individual neuropathic symptoms varied from 35% to 85% among patients with CPTP. Steegers et al. [28] studied the type of pain experienced by those having CPTP and noted that half of the patients with CPTP had neuropathic components to their pain. Of those with CPTP, 23% had definite neuropathic pain, and 30% of patients with CPTP had some component of neuropathic pain. Similar results were noted by Hopkins et al. [29]. They reported that of patients with CPTP, 30% had neuropathic symptoms only and overall almost 55% had pain and neuropathic symptoms. Mongardon et al. [30] noted that approximately 26% of patients with pain 1 year after thoracotomy had neuropathic symptoms. These studies highlight the severity of the pain suffered by a significant portion of those with CPTP.

A number of studies have examined the prevalence of CPTP after thoracic surgery. One of the earliest and most influential studies in this area was that of Katz et al. [31] who demonstrated that up to 50% of patients had long-term pain after thoracotomy. Further studies have confirmed the high rate of chronic pain after thoracotomy [20, 21, 27, 28, 30–36]. Over the years the rate of CPTP has remained surprisingly constant at about 50%. Studies of the impact of less invasive video-assisted thoracoscopy have produced variable results. Steegers et al. [28] reported a slightly higher rate of CPTP in patients having VATS versus those having open thoracotomy (47% vs 40%). More recently Shanthanna et al. [36] reported rates of CPTP of 35% and 54% for VATS and open thoracotomy respectively. Hopkins et al. [29] reported a rate of CPTP among patients having VATS or thoracotomy at 45.3% and 54.7% respectively. This difference did not reach statistical significance. Ochroch et al. [37] reported a 21% rate of CPTP after muscle-sparing thoracotomy with aggressive epidural analgesia. This group [38] reported a similar rate in a study of muscle-sparing vs posterolateral thoracotomy with aggressive epidural analgesia. Peng et al. [39] reported a CPTP rate of 24.9% after 3 months. It is worth noting that although the rate of CPTP appears to hover at about 50%, the rate of severe CPTP is much lower, reported recently at 7–8% 1 year after surgery [27, 35].

The time course of CPTP does not appear to be static. A number of reports have indicated that the prevalence of CPTP gradually decreases over time [27, 39–41]. In addition, the intensity of the pain seems to gradually decrease over time [29, 35]. Studies tracking patients for a number of years indicate that surviving patients tend to gradually improve with respect to the impact of pain on their lives [37,

41]. This does not seem to be true, however, of neuropathic pain [39]. Of particular interest is a report by Hetmann et al. [35]. This study followed 97 patients for 12 months after thoracotomy. While they report that the rate of CPTP is approximately 50% at 6 and 12 months, they note that of the patients not reporting pain at 6 months 20% reported pain at 12 months and of those who reported pain at 6 months 11% did not report pain at 12 months. These results suggest that there are processes continuing well after surgery that contribute to CPTP.

The Impact of Chronic Post-thoracotomy Pain on Function

Chronic pain has significant impact on our society as a whole. Stewart et al. [42] estimated that common pain conditions in the USA were responsible for $62.2 billion per year in losses from lost productivity. This impact is not limited to the wealthy countries as Jackson et al. [43] demonstrated that chronic pain contributed significantly to the global burden of disease in countries with low and middle incomes. Chronic pain in this setting was, not surprisingly, more prevalent in the elderly persons and in workers. Further, a survey of chronic pain in Europe and Israel, countries with robust economies, indicated that almost 1/5 persons suffer from moderate to severe chronic pain [44]. Of those, 21% were also diagnosed with depression, 61% were less able or unable to work, and 60% visited their physician 2–9 times in the preceding 6 months. Fletcher et al. [17] used telephone and e-mail to review more than 3000 patient s in 11 European countries after surgery. Chronic postsurgical pain was reported as moderate in 9.6% and severe in 2.2% of respondents. It is evident that the social and financial burden of this illness is large and likely to grow as the population ages.

The impact of CPTP on individual function is also significant. Chronic pain affects nearly every aspect of daily life. It interferes with the ability of the patient to sleep, work, and interact with others. As such, it has a profound impact upon family life, emotional health, and relationships with friends and co-workers. A number of studies have investigated the impact of this pain condition on function after surgery [20, 37, 38, 45–48]. Persons with chronic pain have lower rates of self-rated health and indicators of increased morbidity and mortality [46–48]. It may also be related to abnormal immune function and changes in stress regulatory mechanisms in the hypothalamic-pituitary-adrenal axis [49–51]. It is closely associated with depression, and there is evidence that suicide risk is significantly increased in persons with chronic pain. Tang and Crane [18] reported that persons with chronic pain have a significantly increased risk of death by suicide. This risk is further borne out by a recent study demonstrating greater risk of suicidal ideation among patients with chronic pain [19].

In 1999 Pertunnen et al. [20] studied 111 patients following thoracotomy and noted that half of patients were having difficulties with normal daily life 12 months after surgery. They also noted that 25–30% of patients had sleep disturbances. Hopkins et al. [29] studied patients who underwent both open thoracotomy and VATS and assessed pain, neuropathic symptoms, symptom distress, mental health symptoms, and quality of life. Patients with CPTP were significantly younger than those without CPTP (average age 65 vs 71 yrs). Patients with CPTP had more symptom distress and lower quality of life [29]. Kinney et al. [52] examined 110 patients involved in a study of preoperative gabapentin for acute post-operative pain 3 months after thoracotomy. Of those 68% had pain at 3 months, and 16% were continuing to use opioid analgesics. The pain group reported lower scores in physical functioning, bodily pain, and vitality. Similar data was also reported by Maguire et al. [27]. Of more than 600 patients queried, 45% reported that pain was their most significant problem, 40% stated that it limited their daily activities, and 40% continued to take analgesic medications. The presence of a neuropathic component to the pain was also noted to lead to worse outcomes [27].

The factors which play a role in the development of disability related to pain and the risk of suicidality related to chronic pain have been examined. Katz et al. [33] utilized a number of pain and disability measurement devices to examine these factors. They determined that pain intensity and emotional numbing predicted pain disability at 6 months after surgery. Later results suggest that over time there is a decoupling of pain intensity and pain disability over the ensuing 6 months. Their results also suggest that pain disability is more closely related to post-operative factors than to preoperative factors or acute movement-related pain. Racine et al. [19] studied suicidality-related chronic pain. They determined that male gender, longer pain duration, high anger levels, feelings of helplessness, greater pain magnification, and being more depressed were significantly independent predictive factors of suicidal ideation. Feelings of better mental health were related to a reduced risk of suicidality. These findings were particularly interesting as many of the negative predictive factors are potentially modifiable [19].

Factors Influencing the Development of Chronic Post-thoracotomy Pain

Pain Before and After Surgery

In the search for factors that may predict long-term pain, pain prior to surgery is clearly associated with the development of chronic post-operative pain states [6, 12, 13, 34, 35, 38, 53–57]. A relationship between preoperative pain and

chronic post-operative pain has been demonstrated in hysterectomy [55, 56], post-amputation pain [12, 13], herniorrhaphy [6, 14, 54], and CPTP [34, 35]. Hoofwijk et al. [58] studied more than 900 patients having surgery. Acute post-operative pain, preoperative pain, and preoperative analgesic use were identified as predictive of chronic post-operative pain. Hetmann et al. [35] studied 170 patients undergoing thoracotomy and noted that preoperative pain and dispositional optimism were predictive of CPTP. This group reported again [34] on 97 patients undergoing thoracotomy. They reported that 50% of those reporting CPTP at 6 months and 48% of those reporting CPTP at 12 months had preoperative pain. Niraj et al. [59] reviewed the records of more than 500 patients and followed with a questionnaire and telephone review. Poorly controlled pain was a key predictor chronic pain at 6 months. These results are supported by the findings of Kinney et al. [60]. In a database study of 66 patients presenting to a tertiary care, pain clinic indicated that those patients who used more opioid in the immediate post-operative period were more likely to have CPTP.

Genetic Factors

Since Watson and Crick first identified the double helix in the 1950s, there has been a tremendous increase in our understanding of the genetics of human illness. The last decade has seen some of that attention turn to the enigma of pain. Genetic variability may affect pain in many ways. These may include the susceptibility to pain, how pain is manifested, and how it is treated. Variants of the catecholamine-O-methyltransferase (COMT) gene have been demonstrated in a number of studies to be linked to the risk of developing pain [58, 61–63]. George et al. [62, 63] have demonstrated that a link between psychosocial constructs such as pain catastrophizing and genetic variability can be predictive of pain outcomes after shoulder surgery. They also identified pain-modifying genetic variants, KCNS1, ADRB2, and GCH1, linked to preoperative kinesophobia, post-operative depression, and anxiety, respectively. Polymorphisms in this gene have been shown to be related to back, but not leg, pain intensity in persons undergoing discectomy [64, 65].

Genetic variability can affect the way that we respond to treatment in a number of ways. The pharmacodynamics and pharmacokinetics of pain treatment are governed by our genetic makeup. Opioid medications are the most studied drugs in relation to pain. Genetic polymorphism can have an effect on transport of the drug across cell membranes [66]. Fentanyl, methadone, and morphine transports into the brain are affected by polymorphism in the ABCB1 gene. Metabolism of prodrugs such as codeine and tramadol are affected by variability in the type of CYP2D6 expressed in the liver [61, 66–68]. Expression of the CP2D6 variants determines the amount of active drug produced by the liver.

Expression of the μ-opioid receptor, a product of the OPRM1 gene is related to the response to opioid medications. A number of studies have demonstrated that this gene is highly variable [58, 66, 68]. This variability is correlated with pain response to opioids and also to the susceptibility to dependence.

These are but a few examples of genetic variability playing a role in the development of pain and the treatment of pain. Much more work is necessary, but the science of pharmacogenomics, targeting drugs to individual genotypes, is growing rapidly. Ultimately, this will allow us to be able to predict who is likely to have pain after surgery, how best to treat it, and who may develop dependence on the medications use to treat the pain.

Anesthetic Factors

Anesthesia has at its heart the prevention of pain in the surgical and perioperative period. Song et al. [69] conducted a prospective, randomized, controlled trial of TIVA vs inhalation anesthesia for 366 patients undergoing thoracotomy. They found a significant difference in CPTP at 3 and 6 months. No difference was noted in acute pain. Although these findings are compelling, the results have not been repeated in other settings.

Post-operative pain control has been identified as a factor in the development of long-term pain after surgery [31, 40, 70]. Several options are available for management of acute post-operative pain. These include regional anesthetic techniques such as thoracic epidural analgesia (TEA), paravertebral blockade (PVB), intercostal blockade, and serratus anterior plane blockade (SAP). Intravenous patient-controlled analgesia (PCA) and oral analgesics are commonly utilized in the perioperative period. Adjunct pain management may involve such modalities as transcutaneous electrical nerve stimulation (TENS).

A recent Cochrane review of pharmacotherapy for prevention of chronic pain after surgery reported that there was modest support for the use of ketamine [71]. Similarly, McNicol et al. [72], in a meta-analysis of studies of ketamine for the prevention of chronic postsurgical pain, found only a modest effect of ketamine in reducing chronic pain after surgery. Interestingly, this result was only present in studies of intravenous and not epidural ketamine [72]. In a randomized controlled trial of S(+) ketamine in the perioperative period, Mendola et al. [73] demonstrated an improvement in perioperative pain control, but this did not translate into reduced rates of CPTP.

Other medications have also been evaluated for efficacy in preventing acute and chronic pain after thoracotomy. Gabapentin was studied in a randomized trial of 120 patients

[52] and reported to have no significant effect on acute or chronic post-thoracotomy pain. However, a small randomized study of 50 patients compared pregabalin for 2 days beginning in the perioperative period with as needed diclofenac [74]. This study reported a significant reduction in CPTP at 24 weeks. Similarly, a small trial of intravenous dexketoprofen with TEA prior to surgery was reported to show an improvement in perioperative acute pain and pain at 3 and 6 months [75]. Another small study of anti-inflammatory effects on CPTP was reported by Ling [76]. They studied the use of intravenous parecoxib in the perioperative period in conjunction with TEA. They report that CPTP, both incisional and evoked, is significantly reduced at 3 and 12 months. These studies indicate that there may be merit to further trials of pharmacologic means to prevent CPTP.

Most patients undergoing thoracotomy have a regional anesthetic. The most common of the techniques for managing acute pain is TEA, typically placed between T5 and T8. Paravertebral catheters may be placed either by the surgeon under direct vision or by the anesthesiologist with the aid of ultrasound. A number of recent meta-analyses comparing these techniques have been published including a Cochrane review [77–79]. These studies concluded that the two techniques provided similar pain relief in the post-operative period and that PVB may have somewhat lower risk of side effects such as hypotension and urinary retention. It is not clear whether this is due to the technique or dose of medication used in the different blocks. None of the studies reported on the impact of these techniques on CPTP.

A number of small studies have evaluated the effect of TEA on CPTP [37, 80–82]. These studies have examined initiation of epidural analgesia before and after thoracotomy incision [37, 38, 80–82]. Different analgesic regimens were studied as were different methods of administering TEA [80, 82]. The effects of TEA on CPTP were varied. A meta-analysis of the effects of preemptive TEA on post-thoracotomy pain did not find sufficient evidence to state that preemptive TEA reduced CPTP. A later Cochrane review by Andrae and Andrae [83] reviewed studies including 250 patients. They concluded that there was evidence to suggest that the use of TEA or regional analgesia reduces the risk of CPTP in one in every three to four patients. Although the methodology of the studies was not strong and the studies were small, the use of TEA or regional anesthesia should be considered for all patients undergoing thoracotomy.

Surgical Factors

Access to the chest cavity can be accomplished in a number of ways as noted in earlier chapters. Surgical methods include the standard posterolateral thoracotomy (PLT), muscle-sparing thoracotomy (MLT), antero-axillary thoracotomy (AAT) and video-assisted thoracoscopic surgery (VATS). Each method brings with it a unique set of challenges. A number of studies have compared posterolateral and muscle-sparing thoracotomy techniques to determine their impact on perioperative outcomes [84]. Nosotti et al. [85] in a large randomized controlled trial demonstrated that post-operative pain outcome was similar but those with PLT used more opioids via patient-controlled analgesia than the MLT group. There was no difference in CPTP between the groups. Pain decreased in both groups over 3 years of follow-up, with 20% of patients reporting pain at that time. Noromi et al. [86] compared AAT and PLT on post-operative pain. In as study of 51 patients, they noted patients having AAT with significantly less pain in the perioperative and at 3- and 6-month follow-up. Axillary MLT was compared to standard PLT in two studies [37, 38]. Data from the initial study was re-examined and published separately [38]. The incidence of CPTP did not vary based on the type of incision. Similarly, a study of 101 patients undergoing MLT or PLT by Athanassiadi et al. [87] did not demonstrate a difference in the quantity of pain at 2 months. Unfortunately, the incidence of CPTP was not reported. Elshiekh and colleagues [84] reviewed evidence comparing MLT and PLT. They determined that MLT techniques may provide an advantage in return to mobility but that there was no clear evidence that pain was improved although there did seem to be an inverse relationship between incision length and post-thoracotomy pain.

The last decade has seen VATS or variations thereof become standard surgical approaches. The procedure is minimally invasive and performed through a series of ports or a combination of ports and mini-thoracotomy incisions. Early studies of VATS suggested that pain following VATS may be related to the type of surgery. Rates of CPTP varied widely from almost zero to more than 61% [4, 88–91]. Two early studies of VATS procedures for benign disease reported an initial rate of CPTP at 20% after a mean follow-up of 34 months declining to 12.5% after 10 years. Early studies of VATS for oncologic disease reported much higher rates of CPTP [4, 92]. More recent studies have compared VATS to anterolateral thoracotomy [93], limited thoracotomy [94], and video-assisted minimal thoracotomy [41, 95] reflecting a shift in surgical practice to less invasive techniques. Yamashita et al. [95] reported that VATS patients had earlier surgical recovery and less post-operative pain as evidenced by less analgesic use than those in the VATS-assisted minimal thoracotomy group. Unfortunately, CPTP rates were not reported. Noromi et al. [94] compared VATS lobectomy to a limited thoracotomy for segmentectomy and wide thoracotomy for segmentectomy. Chronic pain, as assessed by the need for analgesics at 3 months, was reported as 4%, 1%, and 6% respectively. These differences were not statistically significant. VATS was compared to ALT by Bendixen and colleagues [93]. They report that more patients report moder-

ate to severe pain after ALT than VATS at 1 year. The proportion of patients with moderate to severe pain showed a time-dependent decline over the study period. Thus, while the data remains limited and heterogeneous in outcome measures, there appears to be a trend indicating that less invasive forms of surgery reduce the long-term pain associated with chest surgery.

To understand more clearly the impact of shifts in surgical practice on chronic pain, it is important to acknowledge that factors beyond the type of incision may play a role in the development of CPTP. As the surgeon accesses the chest through a thoracotomy incision, the ribs are spread using a rib spreader. This compresses the neurovascular bundle on the cranial rib. During a VATS procedure, the neurovascular bundle may be compressed by instrument ports or directly by the instruments. At the end of surgery, during rib closure, there is risk of compression of the neurovascular bundle as the ribs are approximated. Traditional intercostal suture techniques bring the suture from the superior edge of the cranial rib and through the intercostal muscle inferior to the caudad rib. This risks entrapment and compression of the neurovascular bundle as the sutures are tightened to approximate the rib. Finally, traction on the intercostal nerve occurs as the ribs are spread and the nerve is stretched along the arc of the rib. Injury by compression, traction, or entrapment of the nerve is thought to be the central injury responsible for post-thoracotomy neuropathic pain.

Early reports of the effect of nerve injury studied the superficial abdominal reflexes (in part, mediated by the inferior intercostal nerves) and indicated a strong correlation between the absence of these reflexes and the intensity of post-thoracotomy pain including CPTP in the setting of PLT [96]. Subsequent studies of these reflexes in the setting of PLT and MLT demonstrated that the absence of abdominal reflexes and increased tactile threshold for electrical stimulation were highly correlated to the intensity of CPTP [97]. However, interoperative studies of intercostal nerve motor-evoked potentials demonstrated nerve injury during thoracotomy, but did not correlate to CPTP [98, 99]. In addition to the impact of the thoracotomy or VATS incision, chest drains are also placed through small thoracotomy incisions. Wildgaard et al. [100] reported post-thoracotomy pain and sensory changes at the site of chest drains in a long-term follow-up study. Similarly, Peng et al. [39] noted a significant correlation between CPTP and prolonged presence of chest drains.

A number of studies have begun to address the issue of neurovascular bundle compression on opening and closing of the chest wall. Mongardon [30] reported that the number of chest drains was positively correlated with the development of CPTP suggesting that nerve compression from the chest drain may contribute to the problem. Cerfolio and colleagues [101] studied a technique of intracostal sutures and demonstrated a significant reduction in CPTP. Studies of intercostal muscle flaps, either pedicled or non-pedicled, and nerve-sparing suture techniques [102–108] to prevent compression of the intercostal nerve during rib spreading and at rib closure, demonstrate a reduction in CPTP. However, neurectomy does not appear to provide protection against CPTP. In a parallel-group randomized controlled trial of 161 patients undergoing ALT, Koryllos and colleagues [109] evaluated the effect of a paravertebral neurectomy on CPTP. No difference was found in neuropathic pain after 4 months of follow-up. Garcia-Tirado and Rieger-Reyes [110] reviewed methods of reducing impact of opening and closure techniques on post-thoracotomy pain. They conclude that there is good evidence to indicate that mechanisms to prevent entrapment of the intercostal nerve on closure reduce post-thoracotomy pain, both acute and chronic.

Neuroinflammation, the infiltration of active immune cells into the peripheral or central nervous system, may be a significant mediator of chronic pain. Astrocytes and microglial cells infiltrate the peripheral or central nervous system in response to injury and secrete inflammatory cytokines and chemokines such as TNF and interleukin 1β [111, 112]. In light of the evidence that reducing the compression of the intercostal nerve reduces risk of chronic pain after thoracotomy, it is reasonable to hypothesize that CPTP may be related to neuroinflammation in the intercostal nerve and associated dorsal root ganglion. Certainly data demonstrating sensory changes after thoracotomy [100, 113, 114] are consistent with this hypothesis. Novel therapies with bone marrow stromal cells that modulate neuroinflammation are now at the stage of animal testing [112]. Recent studies of intrathecal injection of these cells resulted in long-term relief of experimental neuropathic pain from peripheral nerve injury [112]. Further, animal studies of intrathecal administration of DNA decoys that inhibit the production of early growth factor response protein 1 (EGR1) in the dorsal root ganglion reduce the acute and chronic pain after experimental nerve injury in rats [115].

The concept of neuroinflammation as a factor contributing to CPTP may be further supported by studies characterizing the neuropathic pain. Neuropathic pain is a result of nerve injury leading to peripheral or central sensitization. Wildegaard and colleagues [100, 113, 114] and Hetmann et al. [34] studied the sensory changes after thoracotomy and VATS. Neurophysiological studies of post-thoracotomy patients suggested nerve injury is common in patients with and without CPTP but it seems to be more severe in those with CPTP [114]. Quantitative sensory testing after VATS did not demonstrate a significant difference in nerve injury between those with and without CPTP suggesting that other factors may be involved in the CPTP after VATS. A similar study of chest drain sites also demonstrated sensory indicating nerve injury both in patients

with and without CPTP [100] and that these changes were related to late nerve injury. Hetmann et al. [34], in a multimodal study of post-thoracotomy pain at 6 and 12 months after surgery, noted that patient self-exploration for sensory changes indicated that 40–60% of patients had some kind of sensory disturbance at 6 months. This declined to 20–50% at 12 months. Sensory disturbances in this study were strongly associated with CPTP. Of considerable interest in this study was the identification of patients who had no pain at 6 months but reported pain at 12 months.

In addition to the concept of neuroinflammation at the level of individual nerves, a number of studies have identified psychological factors that seem to increase the risk of CPTP [33, 35]. Li and Hu [51] reviewed studies of stress regulation on pain the hypothalamic-pituitary-adrenal axis and pain chronification. In addition to changes in the HPA axis, the shift from acute to chronic pain involves changes in a number of areas of the brain. Li and Hu [51] bring these together in a unifying theory of the role of stress regulation on pain chronification. These studies suggest that CPTP, like many other postsurgical pain conditions, is multifactorial in nature and involves changes from the periphery to the central nervous system.

Prevention of Chronic Post-thoracotomy Pain

Management of chronic pain conditions including CPTP differs from acute pain conditions in that the goals are prevention first followed by long-term management. Acute pain states, by their nature, are limited in time and typically have a declining course over that time. Deductive reasoning would suggest that identification of contributing factors should provide a clear path to prevention of CPTP. However, the reality is proving to be more complex. It seems that there are a number of factors that are related to the development of CPTP but clear causality from a single factor has not yet been demonstrated.

As noted previously, in acute pain and preoperative pain, preoperative analgesic use has been identified as a predictor of chronic postsurgical pain including CPTP in number of studies [31, 35, 39, 40, 58–60]. Additionally, psychological states seem to have a predictive relationship with CPTP. Hetmann et al. [35] demonstrated that dispositional optimism was correlated with CPTP at 12 months. Katz et al. [33] reported a relationship between emotional numbing and CPTP at 6 and 12 months. Each of these conditions may be amenable to identification in the preoperative period and modifiable.

Interestingly, an epidemiological study of 189 patients undergoing thoracotomy identified a relationship between CPTP and inhaled β-agonist use [116]. The use of inhaled β-agonist medications in the perioperative period was an independent predictor of CPTP. These results suggest that further study is warranted to more clearly elucidate the relationship between β-agonist medications and CPTP.

Perioperative medication administration to prevent chronic post-operative pain is attractive in its relative simplicity. Humble et al. [117] conducted a systematic review of therapeutic interventions aimed at preventing chronic postsurgical pain. Gabapentinoids reduced chronic pain after mastectomy but were not effective as a single dose to prevent CPTP. Venlafaxine reduced chronic pain after mastectomy as did EMLA and intravenous lidocaine. Preoperative pregabalin was studied in patients undergoing thoracotomy [118]. CPTP was more common in the pregabalin group although those in the pregabalin group had lower pain scores and less neuropathic symptoms.

Age and gender have been implicated as predictors in a number of postsurgical pain conditions [5, 6]. Younger patients have a greater likelihood of developing postsurgical pain after herniorrhaphy [15, 119]. The effect of age is not consistent across studies of CPTP. Some studies have demonstrated an inverse relationship between age and the risk of development of CPTP [9, 27, 41] with that risk declining by about 2% per year of age [27]. Others have found no relationship between age and risk of CPTP [16, 35]. Similarly, the effect of gender on CPTP is not yet certain. Some studies have reported that women have a greater risk of developing CPTP after thoracic surgery [40, 45]. A large study of persistent postsurgical pain in the general population in Norway failed to find a correlation between age and gender with persistent pain states [16]. Similarly, Hetmann et al. [35] did not find a correlation with gender and CPTP. However, Ochroch et al. [45] in a study designed to study the effect of gender on CPTP reported that women were more likely to have pain 49 weeks after thoracotomy and that the pain would be of greater intensity. This study also noted that older patients suffered less CPTP. However, the study was small and the sample size may be a complicating factor.

Granot [120] reviewed studies of static and dynamic responses to pain perception as predictors of acute and chronic post-operative pain. A number of studies of static pain parameters (tolerance, pain threshold, suprathreshold nociceptive stimuli) have been conducted and demonstrate variable predictive capability for acute and chronic post-operative pain [120–122]. Yarnitsky et al. [122] evaluated the diffuse noxious inhibitory control (DNIC) system in patients preparing for thoracotomy. They reported that those persons who have an efficient DNIC are less likely to develop CPTP than those with a less efficient DNIC. This study is measurable preoperatively and may provide a means to predict those with a propensity to develop CPTP and allow appropriate intervention.

Active attempts to predict and prevent chronic postsurgical pain are now becoming reality. Tawfic et al. [123] reviewed the known predictive factors for chronic postsurgical pain. They advocated for active preoperative risk factor identification, patient preparation, optimization of anesthetic and surgical techniques, and careful attention to management of acute pain. They also suggested that high-risk patients have an individualized discharge plan to manage persistent pain early. These interventions should include appropriate use of perioperative multimodal analgesia and TEA or regional analgesia as these have been identified as having benefit on CPTP [83]. Pharmacologic intervention with anti-inflammatory medications and pregabalin may also be efficacious for CPTP prevention [74–76]. Careful surgical attention should be paid to prevention of nerve injury during the procedure. Institutions are now beginning to develop perioperative programs to prevent chronic postsurgical pain. Such a program has been reported [124, 125]. The transitional pain service is an inter-professional program to identify and manage patients who may develop chronic pain after surgery. The effect of this program and others like it will ultimately determine key methods to reduce and mitigate chronic post-operative pain syndromes.

Management of Chronic Post-thoracotomy Pain

Treatment of CPTP begins with assessment of the type and cause of the pain. As with any form of chronic pain, it is important to search for reversible causes of CPTP. Foremost among these in patients with CPTP after cancer surgery is the search for recurrence of tumor. This is true at all visits after thoracotomy. Tumor recurrence may be heralded by onset of new pain or change in existing pain. Treatment for the pain of tumor recurrence differs from that of chronic non-cancer pain and may include chemotherapy, radiation, or further surgical intervention.

Patients presenting post-operatively to surgical clinics or to their primary care practitioner should be evaluated for post-operative pain at each visit. Ideally, the first post-operative visit with the primary care provider would be part of surgical planning. In the first 2–4 weeks after surgery patients should receive appropriate analgesic therapy for their pain. This may include antiepileptic medications, tricyclic antidepressants, or opioids. Opioids should be prescribed carefully and consideration given to tapering and withdrawal after 4–6 weeks. Patients with pain persisting beyond 3 months should be referred to an inter-professional pain clinic.

Once it is established that the pain is not from tumor or other reversible cause such as occult rib fracture or lung herniation [126], it is important to characterize the pain to determine and identify any neuropathic component. A number of screening tools exist to assist in the diagnosis of neuropathic pain [127]. Use of one of the tools on a regular basis may assist in the development of a comprehensive treatment plan.

A number of guidelines have been developed to treat neuropathic pain [128–132]. These guidelines provide advice on pharmacologic treatment. Treatments typically begin with the use of tricyclic antidepressants, SSRI antidepressants, and antiepileptics, as first- and second-line treatment. Opioids and cannabinoids are considered third line in treatment of neuropathic pain. Topical medications such as capsaicin cream or topical lidocaine [132, 133] may be of benefit. Treatment with other medications including compounded topical medications may be undertaken collaboration with specialist pain management providers. In a small subset of patients, pharmacologic treatment will be inadequate to manage the pain sufficiently to allow the patient to function well. A recent report of reprogramming of an indwelling spinal cord stimulator providing relief for CPTP [134] provides promise of a long-term therapy for those with intractable pain after thoracotomy.

Other treatments that have begun to show promise in the treatment of CPTP include transcutaneous electrical nerve stimulation (TENS). The use of this therapy was reviewed by Freynet and Falcoz [135]. It has been demonstrated to have positive effects both in the immediate perioperative setting [136, 137] and in the management of CPTP [135]. Acupuncture treatment in the setting of chronic pain was the subject of a recent meta-analysis [138]. They examined its use in osteoarthritis, musculoskeletal pain, and headache and found that relief obtained from the intervention may be sustained for many months. Acupuncture has not been evaluated for CPTP. Case reports of botulinum toxin for use in mitigating CPTP have indicated that this treatment for CPTP provided relief for at least 12 weeks [139, 140]. It is not known how long the effect may last or whether it can be repeated. This treatment merits further study.

Treatment of CPTP may require trials of a variety of therapies to determine the optimal treatment for each patient. Optimal treatment of CPTP will often involve multiple professions and disciplines. Overall treatment can be summarized as follows:

- Early post-operative assessment of pain to rule out reversible factors
- Treatment with non-opioid medications such as antiepileptic medications antidepressants, and tricyclic antidepressants
- Judicious use of opioids carefully monitored for effect and dosage
- Referral to an inter-professional pain management clinic
- Topical lidocaine, capsaicin, or compounded medications

- Minimally invasive interventions such as TENS, botulinum toxin, and acupuncture
- Invasive strategies including spinal cord stimulation

Clinical Case Discussion

Mrs. VP is a 49-year-old woman referred to the Pain Management Centre by her family physician with a complaint of right-sided chest pain in the area of her thoracotomy scar. She had undergone a VATS right upper lobe lobectomy for Stage I non-small cell lung carcinoma 6 months earlier.

Past Medical/Surgical History

Mrs. VP has a history of 30 pack years of smoking, having quit 2 years prior to her surgery. She has hypertension and diabetes mellitus Type II managed by diet therapy. Her preoperative medications included hydrochlorothiazide 12.5 mg and daily ASA 82 mg.

Perioperative Course

Her interoperative course was uneventful and mediastinal lymph node biopsies were negative. She had a paravertebral block placed by the surgeon at the end of surgery. Her pain was well controlled, and she was started on oral analgesics 24 h after surgery. The paravertebral catheter was removed at day 3 after surgery as were her chest tubes. She was discharged home on day 5. Nursing notes recorded an average pain score of 5/10 at discharge.

First Visit

At the time of presentation, she described a burning, stabbing pain in the area of the thoracotomy scar. Recent chest radiograph and CT scan were negative for recurrent malignancy. She rated the pain as an average of 5/10. She stated that "good days" brought a pain level of 4/10, and "bad days" brought pain at a level of 7–8/10. She had considerably more bad days than good. The pain radiated to the scapula and anterior chest wall. Her sleep was interrupted by the pain, and she was unable to return to her work as a cashier. Treatment at the time of presentation consisted of two acetaminophen 325 mg/oxycodone 5 mg combination tablets four times daily.

Examination revealed allodynia in the area of the scar. The wound appeared to have healed otherwise well. No other abnormalities were noted.

A diagnosis of post-thoracotomy chronic pain with neuropathic features was made, and an inter-professional treatment plan was discussed. The treatment plan was as follows:

1. The patient was referred for rehabilitation physiotherapy and acupuncture. TENS therapy was explained, and written instructions were provided along with a prescription for a TENS unit and pads.
2. She was started on nortriptyline 25 mg qhs. Recommendations were made to her primary care provider to start gabapentin at 300 mg qhs, increasing to 600–1800 mg every 8 h..
3. She was referred to the local pain self-management program, consisting of physiotherapy, occupational therapy, psychology, diet therapy, and vocational therapy.
4. A follow-up appointment was made for 6 months.

Second Visit

Mrs. VP reported mild improvement with the pharmacotherapy regimen and TENS therapy. She continued to have significant burning pain over the thoracotomy site interfering with her ability to return to full function. A prescription for a trial of acupuncture and a compounded topical medication was provided.

Third Visit

Mrs. VP returned to the Pain Management Centre 3 months later. She had minimal relief from her acupuncture. The topical medication was effective for a few hours only. She asked if there was anything more permanent that could be done. A trial of neurostimulation was scheduled.

Fourth Visit

The trial of neurostimulation was successful reducing pain to a level of 1–2/10. A permanent stimulator had been placed. Mrs. VP was discharged from the Pain Management Centre to the care of her family physician. She follows up periodically for management of the neurostimulator.

massive blood loss,fluid management with, 684, 685
nasogastric tube, 683
one lung ventilation, 683
patient positioning, 683
pulmonary artery catheter monitor, 681
renal prodection strategy, 689, 690
spinal cord monitoring, 682
spinal cord protection strategy, 685–687
temperature, 682
transesophageal echocardiogram, 682
vascular access, 683
postoperative care, 690
preoperative evaluation, 680–681
surgical technique, 679
clamp and sew, 679
deep hypothermic circulatory arrest, 679
left heart bypass, 679
partial bypass, 679
Thoracocentesis, 957
Thoracoscopic approach, 402
Thoracoscopic esophagomyotomy, 615
Thoracostomy, 972, 975, 976
Thoracotomy, 450
complications of
atrial fibrillation, 959–960
cardiac herniation, 965–966
chylothorax, 964
lobar torsion, 964
nerve injury, 963–964
pleural space problems, 960–963
pneumonia, 959
postoperative hemorrhage, 964
postpneumonectomy syndrome, 964–965
for lung resection, 898
3-D techniques, 940
3D TEE LV assessment, 490
3D TEE RV assessment, 493
Thrombin-antithrombin complexes, 182
Thrombosis, in extracorporeal membrane oxygenation patients, 931
Thymectomy, 654
Thymic carcinoma, 266
Thymic masses, surgery, 266
Thymic surgery
cardiopulmonary structures, 266
chemotherapeutic agents, 266
indications
MG (*see* Myasthenia gravis (MG))
thymic masses, 266
thymic tissue and perithymic fat removal, 266
Thymoma, 266
cisplatin, 266
doxorubicin, 266
with mass effect, 275
vincristine, 266
Thymus gland, 266
Thyroid cartilage, 66
Thyroid dysfunction, 253
Tidal breathing preoxygenation, 395
Tidal volume(s), 109–112
Tidal volume protective strategy, 380
Tissue and pulmonary edema, 360
Tissue Doppler imaging, 349
Tissue perfusion monitoring, 349, 350
Topical airway anesthetic agents, 211
Torsades de Pointes, 945
Total body weight (TBW), 546
Total intravenous anesthesia (TIVA), 198, 518
anesthetic agents, 222–224
anesthetic depth monitors, 226
dexmedetomidine, 223, 226
emergence, 227
infusion systems, 224–226
ketamine, 223
lidocaine, 224
maintenance, 227
propofol, 222
rationale, 219–222
remifentanil, 223
shunt fraction, 219
situations in, 221
in special thoracic surgical conditions, 221–222
Trachea, 621, 703
anatomy, 234
etiology of, 232–233
extubation, 630
reconstruction, re-intubation after, 244
surgical planning, 233
upper third of, 234
Tracheobronchial and respiratory anatomy
lymphatic system, 69–70
tracheal and bronchial structure, 69
tracheobronchial circulation, 69–70
Tracheobronchial injuries, 854–855
Tracheobronchial rupture (TBR), 887
Tracheobronchial stenosis, 9
Tracheobronchial stenting, 254
Tracheobronchomalacia, 792
Tracheoesophageal fistula (TEF), 246, 615, 628–629
Gross classification, 826
incidence, 826–827
ligation, 827
in pediatric patients, 826–827
primary repair, 827
Tracheo-innominate artery fistula, 743
Tracheomalacia, 256
Tracheostomy/tracheotomy, 781, 917
Tracheostomy hemorrhage, 742
Traditional clamp and sew technique, 856
Training and certification, in echocardiography, 852
Transbronchial needle aspiration, 210
Transbronchial needle aspiration (TBNA), 210
Transcortical motor evoked potentials (tcMEP), 682
Transcutaneous nerve stimulation (TENS), 990, 991
Transducers, 458, 459

Transesophageal echocardiogram (TEE), 682
Transesophageal echocardiography (TEE), 349, 567, 847, 940
  cannulas, 496
  complications, 848
  guidelines recommend using, 848
  hemodynamic unstable thoracic trauma patient, 848
  hypotensive patient, perioperative management of, 848
  hypovolemia, 851
  image acquisition, 848
  vs. invasive hemodynamic monitors, 848
  lung transplantation, 777
