Preface

It has been 8 years since the Associate Editors (Randall Blank, Javier Campos, and Karen McRae) and I assembled the first edition of *Principles and Practice of Anesthesia for Thoracic Surgery*. In this time period, there has been considerable evolution in the anesthetic management of patients requiring anesthesia for non-cardiac intrathoracic diagnostic and therapeutic procedures. We felt that it would be useful to update and expand the original text for practitioners of thoracic anesthesia at all levels including Staff Anesthesiologists, Residents, Fellows, Nurse Anesthetists, Nurse Practitioners, Anesthesia Assistants, and other Allied Health Professionals. We welcome the addition of Jens Lohser, from the University of British Columbia, as an Associate Editor for this second edition.

Among the major advances that we address in this new edition, we include the expanded role of ultrasound beyond transesophageal echocardiography (Chap. 30): Lung ultrasound has evolved from a curious pattern of artifacts to an essential clinical role in chest trauma and management of pleural effusions (Chap. 28). Ultrasound is now an established tool for the placement of many types of central and peripheral vascular access (Chap. 29). And, ultrasound has permitted the development of several new regional anesthetic blocks (e.g., serratus anterior and erector spinae, Chap. 59) that are useful modalities for management of postoperative pain.

Also new in this edition is the role of extracorporeal membrane oxygenation (ECMO) (Chap. 27) in thoracic anesthesia. Veno-venous ECMO is becoming an established therapeutic option for management of intraoperative hypoxemia in complex types of lung and airway surgery and in whole lung lavage. Venoarterial ECMO is rapidly replacing cardiopulmonary bypass as the main method of extracorporeal lung support in lung transplantation (Chap. 47).

There have been major advances in postoperative pain management for thoracic surgery in this decade. In addition to the new blocks mentioned above, the book covers the expanded use of paravertebral blocks and the use of long-acting local anesthetics (Chap. 60). Also, there have been a variety of new bronchial blockers and modified double-lumen tubes developed that facilitate lung isolation in patients with difficult airways (Chaps. 16, 17, and 18).

We would like to welcome the first Authors of new chapters.

Among these are:

- Daniel Sellers (University of Toronto, Intraoperative Extracorporeal Lung Support for Pulmonary and Airway Surgery, Chap. 27)
- Rebecca Klinger (Duke University, Perioperative Fluid Management in Thoracic Surgery, Chap. 21)
- Danielle Shafiepour (McGill University, Trouble-Shooting One-Lung Ventilation, Chap. 26)
- Nathan Ludwig (University of Western Ontario, Lung Ultrasound, Chap. 28)
- Natalie Silverton (University of Utah, Ultrasound for Vascular Access, Chap. 29)
- Alexander Huang (University of Toronto, Pulmonary Resection in the Patient with Pulmonary Hypertension, Chap. 34)
- Helen Lindsay (New Zealand, Anesthesia for Open Descending Thoracic Aortic Surgery, Chap. 41)

- Andrew Levin (Stellenbosch University, Cape Town, South Africa, Bronchopleural Fistula, Chap. 43)
- Maureen Cheng (Cambridge University, Anesthesia for the Patient with a Previous Lung Transplant, Chap. 48)
- Emily Teeter (University of North Carolina, Enhanced Recovery After Thoracic Surgery, Chap. 52)
- Hadley Wilson (University of North Carolina, Trouble-Shooting Chest Drains, Chap. 58)
- Wendell H. Williams III (MD Anderson Cancer Center, Long-Acting Local Anesthetics for Post-Thoracotomy Pain, Chap. 60)

We would also like to welcome several new first Authors of previous chapters, including Drs. Amanda Kleiman (University of Virginia, Non-respiratory Functions of the Lung, Chap. 7), Javier Lasala (MD Anderson Cancer Center, Intravenous Anesthesia for Thoracic Procedures, Chap. 12), Lorraine Chow (University of Alberta, Anesthesia for Patients with Mediastinal Masses, Chap. 14), Daniel Tran (Yale School of Medicine, Lung Isolation in Patients with Difficult Airways, Chap. 18), Jennifer Macpherson (University of Rochester, Intraoperative Ventilation Strategies for Thoracic Surgery, Chap. 22), Florin Costescu (McGill University, Anesthesia for Patients with End-Stage Lung Disease, Chap. 31), George Kanellakos (Dalhousie University, Thoracic Surgery for Morbidly Obese Patients and Patients with Obstructive Sleep Apnea, Chap. 33), Valerie Rusch (Memorial Sloan Kettering Cancer Center, Pancoast Tumors and Combined Spinal Resections, Chap. 37), Swapnil Parab (Tata Memorial Hospital, Mumbai, India, Thoracic Anesthesia in the Developing World, Chap. 42), Timothy Maus (UC San Diego, Anesthesia for Pulmonary Thromboendarterectomy, Chap. 49), Michael Hall (University of Pennsylvania, Anesthetic Management of Post-Thoracotomy Complications, Chap. 53), and Wendy Smith (UC San Francisco, Postoperative Respiratory Failure and Treatment, Chap. 54).

New to the second edition is the incorporation of video. Relevant video clips will be available online to readers of the print text. For the online text, streaming video clips will allow the reader to point and click to see techniques as they are described. This is particularly useful for ultrasound-guided procedures and lung isolation.

Personally, I would like to thank the returning Authors and Coauthors from the first edition for the thorough updates of their previous chapters. Thank you to the Associate Editors for their hard work and support. And, thank you to the Editors at Springer Clinical Medicine, Daniel Dominguez and Becky Amos, for their encouragement.

Toronto, ON, Canada Peter Slinger
March 2018

Contents

Part I Introduction

1 History of Thoracic Anesthesiology 3
Ian Conacher

Part II Preoperative Evaluation

2 Preanesthetic Assessment for Thoracic Surgery 13
Peter Slinger and Gail Darling

3 Thoracic Imaging 43
Javier Campos and Kalpaj R. Parekh

Part III Thoracic Anatomy, Physiology, and Pharmacology

4 Essential Anatomy and Physiology of the Respiratory System and the Pulmonary Circulation 65
J. Michael Jaeger, Brian J. Titus, and Randal S. Blank

5 Physiology of the Lateral Decubitus Position, Open Chest, and One-Lung Ventilation 93
Sean R. McLean and Jens Lohser

6 Clinical Management of One-Lung Ventilation 107
Travis Schisler and Jens Lohser

7 Nonrespiratory Functions of the Lung 131
Amanda M. Kleiman and Keith E. Littlewood

8 Pharmacology of the Airways 151
Cassandra Bailey, Paul J. Wojciechowski, and William E. Hurford

9 Pharmacology of the Pulmonary Circulation 165
Cara Reimer and John Granton

10 Perioperative Lung Injury 181
Peter Slinger

Part IV Diagnostic and Therapeutic Procedures of the Trachea and Airways

11 Bronchoscopic Procedures 197
Gordon N. Finlayson, Tawimas Shaipanich, and Chris Durkin

12 Intravenous Anesthesia for Thoracic Procedures 219
Javier D. Lasala and Ron V. Purugganan

13 Tracheal Resection and Reconstruction 231
Karen McRae

Part V Diagnostic and Therapeutic Procedures of the Mediastinum

14 Anesthesia for Patients with Mediastinal Masses 251
Lorraine Chow

15 Thymic Surgery and Paraendocrine Syndromes 265
Daniel Sellers and Karen McRae

Part VI Anesthetic Management for Intra-Thoracic Surgery

16 Lung Isolation 283
Javier Campos

17 Fiberoptic Bronchoscopy for Positioning Double-Lumen Tubes and Bronchial Blockers 311
Javier Campos

18 Lung Isolation in Patients with Difficult Airways 323
Daniel Tran and Wanda M. Popescu

19 Intraoperative Patient Positioning and Neurological Injuries 337
Cara Reimer and Peter Slinger

20 Intraoperative Monitoring 343
Gabriel E. Mena, Karthik Raghunathan, and William T. McGee

21 Fluid Management in Thoracic Surgery 357
Rebecca Y. Klinger

22 Intraoperative Ventilation Strategies for Thoracic Surgery 375
Jennifer A. Macpherson

23 Anesthesia for Open Pulmonary Resection: A Systems Approach 389
E. Andrew Ochroch, Gavin Michael Wright, and Bernhard J. C. J. Riedel

24 Anesthesia for Video-Assisted Thoracoscopic Surgery (VATS) 413
Edmond Cohen and Peter Slinger

25 Anesthesia for Non-intubated Thoracic Surgery 425
Peter Slinger

26 Troubleshooting One-Lung Ventilation 429
Danielle Sophia Shafiepour

27 Intraoperative Extracorporeal Life Support for Thoracic and Airway Surgery 437
Daniel Sellers, Karen Lam, and Karen McRae

Part VII Applications of Ultrasound in Thoracic Anesthesia

28 Pulmonary Ultrasound 457
Nathan Ludwig and Ahmed F. Hegazy

29 Ultrasound for Vascular Access 471
James P. Lee, Joshua M. Zimmerman, and Natalie A. Silverton

30 Intraoperative Transesophageal Echocardiography for Thoracic Surgery 483
Massimiliano Meineri

Part VIII Specific Patient Consideration

31 Anesthesia for Patients with End-Stage Lung Disease 509
Florin Costescu and Martin Ma

32 Thoracic Surgery in the Elderly 535
Maria D. Castillo, Jeffrey Port, and Paul M. Heerdt

33 Thoracic Anesthesia for Morbidly Obese Patients and Obese Patients with Obstructive Sleep Apnea 545
George W. Kanellakos and Jay B. Brodsky

34 Pulmonary Resection in the Patient with Pulmonary Hypertension 561
Alexander Huang and Katherine Marseu

Part IX Complex Thoracic Surgical Procedures

35 Surgery of the Chest Wall and Diaphragm 583
Peter Slinger

36 Extrapleural Pneumonectomy 587
Ju-Mei Ng

37 Pancoast Tumors and Combined Spinal Resections 597
Valerie W. Rusch, Ilya Laufer, Mark Bilsky, Alexandra Lewis, and David Amar

38 Anesthesia for Esophageal Surgery 609
Randal S. Blank, Stephen R. Collins, Julie L. Huffmyer, and J. Michael Jaeger

39 Anesthesia for Robotic Thoracic Surgery 651
Javier Campos

40 Anaesthesia for Combined Cardiac and Thoracic Procedures 661
Marcin Wąsowicz

41 Open Thoracoabdominal Aortic Aneurysm Repair 675
Helen A. Lindsay, Coimbatore Srinivas, and Maral Ouzounian

Part X Anesthetic Management of Uncommon Pulmonary Procedures

42 Thoracic Anesthesia in the Developing World 699
Swapnil Yeshwant Parab and Sheila Nainan Myatra

43 Bronchopleural Fistulae 717
Andrew Ian Levin

44 Massive Hemoptysis 733
Jean S. Bussières and Marili Frenette

45 Whole Lung Lavage 747
Jean S. Bussières and Etienne J. Couture

Part XI Anesthesia for Surgical Procedures for End-Stage Lung Diseases

46 Lung Volume Reduction 761
Erin A. Sullivan

47 Lung Transplantation 773
Andrew Roscoe and Rebecca Y. Klinger

48 Anesthesia for the Patient with a Previous Lung Transplant 791
Maureen Cheng

49 Anesthesia for Pulmonary Thromboendarterectomy 797
Timothy M. Maus and Dalia Banks

Part XII Anesthesia for Pediatric Thoracic Surgical Procedures

50 Anesthesia for Pediatric Thoracic Surgery 815
Robert Schwartz and Cengiz Karsli

Part XIII Trauma

51 Anesthetic Management of Thoracic Trauma 845
Stephen V. Panaro and Tzonghuei Herb Chen

Part XIV Post-operative Management

52 Enhanced Recovery After Surgery (ERAS) for Thoracic Surgery 873
Emily G. Teeter, Gabriel E. Mena, Javier D. Lasala, and Lavinia M. Kolarczyk

53 Anesthetic Management of Post-thoracotomy Complications 885
Michael A. Hall and Jesse M. Raiten

54 Postoperative Respiratory Failure and Treatment 895
Wendy Smith, Alan Finley, and James Ramsay

55 Postoperative Management of Respiratory Failure: Extracorporeal Ventilatory Therapy 925
Vera von Dossow, Maria Deja, Bernhard Zwissler, and Claudia Spies

56 Cardiovascular Adaptations and Complications 939
Alessia Pedoto and David Amar

57 Post-thoracic Surgery Patient Management and Complications 953
Jean Y. Perentes and Marc de Perrot

58 Troubleshooting Chest Drains 969
Hadley K. Wilson, Emily G. Teeter, Lavinia M. Kolarczyk, Benjamin Haithcock, and Jason Long

59 Pain Management After Thoracic Surgery 981
Stephen H. Pennefather, Clare Paula-Jo Quarterman, Rebecca Y. Klinger, and George W. Kanellakos

60 Long-Acting Local Anesthetics for Analgesia Following Thoracic Surgery 1029
Wendell H. Williams III, Jagtar Singh Heir, and Anupamjeet Kaur Sekhon

61 Chronic Post-thoracotomy Pain 1045
Peter MacDougall

Index 1059

Part I

Introduction

History of Thoracic Anesthesiology

1

Ian Conacher

Key Points

- Because of the concern relating to the natural history of pneumothorax, the development of a thoracic surgery discipline comparatively was late.
- Tuberculosis was the stimulus to overcome concern and caution.
- Control of contaminating secretions was an early anesthesia objective.
- Rigid bronchoscopy, lung separation, and positive-pressure ventilation are milestones of significance.
- Modern materials have enabled considerable advances in essentially early ideas.
- The anesthesia challenge of surgery of respiratory failure is to counteract the negative effects of positive-pressure ventilation.
- Surgery for lung cancer remains the bulk of workload.

Introduction

Infantry in disciplined armies like those of the Romans were trained to inflict a penetrating stab injury to the chest wall. Early depictions capture the paradox of a small and bloodless injury inevitably being fatal: and a dignity to a transition into another world as deep to the wound the lung collapses, respiration becomes paradoxical, and carbon dioxide retention and hypoxia ease the passing. In the nineteenth century, as surgery was advancing apace because of antisepsis and anesthesiology, it was opined that the surgeon's knife would for these old reasons inevitably lead to the death of the patient: surgically attempting to incise into the thorax was something of a taboo, only to be breached by *Ferdinand Sauerbruch (1875–1951)* little more than a century ago (Fig. 1.1).

The late beginning to the thoracic surgery discipline is overlooked. The author occasionally assisted the distinguished *Phillip Ayre (1902–1979)* who had worked with a surgical collaborator of Sauerbruch. This was *Laurence O'Shaugnessy (1900–1940).* A casualty of the Second World War, he left to posterity one of the earliest surgical methods of treatment for angina and distinctive forceps that graced thoracic surgical instrument trays for 60 years and has been modified for minimal access use (Fig. 1.2).

The fatal process – wound, pleural penetration, lung collapse, respiratory, and cardiac arrest – was interrupted with construction of an operating environment that counteracted the elastic force that paralyzes respiratory function. With encasement of the surgeon and patients' torso in a negative-pressure chamber, atmospheric pressure (now positive in physiological terms) operated at the patient's exposed mouth and prevented the lung collapsing as soon as parietal pleura was breeched. Expired tidal ventilation and gas exchange can continue to counter the toxic effect, described as "pendelluft," of moving physiological dead space gas back and forth between the lungs. Accumulation of carbon dioxide in the self-ventilating patients was delayed and albeit limiting operating time was enough to open the historical account of thoracic surgery.

The Sauerbruch technique was replaced by more efficient methods to reverse intrapleural dynamics and based on supra-atmospheric pressures applied to the airway – a move recognizable in modern day practices of tracheal intubation and positive-pressure ventilation. The change is typical of an early phenomenon: the thoracic discipline attracted inspired minds, with ingenious ideas to build on templates of pioneers. Here are to be found stories of great physiologists, physicians, surgeons, and anesthesiologists without whom, for instance, the groundwork for a diversification into cardiac surgery would have been significantly delayed. Indeed in many countries, the latter services still are rooted in establishments that once were sanatoriums, serving the needs of early patients for chest surgery.

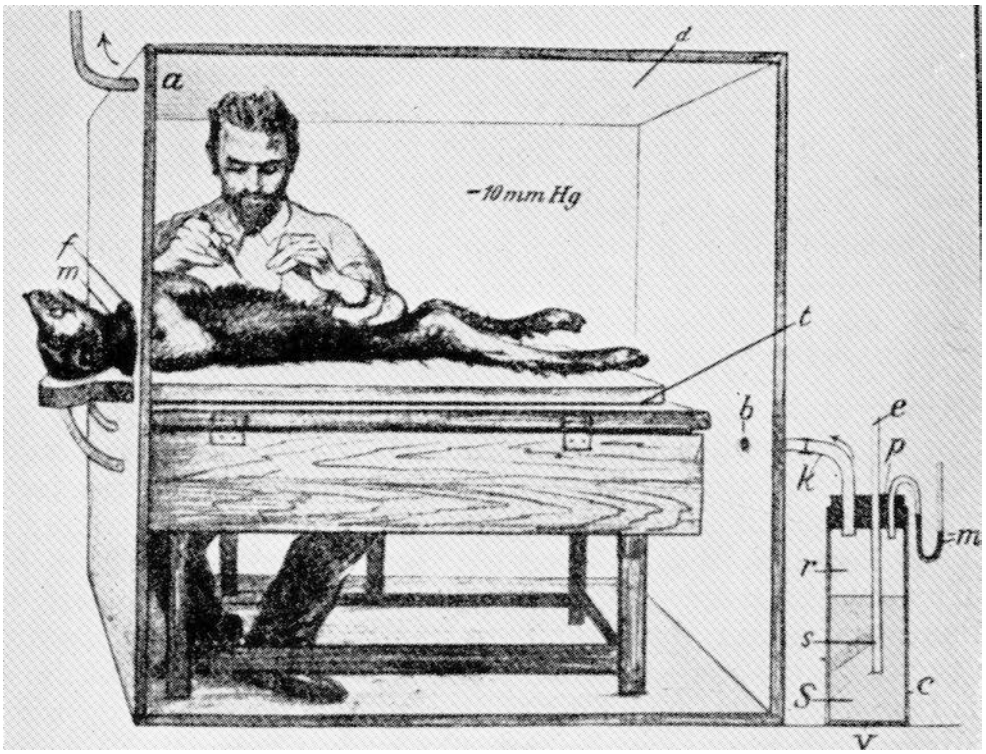

Fig. 1.1 A diagram of Sauerbruch's negative-pressure chamber for thoracic anesthesia. The animal or patient's torso and the surgeons were enclosed in an airtight chamber evacuated to −10 cm H_2O pressure. The subject was then anesthetized breathing air-ether spontaneously from a mask. When the thorax was opened, the lung did not collapse and hypoxemia was averted, although hypercarbia would gradually develop due to pendelluft. This marked the beginnings of elective thoracic anesthesia and surgery. (From Mushin W, Rendell-Baker L. The principles of thoracic anaesthesia. Oxford: Blackwell Scientific Publications; 1953.)

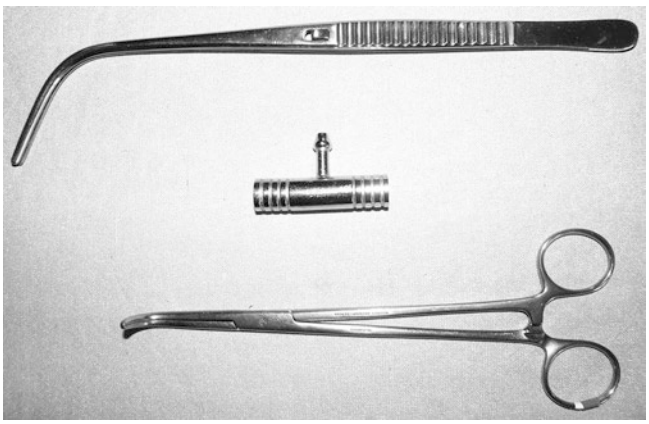

Fig. 1.2 Thoracic ephemera. From top to bottom: Krause's Forceps, Ayres "T" piece, O'Shaughnessy Forceps

In each development, an anesthesiologist of the day has had to innovate, adapt, and change with new ideas, materials, and advances being presented to him or her. A formative beginning with candle power disappeared with antimicrobial therapy but leaves a legacy of thoracoscopy, lateral thoractomy, lung separators, and pain relief techniques that are but little modified.

Paradigm shifts are usually marked by the two World Wars of the twentieth century. Though these are defining elements of any historical analysis, and certainly colored the individuals who are part of the story, developments in thoracic surgery that now govern modern practice are better seen in the light of changes in the medical challenges of disease which changed coincidentally at the same time points.

Ages of Thoracic Surgery

Surgery for Infective Lung Disease

The nineteenth century, a time of great population and societal movement particularly in and from Europe, was blighted by the "white plague" (tuberculosis), an indiscriminate killer – irrespective of class, wealth, national boundaries, and unstoppable, a foreshadowing of AIDS: a heroine in the throes of consumption, a last hemoptysis, death – stuff of opera. Into this hopelessness strides the surgeon to deal with pulmonary cavities, septic foci, decayed and destroyed lung, bleeding points, and copious, poisonous secretions that were more than capable of drowning the patient. Surgical repertoire after the Sauerbruch revelation was the artificial pneumothorax, empyema drainage, plombage (insertion of inert material into the thoracic cavity to promote lung collapse as therapy for tuberculosis), phrenic nerve crush, the thoracoplasty, and some tentative steps at resection – ordeals staged over days and weeks but with an accrual of lifesaving consequences for countless (Fig. 1.3).

With no mechanisms of control of secretions and an ever-present danger of respiratory failure, standards for anesthesiology were sedation with opiates, topical, regional, and field blockade with local anesthetics to preserve self-ventilation so that cough and the ability to clear the airway were not lost.

Operating position became important. That of Trendelenburg was most effective to ensure that secretions, blood, and lung detritus drained gravitationally and not into

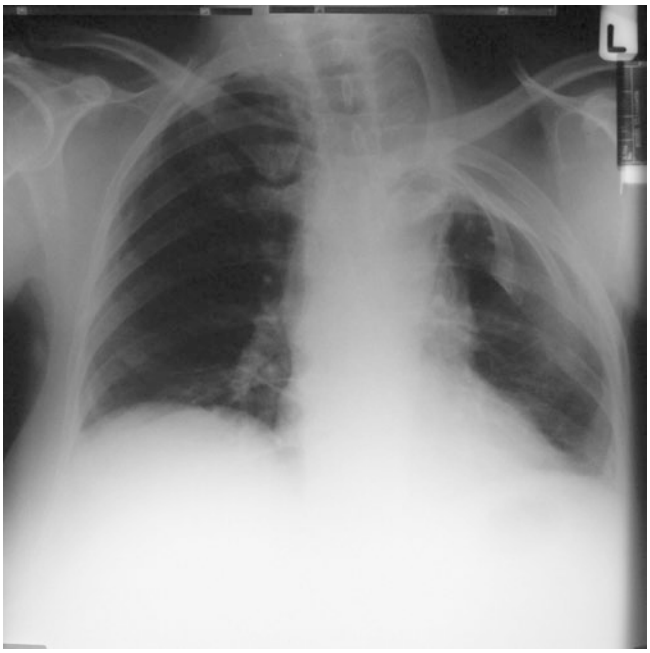

Fig. 1.3 Chest X-ray of a left-sided thoracoplasty, the ribs of the upper left hemithorax have been resected to promote left upper lobe collapse for tuberculosis therapy

the nonoperated lung. But, in the cachectic and septic sufferer of pulmonary tuberculosis or bronchiectasis, adoption of such steep head-down postures could prove fatal. The prone and semiprone positions were gentler and less compromising. Surgeons got used to operating and approaching the lung and its constituents through a posterior thoracotomy. This spawned the posterolateral thoracotomy, once tracheal intubation techniques enabled alternative, nongravitational ways of dealing with the secretion problem. The lung, esophagus, and heart became grist to the thoracic surgical mill.

As the era closed, the anesthesiologist (and the dawn of the specialist was at hand) had an experience of nitrous oxide and several volatile agents other than ether, notably chloroform and cyclopropane. Insufflation techniques, tracheal intubation, and rudimentary bronchial blocking techniques, which required a skill in rigid bronchoscopy, were tools of the expert. Several were using assisted ventilation before the advent of muscle relaxants. Prototype endobronchial tubes, bronchial blockers, and early positive-pressure ventilation techniques were in position for a new age – ushered in with curare.

There is no greater symbol of the transition than the pneumonectomy of the British King, *George VI (1895–1952).* Operated on in 1951 – for lung cancer – by a surgeon (*C. Price Thomas (1893–1973)*) who was credited with his own operation (sleeve resection) for tuberculosis, the anesthesiologist (*Dr R. Machray*) had devised his own tracheal tube (but on the occasion used a Thompson bronchus blocker) and wielded measured doses of diamorphine and pethidine, nitrous oxide, and the new agent, curare. And in the wings, spurred by intraoperative problems with ventilation, a trainee anesthesiologist (*William Pallister (1926–2008)*) was inspired to invent a new endobronchial tube specifically for the surgeon and his operation to avoid such critical incidents in the future. The surgeon later developed lung cancer for which he was operated on! The cigarette was yet to be seen as the cause and that this particular blight was largely man-made.

Surgery for Lung Cancer

Pulmonary resection for lung cancer came to dominate operating lists as the tuberculosis hazard receded to a point of rarity in developed countries with advances in public health that followed the Second World War. The favored method was general anesthesia with volatiles such as the new agent halothane, lung separation – commonly with double-lumen tubes – muscle relaxants, and, after the polio epidemics of the 1950s, positive-pressure ventilation with increasingly sophisticated ventilators. The Academic of the day, having acquired scientific tools, was beginning to recognize and investigate the subtle pathophysiological changes wrought by one-lung anesthesia.

In general, advances were defined by greater understanding of pulmonary physiology, limits and limitations of surgery particularly degree of resectability, and the fitness of patients to withstand ordeals of process, and more regard for quality of postresection existence. The crude practice of inserting a blocker through a rigid bronchoscope under topical anesthesia applied with Krause's Forceps, to test for the potential to survive a pulmonary resection, could be abandoned! Besides safeguarding the technological skills of an earlier era, the anesthesiologist needed to acquire a bedside expertise of the potential for respiratory failure to develop in a particular patient, based on simple pulmonary function tests (wet spirometry). In this era predating a foundation or philosophy for prolonged recovery with ventilator support and postoperative care resource, forecasting was on the basis that fatalities were theoretically due to carbon dioxide retention or right heart failure if excess lung was resected in reaching for a cure for a cancer: in practice sepsis and renal failure usually proved terminal.

The ending of this work pattern followed advances of plastics technology on equipment, fiber optics on diagnostics and operating instruments, and computers on monitoring and performance. Surgery was moving into an age that had a patient demand to push operability beyond limits established for cancer. This desire was to be met with larger resource for intensive levels of postoperative care.

Although advances were truly innovative, these were fraught with risk. For a perspective on this, recall that pulse

oximeters were experimental not universal and end-tidal carbon dioxide measurement nonexistent: operational decisions depended on blood gas monitoring with unsophisticated and slow automated systems and the occasional use outside the laboratory of Swan-Ganz type pulmonary flotation catheters.

Surgery for Respiratory Failure

Defining elements include transplantation but also revisits to treatment of emphysema (which had with chronic bronchitis reached significant proportions in developed countries) and technological and material advances for trachea-bronchial disease which heretofore were off limits to all but a few establishments with special expertise and cardiopulmonary bypass technology.

Orthotopic lung transplantation had been attempted in extremis (1963), but success in terms of long-term viability was not to be achieved for another two decades (1986). A new immunosuppressant therapeutic era was to enable further, and this time, successful efforts. Much of the credit goes to the Toronto group, under Dr. Joel Cooper, whose selection and management templates resolved problems previously encountered by attempting to treat paraquat poisoning, routine use of corticosteroids for airway disease, tracheobronchial dehiscence, and reimplantation. Matching of lung preservation techniques to those for cardiac donors was a final step from experimental to mainstream and to the current healthy state of a thoracic organ transplant discipline.

Chronologically, not far behind, is lung volume reduction surgery, driven by many of the same innovators. Historically, this was just a revisitation of old ideas and not a monumental surgical advance; but the lessons learnt were in particular for anesthesiology. In learning to deal with emphysema lung pathophysiology, a "downside" of positive-pressure ventilation was encountered with great frequency. The prevention and treatment of dynamic hyperinflation scenarios ("breath stacking") is now, after a century, as big a challenge as that of "pendelluft" breathing was in its day.

Lung Separators

Three systems have evolved to facilitate one-lung ventilation: bronchus blocker, endobronchial tube, and double-lumen tube. The first two were of concept and had prototypes about the same time. Gale and Waters in 1931 have the credit for intubation of the contralateral bronchus prior to pneumonectomy: Crafoord and Magill as firsts for bronchial blocking. The double-lumen tube is a later development and as concept was taken from catheters, most notably the Carlens, devised for bronchospirometric research, assessment, and investigation.

Devices were manufactured out of red rubber, and over the years many adaptations were made: right- and left-sided versions, carinal hooks, right upper lobe slots, and extra-inflatable cuffs, cuffs of red rubber and of latex rubber, net-covered – to mention but a few.

The Blocker Story

It is to the particular genius of *Ivan Magill (1888–1986)* that the bronchus blocker is owed. With minor modifications it became a dominant technique for practitioners, use of which, as mentioned, had become a test for fitness for operation. Inserted through a rigid bronchoscope, the blocker could be placed accurately in the most complex of anatomical distortions wrought by tuberculosis. The state-of-the-art device was that of *Vernon Thompson (1905–1995)* (Fig. 1.4). However, endobronchial tube availability and the versatility of double-lumen tubes meant that by the latter part of the twentieth century, there were few but a dedicated band of practitioners with the skill to place and use blockers effectively and first choice status was lost. Plastics and fiber optics led to reinvention for the twenty-first century. "Univent," Arndt, and Cohen systems follow in quick succession as the concept was revitalized.

The Endobronchial Tube Story

These very obvious adaptations of tracheal tubes gave anesthesiologists a range of devices that served purpose for half a century. That of Machray was a long, single-cuffed tracheal tube and was placed in the left main bronchus under direct vision using an intubating bronchoscope as introducer

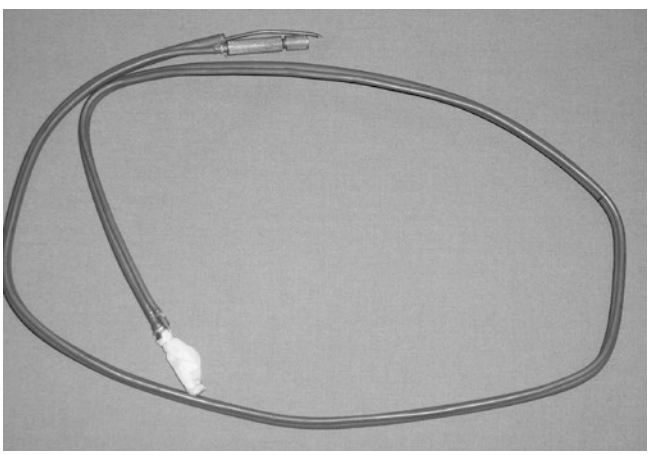

Fig. 1.4 Vernon Thompson bronchus blocker (circa 1943)

Fig. 1.5 Machray endobronchial tube and intubating bronchoscope

(Fig. 1.5). Being able to mount these devices on a rigid scope, again a Magill credited idea, defined these tubes. The characteristic facilitated placement in the most distorted of airways and allowed for ventilation through a wide-bore tube, bettered only by using a bronchus blocker outside and beside an endotracheal tube. Left-sided Macintosh-Leatherdale and Brompton-Pallister and the right-sided Gordon-Green were to prove the most enduring.

The Double-Lumen Tube Story

Unlike the other types of lung separators, the double-lumen tube was adapted and adopted rather than invented for the purpose of one-lung anesthesia and ventilation. The prototypes, notably that of *Eric Carlens (1908–1990)*, were for physiological investigation. Models with the ventilation lumens positioned coaxially and anterior-posterior were tried but that of *Frank Robertshaw (1918–1991)* with its side-by-side lumens, anatomical shape, range of size, and low resistance characteristic dominated, to be later reproduced as plastic and disposable materials (e.g., Sheridan, Broncho-Cath) that replaced the increasingly unsuitable and anachronistic red rubber. The right-sided version was actually invented from a Gordon-Green endobronchial tube, the slot of which has remained the most effective device to ventilate the right upper lobe – an efficacy dependent on properties of red rubber (Fig. 1.6).

Plastic and practice penetration by fiberoptic bronchoscopes of decreasing size and increasing sophistication and practicality led to much contemporary discussion about the "blind" placement of lung separators that replaced the tradition of rigid bronchoscopy as an aid to lung separation and bronchial cannulation. Though modern protocols are more fail-safe than reliance on clinical and observational skills, the modern didactic of medicolegality has trumped debate and stifled argument.

Origins of Thoracic Endoscopy

The ancient entertainment of sword swallowing had long demonstrated the feasibility of inserting rigid instruments into the esophagus. In 1895 a scope was first passed through a tracheotomy opening to be quickly followed by

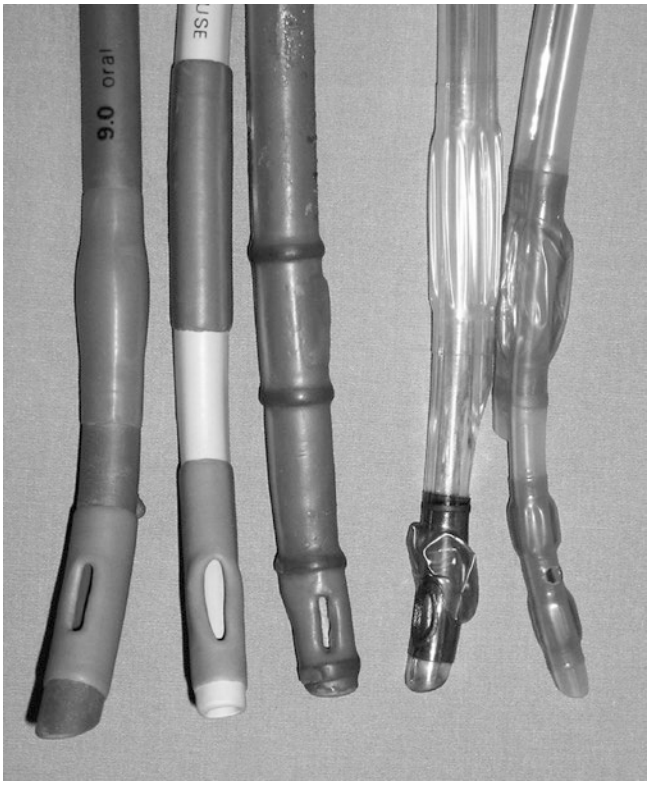

Fig. 1.6 Tubes with right upper lobe ventilation slots. From left to right: Gordon-Green endobronchial, Robertshaw double lumen, Carlens (White model) double lumen, "Broncho-Cath" double lumen, and "Portex" prototype double lumen

endoral attempts but at the limits of proximal lighting systems. *Chevalier Jackson (1865–1958)* was not the originator, but he certainly was a pioneer and the first master of distal lighting systems, with a record on removal of foreign bodies that stands unsurpassed to this day (Fig. 1.7). To him are owed the rules that made the dangerous art of sword swallowing into a scientific tool for therapy and diagnosis both in the esophagus and in the tracheobronchial tree and the subtleties of neck positioning that ensure either the esophagus or trachea is cannulated: a whole philosophy of skill that has been negated by the flexible nature of modern tools.

Now the only indications for rigid bronchoscopy are foreign body removal and occasional stent insertion, but there was a time when rigid bronchoscopy was indispensible for operative assessment, bronchography, diagnostics, insertion of lung separators, postoperative lung toilet, and treatment of bronchopleural fistula. Under careful local anesthetic application, topical, regional, and cricothyroid puncture, the technique could be conducted with such skill that no less an illustrious patient than *Geoffrey Organe (1908–1989)*, the Professor of Anaesthesia, Westminster Hospital, London, was able to declare the experience as "more pleasant than going to the dentist."

Fbdy. 768 	15 yrs.	Safety-pin open	Right main bron-chus, 3 weeks
Fbdy. 786	4 yrs.	Safety-pin open	Larynx, point up, 3 days
Fbdy. 794 41	18 yrs.	Safety-pin open	Right lower lobe bronchus. Point up. 1 yr. 10 mos.

Trying to produce an artificial pneumothorax frequently failed because of adhesions. In 1913, a Swedish surgeon, Hans Christian Jacobaeus, reported on the use of a modified cystoscope to look into the chest and used a second port for instruments, such as probes and cautery, to deal with recalcitrant adhesions. It is not hard to see how this concept has evolved.

Tracheobronchial Stenosis

As technological advance is on the brink of tracheal reconstruction using biological methods, it is important not to forget that this state has been reached by a long and hard struggle to overcome the challenge for surgery and healing inherent in innately poor mammalian vascular supply of the tracheobronchial tree. The era of tracheal resection and repair was to be dominated by *Hermes Grillo (1923–2006)*, the Chief of Thoracic Surgery at the Massachusetts General Hospital. There was a brief period of tracheoplasty and silicon replacements, all of which were major anesthesiological undertakings, but developments in stents, largely modeled on similar devices for esophageal stricture, had become prevalent at the end of the twentieth century. Solid-state devices of silicon were replaced by a range of self-expanding ones made of nonreactive and malleable materials such as nitinol which have resulted in less challenging anesthesia scenarios.

Esophageal Surgery

Originally, surgery on the esophagus was very much a development of chest surgery. Several medical cultures retained a linkage late into the twentieth century, but this was largely a technical connection because of commonality of anesthesiological requirements like lung isolation. Most countries have now broken the connection, and the esophagus is largely seen as outside the hegemony of thoracic practice. Cancer, achalasia, and hiatus hernia, once part of the tougher end of the surgical diet, are now treated less traumatically and invasively.

As with pulmonary resection, early developments were based on totemic patients by small teams, whose successes and tribulations sustained knowledge that relief by surgical means ultimately was going to be of benefit to many more. A single case survivor of 13 years after transpleural esophagectomy by *Franz Torek (1861–1938)* in New York in 1913 was a beacon for three decades. The anesthetist was *Carl Eggers (1879–1957)* who administered ether through a woven silk tracheal tube to a self-ventilating patient. In 1941, the world experience of the technique was 17 survivors of 58 patients.

Pain Relief

Modern analgesics can be traced to the coca leaf, opium poppy, and willow bark, but administration other than by ingestion or inhalation needed the hypodermic needle. Spinal injection (1898), intercostal nerve blockade (1906), paravertebral injection (1906), and extradural (1921) are the historical sequence for local anesthetic procedures of context.

Survivors of thoracoplasty operations tell of hearing their ribs being cracked as, in the later stages of the operation, the thoracic cage was rearranged: few attendants were prepared to risk general anesthesia. A specimen technique of Magill's for this operation, first performed in the UK by *Hugh Morriston Davies (1879–1965)* in 1912, included premedication with opiates, supraclavicular brachial plexus block, intercostal nerve block, dermal infiltration of skin incision site and towel clip points as well as subscapular infiltration and much titration of dilutions of adrenalin (epinephrine). *J Alfred Lee (1906–1989)* (author of the classic *A Synopsis of Anaesthesia*, first produced in 1947) states advantages of local as opposed to general anesthesia: reduced risk of spread of disease, better elimination of secretions as cough reflex is not abolished, quicker convalescence because patient is less upset by drugs and needs less nursing care, and abolition of explosion risk.

Paravertebral blockade, first credited to Sellheim, went on to be used for operative pain relief, postthoracotomy neuralgia, and even angina and thoracic pain of unknown etiology. Subarachnoid block enjoyed a period in thoracic surgery, but the "high" nature meant that it was a hazardous technique because of uncontrolled hypotension and suppression of respiration. Epidural anesthesia was limited by the toxicity of agents, hazard of hemodynamic collapse, the short-lived nature of single-shot procedures, and logistics and feasibility of process in the context of hospital environment. Continuous analgesia perioperatively was only realistic with small-bore tubing and got impetus from the link to improved postoperative respiratory function.

Correlation of pain relief and reversal of some of the negative effects of surgery led to recognition that pain relief objectives could be broadened from humanitarian and reactive. A new philosophy has arisen: it is a proactive one to capitalize on observations that pain relief techniques contribute to the healing process by promoting a sense of well-being, preserving gastrointestinal function, improving anastomotic blood flow, and facilitating management of comorbidity.

Conclusion

The impetus for surgical development and advance are all in context, and in none more than thoracic practice is this true: phases, even paradigm shifts, defined by disease, sociology

and advances in knowledge, and therapeutics and, in the case of anesthesiology, by drugs, materials, and technology. As historical evolution, much of current practice is recognizable.

A modern age is already characterized by a circumspect use of volatile agents, but predictable forces of surgery are the demand for minimal access and the use of once-only disposable materials that have already seen the demise of much of local infrastructure to process sterile equipment and surgical hygiene. Hospital-acquired infection morbidity is a given, as are epidemics of asbestosis-related pleural-pulmonary disease as this ubiquitous "pathogen" escapes from the twentieth-century confines. A new epidemic, obesity, will gain momentum. Lung cancer treatment options show little sign of being bettered by other than surgical methods. Tuberculosis has a new drug-resistant guise. Could history repeat itself? Many countries, notably in Africa and those previously part of the USSR, have endemic populations harboring and, sadly, nurturing drug-resistant tuberculosis. Some are now contemplating revisiting and revising early surgical techniques (e.g., thoracoplasty) to add to future projects to tackle what has to be one of the most predictable and threatening of microbial conditions with a future to impact on thoracic anesthesiology and on all healthcare systems.

Part II

Preoperative Evaluation

Preanesthetic Assessment for Thoracic Surgery

2

Peter Slinger and Gail Darling

Key Points

- All patients having pulmonary resections should have a preoperative assessment of their respiratory function in three areas: Lung mechanical function, pulmonary parenchymal function, and cardiopulmonary reserve (the "three-legged stool" of respiratory assessment).
- Following pulmonary resection surgery, it is usually possible to wean and extubate patients with adequate predicted postoperative respiratory function in the operating room provided they are "AWaC" (alert, warm, and comfortable).
- Preoperative investigation and therapy of patients with coronary artery disease for noncardiac thoracic surgery are becoming a complex issue. An individualized strategy in consultation with the surgeon, cardiologist, and patient is required. Myocardial perfusion imaging and stress echocardiography are used increasingly in these patients.
- Geriatric patients are at a high risk for cardiac complications, particularly arrhythmias, following large pulmonary resections. Preoperative exercise capacity is the best predictor of post-thoracotomy outcome in the elderly.
- In the assessment of patients with malignancies, the "four M's" associated with cancer must be considered: Mass effects, metabolic effects, metastases, and medications.
- Perioperative interventions which have been shown to decrease the incidence of respiratory complications in high-risk patients undergoing thoracic surgery include cessation of smoking, physiotherapy, and thoracic epidural analgesia.

Introduction

Thoracic anesthesia encompasses a wide variety of diagnostic and therapeutic procedures involving the lungs, airways, and other intrathoracic structures. As the patient population presenting for noncardiac thoracic surgery has changed, so have the anesthetic techniques required to manage these patients. Thoracic surgery at the beginning of the last century was primarily for infectious indications (lung abscess, bronchiectasis, empyema, etc.). Although these cases still present for surgery in the post-antibiotic era, now the commonest indications are related to malignancies (pulmonary, esophageal, and mediastinal). In addition, the last two decades have seen the beginnings of surgical therapy for end-stage lung diseases with procedures such as lung transplantation and lung-volume reduction.

Recent advances in anesthetic management, surgical techniques, and perioperative care have expanded the envelope of patients now considered to be operable [1]. This chapter will focus primarily on preanesthetic assessment for pulmonary resection surgery in cancer patients. However, the basic principles described apply to diagnostic procedures, other types of nonmalignant pulmonary resections, and other chest surgeries. The major difference is that in patients with malignancy, the risk/benefit ratio of canceling or delaying surgery pending other investigation/therapy is always complicated by the risk of further spread of cancer

during any extended interval prior to resection. Cancer surgery is never completely "elective" surgery.

A patient with a "resectable" lung cancer has a disease that is still local or local-regional in scope and can be encompassed in a plausible surgical procedure. An "operable" patient is someone who can tolerate the proposed resection with acceptable risk. Anesthesiologists are not gatekeepers. Normally, it is not the anesthesiologist's function to assess these patients to decide who is or is not an operative candidate. In the majority of situations, the anesthesiologist will be seeing the patient at the end of a referral chain from chest or family physician to surgeon. At each stage there should have been a discussion of the risks and benefits of operation. It is the anesthesiologist's responsibility to use the preoperative assessment to identify those patients at elevated risk and then to use that risk assessment to stratify perioperative management and focus resources on the high-risk patients to improve their outcome (Fig. 2.1). This is the primary function of the preanesthetic assessment. However, there are occasions when the anesthesiologist is asked to contribute his/her opinion whether a specific high-risk patient will tolerate a specific surgical procedure. This may occur preoperatively but also occurs intraoperatively when the surgical findings suggest that a planned procedure, such as a lobectomy, may require a larger resection such as a pneumonectomy. For these reasons, it is imperative that the anesthesiologist have a complete preoperative knowledge of the patient's medical status and also an appreciation of the pathophysiology of lung resection surgery. There has been a comparatively small volume of research on the short-term (<6 weeks) outcome of these patients. However, this research area is currently very active, and there are several studies which can be used to guide anesthetic management in the perioperative period where it has an influence on outcome.

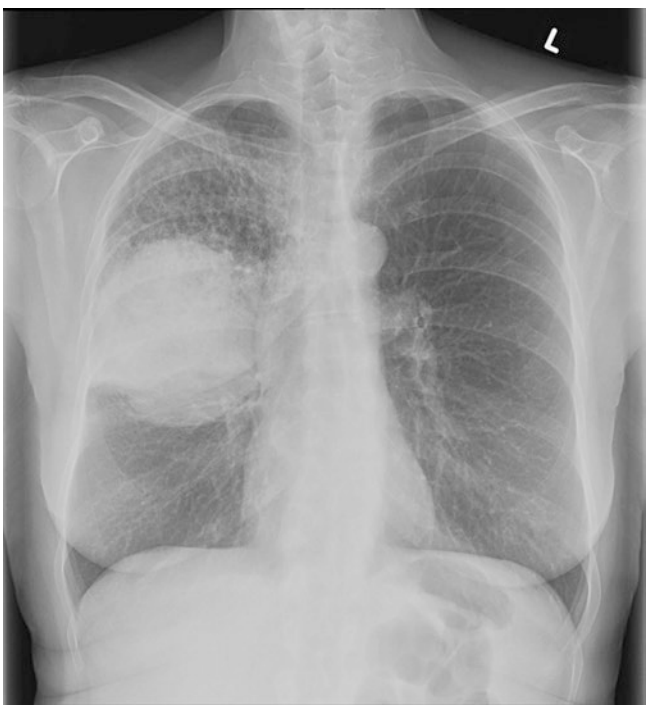

Fig. 2.1 Chest X-ray of a patient with a carcinoma of the right upper lobe scheduled for possible lobectomy or pneumonectomy. The purpose of the preoperative anesthetic assessment of this patient is to stratify the patient's risk and to identify factors which can be managed to improve the perioperative outcome

Thoracic surgeons are now being trained to perform "lung-sparing" resections such as sleeve lobectomies or segmentectomies and to perform resections with minimally invasive techniques such as video-assisted thoracoscopic surgery (VATS) and robotic surgery. The postoperative preservation of respiratory function has been shown to be proportional to the amount of the functioning lung parenchyma preserved. To assess patients with limited pulmonary function, the anesthesiologist must appreciate these newer surgical options in addition to the conventional open lobectomy or pneumonectomy.

Pre-thoracotomy assessment naturally involves all of the factors of a complete anesthetic assessment: past history, allergies, medications, upper airway, etc. This chapter will concentrate on the additional information, beyond a standard anesthetic assessment, that the anesthesiologist needs to manage a thoracic surgical patient. Practice patterns in anesthesia have evolved such that a patient is commonly assessed initially in an outpatient clinic and often not by the member of the anesthesia staff who will actually administer the anesthesia. The actual contact with the responsible anesthesiologist may be only 10–15 min prior to induction. It is necessary to organize and standardize the approach to preoperative evaluation for these patients into two temporally disjoint phases: the initial (clinic) assessment and the final (day-of-admission) assessment. There are elements vital to each assessment which will be described.

Assessment of Respiratory Function

The major cause of perioperative morbidity and mortality in the thoracic surgical population is respiratory complications. Major respiratory complications such as atelectasis, pneumonia, and respiratory failure occur in 15–20% of patients and account for the majority of the expected 3–4% mortality [2]. Cardiac complications such as arrhythmia, ischemia, etc. occur in 10–15% of the thoracic population. Postoperative outcomes after lobectomy are listed in Table 2.1 [3]. The primary focus for the anesthesiologist is to assess the risk of postoperative pulmonary complications.

Table 2.1 Post-lobectomy complications

	Thoracoscopy	Thoracotomy	p value
n	10,173	30,886	
Mortality	1.6%	2.3%	0.06
Length of stay	5 (3–8)	7 (5–9)	<0.001
Any complication	46.5%	50.4%	0.003
Pneumonia	7.3%	8.2%	0.17
Empyema	0.8%	1.4%	0.007
Supraventricular arrhythmia	13.7%	17.9%	<0.0001
Pulmonary embolus	0.6%	1.0%	0.018
Myocardial infarction	0.3%	0.7%	0.01

Based on data from the Nationwide Inpatient Sample Database, Paul et al. [3]

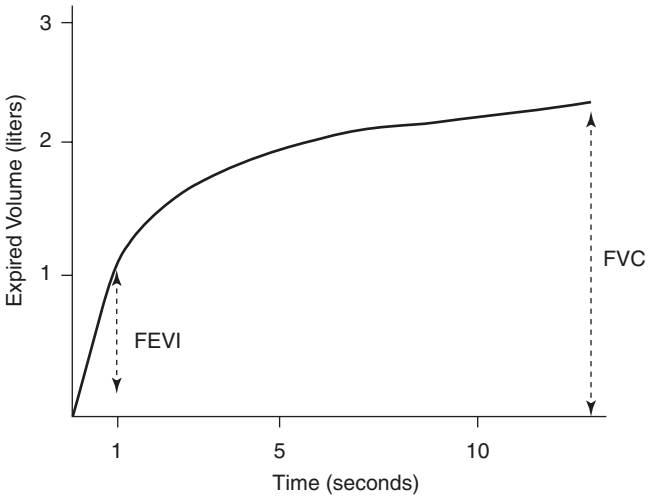

Fig. 2.2 Spirometry should be performed in all pulmonary resection patients to assess the forced expiratory volume in 1 second (FEV1) which can then be corrected for the patient's age, sex, and height to give a percentage of the normal predicted value (FEV1%)

The best assessment of respiratory function comes from a detailed history of the patient's quality of life. All pulmonary resection patients should have baseline simple spirometry preoperatively to measure forced expiratory volume in 1 second (FEV1) and forced vital capacity (FVC) (Fig. 2.2) [4]. Simple portable spirometers are available that can be used easily in the clinic or at the bedside to make these measurements (Fig. 2.3). Objective measures of pulmonary function are required to guide anesthetic management and to have this information in a format that can be easily transmitted between members of the healthcare team. Much effort has been spent to try and find a single test of respiratory function that has sufficient sensitivity and specificity to predict outcome for all pulmonary resection patients. It is now clear that no single test will ever accomplish this. It is useful to assess each patient's respiratory function in three related but largely independent areas: respiratory mechanics, pulmonary parenchymal function, and cardiorespiratory interaction.

Fig. 2.3 An example of a portable handheld spirometer which can be easily used in the preoperative assessment clinic or at the bedside to measure forced expiratory flows and volumes

These can be remembered as the basic functional units of extracellular respiration, which are to get atmospheric oxygen (1) into the alveoli, (2) into the blood, and (3) to the tissues (the process is reversed for carbon dioxide removal).

Lung Mechanical Function

Many tests of respiratory mechanics and volumes show correlation with post-thoracotomy outcome: forced expiratory volume in 1 second (FEV1), forced vital capacity (FVC), maximal voluntary ventilation (MVV), and residual volume/total lung capacity (RV/TLC) ratio. For preoperative assessment, these values should always be expressed as a percent of predicted volumes corrected for age, sex, and height (e.g., FEV1%). Of these the most valid single test for post-thoracotomy respiratory complications is the predicted postoperative FEV1 (ppoFEV1%) [5] which is calculated as:

$$\text{ppoFEV1\%} = \text{preoperative FEV1\%} \times \left(1 - \%\text{functional lung tissue removed} / 100\right)$$

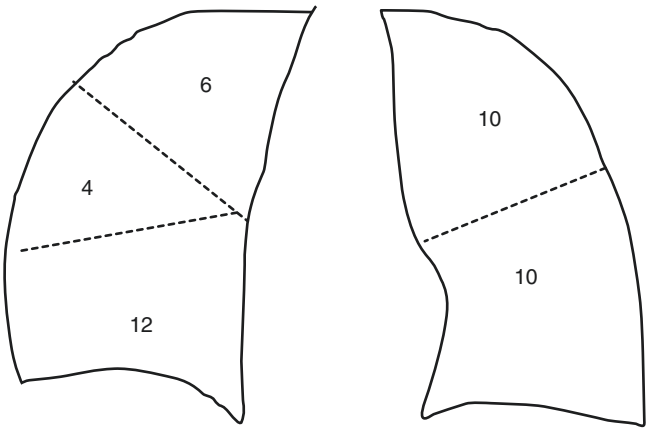

Fig. 2.4 The number of subsegments of each lobe is used to calculate the predicted postoperative (ppo) pulmonary function. For example, following a right lower lobectomy, a patient with a preoperative FEV1 (or DLCO) 70% of normal would be expected to have a ppoFEV1 = 70% × (1–29/100) = 50%

One method of estimating the percent of functional lung tissue is based on a calculation of the number of functioning subsegments of the lung removed (Fig. 2.4). Nakahara et al. [4] found that patients with a ppoFEV1 > 40% had no or minor post-resection respiratory complications. Major respiratory complications were only seen in the subgroup with ppoFEV1 < 40% (although not all patients in this subgroup developed respiratory complications), and 10/10 patients with ppoFEV_1 < 30% required postoperative mechanical ventilatory support. These key threshold ppoFEV1 values 40% and 30% are extremely useful to remember when managing these patients. The schema of Fig. 2.4 may be overly complicated, and it can be useful just to simply consider the right upper and middle lobes combined as being approximately equivalent to each of the other three lobes with the right lung 10% larger than the left. These data of Nakahara are from work done in the 1980s, and recent advances, such as improved postoperative analgesia, have decreased the incidence of complications in the high-risk (ppoFEV1 < 30%) group [6]. The use of minimally invasive thoracic surgery has also allowed safe pulmonary resection to be performed in individuals traditionally considered to have increased risk [7].

However, a ppoFEV1 value of ≤40% remains useful as a reference point for the anesthesiologist to identify the patient at increased risk. The ppoFEV1 is the most significant independent predictor of complications among a variety of historical, physical, and laboratory tests for these patients. In the 30 years since the original publication by Nakahara, repeated trials in different populations have consistently supported the use of ppoFEV1 < 40% as a threshold for increased risk and ppoFEV1 < 30% as the threshold for high risk [8].

Patients with ppoFEV1 values <40% can be operated on with acceptable morbidity and mortality in certain circumstances. Linden et al. [9] reported on a series of 100 patients with ppoFEV1 < 35% who had lung resections for cancer with only 1 mortality and with a 36% complication rate. Whenever possible, these patients had VATS procedures and thoracic epidural analgesia. The authors propose an absolute lower limit of acceptability for resection as a ppoFEV1 < 20%. It should be appreciated that this report is from a center with a very high volume of thoracic surgery and surgical outcomes for lung cancer are correlated to the volume of surgery. High-volume hospitals had complication and mortality rates (20% and 3%, respectively) that were approximately one-half of low-volume hospitals (44% and 6%) [10]. However, the majority of institutions currently perform VATS procedures without thoracic epidural analgesia.

The actual measured postoperative FEV1 will not be the same as the ppoFEV1 for several reasons. First, it is impossible to predict the actual intraoperative surgical trauma to the chest wall and residual lung segments. Most patients will have FEV1 values immediately postoperatively that are less than the ppoFEV1, and these will improve over a period of 6 months [11]. Second, emphysematous patients will tend to have a lung-volume reduction effect on the residual lobe(s) and may exceed their ppoFEV1 if a hyperinflated lobe is resected. The actual postoperative FEV1 has been shown to be a better predictor of outcome than the ppoFEV1; however, the actual postoperative FEV1 is not available preoperatively.

Absolute predicted postoperative values for FEV1 were used in the past to assess patients. Absolute limits for ppoFEV1 such as 0.8 L were suggested as the lower limits of acceptability for resection. However, absolute values for pulmonary function tests do not take into consideration the wide variation in the size of patients who present for thoracic surgery. An absolute FEV1 result of 1 L for an 80-year-old male 5 ft. (152 cm) in height is normal (100% of predicted), but an FEV1 of 1 L for a 6 ft. (183 cm) 50-year-old male is severely abnormal (24% predicted). It is important always to consider patients' spirometry results as a percentage of their predicted normal.

Patients at increased risk of respiratory complications (ppoFEV1 < 40%) should have complete pulmonary function testing in a pulmonary function laboratory which will include an assessment of lung volumes and airway resistance (Fig. 2.5). These are more sensitive than an examination of the FEV1/FVC ratio to distinguish between obstructive and restrictive lung pathologies and will confirm the clinical

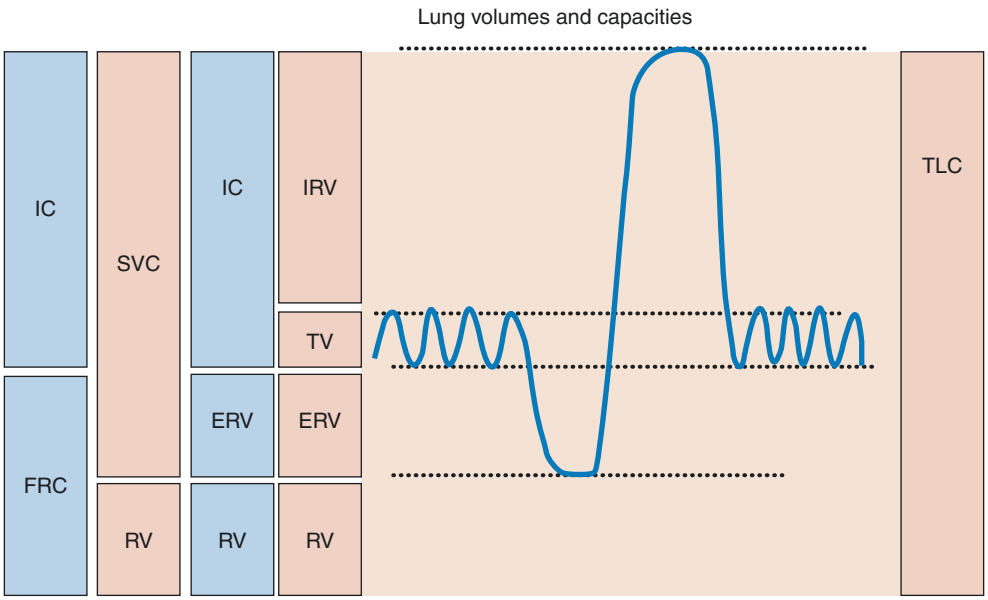

Fig. 2.5 Complete pulmonary function testing will provide data on lung volumes and capacities to differentiate obstructive from restrictive diseases. FRC = functional residual capacity; IC = inspiratory capacity; RV = residual volume; SVC = slow vital capacity; ERV = expiratory reserve volume; TV = tidal volume; IRV = inspiratory reserve volume; TLC = total lung capacity. Measuring closing volume and closing capacity requires insoluble gas washout techniques and is not included in routine pulmonary function testing. However, an appreciation of the variable relationship between closing capacity and FRC and the effects of anesthesia on FRC is essential for the anesthesiologist to understand the changes in gas exchange that occur during anesthesia (the reader is referred to Lumb AB, Nunn's Applied Respiratory Physiology, 7th ed., p. 58, Churchill Livingston Elsevier, Philadelphia, 2010, for a detailed explanation)

diagnosis of the underlying lung disease. Also this permits for optimization of intraoperative management during both two-lung and one-lung ventilation by individualization of settings for mechanical ventilation depending on the lung pathology [12]. There are two basic methods of measurement of lung volumes: insoluble gas dilution and plethysmography (Fig. 2.6). Plethysmography is the common method used in pulmonary function laboratories to measure lung volumes and has largely replaced insoluble gas dilution techniques. The difference (plethysmography-dilution) in measured lung volumes between the two techniques can be used to estimate the volume of bullae in the lung. Previously, maximal breathing capacity was also used to assess patients for pulmonary resection. This simple test was used in the era of pulmonary resection for tuberculosis and has been replaced by modern spirometry.

Pulmonary Parenchymal Function

As important to the process of respiration as the mechanical delivery of air to the distal airways is the subsequent ability of the lung to exchange oxygen and carbon dioxide between the pulmonary vascular bed and the alveoli. Traditionally arterial blood gas data such as PaO_2 < 60 mmHg or $PaCO_2$ > 45 mmHg have been used as cutoff values for pulmonary resection. Cancer resections have now been successfully done or even combined with volume reduction in patients who do not meet these criteria, although they remain useful as warning indicators of increased risk. The most useful test of the gas exchange capacity of the lung is the diffusing capacity for carbon monoxide (DLCO). The DLCO is a reflection of the total functioning surface area of alveolar-capillary interface. This simple noninvasive test which is included with spirometry and plethysmography by most pulmonary function laboratories is a useful predictor of perioperative morbidity and mortality [13]. The corrected DLCO can be used to calculate a post-resection (ppo) value using the same calculation as for the FEV1 (Fig. 2.7). A ppoDLCO <40% predicted correlates with both increased respiratory and cardiac complications and is, to a large degree, independent of the FEV1. The National Emphysema Treatment Trial has shown that patients with a preoperative FEV_1 or DLCO <20% had an unacceptably high perioperative mortality rate [14]. These can be considered as the absolute minimal values compatible with successful outcome. Complete pulmonary function testing, as performed in a pulmonary function laboratory, generates a report with

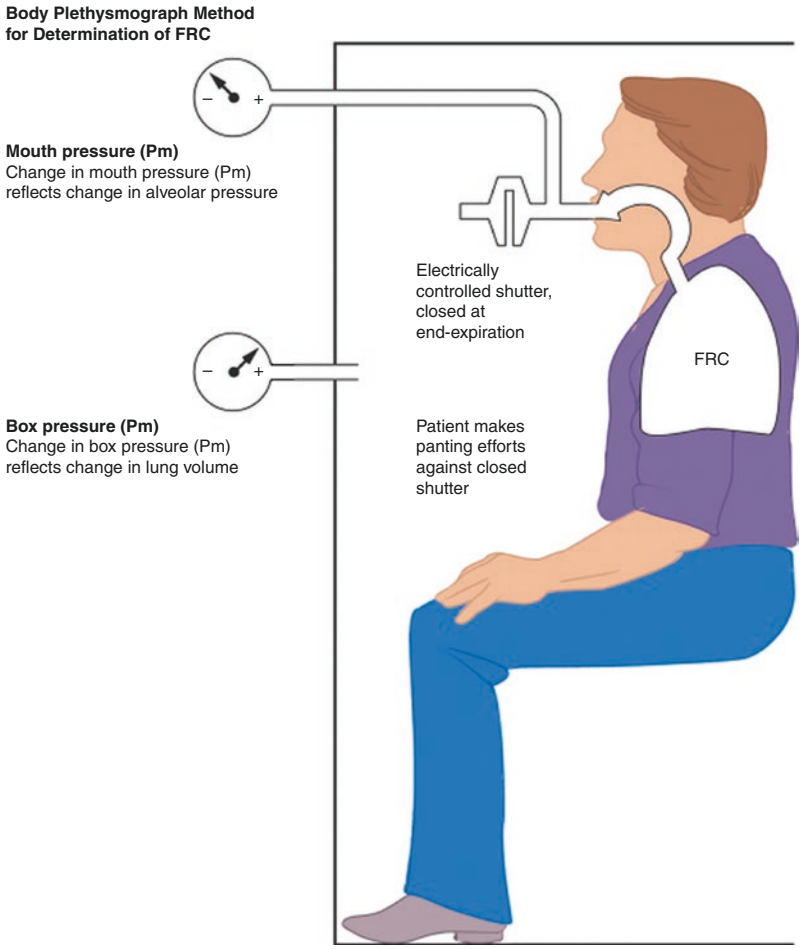

Fig. 2.6 Measurement of lung volumes is commonly performed with whole-body plethysmography with the patient seated in an airtight box. Lung volumes can be calculated from changes in the airway and box pressure since the volume of the box is known

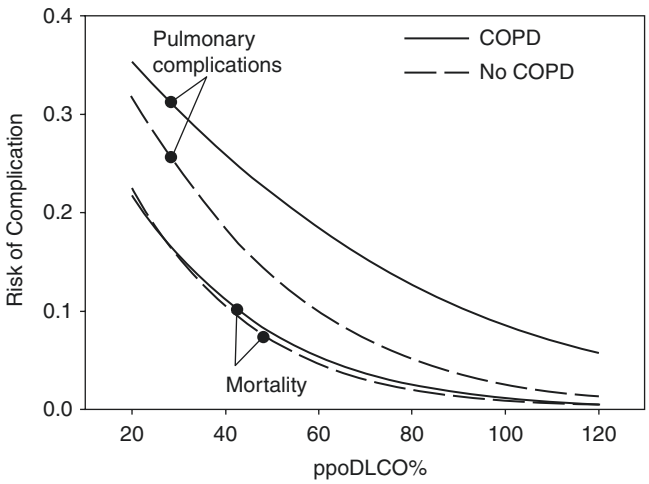

Fig. 2.7 Regression lines for the risk of pulmonary (upper lines) or fatal (lower lines) complications vs. predicted postoperative diffusing capacity for carbon monoxide (ppoDLCO%) following lung resection in patients with (solid lines) and without (dashed lines) chronic obstructive pulmonary disease (COPD). Note that both morbidity and mortality increase sharply when the ppoDLCO falls below a threshold value of 40%. (Reprinted from Ferguson and Vigneswaran [12] with permission)

often >12 test results (Fig. 2.8). Of these results, the two most valid tests for the anesthesiologist to use to assess perioperative risk are the % predicted FEV1 and DLCO. In evaluating a patient for pulmonary resection, the lower of the two values (ppoFEV1 or ppoDLCO) should be used as the guide for risk evaluation [15].

Cardiopulmonary Interaction

The final and perhaps most important assessment of respiratory function is an assessment of the cardiopulmonary interaction. Formal laboratory exercise testing is currently the "gold standard" for assessment of cardiopulmonary function [16], and the maximal oxygen consumption (VO_2 max) is the most useful predictor of post-thoracotomy outcome. The test is performed on a bicycle ergometer or treadmill. Resting measurements are made for 3–5 min. Three minutes of unloaded cycling is performed as a warm-up period. The workload is incremented at a rate designed to allow reaching maximum work capacity in 8–12 min. The test continues to

Fig. 2.8 A copy of the pulmonary function laboratory test report for a patient with severe emphysema. Of the 15 different results in this report, the 2 results highlighted are the % predicted FEV1 and DLCO, which are the most useful tests for the anesthesiologist assessing a patient for possible pulmonary resection. This patient had taken a bronchodilator immediately before the test so the usual post-bronchodilator (Post BD) test was not repeated. Pred. val. = predicted value corrected for the patient's age, sex, and height. Obs. = patient's measured result. VA = the single-breath dilutional estimate of TLC from the DLCO

a point of symptom limitation (e.g., severe dyspnea) or discontinuation by medical staff (e.g., significant ECG abnormalities) or achievement of maximum predicted heart rate. Estimated VO_2 max is based on the patient's age, sex, and height. For sedentary males, estimated VO_2 max (ml/min) = (height [cm] – age [y]) × 20, i.e., for a 50-year-old male, height 170 cm, and weight 70 kg, the predicted VO_2 max = [(170–50) × 20]/70 = 34 ml/kg/min. For a sedentary woman, age 50, 160 cm, and 60 kg, estimated VO_2 max = [(160–50) × 14]/60 = 26 ml/kg/min (for comparison: the highest VO_2 max recorded in an exercise laboratory is 85 ml/kg/min by the American cyclist Lance Armstrong in 2005 [17]).

The risk of morbidity and mortality is unacceptably high if the preoperative VO_2 max is <15 ml/kg/min [18]. Few patients with a VO_2 max >20 ml/kg/min have respiratory complications. Exercise testing is particularly useful to differentiate between patients who have poor exercise tolerance due to respiratory and cardiac etiologies (Fig. 2.9). The anaerobic threshold measured during exercise testing has also been suggested as a predictor of postoperative complications [19]. The anaerobic threshold is the exercise level at which lactate begins to accumulate in the blood and anaerobic metabolism begins. The anaerobic threshold is approximately 55% of VO_2 max in untrained individuals but rises to >80% in trained athletes. The anaerobic threshold can be documented by repeated blood lactate analysis during exercise or by a threshold increase in CO_2 production above the initial respiratory quotient (ratio of CO_2 production to O_2 consumption, commonly approximately 0.8). A threshold value for AT of <11 ml/kg/min has been suggested as a marker for increased risk, but this has not been well validated [20]. Like FEV1 and DLCO, the VO_2 can be corrected for predicted values. A VO_2 max <60% predicted has been suggested as a threshold for increased risk; however, the % predicted VO_2 max has not been shown to be more useful than the absolute value of VO_2 max as a predictor postoperative of outcomes [21].

Complete laboratory exercise testing is time-consuming and thus expensive. It is generally not cost-effective to use as

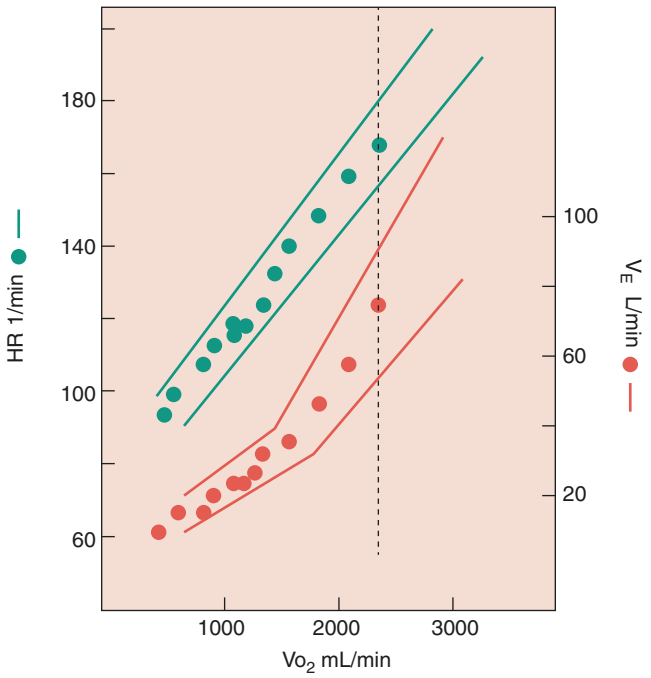

Fig. 2.9 A normal cardiopulmonary exercise test result. As the patient exercises, the increase in oxygen consumption (horizontal axis) is plotted against the heart rate (green dots, left vertical axis) and the minute ventilation (V_E, orange dots, right vertical axis). Normal responses for heart rate and ventilation lie within the green and orange lines. The vertical dashed line is the predicted upper limit of normal based on age. Patients with primarily cardiac causes for exercise limitation will show an excessive increase in heart rate with exercise. Patients with primarily respiratory limitation will show a disproportionate increase in ventilation. Patients with pulmonary vascular disease will have both abnormal heart rate and ventilation responses. (Reprinted with permission from Pearson GF, Thoracic Surgery 3rd. Ed. 2008, Elsevier, Philadelphia, PA)

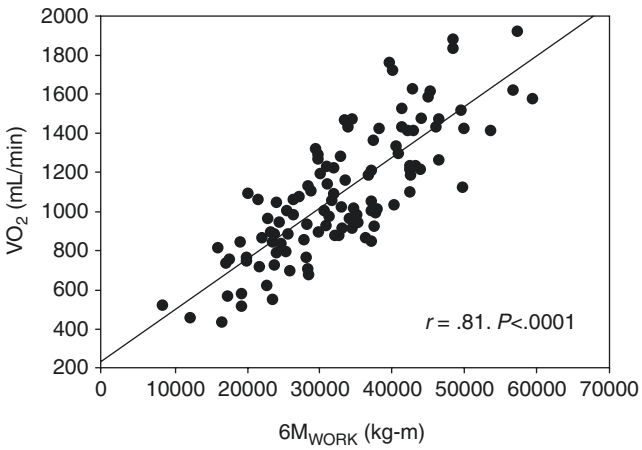

Fig. 2.10 The maximal oxygen consumption VO_2 (ml/min) shows a strong correlation with work ($6M_{WORK}$) for patients with moderate or severe COPD during a 6 min walk test. Work = distance traveled × weight (kg.m). A 70 kg patient who walks 450 m does 31,500 kg.m of work which correlates with an estimated VO_2 max of 1100 ml/min (or 16 ml/kg/min). A simple estimate of the VO_2 max can be made by diving the 6 min walk distance by 30 (i.e., 450 m/30 = 15 ml/kg/min). (Reprinted with permission from Carter et al. [21])

a routine part of the preoperative assessment for all pulmonary resection patients. Several alternatives have been demonstrated to be valid surrogate tests for pre-thoracotomy assessment. The distance that a patient can walk during a 6-minute walk test (6MWT) shows an excellent correlation with VO_2 max and requires little or no laboratory equipment (Fig. 2.10). For patients with moderate or severe COPD, the 6MWT distance can be used to estimate the VO_2 max by dividing by a figure of 30 (i.e., 600-m distance is equivalent to a VO_2 max of 600/30 = 20 ml/kg/min) [22].

The 6MWT has become the most valid low-tech assessment of exercise capacity [23]. In a series of lobectomy patients, those with a preoperative 6MWT <500 m (approximate VO_2 max = 17 ml/kg) had a significantly higher rate of postoperative complications (61% vs. 37%) compared to those with a 6MWT >500 m [24].

Some centers also assess the fall in oximetry (SpO_2) during exercise. Patients with a decrease of SpO_2 > 4% during exercise (stair climbing 2 or 3 flights or equivalent) [25] are at increased risk of morbidity and mortality. Post-resection exercise capacity can also be estimated based on the amount of functioning lung tissue removed (see Fig. 2.4). An estimated ppoVO_2 max <10 ml/kg/min can be considered a contraindication to pulmonary resection. In a small series [26], mortality was 100% (3/3) patients with a ppoVO_2 max <10 ml/kg/min.

The traditional, and still useful, test in ambulatory patients is stair climbing [27]. Stair climbing is done at the patient's own pace but without stopping and is usually documented as a certain number of flights. There is no exact definition for a "flight," but 20 steps at 6 in./step is a frequent value. The ability to climb five flights correlates with a VO_2 max >20 ml/kg/min, and climbing two flights corresponds to a maximal oxygen consumption (VO_2 max) of 12 ml/kg/min. A patient unable to climb two flights is extremely high risk [28].

After pulmonary resection, there is a degree of right ventricular dysfunction that seems to be in proportion to the amount of functioning pulmonary vascular bed removed. The exact etiology and duration of this dysfunction remain unknown. Clinical evidence of this hemodynamic problem is minimal when the patient is at rest but is dramatic when the patient exercises leading to elevation of pulmonary vascular pressures, limitation of cardiac output, and absence of the normal decrease in pulmonary vascular resistance usually seen with exertion [29].

Regional Lung Function

Prediction of post-resection pulmonary function can be further refined by assessment of the preoperative contribution of the lung or lobe to be resected by imaging of regional lung

function [30]. If the lung region to be resected is nonfunctioning or minimally functioning, the prediction of postoperative function can be modified accordingly. This is particularly useful in pneumonectomy patients [31], and regional lung function imaging should be ordered for any potential pneumonectomy patient who has a preoperative FEV1 and/or DLCO <80% (i.e., if ppo values <40% predicted). Regional lung function imaging can be performed by three techniques: radionuclide ventilation/perfusion (V/Q) lung scanning, pulmonary quantitative CT scanning, or three-dimensional dynamic perfusion magnetic resonance imaging (MRI).

Ventilation/perfusion lung scanning is the gold standard. Regional ventilation is assessed by scanning after inhalation of a radiolabeled insoluble gas (commonly xenon-133). Regional lung perfusion is assessed by scanning after intravenous injection of radiolabeled particles that are trapped in the pulmonary capillaries (commonly technetium-99 m macroaggregated albumin) (Fig. 2.11). Actual postoperative lung function has shown a high correlation with predicted values based on preoperative V/Q scanning for FEV1 (r = 0.92), DLCO (r = 0.90), and VO_2 max (r = 0.85). Prediction is more accurate for post-pneumonectomy vs. post-lobectomy values. If there is a discrepancy between the ventilation and perfusion scan results, it is preferable to use the result which attributes the larger proportion of ventilation or perfusion to the diseased lung to estimate the post-resection pulmonary function.

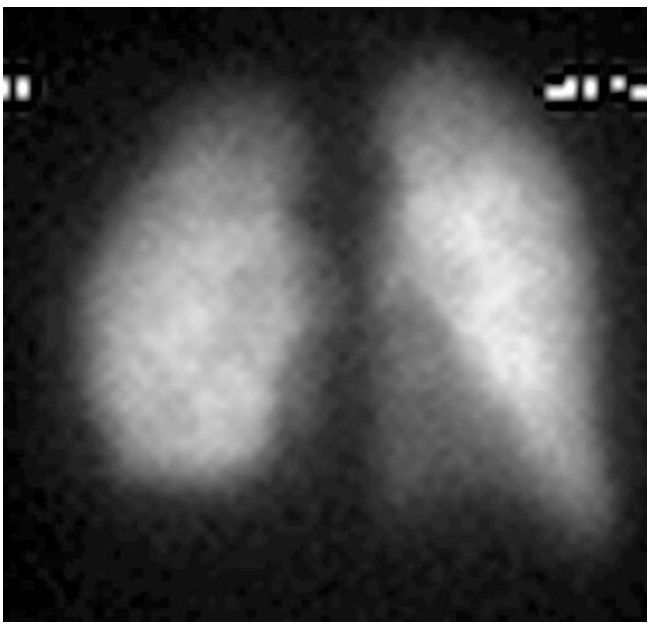

Fig. 2.11 Perfusion scan of a patient with a right lung tumor being assessed for possible pneumonectomy. The perfusion of the right lung (seen on the left in the image) was 37% and the left 63%. Preoperative FEV1 = 74% predicted and DLCO = 70%. Based on the anatomic number of subsegments to be excised, the predicted postoperative (ppo) FEV1 = 74 × 22/42 = 39% and the ppoDLCO = 70 × 22/42 = 37%. Using the regional lung imaging to predict postoperative values, the ppoFEV1 = 74 × 0.63 = 47% and the ppoDLCO = 70 × 0.63 = 44%, which are above the threshold values for increased perioperative risk

Quantitative CT lung scans can be used to estimate post-resection values [32]. Each CT slice is quantified for areas of normal parenchyma, emphysema, and atelectasis. The contribution of each lobe or lung can be estimated based on the volume of normal parenchyma and then used to predict postoperative lung function. Quantitative CT primarily focuses on areas of ventilation and is more accurate for post-lobectomy vs. post-pneumonectomy values. Predicted postoperative values for FEV1 and DLCO were comparable to those derived from V/Q scans but less accurate for VO_2 max. This is a newer technique than V/Q scanning and requires specific imaging expertise. However, due to the routine preoperative CT scanning of most pulmonary resection patients, it may become more available.

Dynamic MRI uses estimates of regional pulmonary blood volume to assess regional blood flow [33]. This is the newest of the three techniques and is not widely used. It has shown a high level of correlation between predicted and actual values for postoperative FEV1. It has not been assessed for predicting DLCO or VO_2 max.

Split-Lung Function Studies

A variety of methods have been described to try and simulate the postoperative respiratory situation by preoperative unilateral exclusion of a lung or lobe with a double-lumen tube or bronchial blocker and/or by pulmonary artery balloon occlusion of a lung or lobe artery [34]. These tests have not shown sufficient predictive validity for universal adoption in lung resection patients. Lewis et al. [35] have shown that in a group of patients with COPD (ppoFEV1 < 40%) undergoing pneumonectomy, there were no significant changes in the pulmonary vascular pressures intraoperatively when the pulmonary artery was clamped but the right ventricular ejection fraction and cardiac output decreased. Echocardiography may offer more useful information than vascular pressure monitoring in these patients [36]. Split-lung function studies have been replaced in most centers by a combined assessment involving spirometry, DLCO, exercise tolerance, and imaging of regional lung function.

Combination of Tests

No single test of respiratory function has shown adequate validity as a sole preoperative assessment. Prior to surgery, an estimate of respiratory function in all three areas, lung mechanics, parenchymal function, and cardiopulmonary interaction, should be made for each patient. These three

aspects of pulmonary function form the "three-legged stool" which is the foundation of pre-thoracotomy respiratory testing (Fig. 2.12). The three-legged stool can also be used to guide intra- and postoperative management (Fig. 2.13) and also to alter these plans when intraoperative surgical factors necessitate that a resection becomes more extensive than foreseen. If a patient has a ppoFEV1 > 40%, it should be possible for that patient to be extubated in the operating room at the conclusion of surgery assuming the patient is alert, warm, and comfortable ("AWaC"). Patients with a ppoFEV1 < 40% will usually comprise about one-fourth of an average thoracic surgical population. If the ppoFEV1 is >30% and exercise tolerance and lung parenchymal function exceed the increased risk thresholds, then extubation in the operating room should be possible depending on the status of associated medical conditions. Those patients in this subgroup who do not meet the minimal criteria for cardiopulmonary and parenchymal function should be considered for staged weaning from mechanical ventilation postoperatively so that the effect of the increased oxygen consumption of spontaneous ventilation can be assessed. Patients with a ppoFEV1 20–30% and favorable predicted cardiorespiratory and parenchymal function can be considered for early extubation if thoracic epidural analgesia is used or if the resection is performed with VATS. Otherwise, these patients should have a postoperative staged weaning from mechanical ventilation. In the borderline group (ppoFEV1 30–40%), the presence of several associated factors and diseases which should be documented during the preoperative assessment will enter into the considerations for postoperative management (see below).

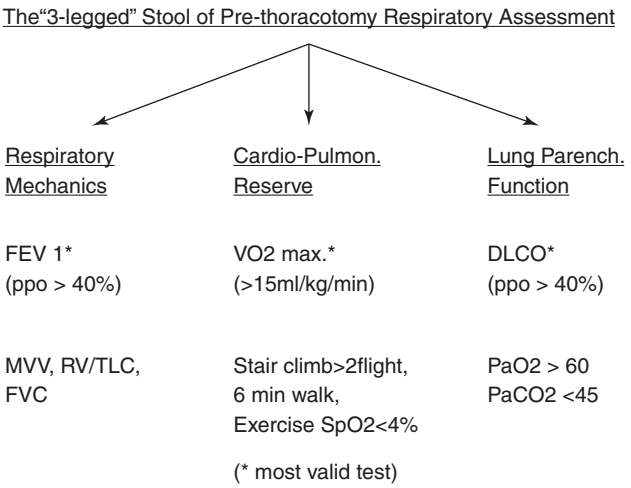

Fig. 2.12 The "three-legged stool" of pre-thoracotomy respiratory assessment involves evaluation of lung mechanical function, pulmonary parenchymal function, and cardiopulmonary interaction for each patient. The most valid test in each area is denoted by *. The threshold values below which risk increases are in parentheses. Ppo = predicted postoperative value as a % of the patient's normal value

Jordan and Evans have outlined a protocol for planned elective admission of pulmonary resection patients to the intensive care unit postoperatively [37]. In their scheme, patients age ≥ 70 years or with fibrotic lung disease or with positive cardiovascular risk assessment or with an elevated ASA score or poor lung function (preoperative FEV <47%) would be admitted to ICU. Others would go to the recovery unit and then a monitored ward bed.

Concomitant Medical Conditions

Cardiac Disease

Cardiac complications are the second most common cause of perioperative morbidity and mortality in the thoracic surgical population. The commonest major cardiac complications are myocardial ischemia/infarction, arrhythmias, and heart failure. Several schemes have been developed to predict overall perioperative cardiac risk (see Table 2.2). The revised cardiac risk score [38] was developed for all major noncardiac sur-

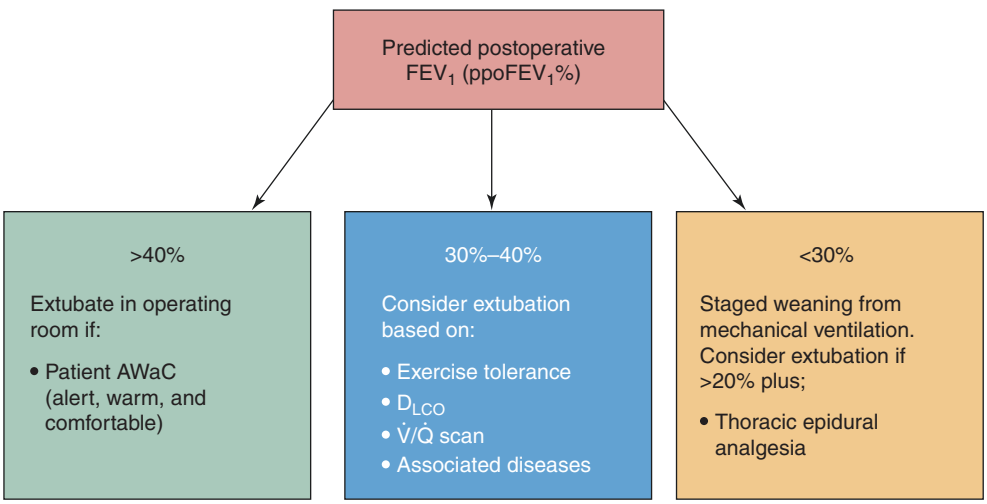

Fig. 2.13 Anesthetic management guided by preoperative assessment and the amount of functioning lung tissue removed during surgery

gery, and the thoracic revised cardiac risk score was developed specifically for thoracic surgery patients [39]. However, the predictive ability of these two scores in prospective studies has not always been high [40]. There is always a delay of several years between the time of development of these risk indices and actual prospective clinical studies. Their lack of accuracy in prospective studies may be due in part to the evolving underlying characteristics of the population with cardiac disease and also due to the rapid progress in preventing and treating major cardiovascular complications. Patients being treated with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers preoperatively are at an increased risk of postoperative cardiovascular complications if these medications are continued in the 24-h period before surgery [41].

Table 2.2 A comparison of the preoperative revised cardiac risk index and the thoracic revised cardiac risk index

Revised cardiac risk index (RCRI)	Points	Thoracic RCRI	Points
High-risk surgery (all major thoracic surgery)	1	Pneumonectomy	1.5
Coronary artery disease	1	Coronary artery disease	1.5
Congestive heart failure	1		
Cerebrovascular disease	1	Cerebrovascular disease	1.5
Diabetes on insulin	1		
Serum creatinine >2 mg/ml (>177 umol/L)	1	Serum creatinine >2 mg/ml (>177 umol/L)	1

Based on Licker et al. [95]
RCRI: 0–1 point = low-risk mortality (0.8%); 2 points = moderate risk (2.4%); >2 points = high risk (5.4%)
Thoracic RCRI: 0 points = low risk (<5%); 1–1.5 points = moderate risk (5–10%); ≥2 points = high risk (11–20%)

Ischemia

Because the majority of pulmonary resection patients have a smoking history, they already have one risk factor for coronary artery disease (other factors include male sex, heredity, diabetes, obesity, high blood pressure, and elevated cholesterol). Elective pulmonary resection surgery is regarded as an "intermediate-risk" procedure in terms of perioperative cardiac ischemia [42]. The overall documented incidence of post-thoracotomy ischemia is 5% and peaks on days 2–3 postoperatively [43]. Beyond the standard history, physical, and electrocardiogram, further routine testing for cardiac disease does not appear to be cost-effective for all prethoracotomy patients.

The American College of Cardiology and American Heart Association have developed algorithms for preoperative cardiac investigations [44]. These guidelines are inclusive for all patients and not specific to thoracic surgery patients. A simplified algorithm, based on these recommendations, is presented in Fig. 2.14. Patients with intermediate clinical predictors of

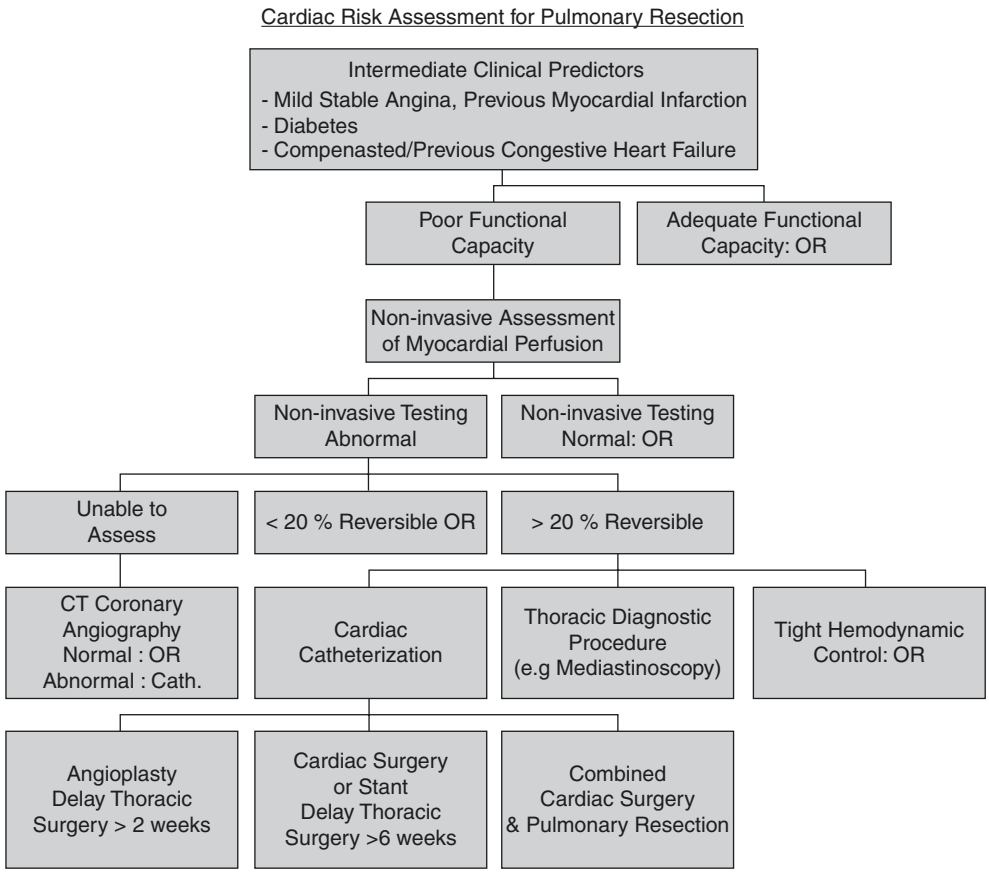

Fig. 2.14 An algorithm for cardiac risk assessment prior to noncardiac thoracic surgery. (Based on Fleisher et al. [43]). OR = operating room (i.e., proceed with surgery without further cardiac investigation). Cath. = coronary catheterization. Once a patient is found to have an abnormal result on noninvasive testing of myocardial perfusion, choosing the optimal pathway becomes complicated and requires a combined consultation with the surgeon, cardiologist, and patient

increased cardiac risk (stable angina, diabetes, etc.) who have adequate functional capacity do not need further cardiac investigation prior to pulmonary surgery. Patients with these intermediate predictors and poor functional capacity should have noninvasive testing of myocardial perfusion at rest and during stress. The estimate of myocardial perfusion can be performed by nuclear medicine (technetium sestamibi or thallium injection) or transthoracic echocardiography at rest and during stress. The stress can be either with exercise or by injection of a coronary vasodilator (dipyridamole) or an inotrope (dobutamine). Based on the results from studies in vascular surgery [45], it can be extrapolated that patients with normal perfusion or who have areas of reversibility in <20% of myocardial segments can proceed to surgery without further cardiac investigation.

For patients who have major reversibility on a myocardial perfusion test, the diagnostic and therapeutic pathway is less clear. The standard recommendation is to proceed to cardiac catheterization. However, in individual circumstances, it could be an option to proceed with a minor diagnostic procedure (such as an endobronchial ultrasound or mediastinoscopy) first if there is a reasonable possibility that the patient may not have a resectable cancer. Or, it may be considered to proceed with the pulmonary resection with very tight perioperative hemodynamic control since it is not clear that coronary intervention improves perioperative outcome in patients who are not clear candidates for intervention outside the perioperative period [46]. The wisdom of elective perioperative β-blockade in these patients is debatable [47]. β-blockade may decrease the perioperative cardiac risk but increase the risk of stroke. Patients who have an indication for β-blockade apart from the perioperative context should be started and continued on these medications perioperatively, appreciating that many thoracic surgical patients have reactive airways disease that may be exacerbated by β-blockade. The use of β-blockers otherwise should be guided by specific hemodynamic indications.

For patients who require coronary catheterization, the results may necessitate angioplasty with or without stenting or coronary artery bypass surgery before or at the same time as pulmonary surgery (see Chap. 40). It is very important that the interventional cardiologist be made aware of the patient's diagnosis and the perioperative context prior to angiography. If bare metal coronary stents are placed, the patient will require dual antiplatelet therapy with a $P2Y_{12}$ receptor antagonist (clopidogrel, prasugrel, or ticagrelor) and aspirin for 4–6 weeks before the $P2Y_{12}$ inhibitor can be stopped (and the aspirin continued) preoperatively [48]. In some cases this is an acceptable delay before a major pulmonary resection or other thoracic surgeries. However, if drug-eluting stents are placed, the risk of stent stenosis, which is often fatal, is unacceptable if dual antiplatelet therapy is discontinued in the first 6 months. This is generally not an acceptable delay for cancer surgery.

Timing of lung resection surgery following a myocardial infarction is always a difficult decision. Limiting the delay to 4–6 weeks in a medically stable and fully investigated and optimized patient seems acceptable after myocardial infarction. The anesthesiologist needs to appreciate that the preoperative assessment and the therapeutic options for patients with significant coronary artery disease presenting for lung surgery are becoming very complicated and no single algorithm can be applied given the complexities of each individual case and the local availability of diagnostic equipment and personnel. Each of these patients needs to be managed by a team consultation that includes the thoracic surgeon, the cardiologist, the anesthesiologist, and the patient and family. The management of a patient who is discovered to have an incidental lung lesion during preoperative assessment for coronary artery or cardiac valvular surgery is discussed in Chap. 40.

Arrhythmias

The management of post-thoracotomy arrhythmias is discussed in Chap. 56. Arrhythmias are a common complication of pulmonary resection surgery, and the incidence is 30–50% of patients in the first week postoperatively when Holter monitoring is used [49]. Of these arrhythmias, 60–70% are atrial fibrillation. Several factors correlate with an increased incidence of arrhythmias; these include extent of lung resection (pneumonectomy 60% vs. lobectomy 40% vs. non-resection thoracotomy 30%), intrapericardial dissection, intraoperative blood loss, and age of the patient. Extrapleural pneumonectomy patients are a particularly high-risk group [50].

Two factors in the early post-thoracotomy period interact to produce atrial arrhythmias.

1. Increased flow resistance through the pulmonary vascular bed due to permanent (lung resection) or transient (atelectasis, hypoxemia) causes, with attendant strain on the right side of the heart.
2. Increased sympathetic stimuli and oxygen requirements, maximal on the second postoperative day as patients begin to mobilize.

In some pneumonectomy patients, the right heart may not be able to increase its output adequately to meet the usual postoperative stress. Transthoracic echocardiographic studies have shown that pneumonectomy patients develop an increase in right ventricular systolic pressure as measured by the tricuspid regurgitation jet (TRJ) on postoperative day 2 but not on day 1. An increase in TRJ velocity has been associated with post-thoracotomy supraventricular tachyarrhythmias [36]. Patients with COPD are more resistant to pharmacologic rate control when they develop post-thoracotomy atrial fibrillation and often require multiple drugs [51].

A wide variety of antiarrhythmics have been tried to decrease the incidence of atrial arrhythmias after lung

surgery. The best known of these are digoxin preparations. It has been demonstrated that digoxin does not prevent arrhythmias after pneumonectomy or other intrathoracic procedures. Other agents which have been tried to prevent post-thoracotomy arrhythmias include β-blockers, verapamil, and amiodarone. All of these agents decrease arrhythmias in thoracic patients. At present the consensus statement of the American Association for Thoracic Surgery [52] recommends continuing β-blockers for patients who are already on them and intravenous magnesium for any patient who may have low or depleted serum and/or body stores of magnesium. In patients at high risk of postoperative supraventricular arrhythmias (lobectomy, pneumonectomy, esophagectomy, etc.), consideration of prophylactic therapy with diltiazem or amiodarone should be considered.

In one study [53] patients who subsequently developed atrial tachyarrhythmias could be identified in the early postoperative period by their right ventricular response to the withdrawal of supplemental oxygen. On the first postoperative day, a decrease of FiO_2 from 0.35 to 0.21 caused a significant rise of right ventricular end-diastolic pressure (RVEDP) in the patients who subsequently developed arrhythmias. Thoracic epidural analgesia (TEA) with local anesthetics may decrease the incidence and severity of arrhythmias. This effect is thought to be due to increasing myocardial refractory period, decreasing ventricular diastolic pressures, and improving endocardial/epicardial blood flow ratios [54].

Age

Perioperative management of the geriatric patient for thoracic surgery is discussed in Chap. 32. There is no maximum age that is a cutoff for pulmonary resection surgery. In one series, the operative mortality in a group of patients 80–92 years of age was 3%, a very respectable figure [55]. However, the rate of respiratory complications (40%) was double than expected in a younger population, and the rate of cardiac complications (40%), particularly arrhythmias, was nearly triple than which would be seen in younger patients. Naturally, the long-term (5-year) postoperative survival is decreased in the geriatric population [56].

In the elderly, thoracotomy should be considered a high-risk procedure for cardiac complications, and cardiopulmonary function is the most important part of the preoperative assessment. An algorithm for the cardiac assessment of the geriatric patient for thoracic surgery is presented in Fig. 2.15. Exercise tolerance seems to be the primary determinant of outcome in the elderly [57]. The ACC/AHA guidelines [43] suggest that with adequate functional capacity, patients with "intermediate" predictors of coronary artery disease do not need further cardiac assessment. However, this recommendation should not be extrapolated to elderly patients. The ACC/AHA guidelines define "adequate functional capacity"

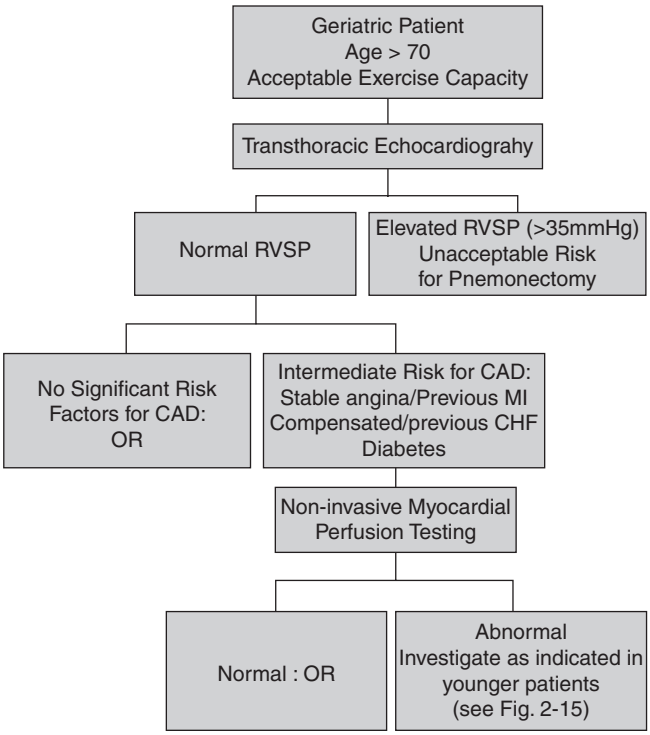

Fig. 2.15 An algorithm for preoperative cardiac investigation in a geriatric patient prior to pulmonary resection surgery. RVSP = right ventricular systolic pressure estimated by echocardiography. CAD = coronary artery disease. OR = operating room (i.e., proceed with surgery without further cardiac investigation)

Table 2.3 Energy consumption in metabolic equivalents (METS) of various activities

Activity	METS
Sitting quietly	1
Walking 1 block	2
Playing the accordion	2
Climbing 1 flight stairs	4
Sexual intercourse[a]	6
Bowling[a]	8
Ice hockey	8
Running 6 mph	10
Cross-country ski racing	14

MET = basal oxygen consumption = 3.5 ml/kg/min. Based on data from Hlatky MA, et al. Am J Cardiol 1989; 64: 651–654; Fleisher et al. [42]
[a]Bowling and sexual intercourse are given fewer METS in some classifications: Ainsworth BA, et al. Med Sci Sports Exerc 1992; 25: 71–80

as four metabolic equivalents (METS). One MET is the basal resting energy output which is commonly equated to an oxygen consumption of 3.5 ml/kg/min. Four METS are the equivalent of climbing one flight of stairs (Table 2.3) which does not represent an adequate level of exercise capacity for a geriatric patient for major pulmonary resection. The elderly should have, as a minimum cardiac investigation, a transthoracic echocardiogram, to rule out pulmonary hypertension. Although the mortality resulting from lobectomy among the elderly is acceptable, the mortality from pneumonectomy,

particularly right pneumonectomy, is excessive [58]. Geriatric patients with intermediate-risk indicators of coronary artery disease should also have noninvasive myocardial perfusion testing. The elderly may benefit from efforts to increase exercise capacity preoperatively. Even a short, 7-day, period of intensive rehabilitation has been shown to increase the 6MWT and decrease pulmonary complications and length of stay in a group of geriatric patients having lung cancer surgery [59].

Renal Dysfunction

Renal dysfunction following pulmonary resection surgery is associated with a high mortality. In 1994, Golledge and Goldstraw [60] reported an incidence of renal impairment after thoracic surgery of 24% with a perioperative mortality of 19% (6/31) in patients who developed a significant elevation of serum creatinine in the post-thoracotomy period, compared to 0% (0/99) in those who did not show any renal dysfunction. Fortunately, a more recent study by Ishikawa et al. has shown that the incidence of postoperative renal injury in thoracic surgery (as defined by the acute kidney injury score) has decreased to 6% and there was no increase in mortality associated with acute kidney injury [61]. Factors associated with an elevated risk of renal impairment were identified in a multivariate analysis by Ahn et al. [62]. (see Table 2.4). Of note, in this study, there was no correlation between intraoperative fluid restriction and postoperative renal dysfunction. Nonsteroidal anti-inflammatory agents (NSAIDs) were not associated with renal impairment in this series but are clearly a concern in any thoracotomy patient with an increased risk of renal dysfunction. The high mortality in pneumonectomy patients from either renal failure or postoperative pulmonary edema emphasizes the importance of fluid management in these patients [63] and the need for close and intensive perioperative monitoring, particularly in those patients on diuretics or with a history of renal dysfunction. The importance of renal dysfunction, either preoperative dialysis or a serum creatinine value >2 mg/dL (>175 umol/L), as a predictor for prolonged length of stay after lobectomy was reconfirmed in an analysis of the Society of Thoracic Surgeons database for the period 2002–2006 [4].

Table 2.4 Factors associated with an increased risk of post-thoracotomy renal impairment

1. Decreased renal function + intraoperative hydroxyethyl starch
2. Preoperative angiotensin-converting enzyme inhibitor/angiotensin receptor blocker therapy
3. Pneumonectomy/esophagectomy
4. Diabetes mellitus
5. Cerebrovascular disease
6. Low serum albumin level

Chronic Obstructive Pulmonary Disease

The most common concurrent illness in the thoracic surgical population is chronic obstructive pulmonary disease (COPD) which incorporates three disorders: emphysema, peripheral airways disease, and chronic bronchitis. Any individual patient may have one or all of these conditions, but the dominant clinical feature is impairment of expiratory airflow [64]. Assessment of the severity of COPD has traditionally been on the basis of the FEV1% of predicted values. The American Thoracic Society categorizes stage I > 50% predicted FEV1% (this category previously included both "mild" and "moderate" COPD), stage II 35–50%, and stage III <35%. Life expectancy may be less than 3 years in stage III patients >60 years of age. Stage I patients should not have significant dyspnea, hypoxemia, or hypercarbia, and other causes should be considered if these are present. A complete discussion of perioperative management of patients with COPD is presented in Chap. 31. Of specific importance in the preoperative assessment of the patient with COPD prior to pulmonary resection is to assess for chronic carbon dioxide retention and to initiate therapy for any potentially treatable complications of COPD.

Carbon Dioxide Retention

Many stage II or III COPD patients have an elevated $PaCO_2$ at rest. It is not possible to differentiate these "CO_2 retainers" from non-retainers on the basis of history, physical examination, or spirometric pulmonary function testing [65]. This CO_2 retention seems to be more related to an inability to maintain the increased work of respiration (W_{resp}) required to keep the $PaCO_2$ normal in patients with mechanically inefficient pulmonary function and not primarily due to an alteration of respiratory control mechanisms. The $PaCO_2$ rises in these patients when a high FiO_2 is administered due to a relative decrease in alveolar ventilation [66] and an increase in alveolar dead space and shunt by the redistribution of perfusion away from lung areas of relatively normal V/Q matching to areas of very low V/Q ratio because regional hypoxic pulmonary vasoconstriction (HPV) is decreased [67] and also due to the Haldane effect [68]. However, supplemental oxygen must be administered to these patients postoperatively to prevent the hypoxemia associated with the unavoidable fall in functional residual capacity (FRC). The attendant rise in $PaCO_2$ should be anticipated and monitored. To identify these patients preoperatively, all stage II or III COPD patients need an arterial blood gas. Also, it is important to know the patient's baseline preoperative $PaCO_2$ to guide weaning if mechanical ventilation becomes necessary in the postoperative period.

Preoperative Therapy of COPD

There are four treatable complications of COPD that must be actively sought and therapy begun at the time of the initial pre-thoracotomy assessment. These are atelectasis, broncho-

Table 2.5 Concurrent problems that should be treated prior to anesthesia in COPD patients

Problem	Method of diagnosis
Bronchospasm	Auscultation
Atelectasis	Chest X-ray
Infection	History, sputum analysis
Pulmonary edema	Auscultation, chest X-ray

spasm, respiratory tract infections, and pulmonary edema (see Table 2.5). Atelectasis impairs local lung lymphocyte and macrophage function predisposing to infection [69]. Pulmonary edema can be very difficult to diagnose by auscultation in the presence of COPD and may present very abnormal radiological distributions (unilateral, upper lobes, etc.) [70]. Bronchial hyper-reactivity may be a symptom of congestive failure [71] or may represent an exacerbation of reversible airway obstruction. All COPD patients should receive maximal bronchodilator therapy as guided by their symptoms. Only 20–25% of COPD patients will respond to corticosteroids. In a patient who is poorly controlled on sympathomimetic and anticholinergic bronchodilators, a trial of corticosteroids may be beneficial [72]. It is not clear if corticosteroids are as beneficial in COPD as they are in asthma; pharmacotherapy for reactive airway diseases is discussed in Chap. 8.

Physiotherapy

Patients with COPD have fewer postoperative pulmonary complications when a perioperative program of intensive chest physiotherapy is initiated preoperatively [73]. Among COPD patients, those with excessive sputum benefit the most from chest physiotherapy. Among the different modalities available (cough and deep breathing, incentive spirometry, PEEP, CPAP, etc.), there is no clearly proven superior method. The important variable is the quantity of time spent with the patient and devoted to chest physiotherapy. Family members or non-physiotherapy hospital staff can easily be trained to perform effective preoperative chest physiotherapy, and this should be arranged at the time of the initial preoperative assessment. Even in the most severe COPD patient, it is possible to improve exercise tolerance with a physiotherapy program. Little improvement is seen before 1 month. In one small study, eight patients who had been refused pulmonary resection on the basis of poor pulmonary function were enrolled in a 4-week program of pulmonary rehabilitation. After the program, the mean 6-min walk test distance for the group increased 29%, and the mean FEV1 increased 5%. All eight patients then had lobectomies without any perioperative mortality [74].

Comprehensive 8–12-week programs of pulmonary rehabilitation involving physiotherapy, exercise, nutrition, and education have been clearly shown to improve functional capacity for patients with severe COPD [75]. These longer programs are generally not an option in resections for malignancy although for nonmalignant resections in severe COPD patients, rehabilitation should be considered. The concept of trying to increase a patient's exercise capacity preoperatively has recently been suggested. In a small randomized controlled trial, Morano et al. [76]. compared standard preoperative chest physiotherapy with pulmonary rehabilitation for a 4-week period before lung resection for cancer in patients with borderline pulmonary function (mean preoperative FEV1 50% predicted). Pulmonary rehabilitation involved 1-h sessions 5 days/week and included periods of interval training to 80% maximal capacity. The 6MWT distance increased significantly in the rehabilitation group (mean 425 to 475 m, $p < 0.05$) vs. no change in the control group, and there was a significant decrease in postoperative morbidity and length of stay (7.8 vs. 12.2 days, $p = 0.04$).

Restrictive Lung Diseases

Restrictive lung physiology is characterized on pulmonary function testing by decreased lung volumes but preserved forced expiratory volume in 1 second to forced vital capacity (FEV1/FVC) ratio. This pattern can be caused by diseases of the lung parenchyma (e.g., interstitial lung diseases), extrinsic problems affecting the pleura or chest wall (e.g., pleural effusions, scoliosis, severe obesity), or disorders causing weakness of the muscles of breathing (e.g., myasthenia gravis, Guillain-Barré syndrome).

Interstitial lung diseases (ILDs) are a heterogeneous group of disorders characterized by inflammation and fibrosis of the lung parenchyma affecting the alveolar-capillary unit. They are usually discerned from other restrictive lung diseases by an impaired diffusion capacity of the lungs for carbon monoxide (DLCO). The most common identifiable causes are related to exposure to occupational or environmental agents (e.g., silica, asbestos), drug-related toxicity (e.g., bleomycin, amiodarone), or radiation-induced lung injury. However, for a significant proportion of patients, a specific cause is never identified. These patients are broadly grouped into the diagnostic category of idiopathic interstitial pneumonia (IIP). There are multiple subcategories of IIP, and unfortunately the terminology has been confusing and overlapping in the literature. Preoperative risk assessment for pulmonary resection in patients with restrictive lung disease should proceed as outlined above with evaluation of ppoFEV1, ppoDLCO, and exercise capacity.

Among the subtypes of IIP, the one which is particularly relevant to the anesthesiologist is idiopathic pulmonary fibrosis (IPF) which is also called usual interstitial pneumonia (UIP). Differentiation of IPF from the other types of IIP is based on a combination of clinical and radiologic findings and may require histologic confirmation [77]. One study of pulmonary resections for non-small cell lung cancer in patients with IIP found significant differences in short- and

long-term morbidity and mortality between an IPF group (n = 46) and non-IPF (n = 57) patients. Although other pre- and intraoperative risk factors were equal, the IPF patients tended to have a lower FRC with a preservation of the FEV1/FRC ratio. IPF patients had a higher 30-day mortality (7%) than non-IPF patients (0%) and a lower 5-year survival: 22% vs. 53%. Patients with IPF seem to be particularly at risk for perioperative lung injury during pulmonary resection [78].

Pulmonary Hypertension

A detailed discussion of the management of the patient with pulmonary hypertension for thoracic surgery is presented in Chap. 34. In one series, 19/279 patients having a lobectomy for cancer had pulmonary hypertension (right ventricular systolic pressure >36 mmHg on preoperative transthoracic echocardiography). Although there were trends toward increased morbidity and mortality in the pulmonary hypertension group, they did not reach statistical significance in this small sample. Pulmonary hypertension is not an automatic contraindication to thoracic surgery.

Smoking

Pulmonary complications are decreased in thoracic surgical patients who cease smoking for >4 weeks before surgery [79]. Carboxyhemoglobin concentrations decrease if smoking is stopped >12 h [80]. It is extremely important for patients to avoid smoking postoperatively. Smoking leads to a prolonged period of tissue hypoxemia. Wound tissue oxygen tension correlates with wound healing and resistance to infection. Wound healing is improved in patients who stop smoking >4 weeks preoperatively [81]. There is no rebound increase in pulmonary complications if patients stop for shorter (<8 weeks) periods before surgery [82]. The balance of evidence suggests that thoracic surgical patients should be counseled to stop smoking and advised that the longer the period of cessation, the greater the risk reduction for postoperative pulmonary complications [83]. Levels of successful cessation of smoking can exceed 50% at 1 year with a program of counseling and nicotine replacement [84].

Type of Surgical Procedure

It is important for the anesthesiologist to have an appreciation of the implications of the proposed type and extent of surgical resection. Pneumonectomy is the classic pulmonary resection operation for lung cancer. Prediction of postoperative pulmonary function and risks with a combination of pulmonary function tests and ventilation/perfusion scans, as outlined earlier, is accurate in pneumonectomy patients. Even in geriatric patients, short-term morbidity and mortality are acceptable using these pre-resection prediction criteria [85]. It has been suggested that a preoperative VO_2 max of 20 ml/kg/min should be used as the lower limit for acceptability in pneumonectomy patients [86]. However, it is now appreciated that many patients do not have an acceptable quality of life after a pneumonectomy [87]. Because of this, surgeons are more likely to use lung-sparing procedures such as a bi-lobectomy or bronchial-sleeve lobectomy whenever possible to avoid a pneumonectomy. The frequency of pneumonectomies as a percentage of all lung cancer operations has decreased in the past 20 years from approximately 20% to 5% [88].

A bi-lobectomy is a useful alternative procedure to a right pneumonectomy when surgically possible. The complication rate following bi-lobectomies is intermediate between that for lobectomies and pneumonectomies and lower for upper bi-lobectomies than lower bi-lobectomies [89]. A nonanatomic wedge resection of a lung cancer is also a possibility in high-risk cases. Although the cure rate is less than an anatomical resection, there is a lower short-term morbidity and mortality in high-risk cases [90].

Minimally invasive video-assisted thoracoscopic surgery (VATS) or robotic surgeries are rapidly becoming the commonest approaches for a majority of pulmonary resections. There is a general consensus that patients have fewer complications and less postoperative pain when comparable resections are performed by VATS than by open thoracotomy [91]. Increased-risk patients with a ppoFEV1 or ppoDLCO <40% seem to have a significantly lower morbidity and mortality after lobectomy via VATS vs. thoracotomy [92]. A non-randomized comparison of matched patients having lobectomies via thoracotomy (n = 167) or VATS (n = 173) suggested that the threshold for increased risk could be shifted down from a ppoFEV1 of 40% in the thoracotomy patients to 30% in the VATS patients (see Fig. 2.16) [93]. It was not possible to identify a lower threshold of ppoDLCO for complications after VATS lobectomy (see Fig. 2.17); however, there were very few patients with a ppoDLCO <40% in this population.

Combined Strategies for Preoperative Assessment

Several multisystemic schemes to assess perioperative risk and guide preoperative evaluation have been developed. The American College of Surgeons has developed an online risk calculator based on the National Surgical Quality Improvement Program (NSQIP) database [94] (http://risk-calculator.facs.org/RiskCalculator). This calculator includes 21 preoperative factors (demographics, comorbidities, and procedure). It allows for individualized estimation of risks of

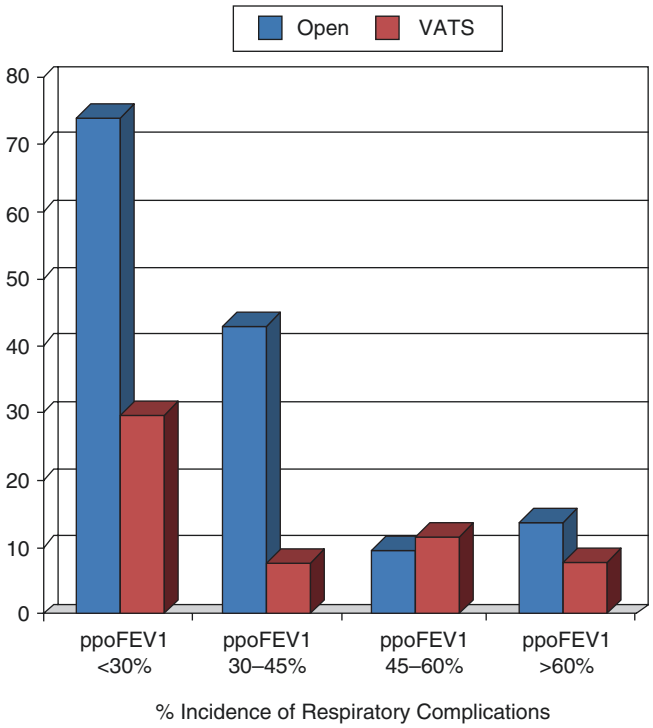

Fig. 2.16 A comparison of the incidence of postoperative respiratory complications after open (thoracotomy) vs. VATS lobectomies for lung cancer. ppo = predicted postoperative value. FEV1 = forced expiratory volume in 1 second. This was a non-randomized retrospective study. It appears that the threshold for increased risk may have decreased from <40% ppoFEV1 in the open group to <30% in the VATS group. (Based on data from Berry et al. [93])

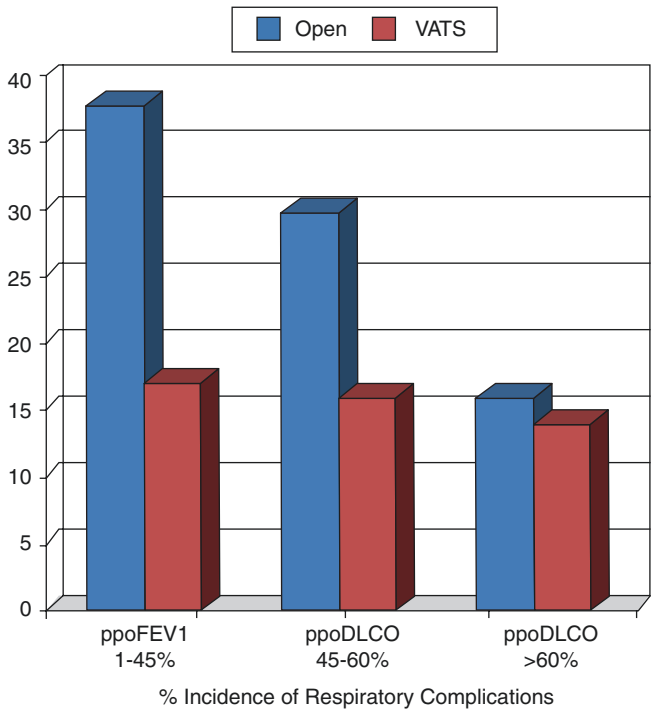

Fig. 2.17 A comparison of the incidence of postoperative respiratory complications after open (thoracotomy) vs. VATS lobectomies for lung cancer. ppo = predicted postoperative value. DLCO = diffusing capacity for carbon monoxide. This was a non-randomized retrospective study. It appears there is a threshold for increased risk in open procedures under 60% ppoDLCO. A threshold for VATS procedures could not be identified; however, there were very few patients with a ppoDLCO <40% in this study. (Based on data from Berry [93])

mortality and specific major complications (see Fig. 2.18). Although this tool is very useful to explain to patients and families the perioperative risks from a specific operation, it does not allow for a stratified approach to preoperative evaluation for an individual patient. A combined cardiorespiratory algorithm specific to patients having lung cancer surgery is presented in Fig. 2.19 [95].

Perioperative Considerations in Thoracic Malignancies

The majority of patients presenting for major pulmonary surgery will have some type of malignancy. Because the different types of thoracic malignancies have varying implications for both surgery and anesthesia, it is important for the anesthesiologist to have some knowledge of the presentation and biology of these cancers. By far the most common tumor is lung cancer. It is estimated that at present rates over 210,000 new cases of lung cancer occur in the United States annually. Of these only 26% will be resectable. However, this represents >55,000 patients/year who can be offered potentially curative surgery [96]. Lung cancer is currently the leading cause of cancer deaths in both sexes in North America subsequent to the peak incidence of smoking in the period 1940–1970 (Fig. 2.20) [97]. The mortality rate from lung cancer has shown a slight decrease in the last decade for men related to decreased smoking rates and appears to have plateaued in women.

Lung cancer is broadly divided into small-cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC), with about 75–80% of these tumors being NSCLC. Other less common and less aggressive tumors of the lung include the carcinoid tumors (typical and atypical) and adenoid cystic carcinoma. In comparison with lung cancer, primary pleural tumors are rare. They include the solitary fibrous tumors of the pleura (previously referred to as benign mesotheliomas) and malignant pleural mesothelioma (MPM). Asbestos exposure is implicated as a causative effect in up to 80% of MPM. A dose-response relationship is not always apparent, and even brief exposures can lead to the disease. An exposure history is often difficult to obtain because the latent period before clinical manifestation of the tumor may be as long as 40–50 years.

Tobacco smoke (both primary and secondhand) is responsible for approximately 90% of all lung cancers, and

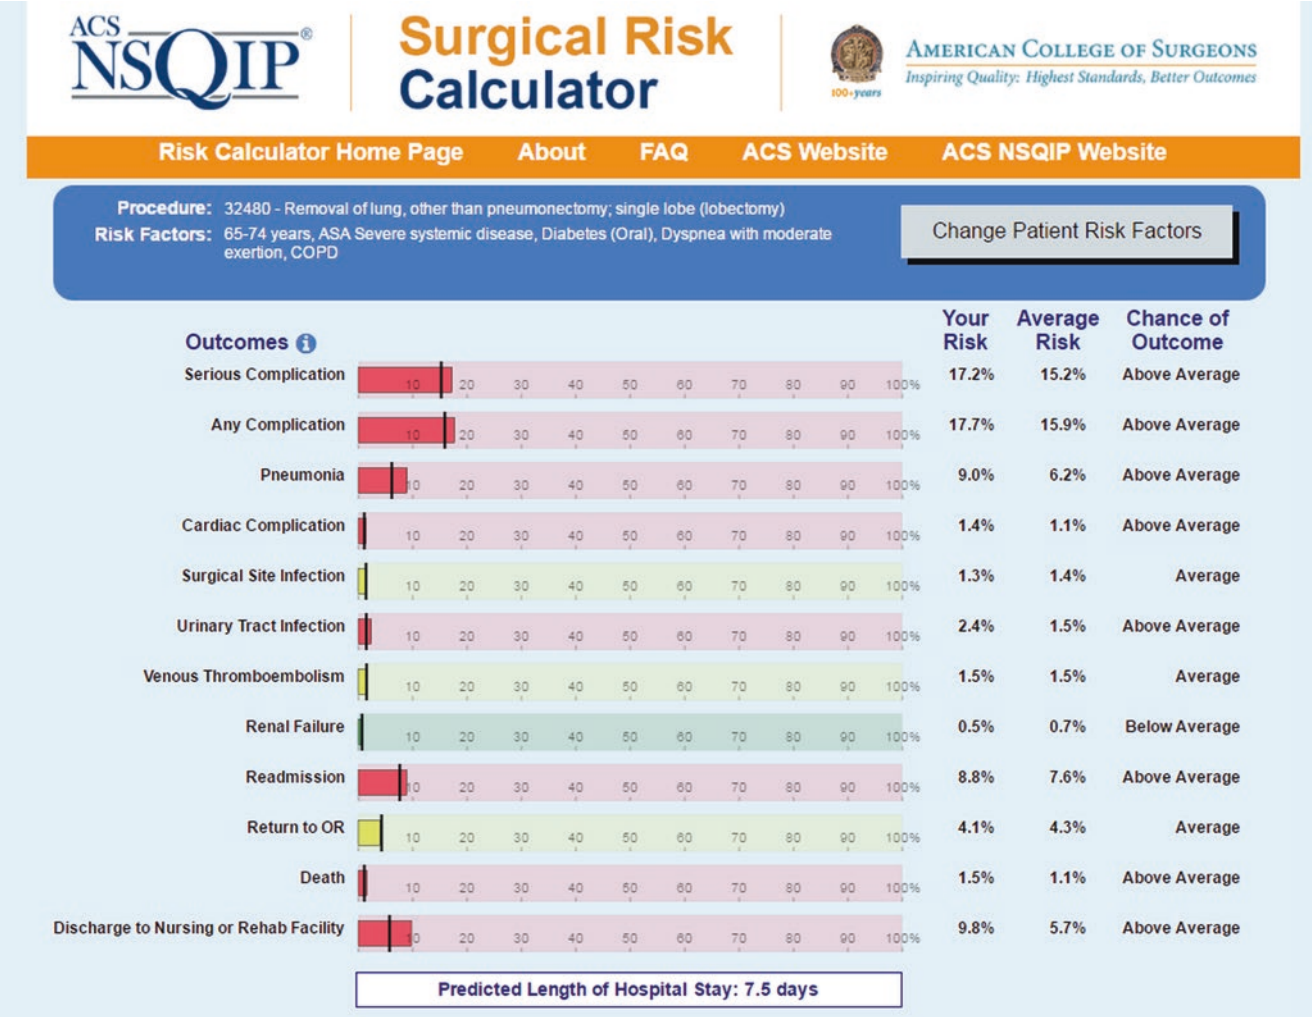

Fig. 2.18 A calculation of perioperative risks for a theoretical 70-year-old, nonobese, male with COPD and non-insulin-dependent diabetes scheduled for a pulmonary lobectomy using the NSQIP web-based calculator (http://riskcalculator.facs.org/RiskCalculator) (Note there is no quantification of the severity of COPD using this calculator)

the epidemiology of lung cancer follows the epidemiology of cigarette smoking with approximately a three-decade lag time [98]. Other environmental causes include asbestos and radon gas (a decay product of naturally occurring uranium) which act as cocarcinogens with tobacco smoke. For a pack-a-day cigarette smoker, the lifetime risk of lung cancer is approximately 1 in 14. Smoking cessation reduces the risk of lung cancer but never to that for never smokers. Assuming current mortality patterns continue, cancer will pass heart disease as the leading cause of death in North America in this decade.

Prior to pulmonary resection, lung cancer patients will undergo staging tests to determine the extent of their cancer. These will include radiographic tests such as CT scan, positron emission tomography (PET), and in some cases brain magnetic resonance imaging. Additionally, many patients will have invasive mediastinal staging to determine histologically whether or not the cancer has spread to the mediastinal lymph nodes. In general, if mediastinal lymph nodes contain cancer, primary surgical resection is not recommended. Cervical mediastinoscopy which is performed under general anesthesia has been the gold standard for invasive mediastinal staging. More recently, endobronchial ultrasound with transbronchial needle aspiration (EBUS-TBNA) and endoscopic ultrasound mediastinal node biopsy have become popular. These procedures may be done under topical anesthesia with intravenous sedation and are less invasive than mediastinoscopy. Regardless of the technique, the indication for invasive mediastinal staging is the same. Any patient with enlarged mediastinal nodes on CT or FDG-avid ("hot") nodes on PET scan should have invasive staging. Additional indications include T3 or T4 tumors, central tumors, and those with suspicion of hilar lymph node involvement [99].

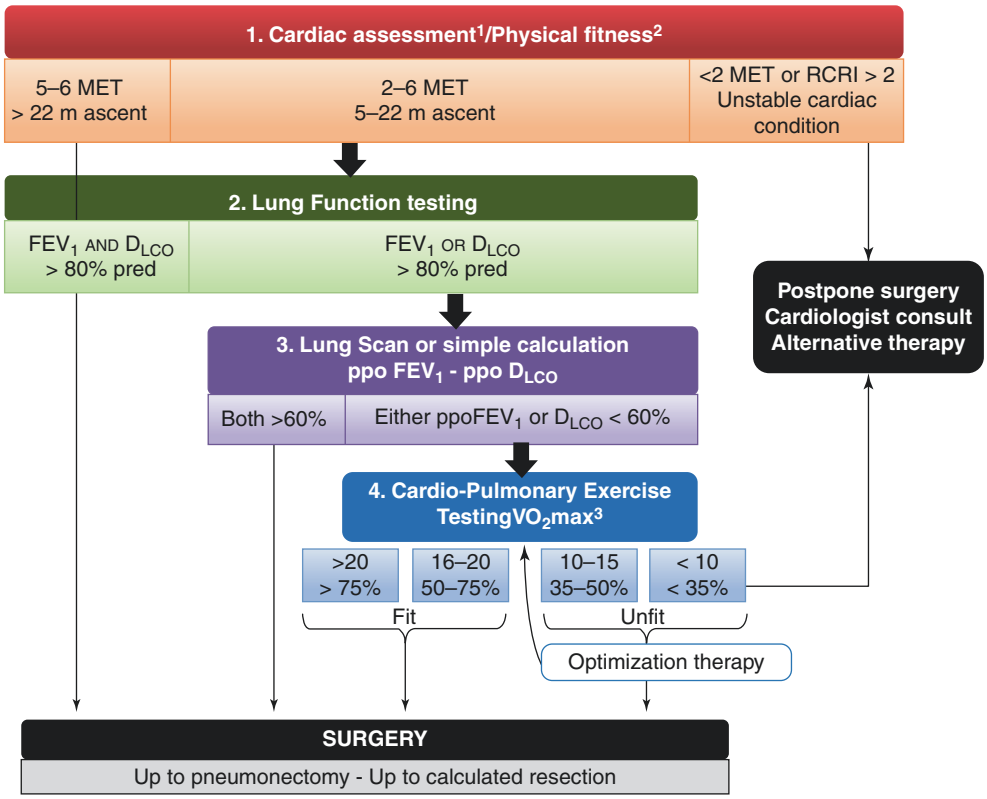

Fig. 2.19 A flow diagram for preoperative evaluation for lung cancer patients. RCRI = Revised Cardiac Risk Index (see Table 2.2). MET = basal oxygen consumption (3.5 ml/kg/min). Ascent = height in meters nonstop stair climbing (Reproduced with permission from Licker et al. [95])

Non-Small Cell Lung Cancer (NSCLC)

This pathologically heterogeneous group of tumors includes squamous cell, adenocarcinoma, and large-cell carcinoma with several subtypes and combined tumors (Table 2.6). This represents the largest grouping of lung cancers and the vast majority of those that present for surgery. They are grouped together because the surgical therapy, and by inference the anesthetic implications, is similar and depends on the stage of the cancer at diagnosis (Tables 2.6, 2.7, and 2.8). Survival can approach 80% for stage I lesions. Unfortunately, 70–80% patients present with advanced disease (stage III or IV). Overall 5-year survival with surgery for NSCLC approaches 40%. This seemingly low figure must be viewed in the light of an estimated 5-year survival without surgery of <10%.

Although it is not always possible to be certain of the pathology of a given lung tumor preoperatively, many patients will have a known tissue diagnosis at the time of preanesthetic assessment on the basis of prior cytology, bronchoscopy, mediastinoscopy, or transthoracic needle aspiration. This is useful information for the anesthesiologist to obtain preoperatively. Specific anesthetic implications of the different types of lung cancer are listed in Table 2.9.

Adenocarcinoma

Adenocarcinoma is currently the most common NSCLC in both sexes. These tumors tend to be peripheral. Tumors identified by CT screening are most often in the adenocarcinoma spectrum. This is partly due to their increased frequency in general but also the slower growth rate of these tumors. Adenocarcinomas have been reclassified to include a broad spectrum of tumors including those previously classified as bronchoalveolar carcinoma (BAC). This spectrum of disease ranges from noninvasive carcinoma in situ to invasive adenocarcinomas. The biologic behavior can be very indolent such as in lepidic predominant (the former BAC) to aggressive with a high propensity for recurrence and metastases (e.g., papillary and micropapillary). With improved CT techniques, it is now recognized that these tumors may be multifocal such that multiple lesions actually represent multiple primary tumors rather than metastases. One variant of adenocarcinoma warrants further discussion: the pneumonic type lepidic variant which mimics pneumonia radiographically and is often associated with bronchorrhea. Because of its low potential to spread outside of the lungs, multifocal BAC may be treated by lung transplantation in selected cases [100].

Adenocarcinoma may invade extrapulmonary structures, including the chest wall, diaphragm, and pericardium. The majority of Pancoast tumors (see Chap. 37) are now due to adenocarcinomas. A variety of paraneoplastic metabolic factors can be secreted by adenocarcinomas such as growth hormone and corticotropin. Hypertrophic pulmonary osteoarthropathy (HPOA) is particularly associated with adenocarcinoma.

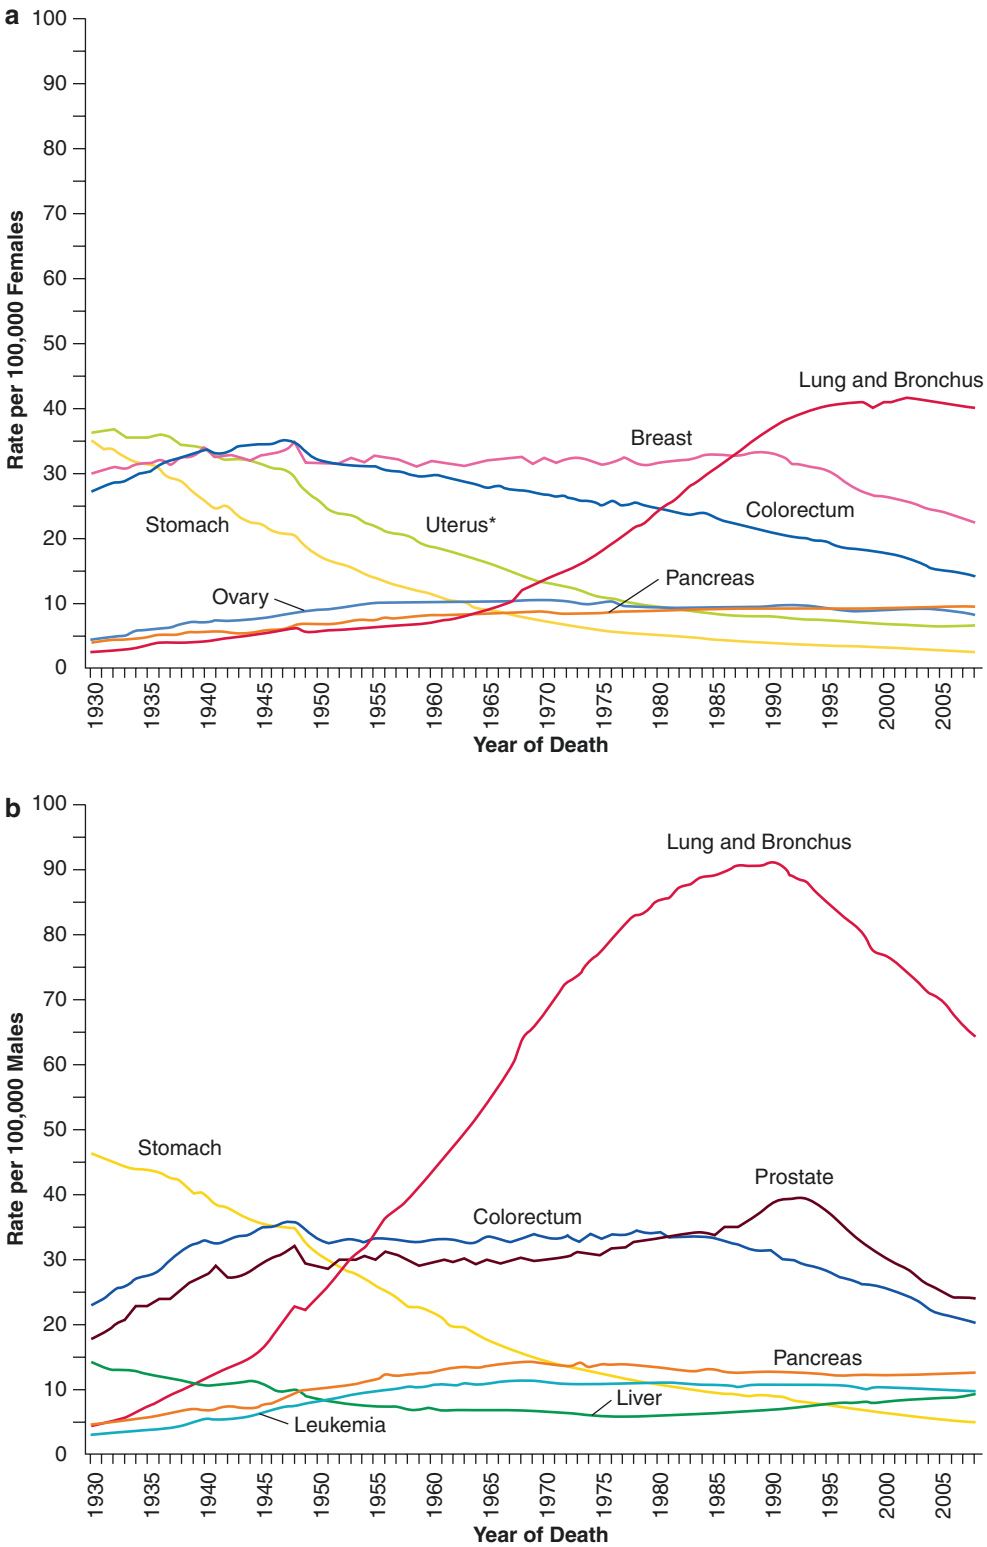

Fig. 2.20 Age-adjusted mortality rates for women (**a**) and men (**b**) in the United States 1930–2008. Respiratory malignancies remain the leading cause of cancer deaths in both sexes, but the incidence has begun to decrease in men and has plateaued in women (National Health Statistics of the United States 2016. www.cancer.org)

Table 2.6 Frequency of cell types of primary lung cancers

Histologic type	Proportion (%)
Adenocarcinoma	40
Squamous cell	27
Small cell	19
Large cell	8

Table 2.8 Indications for surgery in non-small cell lung cancer

Stage I a and b	Primary resection, no postoperative chemo−/radiotherapy
Stage II	Primary resection, adjuvant postoperative chemotherapy
Stage IIIa, N2	Definitive chemoradiotherapy
In select patients induction chemoradiotherapy followed by resection in patients with stable or responding disease	
(For patients with N2 disease identified at thoracotomy: Postoperative chemotherapy, possibly radiation)	
Stage IIIb	Surgery rarely indicated. Chemoradiotherapy
Resection of select T4, N0–1, M0 tumors	
Stage IV	Palliative therapy. Possible exception: Selected patients with a resected isolated cerebral metastasis

Table 2.9 Anesthetic considerations for different types of lung cancer

Type	Considerations
Squamous cell	Central lesions (predominantly)
	Mass effects: obstruction, cavitation
	Hypercalcemia
	Hypertrophic pulmonary osteoarthropathy
Adenocarcinoma	Peripheral lesions
	Metastases (distant)
	Growth hormone, corticotropin
Small cell	Central lesions (predominantly)
	Few surgically treatable
	Paraneoplastic syndromes
	Lambert-Eaton syndrome
	Fast growth rate
	Early metastases
Carcinoid	Proximal, intrabronchial
	Predominantly benign
	No association with smoking
	5-year survival >90%
	Carcinoid syndrome (rarely)
Mesothelioma	Intraoperative hemorrhage
	Direct extension to the diaphragm, pericardium, etc.

Squamous Cell Carcinoma

This is the subgroup of NSCLC most strongly linked to cigarette smoking. The tumors tend to grow to a large size, are often central, and metastasize later than others. They tend to cause symptoms related to local effects of a large tumor mass with a dominant endobronchial component, such as cavitation, hemoptysis, obstructive pneumonia, superior vena cava syndrome, and involvement of the mainstem bronchus, trachea, carina, and main pulmonary arteries. Hypercalcemia is specifically associated with this cell type due to elaboration of a parathyroid-like factor and not due to bone metastases.

Large Cell Undifferentiated Carcinoma

This is the least common of the NSCLCs. They tend to present as large, often cavitating, peripheral tumors. Their rapid growth rate may lead to widespread metastases, similar to adenocarcinoma.

Small-Cell Lung Cancer

This tumor of neuroendocrine origin is considered metastatic on presentation and is usually regarded as a medical, not a surgical disease [101]. Previously, the staging system for small-cell lung cancer was divided simply into limited stage and extensive stage; however, it is now staged according to the TNM system used for NSCLC. Limited disease is defined as disease confined to one hemithorax that may be encompassed by one radiotherapy field. Treatment of limited-stage SCLC with combination chemotherapy (etoposide/cisplatin or cyclophosphamide/doxorubicin/vincristine) gives objective response rates in over 80% of patients. In addition, these patients typically receive radical radiotherapy to the primary lung tumor and prophylactic cranial irradiation. Despite this initial response, the tumor invariably recurs and is quite resistant to further treatment. The overall survival rate is no better than 10%. Extensive-stage disease is treated with chemotherapy and palliative radiation as needed.

There are three situations in which surgery for SCLC might be considered. In the rare instance in which a solitary pulmonary nodule is diagnosed as SCLC (very limited stage or stage I), treatment should be surgical resection followed by chemotherapy. Salvage resection of a residual mass following chemotherapy for limited-stage disease may offer some long-term survival in selected cases. Many of these patients will have mixed SCLC/NSCLC in which the small-cell component has responded to chemotherapy and the non-small cell component is then resected. The third situation wherein patients with treated small-cell lung cancer should be considered for surgery is the finding of a new lung tumor. Patients with treated small cell have an increased rate of second primary lung cancers, which are usually non-small cell.

SCLC is known to cause a variety of paraneoplastic syndromes due to the production of peptide hormones and antibodies. The commonest of these is hyponatremia usually due to an inappropriate production of antidiuretic hormone (SIADH). Cushing's syndrome and hypercortisolism through ectopic production of adrenocorticotropic hormone (ACTH) are also commonly seen.

A well-known but rare neurologic paraneoplastic syndrome associated with small-cell lung tumors is the Lambert-Eaton myasthenic syndrome due to impaired release of acetylcholine from nerve terminals. This typically presents as proximal lower limb weakness and fatigability that may temporarily improve with exercise. The diagnosis is confirmed by electromyography (EMG) showing increasing amplitude of unusual action potentials with high-frequency stimulation and by serum antibodies. Similar to true myasthenia gravis patients (see Chap. 15), myasthenic syndrome patients are extremely sensitive to non-depolarizing muscle relaxants. However, unlike true myasthenics, they respond poorly to anticholinesterase reversal agents [102]. Clinical differences between myasthenia and the myasthenic syndrome are discussed in Chap. 15 [103]. Diaminopyridine has been reported to be useful both as a maintenance medication and to reverse residual postoperative neuromuscular blockade in these patients [104]. Other treatments of the Lambert-Eaton syndrome include plasmapheresis, immunoglobulin, and guanidine. It is important to realize that there may be subclinical involvement of the diaphragm and muscles of respiration. Thoracic epidural analgesia has been used following thoracotomy in these patients without complication. These patients' neuromuscular function may improve following resection of the lung cancer. A patient with a lung cancer and unusual symptoms of weakness should be referred to neurology to rule out myasthenic syndrome. Non-depolarizing muscle relaxants should be avoided, if possible, during anesthesia in these patients.

Carcinoid Tumors

Carcinoid tumors are low-grade neuroendocrine malignancies and may be typical or atypical. Typical carcinoid tumors are most commonly found in the central airways and may present with obstructive symptoms or hemoptysis. Bronchoscopic biopsy or resection may cause significant bleeding. Five-year survival following resection for typical carcinoid exceeds 90%. Metastases to lymph nodes or distant sites are rare. Similarly, the carcinoid syndrome, which is caused by the ectopic synthesis of vasoactive mediators, is rare in pulmonary carcinoid unless the tumor is very large. Carcinoid syndrome is usually seen with carcinoid tumors of gut origin that have metastasized to the liver. Atypical carcinoid tumors are more often peripheral and are more aggressive and have a reduced survival rate. They often metastasize both regionally and systemically.

Perioperative management of intrathoracic atypical carcinoid tumors is discussed in Chap. 15. These tumors can precipitate an intraoperative hemodynamic crisis or coronary artery spasm even during bronchoscopic resection [105]. The anesthesiologist should be prepared to deal with severe hypotension that may not respond to the usual vasoconstrictors and will require the use of the specific antagonists octreotide or somatostatin [106].

Pleural Tumors

Solitary fibrous tumors of the pleura are usually large, space-occupying masses that are usually attached to the visceral pleura. They can be either benign or malignant, but most are easily resected with good results.

Malignant pleural mesotheliomas are strongly associated with exposure to asbestos fibers. Their incidence in Canada has almost doubled in the past 15 years. With the phasing out of asbestos-containing products and the long latent period between exposure and diagnosis, the peak incidence is not predicted for another 10–20 years. The tumor initially proliferates within the visceral and parietal pleura, typically forming a bloody effusion. Patients present with shortness of breath or dyspnea on exertion, dry cough, or pain. Thoracentesis often relieves the symptoms but rarely provides a diagnosis. Pleural biopsy by video-assisted thoracoscopy is most efficient way to secure a diagnosis, and talc poudrage is performed under the same anesthetic to treat the effusion.

Malignant pleural mesotheliomas respond poorly to therapy, and the median survival is less than 1 year. In patients with very early disease, extrapleural pneumonectomy may be considered, but it is difficult to know whether survival is improved. Alternatively, pleurectomy-decortication has been increasingly used. Although by definition a palliative procedure, it is much less morbid than EPP and offers potential for more durable palliation. Recently, several groups have reported improved results with combinations of radiation, chemotherapy, and surgery. Extrapleural pneumonectomy is an extensive procedure that is rife with potential complications, both intra- and postoperative [107]. Blood loss from the denuded chest wall or major vascular structures is always a risk. Complications related to resection of diaphragm and pericardium are additional risks to that of pneumonectomy. Perioperative management for extrapleural pneumonectomy is discussed in Chap. 36.

Preoperative Assessment of the Patient with Lung Cancer

At the time of initial assessment, cancer patients should be assessed for the "four M's" associated with malignancy (Table 2.10): mass effects, metabolic abnormalities, metastases, and medications. The prior use of medications which can exacerbate oxygen-induced pulmonary toxicity such as bleomycin should be considered [108]. Bleomycin is not used to treat primary lung cancers, but patients presenting for excision of lung metastases from germ-cell tumors will often have received prior bleomycin therapy. Although the association between previous bleomycin therapy and pulmonary toxicity from high inspired oxygen concentrations is well documented, none of the details of the association are understood (i.e., safe doses of oxygen or safe period after bleomycin exposure). The safest anesthetic management is to use the lowest FiO2 consistent with patient safety and to closely monitor oximetry in any patient who has received bleomycin. We have seen lung cancer patients who received preoperative chemotherapy with cisplatin, which is mildly nephrotoxic, and then developed an elevation of serum creatinine when they received nonsteroidal anti-inflammatory analgesics (NSAIDs) postoperatively. For this reason, we do not routinely administer NSAIDs to patients who have been treated recently with cisplatin.

Table 2.10 Anesthetic considerations in lung cancer patients (the "four M's")

1. Mass effects: Obstructive pneumonia, lung abscess, SVC syndrome, tracheobronchial distortion, Pancoast's syndrome, recurrent laryngeal nerve or phrenic nerve paresis, chest wall or mediastinal extension
2. Metabolic effects: Lambert-Eaton syndrome, hypercalcemia, hyponatremia, Cushing's syndrome
3. Metastases: Particularly to the brain, bone, liver, and adrenal
4. Medications: Chemotherapy agents, pulmonary toxicity (bleomycin, mitomycin), cardiac toxicity (doxorubicin), renal toxicity (cisplatin)

Postoperative Analgesia

The strategy for postoperative analgesia should be developed and discussed with the patient during the initial preoperative assessment; full discussion of postoperative analgesia is presented in Chap. 46. Many techniques have been shown to be superior to the use of on-demand parenteral (intramuscular or intravenous) opioids alone in terms of pain control [109]. These include the addition of neuraxial blockade, intercostal/paravertebral blocks, interpleural local anesthetics, NSAIDs, etc. to narcotic-based analgesia. Only epidural techniques have been shown to consistently have the capability to decrease post-thoracotomy respiratory complications [110, 111]. It is becoming more evident that thoracic epidural analgesia is superior to lumbar epidural analgesia. This seems to be due to the synergy which local anesthetics have with opioids in producing neuraxial analgesia. Studies suggest that epidural local anesthetics increase segmental bioavailability of opioids in the cerebrospinal fluid [112] and also that they increase the binding of opioids by spinal cord receptors [113]. Although lumbar epidural opioids can produce similar levels of post-thoracotomy pain control at rest, only the segmental effects of thoracic epidural local anesthetic and opioid combinations can reliably produce increased analgesia with movement and increased respiratory function following a chest incision [114, 115]. In patients with coronary artery disease, thoracic epidural local anesthetics seem to reduce myocardial oxygen demand and supply in proportion [116].

It is at the time of initial preanesthetic assessment that the risks and benefits of the various forms of post-thoracotomy analgesia should be explained to the patient. Potential contraindications to specific methods of analgesia should be determined such as coagulation problems, sepsis, or neurologic

disorders. When it is not possible to place a thoracic epidural due to problems with patient consent or other contraindications, a reasonable second choice for analgesia is a paravertebral infusion of local anesthetic via a catheter placed intraoperatively in the open hemithorax by the surgeon [117]. This is combined with intravenous patient-controlled opioid analgesia and NSAIDS whenever possible.

If the patient is to receive prophylactic anticoagulants and it is elected to use epidural analgesia, appropriate timing of anticoagulant administration and neuraxial catheter placement need to be arranged. ASRA guidelines suggest an interval of 2–4 h before or 1 h after catheter placement for prophylactic heparin administration [118]. Low molecular weight heparin (LMWH) precautions are less clear, and an interval of 12–24 h before and 24 h after catheter placement is recommended.

Premedication

Premedication should be discussed and ordered at the time of the initial preoperative visit. The most important aspect of preoperative medication is to avoid inadvertent withdrawal of those drugs which are taken for concurrent medical conditions (bronchodilators, antihypertensives, beta-blockers, etc.). For some types of thoracic surgery, such as esophageal reflux surgery, oral antacid and H_2 blockers or proton pump inhibitors are routinely ordered preoperatively. We do not routinely order preoperative sedation or analgesia for pulmonary resection patients. Mild sedation such as an intravenous short-acting benzodiazepine is often given immediately prior to placement of invasive monitoring lines and catheters. In patients with copious secretions, an antisilalgogue (such as glycopyrrolate) is useful to facilitate fiber-optic bronchoscopy for positioning of a double-lumen tube or bronchial blocker. To avoid an intramuscular injection, this can be given orally or intravenously immediately after placement of the intravenous catheter. It is a common practice to use short-term intravenous antibacterial prophylaxis such as a cephalosporin in thoracic surgical patients. If it is the local practice to administer these drugs prior to admission to the operating room, they will have to be ordered preoperatively. Consideration for those patients allergic to cephalosporins or penicillin will have to be made at the time of the initial preoperative visit.

Summary of The Initial Preoperative Assessment

The anesthetic considerations which should be addressed at the time of the initial preoperative assessment are summarized in Table 2.11. Patients need to be specifically assessed for risk factors associated with respiratory complications, which are the major cause of morbidity and mortality following thoracic surgery. Risk factors which can be modified preoperatively are listed in Table 2.12 [119].

Final Preoperative Assessment.

The final preoperative anesthetic assessment for the majority of thoracic surgical patients is carried out immediately prior to admission of the patient to the operating room. At this time it is important to review the data from the initial prethoracotomy assessment and the results of tests ordered at that time. In addition, two other specific areas affecting thoracic anesthesia need to be assessed: the potential for difficult lung isolation and the risk of desaturation during one-lung ventilation (Table 2.13).

Table 2.11 Initial preanesthetic assessment for thoracic surgery

1. For all patients: Assess exercise tolerance, simple spirometry; estimate ppoFEV1%; discuss postoperative analgesia, smoking cessation
2. Patients with ppoFEV1 < 40%: Full pulmonary function testing to include DLCO, ventilation/perfusion lung scan if possible pneumonectomy, exercise testing
3. Cancer patients: Consider the "four M's," mass effects, metabolic effects, metastases, medications
4. COPD patients: Physiotherapy, bronchodilators, arterial blood gas if moderate or severe COPD
5. Increased renal risk: Measure creatinine

Table 2.12 Probability for preoperative interventions to reduce the risk of pulmonary complications

Risk factor	Intervention	Probability
Smoking	Cessation >8 weeks Cessation <8 weeks	++++ +
Exacerbation of COPD or asthma	Steroids, bronchodilators and delay elective surgery Antibiotics indicated by sputum	++++ +++
Stable COPD or asthma	Physiotherapy Bronchodilators Rehabilitation	++++ +++ ++
Obesity	Physiotherapy Weight loss	++++ ++
Malnutrition	Oral nutrition program	++

From data in Ref. [91]
++++ = Multiple studies confirming
+++ = Both some data and physiologic rationale supporting
++ = Either some data or good physiologic rationale
+ = Limited data or physiologic rationale

Table 2.13 Final preanesthetic assessment for thoracic surgery

1. Review initial assessment and test results
2. Assess difficulty of lung isolation: examine preoperative chest imaging
3. Assess risk of hypoxemia during one-lung ventilation

Difficult Endobronchial Intubation

Anesthesiologists are familiar with the clinical assessment of the upper airway for ease of endotracheal intubation. In a similar fashion, each thoracic surgical patient must be assessed for the ease of endobronchial intubation. At the time of the preoperative visit, there may be historical factors or physical findings which lead to suspicion of difficult endobronchial intubation (previous radiotherapy, infection, prior pulmonary, or airway surgery). In addition, there may be a written bronchoscopy report with a detailed description of anatomical features. The most useful predictor of difficult endobronchial intubation is the plain chest X-ray (Fig. 2.21).

The anesthesiologist should view the chest imaging himself/herself prior to induction of anesthesia since neither the radiologist's nor the surgeon's report of the X-ray is made with the specific consideration of lung isolation in mind. A large portion of thoracic surgical patients will also have had a chest CT scan done preoperatively. As anesthesiologists have learned to assess X-rays for potential lung-isolation difficulties, it is also worthwhile to learn to examine the CT scan. Distal airway problems not detectable on the plain chest film can sometimes be visualized on the CT scan: a side-to-side compression of the distal trachea, the so called "saber-sheath" trachea, can cause obstruction of the tracheal lumen of a left-sided double-lumen tube during ventilation of the dependent lung for a left thoracotomy [120]. Similarly, extrinsic compression or intraluminal obstruction of a mainstem bronchus which can interfere with endobronchial tube placement may only be evident on the CT scan. The major factors in successful lower airway management are anticipation and preparation based on the preoperative assessment. Management of lung isolation in patients with difficult upper and lower airways is discussed in Chap. 18.

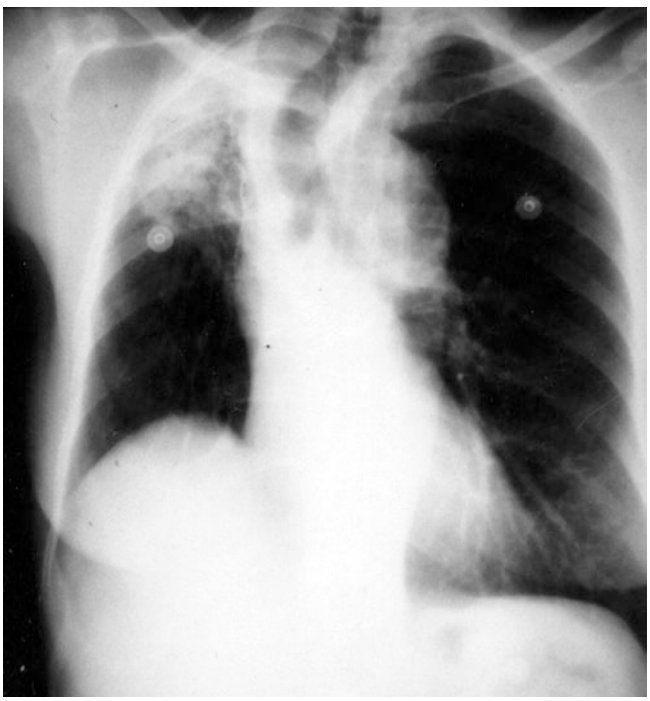

Fig. 2.21 Preoperative chest X-ray of a patient with a history of previous tuberculosis, right upper lobectomy, and recent hemoptysis presenting for right thoracotomy and possible completion pneumonectomy. The potential problems positioning a left-sided double-lumen tube in this patient are easily appreciated by viewing the X-ray but are not mentioned in the radiologist's report. The anesthesiologist must examine the chest imaging himself/herself preoperatively to anticipate problems in lung isolation (From Slinger and Johnston [126] with permission)

Prediction of Desaturation During One-Lung Ventilation

In the vast majority of cases, it is possible to identify preoperatively those patients which are most at risk of desaturation during one-lung ventilation (OLV) for thoracic surgery. The factors which correlate with desaturation during OLV are listed in Table 2.14. In patients at high risk of desaturation, prophylactic measures can be used during OLV to decrease this risk. The most useful prophylactic measures are the use of continuous positive airway pressure (CPAP) 2–5 cm H_2O of oxygen to the non-ventilated lung and/or positive end-expiratory pressure (PEEP) to the dependent lung.

The most important predictor of PaO_2 during OLV is the PaO_2 during two-lung ventilation, specifically the intraoperative PaO_2 during two-lung ventilation in the lateral position prior to OLV [121]. The proportion of perfusion or ventilation to the non-operated lung on preoperative V/Q scans also correlates with the PaO_2 during OLV [122]. If the operative lung has little perfusion preoperatively due to unilateral disease, the patient is unlikely to desaturate during OLV. The side of the thoracotomy has an effect on PaO_2 during OLV. The left lung being 10% smaller than the right, there is less shunt when the left lung is collapsed. In a series of patients, the mean PaO_2 during left thoracotomy was approximately 70 mmHg higher than during right thoracotomy [123]. Finally, the degree of obstructive lung disease correlates in an inverse fashion with PaO_2 during OLV. Other factors being equal, patients with more severe airflow limitation on preoperative spirometry will tend to have a better PaO_2 during OLV than patients with normal spirometry (see Chap. 6) [124].

Table 2.14 Factors which correlate with an increased risk of desaturation during one-lung ventilation

High percentage of ventilation or perfusion to the operative lung on preoperative V/Q scan
Poor PaO_2 during two-lung ventilation, particularly in the lateral position intraoperatively
Right-sided thoracotomy
Normal preoperative spirometry (FEV1 or FVC) or restrictive lung disease
Supine position during one-lung ventilation

Assessment for Repeat Thoracic Surgery

Patients who survive lung cancer surgery form a high-risk cohort to have a recurrence of the original tumor or to develop a second primary. The incidence of developing a second primary lung tumor is estimated at 2%/year. The use of routine postoperative follow-up screening with low-dose spiral CT scans will probably increase the rate of early detection of recurrent or repeat primary tumors [125]. Patients who present for repeat thoracotomy should be assessed using the same framework as those who present for surgery the first time. Predicted values for postoperative respiratory function based on the preoperative lung mechanics, parenchymal function, exercise tolerance, and the amount of functioning lung tissue resected should be calculated and used to identify patients at increased risk.

Clinical Case Discussion

Case A 65-year-old male presents for anesthesia preoperative assessment (Fig. 2.22). He is scheduled for a bronchoscopy/mediastinoscopy and right pneumonectomy. He is a smoker who presented to his family doctor 2 weeks ago after minor hemoptysis. He has no significant known comorbidities and past history is otherwise unremarkable. A fine needle biopsy has confirmed the diagnosis of non-small cell lung cancer. The anesthesia team will need to decide if the patient will tolerate the proposed procedure and, if so, then what management strategies can be used to improve the perioperative outcome.

Fig. 2.22 Chest X-ray of a 65-year-old male with carcinoma involving the right middle and lower lobes, being assessed for possible right pneumonectomy

Questions

Apart from routine preoperative assessment for major surgery:

- What pulmonary function tests are indicated?
- What cardiac investigations are indicated?
- What specific anesthetic considerations are related to the patient's lung cancer?
- What other system function should be documented?

Focused Preoperative History, Physical and Investigations:

- Pulmonary function evaluation: lung mechanical function (spirometry: FEV1), pulmonary parenchymal function (DLCO), exercise capacity, and ventilation/perfusion scan (see Assessment of Respiratory Function)
- Cardiac evaluation: ECG (echocardiography and stress testing not indicated) (see Cardiovascular Disease)
- Tumor mass effects, metabolic (paraneoplastic) effects, metastases, and adjuvant medications
  Other systems: renal function

Will the patient tolerate the procedure?

- Results of investigations: FEV1 65%, DLCO 70%, exercise tolerance: the patient can climb four flights of stairs without stopping. V/Q scan R/L 40/60 for both V and Q. Other investigations are all within normal limits.
- Predicted postoperative (ppo) FEV1 and DLCO will be in the range of 30–35% and adjusted for the V/Q scan possibly higher. These indicate increased risk but acceptable survival given the patient's age < 70. A bi-lobectomy could be considered for elderly or high-risk patients (see Age).

What management strategies will improve the patient's outcome?

- Smoking cessation
- Pre- and postoperative chest physiotherapy
- Thoracic epidural analgesia has not been clearly proven to improve outcomes in patients with normal pulmonary function but does improve function in moderate and severe COPD. This patient's risk of respiratory complications may be improved by either thoracic epidural or paravertebral analgesia (see also Chap. 59).
- Moderate perioperative fluid restriction and lung-protective ventilation are associated with a decreased risk of postoperative acute lung injury particularly after pneumonectomy (see also Chap. 10 and 21).
- Calcium channel blockers may be associated with a decreased risk of postoperative atrial fibrillation (see also Chap. 56).
- Preoperative ß-blockade, statins, or α-2 blockers are not proven to decrease cardiac ischemic risks in this patient at low risk of perioperative ischemia.

Thoracic Imaging

3

Javier Campos and Kalpaj R. Parekh

Key Points

- Radiological images play an important role during the evaluation of patients undergoing thoracic surgery.
- Radiological studies must be reviewed, including a posterior–anterior chest radiograph and computed tomography scan of the chest.
- Special emphasis should be given to mediastinal mass with compromise to the airway or great vessels by reviewing the computed tomography scan of the chest.
- Multidetector computed tomography (CT) scan and tracheobronchial reconstruction are more specific studies in the thoracic surgical patient and allow measurements of the airway.
- Magnetic resonance imaging (MRI) provides greater contrast resolution than CT scans and offers the potential for tissue characterization. An MRI is indicated in selected cases, i.e., mediastinal mass with invasion of the superior vena cava.

Introduction

Radiological images play an important role in the preoperative, intraoperative, and postoperative evaluation and diagnosis of patients undergoing thoracic surgery. During the preoperative visit evaluation of the thoracic surgical patient, the clinician must have an understanding of the disease and also become familiar with radiological studies to be able to identify abnormal airway anatomy or compromises to the airway or to use caliper measurements in the tracheobronchial tree if necessary when selecting lung isolation devices. Another important component to a successful preoperative evaluation is an understanding of normal tracheobronchial anatomy. This chapter will be focused on reviewing normal tracheobronchial anatomy and radiological images, with special interest for anesthesiologists involved in the care of the thoracic surgical patient.

Normal Tracheobronchial Anatomy

The trachea is a cartilaginous and fibromuscular structure that extends from the inferior aspect of the cricoid cartilage to the level of the carina [1]. The adult trachea is, on average, 15 cm long. The trachea is composed of 16–22 C-shaped cartilages. The cartilages compose the anterior and lateral walls of the trachea and are connected posteriorly by the membranous wall of the trachea, which lacks cartilage and is supported by the trachealis muscle.

The average diameter in a normal trachea is 22 mm in men and 19 mm in women. In men, the coronal diameter ranges from 13 to 22 mm, and the sagittal diameter ranges from 13 to 27 mm. In women, the average coronal diameter is 10–21 mm and the sagittal is 10–23 mm [2]. The tracheal wall is about 3 mm in thickness in both men and women, with a tracheal lumen that is often ovoid in shape.

The trachea is located in the midline position but often can be deviated to the right at the level of the aortic arch, with a greater degree of displacement in the setting of an atherosclerotic aorta and advanced age or in the presence of severe chronic obstructive pulmonary disease (COPD). With COPD or aging, the lateral diameter of the trachea may decrease with a corresponding increase in the antero-

posterior diameter. Conversely, COPD may also lead to softening of the tracheal rings with a decrease in the anteroposterior diameter of the trachea [3]. The cricoid cartilage is the narrowest part of the trachea with an average diameter of 17 mm in men and 13 mm in women.

The trachea bifurcates at the carina into the right and left mainstem bronchus. An important fact is that the tracheal lumen narrows slightly as it progresses toward the carina. The tracheal bifurcation is located at the level of the sternal angle anteriorly and the fifth thoracic vertebra posteriorly. The right mainstem bronchus continues as the bronchus intermedius after the takeoff of the right upper lobe bronchus. In men, the average distance from the tracheal carina to the takeoff of the right upper lobe bronchus is 2.0 cm, whereas it is approximately 1.5 cm in women. One in every 250 individuals from the general population may have an abnormal takeoff of the right upper lobe bronchus emerging from above the tracheal carina on the right side [4]. The diameter of the right mainstem bronchus is an average of 17.5 mm in men and 14.0 mm in women. The trifurcation of the right upper lobe bronchus consists of the apical, anterior, and posterior divisions. The average distance from the tracheal carina to the bifurcation of the left upper and left lower lobe is approximately 5.0 cm in men and 4.5 cm in women. The left mainstem bronchus is longer than the right mainstem bronchus, and it divides into the left upper and the left lower lobe bronchus. The left upper lobe bronchus has a superior and inferior division [5].

Chest Radiographs

The most common study in the patient undergoing thoracic, esophageal, or cardiac surgery is the chest X-radiograph (X-ray). The standard routine chest radiography consists of an erect radiograph made in the posterior–anterior (PA) projection and a left lateral radiograph, both obtained at full inspiration. The normal chest cavity contains four radiographic densities that are easily identified: air, fat, water, and calcium and other metals including bones, granulomas, and vascular calcification. The lungs, which are mostly air and contain some water, blood vessels, bronchi, nerves, lymphatics, alveolar walls, and interstitial tissues, provide the natural contrast that is the basis of chest radiology. When evaluating a chest X-ray, the changes in these densities, which provide natural contrast, are what are observed.

Radiologists in general refer to two regions: the silhouette sign and summation. Depending on the part or parts of the lungs that are involved, the result of this change in the absorption of X-rays is seen by the effect on the normal surface of a hemidiaphragm, for example, or if the descending aorta cannot be seen, then this is an indication that an unusual amount of aerated lung no longer touches the anatomic part. This occurs in part because the alveolar spaces are wholly or partially filled with fluid usually blood, pus, or water or in part because the lung has collapsed and decreased the normal ratio of air and soft tissue. The end result in the latter case would be an increase in opacity which is what the X-ray beam reveals. The heart border and the diaphragm are normally seen because of their interface with aerated lung. When the contiguous lung is not aerated, the opaque tissue of the affected lung blends visually with the soft tissue opacity of the heart, and the heart border is no longer visible. This is what is termed the silhouette sign. Summation by definition is the result of superimposition of many layers of lung tissue, so that the final visual effect is that of a greater amount of tissue in the path of a particular part of the X-ray beam. This is observed when the opacity of fluid in the pleural space, interstitial space, or even lung parenchyma is added on the normal structure of the lung [6]. The most important skill for evaluating a chest X-ray is the knowledge of normal anatomic variants, the specific patterns with pathological changes, and the common signs of abnormal states. Lateral decubitus radiographs are commonly employed to determine the presence or mobility of pleural effusions. These views can also be obtained to detect small pneumothoraces, particularly in patients who are confined to bed and unable to sit or stand erect. A new generation of digital X-ray systems based on flat panel detections is now emerging, and these provide good image quality and very rapid direct access to digital images.

Chest Radiographs and Pulmonary Disease

The basic underlying change in the chest film that allows the detection and diagnosis of abnormalities is usually due to an alteration in lung opacity. This can be caused by technical factors, physiologic variation, or pathologic mechanisms [7]. Diseases that affect the chest can usually be thought of as either those that make the film lighter (increase opacity) or those that make it darker (increase lucency).

For chest disease with increased opacity on radiographs, the conditions that are marked by focal or global increase in the opacity of the film are first examined. These conditions include atelectasis, pulmonary edema, acute respiratory distress syndrome, etc.

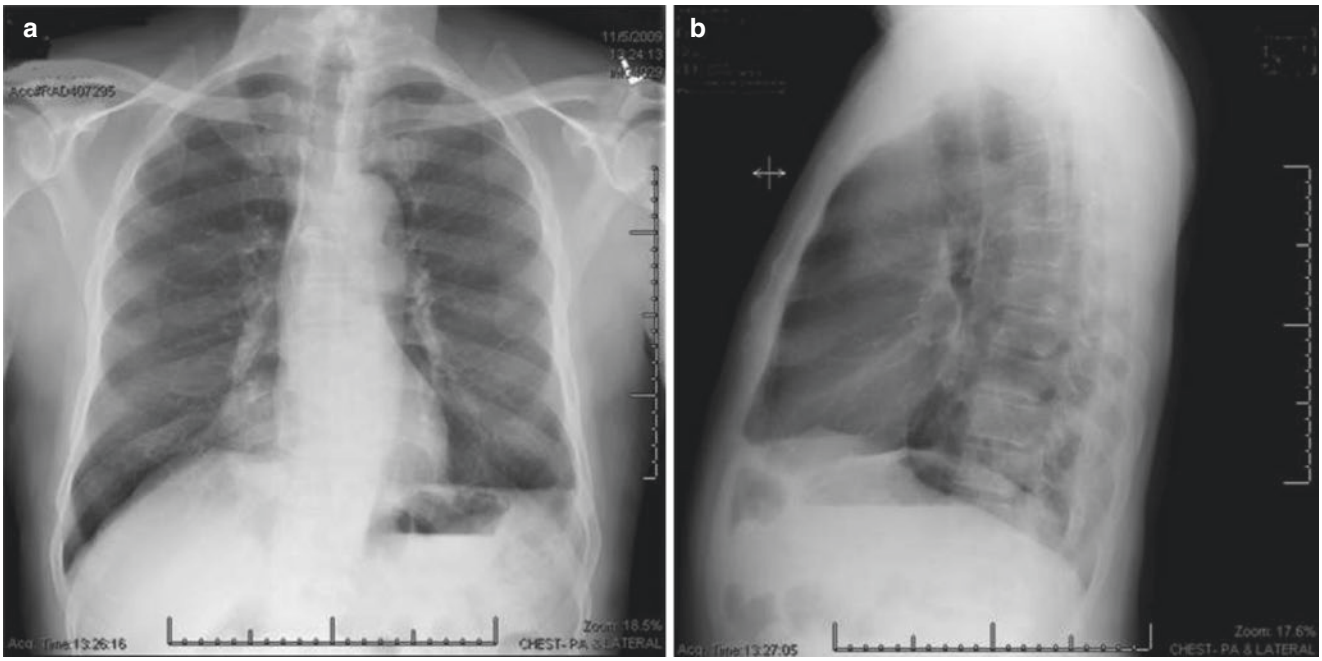

Fig. 3.1 (**a**) Shows a posteroanterior chest radiograph on a 68-year-old male with a lung neoplasm on the right lower lobe. The mass is clearly visible between the 8th and 9th rib on the right hemithorax. (**b**) Shows a lateral chest radiograph showing a round mass on the right hemithorax

Lung Mass and Chest X-Rays

Pulmonary neoplasia presents as opacities on films although usually as a more focal area with varying contours. However, smaller lesions may be very difficult to visualize, particularly when there are overlying bones or other soft tissue. Figure 3.1a shows a posteroanterior chest radiograph on a 68-year-old male with a lung neoplasm on the right lower lobe. The mass is clearly visible between the eighth and ninth rib on the right hemithorax. Figure 3.1b shows a lateral chest radiograph showing a round mass on the right hemithorax.

Mediastinal Mass and Chest X-Rays

In order to understand mediastinal masses and radiological images, it is important to be familiar with the anatomy of the mediastinum. The mediastinum is situated between the two pleural cavities. It extends superiorly from the root of the neck and the thoracic inlet to the hemidiaphragm inferiorly. It is divided into the superior and inferior mediastinum by the transverse thoracic plane, which is an imaginary plane extending horizontally from the sternal angle anteriorly to the border of the fourth thoracic vertebra posteriorly. The inferior mediastinum is subdivided into anterior, middle, and posterior compartments. The anterior mediastinum contains the thymus, trachea, esophagus, vessels, and arteries as well as lymph nodes; any abnormal growth in this region will affect the adjacent area. A mass in this area may compress the tracheobronchial tree and/or major vessels (superior vena cava and pulmonary vessels). The middle mediastinum is the space occupied by the heart and pericardium [8, 9]. Figure 3.2a shows a schematic representation of mediastinal anatomy and Fig. 3.2b a lateral normal radiograph of the chest showing the potential location of mediastinal mass. A variety of neoplasms and other lesions present with anterior mediastinal involvement. Thymoma is the most common primary neoplasm of the anterior mediastinum [10].

Regarding radiological studies in patients with a suspected anterior mediastinal mass, the initial study generally is a standard biplane chest radiography, which will identify up to 97% of mediastinal tumors. The chest X-ray also provides important information regarding the size and the location of the mass [11].

In addition, in this patient group in particular, special attention must be paid to the lateral radiography of the chest to determine the overall extent of the mass and potential involvement of adjacent structures. A barium contrast

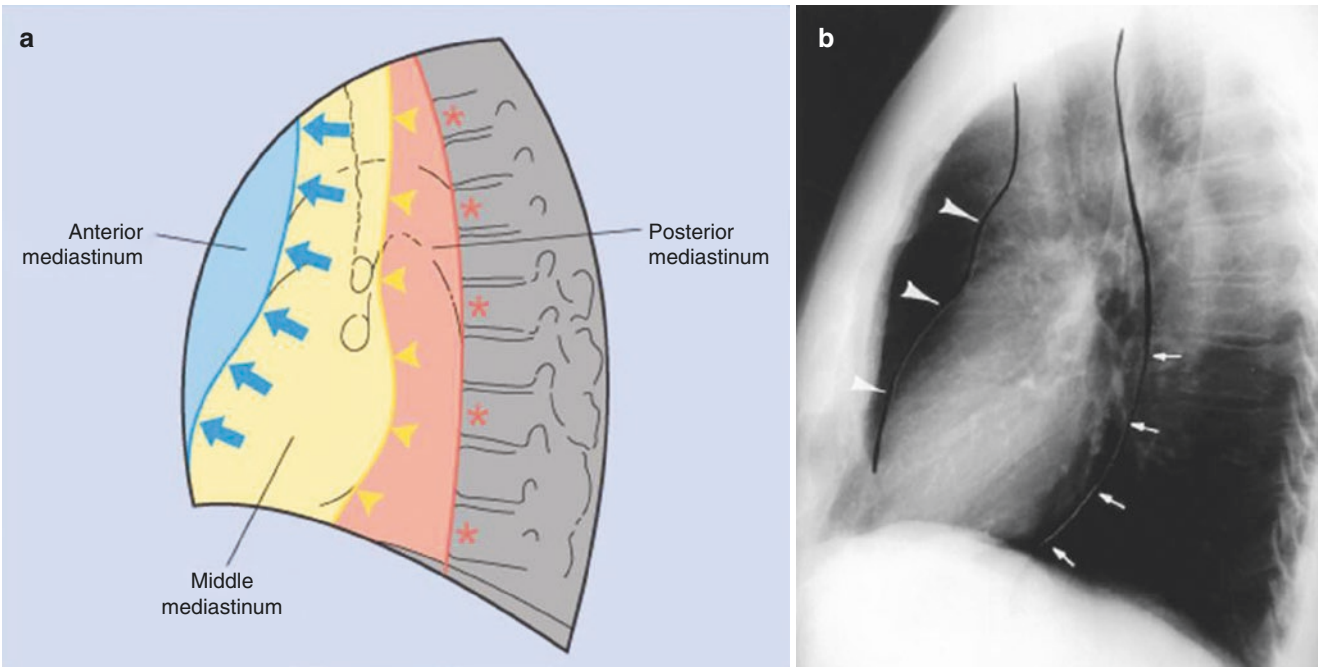

Fig. 3.2 (**a**) Shows a schematic representation of mediastinal anatomy and (**b**) a lateral normal radiograph of the chest showing the potential location of mediastinal mass. (With permission Ref. [10])

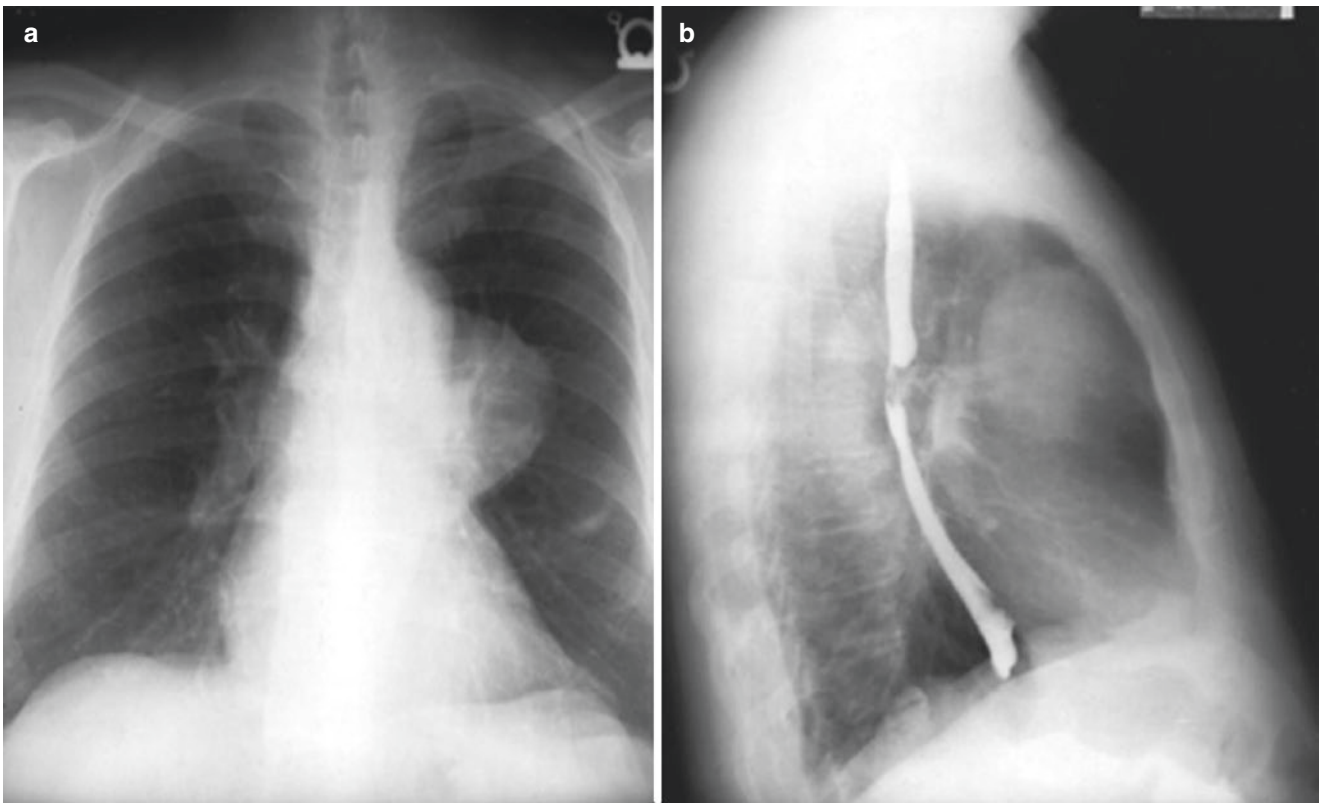

Fig. 3.3 (**a**) Shows an anterior mediastinal mass in the left hemithorax of the posteroanterior chest radiograph. (**b**) Shows a lateral radiograph with esophageal contrast where there is a mediastinal mass without compromise to the tracheobronchial tree

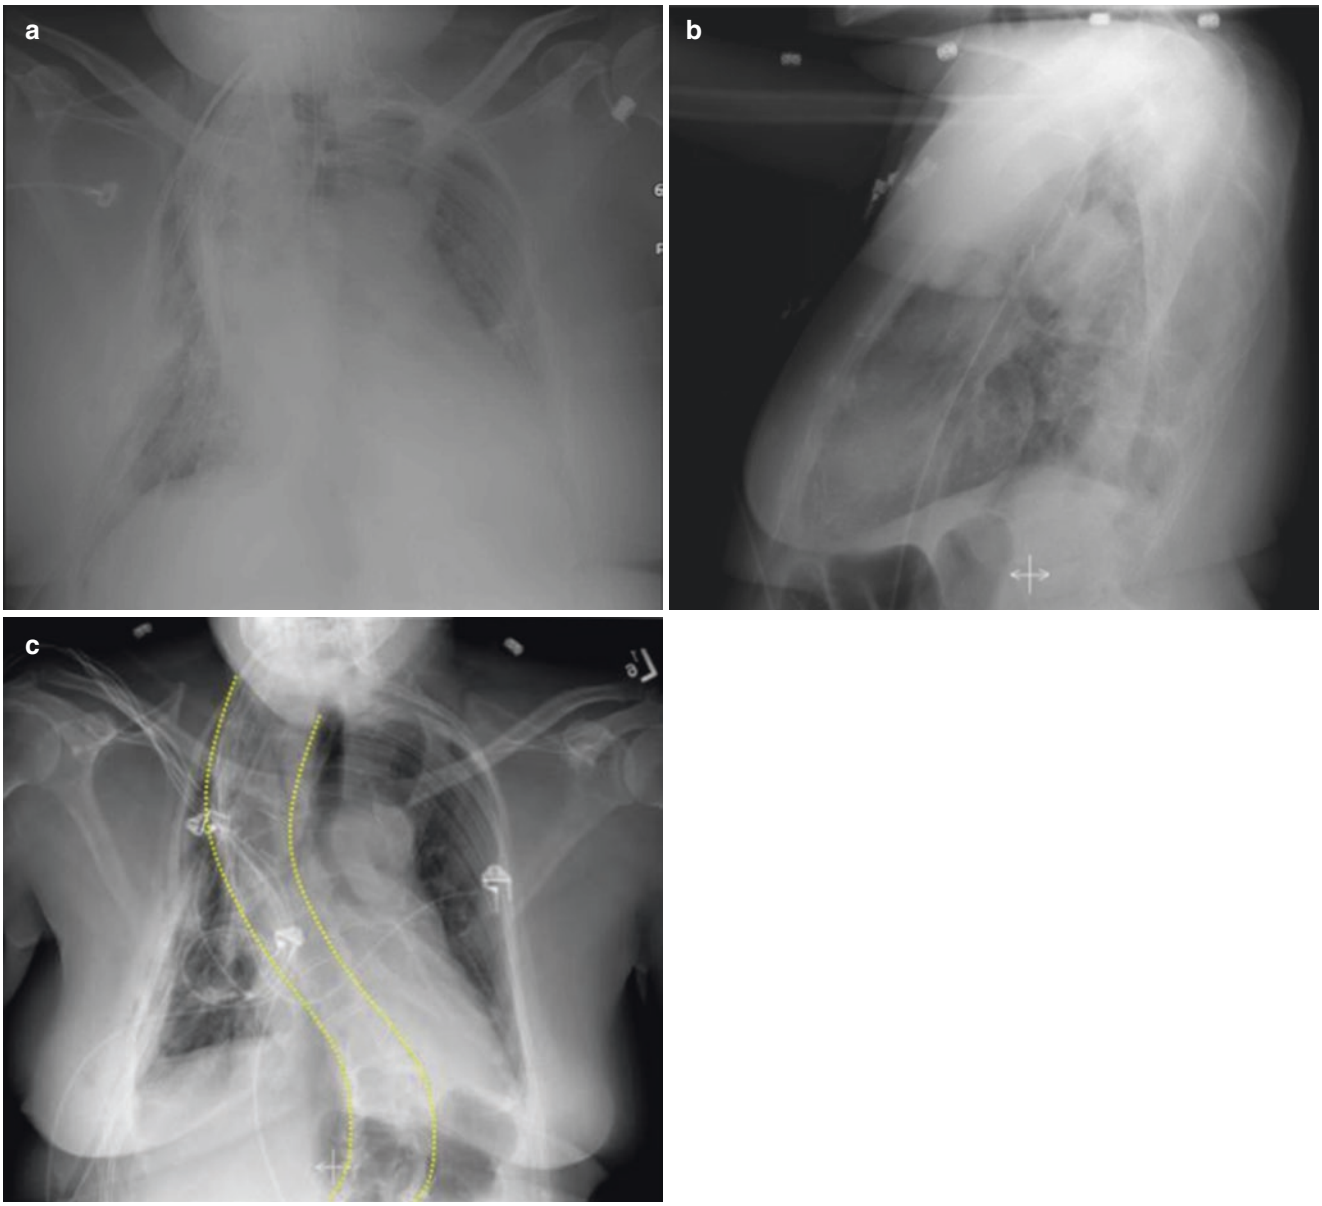

Fig. 3.4 Shows (**a**) a posterior mediastinal mass in the right hemithorax of the posterior–anterior chest radiograph in a female with severe kyphoscoliosis (**b**) a lateral radiograph showing the posterior mediastinal mass, (**c**) a portable posterior–anterior chest radiograph in the postoperative acute care unit after the resection of the posterior mediastinal mass. The yellow dots are showing the contour of the thoracic column showing severe kyphoscoliosis

esophagogram may help to determine whether there is esophageal or tracheobronchial involvement. Figure 3.3a shows an anterior mediastinal mass in the left hemithorax of the posteroanterior chest radiograph. Figure 3.3b shows a lateral radiograph with esophageal contrast where there is a mediastinal mass without compromise to the tracheobronchial tree (Fig. 3.4).

Bullae

Emphysema is characterized by a permanent increase in air spaces distal to the terminal bronchiole beyond the normal size. There is destruction of tissue, leading to a loss of alveolar surface available to participate in air exchange and, sometimes, severe displacement of the adjacent normal lung.

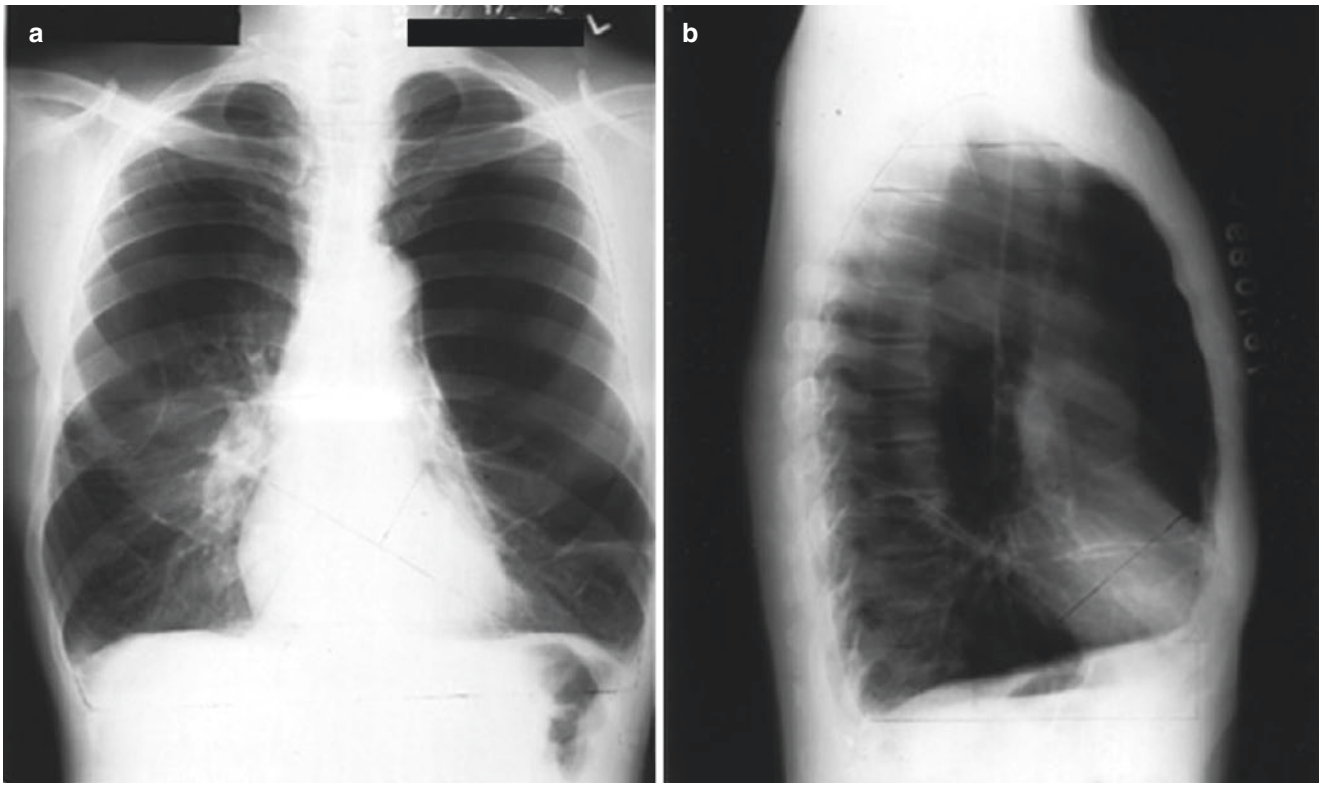

Fig. 3.5 (**a**) Shows a patient with emphysema. There is a marked hyperinflation with an increase in the anterior–posterior diameter of the chest. Also, there are flattening of the diaphragm bilaterally and generalized increase in the blackness of the film. (**b**) Shows the same patient a lateral chest X-ray

Many of the cases of emphysema seen in adult patients are strongly associated with cigarette smoking. The most striking image in a patient with advanced emphysema is a marked hyperinflation with an increase in the anteroposterior diameter of the chest, flattening of the diaphragmatic surfaces, and a generalized increase in the blackness of the film. Also there is a change in the vascular pattern, with attenuated vessels thinned and spread apart.

Often bullous areas are noted as large thin-walled air cysts, especially the apices. A bulla is defined as an air-filled space 1 cm or greater in diameter within the lung parenchyma that forms as a result of this destructive process. Rarely, one or more bullae enlarge to such a degree that they occupy more than one-third of the hemithorax. The term giant bullae is then applied. These easily distensible reservoirs are preferentially filled during inspiration, causing the collapse of adjacent, more normal lung parenchyma [12, 13]. Figure 3.5a shows a patient with emphysema, and Fig. 3.5b shows a lateral chest radiograph of the same patient. Figure 3.6 shows a PA chest X-ray and lateral radiograph of a patient with bullae. Figure 3.7 displays the chest X-ray showing a giant bulla occupying more than two-thirds of the right hemithorax and compressing the underlying lung.

Pneumothorax

Pneumothorax is the presence of air in the pleural space that is between the lung and the chest wall. Primary pneumothoraces arise in otherwise healthy people without any lung disease. Secondary pneumothoraces arise in subjects with underlying lung disease. Despite the absence of underlying pulmonary disease in patients with primary pneumothorax, subpleural blebs and bullae are likely to play a role in the pathogenesis. It is frequently the result of trauma, although sometimes the source of air leak cannot be readily detected.

The radiographic diagnosis of pneumothorax is usually straightforward. A visceral pleural line is seen without distal lung markings. On standard lateral views, a visceral pleural line may be seen in the retrosternal position or overlying the vertebrae, parallel to the chest wall [14, 15].

Pneumothoraces present as appearances on lateral chest radiographs; although the value of expiratory views is controversial, many clinicians still find them useful in the detection of small pneumothoraces when clinical suspicion is high and an inspiratory radiograph appears normal. The British Thoracic Society guidelines divide pneumothoraces into small and large based on the distance from visceral

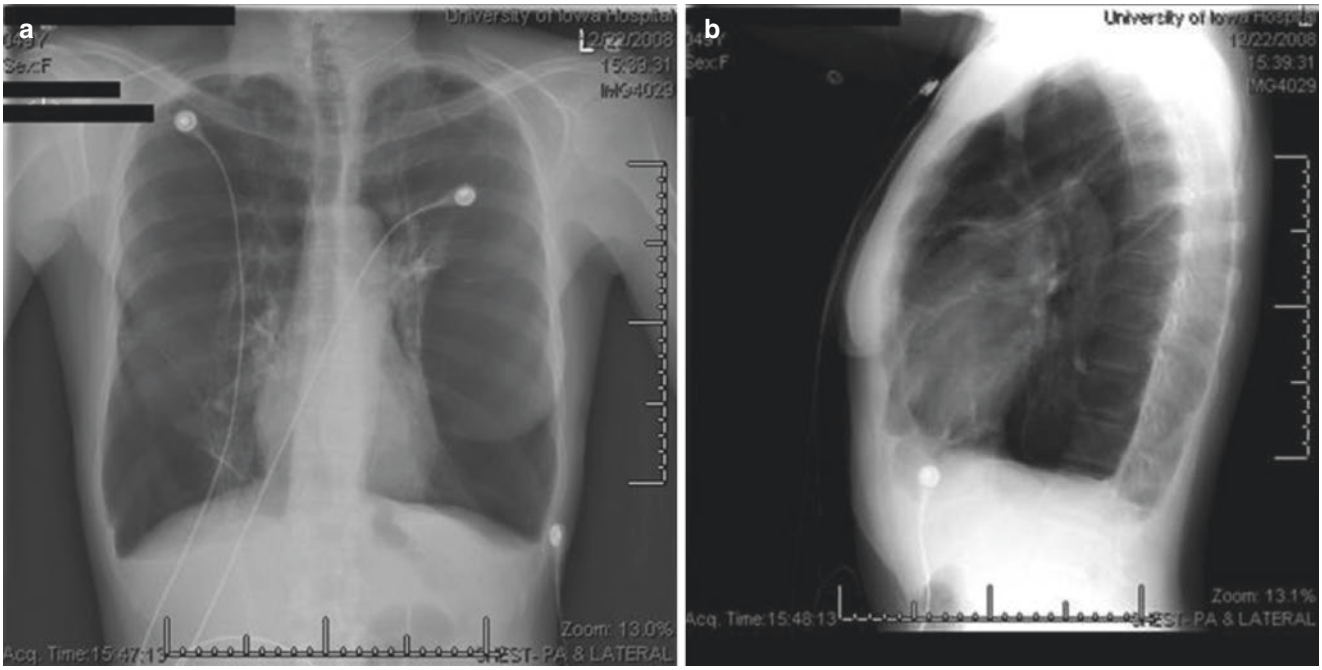

Fig. 3.6 (**a**) Shows a posterior–anterior chest X-radiograph of a patient with a bullae on the left hemithorax. (**b**) Shows the same patient on the lateral radiograph

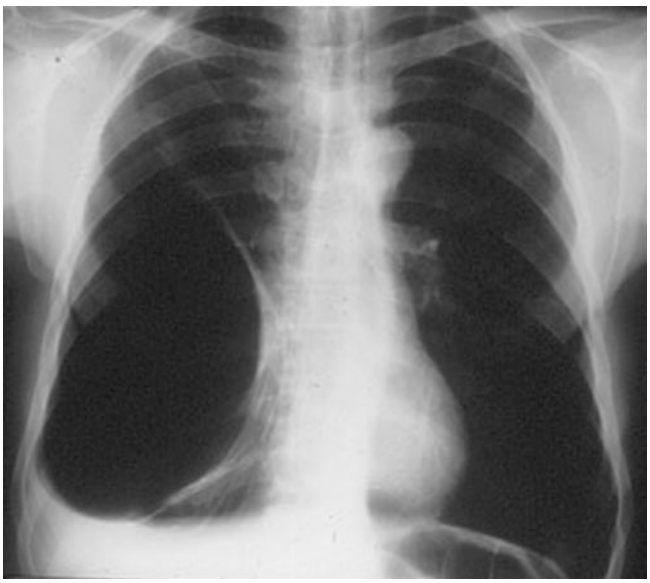

Fig. 3.7 Displays the chest X-ray showing a giant bullae occupying more than two-thirds of the right hemithorax and compressing the underlying lung

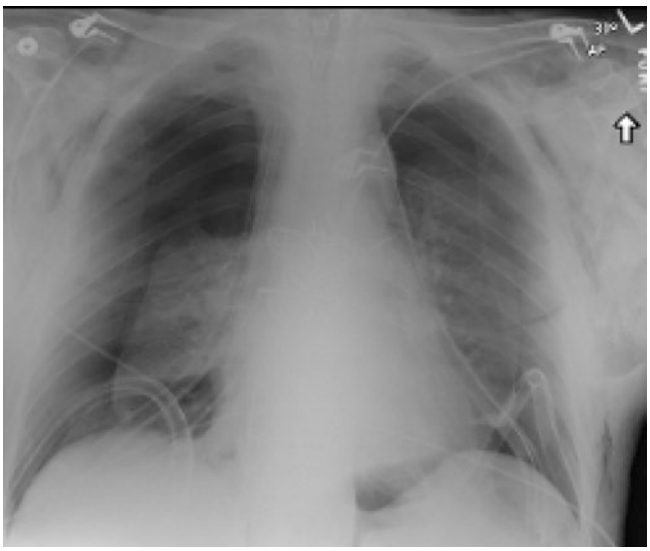

Fig. 3.8 Shows the chest radiograph of a patient with right-sided pneumothorax and bilateral chest tubes

pleural surface (lung edge) to chest wall, with less than 2 cm being small and more than 2 cm large [16]. A small rim of air around the lung actually translates into a relatively large loss of lung volume, with a 2-cm-deep pneumothorax occupying about 50% of the hemithorax.

In the supine position, air in the pleural space will usually be most readily visible at the lung bases in the cardiophrenic recess and may enlarge the costophrenic angle. Figure 3.8 shows the chest radiograph of a patient with right-sided pneumothorax.

Several well-known artifactual appearances can mimic the presence of a pneumothorax and should always be remembered during evaluation of chest radiography. The medial border of the scapula can imitate a lung edge but once considered can be traced in continuity with the rest of the bone, revealing its true nature. Skinfolds overlying

the chest wall can simulate a visceral pleural line and, with the relative lack of lung markings in the upper zones, can lead to erroneous diagnosis. Once considered, however, the true nature of the image is readily apparent. Skinfolds are usually seen to pass outside the chest cavity, are straight or only minimally curved, and do not run parallel to the chest wall as with a true visceral pleural line. Skinfolds also form a dense line that is sharp on one side and blurred on the other in contrast to the less dense visceral pleural line. Also, radiopaque lines are often seen accompanying the inferior margins of ribs, which may simulate a visceral pleural line. These are often called companion shadows although some restrict this term to densities accompanying the first and second ribs. They are caused by protruding extrapleural fat or the subcostal grove.

Tension pneumothorax occurs when the intrapleural pressure exceeds the atmospheric pressure throughout inspiration as well as expiration. It is thought to result from the operation of a one-way valve system, drawing air into the pleural space during inspiration and not allowing it out during expiration. The development of tension pneumothorax is often, but not always, heralded by a sudden deterioration in the cardiopulmonary status of the patient related to impaired venous return, reduced cardiac output, and hypoxemia. The development of tension in a pneumothorax is not dependent on the size of the pneumothorax, and the clinical scenario of tension pneumothorax may correlate poorly with chest radiographic findings [17, 18]. In extreme cases of tension pneumothorax, the air leak brings about significant displacement of the mediastinum and contralateral lung into the opposite hemithorax causing significant hemodynamic instability.

Pleural Effusion

Pleural effusion does not involve the lung parenchyma; it can be the source of a significant amount of absorbing material in the path of the X-ray beam, causing opacity on the films. Large pleural effusions are easy to spot on a chest radiograph, but small pleural effusions can be overlooked easily, especially on portable films because the patients are almost always supine or semierect, and the fluid can collect either in a subpulmonic location or deep in the posterior costophrenic sulcus where it is hidden from view. Most often smaller effusions are seen as a veil-like opacity that is most pronounced at the base and tapers toward the lung apex. Figure 3.9 shows a male patient with a large pleural effusion of the left hemithorax occupying two-thirds of the chest cavity on the left side.

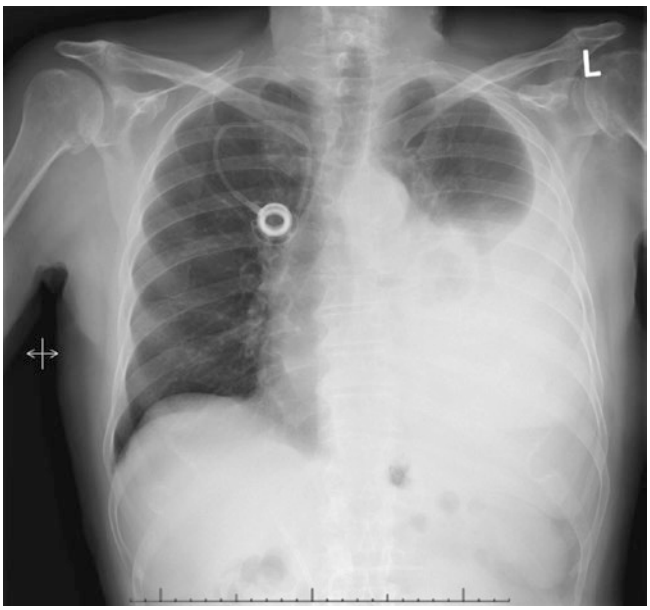

Fig. 3.9 Shows a male patient with a large pleural effusion on the left hemithorax occupying two-thirds of the chest cavity on the left side. Also there is the presence of an infusion port device on the right hemithorax

Chest Tube Placement

In general, appropriate use of chest tubes results in complete drainage of the collected air and fluid in the pleural space and allows full expansion and occupation of the entire pleural space by the lung, thus protecting the lung and pleural space from subsequent complications. Chest tubes are used routinely in the thoracic surgical patient. In practice, there are three main types that are used: (a) the large-caliber chest tube that involves the use of a 20–30 F size, (b) the small-caliber tube, and (c) the pigtail catheters. The typical and most common tubes have a side hole and end hole, and, in addition, they have an opaque marker that can be clearly seen in the chest X-radiograph. Many of those chest tubes can be inadvertently placed either in the major fissure, in lung parenchyma, or too high in the apex, and this can cause severe pain or damage to the lung.

In order to evaluate the position of a chest tube, an anterior–posterior chest radiograph or lateral films are useful [19]. In some circumstances, computed tomography (CT) scans of the chest are valuable for assessing chest tube position, for example, when misplacement is suspected but not confirmed on a plain radiograph [20]. Figure 3.10 shows a chest tube in a female patient placed in the right hemithorax.

Surgical emphysema is a well-known complication of intercostal tube drainage [21]. The development of surgical

Fig. 3.10 Shows a chest tube on the right hemithorax. The tip of the tube can be clearly seen at the level of the 6th intercostal space. Also, there is a PIC line going from a vein in the right arm to the entrance of superior vena cava

emphysema associated with pneumothorax involves an air-filled space, not formerly in communication with the subcutaneous tissue, being brought into communication with subcutaneous tissue. This may occur in the presence of a malpositioned, kinked, blocked, or clamped tube. Likewise, a small tube in the presence of a very large leak may potentially cause surgical emphysema. Any malpositioned chest tube should be visible with the chest radiograph. If the emphysema results in airway obstruction or thoracic compression, it may lead to severe respiratory insufficiency. The treatment is usually conservative, but in life-threatening situations, skin incision decompression and insertions of large-bore modified subcutaneous chest drains have all been used successfully.

Previous Lobectomy

Resection of a segment of the lung will produce changes somewhat similar to segmental atelectasis in that a portion of the lung is no longer present, and the remaining segments of the lobe, and other lobes on that side, will expand to fill the space. The chest radiograph will show a displacement of the interlobar fissure and elevation of the diaphragm. There might be a displacement of the hilum. Often the most common sign of the surgery in the chest is the presence of fine

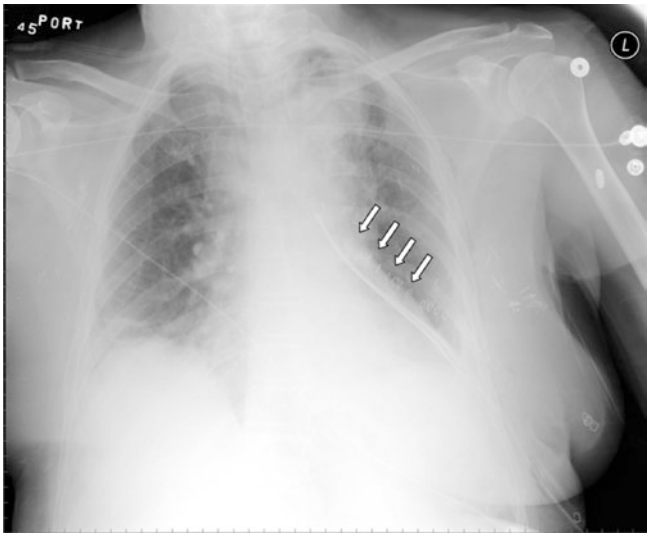

Fig. 3.11 Shows a chest X-ray of a female patient who had a left lower lobe lobectomy. The arrows are pointed to where the stapling line is. Also, there is a bilateral infiltrates postlobectomy

metallic sutures on the pleural surface at the site of the resection and, if it is an acute resection (after surgery), the presence of a chest tube. Also, an osteotomy of a rib can be seen in the chest radiograph.

The lobectomy patient will often lead to a greater initial deformity of the involved hemithorax and some shift of the midline structures. As in cases of atelectasis, there should be compensatory overinflation of the noninvolved lobes. Figure 3.11 shows a chest X-ray of a female patient who had a left lower lobe lobectomy.

An important piece of information after lobectomy is the juxtaphrenic peak sign indicating upper lobe collapse. This is a common finding on chest radiographs of patients after upper lobectomy. It is more frequently seen after right upper lobectomy than after left upper lobectomy, and it is more often seen on erect than on supine radiographs. A study has shown that a juxtaphrenic peak can be expected to appear on chest radiographs in about 70% of patients 1 month or more after right upper lobectomy and in 50% after left upper lobectomy [22]. Figure 3.12 shows a patient who had a right upper lobectomy showing a thin juxtaphrenic peak.

Pneumonectomy

Removal of an entire lung leads to more drastic radiographic changes that evolve with the passage of time. Initially the affected side shows expected postoperative changes at the hilum and chest wall with a complete absence of lung tissue, leaving a very stark, air-filled cavity with extremely sharp

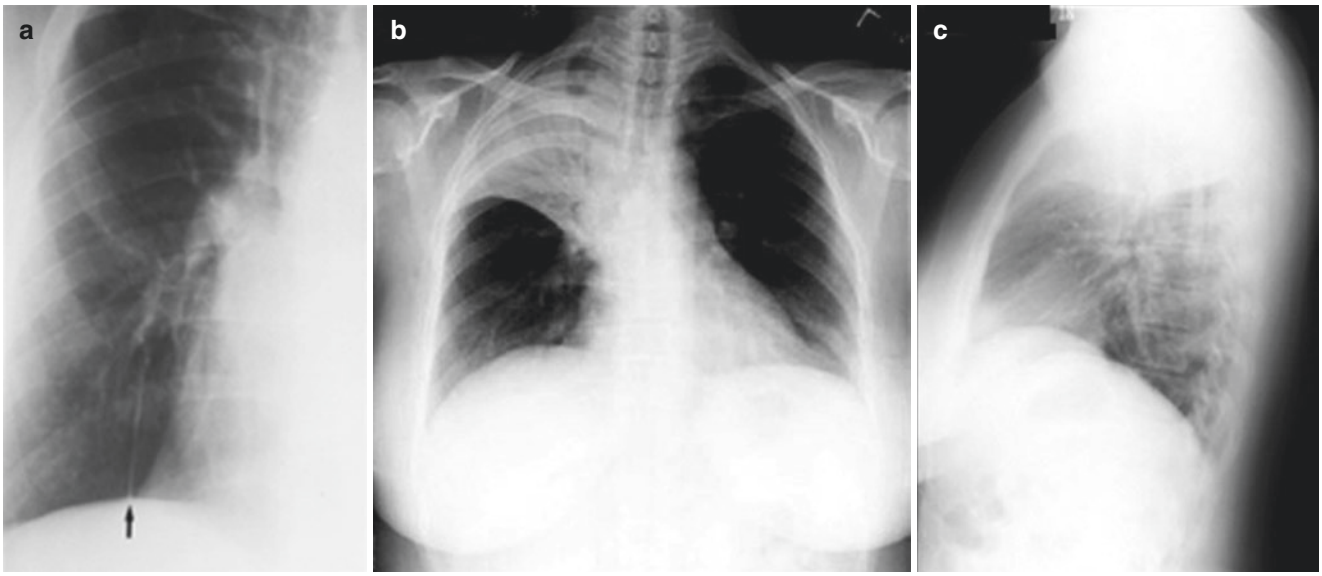

Fig. 3.12 (**a**) Shows a patient who had a right upper lobectomy showing a thin juxtaphrenic peak pointed with an arrow. (**b**) Shows a right upper lobectomy without the juxtaphrenic line. (**c**) Shows the same patient with the lateral chest radiograph

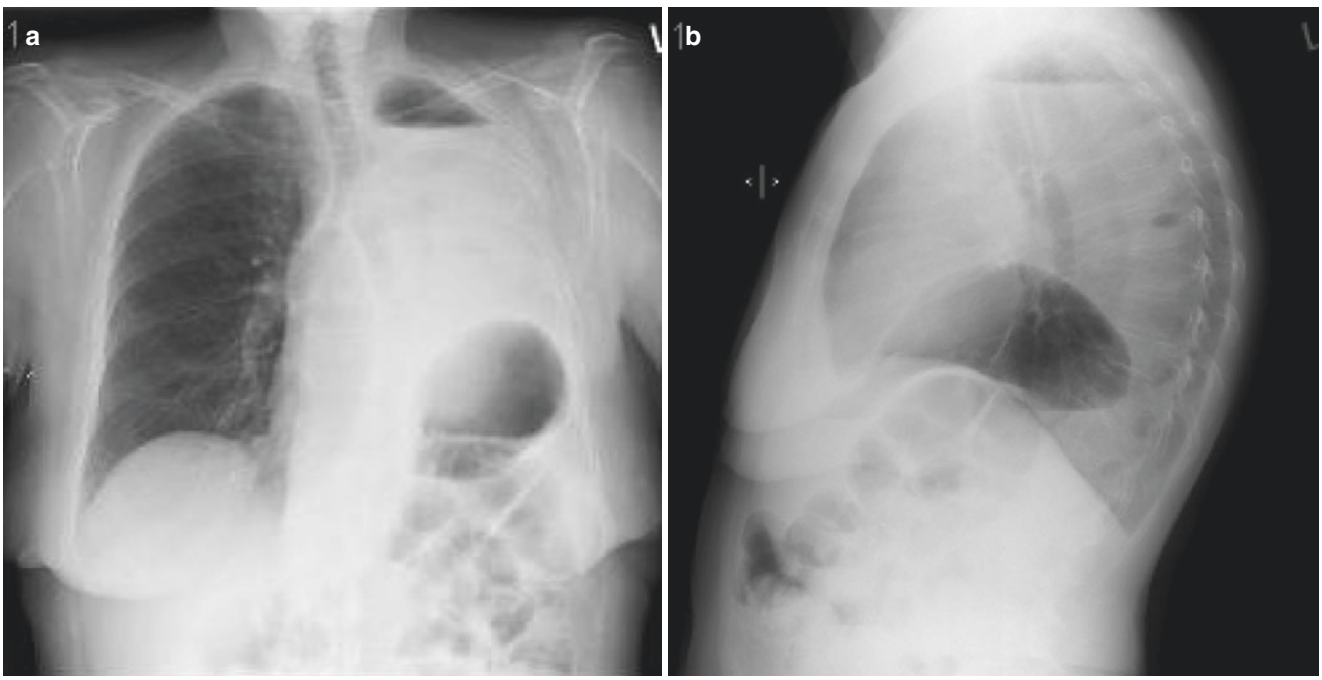

Fig. 3.13 (**a**, **b**) Shows a chest radiograph in anterior–posterior and lateral position in a patient with a left-sided pneumonectomy. On the left hemithorax, the white image corresponds to fluid in the hemithorax

margins of the heart and diaphragm. After pneumonectomy, air in the operated hemithorax is gradually reabsorbed and replaced by fluid with a net volume loss. As a result, the trachea and mediastinum gradually shift toward the surgical side. In the immediate postoperative period, a mediastinal shift away from the surgical side indicates atelectasis of the contralateral lung or an abnormal accumulation of air or fluid on the surgical side [23]. A rapid mediastinal shift can signify the presence of an air leak with a "ball valve" effect leading to a tension pneumothorax. There are usually some elevation of the hemidiaphragm and a shift of the heart and other midline structures toward the operated side as the remaining lung expands to take some of the space. Gradually the hemithorax fills with fluid, showing a distinct air fluid level if the patient is upright, or a more subtle increase in opacity if the patient is in the supine position. Figure 3.13

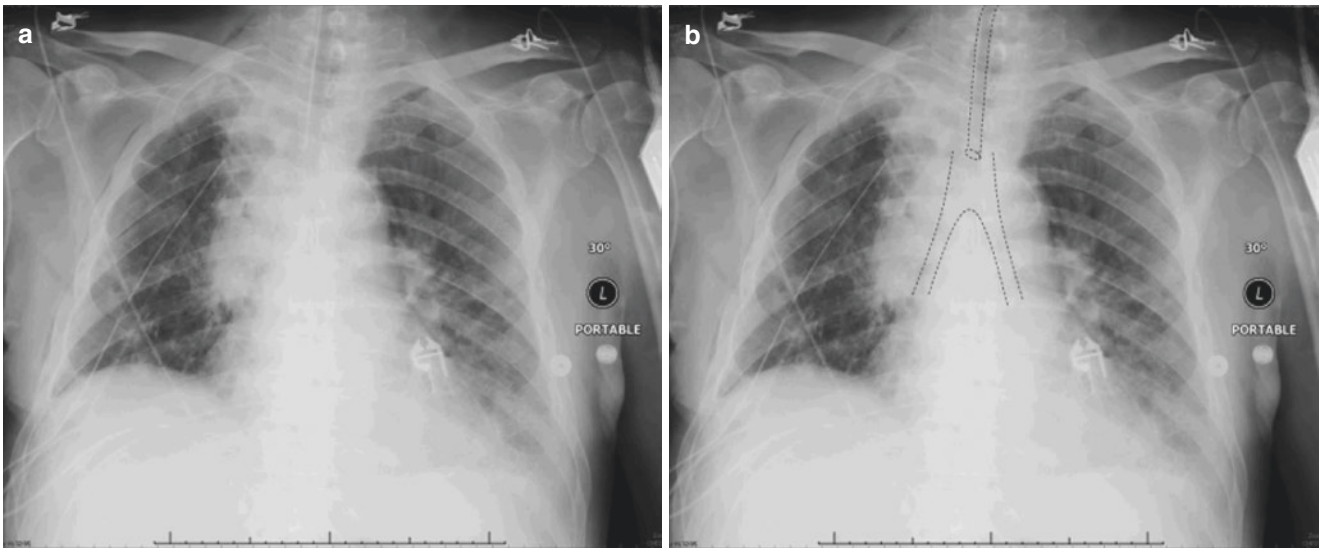

Fig. 3.14 (**a**) Shows a male patient who underwent a right upper lobectomy and remained intubated in the postoperative period with a single-lumen endotracheal tube. (**b**) Shows the same patient with a reconstruction of the single-lumen endotracheal tube. Notice that the tip of the single-lumen endotracheal tube should be placed 3 cm above the tracheal carina

shows a chest radiograph in anterior, posterior, and lateral position in a patient with a left-sided pneumonectomy.

After a thoracic surgical procedure, a chest radiograph film is required in order to assess lung expansion and chest tube placement, and if the patient remains intubated, the proper placement of the endotracheal tube must be assessed. The proper position of a single-lumen endotracheal tube as seen in the chest radiograph is that the distal tip of the tube is located approximately 3 cm above the tracheal carina. All endotracheal tubes have opaque markers that can be clearly identified in the radiographs. Figure 3.14a shows a male patient that underwent a right upper lobectomy and remained intubated in the postoperative period with a single-lumen endotracheal tube. Figure 3.14b shows the same patient with a reconstruction of the single-lumen endotracheal tube.

Double-Lumen Endotracheal Tubes

With any thoracic surgical procedure involving lung isolation devices, the anesthesiologist must review the tracheobronchial anatomy in the preoperative visit to determine whether or not abnormal anatomy exists. A view of the posteroanterior chest radiograph will allow assessment of the shadow of the tracheobronchial anatomy along with the bronchial bifurcation. It is estimated that in 75% of the films, the left mainstem bronchus shadow is seen. In addition, the chest radiograph can be useful to determine the proper size of a left-sided DLT. Brodsky et al. [24] reported that measurement of the tracheal diameter at the level of the clavicle on the preoperative posteroanterior chest

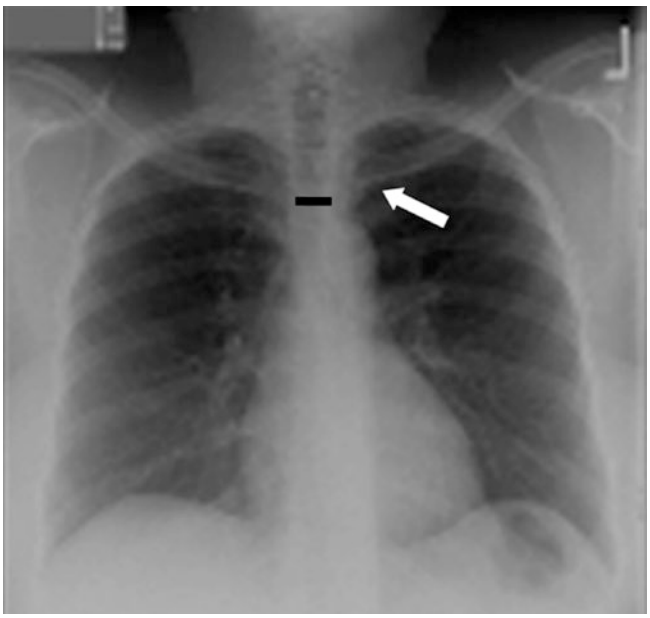

Fig. 3.15 Shows the measurement of the tracheal width at the level of the clavicles to estimate the proper size of the left-sided DLT from a chest radiograph

radiograph can be used to determine proper left-sided DLT size (refer to Chap. 16). Figure 3.15 shows the measurement of the tracheal width at the level of the clavicles to estimate the proper size of the left-sided DLT from a chest radiograph. In addition, the chest radiograph will allow the visualization of the already placed DLT. The tip of each lumen is identified with a radiopaque marker. Figure 3.16a shows the chest radiograph of a patient with a left-sided

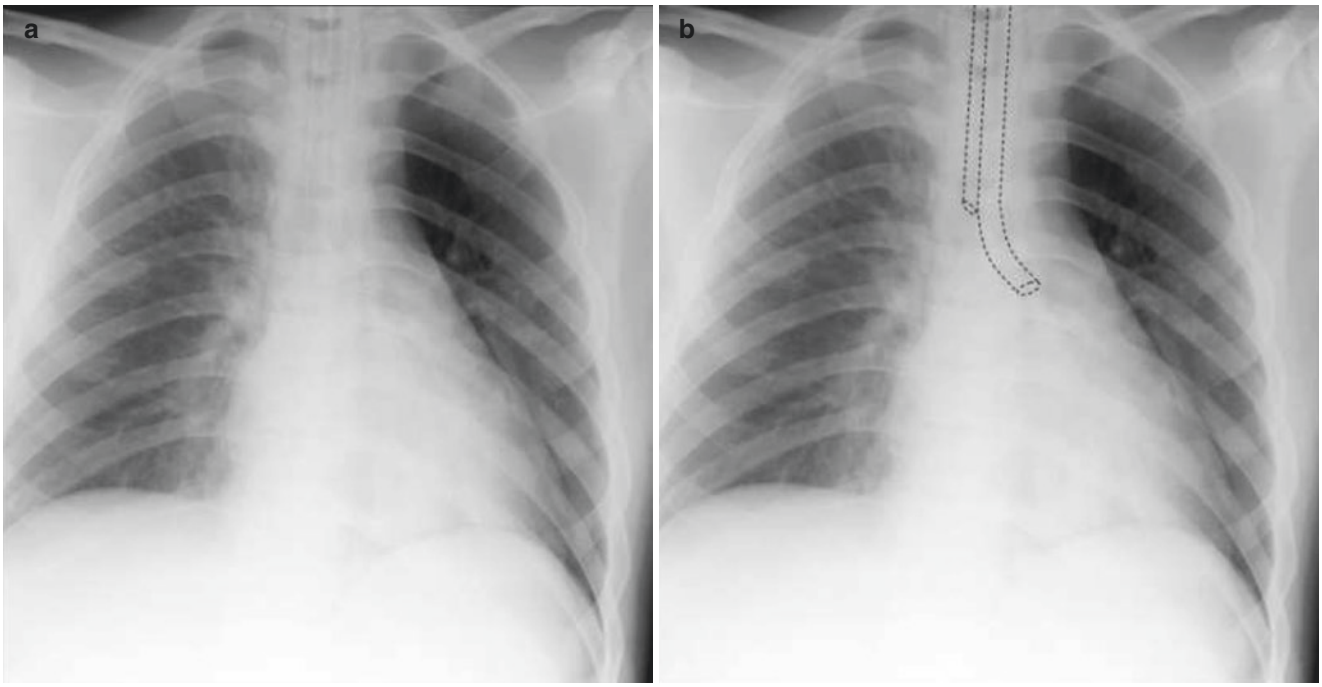

Fig. 3.16 (**a**) Shows the chest radiograph of a patient with a left-sided DLT in place. Notice the endobronchial lumen is approximately 2 cm below the tracheal carina into the left mainstem bronchus. (**b**) Shows a reconstruction of the DLT which is marked in the chest radiograph

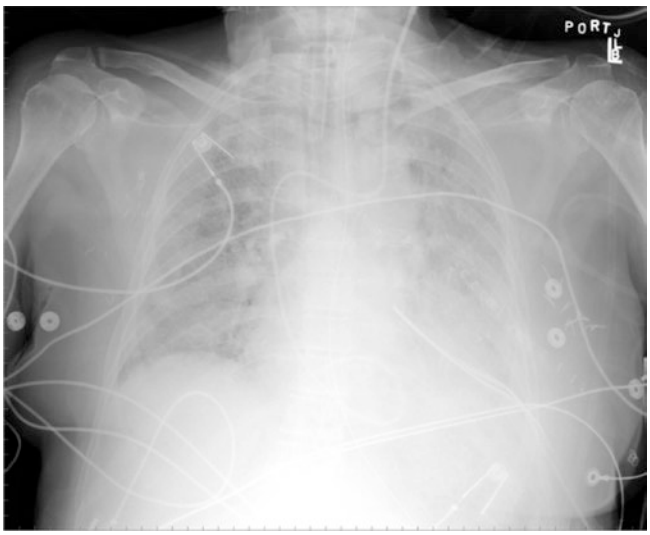

Fig. 3.17 Shows a patient with an acute lung injury (ALI) 72 h after the interstitial edema has progressed in the chest X-radiograph. There is a single-lumen endotracheal tube in place; also a pulmonary artery catheter introduced via the left internal jugular vein is seen. The chest radiograph also shows bilateral diffuse fluffy opacities typical of interstitial pulmonary edema postlobectomy

DLT in place. Notice the endobronchial lumen is approximately 2 cm below the tracheal carina into the left mainstem bronchus. Figure 3.16b shows a reconstruction of the DLT which is marked in the chest radiograph.

Postoperative Acute Lung Injury

Acute lung injury (ALI) may complicate thoracic surgery and is a major contributor to postoperative mortality. The incidence of ALI after thoracic surgery is estimated to be 4.2% [25, 26]. In a study by Licker et al. [25], they found a biphasic distribution pattern of ALI after lung resection. The primary form developed within the first 3 days after surgery and a secondary form triggered the onset of ALI after the third postoperative day.

The clinical presentation is a severe respiratory insufficiency with a progressive hypoxemia that does not respond to a conventional treatment including O_2 therapy. The chest radiograph of a patient with an ALI appears as patchy, unilateral or bilateral infiltrates, dependent pulmonary edema. In addition, atelectatic zones can be seen in the chest radiograph. Figure 3.17 shows a 60-year-old female following a left lower lobectomy who developed ALI in the immediate postoperative period; on the chest radiograph taken after 72 h, the interstitial edema has progressed. There is a single-lumen endotracheal tube in place; also a pulmonary artery catheter introduced via the left internal jugular vein can be seen. The chest radiograph also shows bilateral diffuse fluffy opacities typical of interstitial pulmonary edema postlobectomy after ALI.

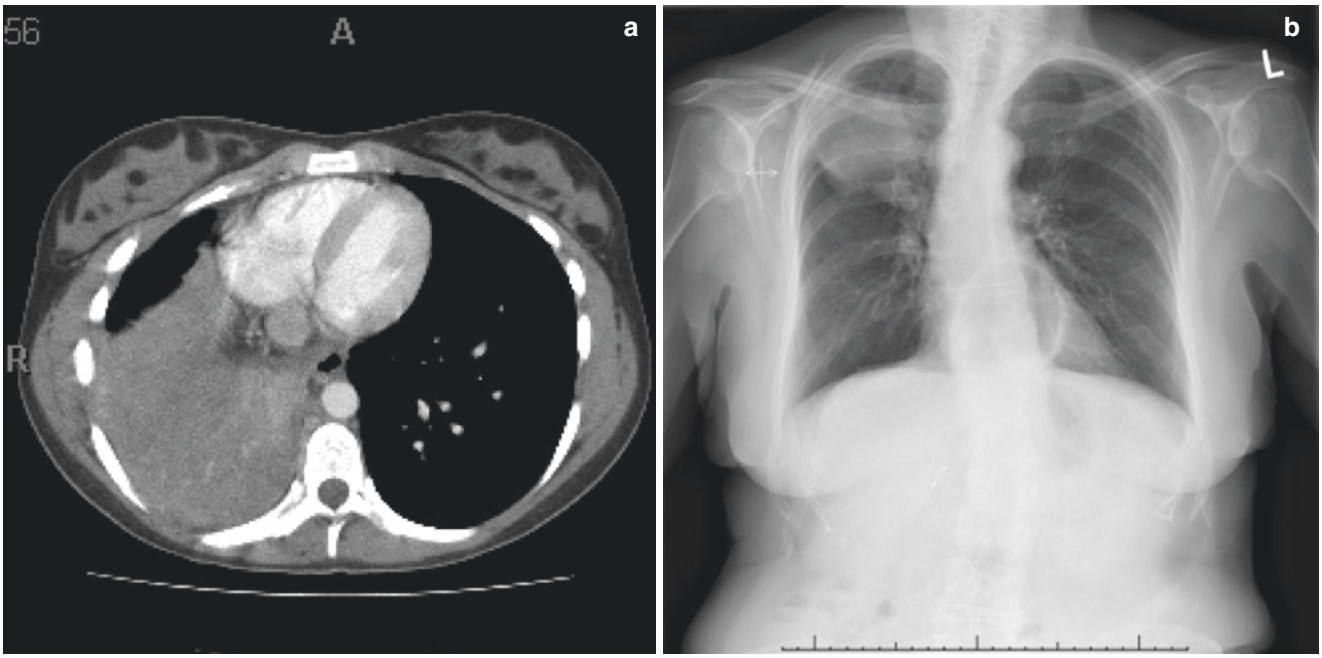

Fig. 3.18 (**a**) Shows a computed tomography (CT) scan of the chest. Diagnosis of pseudotumor of the lung. (**b**) Shows the chest radiograph showing the lung mass in the right upper lobe in the same patient. Diagnosis of right upper lobe adenocarcinoma

Computed Tomography Scan and Pulmonary Disease

CT scan of the chest is used as a diagnostic study; this is usually done after abnormal findings on a standard chest radiograph [27]. Common indications of CT include staging of lung cancer, solitary pulmonary nodule, mass or opacity, diffuse infiltrative lung disease, widened mediastinum, mediastinal mass, or other abnormalities of the mediastinum pleural abnormities, chest wall lesions, trauma, etc. Also, CT provides valuable information for the clinician with regard to the airway compression at any level of the tracheobronchial tree, as well as vascular compression diagnosis [28–31].

CT scans are performed in deep inspiration and at total lung capacity. For a routine helical CT of the chest, 2.5–5 mm sections are usually recommended. Thinner (1–2.5 mm) sections can be used to study fine details of the lung parenchyma. On routine studies, the field of view is adjusted to the size of the thorax, but small fields of view may be selected for smaller anatomic parts that require study. In addition, a contrast CT scan is useful in suspected vascular abnormalities such as pulmonary embolism. Recent improvements in scanner technology have led to the introduction of spiral or helical volumetric CT.

Computed Tomography Scan and Lung Mass, Mediastinal Mass, Pleural Effusion, and Pericardial Effusion

CT scan of the chest will confirm the presence of a mass in the chest and in many instances the specific location. Figure 3.18a shows a CT scan of the chest. There is the presence of a lung mass on the right lung. Figure 3.18b shows the chest radiograph showing the lung mass in the right upper lobe in a female patient. In addition, the CT scan of the chest will define the precise size and location of the mediastinal mass, any involvement with adjacent structures, as well as the degree of compression of the airway (trachea and/or bronchi). It is important during the assessment of the CT scan to identify the location of the mass, define its relationship to adjacent structures, assess the extent and degree of tracheal and/or vascular compression, and assess the patency of the airway at the tracheal and bronchial level. The CT scan also will permit accurate measurement of the airway diameter and will determine the precise level and extent of compression of the trachea. As mentioned previously, the average cross-sectional diameter of the trachea in a 70-kg, 170-cm tall person is approximately 18–23 mm. A tracheal diameter narrowing of 10 mm on CT corresponds to a 50% reduction in the tracheal cross-sectional area at

that level. Figure 3.19 shows a CT scan of the chest with a large anterior mediastinal mass in the left hemithorax. Figure 3.20 shows a CT scan of the chest with a large anterior mediastinal mass on the left side causing compression to the entrance of the left mainstem bronchus.

A CT scan of the chest allows precise location of the extrapulmonary fluid whether in the peripheral pleural space or the interlobar fissure. Figure 3.21 shows a CT scan of the chest showing a large pleural effusion on the left hemithorax. Also, the CT scan is very useful for the diagnosis of pericardial effusions, because the precise location can be identified with this method. Figure 3.22 shows a pericardial effusion; notice the fluid in the pericardial sac.

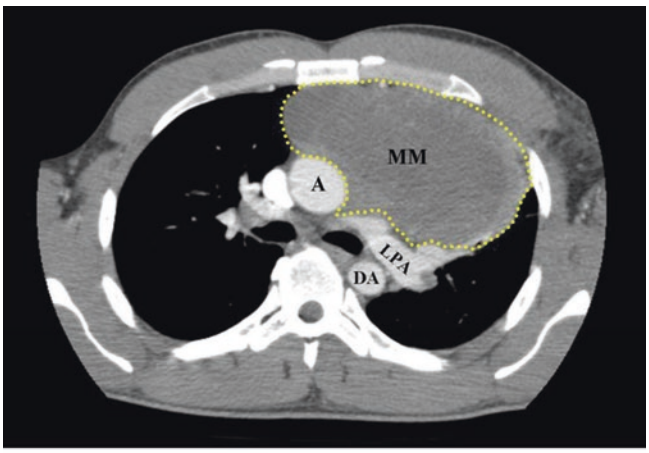

Fig. 3.19 Shows a computed tomography scan of the chest with a large anterior mediastinal mass on the left hemithorax (the dotted line is surrounding the mass). This patient has a diagnosis of mediastinal mass and diffuse B-cell lymphoma. MM mediastinal mass, LPA left pulmonary artery, A ascending aorta, DA descending aorta, R right, L left

In addition, a different alternative to assess the airways while using a CT scan is with the three-dimensional (3D) reconstruction of the airway using a workstation connected to a multidetector CT (MDCT) scanner. The MDCT provides high spatial resolution images of the whole lung without any anatomical gap. The technique consists of projecting the voxels with the lowest alteration value in every view through the volume explored, at various angles depending on the airway involved. If a tracheobronchial injury is suspected, 3D extraction of the airways may be useful by focusing the 3D volume-rendering technique to the tracheobronchial tree [32]. This technique is used for analyzing stenosis or distortion of the tracheobronchial tree but also may allow the diagnosis of tracheobronchial injury by demonstrating a wall defect and/or abnormal position of lobar and segmental bronchi [33, 34].

Also, a 3D scan of the chest is another modality to identify lymph nodes. The development of virtual bronchoscopy has led interest in introducing CT-based computer graphic techniques into the procedure of lung cancer staging. In virtual bronchoscopy, the 3D CT image serves as a high-resolution digital image replica of the chest [35]. Endoluminal renderings of the airways can be generated along paths following the airway central axes and lead to an off-line simulation of videobronchoscopy as virtual endoscopy; interior views are computer-generated from radiological images (see also Chap. 16, Fig. 16.14).

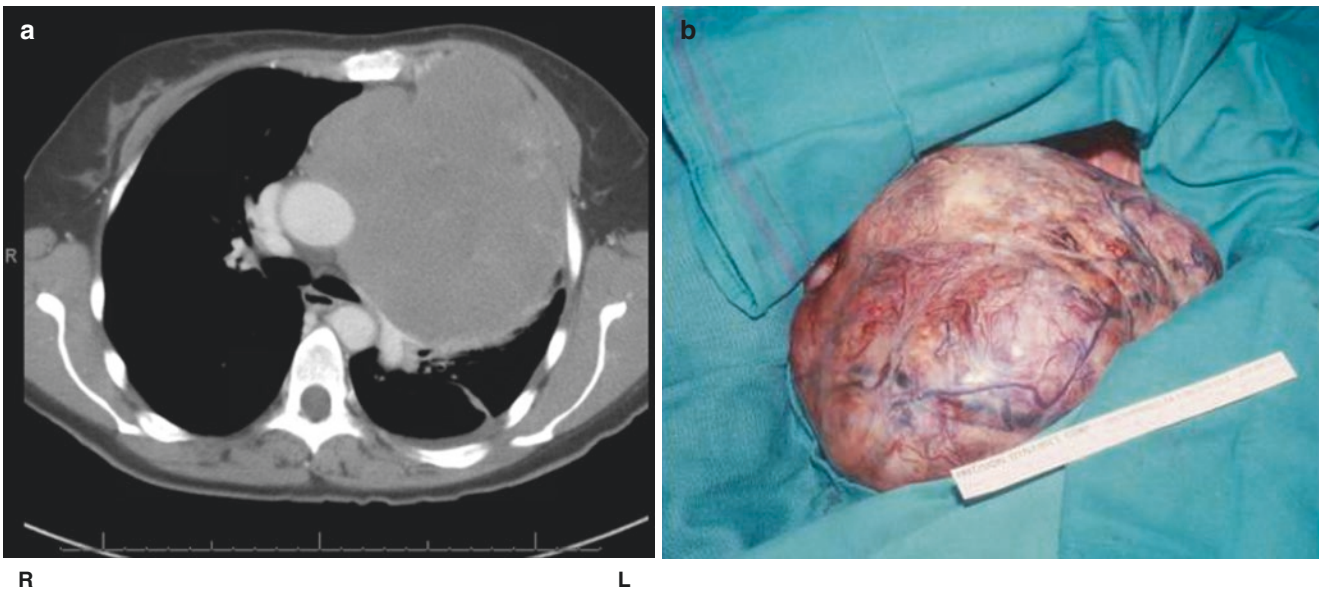

Fig. 3.20 (**a**) A computed tomography scan of the chest with a large anterior mediastinal mass on the left side causing compression to the entrance of the left mainstem bronchus. Diagnosis in this patient is germ cell tumor. (**b**) Showing a large mediastinal mass on left hemithorax

Fig. 3.21 Shows a CT scan of the chest showing a large pleural effusion on the left hemithorax. Also, the CT scan is very useful for the diagnosis of pericardial effusion, because of the precise location with this method

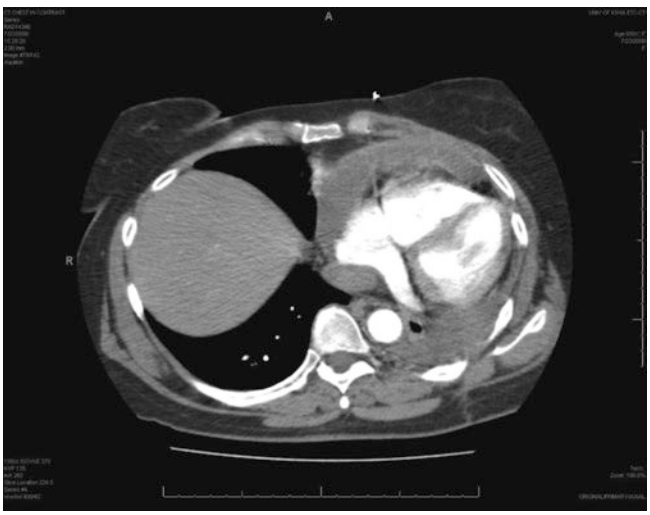

Fig. 3.22 Shows a pericardial effusion; notice the fluid in the pericardial sac

Imaging of the tracheobronchial tree has improved recently, in large part due to the advancement of CT, allowing for volumetric isotropic voxel imaging and its associated improvements in part processing software that allows for advanced three-dimensional (3D) visualization [36]. Thus airway imaging has become a tool that physicians can use to plan interventional procedures such as stent placement, surgery, and subsequent follow-up.

Patients undergoing thoracic surgical procedures who have large mediastinal mass with severe compromise of the airway require the placement of an airway stent; therefore, it is crucial to review CT scan in patients who have stent in place prior to surgery to assess the patency of the airway [37] (Fig. 3.23).

Multidetector Computer Tomography Scan of the Chest

Modern MDCT scanners readily provide very large high-resolution 3D volumetric images of the chest. Many 3D visualization techniques have been devised for more exhaustively viewing of the information contained in 3D MDCT chest images. The 3D MDCT image provides views of the segments of the airway tree, computes the central axes of the extracted airways, and also defines the endoluminal and exterior surfaces of the segmented airway tree and the exterior surfaces of the regions of interest for rendering [38].

One of the advantages of the MDCT and 3D reconstruction of the tracheobronchial tree is that it allows us to appreciate distorted tracheobronchial anatomy or changes in the airway with age. Figure 3.24 shows a MDCT scan of the chest on a male patient.

Magnetic Resonance Imaging and Pulmonary Disease

MRI produces images that superficially appear similar to CT scans. The MRI provides greater contrast resolution than CT scans and offers the potential for tissue characterization [39]. Also MRI of pulmonary parenchymal disease using a modified breath-hold 3D gradient echo technique allows imaging of a wide spectrum of solid and nonsolid pulmonary parenchymal diseases with reproducible high image quality, effective suppression of artifacts, and high resolution and visualization [40]. The 3D gradient echo technique allows better visualization of the peripheral and central parenchyma, pulmonary arteries, heart, and esophagus.

The MRI images are computer-generated images, usually in cross-sectional orientation but also with direct sagittal or coronal views, with tissues displayed in varying shades of black, white, and gray. MRI scans rely primarily on the evaluation of the amount of protons (water) in different tissues. This data information is acquired by placing the patient in a powerful magnetic field and interrogating the body with radio waves of a specific frequency and then listening for the response. By varying the frequency of the radio wave, the body can be imaged in multiple planes, not

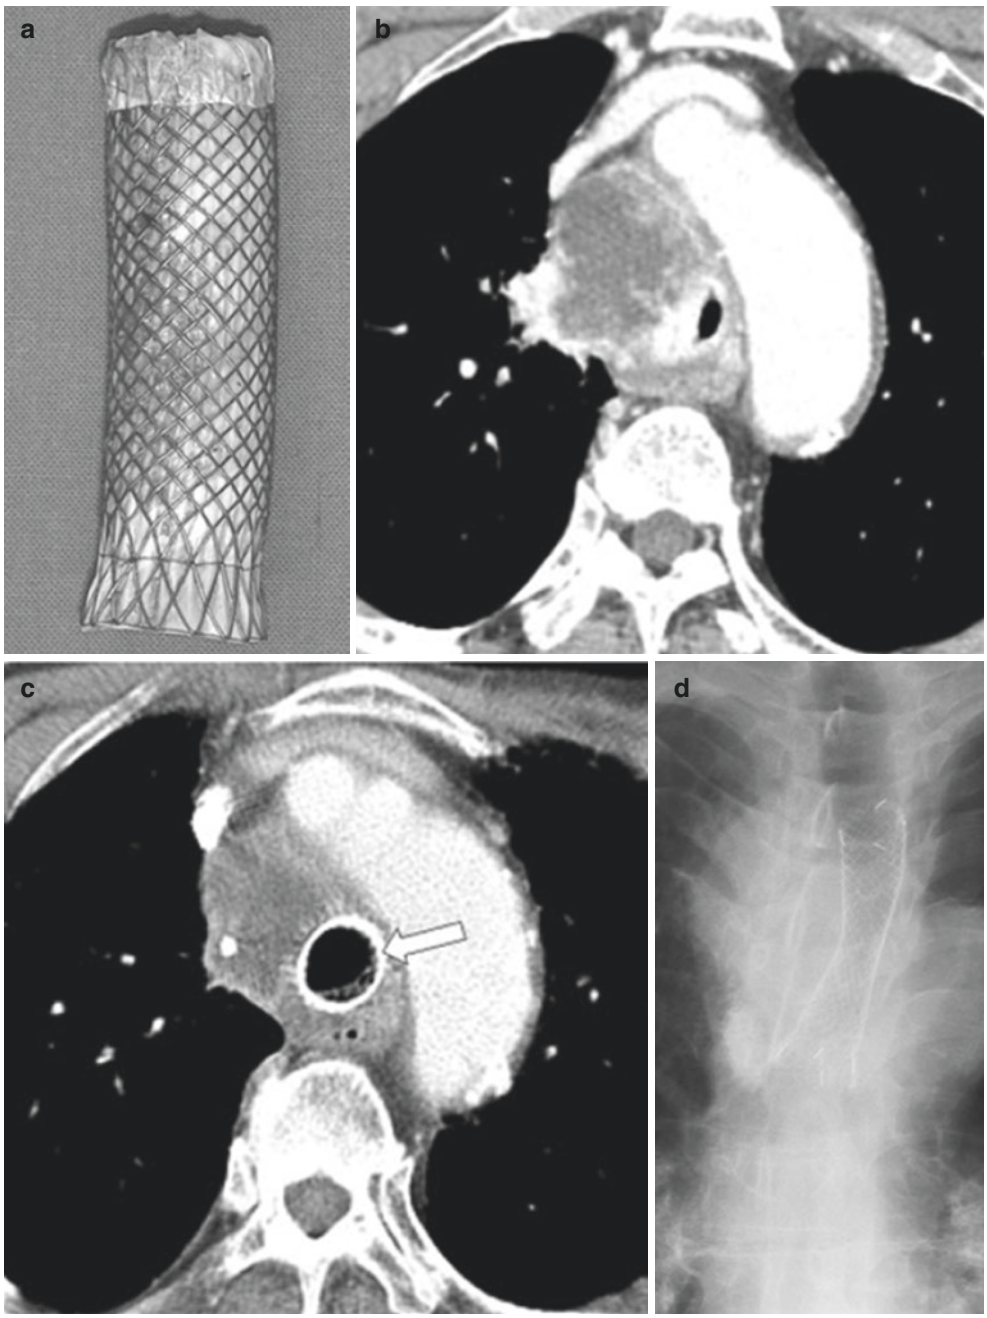

Fig. 3.23 Shows a tracheal stent in a patient with mediastinal mass. (**a**) Metallic expandable stent, (**b**) CT scan showing a mediastinal mass compressing the trachea, (**c**) airway stent in place seen by CT scan, (**d**) a chest X-ray showing the stent in place. (With permission Ref. [37])

just in axial sections. Direct sagittal and coronal images enable the radiologist to evaluate involvement of lung parenchyma [41], mediastinal structure, and the chest wall with greater clarity than with a CT scan. In addition, MRI is an adjunct to CT scan evaluation reserved for patients in whom CT scans did not resolve the anatomic issues or for whom additional information about the mediastinal and its relationship to other vital organs are required including invasion to heart or great vessels [30, 42, 43]. Figure 3.25 shows MRI of the chest in a patient with a mediastinal mass.

Summary

Radiological studies play an important role in the diagnosis and treatment of the thoracic surgical patient in the preoperative, intraoperative, and postoperative period. Chest radiographs allow us to identify distorted tracheobronchial anatomy, presence of lung masses, lung collapse, chest tube placement, endotracheal tube placement, and lung expansion or shifting of mediastinum in cases of tension pneumothorax. CT scans of the chest permit an identification and precise location of lung masses and mediastinal masses or the presence of fluid and compromise to adjacent structures; in addition it allows to identify the precise location of airway stents [44].

Multidetector computed tomography scan and 3D reconstruction allow identification of tracheobronchial anatomy in a more precise form. All radiological studies must be reviewed in the preoperative evaluation of thoracic surgical patients. In cases where the diagnosis or anatomy is unclear, these studies must be reviewed in conjunction with a thoracic surgeon or a radiologist.

Part III

Thoracic Anatomy, Physiology, and Pharmacology

Essential Anatomy and Physiology of the Respiratory System and the Pulmonary Circulation

4

J. Michael Jaeger, Brian J. Titus, and Randal S. Blank

Key Points

- Knowledge of the clinical anatomy and function of the respiratory system is essential for the safe, efficient, and appropriate perioperative management of intubation, mechanical ventilation, and anesthesia for the thoracic surgical patient.
- The lung has ten (third-generation airway) bronchopulmonary segments on the right and eight segments on the left that are readily identifiable by fiberoptic bronchoscopy (two segmental bronchi on the left are considered "fused").
- The anesthetic employed, both general and regional, will impact the control of respiration, reactivity of the airways, and the patient's ability to maintain their airway, take a deep breath, and cough.
- Dynamic influences of ventilatory pattern, posture, body habitus, agitation or pain, and inflammation can cause "air trapping" and drastically reduce alveolar ventilation.
- The compliance and resistance of the respiratory system will change during the course of surgery, especially those procedures requiring one-lung ventilation, and may necessitate frequent adjustments of the ventilator to optimize gas exchange and reduce lung injury.
- Many drugs employed during cardiothoracic surgery will impact the lung's intrinsic mechanisms to match ventilation to perfusion matching either directly on hypoxic pulmonary vasoconstriction (HPV) or indirectly by altering cardiac output or vascular resistance.

Introduction

Appropriate perioperative management of the thoracic surgical patient requires an appreciation of the uniqueness and complexity of the anatomy and function of the respiratory system. It is particularly suited to perform a wealth of tasks including gas exchange between the lungs and blood, speech, protection from airborne environmental insults and pathogens, and a host of metabolic functions (repair, growth). While some of these functions have little importance to the anesthesiologist during the course of a surgical procedure, optimizing gas exchange, controlling pulmonary arterial pressure, and maintaining blood flow require constant attention. Furthermore, the dynamic interaction between the cardiovascular system and the respiratory system can be altered by changes in position, medications and anesthetics, mechanical ventilation, surgical interventions, disease processes, etc. The impact of these alterations cannot be underestimated. The entire cardiac output passes from the right side of the heart to the left side with each heartbeat; therefore what affects the pulmonary circulation ultimately impacts the systemic circulation. While an in-depth discussion of the physiology and anatomy of the entire respiratory system is beyond the scope of this chapter, the essentials will be discussed with the goal of providing insights into the clinical relevance and application of this knowledge by the thoracic anesthesiologist.

defined as the functional upper airway. This airway complex serves a host of functions: warming and humidifying the passage of air, filtering particulate matter, and preventing aspiration during deglutition.

In normal quiet breathing, air enters the nose, a complex chamber separated medially its entire length by a cartilaginous and bony septum (vomer). It is bounded laterally by the inferior, middle, and superior turbinates overlying the sinus ostia and inferiorly by the hard and soft palates before emptying into the nasopharynx. The mucosa covering these structures is highly vascular and innervated which must be appreciated when performing nasopharyngeal intubation with endotracheal tubes and passage of nasogastric sumps, feeding tubes, or fiberoptic bronchoscopes. Furthermore the nasal passages represent a significant resistance to airflow, normally double that found in mouth-breathing. Airflow resistance increases dramatically when nasal polyps are present, the mucosa is inflamed and edematous, or when high air flows must be achieved as in heavy exercise.

The adult pharynx is 12–15 cm long and is divided into the nasopharynx (from the soft palate to the tip of the uvula), the oropharynx (from the anterior pillars of the tonsillar fossa to the epiglottis) that includes the pharyngeal portion of the genioglossus muscle, and finally the laryngopharynx lying posterior to the larynx. Supination, sleep, and general anesthesia may promote obstruction of the oropharynx by the tongue, hard palate, and pharyngeal musculature as their tone decreases [1, 2]. Hyperextension or hyperflexion of the cervical spine generally increases upper airway resistance [3]. During inspiration, a non-sedated, spontaneously breathing patient dilates the oropharyngeal pharynx by contracting the genioglossus muscle and elevating the tongue off the pharyngeal wall in a coordinated reflex possibly involving thoracic muscle activity [2, 3].

Larynx

The larynx is a complex structure overlying the fourth to the sixth cervical vertebra and consists of several muscles, their ligaments and cartilaginous anchors, and significant innervation (Fig. 4.1). The inlet of the larynx is defined by the epiglottis, aryepiglottic folds, and the arytenoids. The larynx itself bulges into the pharynx posteriorly creating a deep pharyngeal recess anterolaterally on either side, the pyriform fossa. The bilateral pyriform fossae or recesses are clinically relevant because of their tendency to trap food or foreign objects (and tubes or probes) in the pharynx and as potential sites for the application of topical anesthesia to block the internal branch of the superior laryngeal nerve. The larynx serves as the organ of phonation, plays an important role in coughing, and in protection of the airway during deglutition [4].

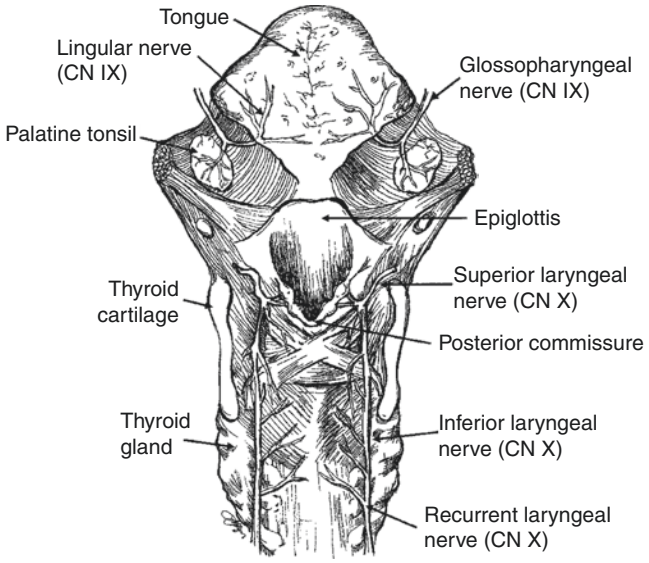

Fig. 4.1 Diagram of the larynx from the base of the tongue to below the thyroid cartilage as viewed from its posterior aspect. Note the relationship of the superior laryngeal, inferior laryngeal, and recurrent laryngeal nerves and the posterior aspect of the larynx, thyroid, and trachea. Tracheal and thyroid surgery places these nerves at risk

The primary structure of the larynx is the thyroid cartilage that forms the point of articulation of the paired arytenoid cartilages with the vocal ligaments and their controlling musculature. However other essential structures include the hyoid bone and its attachments, the epiglottis, the cricoid cartilage, and the corniculate cartilages. The hyoid bone is a U-shaped bone that is attached to the mandible and tongue by the hyoglossus, the mylohyoid, geniohyoid, and digastric muscles, to the stylohyoid ligament and muscle, and to the pharynx by the middle pharyngeal constrictor muscle. Beneath the hyoid bone is slung the remainder of the larynx by its attachment, the thyrohyoid membrane and muscle. While its function other than as a flexible anchor is unclear, it is possible to bisect its mandibular attachments ("suprahyoid release") and mobilize the larynx in order to facilitate its caudal displacement in tracheal resection procedures. The epiglottis is the midline "leaf-shaped" elastic cartilage found inferior to the base of the tongue. It is anchored anteriorly to the hyoid bone and inferiorly to the inside of the anterior portion of the thyroid cartilage immediately above the vocal cords. Bilateral folds of the epiglottis curve posteriorly to form a mucosal ridge attaching to the arytenoid cartilages sitting on top of the posterior lamina of the cricoid, the aryepiglottic folds. The epiglottis, aryepiglottic folds, and the corniculate tubercles form the readily recognizable inlet into the glottis below. The large thyroid cartilage defines the larynx with its paired lamina fused anteriorly at the laryngeal prominence and extending posteriorly to terminate in superior and inferior horns or cornu. The thyroid cartilage serves

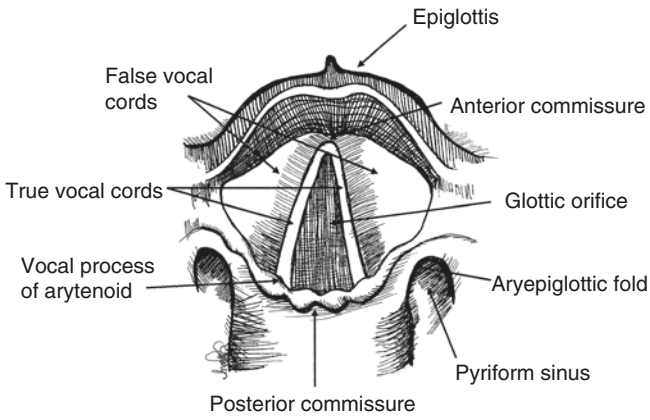

Fig. 4.2 Diagram of the glottis as seen from above using a laryngoscope or fiberoptic bronchoscope. Note the triangular shaped glottic introitus with its narrowest aspect at the anterior commissure. Passage of bronchoscopes, endotracheal tubes, and especially double-lumen tubes should be directed posteriorly where the vocal cords will spread the widest. Note that the vocal process of the arytenoid cartilage pivots on a small point and can be traumatized and displaced with rough handling

as a stable point of attachment for numerous small muscles and ligaments that manipulate the small arytenoids, corniculates, and vocal cords. The thyroid cartilage also attaches to the cricoid ring in ways that afford it some degree of mobility. One key ligament deserves special attention, the vocal ligament or true vocal cord. The paired vocal cords attach posteriorly to the vocal process of each arytenoid and stretch anteriorly to meet at the junction of the thyroepiglottic ligament of the anterior thyroid cartilage. The triangular opening formed by the vocal ligaments is the glottis with its apex anterior (Fig. 4.2). The mean length of the relaxed open glottis is approximately 23 mm in males and 17 mm in females. The glottis at its widest (posterior) point is 6–9 mm but can be "stretched" to 12 mm [5]. It should be noted that the vocal cords are covered by only a thin, adherent mucosa, producing the pearly white appearance. The absence of any submucosa implies that the vocal cords are unlikely to "swell" significantly as there is minimal space to accumulate edema fluid. The folds of mucosa and fibrous tissue lying parallel to the true vocal cords and just superior within the glottis, known as the vestibular folds or "false vocal cords," can become edematous. The intrinsic laryngeal musculature function to open the glottis in inspiration, close the glottis and constrict the superior structures in deglutition, and finely control abduction, adduction, and tension of the true vocal cords in phonation.

Pharyngeal Innervation

Innervation of the pharynx is distributed among several sensory and motor branches of the glossopharyngeal and vagus (external and internal branches of the superior laryngeal nerves, recurrent laryngeal nerves). The nasopharynx sensory innervation is derived from the maxillary division of the trigeminal nerve, while the oropharynx is diffusely innervated by sensory branches from the glossopharyngeal nerve. The internal branch of the superior laryngeal nerve pierces the lateral aspect of the thyrohyoid membrane along with the superior laryngeal artery and vein to provide sensation for the base of the tongue, vallecula, epiglottis, aryepiglottic folds, pyriform recesses, and the superior aspect of the true vocal cords. The external branch of the superior laryngeal nerve provides motor to the cricothyroid muscle, a tensor of the true vocal cords. The recurrent laryngeal nerves supply sensation to the vocal cords and tracheobronchial tree as well as motor to the remaining intrinsic musculature of the larynx. The right recurrent laryngeal nerve originates at the level of the right subclavian artery but the left originates at the level of the aortic arch and loops around the ligamentum arteriosum before both ascend cephalad along the tracheoesophageal groove. This relationship must be appreciated during esophageal surgery and during both cervical and anterior mediastinoscopy, as these structures can be at risk. The larynx receives its blood supply from the superior and inferior laryngeal arterial branches of the superior and inferior thyroid arteries, respectively [6]. These arteries follow the course of the superior and recurrent laryngeal nerves.

Upper Airway Function

Homeostatic Mechanisms

The most obvious function of the upper airways is to provide a durable protective conduit for the initial inhalation and then exhalation of gases to and from the lung while simultaneously performing multiple other functions, e.g., eating, drinking, speaking, etc. With respect to inhalation, the nasopharynx and posterior pharynx warm the inspired gas close to body temperature and humidify it to a water vapor pressure of 47 mmHg at 37 °C. This aids in maintaining core temperature and protects the more delicate epithelia lining the lower airways from desiccation. Glandular cells within the airway epithelium secrete mucus which coats the airway surface and maintains tissue hydration and also serves to trap particulate matter, bacteria, and viruses. Mucus also contains a number of enzymes with antioxidant, antiprotease, and antibacterial properties [7].

Another important role of the airways and its mucus coat is the filtering of inhaled particulate matter by an elaborate defense system that takes advantage of the airflow characteristics of the upper and lower airways and their associated epithelium. There are three mechanisms at

work to produce mechanical filtering. The first, inertial impaction, is capable of trapping particulates larger than 10 μm by virtue of the turbulent flow, mucus lining the passageways, and complex structure. It accomplishes this task in minutes with mucus and saliva eventually swallowed. The bifurcating and branching tracheobronchial tree slows the gas flow until it becomes more laminar. Particulates impact the airway wall according to particle size (sedimentation). Normally the particles, bacteria, etc. trapped in the mucus at this level are transported cephalad by the constant motion of the cilia, an apical feature of the respiratory epithelium, at a rate of approximately 2.5 mm/min in the bronchi but over 5 mm/min in the trachea [8]. Lower airway mucus is usually cleared in about 24 hours although this can be drastically retarded in disease states such as cystic fibrosis or chronic bronchitis or conditions altering ciliary function or growth, e.g., smoking [9]. The filtering processes appear effective down to particles approximately 0.01 μm in diameter.

The Cough Reflex

An essential protective function of the respiratory system for expelling secretions and foreign bodies from the respiratory tract is the cough. The cough is a complex maneuver that is either voluntary or triggered by stimulation of airway irritant mechanoreceptors diffusely distributed throughout the larynx, trachea, and bronchi, especially the carina. Irritant chemoreceptors are distributed more diffusely in the distal central airways and at airway junctions, where noxious vapor particles are more likely to rain out on the epithelium. The vagus nerve serves as the primary afferent limb of the cough reflex, but the efferent limb encompasses the motor input to the phrenic, intercostal, other spinal motor neurons to the accessory respiratory muscles and the vagus nerve branches to the larynx and pharynx.

There are several acts involved in generating an explosive flow of air and material out of the airways. The first is an exaggerated inspiration through a widely abducted glottis to achieve a high lung volume, which may be as high as 50% of vital capacity. By enlarging the intrathoracic volume, this produces a lengthening in the expiratory muscles and improves their length-tension relationship allowing greater force generation. The second compressive phase begins with rapid adduction of the glottis simultaneous with the onset of expiratory muscle contraction. Glottic closure is accentuated by the tight adduction of the supraglottic ventricular folds. This phase lasts only hundredths of a second but is sufficient to produce a coordinated compression of the alveolar gas and increase in the intrathoracic pressure, briefly as high as 300 cm H_2O [4]. Abrupt initiation of the final expiration phase occurs with glottic release of this pressure producing nearly a subatmospheric drop in central airway pressures accentuating the pressure gradient from the continually rising alveolar and pleural pressures as a consequence of expiratory muscle contraction. An additional effect is dynamic compression of the airways which increases airflow velocity in relation to the volume of air expired per second. The total effect is a shearing force across the surface of the mucus-covered airway epithelia and mucus expulsion.

Clinical Issues

Airway Obstruction

Patients with tracheal or laryngeal mass lesions and those with vocal cord dysfunction can have significant flow resistance during inspiration and/or expiration depending on the intrathoracic vice extrathoracic location of lesions. High airflow rates through the site of the restrictive lesion can accentuate the increase in airway resistance. Less obvious is the effort-dependent dynamic compression that can occur in those portions of the airway that lie on either side of the lesion during the period of high flow [10]. Attempts to generate high flows create the greatest Bernoulli effect (acceleration-induced negative pressure) on the surrounding structures and can result in airway narrowing. This has clinical importance in managing patients pre- and post-procedure for laryngeal or tracheobronchial resections. Slow, easy breathing is more efficacious than rapid, forced breaths; therefore judicious use of a sedative in addition to good postoperative pain management may improve gas exchange. This scenario is in contrast to that of patients with primary muscle weakness of the upper airway musculature either from residual neuromuscular blockade, general anesthesia, myasthenia, or extrapyramidal disorders [11]. These conditions require mechanical support until strength can be recovered or optimized.

Nebulized Medications

The features of the upper airway also impact the design and utility of multidose inhalers and medication nebulizers. Typically less than 30% of aerosolized drug delivered with the standard nebulizer or inhaler reaches the small airways [12]. Most drug particles in current inhalers range in size from 1.5 to 4.0 μm [13, 14]. Consequently, these particles frequently fail to reach the distal small airways sufficiently such that even with new particle manufacturing technologies, only about 50% of the drug penetrates to the intended target [13, 14]. Even aerosolizing chambers attached to endotracheal tubes or ventilator circuits provide only a marginal improvement in efficiency at delivering drug to the distal airways.

Tracheobronchial and Respiratory Anatomy

Tracheal and Bronchial Structure

The trachea originates at the cricoid cartilage (opposite vertebra C6) and extends approximately 12 cm (females) to 14 cm (males) to terminate in a bifurcation (carina) at the T4/5 vertebral level (second intercostal space, the angle of Louis). It is about 22 ± 1.5 mm (males) to 19 ± 1.5 mm (females) in diameter and consists of 16–20 U-shaped cartilaginous "rings" that are closed posteriorly by fibrous tissue and a longitudinal smooth muscle band or trachealis muscle.

The right main bronchus is wider (14–17.5 mm), shorter (1.4–1.8 cm), and more vertical than the left. The right main bronchus gives off the upper lobar bronchus then continues on as the bronchus intermedius giving off the right middle lobar bronchus and right lower lobar bronchus at the hilum of the lung at T5. The azygos vein arches over it from behind to reach the superior vena cava. The right pulmonary artery lies first inferiorly and then anterior to the bronchus intermedius. The left main bronchus ranges an average of 4.4–4.9 cm in length and 13–16.5 mm in diameter. It passes inferiorly and laterally below the aortic arch, anterior to the esophagus and descending thoracic aorta to reach the hilum of the lung opposite T6. At this point, it first lies behind and then slightly below the left pulmonary artery in its course. These dimensions can be quite variable among individuals, and chest pathology can drastically change the anticipated relationships. We recommend always consulting available computed tomograms of the chest prior to any thoracic procedure to provide the anesthesiologist with more appropriate dimensions and structural relationships in their patient.

The lobar bronchi (right upper, right middle, right lower and the left upper, left lower) diverge into their segmental bronchi that can be readily visualized during flexible bronchoscopy (Table 4.1). The right upper lobar bronchus gives off three segmental bronchi (apical, anterior, posterior), the right middle lobar bronchus splits into two segmental bronchi (lateral, medial), and the right lower lobar bronchus diverges into the superior segment with the basal segmental bronchus immediately diverging into four additional segments (medial basal, anterior basal, lateral basal, posterior basal) for a total of ten segmental branches on the right. The left upper lobar bronchus splits into the superior division with "three" segments (a "fused" apical-posterior, anterior) and the inferior division or lingual with two segments (superior lingular, inferior lingular). The left lower lobar bronchus branches into four lower segmental branches (superior, another "fused" anteromedial basal, lateral basal, posterior basal) for a total of "ten" segments on the left. Note that segmental nomenclature can vary in the literature [15].

Table 4.1 Bronchopulmonary segments

	Right lung			Left lung
		Upper lobe		
Apical	1		*Superior division*	
Anterior	2		Apical + posterior	1 + 3
Posterior	3		Anterior	2
			Inferior division – lingula	
			Superior lingular	4
			Inferior lingular	5
		Middle lobe		
Lateral	4			
Medial	5			
		Lower lobe		
Superior	6		Superior	6
Medial basal	7		Anteromedial basal	7 + 8
Anterior basal	8		Lateral basal	9
Lateral basal	9		Posterior basal	10
Posterior basal	10			

Tracheobronchial Circulation and Lymphatic System

The trachea and bronchi derive their blood supply from branches of several sources, and the variation can be substantial. The common pattern is as follows. The cervical trachea derives its blood supply from branches of the inferior thyroid artery. The carina and distal trachea receive their blood supply from the bronchial arteries (superior, middle, and inferior) coming off of the internal thoracic artery, branches from the innominate artery, and the descending aorta [6]. The segmental branches off the three bronchial arteries then form a longitudinal network over the length of the tracheal lateral wall. These arteries subsequently branch into an anterior and posterior intercartilagenous arteries. The anterior vessels enter the tracheal wall bilaterally, join within the wall at the midline, and then form a diverse submucosal vascular net that supplies their respective segment of trachea. The posterior intercartilagenous branches join with branches from esophageal segmental arteries to provide the blood supply to the membranous portion of the trachea.

There is great variation in the bronchial blood supply as well. In general though, the left mainstem bronchus is perfused by the inferior bronchial artery derived from two left-sided aortic sources. The right mainstem bronchus is most often supplied by a single branch from a right-sided aortic source [6]. The bronchial arteries frequently originate from the descending aorta between the level of the 5th and 6th thoracic vertebral level, but contributions can come from

branches off of the arch or subclavian arteries [16]. The bronchial arteries originate from the anterolateral aspect of the descending aorta in a somewhat "tight" group of usually four ostia approximately 18 mm apart. This becomes relevant in lung transplantation as this "aortic patch of bronchial arteries" could be harvested *in toto* for bronchial revascularization.

Lymphatic drainage of the lung parenchyma occurs through a network of lymph capillaries located in the connective tissue surrounding the airways and their accompanying vascular structures. The lymphatic vessels are located between the alveolar walls and the assorted interlobular, peribronchial, and perivascular structures. However, they do not reside in any of the alveolar septae specialized for gas exchange nor are they within the interalveolar septum [16]. Lymphatic capillaries also course over the surface of the lung where they become confluent and join at the hilum with the peribronchial vessels. Smooth muscle and unidirectional valves within the lymphatic vessel walls ensure antegrade flow of the fluid. Of course lymph nodes are abundant within the lung and mediastinum belying their proximity to the airways exposed to the environment. Ultimately the lymphatic system drains into the venous system either via the internal jugulosubclavian venous confluence or via the thoracic duct after joining [17].

Respiratory Airways and Alveolar Histology

The airways continue to diverge into smaller and smaller diameter conduits until one arrives at the bronchioles with diameters less than 0.8 mm. At this level the airways lose all remnants of cartilage and begin the transformation from purely conducting airways to those described as respiratory bronchioles. Respiratory bronchioles eventually diverge into the final four generations of alveolar ducts that consist primarily of openings into the terminal alveolar sacs. In the descriptive model of E.R. Weibel, the trachea branches into 23 generations of pulmonary airways. The first 15 generations serve as conducting airways, and the subsequent 8 generations become sufficiently thin-walled to allow some degree of gas exchange and bear the moniker, acinar airways. One clinical aspect of this geometric progression of increasingly narrower airways (and blood vessels) by divergence and multiplication is that the overall cross-sectional area and therefore resistance to gas flow (or blood flow) becomes markedly less compared to the resistance of the individual airway (or blood vessel). This has an important impact on distribution of gas and blood flow, flow velocity, and, hence, transit time through key areas of gas exchange.

The trachea interior is lined with ciliated columnar epithelium, Goblet cells responsible for mucus production, and with interspersed specialized chemical and tactile afferent nerve receptors. This transitions from pseudostratified columnar epithelia in the larger bronchi to a thinner cuboidal ciliated variety in the small bronchi. The airway epithelium and submucosa also contain lymphocytes, mast cells, and a variety of neuroendocrine cell types. The next layer consists of circumferential bands of smooth muscle cells and a connective tissue layer containing submucosal glands and plates of cartilage (replacing the solid cartilage rings in the very large airways). The outermost layer is a loose adventitial shell with lymphatic vessels, sympathetic and parasympathetic nerves, and nourishing blood vessels.

The respiratory bronchioles empty into a pulmonary acinus, which has the appearance of a cluster of grapes on a network of stems. Each pulmonary acinus may contain multiple alveolar ducts communicating with 2000 alveoli arranged in a ring-like, honeycomb network. The alveolus is considered the primary site of gas exchange between the blood and gas in the lung. The alveolar septa are about 5–8 μm thick and are opposed by an alveolar surface on either side with the alveolar capillary bed sandwiched inside. The walls of the alveoli are extremely thin, between 0.1 and 0.2 μm, a feature that promotes rapid equilibration of gas by diffusion with the pulmonary capillary blood. In addition, gas can exchange between alveoli through pores of Kohn. There are approximately 300 million alveoli in the human lung that provide an extraordinary surface area for gas exchange (70 m^2).

There are three major cell types found in the alveolus: Alveolar Type I, Alveolar Type II, and alveolar macrophages. However, there are others found under certain conditions in the lung, e.g., inflammation. Alveolar Type I cells are a squamous epithelium class that cover an estimated 95–97% of the total alveolar surface [18]. These nucleated cells have few cytoplasmic organelles and a sparse cytoplasm splayed out in sheets over the alveolar surface forming a thin barrier between the air space and the pulmonary capillary endothelium. While their role in gas exchange is obvious, new information suggests a more diversified role than previously thought. New protein analysis of the Type I cells suggests that they may play an important role in regulation of cell proliferation, ion transport and water flow, peptide metabolism, and signaling events in the peripheral lung [19]. Alveolar Type II cells are fewer in number, somewhat spherical, and coated on their apical surface with microvilli. In contrast to Type I cells, Alveolar Type II cells possess many organelles including multilayered granular structures called lamellar bodies. These lamellar bodies are considered the source of pulmonary surfactant, a lipoprotein coating the interior surface of the alveolus, and capable of significantly reducing the surface tension of the alveolus air-surface interface. Surface tension reduction is considered an important physical mechanism to reduce any tendency for alveolar collapse at very low lung volumes.

The immune defenses of the lung are extremely important because of its relative exposure to the environment via the airways. There are a number of excellent reviews of the immune function of the lung, but it is important to realize that there are many questions unanswered about how the lung responds to invasion and inflammation [20]. From a clinical standpoint, the pulmonary inflammatory response will greatly influence the perioperative management of the thoracic surgical patient. A few major defensive cell types residing in the alveolar air spaces and interstitium are worth mentioning. Alveolar macrophages are derived from bone marrow monoblast precursor cells and migrate to the lung parenchyma [21]. Alveolar macrophages are free to move over the surface of the alveolus and phagocytize foreign material that enters the alveolus including bacteria and particulates. Macrophages are cleared either through the lymphatics or are carried up and expelled via the airways. Lymphocytes, largely T-lymphocytes, are widely distributed in the normal lung within paratracheal and hilar lymph nodes, in the interstitium of the bronchial tree as nodules or individual cells, in the alveolar walls, and on the surface of the alveolus [22]. They play a critical role in the lung's primary immune response to inhaled antigens. Under some pathologic conditions in the lung, it is becoming apparent that an exaggerated inflammatory response and the activity of these cells and others may be harmful to the lung; the acute respiratory distress syndrome (ARDS) and emphysema are examples. Recent investigations have revealed another key cell in the lung's immune response to foreign material. Dendritic cells are potent antigen-presenting cells in the respiratory tract and elsewhere that possess dendrites that project to the airway luminal surface between the epithelial cells [23]. Dendritic cells are capable of sampling luminal contents, binding to foreign peptides, and then migrating to regional lymph nodes where they present these peptides to antigen-specific T-cells. In addition, they are sensitive to environmental signals from microbes, allergens, pollutants, or the products of tissue damage [23].

Innervation

The hilum of each lung serves as the entry point of the bronchi, pulmonary vessels, bronchial vessels, lymph vessels, and nerves. The lungs receive their innervation from the autonomic nervous system with branches from the vagus nerves and upper thoracic sympathetic ganglia (primarily second, third, and fourth). The vagal and thoracic sympathetic ganglia form anterior and posterior pulmonary plexuses at the hilum. From there, two main neural networks develop; one accompanies the bronchi, the peribronchial plexus, and the other associates with the pulmonary vasculature, the periarterial plexus. Virtually all afferent nerve fibers entering the CNS from the airways travel through the vagus nerve [24].

Neural Control of Respiration

Respiratory Centers

It is generally accepted that the medulla contains the respiratory centers within the brain that are responsible for coordinating numerous voluntary and involuntary inputs that generate the appropriate respiratory pattern to fulfill the body's requirements. The classical view described a dorsal respiratory group of neurons receiving modulatory input and controlling the timing of inspiration. A ventral respiratory group of dispersed nuclei was responsible for both inspiratory and expiratory respiration [25].

New evidence has led to the concept of a three-phase respiratory pattern in normal or "eupneic" breathing controlled by a complex architectural network of nuclei from the pons to the medulla that is highly conserved phylogenetically in mammals [26]. The three phases are inspiration, post-inspiration (post-I), and active expiration (E-2) [26, 27]. Inspiration begins with a synchronized neuronal discharge that increases to a maximal intensity then abruptly terminates. Subsequently, a secondary declining neuronal burst termed "post-inspiratory (post-I) afterdischarge" represents the active phase of the "passive" exhalation (E-2) from the lungs that is controlled by the upper airway adductor muscles [25–28].

The critical nucleus for inspiratory rhythm generation is widely accepted as centered in the pre-Bötzinger complex (pre-BötC) located in the ventral medulla respiratory column (Fig. 4.3). The pre-BötC neurons in turn project to numerous other neuron groups, e.g., rostral to the adjacent Bötzinger complex (BötC), which modifies and refines the post-inspiratory and expiratory phases [28]. BötC and pre-BötC are influenced by convergent inputs including the retrotrapezoid nucleus/parafacial respiratory group (RTN/pFRG) that are thought to provide a rhythmic expiratory drive. It is this region with its chemosensitive neurons in conjunction with input from the dorsal group of respiratory neurons in the nuclei of the solitary tract (NTS) that is poised to modify respiratory drive to match metabolic needs [29]. The NTS receives tonic activation from peripheral arterial chemoreceptors and from rhythmically activated lung stretch receptor afferent inputs. The NTS responds by influencing inspiratory termination after lung inflation [28]. Of note, there is debate whether lung stretch receptor reflexes actually play a significant role in humans as they clearly do in lower mammals [25]. One final important respiratory control center resides in the rostral pons. Here the Köllicker-Fuse (KF) and parabrachial nuclei are essentially relay nuclei for a large array of inputs from reflex afferents and higher CNS input controlling breathing. In particular, the KF area may regulate the inspiratory-expiratory phase transition and the dynamic control of upper air-

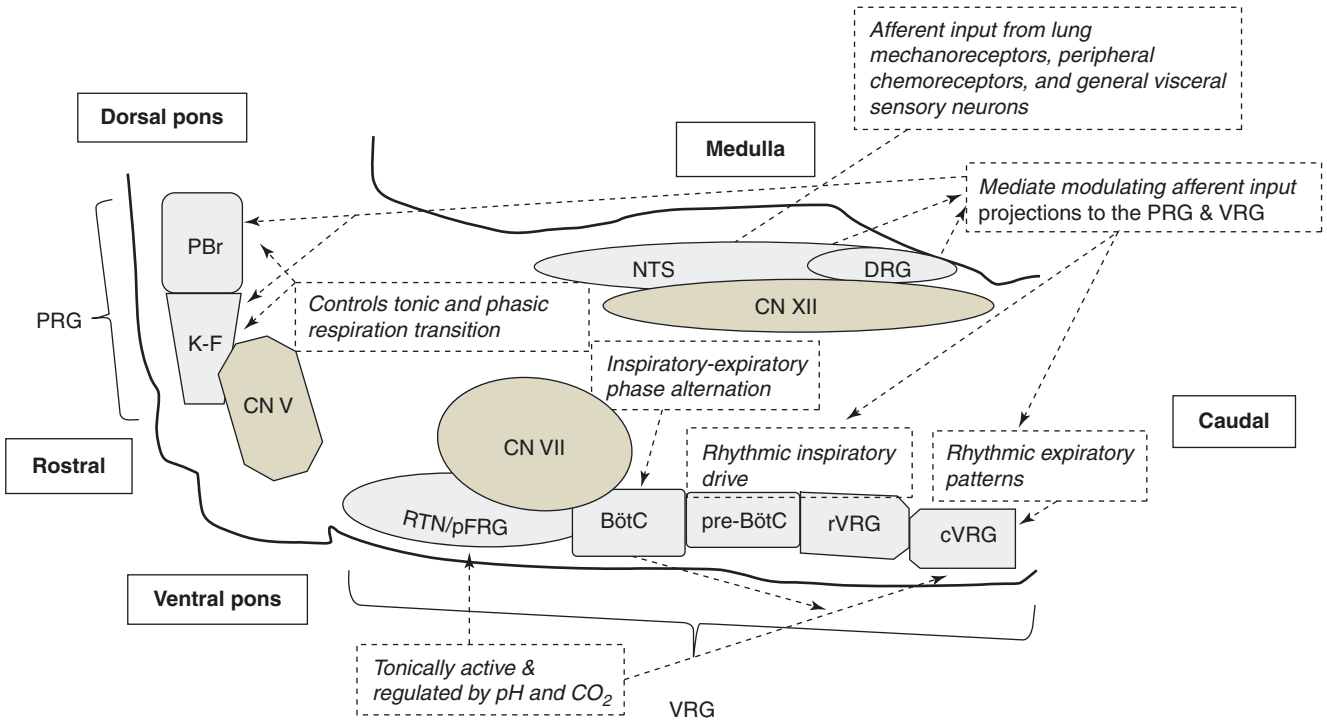

Fig. 4.3 Diagram of brainstem respiratory centers demonstrating the locations and relationships between key control centers, both ventral and dorsal respiratory groups. Rostral pons includes the pontine respiratory group (PRG) containing the Kölliker-Fuse (K-F) and parabrachial nuclei (PBr) important in phase transition from inspiration to expiration. These centers receive modulating input from the caudal nucleus tractus solitaries (NTS) and dorsal respiratory group (DRG). Located caudally in ventral respiratory group (VRG) are the tonically active retrotrapezoid nucleus (RTN)/parafacial respiratory group (pRFG) which generate rhythmic patterns and receive input from the central chemoreceptors. More caudal still lie the pre-Bötzinger complex (normal rhythmic inspiratory phase) and the Bötzinger complex (control inspiratory-expiratory phase transitions). Both of these areas receive modulating input from other sites and integrate the signals to produce the desired breathing pattern. The NTS and associated afferent nuclei of the DRG are sites of chemoreception and integration of afferent input from peripheral sensory neurons. This sensory integration modifies depth and rate of respiration and the states of arousal and airway patency to maintain homeostasis. (From data in Refs. [26–29])

way during the respiratory cycle and receives input from visceral sensory afferents via the vagus and glossopharyngeal nerves [25, 27, 28, 30].

Chemoreception and Respiratory Control

A fundamental concept in the regulation of breathing rate and depth is maintenance of an appropriate arterial PCO_2 and PO_2 as important components of acid-base regulation in a bicarbonate-based buffer system and of oxygen delivery, respectively [31]. The system must be able to adapt to a wide variety of conditions: awake at rest, during exercise, asleep, pregnancy, high-altitude exposure, or during illness, for example. Ventilation is far more sensitive to alterations in arterial PCO_2 within a fairly restricted range when compared to arterial PO_2. Determining the transduction mechanisms and location of the chemoreceptors as well as their relative contribution to control rate and depth of breathing has been difficult [32]. The experimental process may confound the results especially those studies performed on anesthetized subjects since many anesthetics have the ability to blunt respiratory drive via effects on reflex pathways and directly on chemoreception as a consequence of inducing acidosis in plasma and cerebrospinal fluid [33]. Nonetheless it is clear that there are central chemoreceptor areas and specific peripheral chemoreceptor structures that are capable of measuring arterial CO_2, hydrogen ions, and arterial O_2 and then generate a graded signal response transmitted to the central respiratory centers. There is also good evidence for the modulation of the inputs from these chemoreceptor sites by their interaction. Subsequent elegant studies performed in awake animals in the 1960s established the view that the respiratory centers were primarily sensitive to CO_2 and hydrogen ion concentration measured by central chemoreceptors located in the ventrolateral medulla [34, 35]. They found that a decrease of 0.05 pH unit can double alveolar ventilation, and inhalation of 5.6% CO_2 increases alveolar ventilation by 300% [34]. Further refinement of these studies and the addition of multiple new, sophisticated techniques revealed a

more complicated picture involving multiple central and peripheral sites integrated to coordinate the response to acidemia, alkalemia, hypercarbia, and hypoxemia. It is estimated that approximately two-thirds of the ventilator response to CO_2 or hydrogen ions is contributed by the central chemoreceptors, while the remaining third is contributed by peripheral chemoreceptors, mainly the carotid body [33].

The molecular mechanism involved in the transduction of CO_2 or hydrogen ions into a graded signal relayed to the respiratory control centers remains a matter of debate [36]. The molecular details are beyond the scope of this chapter (for excellent review, see reference [37]). However, it has become clearer that it involves several different potassium ion channels (leading candidates are in the Kir and K_{2P} subfamilies) that either respond directly to pH changes or indirectly as effectors responding to an unidentified, possible G-protein coupled, proton-sensitive membrane receptor [37, 39]. It is well established that inhibition of one or more of these potassium channels results in depolarization of afferent neurons in the retrotrapezoid nucleus (RTN), locus coeruleus (LC), nucleus tractus solitarius (NTS), and medullary raphe, all in superficial locations readily exposed to CSF and the generously vascular areas within the ventrolateral and caudodorsal medulla [36–39].

The ventilator response to hypoxia is primarily initiated by the carotid bodies with O_2 sensors in the aortic bodies secondary. The carotid bodies are located bilaterally in the carotid bifurcations close to the carotid sinus. For their small size, they are complex organs that are richly innervated and possess a dense network of capillaries. The latter enable a relatively high degree of blood flow delivery with small diffusion distances between cells. The carotid bodies sensitivity to arterial PO_2 is a primary response, but they also have been shown to respond to pressure, hypercapnia, acidosis, hyperkalemia, hypoosmolality, certain hormones, hyperthermia, and hypoglycemia [40]. Two unique types of cells are present. Type I glomus cells similar to sensory neurons and a Type II glial-like "supportive" cells. The role of the latter remains unclear and will not be discussed further.

Carotid body Type I cells appear to contain the O_2-sensing apparatus that, when appropriately stimulated, release excitatory neurotransmitters, perhaps ATP, dopamine, or acetylcholine (ACh), which act on adjacent afferent nerve endings of the carotid sinus nerve. The carotid sinus (and carotid body) nerve is a component of the glossopharyngeal nerve and transmits a corresponding intensity of nerve impulses to the NTS [41]. Sensory discharge under normal conditions (arterial PO_2 of approximately 100 mmHg) elicits a low rate of neuronal discharge but increases exponentially beginning with only modest degree of hypoxemia (arterial PO_2 of approximately 60 mmHg). It appears to plateau at an arterial PO_2 of about 30–40 mmHg, but the gain can be modulated depending on local pH [42, 43]. As with the central chemoreceptor cells, the actual mechanism of O_2 sensing is debatable. Many hypotheses have been put forth but most incorporate some pathway that ultimately inhibits potassium ion channels (TASK family) or activates voltage-dependent calcium ion channels resulting in membrane depolarization of the Type I glomus cell and the release of vesicles containing neurotransmitter [44, 45]. The exact mechanism varies. One hypothesis suggests that Type I cell mitochondria possess a unique cytochrome oxidase with an especially low affinity for O_2 such that electron transport system and ATP production are affected far sooner than in other mitochondria [45]. Others have suggested that reactive oxygen species or a number of "gasotransmitters" such as nitric oxide, carbon monoxide, or hydrogen sulfide might modulate carotid body chemotransduction by virtue of their production by heme-containing proteins and a requirement for molecular O2 as found in mitochondria [46, 47]. Obviously further work needs to be done and the mechanism substantiated in humans. For an extensive review of O_2-sensing mechanisms in the carotid body, see reference [48].

Finally, it is well established that there is considerable cross talk between the peripheral chemoreceptors and the central chemoreceptors in all mammals including humans [49]. While stimulation of central chemoreceptors likely does not impact the output of the peripheral chemoreceptors, there is considerable evidence that the gain of the central chemoreceptors to CO_2 and hydrogen ion concentration can be critically dependent upon activity in the carotid body afferent nerve output [50–52]. These relationships must be appreciated when managing patients intraoperatively under anesthesia and postoperatively where residual sedation, opioid analgesia, and a degree of metabolic disarray may exist. In addition, all of the aforementioned respiratory control processes are altered or dysfunctional in common conditions such as aging or immaturity, congenital central hypoventilation syndrome, obstructive sleep apnea, or central sleep apnea secondary to congestive heart failure [25].

Neural Control of the Airways

Neural control of the airway smooth muscle is important in determining airway caliber, and pharmacologic modulation of this input is clinically relevant. The main neurotransmitters identified are acetylcholine (ACh) that acts on several muscarinic subtypes, epinephrine and norepinephrine acting on both α- and β-adrenergic receptors, and a variety of purported non-adrenergic, non-cholinergic neurotransmitters such as vasoactive intestinal peptide (VIP), nitric oxide (NO), substance P, and neurokinin A acting via second messenger cascades to elicit a variety of responses. See Barnes for a detailed discussion [53]. Although some of these neurotransmitters can have non-pulmonary sources, it is now

clear that airway parasympathetic and sympathetic nerves can release more than one class of neurotransmitter. The end terminals of parasympathetic nerves can release ACh, VIP, NO, and others that have inhibitory and excitatory properties on either the primary target end-organ or the presynaptic terminus to modify release of the primary neurotransmitter. Similarly, sympathetic nerves release norepinephrine but also may secrete substance P, neurokinin A, VIP, calcitonin gene-related peptide, cholecystokinin octapeptide, etc. [54]. The effects of many of these substances on the airway diameter, mucus secretion, and blood flow are still to be defined.

Cholinergic nerve influence on the human respiratory system is mediated via a family of muscarinic receptors on airway smooth muscle. Five muscarinic subtypes have been cloned, but only four have been identified in the lungs. These are M_1, M_2, M_3, and M_4 receptors, although only M_3 appears to be responsible for the contractile response on human airway smooth muscle [55]. M_2 receptors on the airway smooth muscle cells act through an inhibitory G-protein to block adenyl cyclase activity and lower cyclic AMP concentrations. Its role is yet to be determined, perhaps opposing the effects of β_2 agonists. However, M_2 receptors are also found on the human cholinergic presynaptic nerve terminal and likely functional as feedback inhibition to the further release of ACh. Alterations in the sensitivity or function of these receptor subtypes have been implicated in several disease states, especially influenza, asthma, and emphysema.

Adrenergic innervation of the human airways is present but despite the fact that airway smooth muscle possesses both α- and β-adrenergic receptors, direct adrenergic bronchodilator activity has not been demonstrated in contrast to observations in many animal models [56]. It appears that the more dominant role of adrenergic nerve stimulation is in presynaptic modulation of ACh release from airway cholinergic nerves via pre-junctional β_2-adrenergic receptors. Of note, β-blockers can have a profound negative impact on asthma exacerbations and yet have minimal effect on the bronchial tone of normal individuals. The mechanism behind this clinical observation is not known but may reflect expression of the asthmatic disease genotype. The absence of α-adrenergic receptors on human airway smooth muscle suggests that neuronal and adrenal catecholamines act directly only on arterial smooth muscle in the lung.

Respiratory Muscles

Bulk movement of air into and out of the lungs occurs as a result of changes in intrathoracic pressure created by rhythmic changes in the volume of the thorax. Expansion of the chest cavity occurs when three distinct respiratory muscle groups work in concert. The diaphragm, intercostal muscles, and the accessory muscles (sternocleidomastoids, scalenes) are controlled by the respiratory centers of the brain to contract in a rhythmic pattern designed to carefully match ventilation to gas exchange requirements. The abdominal musculature (rectus abdominis, external oblique, internal oblique, and transversus abdominis) can be recruited when more force is required for exhalation, although abdominal muscle tone may stabilize the rib cage during inspiration as well.

Inspiration

The diaphragm is unique in that its muscle fibers radiate from a central tendinous structure to insert peripherally on the ventrolateral aspect of the first three lumbar vertebrae and on the aponeurotic arcuate ligaments, and the costal portion inserts on the xiphoid process and the upper margins of the lower six ribs. Its motor innervation is solely from the right and left phrenic nerves that originate from the third, fourth, and fifth cervical nerve roots. In the relaxed state, it forms a pronounced "dome" that closely apposes the chest wall for some distance before arching across the midline. Contraction of the diaphragm causes a large caudal displacement of the central tendon resulting in a longitudinal expansion of the chest cavity. Simultaneously, its insertions on the costal margins cause the lower ribs to rise and the chest to widen. This diaphragmatic motion is responsible for the majority of quiet respiration. Note that as the dome of the diaphragm descends, it displaces the abdominal contents caudally. The fall in pleural pressure and accompanying lung expansion produce an increase in abdominal pressure and some outward movement of the abdominal wall. The supine and Trendelenburg positions or surgical retractors can significantly impact this abdominal motion especially in the morbidly obese necessitating controlled ventilation under anesthesia.

The intercostal muscles are thin sheet-like muscles with origins and insertions between the ribs. The internal intercostal muscles have their fibers oriented obliquely caudad and dorsally from the rib above to the rib below. The external intercostal muscles have their fibers oriented obliquely caudad and ventrally from the rib above to the rib below. All intercostals are innervated by the intercostal nerves running in the neurovascular bundle within a groove on the inferior aspect of each rib. Contraction of the external intercostals produces an inspiratory action by elevating the upper ribs to increase the anteroposterior dimensions of the chest in a "well pump-handle" motion. The lower ribs are also elevated by virtue of the force applied and their point of rotation to increase the transverse diameter of the thorax. The internal intercostals apply their force in such a direction as to rotate the ribs downward, decreasing the thoracic anteroposterior dimension to aid in active expiration. In general,

the intercostal muscle activity is minimal in quiet respiration but increases in conditions requiring a high minute ventilation like exercise.

The principal accessory respiratory muscles are the sternocleidomastoid and scalenes. The scalene muscles originate from the transverse processes of the fourth through the eighth cervical vertebrae and slope caudally to insert on the first two ribs. Their contraction during periods of high ventilatory demand elevates and fixes the cephalad rib cage during inspiration. Similarly, the sternocleidomastoid elevates the sternum and increases the longitudinal dimensions of the thorax.

Expiration

Expiration is a passive process in quiet breathing. It is a response to relaxation of the inspiratory muscles and the balance of forces generated by the elastic recoil of the lungs and chest wall. When high levels of ventilation are required as in exercise or if airway resistance increases as in exacerbations of asthma, the expiratory phase becomes an active process with forceful contraction of the rectus abdominis, the transverse abdominis, and the internal and external oblique muscles. The contraction of the abdominal musculature retracts the abdominal wall and pulls the lower ribs downward which increases intra-abdominal pressure and accelerates the cephalad displacement of the diaphragm during exhalation. The internal intercostal muscles depress the rib cage and provide a minor contribution to forced expiration. Innervation of the abdominal musculature is from thoracic nerves 7 through 12 and the first lumbar nerve. These nerves are commonly affected by epidural anesthesia and thus can impact cough and other forced expiratory maneuvers.

Like most skeletal muscles, the diaphragm and intercostal muscles are a heterogeneous mix of fiber types, containing between 40% and 60% slow oxidative (Type I) fibers. The human diaphragm probably has between 49% and 55% Type I fibers, the remainder a mix of the "faster-high activity" Type IIA and IIB fibers [57]. The types of skeletal muscle fibers seem to be distributed fairly evenly throughout the diaphragm. Of note, the respiratory muscles, especially the diaphragm, retain the ability to adapt to stress and training [58]. Not all adaptation is favorable. Mechanical ventilation (>18 hours) rapidly produces atrophy and dysfunction in the human diaphragm [59]. Diaphragm muscle fibers show increased proteolysis, reduced protein synthesis, possible mitochondrial oxidative stress (mitochondrial DNA deletions), and sarcoplasmic lipid accumulation [60, 61]. Lung pathology can produce maladaptive responses as well. Emphysema is a good example. The diaphragm undergoes changes at the sarcomere level, physically "losing or altering" key sarcomere proteins (slow heavy myosin, titin) and changes in the proportion of Type I to Type II fibers [62–64]. These changes result in an easily fatigued diaphragm and intercostal muscles causing the characteristic increased thoracic dimensions and "flattening" of the diaphragm, thus contributing to the limited exercise capacity in these patients [62].

The Respiratory "System"

The Pleural Pressure

The lungs and chest wall move together as a system. This is made possible by the enclosed, airtight thoracic cavity where the outer surface of the lungs and its visceral pleura are in close proximity to the parietal pleura covering the chest wall and mediastinal structures. Changes in the intrathoracic volume are only possible because the inside of the lung is in continuity with the ambient atmosphere outside the thorax via the trachea and pharynx. The intimate contact between the layers of pleura are maintained by a negative intrapleural pressure generated in part by the intermolecular forces of the pleural fluid excluding gas from this space. This lubricating fluid allows freedom of the pleural layers to slide over one another but highly resists separation of the layers much like two panes of glass with a thin layer of water between them. Deforming forces are thereby directly and reliably transmitted between the chest wall and lung and allow for a unified motion.

Normally the intrapleural pressure is about −5 cm H_2O when the respiratory system is in a "resting configuration or equilibrium state," but it can vary significantly. Recoil of the chest wall either outward or inward as with active exhalation and changes in elastic recoil of the expanded or contracted lung, diaphragm position, and body position (gravitational effects) will summate to define the magnitude of the intrapleural pressure (Fig. 4.4). Pathologic conditions like the introduction of air or blood into the intrapleural space can rapidly disrupt this relationship leading to a compromise in respiratory function but also interfere with cardiovascular function. Examples of disruption of the intrapleural space would be a pneumothorax, a large empyema or pleural effusions, or a tension pneumothorax.

Lung Volumes

Clinical pulmonary physiology is based in part upon a common nomenclature of the measured lung volumes during a variety of respiratory maneuvers. Mastering this language facilitates effective communication across all disciplines within medicine and surgery. First, most lung volumes and

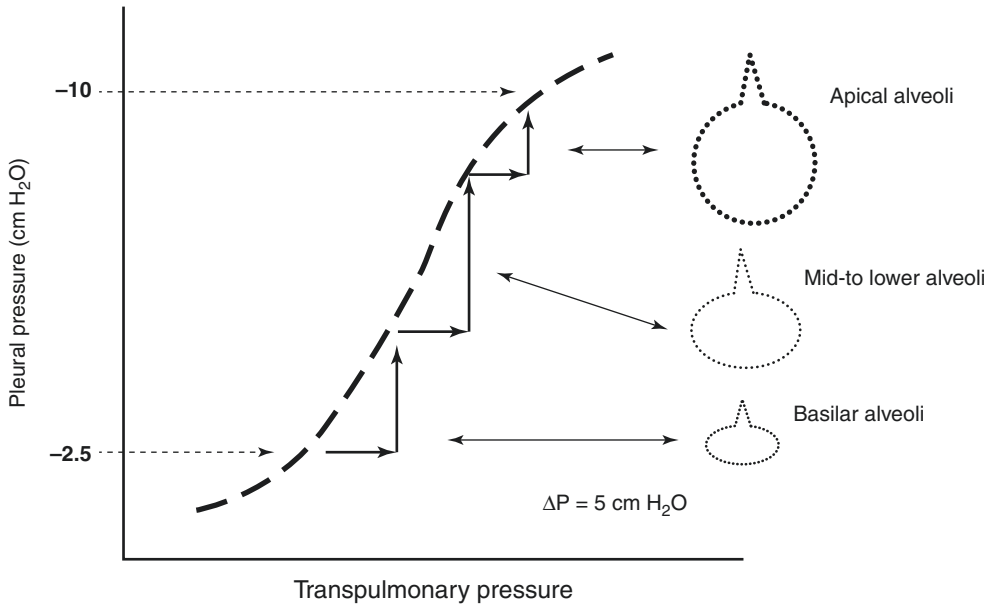

Fig. 4.4 The static relationship between the transpulmonary pressure (alveolar pressure – pleural pressure) and the pressure in the pleural space. Pleural pressure is normally negative relative to atmospheric pressure. The gradient is small at the base of the lung (P_{pl} least negative) but larger at the apex (P_{pl} most negative) because of the recoil pressure of the elastic lung tissue. This disparity results in larger alveoli at the apex then the dependent alveoli at the base. When atelectasis develops the alveoli are collapsed, a condition frequently seen in patients post-thoracotomy even when sitting upright. As a result a given change in transpulmonary pressure produces the largest change in volume (and pleural pressure) where the alveoli sit on the steepest portion of this curve

capacities are measured by a device referred to as a spirometer. Spirometry and other associated measurement techniques have combined to define four major subdivisions of *lung volume*: (1) residual volume (RV), (2) tidal volume (TV), (3) expiratory reserve volume (ERV), and (4) inspiratory reserve volume (IRV). These four lung volumes then can be combined to define the clinically useful four *lung capacities*: (1) total lung capacity (TLC), (2) vital capacity, (3) inspiratory capacity (IC), and (4) functional residual capacity (FRC). These terms and relationships are defined in Table 4.2. Details of their measurement are described in Chap. 2.

Differences in individual lung volumes are related to a large extent by body habitus, in particular, height. However, since TLC is influenced by lung and chest wall elastic recoil properties, inspiratory muscle strength, and body position, many conditions can alter its measurement. As an example, a "standard young adult male of average height" would likely have a TLC of about 6.5 L, of which 1.56 L is residual volume. Therefore his vital capacity would be about 5 L. However the magnitude of the residual volume, RV, is a balance between expiratory muscle strength and the outward recoil of the chest wall at complete active exhalation. Although these predominantly static measurements are made without any confounding flow resistance factors, "dynamic compression" of the airways from either extreme expiratory effort or loss of structural integrity with aging does occur and will increase lung residual volume. The lung volume at the end of a spontaneous exhalation during quiet breathing, the functional residual capacity or FRC, marks a passive balance between the opposing elastic forces of the lung and the chest wall, i.e., the resting volume of the respiratory system. At this lung volume, airway pressure is zero (or equal to ambient atmospheric pressure), i.e., no pressure gradient exists between the inside of the alveoli and the mouth and therefore no air flow.

Table 4.2 Lung volumes and capacities

	Definition
Lung volumes	
Tidal volume (V_T)	Air volume inspired and expired during a relaxed breathing cycle
Residual volume (RV)	Volume remaining in the lung after a maximal expiratory effort
Expiratory reserve volume (ERV)	The volume of air that can be forcibly exhaled between the resting end-expiratory volume and RV
Inspiratory reserve volume (IRV)	The volume of air that can be inspired with maximal effort above the normal resting end-expiratory position of a V_T
Lung capacities	
Vital capacity (VC)	The amount of air that can be exhaled from the point of maximal inspiration to the point of maximal expiration [IRV+ERV]
Total lung capacity (TLC)	Total volume of air in the lungs after a maximal inspiration [IRV+ERV+RV]
Functional residual capacity (FRC)	Amount of air in the lung at the end of a quiet exhalation [ERV+RV]

Dynamic Mechanical Aspects of the Respiratory System

The Pressure-Volume Relationship

Both the chest wall and lungs are elastic structures, and each has unique physical properties that define this elasticity. As elastic structures, the lungs and chest wall will return to their original configuration when deforming forces are removed. The equilibrium positions or volumes are not the same for the lung and chest wall. In fact, it is possible to define the relationship between volume of the lung or chest wall (thoracic cavity) and a deforming pressure independently under experimental conditions. The static pressure-volume curve for an isolated lung is compared to that of a chest wall in Fig. 4.5. Note that the equilibrium position of the lung is at or near residual volume, RV. To sustain any lung volume above, this point requires the application of a distending force. The lung will recoil with an equal and opposing force. At all volumes above RV, the lung tends to recoil inwards as indicated by the positive pressure or distending force required (*x*-axis). On the other hand, the equilibrium position of the chest wall is at a relatively large volume, estimated at approximately 60% of the total lung capacity. To attain any "chest wall volume" above, this point requires active inspiratory muscle force, and likewise to decrease the volume below, this point requires a significant input of expiratory muscle force. The thick solid line shows a summation of the two individual curves to define the static volume-pressure relationship for the total respiratory system. The recoil pressure of the respiratory system (P_{rs}) is defined as the algebraic sum of the individual recoil pressures of the lung (P_L) and the chest wall (P_{cw}).

$$P_{rs} = P_L + P_{cw}$$

The volume at which the P_{rs} is zero is the relaxation volume (V_{rx}) of the respiratory system. In the normal healthy individual during quiet breathing, the volume of the lung at end of expiration (FRC) approximates the V_{rx}. However, under different circumstances, FRC may deviate from V_{rx} significantly. Numerous static factors such as posture, respiratory muscle tone, body habitus, and other external forces may reduce end-expiratory lung volume, while dynamic mechanisms such as dynamic airway compression or asthma may increase it.

Postural influences on the pressure-volume relationship of the respiratory system are primarily related to gravitational forces on the abdominal contents. In the erect posture, the downward pull of gravity displaces the abdominal contents and tends to exert an inspiratory action on the

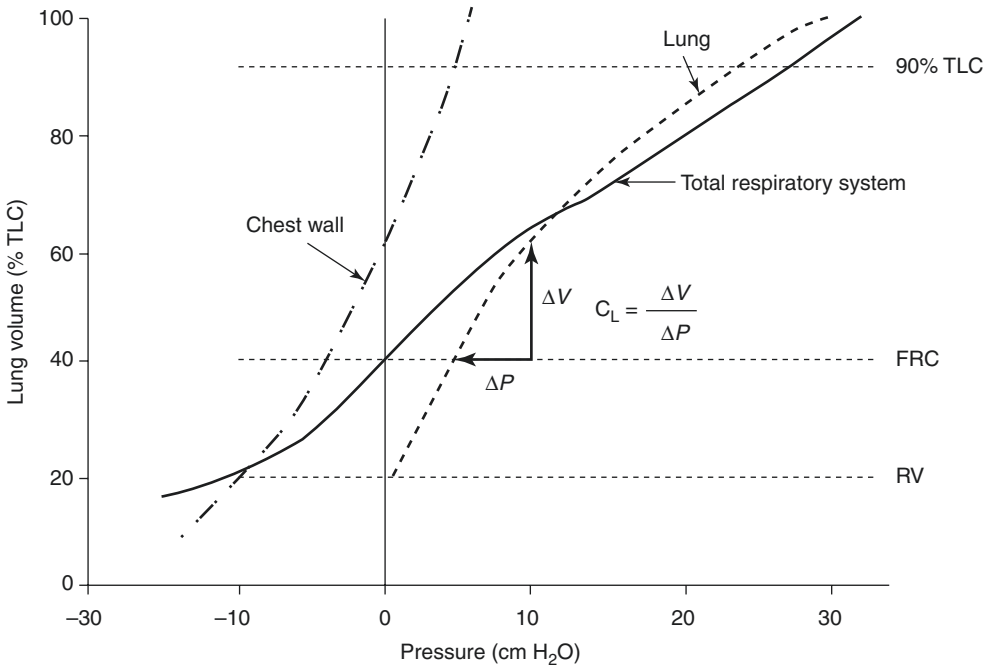

Fig. 4.5 Static pressure-volume curves of the respiratory system. The isolated chest wall pressure (P_{cw}) – thoracic cavity volume curve (large dash-dot line) crosses the zero pressure or equilibrium point at approximately 60% of TLC. The isolated lung pressure (P_L) – volume curve (small dash-dot line) approaches its equilibrium point at about 20% TLC or RV. Note that P_{cw} can be positive (force provided by contraction of the inspiratory muscles to achieve TLC) or negative (even greater force exerted by expiratory muscles to collapse the chest wall to reach RV). The algebraic summation of the chest wall and lung compliance ($\Delta V/\Delta P$) curves defines the static pressure-volume relationship of the total respiratory system (solid line). Note that in the totally relaxed state, the balance between outward recoil of the chest wall and the inward recoil of the lung is at a lung volume (V_{rx}) that usually approximates FRC

diaphragm. In contrast, the upright posture affects the rib cage in a manner more like expiration, with gravity pulling the rib cage inward and downward. In the supine position, gravity exerts a small expiratory action on the rib cage but a more pronounced expiratory action on the abdominal contents and diaphragm. The pressure-volume curve for the chest wall is shifted to the right (i.e., produces less opposition to the inward recoil of the lung) and results in a shift in the V_{rx} and, hence, FRC to smaller volumes (in normal individuals about 10% or more). The Trendelenburg position can emphasize this decrease in FRC by an additional 10% of TLC. This fact should be kept in mind when a patient is emerging from anesthesia following surgery in the supine or Trendelenburg position.

Lung Compliance, Lung Volume, and Dynamic Modifiers

Healthy adults with relatively stiff chest walls or low chest wall compliance (C_{cw}) tend to breathe near their relaxation volumes or FRC because the respiratory system is most efficient when under these conditions. In other words, the necessary pressure gradient (ΔP) that must be generated to produce an adequate resting tidal volume (V_T or ΔV) is optimized on the steeper slope of this pressure-volume relationship to require the least amount of work of breathing (WOB). The slope of the pressure-volume relationship defines the respiratory system compliance (C_{rs}). For the sake of brevity, we will only discuss static (vs dynamic) compliance. The compliance of the respiratory system is calculated in a similar fashion to P_{rs}. Since the pressure (at a given volume) is inversely proportional to compliance, the total compliance of the respiratory system (C_{rs}) is the algebraic sum of the reciprocals of the compliance of the lung (C_L) and the chest wall (C_{cw}). Therefore, the equation of respiratory system recoil pressure can be rewritten as follows:

$$\frac{1}{C_{rs}} = \frac{1}{C_L} + \frac{1}{C_{cw}}$$

By definition, compliance, C_{rs}, equals $\Delta V_{rs}/\Delta P_{rs}$ and is normally in the range 50–80 mL/cm H_2O. To estimate the lung compliance and potential stress to the lung parenchyma would require a substitution of the transpulmonary pressure gradient. The traditional definition of transpulmonary pressure is the pressure difference between the airway opening (mouth) and the pleural space as estimated by esophageal manometry; both measured with respect to atmospheric pressure. Caution should be exercised in its interpretation [65]. Examples of pathologic conditions that alter respiratory system compliance are pulmonary fibrosis (a decrease in lung compliance) and scoliosis (a decrease in chest wall compliance) through its effect on the spine and rib cage. To sustain the respiratory system at high lung volumes is disadvantageous from a mechanical standpoint and requires a considerable increase in work of breathing to balance the increased elastic chest wall and lung components. A secondary factor establishing the FRC is the interplay of dynamic factors [66]. During quiet breathing, there is sufficient time for passive emptying of the lungs. However at high rates of ventilation during exercise or when emptying is delayed because of obstruction to flow, end-expiratory volumes may be determined more by dynamic factors rather than a static equilibrium. In obstructive lung diseases, despite the general increase in C_L by destruction of the alveolar architecture and decline in elastic recoil, the increase in V_{rx} (FRC) is as much a reflection of effort-dependent dynamic airway compression and expiratory flow limitation. Therefore, dynamic factors can play an important role in setting the equilibrium point for the volume of the respiratory system and FRC.

The notion that dynamic factors can impact FRC is an important one that influences not only normal physiology but thoracic pathology and artificial conditions such as general anesthesia and mechanical ventilation. Dynamic FRC is determined by the balance between two major factors: the time available for expiration (t_E) and the rate of lung emptying or flow. The expiratory time (t_E) is highly influenced by the expiratory time constant (τ), which in its simplest form is the product of airway resistance to flow (R_{aw}) and compliance (C_{rs}). As an example, neonates have an increased R_{aw} because of the small diameter of their airways and have a highly compliant chest wall (increased C_{rs}) due to their underdeveloped rib cage and musculature. Thus τ, which equals ($R_{aw} \times C_{rs}$), is relatively prolonged. If the ratio t_E/τ is less than 3, dynamic FRC exceeds V_{rx}, and airway pressure at end-expiration does not reach zero. Therefore, there is incomplete expiration down to V_{rx}, and retention of gas occurs. This phenomenon continues to about 1 year of age whereupon sufficient maturity of the respiratory system produces a reduction in τ and increases in t_E to favor the normal adult pattern [67].

The same "air trapping" process can occur in adult individuals with prolonged expiratory times as a result of airway obstruction from COPD, asthma, or external airway compression from masses, for example. Incomplete expiration may occur during either spontaneous or mechanical ventilation. When describing a mechanically ventilated patient, the condition is referred to as "dynamic hyperinflation" and reflects a measurable increase in airway pressure above the normal zero pressure at end-expiration. In the literature, this has often been referred to as "intrinsic PEEP" and reflects the pulmonary end-expiratory pressure produced by the elastic recoil of the respiratory system at the higher lung volume.

Distribution of Ventilation

Ventilation is not homogeneous in the lung due to a number of factors, some of which still remain controversial. The most frequent explanation for this nonuniformity is the effect of gravity and the balance of all of the previously mentioned forces acting on the lung and chest wall. In the upright posture, the lung attains its greatest vertical height. Because the lung consists of a honeycomb of interconnected thin-walled sacs and airways and holds a considerable volume of blood within the blood vessels interspersed within its structure, it has mass that is acted upon by gravitational forces. Gravity will tend to favor blood flow to the dependent portions of the lung, and therefore, its weight will add to the weight of the lung tissue. This has multiple effects. First since the elastic lung septae are all interconnected, they distribute this force throughout the lung. The tendency for the lung to retract away from the chest wall at its apex creates a more negative (subatmospheric) pleural pressure than the pleural pressure at the lower dependent portions of the lung where its weight reduces the magnitude of the negative pleural pressure [68]. The gradient of pleural pressure from the lung apex to its base has been estimated at 0.4 cm H_2O per each centimeter of vertical height. Second, the increased stretch on the alveoli at the apex of the upright lung creates regions of larger, more inflated alveoli that become progressively smaller as one moves closer to the dependent lung base (Fig. 4.4). A consequence of this apical alveolar enlargement is to decrease compliance and create an inhomogeneous distribution of air within the lung during a breath at FRC, greater distribution of the breath to the base as opposed to the apex [68, 69]. Obviously, one might expect less of a transpulmonary pressure gradient from nondependent to dependent portions of the lung when supine or prone as compared to the upright position. In addition, the bronchi are supported by the radial traction of the surrounding lung parenchyma. Airway caliber will increase as the lung expands and contract when the lung shrinks significantly impacting airway resistance. At very low lung volumes, the small airways may close completely, a condition frequently seen at the very base of the lung where it is less well expanded. Also, the rate of inspiration directly impacts the homogeneity of gas distribution. At high inspiratory rates, air is distributed more evenly throughout the lung than at very slow rates [70].

In summary, numerous studies using a variety of tracer gases (e.g., N_2, He, ^{133}Xe) to measure alveolar gas washout have demonstrated that inspired gas distribution is inhomogeneous [69]. In the ideal, upright individual, during a spontaneous breath, inspired gas will tend to preferentially enter those open alveoli near the base of the lung which are the most compliant. As the breath continues, the gas will enter the more apical, less compliant alveoli and any previously atelectatic basilar alveoli as they become recruited by the traction exerted by the remainder of the expanding lung. In other words, although the nondependent lung areas are more distended at FRC, a given transpulmonary pressure gradient generated during a normal breath produces a greater volume change and therefore ventilation, to the dependent areas. Review Figs. 4.4 and 4.5. Numerous factors are responsible for the distribution of ventilation, and their potential impact in the thoracic surgical patient must be anticipated as body position, anesthetic gases, intravenous fluid shifts, surgical trauma, one-lung ventilation with positive pressure, and any broncho- or vasoactive drugs are introduced. These regional differences in ventilation are important in matching ventilation to perfusion for optimal gas exchange.

The Physiology of the Pulmonary Circulation

Anatomical Considerations

The lung circulation is comprised of two sources of blood flow: the pulmonary circulation from the main pulmonary artery and the smaller, bronchial circulation arising from the aorta [6]. The pulmonary circulation dominates, by volume, and serves to deliver the mixed venous blood to the alveolar capillaries to facilitate gas exchange and to act as a large, low resistance reservoir for the entire cardiac output from the right ventricle. The bronchial circulation serves to provide nutritional support to the airways and their associated pulmonary blood vessels [71]. The bronchial circulation also provides a constant source of heat and moisture for warming and humidification of the inspired air. Of note, not all of the bronchial circulation drains into the systemic venous system. A small portion of the bronchial venous drainage mixes with the pulmonary venous drainage and contributes a small physiological shunt.

Pulmonary Hemodynamics

Despite receiving all of the cardiac output from the right ventricle, the pulmonary vasculature maintains a relatively low pulmonary blood pressure. The normal adult mean pulmonary artery pressure (P_{PA}) is between 9 and 16 mmHg with systolic P_{PA} between 18 and 25 mmHg. Several features enable the pulmonary circulation to maintain this high flow at such low pressures. First, the pulmonary vasculature is extremely thin-walled with far less arterial vascular smooth muscle than its systemic counterparts. The result is a highly compliant reservoir capable of accommodating an average 3.2 L/min/m^2 blood flow at rest or six to eight times that flow during exercise. Second, the total pulmonary vascular resistance (PVR) is quite low, on the order of less than 250 dynes/s/cm^5. This minimizes the pressure work faced by the

less robust right ventricle while still enabling the right ventricle to match the output of the left ventricle. Pulmonary vascular resistance can change as a result of numerous factors, hypoxia, acidosis, mitral valve stenosis or regurgitation, left ventricular failure, primary pulmonary hypertension, or pulmonary emboli, to name just a few. Pulmonary vascular resistance can be calculated using data from a pulmonary artery catheter as:

$$\mathrm{PVR} = \left[\frac{\left(P_{\mathrm{PA}} - \mathrm{PAOP}\right)}{\mathrm{CO}}\right] \times 79.9$$

where PAOP is the pulmonary artery catheter occlusion pressure which is assumed to reflect the left atrial pressure, CO is cardiac output (L/min), and the factor, 79.9, converts from mmHg/L/min to units of absolute resistance, dynes.s/cm^{-5}.

Cardiopulmonary Interactions

Factors Affecting Right Ventricular Performance

Cardiopulmonary interactions can be described based on the effects of both changes in intrathoracic pressure and tidal volumes on venous return and left ventricular (LV) cardiac output and the energy required to create these changes. During spontaneous ventilation (normal breathing), venous return (right atrial filling) increases congruently with negative deflections in intrathoracic pressure, which, in turn, increases right ventricular (RV) volume and causes leftward deviation of the intraventricular septum. This, in turn, causes a spontaneous inspiration-associated decrease in left ventricular end-diastolic volume and decreased left ventricular diastolic compliance. The resultant attenuated left ventricular preload causes an immediate decrease in left ventricular stroke volume and pulse pressure which is referred to as *pulsus paradoxus* – its degree directly related to the magnitude of the resultant negative intrathoracic pressure [72, 73].

Both spontaneous and positive-pressure ventilation can significantly alter cardiopulmonary physiology through numerous complex interactions involving myocardial reserve, ventricular pump function, intravascular volume, autonomic vascular tone, lung volume, and intrathoracic pressure [72]. During spontaneous inspiration, intrathoracic pressure *decreases* (as described previously). During positive-pressure lung inflation, intrathoracic pressure *increases* (as a result of passive lung inflation and increasing airway pressure) [74].

As the right atrium is located within the thorax, spontaneous inspiration leads to a decrease in right atrial pressure relative to atmospheric pressure. Right atrial pressure is effectively the resistance to systemic venous return, which should result in augmentation of the pressure gradient of systemic venous return and thereby accelerate blood flow toward the right heart and increase preload [73, 75].

In healthy humans, ventilation typically requires less than 5% of total oxygen consumption. However in critically ill patients and those with pulmonary disease, the metabolic consequences of increased respiratory work of breathing may demand up to 25% of the total oxygen delivery [76, 77]. It therefore follows that if cardiac output is also reduced, through preexisting heart failure or other structural pathology (e.g., aortic stenosis, mitral regurgitation), blood flow and – more specifically – oxygen delivery to end organs can be significantly compromised [74]. Use of mechanical ventilation is known to decrease intrinsic work of breathing. In fact, even noninvasive modalities such as BiPAP and CPAP have been demonstrated to improve both cardiac output and oxygen delivery [78].

The process of lung inflation, either through normal spontaneous breathing or through positive-pressure mechanical ventilation, results in various and specific effects on a number of cardiopulmonary parameters. Chief among them are changes in autonomic tone, cyclical alterations in intrathoracic pressure, changes in systemic venous return, variation in both right and left ventricular output and afterload, and perturbations of intraventricular interdependence.

Increases in lung volume have immediate and significant effects on autonomic tone. Lung inflation provokes immediate changes in autonomic output [79], resulting in increases in heart rate – otherwise referred to as *respiratory sinus arrhythmia* [80], which occurs in humans with intact (normal) autonomic responsiveness [81]. Lung hyperinflation (>15 mL/kg PBW) results in relative bradycardia (which may be profound) through vagal responses and withdrawal of sympathetic tone. Additionally, several studies have demonstrated a reflex arterial vasodilation caused by lung overinflation through pathways involving inducible nitric oxide production [82].

Pulmonary Vascular Resistance

Increases in lung volume have a significant influence on cardiac performance through its effects on altering right ventricular preload and afterload [83]. Additionally, ventilatory changes can have a profound effect on RV afterload through hypoxic pulmonary vasoconstriction, which typically becomes clinically relevant when regional alveolar PO_2 falls below 60 mmHg: pulmonary vasoconstriction occurs, reducing local blood flow [84]. Patients with acute hypoxemic (Type I) respiratory failure typically have small lung volumes [85]. Decreases in end-expiratory lung volumes promote alveolar collapse that will increase PVR to a degree that may trigger acute RV failure. Restoration of normal lung volumes through standard recruitment maneuvers and the addition of extrinsic PEEP typically reverses this reduction in PVR**.** However, lung hyperinflation also results in the compression of alveolar ves-

sels that serves to increase PVR [85]. Significant increases in pulmonary hypertension can cause acute RV failure or cor pulmonale [86] and RV ischemia [87]. PEEP then will have differential effects on pulmonary hypertension depending on the clinical context: it may serve to decrease PVR and RV afterload if it reduces hypoxic pulmonary vasoconstriction (see section on HPV below) [88], or it has potential to increase PVR if the end result is lung overinflation [89].

Changes in Intrathoracic Pressure

As the heart is a pressure-producing chamber that functions within a pressure chamber, it follows that changes in intrathoracic pressure (ITP) will affect the pressure gradients for both systemic venous blood return to the RV and systemic blood outflow from the LV (independent of intrinsic myocardial function). Interventions which cause an *increase* in intrathoracic pressure (e.g. positive-pressure ventilation) will cause an increase in right atrial pressure and a decreased transmural LV systolic pressure, reducing the pressure gradients for venous return and LV ejection and decreasing intrathoracic blood volume. *Decreases* in intrathoracic pressure will augment venous return, impede LV ejection, and increase intrathoracic blood volume.

Systemic Venous Return

Right atrial pressure (RAP) is essentially resistance to systemic venous return [90] which is comprised of low pressure, low resistance venous circuits. RAP is known to change rapidly throughout the ventilatory cycle due to simultaneous changes in ITP [91]. As mentioned previously, positive-pressure ventilation increases ITP and RAP decreasing the pressure gradient for venous blood return, resulting in decreased RV stroke volume and ultimately cardiac output [92]. However, decreases in venous return in the setting of increased ITP are offset to some extent by the resulting increase in intra-abdominal pressure caused by the caudal movement of the diaphragm and contraction of abdominal wall muscles [93]. Van den berg demonstrated that increasing CPAP up to 20 cm H_2O does not seem to have clinically relevant effects on cardiac output, provided that intra-abdominal pressures also increased similarly [94].

Factors Affecting Left Ventricular Performance

LV Preload and Ventricular Interdependence

Changes in venous return (and therefore RV output) necessarily influence LV preload and systemic cardiac output (where changes are typically observed after two to three beats, as observed with a standard Valsalva maneuver) [95]. This inherent phase delay between RV output and LV output is exaggerated in two clinical situations: hypovolemia and high tidal volumes [96].

Ventricular interdependence can be modified by a number of clinically relevant conditions. Increasing RV volume shifts the intraventricular septum into the LV throughout the cardiac cycle and simultaneously decreases LV diastolic compliance. During positive-pressure ventilation, RV volumes are typically decreased, minimizing ventricular interdependence [96, 97]. Positive-pressure ventilation-induced increases in lung volume compress the two ventricles into each other, decreasing biventricular volumes [98]. Restoring LV end-diastolic volume with fluids returns cardiac output during PEEP therapy without LV diastolic compliance changes [99]. However, during spontaneous inspiration, as RV volumes transiently increase, septal shift into the LV lumen is the rule [100], decreasing LV diastolic compliance and end-diastolic volume [88, 97]. This interdependence is the primary cause of inspiration-associated decreases in arterial pulse pressure, otherwise known as *pulsus paradoxus* [73].

LV Afterload

Maximal LV wall tension, or afterload, normally occurs at the end of isovolumic contraction. LV afterload normally decreases during ejection because LV volume decreases markedly despite the small increase in ejection pressure. With LV dilation, however, as in congestive heart failure, maximal LV wall stress occurs during LV ejection, making the heart more sensitive to changes in ejection pressure. Since arterial pressure with respect to atmosphere is kept constant by baroreceptor feedback [101], if arterial pressure were to remain constant as ITP increases, then LV ejection pressure must decrease [102]. Similarly, decreases in ITP with a constant arterial pressure will increase LV ejection pressure [102, 103]. As such, any process associated with significant decreases in ITP must also be associated with increased LV afterload and myocardial oxygen consumption; consider weaning-induced cardiac stress.

Rapid increases in ITP, as in coughing, will increase arterial pressure but not alter LV ejection pressure [73, 104] or aortic blood flow [105]; however, sustained increases in ITP, as seen with a Valsalva maneuver, will eventually decrease aortic blood flow and arterial pressure because venous return decreases [73].

The cardiovascular benefits of positive airway pressure can be achieved by withdrawing negative swings in ITP (which attenuate preload and augment LV afterload). Increasing levels of CPAP improve cardiac function in patients with heart failure but only once the negative swings in ITP are abolished [106]. Interestingly, prolonged nighttime nasal CPAP can selectively improve respiratory muscle strength, as well as LV contractile function if the patient had preexisting heart failure [107].

Hyperinflation, as can occur in obstructive airway diseases, for example, will compress the heart, increase PVR,

and impede RV filling. Intrinsic PEEP (hyperinflation) alters hemodynamic function similar to extrinsic PEEP; thus, matching intrinsic PEEP with ventilator-derived PEEP does not alter hemodynamics [108]. There is little hemodynamic difference between increasing airway pressure to generate a breath and decreasing extrathoracic pressure (iron lung-negative pressure ventilation) [109].

Impact of Weaning from Mechanical Ventilation

The process of weaning from mechanical ventilator support is a significant cardiovascular stressor [74]. It is therefore not surprising that various studies have demonstrated ECG and thallium perfusion evidence of myocardial ischemia [110, 111]. Likewise, initiation of mechanical respiratory support in patients with heart failure can attenuate some of the signs of ischemia [112]. Ventilator-dependent patients who fail a weaning trial may show signs of heart failure only during the weaning process; transitioning from positive pressure to spontaneous breathing can induce pulmonary edema [113], tachycardia [110], mesenteric ischemia [114], and myocardial ischemia [115]. Jubran and colleagues showed that all subjects increased their cardiac output during the transition from positive pressure to spontaneous breathing as a result of increased metabolic demand [115]. Those patients who subsequently failed to wean showed an increase in their S_VO_2. Of note, some patients who fail a T-tube trial actually pass an extubation trial, likely reflecting increased work of breathing to overcome increased flow resistance through the endotracheal tube and not inherent respiratory dysfunction [116].

Distribution of Lung Perfusion

Gravity and Pulmonary Blood Flow

Blood flow within the normal lung is distributed in a non-homogeneous fashion. Many studies have demonstrated this behavior although explanations vary [117–119]. The earliest studies used radioactive tracers injected into the bloodstream and measured the radioactive emissions by sandwiching the subject between two external arrays of scintillation counters. The most common tracer employed was xenon-133 which has an extremely low solubility in the blood so most of it rapidly moves into the alveoli during the first pass, i.e., little recirculation. The time to achieve a steady state in the lung after injection was estimated at 3–4 s. Data acquisition of a 30 cm scan of the chest could be completed in about 30 s enabling single breath-hold studies at different static lung volumes. The data were limited to a two-dimensional representation of the lung and failed to account for the very apex and base of the lung for technical reasons. Nonetheless the studies clearly showed a gradient of perfusion from the apex and increasing toward the base in the upright lung, presumably reflecting the effects of gravity [159]. However more refined techniques using radioactive microspheres and advanced computerized three-dimensional imaging techniques have revealed that blood flow distribution is highly variable even in those portions of the lung at a uniform vertical height [120, 121]. Indeed it appears that there are "high-flow" and "low-flow" regions of the lung whose perfusion is only minimally altered by changes in body position. Several studies performed under zero gravity [122, 123] and microgravity [124] support the notion that the whole-lung gravitational and postural changes seen in blood flow distribution are primarily determined by shifts in the lung parenchymal density which are augmented by smaller gravitational contributions to individual alveolar flow within the dependent regions of the lung.

Architecture and Pulmonary Blood Flow

If gravitational influences fail to completely explain the heterogeneity of lung perfusion, then other factors must be present. One popular concept is the role played by the branching pattern of the blood vessels. At each pulmonary vascular branch point, that proportion of the pulmonary blood flow that continues down each subsequent arterial branch is dependent upon its downstream resistance to flow. The progressive branching pattern of the blood vessels is assumed to be similar in geometry within each generation. However the number of generations will be influenced by the size of lung region. This "fractal geometry" theory has been employed in a number of biological systems to analyze flow [125]. However, its use as a foundation to explain heterogeneity in the distribution of gas and blood through generations of branching airways and vasculature has proven particularly useful [126, 127].

When ^{133}Xe blood flow studies are performed at different lung volumes in the same individual, a marked variation in the distribution occurs [128]. The greatest changes occur at the apex and base of the lung. Going from TLC to RV results in large drop in the percentage of blood flow to the base, while a modest increase in the flow to the apex occurs at RV compared to TLC. One explanation for this pattern of regional blood flow is that, similar to the effects on airway resistance, traction exerted on the small arteries within the lung parenchyma decreases their resistance. The greater the traction, e.g., at high lung volumes, the lower the arterial resistance. However to explain the improvement in apical blood flow at RV requires that we suppose that large lung

volumes compress the alveolar capillaries and increase their resistance to flow. Therefore there must be a balance between alveolar pressure effects on the alveolar capillaries and the interstitial traction effects on the extra-alveolar pulmonary arterioles. Figure 4.5 illustrates this concept of lung volume and vascular resistance of intra-alveolar and extra-alveolar blood vessels.

Regional "Zones of Blood Flow"

A common conceptualization of the effects of posture and hemodynamics on the distribution of blood flow within the whole lung, the "Zones of West" model, has been useful clinically. First described in 1964 by J. B. West and colleagues, the model describes the dependence of pulmonary perfusion upon the interaction between three basic pressures: alveolar pressure, pulmonary arterial, and venous pressures [129, 159]. The notion of three (or four) "lung zones" dictated the blood flow through the acinus (see Table 4.3). In Zone 1 the alveolar pressure (P_A) is considered to be greater than both the arteriole (P_a) and venule (P_v) pressures thus creating a decreased transmural pressure favoring compression of the alveolar capillary and impeding blood flow (Fig. 4.6). Zone 1 (most nondependent region of the lung) is considered to be fairly small in the spontaneously breathing individual but can enlarge during positive-pressure ventilation. Zone 2 (a transition region between the most nondependent and dependent regions) is where the arteriole pressure (P_a) is greater than alveolar pressure (P_A) but venule pressure (P_v) remains less than the other two pressures throughout most of the respiratory cycle. The net effect is a resistance to blood flow governed by the difference between P_a and P_A. The transition is likely a gradual one and will vary throughout the respiratory cycle, especially when mechanical ventilation is employed. The size of Zone 2 will be subject to a wide variety of clinical conditions. The bulk of the normal lung is likely described by Zone 3 (dependent region of the lung) where both arteriole and venule pressures are greater than alveolar pressure during all phases of the respiratory cycle such that blood flow is unimpeded and, presumably, gas exchange continues unabated. Finally, Zone 4 has been proposed. It is that region where atelectasis or severe pulmonary interstitial edema has developed and results in blood flow determined by the difference between P_a and the pulmonary interstitial fluid pressure (P_{isf}).

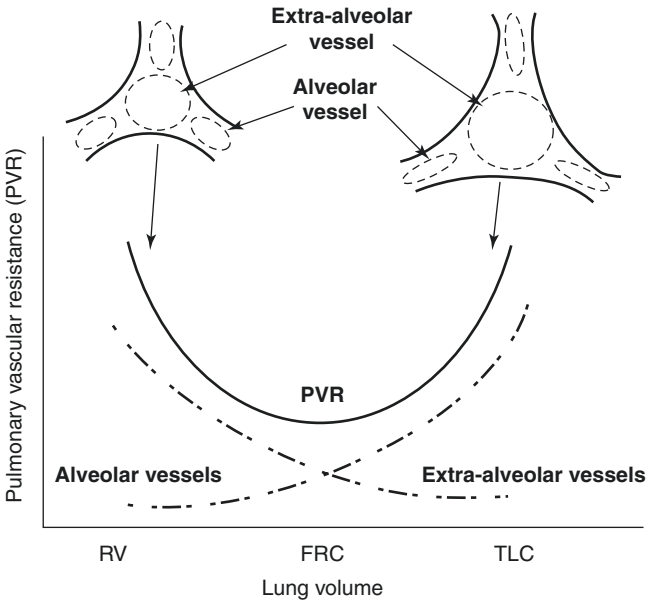

Fig. 4.6 Pulmonary vascular resistance changes with lung volume. Small pulmonary blood vessels are affected by lung volume as a result of their location with relation to alveolar sac. Alveolar capillaries are most compressed between alveoli at high lung volumes, while extra-alveolar vessels are stretched by the radial traction of the lung elastic recoil. The relationship is just the opposite at low lung volumes. As a result total pulmonary vascular resistance is highest at both extremes of lung volume and has its nadir at FRC

Table 4.3 Regional flow zones of the lung

Zone	Pressure relationships	Blood vessels	Determinants of blood flow
1	$P_{alv} > P_{pa} > P_v$	Collapsed	Minimal flow
2	$P_{pa} > P_{alv} > P_v$	Intermittent patency	$P_{pa} - P_{alv}$
3	$P_{pa} > P_v > P_{alv}$	Distended	$P_{pa} - P_v$
4	$P_{pa} > P_{isf} > P_v > P_{alv}$	Restriction	$P_{pa} - P_{isf}$

P_{alv} alveolar pressure, P_{pa} pulmonary artery pressure, P_v pulmonary venous pressure, P_{isf} interstitial fluid pressure

The pulmonary vasculature can best be viewed as a large branching tree with two components defining the distribution of blood flow within it. One component is the fixed structure that is the primary determinant of regional perfusion. However superimposed on this fixed component is a highly variable component that is influenced by numerous local factors. While fractal geometry can explain properties of the fixed component, the variable component is less predictable and subject to both passive and active regional factors. Some examples of regional factors are recruitment and distension due to changing cardiac output and blood pressure, lung distension, or vasomotion in response to hypoxic pulmonary vasoconstriction, shearing stresses, or pharmacologic interventions. The importance of all of these influences on ventilation and perfusion in the lung cannot be overstated. To optimize gas exchange requires the best possible "match" between alveolar ventilation and the delivery by the blood of CO_2 to the alveolus for removal and the absorption of O_2 for delivery to the body to sustain metabolism.

Ventilation to Perfusion Matching (The V_A/Q Ratio)

In a perfect world, the ventilation perfectly matches the perfusion in the lung. Therefore with a typical resting value of alveolar ventilation of 4 L/min and 5.1 L/min for pulmonary blood flow, we could calculate a global ventilation to perfusion ratio (V_A/Q) of 0.8. However as we have already discussed, the lung does not enjoy a homogeneous distribution of either ventilation or perfusion. A gradation exists between alveoli that are underventilated to those that are grossly underperfused. As expected, the V_A/Q ratios will vary from zero where an alveolus is perfused but not ventilated to a V_A/Q ratio of infinity where there is no alveolar blood flow but the alveolus remains ventilated. Useful physiologic descriptors of these two extremes are "physiological shunt" for a V_A/Q ratio nearing zero and "physiological dead space" when the V_A/Q ratio approaches infinity. The prefix "physiological" connotes that physiologic events can be superimposed to create these conditions in contrast to fixed anatomical arterial-venous shunts or the non-respiratory airways, i.e., anatomical dead space.

In the healthy conscious individual, the expected shunt or venous admixture is only about 1–2% of the cardiac output. This degree of venous admixture is likely to produce an alveolar to arterial PO_2 gradient of about 7 mmHg or less in someone breathing ambient air. However, the degree of venous admixture has been shown to increase with age. Administration of 100% inspired oxygen can achieve acceptable PaO_2 in the face of venous admixture up to about 30%. During most general anesthetics, an inspired FiO_2 of 40% is sufficient unless moderately severe shunting is present. Shunting developing during general anesthesia likely has two sources, atelectasis and redistribution of ventilation to regions of high V_A/Q ratio. The former can be corrected or significantly reduced by the application of PEEP. The latter may actually be worsened by PEEP. The end result will depend on the condition predominantly causing the increased venous admixture.

These conditions have significant consequences for metabolic homeostasis because of its impact on gas exchange. Alveoli with no ventilation will have a P_AO_2 and P_ACO_2 identical to that of mixed venous blood because the trapped alveolar gas will equilibrate with the CO_2 and O_2 levels in the mixed venous blood. Likewise for those alveoli ventilated but not perfused, the P_ACO_2 and P_AO_2 will be identical to the inspired gas since there is no blood to either add CO_2 or remove O_2 from the alveolus. Therefore for all alveoli with ratios in-between these extremes, their alveolar gas partial pressures will reflect the degree of both ventilation and perfusion. V_A/Q ratios have been measured under a variety of conditions and modeled to show a basic pattern in the normal upright lung under spontaneous respiration (see Fig. 4.7).

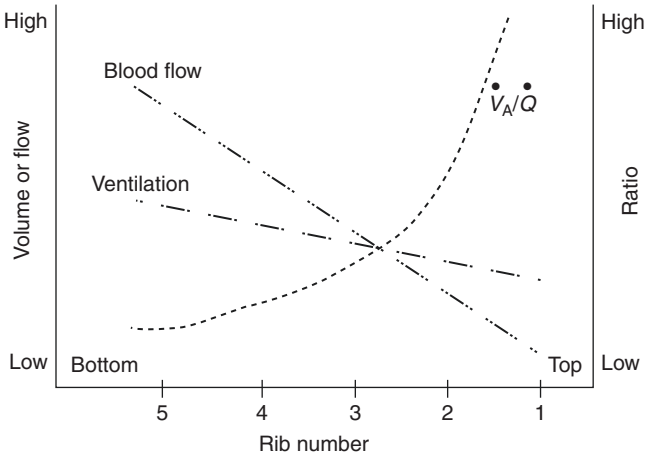

Fig. 4.7 General distribution of blood flow and ventilation and the ventilation-to-perfusion ratio as a function of distance from the base of the upright lung to its apex. Both ventilation and blood flow are significantly greater at the base of the lung than its apex. However the relation is much steeper for blood flow than for ventilation. Therefore the ventilation-perfusion ratio (V_A/Q) is greater at the apex or nondependent regions of the lung than the base or dependent regions of the lung

Note that perfusion changes relatively more than ventilation as you progress from the lung base to its apex resulting in V_A/Q ratios ranging from 0.6 to 3.3 [129]. Even these ratios may not represent the extreme values in the upright lung since the apex and base of the lung do not lend themselves to accurate assessment for technical reasons.

One method that has been used extensively in the laboratory to detect and quantify the disparity between ventilation and perfusion in normal and diseased human lungs is the multiple inert gas elimination technique (MIGET) [130]. Multiple tracer gases dissolved in a physiologic medium are infused intravenously for 30 min. The original mix included SF6, ethane, cyclopropane, halothane, ether, and acetone that are nonreactive with hemoglobin and possess a wide range of solubilities. After 30 min, mixed venous, arterial and mixed expired samples are taken and analyzed by gas chromatography for the arterial retention and alveolar excretion of each gas. Cardiac output and minute ventilation are measured. Each tracer gas has a linear dissociation curve and a single blood-gas solubility coefficient. Plots of ventilation and blood flow versus calculated V_A/Q ratio are derived for each gas. The composite V_A/Q distribution is fitted to 48 discrete compartments plus 1 for shunt ($V_A/Q = 0$) and 1 for alveolar dead space ($V_A/Q = \infty$). Note the characteristic plots in Fig. 4.8. Figure 4.8a shows a normal subject characterized by a near-perfect match between the blood flow curve and the ventilation curve. You should note that both distributions are bell-shaped curves supporting the notion of heterogeneity of both ventilation and perfusion in the normal lung. In comparison, Fig. 4.8b demonstrates a characteristic graph with a large degree of mismatch produced, in this case, by multiple pulmonary emboli. Note the significant physiologic

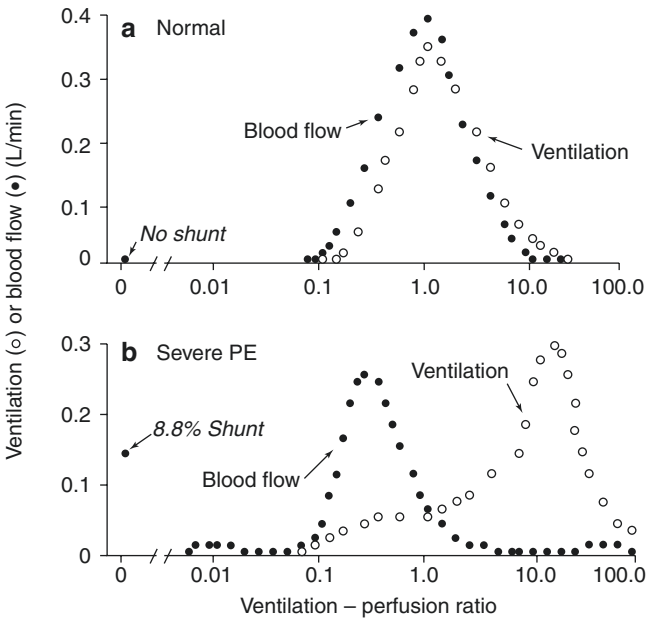

Fig. 4.8 Ventilation (open circles) or pulmonary blood flow (closed circles) as a function of computed ventilation-perfusion ratio (V_A/Q) using the multiple inert gas elimination technique (MIGET). See text for details of the experimental method. (**a**) Normal distribution of ventilation, blood flow and calculated V_A/Q ratios demonstrating a good match between alveolar blood flow and alveolar ventilation. (**b**) A characteristic plot in the presence of multiple pulmonary emboli. Note the dispersion of blood flow to regions of the lung with low V_A/Q ratios and the ventilation distributed to areas of high V_A/Q ratios. Ventilation is wasted presumably because of the obstruction of the pulmonary blood flow to many regions by emboli. The high calculated shunt of 8.8% likely reflects pulmonary edema and possibly the increased blood flow through anatomic arterial-venous shunts as a result of pulmonary hypertension. (Based on data from Wagner et al. [181])

dead space indicated by considerable ventilation to underperfused regions. In addition, there are large regions of perfusion to areas that are relatively underventilated producing areas in the lung of physiologic shunt. Finally, note the calculated shunt fraction of 8.8%, likely the result of pulmonary edema. It is also possible that under this pathologic condition, a portion of the cardiac output is passing through the lung through anatomic a-v shunts as well. These paths may become recruited when pulmonary vascular resistance increases as a compensatory mechanism to limit the increase in PVR or to accommodate gross increases in pulmonary blood volume as in congestive heart failure.

Hypoxic Pulmonary Vasoconstriction

Hypoxic pulmonary vasoconstriction (HPV) is an adaptive vasomotor response to alveolar hypoxia, which redistributes blood to optimally ventilated lung segments by an active process of vasoconstriction, thereby improving ventilation-perfusion matching. This is the major intrinsic mechanism of the lung to divert blood flow from pulmonary acini served by occluded or partially ventilated bronchioles to neighboring well-ventilated pulmonary acini. Such conditions can transiently develop under a number of conditions, microatelectasis, mucus plugging, edema or inflammation, for example. HPV provides for a rapid and reversible response to changing conditions in the local environment. The mechanism is most efficient when the adjustments are restricted to small distances between adjacent pulmonary acini or at most, bronchiole segments. It tends to be less effective when the involved areas become large such as whole-lung segments or lobes. When global hypoxia is present as in the fetus in utero, HPV mechanisms lead to very high pulmonary arterial pressures that divert blood through the foramen ovale and ductus arteriosus, a useful adaptation to life with a placenta. However when alveolar hypoxia is global as upon ascent to high altitude, acute respiratory distress syndrome, hypoventilation syndromes, severe cystic fibrosis, or emphysema, HPV responses can be maladaptive and lead to pulmonary hypertension and potentially right heart failure.

The molecular and subcellular mechanisms subserving HPV are a contemporary polemic. However several aspects are well documented and are important to the clinician. We will focus on these in our discussion. Bradford and Dean were credited with the first modern observation of HPV as a result of asphyxia in 1894 and noted the dichotomy between the vasodilatory response of systemic arteries and the vasoconstriction of pulmonary arteries by the same stimulus [131]. Recognition of HPV as an important adaptive mechanism for ventilation-perfusion matching is attributed to Von Euler and Liljestrand in 1946 [132]. They noted the vasoconstriction of small intrapulmonary arteries in response to hypoxia without hypercapnia, a response limited to the pulmonary circulation. Later it was shown that the predominant stimulus was an inspired hypoxic gas mixture and not hypoxemia per se. Initial animal experiments showed that if the normal alveolar O_2 partial pressure was maintained in the face of a hypoxic blood perfusate to the lung, minimal HPV occurred [133, 134]. However, subsequent studies have clearly demonstrated that a low mixed venous PO_2 and therefore low pulmonary artery P_aO_2 will augment the HPV response to a hypoxic F_iO_2 but low pulmonary venous PO_2 has no effect [135, 136]. Indeed, as the size of the hypoxic lung increases, pulmonary vascular resistance increases, mixed venous oxygen tensions begin to fall, and the ability of HPV to shunt blood to the remaining well-ventilated lung becomes compromised. In fact if mixed venous PO_2 drops significantly, P_AO_2 in the ventilated alveoli drops sufficiently that the pulmonary perfusion pressure of those segments increases as well [135, 137]. Others have demonstrated that HPV remains intact despite chemical sympathectomy, bilateral vagotomy, and denervation of the carotid and aortic chemoreceptors [138, 139]. Finally bilateral lung transplants in

man retain their hypoxic pulmonary vasoconstrictive responses [140]. HPV is augmented by conditions and chemicals which globally enhance pulmonary vascular resistance such as acidemia, hypercapnia, histamine, serotonin, and angiotensin II to name a few.

The actual cellular oxygen sensor has yet to be determined. Current research appears to implicate the mitochondria and regulatory processes of intracellular calcium within the pulmonary vascular smooth muscle cell as the primary site [141–143]. Numerous biochemical studies have indicated that selective interruption of the mitochondrial electron transport chain complexes can impair HPV. Some favor a hypoxia-induced change in the level of oxygen free radicals and hydrogen peroxide in the smooth muscle cell [144]. These changes affect the release of calcium from the sarcoplasmic reticulum and the voltage-dependent membrane conductance to potassium resulting in depolarization and contraction of the smooth muscle, hence vasoconstriction [141, 142, 145]. There appears to be a two-step response to hypoxia with an immediate increase in PVR and pulmonary perfusion pressure occurring within minutes followed by gradual increase to a maximum that occurs over hours and can be sustained [146–148]. The response can be enhanced by hypercapnia and may involve decreased production of nitric oxide by the pulmonary epithelium and endothelium [146].

Clinical Applications

Anesthesia and Atelectasis

J.F. Nunn was one of the first to show that during anesthesia and spontaneous ventilation, gas exchange was altered by shunt and inhomogeneous *V/Q* ratios [149]. He concluded from his observations that a normal range of P_aO_2 could be maintained if the alveolar PO_2 (P_AO_2) was at least 200 mmHg which would require an F_iO_2 of at least 35%. Many have speculated that induction of general anesthesia led to the decline in oxygenation as a result of alveolar collapse (atelectasis), but it was an important observation by Brismar and colleagues in 1985 that demonstrated the regional collapse of the lung. They were able to demonstrate using computed tomography that within 5 min of the induction of anesthesia, dependent edges of the lung developed an increase in density consistent with atelectasis [150]. It is now accepted that this occurs in dependent lung regions in approximately 90% of patients who undergo general anesthesia using a wide variety of agents [151]. Epidural anesthesia may be the one modality that appears to cause very little atelectasis and no change in V_A/Q matching or oxygenation [152, 153].

Three basic mechanisms are currently implicated in the cause of atelectasis under general anesthesia. See the excellent review of the topic by Magnusson and Spahn [154]. The near universal finding of rapid lung collapse upon induction of anesthesia and the rapid reappearance after discontinuation of PEEP has led to the conclusion that atelectasis was due to compression of lung tissue rather than alveolar gas absorption behind occluded airways [150]. The fluoroscopic study by Froese and Bryan of the diaphragmatic motion of spontaneously breathing volunteers demonstrated that in the supine position, the dependent portion of the diaphragm had the greatest caudad displacement. Initiation of paralysis with neuromuscular blocking agents and positive-pressure ventilation created a reversal of this motion with the nondependent or superior aspect of the diaphragm which underwent the greatest displacement with each ventilated breath [155]. Others have confirmed and extended these observations using CT scans [156, 157]. It is now apparent that the geometry of the chest and diaphragm is altered under general anesthesia with greater relaxation of the chest wall and a marked cephalad displacement of the most dorsal portion of the diaphragm in end-expiration.

Absorption atelectasis can occur when the rate of gas uptake into the blood exceeds the rate of ventilation of the alveolus. The extreme condition is total occlusion of an airway that isolates the alveolar gas in the distal alveolar and respiratory airways. The gas pressure within this compartment initially is nearly at atmospheric pressure. However given that mixed venous blood continues to perfuse this area, and the fact that the sum of the gas partial pressures within mixed venous blood is subatmospheric, gas uptake from the occluded compartment by blood continues and the alveoli collapses [158]. Computer modeling has demonstrated that the rate of gas absorption from unventilated areas is dependent upon the initial F_iO_2 [159]. However in many clinical situations, the airways are not completely occluded, but rather ventilation to an area becomes severely reduced. If the inspired V_A/Q ratio of a respiratory unit is reduced, a point is reached where the rate at which inspired gas enters the alveolus is exactly balanced by the gas uptake into the blood. If V_A/Q ratio drops below this critical equilibrium point, the volume of the alveolus declines and collapse ensues. Again this process is augmented by the presence of a high P_AO_2 and a rapid rate of gas uptake [160, 161].

Finally, loss of alveolar surfactant may play a role in alveolar instability at low alveolar volumes and collapse. The rapidity of alveolar collapse following alveolar recruitment maneuvers and discontinuation of PEEP has suggested that atelectasis per se may interfere with surfactant production. Therefore, atelectatic regions of the lung may be predisposed to recurrence of collapse because of reduced levels

of surfactant, increased alveolar surface tension, and the aforementioned mechanisms, all contributing to reduced alveolar volumes.

Anesthesia and V_A/Q Matching

Of great interest to anesthesiologists is the impact of their anesthetic or pharmacologic interventions on the pulmonary homeostatic mechanisms. A wide variety of drugs have been investigated with their respect to hypoxic pulmonary vasoconstriction and V_A/Q matching. See review by Lumb and Slinger [162]. In general volatile anesthetics do not have a large impact on HPV. However volatile anesthetics could have a significant clinical effect in those patients with diseased lungs or poor cardiac function. Isoflurane can decrease cardiac output and is a potent vasodilator. As such it has been possible to demonstrate a concentration-dependent reduction of regional HPV by isoflurane during one-lung ventilation in experimental animals [163]. Domino and colleagues calculated that this increased the degree of shunt flow by approximately 4%. It is likely that this effect on blood flow and V_A/Q mismatch would be amplified in a thoracotomy patient with diffuse lung disease and with a significant preoperative fraction of cardiac output going to the nondependent lung. The newer volatile anesthetics cause less vasodilation but still produce some, albeit small, degree of shunt possibly through their general effects on cardiac output [164–166]. Studies in animals indicate that 70% nitrous oxide moderately diminishes the HPV response [167]. The general impression is that all volatile anesthetics can affect the HPV mechanism to some degree, but rather it is their impact on the patient's general physiology that may warrant greater consideration in their selection. When volatile anesthetics are compared with propofol or propofol and narcotic infusions, there appear to be only slight differences, none reaching statistical significance [166, 168, 169]. Intravenous drugs of most classes used in anesthesia such as barbiturates, opioids, benzodiazepines, and ketamine do not appear to have a measurable effect on the HPV response. However these drugs can still influence hemodynamics in other ways that can impact blood flow through the lung. Therefore except for possible changes in emergence pharmacokinetics or pharmacodynamics, there are no known significant advantages of using total intravenous anesthesia over volatile anesthetics with regard to HPV in the thoracotomy patient.

The effects of thoracic epidural anesthesia or analgesia on hypoxic pulmonary vasoconstriction have not been as extensively studied. However those animal studies examining the effects of thoracic epidural local anesthetics have not seen a significant blunting of HPV and any changes in shunt fraction are more likely to represent changes in global hemodynamics [170].

Non-anesthetic Drugs and HPV

In addition to volatile anesthetics, there are numerous drug classes that influence pulmonary vascular resistance, and several have been shown to modify HPV directly. A partial list of common drugs that can affect the pulmonary vasculature is compiled in Table 4.4. Unfortunately detailed pharmacodynamic studies are missing for many of these drugs that are commonly being used in patients. So it is quite difficult to extrapolate experimental findings to the clinical setting. Nonetheless the thoracic anesthesiologist must be aware of the potential effects of using vasoactive drugs in a perioperative setting where undesirable effects on HPV may be manifest.

Interventions to modify blood pressure or improve inotropic state can have direct effects on the pulmonary vasculature. Sodium nitroprusside, nitroglycerin, and hydralazine are potent vasodilators that can worsen P_aO_2 rapidly by reducing HPV, although preexisting vascular tone can influence the response [171, 172]. Attempts to improve the inotropic state of the heart, especially the right ventricle, with milrinone will concurrently vasodilate the pulmonary vasculature [173]. The improvement in cardiac output can enhance systemic O_2 delivery and mixed venous PO_2 so that the net effect on V_A/Q matching could be beneficial. Perioperative administration of inhaled nitric oxide (NO), inhaled PGI_2, and sildenafil to control pulmonary hypertension and improve the right ventricular afterload will also modulate HPV [174, 175]. Fortunately inhaled pulmonary vasodilators are more selective and theoretically are distributed to those better-ventilated lung regions to enhance pulmonary blood flow [176]. The intention is to amplify the response of HPV in the poorly ventilated regions. Newer pharmacologic approaches to treating coronary artery disease and chronic heart failure including those with chronic pulmonary hypertension have salient effects on the remodeling of both the heart and pulmonary vasculature. However new findings also suggest that angiotensin II receptor blockers and angiotensin-

Table 4.4 Drug Effects on Pulmonary Vascular Resistance

Decrease PVR	Increase PVR
Angiotensin II receptor blockers	α_1-Adrenergic receptor agonists
ACE inhibitors	Almitrine

converting enzyme inhibitors may attenuate HPV response in acute hypoxia [177, 178].

Finally, future research will need to sort out the effects of acute hypoxia from chronic hypoxemia. It is apparent that a condition of chronic hypoxemia such as can be found in chronic pulmonary disease can slowly alter the normal acute response to a drop in inspired FiO2 [179]. A downregulation of the HPV mechanisms might occur in the face of chronic hypoxia such that interventions such as inhaled NO may prove less efficacious [180].

In summary, the etiology of abnormal gas exchange in the patient undergoing thoracic surgery is complex, highly variable, and in a state of flux throughout the course of surgery. While certain aspects of the effect of pulmonary mechanics and control of pulmonary blood flow distribution are known, the subtle interaction between the inflammatory response to surgical trauma, mechanical ventilation (especially one-lung ventilation), and the poorly understood impact of both acute and chronic pharmacologic interventions have yet to be satisfactorily defined. Until more is known, it will be extremely difficult to predict with any certainty the consequences of our anesthetic management.

5 Physiology of the Lateral Decubitus Position, Open Chest, and One-Lung Ventilation

Sean R. McLean and Jens Lohser

Key Points

- Ventilation and perfusion matching is optimized for gas exchange.
- Induction of anesthesia, one-lung ventilation (OLV), and opening of the chest progressively uncouple ventilation–perfusion (*V*/*Q*) homeostasis.
- Hypoxic pulmonary vasoconstriction (HPV) improves *V*/*Q* matching during OLV but can be impaired by anesthetic interventions.

Introduction

Early attempts at intrathoracic surgery in nonventilated patients were fraught with rapidly developing respiratory distress and a fast moving operative field. The difficulty with performing a thoracotomy in a spontaneously breathing patient, for both the patient and the surgeon, is explained by two phenomena: *pendel-luft* and *mediastinal shift* (Fig. 5.1) [1]. Both phenomena occur due to the fact that the pleural interface has been disrupted in the open hemithorax, which means that no negative intrathoracic pressure is being created in response to a spontaneous inspiratory effort and chest-wall expansion. In the closed hemithorax, on the other hand, chest-wall expansion and the resulting negative intrathoracic pressure will produce gas flow into the lung via the mainstem bronchus. However, inspiratory gas flow will not only come from the trachea but also from the operative lung, which is free to collapse due to the surgical pneumothorax. Inspiration therefore results in nonoperative lung expansion and operative lung retraction. The reverse process occurs during expiration, where bulk expiratory gas flow, from the nonoperative lung, not only escapes via the mainstem bronchus into the trachea but also back into the operative lung causing it to re-expand. This process results in the "pendular" motion of the lung with inspiration and expiration. Mediastinal shift occurs due to a similar process. The negative inspiratory pressure in the closed hemithorax is equally applied to the mediastinum, which is secondarily pulled away from the open thorax during inspiration. The reverse is true during expiration, where positive intrathoracic pressure pushes the mediastinum across into the open thorax. When combined, these two mechanisms explain the difficulty encountered by the operating surgeon in terms of a fast moving operating field and the potential for rapidly developing respiratory distress in the patient secondary to inefficient to-and-fro ventilation with limited CO_2 elimination and fresh gas entrainment (Fig. 5.1).

Selective ventilation of one lung was first described in 1931 and quickly resulted in increasingly complex lung resection surgery [3]. While infinitely better tolerated than spontaneous respiration, hypoxia was a frequent occurrence during the early years of OLV. Extensive research over the ensuing decades has clarified the basic physiology governing pulmonary perfusion (*Q*) and ventilation (*V*), as well as the disturbances that are caused by anesthetic and surgical interventions. Knowledge of the basic physiology is necessary to appreciate ventilation/perfusion (*V*/*Q*) disturbances during OLV.

Perfusion

Pulmonary blood flow is essential for multiple processes. Pulmonary arterial blood carries carbon dioxide to the alveoli for removal and exhalation. Pulmonary venous blood provides filling and oxygen to the left heart to support systemic perfusion and metabolic oxygen demand, respectively. Because of the closed nature of the circulatory system, the entire cardiac output (CO) has to pass through the pulmonary circulation. Pulmonary perfusion pressures are significantly

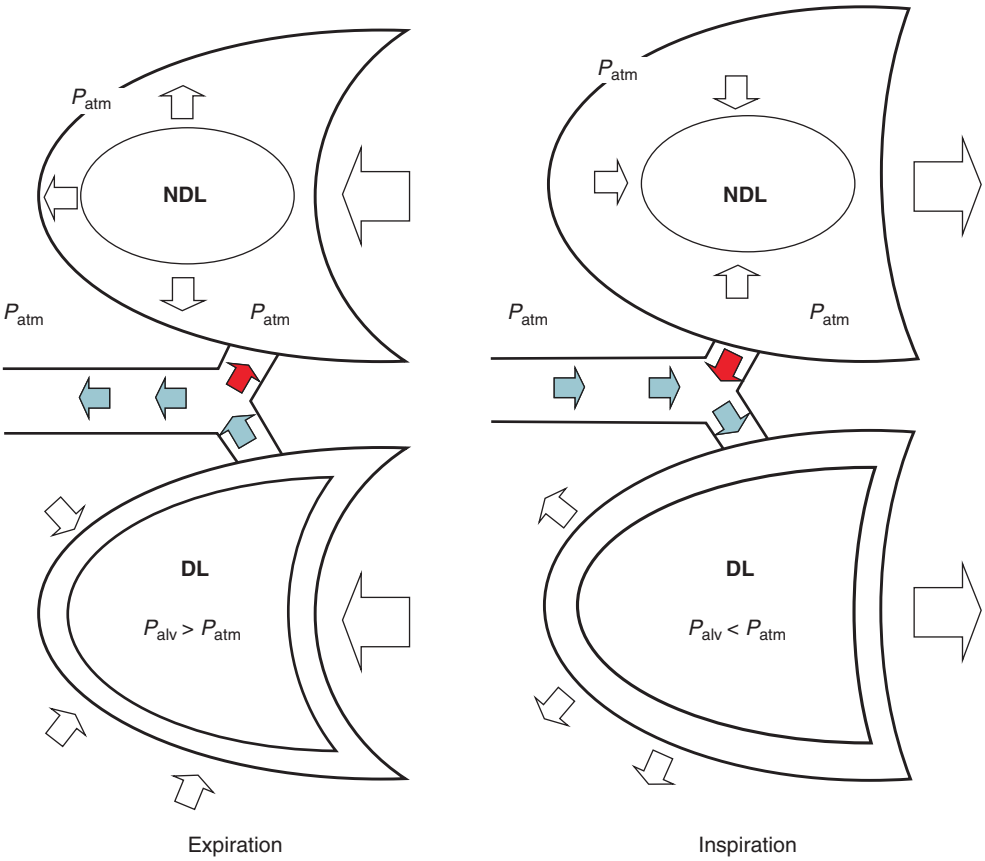

Fig. 5.1 Pendel-luft and mediastinal shift in an awake subject in the lateral decubitus with a surgical pneumothorax. During expiration, air moves out (blue arrows) from the dependent lung (DL) since alveolar pressure (P_{alv}) becomes higher than atmospheric pressure (P_{atm}). Part of the exhaled gases inflate (red arrow) the nondependent lung (NDL), in which Palv equalizes (P_{atm}). During inspiration, atmospheric air inflates the DL in which Palv becomes subatmospheric, whereas the NDL deflates, contributing (red arrow) to the ventilation of the DL. (Modified from Pompeo, 2012 with permission [2])

lower than systemic perfusion pressures and become further reduced by 1 cm H_2O for each centimeter of elevation that blood flow has to travel above the level of the heart. Perfusion is therefore not uniform across the lung, as pulmonary arterial (P_{pa}) and venous (P_{pv}) pressures are dependent on the relative elevation above the heart, whereas the extrinsic compressive force of the alveolar distending pressure (P_A) is relatively constant. The interplay of pressures across the lung results in distinct territories of lung perfusion, which are known as the West zones (Fig. 5.2a) [4, 5]. Zone 1 exists in the most superior aspect of the lung and is characterized by alveolar pressures that exceed intravascular pressures ($P_A > P_{pa} > P_{pv}$). This results in capillary collapse and secondary complete obstruction of blood flow. Zone 1 therefore represents alveolar "dead space." While Zone 1 is minimal under normal circumstances, it may increase in the presence of increased P_A (positive-pressure ventilation) or decreased P_{pa} (decreased CO). Moving inferiorly in the lung, P_{pa} values increase due to the lesser elevation above the heart and begin to exceed P_A. This characterizes Zone 2 ($P_{pa} > P_A > P_{pv}$), where P_{pa} exceeds P_A resulting in capillary blood flow. As P_A continues to exceed P_{pv}, capillary blood flow remains dependent on the differential between P_{pa} and P_A. This relationship has been likened to a waterfall, as the amount of flow is dependent on the upstream "water level" (P_{pa}), relative to the height of the dam (P_A), but independent of the downstream "water level" (P_{pv}). Zone 3 ($P_{pa} > P_{pv} > P_A$) is reached when P_{pv} begins to exceed P_A, resulting in pulmonary perfusion independent of P_A and only determined by difference between P_{pa} and P_{pv}. Zone 4 ($P_{pa} > P_{is} > P_{pv} > P_A$) is that portion of the lung where interstitial pressure P_{is} is higher than venous pressure P_{pv}, resulting in a reduction in blood flow relative to the pressure differential between P_{pa} and P_{is}. This is analogous to the patient with increased intracranial pressure (ICP), where the "interstitial" pressure (analogous to ICP) exceeds the venous outflow pressure (CVP) and therefore reduces the cerebral perfusion pressure. Zone 4 can exist in the most inferior portions of the lung or may alternatively be created by exhalation to low lung volumes or increased interstitial pressures such as in volume overload [5]. One should keep in mind that the West zones are an oversimplified static picture of a dynamic, cyclical system, as lung regions may move through various zones depending on the stage of the cardiac and respiratory cycle that they are in. For example, a given Zone 2 lung region may become Zone 1 during diastole (low P_{pa}) and positive-pressure inspiration (high P_A) or may become Zone 3 in systole (high P_{pa}) and mechanical expiration (low P_A). The gravitational model of the West zones helps to illustrate the basis of *V*/*Q* mismatch in the lungs but only partially reflects human physiology. In vivo perfusion scanning has demonstrated a combination of gravitational distribution and an "onion-like" layering, with

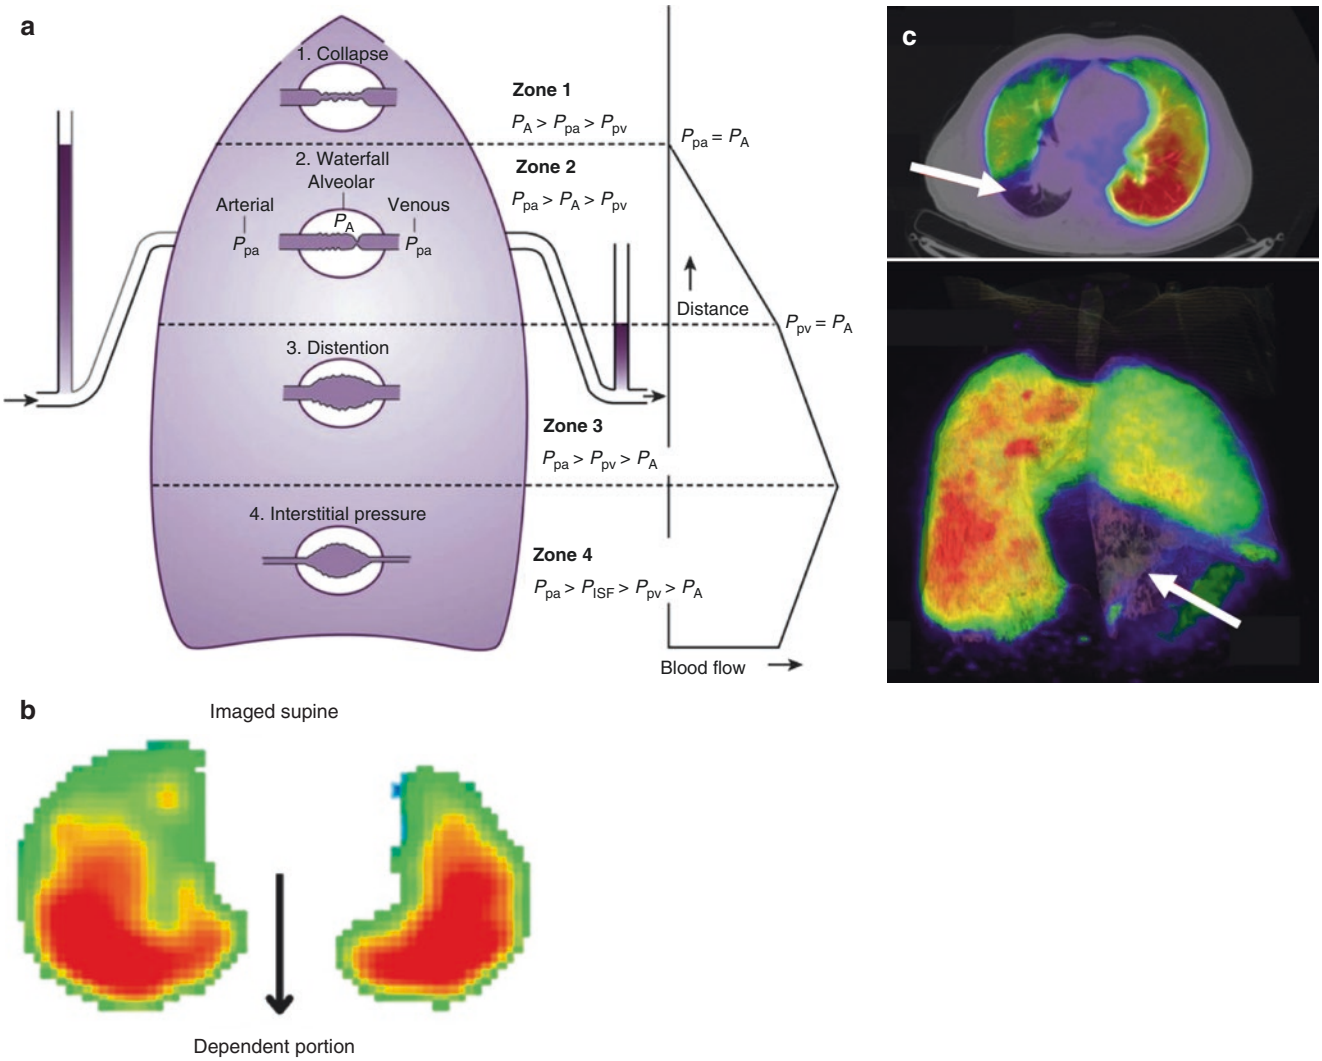

Fig. 5.2 Classic West zones of blood flow distribution in the upright position. Pulmonary blood flow distribution as it relates to the alveolar pressure (P_A), the pulmonary arterial pressure (P_{pa}), the pulmonary venous pressure (P_{pv}), and the interstitial pressure (P_{is}) at various gravitational levels (**a**). In vivo perfusion scanning illustrating central-to-peripheral, in addition to gravitational blood flow distribution, in the upright position (**b**). Single-photon emission computed tomography (SPECT) images of perfusion in a transverse section of the lung. Coloring is according to a relative scale of perfusion with red representing maximal and green representing minimal perfusion (**c**). Positron emission tomography/computed tomography (PET/CT) demonstrates both a gravity-dependent distribution and an onion-layered type perfusion distribution. The arrow indicates a perfusion defect secondary to cancer. (Modified from (**a**) West [4], (**b**) Petersson [6], and (**c**) Siva [7] with permission)

reduced flow at the periphery of the lung and higher flow toward the hilum (Fig. 5.2b, c) [6, 7]. It has also been shown that the perfusion of the left lung, in the dependent left lateral decubitus position, is lower than would be expected based simply on gravity redistribution. Compression and/or distortion elicited by the heart and mediastinum is the likely cause for this reduction [8].

The pulmonary vascular bed is a low-resistance conduit and possesses significant recruitable territory, which helps to offset any increases in pressure. Initial increases in P_{pa} or flow cause progressive recruitment of previously nonperfused vasculature. Once recruitment is complete, further increases in P_{pa} distend the pulmonary vessels, which mitigates increases in blood flow and helps to minimize increases in right ventricular afterload. These modifications allow pulmonary pressures to stay low, even when CO is increased to levels as high as 30 L/min during exercise [9]. At extreme levels of P_{pa}, distention of blood vessels will fail to decrease intravascular pressures resulting in transudation of fluid into the interstitium via mechanotransduction of the endothelial surface layer [10, 11]. Vascular resistance within the pulmonary circulation is also influenced by the degree of lung inflation. Overall pulmonary blood volume changes more than two-fold throughout the respiratory cycle, from a peak

at end expiration (i.e., residual volume) to a nadir at total lung capacity. There are two populations of pulmonary vessels that exhibit opposing responses to lung inflation. Alveolar capillaries are exposed to intra-alveolar pressures and therefore experience increasing resistance to flow, or may actually collapse, as lung volumes increase. Intraparenchymal, extra-alveolar vessels, on the other hand, experience outward radial traction with lung expansion, which progressively decreases their resistance. The cumulative effect is a parabolic resistance curve, with minimal pulmonary vascular resistance (PVR) at functional residual capacity (FRC) and progressive increases in resistance at extremes of lung volume.

Hypoxic Pulmonary Vasoconstriction (HPV)

Oxygen-sensing mechanisms in the human body, including HPV of the pulmonary arterial bed, have been well studied and reviewed extensively [12, 13]. In the fetus HPV-induced high PVR results in diversion of blood flow across the foramen ovale and ductus arteriosus. HPV remains important ex utero, as it allows *V*/*Q* matching by reducing perfusion to poorly oxygenated lung tissue. HPV is active in the physiologic range (P_AO_2 40–100 mmHg in the adult) and proportional to not only the severity of the hypoxia but also the amount of hypoxic lung. HPV is maximal if between 30% and 70% of the lung is hypoxic. Low partial pressure of oxygen results in inhibition of potassium currents, which leads to membrane depolarization and calcium entry through L-type calcium channels. Extracellular calcium entry, plus calcium release from the sarcoplasmic reticulum, culminates in smooth muscle contraction, primarily in low-resistance pulmonary arteries with a diameter less than 500 μm [12]. The primary stimulus for HPV appears to be the alveolar partial pressure of oxygen (P_AO_2); however, the pulmonary venous partial pressure of oxygen (P_vO_2) is also involved. HPV is maximal at normal P_vO_2 levels but is inhibited at high or low levels. Low P_vO_2, for example in low CO states, results in a decrease in P_aO_2 and therefore generalized, competing vasoconstriction. Conversely, high P_vO_2 in the setting of sepsis will decrease the vasoconstrictor response in hypoxic areas due to the generalized increase in P_aO_2. Vasoconstriction occurs in a biphasic temporal fashion. The early response occurs within seconds and reaches an initial plateau at 15 min, followed by a late response resulting in maximal vasoconstriction at 4 h [14–17] (Fig. 5.3a). There is animal data demonstrating that this HPV response persists for at least 90 min after the restoration of normoxemia (Fig. 5.3a) [18]. HPV reduces the shunt flow through the operative lung by roughly 40%, facilitating the safe conduct of OLV (Fig. 5.4), although some have questioned its true clinical importance [19].

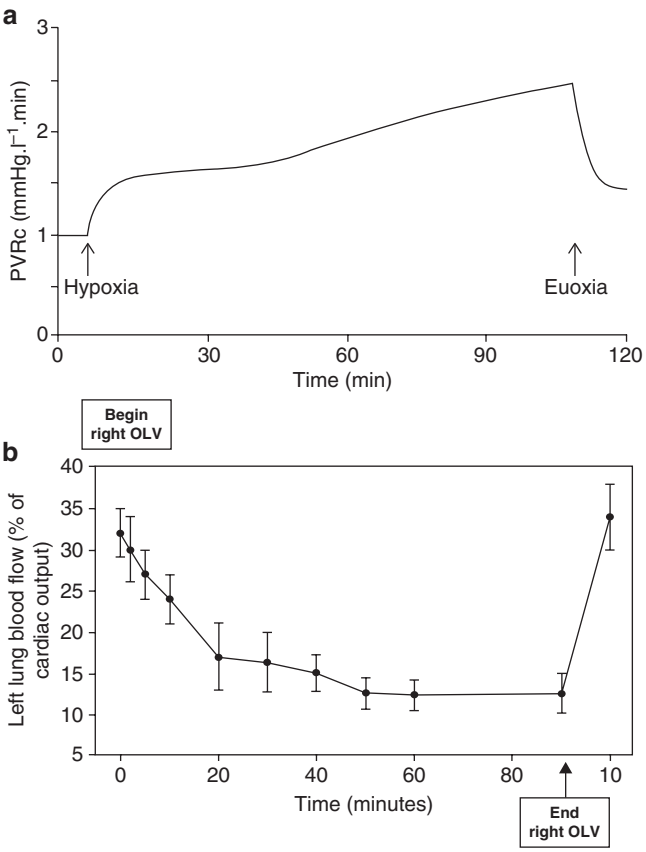

Fig. 5.3 (**a**) The biphasic nature of hypoxic pulmonary vasoconstriction (HPV) in hypoxic healthy subjects (end-tidal PO2 of 50 mmHg). Phase 1 of the response is complete within minutes, with a second phase occurring approximately 40 min later. Note the incomplete release of HPV after restitution of normoxemia. *PO2* partial pressure of oxygen, PVRc pulmonary vascular resistance corrected for cardiac output. (Reproduced from Lumb and Slinger with permission [13]). (**b**) The time course for redistribution of pulmonary blood flow to the nonventilated left lung of anesthetized dogs over a 90-min interval of right-lung ventilation. (Reproduced from Heerdt with permission [20])

Extremes of HPV may cause harm. Overactivity, particularly during exercise at high altitudes, may result in high-altitude pulmonary edema [15]. The opposite is true in thoracic anesthesia where inhibition of HPV may result in intraoperative hypoxemia. Many studies have attempted to

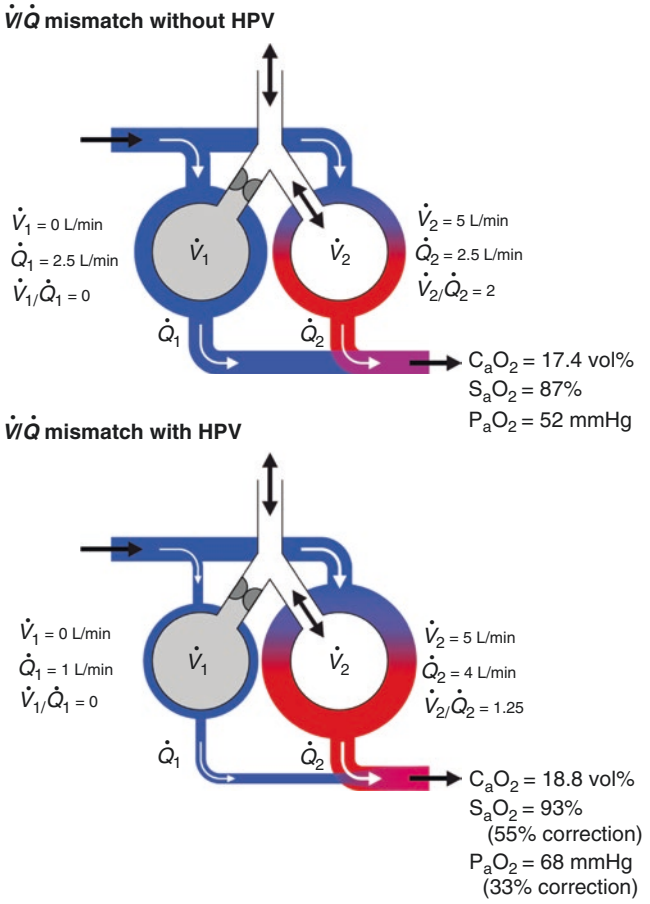

Fig. 5.4 Effects of ventilation–perfusion ($\dot{V}/\dot{Q}$) relationships on oxygen exchange in a 2-compartment lung during $\dot{V}/\dot{Q}$ mismatch without hypoxic pulmonary vasoconstriction (HPV) (top) and $\dot{V}/\dot{Q}$ mismatch with HPV (bottom). Values for total ventilation ($\dot{V}$), inspired O2 tension (PIO2), total cardiac output ($\dot{Q}$), and mixed venous O2 concentration (CmvO2), tension (PmvO2), and hemoglobin saturation (SmvO2) shown are the same for all conditions. Compartmental ventilation ($\dot{V}$ 1, $\dot{V}$ 2), perfusion ($\dot{Q}$ 1, $\dot{Q}$ 2), ventilation–perfusion ratio ($\dot{V}$ 1/$\dot{Q}$ 1, $\dot{V}$ 2/$\dot{Q}$ 2), the resulting systemic arterial O2 concentration (CaO2, calculated as the perfusion-weighted mean of the O2 concentrations in blood flowing from each compartment), and corresponding systemic arterial oxyhemoglobin saturation (SaO2) and O2 tension (PaO2) are also indicated for each condition. For simplicity, O2 concentrations were calculated as the product of hemoglobin concentration (15 g/dl), hemoglobin O2 binding capacity (1.34 vol% per g/dl), and oxyhemoglobin saturation, and ignore the concentration of O2 physically dissolved in plasma, which would be small at these O2 tensions. Vol% indicates ml O2/100 ml blood. (Reproduced from Sylvester with permission [21])

identify agents or interventions that potentiate or inhibit the pulmonary vasoconstrictor response to hypoxia. Most research has been performed on animals, as interventions are more easily standardized. Perioperative HPV modifiers are summarized in Table 5.1.

Anesthetic Modifiers

Inhibition of HPV by inhalational anesthesia has long been recognized. Ether, halothane, and nitrous oxide inhibit HPV in a dose-dependent fashion, and the underlying intracellular mechanisms have been described for halothane [71]. The effect of the newer inhalation anesthetics such as isoflurane, desflurane, and sevoflurane is less certain. All three of these agents appear to be equally neutral toward HPV or at least not cause significant depression at clinically relevant doses. Intravenous anesthesia with propofol has been proposed as a means of avoiding HPV modulation, but the improvement in oxygenation is clinically insignificant, except in marginal patients. Results on the influence of thoracic epidural anesthesia (TEA) on oxygenation have been conflicting. Garutti et al. showed an increase in pulmonary venous admixture and secondary worse oxygenation, which may have been due to a drop in CO [72]. Multiple other studies failed to demonstrate an effect of TEA on oxygenation during OLV, when hemodynamic variables were maintained [38–40]. Traditional thoracic teaching has emphasized to keep patients warm and dry, which is supported by the fact that hypothermia and both, hemodilution and increased left atrial pressure, inhibit HPV. Although altering HPV to improve oxygenation during OLV would be an appealing premise, studies have failed to elucidate an HPV modifying agent for routine use. Amiltrine, which is not available in North America, augments the HPV response, increases pulmonary vascular resistance on OLV, but fails to improve oxygenation [73]. Endogenous NO causes vasodilation and thereby inhibits HPV; if given by the inhalational route to the ventilated lung during OLV, exogenous NO causes localized vasodilation and thereby decreases shunt fraction. However, it has been demonstrated that, in the absence of arterial hypoxemia or pulmonary hypertension, inhaled NO does not improve oxygenation during OLV [74]. Therefore European consensus guidelines do not recommend the routine use of NO or amiltrine for desaturation during OLV [75]. Initial studies of other HPV augmenting agents, such as phenylephrine [76] and intravenous iron [77], have demonstrated improvements

in oxygenation, although further studies for use in OLV are warranted. Although clearly efficacious, the focus on HPV manipulation with potentially dangerous agents such as almitrine has been called a distraction from more common reasons for desaturation, such as hypoventilation of the dependent lung [19].

Other Modifiers of HPV

Surgical retraction can assist HPV by increasing PVR in the operative lung [36]; however, the release of vasoactive substances secondary to the manipulation may conversely result in an inhibition of HPV [78]. Ligation of pulmonary vessels during lung resection results in the permanent exclusion of vascular territory and thereby a reduction in shunt flow [78]. The side of surgery influences the extent of shunt flow, as the larger right lung receives a 10% higher proportion of CO than the left lung. Positioning is important as the lateral decubitus position allows for a gravity-induced reduction in shunt flow to the nondependent lung. Procedures that call for supine positioning, on the other hand, are hampered by higher shunt flow to the nondependent lung and may have higher rates of intraoperative desaturations [35]. Similarly, addition of a head-down tilt to the left lateral position has been shown to worsen oxygenation during OLV, likely due to dependent lung compression by abdominal contents [34].

Cardiac Output and Arterial Oxygenation

Arterial oxygen content (CaO_2) is influenced by end-capillary oxygen content (CcO_2), oxygen consumption (VO_2), CO (Q_t), and shunt flow (Q_s). CaO_2 can be calculated using Eq. (5.1):

$$CaO_2 = CcO_2 - \left(VO_2 / Q_t\right) \times \left(\frac{Q_s / Q_t}{10 \times \left(1 - Q_s / Q_t\right)} \right) \quad (5.1)$$

The influence of CO on arterial oxygenation during OLV has been studied repeatedly. Slinger and Scott showed a direct correlation between increasing CO and improving oxygenation in patients during OLV [79]. Similarly, CO augmented by a small dose of dobutamine (5 μg/kg/min) has been shown to improve arterial oxygenation and decrease shunt fraction [80, 81]. However, larger doses of dobutamine have been shown to adversely affect arterial oxygenation in a porcine model of OLV. Russell and James increased CO to supranormal levels (two to three times normal) with dopamine, dobutamine, adrenaline, or isoproterenol [82, 83]. They demonstrated that while high CO increases mixed venous oxygenation, this benefit is overridden by an increase in shunt fraction, resulting in impaired arterial oxygenation. The shunt fraction is likely increased due to weakened HPV in the face of increases in pulmonary arterial pressure and increased P_vO_2 [32, 84]. Animal studies have similarly shown that high doses (20–25 μg/kg/min) of dopamine and dobutamine inhibit HPV response in dogs with left lower lobe hypoxia [85] and one-lung atelectasis [58]. At low CO, oxygenation will therefore be impaired secondary to a low mixed venous oxygen saturation, despite a relatively low shunt fraction. At supranormal CO, on the other hand, oxygenation will be impaired due to an increased shunt fraction, despite the high mixed venous saturation (Fig. 5.5). This interplay bears some resemblance to the opposing effects of alveolar and parenchymal vascular resistance on PVR. Maintenance or restoration of "normal" CO is therefore important for oxygenation during OLV. The availability of noninvasive monitoring devices makes CO data more readily available and allows for appropriate titration of inotropes when required.

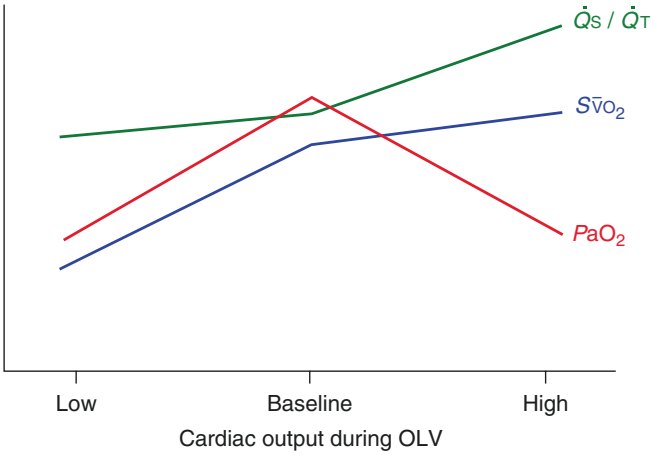

Fig. 5.5 Effect of cardiac output on PaO2 during OLV (on the basis of the data from Slinger and Scott [79] and Russell and James [82]. (Reproduced from Lumb [13] with permission)

Ventilation

Similar to pulmonary perfusion, gravitational forces also affect the distribution of ventilation throughout the lung. The negative pressure of the visceral–parietal pleural interface forces the lung to maintain the shape of the hemithorax. Disruption of that interface (as in a pneumothorax) results in recoil deflation of the lung, which, analogous to a fluid-filled balloon, will take on a more globular shape. The same forces are active even with an intact pleural interface and affect the cumulative transpulmonary pressure. The inherent tendency of the lung to want to collapse away from the upper chest wall adds to the negative pleural pressure at the top of the lung, while the tendency of the dependent lung to want to push outward reduces negative pleural pressure at the bottom of the lung. The resulting vertical pressure gradient accounts for a change of 0.25 cm H_2O per centimeter of vertical distance along the lung. On the basis of a height of 30 cm of the upright lung, this corresponds to a change in transpulmonary pressure (P_{pl}) of $30 \times 0.25 = 7.5$ cm H_2O between the top and the bottom of the lung [86]. The distending force (P_A) is the same for all alveoli; however, P_{pl} becomes less negative toward the bottom of the lung. The net effect is that the transpulmonary pressure ($P_A - P_{pl}$) is higher at the top of the lung, resulting in a larger alveolar volume compared to the bottom of the lung. In fact, this difference in size can be as much as fourfold. While the dependent alveoli are relatively small and compressed, they fall on the steep (compliant) portion of the volume–compliance curve and receive a disproportionately larger amount of the alveolar ventilation. The larger alveoli of the upper lung fall on the flat (noncompliant) portion of the volume–compliance curve and therefore change little during tidal respiration [87]. While this model of ventilation distribution is applicable to the healthy lung, recent advances in the imaging of dynamic changes in the distribution of ventilation during tidal breathing have confirmed that ventilation in the diseased lung (e.g., COPD) is much more heterogeneous [88].

Ventilation–Perfusion Matching

Efficient gas exchange hinges on matching of perfusion and ventilation. Both ventilation and perfusion increase progressively from nondependent to dependent areas, but the change in perfusion is more extreme and ranges from zero flow to high flows. As a result, nondependent areas tend to be relatively underperfused ($V/Q \gg 1$), whereas the dependent areas are relatively overperfused ($V/Q \ll 1$). Postcapillary blood from the underventilated, dependent lung zones ($V/Q \ll 1$), therefore, tends to be relatively hypoxemic and slightly hypercapnic. Nondependent lung zones, which are relatively overventilated ($V/Q \gg 1$), are able to compensate by removing excess CO_2, but due to the flat O_2-hemoglobin curve, they are less capable of increasing oxygen uptake. High V/Q areas therefore compensate for carbon dioxide, but not for oxygen, exchange. As a result, the alveolar–arterial ($A–a$) gradient, in the setting of significant V/Q mismatch, is large for oxygen and relatively small for carbon dioxide [89].

OLV provides a significant challenge to V/Q matching. Once lung isolation has been established, residual oxygen is gradually absorbed from the nonventilated lung until complete absorption atelectasis has occurred. At that point, pulmonary blood flow to the operative lung is entirely wasted perfusion. The resulting right-to-left shunt through the nonventilated lung is in addition to the normal 5% of shunt in the ventilated lung. As blood flow to each lung is roughly equal (right lung 55% of CO, left lung 45% of CO), this mathematically results in a shunt fraction upwards of 50%, at which point even high oxygen administration would be incapable of ensuring normoxemia (Fig. 5.6). Observed shunt fractions are fortunately much lower as illustrated above (Fig. 5.4).

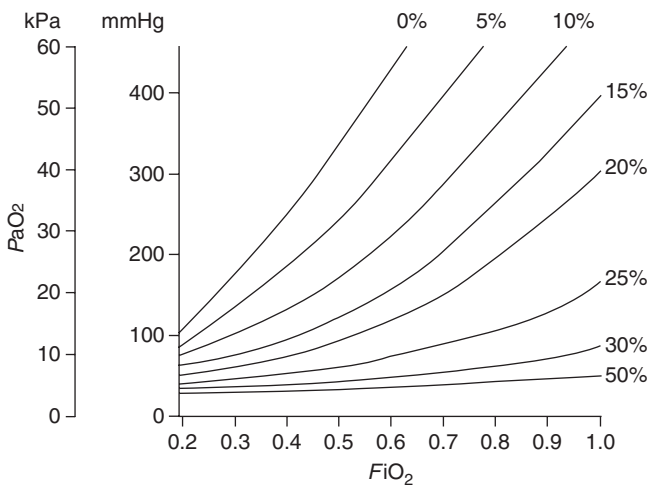

Fig. 5.6 Isoshunt diagram. Theoretical relationship between arterial oxygen (PaO2) and inspired oxygen concentration (FiO2) for different values of shunt at stable levels of hemoglobin, arterial carbon dioxide, and Alveolar–arterial gradient. (Modified from Benatar with permission [90])

Both passive and active mechanisms decrease the blood flow through the operative lung. Surgical manipulation and, in the lateral position, gravity passively reduce the blood flow to the nonventilated lung. In addition, HPV actively increases vascular resistance in the nonventilated lung, resulting in a gradual decrease in shunt fraction.

V/Q Matching in the Lateral Position

Awake

The distribution of alveoli on the compliance curve is maintained when an awake, spontaneously breathing patient assumes the lateral position. Dependent alveoli remain small and compliant, whereas nondependent alveoli stay large and noncompliant. Because of the position change, however, different areas of the lung are now dependent and nondependent. While caudal regions are small and compliant in the upright position, in the lateral position, it is the dependent (down) lung, which receives most of the ventilation. Additionally, the cephalad displacement of the dependent diaphragm by abdominal contents results in more effective diaphragmatic muscle contraction. The net result is preferential ventilation of the dependent lung in the lateral position relative to the nondependent lung [16, 91].

Perfusion is similarly altered by assuming the lateral decubitus position. The gravity-dependent distribution of flow is maintained, with a roughly 10% shift of CO to the dependent lung. A dependent right lung will therefore receive 65% of CO, compared to the 55% it receives in the upright or supine position. For a dependent left lung, this will result in an increase from the normal 45% of CO toward 55% of CO [92]. When combined, the lateral position favors the dependent lung in ventilation and perfusion, and V/Q matching is maintained similar to the upright position.

Anesthetized

Induction of anesthesia decreases diaphragmatic and inspiratory muscle tone, which results in a 15–20% drop in FRC in both lungs [93]. The change in lung volume alters the relative position of each lung on the compliance curve. The dependent lung drops from the steep portion of the volume–pressure curve, to the flat, noncompliant position. The nondependent lung on the other hand drops from the shallow position of the curve into the steeper portion previously occupied by the dependent lung. As a result, the nondependent lung is now more compliant than the dependent lung and becomes preferentially ventilated [91, 94, 95]. The distribution of perfusion, on the other hand, is not affected by the induction of anesthesia. The reduction in

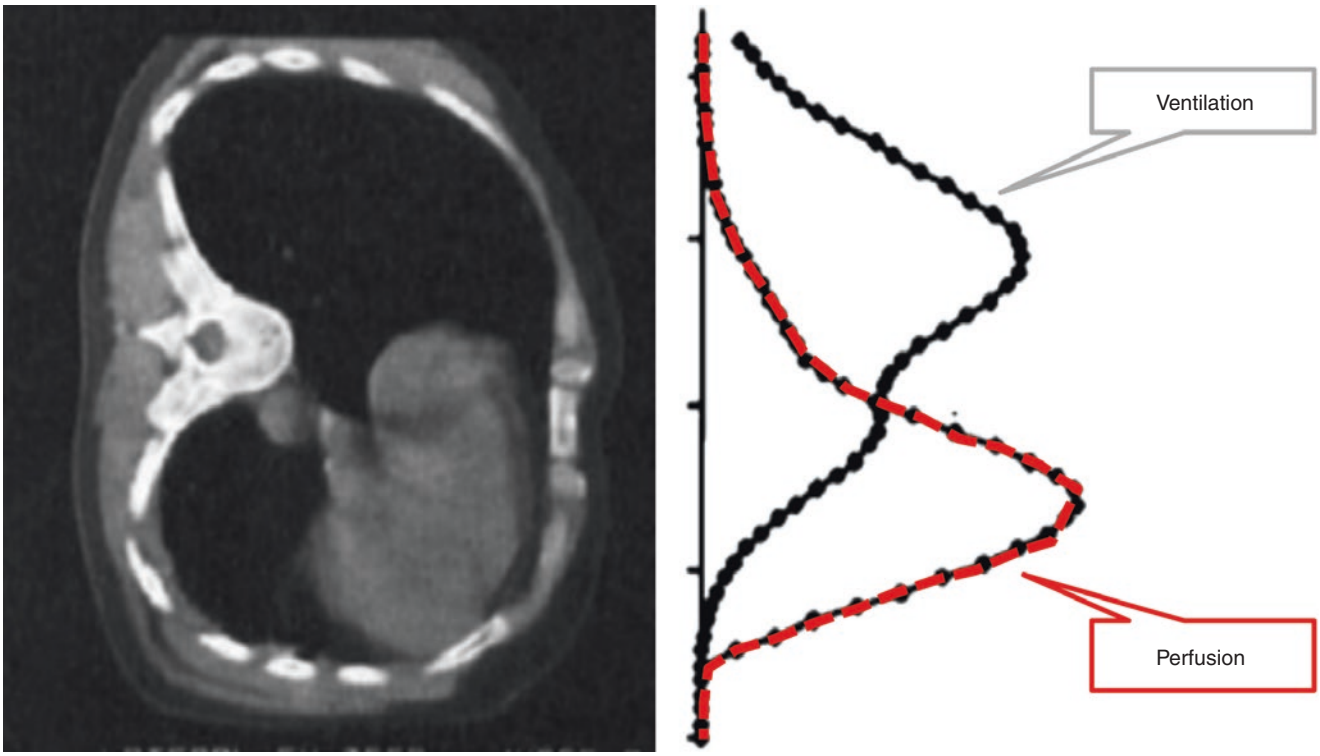

Fig. 5.7 Computed tomography image of a patient in the lateral decubitus position during mechanical two-lung ventilation and paralysis, demonstrating gravity-dependent mediastinal shift (**a**). Ventilation/perfusion diagrams in the same patient scenario indicating uncoupling of ventilation and perfusion (**b**). (Modified from Klingstedt with permission [97])

ventilation of the dependent lung disrupts *V*/*Q* matching beyond what was seen for the anesthetized, spontaneously breathing patient [91].

Paralyzed/Ventilated

Muscle relaxation, which entirely removes diaphragmatic and inspiratory muscle tone, further alters the distribution of ventilation. Diaphragmatic contraction played a more dominant role due to the favorable, higher resting position in the lateral decubitus position. Once paralyzed, static displacement of the relaxed diaphragm by abdominal contents and the gravitational force of the mediastinum further compromise the compliance of the lower lung and result in a 35% decrease in lower lung FRC [96] (Fig. 5.7). Coupled with the institution of positive-pressure ventilation, this further favors nondependent lung ventilation. Pulmonary perfusion is unaffected by muscle relaxation. However, the increase of P_A due to the institution of positive-pressure ventilation will increase Zone 1 ($P_A > P_{pa}$) and Zone 2 territory ($P_A > P_{pv}$). Consequently, ventilation and perfusion have become uncoupled with the nondependent lung receiving the bulk of ventilation (but little perfusion) and the dependent lung receiving the majority of perfusion (but little ventilation) [16, 91].

Open Chest

Establishment of the surgical pneumothorax with its loss of negative intrapleural pressure releases the mediastinal weight onto the dependent lung, further compromising its compliance. The nondependent lung on the other hand is now free to move independent of chest-wall constraints, solely based on parenchymal compliance. Consequently, the lung will collapse, if lung isolation has been applied, or will be able to herniate through the thoracotomy incision if still ventilated. The distribution of pulmonary blood flow will not be affected by opening the chest unless there is distortion of the mediastinal structures. *V*/*Q* matching will depend on whether lung isolation is being employed. During TLV, opening of the chest will result in a deterioration of *V*/*Q* matching, due to increase in Zone 1 ventilation with nondependent lung herniation through the thoracotomy incision. Application of lung isolation, however, will divert all ventilation to the dependent lung, which already receives most of the perfusion and therefore dramatically improves *V*/*Q* matching.

Most thoracic procedures are accomplished in the anesthetized, paralyzed, and mechanically ventilated patient. As we have seen in the preceding sections, induction of anesthesia, lateral decubitus positioning, paralysis, and mechanical ventilation result in progressive disruption of the close *V*/*Q* matching that is part of normal physiology. Pulmonary

perfusion has remained rather undisturbed, with preferential perfusion of dependent areas. Conversely, ventilation has become progressively diverted to the nondependent lung, as the dependent lung experiences extrinsic compression by mediastinum and abdominal contents. The application of lung isolation forces ventilation back into the dependent lung and reestablishes relative *V*/*Q* matching in the dependent lung, at the expense of true shunt in the nondependent lung [16, 91].

Positions Other Than Lateral

Supine

Although not routine for thoracic surgery, a certain number of OLV cases are being performed in the supine position (e.g., chest-wall resections, sympathectomy, minimally invasive cardiac procedures). Lung compliance changes occur with induction of anesthesia, paralysis, and mechanical ventilation, as previously described, however, unlike the lateral decubitus position, now affect both lungs equally. Abdominal, and to some degree mediastinal, compression affects each lung. Pulmonary perfusion gradients are maintained in the supine position with preferential perfusion of dependent areas. As gravity affects both lungs equally, the percentage of CO perfusing each lung is unaffected. *V*/*Q* matching is disturbed, with dependent areas receiving more perfusion but less ventilation. Because of the minimal vertical distance from anterior to posterior compared to the lateral position, this disruption is relatively minimal in the supine position. However, initiation of OLV in the supine position is less well tolerated than in the lateral position. Because of the lack of gravity redistribution of blood flow, the shunt through the nonventilated lung is substantially larger than in the lateral decubitus position, resulting in worse oxygenation [35].

Prone

OLV in the prone position is rare; however, isolated reports of lung resection and minimally invasive esophagectomy in the prone position have been published [98–100]. In fact, prone positioning for minimally invasive esophagectomy may obviate the need for lung isolation due to the gravity displacement of the lung from the surgical field even during TLV [99]. The effects of prone positioning during TLV have been extensively investigated [101]. In contrast to the supine position, *V*/*Q* matching and FRC are better maintained, with secondary marked improvement in P_aO_2 values. Lung compliance is improved, in part due to the lack of compression of lung tissue by mediastinal structures [102]. The prone position lacks gravity redistribution of pulmonary blood flow similar to the supine position. The shunt fraction and oxygenation during OLV should therefore be comparable or better than the supine position but worse than the lateral position.

Alternative Approaches

Capnothorax

Intrathoracic CO_2 insufflation has been used routinely to facilitate thoracoscopic surgery when lung isolation is difficult or impossible to achieve, particularly in the neonatal and pediatric setting [103]. In the adult setting, CO_2 insufflation may be required to improve surgical exposure during OLV, particularly during mediastinal or cardiac procedures [104, 105]. Even reasonably low insufflation pressures of 10 mmHg result in decreases in cardiac index during minimally invasive cardiac procedures [104]. Insufflation pressures above 10 mmHg should likely be avoided as they are associated with increases in HR, CVP, PAP, and peak inspiratory pressures with concomitant decreases in cardiac index, arterial O_2 tension, and mixed venous oxyen saturation [105, 106].

Awake Non-intubated Lung Surgery

Minimally invasive techniques are associated with accelerated postoperative recovery and have enabled lung surgery in progressively older and sicker patients, a trend that is likely to continue. There is renewed interest in non-intubated lung surgery, given that thoracoscopic surgery, which avoids opening of the hemithorax, minimizes the degree of pendelluft and mediastinal shift [107]. The combination of video-assisted thoracoscopic surgery (VATS) in a non-intubated patient (known as NIVATS), which can be performed under regional anesthesia with sedation, has been touted as a further reduction in invasiveness to facilitate surgery in high-risk candidates [108–110]. Current support for this approach beyond minor pleural-based procedures to actual anatomic resections is restricted to a limited number of institutions [2].

Summary

OLV is a well-established anesthetic technique that is routinely used to improve surgical exposure for a myriad of pulmonary and nonpulmonary intrathoracic procedures. Although well tolerated in the majority of patients, lung compliance and oxygenation are significantly impaired and may complicate the care of some patients. A thorough knowledge of pulmonary physiology explains the majority of the intraoperative trespasses that one encounters during OLV and enables appropriate interventions.

Clinical Management of One-Lung Ventilation

6

Travis Schisler and Jens Lohser

Key Points

- OLV needs to be individualized for the underlying lung pathology, BMI, and ventilatory mechanical characteristics.
- OLV is a modifiable risk factor for acute lung injury.
- Protective OLV is a combination of small tidal volumes, low peak and plateau pressures, routine PEEP (adequate PEEP to facilitate open lung ventilation), and permissive hypercapnia.
- Hypoxemia during one-lung ventilation is rare and often secondary to alveolar de-recruitment in the face of hypoventilation.
- Management of hypoxemia requires a structured treatment algorithm.

Introduction

The development of thoracic surgery as a subspecialty only occurred after lung isolation and OLV had been reported. Prior to the description of endotracheal intubation and the cuffed endotracheal tube, only short intrathoracic procedures had been feasible [1]. Rapid lung movement and quickly developing respiratory distress due to the surgical pneumothorax made all but minimal procedures impossible. Selective ventilation of one lung was first described in 1931 by Gale and Waters and quickly led to increasingly complex lung resection surgery, with the first published pneumonectomy for cancer in 1933 [1]. Much has since been learned about the physiology of OLV, particularly the issue of ventilation/perfusion matching (see Chap. 5). Hypoxemia used to be the primary concern during OLV. However, hypoxemia has become less frequent due to more effective lung isolation techniques with routine use of fiber-optic bronchoscopy and the use of anesthetic agents with little or no detrimental effects on hypoxic pulmonary vasoconstriction (HPV). Acute lung injury (ALI) has replaced hypoxemia as the chief concern associated with OLV [2]. Data has emerged in the past 10 years from both critical care and the operating room that has better elucidated the causative biomechanical and ventilatory factors involved in ventilator-induced lung injury (VILI). Translation of this data has yielded significant progress in harm reduction strategies in the routine application of mechanical ventilation.

Acute Lung Injury

Lung injury after lung resection was first recognized in the form of post-pneumonectomy pulmonary edema [3], which is now referred to as post-thoracotomy ALI [4]. Pneumonectomy carries a particularly high risk of lung injury, but lesser lung resections and even non-pulmonary intrathoracic procedures, which employ OLV, can create the same pathology [5]. Post-thoracotomy ALI is part of a spectrum of disease, which in its most severe form is recognized as acute respiratory distress syndrome (ARDS). Diagnosis is based on the oxygenation index of PaO_2/FiO_2 (P/F). Critical care consensus guidelines define ALI as a P/F ratio < 300 and ARDS as a P/F ratio < 200 [6]. The criteria have recently been made more stringent by requiring that a minimum of 5 cmH_2O of PEEP or CPAP be applied at the time of the P/F ratio determination [7]. ALI after lung resection is fortunately infrequent, occurring in 2.5–3.1% of all lung resections combined; however, the incidence can be as high as 7.9–10.1% after pneumonectomies. Although infrequent, ALI after lung resection may be associated with significant morbidity (prolonged intubation and hospitalization) and

mortality [5]. Mortality, which was reported to be as high as 37–64% among patients with ALI [8–10], appears to be on the decline, as more recent reports indicated a mortality rate of 25–40% [11]. Similarly, Tang et al. reported a decrease in both the ARDS incidence of (3.2–1.6%) and mortality (72–45%) after pulmonary resection in a single institution cohort over a 10-year period. Their data have to be interpreted with caution, however, as the number of pneumonectomies was drastically higher in the historical cohort (17.4 versus 6.4%), which may explain the higher morbidity and mortality [12].

The etiology of lung injury is complex and likely multifactorial (Fig. 6.1). Historically, risk factors were felt to be right-sided surgery and large perioperative fluid loads. However, impaired lymphatic drainage, surgical technique, mechanical ventilation, transfusion, aspiration, infection, oxidative stress, and ischemia-reperfusion have all since been implicated (Table 6.1) [13]. The fact that ventilation may have detrimental effects in the critically ill patients in the form of ventilator-induced lung injury has long been recognized. Early animal studies demonstrated that high tidal volumes (45 mL/kg) are particularly injurious to the lung, irrespective of the applied pressure. This has led to the term "volutrauma" and the realization that end-inspiratory stretch plays a dominant role in lung injury [14]. In ARDS patients, application of protective lung ventilation (PLV) with smaller tidal volumes and high positive end-expiratory pressure (PEEP) improved survival [15]. Additionally, protective ventilation was shown to inhibit progression of lung injury compared to high tidal volume ventilation [14] and to inhibit the development of lung injury in ICU patients [16–19]. It is now generally accepted that mechanical ventilation by itself may induce lung injury even in the patient with healthy lungs [20]. In patients undergoing either non-thoracic or thoracic surgery, mechanical ventilation with high tidal volumes and low PEEP is associated with lung injury, increased postoperative morbidity (including prolonged hospital and critical care length of stay), and most importantly increased mortality [21]. The first large-scale multicenter randomized controlled trial to investigate this

principle occurred in 2013 in high-risk patients undergoing major abdominal surgery. Patients were randomized to a protective two-lung ventilation (TLV) strategy characterized by tidal volumes of 6–8 mL/kg, PEEP 6 to 8 cmH_2O, and frequent recruitment maneuvers or to a conventional strategy with tidal volumes of 10 mL/kg, no PEEP, and no recruitment maneuvers. Postoperative pulmonary complications occurred in 27% of the conventional ventilation group and in only 10% of the protective ventilation group [22]. Several studies have substantiated this report, and meta-analyses support the use of low tidal volumes (< 8 mL/kg during TLV) and some PEEP (greater than 3 cmH_2O) [23, 24]. It should be pointed out that low tidal volumes without adequate PEEP are harmful as evidenced by a greater incidence of hypoxemia, postoperative complications, and mortality [25]. Sufficient PEEP in addition to low tidal volumes is equally important in thoracic surgery and supported by an ever-increasing body of literature. In patients undergoing lobectomy, protective ventilation led to fewer postoperative pulmonary complications [26]. A retrospective analysis of over a thousand patients undergoing one-lung ventilation found that low tidal volume ventilation was protective but only when accompanied with adequate PEEP [27]. During

minimally invasive three-hole esophagectomy, a protective strategy reduced postoperative pulmonary complications [28]. Tidal volume reduction to 4–6 mL/kg for all patients undergoing one-lung ventilation with PEEP titrated to at least 5–10 cmH_2O should now be considered routine practice [29].

OLV predisposes the patient to ALI. Radiologic density changes in patients with ALI after thoracic surgery are more pronounced in the nonoperative, ventilated lung [30]. An increased duration of OLV was found to be an independent predictor of ALI in a retrospective analysis [8]. In animal models, OLV causes histological changes compatible with lung injury, including vascular congestion, diffuse alveolar wall thickening and damage, as well as a decrease in nitric oxide in the ventilated lung [31, 32]. Re-expansion of lung tissue after short-term OLV incites pro-inflammatory cytokine release in animals [33]. Similar cytokine elevations are found in patients undergoing thoracic surgery [34, 35]. Much of the early attention focused on the use of high tidal volumes during OLV. The analogy to ARDS has been drawn, as both involve ventilation of a so-called "baby lung" with reduced lung capacities [36]. Analogous to ARDS, high tidal volumes were therefore hypothesized to cause excessive end-inspiratory stretch during OLV.

Beyond ventilatory management, even anesthetic agents themselves appear to have the potential to modify the inflammatory response to OLV and surgery. De Conno et al. allocated adult patients undergoing lung resection surgery to propofol or sevoflurane anesthesia and found that the increase in inflammatory mediators during OLV was significantly less pronounced in the sevoflurane group. Composite adverse events were significantly higher in the propofol group, but the groups differed in OLV duration and the need for surgical re-exploration [37]. The possible benefit of inhalational anesthesia is not without merit, as volatile anesthetics have been shown to confer attenuating effects in a model of alveolar epithelial injury [38]. Inhalational anesthesia has been shown to minimize ischemia-reperfusion injury [39] and secondary glycocalyx breakdown [40, 41]. Significantly elevated levels of pro-inflammatory cytokine levels have been demonstrated in the alveolus of patients undergoing thoracic surgery under propofol anesthesia, when compared to patients done using inhalational anesthesia with sevoflurane or desflurane [42, 43], although no difference was demonstrated in circulating cytokine levels [43]. These studies indicate that anesthetic agents themselves may influence the pro-inflammatory response to OLV, but the true clinical relevance of that decrease remains to be established. This however illustrates the fact that the true answer to lung injury avoidance is more complex than simple tidal volume reduction.

Individual Ventilator Settings

Tidal Volume

Tidal volumes used during TLV (10–12 mL/kg) used to be maintained into the period of OLV [44, 45]. Large tidal volumes were recommended because they had been found to improve oxygenation and decrease shunt fraction, during both TLV [46] and OLV, irrespective of the level of PEEP applied [47]. Large tidal volumes were shown to provide end-inspiratory alveolar recruitment (Fig. 6.2), resulting in improved oxygenation in the setting of zero end-expiratory pressure (ZEEP). Excessive tidal volumes (e.g., 15 mL/kg), on the other hand, were shown to worsen oxygenation, secondary to elevations in pulmonary vascular resistance (PVR) resulting in increased shunt flow [48]. However, computed tomography images demonstrate gross overexpansion of the dependent lung during OLV in pigs when using tidal volumes of 10 ml/kg as compared to 5 ml/kg (Fig. 6.2). Based on the recent literature on patients with both healthy and injured lungs, it is clear that large tidal volumes during OLV expose the patient to undue risk of postoperative respiratory complications.

Two retrospective case series by Van de Werff and Licker identified multiple risk factors among more than 1000 patients undergoing lung resection surgery. Both studies demonstrated a significant association between high ventilating pressures and ALI but failed to provide a link to intraoperative tidal volumes [8, 50]. Fernández-Pérez et al., on the other hand, showed a significant association between larger intraoperative tidal volumes (8.3 vs. 6.7 mL/kg) and the development of postoperative respiratory failure in a single institution review of 170 pneumonectomies [51]. The study was criticized for the fact that ventilatory pressures were not analyzed; tidal volumes referred to the largest volume charted on the anesthetic record, with the assumption that they had been carried over to OLV; and patients that developed respiratory failure received a median of 2.2 liters of fluid intraoperatively [52]. However, the results were essentially duplicated in another single-institution review of 146 pneumonectomy patients. In that study, larger tidal volumes were independently associated with the development of ALI/ARDS (8.2 vs. 7.7 mL/kg) with an odds ratio (OR) of 3.37 per one mL/kg increase in tidal volume per predicted body weight (95% confidence interval 1.65–6.86). Peak airway pressure was an additional independent risk factor with an OR 2.32 per cmH_2O increase (95% confidence interval 1.46–3.67) [53].

One of the earliest trials of tidal volume reduction during OLV was an animal study published in 2003 [54]. Isolated rabbit lungs were subjected to OLV with either 8 mL/kg ZEEP or the "protective" 4 mL/kg – average PEEP 2.1 cmH_2O (based on the dynamic pressure-time curve). OLV was

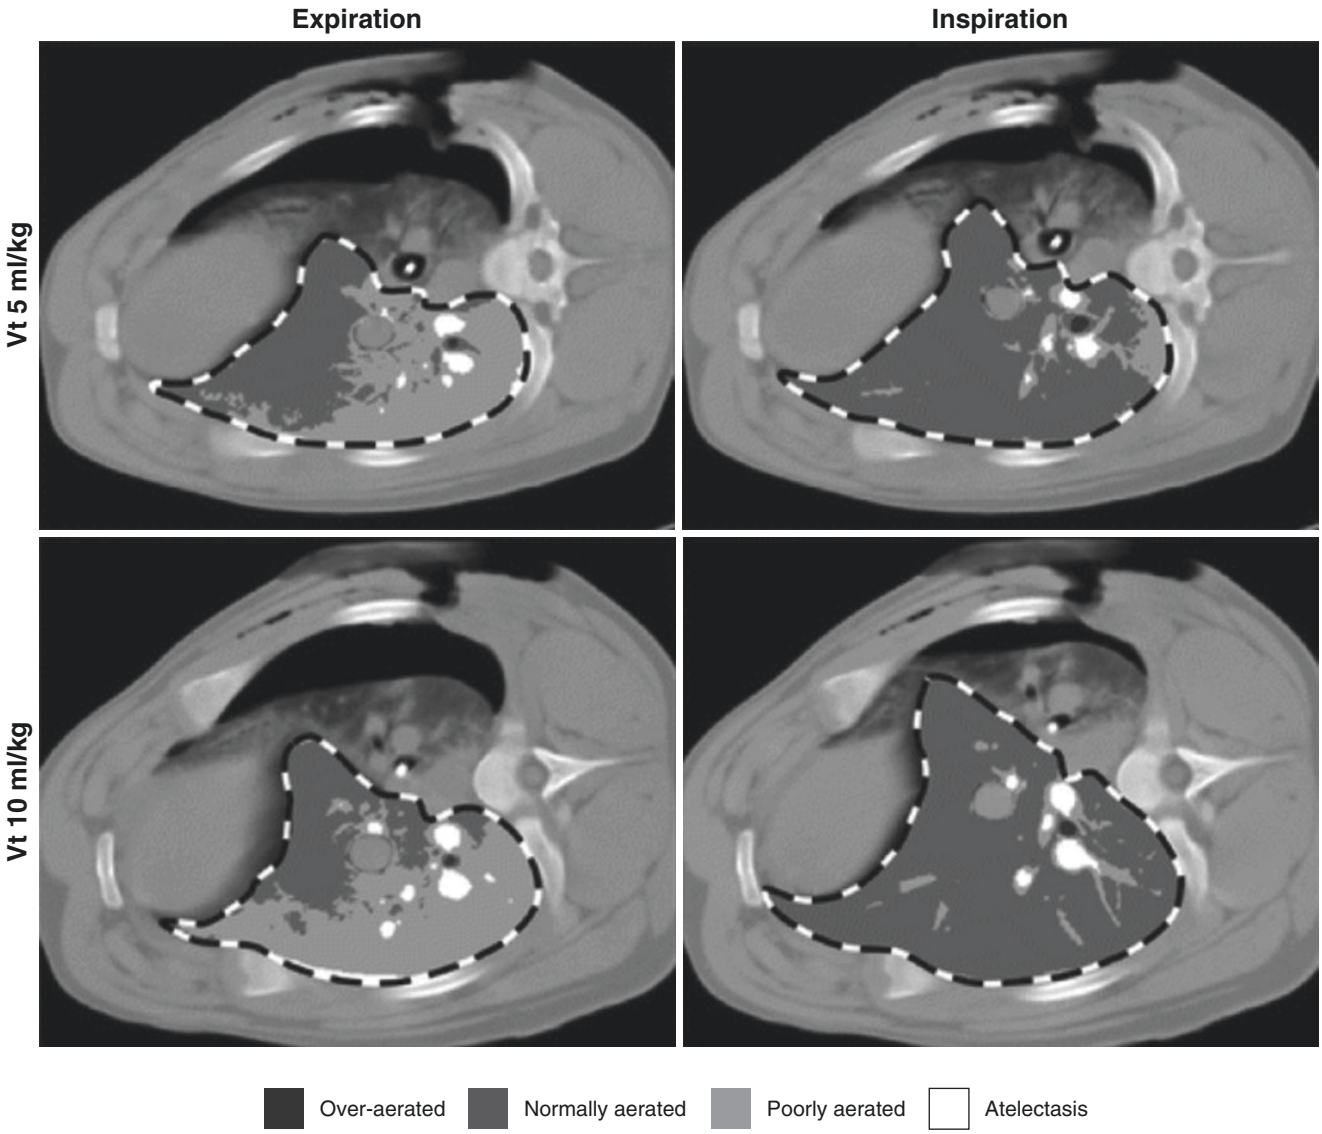

Fig. 6.2 Juxtadiaphragmatic lung computed tomographic scans of pigs during one-lung ventilation (OLV) with a tidal volume of 5 or 10 ml/kg. In each image, the region of interest includes the following (Hounsfield units in parentheses): over-aerated (from −1000 to −900), normally aerated (from −900 to −500), poorly aerated (from −500 to −100), and atelectatic (from −100 to 100) lung areas. The regions are coded by gray scale. The dependent lung border is outlined by the dashed line. Note the marked lung heterogeneity at end-expiration and the marked hyperinflation at end-inspiration with 10 ml/kg tidal volume. (Reprinted from Kozian et al. [49] with permission)

associated with increases in multiple surrogate markers of lung injury (pulmonary artery pressure [PAP], lung weight gain [LWG], and TXB_2 cytokine levels), which occurred to a lesser degree in the protective ventilation group. The protective ventilation group, however, only received half the minute ventilation of the control group, as no compensatory increase in respiratory rate was used in the low tidal volume group. Based on the study design, it was therefore not possible to state whether the outcome benefit was due to any one, or all, of minute ventilation reduction, tidal volume reduction, and/or application of external PEEP [54]. Kuzkov et al. showed that when comparing equal minute ventilation in anesthetized sheep undergoing pneumonectomies, protective ventilation with 6 mL/kg PEEP 2 cmH_2O lowered extravascular lung water (EVLW, a surrogate for lung injury), compared to 12 mL/kg ZEEP [55]. This finding has recently been refined in a trial demonstrating increases in EVLW when using tidal volumes of 6 or 8 ml/kg during OLV, while EVLW actually decreased when using tidal volumes of 4 ml/kg (Fig. 6.3) [56]. Tidal volume reduction by itself, however, is unlikely to be sufficient to improve outcomes. This point was best illustrated by an animal study comparing low versus high tidal volume ventilation with or without PEEP in ALI. While animals with high tidal volume ventilation and ZEEP clearly had significant cytokine elevations, all animals exposed to low tidal volumes and ZEEP died during the experiment [57].

(Reproduced from Qutub [56] with permission)

Due to the infrequent occurrence of lung injury, prospective clinical studies have focused on cytokine levels as a surrogate marker for potentially harmful ventilation. Cytokine elevations are part of the disease process, as levels of IL-6, IL-8, sICAM-1, and vWF are elevated even prior to intubation in patients with ALI [58] and baseline plasma levels of IL-6, IL-8, and IL-10 are associated with an increased risk of death in patients with ARDS [59]. Wrigge et al. failed to demonstrate a difference in tracheal cytokine levels between patients ventilated with 12–15 mL/kg ZEEP or 6 mL/kg PEEP 10 cmH_2O during TLV and OLV for laparotomy or thoracotomy. Cytokine levels before, during, and after OLV were no different between the groups [60]. However, tracheal aspirates may not be sensitive enough to detect early alveolar damage. Michelet randomized 52 patients with normal lung functions undergoing esophagectomy to OLV 9 mL/kg ZEEP or 5 mL/kg PEEP 5 cmH_2O. In this study, serum cytokine levels (IL-1, IL-6, IL-8) increased perioperatively, but to a lesser degree in the protective ventilation group [35]. The degree of lung injury and cytokine elevation may have been exaggerated by the fact that despite an average of 6 h of mechanical ventilation and 8 liters of fluid, only the low tidal volume group received PEEP during OLV, and no patient received PEEP during the remainder of the operation [35]. Esophageal surgery may also present a higher risk for lung injury as it is associated with cytokine elevations secondary to intestinal ischemia, potentially acting as a first hit [61]. The most compelling experimental evidence that tidal volumes per se are linked to the etiology of ALI after lung surgery comes from a randomized trial, which investigated 32 patients scheduled for OLV and thoracotomy. Patients received OLV with 10 or 5 mL/kg, both without PEEP but identical minute ventilation. While OLV increased cytokine levels (TNF-α, sICAM-1) in both groups, levels were lower in the low tidal volume ventilation group [34].

More important than cytokine elevations, clinically significant outcomes of ALI, ICU admission, and hospital stay were shown to be reduced in a cohort analysis of patients who routinely received PLV (2003–2008), as compared to historical controls (1998–2003) [4]. While historical controls are fraught with limitations due to concomitant developments and improvements in medical care, this analysis by Licker et al. showed a dramatic reduction in adverse postoperative respiratory outcomes after the routine implementation of a PLV strategy. The ventilation strategy consisted of an open lung concept, with tidal volumes <8 mL/kg, routine PEEP, pressure-control ventilation (PCV), and frequent recruitment maneuvers. The statistically averaged ventilation parameters among the 558 patients in their protective ventilation group consisted of a tidal volume of 5.3 mL/kg (standard deviation [SD] 1.1), plateau pressure of 15 cmH_2O (SD 6), PEEP of 6.2 cmH_2O (SD 2.4), and respiratory rate of 15 bpm (SD 2). While the historical control already had a mean tidal volume of 7.1 mL/kg, only 24% of patients received tidal volumes less than 8 mL/kg, compared to the 92% compliance with low tidal volumes in the PLV cohort. As mentioned above, historical comparisons of ICU admission and length of hospitalization are difficult to interpret as criteria change, and moves toward fast-tracking of patients are established. However, the definition of ALI was consistent during the study period, and the authors were able to show a significant reduction in ALI from 3.8% to 0.9% [62].

While the benefits of protective ventilation for lung injury prevention are becoming clearer, its impact on oxygenation is uncertain. Two studies that investigated PLV (lower tidal volume and PEEP) during OLV reported improved oxygenation and shunt fraction as compared to traditional high tidal volume OLV [35, 55]. However, with inadequate or no PEEP, low tidal volume ventilation may be associated with worse shunt and oxygenation [34]. Recruitment studies performed during protective OLV have shown that despite a PEEP of 8 cmH_2O, patient ventilated with a tidal volume of 6 mL/kg showed significant recruitability of the ventilated lung, suggesting relative hypoventilation and atelectasis formation (see expiratory images in Fig. 6.2). Despite the presence of atelectatic lung prior to the recruitment maneuver, however, oxygenation was adequate in all patients [63]. Postoperative arterial oxygenation was not affected in a historical cohort analysis of patients undergoing lung cancer surgery with a PLV protocol incorporating lower tidal volumes [62].

Additional tools are emerging to support the clinician in the appropriate selection of tidal volume during one-lung

ventilation. Hoftman and colleagues demonstrated that forced vital capacity (FVC) may be a better predictor of ideal tidal volume during thoracic surgery than predicted body weight. FVC below 3.5 liters was found to be a good predictor of reduced lung compliance, and adjustment for preoperative FVC (VT = FRC/8) allowed for more appropriate one-lung tidal volume selection [64].

PEEP

Positive-end expiratory pressure minimizes alveolar collapse and atelectasis formation by providing resistance to airway collapse during exhalation. Applied PEEP should therefore be routine for all ventilated patients during TLV [65]. Klingstedt et al. demonstrated that the mediastinal weight results in significant compression of the dependent lung in the lateral position during TLV, which can be resolved with the application of selective PEEP to the dependent lung [66]. Due to the relative position of the heart in the left hemithorax, mediastinal shift and dependent lung compression are more marked in the left lateral position than the right lateral position (Fig. 6.4) [67].

PEEP does attenuate lung injury, both in the setting of high and low tidal volumes [13]. Intrinsic or auto-PEEP occurs if expiratory time is too short to allow lung units to empty toward their resting volume. Lung areas with high compliance, characteristically found in patients with emphysema, are particularly prone due to their poor elastic recoil. Auto-PEEP is inhomogeneous throughout the lung and can therefore not be relied upon for effective avoidance of derecruitment [68]. The total PEEP after application of external PEEP is also unpredictable, due to the heterogeneous nature of auto-PEEP [69].

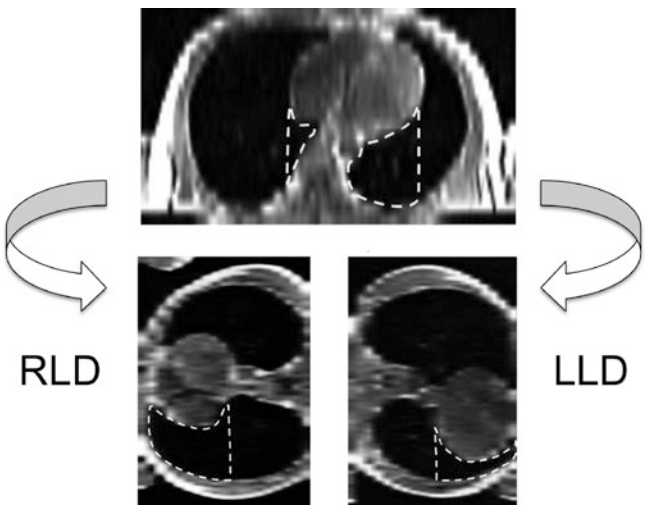

Fig. 6.4 Mediastinal shift as imaged with magnetic resonance images. Hashed areas indicate compressed areas of the lung. Note that while right lateral decubitus does expose more lung area to compression, the compression is more severe in left lateral decubitus. (Modified from an open access article by Mase et al. [67])

Endotracheal intubation prevents glottic closure, resulting in complete absence of auto-PEEP in patients without obstructive lung disease on TLV. However, initiation of OLV with 10 mL/kg ZEEP has been shown to create auto-PEEP and air trapping. Measured auto-PEEP was minimal in patients without obstructive lung disease, but patients with severe COPD developed auto-PEEP levels up to 16 cmH_2O, which was associated with air trapping of 284 mL [68]. These values are unlikely to be reflective of the amount of auto-PEEP that develops with one-lung tidal volumes of 4–5 ml/kg. Patients with preexisting auto-PEEP have an unpredictable response to the application of extrinsic PEEP. In a study of ICU patients on TLV, application of PEEP changed total PEEP up, down, or not at all [70]. In a small study of patients during OLV, the additive effect of applied PEEP to auto-PEEP was inversely related to the preexisting auto-PEEP level. In other words, extrinsic PEEP contributed less to total PEEP in patients with already high auto-PEEP than patients with low auto-PEEP; however, the extent of the response was not predictable [69]. Excessive total PEEP and dynamic hyperinflation are clearly undesirable as they may cause cardiovascular depression and may require fluid loading and/or inotropic support [71].

Traditionally OLV has been performed with ZEEP, with selective application of PEEP to the nonoperative lung as part of a hypoxemia treatment algorithm. The effect of PEEP on oxygenation during OLV is variable. It is beneficial in patients whose intrinsic PEEP is well below the lower inflection point (LIP) of the compliance curve, more commonly the patient with normal lung function. In that scenario application of external PEEP will increase the total PEEP toward the LIP of the pressure-volume curve, resulting in more open (recruited) lung and improved oxygenation. Oxygenation is worse, however, if total PEEP is increased well above the LIP, likely due to alveolar overdistension, and increases in PVR resulting in an increased shunt fraction (Fig. 6.5) [72]. Neither intrinsic PEEP nor the compliance curve is routinely or easily acquired during thoracic surgery, which is why preoperative prediction of PEEP responders would be ideal. Valenza et al. showed that patients with relatively normal lung function (FEV_1 > 72%) exhibited improved oxygenation on application of PEEP 10 cmH_2O during OLV [73].

Whether applied PEEP is able to decrease ALI after OLV is unclear, as it has not been studied in isolation. PEEP application as part of a "protective" ventilation regime has been shown to decrease surrogate markers of lung injury [35, 54, 55]. Additionally, routine PEEP in patients with or without COPD as part of a PLV strategy was shown to be associated with a significant decrease in the incidence of ALI and atelectasis after OLV [62].

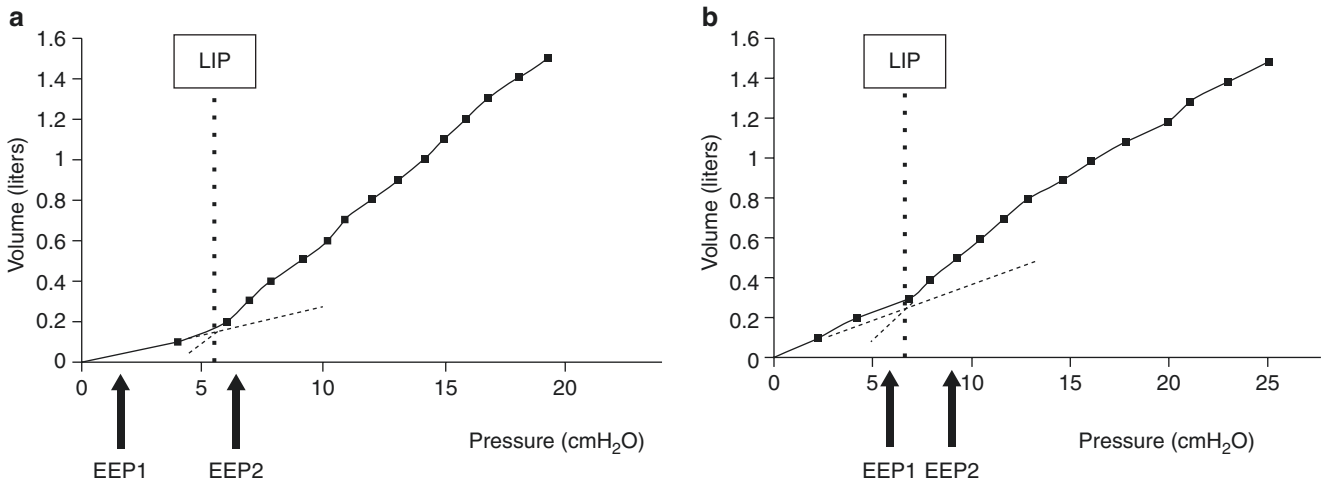

Fig. 6.5 Effect of applied PEEP on total PEEP and oxygenation during OLV. Static compliance curves of patients undergoing OLV. End-expiratory pressure before (EEP1) and after application of 5 cmH2O PEEP (EEP2) as well as lower inflection points (LIP) are indicated. Patients with normal pulmonary function and low EEP1 (**a**), in whom EEP2 moved closer to LIP, were more likely to show oxygenation benefits after PEEP application than patients with poor lung function and intrinsic PEEP (**b**). See text for details. (Modified from Slinger et al. with permission [72])

Use of "protective" OLV with low tidal volumes but no PEEP does not appear sensible, as de-recruitment is harmful and auto-PEEP unreliable in terms of homogeneous lung recruitment. Additionally, due to the compression by abdominal contents and the mediastinal structures, marked de-recruitment and lung heterogeneity is present in the dependent lung at end-expiration (Fig. 6.2). Lack of PEEP in the setting of low tidal volume OLV has been shown to worsen oxygenation [34]. Low levels of PEEP are safe, likely beneficial for lung injury avoidance, and should be used in all patients. The only true contraindication to PEEP application would be the presence of a bronchopleural fistula. PEEP levels, however, need to be adjusted to the individual and their respiratory mechanics. Patients with normal lung function or restrictive lung disease should benefit from, and will tolerate, 5–10 cmH_2O PEEP or more. Patients with severe obstructive lung disease, as evidenced by preoperative hyperinflation (RV/TLC > > 140%), exhibit significant air trapping during OLV, but as previously stated may not exhibit a significant increase in total PEEP with the application of external PEEP. Low levels of extrinsic PEEP 2–5 cmH_2O are likely well tolerated and should routinely be applied. Clearly dynamic hyperinflation must be considered in the differential for intraoperative hypotensive episodes in patients at risk. However, based on the static compliance analysis by Licker et al., who used routine PEEP in all patients as part of their PLV strategy, hyperinflation (and secondary decrease in static compliance) does not appear to be a significant concern, as the compliance actually increased in their cohort exposed to PLV with routine PEEP [62]. Early, routine application of PEEP helps to prevent atelectasis and shunt formation and thereby improves oxygenation during OLV [74].

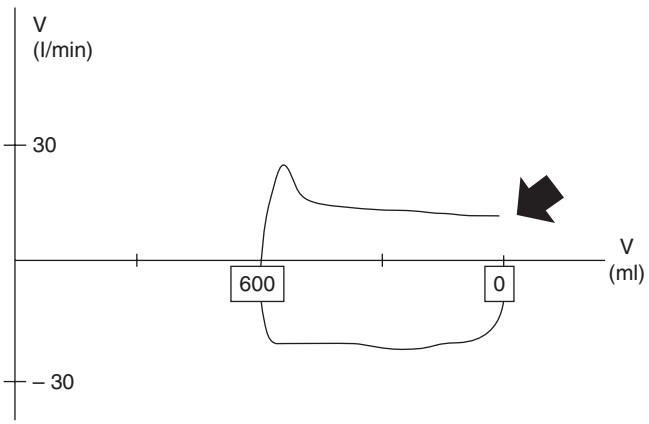

Fig. 6.6 Auto-PEEP detection by in-line spirometry. Flow-volume curve with expiration above and inspiration below the line. Expiratory flow normally returns to zero prior to inspiration. Interrupted airflow at end-expiration (arrow) indicates the presence of auto-PEEP. (Modified from Bardoczky et al. [75] with permission)

Clearly it would be best to measure total PEEP for each patient in order to rationally apply external PEEP [69]. This, however, is difficult or impossible in most intraoperative settings due to the inability of anesthetic ventilators to perform an end-expiratory hold maneuver. The simplest approximation of intrinsic PEEP can be derived from inline spirometry where interruptions of the end-expiratory flow curve indicate the presence of auto-PEEP (Fig. 6.6) [75]. Alternatively, compliance can be approximated by simple calculation (compliance = tidal volume/driving pressure), which may serve as an indicator of potential air-trapping, realizing that hyperinflation is only one of the possible explanations for a decrease in compliance.

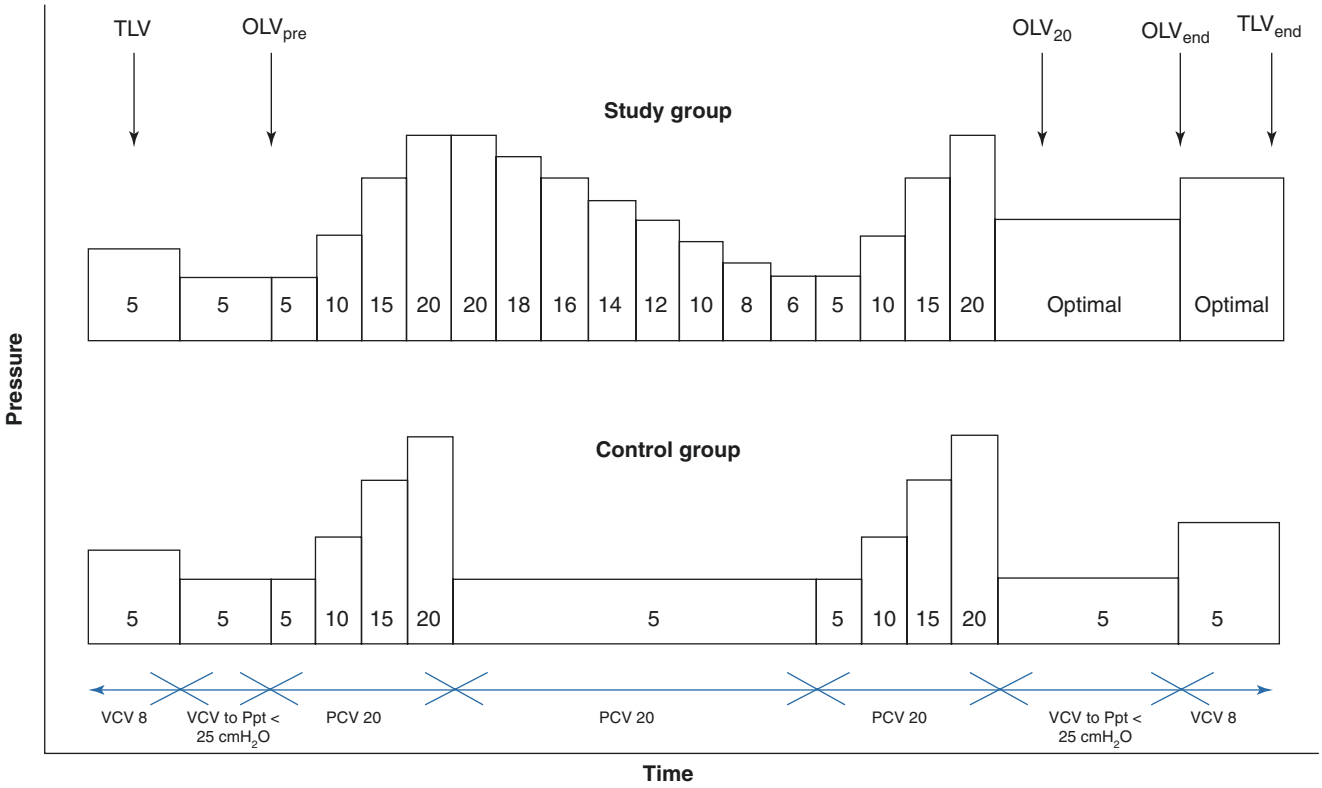

Fig. 6.7 PEEP titration during OLV after formal lung recruitment. In the study arm, optimal PEEP was determined by a stepwise decrement trial toward the point of optimal lung compliance. The control arm patients received a standard PEEP of 5 cmH2O. Individualized PEEP was higher than routinely used (10 ± 2 cmH2O) and resulted in better oxygenation both during and after OLV. (Reproduced from Ferrando et al. with permission [78])

It is possible to find the optimal level of PEEP for each individual patient during both one- and two-lung ventilation [76]. Static or dynamic lung compliance as calculated from the ventilator is influenced by FRC and the recruitable lung volume [76]. As the lung is recruited and FRC improves, so do PaO_2, dead space, and lung compliance. Lung compliance is therefore a reliable surrogate of FRC during general anesthesia. A PEEP titration study utilizing a PEEP decrement trial whereby PEEP is titrated to the best compliance following a recruitment maneuver is a reliable method to determine adequate PEEP [77] and tends to result in higher levels of PEEP than traditionally selected (Fig. 6.7) [78].

FiO_2

One hundred percent oxygen used to be a routine component of OLV, as hypoxemia was its most feared complication. However, with the decline in the incidence of hypoxemia and the realization that high FiO_2 may be detrimental, even this practice has been questioned. Oxygen toxicity is a well-recognized consequence of prolonged exposure to high FiO_2, characterized by histopathologic changes similar to ALI. Oxygen toxicity occurs during OLV and involves ischemia-reperfusion injury and oxidative stress [13]. Collapse of the operative lung and surgical manipulation results in relative organ ischemia, and reperfusion at the time of lung expansion leads to the production of radical oxygen species. Increasing durations of OLV and the presence of tumor result in increased markers of oxidative stress, which after 120 min are associated with significant increases in the rates of respiratory failure and death [79]. Lung re-expansion should likely occur at a lower FiO_2, as hypoxemic reperfusion has been shown to attenuate the reperfusion syndrome [80]. This is of particular relevance after lung transplantation. Even short-term exposure to high FiO_2 during the induction of anesthesia has been shown to cause significant absorption atelectasis [81]. Studies have shown that an FiO_2 as low as 0.4 may provide adequate oxygenation for OLV in the lateral decubitus position [82]. Due to the potential for lung injury, particularly in the high-risk patient, after adjuvant therapy or undergoing lung transplantation, FiO_2 should be titrated to effect. At the initiation of OLV, a FiO_2 of 0.8 may be appropriate, but 15–20 min later, when the nadir of oxygenation has occurred, the FiO_2 should be gradually decreased to the minimum that is required to maintain a stable saturation level above 90–92%. During lung resection surgery, further reductions in FiO_2 are possible once the vasculature to the resected

lobe or lung has been disrupted. Stapling of the vasculature effectively reduces, or, in the setting of a pneumonectomy, essentially eliminates the shunt flow.

The oxygen content and gas mixture are not only important for oxygenation but also for the speed of nonventilated lung collapse during OLV. This is of particular importance for surgical exposure during video-assisted thoracoscopic surgery (VATS). Ko et al. compared three different gas mixtures during TLV immediately prior to OLV (air/O_2, N_2O/O_2, O_2) and investigated which gas mixture would best collapse the operative lung while maintaining arterial oxygenation in patients undergoing lung resection surgery [83]. FiO_2 was 0.4 in the air/O_2 and N_2O/O_2 group and 1.0 in the O_2 group during TLV. All groups received 100% oxygen on initiation of OLV. Not surprisingly, lung deflation was worse if nitrogen (i.e., air) was administered prior to lung collapse, due to the poor solubility of nitrogen in blood. A nitrous oxide/O_2 mixture was superior to oxygen alone for lung collapse, but nitrous oxide is rarely used nowadays. Administering 100% oxygen pre-OLV temporarily improved OLV oxygenation but only until the nonventilated lung becomes atelectatic. Once the operative lung has collapsed at around 15 min of OLV, that oxygen reservoir and any benefit from it have disappeared [83].

While 100% oxygen facilitates collapse of the operative lung, it also facilitates the development of de-recruitment and atelectasis in the nonoperative lung, producing shunt and facilitating hypoxemia. The greater the FiO_2 following endotracheal intubation, the larger the degree of atelectasis is seen on computed tomography [84]. While no prospective studies have evaluated the impact of lower than 100% oxygen prior to lung collapse, the individual practitioner should weigh the risks and benefits of lower FiO_2 and consider using the lowest inspired oxygen necessary to maintain acceptable arterial oxygenation.

Minute Ventilation/Permissive Hypercapnia

Permissive hypercapnia has been a key component of the critical care management for ALI/ARDS. Reduction of the minute ventilation allows for a decrease in tidal volumes and ventilatory pressures, thereby minimizing mechanical stress and secondary volu- or barotrauma. Beyond the reduction in minute ventilation and mechanical trauma, the actual elevated CO_2 level itself may be beneficial [85], as hypercapnia appears to attenuate the cytokine response [86].

Permissive hypercapnia has been investigated in the OLV setting. In the previously mentioned study by Gama de Abreu et al., isolated rabbit lungs were exposed to OLV with 8 mL/kg ZEEP or 4 mL/kg PEEP 2.1 cmH_2O (based on the dynamic pressure-time curve), without respiratory rate compensation. The protective ventilation group, which received half the minute ventilation, exhibited a reduction in surrogate markers for lung injury (PAP, LWG, cytokine levels) [54]. Similar ventilatory parameters were studied during OLV in thoracotomy patients. Sticher et al. ventilated patients with 7 mL/kg PEEP 2 cmH_2O or 3.5 mL/kg PEEP 2 cmH_2O, again without respiratory rate compensation, effectively halving minute ventilation similar to Gama de Abreu. $PaCO_2$ values rose from 42 to 64 mmHg, which was associated with a 42% increase in PVR, but no change in oxygenation. Hypercapnia was well tolerated; however, higher-risk patients with pulmonary hypertension or major cardiac rhythm disturbances were excluded [87]. In a case series of 24 patients undergoing volume reduction surgery for advanced emphysema, permissive hypercapnia was used electively as part of a barotrauma avoidance strategy. The mean $PaCO_2$ value was 56 mmHg with a peak of 86 mmHg, resulting in pH values between 7.11 and 7.41 (mean 7.29). The authors state that hypercapnia was well tolerated; however, inotropic support was required in over 50% of patients [88]. Even higher $PaCO_2$ levels have been described in a small series of ten patients with severe emphysema that were again managed with elective hypoventilation for barotrauma avoidance. $PaCO_2$ values rose to peak levels of 70–135 mmHg, resulting in pH values as low as 7.03 (despite bicarbonate administration). Hypercapnia was poorly tolerated at these high levels. All patients required inotropic support during anesthesia. Four patients developed ventricular dysrhythmias and three patients required tracheal gas insufflation for treatment of hypoxemia [89]. Significant hypercapnia can cause increased intracranial pressure, pulmonary hypertension, decreased myocardial contractility, decreased renal blood flow, and release of endogenous catecholamines. At extremely high levels, CO_2 can be lethal due to excessive sympathetic stimulation, cardiac rhythm disturbances, and/or cardiac collapse [71, 89]. Moderate hypercapnia potentiates the HPV response and is therefore unlikely to adversely affect oxygenation [90]; however, the same may not hold true for extreme CO_2 elevations [89]. A protective ventilation strategy including permissive hypercapnia has been shown to reduce the incidence of ALI in a cohort analysis by Licker et al. [62]. While not explicitly discussed in the manuscript, permissive hypercapnia clearly was part of their strategy. The PLV group had significantly lower tidal volumes with only marginal rate compensation. Based on the manuscript, the minute ventilation of the historical cohort was 92 vs. 80 mL/kg/min in the PLV group. The PLV group therefore had smaller minute ventilation and increased anatomic dead space ventilation (increased respiratory rate), resulting in decreased CO_2 elimination [62]. Permissive hypercapnia should be considered a routine component of a PLV strategy for OLV. Assuming a reasonable cardiovascular reserve, and in particular right ventricular function, $PaCO_2$ levels

<70 mmHg are well tolerated in the short term and clearly beneficial in terms of lung injury avoidance and attenuation. Higher levels should be avoided in the majority of patients due to the risk of hemodynamic instability.

I:E Ratio and Respiratory Rate

Each ventilatory cycle consists of time spent in inspiration and expiration. The appropriate ratio of inspiratory to expiratory (I:E) time depends on underlying lung mechanics. Restrictive lung disease is characterized by poorly compliant lungs, which resist passive lung expansion but rapidly recoil to FRC. Increasing the I:E ratio to 1:1 (or using inverse ratio ventilation) maximizes the time spent in inspiration, thereby reducing peak and plateau ventilatory pressures. For illustration, at a respiratory rate of 15 bpm and an I:E ratio of 1:1, each respiratory cycle lasts 4 s, with 2 s spent in each of inspiration and expiration, respectively. Obstructive lung disease, on the other hand, is characterized by lungs, which have difficulty to empty toward FRC, due to poor elastic recoil and conducting airway collapse. Decreasing the I:E ratio toward 1:4 allows for more expiratory time and helps to minimize the risk of auto-PEEP and dynamic hyperinflation. For illustration, at a respiratory rate of 15 bpm, now with the I:E ratio to 1:4, each respiratory cycle is still 4 s; however, expiration now takes up 3.2 s of the entire cycle.

Respiratory rate modification may be equally necessary depending on the underlying lung mechanics. Extreme airflow obstruction may require very long expiratory times. After reducing the I:E ratio to the minimum of 1:4, this can only be achieved by increasing the overall cycle length, i.e., reducing the respiratory rate. Clinical examples, such as the patient with severe cystic fibrosis requiring a respiratory rate of 4–6 to allow for complete exhalation have been reported [91]. In restrictive lung disease, on the other hand, dividing a given minute volume by a higher respiratory frequency may be beneficial in reducing peak and plateau ventilatory pressures. It has to be realized, however, that as anatomic dead space remains unchanged, dividing the minute volume by a higher respiratory rate results in reduced CO_2 elimination as the unchanged size of the anatomic dead space makes up a larger component of the tidal volume [92]. For illustration, a patient ventilated at 20 bpm of 400 ml receives the same minute ventilation as a patient ventilated at 10 bpm of 800 ml. However, dead space ventilation, which occupies about 150 mL of each breath, has doubled from 1500 mL at 10 bpm to 3000 mL at 20 bpm. Alveolar ventilation has therefore been reduced from 6500 mL (8000–1500) to 5000 mL (8000–3000). Additionally, OLV with small tidal volume and rapid respiratory rate results in statistically higher auto-PEEP [65]. While auto-PEEP elevations in this study were unlikely to be clinically significant, they serve as a reminder that rapid, shallow ventilation has the potential to increase dynamic hyperinflation.

Peak/Plateau Pressure

The peak inspiratory pressure is a reflection of the dynamic compliance of the respiratory system and airway resistance. It depends on tidal volume, inspiratory time, endotracheal size, and airway tone (bronchospasm). Plateau pressure, on the other hand, relates to the static compliance of the respiratory system, i.e., chest wall and lung compliance. Double-lumen endobronchial tubes have small internal diameters resulting in increased resistance to air flow [93]. Application of the full TLV minute volume to a single lumen of the double lumen tube (DLT) results in a 55% increase in peak inspiratory pressure and 42% increase in plateau pressure [92]. While plateau pressure reflects alveolar pressure, peak pressure is unlikely to be fully applied to the alveolus. A retrospective study of 197 pneumonectomy patients did, however, show that peak ventilation pressures above 40 cmH_2O were associated with the development of PPPE [50]. Recently, Fernández-Pérez et al. reviewed 4420 consecutive patients without preexisting lung injury undergoing high-risk elective surgeries for postoperative pulmonary complications and demonstrated that mean first hour airway pressure (OR 1.07; 95% CI 1.02–1.15 cmH_2O) but not tidal volume, PEEP, or FiO_2 were associated with ALI after adjusting for nonventilatory parameters [94]. Similarly, patients exposed to a plateau pressure of 29 cmH_2O were at significantly higher risk of developing ALI after lung resection surgery than those with a plateau pressure of 14 cmH_2O [7]. Based on the critical care literature, there does not appear to be a critical plateau pressure level above which injury occurs, but rather any elevation in plateau pressure increases the relative risk of lung injury. With the implementation of permissive hypoventilation, peak pressure levels less than 35 cmH_2O and plateau pressures less than 25 cmH_2O should therefore be achievable in the majority of patients during OLV. This was confirmed in the cohort study by Licker et al. who showed that implementation of a PLV strategy for OLV resulted in mean plateau pressures of 15 cmH_2O [62].

Driving Pressure

One of the primary mechanisms driving ventilator-induced lung injury (VILI) is excessive stress and strain on lung parenchyma during inspiration. Transpulmonary pressure is calculated as plateau pressure minus pleural pressure and is a surrogate of both lung stress and strain [95]. Calculating transpulmonary pressure requires a plateau

pressure measurement. Plateau pressure can be measured on most present-day anesthetic machines by simply setting an inspiratory hold of at least 40% of the delivery time during a square wave flow delivery (volume control ventilation) [96]. Driving pressure is calculated as the plateau pressure minus the PEEP and frequently and closely approximates transpulmonary pressure when PEEP equals pleural pressure [95]. Driving pressure is a surrogate of lung stress and strain and should be kept as low as possible and ideally below 13 cmH_2O [97] as higher levels are associated with excessive lung stress [95]. Driving pressure is now considered an important independent predictor of mortality in ARDS and more influential than tidal volume or plateau pressure. In fact, any ventilator maneuver (PEEP titration, tidal volume titration) that reduces driving pressure also reduces mortality in patients with ARDS [97]. Driving pressure is also an important marker of postoperative pulmonary complications in patients with healthy lungs in the operating room. An analysis of individual patient data from several randomized controlled trials demonstrated that an increase in driving pressure resulted in a greater incidence of postoperative pulmonary complications [98]. Importantly, any change in PEEP (increase or decrease) that resulted in a lower driving pressure translated to a lower incidence of postoperative pulmonary complications. To date, a similar analysis has not been reported in patients undergoing one-lung ventilation; however Blank and colleagues found an association between driving pressure and postoperative pulmonary complications in their retrospective analysis [27].

Ventilatory Mode

Volume-control ventilation (VCV) has been the predominant ventilatory mode both in the intensive care and operating room. VCV uses a constant inspired flow (square wave), creating a progressive increase in airway pressure toward the peak inspiratory pressure, which is reached as the full tidal volume has been delivered. Inspiratory pressure during VCV depends on the set tidal volume and PEEP, gas flow rates and resistance, as well as respiratory system compliance. The set tidal volume will be delivered unless the inspiratory pressure exceeds the pressure limit, in which case the flow ceases. With the realization that ventilatory pressures may be one of the inciting factors of lung injury, other ventilatory modes have been explored.

Pressure-control ventilation (PCV) uses a decelerating flow pattern, with maximal flow at the beginning of inspiration until the set pressure is reached, after which flow rapidly decreases balancing the decreasing compliance of the expanding lung. This resembles the spontaneous mammalian breath, which also follows a decelerating pattern, as negative intrathoracic pressure induced by contracting diaphragm and intercostal muscles cause a high initial airflow [65]. Tidal volumes can be highly variable during PCV and may fall precipitously with changes in lung compliance, particularly with surgical manipulation. As the majority of the tidal volume is delivered in the early part of the inspiration, mean airway and alveolar pressure tend to be higher during PCV. The decelerating flow pattern results in a more homogeneous distribution of the tidal volume, improving static and dynamic lung compliance due to recruitment of poorly ventilated lung regions and improving oxygenation and dead space ventilation [99]. Whether PCV during OLV improves oxygenation is controversial. Tuğrul et al. studied 48 patients undergoing thoracotomy and lung resection. Patients received VCV or PCV during OLV, both delivering 10 mL/kg ZEEP 100% O_2, in a crossover fashion. PCV was associated with statistically significant decreases in peak and plateau airway pressures, as well as improved oxygenation and shunt fraction. Oxygenation improved more in patients with poor preoperative lung function, which may relate to the more homogeneous distribution of ventilation achieved with the pressure-control breath [100]. The same group investigated the benefit of adding PEEP 4 cmH_2O to OLV with PCV and showed that it provided an additional significant improvement in oxygenation and shunt fraction in their patients [101]. Other groups, however, have failed to reproduce the oxygenation benefit in PCV studies during OLV [102–104].

The effect of intraoperative ventilatory mode on postoperative oxygenation is equally controversial. Although a better postoperative oxygenation was shown in the PCV group compared with VCV in a trial of patients undergoing MIDCAB surgery [105], no significant difference was demonstrated in a study of patients after thoracic surgery [106]. Despite the lack of a clear oxygenation benefit, PCV is likely preferable over VCV due to the potential to decrease ventilatory pressures and the ability to recruit lung units.

High-frequency jet ventilation (HFJV) is another ventilatory mode that has been successfully used in thoracic surgery [107]. HFJV, when applied to the operative lung during prolonged OLV in aortic surgery, is more effective than continuous positive airway pressure (CPAP) in improving PaO_2 [108]. This may be particularly relevant in the poor operative candidate after prior contralateral lung resection [109, 110]. Misiolek et al. evaluated the value of two-lung HFJV via a standard endotracheal tube for thoracic surgery. Sixty patients were randomized to HFJV (1 atm pressure, rate 200/min, 100% O_2) or standard OLV (10 mL/kg, 100% O_2, ZEEP). HFJV was associated with lower ventilating pressures, improved oxygenation, and shunt fraction and importantly no detriment in surgical exposure or intraoperative hemodynamic variables [111]. Buise et al. reported that HFJV was associated with a lower mean blood loss and less

crystalloids administration during esophagectomy, compared with the OLV group. They speculated that higher ventilatory pressures in the OLV group resulted in higher intrathoracic pressure and central venous pressure, and thus splanchnic congestion, which increased blood loss relative to the HFJV group [112]. Difficulties in monitoring ventilatory pressures, tidal volumes, and end-tidal CO_2 concentrations, in addition to the inherent risks of barotrauma associated with this technique, continue to limit its widespread adoption [107].

Another ventilatory mode, which has only been used as a CPAP equivalent at this point, is high-frequency percussive ventilation (HFPV). It is a ventilatory technique providing convective and diffusive ventilation that can reduce the physiologic right-to-left shunt and improve arterial oxygenation [113–115]. Lucangelo et al. assessed the effects of HFPV (FiO_2 1.0, 500 cycles/min, mean pressure 5 cmH_2O, with pressures oscillating between 2 and 8 cmH_2O) applied to the nondependent lung compared to standard CPAP in patients undergoing elective lung resection. HFPV patients showed higher PaO_2 during OLV than CPAP and exhibited better clearance of secretions and shortened hospital stays [116].

Recruitment/Re-expansion

Atelectasis has long been known to occur in dependent lung areas of anesthetized patients. The primary reasons for alveolar collapse during anesthesia are extrinsic compression and gas resorption. Studies have shown that atelectatic alveoli are not simply airless, but may also be fluid- or foam-filled. Beyond simple lung collapse, atelectasis is therefore now considered both a potential cause and a manifestation of ALI [81]. Interestingly, re-expansion of collapsed alveoli causes injury not only to the alveoli that are being recruited but also to remote nonatelectatic alveoli [81]. This may be in part due to the early realization by Mead that expansion of a gas-free alveolus with a transpulmonary pressure of 30 cmH_2O creates a shear force of 140 cmH_2O to adjacent alveoli [14, 117]. PEEP has been shown to prevent lung injury associated with both high and low tidal volumes, by stabilizing alveoli and preventing their collapse [81]. In animal models of ARDS, it has been shown that atelectasis is associated with vascular leak, right ventricular failure, and eventual death in 31% of rats and is easily avoided with PEEP [118].

Atelectasis formation in the nonoperative lung is highly undesirable during OLV as it worsens the already high shunt fraction, increasing the potential for hypoxemia. Among the risk factors that predispose to lung de-recruitment during OLV are high FiO_2, traditional lack of PEEP, and extrinsic compression by abdominal contents, the heart and mediastinum. The best evidence for the presence of atelectasis during OLV comes from a lung recruitment study, which investigated an aggressive alveolar recruitment maneuver (ARM) with increasing pressure breaths over a 4-min period up to a peak pressure of 40 cmH_2O and a PEEP level of 20 cmH_2O (Fig. 6.7). Recruitment increased PaO_2 on OLV from a mean of 144 mmHg to a mean of 244 mmHg (Fig. 6.8) [63].

However, it is not only for oxygenation purposes that lung recruitment is important. Establishment (and retention) of open lung optimizes lung compliance and optimizes ventilation by reducing dead space ventilation to its lowest level (Fig. 6.9). It is an often overlooked benefit of lung recruitment that it optimizes the amount of CO_2 clearance and therefore may in fact allow for a reduction in minute ventilation with secondary further decreases in lung stress and strain.

Cinnella et al. demonstrated that the alveolar recruitment achieved by a formal ARM resulted in a significant decrease in static elastance of the dependent lung [120]. Hemodynamic instability is a well-recognized risk of such an aggressive ARM as the sustained intrathoracic pressure increases right ventricular afterload, resulting in impaired venous return and left heart preload [35, 121]. A recent study showed that stroke volume variation (an indicator of preload responsiveness) increases dramatically after an ARM, while both

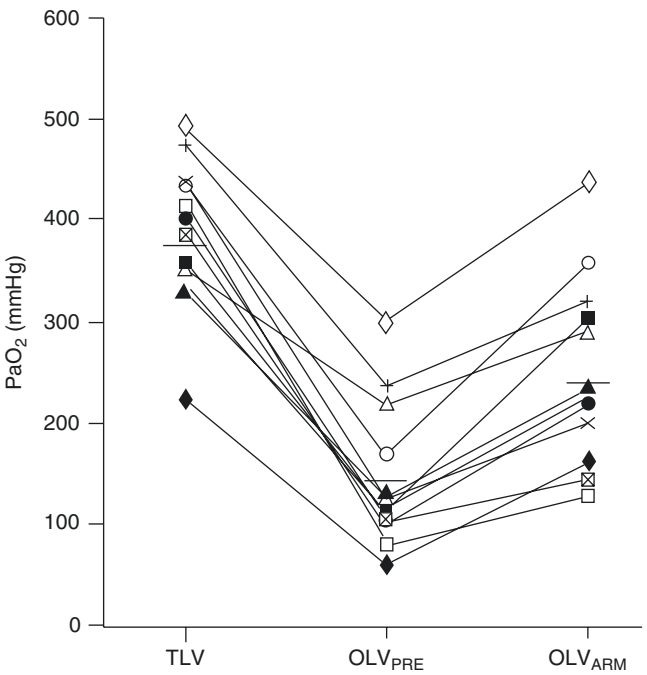

Fig. 6.8 Lung recruitment improves oxygenation during OLV. PaO2 (mmHg) in all patients during two-lung ventilation (TLV) and during one-lung ventilation before (OLVPRE) and after (OLVARM) the alveolar recruitment maneuver consisting of stepwise increases in PEEP from 5 to 20 cmH2O with a stable pressure-control driving pressure. Each symbol represents one patient in every point of the study. Horizontal bars represent mean values at each point. (Reprinted from Tusman et al. [63] with permission)

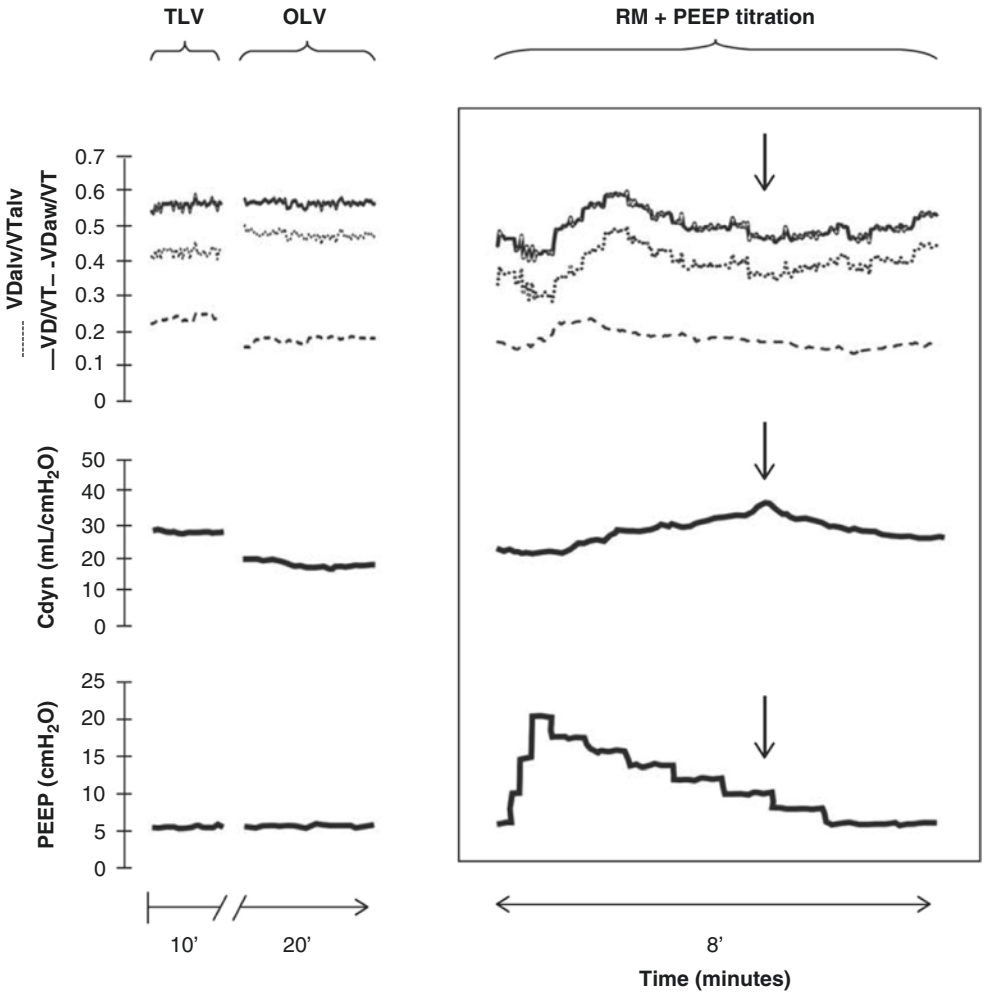

Fig. 6.9 Dynamic changes in dead space during thoracic surgery in one representative patient. All the measurements were performed in the right lateral position. The PEEP at the bottom is used as a marker of the RM and PEEP titration. The sequences of different representative periods of ventilation with two-lung (TLV, VT 8 ml/kg) or one-lung (OLV, VT 6 ml/kg) before and after RM are depicted. Rectangle: the time scale of the RM and PEEP titrations was magnified to highlight the interventions and their effects. The arrows indicate the closing pressure, thus the level of PEEP needed to maintain the lungs open after the RM, as identified by the highest dynamic compliance (Cdyn), which coincides with the lowest physiological (VD/VT) and alveolar (VDalv/VTalv) dead space values. PEEP, positive end-expiratory pressure; RM, recruitment maneuver. (Modified from Tusman et al. with permission [119])

cardiac index and venous oxygen saturation decrease. These changes, however, were transient and completely recovered within 3 min [122].

Caution is required with the implementation of PLV, as low tidal volumes and plateau pressures may promote atelectasis formation and increase FiO_2 and PEEP requirements [71]. Frequent de-recruitment and therefore need for repeated recruitment maneuvers, as may be the case with low tidal volume ventilation with insufficient PEEP, are potentially deleterious. In animal models of lung injury, repeated de-recruitment and recruitment maneuvers are associated with histological evidence of lung injury [123, 124]. Even a single recruitment maneuver of 40 cmH_2O for 40 s has been shown to elevate biomarkers of lung injury in the rat model without preexisting lung injury [125]. The same may potentially be true in humans, although this aspect has only been studied in critically ill patients. Halbertsma et al. demonstrated that a single ARM could increase translocation of pro-inflammatory cytokines from the alveolar space into the systemic circulation in ventilated critically ill children. Fifteen minutes after the ARM, an increase was observed in plasma TNFα, IL-6, and IL-1β [93]. Another critical care study found that 4 out of 28 patients with ALI/ARDS developed barotrauma necessitating intervention following an ARM [126]. This does create a curious dilemma as the increased use of PLV, with low tidal volumes, may promote atelectasis formation and therefore increase the need for recruitment maneuvers [71]. The best ventilatory strategy is therefore one that follows the "open lung" concept and maintains lung recruitment with appropriate levels of PEEP.

Atelectasis formation in the operative lung is routine and occurs gradually over a 10–20-min period as residual oxygen is being absorbed, which parallels the gradual decline in PaO_2 on OLV. Ko et al. compared three different gas mixtures during TLV immediately prior to OLV (air/O_2, N_2O/O_2, O_2) and investigated which gas mixture would best collapse the operative lung while maintaining arterial oxygenation in patients undergoing lung resection surgery. FiO_2 was 0.4 in the air/O_2 and N_2O/O_2 group and 1.0 in the O_2 group during TLV. All groups received 100% oxygen on initiation of OLV. Not surprisingly, lung deflation was worse if nitrogen (i.e., air) was administered prior to lung collapse, due to the poor solubility of nitrogen in blood. A nitrous oxide/O_2 mixture was superior to oxygen alone for lung collapse, but

nitrous oxide is contraindicated in many thoracic patients. Administering 100% oxygen pre-OLV temporarily improved OLV oxygenation but only until the nonventilated lung becomes atelectatic. Once the operative lung has collapsed at around 15 min of OLV, that oxygen reservoir and any benefit from it have disappeared [83].

Atelectasis is complete, unless CPAP is applied to the operative lung. CPAP, or its variant HFJV, if applied to the at least partially recruited operative lung, effectively improves *V*/*Q* matching and hypoxemia [108]. Gradual re-expansion of the operative lung at the conclusion of OLV is achieved with a continuous pressure hold of 20–30 cmH_2O, which is lower than standard recruitment regimens, in order to prevent disruption of staple lines. As discussed, re-expansion of lung tissue may be harmful. Re-expansion injury after prolonged lung collapse consists of alveolar-capillary membrane edema and increase in lymphocyte and neutrophil infiltration [127]. Re-expansion of isolated rabbit lungs after 55 min of lung collapse showed significant elevations in myeloperoxidase (MPO) levels, as well as IL-1β and TNF-α mRNA, when compared to an open lung control [33]. Intermittent lung re-expansion may mitigate these effects, as intermittent recruitment of the operative lung during OLV has been shown to decrease pro-inflammatory mediators during esophagectomy [128]. Lung recruitment with continuous high-pressure hold may result in significant hypotension if applied to both lungs. However, even in the setting of hypovolemia, recruitment is well tolerated, if it is selectively applied to one lung at a time, with the other lung open to the atmosphere [129]. Re-expansion pulmonary edema is fortunately rare if a gradual, gentle recruitment technique is applied and is more likely after sudden recruitment of long-standing lung collapse [130]. Low oxygen tensions should likely be used for re-expansion, as recruitment of the operative lung is associated with substantial oxidative stress, particularly after prolonged OLV [79, 80].

OLV Duration

Mechanical stress due to OLV can be minimized by optimization of ventilatory parameters. However, even minimal stress using "protective" parameters becomes significant if exposure is prolonged. Retrospective case series have shown that OLV lasting more than 100 min is associated with an increased risk for postoperative lung injury [8]. Part of the damage may be due to oxidative stress. A recent animal study exposed rats to increasing durations of OLV from 1 to 3 h. At the conclusion of the experiment, animals were sacrificed and analyzed for biochemical indicators of oxidative stress and histologic changes in lung tissue. Increasing the duration of OLV from 1 to 3 h resulted in significant elevations of malondialdehyde (MDA) activity and increased the amount of tissue damage on histological analysis [131]. A prospective analysis of patients undergoing lobectomy for non-small cell cancer with either TLV or OLV lasting more than 60, 90, or 120 min compared MDA plasma levels at lung re-expansion. Again, MDA levels increased significantly with increasing OLV duration, indicating cumulative oxidative stress [79]. Anesthesiologists have limited control over the duration of OLV as it is mostly determined by the surgical procedure. However, initiation of OLV should occur as close to pleural opening as possible (except for thoracoscopic procedures), and TLV should resume as early as possible. With the increasing use of OLV outside the thoracic theater, it is essential to ensure that the nonthoracic surgeon appreciates the need to minimize the length of OLV.

Combined Ventilator Strategy

The cumulative evidence is overwhelmingly in favor of adopting a protective lung ventilatory strategy for OLV, which has been shown to decrease surrogate markers of lung injury as well as the incidence of ALI itself. Protective ventilation is not synonymous with low tidal volume ventilation but also must include all of routine PEEP (set above the closing pressure and lower inflection point), lower FiO_2 (sufficient to maintain adequate arterial oxygenation), and particularly lower ventilatory pressures (driving pressure primarily) through the use of PCV and permissive hypercapnia. This strategy follows the "open lung" concept that has been widely adopted for the critical care management of ARDS patients but has since been expanded to include patients in the ICU without ARDS and to high-risk patients in the operating room or those undergoing major surgery. As part of the open lung concept, frequent recruitment of the lung has to be considered as another component of a PLV strategy. Recruitment should occur at a minimum following endotracheal intubation, at the beginning of OLV and on resumption of TLV. In addition, lung recruitment should be considered whenever oxygenation and lung compliance deteriorate. Lung de-recruitment may potentially be more prevalent with low tidal volumes due to the loss of end-inspiratory stretch in the setting of high FiO_2. Appropriate levels of external PEEP minimize de-recruitment in the setting of low tidal volume ventilation. PEEP titration is possible in the operating room with the use of spirometry and real-time measurement of pulmonary compliance. When PEEP is titrated to the best pulmonary compliance following maximal recruitment, FRC is maximized, atelectasis and dead space are reduced, oxygenation is improved, and atelectrauma is lessened [70]. Titrating PEEP to compliance individualizes the ventilator strategy to each patient's unique respiratory pathophysiology. As driving pressure is equal to tidal volume divided by pulmonary compliance, a reduction in driving pressure is achieved through an improvement in compliance. Titrating

PEEP allows one to also avoid overdistension which may produce pulmonary blood flow diversion to the operative lung and worsen hypoxemia and, as mentioned above, increases pulmonary complications [98]. There is no one-size-fits-all solution to PEEP selection as has become evident in recent RCTs [23]. Meta-analyses in both the ICU and the operating room have clearly demonstrated that PEEP titration toward lower driving pressure (due to improved compliance) improves patient outcomes [97, 98]. Once PEEP has been titrated to an optimal setting, the provider should then turn their attention to tidal volume. Excessive tidal volumes are often unintentionally provided in females, in the morbidly obese, and in patients of shorter stature, a fact that is avoidable by calculating ideal or predicted body weight [132]. Using driving pressure to optimize tidal volume is an important area that requires further investigation keeping in mind that driving pressure greater than 13 cmH_2O is an independent risk factor for postoperative pulmonary complications. One should consider decreasing tidal volume if this driving pressure threshold has been reached until more definitive data emerges.

Other than the ICU, where as long as cardiac output is maintained, PEEP can be increased to maintain "open lung"; in the OLV setting, excessive PEEP will cause pulmonary blood flow diversion to the operative lung and worsens oxygenation. As such, low tidal volume ventilation has the potential to worsen oxygenation, either due to lung de-recruitment with inadequate PEEP or due to pulmonary blood flow diversion with excessive PEEP. Low tidal volume ventilation increases dead space and CO_2 elimination is therefore consistently worse with this technique. This should not present a problem in the majority of patients, unless CO_2 elimination is already compromised by severe obstructive lung disease (e.g., cystic fibrosis). In cases of severe respiratory acidosis, marked pulmonary hypertension, or right ventricular dysfunction, "protective" low-tidal volume – high rate ventilation – may need to be aborted in favor of higher tidal volume ventilation at a lower respiratory rate (to maximize CO_2 elimination), as the imminent risk of hemodynamic dysfunction trumps the potential risk of ALI. Dynamic hyperinflation is common during OLV and is increased with the application of PEEP and the use of higher respiratory rates. The risk of hyperinflation may be increased with a PLV strategy, which has to be considered, particularly in patients with severe emphysema and during periods of hemodynamic instability. Providing adequate expiratory time and use of permissive hypoventilation should minimize the risk of significant hyperinflation in all but the patients with the most severe form of obstructive lung disease.

While PLV should be the norm for all patients, it is particularly important in patients with risk factors for ALI and during procedures that trigger a higher inflammatory response, such as pneumonectomy, esophageal surgery, or lung transplantation. Respiratory mechanics vary widely between restrictive and obstructive lung disease so that any ventilatory strategy needs to be individualized for the particular patient (Table 6.2).

Table 6.2 Summary of ventilatory strategies

Tidal volume: protective, 3–5 mL/kg; hypoxemia or severe hypercapnia (consider 6–8 mL/kg (with decreased RR))
PEEP (approximate): normal lungs, 10 cmH_2O; obstructive, 2–5 cmH_2O (minimize intrinsic PEEP); restrictive, 10+ cmH_2O
RR: protective, 12–15 bpm; severe hypercapnia, 6–8 bpm (with increased VT)
FiO_2: transplant: 21%+, routine 50–80%, hypoxemia 100%
I:E ratio: restrictive, 1:1 or inverse ratio; normal, 1:1–1:2; obstructive, 1:3–4 (reduced RR)
Pressures: driving <15 cmH_2O, plateau <20 cmH_2O, peak <35 cmH_2O
Minute volume: $PaCO_2$ 40–60 mmHg (rarely higher: severe obstruction, lung transplantation)
Ventilator mode: PCV

Hypoxemia

Prediction

Hypoxemia used to be the major concern during OLV. Early reports indicated that 40–50% of patients suffered hypoxemia during OLV [133]. Predictors for possible desaturation have been identified (Table 6.3). Hurford et al. examined the intraoperative oxygenation of patients who had undergone preoperative *V*/*Q* scanning [133]. They found that the amount of preoperative perfusion (and ventilation) to the operative lung inversely correlated with PaO_2 after 10 min of OLV. As HPV is only able to halve blood flow through the operative lung during OLV, the authors concluded that the extent of preoperative blood flow helped to predict the amount of intraoperative shunt. Slinger et al. showed that PaO_2 during OLV relates to multiple factors. Poor oxygenation during TLV was predictive of continued oxygenation difficulties as were right-sided operations (due to the increased perfusion to that side). Good preoperative pulmonary function (FEV_1) was found to be predictive of poor OLV oxygenation, which is felt to be due to the lack of auto-PEEP and secondary de-recruitment in normal lungs [134]. Two recent studies correlated the risk of hypoxemia to the end-tidal CO_2 gradients. One study showed that the difference of end-tidal CO_2 between the lungs in the lateral position significantly correlates with the P/F ratio at 15 min of OLV [135]. The other study demonstrated that there was a significant negative correlation between the lowest PaO_2 recorded during the first 45 min of OLV and the end-tidal CO_2 difference between TLV and the early phase of OLV [136]. Both studies postulated that elevated CO_2 gradients

Table 6.3 Predictors of hypoxemia during one-lung ventilation

Preferential perfusion of the operative lung
Right-sided surgery
Prior contralateral resection
Supine position
Normal FEV_1
Poor oxygenation on TLV
High *A–a* gradient for CO_2

were indicative of *V*/*Q* mismatching and therefore explained the risk of hypoxemia.

Over the years the incidence of hypoxemia has been declining. Improvements in anesthetic technique including improved lung isolation, confirmation of lung isolation with fiber-optic bronchoscopy, and use of anesthetic agents with less effects on HPV are being credited for the reduction of oxygenation difficulties. In 1993 the incidence of hypoxemia (SpO_2 < 90%) occurring during OLV was quoted at 9% [133]. By 2003 the published incidence of hypoxemia was down to 1% of OLV cases in some hands [137]. However, another more recent study again showed a 10% incidence of hypoxemia <90% in a single institution between 2003 and 2004. The discrepancy could be due to variations in clinical management. Alternatively, it may indicate the difference between manual and electronic charting, as the latter study consisted of automatic recording of saturation every 30 s [138]. Although rare, significant hypoxemia may still occur, at times without warning [139].

Treatment

For a rational approach to hypoxemia during OLV, it has to be appreciated that CPAP and TLV are uniformly effective (Table 6.4). CPAP always decreases shunt flow and TLV essentially eliminates shunt flow. Aside from procedures such as pneumonectomy and lung transplantation where these techniques are not available, patients should therefore not have to suffer prolonged hypoxemia. Assuming that the lung isolation device is properly positioned, these two maneuvers are the most effective treatments for hypoxemia. They are not chosen as first-line interventions, however, because they will impair surgical access to the lung, particularly during thoracoscopic procedures. CPAP is easily applied via one of the commercially available units that connect to the open lumen of the DLT, or the suction port of the bronchial blocker via the CPAP adaptor. Alternatively, a standard AMBU bag with a PEEP valve can be used if no CPAP unit is available. CPAP does require some degree of lung recruitment, which is not always feasible (lung lavage, bronchopleural fistula) and will impact surgical exposure. Recently, Russell et al. described an intermittent positive airway pressure (IPAP)

Table 6.4 Approach to hypoxemia during one-lung ventilation

Mild hypoxemia (90–95%)
Confirm position of lung isolation device
Recruit ventilated lung
Ensure adequate cardiac output
Increase FiO_2 toward 1.0
Optimize PEEP to nonoperative lung (up or down, toward lower inflection point)
CPAP/HFJV/O_2 insufflation to operative lung (IPAP, FOB)
Consider reduction in vapor anesthetic and/or total intravenous anesthesia
Ensure adequate oxygen carrying capacity (hemoglobin)
Severe (<<90%) or refractory hypoxemia
Resume TLV with 100% O_2
If not possible, consider
Pulmonary artery clamp on operative side during pneumonectomy, transplant
Inhaled NO and/or infusions of almitrine/phenylephrine
Extracorporeal support (ECMO, CPB)

technique, which does not elicit lung inflation and therefore should not impact surgical exposure. While the technique does not call for lung recruitment, it is unlikely to be of benefit in the setting of complete lung collapse. It is based on intermittent delivery of short bursts of low-flow oxygen (2 LPM) to the nonventilated lung to treat hypoxemia, circumventing significant lung movement in the surgical field. Placing a standard bacteriostatic filter on the open lumen of the DLT, with oxygen connected to the CO_2 sampling port, manual occlusion of open filter end allows for "jet insufflation" of oxygen into the collapsed lung. A 2-second burst of flow will deliver 66 mL of oxygen to the nonventilated lung. In their study, all patients with relative hypoxemia (SpO_2 < 95%) were successfully treated with repeated 2-second bursts of oxygen, followed by 10-second exhalations, while no impairment in surgical exposure was noted [140]. Apneic oxygen insufflation via an endotracheal suction catheter at 3 LPM is another successful method that has been shown to reduce the incidence of hypoxemia while on OLV. This technique should result in fewer interruptions to surgery during a VATS procedure [141].

Hypoxemia during OLV for VATS presents a particular problem, as TLV and CPAP techniques are generally considered to be contraindicated. Ku et al. presented a novel method, which may be of benefit in select cases. They described the treatment of refractory hypoxemia during left-sided VATS for lung volume reduction surgery. A 4-mm fiber-optic bronchoscope was inserted into the basilar segment of the left lower lobe bronchus, and 5 L/min of oxygen was insufflated for approximately 20 s via the suction port (Fig.6.10). Oxygenation successfully recovered within 2 min without impairing the surgical field and remained adequate for 20 min. There are two important considerations to this technique. First, it can only be applied if the insufflation occurs in a lung territory that is remote to the surgical site

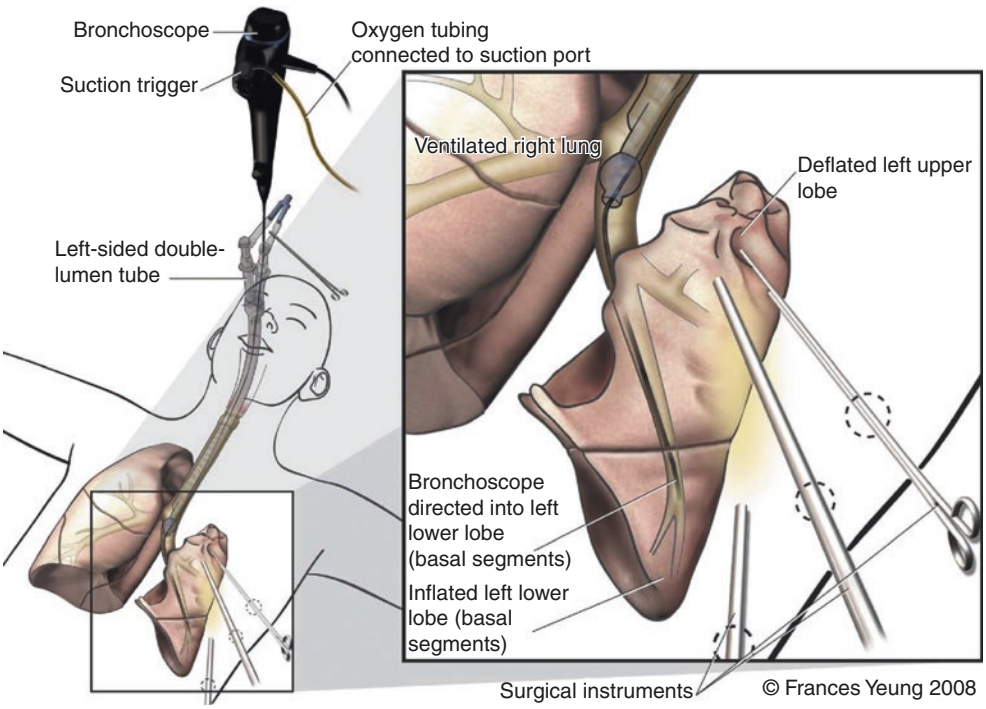

Fig. 6.10 Schematic illustration of oxygen supplementation during thoracoscopic surgery via bronchoscopy suction channel. See text for details. (Reprinted from Ku et al. [142] with permission)

and is therefore unlikely to be successful in case of a central lesion. In this case report, oxygen was insufflated into basilar segments while lung resection occurred at the apex. Second, insufflation of relatively high-flow oxygen has the potential to cause lung overdistension or barotrauma if the bronchoscope tip is allowed to wedge in the airway. The authors guarded against this by having the surgeon visualize the basilar lung segments throughout the period of insufflation [142]. Distal oxygen insufflation, particularly at relatively high flow rates as described in this report, should never be applied blindly. As another option, HFJV has been successfully employed during VATS procedures [143]. In order for this technique to succeed, the lung has to be allowed to collapse away from the chest wall prior to the institution of HFJV, and driving pressures have to be low enough to only cause partial lung inflation. As previously stated, however, with proper attention to adequate lung isolation, "open lung" ventilation, and maintenance of a normal cardiac output, these interventions should rarely be necessary.

Lung de-recruitment in the ventilated lung is common, easily reversed with recruitment maneuvers and preventable with appropriate PEEP levels. Low mixed venous oxygen saturation secondary to low cardiac output is another frequent and easily treatable cause of desaturation. Pharmacological modulation with vasoconstrictors (almitrine, phenylephrine) to strengthen HPV in the operative lung and vasodilators (inhaled NO) to improve pulmonary vascular capacitance in the ventilated lung may be helpful in extreme cases.

Systemic Effects

Even though hypoxemia has become less of an anesthetic issue during OLV, relative hypoxemia may have a significant impact on vital nonpulmonary organ function given the ever-increasing rate of comorbid conditions in thoracic patients. In addition to hypoxemia, release of inflammatory cytokines and reactive oxygen metabolites may have yet unknown effects on organ function.

A recent study by Mierdl et al. analyzed the impact of hypoxemia during OLV on myocardial metabolism in patients with severe multivessel coronary artery disease. Patients underwent minimally invasive coronary artery bypass grafting via small lateral thoracotomy. In their study measurements of arterial and coronary sinus PO_2, pH and lactate did not show any evidence of anaerobic metabolism, despite arterial PaO_2 values between 50 and 70 mmHg during OLV. Additionally, no patient exhibited myocardial ischemia, which led the authors to conclude that OLV may be used in patients with multivessel coronary artery disease with an acceptable low risk of inducing anaerobic myocardial metabolism [144].

Neurocognitive dysfunction is a well-known complication of cardiac surgery and has been shown to be associated with intraoperative episodes of cerebral oxygen desaturation. Standard pulse oximetry is insufficient to detect these events. Monitoring for and treating cerebral desaturation events may decrease the incidence of postoperative neurocognitive dysfunction [145, 146]. Tobias et al. investigated the incidence and risk factors for cerebral desaturation by monitoring

cerebral oxygenation (rSO_2) using near-infrared spectroscopy in patients who required OLV for thoracic surgery [147]. In 8 of 40 patients, prolonged decreases in rSO_2 to less than 75% of the baseline value were recorded during OLV. These eight patients were older, weighed more, and were more likely to be ASA III than the remainder of the patients. Since there was no significant difference in patient background or other monitoring values, the authors concluded that rSO_2 monitoring might be useful to detect cerebral desaturation and allow for early intervention in patients during OLV. Jugular bulb venous oxygen saturations during OLV were assessed in a study comparing sevoflurane- and propofol-based anesthesia in patients undergoing lung surgery [148]. The SjO_2 values were significantly higher in the sevoflurane group than in the propofol group, despite identical SaO_2 values. The lower SjO_2 values observed with propofol anesthesia may be explained by the fact that propofol reduces cerebral blood flow more than cerebral metabolic rate [149, 150].

Interestingly, cerebral oxygen desaturation also appears to be predictive of noncerebral postoperative complications. In a trial of 50 patients undergoing major thoracotomy with OLV, a minimal absolute regional cerebral oxygen saturation of less than 65% was found to be predictive of postoperative organ dysfunction based on the Sequential Organ Failure Assessment (SOFA) scoring system with an OR of 2.37 (95% CI 1.18–4.39, $P = 0.043$) [151]. Cerebral tissue oxygenation depends on arterial oxygen content, oxygen delivery (cardiac output), and metabolic consumption and may therefore be a superior monitor to simple pulse oximetry.

Reactive oxygen metabolites are known to occur after re-expansion of the nonventilated lung. These metabolites may have deleterious effects on cellular function. Yuluğ et al. investigated the effects of OLV and re-expansion on the tissue damage of the liver and ileum in rats [152]. Plasma aspartate aminotransferase (AST), alanine aminotransferase (ALT), tissue MDA, and MPO activities in both tissues were significantly increased associated with OLV and re-expansion. Tissue damage and apoptotic index increased in rats with longer OLV duration, suggesting that OLV may cause tissue damage in the liver and ileum. These are some of the early indicators that OLV may indeed have effects beyond lung tissue; future research will help to delineate the significance of these findings.

Alternatives to One-Lung Ventilation

With the uncommon yet legitimate concern about acute lung injury following one-lung ventilation, clinicians have sought alternatives to general anesthesia and positive pressure ventilation for patients undergoing thoracic surgery. One approach which has reemerged is the avoidance of endotracheal intubation and mechanical ventilation for thoracic surgery [153]. This has also been termed NIVATS, which stands for non-intubated video-assisted thoracic surgery. The goal of NIVATS is to avoid the risks associated with endotracheal intubation, general anesthesia, and positive pressure ventilation including mechanical airway injury, ventilator-induced lung injury, hypoxemia, cardiac arrhythmias, cognitive dysfunction, and other organ injury [154]. NIVATS has been used for a range of thoracic procedures from simple pneumothorax, effusions and empyema, wedge resection, mediastinal biopsy, bullectomy to more invasive procedures including lobectomy, pneumonectomy, thymectomy, and even carinal and tracheal resection. NIVATS is often facilitated with varying degrees of conscious sedation combined with regional anesthesia via an epidural, paravertebral, intercostal, or serratus anterior block with the maintenance of spontaneous ventilation in the lateral position, which favors ventilation perfusion matching. Complications associated with NIVATS include hypercapnia, coughing, disruption of the surgical field from mediastinal and diaphragm motion, and patient intolerance, which may require conversion to general anesthesia [155]. In a recent survey to members of the European Society of Thoracic Surgeons, 62 out of 105 respondents claimed an experience with NIVATS. The most common approach included intercostal blocks with minimal sedation followed by laryngeal mask with sedation and thoracic epidural blockade with sedation. The most common procedures in which NIVATS was utilized included the management of pleural effusion and lung or mediastinal biopsy [157]. So far data on outcomes using NIVATS compared to general anesthesia (GAVATS) is sparse but points to shorter hospital length of stay and less postoperative morbidity in high-risk individuals [154]. NIVATS offers a promising alternative to general anesthesia and endotracheal intubation in high-risk individuals for primarily simple thoracic procedures when the thoracic surgeon and anesthesiologist are comfortable using this modality and are prepared to convert to general anesthesia if the need arises. There is insufficient evidence to recommend this approach in more involved lung resections.

Conclusion

The last two decades have seen a shift in OLV research from studies investigating hypoxemia to various aspects of lung injury pathophysiology and prevention. Much has been learned about ventilation strategies that minimize lung injury. Evidence to date supports PLV based on reduction of surrogate markers but more importantly now also indicates reduction of adverse outcomes. Ventilatory parameters have to be individualized for each patient's unique pulmonary mechanics but should focus on an "open lung" strategy.

Performing a PEEP titration study and routinely monitoring and limiting driving pressure are two recent developments in the literature that deserve special attention and further investigation. Hypoxemia is infrequent and should lead to a re-evaluation of ventilatory parameters. Routine algorithms for treatment of hypoxemia, as well as advanced management techniques, are available, such that prolonged hypoxemia should be exceedingly rare. There are early indicators that OLV may impact systemic organ function, but future research is needed to address end-organ effects.

Nonrespiratory Functions of the Lung

7

Amanda M. Kleiman and Keith E. Littlewood

Key Points

- Pulmonary endothelial cells metabolize endogenous substances and xenobiotics via ectoenzymes on their luminal surface and caveolae as well as enzyme systems within their cytosol.
- Pulmonary metabolism results in the activation of several endogenous substances and medications of importance to the anesthesiologist.
- Pulmonary uptake is often not associated with metabolism, but still markedly affects pharmacokinetics by initially attenuating peak concentrations and then returning unchanged substance to the circulation.
- The lung's ability to serve as a vascular reservoir is directly related to the capacitance of the pulmonary vessels.
- The lung serves as a physical filter, but this function may be compromised with high cardiac output and in several disease states.
- The respiratory epithelium's functions include humidification and trapping of particles and pathogens.
- The airway surface film has antimicrobial capacity beyond its mechanical removal of debris from the airway.

Introduction

For nearly two millennia of Western medicine, the lungs were thought to primarily protect the heart from overheating by exhaling warm air and from direct injury both by their position and cushioning structure. These views are ascribed to the teachings of Galen and, to some extent, Aristotle [1, 2]. Traditional Chinese medicine emphasized the interconnectedness of the organ groupings of the five phases, but within this construct, the lung was seen as a minister to the emperor heart and in partnership with the bowel to have the responsibility of maintaining the boundary of the body and outside world. In the thirteenth century, Ibn-an-Nafis of Cairo described the purification of blood by mixing with air in the lungs in one of the earliest known descriptions of gas exchange [3].

Over the last sever-al centuries, however, the biochemistry and physiology of respiration have become essentially synonymous with the lungs. From the work of pioneers such as Boyle, Lower, Priestly, Haldane, and others, most clinicians now think of the lung first and foremost as an organ of gas exchange. In more recent years, other important roles of the lung have emerged, roles that are largely in keeping with the concepts of our medical heritages.

In this sense, we now return to historic views of the lung as protector and modulator. Specifically, nonrespiratory functions of the lung including its metabolic processes, endocrine role, mechanical filtration of venous blood, warming of inspired gasses, and protection against inhaled pathogens and toxins are discussed. Focused aspects of organ structure and cellular function are reviewed as required by this discussion.

Uptake and Metabolism Within the Lung

The lungs are particularly suited for critical metabolic activities. They continuously receive essentially the entire cardiac output, and their vascular area, depending upon the

degree of recruitment, is an enormous 70–100 m^2. Further, the lungs contain nearly half of the body's endothelium [4] and have an extraordinarily high perfusion of 14 mL/min/g tissue (as opposed to the next-highest renal perfusion of 4 mL/min/g tissue). Thus, there is ample blood–endothelial interface for surface enzyme activity as well as uptake and secretion. The largest population of cells involved in pulmonary metabolism of blood-borne substances is, as might be expected, the pulmonary endothelium. Consistent with high metabolic activity, endothelial cells have both extensive cytoplasmic vesicles and prominent caveolae. The caveolae are tiny membrane invaginations and near-membrane vesicles similar to those found elsewhere in the body, measuring 50–100 nm, associated with caveolin proteins, and derived from lipid rafts within the membrane. The predominant activities of these caveolae, thought to include endocytosis [5] and signal transduction, have not been fully delineated and may be pleiotropic [6]. The endothelial cells structurally have large luminal projections and invaginations, providing an even greater interface area at the microscopic level.

Metabolism by the endothelial cell occurs either on the surface of the cell via enzymes associated with the membrane ("ectoenzymes") or by cytosolic processing after the substances are taken up by the cell. Some surface enzymes are distributed along the luminal membrane [7], while others are associated exclusively with the caveolae [8]. Figure 7.1 schematically depicts these processes with example substances and pathways. Metabolism may be further divided into exogenous vs. endogenous substances as well as deactivated vs. activated products. Regardless of these considerations, it should be remembered that intensive investigation of pulmonary metabolism has developed only over the last several decades [9]. Much remains to be discovered, and conflicting data exist for drugs as central to clinical anesthesiology as propofol [10, 11].

The literature's terminology of pulmonary metabolism can be confusing and sometimes inconsistent. The careful reader must sometimes deduce the actual processes described and investigated through context. In general, "pulmonary uptake" or "extraction" is simply used to describe transfer from blood to the lung and does not indicate whether the substance of interest is subsequently metabolized or returned back into the blood with or without alteration. "First-pass" uptake is used to describe the amount of substance removed from the blood on the first cycle through the lungs, although data from techniques such as tissue slices have been used to infer this behavior. "Extraction" is also sometimes used synonymously with first-pass uptake. "Clearance" may be used to describe a substance undergoing actual elimination, either in terms similar to renal clearance as volume of blood from which the substance would be completely removed (mL/min or mL/kg min) or as a comparison of pulmonary arterial concentration vs. systemic arterial concentration. Terms used for isolated lung studies include "accumulation," the percentage of substance retained in the lungs after equilibrium, and "persistence," percentage of substance retained after washout.

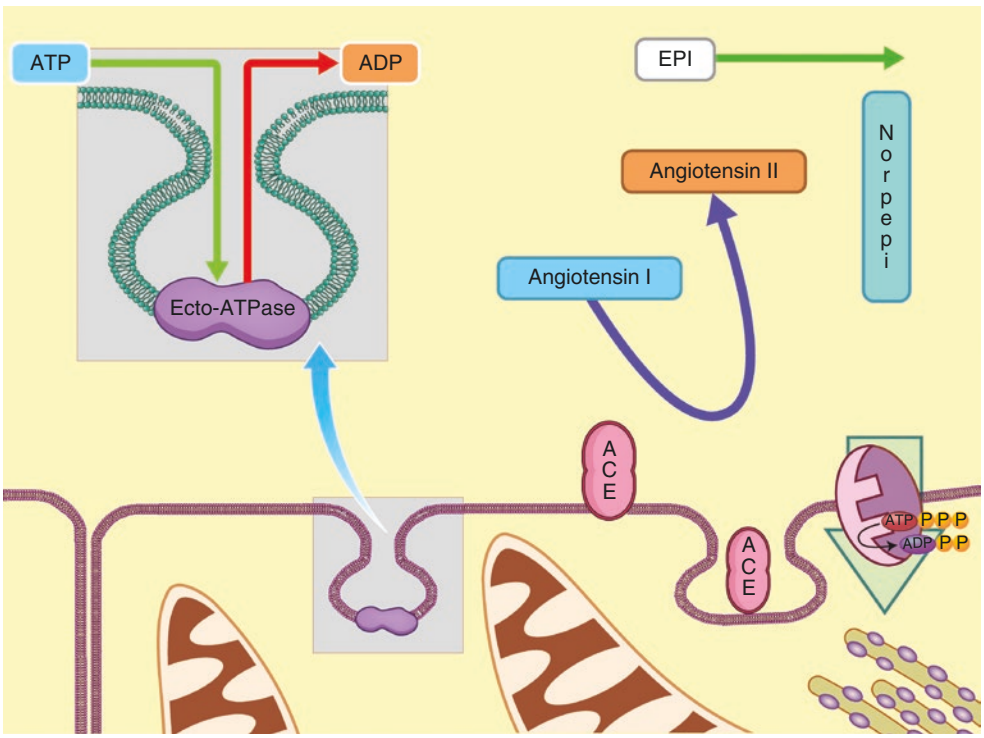

Fig. 7.1 Schematic examples of pulmonary endothelial metabolism. Surface enzymes may be restricted to the caveolae (Ecto-ATPase in the inset above is an example) or present on both the luminal surface and caveola (e.g., angiotensin-converting enzyme [ACE]). Another characteristic of pulmonary endothelium is selective uptake, here exemplified by the ATP-dependent uptake of norepinehrine (NOREPI), while epinephrine (EPI) is not taken up. See text for details

It is beyond the scope of this discussion to fully detail the experimental methods used in the investigation of pulmonary metabolism, but the challenges of investigation and data interpretation merit at least mention. As implied above, lung metabolism has been investigated in vitro and in vivo. In vitro techniques include the use of cellular fractionates, tissue homogenates, and tissue slices. Recent advances in uniform preparation and cryoprotection have made tissue slices an attractive, cost-efficient option [12] despite concerns regarding the impact of processing on enzyme behavior. Tissue slices have a particular advantage in lung research because they include all cell types. The isolated and perfused animal lung model represents the next level of fidelity. The lung can remain within the animal or be explanted, and the uses of various perfusion managements (e.g., nonpulsatile vs. pulsatile, blood vs. crystalloid, and one-pass vs. recirculation) have been described with little standardization. Further, various investigators commonly subject the lung to no inflation, constant airway pressure, or positive pressure ventilation. The impact of these differences in ventilation on resultant data is unknown. In the next level of modeling, in intact animals and human subjects, the pulmonary uptake is assessed by measurements of the difference between pulmonary arterial and pulmonary venous (animals) or systemic arterial (human) concentrations of the substance in question, typically after a controlled bolus and/or infusion when possible. These invasive requirements do not lend themselves to large volunteer studies. In fact, most human subjects are critically ill and/or undergoing complex procedures. This variation in disease and treatment may produce data that in turn has great variance [13]. Conversely, inclusion criteria rigorous enough to provide consistent results produce a patient population in which the results are of limited general applicability [14]. A variation of the method just described is the double-indicator dilution technique [15]. In this technique, the substance of interest and a substance with no (or no known) pulmonary uptake are injected, typically into the right atrium. Samples are then taken from a systemic artery, with the known substance serving as the control to which the investigated substance's concentration curve is compared. This technique is more practical in terms of decreased frequency of sampling and somewhat decreased invasiveness.

It is important to reemphasize that the lung has a profound impact on the blood concentration of substances even when it does not ultimately metabolize or secrete them. This is because of the simple uptake and retention of substances, often followed by release back into the blood. This "capacitor effect" [16] of the lungs in which any rapid rise or fall in concentration is attenuated will be revisited in the discussion below as it pertains to local anesthetic toxicity.

With these limitations in mind, we shall first review the current understanding of drug metabolism with focus on medications of particular interest to the anesthesiologist, and then look at metabolism of endogenous substances. Even though they are also administered therapeutically and duplicated in the summary of medications, endogenously produced substances such as catecholamines will be included in the latter discussion (Table 7.1).

Table 7.1 The lung and medications of interest to anesthesiologists

Drug class	Impact of passage through the pulmonary circulation	
	Minimal or none	First-pass uptake and/or metabolism
Hypnotics		Thiopental +
		Ketamine ++
		Propofol ++
Benzodiazepines		Diazepam ++
Nondepolarizing muscle relaxants	Rocuronium	
	Vecuronium	
	Rapacuronium	
	d-tubocurarine	
Opiates	Morphine	Fentanyl ++
		Sufentanil +
		Alfentanil ±
Catecholamines	Dopamine	Norepinephrine +
	Epinephrine	
	Isoproterenol	
Local anesthetics		Bupivacaine +
		Lidocaine ++

Drugs

The cytochrome P-450 monooxygenase enzyme systems are the most studied metabolic pathways for medications. The lungs have substantial concentrations of P-450 isoenzymes, particularly within type II pneumocytes, Clara cells, and endothelial cells [17]. This implies that the lung has the capacity for drug metabolism via P-450 systems. While P-450 and other enzyme systems have long been known to exist in the human lung (Table 7.2), the actual activity of lung enzymes ranges from negligible to 33% of that of the liver [19]. The difference between organ enzyme activity of different species is large (lung to liver activity varying from a few percent to 111%) and mandates caution when interpreting animal data [20].

Opioids

Fentanyl has been shown to have a markedly variable first-pass uptake of up to 90% in humans [21]. The same investigators found that significant amounts of fentanyl are returned from the lungs into the blood with a biphasic pattern, equilibrating after about a minute in the fast phase and nearly 25 min for the slow phase. The uptake of fentanyl is higher than expected even for this basic and lipophilic drug. In fact,

active uptake of fentanyl has been demonstrated in human lung endothelial cells [22].

The study of alfentanil has led to widely variant first-pass uptake data. Uptakes of 67% have been reported [21], although more commonly uptakes of approximately 10% are reported [23]. Of note, these studies included other medications (sufentanil and morphine in one study and fentanyl in the other) that were found to behave similarly to accepted data for those drugs. This makes the discrepancy for alfentanil behavior particularly hard to interpret.

Sufentanil demonstrates uptake that is a little more than half that of fentanyl. A study in which patients had received alfentanil for induction followed by a sufentanil infusion of 50 μg/min for 10 min showed sufentanil first-pass uptake of about 50% with a 20-min retention of about 20% [24]. The investigators incidentally noted that smokers had a statistically higher retention of the infused dose.

Early work with morphine in the perfused rabbit lung model showed about 30% first-pass uptake [25]. Interestingly, subsequent work in intact animals and in humans has found much lower uptake of about 10% [23, 26], including postoperative bolus and infusion [27]. Metabolism has generally been found to be negligible.

Muscle Relaxants

There is a paucity of data on pulmonary pharmacokinetics of muscle relaxants. This may be because the agents studied, including vecuronium, rocuronium, d-tubocurarine, rapacuronium, and Org 7617, demonstrated no first-pass uptake or metabolism in the intact porcine model [28]. This would appear to have generated little enthusiasm for further investigation of this class of drugs.

Local Anesthetics

Lidocaine has a long history of investigation in terms of pulmonary uptake and metabolism. The general consistencies across species include a first-pass uptake of approximately 50% with significant retention at 10 min [29–31]. The uptake of lidocaine has also been examined in a variety of physiological circumstances. Under extremes of metabolic acidosis and alkalosis [30], lidocaine demonstrates increased uptake with higher blood pH. It is postulated that this finding is the consequence of increased drug lipophilicity, since, in a less acidic environment, more of the drug is in its nonionized form. Under extremes of FiO_2 in in vivo isolated lobes of dogs under nitrous oxide and halothane anesthesia, there were no differences demonstrated in lidocaine uptake [32]. Of interest, the prolonged retention in all groups was less than that commonly reported in other studies, raising the issue of the effects of this particular model on uptake.

Bupivacaine has been investigated less extensively than lidocaine with less consistent results. In most animal species, peak extraction has been reported as high with variable first-pass retention between species and methodology [33–35]. In humans, however, the effective first-pass extraction appears to be lower when studied by epidural dosing [36, 37]. As in the case of lidocaine, the pulmonary pharmacokinetics of bupivacaine have also been investigated in acidosis. In a rabbit model, animals with a pH of 7.0–7.1 demonstrated decreased maximum pulmonary extraction as a group [38] with resultant higher peak systemic concentrations of drugs.

Two recent areas of interest in the practice of clinical anesthesia are intimately linked with the pulmonary uptake of local anesthetics. The first is the relative safety of levobupivacaine and ropivacaine in comparison to bupivacaine. These drugs have, in fact, been the subject of several investigations. Early animal studies suggested decreased toxicity of these newer preparations [39, 40]. The discussion continues, however, with more recent work regarding the pulmonary uptake of these drugs. In rabbits, for example, the uptake of levobupivacaine is higher than ropivacaine with resultant lower systemic blood concentrations of levobupivicaine [41]. The authors thus caution that the lower absolute toxicity of ropivacaine may be tempered by the lung's greater attenuation of peak levobupivacaine levels in inadvertent intravenous injections. A recent review of the pharmacodynamics and pharmacokinetics of local anesthetics [42] focuses on the challenges of comparing toxicities in clinical practice [43–45]. Animal models, with the limitations already discussed among many more [46], must be utilized since clinical toxicity is an uncontrolled, rare, and dangerous event [47]. Other questions are raised by the relative central nervous system and cardiovascular toxicity between drugs and study variation in drug administration and measurement. The inconsistencies in the data of pulmonary uptake are thus one of many challenges in understanding the clinical toxicities of local anesthetics.

A second, related, area of great contemporary interest is the treatment of local anesthetic toxicity with lipid emulsion [48, 49]. A recent case report, in particular, is germane to the

discussion of pulmonary uptake [50]. Briefly, a patient undergoing brachial plexus block with bupivacaine demonstrated evidence of toxicity by progressive symptomatology, seizures, widening QRS tachycardia, and asystole. Successful emulsified lipid "rescue" was followed nearly an hour later by recurrence of episodic ventricular tachycardia. The authors believe that this represented the first reported recurrence of toxic bupivacaine levels after lipid treatment. Several possible causes were postulated for this phenomenon, including postresuscitation hepatic dysfunction, reversal of generalized peripheral ion trapping of bupivacaine, and, appropriately, release of bupivacaine from the pulmonary vasculature. Thus, it seems that the issue of pulmonary uptake and release of local anesthetics must be considered in the treatment of suspected local anesthetic toxicity with emulsified lipid.

Hypnotics

There are limited, and sometimes dated, data regarding the pulmonary metabolism of intravenous induction agents. Thiopental has been found to have nearly 15% first-pass uptake in humans [51] with little or no metabolism. Ketamine shows marked species variation in its metabolism. In rabbit homogenate, the eventual complete disappearance of ketamine with only half being metabolized to norketamine implies the production of other metabolite(s) [52]. Lung tissue homogenate was more quickly saturated than liver tissue. As previously mentioned, the applicability of this homogenate data to intact animals, and certainly to humans, is unknown. In dogs under halothane anesthesia, the pulmonary uptake of ketamine was found to be slightly less than 10% without subsequent metabolism [53]. Human data are lacking.

The clarification of propofol uptake and metabolism by the lungs has taken many turns. One of the earliest studies in sheep with propofol administered as the sole medication demonstrated an apparent steady-state pulmonary clearance of 1.21 L/min [54] with negligible drug accumulation in the lung tissue, while a later study in sheep demonstrated a similar 1.14 L/min pulmonary clearance [55]. Other early works found that propofol uptake in cats was nearly 60%, but this uptake was particularly decreased in the presence of halothane or fentanyl [56]. Microsomal fractions from rat, rabbit, and human lung showed no glucuronidation of propofol [57]. Turning to data from human clinical studies, most recent work shows about 30% first-pass uptake and negligible metabolism of propofol by the lungs [11, 58]. It is interesting that a recently developed model of propofol pharmacodynamics and pharmacokinetics [59] has produced a very good fit with data from human studies [60, 61]. In this work, the lung is modeled as three tanks in series with the full cardiac output sequentially flowing to each, a model previously proven effective [62] in simulating the behavior of markers indocyanine green and antipyrine as well as the narcotic alfentanil.

Inhaled Medications

A number of medications include inhaled formulations. The inhaled route offers multiple benefits for drug delivery including a large absorptive surface area, high epithelial permeability, increased vascularity, avoidance of first-pass metabolism, and fast onset [63]. The majority of inhaled medications are used to treat the lungs directly, offering localized, targeted delivery and avoidance of systemic absorption. However, several drugs to treat illnesses from migraine headaches to diabetes are currently under development [63].

The handling of aerosolized drugs occurs via four processes including deposition, dissolution, absorption, and clearance. The site of deposition in the respiratory tract determines the treatment of most inhaled medications and is determined by the size of the particle. Chronic lung diseases including asthma, chronic bronchitis, and emphysema affect the deposition of aerosolized particles by narrowing the smaller airways resulting in deposition in larger airways [64]. The epithelial lining fluid has direct contact with the aerosolized particles, and the thickness and composition of the layer vary according to the site of deposition. Dissolution of particles into the fluid layer is controlled by the hydrophilicity of the particle. Water-soluble particles (e.g., albuterol, insulin) dissolve into the fluid and are freely absorbed [65]. In poorly water-soluble drugs (e.g., budesonide, fluticasone), the dose exceeds the aqueous solubility and the absorption is determined by dissolution-controlled kinetics [65]. Once dissolved, the speed of absorption depends on the size of the particle with smaller drugs quickly absorbed within minutes. The absorption of larger proteins is more complex but typically slower with more variable bioavailability [66]. Absorption occurs via several mechanisms. Passive diffusion occurs primarily via intercellular junction pores for hydrophilic compounds and transcellular diffusion for hydrophobic compounds. Drugs with low passive permeability utilize drug carrier transporters for uptake and transfer across cell membranes [67]. Like deposition, absorption may be impacted by chronic pulmonary disease due to deposition in the diseased upper airways, thickened mucous, and reduced surface area of diseased lungs. This may be beneficial in the treatment of chronic pulmonary diseases by preventing systemic absorption and increasing local drug effects. Hydrophilic substances may have increased absorption in the presence of chronic inflammation due to decreased epithelial barrier function and tight junction dysregulation with

increased permeability [67]. Clearance of aerosolized drugs occurs via mucociliary clearance and macrophage uptake, both of which will be discussed later.

Pulmonary Handling of Endogenous Substances

Angiotensin-Converting Enzyme

This section will discuss the activity of angiotensin-converting enzyme (ACE) and two important substrates, angiotensin I and bradykinin. The lung plays a critical role in the renin–angiotensin system because of the pulmonary endothelium's high concentration of ACE. When the kidney responds to changes in physiologic parameters including vascular volume, blood pressure, and adrenergic stimulation by the cleaving of prorenin, the resultant renin catalyzes the formation of angiotensin I from angiotensinogen. ACE then converts angiotensin I to the critically important vasoconstrictor, angiotensin II. Although ACE can be found on vascular endothelium throughout the body as well as in the plasma, the pulmonary endothelium has an abundance of ACE as a surface or ectoenzyme on the vascular membrane [68, 69], including the caveolae (Figs. 7.1 and 7.2). The newly formed angiotensin II is not, in health, taken up or further metabolized by the endothelial cell, but rather immediately returns to the blood. Clinically, ACE inhibitors have been useful drugs in the management of systemic hypertension. As will be

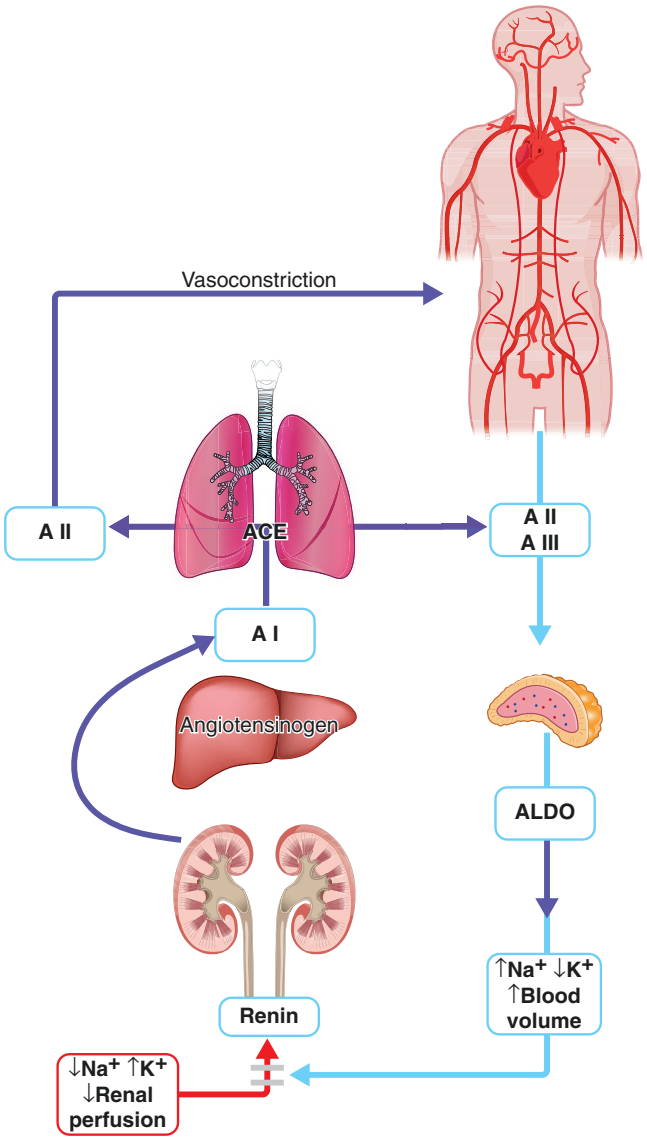

Fig. 7.2 An example of the lung's central role in the body's endocrine processes, in this case the renin–angiotensin–aldosterone axis. In response to sodium, potassium, and renal perfusion changes, renin is secreted by the kidneys. Renin cleaves angiotensinogen (renin substrate) from the liver to form angiotensin I (AI). The lung then converts AI to AII through the action predominately of endothelium-associated angiotensin-converting enzyme (ACE). AII causes vasoconstriction and is involved in stimulation of aldosterone (ALDO) secretion by the adrenal gland, resulting in retention of sodium and volume by the kidney

discussed below, the effects of these drugs are not limited simply to decreased levels of angiotensin II.

Bradykinin is a nine-amino-acid peptide produced in multiple sites throughout the body from kininogen through the action of plasma kallikrein. It is in turn metabolized by several peptidases. Pertinent to this discussion, bradykinin is degraded by ACE, and, in fact, more than 90% of bradykinin is eliminated on first-pass through the lungs [70]. Bradykinin's effects are wide-ranging, including antithrombotic and profibrinolytic activity in the coagulation system, as well as modulation of nitric oxide and prostacyclin release. Specific to the lung, bradykinin was shown some time ago to have vasodilating effects on normal pulmonary vessels but to be vasoconstrictive when the pulmonary endothelium was destroyed in animal models [71, 72]. Bradykinin has also been long described as a bronchoconstrictor [73, 74] and is still considered a prototypical bronchoconstricting substance [75]. The complexities of the kallikrein–kinin system's effect on endothelial cells, the myocardium, and vascular smooth muscle and its role in phenomena of cardiovascular injury are beyond the scope of this discussion, and the interested reader is referred to extensive reviews elsewhere [66, 76].

ACE is probably best known to clinicians through the drugs that block its activity, and, in fact, ACE inhibitors remain one of the most commonly prescribed group of drugs in the United States [77]. They are effective antihypertensive medications and have been shown to decrease the incidence of congestive heart failure after myocardial infarction [76]. It is now believed that some side effects of ACE inhibitors, such as angioedema and cough, and some of the beneficial impact, such as decreased myocardial infarctions and improved renal function, involve modification of bradykinin metabolism [66].

Biogenic Amines

Histamine, serotonin (5-hydroxytryptamine or 5-HT), and the three naturally occurring catecholamines (dopamine, norepinephrine, and epinephrine) comprise the group commonly termed biogenic amines. Studies looking into the uptake and metabolism of serotonin by the pulmonary circulation were among the earliest investigations of pulmonary pharmacokinetics [9, 78]. Subsequent work has made the behavior of this compound among the best understood in terms of pulmonary uptake and metabolism.

5-HT is produced predominately by the gastrointestinal tract's chromaffin cells. Ingested tryptophan undergoes a two-step conversion first by tryptophan-5-hydroxylase and then by L-amino acid decarboxylase to serotonin. Mast cells and neuroendocrine cells in the lung are also capable of producing serotonin by uptake of tryptophan along the same enzymatic pathway. However, the lung normally contributes minimally to systemic 5-HT production because of lesser tryptophan availability and much slower reaction rates [79]. Once released from the gastrointestinal tract, there is avid uptake of 5-HT, particularly by nerve endings and platelets. These cells do not metabolize 5-HT to any great extent. The remainder of 5-HT is extracted by the lung and, to a lesser degree, the liver. In the case of these organs, the 5-HT is metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by cytosolic monoamine oxidase and aldehyde dehydrogenase. 5-HIAA is, of course, a clinically useful marker of carcinoid syndromes associated with increased histamine turnover. It has been found that monoamine oxidase inhibitors block the cytosolic metabolism of 5-HT but not its uptake, while several drugs, including volatile anesthetic agents, block uptake but not intracellular metabolism [80].

Because it is not lipophilic, the pulmonary uptake of 5-HT is an active process, predominately via endothelial cells, with some variability between species. Several details of this uptake have been delineated as an ATPase-dependent active carrier process [81]. The pulmonary uptake of 5-HT by the lung is typically reported to be 90% or greater with little 5-HT reaching the systemic vasculature under normal circumstances. This model of production and uptake of 5-HT plays a pivotal role in several pathological processes relevant to clinical anesthesiology. In carcinoid syndrome, for example, the right heart receives a high concentration of 5-HT (and other substances) before being extracted and metabolized by the pulmonary circulation. This is thought to be the reason that the right heart shows the greatest myocardial and valvular injury in this syndrome [82–84]. This model is supported by other clinical observations. The valvular injury of substances related to 5-HT such as methysergide and ergotamine, those that increase 5-HT such as the infamous fenfluramine, and more recently the recreational drug "ecstasy" (3,4-methylenedioxymethamphetamine), known to activate 5-HT receptors, are all similar to carcinoid cardiac disease [85, 86]. Moreover, when an intracardiac right-to-left shunt is present in the carcinoid patient with bypass of the pulmonary circulation, the left heart demonstrates valvular injury similar to that of the right heart [18].

Pulmonary embolism presents another clinical situation pertinent to 5-HT activity. It has long been appreciated that the mass effect of embolism does not, in itself, account for the typical cardiopulmonary consequences including pulmonary hypertension. The platelet aggregation and activation associated with acute pulmonary embolism results in degranulation with the release of 5-HT, well known to be a potent vasoconstrictor and to increase bronchial smooth muscle tone. This release of 5-HT and, perhaps, decreased local uptake of 5-HT are postulated to cause local and regional vascular changes [87]. Other actions of elevated 5-HT, such as promotion of further platelet aggregation and inhibition of the vasodilating prostacyclin, likely also play a role in the

full response to pulmonary embolism [88]. The infusion of a serotonin antagonist in animals was found to attenuate the increase in pulmonary pressures associated with pulmonary embolism [89], supporting the role of 5-HT in this response.

Histamine, in contrast to 5-HT, has almost no uptake in the pulmonary circulation. Lung homogenates are capable of histamine metabolism [90], but the intact lung appears to lack an uptake mechanism for histamine.

Just as the lung has the enzymes to metabolize both histamine and serotonin but the ability to take up only serotonin, its uptake of catecholamines also demonstrates marked selectivity. Norepinephrine demonstrates a 35–50% first-pass uptake with subsequent metabolism by catechol-O-methyltransferase (COMT), MAO, aldehyde reductase, and aldehyde dehydrogenase [91]. Dopamine and epinephrine, however, have essentially no uptake although they would be susceptible to the cytosolic enzymes, as again proven by cell homogenates. The synthetic catecholamine isoproterenol also has no appreciable uptake by the lung.

Arachidonic Acid Metabolites

Extensive production and metabolism of arachidonic acid derivatives occur in the lung. The term eicosanoids refers to the 20-carbon carboxylic acids derived from the metabolism of the lipid membrane component icosatetraenoic acid, more commonly known as arachidonic acid. The action of phospholipase A_2 converts the esterified form, as found in the membrane, and releases arachidonic acid from structural glycerol. Once free, arachidonic acid may follow three main metabolic pathways in the lung. The lipoxygenase pathway produces leukotrienes, lipoxins, and some of the hydroxyeicosatetraenoic acids (HETEs). The cyclooxygenase (COX) pathway produces prostaglandins, thromboxane, and prostacyclin. The cytochrome P-450 monooxygenase system produces cis-epoxyeicosatrienoic acids and HETEs that are different than the products of the lipoxygenase pathway.

The lipoxygenase pathways produce leukotrienes and lipoxins. The formation of all leukotrienes starts from a common precursor. 5-Lipoxygenase, located in the perinuclear cytosol, responds to increased calcium in concert with its activating protein to generate 5-hydroperoxyeicosatetraenoic acids (5-HPETE) from arachidonic acid. A dehydrase then yields the relatively unstable leukotriene A_4 (LTA_4), which may undergo transformation by epoxide hydrolase (LTA_4 hydrolase) to LTB_4 which leaves the cell via a transport protein. The alternative pathway for LTA_4 is via LTC_4 synthase to form LTC_4, which is converted by nonspecific interstitial peptidases to the leukotrienes LTD_4 and LTE_4 (commonly referred to as slow-reacting substance of anaphylaxis). Whereas closely related prostanoids (see below) demonstrate opposing biological actions, the leukotrienes uniformly promote inflammatory responses in the lung. They are responsible for bronchoconstriction and increased pulmonary vascular permeability, are chemotactic and chemokinetic for neutrophils, and facilitate eosinophil degranulation [92–94]. They are produced by activated inflammatory cells within the lung as well as those arriving in response to inflammation. It should be no surprise that leukotrienes have been the subject of investigation in processes ranging from hypoxic pulmonary vasoconstriction in normal as well as damaged lungs [95, 96] to the pathogenesis of adult respiratory distress syndrome (ARDS) [97–99] and asthma [100]. This work has been especially fruitful in the case of asthma, for which leukotriene modifiers are a mainstay of treatment [101–103].

There appears to be little specialized pulmonary uptake or metabolism of the leukotrienes beyond the inactivation of LTB_4 and LTC_4 by neutrophils in the lung. Nonspecific hydroxylation and carboxylation of leukotrienes also occur in the interstitium, similar to that of other tissues [104].

The lipoxins have been identified as critical factors in the resolution of inflammation throughout the body, now seen more as an active process than the simple "burnout" of pro-inflammatory processes [105, 106]. There are three main synthetic routes of lipoxin formation, involving interactions of products from 5-lipoxygenase, 15-lipoxygenase, and/or 12-lipoxygenase, with the eventual formation of the two lipoxins, the positional isomers lipoxin A_4 (LxA_4) and B_4 (LxB_4). The lipoxins have a variety of antiinflammatory effects. They inhibit eosinophil and neutrophil chemotaxis and adhesion, as well as natural killer cell activation [107–110]. They are endothelium-dependent vasodilators of both pulmonary and systemic vasculature [111]. The lipoxins have been investigated extensively for their role in lung physiology and disease. Asthma, in particular, has received a great deal of attention [112]. Work thus far indicates that lipoxins are decreased in the sputum [113] and blood [114] of patients with severe asthma. The balance between leukotriene and lipoxin activity, in particular, has been found related to disease severity [115], raising the possibility of inducing lipoxin activity [116] as an adjunct to leukotriene modifiers. The role of lipoxins has also been considered in the active resolution of acute lung injury [117].

The lipoxins are predominately taken up by circulating monocytes with subsequent dehydrogenation [118]. No specific pulmonary uptake or metabolism of lipoxins has been described.

As implied by its name, COX catalyzes the cyclization and oxygenation of arachidonic acid, producing prostaglandin PGG_2, which is converted by nonspecific peroxidase(s) to the unstable precursor PGH_2. There are subtypes of COX, most notably COX-1 and COX-2. There has been great interest in COX-2 since its discovery in the 1990s because its inhibition was hoped to be more specific in controlling pain and inflammation without injury to the gastroduodenal mucosa [119,

120]. Although effective, the emergence of a small but real increase in cardiovascular risk of COX-2 inhibitors [121] has tempered their use. Complicating this issue further is that many of the "traditional" COX inhibitors such as acetaminophen, salicylates, and the nonsteroidal antiinflammatory agents ibuprofen and naproxen show only slightly less COX-2 avidity than some of the newer COX-2 inhibitors.

Following the production of PGH_2, the metabolic pathway divides into branches producing the various bioactive prostanoids; the enzymes of particular interest here are PGD synthase, PGE synthase, prostacyclin synthase, and thromboxane synthase. The final products of these pathways typically have oppositional or balancing effects locally and regionally. Prostaglandin E_2 (PGE_2) and PGI_2 are bronchodilators, for example, while $PGF_{2\alpha}$, PGD_2, and thromboxane A_2 (TXA_2) cause bronchoconstriction. Similarly, PGD_2, PGE_2, $PGF_{2\alpha}$, and TXA_2 are potent vasoconstrictors, while PGE_1 and PGF_2 are vasodilators.

Pulmonary endothelial cell cultures demonstrate virtually all COX pathway products to some extent, but the level of in vivo production is less clear. PGI_2 appears to be continuously produced, with modulation by vascular flow [122]. PGD_2, PGE_1, PGE_2, PGI_2, $PGF_{2\alpha}$, and TXB_2 have all been found to be produced by human lungs, although under varying circumstances [123, 124].

The discussion of the pulmonary metabolism of COX products includes the now familiar theme of a broad range of intracellular enzymes (by cell culture and cellular homogenate investigation) but selective uptake. In this way, at least 80–90% of PGD_1, PGE_2, and $PGF_{2\alpha}$ are taken up and metabolized in a first-pass through intact pulmonary circulation; but PGA_1, PGA_2, and PGI_2 demonstrate essentially no uptake [24, 125, 126]. TXA_2, a relatively unstable compound, presents a special case in the discussion of pulmonary uptake. TXA_2 undergoes hydrolysis in the blood, forming TXB_2. It is TXB_2 that is taken up by a carrier for cytosolic metabolism and is often utilized as an investigative marker of TXA_2 activity [127].

The P-450 monooxygenase system provides three pathways of arachidonic acid metabolism which results in epoxyeicosatetraenoic acids (EETs), HETEs, or dihydroxyeicosatetraenoic acids (dHETEs). These pathways are not unique to the endothelium, epithelium, and smooth muscle of the lung, being found in several other organs including the gastrointestinal tract, liver, and kidney [128]. Subfamilies of cytochrome P-450 systems have been identified within the lung. The CYPA4 family produces 20-HETE, while the CYP2J family is found in epithelial, bronchial, and vascular smooth muscle cells, as well as endothelial and alveolar macrophages [129].

The HETEs and EETs have been shown experimentally to affect pulmonary vascular and bronchomotor tone. 20 HETE and 5, 6, 11, and 12-EETs all have relaxing effects on both the lung vasculature and airways [130, 131]. They are further known to have general antiinflammatory effects, to modulate reperfusion injury, and to inhibit platelet aggregation. Within the lung, 15-HETE and 20-HETE may both modify hypoxic vasoconstriction [132].

Natriuretic Peptides

The natriuretic peptides currently consist of, in order of their discovery during the 1980s, atrial natriuretic peptide (ANP), brain natriuretic peptide, and C-type natriuretic peptide. ANP has received the most attention in terms of pulmonary pharmacokinetics. It is a pulmonary artery (and to a lesser extent, venous) vasodilator whose action is independent of endothelial function. ANP is known to interact with the renin–angiotensin–aldosterone system at several points. Best described are suppression of renin release, decrease in angiotensin-converting enzyme activity, and blocking of aldosterone release. These actions promote natriuresis and diuresis. ANP is mainly produced in the cardiac atria, but both ANP and its prohormone have been found in the human fetal lung [133] and adult pulmonary veins [134]. Lung production is suppressed by hypovolemia and increased with hypoxemia, hypervolemia, and in the presence of glucocorticoids. In terms of elimination, the rabbit lung demonstrates a 25% first-pass uptake of ANP [135].

Other Endogenous Substances

The number of substances handled by the lung and the intricacies of their metabolism precludes full discussion here. For the interested reader, several historically and/or clinically important substances are listed in Table 7.3, and references

Table 7.3 Lung effects on endogenous substances relevant to the anesthesiologist

Group	Impact of passage through the pulmonary circulation		
	Activated	Minimal or none	First-pass uptake and/or metabolism
Peptides	Angiotensin I	Angiotensin II	Endothelins
		Vasopressin	Bradykinin
		Oxytocin	
		Atrial natriuretic peptide	
Steroids	Cortisone		Beclomethasone
			Progesterone
Purine family			Adenosine phosphates (AMP, ADP, ATP)
Arachidonic acid family		PGA_2	PGD_2
		Prostacyclin (PGI_2)	PGE_2
			PGF_2
			Leukotrienes
Biogenic amines		Dopamine	5-HT
		Epinephrine	Norepinephrine
		Histamine	

are provided for the activation of cortisone to cortisol in health [136, 137] and disease [138], the behavior of endothelin in several clinical circumstances [76, 139, 140], and new perspectives on purine metabolism by endothelial ectoenzymes [138].

The Lung as Vascular Reservoir and Filter

The volume of blood within the lungs under various conditions has been a subject of investigation for over 80 years [141]. What is known is that the pulmonary vasculature in health has remarkable capacitance, allowing it to accept wide ranges of right ventricular output with minimal change in pressure. This ability to load and offload volume allows the lungs to serve as a vascular reservoir to meet the preload needs of the left heart as they change due to factors such as posture, exercise, changes in intrathoracic pressure (e.g., Valsalva maneuver), and daily volume shifts [142]. The role of pulmonary vascular capacitance is also emerging in our understanding of disease processes relevant to clinical anesthesiology. Models of heart failure, for example, now incorporate the role of vascular compliance in general and the pulmonary vasculature capacitance and permeability specifically [143]. Also of interest to anesthesiologists, researchers have found that following the release of the tourniquet in total knee arthroplasty, there is an actual decrease in pulmonary vascular resistance. A clue to the mechanism of this finding was metabolic evidence of increased endothelial recruitment with this obligatory microembolism [144].

The unique anatomical position of the lungs as they receive the entire right heart output allows them to serve as physical filters, in much the same way that they metabolically play a pivotal role in the uptake of endogenous substances and xenobiotics. Particles normally filtered by the lung before reaching the systemic circulation include small blood clots, fat droplets, agglutinated white blood cells, and amniotic fluid in the case of pregnancy. The literature commonly alludes to the ability of 350 and even 500 μm glass beads to pass through the pulmonary vasculature in animal models. Given that normal pulmonary capillaries have a diameter of 7–10 μm, this implies other arteriovenous communications under normal conditions. Recent work in isolated, but normally ventilated, animal and human lungs and, especially, exercised human subjects implies a more complicated picture. It now appears that, indeed, arteriovenous passage of particles larger than 50 μm occurs in isolated lungs, although more than 99% of such glass microspheres are trapped by the lungs [145]. In human volunteers, aggregated albumin tagged with technetium-99 and with diameters of 7–25 μm was found to have about 0.7% transpulmonary passage at rest. This rose to 3% passage with exercise, as demonstrated by aggregate trapping in systemic capillaries. This implies the recruitment of intrapulmonary arteriovenous pathways with exercise which presumably allow decreased resistance to flow but also compromise the lung's competence as a mechanical filter [146]. The lung's protection of systemic circulation from embolus can also, of course, be completely subverted by anatomic variants and pathological states. The latter is exemplified by the hepatopulmonary syndrome's intrapulmonary vascular dilatations, which have been associated with patient injury from embolism [147]. The patent foramen ovale and its potential for catastrophic embolic phenomena in the perioperative period [18, 146, 148] have long been appreciated and feared by anesthesiologists as the classic anatomic variant which bypasses the protective filtration of the pulmonary vasculature.

The Respiratory Epithelium

The lung defends the body not only by mechanical filtration and metabolism of substances from the blood but also from airborne agents. In this way, the constantly renewing airway epithelium is responsible for helping to maintain normal gas exchange from the trachea to the terminal alveoli. The respiratory epithelium represents a huge surface area that is a gateway from the outside world to the exquisitely delicate alveoli, a path taken by both life-sustaining oxygen and potentially damaging particles and gasses. This defensive challenge is especially impressive when considering both the wide range of conditions to which the modern human is exposed and the simple fact that even a somewhat sedentary adult can be expected to inhale well over 10,000 L of gas from his/her environment in a day. The discussion below will briefly review the structure and function of this system and then the way in which it provides protection through the mucociliary apparatus, trapping of particles, and response to particles and pathogens.

The Cells of the Respiratory Epithelium

While some 50 distinct cell types have been identified in the human airway [149], our discussion will focus on those most important to the lung's nonrespiratory functions.

Ciliated Columnar Cells

These cells are the most common of the respiratory epithelium. Their most obvious defining feature is several hundred cilia moving at a rate of about 12 cycles per second, always toward the trachea. As might be expected, this

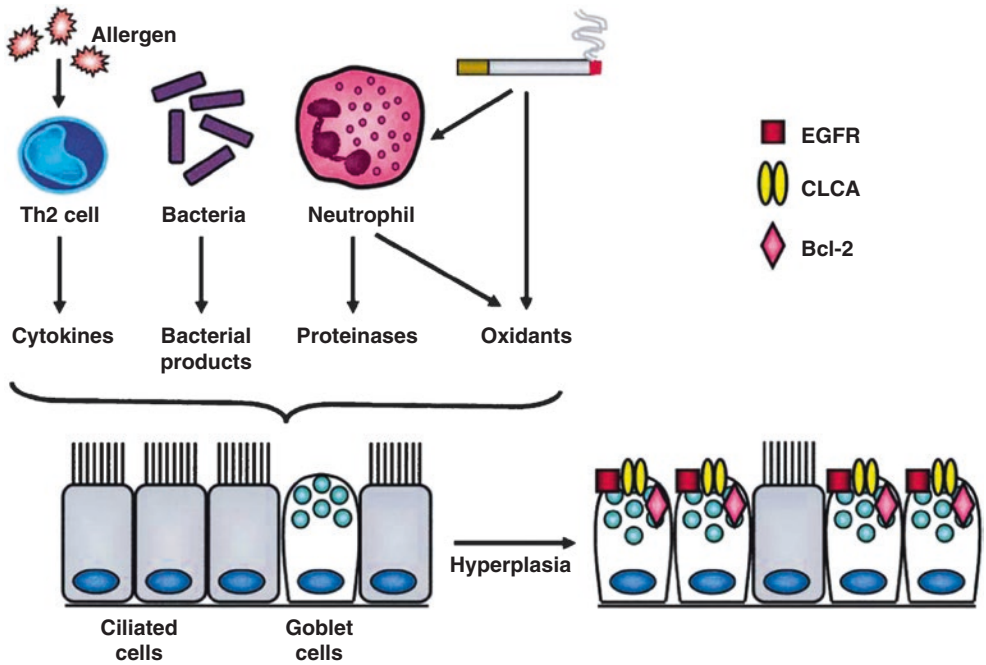

Fig. 7.3 Airway goblet cell hyperplasia. Simplified schematic outlining selected pathways generating increased epithelial mucin production. Cytokines (e.g., interleukin-4, interleukin-9 and interleukin-13), bacterial products (e.g., lipopolysaccharide and lipoteichoic acid), proteinases (e.g., elastase and cathepsin G), and oxidants from T helper-2 (Th2) lymphocytes, bacteria, neutrophils, and cigarette smoke upregulate mucin production and/or induce goblet cell hyperplasia with associated increases in expression of epidermal growth factor receptors (EGFR), calcium-activated chloride channels (CLCA), and the anti-apoptotic factor Bcl-2. Note: not all stimuli have yet been shown to induce expression of each of EGFR, CLCA, and Bcl-2. In addition, production of new goblet cells appears to involve differentiation of non-granulated epithelial cells rather than goblet cell division. (Reproduced with permission. Rogers [150]. Copyright Elsevier)

process requires large energy expenditures, and, in fact, the cells have extensive populations of mitochondria for energy production. The cellular architecture and shape change according to position in the respiratory tract. In the nose, pharynx, and large airways, the columnar cells are pseudostratified, layered over the basal cells which are thought to be the stem cells for both ciliated and goblet cells. Moving down the bronchi, they gradually thin to a single layer. Further still, in the bronchioles, the columnar cells transition to a layer of cuboidal cells and then, approaching the terminal airways, they mix with type I alveolar cells.

Goblet Cells

These specialized columnar epithelial cells can rapidly secrete mucins (high molecular weight mucous glycoproteins) which provide a protective layer over the epithelium when it combines with other lipid, glycoconjugate, and protein components [150]. Mucin is released by exocytosis in response to a variety of stimuli such as dust, microorganisms, fumes, and debris within the airway. Hyperplasia in response to chronic stimulation is a hallmark of the goblet cell population (Fig. 7.3) and typical of disease processes such as asthma, bronchitis, and cystic fibrosis [151].

Submucosal Secretory Cells

There are actually two types of submucosal secretory cells. Both are associated with the submucosal glands of the trachea and large bronchi. These glands are innervated by cholinergic fibers from the vagus [152] and are located in the submucosa between the smooth muscle and cartilage plate. The serous-type cells account for more than half of the submucosal gland in health and contain multiple secretory granules. Proteoglycans, lysozyme, lactoferrin, IgA receptor complex, peroxidase, and antiproteases are among the contents of these granules. The mucous-type cells are columnar cells with a high density of cell granules containing mucin. It is thought that serous cells transdifferentiate to mucous cells in response to injury from inhaled agents and the resulting predominance of mucous cells plays a role in the change of the character of mucus in response to injury. While it is accepted that both the submucosal secretory cells and goblet cells contribute to airway mucus, there

is apparent variability in the relative contribution of these cells on the basis of airway level, experimental model, and species [153–156].

Clara Cells

Clara cells (nonciliated bronchial secretory cells) are normally found predominately in the terminal bronchioles (Fig. 7.4). Their granules secrete Clara cell secretory protein (CCSP), the function of which is poorly defined. In an animal model, antigenic challenge results in proliferation of tracheobronchial Clara cells that secret not only CCSP but also demonstrate secretion of mucin [156]. Conversely, in normal humans, bronchiolar goblet cells have been found to secrete CCSP, leading to speculation that Clara cells may be goblet cell precursors [158], as well as progenitors of the epithelium [157].

Mast Cells

Mast cells are located throughout the lung, from typical locations under the airway epithelium and in the alveolar septum to those freely positioned in the airway. They have traditionally been associated with acquired immunity, but recent evidence indicates that mast cells also have important roles in innate immunity and inflammatory regulation [159]. Specifically, their role as sentinel for innate immunity seems to bridge the classic with the more recently appreciated roles [160].

Macrophages and Monocytes

Macrophages and monocytes can be categorized as (1) airway and alveolar macrophages, (2) interstitial macrophages, and (3) pulmonary vascular monocytes. This scheme does not include the monocyte derivative dendritic cells. There are limited data regarding the sparse interstitial macrophage population, mostly from animal preparations. There is no evidence that the intravascular monocytes of the lung are particularly different from monocytes throughout the body's vascular system, transforming into macrophages within the tissue to which they migrate.

The alveolar macrophages must routinely phagocytize a dizzying array of invaders of the airspace. These include dust and particulates as well as bacteria, yeasts, and other organic and inorganic debris. Phagosomes initially envelope the ingested target and then are merged with lysosomes. The latter contain hydrolytic enzymes, which efficiently destroy the majority of bacteria, yeasts, and debris encountered. For some

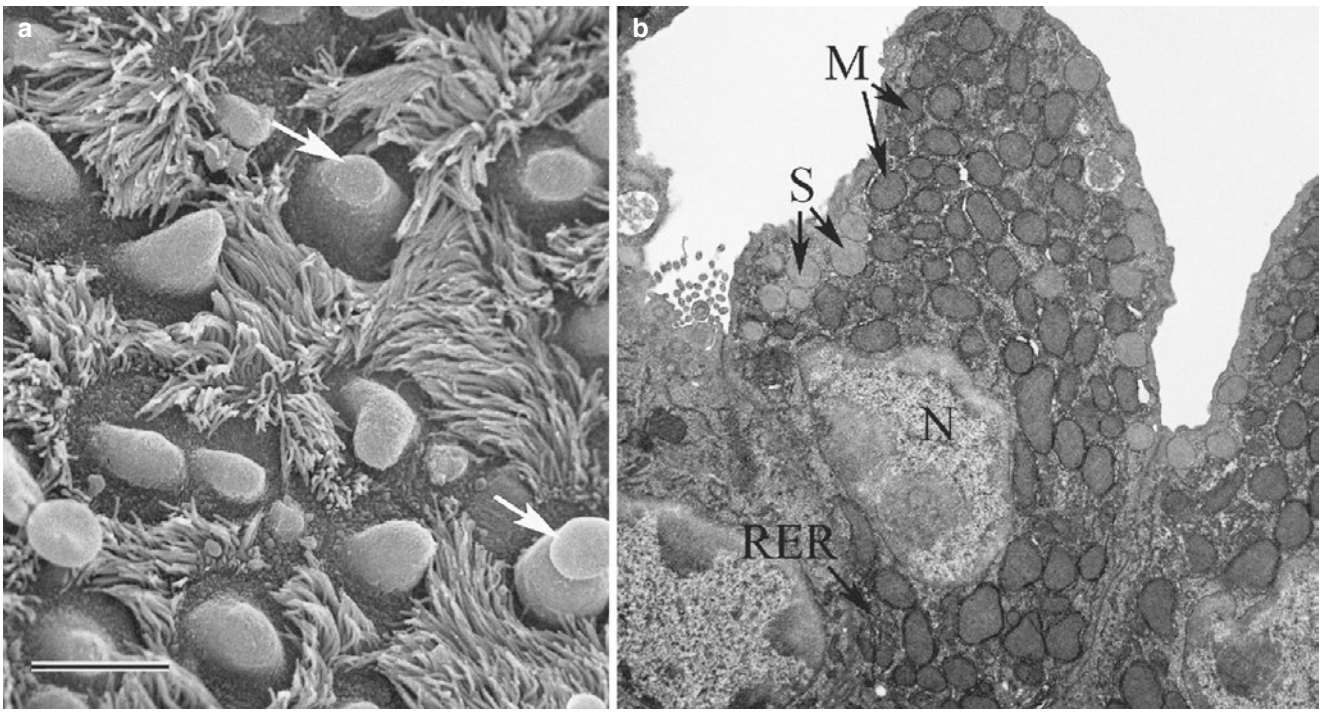

Fig. 7.4 (**a**) Scanning electron micrograph of the lining of the proximal bronchiole of a rat showing Clara cells, some of which are undergoing apocrine secretion (*arrows*), surrounded by ciliated cells (bar = 10 μm). (**b**) Transmission electron micrograph of a terminal bronchiolar Clara cell. Numerous mitochondria (M), secretory granules (S), rough endoplasmic reticulum (RER), and the basal nucleus (N) are indicated. (Reproduced with permission. Reynolds and Malkinson [157]. Copyright Elsevier)

microorganisms (e.g., mycobacteria and many gram-negative bacteria) and materials, the lysosomal system is not effective. In this case, secondary lysosomes are now used essentially as storage areas, where the material is isolated for the life of the macrophage. The fate of these laden cells is not uniform. It appears that some are swept away by the mucociliary apparatus for mechanical elimination and others remain in the lung for as long as months before dying and releasing their sequestered contents for uptake by successor macrophages. There has been recent attention to the translocation of particles from the lung to lymph nodes and other organs [161, 162], presumably in conjunction with alveolar macrophage activity.

Alveolar Epithelial Cells

Alveolar epithelial type I and type II cells (also referred to as type I and II pneumocytes) line the terminal alveoli. Type I cells are thin sheets lining the alveoli with each covering several capillaries. Type I cells cover approximately 90% of lung surface area and are responsible for maintaining lung fluid homeostasis. The tight junctions between cells are well described and thought to provide only a 1-μm gap under normal circumstances. Historically thought to serve as a barrier to the movement of solutes and water into the alveoli, more recent work with sodium and chloride transporters has found evidence of active epithelial mechanisms for fluid transport in both health and diseased states [163, 164]. Additionally, the presence of caveolae and intracellular vacuoles suggests that type I cells may also have endocytic function and participate in metabolic activities [165]. Type II alveolar epithelial cells tend to be clustered at alveolar junction points. They are cuboidal cells with lamellar bodies in the cytoplasm and numerous mitochondria. The lamellar bodies are inclusions of variable size and composed of stacked layers of membrane-like material. It is this material which is processed and released as surfactant by the type II cell [166]. Four types of surfactant proteins A, B, C, and D (SP-A through SP-D) have been identified. SP-A and SP-D modulate surfactant release, while SP-B and SP-C stabilize the surfactant monolayer discussed below [167]. SP-B is the protein absolutely required for survival, but important contributions have been discovered for the other SP proteins. SP-A and SP-D, for example, play immune roles by direct antimicrobial activity and enhancement of macrophage recognition of microorganisms.

Functions of the Respiratory Epithelium

The functions of the respiratory epithelium that will be reviewed here include maintenance of the complex liquid film of the airway, humidification, removal of inhaled materials, and response to inhaled pathogens.

Airway Surface Film

The surface liquid of the airway, in health, is about 10 μm thick. It consists of two layers, namely, the periciliary sol underneath a second layer of mucus gel. The sol is a low-viscosity watery liquid that surrounds the cilia. The mucus, as discussed previously, is produced by the submucosal glands and goblet cells in response to a variety of irritants. The complex gel-aqueous becomes progressively thinner from the trachea (100 μm) to the bronchi (8 μm) and then to terminal bronchioles (3 μm) [168]. The cilia are too tightly arranged for the mucus gel to find its way between cilia, thus the gel layer contacts only the ciliary tips along its bottom edge. The cilia, then, are free to move in their well-characterized rhythmic pattern with relatively less resistance from the minimally viscous sol. In this manner, the cilia propel the mucous layer toward the trachea at a rate of 3–4 mm/min [169]. The thickness of the layers of this system, especially the sol, must be maintained within very narrow tolerances for mechanical efficiency. This is achieved in large extent by simple osmotic gradient and probably accounts for much of the adjustment that occurs as larger amounts of mucus converge in the larger airways. Adjustments of sol osmolarity to effect this mechanism occur through the activity of the amiloride-sensitive chloride channel, more commonly referred to as the cystic fibrosis transmembrane conductance regulator (CFTR) protein. Indeed, the ravages of cystic fibrosis are now thought to start at least in part because of the relative depletion of the sol, emphasizing the delicate nature of the system just described [170]. The antimicrobial capabilities of the mucociliary apparatus will be discussed below.

Humidification

The respiratory system has enormous capacity to humidify inspired gas. At rest, air is completely saturated with water vapor as it passes through the nose and upper airway, before it reaches the trachea. As minute ventilation (MV) increases, smaller and smaller airways are required to contribute to humidification, such that at a MV of 50 L min^{-1}, airways of only a few millimeters in diameter receive incompletely humidified gas [171]. The airways do reclaim some of the heat and moisture imparted on the inhaled gas during its exhalation. Thus, bypassing of the nasopharyngeal passages and upper trachea by devices such as endotracheal tubes not only decreases humidification of the gasses delivered to the distal airways but also cheats the opportunity to recoup heat and moisture on exhalation.

Removal of Inhaled Particles

The regions of the respiratory tract in which particles are deposited depend upon respiratory pattern, environmental conditions, and the nature of the particles themselves. Accepting these variations, it is possible to generalize particle behavior under normal circumstances. Particles larger than 10 μm (e.g., dust and particulates from low-grade petroleum combustion) are often trapped at the level of the nose or pharynx. Those that enter the airway of the lung, and particles of 3–10 μm, are caught on the liquid film layer and transported out of the lung for swallowing or expectoration as previously described. They tend to be deposited in higher concentration in areas of high turbulence such as airway bifurcations. Particles smaller than 3 μm may reach the alveoli. They will either be subsequently exhaled or settle in the alveolus, where they will be subject to the activity of macrophages as discussed in a previous section. There are, of course, particular substances that instigate a detrimental response from the body, for example, asbestos with resultant pulmonary fibrosis.

Response to Inhaled Organisms

There are several mechanisms with which the airway defends the body against inhaled microorganisms. The first is simple impact and capture by the nasal and pharyngeal mucosa with subsequent swallowing and destruction in the hostile gastrointestinal tract or expectoration. Those organisms that enter the lung may be similarly trapped on the surface film and moved out of the lung by ciliary action. The surface film is more than a simple transport mechanism, having a variety of antimicrobial mechanisms. These capabilities make teleological sense, because the potentially damaging agents are not immediately removed.

Surfactants, consisting of 80% phospholipids, 5–10% proteins, and 5–10% other lipids, are best known for their ability to reduce surface tension and thus equalize pressures within airspaces of differing sizes [168]. Less appreciated is the fact that SP-A and SP-D (following terminology introduced in the discussion of type II alveolar cells) are members of the collectin protein family. Collectins have an N-terminal collagen-type region and a C-terminal lectin region that bind carbohydrates. The C-terminal's preferential binding site is nonhost oligosaccharides, giving them the ability to opsonize bacterial and viral pathogens and to facilitate macrophage phagocytosis [172]. SP-A and SP-D are also known to be directly antimicrobial, without immune cells, against a variety of pathogens [173, 174].

The surface films of the large bronchi (and the mucosa of the nasopharynx) have generous amounts of IgA, which acts as an opsonin and has a role in complement induction. In smaller airways and alveoli, IgG becomes the predominant surface antibody in normal circumstances.

The airway epithelium also acts as an immune barrier via interactions between Fas receptors (CD95/Apo-1) and Fas ligand (FasL, CD95L, CD178), found on airway epithelium, in response to immune reactions and infection [175, 176]. The interaction between Fas and FasL activates intracellular caspases leading to apoptosis of infiltrating immune cells, protecting against tissue injury [177, 178]. FasL appears to be cleaved and made inactive in asthma, contributing to the chronic inflammation and damage to the epithelium seen in chronic lung diseases [179]. Toll-like receptors are also found in airway epithelial cells, upregulating the production of cytokines, chemokines, and other antimicrobial peptides in response to bacteria and viruses [180, 181]. Epithelial cells also secrete antimicrobial peptides including ß-defensins and LL-37, preventing the growth of inhaled microorganisms prior to clearance or phagocytosis [181].

Lung epithelial cells can release soluble factors including IL-1ß and IL-8, while alveolar macrophages release TNF-α and IL-6 resulting in the release of neutrophils from bone marrow as well as neutrophil chemotaxis in response to pollutants, including cigarette smoke, and pathogens [182, 183]. Once present at the source of infection, neutrophils secrete granules containing lactoferrin, lysozymes, defensins, and other proteolytic enzymes as well as generate oxygen free radicals to destroy pathogens [184]. Stimulated bronchial epithelial cells can also secrete and/or facilitate adhesion molecules, growth factors, and collagen. Epithelial cells produce high levels of nitric oxide (NO), and production is increased in the presence of respiratory viruses acting to inhibit viral replication [185]. The absence of upregulation of nitric oxide synthase-2 in cystic fibrosis is implicated in increased viral susceptibility in these patients [186].

Summary

Historically, practitioners of the medical arts from around the globe viewed the lung as a defender of the body from a hostile outside world and as a trusted modulator of its internal processes. More recently, respiratory function became the focus of attention with advances that have been central to the development of anesthesiology and upon which modern clinicians base much of our practice in cardiopulmonary medicine. The purpose of this discussion, which returns to the concepts of lung as protector and minister, has been to highlight important nonrespiratory lung functions in terms of both current areas of discovery and clinical implications. It is hoped that the reader will agree that familiarity with these aspects of pulmonary function is pivotal to a complete understanding of the lung and to the advancement of clinical practice.

Pharmacology of the Airways

8

Cassandra Bailey, Paul J. Wojciechowski, and William E. Hurford

Key Points

- Short-acting beta-2 adrenergic agonists are administered for the acute relief of bronchospasm, wheezing, and airflow obstruction. Long-acting beta-2 adrenergic agonists are for long-term control of symptoms.
- Inhaled anticholinergics are first-line therapy in COPD. They are useful for both maintenance therapy and in acute exacerbations.
- Inhaled corticosteroids are used to control inflammation in asthma and COPD. In asthma, they can be used as monotherapy. In COPD, they are used in conjunction with long-acting beta-adrenergic agonists.
- Systemic corticosteroids are used for the reduction of inflammation in asthma and COPD exacerbations and are not typically prescribed as maintenance therapy.
- Phosphodiesterase 4 inhibitors can be used in patients with severe COPD, chronic bronchitis, and a history of exacerbations.
- Leukotriene modifiers, mast cell stabilizers, and methylxanthines are alternative therapies used in asthma when symptoms are not well-controlled on first-line therapy.
- Volatile and intravenous anesthetics provide a degree of bronchodilation that may be useful in treating intraoperative bronchoconstriction.
- Helium/oxygen mixtures, antihistamines, and magnesium sulfate are alternative therapies used when bronchospasm does not respond to conventional therapies.

Introduction

This chapter reviews the pharmacology of agents commonly encountered in anesthetic practice that are either administered to treat pulmonary diseases or administered into the airway for action at end organs other than the lung but have effects on the airway. Drugs that modify the state of the autonomic nervous system (ANS) and the airway will be reviewed along with medications that modify or suppress inflammation of the airway. Lastly, the action of anesthetic agents on the airway will be reviewed along with the actions of several adjunctive agents.

Pharmacologic agents administered via the lungs take advantage of the unique interface between air and blood allowing for rapid uptake of drugs into the bloodstream or immediate utilization by cells that populate the airway. The delivery of medications to the lungs can have systemic effects, direct effects on the airway, or both. For example, inhaled anesthetics are delivered via the lungs to act in the brain and have bronchodilatory effects. Conversely, beta-adrenergic agonists delivered via aerosol exert direct effects on bronchial smooth muscle with few systemic effects. Drugs administered directly to the airway are ideal for treating pulmonary parenchymal diseases such as asthma and chronic obstructive pulmonary disease (COPD).

Influence of the Autonomic Nervous System on the Airway and Modulation of the Response

Traditionally, the ANS has been divided into two major parts, the parasympathetic and sympathetic nervous systems. The parasympathetic nervous system regulates airway caliber, airway glandular activity, and airway microvasculature [1–4]. The vagus nerve provides the preganglionic fibers which synapse with postganglionic fibers in airway parasympathetic ganglia [1–4]. Acetylcholine activates the muscarinic (M3) receptor of postganglionic fibers of the parasympathetic nervous system to produce bronchoconstriction [5]. Anticholinergics can provide bronchodilation even in the resting state since the parasympathetic nervous system produces a basal level of resting bronchomotor tone [3, 4, 6]. Activated eosinophils may play a role in airway hyperresponsiveness through release of major basic protein that prevents acetylcholine from binding the M2 receptors, leading to inhibition of negative feedback control and increasing release of acetylcholine [7].

Although the sympathetic nervous system plays no direct role in control of airway muscle tone, beta-2 adrenergic receptors are present on airway smooth muscle cells and cause bronchodilation via G-protein and secondary messenger mechanisms [1–5]. The abundance of these receptors in the airway allows for pharmacologic manipulation of airway tone [8].

The ANS also influences bronchomotor tone through the nonadrenergic noncholinergic (NANC) system [2, 4, 9, 10]. The exact role of NANC in humans is not well defined; it has excitatory and inhibitory neuropeptides that influence inflammation and smooth muscle tone, respectively [2, 9]. Vasoactive intestinal peptide (VIP) and nitric oxide (NO) are the main inhibitory transmitters thought to be responsible for airway smooth muscle relaxation [2, 9]. Substance P (SP) and neurokinin A (NKA) are the main excitatory transmitters and have been shown to cause neurogenic inflammation, including bronchoconstriction [2, 9]. The precise role of NANC in healthy and diseased human lung is unclear. Further study is needed to fully elucidate the role that this group of neuropeptides has in the regulation of bronchial smooth muscle responsiveness.

Inhaled Adrenergic Agonists

The mainstay of therapy for bronchospasm, wheezing, and airflow obstruction is beta-adrenergic agonists. Beta-adrenergic agonists used in clinical practice are typically delivered via inhalers or nebulizers, are beta-2 selective, and are divided into short- and long-acting therapies [11]. Short-acting beta-2 agonist therapy is effective for the rapid relief of wheezing, bronchospasm, and airflow obstruction [11]. Longer-acting beta-2 agonists are used as maintenance therapy providing improvement in lung function and reduction in symptoms and exacerbations [11]. Please refer to Table 8.1 for a selection of beta-2 selective agonists that play a role in the management of airway diseases and symptoms both in and out of the operating room.

Table 8.1 Pharmacologic influence on the autonomic nervous system

Systemic adrenergic agonists	Inhaled adrenergic agonists	Inhaled cholinergic antagonists	Systemic cholinergic antagonists
	Short-acting	Short-acting	
Terbutaline	Albuterol	Ipratropium	Atropine
Epinephrine	Levalbuterol		Scopolamine
Albuterol	Metaproterenol		Glycopyrrolate
	Pirbuterol		
	Long-acting	Long-acting	
	Salmeterol	Tiotropium	
	Formoterol		
	Arformoterol

Mechanism of Action

Short-acting beta-2 agonists bind to the beta-2 adrenergic receptor located on the plasma membrane of smooth muscle cells, epithelial, endothelial, and many other types of airway cells [8, 12]. Figure 8.1 demonstrates how a ligand binding to the receptor causes a G-stimulatory protein to activate adenylate cyclase-converting adenosine triphosphate (ATP) into cyclic adenosine monophosphate (cAMP) [8, 12]. It is unknown precisely how cAMP causes smooth muscle relaxation; however, decreases in calcium release and alterations in membrane potential are the most likely mechanisms [8]. Longer-acting beta-2 agonists have the same mechanism of action as short-acting beta-2 agonists; however, they have unique properties that allow for a longer duration of action. For example, salmeterol has a longer duration of action because a side chain binds to the beta-2 receptor and prolongs the activation of the receptor [12, 13]. The lipophilic side chain of formoterol allows for interaction with the lipid bilayer of the plasma membrane and a slow, steady release prolonging its duration of action [12].

Clinical Applications

Beta-2 agonists have a central role in the management of obstructive airway diseases allowing for control of symptoms and improvement in lung function. Short-acting beta-2 agonists such as albuterol, levalbuterol, metaproterenol, and pirbuterol are prescribed for the rapid relief of wheezing, bronchospasm, and airflow obstruction [11]. Clinical effect is seen in a matter of minutes and lasts up to 4–6 h [12]. Scheduled, daily use of short-acting beta-2 agonists has

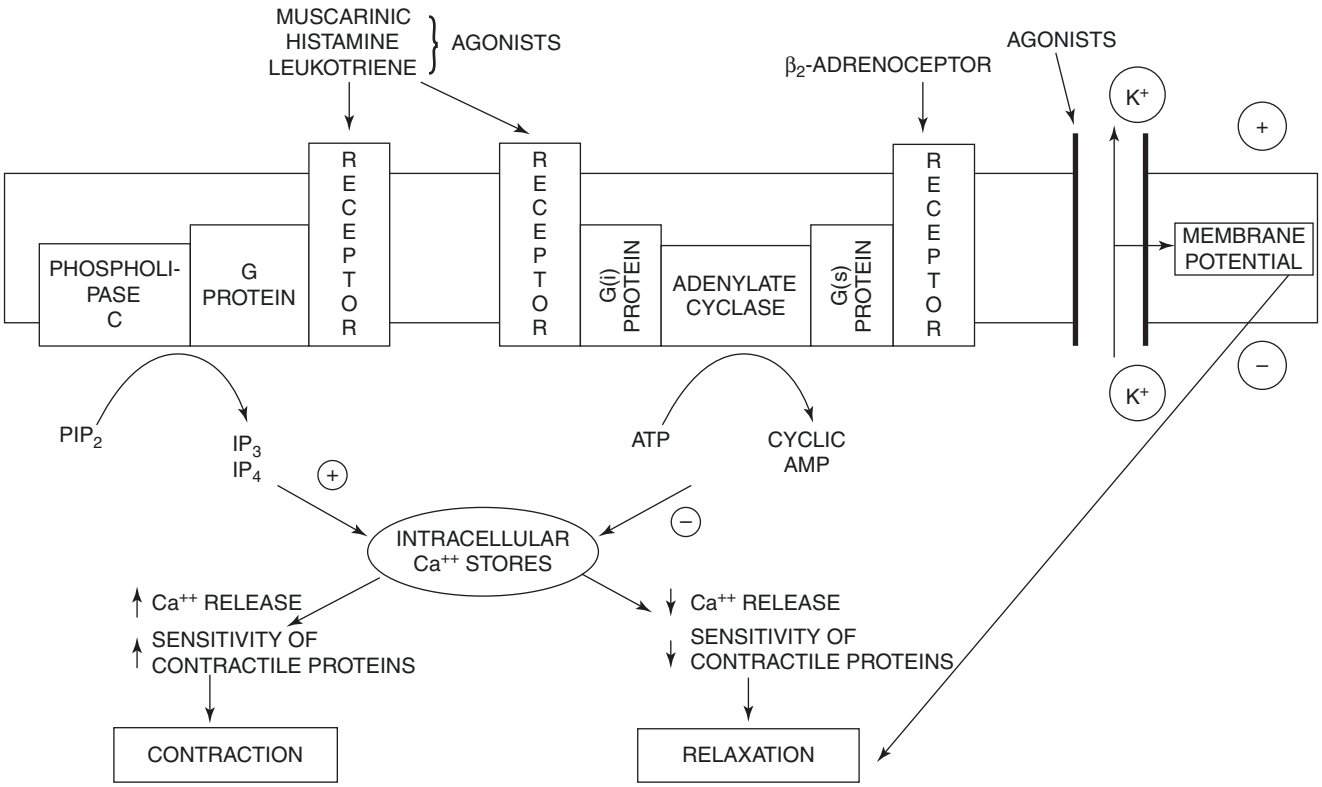

Fig. 8.1 Effects of agonists at the beta-2 receptor and at the muscarinic receptor. Stimulation of the beta-2 receptor will cause a decrease in calcium release and relaxation of smooth muscle. Blockade of the muscarinic receptor will prevent the release of calcium and smooth muscle contraction. ATP, adenosine triphosphate; AMP, adenosine monophosphate; IP, inositol phosphate; PIP2, phosphoinositide bisphosphate. (Reprinted with permission of the Thoracic Society. Copyright© American Thoracic Society. Johnson [8]. Official Journal of the American Thoracic Society)

fallen out of favor, and they are now used primarily as rescue therapy [14–16]. Long-acting beta-2 agonists can be prescribed for control of symptoms when rescue therapies (i.e., short-acting beta-2 agonists) are used frequently within a week [11, 17]. In asthma, combination therapy including a long-acting beta-2 agonist and an inhaled corticosteroid (IC) are effective in reducing symptoms, reducing the risk of exacerbation, and improving lung function while minimizing the dose of IC [11, 18]. In COPD, combination therapy composed of inhaled long-acting beta-2 agonists, IC, and long-acting muscarinic antagonists can improve lung function and reported patient outcomes; however more studies are needed before triple therapy can be fully recommended [19].

Side Effects

Systemic absorption of inhaled beta-2 agonists is responsible for a myriad of side effects, most of which are not serious. Most commonly, beta-2 agonist therapy leads to tremors and tachycardia secondary to direct stimulation of the beta-2 adrenergic receptor in skeletal muscle or vasculature, respectively [11, 12, 20, 21]. In severe asthma, beta-2 agonists may cause a temporary reduction in arterial oxygen tension of 5 mmHg or more secondary to beta-2-mediated vasodilation in poorly ventilated lung regions [12, 22]. Hyperglycemia, hypokalemia, and hypomagnesemia also can occur with beta-2 agonist therapy, but the severity of these side effects tends to diminish with regular use [12]. Tolerance to beta-2 agonists can occur with regular use over a period of weeks and, while not affecting peak bronchodilation, can be evidenced by a decrease in the duration of bronchodilation and the magnitude of side effects (tremor, tachycardia, etc.) [12, 23, 24]. Tolerance likely reflects beta-2 adrenergic receptor downregulation [12]. Last, beta-2 agonist therapy withdrawal after regular use can produce transient bronchial hyperresponsiveness [12].

Safety Concerns

Evidence has associated the use of long-acting beta-2 agonist therapy without concomitant use of a steroid inhaler with fatal and near-fatal asthma attacks [11, 25]. In light of this evidence, it seems prudent to save long-acting beta-2 agonists for asthmatic patients that are poorly controlled on inhaled steroids alone or for those patients with symptoms sufficiently challenging to warrant the potential extra risk associated with use of the agents [11, 25].

Systemic Adrenergic Agonists

Systemic administration of adrenergic agonists for asthma was used more frequently in the past. Oral, intravenous, or subcutaneous administration of beta-specific or nonspecific adrenergic agonists is now reserved for rescue therapy.

Mechanism of Action

The mechanism of action of systemically administered adrenergic agonists is the same as it is for inhaled agents. Binding of the drug to the beta-2 adrenergic receptor on smooth muscle cells in the airway is responsible for the bronchodilatory effects [8]. Specifically, beta-2 receptor stimulation induces a G-stimulatory protein to convert ATP to cAMP and in turn reduces intracellular calcium release and alters membrane potential [8, 12].

Clinical Applications

Terbutaline can be given orally, subcutaneously, or intravenously (IV), albuterol (salbutamol) can be given intravenously, and epinephrine is usually given subcutaneously or intravenously. Regardless of the route of administration, all three will produce bronchodilation. Comparison of intravenous and inhaled formulations of terbutaline failed to demonstrate any difference in bronchodilation, and, with the propensity for IV formulations to cause side effects, inhaled therapy should be considered the first-line treatment [26, 27]. This principle not only applies to terbutaline but also to all beta-adrenergic agonists that are available in IV and inhaled forms [17]. If inhaled therapy is not readily available or if inhaled therapy is maximized and symptoms persist, then subcutaneous epinephrine or terbutaline can be administered with improvement in symptoms and spirometry values [28]. In summary, subcutaneous or IV beta agonists should be reserved only for rescue therapy.

Side Effects

The side-effect profile of systemic adrenergic agonists is similar to that for inhalational adrenergic agonists. The most common side effects are tremor and tachycardia [11, 12]. Arterial oxygen tension can be transiently decreased, and hyperglycemia, hypokalemia, and hypomagnesemia can also be present [11, 12]. Escalating oral, subcutaneous, or IV doses can be associated with a greater incidence of side effects for the same degree of bronchodilation compared to inhaled beta-adrenergic agonists [11, 12].

Inhaled Cholinergic Antagonists

The use of anticholinergics (antimuscarinics) for maintenance therapy and treatment of acute exacerbations in obstructive airway diseases is common. The parasympathetic nervous system is primarily responsible for bronchomotor tone, and inhaled anticholinergics act on muscarinic receptors in the airway to reduce tone [2]. The parasympathetic nervous system plays a role in determining resting heart rate, and suppression of the parasympathetic nervous system can cause tachyarrhythmias. The use of inhaled anticholinergics (see Table 8.1) in COPD as maintenance and rescue therapy is considered first-line, standard treatment [29]. Anticholinergics are not used for first-line maintenance therapy in asthma and are only recommended for use in acute exacerbations or as therapy steps up [11, 17, 29, 30].

Mechanism of Action

The targets of therapy for anticholinergics are the muscarinic receptors located in the airway. There are three subtypes of muscarinic receptors found in the human airway [31]. Muscarinic 2 (M2) is present on postganglionic cells and is responsible for limiting production of acetylcholine and protects against bronchoconstriction [31]. M2 is not the target of inhaled anticholinergics but is antagonized by them [31]. Muscarinic 1(M1) and muscarinic 3 (M3) receptors are responsible for bronchoconstriction and mucus production and are the targets of inhaled anticholinergic therapy [31]. Acetylcholine binds to the M3 and M1 receptors and causes smooth muscle contraction (see Fig. 8.1) via increases in cyclic guanosine monophosphate (cGMP) or by activation of a G-protein (Gq) [5, 6, 31]. Gq activates phospholipase C to produce inositol triphosphate (IP3), which causes release of calcium from intracellular stores and activation of myosin light-chain kinase causing smooth muscle contraction [5, 6, 31]. Anticholinergics inhibit this cascade and reduce smooth muscle tone by decreasing release of calcium from intracellular stores [5, 6].

Clinical Applications

Inhaled antimuscarinics are approved for the treatment of obstructive airway diseases. Ipratropium is classified as a short-acting anticholinergic and is commonly used as maintenance therapy for COPD and as rescue therapy for both COPD and asthmatic exacerbations [29, 31]. It is not indicated for the routine management of asthma [11, 17, 29, 30]. Patients treated with ipratropium experience an increase in exercise tolerance, decrease in dyspnea, and improved gas exchange [31]. Tiotropium is an example of inhaled long-acting antimuscarinic available for COPD maintenance therapy. Tiotropium has been shown to reduce COPD

exacerbations, respiratory failure, and all-cause mortality [32]. Combination bronchodilators with both LABA and LAMA are available and improve symptoms and reduce exacerbations greater than with a single bronchodilator. Tiotropium also improves the effectiveness of pulmonary rehabilitation [19]. The newer long-acting muscarinic antagonist, inhaled glycopyrronium, has a faster onset of bronchodilation on the first day when compared to tiotropium. A randomized controlled trial showed comparable improvements in lung function and health status when combination glycopyrronium with LABA and ICs was compared to tiotropium with LABA and ICs. This study also demonstrated benefits of triple therapy compared to combination LABA/ICs [33]. In asthmatics who are poorly controlled on ICs and LABA, the addition of tiotropium reduces severe exacerbations [34].

Side Effects

Inhaled anticholinergics are poorly absorbed and therefore serious side effects are uncommon. Most commonly, patients experience dry mouth and urinary retention and can experience pupillary dilation and blurred vision if the eyes are inadvertently exposed to the drug [31]. Inhaled anticholinergic medications have been shown to increase the risk of serious cardiovascular events including cardiovascular mortality [35]. Tachyarrhythmias and atrial tachycardias are side effects, and inhaled anticholinergics should be used with caution in patients with known concomitant cardiovascular disease.

Systemic Cholinergic Antagonists

The systemically administered anticholinergics atropine and glycopyrrolate act via the same mechanisms as inhaled anticholinergics. While these anticholinergics can be administered by IV or inhalation, significant systemic absorption occurs, and their use is generally limited by side effects. Atropine, in particular, is limited in use because of its tertiary ammonium structure [29]. It has a tendency to cause tachycardia, gastrointestinal upset, blurred vision, dry mouth, and central nervous system effects secondary to its ability to cross the blood–brain barrier [29]. Glycopyrrolate has a quaternary ammonium structure and is insoluble in lipids, similar to ipratropium and tiotropium, and has fewer systemic side effects than atropine [29, 31]. Intravenous glycopyrrolate is also clinically limited in use secondary to side effects [36]. Glycopyrrolate has been studied as inhaled therapy, however, and is an effective bronchodilator with an intermediate duration of action [37–40]. Clinically, it has never been popular as a mainstay of therapy for obstructive airway diseases. Atropine and glycopyrrolate are both used clinically to reduce secretions.

Influence of Inflammation on the Airway and Modulation of the Response

Asthma and COPD, the most common obstructive airway diseases, have a component of inflammation as part of their pathogenesis. Although inflammation is a common pathogenesis, the characteristics and prominent cellular elements involved in the inflammatory process for each disease are distinct [41]. In COPD, neutrophils, macrophages, CD8+ T lymphocytes, and eosinophils are more prominent in the inflammatory composition [41]. In asthma, eosinophils play a more prominent role followed by mast cells, CD 4+ T lymphocytes, and macrophages in the inflammatory composition [41]. Inflammatory cell types present in sputum, biopsy specimens, and bronchoalveolar lavage fluid can help predict the response to anti-inflammatory therapy [41]. For example, eosinophilia in induced sputum of a patient presenting with a COPD exacerbation predicts an increase in steroid responsiveness [41–43]. Treatment aimed at reducing eosinophilia in COPD patients has been shown to reduce exacerbations and hospitalization [44, 45]. Patients presenting to the operating room with obstructive airway diseases have a high likelihood of being prescribed and taking or being exposed to one of the anti-inflammatory therapies in Table 8.2 for control of their disease.

Table 8.2 Pharmacologic influence on inflammation

Inhaled corticosteroids	Leukotriene modifiers	Mast cell stabilizers	Methylxanthines

Inhaled Corticosteroids

In the treatment of asthma, the use of ICs reduces the inflammatory changes associated with the disease, thereby improving lung function and reducing exacerbations that result in hospitalization and death [11, 46–48]. On the contrary, the use of ICs as monotherapy in COPD is discouraged [31]. In COPD, ICs are used as a part of combination therapy along with long-acting beta-adrenergic agonists (LABA) and possibly long-acting antimuscarinic antagonists [19]. The combination of drugs acts synergistically and is useful for reducing inflammation [31]. Currently, combination therapy of ICs and LABA is recommended for use in severe to very severe COPD [31, 49]. Triple therapy with ICs, LABA, and LAMA improves lung function and reduces exacerbations more than ICs combined with only LABA [19].

Mechanism of Action

The glucocorticoid receptor alpha (GRα) located in the cytoplasm of airway epithelial cells is the primary target of ICs [50, 51]. Passive diffusion of steroids into the cell allows for binding of the steroid ligand to GRα, dissociation of heat shock proteins, and subsequent translocation to the nucleus [51]. Figure 8.2 shows how the steroid–receptor complex can have a multitude of actions when it enters the nucleus [51]. The complex can bind to promoter regions of DNA sequences and either induce or suppress gene expression [51]. Additionally, the steroid–receptor complex can interact with transcription factors already in place, such as the ones responsible for proinflammatory mediators, without binding to DNA and repressing expression of those genes [50, 51]. Corticosteroids may inhibit the transcription of proinflammatory mediators and upregulate production of anti-inflammatory proteins [52]. The steroid–receptor complex also can affect chromatin structure by association with transcription factors that influence the winding of DNA around histones, reducing access of RNA polymerase and other transcription factors, and thus reducing expression of inflammatory gene products [50, 51]. Corticosteroids are able to modulate B2-adrenoreceptor and their function by protecting against desensitization and development of tolerance, increasing the efficiency of receptor coupling, and mitigating the risk of inflammation-induced receptor down-regulation and uncoupling [52].

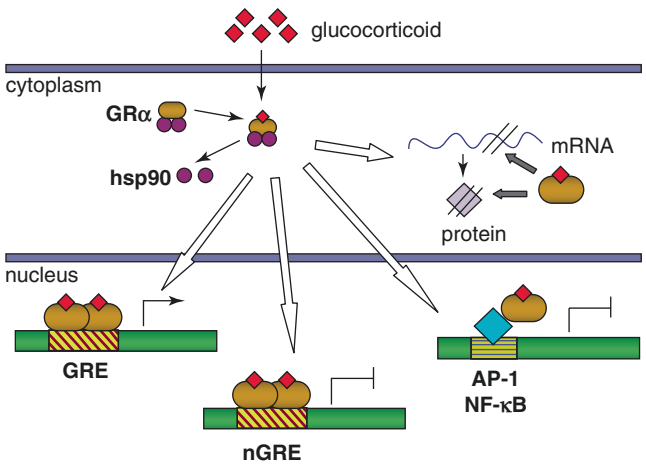

Fig. 8.2 Action of glucocorticoids. Glucocorticoids can bind to promoter regions inducing or repressing gene expression, act on promoters with transcription factors in place, or influence the structure of chromatin. Clinical Applications

ICs are used in asthma as part of a multimodal treatment regimen and are added to a therapeutic regimen when there is an increase in severity or frequency of asthma exacerbations [11]. There is good evidence to show that ICs can reduce both hospitalizations and death in asthma [47, 48]. The use of ICs in COPD is limited to use in severe to very severe COPD and in combination with LABA [19, 31]. Although no improvement in mortality has been consistently demonstrated with combination therapy (ICs/LABA), an ICs combined with LABA is more effective than the individual components in improving lung function and health status and reducing exacerbations [19]. Triple therapy with the addition of LAMA is more effective in reducing exacerbations. In COPD, the benefits of corticosteroids have been shown to be greater in patients with eosinophilic airway inflammation [19]. Research is ongoing looking at the use of eosinophil counts as potential biomarkers to direct treatment decisions. Further investigation is needed, but the use of eosinophil counts may lead to an improved risk–benefit ratio for inhaled corticosteroid treatment in severe COPD [53].

Side Effects and Safety Concerns

Side effects have been reported with the use of ICs in asthma and COPD. A recent meta-analysis reported an increase in pneumonia and serious pneumonia but not pneumonia-related deaths when ICs was used in the treatment of COPD [54]. Patients at higher risk of pneumonia are smokers, age 55 years or older, BMI less than 25 kg/m^2, or have a history of prior pneumonia or exacerbations [55]. Other reported side effects in COPD and asthma include oropharyngeal candidiasis, pharyngitis, hoarseness, easy bruising, osteoporosis,

cataracts, elevated intraocular pressure, dysphonia, cough, and growth retardation in children [11, 31, 49]. As with any pharmacotherapy, the risks and benefits of therapy must be weighed, and the patient must be carefully monitored for adverse effects. This is especially true with the use of ICs in obstructive lung diseases.

Systemic Corticosteroids

Systemic corticosteroids given in intravenous or oral form are used for treatment of asthma and COPD exacerbations. The mechanism of action is the same as it is for ICs, activation or suppression of gene products at a transcriptional level and alteration of chromatin structure [50, 51]. Patients that are hospitalized with a COPD exacerbation will typically receive corticosteroids to suppress any inflammatory component that may be contributing to the flare-up. Therapy with oral prednisolone is equally as effective as IV administration [56]. A study done at the Veterans Affairs medical centers in the United States published in 1999 reported that corticosteroid therapy shortened hospital length of stay and improved forced expiratory volume in 1 second vs. placebo. The study also compared a 2-week regimen vs. an 8-week regimen of corticosteroids and found no difference [57]. The REDUCE randomized clinical trial compared 5 days to 14 days of therapy with 40 mg prednisone daily for treatment of COPD exacerbations. The trial showed that 5-day treatment was noninferior [58]. Current guidelines state that duration of therapy for systemic corticosteroids should not be more than 5–7 days [19]. In asthma, corticosteroids are recommended for exacerbations that are either severe, with a peak expiratory flow of less than 40% of baseline, or a mild to moderate exacerbation with no immediate response to short-acting beta-adrenergic agonists [17]. The recommended duration of therapy is 3–10 days without tapering [17]. Alternatively, some patients with asthma and COPD will be receiving long-term oral corticosteroid therapy because their disease is difficult to manage. Side effects of systemic corticosteroids are well described and numerous. Hypertension, hyperglycemia, adrenal suppression, increased infections, cataracts, dermal thinning, psychosis, and peptic ulcers are reported complications of corticosteroid therapy [59].

Leukotriene Modifiers

Leukotriene modifiers can be used for the treatment of asthma. They are prescribed primarily for long-term control in addition to short-acting beta-adrenergic agonists or in conjunction with ICs and short-acting beta agonists. Leukotriene modifiers are taken by mouth, produce bronchodilatation in hours, and have maximal effect within days of administration [11]. Their role in the management of COPD is not defined. Future investigations will need to focus on the role these medications can play in the outpatient management of COPD [60].

Mechanism of Action

Arachidonic acid is converted to leukotrienes via the 5-lipoxygenase pathway [61]. Leukotrienes C_4, D_4, and E_4 are the end products of the pathway and cause bronchoconstriction, tissue edema, migration of eosinophils, and increased airway secretions [61]. Leukotriene modifiers come in two different varieties, leukotriene receptor antagonists and leukotriene inhibitors [11]. Figure 8.3 shows how the binding of leukotrienes C_4, D_4, and E_4 at the type 1 cysteinyl leukotriene receptor is blocked by the leukotriene receptor antagonists montelukast, zafirlukast, and pranlukast (not available in the United States) [11, 61]. The leukotriene inhibitor zileuton antagonizes 5-lipoxygenase (Fig. 8.3), inhibiting the production of cysteinyl leukotrienes [11, 61].

Clinical Applications

Leukotriene modifiers improve lung function, reduce exacerbations, and are used as long-term asthma therapy [11, 17, 62, 63]. Clinical trials have reported that ICs are superior to leukotriene modifiers for long-term control and should be the first-line choice [17, 64, 65]. Leukotriene modifiers provide an additional pharmacologic option for the control of asthma. Addition of leukotriene modifiers to ICs will improve control of symptoms of asthma as opposed to ICs alone [66].

Side Effects

Overall, leukotriene antagonists are well-tolerated without significant side effects. Links between Churg-Strauss syndrome and the use of leukotriene antagonists have been reported, but it is not clear whether these reports reflect unmasking of a preexisting condition or whether there is a direct link between the two [11, 61]. Zileuton is known to cause a reversible hepatitis in 2–4% of patients [11]. Liver function tests should be checked frequently at first and periodically thereafter to monitor for hepatocellular damage [11, 61].

Mast Cell Stabilizers

Cromolyn sodium and nedocromil are the two prototypical agents in this category that are used in the treatment of asthma. These agents are delivered by powder inhaler and are not first-line therapy for asthma. They do provide an alternative treatment when the control of asthma is not optimal on other conventional therapies [17].

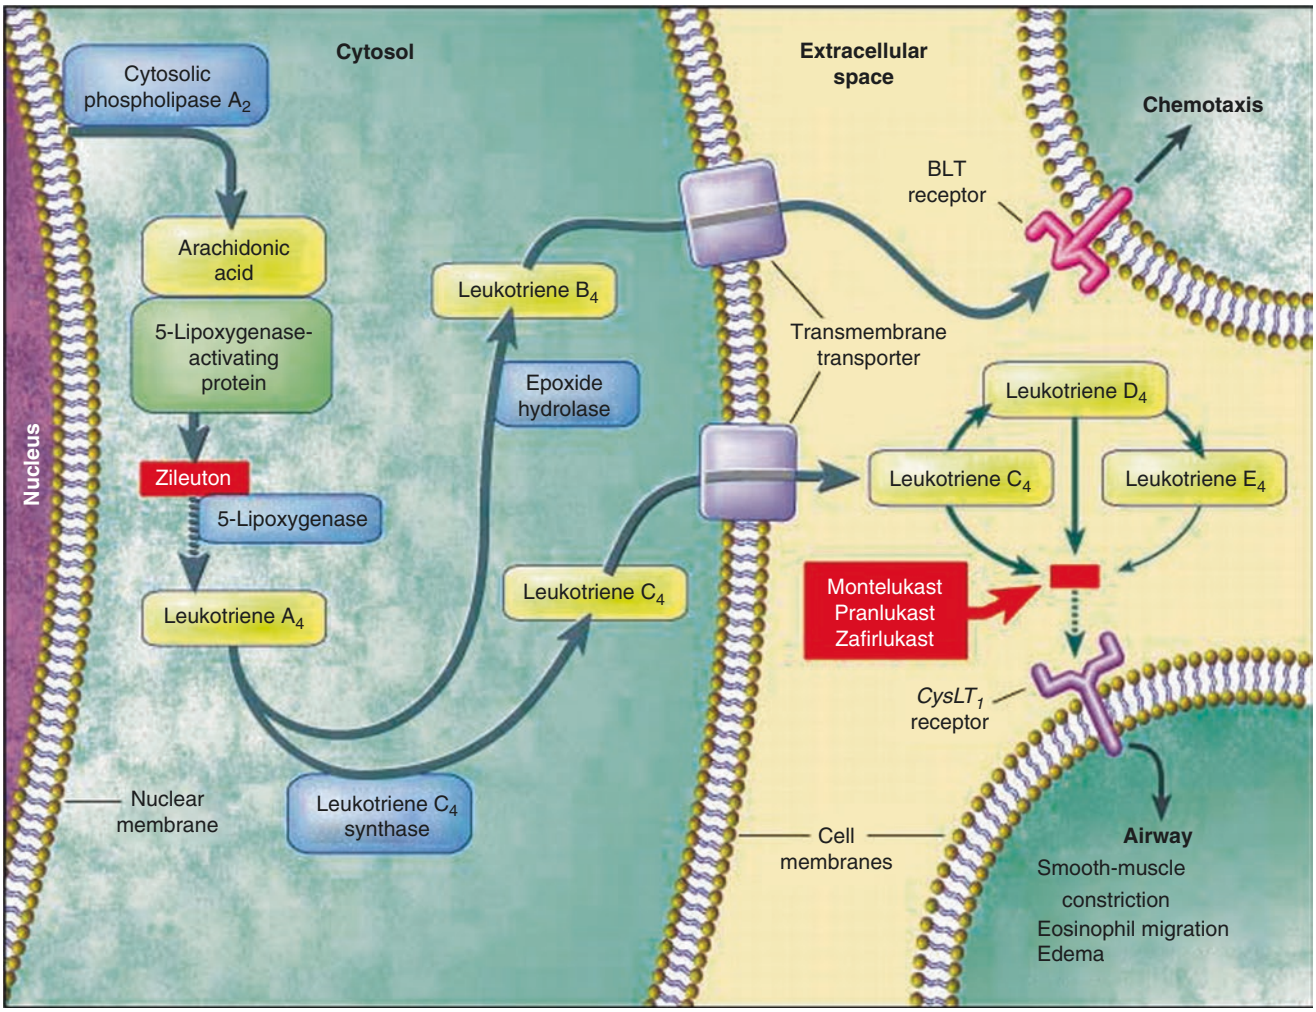

Fig. 8.3 Generation of leukotrienes and action of leukotriene-modifying drugs. Leukotriene antagonists block the action of leukotrienes at the cysteinyl leukotriene receptor (CysLT1), and leukotriene inhibitors block the conversion of arachidonic acid to leukotriene A4. BLT leukotriene receptor B. (Reprinted from Drazen et al. [61] with permission, © 1999 Massachusetts Medical Society. All Rights Reserved)

Mechanism of Action

Cromolyn sodium and nedocromil stabilize submucosal and intraluminal mast cells [17, 67]. These drugs interfere with the antigen-dependent release of mediators, such as histamine and slow-reacting substance of anaphylaxis, that cause bronchoconstriction, mucosal edema, and increased mucus secretion [67].

Clinical Applications

Large systematic reviews of the available literature and consensus statements favor the use of ICs over cromolyn sodium or nedocromil as first-line agents to control symptoms of asthma [17, 68]. Alternatively, cromolyn sodium and nedocromil may be used as preventative treatment before exercise or known allergen exposure causing symptoms of asthma [17].

Side Effects

There are no major side effects reported with the use of cromolyn sodium and nedocromil. The most commonly reported side effects are gastrointestinal upset and coughing or irritation of the throat [67].

Methylxanthines

The role of theophylline, a prototypical methylxanthine, has changed since the introduction of ICs and LABA. Theophylline was a common choice for the control of asthma and COPD because of its bronchodilatory and anti-inflammatory effects [69]. Currently, theophylline is recommended only as an alternative therapy and is not a first-line choice for asthma or COPD [17, 70, 71].

Mechanism of Action

Theophylline is thought to act via multiple pathways causing improvement in symptoms in obstructive lung diseases. Theophylline is a nonselective inhibitor of phosphodiesterase and increases levels of cyclic AMP and GMP causing smooth muscle relaxation [69]. Antagonism of the A_1 and A_2 adenosine receptors also causes smooth muscle relaxation via inhibition of the release of histamine and leukotrienes from mast cells, another reported action of theophylline [69]. In asthma, theophylline reduces the number of eosinophils in bronchial specimens and, in COPD, reduces the number of neutrophils in sputum, having an anti-inflammatory effect in both conditions [69]. In addition, theophylline activates histone deacetylase and reduces the expression of inflammatory genes [69]. Theophylline and aminophylline are reported to improve diaphragmatic function; however data have not demonstrated this effect consistently [69, 72].

Clinical Applications

Theophylline has been relegated to an alternative therapy in both asthma and COPD. This has occurred largely because of its significant side-effect profile and the subsequent need for monitoring of blood levels [17, 69–71]. Patients that are already on an ICs and a LABA and still have symptoms may benefit from the addition of theophylline, especially if leukotriene modifiers and other alternatives are not tolerated [17, 70, 71]. Theophylline is not recommended for use in COPD exacerbations due to significant toxicity.

Side Effects

Theophylline can cause significant and life-threatening side effects if not dosed carefully and monitored appropriately. Toxicity is dose related, and side effects tend to be more prominent when blood levels exceed 20 mg/L [69]. The most common side effects include headache, nausea, vomiting, restlessness, abdominal discomfort, gastroesophageal reflux, and diuresis [69]. The most significant side effects include seizures, cardiac arrhythmias, and death [69]. Adverse effects from theophylline may be avoided if the clinician follows the patient carefully, monitors blood levels regularly, and educates the patient on the signs and symptoms of overdose.

Phosphodiesterase 4 Inhibitors

Mechanism of Action

Phosphodiesterase 4 (PDE4) is an enzyme that breaks down cyclic AMP. The enzyme is present in inflammatory and immune cells such as eosinophils, macrophages, and T lymphocytes. Inhibition of PDE4 has anti-inflammatory effects. Roflumilast, a PDE4 inhibitor, has been shown to decrease the expression of T cell adhesion molecules and decrease release of inflammatory mediators and cytokines [73].

Clinical Applications

Roflumilast is available for management in COPD in patients whose disease is not adequately controlled with long-acting bronchodilators. It is recommended for patients with severe airflow limitation, symptoms of chronic bronchitis, and history of exacerbations [74].

Side Effects

PDE4 inhibitors have a significant side-effect profile, which has limited their use. The main side effects are nausea, weight loss, and diarrhea. Less frequent side effects include insomnia, anxiety, and depression. In clinical trials, the side effects appeared to be dose dependent. Other PDE4 inhibitors are being studied for use in asthma and COPD [73, 74].

Influence of Anesthetics on the Airway

Volatile Anesthetics

Volatile anesthetics have a host of effects on the respiratory system. Volatile anesthetics reduce bronchomotor tone. All commonly used volatile anesthetics (see Table 8.3), except desflurane, produce a degree of bronchodilatation that may be helpful in patients with obstructive lung disease or in patients that experience any degree of bronchoconstriction [75, 77]. Rooke and colleagues in 1997 reported that sevoflurane produced a greater reduction in respiratory system resistance than isoflurane or halothane 10 min after the induction of anesthesia [75].

Mechanism of Action

The precise mechanisms by which volatile anesthetics induce bronchodilatation are not completely clear. Animal studies

Table 8.3 Anesthetics with a favorable influence on bronchomotor tone

Volatile anesthetics[a]	Intravenous anesthetics[b]
Isoflurane	Propofol
Sevoflurane	Ketamine
Halothane	Midazolam

[a]Adapted from Rooke et al. [75]
[b]Adapted from Cheng et al. [76]

suggest that volatile anesthetics inhibit tracheal smooth muscle contraction by decreasing intracellular calcium, mediated by an increase in intracellular cAMP and by suppression of protein kinase C which, in the absence of volatile anesthetics, sensitizes contractile elements to calcium and inhibits myosin light-chain phosphatase [78]. The effect is seen to a greater degree in distal airway smooth muscle secondary to the T-type voltage-dependent calcium channel, which is sensitive to volatile anesthetics [79].

Clinical Applications

Volatile anesthetics are administered to provide amnesia and blunt the response to surgical stimulation but can be of use in patients who have obstructive airway diseases or experience bronchoconstriction in the operating room. Multiple case reports provide examples of how volatile agents were used solely for the treatment of status asthmaticus [80–83].

Side Effects

The main concern with the use of volatile anesthetics is the rare occurrence of malignant hyperthermia. Hypotension can also be a concern with volatile anesthetics; however the blood pressure is usually easily restored with small amounts of IV fluids or vasopressors. Nausea and vomiting is a known side effect of volatile anesthetics, and prophylactic antiemetics should be considered based on patient risk factors. Deep levels of anesthesia associated with high concentrations of volatile anesthetics may be undesirable, and prolonged administration outside the operating room is problematic.

Intravenous Anesthetics

Intravenous anesthetics can have positive effects on bronchomotor tone when used for induction or intravenous anesthesia in the operating room. Ketamine, propofol, and midazolam (see Table 8.3) have relaxant effects on airway smooth muscle [76]. Etomidate and thiobarbiturates do not affect bronchomotor tone to the same extent [84]. The choice of intravenous anesthetics for induction and maintenance of anesthesia may be important for a patient with hard to manage bronchospasm or reactive airway disease.

Mechanism of Action

The precise mechanism of reduction of bronchomotor tone for the intravenous anesthetics is largely unknown. Ketamine is thought to have a direct relaxant effect on smooth muscle [85]. Propofol is thought to reduce vagal tone and have a direct effect on muscarinic receptors by interfering with cellular signaling and inhibiting calcium mobilization [86, 87]. The preservative metabisulfite in propofol prevents the inhibition of vagal-mediated bronchoconstriction [88].

Clinical Applications

Choosing an agent such as propofol or ketamine can be beneficial in patients with bronchospasm or obstructive airway disease [76, 84]. The use of these intravenous agents for induction or maintenance of anesthesia over other agents can be useful in minimizing the intraoperative effects of bronchospasm.

Side Effects

Although each of the intravenous anesthetics carries a unique side-effect profile, the major effects are not related to the airway. The use of ketamine is associated with increased salivation, and coadministration of a small dose of anticholinergic can attenuate secretion production. Propofol is associated with hypotension that usually is easily corrected with IV fluids and vasopressors.

Local Anesthetics

Local anesthetics are primarily used to suppress coughing and blunt the hemodynamic response to tracheal intubation [89, 90]. Although animal models have demonstrated some ability of local anesthetics to relax bronchial smooth, in clinical practice the use of local anesthetics as pure bronchodilators is limited by toxicity and the ready availability of more potent bronchodilators such as short-acting beta-adrenergic agonists [85].

Influence of Adjunctive Agents on the Airway

Heliox

Helium (administered as a mixture of helium and oxygen [heliox]) has the advantage of having a low Reynolds' number and less resistance during turbulent airflow especially in large airways [6]. Helium and oxygen mixtures are recommended as alternative therapies in asthma to support patients when traditional therapies have initially failed to make improvements [17, 70]. A recent trial in patients with COPD exacerbations failed to demonstrate a statistically significant reduction in the necessity for endotracheal intubation in patients treated with noninvasive ventilation and helium/

oxygen mixtures [91]. The use of helium–oxygen mixtures is limited by a progressive reduction in efficacy at higher inspired oxygen concentrations.

Antihistamines

Histamine release from mast cells and basophils is responsible for airway inflammation and bronchoconstriction in asthma [92]. Antihistamines are not standard therapy for asthma, but the use of antihistamines and leukotriene modifiers for allergen-induced bronchoconstriction has shown promise for diminishing the early and late responses to allergens [92, 93]. Patients that have allergen-induced asthma or patients that experience an allergic reaction in the operating room may benefit from antihistamines to attenuate the role that histamine plays in bronchoconstriction.

Magnesium Sulfate

Magnesium sulfate is not a standard therapy for asthma exacerbations. Magnesium sulfate is thought to produce additional bronchodilation when given in conjunction with standard therapy for asthma exacerbations. Currently, intravenous magnesium therapy is reserved as an alternative therapy when the patient has not responded to standard therapy [17, 70, 94]. The combination of nebulized magnesium sulfate and beta-adrenergic agonists has also been studied and shows potential benefit in asthma exacerbations [95]. Overall, magnesium sulfate, IV or nebulized, is not a first-line therapy for asthma exacerbations and should be reserved for situations when the patient is not responding to conventional therapy [17, 70].

Summary

Patients with obstructive lung diseases presenting to the operating room for thoracic surgical procedures usually will be receiving pharmacotherapy to modify their symptoms or disease process. Understanding the role of pharmacotherapy in obstructive lung disease is essential to proper preoperative evaluation, perioperative risk reduction, and intraoperative management.

Clinical Case

A 65-year-old-man with COPD who quit smoking 2 years ago now presents to the preoperative clinic for evaluation before a right upper lobe lobectomy for a lung nodule. The patient has no other medical history and a recent cardiac stress test is normal.

Questions

Preoperative evaluation:

- How often does he need rescue inhalers? Has the frequency increased recently?
- When was the last time he was in the hospital with a COPD exacerbation?
- What medications for the treatment of COPD is the patient receiving?
- When was the last time he needed systemic corticosteroids for an exacerbation?
- Has there been any recent change in sputum or use of antibiotics?

Intraoperative Management:

- What medications will provide quickest relief of wheezing?
- Are prophylactic systemic corticosteroids indicated?
- What role do helium/oxygen mixtures and magnesium sulfate play in the management of wheezing?

Answers

Preoperative evaluation:

- Asking patients about the use of rescue inhalers gives some indication of how well their symptoms are controlled at baseline. Any increase in frequency of inhaler use may indicate disease progression or potential acute exacerbation.
- Inquiring about previous hospitalizations and the extent of illness (i.e., intubation, ICU admission) is important in determining the severity of disease.
- This patient will likely present on an IC and long-acting beta-adrenergic agonist combination along with an antimuscarinic such as ipratropium.
- The most recent use of systemic corticosteroids not only provides information as to how well the disease is being controlled but also gives the evaluator an idea if the patient is prone to adrenal suppression during surgical stress.
- Discussing the use of antibiotics and changes in sputum allows the evaluator to know if the patient is experiencing an exacerbation or if the patient is at risk for infection with multidrug-resistant bacteria.

Intraoperative management:

- Intraoperative wheezing can be due to endotracheal intubation, light anesthesia, or allergic reaction. Short-acting

beta-2 adrenergic agonists, followed by inhaled anticholinergics, will give the most prompt relief. The additional use of intravenous and inhaled anesthetics may also be an effective treatment of bronchoconstriction. Epinephrine may be used for severe bronchoconstriction.

- Prophylactic IV corticosteroids are not indicated. Steroids should be given if the patient has recently received steroids and stress doses are needed or the patient experiences an allergic reaction and steroids are administered to reduce the inflammatory response associated with the exposure.
- Helium/oxygen mixtures and magnesium sulfate are only indicated when the patient fails to adequately respond to maximum conventional therapy.

Pharmacology of the Pulmonary Circulation

9

Cara Reimer and John Granton

Abbreviations

(m)PAP	(mean) Pulmonary artery pressure
CI	Confidence interval
CO	Cardiac output
LAP	Left atrial pressure
PHTN	Pulmonary hypertension
PVB	Paravertebral block
PVR(I)	Pulmonary vascular resistance (index)
SVR(I)	Systemic vascular resistance (index)
TEA	Thoracic epidural analgesia

Key Points

- The pulmonary vasculature is a complex system, and studies of the effects of anesthetic drugs on this system are often contradictory.
- A balanced anesthetic technique with adherence to the hemodynamic goals of maintenance of right ventricular preload and right coronary perfusion is the safest choice for patients with PHTN.
- There are no absolute contraindications to most anesthetic drugs in patients with pulmonary hypertension.
- Inhaled pulmonary vasodilators can be used to optimize hemodynamic variables perioperatively, although effects on gas exchange are variable.

Introduction

Drugs affecting the pulmonary vascular bed are routinely administered perioperatively in thoracic anesthesia, and their effects are of particular interest in patients with pulmonary hypertension (PHTN). In addition, the increase in right ventricular (RV) afterload afforded by positive pressure ventilation may have adverse effects on patients with more advanced PHTN and reduced RV function.

Pulmonary hypertension is defined as a mean pulmonary arterial pressure ≥25 mmHg at rest. PHTN is classified according to the recent international guidelines into five groups: pulmonary arterial hypertension (PAH; group 1), PHTN secondary to left-sided heart or valvular disease (group 2), PHTN secondary to parenchymal or hypoxic/hypercapnic respiratory disease (group 3), chronic thromboembolic pulmonary hypertension (CTEPH; group 4), and miscellaneous causes of PHTN (group 5) [1, 2]. Group 1 PHTN embraces idiopathic, heritable, congenital cardiac, connective tissue disease, HIV, portal hypertension, and schistosomiasis-related pulmonary arterial hypertension. The rational for differentiation of PAH from other forms of PHTN relates to the distinctive arteriopathy that characterizes this condition as well as response to pulmonary vasodilator therapies. Irrespective of the etiology, patients with PHTN are high-risk candidates for cardiothoracic and non-cardiothoracic surgery. Although defined as an increase on pulmonary pressure, the consequence and severity of PHTN are likely best judged by the degree of right ventricular function [3]. Although the studies to date have not systematically evaluated the degree of RV function and outcome in patients with PHTN undergoing surgery, data from mixed populations of patients undergoing cardiac surgery supports the notion that RV function is associated with short- and longer-term outcomes [4]. Owing to the influence of afterload on the thinner walled RV, these patients have poor cardiorespiratory reserve and are at risk of having perioperative complications including pulmonary hypertensive crises with resultant heart failure, respiratory failure, and dysrhythmias [5, 6]. patients undergoing valve repair or coronary artery bypass surgery, the presence of preoperative PHTN is associated with worse perioperative and long-term outcomes [7–9]. Management of these patients should not focus on pulmonary arterial pressure rather the goals should be centered on improving RV function and oxygen delivery [10]. Owing to the limited reserve of the RV, however, anesthetic management of these patients can be complex and challenging.

Drugs can interact with the pulmonary vascular bed both directly, through receptor binding, and indirectly, by changes in cardiac output. The effects of anesthetic, vasopressor, and vasodilator drugs on the pulmonary vessels will be reviewed in this chapter, with a special emphasis on perioperative drug choices in patients with pulmonary hypertension.

Anesthetic Drugs

Introduction

Evaluating the effects of anesthetic drugs on the pulmonary vasculature is challenging. In clinical practice, these drugs are rarely administered in isolation. Their administration can lead to concurrent changes in non-pulmonary hemodynamic parameters such as cardiac output (CO) that ultimately affect pulmonary artery pressure (PAP). An increase in PAP may be the result of increased PVR, increased CO, or an increase in LAP (PAP = (PVR × CO) + LAP). In addition, general anesthesia involves manipulation of variables that affect PVR, including FiO_2, carbon dioxide (CO_2), and positive pressure ventilation (PPV). Issues that arise in interpreting studies and making useful conclusions include reliance on and extrapolation from animal data, small study sample sizes, the questionable application of results in normal patients to patients with PHTN, children to adults and vice versa, and a vast supply of contradictory results. It is with acknowledgment of these limitations that we will review the effects of routinely administered anesthetic drugs on the pulmonary system.

Ketamine

Ketamine has occupied a controversial position in anesthesia for patients with PHTN [11]. Despite its current widespread use in these challenging patients, it has been classically taught that ketamine causes pulmonary vasoconstriction and should be used with extreme caution in this group.

The mechanism of action of ketamine is complex and not fully elucidated. It is an N-methyl-D-aspartic acid (NMDA) receptor antagonist and also binds to opioid receptors and muscarinic receptors [12]. It appears to stimulate release [13] as well as inhibit neuronal uptake of catecholamines [14] which may account for its cardiostimulatory and bronchodilatory effects. Some animal studies have shown an endothelium-independent vasodilatory response to ketamine in the pulmonary bed [15, 16]. NMDA receptor subunits have been demonstrated in human pulmonary vascular cells, and antagonism of NMDA receptors prevents glutamate-mediated lung injury and reverses pulmonary hypertension in rats [17].

The effects of ketamine on the human pulmonary vasculature appear to be complex, and, indeed, review of the clinical literature reveals heterogeneity in regard to results. Factors known to affect pulmonary vasoreactivity such as FiO_2, CO_2, presence of PHTN, and presence of premedicants are not reported or acknowledged in many studies. The hemodynamic effects of a bolus of ketamine can be attenuated or abolished with premedicants like droperidol [18], dexmedetomidine [19], or benzodiazepines [20].

Early study of the drug's hemodynamic profile in adult patients showed increases of PAP and PVR in the range of 40–50% [21, 22]. This, combined with increases in variables contributing to myocardial oxygen consumption, raised concern about the use of ketamine in patients with CAD and PHTN. In the pediatric literature, Williams et al. [23] showed no change in PVR or mPAP after ketamine administration in spontaneously breathing children with severe pulmonary hypertension undergoing cardiac catheterization. In another pediatric study, ketamine maintained pulmonary to systemic blood flow and did not affect pulmonary pressure or resistance in children with intracardiac shunt undergoing cardiac catheterization [24]. Propofol, on the other hand, decreased SVR leading to increased right to left shunting in this study. More recently, a bolus of ketamine (2 mg/kg) has been shown to increase mPAP by a negligible amount clinically (mean 2 mmHg [95% CI 0.2, 3.7]) in pediatric patients with pulmonary hypertension with no change in PVRI or SVRI [25]. As part of a balanced anesthetic induction for open lung biopsy, ketamine has been used in Eisenmenger syndrome with good results [26]. In adult patients undergoing OLV for lung resection, ketamine did not significantly increase PAP or PVR compared to enflurane [27]. Other case reports highlight the value of the cardiostability of the drug in patients with minimal cardiorespiratory reserve [28–30]. Many clinicians, including those at our institutions, incorporate this drug into their routine inductions for patients with severe pulmonary hypertension. The advantages, in particular maintenance of stable hemodynamics and coronary artery perfusion pressure, seem to outweigh the potential disadvantages.

Propofol

Propofol is ubiquitously used in anesthesia, including for patients with pulmonary hypertension. It is frequently used to maintain anesthesia during and after lung transplantation.

The effects of propofol are thought to be primarily mediated by GABA receptors [31]. GABA inhibits peripheral sympathetic neurotransmission, and chronic treatment with GABA has been shown to decrease extent of pulmonary artery medial thickening and decrease right ventricular hypertrophy in mice with induced pulmonary hypertension [32].

As mentioned in the discussion on ketamine, the concerning hemodynamic effect of propofol in the context of pulmonary hypertension is a decrease in SVR, which can not only have effects on intracardiac shunting if present, but can lead to decreased coronary artery perfusion of the right ventricle and resultant right ventricular dysfunction. In regard to direct effects on the pulmonary vasculature, animal studies have shown that during increased tone conditions in the pulmonary vasculature, propofol may act as a pulmonary vasoconstrictor [33, 34]. Propofol has also been shown to interfere with acetylcholine-induced pulmonary vasodilation in dogs [35]. On the other hand, in isolated pulmonary arteries from human and chronically hypoxic rats, etomidate and (to a lesser extent) propofol showed vessel relaxation [36]. The clinical significance of these contradictory results is unknown. It has been suggested that to avoid hypotension, a vasopressor should be used at the time of anesthetic induction with propofol, etomidate, or volatile gas in patients with Eisenmenger syndrome [37].

Etomidate

Etomidate is an imidazole that mediates its clinical actions primarily at GABA A receptors. As mentioned above, it appears to have vasorelaxant properties in isolated pulmonary arteries [36]. Its major attribute as an induction agent is its stable hemodynamic profile. In patients with cardiac disease, an induction dose of etomidate increased MAP, decreased SVR, and decreased PAP [38]. In pediatric patients without pulmonary hypertension presenting for cardiac catheterization, there were no significant changes in any hemodynamic parameters, including PAP, after a bolus dose of etomidate (0.3 mg/kg) [39].

The drug has successfully been used in patients with pulmonary hypertension in obstetrics [40] and other procedures requiring general anesthesia or sedation [37].

Dexemedetomidine

An α2 adrenergic agonist, dexmedetomidine acts at preganglionic sites in the central nervous system and the autonomic nervous system to inhibit norepinephrine release, in addition to acting on postsynaptic receptors to cause vasoconstriction and vasodilation [41, 42]. Whereas the sympathetic nerve fibers of the human pulmonary artery possess presynaptic α2 receptors [43], there is minimal evidence for postsynaptic α2 receptors in the arterial system of the lung [44]. However, this data is from canine pulmonary arteries which may have a different α2 receptor distribution than humans [45].

The drug has been shown to cause transient increases in MAP and a dose-dependent persistent decrease in noninvasively measured CO and increase in SVR at higher bolus doses (>1 mcg/kg over 2 min) in healthy volunteers [45]. These higher bolus doses caused small increases (~5 mmHg) in CO_2 and decrease in minute ventilation by approximately 30% [46]. Dose-dependent increases in dexmedetomidine cause increases in PAP, PVRI, and SVRI in healthy volunteers with pulmonary artery catheters [47]. While a bolus dose of 0.5–1 mcg/kg dexmedetomidine over 10 min caused an increase in MAP and SVRI, there were minimal changes in PAP and PVRI in children with pulmonary hypertension undergoing cardiac catheterization [48]. The increase in SVRI was theorized to take place via stimulation of postsynaptic α1 receptors in the peripheral vessels. A 1 mcg/kg bolus followed by 0.4 mcg/kg/h infusion prior to surgical incision in patients with pulmonary hypertension undergoing mitral valve replacement surgery caused significant decreases in HR, MAP, CI, and mPAP with no significant increases in PVRI or SVRI. The decrease in heart rate seen with dexmedetomidine is thought to occur via decreased inhibition of cardiac vagal neurons [49]. It would appear that (as with most drugs used in patients with pulmonary hypertension) titrated lower bolus doses of dexmedetomidine (<1 mcg/kg) with subsequent infusion titration would be appropriate for patients with pulmonary hypertension given the widespread hemodynamic effects of the drug. Dexmedetomidine used during one-lung ventilation decreased volatile and opioid requirements and increased phenylephrine requirements in a randomized trial [50].

Opioids

Mu, delta, and kappa opioid receptors have been shown to exist in the pulmonary artery of rats [51]. The number of kappa opioid receptors in rat pulmonary artery is increased under hypoxic conditions [52]. Kappa receptor agonism attenuates proliferation of pulmonary artery smooth muscle cells and lowers mean pulmonary artery pressure in these animals [53].

In anesthetized cats, administration of histamine, morphine, fentanyl, remifentanil, and sufentanil causes a vasodilatory response under elevated tone conditions in isolated lobar artery [54]. The mechanism seems to involve histamine- and opioid-mediated receptor pathways. Morphine causes a prostanoid-dependent vasodilation in isolated dog pulmonary arteries and veins [55].

The presence of opioid receptors and their significance in human pulmonary arteries are unknown as per the author's literature search. Clinical experience would echo the cardiostability of judicious opioid administration in hemodynamically fragile patients.

Neuromuscular Blockers

Pancuronium increases PAP in dogs with lung injury [56]. It is theorized to do so indirectly by increases in cardiac output and directly by increasing PVR, possibly by its antagonist actions at muscarinic receptors in the pulmonary vasculature. The drug has been shown to be an antagonist at acetylcholine M3 receptors in transfected hamster cells [57]. Rocuronium and succinylcholine also were antagonists at M3 receptors in this study, but not at clinically relevant concentrations. In human pulmonary arteries, M3 receptors present on endothelial cells are involved in vasodilation, and M3 receptors on smooth muscle cells mediate vasoconstriction [58].

In humans, rocuronium, cisatracurium, and vecuronium have little to no effect on most cardiac indices in patients undergoing CABG [59, 60].

Vasopressors and Inotropes

Vasopressors and inotropes are commonly required in thoracic anesthesia to counteract the effects of cardiodepressant and vasodilating drugs. Treatment of hypotension in these patients can be difficult to manage given the typical cautious fluid administration in this patient population. Neurotransmitter receptors in this system include those from the adrenergic, cholinergic, and dopaminergic families as well as histamine, serotonin, adenosine, purines, and peptides [61]. The pulmonary vasculature's response to sympathetic activation will generally result in an increase in PVR [62]. In human pulmonary artery, administration of acetylcholine induces pulmonary relaxation at the endothelial level [58, 63].

The response of the pulmonary system to exogenous vasoinopressor administration is dependent on the clinical situation. Consequently, results of studies are heterogeneous. In anesthetized dogs without pulmonary hypertension, dopamine, epinephrine, norepinephrine, and phenylephrine all increase PAP to varying degrees by varying mechanisms but with no drug is there a significant increase in PVR [64]. Dopamine does not increase PVR after lung transplantation in pigs [65]. In anesthetized patients with chronic secondary pulmonary hypertension undergoing cardiac surgery, both norepinephrine and phenylephrine increase PAP and PVRI with minimal change in CI [66]. Within the clinically relevant MAP target in this study, norepinephrine decreased the mPAP to MAP ratio, but phenylephrine did not, suggesting it (norepinephrine) may be a better choice in this patient cohort. In a dog model of acute pulmonary hypertension, however, phenylephrine restored perfusion to the ischemic right ventricle and therefore increased CO [67]. This is a relevant observation, as it illustrates the importance of coronary artery perfusion in the setting of right ventricular strain and that maintenance of systemic pressure by whatever method may be the most important guiding principle in this subset of patients.

Vasopressin has also been studied. In a chronic hypoxic rat model, vasopressin administration resulted in a V1 receptor-mediated pulmonary vasodilation [68]. In an acute PHTN model in dogs, vasopressin increased PVR and resulted in a substantial decrease in right ventricular contractility [69]. Human studies of the effects of vasopressin on the pulmonary vasculature are limited. Vasopressin has been used successfully after cardiac surgery in patients with pulmonary hypertension and resistant hypotension [70]. The use of vasopressin to treat acute right ventricular failure in patients with IPPH has been described in obstetric anesthesia [71]. In isolated human pulmonary arteries, both norepinephrine and phenylephrine cause vasoconstriction, whereas vasopressin does not [72]. In dogs, phenylephrine and vasopressin have been shown to increase pulmonary artery pressure "passively" by increasing pulmonary blood volume. This is associated with minimal increases in PVR, increases in left atrial pressure, and SVR and is worse during left ventricular dysfunction [73].

Magnesium

Magnesium is a vasodilator in both the systemic and pulmonary circulations. The mechanism of action of magnesium's effects on vasodilation is likely through its effects on membrane channels involved in calcium flux and through its action in the synthesis of cyclic AMP [74]. It would appear to be an important cofactor for endothelial-dependent pulmonary vasodilation [75]. It has been used successfully to wean nitric oxide in pulmonary hypertension [76]. Increasing doses of magnesium in piglets with acute embolic pulmonary hypertension decreased mean PAP, increased CO, and decreased PVR [77]. Magnesium has been used to treat persistent pulmonary hypertension of the newborn, but controversy surrounds its use here, and a systematic review concluded that there is a lack of evidence to support its use in this population [78].

Volatile Anesthetics

At clinically relevant concentrations, modern volatile anesthetics likely have little to no direct vasodilating effect on the pulmonary vasculature. At MAC levels of 1.5, neither sevoflurane

nor desflurane had an effect on the relationship between the pulmonary artery pressure-left atrial pressure gradient and pulmonary blood flow in healthy dogs [79]. In a dog model (without PHTN), isoflurane decreased right ventricular function more than left ventricular function with no effect on PVR [80]. Likewise in pigs, sevoflurane administration depressed right ventricular function with no change in PVR [81]. This suggests that the decreases in PAP observed with volatile anesthetics [82] may partially occur secondary to the decreases in cardiac output seen with these agents. Nitrous oxide is typically avoided in patients with pulmonary hypertension as it is believed to cause pulmonary vasoconstriction, perhaps via release of catecholamines from sympathetic nerves supplying the pulmonary vasculature [83]. In patients with mitral stenosis and pulmonary hypertension presenting for cardiac surgery, administration of nitrous oxide after fentanyl anesthesia (7.5–10 mcg/kg) increased PVR, PAP, and CI [84]. However, a subsequent study showed that in the presence of high-dose fentanyl (50–75 mcg/kg), 70% nitrous oxide actually was associated with a decrease in PAP and CO in patients with secondary PHTN, with no echocardiographic changes in right ventricular function [85]. Interestingly, in univariate analysis in one retrospective cohort study, *not* using nitrous oxide was associated with postoperative mortality and increased length of stay in patients with PHTN presenting for non-cardiac surgery [5]. The ENIGMA-II international randomized trial demonstrated the safety of nitrous oxide use in a large group of patients with coronary artery disease undergoing non-cardiac surgery [86]. The incidence of pulmonary hypertension in this cohort of patients was not indicated, but thoracic procedures were excluded given the usual requirement for higher FiO_2 in these patients. Death and cardiovascular complications occurred with equal frequencies in both intervention and control groups. In addition, the risk of postoperative nausea was only slightly increased in the nitrous oxide group (15% vs 11%). Similarly at 1-year follow-up, nitrous oxide did not increase the risk of death or complications [87].

Perioperative Analgesia

Pain can increase PVR [88]. Perioperative thoracic epidural analgesia (TEA) and paravertebral blockade (PVB) are used routinely in thoracic surgery. TEA may decrease PAP through decreases in CO or via attenuation of the pulmonary sympathetic outflow [89]. In humans without pulmonary hypertension, TEA during one-lung ventilation depresses right ventricular contractility but maintains cardiac output by increases in right diastolic function and a decrease in pulmonary artery elastance [90]. In this study, right ventricular contractility increased in response to pulmonary artery clamping. Unilateral thoracic paravertebral block with lidocaine has been shown to decrease myocardial contractility up to 30% and significantly decrease systemic pressure, an effect that may be attenuated by epinephrine [91]. In general, the potential benefits of regional anesthesia in thoracic surgery probably outweigh the risks of hypotension and right ventricular dysfunction. As with most anesthetic interventions in patients with PHTN, careful titration and monitoring are paramount. Indeed, case reports illustrate successful use of epidural analgesia in this patient population [92–94].

Conclusion

In general, no anesthetic drug is contraindicated in patients with PHTN. The aim of any anesthetic intervention in these patients is hemodynamic neutrality, which can be accomplished by a variety of agents and techniques. An awareness of the potential advantages and disadvantages of drugs is key to proper decision-making. In the PHTN population, the general principles remain the same: adequate anesthesia and analgesia, maintenance of gas exchange to the best extent possible, and support of the right ventricle. In reality, most clinicians who deal with these patients regularly use a wide variety of medications with success.

Support of the Right Ventricle

RV failure can occur acutely when the right ventricular afterload suddenly increases. Unlike the left ventricle, the naïve right ventricle is not capable of generating flow against a high afterload. In the setting of chronic pulmonary hypertension, RV failure can occur following arrhythmias, sepsis, pulmonary embolism, pregnancy, surgery/anesthesia, or progression of their primary disease [95]. The mainstay to supporting the right ventricle includes ensuring an adequate systemic blood pressure (to preserve coronary perfusion), optimizing RV volumes (to reduce RV wall tension and myocardial work and improve RV–LV interaction), and reducing RV afterload [10, 96]. Inotropes may not be effective in acute RV failure owing to the relatively small muscle mass of the right ventricle or the presence of RV ischemia. Additionally, inotropes may lead to an increase in heart rate and a reduction in RV and LV filling time. In addition to avoiding agents that may have a direct adverse effect on cardiac function or those that may adversely increase RV afterload, agents that can reduce RV afterload can be used acutely. Although not systematically studied in the context of acute RV failure, the anesthetist should have an understanding of the agents used to treat chronic pulmonary arterial hypertension and how to manage these agents in the perioperative setting.

Pulmonary Vasodilators (PO/IV/Inhaled)

Pulmonary vascular resistance (PVR) is commonly considered clinically as reflective of the degree of right ventricular afterload. However, afterload to the right ventricle also includes pulmonary vascular compliance and impedance as well as RV wall tension [97, 98]. The naïve and decompensated RV is exquisitely sensitive to increases in its afterload. Consequently, even small changes in RV afterload may have profound effects on RV function. There are three main pathways that have been exploited acutely and more commonly chronically to reduce right ventricular afterload and increase cardiac output and oxygen delivery to metabolically active tissues. The various agents, pathway, and route of administration are provided in Table 9.1. Therapies directed toward the nitric oxide/guanylate cyclase pathway, the endothelin pathway, and the prostanoid/adenylate cyclase pathway have been the subject of several randomized controlled trials in patients with WHO group I pulmonary hypertension (pulmonary arterial hypertension – PAH). The use of these agents in the acute setting however is based more on biological plausibility and often small case series. In the acute setting, the ideal pulmonary vasodilator would have a rapid onset, short half-life, and selectivity for the pulmonary (as opposed to systemic) vasculature. In general, the only way to confer pulmonary vascular selectivity is by delivering the drug by inhalation. However, many agents administered by inhalation may be absorbed and "spill over" producing systemic effects. Systemic agents are also limited by possible increase in ventilation perfusion mismatching (shunt) owing to dilation of blood vessels to alveolar units that are not effectively participating in gas exchange.

Table 9.1 Comparison of currently available pulmonary vasodilators used to treat pulmonary hypertension and RV failure

Pathway	Agent/therapy	Route
Prostanoids		
Prostaglandin analogues	Epoprostenol sodium	IV, Inhaled
	Treprostinil	IV, SC, Inhaled
	Beraprost sodium	Oral
Prostaglandin receptor agonist	Selexipag	Oral
Endothelin		
Endothelin receptor blockers	Bosentan, ambrisentan, macitentan	Oral
Nitric oxide/cGMP		
	Nitric oxide	Inhaled
Inhibition of phosphodiesterase	Sildenafil	Oral, IV
	Tadalafil	Oral
Guanylate cyclase agonist	Riociguat	Oral

Nitric Oxide/Cyclic-GMP Pathway

Nitric oxide (NO) exerts its vasodilatory effects, in part, by binding to soluble guanylate cyclase (sGC) leading to the production of cyclic GMP (cGMP) that in turn activates protein kinase G [99–101]. The ensuing reduction in cytosolic calcium causes smooth muscle dilation by inhibition of phosphorylation and subsequent cross-linking of myosin or through activation of myosin light chain phosphatases that dephosphorylate myosin light chains. Direct activation of calcium-dependent potassium channels is another mechanism and leads to hyperpolarization of cells/reduced contraction [100].

Nitric Oxide

Inhaled nitric oxide (iNO) leads to an improvement in perfusion to alveoli that can participate in gas exchange. This "selective effect" leads to a decrease in intrapulmonary shunt [102, 103]. Nitric oxide may be administered either noninvasively or through a ventilator circuit using a device that can regulate the concentration of NO and monitor levels of nitrogen dioxide – a byproduct of NO when it combines with oxygen. Although there is controversy about a dose response relationship for NO and pulmonary vasodilation, the typical dose ranges from 10 to 40 ppm [104, 105]. The effect of NO on gas exchange and hemodynamics may be increased when used in combination with phosphodiesterase inhibitors [106–108]. Methemoglobin levels need to be monitored when NO is administered for more than 24 h. At present iNO is only approved for infants with respiratory distress syndrome. This approval stems from two large prospective placebo controlled studies demonstrating that NO reduced the need for ECMO and reduced the requirement for oxygen therapy following ICU discharge [109, 110]. However, iNO is still used for patients with refractory hypoxemia, acute pulmonary hypertension and RV failure, primary graft dysfunction, and acute RV failure following heart transplant [111, 112]. The acute right ventricular failure complicating heart transplantation may be attenuated with the use of a pulmonary vasodilator. Although several studies suggest that NO may be useful preoperatively in risk stratifying patients scheduled for cardiac transplant, only case series support the use of inhaled NO to reverse the right ventricular dysfunction following cardiac transplant [111, 113]. However, based on clinical experience, inhaled NO has become a standard of care in many transplant centers for the management of primary graft dysfunction (PGD). The beneficial immune-modulating effects of inhaled NO in addition to its vasodilating properties were felt to be responsible for preliminary studies of using inhaled NO to prevent PGD after lung transplantation [114, 115]. Although a randomized clinical trial failed to

show benefit in preventing PGD, it is commonly used to treat the hypoxemia and pulmonary hypertension seen in established, severe PGD [116]. Owing to the inherent cost of using inhaled NO, other pulmonary vasodilators have been evaluated.

In non-transplant thoracic surgery, NO has been studied as a potential treatment for the gas exchange abnormalities associated with OLV. Its effects are controversial, but it would appear that it exerts its maximal benefits in patients with elevated PVRI and the poorest gas exchange before administration [117–120]. There is no evidence for the routine use of this expensive drug in otherwise normal patients undergoing routine thoracic surgery.

cGMP/cAMP Pathway

Phosphodiesterase (PDE) inhibitors prevent the degradation of cyclic guanosine monophosphate (cGMP) and adenosine monophosphate (cAMP). Owing to the relatively higher expression of PDE_5 in the pulmonary circulation relative to the systemic circulation, PDE_5 inhibitors have a relative selective effect on PVR as opposed to SVR [121, 122]. In addition to their relatively selective pulmonary vasodilatory effects, their effects on smooth muscle proliferation and cellular apoptosis [123, 124] may be responsible for benefit of these agents when administered chronically in patients with idiopathic PAH [125, 126]. A direct inotropic effect of sildenafil on the right ventricle has been postulated; however, the clinical relevance of this finding is uncertain [127].

Although the benefits of sildenafil and tadalafil in chronic PAH have been evaluated in prospective controlled trials, most of the acute applications for these agents have been described in case reports or small cohort studies and as such have not been approved for these indications. In the acute setting, sildenafil has been demonstrated to enhance the effects of inhaled NO and may also be useful in blunting the rebound in pulmonary pressures that occurs during weaning of inhaled NO [106, 121, 128]. The benefits of sildenafil in acute pulmonary embolism and cardiac transplantation and in patients with pulmonary hypertension being considered for pulmonary thromboendarterectomy have also been described [107, 108, 129–131]. Although pulmonary vasodilators can improve hemodynamics in patients with CTEPH [132], the merits of attempting to optimize RV function in patients with pulmonary hypertension and planned pulmonary thromboendarterectomy were recently challenged in a retrospective analysis of chronic thromboembolic pulmonary hypertension patients referred to a single center during 2005–2007 [133]. There was minimal benefit of treatment with medication on pre-PTE mean pulmonary artery pressure, but its use was associated with a significant delay in time to referral for PTE. Importantly the two groups did not differ significantly in any post-PTE outcome. Although this study did not specifically evaluate the use of sildenafil for this purpose, it suggests at the very least that planned, potentially curative surgery should not be delayed while exploring theoretic benefits of this agent on RV function. Whether it can modify surgical risk in patients with very high PVR or who have evidence of shock remains speculative [134]. Although some reports have demonstrated acute beneficial effects of sildenafil in patients with pulmonary hypertension in the context of systolic and diastolic dysfunction [135–138], and in patients undergoing valve surgery [139], the negative results of a study evaluating continuous intravenous epoprostenol for the same purpose supports the notion that a controlled trial be conducted before these agents are routinely used for this purpose [140, 141].

The activity of soluble guanylate cyclase (sGC) may also be directly influenced by sGC activators and stimulators [142]. Riociguat (sGC stimulator) has a dual mechanism of action on sGC by increasing both the sensitivity of sGC to endogenous NO and via a direct (NO independent) stimulation of sGC [143]. Unlike other agents mentioned thus far, riociguat must be up-titrated gradually over several weeks to ensure that the medication is tolerated. The efficacy of riociguat has been demonstrated in chronic pulmonary hypertension. In patients with PAH and in inoperable or persistent chronic thromboembolic disease post-endarterectomy [144, 145], riociguat improved exercise capacity (assessed by 6-min walk distance), symptoms of dyspnea, quality of life, and hemodynamics. The main relevant limitation to riociguat is twofold. First hemoptysis and pulmonary hemorrhage have been reported within the confines of the acute and long-term trials (generally less than 3% of the study cohort). Second, riociguat can cause systemic hypotension. Particularly noteworthy is the adverse interaction between this agent and the PDE_5 inhibitor class of agents and a theoretic adverse interaction between this agent and NO donors, in causing systemic hypotension [146]. The effects of endogenous/inhaled NO in combination with riociguat have not been systematically evaluated.

Endothelin Antagonists

Endothelin-1 (ET-1) is a peptide produced primarily by endothelial cells. It acts on ET-A and ET-B receptors, both of which are located on pulmonary vascular smooth muscle cells. The ET-B receptor is also located on endothelial cells. Abnormally high concentration of ET-1 in PAH is the result of increased production and decreased clearance of the peptide [147, 148]. Both circulating and pulmonary concentrations of ET-1 have been correlated with disease severity and prognosis in PAH [149].

Bosentan, ambrisentan, and macitentan are approved as treatment for patients with PAH. Both ambrisentan and bosentan have been shown to improve symptom severity, hemodynamics, and exercise capacity (quantified by improvements in the standardized 6-min walk test – 6MWT) [150]. The SERAPHIN trial (macitentan 3 mg vs 10 mg vs placebo) was the first endpoint-driven trial and demonstrated an improvement in time to clinical worsening (hospitalizations, escalation in treatments, death, or transplantation) [151]. This composite primary endpoint was primarily driven by a reduction in hospitalizations or escalation in medical treatments for PAH.

The tolerability as a class is most commonly limited by hepatotoxicity, followed by several less frequent hematologic, neurologic, cardiovascular, respiratory, and gastrointestinal adverse effects. The newer agents, ambrisentan and macitentan, have the lowest incidence of hepatotoxicity and fewer drug-drug interactions than bosentan [152]. However, interactions with agents undergoing CYP metabolism remain a potential concern for this class. The effect on cyclosporine metabolism is particularly relevant. Although effective in the chronic setting, these agents have not been utilized for acute RV failure or acute pulmonary hypertensive crisis.

In the chronic setting, medical therapies are often combined to capitalize on the different therapeutic pathways. Indeed, recent data from a randomized controlled trial suggests that upfront combination therapy (ambrisentan and tadalafil) is associated with improved outcomes compared to monotherapy with either agent [153]. In the acute setting, combination therapy (e.g., with iNO and a PDE_5 inhibitor) may also be of benefit.

Milrinone is an adenosine-3′, 5′-cyclic monophosphate (cAMP)-selective phosphodiesterase enzyme (PDE) inhibitor. When nebulized it has been shown to lead to a relative reduction in PVR compared to SVR [154–156]. Haraldsson et al. evaluated a cohort of post cardiac surgery patients and reported upon the hemodynamic effects of the combination inhaled milrinone and inhaled prostacyclins [157]. The inhalation of milrinone selectively dilated the pulmonary vasculature without systemic effects. When milrinone is combined with inhaled prostacyclin, there appears to be a potentiation and prolongation of the pulmonary vasodilatory effect [157, 158].

Prostaglandins

Prostanoids induce relaxation of vascular smooth muscle, inhibit growth of smooth muscle cells, and are powerful inhibitors of platelet aggregation [159]. Inhaled prostanoids involve an aerosol delivery system that uses a nebulizer attached to the ventilator circuit. Treatment may be limited by inefficiencies in aerosolization. Owing to the short half-life of epoprostenol, the drug must also be continuously nebulized. As a result, changes of dose delivery with alterations in ventilator volumes, FiO_2, airway pressures, and solvent evaporation may be challenging [160]. The synthetic prostanoids, treprostinil and iloprost, hold promise as inhaled vasodilators as they may only require intermitted administration. Studies of prostanoids in chronic PAH demonstrated that they were effective in improving symptoms and exercise tolerance [161, 162]. When nebulized, prostanoids can lead to similar improvements in oxygenation and pulmonary pressures as compared to inhaled NO [163–167]. Indeed, several cohort studies have failed to demonstrate a benefit of iNO over inhaled prostanoids in treating acute pulmonary hypertension [168, 169]. Similarly in critically ill patients with refractory hypoxemia, inhaled epoprostenol (n = 52) and iNO (n = 53) had similar acute effects on gas exchange. The effects on pulmonary pressures or RV function were not assessed [170]. Similar to iNO, the effects of inhaled prostanoids on gas exchange and hemodynamics may be increased with the co-administration of PDE_5 inhibitors [171].

Use of intravenous prostaglandins during OLV results in a decrease in both systemic and pulmonary pressures and either no change or a decrease in PaO_2 [172, 173]. Selective infusion of prostaglandin into the pulmonary artery of the ventilated lung in a dog model during OLV resulted in stable systemic pressure and a reduction in PVR and increase in PaO_2 [174]. However, this route of administration is not practical in routine thoracic anesthesia practice. Inhaled prostacyclin decreases PVRI and PAP with maintenance of favorable systemic pressures but does not change PaO_2 during OLV [173].

Both inhaled nitric oxide and prostaglandins have been shown to affect platelet function [175, 176]. This could theoretically contribute to perioperative bleeding during large surgeries such as lung transplantation and a consideration in regard to the risks of neuraxial analgesia. It is important to emphasize however that the clinical relevance of platelet inhibition with these inhaled agents has not been systematically evaluated. Indeed, in cardiac surgery patients, laboratory confirmation of platelet dysfunction with inhaled prostacyclin did not correlate with chest tube losses [175]. Also, in an obstetrical patient with pulmonary hypertension on intravenous prostacyclin, conversion to inhaled prostacyclin allowed for a successful labor epidural placement with no complications [177].

Until recently an efficacious oral prostanoid has remained elusive. Selexipag is an oral selective IP receptor agonist that was shown to reduce clinical events (time to clinical worsening endpoints such as hospitalization and escalation of PAH treatments) compared to placebo in patients with group I PH. Although of benefit when administered chronically, it is unlikely that this oral agent will have clinical utility in the

acute setting as it shares the same limitations as other parenteral prostanoids for the management of acute RV failure/pulmonary hypertension.

Pulmonary Vasodilators in Thoracic Surgery

Unsurprisingly, the bulk of research studying pulmonary vasodilators in thoracic surgery is in lung transplantation. Preoperatively transplant patients may be on oral, intravenous, or inhaled drugs for pulmonary hypertension. These must be continued perioperatively. Intraoperatively, inhaled pulmonary vasodilators such as nitric oxide (NO) and prostaglandins are commonly employed in attempts to decrease right ventricular afterload and optimize gas exchange. Addition of inhaled prostacyclin to inhaled NO after implantation of the first lung during bilateral sequential transplantation decreases pulmonary shunt, $PaCO_2$, and PAP while increasing PaO_2/FiO_2 with no effect on systemic hemodynamics [119]. Posttransplant, these drugs have been shown to improve the gas exchange abnormalities and increased pulmonary pressures associated with reperfusion injury [163] [114, 178]. Initial excitement over the potential ability of prophylactic NO to prevent acute graft rejection after lung transplantation [179] was tempered when a randomized trial did not show a statistically significant difference between placebo and NO for preventing reperfusion injury or changing postoperative outcome when administered 10 min after reperfusion in the operating room [116].

In non-transplant thoracic surgery, NO has been studied as a potential treatment for the gas exchange abnormalities associated with OLV. Its effects are controversial, but it would appear that it exerts its maximal benefits in patients with elevated PVRI and the poorest gas exchange before administration [117, 118, 120]. There is no evidence for the routine use of this expensive drug in otherwise normal patients undergoing routine thoracic surgery.

Inhaled prostacyclin decreases PVRI and PAP with maintenance of favorable systemic pressures but does not change PaO_2 during OLV [173].

Use of intravenous prostaglandins during OLV results in a decrease in both systemic and pulmonary pressures and either no change or a decrease in PaO_2 [172]. Selective infusion of prostaglandin into the pulmonary artery of the ventilated lung in a dog model during OLV resulted in stable systemic pressure and a reduction in PVR and increase in PaO_2 [174]. However, this route of administration is not practical in routine thoracic anesthesia practice.

Both inhaled nitric oxide and prostaglandins have been shown to affect platelet function [175, 176]. This could theoretically contribute to perioperative bleeding during large surgeries such as lung transplantation and is a concern in regard to neuraxial analgesia. The clinical relevance of platelet inhibition with these inhaled agents is unknown. Indeed, in cardiac surgery patients, laboratory confirmation of platelet dysfunction with inhaled prostacyclin did not correlate with chest tube losses [175]. Also, in an obstetrical patient with pulmonary hypertension on intravenous prostacyclin, conversion to inhaled prostacyclin allowed for a successful labor epidural placement with no complications [177].

To date there are few systematic concealed trials of pulmonary vasodilators on the acute management of intraoperative/perioperative pulmonary hypertension or RV failure. A recent systematic review of inhaled pulmonary vasodilators in cardiac surgery identified ten studies of inhaled pulmonary vasodilators (vs intravenous route or placebo) [180]. The authors concluded that while these agents seemed to be acutely better than systemic agents in improving RV function, there was no clear benefit of these agents when compared to placebo on clinical outcomes. Given the costs associated with these agents, a systematic study of their benefit to patient-relevant outcomes is needed.

Clinical Case Study

A 46-year-old woman with interstitial lung disease (ILD) presents to the pre-anesthetic clinic before an open lung biopsy.

What are the Anesthetic Considerations for This Case?

Considerations include those of ILD and the proposed case itself. In regard to the ILD, its etiology and severity (including associated connective tissue disorders and multisystem involvement), and associated right heart dysfunction should be delineated. In regard to the biopsy, the usual considerations of lung separation, analgesic options, invasive monitoring and, in this patient, the potential requirement for perioperative inhaled vasodilator therapy are present.

Besides the Usual Anesthetic History and Physical, What Would You Want to Elicit on History and Look for on Physical Exam in This Case?

On history, a careful assessment of functional status and current symptoms, personal and family history of connective tissue diseases should be undertaken.

On physical exam, vital signs including respiratory rate, potential clubbing, crackles on lung auscultation, and signs of right heart dysfunction (including increased JVP, hepatomegaly, lower extremity edema, increased P2 on heart auscultation and right ventricular heave on palpation) should be assessed.

The patient has been experiencing progressive worsening of shortness of breath for approximately 2 years. Her ability to exercise has declined markedly, to the point where she cannot climb a flight of stairs. She had a recent admission to hospital where she was started on home oxygen therapy and referred to a respirologist. An echocardiogram done at that time revealed an RVSP of 89 with mild right ventricular

dilation and hypokinesis. ECG shows sinus tachycardia at 105. The respirologist suggests a biopsy to shed light on the etiology.

Physical exam reveals a thin woman with a respiratory rate of 18 wearing oxygen via nasal prongs at 4 L/min. Her oxygen saturation is 95%, her heart rate is 95, and her blood pressure is 100/60. Airway exam is reassuring. She has coarse crackles bilaterally. JVP is normal, but P2 is increased on cardiac auscultation. There is no hepatomegaly or pedal edema.

What Can be Done to Optimize These Patients' Perioperative Course?

After communicating with the patient's respirologist, a decision is made to bring the patient to the hospital the day before the planned operation to perform a right heart catheterization and assess the patient's response to inhaled prostacyclin. A pulmonary artery catheter is inserted under local anesthesia in the intensive care unit. PAP is 75/40. Systemic blood pressure is 90/60. After institution of inhaled prostacyclin, the PAP decreases to 60/30 with no change in systemic pressure.

What is the Anesthetic Plan?

TEE is arranged to be available for the case. After an appropriate fasting interval, the patient is transferred to the operating room with inhaled prostacyclin (10 ng/kg/min) and oxygen. A baseline ABG is drawn and shows pH of 7.38, $PaCO_2$ 44, PaO_2 65, and HCO_3 28. Baseline vital signs are sinus tachycardia 103, PAP 65/37, BP 98/62, and 96% on FiO_2 40%. An epidural is placed and tested at T5/6. An epidural infusion of bupivacaine and hydromorphone is started. Preoxygenation continues without interruption of the inhaled prostacyclin, and norepinephrine is started at 0.05 mcg/kg/min. After ensuring the surgeons are in the room, induction medications are titrated to effect and include midazolam 2 mg, fentanyl 250 mcg, and ketamine 50 mg. Rocuronium 50 mg is given to facilitate endotracheal intubation. A 37F left-sided double-lumen tube is placed without difficulty, and anesthesia is maintained with sevoflurane and 100% oxygen. Inhaled prostacyclin is continued via the anesthetic circuit. Vital signs are stable with assumption of positive pressure ventilation. The patient is turned to the lateral position and surgery is started. After commencement of OLV, the patient's PAP climbs to 80/45, BP decreases to 78/40, and ST depression occurs in lead II on ECG. Oxygen saturation drops to 87% on 100%. Pre-existing right ventricular hypokinesis and dilation are seen to worsen on TEE. A temporizing bolus of phenylephrine 200 mcg is given, while the norepinephrine is titrated up to 0.1 mcg/kg/min. A bolus of 250 cc of normal saline is administered, keeping in mind the delicate balance between overloading a failing right ventricle and maintenance of adequate preload to ensure systemic cardiac output. Inhaled prostacyclin is titrated up to 30 ng/kg/min. Vital signs move back toward baseline. The surgery is completed, the patient is extubated, awake, and comfortable. Norepinephrine is titrated off in recovery, and the prostacyclin is titrated down to baseline. The patient returns back to intensive care for close observation.

Perioperative Lung Injury

10

Peter Slinger

Key Points

- Traditional patterns of mechanical ventilation with large (e.g., 10–12 mL/kg) tidal volumes and without PEEP cause a subclinical injury in healthy lungs in proportion to the duration of ventilation.
- Perioperative acute lung injury becomes clinically important when injurious ventilation patterns are used in patients who have other concomitant lung injuries such as large pulmonary resection, cardiopulmonary bypass, or transfusion-related lung injury.
- One-lung ventilation causes a lung injury in both the ventilated and non-ventilated lungs.
- This lung injury is usually subclinical and increases with the duration of one-lung ventilation.
- Lung-protective patterns of mechanical ventilation, using more physiologic tidal volumes and appropriate PEEP, appear to reduce the severity of this lung injury.
- At present, there is no convincing evidence that the use of lung-protective strategies has improved patient outcomes in thoracic surgery.
- The majority of the recent decrease in the incidence of lung injury after pulmonary resections is primarily due to a decrease in the frequency of pneumonectomy.

Introduction

Perioperative lung injury is defined as pneumonitis or acute respiratory distress syndrome (ARDS) occurring in the immediate postoperative period during the initial hospitalization. ARDS definitions include a PaO_2/FiO_2 ratio (mild <300, moderate <200, and severe <100) and radiographic infiltrates characteristic of pulmonary edema in accordance with the European Society of Intensive Care Medicine definition [1]. Lung injury following thoracic surgery has been described by a number of terms over the past 30 years including post-pneumonectomy pulmonary edema, permeability pulmonary edema, and postoperative lung injury. While other causes of postoperative morbidity and mortality in thoracic surgery such as atelectasis, pneumonia, and bronchopleural fistula have declined dramatically in the past 30 years [2], lung injury remains a major problem and now has become the leading cause of death after pulmonary surgery [3].

Acute Lung Injury in Patients with Healthy Lungs

Traditionally, anesthesiologists have been taught to ventilate patients in the operative and postoperative periods with relatively large tidal volumes. Volumes as large as 15 mL/kg ideal body weight have been suggested to avoid intraoperative atelectasis [4]. This far exceeds the normal spontaneous tidal volumes (6 mL/kg) common to most mammals [5]. The use of nonphysiologic large tidal volumes for one-lung anesthesia evolved in the 1960–70s because it was discovered that very large tidal volumes improved PaO_2 during thoracic surgery [6]. However, the incidence of serious oxygen desaturation during one-lung ventilation has decreased from approximately 20–25% of cases in the 1970s to <5% currently [7]. This decrease is primarily due to the development of anesthetic agents that cause less inhibition of hypoxic pulmonary vasoconstriction (see Chaps. 6 and 26) and improved

lung isolation techniques (see Chaps. 16 and 17). Thus, it is no longer necessary to use large tidal volumes during one-lung anesthesia.

Recently, it has become obvious that these nonphysiologic large tidal volumes can cause a degree of subclinical injury in healthy lungs. Gajic et al. [8] reported that 25% of patients without lung injury ventilated in an ICU setting for 2 days or longer developed acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). The main risk factors associated with the development of lung injury were the use of large tidal volumes, restrictive lung disease, and transfusion of blood products. In a prospective study, the same group have found that tidal volumes >700 mL and peak airway pressures >30 cm H_2O were independently associated with the development of ARDS [9]. In an intraoperative study of patients having esophageal surgery, Michelet et al. [10] compared the use of tidal volumes of 9 mL/kg without positive end-expiratory pressure (PEEP) during two- and one-lung ventilation vs. 9 mL/kg during two-lung ventilation and 5 mL/kg during one-lung ventilation with PEEP 5 cm H_2O throughout. They found significantly lower serum makers of inflammation (cytokines IL-1ß, IL-6ß, and IL-8ß) in the lower tidal volume plus PEEP group (see Fig. 10.1). This study did not find any major difference in postoperative outcome between the two groups; however, it was not powered to do this. The study did demonstrate better oxygenation in the lower tidal volume group during and immediately after one-lung ventilation (see Fig. 10.2) but not after 18 h. In a study of major abdominal surgery patients ventilated for >5 h, Choi et al. [11] compared the use of 12 mL/kg tidal volumes without PEEP vs. 6 mL/kg plus PEEP 10 cm H_2O. Bronchiolar lavages were performed before and after 5 h of mechanical ventilation. Lavage fluid from the high tidal volume group showed a pattern of leakage of plasma into the alveoli with increased levels of thrombin-antithrombin complexes (see Fig. 10.3), soluble tissue factor, and factor VIIa. This is the hallmark of alveolar lung injury. A clear pattern seems to be appearing from the clinical research that, even in patients with no lung disease, the use of nonphysiologic patterns of ventilation with large tidal volumes and without PEEP causes a degree of systemic inflammation and lung injury. The severity of this injury seems to be directly related to the duration of mechanical ventilation.

Atelectasis is a frequent postoperative complication of surgical procedures. Atelectasis occurs intraoperatively as part of essentially any general anesthetic [12]. Anesthesiologists are aware of this, and techniques to avoid it with air-oxygen mixtures, PEEP, and recruitment maneuvers are used frequently

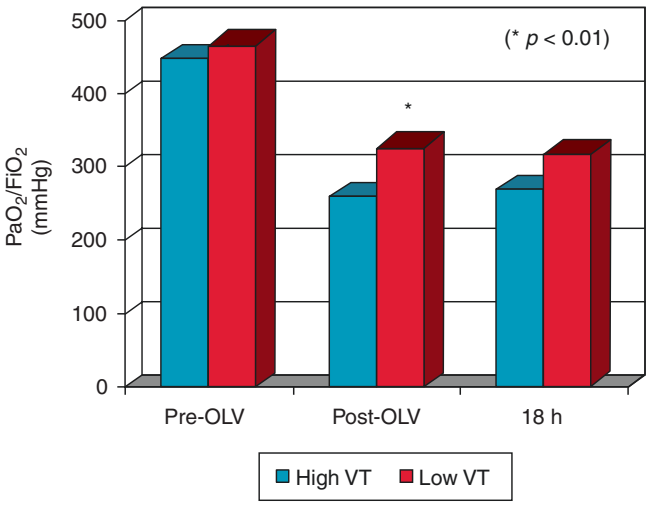

Fig. 10.2 Ratio of arterial oxygen tension to inspired oxygen concentration (PaO_2/FiO_2) in patients ventilated with either a large tidal volume (9 mL/kg) or a small tidal volume (5 mL/kg) plus PEEP (5 cm H_2O) during OLV. (Based on data from Ref. [10])

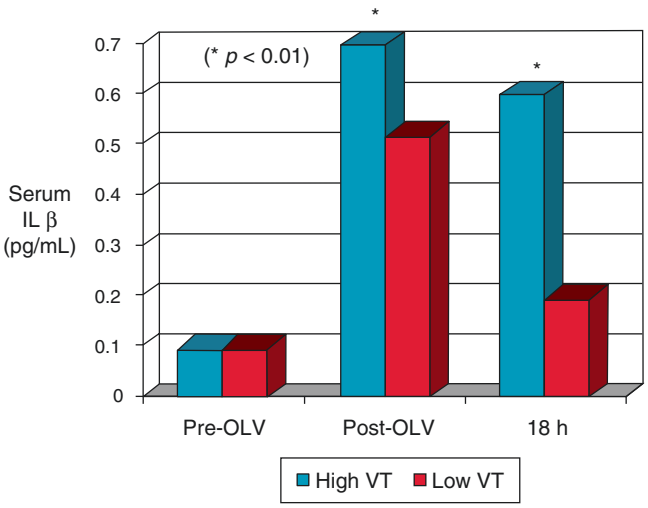

Fig. 10.1 Serum levels of inflammatory cytokine IL-1ß before and after periods of one-lung ventilation (OLV) in patients having esophagectomies. Patients' lungs were ventilated with either a large tidal volume (9 mL/kg) or a small tidal volume (5 mL/kg) plus PEEP (5 cm H_2O) during OLV. (Based on data from Ref. [10])

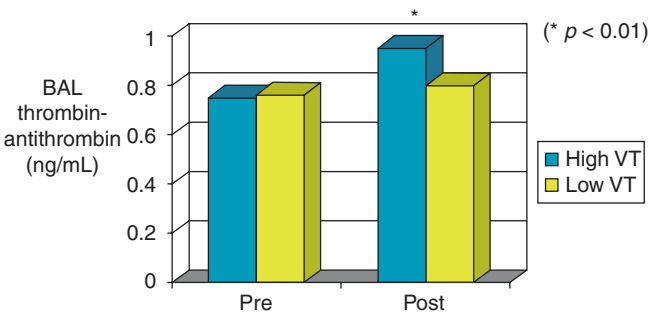

Fig. 10.3 Bronchoalveolar lavage (BAL) levels of thrombin-antithrombin complexes as a marker of lung epithelial injury in patients ventilated for >5 h during abdominal surgery with either a large tidal volume (12 mL/kg) without PEEP vs. a small tidal volume (6 mL/kg) with PEEP (10 cm H_2O). (Based on data from Ref. [11])

[13]. However, anesthesiologists are often not aware that atelectasis is a pathological state and, if it persists in the postoperative period, leads to an increased capillary permeability and an inflammatory response with subsequent lung injury. Atelectasis injures the lung while it is atelectatic due to local release of inflammatory mediators, and it injures the lung if the lung is repeatedly subjected to collapse and recruitment [14]. Atelectasis also contributes to injury in the non-atelectatic lung regions which develop a volutrauma injury due to excessive distribution of inspiration to these remaining, ventilated, lung regions [15]. Both retrospective [16] and prospective [17] studies have consistently shown that appropriate thoracic epidural analgesia reduces the incidence of respiratory complications (atelectasis, pneumonia, and respiratory failure) after major abdominal and thoracic surgery. The benefits of epidural analgesia seem to be in direct proportion to the severity of the patients underlying lung disease. Patients with COPD seem to derive the most benefit from epidural analgesia. It has also been recently demonstrated that aggressive physiotherapy with CPAP in the postoperative period in patients who develop early desaturation after major abdominal surgery leads to lower rates of major respiratory complications [18].

Pulmonary Resection

There are some situations when the anesthesiologist appreciates that a patient presenting for surgery may have a lung injury (trauma/ARDS, lung transplantation, etc.). However, there are many more cases where the lung injury is subclinical and underappreciated in the perioperative period (cardiopulmonary bypass, large pulmonary resections [19]). Acute lung injury following pulmonary resection has been described since the beginning of one-lung ventilation (OLV) for thoracic surgery. One-lung ventilation is injurious to both the ventilated and non-ventilated lung. This injury seems to be more serious in the ventilated lung (see Fig. 10.4), and this injury increases with the duration of one-lung ventilation [20].The most publicized report is a compilation of ten cases of pulmonary edema following pneumonectomy published in 1984 [21] which focused on the role of intravenous overhydration as a cause of post-pneumonectomy pulmonary edema. Subsequently there have been several reviews of this topic identifying a variety of other potentially causative factors for lung injury such as the administration of fresh frozen plasma, mediastinal lymphatic damage, inflammation, and oxygen toxicity [22]. The most thorough study to date [23] is a retrospective survey of 806 pneumonectomies which found 21 cases (2.5%) of post-pneumonectomy pulmonary edema, one of the lowest incidences reported of this complication. There were no differences in perioperative fluid balance between post-pneumonectomy pulmonary edema cases (positive fluid balance at 24 h, 10 mL/kg) and matched pneumonectomy controls (13 mL/kg). These authors used rigorous fluid restriction compared to other reports [24] (e.g., 24 h positive balance, 21 ± 9 mL/kg) suggesting that limiting intraoperative fluids might decrease but not eliminate post-pneumonectomy pulmonary edema. Subsequent reports demonstrate improved survival from post-pneumonectomy pulmonary edema due to improved postoperative management of established cases [25].

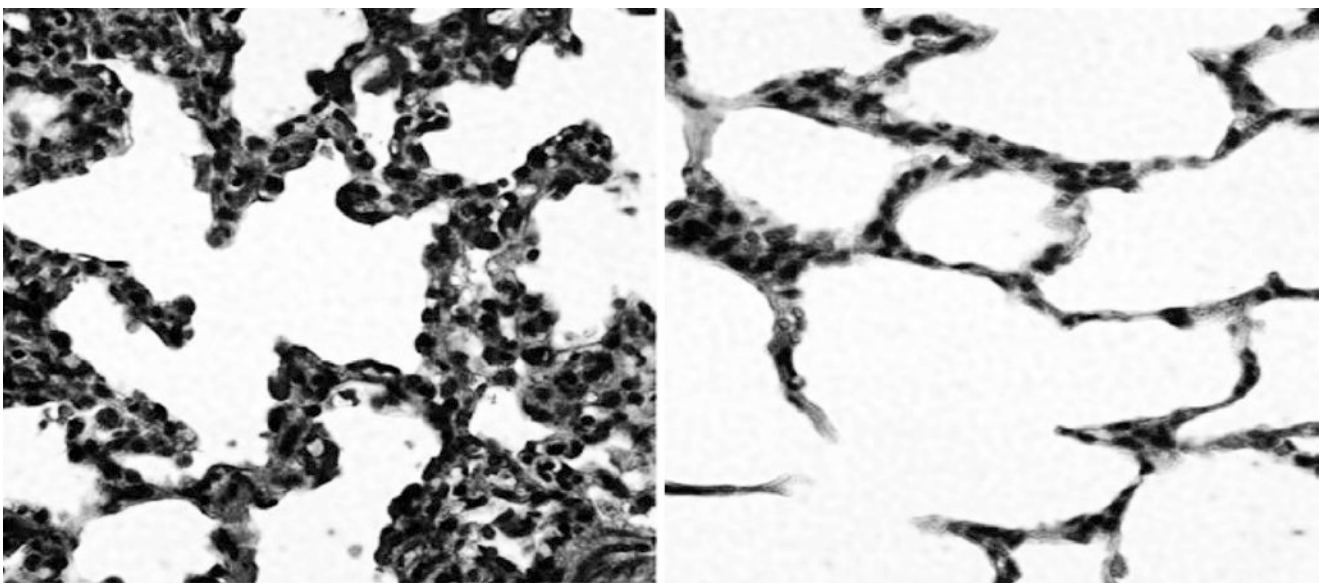

Fig. 10.4 Histologic specimens from the ventilated lung (left) and the non-ventilated lung (right) show evidence of lung injury with neutrophil infiltration in the alveolar septa after 90 min of one-lung ventilation in a pig model. The injury is more severe in the ventilated lung. (Reproduced with permission from Lohser and Slinger [20])

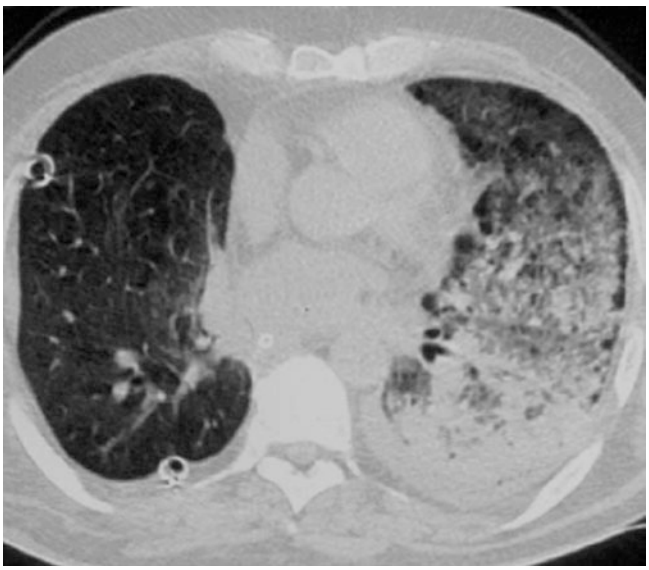

Fig. 10.5 Axial CT scan image of a patient who developed acute lung injury of the left lung (on the right in the image) after a right-sided lobectomy. The majority of lung injury after lobectomy presents in the ventilated (anesthesiologist's) lung, not the non-ventilated (surgeon's) lung

Table 10.1 Factors associated with acute lung injury following pulmonary resection

Large pulmonary resections (right pneumonectomy, extrapleural pneumonectomy)
Large tidal volumes during OLV (>9 mL/kg ideal body weight)
Excessive intravenous fluids (>20 mL/kg positive fluid balance first 24 h)
Decreased lung function (low predicted postoperative DLCO or FEV1)
Duration of OLV
Preoperative chemotherapy
Restrictive lung disease
Administration of fresh frozen plasma and other blood products
Age
Preoperative alcohol abuse

DLCO diffusing capacity of the lung for carbon monoxide; *FEV1* forced expiratory volume in 1 s

Table 10.2 Causes of post-resection lung injury

Probable	Possible
Endothelial injury	Inflammatory response
Epithelial injury (large tidal volumes)	Right ventricular dysfunction (raised CVP)
Increased pulmonary capillary pressure	Oxygen toxicity
Fluid overload	
Lung lymphatic injury	

Post-pneumonectomy lung injury [26] has been found to have a bimodal distribution of onset. Late cases (10/37, 27%) presented 3–10 days postoperatively and were secondary to obvious causes such as bronchopneumonia, aspiration, etc. "Primary" lung injury (27/37, 73% of cases) presented on postoperative days 0–3. Four factors were independently significant predictors of primary lung injury: high intraoperative ventilation pressures, excessive intravenous volume replacement, pneumonectomy, and preoperative alcohol abuse. The known facts about lung injury following lung surgery include an incidence of 2–4% following pneumonectomy, greater frequency in right vs. left pneumonectomies, symptomatic onset 1–3 days after surgery, high associated mortality (25–50%), and resistance to standard therapies. While lung injury occurs following lesser pulmonary resections such as lobectomy, it has a much lower mortality rate. Of interest, in 8/9 cases who developed unilateral lung injury following lobectomy, the injury was in the nonoperated (i.e., the ventilated) lung (see Fig. 10.5) [27].

While there is some association between postoperative lung injuries with fluid overload, the finding of low/normal pulmonary artery wedge pressures and high-protein edema fluid in affected patients suggests a role of endothelial damage (low-pressure pulmonary edema). Postoperative increases in lung capillary permeability of the nonoperated lung occur after pneumonectomy but not lobectomy [28]. This capillary-leak injury may be due to an inflammatory cascade affecting even the nonoperative lung that is triggered by lung resection and is proportional to the amount of lung tissue resected (Table 10.1) [29, 30]. Free oxygen radical generation in lung cancer patients is related to the duration of OLV [31]. Nonetheless, there is no single mechanism that can fully explain acute lung injury after lung resection, and its etiology is likely multifactorial (Table 10.2). A unifying hypothesis is that post-pneumonectomy pulmonary edema is one end of a spectrum of lung injury that occurs during all lung resections. The more extensive the resection, the more likely there is to be a postoperative injury (see Fig. 10.6). The increased dissection and trauma associated with extrapleural pneumonectomy place these patients at high risk to develop postoperative ALI [32].

Understanding that lung endothelial injury occurs after lung resection supports management strategies similar to other conditions associated with ARDS. As a general principle, it seems that the lung is least injured when a pattern of ventilation as close as possible to normal spontaneous ventilation can be followed: FiO_2 as low as acceptable, variable tidal volumes [33], beginning inspiration at FRC, and avoiding atelectasis with frequent recruitment maneuvers [34]. Studies in ARDS demonstrate that lung injury is exacerbated by the use of large tidal volumes and that lung-protective ventilation strategies with low tidal volumes and PEEP are less injurious. The most important factor in the etiology of ventilator-induced lung injury seems to be the end-inspiratory lung volume [35]. Many patients, particularly those with emphysema, develop auto-PEEP during one-lung ventilation [36], thus beginning inspiration at a lung volume above functional

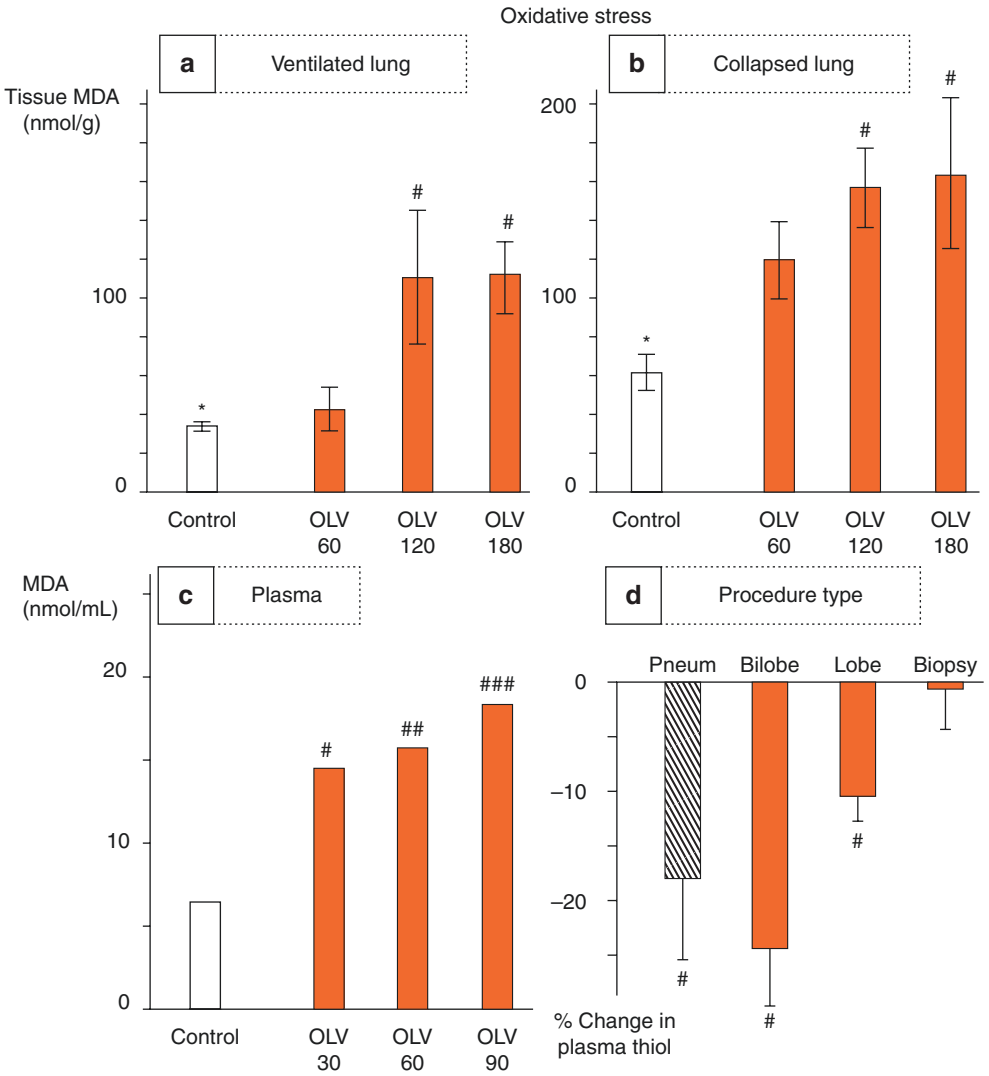

Fig. 10.6 Oxidative stress rises with increasing OLV duration and is more pronounced in the collapsed lung. Panel (**a/b**): bronchoalveolar MDA levels are higher during OLV than TLV controls at all time points (*; $p < 0.01$). The increase is time-dependent, with levels at 120 and 180 min significantly higher than after 60 min (#; $p < 0.005$). Higher levels are achieved in the collapsed lung (**b**) than the ventilated lung (**a**). Panel (**c**): plasma MDA levels increase dramatically after re-ventilation of the collapsed lung. Each increase in OLV duration of 30 min was associated with a significant increase in MDA levels over shorter OLV durations (#/##/###; $p < 0.001$). Panel (**d**): changes in plasma thiol concentration associated with OLV comparing levels from post-induction and postemergence. Major lung resections cause significant decreases in antioxidant activity from baseline values (#; $p < 0.05$), as opposed to lung biopsy or wedge resections. Bx, lung biopsy; lobe, lobectomy; 2-lobe, bilobectomy; MDA, malondialdehyde; OLV, one-lung ventilation; pneum, pneumonectomy. (Reproduced with permission from Lohser and Slinger [20])

residual capacity. It is conceivable that routine use of a large tidal volume (10–12 mL/kg) during OLV in such patients produces end-inspiratory lung volumes close to levels that contribute to lung injury.

Changes in respiratory function during OLV in the lateral position with an open nondependent hemithorax are complex. Initial studies of the application of PEEP during OLV suggested that it led to a deterioration of arterial oxygenation [37]. It is now appreciated that the effects of applied PEEP during OLV depend on the lung mechanics of the individual patient. Most patients with COPD develop auto-PEEP during OLV, and thus adding external PEEP leads to hyperinflation and increased shunt [38] (see Fig. 10.7). However, patients with normal lung parenchyma or those with restrictive lung diseases tend to fall below their FRC at end-expiration during OLV (see Fig. 10.8) and benefit from applied external PEEP [39]. Intraoperative atelectasis may contribute to injury in the dependent lung. It is now appreciated that atelectasis is a pre-inflammatory state predisposing to injury both in the atelectatic portion of the lung and in ventilated regions in the same lung which become hyperinflated [40].

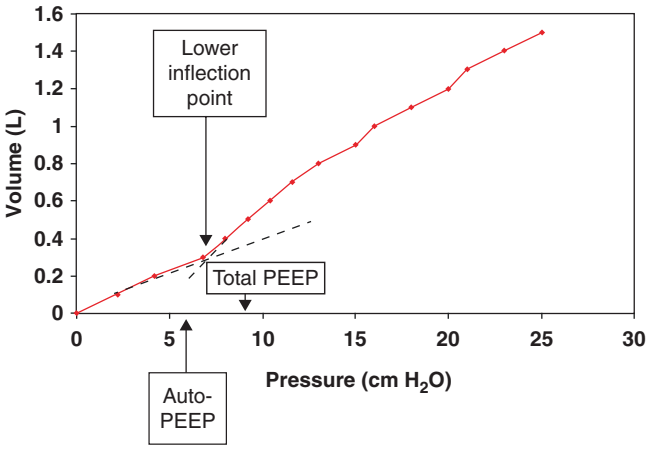

Fig. 10.7 The inspiratory compliance curve (lung volume vs. airway pressure) during one-lung ventilation as the lung is slowly inflated by 100 mL increments in a patient with COPD. The lower inflection point of the curve (thought to represent functional residual capacity (FRC)) is at 7 cm H_2O. During OLV this patient developed an intrinsic PEEP (measured by end-expiratory airway occlusion plateau pressure "auto-PEEP") of 6 cm H_2O. The addition of 5 cm PEEP through the ventilator resulted in a total PEEP in the circuit of 9 cm. The addition of PEEP in this patient raised the end-expiratory lung volume above FRC, thus raising pulmonary vascular resistance in the ventilated lung and caused a deterioration in oxygenation. (Based on data from Ref. [36])

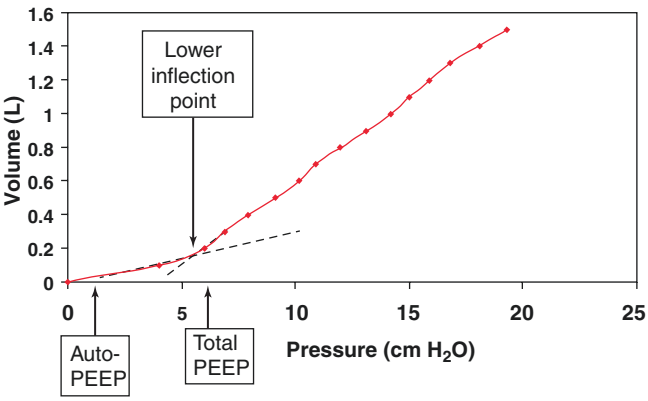

Fig. 10.8 The inspiratory compliance curve during OLV in a patient with normal pulmonary function. The lower inflection point of the curve is at 6 cm H_2O. During OLV this patient developed an intrinsic PEEP of 2 cm H_2O. The addition of 5 cm PEEP through the ventilator resulted in a total PEEP in the circuit of 7 cm. The addition of PEEP in this patient raised the end-expiratory lung volume to FRC, thus decreasing pulmonary vascular resistance in the ventilated lung and caused an improvement in oxygenation. (Based on data from Ref. [36])

There is evidence that when an element of lung injury is added to large tidal volume ventilation during OLV, this contributes to lung injury. In a rabbit model of OLV during isolated perfusion, large tidal volume (8 mL/kg) ventilation produced a picture of lung injury absent in animals randomized to a lung-protective ventilation pattern (4 mL/kg plus PEEP). Another consideration is the management of patients who have received preoperative chemotherapy with agents

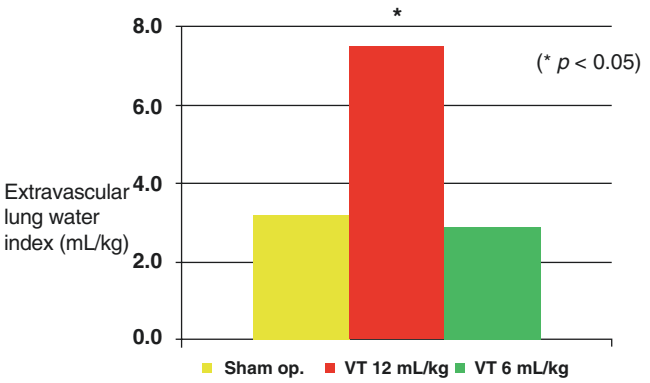

Fig. 10.9 Postmortem extravascular lung water index measured by gravimetry after 4 h of mechanical ventilation in sheep. Sham op. = control thoracotomy group, no lung resection, tidal volume two-lung ventilation 12 mL/kg. VT 12 mL/kg = pneumonectomy group ventilated with tidal volume 12 mL/kg no added PEEP. VT 6 mL/kg = pneumonectomy group ventilated with tidal volume 6 mL/kg + PEEP 5 cm H_2O. (Based on data from Ref. [44])

such as cis-platinum and gemcitabine that may affect respiratory function and may increase the risk of postoperative respiratory complications including lung injury in some patients [41]. Large pulmonary resections (pneumonectomy or bilobectomy) should be considered to be associated with some degree of lung injury. Acute lung injury, diagnosed radiographically, was reported in 42% of pneumonectomy patients who had been ventilated with peak airway pressures >40 cm H_2O [42]. A small retrospective study found that post-pneumonectomy respiratory failure was associated with the use of higher intraoperative tidal volumes (8.3 vs. 6.7 mL/kg in pneumonectomy patients who did not develop respiratory failure) [43]. In a sheep model, Kuzkov et al. demonstrated that the use of large tidal volume ventilation without PEEP for 4 h following a pneumonectomy resulted in an increase of extravascular lung model more than double compared to a control (sham operation) group or a pneumonectomy group ventilated with 6 mL/kg tidal volume plus PEEP 5 cm H_2O (see Fig. 10.9) [44].

Since it is not always possible to predict which patient scheduled for a lobectomy may require a pneumonectomy for complete tumor resection, the routine use of several lung-protective strategies during OLV seems logical. Overinflation of the nonoperated lung should be avoided using lung-protective ventilation (5–6 mL/kg) adding PEEP to those patients without auto-PEEP and limiting plateau and peak inspiratory pressures to <25 cm H_2O and <35 cm H_2O, respectively. Minimizing pulmonary capillary pressures by avoiding overhydration for patients undergoing pneumonectomy is reasonable while acknowledging that not all increases in pulmonary artery pressures perioperatively are due to intravascular volume replacement. Other factors such as hypercarbia, hypoxemia, and pain can all increase pulmonary pressures and must be treated. Finally, it must be appreciated that not all

hyperinflation of the residual lung occurs in the operating room. Overexpansion of the remaining lung after a pneumonectomy may occur postoperatively either with or without a chest drain in place. The use of a balanced chest drainage system to keep the mediastinum in a neutral position and avoid hyperinflation of the residual lung following a pneumonectomy has been suggested to contribute to a marked decline in this complication in some centers [45].

Cardiopulmonary bypass causes a subclinical lung injury that can be aggravated by injurious ventilation patterns. Zupancich et al. [46] compared the use of non-protective high tidal volumes (10–12 mL/kg) plus low PEEP (2–3 cm H_2O) vs. lung-protective low tidal volumes (8 mL/kg) plus high PEEP (10 cm H_2O) in patients ventilated for 6 h following cardiopulmonary bypass for coronary artery bypass surgery. Serum and bronchiolar lavage levels of the inflammatory cytokines IL-6 and IL-8 were significantly increased at 6 h only in the non-protective ventilation group.

The Role of the Glycocalyx in Lung Injury

The glycocalyx is a dynamic, fragile, and complex layer of membrane-bound macromolecules that forms an intravascular carpet on the luminal surface of the vascular endothelium [47]. The composition and thickness of the glycocalyx change constantly, as it is continually sheared by plasma flow and replaced. Its components have a net negative charge and therefore repel negatively charged molecules and blood cells. A primary function of the endothelial glycocalyx is to regulate and influence vascular permeability [48]. Together with circulating substances, it forms a barrier that prevents circulating cells and macromolecules from entering the interstitium. In contrast to the original Starling model, which explained the regulation of fluid balance occurring across the entire endothelial cell, a revised model has been proposed whereby the hydrostatic and osmotic forces act only across the glycocalyx surface layer on the luminal aspect of the endothelium. These forces reach equilibrium very quickly, resulting in a much lower fluid flux than predicted by the traditional Starling equation.

The glycocalyx has other functions. It regulates blood cell-endothelial interaction by its negative charge and via specific adhesion molecules for leukocytes and platelets. These are normally hidden deep within the glycocalyx structure but become exposed following damage to the glycocalyx. It also protects the vascular endothelium from shear stress and oxidative damage via nitric oxide-induced vasodilation and scavenging of oxygen free radicals.

The glycocalyx may be injured by inflammatory cytokines, surgical trauma, and ischemia-reperfusion (see Fig. 10.10). Hypervolemia damages the glycocalyx, both by dilution of plasma proteins and via release of atrial natriuretic peptide, which strips the glycocalyx. Loss of the intact glycocalyx causes increased vascular permeability and fluid extravasation. Loss of plasma proteins further compounds this. Leukocyte adhesion molecules are exposed, promoting cellular adhesion,

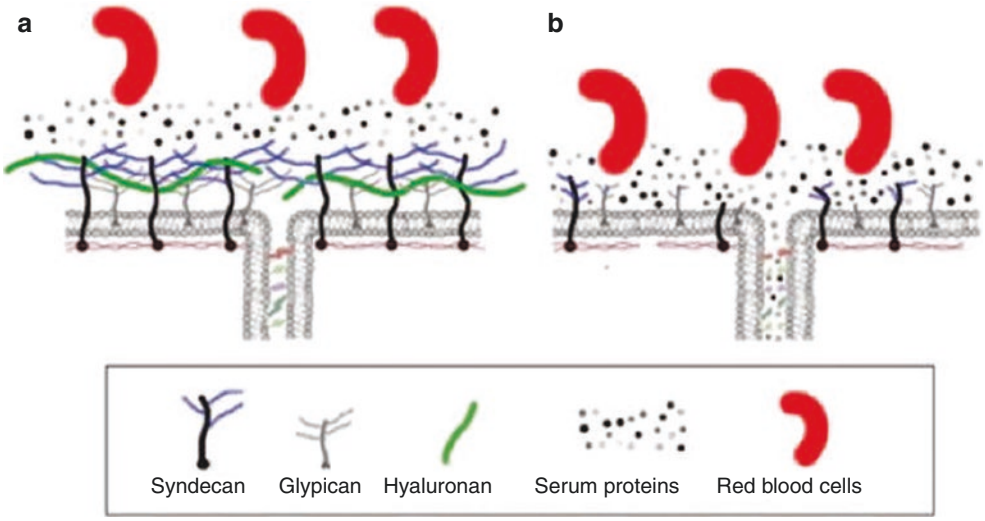

Fig. 10.10 The glycocalyx is a complex layer of proteoglycans, glycosaminoglycans, and glycolipids on the endothelial surface. (**a**) An intact glycocalyx limits water and protein flux into the cell-cell junction by forming a molecular filter over the junctional orifice. The glycocalyx also creates scaffolding on which serum proteins accumulate and form the immobile plasma layer directly adjacent to the vessel wall. Collectively the glycocalyx and the protein layer create the red blood cell exclusion zone used to determine the functional thickness of the glycocalyx. (**b**) During inflammation, proteases degrade the glycocalyx, and endothelial cells shed constituents through cell-associated sheddases. Loss of the glycocalyx scaffolding eliminates the immobile plasma layer. Breakdown of the glycocalyx is associated with increased vascular permeability due to loss of the junctional barrier and opening of the intracellular junction, as evidenced by increased water and protein flux through the junction. Note the protein-free space under the glycocalyx (left panel) that may significantly affect Starling forces across the cell-cell junction. (Reproduced form Ref. [48] with permission)

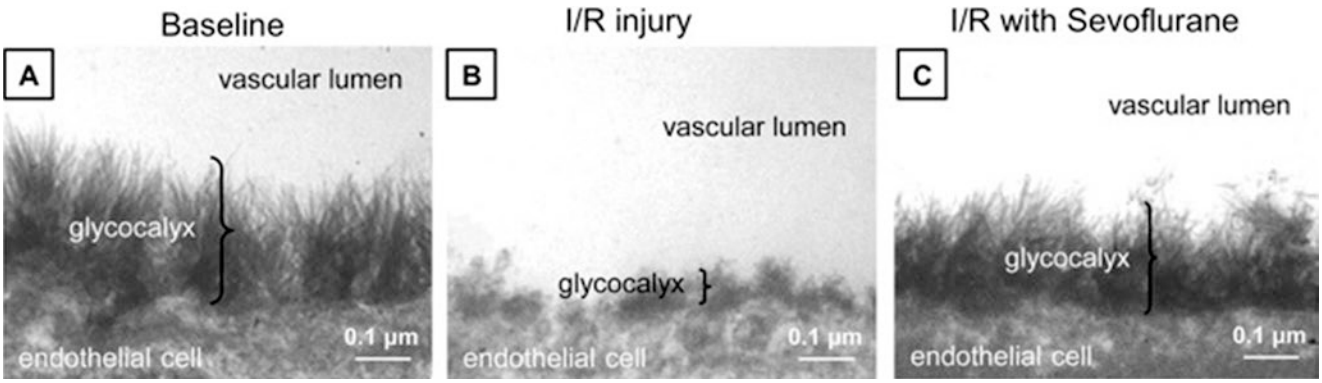

Fig. 10.11 (**a**) Electron micrograph of an intact endothelial glycocalyx from a guinea pig heart. (**b**) The glycocalyx from an animal exposed to ischemia-reperfusion (I/R) injury. (**c**) The glycocalyx from an animal exposed to I/R after pretreatment with sevoflurane. (Reproduced from Ref. [20] with permission)

migration, and further inflammation. This vicious cycle of increased permeability, extravasation, and inflammation leads to pulmonary edema, as is observed in ALI.

Several empiric strategies, based on animal experiments, have been proposed to protect the glycocalyx, including avoiding hypervolemia, albumin infusion, corticosteroids, antithrombin III, and direct inhibitors of inflammatory cytokines. Volatile anesthetic agents have been associated with less injury to the alveolar-capillary tight junction [49], less local release of inflammatory mediators, and less glycocalyx destruction (see Fig. 10.11) [20].

Transfusion-Related Acute Lung Injury (TRALI)

Over the past 30 years, acute lung injury secondary to transfusion of blood products has become recognized as a distinct clinical entity. It crosses the boundaries between patients with and without lung injury because it can cause injury to healthy lungs or it can exacerbate incipient lung injury [50]. The etiology of TRALI is primarily due to anti-white blood cell antibodies in the transfused serum. These antibodies can be either human leukocyte antigens (HLAs) or human neutrophil antigens (HNAs). HNA antibodies can bind to and trigger neutrophils and leukocytes in the recipient. HLAs are more widespread, and these antibodies can react with white blood cells and/or the pulmonary endothelium of the recipient. Neutrophils normally are flexible and are deformed as they pass through the lung, since the diameter of 50% of the pulmonary capillaries is smaller than the neutrophils. Priming of the neutrophils by sepsis, inflammation, or immune triggering (as in the case of TRALI) stiffens the neutrophils which then become sequestered in the pulmonary capillary bed. This process can be aggravated by any physical injury to the endothelium which causes the release of intercellular adhesion molecules which then cause trans-endothelial migration of the sequestered neutrophils into the interstitium of the lung parenchyma, beginning the process of injury. The process seems to be a two-hit phenomenon usually requiring both a degree of lung injury and priming of the circulating neutrophils. Although TRALI can occur unrelated to surgery, a disproportionate number of cases occur in the perioperative period [51]. Since its first identification 30 years ago, the incidence of TRALI has decreased primarily due to donor management strategies for plasma-containing products that have been adopted by blood bankers. These strategies include some or all of donor deferral based on antibody screening, donor deferral based on a history of pregnancy or transfusion, and deferral of all female donors [52]. However the major burden of prevention falls on the anesthesiologist to avoid unnecessary transfusion of blood products and to decrease the potential for perioperative mechanical lung injury.

Prevention and Therapy for Acute Lung Injury

Much of the research on lung injury due to ARDS has focused on high volume overdistention of distal lung units (volutrauma). However, there is another facet to lung injury in ARDS that involves repeated tidal opening and collapse of alveolar units at low lung volumes [53]. This repeated opening is referred to by several names such as atelectrauma and repeated alveolar collapse and expansion (RACE). Although the histological lung injury may be similar between atelectrauma and volutrauma, the inflammatory response appears to be less with atelectrauma [54]. However, the inflammatory response to atelectrauma appears to be more severe than that due to atelectasis [55]. As can be seen from Fig. 6.2, it appears that between 1/2 and 2/3 of the ventilated lung is repeatedly opening and closing every breath during one-lung ventilation. Thus, a degree of ventilator-induced lung injury to the ventilated lung seems almost unavoidable with our present techniques of anesthetic management.

Apart from mechanical ventilation strategies, a number of other therapies have been suggested to prevent or treat acute lung injury. Early reports comparing the use of volatile vs. intravenous anesthetics [56] have shown mixed results with respect to the ability of anesthetic agents to affect immune

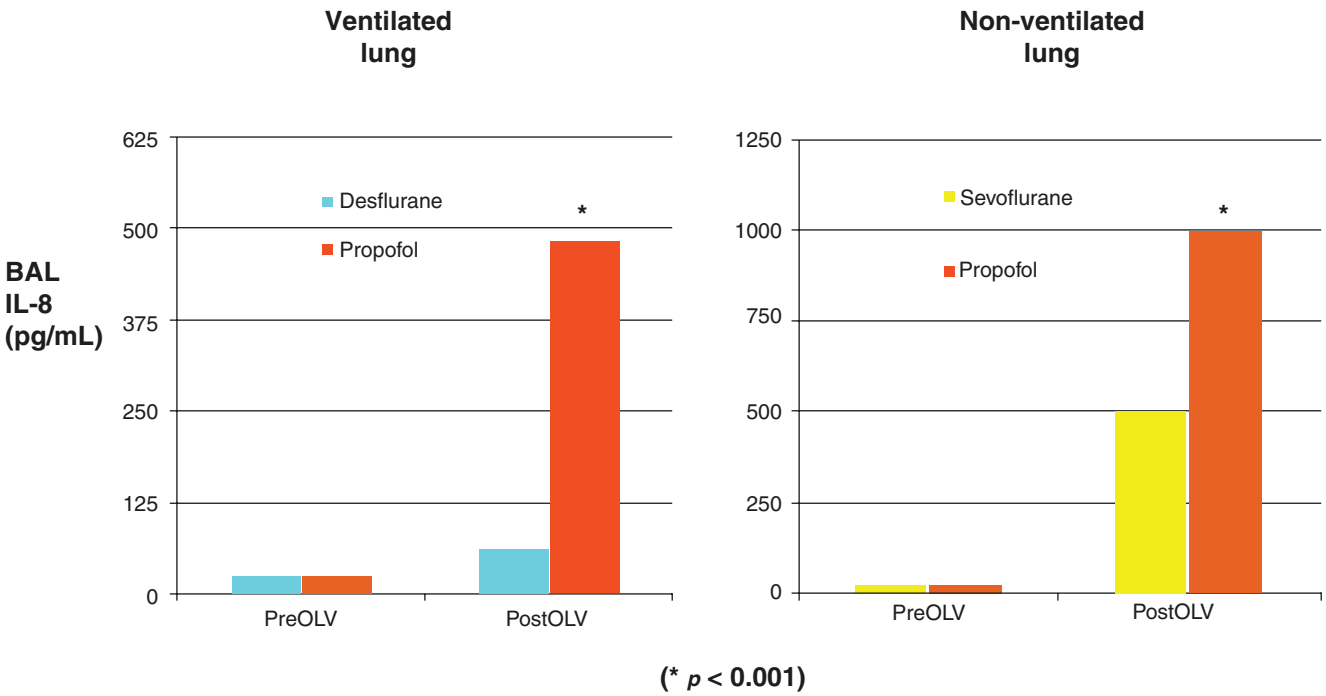

Fig. 10.12 A comparison of intravenous anesthesia (propofol) vs. volatile anesthesia on the inflammatory cytokine IL-8 obtained by bronchoalveolar lavage (BAL) from the ventilated lung (left) and the non-ventilated lung (right) before (preOLV) and after (postOLV) one-lung ventilation for thoracic surgery. The increase in inflammatory markers was significantly attenuated in both lungs by volatile anesthesia. (Based on data from Refs. [62, 63])

responses and lung endothelial injury [57]. Randomized placebo-controlled trials of several different therapies including surfactant, prone positioning, inhaled nitric oxide, and anti-inflammatories have not shown significant clinical benefits in patients with established acute lung injury [58]. ß-Agonists increase the rate of alveolar fluid clearance by increasing cellular cyclic adenosine monophosphate (cAMP) in the epithelium [59], and ß-agonists have anti-inflammatory properties. In a randomized placebo-controlled study in 40 patients with acute lung injury, Perkins et al. [60] found that the use of intravenous salbutamol decreased lung water and plateau airway pressure, although there were no significant differences in outcome. A randomized study of inhaled salmeterol has shown that it can reduce the incidence of high-altitude pulmonary edema in subjects at risk [61].

The use of volatile vs. intravenous anesthetics for one-lung ventilation has been shown to decrease the local inflammatory response of both the ventilated [62] and non-ventilated lung [63] (see Fig. 10.12). Also, volatile anesthetics have been shown to decrease ischemia-reperfusion injury in an animal model of lung transplantation (see Fig. 10.13) [64].

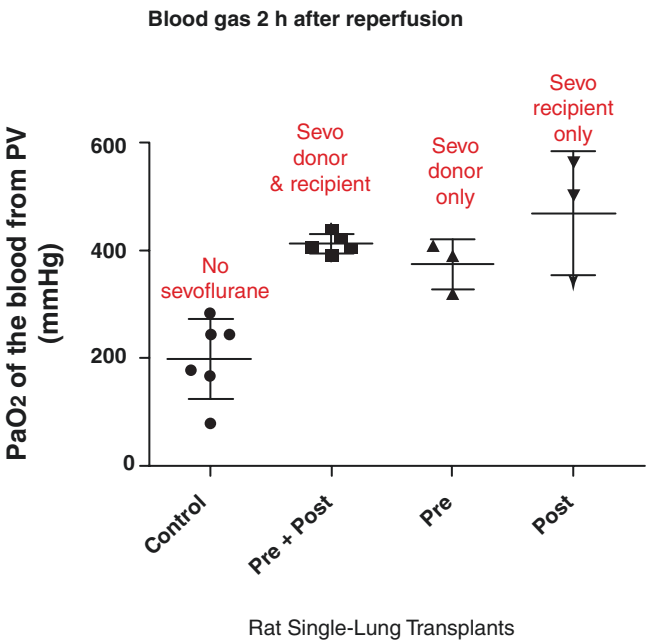

Fig. 10.13 The PaO_2 of the blood from the pulmonary vein (PV) of the donor's lung 2 h after single-lung transplantation. One MAC sevoflurane was associated with significantly improved oxygenation when administered to the donor (pre) and/or the recipient (post). (Based on data form Ref. [64])

Outcomes

There have been no convincing data that demonstrate that the lung-protective strategies outlined above actually improve patient outcomes. In a retrospective study of over 1000 thoracic surgery cases involving OLV, tidal volumes of 5–8 mL/kg ideal body weight were recorded during OLV [65]. There was an inverse relationship between OLV tidal volume and respiratory complication and postoperative morbidity (i.e., low tidal volumes tended to be associated with poorer

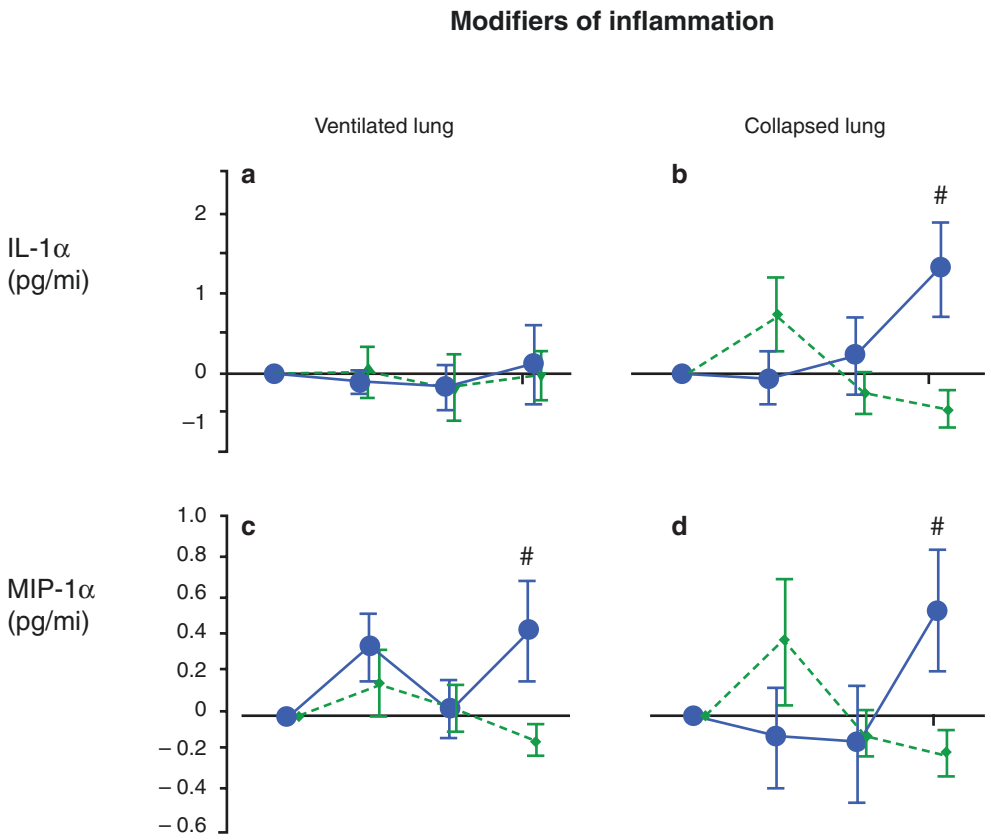

Fig. 10.14 The inflammatory cytokine response to OLV can be modulated with continuous CPAP to the non-ventilated lung. Bronchoalveolar lavage cytokine levels in the ventilated and collapsed (non-ventilated) lung during and after OLV in patients undergoing transthoracic esophagectomy. Panel (**a**): the application of CPAP (green dashed line) to the collapsed lung does not significantly decrease cytokine IL-1α levels in the ventilated lung vs. control (blue solid line) but (panel **b**) does in the collapsed lung itself (#; $p < 0.03$). Panels (**c**) and (**d**): the application of CPAP abolishes the postoperative increase in MIP-1α in both the ventilated and collapsed lungs. Time points: preoperative, 2 h after collapse, 2 h after re-insufflation, postoperative. CPAP, continuous positive airway pressure; IL-1α, interleukin 1 alpha; MIP-1α, macrophage inflammatory protein 1α; OLV, one-lung ventilation. (Based on data from Ref. [67])

outcomes). There was a positive association between ventilator driving pressure (plateau airway pressure, PEEP) and complications. The use of PEEP and recruitment maneuvers could not be analyzed from the data in this study.

A randomized controlled study [66] of >400 patients having lung surgery and OLV compared volatile anesthesia with desflurane vs. intravenous anesthesia with propofol. The incidence of major complications within 6 months of surgery (propofol 40.4%, desflurane 39.6%) was not different between the groups. At present, the reasons why logical strategies for lung protection have not been shown to improve outcome in thoracic surgery remain unclear. This may be because simple strategies to avoid lung injury, such as small tidal volumes, PEEP, and volatile anesthetics, have a small effect compared to the large proportion of the ventilated lung that is exposed to cyclic atelectrauma during OLV.

Avoiding One-Lung Ventilation

Since there seems to be some subclinical lung injury associated with the use of one-lung ventilation, it seems reasonable to limit periods of one-lung ventilation to those clinical situations where it is necessary or to avoid one-lung ventilation whenever possible. Several strategies to modify or avoid one-lung ventilation have been described.

The use of continuous positive airway pressure (CPAP) to the non-ventilated lung whenever possible will improve oxygenation and may decrease the inflammatory response to OLV in both the ventilated and non-ventilated lungs (see Fig. 10.14) [67]. Although the use of CPAP can impede surgery during VATS lung procedures, for many other intrathoracic operations such as open thoracotomies, esophagectomies, vascular surgery, and minimally invasive cardiac

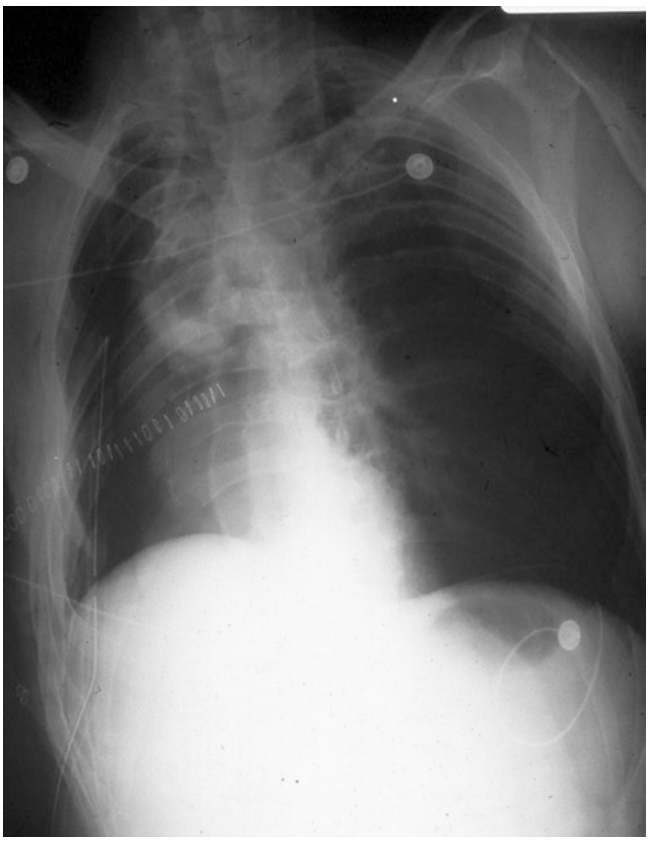

Fig. 10.15 Immediate postoperative chest X-ray of a 68-year-old male following a right pneumonectomy. This is normal post-pneumonectomy film

Fig. 10.16 Chest X-ray on postoperative day 3 of the same patient in Fig. 10.15. The patient has gradually become more dyspneic and has significant arterial oxygen desaturation breathing air. Chest X-ray shows signs of increased lung interstitial markings suggestive of pulmonary edema

procedures, the use of CPAP should be considered if a prolonged period of OLV is foreseen.

In some clinical situations, it may be possible to avoid OLV by maintaining spontaneous two-lung ventilation during thoracic procedures [68]. There has been an increase in the reports of case series of non-intubated VATS procedures (see Chap. 25). To date, the numbers are too small to be certain if the outcomes are improved compared to more traditional anesthetic techniques.

Clinical Case Discussion

A 68-year-old 70 kg male presents with bronchogenic carcinoma of the right middle and lower lobes. The patient is a smoker (30 pack-year) with good exercise tolerance. Preoperative FEV1 is 80% predicted and DLCO is 70% predicted. V/Q scan shows 50% ventilation and perfusion to the right lung. The patient has an uncomplicated 3 h right pneumonectomy. During the procedure, he receives 1.5 L of crystalloid and is ventilated with a tidal volume of 700 mL, FiO_2 1.0, during both two- and one-LV. Postoperatively, the patient is stable in the recovery room (see Fig. 10.15) with thoracic epidural analgesia and is discharged to the thoracic surgical floor.

On postoperative day 3, the patient complains of increasing dyspnea. The patient's oximetry saturation is 85% on air and 93% with FiO_2 0.4 mask. His pulse is sinus rhythm at 104 and blood pressure 130/80. A repeat chest X-ray is taken (see Fig. 10.16).

- What is the differential diagnosis?
- How can the diagnosis be confirmed?

The differential diagnosis should include post-thoracotomy ARDS, pulmonary embolus, congestive heart failure and/or myocardial ischemia, aspiration, and pneumonia. ARDS in this setting is a diagnosis of exclusion. A perfusion lung scan should be obtained to rule out emboli and an electrocardiogram to rule out subclinical ischemia, which is

unlikely in the absence of a prior history of coronary heart disease or diabetes. A transthoracic echocardiogram should be performed to rule out myocardial dysfunction. Major aspiration is unlikely without a history of a decreased level of consciousness. Pneumonia is a possibility, but unlikely without signs of sepsis or an elevated white blood cell count, sputum for culture and sensitivity should be obtained. If other common possibilities of postoperative respiratory failure are ruled out, the provisional diagnosis is ARDS.

- What therapy is indicated?

The patient should be transferred to an intensive care unit. All therapy is basically palliative with the aim to support respiratory function and minimize any exacerbation of the lung injury pending spontaneous resolution. Initially respiratory support should begin with noninvasive ventilation and minimizing the FiO_2 to maintain normal physiologic oxygen saturations. Attempts to reduce the pulmonary vascular pressures with inhaled nitric oxide or prostacyclin are logical although not proven and are unlikely to cause harm. The same applies to inhaled β-adrenergic agents. The benefit of corticosteroids is uncertain. If gas exchange deteriorates, then mechanical ventilation using the principles of lung protection will need to be added. In severe ARDS, unresponsive to conventional therapy, the use of extracorporeal lung support should be considered (see also Chap. 55).

Part IV

Diagnostic and Therapeutic Procedures of the Trachea and Airways

Bronchoscopic Procedures

11

Gordon N. Finlayson, Tawimas Shaipanich, and Chris Durkin

Key Points

- Diagnostic flexible bronchoscopy is safely performed outside of the operating room with light to moderate sedation and topical anesthesia.
- Rigid bronchoscopy is typically performed in patients with central airway obstruction and major comorbidities. Primary concerns include the risk of complete airway obstruction and inability to ventilate or dynamic hyperventilation with hemodynamic compromise.
- A fluid transition between ventilation strategies is often required for these procedures.
- Extracorporeal membrane oxygenation may be utilized in high-risk cases.
- Multimodal techniques employed by interventional bronchoscopists to acutely re-establish patency of obstructed central airways include stenting, laser, endobronchial electrosurgery, cryotherapy, argon plasma coagulation, and balloon bronchoplasty.
- Major intraoperative complications associated with these techniques include hemorrhage, airway trauma, perforation, fire, systemic gas embolism, and dissemination of postobstructive pneumonia.
- Alternative indications for these procedures include treatment of low-grade malignancies and carcinoma in situ. These lesions may also respond to brachytherapy, cryotherapy, or photodynamic therapy.
- Interventional bronchoscopy is an evolving field with expanding applications. Future indications may include endobronchial valve insertion for persistent air leaks and COPD as well as bronchial thermoplasty for treatment-resistant asthma.

Introduction

Routine diagnostic flexible bronchoscopy is a well-established, safe procedure that rarely demands the presence of an anesthesiologist. Interventional bronchoscopy is an evolving, specialized discipline that has a pivotal role in the strategic relief of central airway obstruction and the anastomotic complications of lung transplantation. Many of these procedures require general anesthesia and provide significant challenges in establishing a patent airway and maintaining adequate ventilation. There are a number of newer interventions adopted by bronchoscopists for the detection and management of precancerous lesions and early-stage malignancies. With improvements in lung cancer screening, the frequency of these procedures is expected to increase substantially in the coming years. Emerging roles for interventional pulmonologists include minimally invasive lung volume reduction with placement of endobronchial valves and bronchial thermoplasty for severe asthma.

Anesthetic Considerations

Therapeutic bronchoscopic interventions have historically been aimed at the relief of airway obstruction using a rigid endoscope. The first reported use of bronchoscopy by Gustav Killian in 1897 was for the removal of a right mainstem foreign body. Soon thereafter, attempts were aimed at resection of tumor, dilation of infectious strictures, and drainage of obstructive secretions [1].

Rigid bronchoscopy involves the placement of a non-cuffed, straight metal endoscope directly into the trachea, precluding the placement of an endotracheal tube. This is a key distinction when compared to flexible bronchoscopy which can be performed on an intubated patient with a secured airway. Rigid rather than flexible bronchoscopy is most commonly used for interventional procedures, as it allows for the passage of large instruments and removal of bulky objects while simultaneously providing a patent airway for provision of positive pressure ventilation (Table 11.1).

During rigid bronchoscopy gas exchange is most commonly maintained by jet ventilation as the open-circuit design renders conventional positive pressure ventilation prone to gas leak. Using a handheld injector or high-frequency jet ventilator, high-flow oxygen at variable concentrations can be delivered to the lungs. The precise fraction of inspired oxygen achieved is somewhat less than that selected on the injector because entrainment of room air ultimately dilutes the delivered oxygen content. Similarly, the use of volatile agents is unreliable because its delivery and measurement cannot be guaranteed. Since the breathing circuit is not sealed, leakage of anesthetic gas also contaminates the operating room. Jet injection of a blended oxygen/air mixture is typically delivered through high-pressure tubing connected either directly to an intraluminal port incorporated in the bronchoscope or to a catheter placed within the airway.

Table 11.1 Comparison of flexible and rigid bronchoscopy

Flexible bronchoscopy	Rigid bronchoscopy
Minimal sedation	Requires general anesthesia
May be used through endotracheal tube	Difficult with endotracheal tube in situ
No absolute contraindications	Cervical spine pathology contraindicated
Minimal risk of trauma	Significant risk of trauma
Inability to ventilate through scope (?Excluding HFJV)	Provides airway for ventilation
Requires small instruments	May use larger instruments
May need to remove scope when extracting specimen	Able to remove large objects through scope
Can access distal airways	Limited to central airways
Technically straightforward	Specialized training required

Various other ventilation strategies are also available during rigid bronchoscopy though these may be more challenging to perform effectively. Spontaneous breathing is an option [2]; however many bronchoscopists insist on paralysis as unanticipated coughing or straining may lead to increased technical challenges and complications. Placement of a rigid bronchoscope requires considerable neck extension and extensive manipulation of the airway such that most patients are intolerant without inducing apnea. There are ventilating bronchoscopes available that are designed to allow the use of an anesthetic breathing circuit; however these mandate closely matching the size of the bronchoscope with the trachea, to prevent gas leakage [3]. Theoretically it is possible to provide conventional ventilation in this circumstance, but any significant leak would reduce the efficacy of this technique. Finally, with judicious preoxygenation and passive insufflation of oxygen, short periods of apnea are generally well tolerated in select patients. For procedures requiring extended airway manipulation, this strategy may be interrupted intermittently to provide positive pressure ventilation.

Anesthetic considerations for interventional bronchoscopy include the operative indication, patient comorbidities, and appreciation of procedure-specific complications. Airway obstruction remains the most common indication requiring bronchoscopic intervention, and these procedures are typically performed urgently or emergently on physiologically distressed patients [4]. Ultimately, this may lead to conflicting anesthetic goals including balancing a full stomach with an unsecured airway, high oxygen requirements with the risk of fire ignition, and jet ventilation through obstructing stenoses with the risk of air trapping and barotrauma (Table 11.2).

Total intravenous anesthesia (TIVA) avoids operating room contamination with inhalational agents during

Table 11.2 Anesthetic considerations of rigid bronchoscopy

interventional bronchoscopy [5] (see Chap. 12). Another advantage of intravenous agents is avoiding the dependence of anesthetic delivery on ventilation – an important consideration when novel ventilation strategies are anticipated. Standard monitors recommended by the American Society of Anesthesiologists are mandatory for interventional procedures. Arterial cannulation or transcutaneous pCO_2 monitoring is useful for assessing the adequacy of gas exchange because of the frequent interruption to end-tidal carbon dioxide sampling. Patients receiving TIVA and muscle relaxants are at higher risk for awareness; therefore extended monitoring (e.g., BIS) and the addition of benzodiazepines may be considered. As the presence of an intratracheal instrument is a strong stimulator of cough, patients almost invariably require paralysis. Including a potent, short-acting opioid (e.g., remifentanil) in the TIVA regimen can help suppress this powerful and disruptive reflex. Given the unique and potentially unanticipated technical challenges presented by these cases, an extended procedural duration may require ongoing neuromuscular blockade with close monitoring of depth of paralysis.

Complications of rigid bronchoscopy including dental, vocal cord, and airway trauma usually occur during placement of the scope. The potential for difficulties in tracheal intubation must be kept in mind as this may result in a catastrophic inability to ventilate the patient, specifically in those with difficult anatomy or supraglottic distortion. Often these procedures are performed in nonoperative settings; these unfamiliar surroundings have been shown to be a factor in increasing the risk of adverse events [6]. Emergency equipment should include alternatives to direct laryngoscopy and possibly setup for surgical airway access. Other complications associated with specific interventional bronchoscopic procedures include airway fire, air embolism, and severe hemorrhage; these are discussed in more detail in the remainder of the chapter.

Central Airway Obstruction

Central airway obstruction may originate from intrinsic, extrinsic, or mixed lesions (Fig. 11.1) [7]. These lesions are further characterized by location (intrathoracic vs. extrathoracic), etiology (malignant vs. nonmalignant) (Table 11.3), and presence of fixed or dynamic airflow obstruction [8]. Specific interventional strategies for alleviating an obstruction are dictated by these features and considered within the context of the patient's appropriate level of care. Generally speaking, the comorbidities of these patients reflect the predisposing risks of the underlying malignancy, extrapulmonary features of an associated systemic inflammatory disease, or posttransplant status. Because central airway obstructions often progress insidiously, symptoms of dyspnea, wheeze, or stridor only manifest with advanced (5–8 mm) airway narrowing [9]. Still, lesions that rapidly encroach upon the airway or involve long segments may prove symptomatic with lesser degrees of obstruction.

Owing to its relative infancy, the perioperative risks of therapeutic bronchoscopy for the relief of central airway obstruction are not clearly defined. Although interventional bronchoscopy may efficiently re-establish patency of an obstructed airway, data from high-volume centers underscore the vigilance demanded in caring for these patients. Approximately 20% of patients will experience perioperative complications with an overall 30 day mortality of 7.8% (primarily attributed to underlying disease progression) [4].

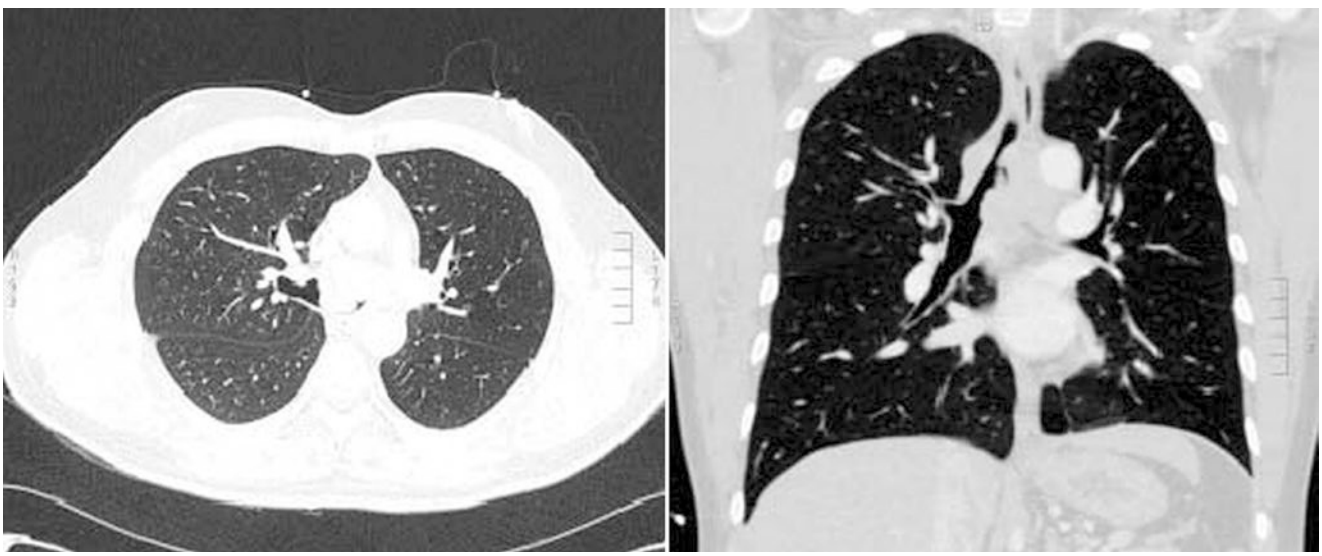

Fig. 11.1 CT demonstrating severe intrinsic central airway obstruction involving the tracheal carina and left main bronchus

Table 11.3 Causes of central airway obstruction

Benign
Traumatic: Post intubation; blunt, penetrating, or inhalational injury
Inflammatory: Wegener's; amyloidosis; SLE
Infectious: Papillomas; tuberculosis; rhinoscleroma; viral tracheobronchitis; bacterial tracheitis; diphtheria
Vascular: Rings; aneurysms; postpneumonectomy syndrome; anomalies (e.g., right innominate artery; double aortic arch)
Neoplastic: Neurofibroma, chondroma, chondroblastoma, hemangioma, pleomorphic adenoma
Anastomotic: Lung transplant; sleeve resection
Other: Tracheomalacia; relapsing polychondritis; sarcoidosis; foreign body
Malignant
Primary malignancy intraluminal
Adenoid cystic
Carcinoid
Mucoepidermoid
Bronchogenic
Primary malignancy extraluminal
Esophageal
Mediastinal (thymus, thyroid, germ cell)
Lymphoma
Sarcoma
Metastatic malignancy
Bronchogenic
Renal cell
Breast
Thyroid
Melanoma
Colon

Evaluation of patients with central airway obstruction is largely determined by clinical status and degree of physiologic compromise. Excluding those with impending respiratory arrest, the nature and extent of obstruction must be clearly defined [10]. Traditionally, evaluation with flow volume loops has been advocated. While considered crucial in the assessment of patients suspected of central airway obstruction, their value in preoperative planning is limited [11]. Furthermore, performance of spirometry may provoke respiratory failure in advanced obstructions [12]. Reconstructed, multislice CT scans of the airway convey crucial information regarding location, extent, dynamic collapse, and invasion of adjacent structures that is paramount for safe preoperative planning [13–16]. If demanded by the patient's symptoms, CT scanning may be performed in the prone position.

Owing to the clinical urgency of these cases, the opportunity for optimization of medical comorbidities is limited. Depending upon the indication for intervention, several comorbidities including tobacco use, hypertension, moderate to severe COPD, and diabetes have been associated with increasing the likelihood of complications including bleeding and hypoxemia [4]. Although yet unproven to influence perioperative outcomes for these types of cases, attentive management of coexisting illnesses seems prudent. Preoperatively, selective use of antisialogogues [17] is beneficial for facilitating airway topicalization and fiber-optic examination. Steroids are advocated when repeated instrumentation of the airway threatens postoperative glottic edema [18]. In patients with respiratory distress, heliox (gas mixtures of helium and oxygen, usually with an FiO_2 approximately 30%) can temporarily reduce work of breathing and improve gas exchange when the obstruction causes turbulent airflow [19].

Of foremost concern in managing patients with central airway lesions is the threat of precipitating complete obstruction with routine induction of general anesthesia. Critical central obstructions may also contribute to dynamic hyperinflation and cardiovascular compromise [17]. Because there is a paucity of literature to guide critical decisions in these challenging patients, strategies for the provision of safe anesthesia depend heavily on experience and judgment.

Traditional teaching advocates anesthetic techniques that maintain spontaneous ventilation during acute obstruction in order to avoid airway collapse after paralysis of respiratory musculature [20]. However, experienced centers have documented successful management with intravenous induction and neuromuscular blockade in patients with stridor at rest [21]. Similarly, case series attest to the safe application of innovative ventilation strategies during interventional bronchoscopy [22]. Effective ventilation may be maintained with intermittent, assisted, positive pressure delivered through the side-arm adapter of a rigid bronchoscope. The Sanders technique of manual jet ventilation also provides uninterrupted ventilation delivered through the rigid bronchoscope [8]. High-frequency jet ventilation demonstrates reliable gas exchange and operative conditions without relying on the presence of a rigid bronchoscope [22]. Finally, for those patients with reversible illnesses and critically obstructive lesions, selected use of extracorporeal membrane oxygenation may be justified [23, 24]. Unfortunately, there are limited data comparing the effectiveness and safety of these ventilation techniques during therapeutic endoscopy [25]. Whichever technique is employed, attention should be dedicated to reassessing the adequacy of ventilation and presence of dynamic hyperinflation throughout the procedure. Oftentimes these cases demand dynamic decision-making and flexible transition between various modes of ventilation – preparation is crucial.

The fundamental components to the safe relief of a central airway obstruction include a wide selection of rigid bronchoscopes and a veteran endoscopist to immediately access the airway. Although few general respirologists maintain competency in rigid bronchoscopy [26], many interventional pulmonologists are highly qualified [27]. If there is an anticipated potential for an emergent thoracotomy, the presence of a thoracic surgeon is mandatory. Blind tracheal intubation in

patients with central airway lesions should be avoided as it risks precipitating hemorrhage or airway obstruction from unnecessary trauma. Routine use of flexible bronchoscopy will help minimize these complications.

Within the past decade, worldwide utilization of veno-veno (VV) extracorporeal membrane oxygenation (ECMO) has increased. While reported applications for managing central airway obstruction continue to evolve, high-volume centers have developed clinical maturity in managing patients on ECMO for alternate indications [28]. Veno-veno ECMO can replace gas exchange when native pulmonary function is impaired or absent; venoarterial (VA) ECMO can be utilized when cardiac function is inadequate. While a comprehensive discussion of the considerations of ECMO is beyond the scope of this chapter, there are some important practicalities to highlight when relying on this technology for patients with central airway obstruction not treatable by conventional approaches. First and foremost, ECMO is best instituted by an experienced team with flexibility in approaches to cannulation and its various configurations. Cannulation is usually performed with transient anticoagulation (typically 5000 units unfractionated heparin), but is not imperative. Fluoroscopy and/or echocardiography is needed to ensure safe and appropriate cannula positioning. Maintenance anticoagulation can be withheld for patients requiring VV ECMO, if heparinization is deemed prohibitive and bleeding risk is excessive. Experienced operators can successfully cannulate within ~20 min, but additional time is required for mobilization of equipment and human resources. These time limitations must be recognized if ECMO is employed to manage a critically obstructed airway at risk of cardiac/respiratory arrest. Initiation of ECMO can be performed in awake (or lightly sedated) patients, but is more challenging if there is no capacity to lie supine (Fig. 11.2).

Finally, if the indication for ECMO is to entirely replace native gas exchange, cannula size and circuit configuration should establish sufficient flow to match a patient's intrinsic cardiac output. Recent case reports and case series emphasize the utility of ECMO in managing impending airway obstruction – either in lieu of establishing a secured airway or to facilitate bronchoscopic or surgical intervention [29–34].

Successful bronchoscopic management of central airway lesions often mandates multimodal techniques. The following sections will highlight these techniques and specific anesthetic considerations.

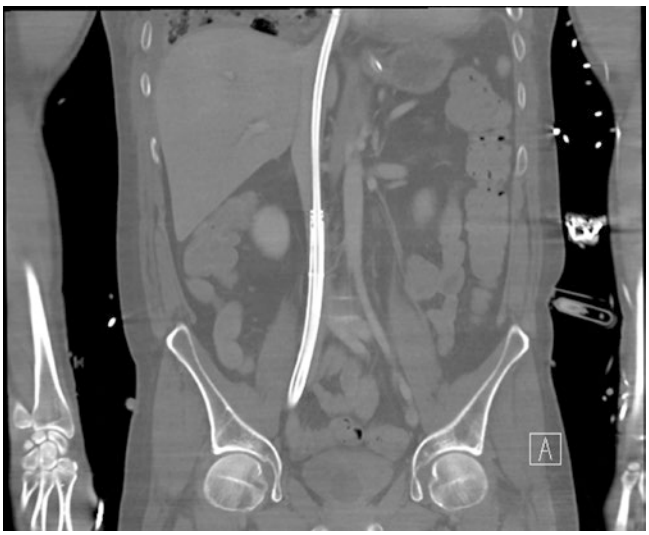

Fig. 11.2 VV ECMO can be employed by cannulating only the femoral vessels if dictated by the clinical circumstance. This CT image depicts a dual lumen femoral venous cannulae with access ports in the distal IVC and the returning orifice in the right atrium

Airway Stents

Montgomery pioneered the application of airway stents for the management of subglottic stenosis in the 1960s [35]. In 1990, Dumon introduced a silicone stent positioned completely within the tracheal lumen [36]. Today, the armamentarium of interventional bronchoscopists includes a wide selection of stents aimed at restoring the patency of obstructed airways. Generally speaking, modern stents are composed of silicone, metal, or combination thereof. Ideally, an airway stent should demonstrate easy insertion and removal, stability within the airway limiting the tendency for migration, durability to compressive forces and sufficient elasticity to conform to the airway, resistance to granuloma formation and infection, and preservation of mucociliary transport [18, 37].

Currently there are no manufactured stents that satisfy these demanding design properties, though innovations in stent technology continue to progress [38]. Silicone stents are suitable for benign diseases of the central airways because of their ease of removal. Limitations of silicone stents include migration, obstruction with secretions, flammability, and reduced inner diameter [39]. Both bare metal stents and covered metal stents are available (Fig. 11.3) (Table 11.4). Advantages of metal stents include preservation of mucociliary transport, large inner diameter, and relatively easier placement. The Achilles heel of metal stents remains their tendency toward granuloma formation. Additionally, bare metal stents can transmit laser energy and injury surrounding tissue, while covered versions may pose a fire risk during laser procedures [40, 41]. Because of concerns surrounding in-stent obstruction and complicated removal, experts suggest that metal stent insertion should be reserved for malignant or palliative situations [42, 43]. Despite this consideration, other authors report successful management of benign

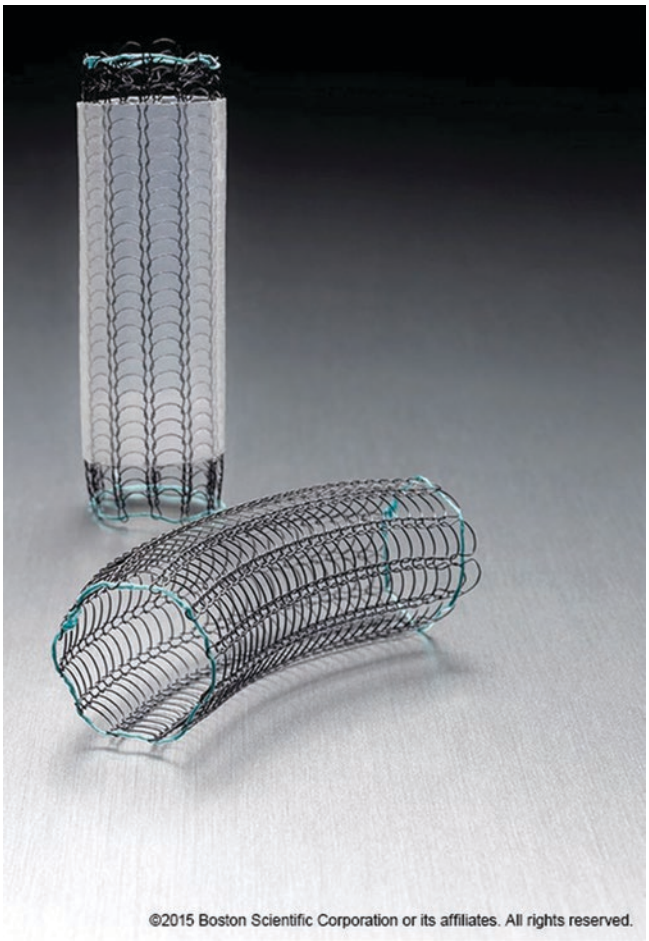

Fig. 11.3 Example of covered and uncovered varieties of expandable metal stents. (Image courtesy of Boston Scientific)

Table 11.4 Stent properties

Metal
Advantages
Large inner to outer diameter ratio
Resistant to migration
Preserved mucociliary clearance
May be placed under local anesthesia
Disadvantages
Prone to granulation and restenosis
Transmission of laser energy
Flammable when covered
Risk of long-term airway perforation
Difficult removal (*considered permanent*)
Silicone
Advantages
Easily repositioned and extracted
Disadvantages
Requires rigid bronchoscopy
Reduced inner to outer diameter ratio
Prone to migration
Inhibition of mucociliary clearance
Secretion impaction
Flammable

conditions with application of metal stents, though thoughtful patient selection is crucial [44, 45].

Deployment of silicone stents requires the use of rigid bronchoscopy. Metal stents can be positioned in the airway using flexible bronchoscopy or fluoroscopy (Fig. 11.4). Primary anesthetic considerations for airway stenting overlap with the guiding principles of managing central airway lesions. During stent placement, maintenance of an immobile surgical field is preferred. Strategies to avoid coughing, including judicious airway topicalization, are advocated to minimize the risk of stent dislodgment. Specific intraoperative complications include airway hemorrhage, obstruction, and perforation with resultant pneumothorax or pneumomediastinum. When relieving a chronic airway obstruction, positioning maneuvers to minimize dissemination of a postobstructive pneumonia are recommended [13, 46]. Major chronic complications of airway stents include fistula formation to adjacent structures, which may lead to massive hemoptysis as a result of a bronchovascular fistula or aspiration pneumonia due to an esophagorespiratory fistula [47].

In instances where patients have had remote airway stenting, preoperative evaluation should consider the possibility of stent migration or obstruction from secretions, granuloma formation, or tumor invasion. Generally speaking, airway

instrumentation should be avoided in these patients, with preference given to regional anesthesia if feasible. For general anesthesia, use of a laryngeal mask avoids stent disruption [48]. When tracheal intubation is indicated, fiber-optic inspection of the airway should guide tube placement proximal to (preferred) or within the stent lumen and should be repeated upon extubation [36, 49].

Other Modalities

Since the advent of flexible bronchoscopy as a diagnostic tool in the 1960s, there has been a push to use this versatile instrument for therapeutic purposes as well. Contemporary indications for therapeutic bronchoscopy extend beyond providing relief of acute central airway obstruction. The innovative techniques of interventional bronchoscopists have facilitated new opportunities for palliation of intraluminal obstructing lesions and curative resection of early-staged cancers. Often these bronchoscopic interventions are used in concert with external beam radiation or chemotherapy to facilitate surgical debulking (Fig. 11.5).

Laser

Laser technology involves the focused synchronization of light at a specific wavelength to induce thermal changes leading first to photocoagulation and ultimately to vaporization of tissue [50]. The term is an acronym for light amplification by stimulated emission of radiation. At shorter wavelengths, the beam coagulates vascular structures and prevents bleeding. At longer wavelengths, the energy delivered can be used to resect tissue as it induces vaporization. The application of laser can be accomplished by contact or noncontact probes (usually <1 cm). There are a variety of lasers available; however for medical purposes, the Nd:YAG (neodymium/yttrium aluminum garnet, wavelength 1064 nm) and CO_2 (wavelength 10 μm) types are most widely used [51]. The former is preferred by bronchoscopists as it offers a better coagulation profile and can be used through either a flexible or rigid bronchoscope, though incisions are less precise. CO_2 laser equipment is cumbersome, and its articulated arm cannot deliver the beam around corners, beyond the trachea. As such, its use is better suited for otolaryngologists working above the carina and around the larynx.

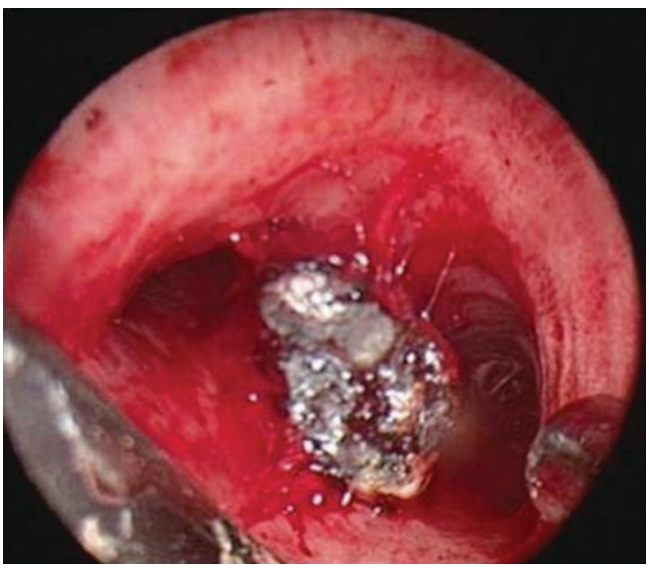

Fig. 11.5 Example of tumor debulking. (Image courtesy of Dr. Tawimas Shaipanich BC Cancer Agency)

Surgical laser can be applied by interventionalists through flexible or rigid bronchoscopes. Experienced practitioners prefer rigid bronchoscopy because of the improved airway access and control [52]. In addition to isolated laser vaporization of the tumor, an alternate strategy is to devascularize and core out the bulk of the mass in combination with physical resection using forceps or a scalpel [53]. Beyond the general anesthetic considerations of bronchoscopy, the use of laser confers the rare but catastrophic risk of airway fire. For this reason, it is prudent to minimize the inspired oxygen concentration (<40% FiO_2) as tolerated. Should an endotracheal tube be required during fiber-optic laser use, specialized tubes or reflective wrap may be utilized to minimize the risk of plastic combustion with the CO_2 laser [54]. However, no material used in an airway device, except metal, is completely safe from combustion if struck by a Nd:YAG laser.

Overall, complication rates are low with laser (~1%) [55] and include the aforementioned risk of endobronchial burns, hemorrhage, airway perforation, hypoxemia, arrhythmia, and even stroke. The remote possibility of cerebral air embolism is caused by the use of air for coaxial cooling of the laser and is greatly reduced by substituting CO_2 for this purpose [56]. Extra care must be taken when using laser on highly vascular posterior structures for this reason. Also, Nd:YAG laser light can lead to retinal damage in the case of inadvertent exposure; protective eyewear is recommended for all operating room occupants. Similarly, smoke evacuation systems have been advocated in response to reports that viral particles are present in laser plume [57]. In fact, transmission of HPV to physicians during laser vaporization of papillomas has been documented [58], though others have shown that HIV particles isolated from laser exhaust are not viable in vitro [59].

Endobronchial Electrosurgery

Endobronchial electrosurgery (EBES) refers to therapeutic interventions using the direct application of electric current to tissue in a patient who is electrically grounded with an adhesive grounding pad. The delivery of thermal energy by this method

will either induce coagulation or incision ("cut") depending on the precise levels of amperage and voltage [60]. Practitioners can blend these two parameters to induce the type of tissue changes they are seeking (e.g., arrest of bleeding or resection of tissue). Using a wire loop, pedunculated lesions can be cleanly excised by circumferential cutting of the supporting stalk, while sessile lesions can be debulked with dissecting probes. Essentially, the technology can be employed in virtually the same scenarios as those where laser is applied [61]. The main difference between the two is that EBES is much less expensive and requires less sophisticated equipment and technical expertise to perform [62]. Complications are also largely the same as those for laser with a significant risk of airway fire during cauterization of tissue. Electromagnetic interference during EBES may lead to malfunction of implanted electrical devices including pacemakers and AICDs [63].

Argon Plasma Cautery

Argon plasma cautery (APC) also uses electrical current to induce thermal destruction of endobronchial tissues for resection and coagulation. However, rather than using direct contact with an electrically grounded patient to conduct current, ionized argon gas released from the tip of the probe acts as the conductor allowing for a noncontact technique [64]. The nature of the gas flow allows for energy to be directed in multiple planes from the probe tip and for targeting lesions that would otherwise be inaccessible by other modalities [65].

The depth of penetration using APC is less than that of laser or EBES, so it is most useful for superficial lesions (e.g., hemorrhagic foci) and may be used more safely near endobronchial stents [66]. Along with the usual complications of interventional bronchoscopy, APC confers both the risk of electromagnetic interference and air embolus (thought to be related to entrainment of argon gas) [67].

Balloon Bronchoplasty

Balloon bronchoplasty involves navigating a silicone balloon into a stenotic region using fiber-optic or rigid bronchoscopy alone or in combination with fluoroscopy and then applying incremental, pressurized inflation. Oftentimes the airway patency achieved with isolated balloon bronchoplasty is not sustained, and either demands repeated attempts or combined intervention (e.g., stenting). Malignant strictures are at notable risk for rapid restenosis. Although mucosal damage associated with balloon bronchoplasty is limited when compared with laser photoresection or bougie dilation, airway rupture and hemorrhage remain a risk. Other reported complications with this technique include bronchospasm, tracheitis, fever, atelectasis, and pneumomediastinum [68].

Delayed Resection Techniques

A major advantage of laser, EBES, APC, and balloon bronchoplasty is the immediate effective relief of airway obstruction and return of airway patency. There are a number of other techniques (Table 11.5) whose mode of action is delayed including photodynamic therapy, cryotherapy, and brachytherapy. They are most often employed for nonsurgical candidates with nonobstructing lesions, for palliation of advanced malignancy, and for potential cure of early-stage cancer, such as carcinoma in situ [69]. They can all be performed via fiber-optic bronchoscopy and therefore rarely require the service of an anesthesiologist (except cryoadhesion and spray cryotherapy; see below). Acute decompensation due to procedural complications with these techniques is less frequent than with the more invasive techniques described above.

Of the delayed resection techniques, cryotherapy is the most commonly applied therapy (Fig. 11.6). Utilizing the cytotoxic effects of rapid freezing and thawing cycles, it can destroy (cryoablation), adhere (cryoadhesion), or biopsy (cryobiopsy) tissue. Destruction of biologic material is influenced by the cooling and thawing rates as well as the lowest temperature delivered. Exploitation of the Joule-Thomson effect (rapid cooling of a gas as it expands from a high-pressure delivery system to the atmosphere) enables this process, with nitrous oxide being the favored agent. Monitoring of tissue freezing remains a problem, relying on operator experience although a usual freeze cycle is approximately 30 s and repeated two or three times. Tissues with high cellular water content (tumor cells, skin, mucous membranes, granulation tissue) are more sensitive than those without (fat, cartilage, connective tissue). Delivery requires a cryoprobe, bronchoscope, and cooling agent. Initially only available as a rigid probe which demanded a rigid bronchoscope, the advent of flexible devices with delivery via the working

Table 11.5 Nonoperative tumor resection techniques

Modality	Description	Complications
Photodynamic therapy	Injection of photosensitive agent (dihemato-porphyrin ester) which is activated by direct exposure to light	Prolonged susceptibility to burn from sunlight
		Requires bronchial lavage due to pronounced tissue sloughing
Cryotherapy	Tissue destruction by rapid freezing using decompressed gas	Requires bronchial lavage due to pronounced tissue sloughing
		Transient fever
Brachytherapy	Radioactive beads (iridium 192) placed directly in tumor	Hemorrhage
		Fistula formation
		Bronchial stenosis
		Radiation exposure

Fig. 11.6 Cryotherapy of a left upper lobe tumor; picture shows ice crystal formation at the catheter

channel of a flexible bronchoscope has expanded the diagnostic and therapeutic utility.

The primary role of cryotherapy remains palliative or adjunctive therapy for inoperable malignant central airway obstruction where supportive literature (primarily observational) suggests symptomatic relief in over 90% of patients [70, 71]. Minimal complications, relative ease of use, and economical superiority are advantages as compared to other modalities [71]. Occasionally, it is used in nonmalignant central airway obstruction (granulation tissue, blood clots, and mucus plug) but should be avoided in fibrotic processes as these are cryoresistant and may be exacerbated. Tissue sloughing continuing for days afterward is the main limitation and necessitates repeat bronchoscopy 5–10 days following the index procedure. Depth of penetration is low (3 mm) allowing for a reduced risk of airway perforation, and the lack of spark eliminates any concern of airway fire.

Cryoadhesion is a relatively new technique that facilitates tissue removal (tumor debulking) faster than standard cryoablation by allowing the frozen probe tip to "stick" to the tissue of interest with rapid removal prior to the thaw cycle. Extraction of large samples can be achieved although bleeding refractory to conservative measures that requires APC or electrocautery remains a concern (~4%) [72]. This technique mandates general anesthesia with a laryngeal mask or endotracheal tube to allow frequent, repeated removal of specimen. The same principle has been applied to allow for intraluminal tissue biopsy (cryobiopsy) with a high diagnostic yield as well as transbronchial biopsy of peripheral lung lesions using fluoroscopic guidance, although this is currently used for investigation purposes only.

Recently, a special catheter (cryospray) was released allowing for the treatment of large areas rapidly and uniformly without the requirement of direct contact [73]. Instead of nitrous oxide, liquid nitrogen (LN_2) is used which brings a unique set of anesthetic considerations centered around barotrauma from rapid gas expansion and hypoxemia as LN_2 displaces inspired oxygen [74]. Additionally, delivery over 5–10 s requires apnea. This constellation of issues requires general anesthesia with an open ventilation circuit (deflate endotracheal cuff if intubated). Newer units reducing the flow of LN_2 are mitigating these risks. Delayed treatment effect with an inflammatory response is similar to standard cryotherapy.

Foreign Body Extraction and Emerging Techniques

In the absence of history, the diagnosis of foreign body aspiration may be allusive. The classic "penetration syndrome" of choke, cough, and wheeze is present only in a fraction of patients. Patients at extremes of ages are at greatest risk for aspiration owing to immature or blunted airway and swallowing reflexes [75]. In adults, the foreign body tends to impact in the distal airway, whereas in children, the material often settles in the mainstem bronchi (R > L).

The host response and complications of foreign body aspiration are primarily dependent upon the physical properties of the aspirated object (organic vs. inorganic; sharp vs. dull), location, and duration of involvement. Organic material elicits a robust local inflammatory response culminating in tissue granulation. Prolonged impaction may cause atelectasis, postobstructive pneumonia, bronchiectasis, and bronchial stenosis. Perforation or erosion of the airway may be associated with pneumothorax, pneumomediastinum, or hemoptysis [75].

Traditionally, the rigid bronchoscope has been the instrument of choice for foreign body extraction. Contemporary strategies for managing foreign body aspiration in adults primarily employ flexible bronchoscopy [76]. Diagnostic imaging (e.g., CXR and CT scan) has a limited role in evaluating foreign body aspiration; flexible bronchoscopy remains the gold standard for diagnosis. Further, the armamentarium of devices deployed through the working channel of a flexible bronchoscope typically obviates the need for rigid bronchoscopy. These tools include a selection of grasping forceps, balloon catheters, baskets, snares, magnets, as well as laser and cryotherapy probes (cryoadhesion).

Extraction in adults is often performed with airway topicalization, light sedation, and spontaneous ventilation. If clinical status permits, an appropriate period of fasting should be respected to minimize the risk of aspiration. Tracheal intubation and mechanical ventilation may be

required in the subset of patients with respiratory distress preoperatively or in those at high risk of aspiration. In either case, experts advocate strategies to avoid distal dislodgement of the foreign body during the procedure. Assuming a low risk of airway perforation or laceration, this typically will involve placement of a balloon catheter beyond the object and pulling it proximal to the tracheal carina. Once in the trachea, the foreign body can then be secured with a grasping device that is then removed from the patient's airway in tandem with the bronchoscope. For ventilated patients, temporary tracheal extubation during the final stage of removal may avoid the need to navigate the object through an endotracheal tube and the attendant risk of dislodgement or airway obstruction.

Pediatric foreign body removal is typically performed in the operating room under general anesthesia with rigid bronchoscopy. Owing to the reduced airway diameter, there is a greater perceived risk of obstruction and asphyxiation as well as air trapping from a ball valve mechanism. Gas exchange is supported with either spontaneous ventilation or intermittent positive pressure ventilation. Theoretical advantages of a spontaneous breathing technique include fewer interruptions to ventilation, as well as a reduced risk of distal dislodgement and dynamic hyperinflation. Advocates of positive pressure ventilation cite a quiet operative field as advantageous. Evidence supporting the superiority of either technique is lacking [77].

Endobronchial Valves

Newly defined roles for interventional bronchoscopists continue to emerge. Specifically, innovative interventional techniques are evolving in the management of severe emphysema and asthma. Unlike interventional strategies designed to relieve acute central airway obstruction, the role of bronchoscopy in these areas is suited for evaluation in well-designed clinical trials.

Lung volume reduction surgery (LVRS) improves pulmonary function, exercise capacity, and quality of life in selected patients at the expense of high perioperative morbidity [78]. Patients with a heterogeneous pattern of emphysema most predictably benefit from LVRS. Bronchoscopic lung volume reduction surgery (bLVRS) arose in response to the excessive morbidity associated with LVRS (see Chap. 36) and may target a wider population to include those with homogenous emphysema [79].

Bronchoscopic management of severe heterogeneous emphysema involves insertion of one-way endobronchial valves (Fig. 11.7) in segmental or subsegmental bronchi thereby restricting flow during inspiration and allowing passive exhalation and secretion clearance. Ultimately, the physiologic intent is to minimize dynamic hyperinflation through atelectasis (Fig. 11.8). Radiographic documentation of atelectasis in targeted lung segments is infrequently achieved, though clinical improvement often persists [80]. Improvement in cardiac function, diaphragm and inspiratory muscle performance, as well as recruitment of compressed alveoli may account for the clinical response [80]. A multicenter randomized controlled trial (VENT) in this population demonstrated improved exercise tolerance and modest improvement in quality of life but was hampered by a significant incidence of complications [81]. A more recent trial selecting for patients with a low probability of collateral ventilation, cited as the mechanism for failure to achieve the intended atelectasis, similarly demonstrated improved pulmonary function and exercise tolerance, but the frequent occurrence of serious adverse events has reduced enthusiasm for this technique [82]. Endobronchial valve technology continues to be limited to clinical trials until an improved safety profile can be achieved. Recently, a number of studies have considered the utility of bronchoscopic deployment of coils into subsegmental airways to allow for collapse of emphysematous tissue but have shown variable improvement and encountered similar limitations to endobronchial valves [83, 84].

Insertion may be performed under local or general anesthesia using flexible bronchoscopy. Relatively common complications include bronchospasm, COPD exacerbation, and pneumothorax (~20%) [82]. Valve migration and obstructing pneumonia are less frequent (~5%); fortunately, device extraction is easily performed [78]. Interestingly, compassionate use of endobronchial valves has aided in the successful management of persistent postoperative air leaks (Fig. 11.9) [85]. In all likelihood this will materialize as a new indication for device insertion.

Bronchoscopic lung volume reduction may benefit patients with homogenous emphysema where hyperinflation occurs from closure of small airways. An airway bypass system that establishes a shunt between a central airway and targeted region of hyperinflated lung theoretically allows for more efficient lung emptying. This technique involves endobronchial ultrasound for vascular mapping, followed by targeted radiofrequency ablation and drug-eluting stent insertion [86]. Although preliminary literature was promising, a multicenter randomized trial (EASE) failed to show benefit of this modality and has halted further evaluation [87].

Bronchial Thermoplasty

Difficult-to-control asthma has also received attention from bronchoscopists. Bronchial thermoplasty is a technique of applying radiofrequency energy to the airway wall, generating a tissue temperature of ~65 °C. This thermal injury reduces smooth muscle mass but avoids tissue destruction and scarring [88]. Reduction in smooth muscle mass should

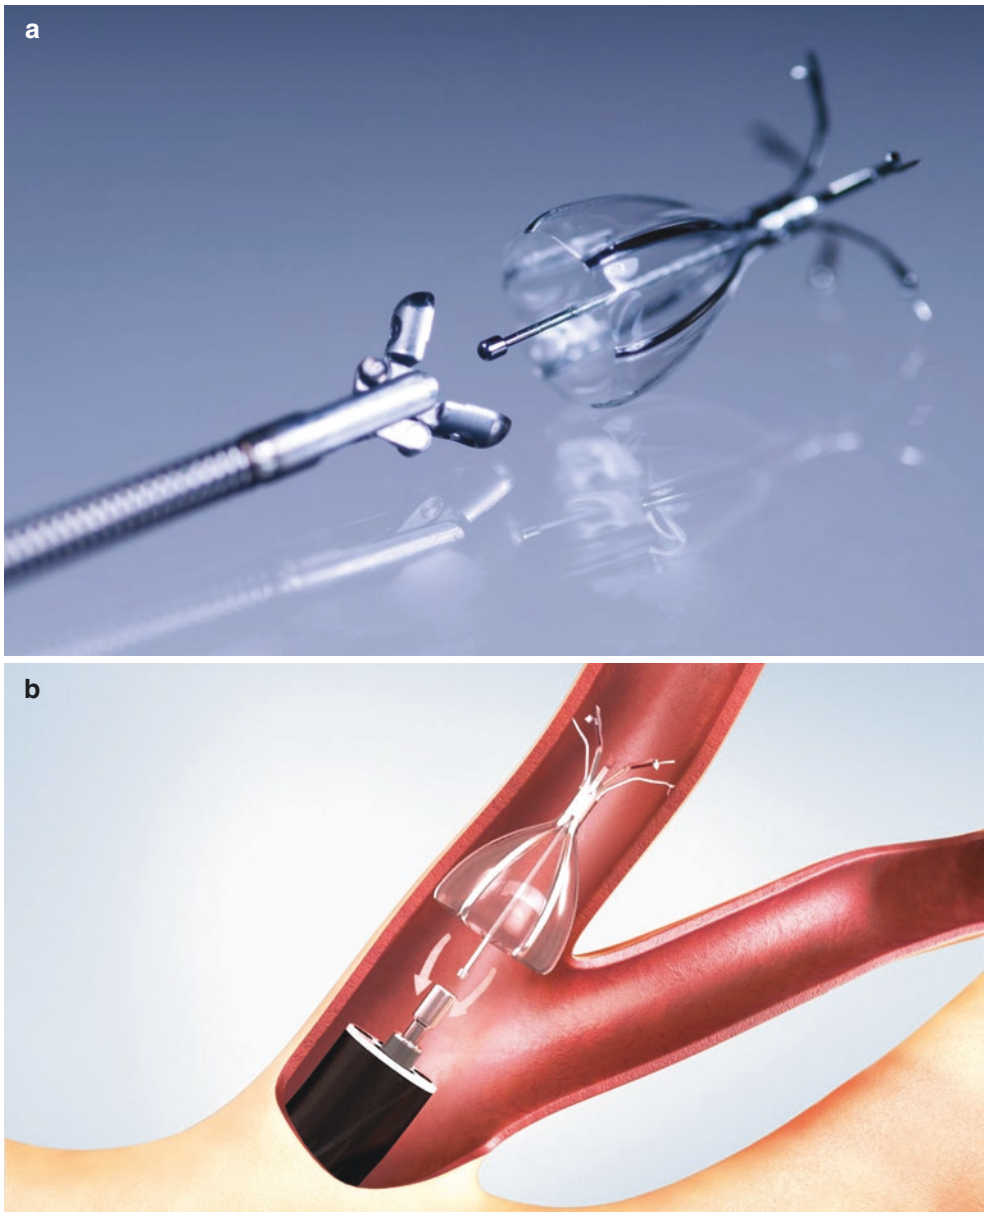

Fig. 11.7 (**a**) Olympus endobronchial valve and (**b**) schematic representation of device deployment. (Images courtesy of Olympus)

theoretically improve airflow in asthmatics with airway hyperresponsiveness [89]. Further randomized studies are required in this area to elucidate the safety profile and ideal candidates.

Diagnostic Bronchoscopy

Diagnostic bronchoscopy is almost exclusively practiced in nonoperative settings, using a flexible bronchoscope with topicalized local anesthesia and intravenous sedation. The presence of an anesthesiologist is generally reserved for patients who have tenuous cardiopulmonary reserve, impending airway compromise, or for procedures which are likely to require rigid bronchoscopy or immediately before or after other thoracic surgical procedures. Flexible bronchoscopy can be supplemented by a variety of modalities to aid in the diagnosis and staging of lung cancer, as well as a host of other pulmonary diseases. Aside from endobronchial assessment of the large airways via direct visualization, the addition of bronchial brushing, lavage, and sampling expands the diagnostic yield significantly [90]. Sampling submucosal and peribronchial lesions, which cannot be directly visualized, is aided with autofluorescence bronchoscopy, optical coherence tomography (OCT), CT, fluoroscopy, or endobronchial ultrasound imaging to improve diagnostic yield and limit complications. Complications attributable to these procedures are reported as less than 0.3% and include hypoxemia and cardiac arrhythmias, which are generally transient and rarely life-threatening [91].

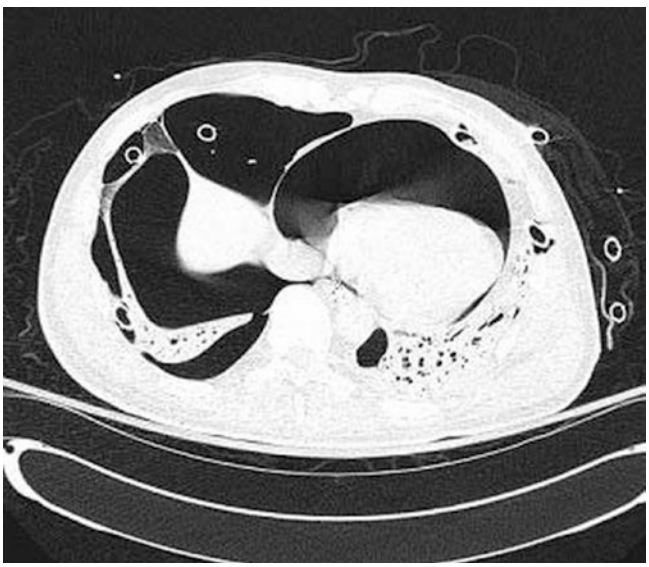

Fig. 11.9 Endobronchial valve placement was considered in this young patient with a massive air leak associated with tumor necrosis following induction chemotherapy for lymphoma

Optical coherence tomography (Fig. 11.10a) is a new imaging modality in pulmonary medicine. It enables higher-resolution (at least an order of magnitude) imaging as compared to conventional white-light bronchoscopy, facilitating subluminal airway examination and early lung cancer detection. Ex vivo studies have shown that OCT can visualize structural features associated with pulmonary nodules that precisely correlate with those on histopathology [92] and trained readers can identify nodules from normal lung tissue with good sensitivity and specificity [93]. It can be performed via flexible bronchoscopy with light sedation although deep sedation can improve exam accuracy due to reduced respiratory motion. Miniaturized fiber-optic OCT catheters allow endoscopic imaging of peripheral airways, while extensions of OCT such as Doppler and polarization-sensitive OCT can be used to examine pulmonary vasculature. Additionally, in benign airway stenosis such as relapsing polychondritis and granulomatosis with polyangiitis (formerly Wegener's granulomatosis), OCT has been used in airway diameter measurement to improve accuracy and assist therapeutic balloon dilation.

Noninvasive Techniques

Bronchial washing involves the use of small amounts (10–15 mL) of fluid instilled in the bronchial tree to be suctioned through the bronchoscope and then sent for culture, stain, and cytology. Bronchoalveolar lavage (BAL) is the same process using larger volumes of fluid (100–200 mL) which may have greater sensitivity for the diagnosis of *Pneumocystis jirovecii* (formerly *P. carinii*), legionella, tuberculosis, and respiratory viruses such as influenza and respiratory syncytial virus. Additionally, BAL may establish a diagnosis for other noninfectious pulmonary pathologies including malignancies, alveolar proteinosis (where it can also be used therapeutically), and histiocytosis, for example [94].

Complications encountered during these procedures are generally the same as those for fiber-optic bronchoscopy,

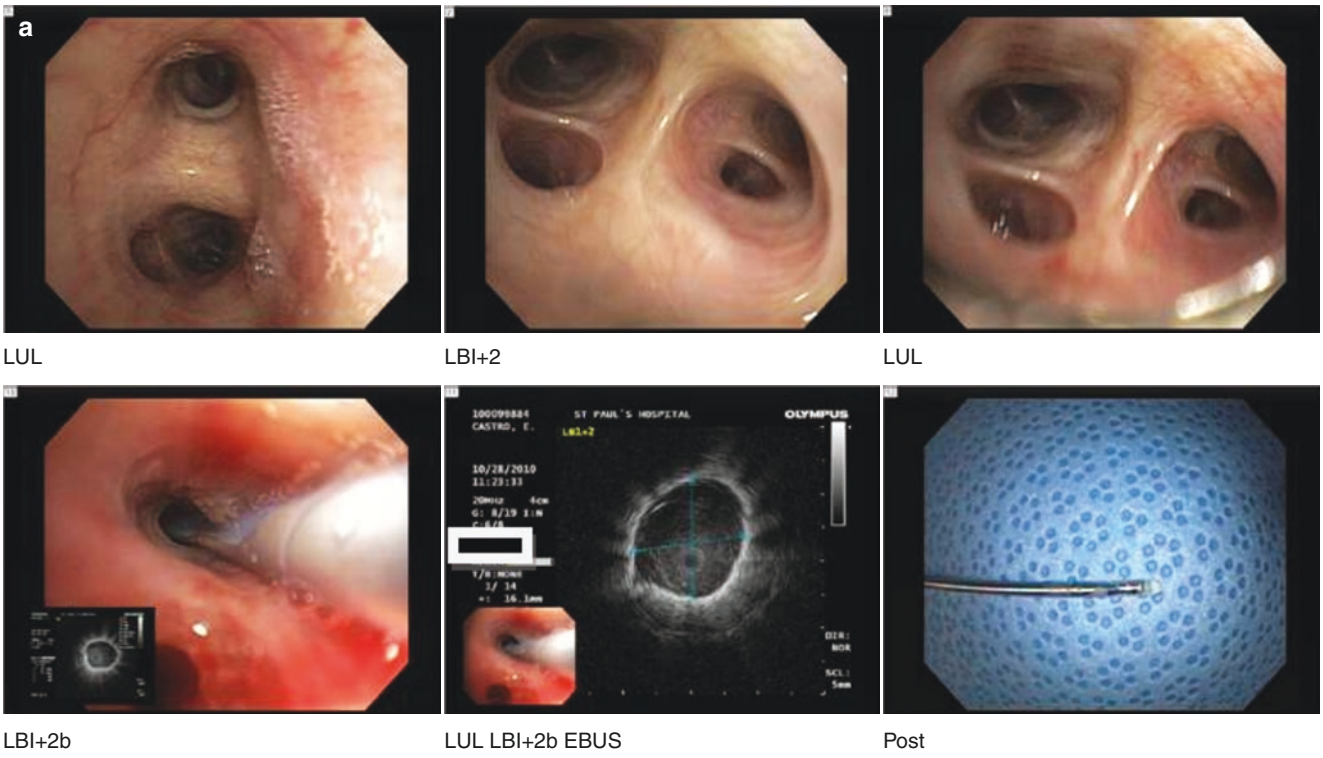

Fig. 11.10 (**a**) OCT examination of the tracheal stenosis with detailed airway measurement. (**b**) Linear EBUS examination of a paratracheal lymph node with elastography study (blue area indicates hard texture of the lymph node comparing to adjacent tissue)

though hypoxemia may be more profound depending on the amount of fluid administered and the number of lung segments involved [95]. It seems that temperature of the lavage fluid can also have an impact on respiratory mechanics – room temperature fluids have been shown to lead to impaired TLC, FEF 25–75, and increased RV [96]. These changes do not occur with fluids at body temperature. Lavage can precipitate bronchospasm in patients with reactive airways, and

thus pretreatment with beta-agonists and steroids, as well as the use of warmed fluid, has been advocated [97]. The release of cytokines resulting from inflamed tissues may lead to transient fevers and chills. Hemorrhage is rare and self-limiting, occurring mainly in patients with bleeding dyscrasias or uremia. Alveolar infiltrates may remain present on chest X-ray for up to 24 h [98].

Invasive Techniques

Bronchoscopic lung biopsy (BLB) and transbronchial needle aspiration (TBNA) are nonsurgical approaches for the procurement of tissue samples required for diagnosing and staging lung pathology. The main issue with these techniques is the difficulty in delineating the location of pathologic tissue and avoiding important intrathoracic and mediastinal structures. This is problematic for two reasons: firstly, diagnostic yields are low using a blind technique, and secondly, the opportunity for iatrogenic misadventure resulting in hemorrhage or air leak is heightened. The use of high-resolution CT and real-time fluoroscopy goes a long way to resolving these issues; however, these strategies are cumbersome and require a higher level of technical skill and resources. Due to the increased risk of serious complications, these approaches have fallen out of favor with many bronchoscopists and surgeons [99].

In recent years, the advent of endobronchial ultrasound (EBUS) has led to a resurgence in the interest in transbronchial tissue sampling [100]. There are two main types of EBUS technology. An EBUS radial probe is a small ultrasound catheter that can be inserted via the working channel of a regular bronchoscope to assist with locating peripheral lung lesions that can then be biopsied using a guided sheath system. Linear EBUS (as opposed to radial) uses a small ultrasound probe on the end of a larger fiber-optic bronchoscope to identify mediastinal and hilar lymph nodes. Transbronchial needle aspiration can then be performed via the linear EBUS scope under direct and real-time visualization. Doppler ultrasound can be used to identify adjacent vascular structures that need to be avoided. Moreover, elastography is an additional feature of the EBUS which can examine density of the lymph nodes and help select site of biopsy within the targeted lymph node in order to increase sensitivity and specificity of the biopsy (Fig. 11.10b).

Accurate sampling with EBUS is cited to exceed 90% [101, 102]. The same technology has been applied to esophagoscopy (EUS); the combination of the two approaches allows for a complete assessment of the mediastinum including all nodes accessible via traditional mediastinoscopy [103]. Both EBUS and EUS can be done under local anesthetic with sedation; however, in some centers they are conducted in the operating room under general anesthesia in conjunction with other surgical procedures.

Serious complications associated with endobronchial tissue sampling result primarily from bleeding or pneumothorax [104]. Rarer issues include transient fever, purulent pericarditis, or hemomediastinum [105]. Overall, complication rates for BLB are the highest among these techniques with as many as 3% of cases reported to have an adverse event of some kind and associated mortality of up to 0.1% [106]. Contraindications to BLB include coagulopathy, extensive bullous disease, vascular malformations, severe asthma, uncontrollable cough, or inability to cooperate during the procedure. Work-up should include an assessment of coagulation profile, including platelet count and kidney function. Pretreatment may include the use of DDAVP, cough suppressant, and bronchodilators. Cessation of antiplatelet agents for 5–7 days before the procedure reduces the incidence of bleeding significantly [107].

Mechanical ventilation is not a contraindication to BLB; however, the risk of pneumothorax is three times higher in this population than in spontaneously breathing patients [108]. Reduction of PEEP below 5 cmH_2O, adequate sedation, and prophylactic neuromuscular blockade may reduce the risk of pneumothorax. In anticipation of potential cardiopulmonary collapse due to tension pneumothorax, the availability of thoracostomy tube and personnel facile in rapid insertion are recommended [109].

Airway bleeding can usually be efficiently handled by the interventionalist using equipment available in the bronchoscopy suite. Standard techniques include wedging the bronchoscope into the involved segment to tamponade bleeding or instilling 10–15 mL of iced saline (with or without epinephrine) to induce vasoconstriction [90]. Should bleeding prove more severe and unresponsive to these simple interventions, isolation of the affected lung with either a double-lumen endobronchial tube or bronchial blocker may be required to prevent widespread aspiration of blood. Ultimately, urgent embolization of bronchial arteries or even surgical resection may be necessary in severe cases.

Awake Fiber-Optic Intubation

Fiber-optic bronchoscopy is often employed by anesthesiologists to facilitate safe tracheal intubation in situations where conventional laryngoscopy is difficult or contraindicated. Difficult laryngoscopy may be encountered in patients with distorted anatomy or limited neck or soft tissue mobility that impedes the direct visualization of the larynx. Mask ventilation may also be a challenge in these patients, culminating in a potentially catastrophic “can’t intubate, can’t ventilate” scenario if spontaneous ventilation is compromised. Relative contraindications to direct laryngoscopy include situations where manipulation of the cervical spine may be harmful, as with ligamentous instability or unstable fractures.

The advantage of a fiber-optic bronchoscopic intubation (FOBI) is that excessive movement of the patient's neck or mouth is not required to enable visualization of the upper airway and trachea. The bronchoscope can be guided through relatively small openings (either orally or nasally), and its maneuverability allows the operator to achieve excellent visualization without necessitating the same anatomic alignment required with direct laryngoscopy. Once the bronchoscope has been positioned beyond the vocal cords into the trachea, it can serve as a guide over which an endotracheal tube can be passed. Some advocate approaching FOBI through the nose, as the natural curvature of the nasopharynx often results in the bronchoscope being aligned directly at the laryngeal inlet. However, nasal intubation may be less tolerated by patients, demands the use of a smaller tube, and can precipitate epistaxis. The decision as to which approach is used depends on the circumstances of the individual case.

When access to the larynx is likely to be difficult, maintenance of spontaneous ventilation during intubation is the safest method of securing the airway. Often described as an awake intubation, the technique is best performed with an appropriately sedated (ideally cooperative) and reasonably comfortable patient. The type of sedation used is preferably short acting or quickly reversible, to allow for rapid return of spontaneous ventilation should the patient become apneic. Used judiciously, short-acting opioids such as fentanyl or remifentanil provide excellent sedation though they can easily lead to apnea if overdosed. Midazolam is a rapid onset intravenous benzodiazepine with amnestic properties that has a higher threshold for suppressing respiration. It should be kept in mind that the combined use of sedatives may have synergistic effects resulting in an unconscious or apneic patient at lower than anticipated doses. Reversal agents including naloxone and flumazenil should be available in case of accidental overdose. In recent years dexmedetomidine, a short-acting highly selective alpha-2-adrenoceptor agonist, has gained popularity due to its favorable sedative and anxiolytic effects combined with a minimal impact on respiratory drive. The ability to induce a level of sedation similar to sleep while the patient remains easily rousable and cooperative makes it an appealing agent for awake intubation. Other adjuvant medications to consider include antisialogogues to reduce airway secretions. Anticholinergic agents used for this purpose include atropine, glycopyrrolate, and scopolamine, each of which has a characteristic side-effect profile, including tachycardia (atropine > glycopyrrolate) and sedation (scopolamine > atropine) [110, 111].

As previously described, awake patients often poorly tolerate the placement of a bronchoscope and endotracheal tube in the oropharynx and trachea. Even with effective sedation, the cough and gag reflexes are difficult to suppress and remain disruptive to the bronchoscopist. These powerful reflexes are key defenses in protecting the lungs from aspiration and are rudimentary indicators of intact brainstem function. An understanding of the basic innervation of the pharynx and larynx allows one to interrupt the afferent and efferent neural limbs to facilitate instrumentation of the airway. Basically, there are three nerves responsible for sensation in the airway: the trigeminal nerve supplies the nasopharynx, the glossopharyngeal supplies the oropharynx, and the vagus supplies the larynx and the trachea [112]. In the upper airway, the gag response includes afferent input from the glossopharyngeal and an efferent motor arc from branches of the vagus nerve. In the lower airway, innervation above the vocal cords is primarily provided by the superior laryngeal nerve (SNL) and below the cords by the recurrent laryngeal and external SNL, all of which are vagal branches. As such the SNL controls the glottic closure reflex (which leads to laryngospasm if hyper stimulated), while the remaining vagal inputs control the cough reflex.

The application of topical anesthetic to the mucosal surfaces of the airway is the simplest way to minimize sensory stimulation and thus interrupt the afferent arm of the airway reflexes before attempting an awake intubation [113]. These can be administered either by inhalation of a nebulized liquid (via face mask), direct application using an atomized spray (either blindly or through the bronchoscope itself), placement of gauze soaked in local anesthetic solution (intranasally or at the tonsillar bases), or gargling [114]. The ideal agent for topicalization is one that is quick in onset and has a few side effects, with limited risk of toxicity. Absorption of these drugs through the mucous membranes of the oropharynx and lungs is unpredictable; it is possible to achieve toxic plasma levels with excessive topicalization [115]. Table 11.6 outlines the most commonly used topical agents.

Through effective topicalization, practitioners are able to achieve excellent conditions for awake intubation. Despite this, some advocate the use of nerve blocks to enhance the blunting of airway reflexes by selectively targeting the three nerves described above. These blocks are useful in clinical scenarios when local infection, blood, or secretions hinder effective

Table 11.6 Topical airway anesthetic agents

Agent	Speed of onset	Duration (min)	Maximum dose	Toxicity
Cocaine	Slow	30–60	1.5 mg/kg	Hypertension, myocardial ischemia
Lidocaine	Moderate	30–60	3 mg/kg (7 mg/kg with epinephrine)	Tinnitus, seizures, arrhythmia
Benzocaine	Fast	5–10	200 mg	Methemoglobinemia

Table 11.7 Airway nerve blocks

Nerve	Approach	Considerations
Glossopharyngeal	Intraoral: Injection at base of posterior tonsillar pillar	Requires adequate mouth opening
		Risk of carotid injection
	Peri-styloid: Injection between the mastoid process and angle of jaw	Requires palpable landmarks
		Risk of carotid injection
Superior laryngeal	Injection between the greater cornu of hyoid bone and superior cornu of thyroid cartilage	Requires palpable landmarks and neck extension
		Risk of intravascular injection
Vagus (infraglottic and upper tracheal)	Intratracheal injection through cricothyroid membrane	Requires palpable landmarks
		Risk of airway compromise from bleeding or trauma

topicalization. Lidocaine is usually the agent of choice for airway blocks. If nerve blocks are used in addition to topical agents, be wary of exceeding toxic levels. Obviously, these techniques involve a higher level of skill and risk the complications of intravascular injection, hematoma, and nerve injury. Further, as they require insertion of needles in the patient's neck, the performance of these blocks may themselves add to an already anxiety provoking procedure. Table 11.7 outlines the main approaches to airway nerve blocks.

Clinical Case Discussion

A 65-year-old woman with a remote transhiatal esophagectomy for cancer presented with 2 days of increasing dyspnea. She remains hypoxemic following intubation for respiratory failure in the emergency department, despite maximal conventional ventilation. CT imaging demonstrates near-complete obstruction of the left main bronchus and significant obstruction of the right main bronchus (Fig. 11.11). The Interventional Pulmonologist intends to perform balloon dilatation, tumor resection, and stent insertion in the left main bronchus via rigid bronchoscopy.

Questions

Outline the considerations of providing anesthesia for patients with central airway obstruction:

- Risk of complete airway obstruction and impossible ventilation
- Potential for dynamic hyperinflation resulting in hemodynamic compromise or barotrauma
- Considerations and complications of rigid and interventional bronchoscopy

Describe the ventilation techniques applied during rigid bronchoscopy:

- Spontaneous
- Assisted
- Sanders jet ventilation
- HFJV

Describe the acute complications of balloon bronchoplasty, airway stenting, and electrocautery:

- Tracheitis
- Fever
- Atelectasis
- Bronchospasm
- Airway disruption
- Dissemination of obstructing pneumonia
- Hemorrhage
- Airway fire
- Electromagnetic interference

Authors' Management

General anesthesia was maintained by TIVA and neuromuscular blockade. Fiber-optic inspection of the tracheobronchial tree was expeditiously performed to further evaluate the tumor and characterize the anatomy of the obstruction. Given the degree of hypoxemia, an exchange catheter was inserted adjacent to the endotracheal tube, to allow for temporary oxygenation during the transition between tracheal extubation and access with the rigid bronchoscope. Ventilation following tracheal placement of the rigid bronchoscope was supported with a Sanders jet injector. Left mainstem patency was re-established using a combination of balloon dilation, electrocautery, and stent placement. Following restoration of normal gas exchange, balloon dilation of the right mainstem was employed, the trachea was extubated, and a laryngeal mask was inserted. Once the patient recovered from intravenous anesthesia, neuromuscular blockade was reversed, adequate spontaneous ventilation was established, and the patient was observed in the operating room until fully awake (Fig. 11.11).

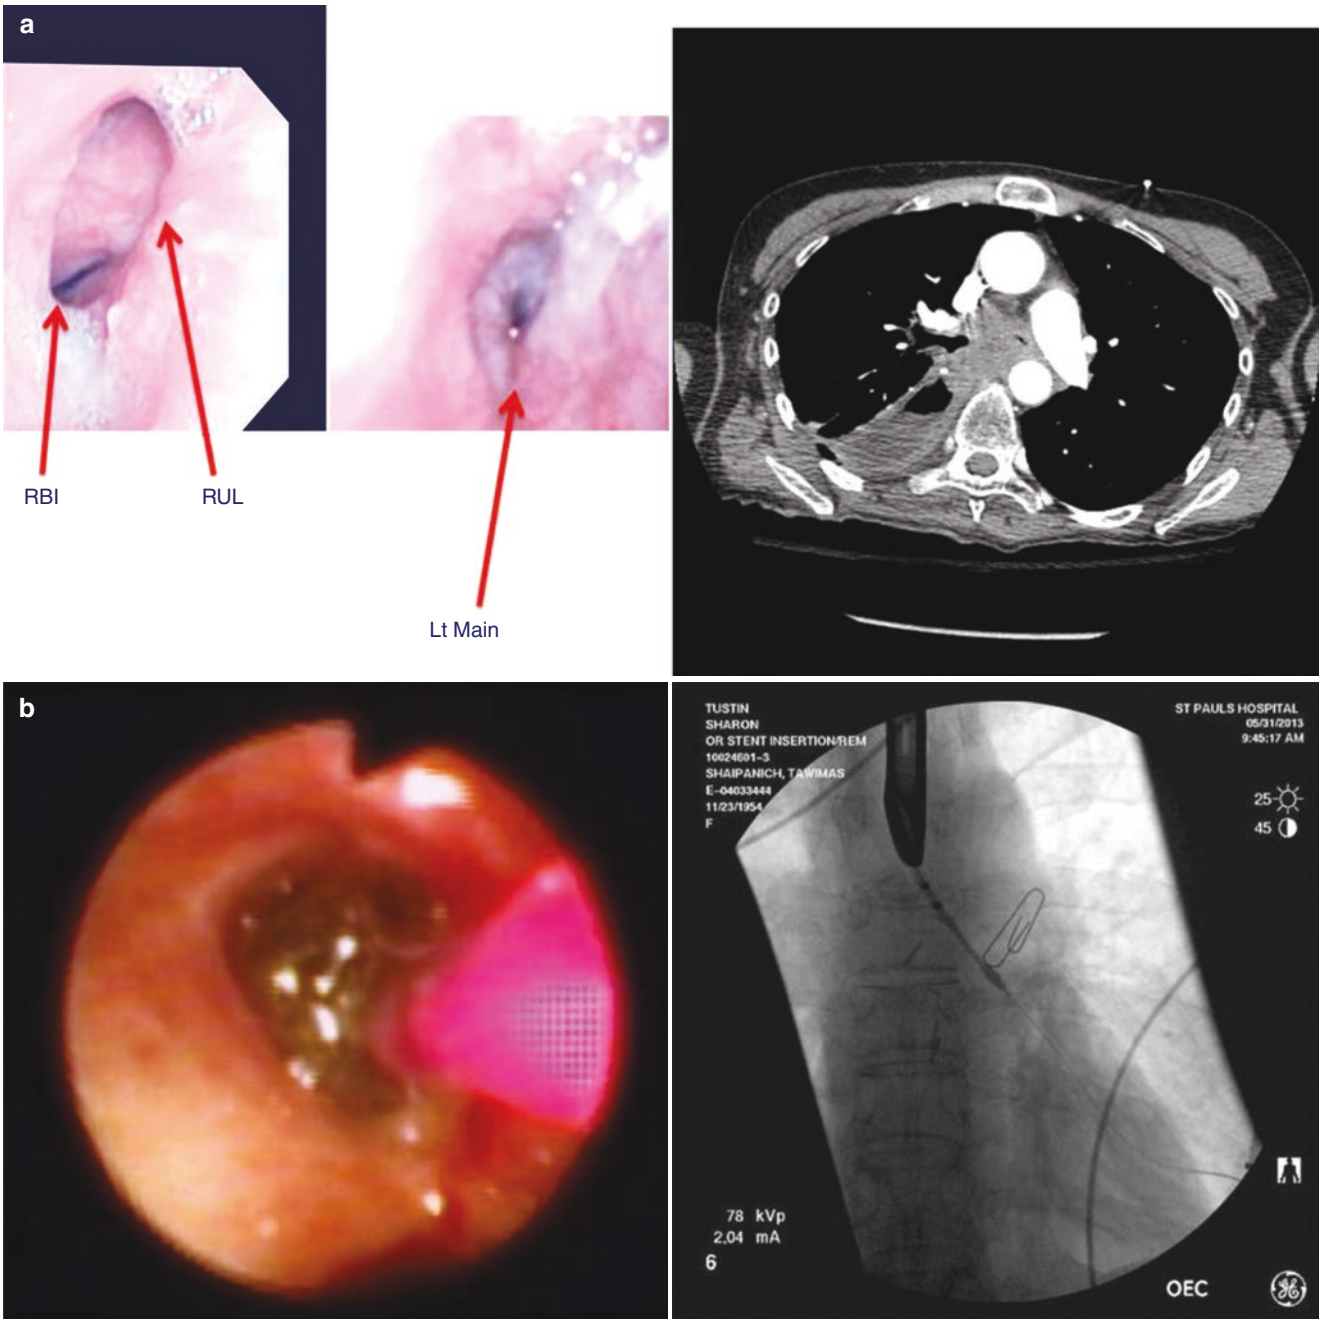

Fig. 11.11 (**a**) Bronchoscopic picture of the right bronchus intermediate (RBI) stenosis and left main bronchial stenosis (Lt main); CT scan of the chest demonstrates near occlusion of the left main airway by tumor. (**b**) Balloon dilation of the left main bronchus (left). Fluoroscopy image shows stent insertion via rigid bronchoscopy (right) (**c**) Bronchoscopic examination shows left main airway stent and patent right main airway post balloon dilation and stent placement

Intravenous Anesthesia for Thoracic Procedures

12

Javier D. Lasala and Ron V. Purugganan

Key Points

- Total intravenous anesthesia (TIVA) is indicated for procedures in which inhalational anesthetics may not be safely or effectively delivered, including endobronchial procedures using flexible or rigid bronchoscopy and proximal airway-disrupting surgeries. TIVA may also be beneficial in lung volume reduction surgery, lung transplantation, and thymectomy.
- TIVA is safer and more practical for thoracic procedures performed outside of the operating room, such as off-site locations, military field, or impoverished areas of the world.
- Target-controlled infusion (TCI) is a delivery system for TIVA that is based on pharmacokinetic models to optimize intravenous anesthetic delivery. TCI has many advantages over conventional calculator pumps but is not currently available in the United States.
- Because well-established MAC-type systems for intravenous anesthetics are not available, anesthetic depth monitors are useful in monitoring patients undergoing TIVA.
- Propofol, dexmedetomidine, ketamine, lidocaine, and remifentanil may be used in combination with anesthetic depth monitoring to execute an effective TIVA regimen.
- This chapter reviews the balanced TIVA technique currently used at the University of Texas MD Anderson Cancer Center, which encompasses enhanced recovery after surgery principles.

Introduction

Over the last century and a half, thoracic surgery has evolved from hurried operations with high mortality to relatively safe and controlled procedures with a good chance of survival. In early procedures, anesthetic agents and their delivery were crude, resulting in suboptimal surgical conditions in which anesthetic depth was questionable, hemodynamics were unstable, and ventilation/oxygenation is subpar. The development of endotracheal intubation, lung isolation techniques, and modern anesthetic drugs was instrumental in the evolution of thoracic surgery. Modern anesthetics can reliably render a patient unconscious and immobile while maintaining hemodynamic and respiratory stability. Through these improvements of surgical conditions, more complex and time-consuming operations became possible. Furthermore, the continued evolution of intravenous anesthetic agents has made it possible for thoracic anesthesiologists to better adapt their techniques to suit specific surgical scenarios. This chapter reviews the rationale for using intravenous anesthesia for thoracic operations, the drugs and equipment required, and the methodology involved.

Rationale for Total Intravenous Anesthesia

Traditional inhalational anesthetics have been associated (at least in animal studies) with a direct inhibition of hypoxic pulmonary vasoconstriction (HPV), the reflex arteriolar constriction that diverts blood from hypoxic segments of the lung to normal areas of the lung, thereby decreasing shunt fraction. In

thoracic procedures, this inhibition of HPV may be detrimental to patient oxygenation levels during one-lung ventilation. In contrast, intravenous anesthetics do not appear to directly inhibit HPV, in vitro or in patients. Consequently, interest has focused on whether total intravenous anesthesia (TIVA) might provide better oxygenation and lesser shunt fraction than inhaled anesthetics in thoracic procedures. As little work has been done to answer this question more recently, research published in the last decade is summarized here.

Several studies have shown an advantage to using TIVA. Abe and colleagues studied patients receiving either isoflurane or sevoflurane followed by TIVA (propofol). PaO_2 increased significantly, and shunt fraction decreased significantly after the initiation of TIVA [1]. In another study, PaO_2 was also significantly higher in patients who received TIVA for pulmonary resection than in those who received volatile anesthetics [2]. Özcan and colleagues compared oxygenation and shunt fraction in 100 patients undergoing one of four anesthesia techniques during one-lung ventilation: TIVA with or without thoracic epidural anesthesia (TEA) and isoflurane with or without TEA. Patient oxygenation was significantly higher, and shunt was significantly lower in the two groups receiving TIVA; the addition of TEA in either study group had no significant effect [3]. A retrospective study examined changes in saturation in patients receiving propofol and fentanyl intravenous anesthesia compared to inhalation anesthesia. In this study they showed patients in the TIVA group to have an 8% chance of developing hypoxemia compared to literature, which suggests hypoxemia ranging from 13% to 40% in patients receiving inhalation anesthesia, hence demonstrating TIVA as a suitable anesthetic to maintain saturation during one-lung ventilation [4]. A study conducted on the effect of remifentanil on arterial oxygenation during one-lung ventilation revealed that an infusion can be successful with propofol during one-lung ventilation without significant changes in PaO_2 [5].

Alternatively, a few studies fail to support any advantage of TIVA. Beck and colleagues studied 40 patients who received either propofol or sevoflurane during one-lung ventilation for thoracic surgery. They found no significant difference in shunt fraction between the two groups. Hemodynamic variables known to influence HPV (cardiac index, mixed venous oxygen tension, and arterial carbon dioxide partial pressure) were also similar between the two groups [6]. Pruszkowski and colleagues compared oxygenation levels in patients undergoing lung lobectomy. The patients received a thoracic epidural and either sevoflurane or propofol at levels required to maintain a bispectral index (BIS) between 40 and 60. The authors found no difference in PaO_2 levels between the sevoflurane and propofol groups. They suggest that the titration of anesthetics to appropriate BIS levels (which distinguished their study) could avoid potential negative effects of inhalational anesthetics on hemodynamics that affect the shunt [7]. Yondov and colleagues in a comparative study of the effect of halothane, isoflurane, and propofol on partial arterial oxygen pressure during one-lung ventilation concluded that TIVA with propofol/fentanyl can be applied as an alternative of general anesthesia with halogenated volatile anesthetics, as there was no significant difference in the PaO_2 between the three groups during ventilation [8]. Lastly, Von Dossow and colleagues divided 50 patients undergoing pulmonary surgery into two groups—isoflurane with TEA or TIVA (propofol)—and measured shunt fraction, PaO_2, and cardiac output. They found that the decrease in PaO_2 level following the conversion from two-lung to one-lung ventilation was less in the isoflurane group. Shunt fraction remained the same in both groups. Cardiac output was greater in the TIVA group, which may have contributed to the effect on PaO_2 [9].

Most likely, even though inhalational anesthetics suppress HPV, other factors such as surgical manipulation, cardiac output, mixed venous oxygen tension, and positive end-expiratory pressure may have a greater influence on shunt fraction than the influence of inhalational agents on HPV. Therefore, further studies are required to define the clinical significance of inhaled anesthetics on HPV in thoracic surgery.

Immunomodulatory effects of inhaled vs. TIVA techniques on the lung are another area of ongoing investigation. Animal studies have shown that propofol may have a protective effect on the lungs, especially in acute lung injury resulting from endotoxin exposure [10]. In patients undergoing cardiopulmonary bypass, propofol has been shown to regulate the pulmonary inflammatory response [11]. However, studies of thoracic surgery patients undergoing one-lung ventilation may favor the use of volatile anesthetics to decrease the inflammatory response to lung isolation [12–14]. Resuming two-lung ventilation from one-lung induces oxidative stress; this attributed to superoxide release. Huang and colleagues looked to see if there was any difference between inhalational anesthesia with isoflurane and propofol infusion. They measured reactive oxygen species and total antioxidant status before one-lung ventilation, before resuming two-lung ventilation, and at intervals of 5 and 20 min after resuming two-lung ventilation. They revealed that propofol infusion, compared with isoflurane, attenuates reactive oxygen species production and limits it for 20 min after resuming two-lung ventilation [15]. In another investigators looked to see the effects of sevoflurane inhalation anesthesia only versus propofol total intravenous anesthesia on perioperative cytokine balance in lung cancer patients. Venous blood samples were obtained before one-lung ventilation, before the conclusion of one-lung ventilation, after closed chest surgery, and after 24 h; they measured the serum concentrations of IL-6, IL-8, and IL-10 by ELISA. It was shown that propofol causes less inflammatory mediator release and can also modulate the balance of cytokines. In the authors' opinion, they advocate that propo-

fol is a better anesthetic for lung cancer than sevoflurane [16]. Wakabayashi and colleagues study the effects of anesthesia with sevoflurane and propofol on the cytokine/chemokine production at the airway epithelium during esophagectomy; the levels of inflammatory cytokines and chemokine in the epithelial lining were obtained from the ventilated dependent lung and collapsed non-dependent lung by bronchoscopic microsampling method, and these were measured before and after one-lung ventilation. The results of the study suggest that propofol anesthesia more potently suppresses the surgical stress-induced inflammatory perturbation at the local milieu of the airway during esophagectomy compared with sevoflurane anesthesia [17]. Wigmore and colleagues looked at overall long-term survival for patients undergoing volatile versus IV anesthesia for all cancer surgical procedures. In this retrospective analysis, the authors compared mortality after cancer surgery in more than 7000 patients given volatile general anesthesia or total IV anesthesia. This retrospective analysis demonstrates an association between the type of anesthetic delivered and survival; mortality was approximately 50% greater with volatile than IV anesthesia, with an adjusted hazard ratio of 1.46 (1.29–1.66) [18]. Alternatively, one study comparing pulmonary morbidity using sevoflurane or propofol-remifentanil anesthesia in an Ivor Lewis operation showed different results in regard to IL-6 levels. In this study sevoflurane anesthesia attenuated an increase in blood IL-6 at the end of surgery but did not provide any advantages over propofol-remifentanil in terms of postoperative pulmonary complications [19]. These studies are promising in that they show not only a significant reduction in measured inflammatory response but also an improvement in clinical outcome. Further studies are warranted.

Although neither TIVA nor inhaled anesthetic agents provide a clear *physiologic* advantage over the other for thoracic surgery, there is solid rationale for the use of TIVA in certain circumstances (Table 12.1):

- When the delivery of inhaled anesthetics is impossible or disadvantageous, due to the nature of the operation
- In scenarios where traditional anesthetic delivery systems may be unavailable or impractical

Table 12.1 Situations in which TIVA may be indicated

Special surgical conditions
Tracheal/carinal surgery
Lung volume reduction surgery
Lung transplantation
Endobronchial procedures
Thymectomy
Non-ideal environments
Off-site locations requiring anesthesia
Austere environments (military, developing countries)

TIVA in Special Thoracic Surgical Conditions

Procedures or trauma that disrupts the trachea and carina complicate the delivery of inhaled anesthesia. When the proximal airways are breached, volatile agents may escape, and the quantity of anesthesia reaching the patient is uncertain. Also, the operating room is at risk of pollution from the escaped anesthetics, posing a hazard to personnel. This situation is most likely during cross-field ventilation, a technique in which the distal airways (main bronchi) are directly intubated in the surgical field to facilitate ventilation and oxygenation. Intubation and extubation are often repeated, and airway seals are frequently compromised. Also, certain cases may require high-frequency jet ventilation or other specialized modes of ventilation incompatible with the delivery of inhalational anesthetics [20].

Patients undergoing lung volume reduction surgery (LVRS) also benefit from a TIVA approach. Because these patients suffer from chronic obstructive pulmonary disease (COPD) and have increased dead space, end-tidal volatile anesthetic concentration is inaccurate and anesthetic levels questionable [21]. Also, air trapping is common, and the elimination of volatile anesthetic may be hindered, delaying awakening and extubation.

In the case of lung transplantation, volatile anesthetics have several drawbacks. During lung transplantation, the right ventricle is subject to increased afterload and potential failure, and the cardiodepressant effects of volatile anesthetics could be detrimental. In addition, significant intrapulmonary shunt and dead space in the transplanted lung interfere with the accuracy of end-tidal anesthetic measurements. Consequently, narcotic-based anesthetic regimens are usually administered for lung transplantation surgery. However, this is not always an ideal solution, because narcotic levels may decline unpredictably during the procedure. This decline has several possible causes: (1) narcotics may be sequestered in the CPB circuit in cases using cardiopulmonary bypass (CPB); (2) narcotics tend to accumulate in lung tissue during first pass, and a considerable amount of drug might be removed when the diseased, native lung is resected; and (3) when the donor lung is transplanted, first-pass uptake is repeated, and systemic narcotic levels may again drop [22]. When narcotic levels drop, more volatile anesthetics and/or narcotics must be given—but with older anesthetics, overaccumulation and delayed awakening may occur. Newer, rapidly metabolized intravenous anesthetics, on the other hand, are able to rapidly counter changes in anesthetic depth without significant risk of overaccumulation. Furthermore, in pulmonary transplant surgery requiring CPB (i.e., double-lung or heart-lung transplant), TIVA allows an uninterrupted transition to the CPB phase and back to native circulation.

Endobronchial procedures that use flexible or rigid bronchoscopy (e.g., stent placement, dilatation, biopsy, and laser procedures) also benefit from a TIVA approach. These procedures are frequently complicated by periods of apnea, the need for special ventilatory techniques such as high-frequency jet ventilation, and compromised airway seals. Thus, the delivery of volatile anesthetics may be problematical. Furthermore, these procedures frequently involve repeated alternating periods of high and low stimulation, and intravenous anesthetics can be more rapidly titrated to meet fluctuating demands. Lastly, accurate measurements of volatile anesthetics by standard mass spectrometry are hindered in procedures where helium/oxygen will be used [23].

Lastly, patients with myasthenia gravis undergoing thymectomy may benefit from a TIVA approach. Myasthenia gravis (MG) is associated with autoimmune damage to the acetylcholine (ACH) receptors; therefore, patients exhibit baseline muscle weakness. The thymus gland is implicated in the autoimmune response against the ACH receptors; in a select population of those with MG, symptoms improve post-thymectomy. MG patients are exquisitely sensitive to neuromuscular blocking agents and volatile anesthetics, which may cause prolonged paralysis or residual muscle weakness [24]. The ideal anesthetic for such patients would avoid neuromuscular blocking agents and volatile anesthetics. Successful thymectomies have been performed without neuromuscular blocking agents using TIVA +/− high thoracic epidurals. Conditions for intubation and surgery were excellent [25, 26].

Scenarios that Benefit from TIVA

TIVA is the anesthetic administration system of choice in scenarios where the logistics of having fully functional anesthesia machines may be impractical or impossible. For example, off-site anesthesia has recently become more commonplace. Many minimally invasive thoracic procedures are being carried out in nonoperating room "procedure suites." In these circumstances, TIVA is more versatile because (1) its administration does not require a full anesthesia machine setup, and (2) it can provide different levels of anesthesia (from MAC/sedation to general).

TIVA also offers several advantages in austere environments such as battlefields, disaster zones, and developing nations. For example, volatile anesthetics are considered hazardous materials—they are difficult to store and transport, and they generate waste gases that must be properly scavenged. In addition volatile anesthetics are known emitters of greenhouse gases. Sherman and colleagues looked at the greenhouse gas emissions of anesthetic drugs and their environmental impact, and the entire life cycle of five anesthetic drugs were examined: sevoflurane, desflurane, isoflurane, nitrous oxide, and propofol. Data from their study reveals and reiterates previous data regarding the greenhouse gases emitted by volatile anesthetics. From the results techniques that can substitute volatile anesthetics, such as total intravenous anesthesia and neuraxial or peripheral nerve blocks, would be the least harmful to the environment [27]. In contrast, TIVA agents are more easily stored, transported, and disposed. A second advantage is the reduced logistical footprint—basic TIVA equipment (infusion pump and ventilator) eliminates the traditional anesthesia machine. Additionally, TIVA equipment is more robust than traditional anesthesia machines and is more likely to perform reliably in less-than-ideal conditions. Although specialized anesthesia machines developed for military applications are available, they are more costly and complex than a simple ventilator and infusion pump setup. In fact, in its most basic form, TIVA can be administered with only a syringe and ambu-bag, which is even simpler than a basic draw-over (volatile) system. Hospitals in developed countries are routinely set up for inhalational anesthetics; thus, TIVA is usually more costly, due to the price of the agents. In developing nations, however, the cost of hardware and its maintenance usually outweighs the cost of drug, making TIVA a more economical option.

Intravenous Anesthetic Agents

Several intravenous anesthetic agents may be used in combination to execute an effective TIVA regimen. Propofol, the model drug for TIVA, and useful adjuncts for TIVA—dexmedetomidine, remifentanil, ketamine, and lidocaine—are reviewed below.

Propofol

Propofol remains the mainstay drug for TIVA. In addition to its favorable pharmacodynamics and pharmacokinetic profile, propofol offers distinct benefits over inhaled anesthetics. In studies comparing propofol with inhaled anesthetics in thoracic procedures, propofol reduced the postoperative decline of lung function after lung resection [28] and inhibited the catecholamine surge and adrenocorticotropic hormone (ACTH) response during lung lobectomy [29]. Studies of propofol in non-thoracic operations have also shown advantages that may apply to thoracic procedures; propofol reduced coughing during emergence from anesthesia [30] and the depression in bronchial mucus transport velocity associated with general anesthesia [31]. In addition, the stress hormone response [32] and the expression of pro-inflammatory cytokines in alveolar macrophages [33] were lower in patients receiving propofol

than in those receiving inhaled anesthetics. When looking at the effects of propofol versus isoflurane on liver function after open thoracotomy, both have a comparable minor effect on liver function after an elective thoracotomy [34]. Given that thoracotomy is one of the most painful surgical incisions, another study focused on the incidence of post-thoracotomy pain, comparing total intravenous anesthesia and inhalational anesthesia. A prospective randomized trial looked at two groups' propofol and remifentanil versus sevoflurane anesthesia. The incidence of chronic post-thoracotomy pain syndrome was compared at 3- and 6-month intervals. Results demonstrated total intravenous anesthesia may reduce the incidence of chronic post-thoracotomy pain syndrome at 3 and 6 months [35].

Dexmedetomidine

Dexmedetomidine is an alpha-2 agonist sedative-analgesic that inhibits endogenous norepinephrine release. Dexmedetomidine is eight times more selective for the alpha-2 receptor than clonidine, with an alpha-2/alpha-1 receptor ratio of 1600:1 [36]. Evidence suggests that its main effector sites are the locus coeruleus for sedative action and the spinal cord for analgesic action. Interestingly, sedation with dexmedetomidine has been observed to mimic natural sleep in that hypercapnic arousal phenomenon upon exposure to a CO_2 challenge is preserved [37]. In addition to its direct sedative-analgesic properties, dexmedetomidine also reduces opioid requirements [38–45] and minimum alveolar concentration levels for inhalational anesthetics [46–48].

In thoracic surgery, dexmedetomidine may offer several physiologic benefits. It reduces perioperative oxygen consumption [49] and the sympathetic response to surgical stimulus [38, 50, 51], which may confer cardioprotective benefits. In studies of thoracic surgery patients, the use of dexmedetomidine as an adjunct to epidural analgesia reduced the need for epidural fentanyl [45] and resulted in postoperative diuresis and favorable indices of glomerular filtration, suggesting enhanced renal function [52]. In patients with pulmonary hypertension undergoing mitral valve replacement, dexmedetomidine lessened the rise in systemic and pulmonary vascular resistance post-sternotomy and decreased mean arterial, mean pulmonary artery, and pulmonary capillary wedge pressures [53]. Lastly, patients recovering from thoracic surgery may benefit from the reduced occurrence of respiratory depression [54–56], improved pain control [57–59], and postoperative shivering [60, 61] associated with dexmedetomidine. Of note the use of intraoperative dexmedetomidine is not associated with a reduction in acute kidney injury after lung cancer surgery [62]. Dexmedetomidine is clearly an important adjuvant for total intravenous anesthesia for the thoracotomy patient.

Remifentanil

Remifentanil is an ultrashort-acting fentanyl derivative that is particularly suited to thoracic procedures. Remifentanil's rapid onset time (1 min) and short duration of action (3–10 min) [63] are ideal for managing the fluctuating periods of high and low surgical stimulations that characterize most thoracic procedures. Because thoracic epidural anesthesia is the main modality for pain relief in most thoracic surgeries, there is little need for long-acting IV narcotics that may prolong extubation and cause postoperative respiratory depression. Some situations, however (e.g., multiple surgical sites), require supplemental longer-acting narcotics for adequate postoperative analgesia. In these cases, remifentanil may be co-administered with longer-acting narcotics to provide intraoperative analgesia for periods of high surgical stimuli without risk of overaccumulation of the accompanying narcotics.

Ketamine

Ketamine is an N-methyl-o-aspartate receptor antagonist that induces a "dissociative state" in which sensory input (sight, hearing, touch) normally perceived by the patient is blocked from reaching consciousness. Because of its profound analgesic, sedative, and amnestic properties, it is occasionally used as an adjunct to propofol in TIVA regimens. Ketamine is particularly valuable for thoracic surgery because it (1) has bronchodilating properties; (2) does not depress respiration; (3) may reduce pain for up to 3 months postoperatively when used in conjunction with TEA for thoracotomy [64]; (4) reduces narcotic requirement; and (5) exerts sympathomimetic effects, which may be beneficial in thoracic trauma and in situations where perfusion pressure must be maintained in the presence of volume restriction. In thoracotomies preemptive administration of ketamine may be an effective adjuvant; a study by Fiorelli and colleagues showed patients in a ketamine group compared to a placebo to have better satisfaction of pain relief, significant reduction in inflammatory response, and decreased morphine consumption [65]. There is still ongoing research needed in relation to post-thoracotomy pain syndrome. Moyse and colleagues reviewed evidence for the efficacy of intravenous and epidural administration of ketamine in acute post-thoracotomy pain management and its effectiveness. They concluded that the majority of randomized controlled trials presently show no role for ketamine in attenuating or preventing post-thoracotomy pain syndrome although there is clear benefit for acute post-thoracotomy pain [66]. There is potential for ketamine to have benefits in reducing chronic postoperative pain, but the optimum treatment duration and dose for different operations have yet to be identified [67].

Lidocaine

Intravenous lidocaine has also been described as an adjuvant in total intravenous anesthetics. It has been described as having analgesic, antihyperalgesic, and anti-inflammatory properties. The mechanism of action and mechanism of analgesia of intravenous lidocaine reveal its potential advantages in a total intravenous anesthetic technique. Intravenous lidocaine infusion in the perioperative period is safe and has clear advantages, such as decreased intraoperative anesthetic requirements, lower pain scores, reduced postoperative analgesic requirements, as well as faster return of bowel function and decreased length of hospital stay [68–75]. The final analgesic action of intravenous lidocaine is a reflection of its multifactorial action. It has been suggested that its central sensitization is secondary to a peripheral antihyperalgesic action on somatic pain and central on neuropathic pain, which result in the blockade of central hyperexcitability. The intravenous dose should not exceed the toxic plasma concentration of 5 microg mL (−1); doses smaller than 5 mg kg (−1), administered slowly (30 min), under monitoring, are considered safe [76]. Its use in thoracic surgery still requires more studies to find its true benefit in this specific population, but the evidence for its use as an adjuvant and part of a total intravenous anesthetic is compelling.

Infusion Systems

Delivery of TIVA is more complicated than that of volatile anesthetics via the lung. While concentrations of volatile anesthetics may be approximated intraoperatively by MAC, the "MAC equivalent" for IV agents, Cp50—the plasma concentration that will prevent a response to a given stimulus in 50% of patients—has not been fully developed for the wide range of IV anesthetics and specific clinical conditions in which they are used.

Traditionally, TIVA has been administered through calculator pumps that deliver a preset dose per unit of time. Dosages are based on recommended minimum infusion rates determined by the drug's manufacturer and titrated to clinical effect through measurement of hemodynamics and subjective patient assessment. However, intravenous agents have a narrow therapeutic window that may be difficult to target and maintain [77]. Additionally, calculator pumps are not capable of adjusting infusion rates in response to the dynamic real-time changes in pharmacodynamics and pharmacokinetics, which can lead to under- or overdosage of the anesthetic. Therefore, computer-controlled IV drug delivery systems, or target-controlled infusion (TCI) systems, have been developed to address the shortcomings of traditional calculator pumps and mimic the convenience, advantages, and familiarity of vaporizers [78].

TCI systems (Fig. 12.1) administer intravenous anesthesia based on real-time pharmacokinetic models, derived from population studies specific for each intravenous agent. These studies consider multiple factors—demographics, altered physiology, or comorbidities—that may influence drug pharmacokinetics. Appropriate administration is accomplished by incorporating a computer program coded with pharmacokinetic models of the selected agent to drive its rate of delivery—a more sensitive and accurate method of controlling concentrations than the constant rate of infusions provided by calculator pumps to achieve steady state. In other words, the practitioner focuses on target concentration, not infusion rate. The computer adjusts infusion rate constantly based on pharmacokinetic simulation of the current serum concentration of anesthetic agent in a particular patient. TCI systems reduce the subjective estimation of TIVA delivery, may deliver more consistent levels of anesthesia, and can automatically tailor the dose of anesthetic to specific phases of the surgery.

While pharmacokinetic models serve as the computational basis for TCI drug delivery, the regimen is based on the method of bolus-elimination-transfer (BET) [79, 80]. The system delivers a bolus (B) to achieve target concentration, compensates for elimination (E) by continuous infusion, and corrects for transfer (T) to peripheral tissues with an exponentially decreasing infusion. The software allows the fine-tuning of anesthetic delivery to target the steep slope of the concentration-effect curve, in which small changes in anesthetic concentration have a relatively large effect. This tuning is accomplished through three approaches: pharmacodynamics, pharmacokinetic, and pharmaceutical [81].

The pharmacodynamic approach examines the response of the body to the anesthetic agent and adjusts delivery as needed to achieve the desired effect. This approach is usually linked with some sort of monitoring device. In contrast, the pharmacokinetic approach focuses on achieving absolute target concentrations, based on known therapeutic windows appropriate for specific anesthetic applications. Drug effect in this approach is not considered. Lastly, the pharmaceutical approach is tied to the short action (favorable pharmacokinetics) of the newer anesthetic agents. Because these agents are short-acting, it is easier to maintain a patient in the steep slope of the concentration-effect curve. If the patient is over-anesthetized, a rapid titration down of anesthetic agent results in a quick correction; if under-anesthetized, a rapid titration up is better controlled, and the patient is unlikely to experience the adverse effects of "overshooting" for a prolonged period.

Because TCI systems work by *estimating* drug concentration in the bloodstream, concerns arise over the accuracy of this estimation and overall performance of TCI. Evaluation of TCI performance depends on four parameters [82]:

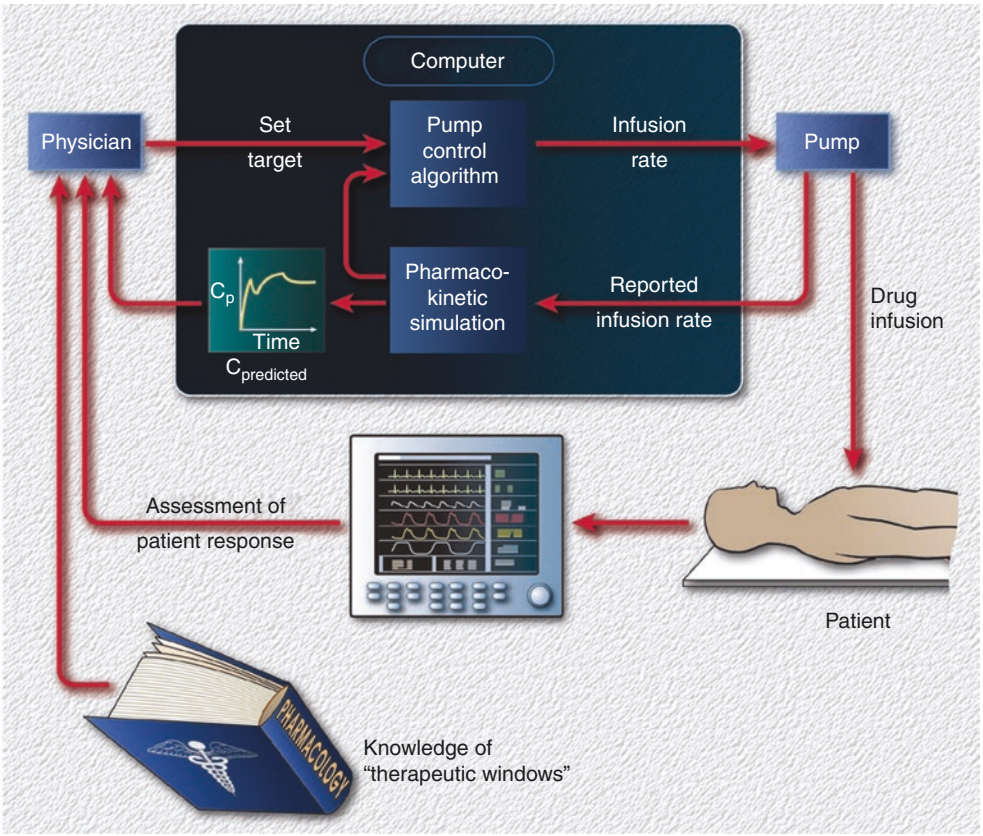

Fig. 12.1 Delivery of intravenous anesthetic agents via target controlled infusion (TCI) The practitioner sets a target for anesthetic concentration based on three pieces of information: knowledge of therapeutic windows for a particular drug, assessment of patient response, and predicted current concentration in the bloodstream (Cpredicted). The TCI computer calculates an infusion rate based on the input target concentration and pharmacokinetic models for the drug. The pump delivers the anesthetic at the calculated rate and reports this rate back to the computer, which uses pharmacokinetic simulation to update Cpredicted. (Adapted from [78], used with permission; adapted from Ron V Purugganan, in the journal *Current Opinion in Anaesthesiology*, published by Wolters Kluwer Health/Lippincott Williams & Wilkins, 2008, Vol. 21, pp 1–7 Reprinted with permission)

- Median absolute performance error (MDAPE): a measure of the accuracy of the TCI system—the median value for how close each estimate is to actual concentration
- Median prediction error (MDPE): a measure of the direction of error of the estimates—whether the system tends to over-administer or under-administer
- Divergence: fluctuation in the difference between estimated and actual concentrations (accuracy) over time
- Wobble: failure to maintain a stable plasma concentration over time.

Typical MDAPE for TCI systems ranges from about 15–30%, while typical MDPE ranges from 3% to 20% (reviewed in [78]). MDPE has been called "clinically acceptable" in the 10–20% range [83].

Research and development for TCI currently focuses on several areas. Among the greatest of these is the fact that TCI targets plasma (not effect-site) concentration. To address this discrepancy, research is focused on further modifying and refining the pharmacokinetic models to take into account effect-site concentration instead of plasma concentration and achieving effect-site control via closed loop systems (e.g., anesthetic depth monitoring) [77, 84]. In the pain management of post-thoracotomy patients, newly developed pharmacokinetic models for TCI patient-controlled analgesia may be an alternative to the standard method of postoperative pain management—thoracic epidural—when it is contraindicated or not feasible [85]. In fact, the greater control offered by TCI may be advantageous in these patients, who are more susceptible to the adverse effects of inadequate or excessive narcotic dosing. Another area of investigation is the use of simulation of drug delivery to compare context-sensitive half-times (CSHTs)—that is, the time required to reduce by half the drug concentration after terminating an infusion at steady state [86].

Although TCI systems are widely available throughout the world, in at least 96 countries, they have yet to be introduced commercially in the United States, the use only for propofol and opioids if using research software in IRB-approved research studies. Because TCI systems inherently

fuse drug and device, the US Food and Drug Administration is uncertain whether to regulate TCI as a drug or a device and has stalled TCI system approval; this regulatory roadblock has, unfortunately, hindered commercial interest in furthering TCI technology for the US market [78, 87, 88].

Anesthetic Depth Monitors

Anesthetic depth monitors analyze and process a patient's spontaneous electroencephalogram (EEG) and/or mid-latency auditory evoked potentials (MLAEP) to gauge hypnotic depth [89]. To date, however, studies have failed to show that anesthetic depth monitors are consistently capable of either detecting intraoperative awareness or distinguishing between consciousness states [90], although anecdotal reports are encouraging. This may be of concern to anesthesia providers who consider TIVA more difficult to administer and worry that the risk of intraoperative awareness may be increased. Many of these providers are less familiar with TIVA administration than volatile anesthetic administration; for instance, they may be less familiar with the concept of Cp50 than with the analogous minimum alveolar concentration for volatile anesthetics. And even with advanced delivery systems such as TCI, direct control of effect-site concentrations is currently not available.

However, an increased risk of intraoperative recall in TIVA has never been documented using the Brice interview [91] (the primary diagnostic structured interview for the assessment of intraoperative recall). Furthermore, the anesthetic depth monitor is more properly used as part of a larger overall clinical assessment scheme. Certainly, in combination with other clinical signs of inadequate hypnosis (themselves nonspecific), anesthetic depth monitors may help in the titration of intravenous anesthesia. This may be particularly important for unstable patients susceptible to the cardiovascular depressant effects associated with moderate to high doses of anesthetic agents [92]. In fact, in a study of non-cardiac surgery patients, mortality was correlated with cumulative deep hypnotic time as measured by bispectral index (BIS) <45 [93].

Methodology

At the University of Texas MD Anderson Cancer Center, our TIVA technique for special thoracic procedures is a balanced technique, which allows for reduced dosages of medications and opioid sparing/reduction. Our regimen consists of midazolam for amnesia, propofol and dexmedetomidine for hypnosis, and ketamine and lidocaine as adjuvants if clinically applicable, and TEA or posterior intercostal block by the surgeon for analgesia, and muscle relaxants for immobilization. Anesthetic depth monitors are used routinely. Our protocol is detailed below; drug dosages are typical (and may be adjusted according to patient variability). Currently, we practice using principles of enhanced recovery after thoracic surgery, which can be found more in depth in the corresponding chapter dedicated to this modality of care.

Premedication and Thoracic Epidural Placement

In the holding area, supplemental oxygen and IV midazolam (0.5–2 mg) are administered. Immediately prior to transport to the operating room by the anesthesia team, a dexmedetomidine infusion (0.2–0.4 mcg/kg/h) is begun. A small bolus of dexmedetomidine (0.1–0.2 mcg/kg) is administered rather than the manufacturer's recommended bolus-loading dose (1 mcg/kg) to minimize the adverse effects associated with dexmedetomidine loading—hypo-/hypertension, bradycardia, and atrial fibrillation [94]. During transport, pulse oximetry and constant communication are used to monitor the patient.

In the operating room, additional monitors (BP cuff and ECG) are applied, and the patient is positioned for thoracic epidural placement. Upon completion of the epidural placement, anesthetic depth monitoring is initiated, and a smooth transition to induction is accomplished by adding a propofol infusion (20–50 mcg/kg/min) and gradually increasing the infusions of dexmedetomidine (to 0.5–0.7 mcg/kg/h). If no epidural is placed, another technique utilized is the posterior intercostal block by the surgery team using liposomal bupivacaine [95].

Induction

Infusions are continued through induction. Hemodynamics, anesthetic depth monitoring, and subjective assessment guide the induction dosing of propofol (10–30 mg) and muscle relaxant to achieve adequate conditions for intubation.

Once the airway is secured, preoperative fiber-optic bronchoscopy is performed to assess airway anatomy. This potentially stimulating time for the patient may be remedied with small boluses of propofol (20–40 mg). In addition, laryngotracheal anesthesia (2% lidocaine) administered prior to bronchoscopy may lessen this response.

Invasive monitors and additional IV access may be placed pre- or post-induction as needed. A dedicated infusion line(s) ensures proper titration of IV anesthetics and prevents incompatibility issues that may arise between different medications.

Upon completion of the initial bronchoscopy, lung isolation devices are placed (if necessary), and the patient is

positioned and prepped for surgery. Epidural narcotics if applicable are administered prior to skin incision, and dexmedetomidine, propofol, and remifentanil/narcotic infusions are adjusted to reflect changes in anesthetic depth monitoring and/or hemodynamics.

Maintenance

Anesthesia is maintained with propofol and dexmedetomidine titrated according to anesthetic depth monitoring and hemodynamics; as stated above ketamine and lidocaine infusions are used as adjuvants if indicated. Muscle relaxants are used if spontaneous ventilation is not required; they are administered by infusion to keep a train-of-four ratio of 0.4–0.5. If necessary, IV antihypertensive (rather than more anesthesia) may be used in situations where sympathetic stimulation is high, yet a sufficient amount of anesthesia is being administered, and anesthetic depth monitoring shows an adequate depth of hypnosis. Administration of local anesthesia via the epidural if in place is usually withheld or administered in dilute concentrations to avoid sympathectomy in patients where strict volume restriction will be followed.

Emergence

In preparation for emergence, a bolus of local anesthesia followed by a constant infusion is administered via the thoracic epidural. At the start of skin closure, propofol is discontinued, and muscle relaxant reversal is administered. The patient is maintained on dexmedetomidine (0.1–0.2 mcg/kg/h) until extubation in order to impart the cardioprotective benefits of alpha-2 agonism: stable hemodynamics and rapid awakening/extubation.

Clinical Case Discussion: TIVA for Thoracic Procedures (Fig. 12.2)

Case A 52-year-old male smoker diagnosed with advanced pulmonary squamous cell carcinoma (stage IV) presents with progressive shortness of breath and orthopnea. Bronchoscopy reveals a distal tracheal mass causing moderate to severe airway obstruction. He is scheduled for rigid bronchoscopy with stent placement to lessen tracheal obstruction. This procedure will be performed in the pulmonary procedure suite.

Questions

1. What are the disadvantages of using volatile anesthetics in this operation?

   For discussion, see section "TIVA in special thoracic surgical conditions" and "Scenarios that benefit from TIVA."
2. What are the advantages of using (1) propofol, (2) dexmedetomidine, (3) remifentinil in this patient?

   For discussion, see section "Intravenous anesthetic agents."
3. What is the basic concept of target controlled infusion, and how is it advantageous over manually controlled infusion?

   For discussion, see section "Infusion systems."

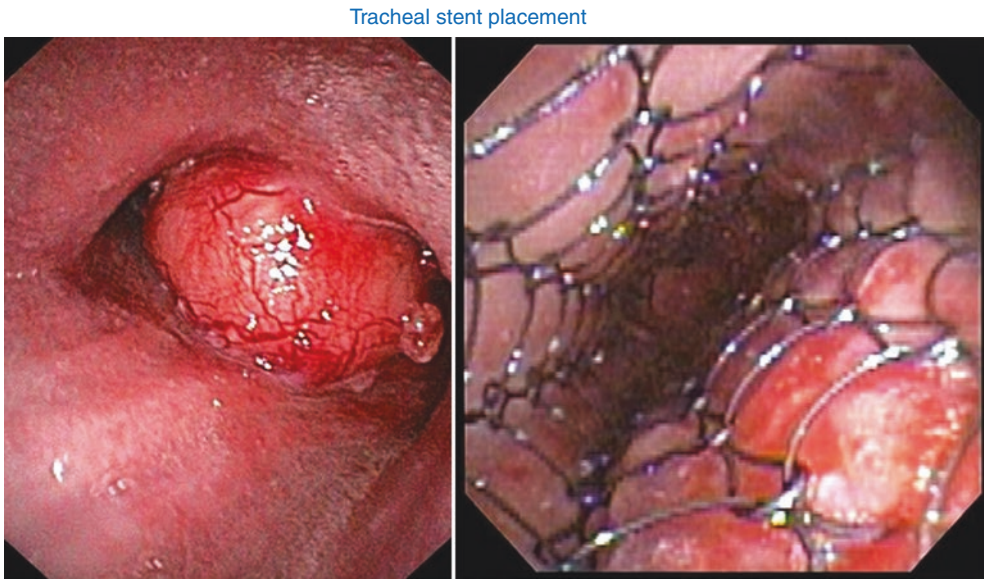

Fig. 12.2 Left: rigid bronchoscopy view of an intratracheal mass obstructing the airway. Right: trachea after stent placement

Tracheal Resection and Reconstruction

13

Karen McRae

Key Points

- The tracheal imaging (CT scan and/or MRI) must be examined by the anesthesiologist to plan the anesthetic management.
- Patients with tracheal stenosis may not become symptomatic until the tracheal diameter is narrowed to <50% of normal.
- Initial surgical management for tracheal stenosis will commonly involve rigid bronchoscopy and dilation.
- The two major methods of distal airway management for resection of tracheal stenosis are cross-field ventilation with an endotracheal tube or jet ventilation with a tracheal catheter.
- Maintenance of anesthesia during the period of tracheal resection is commonly managed with intravenous anesthesia techniques.

Historical Note

Surgery of the conducting airway requires diagnostic and therapeutic manipulation of the respiratory tree despite ongoing ventilation. From the very beginning of tracheal surgery, the greatest challenge facing the anesthesiologist has been how to ventilate the patient adequately before and during airway resection. Close collaboration between anesthesia and surgical colleagues was required. Early reports of tracheal tumor resection by Belsey [1] described reconstruction of the mid-trachea after the intratracheal tube was advanced by the surgeon beyond the tracheal defect. A wire coil was constructed over the cuff of the intratracheal tube, a free graft of fascia covered the wire skeleton, and the intratracheal tube was withdrawn. In 1957 Barclay [2] reported the resection of the carina for a low tracheal tumor with deliberate endobronchial intubation of the left side by the surgeon across the surgical field. The right main stem bronchus was sutured to the remaining trachea, while the left lung was ventilated. Ventilation was then resumed via the orotracheal tube, and the left bronchial was sutured to the right bronchus intermedius during intermittent periods of apnea. In 1963 Grillo and Bendixen [3] described the performance of a similar procedure under critical circumstances, in a patient whose tracheal obstruction had progressed to severe dyspnea and pulmonary hyperinflation. During cross-field ventilation of the left lung, the right pulmonary artery was lightly clamped so that the unventilated lung was not perfused (Fig. 13.1). Elimination of shunt maintained "the best possible tissue oxygenation" permitting an unhurried reconstruction. "The operative requirement for complete anesthetic control during all phases of tracheal surgery is met by the technic of transitory physiologic pneumonectomy." The same group in 1969 reported the anesthetic management of 31 patients who underwent tracheal resection and reconstruction [4]. The problems of anesthetic induction and control of the airway were fully described in a paper first presented at the International Anesthesia Research Society in March 1969. The upper and lower airway management strategies used during a pivotal period of the development of tracheal resection and reconstruction at the Massachusetts General Hospital were elegantly presented. The discussion of the paper at the meeting reveals the increasing appreciation of the etiology of post-intubation stenoses and the clinical dilemmas these injuries presented.

Prolonged incision and complex reconstruction of the airway in patients with compromised pulmonary function have demanded further innovation on the part of anesthesiologists and surgeons. A spectrum of ventilation strategies has been used, not only to maintaining ventilation but to optimize

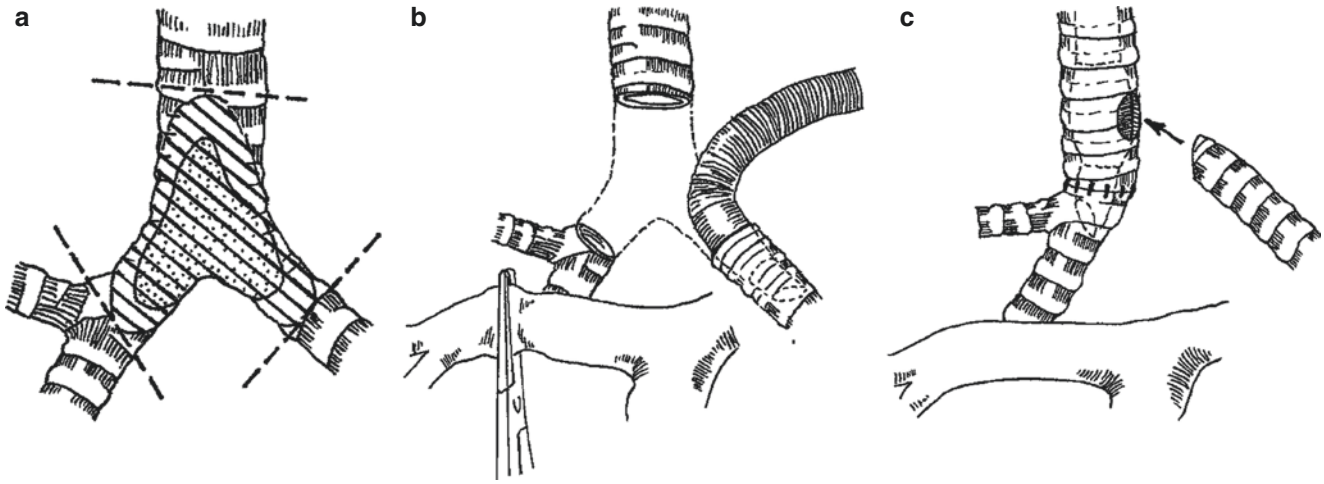

Fig. 13.1 Cross-field ventilation for carinal resection. (**a**) The tumor is at the carina; the patient is intubated with an orotracheal tube (not shown). (**b**) A sterile endobronchial tube is placed across the surgical field after the left main stem bronchus is incised. (**c**) After anastomosis of the right main stem bronchus to the remaining trachea, the cross-field endobronchial tube is removed; the orotracheal tube is advanced into a right endobronchial position, during anastomosis of the left main stem bronchus to the trachea. Early descriptions of this technique included snaring of the right pulmonary artery during (**b**) to minimize shunt during one-lung ventilation (as shown here); this was later deemed unnecessary in most cases. (Adapted from Ref. [3])

operating conditions. Evidence of the success of this evolving collaboration lies in the large series of successful procedures reported.

Etiology of Tracheal Lesions

The trachea, carina, and major bronchi may be affected by a variety of conditions that are amenable to surgical resection and reconstruction. Airway lesions can be a result of benign or malignant etiologies (Table 13.1) and may or may not result in significant stenosis. Congenital stenosis is typically resected during infancy, after presentation in the first few months of life. In adults many cases of subglottic stenosis are idiopathic; frequently patients have increasing respiratory symptoms for many years, often incorrectly attributed to asthma. Post-intubation injury is the most common cause of benign tracheal stenosis despite the widespread use of high-volume, low-pressure cuffs. Posterior glottic stenosis and circumferential subglottic stenosis are the result of direct trauma from the tube and the cuff, respectively. This results in mucosal ulceration; subsequently the exposed tracheal cartilage is devitalized and disappears, followed by replacement of the tracheal wall with scar tissue [5]. Mucosal injury leading to ulceration has been observed after as little as 2–3 h of intubation with a high-volume low-pressure cuff in a subgroup of patients who received standard anesthesia care [6]. After extubation most lesions heal as a fibrous scar; however some lesions develop malacic components. Post-intubation strictures typically show concentric narrowing, whereas post-tracheotomy stomal strictures tend to result in more side-to-side rather than

Table 13.1 Etiology of tracheal lesions amenable to resection and reconstruction

Benign lesions
Congenital
Tracheal atresia
Congenital stenosis
Congenital chondromalacia
Vascular rings
Idiopathic
Post-intubation or post-tracheotomy injury
Posterior glottic stenosis
Subglottic stenosis (including cuff injuries)
Tracheoinnominate artery fistula (anterior trachea)
Tracheoesophageal fistula (posterior trachea)
Stomal stenosis (from tracheotomy)
Trauma
Inflammatory
Wegener's granulomatosis
Postinfection (after treatment)
Tuberculosis

Secondary malignancies
Bronchogenic carcinoma
Thyroid carcinoma
Laryngeal carcinoma
Esophageal carcinoma

anteroposterior narrowing. Penetrating or blunt trauma may cause life-threatening tracheal disruption or, if less severe and unrecognized, may present later as stenosis [7]. A variety of inflammatory diseases can cause airway stenosis; however due to widespread involvement of the airway, few are considered suitable for surgical resection. Most inflammatory lesions are therefore treated with chronic tracheostomy, intermittent dilation, or stenting. A notable exception is Wegener's granulomatosis, which can produce focal stenosis amenable to resection. Postinfectious stenotic lesions may be resected after treatment of the underlying infection. Tracheal resection is performed for primary malignancies unless metastases preclude curative surgery; secondary neoplasms invading the trachea typically arise from the adjacent structures and are less often amenable to surgical resection. When curative resection is not possible, many patients are treated with palliative endoscopic debridement. Similarly, endoluminal metastases which are the result of hematogenous spread from distant malignancies (including breast, colon and renal cell carcinomas, and melanoma) are typically debrided or stented.

Planning Tracheal Surgery

Planning is essential in these challenging and varied procedures and should be clearly outlined in the preoperative interdisciplinary checklist (Table 13.2). A number of elements are required, starting with a clear understanding of the patient's tracheal anatomy and the resection proposed. A detailed plan for ventilation throughout induction, during the period of open airway and on emergence, must be clear to the anesthesia and surgical teams. Appropriate airway equipment should be assembled and tested to ensure that it is in good working order including rigid bronchoscopes of a variety of diameters and a way of ventilation through a bronchoscope. A supraglottic airway device usually a laryngeal mask airway (LMA) should be available, as well as endotracheal tubes in a range of sizes to be placed orotracheally or into the distal airway by the surgeon. If cross-field intubation is anticipated, sterile endotracheal tubes and a sterile breathing circuit are needed.

Analgesia
Emergence, airway configuration at the end of the case

Fundamental questions in planning a case include whether there is airway stenosis, where it lies within the airway, and how small is the residual airway. Glottic and subglottic lesions almost always require dilation by the surgeon at the beginning of the procedure usually with rigid bronchoscopes of increased diameter, although some centers use smooth round dilators. An endotracheal tube may be then be placed, although often of a smaller size than would usually be used. If the lesion is in the mid-trachea or lower, and the lumen is adequate, an endotracheal tube may be placed above the lesion, without prior dilatation. The anesthetic technique has influenced the chosen mode of ventilation. Anesthetic agents with rapid onset and short duration permit a deep plane of general anesthesia with prompt recovery and resumption of spontaneous ventilation necessary to successful extubation of patients with compromised airway anatomy. A crucial decision is when it is appropriate to suppress the patient's spontaneous breathing and conversion to controlled techniques. In some centers it is preferred to secure the airway each time with an inhalational induction, maintenance of spontaneous ventilation, and avoidance of muscle relaxants until the initial airway is established. Most airway resections are performed in centers with experienced surgical and anesthesia teams. In many circumstances it is suitable to induce general anesthesia with intravenous agents and give muscle relaxant prior to rigid bronchoscopy, dilation, or laser resection of the airway in preparation for definitive resection. This is particularly true of patients who have had a recent, uneventful rigid bronchoscopy as part of their preoperative care.

Many experienced clinical groups recommend a staged approach which starts with cautious fiberoptic bronchoscopy, after airway topicalization in the awake, spontaneously breathing patient. This permits evaluation of vocal cord function and for any malacic segments. This is often followed by rigid bronchoscopy under general anesthesia to dilate stenosis or debride obstructing tumor from the airway. The rigid bronchoscope is also the best tool to measure the position and length of the lesion in the trachea. The following measurements are made relative to the patient's upper incisors: the carina, the distal and proximal ends of the lesion, and the vocal cords. This permits an estimate of both the length of the lesion and the remaining trachea available for reconstruction. The airway can be temporarily improved in the vast majority of patients allowing patient optimization for the definitive resection, to ensure that any bronchospasm and pulmonary infections are reversed, and weaning of steroids if needed.

Excellent analgesia is required to optimize the chances of prompt extubation and is planned according to the incision required by the resection. Postoperative positive pressure ventilation is undesirable as pressure on new anastomoses increase the risk of airway dehiscence.

Tracheal Anatomy and Surgical Management

The position of the lesion within the trachea will determine the site of incision and the extent of trachea requiring resection. This is often described by the number of tracheal rings removed. Using cadaver studies, Grillo investigated how much of the trachea could be removed with end-to-end reconstruction without causing undue tension or compromise of the blood supply. He determined that a median length of 4.5 cm was achievable, equivalent to seven rings [8]. The blood supply to the upper trachea is predominantly from the inferior thyroid artery, whereas the lower trachea and carina are supplied by the bronchial arteries [9]. The blood supply enters the walls of the trachea laterally in a segmental fashion; therefore the trachea is best mobilized with anterior and posterior dissection to prevent devascularization.

Knowledge of the location of the tracheal lesion and the proposed extent of airway resection are essential for planning the induction of anesthesia and the maintenance of oxygenation and ventilation. Additionally, the position of the lesion will determine the incision required and the patient position.

The Subglottis and Upper Trachea

Resection of the subglottis and upper third of the trachea may be accomplished via a collar (cervical) incision with the neck fully extended and a bolster placed behind the scapulae. The subglottic airway extends from just below the vocal cords to the lower border of the cricoid cartilage. Post-intubation stenosis is the most common cause of subglottic stenosis. Complete transection of the subglottic airway will divide the recurrent laryngeal nerves; resection is therefore modified to preserve the posterior shell of the cricoid cartilage in order to protect the entry point of these nerves [10]. Most post-intubation strictures involve relatively short segments, between 1 and 4 cm, and can be managed by segmental resection and reconstruction with a primary anastomosis. Malignancies may require more extensive resection including concomitant laryngectomy.

Prolonged trans-laryngeal intubation frequently results in synchronous laryngotracheal injury. The most common glottic injury is a posterior inter-arytenoid stenosis, which restricts vocal cord movement. These combined injuries require simultaneous high tracheal resection and laryngofissure, with excision of the inter-arytenoid scar. When the subglottic anastomosis lies within a few millimeters of the vocal cords, there is significant risk of glottic edema. A Montgomery T-tube (Fig. 13.2) is placed to support the airway and left in place several months to minimize restenosis. The T-tube is a cylindrical silicone stent with a perpendicular limb which is positioned in a small tracheostomy which makes it unlikely to become dislodged or migrate [11]. Following laryngotracheoplasty the upper limb of the silicone stent lies 0.5–1.0 cm above the cords. In cases of stenotic or malacic segments of the cervical trachea without laryngeal injury, a T-tube may be left in place with the upper limb of the T-tube that is positioned below the cords, allowing for voice preservation.

Head flexion during primary anastomosis delivers the cervical trachea into the mediastinum to facilitate re-approximation of the edges of the trachea, and if the anastomosis appears to be at risk of being under tension, a guardian stitch is placed after skin closure, between the skin of the chin and the anterior chest and maintained for approximately a week (Fig. 13.2).

Mid-Trachea

A cervico-mediastinal incision is used for tumors of the mid-trachea (Fig. 13.3) and most benign lesions throughout the trachea. The upper trachea is explored through a cervical incision, which is extended via a partial sternotomy to just below the sternal angle, and separated with a pediatric chest spreader. Through this incision the anterior carina and the right and left tracheobronchial angles can be exposed without sacrifice of the innominate vein, artery, or other great vessels. The trachea is then mobilized and incised and distal ventilation is secured. Many surgeons will request for the patient's neck to temporarily be flexed to test the ease with which the tracheal ends will come together. The length of trachea that can be safely incised is influenced by the patient's age, body habitus, pathology, and prior treatment. If it is clear that the anastomosis will be under excessive tension, or a long segment of trachea requires resection, a release maneuver is performed, most often a suprahyoid release. Muscle attachments to superior surface of the hyoid bone and the hyoid bone itself are divided allowing the larynx to drop, adding between 1 and 2 cm of additional mobility to the trachea [12].

The resection of long segments of trachea which cannot be repaired with a primary anastomosis presents a formidable problem and underscores the fact that the trachea is not simply a tube but is an armored structure capable of sustaining cyclical intrathoracic pressures. Historically, prosthetic grafts fail in the long term due to the formation of granulation tissue and fistulas, and while devascularized aortic grafts have been used, they tend to develop malacic components. More promising reconstructive techniques include fasciocutaneous forearm flaps stiffened with C-shaped segments of rib cartilage [13]. Reports of decellularized tracheal allograft repopulated with the recipient's own chondrocytes and airway epithelial cells were recently used to replace the trachea in a small number of patients, by a single lead surgeon [14].

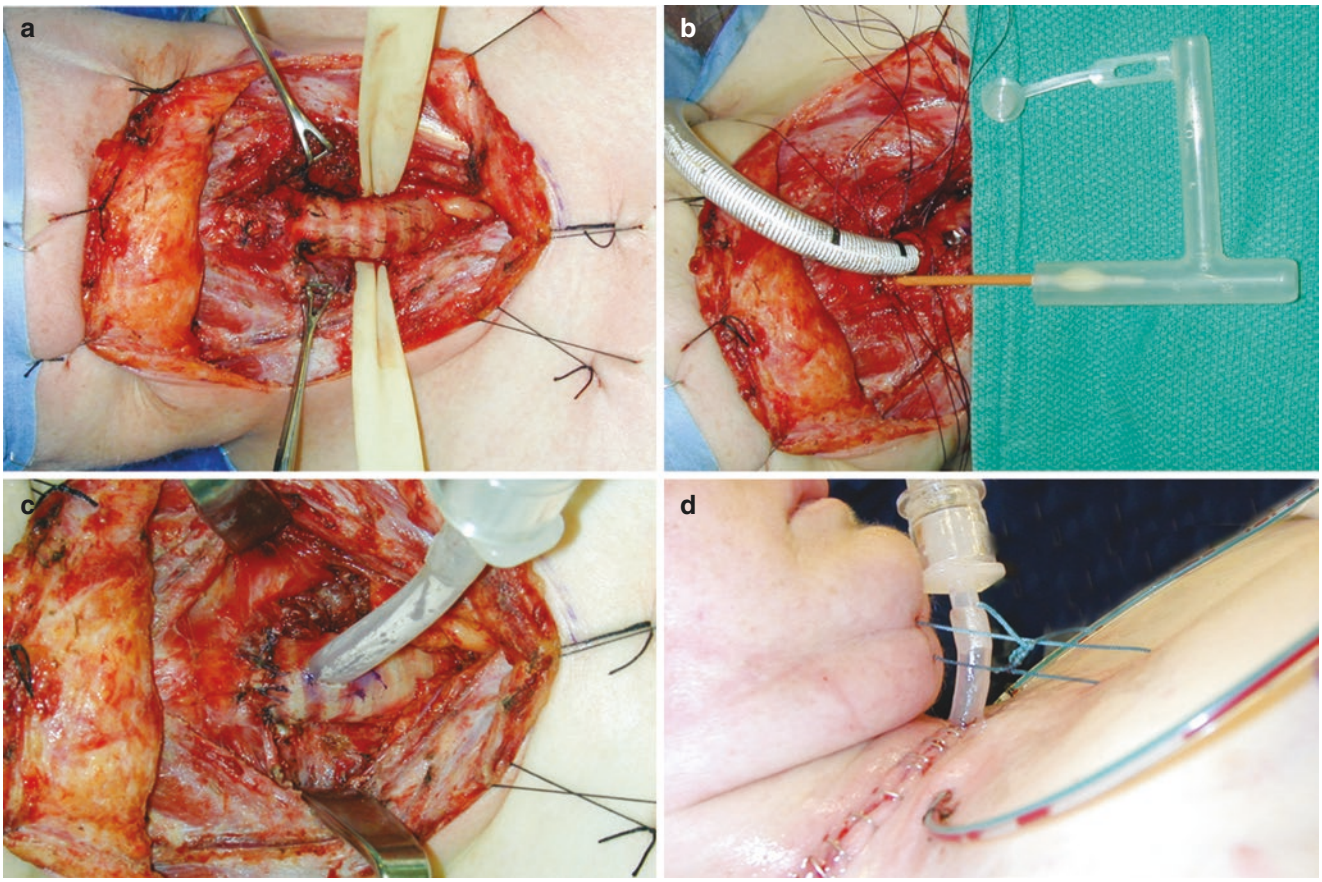

Fig. 13.2 Airway management for high tracheal resection. (**a**) Mobilization of the trachea, the patient's head is to the left of the photograph. (**b**) A sterile cross-field endotracheal tube has been placed in the distal trachea. A Montgomery T-tube will be placed; the balloon of a Fogarty catheter will be inflated to obstruct the proximal limb, to allow ventilation via the distal limb. The Fogarty catheter is passed retrograde through the patient's mouth. (**c**) Ventilation via the Montgomery T-tube external limb during closure of the incision. A standard endotracheal tube connector has been inserted into the external limb of the T-tube. (**d**) Head flexion and the guardian ("chin") stitch. The Fogarty catheter is deflated and removed when spontaneous ventilation is reestablished. The guardian stitch is removed after a week. This clinical experience that has been recently heavily criticized for incomplete reporting of poor long-term outcomes must be considered experimental at this time.

Carinal Resection

The incision depends on the type of carinal resection. Carinal resection without pulmonary parenchymal resection is approached through a full sternotomy. The pericardium is opened anteriorly, and the exposure is facilitated by mobilization of the aorta and both main pulmonary arteries (Fig. 13.4). Tracheal resection is usually limited to less than 4 cm at the carinal level. When there is anastomotic tension, a hilar release is performed with a U-shaped incision of the pericardium, which allows hilar structures to advance by about 2 cm. Laryngeal release is not deemed helpful for carinal resection and a chin stitch is not routinely used. Resection of the carina may be combined with a right or left pneumonectomy or right upper lobe bronchial sleeve resection. Left carinal pneumonectomy may be performed via a sternotomy, a left posterolateral thoracotomy, or clamshell incisions. When all or part of the right lung requires resection, a right posterolateral approach is used. Careful patient selection and optimization are essential to the success of these technically demanding and high-risk surgeries [15].

Patient Characteristics

Idiopathic tracheal stenosis is a diagnosis almost exclusively in females often presenting for resection in their fifth decade of life; many have had progressive symptoms for up to 10 years. At least one third report clinically significant reflux, and at least as many are obese which may be due to their exercise limitation. Patients with post-intubation and post-tracheotomy stenoses have a mean age in their 40s at the time of presentation and not infrequently have diabetes

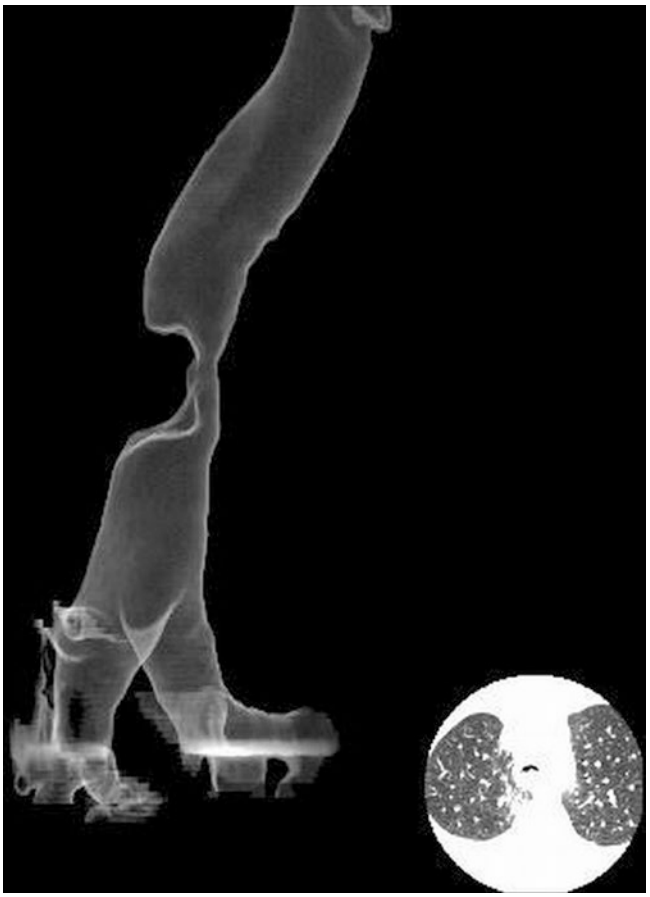

Fig. 13.3 A three-dimensional CT reconstruction of a mid-tracheal tumor. This patient was managed with rigid bronchoscopy and debridement prior to tracheal resection

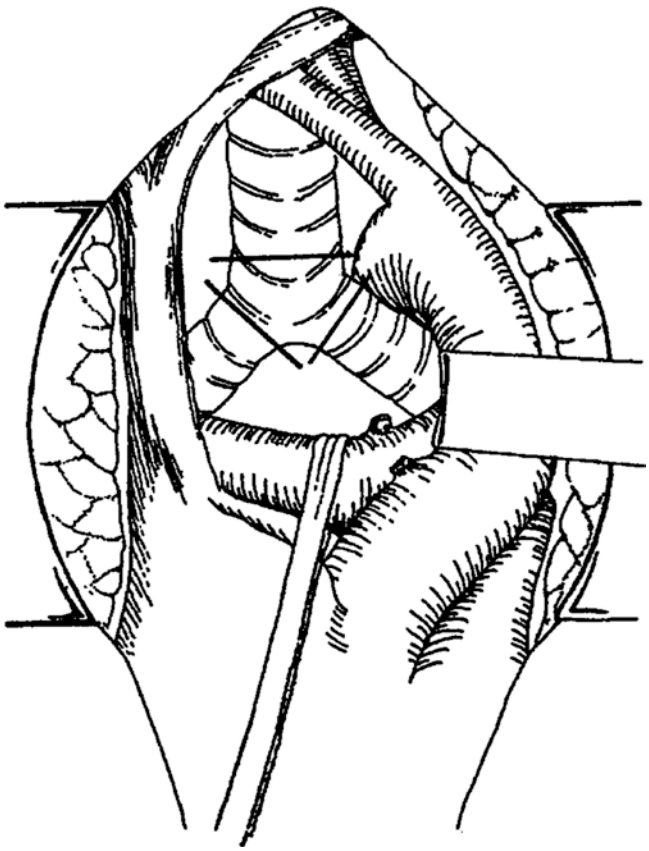

Fig. 13.4 Exposure of the carina via a sternotomy

mellitus, cardiovascular disease, asthma, or chronic obstructive pulmonary disease, all conditions that may have required prior intubation. These comorbidities increase the likelihood of perioperative complications. Patients with tracheal tumors tend to be a decade older, tend less to be diabetic or obese, and are more likely to smoke, with the associated risk of vascular disease. It must be noted that some primary tracheal tumors are not associated with smoking and can present at any age [16].

Most patients are symptomatic, the most common being dyspnea on exertion, but a careful history may reveal orthopnea, a brassy cough, difficulty clearing secretions, and wheezing. Malignant tumors may produce hemoptysis. Patients should be examined for evidence of airway obstruction and the use of accessory muscles or stridor. In adults narrowing of the lumen to less than 50% of its normal cross section results in dyspnea with significant exertion, and narrowing to less than 25% of its normal cross section will usually produce dyspnea and stridor at rest. Stridor is a sign of significant airway obstruction; likely the tracheal diameter is 6 mm or less [17]. These patients are at risk of acute airway obstruction with a mucus plug. Stridor is classically more pronounced in inspiration when stenosis is extra-thoracic; if the lesion is intrathoracic, the stridor may be predominant in expiration, particularly if there is significant malacia. In addition to auscultation of the lungs and trachea, patient's neck mobility should be evaluated.

Preoperative Assessment

The anesthesiologist should review all available information delineating the patient's airway pathology. The chest X-ray may be deceptively normal. A CT scan of the neck and thorax will have typically been performed, with thin cuts along the entire airway. Increasingly three-dimensional images are being constructed from helical CT data. This imaging is helpful in defining the relationship of the lesion to the vocal cords and carina and, as a complement to prior endoscopy, helps in planning airway management.

Pulmonary function tests, including spirometry and flow-volume loops, are usually performed unless the patient is at risk of imminent airway obstruction. Fixed airway stenoses cause limitation of both inspiratory and expiratory flow at similar flowrates. A variable extra-thoracic airway obstruction

limits inspiration much more than exhalation. Conversely, with a variable intrathoracic lesion, the patient is able to inhale reasonably well, but expiratory flow limitation is produced. It should be noted that the quality of flow-volume loops is very much dependent on patient effort. The characteristic findings of expiratory flow limitation may be obscured by small airways disease such as asthma or COPD [18]. The absence of classic spirometric patterns does not predict the absence of pathology, and the presence of findings does not reliably indicate the degree of obstruction. Imaging of the airway is far more useful in planning surgery.

Manipulation of airway and mediastinal structures intraoperatively may provoke a significant sympathoadrenal stress response [19]. Increases in heart rate and both systemic and pulmonary artery pressures are seen and may be prolonged. Myocardial oxygen consumption rises and dysrhythmias may occur. The incidence of myocardial ischemia in older smokers during and after rigid bronchoscopy alone may be as high as 10–15% of patients [20]. Preoperative ECG should be obtained in all patients to assess cardiac rhythm. Patients over 40 with symptoms or significant risk factors for coronary artery disease should be investigated with echocardiography, Persantine-thallium stress testing, and coronary angiography if indicated. Risk stratification is then possible, with appropriate institution of treatment. Cardiac assessment is recommended when carinal resection is required especially when combined with pneumonectomy. If significant coronary artery lesions are identified, the decision to proceed with definitive surgery rather than palliation should be decided on a case-by-case basis. Quantitative ventilation and perfusion scans may be warranted when the resection of considerable lung parenchymal is anticipated [21]. In all patients considered for tracheal resection, the identification and treatment of reversible pulmonary disease are important. Repeated airway dilation or stenting may permit a period of medical optimization of the patient [22]. Smoking cessation is vital, particularly as patients who have undergone airway resection often struggle to mobilize secretions. Postoperative mechanical ventilation is undesirable: the presence of an endotracheal tube may predispose new suture lines to necrosis and dehiscence. Severe respiratory compromise due to parenchymal lung disease or neuromuscular disorder is a serious concern and may preclude tracheal resection [23].

Patient Monitoring

In addition to secure peripheral intravenous access and standard anesthetic monitors, an arterial catheter is placed for continuous blood pressure measurement. When an intrathoracic approach to the trachea is used, many anesthesiologists choose the left side for the radial arterial line; the innominate artery lies anterior to the trachea, and compression or division of this vessel will render inaccurate arterial measurement in the right arm. Arterial cannulation also provides immediate access to blood gas analysis essential during interrupted ventilation, during ventilation with techniques that preclude capnography, and in the event of postoperative respiratory distress. Central venous cannulation may be used if indicated by the proposed surgery (i.e., including a major pulmonary resection) and cardiopulmonary status of the patient. Avoidance of the area of incision must be considered in catheter placement; jugular, subclavian, or antecubital approach may be used. A urinary catheter is placed, even if a simple resection is accomplished quickly; the patient's mobility is often reduced for several days due to postoperative neck flexion. The patient's temperature is monitored and normothermia should be maintained. In the rare instance of cervical exenteration, where elective division of the innominate artery is contemplated, placement of EEG monitoring has been recommended [7].

Ventilation Strategies

Surgical intervention in the airway presents unique ventilation difficulties. Clinicians have devised creative solutions for these challenges, and there has been a proliferation of ventilation techniques applied to the open airway (Table 13.3). Overarching consideration includes adequate gas exchange while minimizing airway occupancy, movement and the spraying of blood, and secretions.

Distal Tracheal Intubation, Intermittent Positive Pressure Ventilation (IPPV)

Early reports of tracheal tumor resection described reconstruction of the trachea after an intratracheal tube was advanced by the surgeon beyond the tracheal defect [1]. Advancement of a full-sized orotracheal tube across the surgical field into the distal trachea or bronchus is an option currently seldom used, as the large diameter obstructs access to the surgical field. Endobronchial tubes are long tubes of reduced diameter, with a small volume and shorter cuff positioned close to the tip. They are favored by some clinicians for certain tracheal resections. They can be positioned in the trachea beyond the lesion under bronchoscopic guidance past a mid-tracheal lesion or placed in the contralateral bronchus when a thoracotomy is required for carinal resection or carinal pneumonectomy. The endobronchial tube's slender profile allows much of the surgery to be accomplished while the tube remains within the tracheal lumen, and distal ventilation is maintained. Alternatively, these tubes can be withdrawn when the airway is opened and distal ventilation

Table 13.3 Characteristics of modes of ventilation during airway surgery

	Able to ventilate open airway	Immobility of operative field	Specialized equipment required	Airway pressure – pressure/ monitoring	Potential for barotrauma	Gas entrainment	Airway gas composition
IPPV	No	No	No	Pressure is dependent on ventilator settings/reliable	Minor	No	Stable, accurate monitoring
LFJV	Yes	No	No	Intermittently high/difficult	Yes, high	Yes	Variable, difficult to monitor
HFJV	Yes	Yes	Yes	Can be high, gas trapping common/difficult, especially around jet nozzle	Yes	Yes	Variable, difficult to monitor
HFPPV	Yes	Yes	Yes	Low peak and mean transpulmonary pressure/ difficult	Yes	Minor	Stable, accurate monitoring

IPPV intermediate positive pressure ventilation, *LFJV* low-frequency jet ventilation, *HFJV* high-frequency jet ventilation, *HFPPV* high-frequency positive pressure ventilation

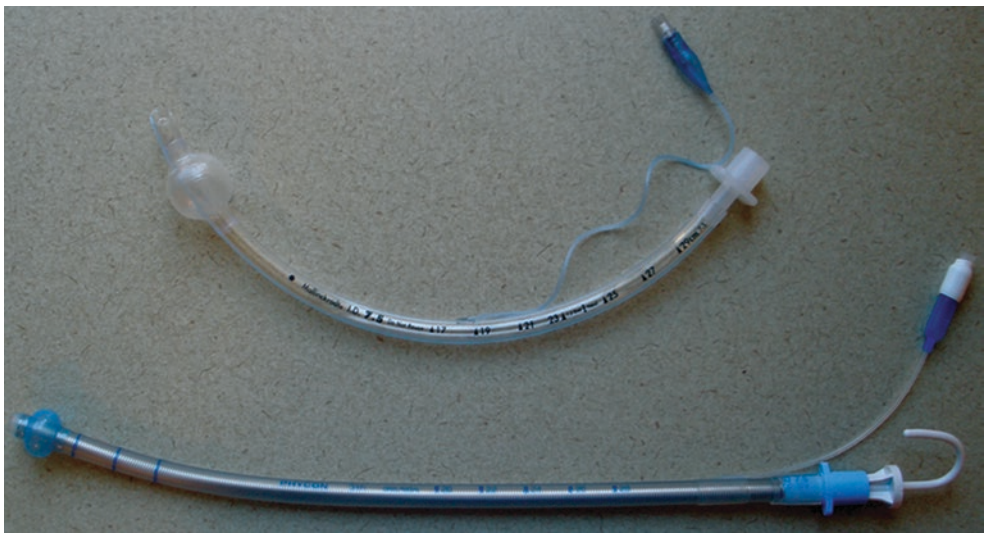

Fig. 13.5 A 7.5 mm ID Phycon endobronchial tube (lower tube) (Fuji Systems, Tokyo, Japan) as compared to a 7.5 mm ID standard endotracheal tube (above). The standard tube is 32 cm long; the armored endobronchial tube is 40 cm and is also available in 5.5 and 6.5 mm ID sizes. Note the small endobronchial cuff size, the lack of both bevel and Murphy eye on the distal end of the endobronchial tube

provided on the surgical field. Drawbacks of these tubes include the frequent air leak that occurs when an endobronchial tube is positioned in the trachea, as the balloon has a relatively small volume.

The cuffs are prone to being ruptured when the trachea is being repaired around its circumference, requiring replacement [24]. A variety of endobronchial cuffs have been described although many are no longer available [25]. In our institution, the Phycon endobronchial tube (Fuji Systems, Tokyo, Japan) is used (Fig. 13.5). The ideal endotracheal tube for tracheal reconstruction has been described as a long, flexible, reinforced tube with a short, low-pressure, high-volume cuff and a short segment beyond the cuff, to allow the ventilation of both lungs through a short tracheal stump without encroachment on the operative site; unfortunately no such endotracheal tube is currently manufactured [26].

The use of cross-field intubation and ventilation of the distal airway was first described for the resection of a low tracheal tumor; the left bronchus was cannulated on the field by the surgeon, while the right main stem bronchus was sutured to the remaining trachea. Ventilation was then resumed via the endotracheal tube and left bronchial anastomosis was performed [2]. Geffin fully described the variations of cross-field ventilation to be used for high and low tracheal lesions [4]. An orotracheal tube is placed, above the lesion. As the airway is divided, the surgeon advances a second, sterile endotracheal tube across the field into the distal trachea (Fig. 13.6). In our institution, when subglottic resection is performed, a sterile reinforced endotracheal tube is inserted in the distal trachea, and the proximal end of the tube is passed by the patient's cheek, under the sterile drapes to be connected to the anesthetic circuit. Resection of the mid- or lower trachea necessitates the use of a second, sterile anesthetic circuit originating from the surgical field, passed over the drapes. Typically, a relatively small endotracheal tube is placed in the distal airway to permit the placement of posterior sutures, while the tube remains in the distal airway, held anterior by the surgeons. After reanastomosis of the posterior trachea, the distal tube is withdrawn; the orotracheal tube is readvanced and is used

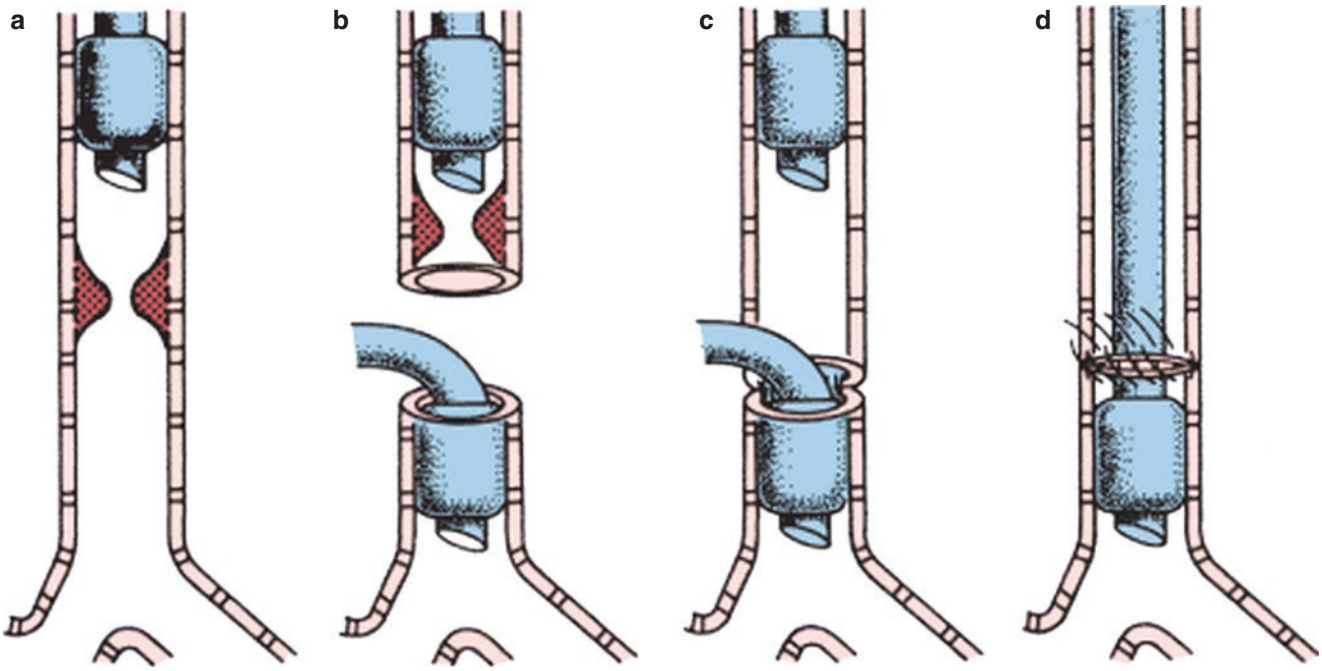

Fig. 13.6 Airway management for resection of a high tracheal lesion. (**a**) Orotracheal intubation above the lesion. (**b**) With tracheal incision, a sterile cross-field endotracheal tube is placed distal to the lesion. (**c**) The posterior wall of the anastomosis is sutured. (**d**) The cross-field endotracheal tube is removed, the orotracheal tube is advanced across the anastomosis, and the anterior anastomosis is completed. (With permission from the Society for Thoracic Surgeons, previously published in [84])

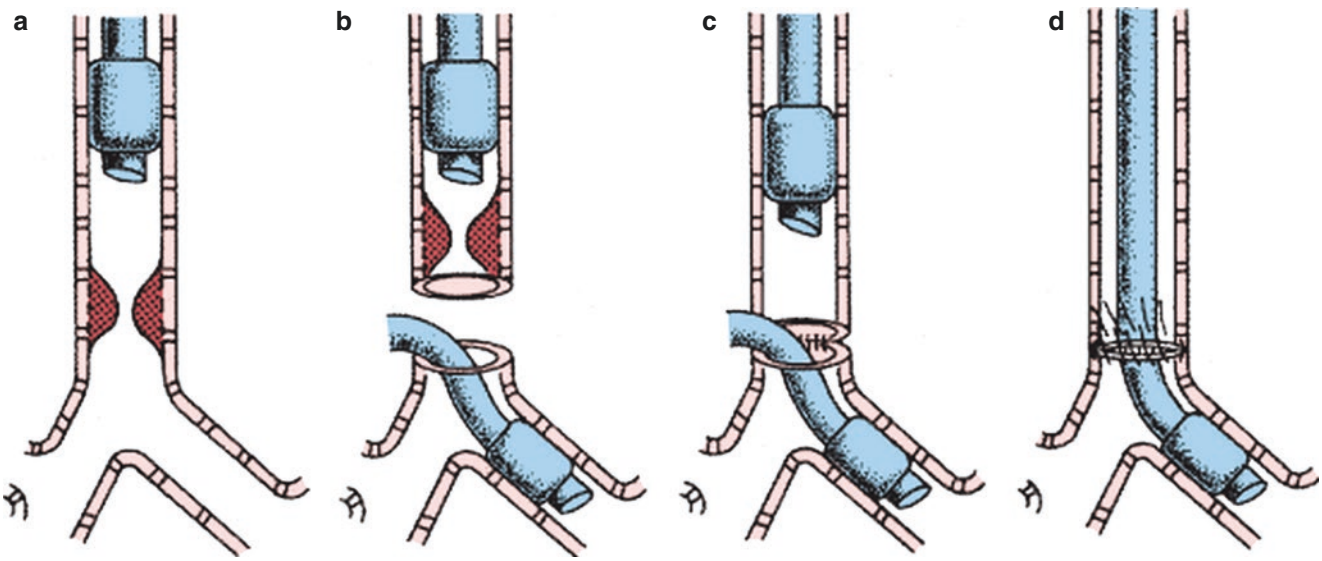

Fig. 13.7 Airway management for resection of a low tracheal lesion. (**a**) Orotracheal intubation above the lesion. (**b**) A sterile cross-field endotracheal tube is placed in the left main stem bronchus. (**c**) The posterior wall of the anastomosis is sutured. (**d**) The cross-field endotracheal tube is removed, the orotracheal tube is advanced across the anastomosis into an endobronchial position, and the anterior anastomosis is completed. (With permission of the Society for Thoracic Surgeons, previously published in [84])

for ventilation. Lower tracheal and carinal resection requires some modification of the technique (Fig. 13.7). The distal tube is advanced into the left main stem bronchus below the lesion. The resected trachea and the right main stem bronchus are anastomosed, the orotracheal tube is advanced through the suture line, and one-lung ventilation to the right side is accomplished, while the left main stem bronchus is anastomosed to the side of the trachea. The orotracheal tube is withdrawn above both suture lines until extubation. This technique necessitates intermittent periods of apnea as surgeons withdraw the distal tracheal tube for better exposure and placement of sutures. Increased

oxygen concentration is used when ventilating (>70%) in order to delay desaturation. Periods of moderate hypercapnia are inevitable but are usually well tolerated. Independent distal cannulation of both bronchi has been described; a variety of endotracheal tubes of different sizes should be available for distal cannulation [27].

Low-Frequency Jet Ventilation (LFJV)

Jet ventilation releases high gas flow through a small orifice, permitting ventilation via laryngoscopes, bronchoscopes, and the open airway with minimal obstruction of the surgical field. Low-frequency jet ventilation (LFJV) is accomplished by the release of gas under high-pressure (50–60 psi) through an orifice (~1 mm) as described by Sanders [28]. A pressure regulator is required to maintain constant flow, and a handheld on-off valve is released intermittently; jet pulses are delivered at a rate of 10–20/min. A distinct advantage of this approach is its simplicity and lack of specialized equipment. The use of lengthy catheters of small caliber, advanced through the orotracheal tube, permits ventilation of distal airways. Physiologic tidal volumes are generated and chest or lung movement is clearly visible.

LFJV with intermittent apnea was first described in tracheal resection in the 1970s [29, 30], and a variation of this technique is still favored by some groups [31]. The use of a narrow lengthy catheter permits ventilation of the distal airway using a device well away from the surgical field; their diameter is unlikely to obstruct surgical access to the airway. The ultimate catheter position varies with the procedure performed. A high tracheal stenosis may not admit a regular size endotracheal tube; jet ventilation via a long small orotracheal tube has been used throughout resection [32]. More often an orotracheal tube is placed above the tracheal lesion, and the narrow ventilation catheter is advanced into the distal airway after incision of the trachea. The use of independent, simultaneous catheter ventilation of each bronchus has been described in carinal resection [33]. Unpredictable tidal volumes are generated using LFJV; they are however sufficiently large to cause disruption of the surgical field, and intermittent apnea is usually required. When high driving pressure (50–60 psi) is used through a narrow catheter, a high flow jet is produced (up to 100 l/min) entraining air, blood, and debris from the field into the distal airway. Blood may spray from the surgical field. When larger ventilation catheters are used, high flows can be maintained with lower driving pressure; air entrainment is reduced, permitting less dilution of the oxygen jet as demonstrated by the high arterial oxygen tensions that can be achieved; longer periods of apnea are therefore possible [30].

High-Frequency Jet Ventilation

High-frequency jet ventilation (HFJV) resembles its low-frequency counterpart in that gas is delivered from a high-pressure gas source via a stiff, small-bore catheter positioned in the airway. Rather than a handheld switch, the jet stream is cut by a high-frequency pneumatic or electronically controlled flow interrupter. As the high-velocity gas jet enters the airway, additional gas is entrained at the jet nozzle, contributing to the delivered tidal volumes which remain small compared to conventional ventilation considerably less than airways dead space [34]. Variables that can be regulated during HFJV include driving pressure, frequency, and inspiratory time, usually set at 20–30% of the cycle. Ventilation rates span 100–400 breaths/min; tidal volumes delivered are 2–5 ml/kg. The mechanical effects of the use of high frequencies are crucial to the understanding of gas transfer in high-frequency ventilation. Increasing the respiratory rate decreases the emptying time of the lung, moderate gas trapping occurs, and the lung is held in a distended state. Peripheral airway pressures have been shown to be continuously positive using all high-frequency techniques with low mean and peak pressures maintained [34–37]. An obvious advantage when ventilating the open airway is that lower peak pressures are generated as compared to conventional ventilation optimizing lung recruitment with much less air leak. The use of low tidal volumes at high respiratory rates produces minimal movement of the operative field, and interruption of ventilation is not required during many procedures. The slender catheters used minimally obstruct the surgical field.

HFJV has been studied in experimental tracheal airway disruption; the gas driving pressure and size of the jet nozzle were shown to be crucial. When a constant driving pressure was used, increased nozzle size was required to maintain gas exchange with increasing air leak; however a larger nozzle used with a smaller air leak resulted in lung overdistension and systemic hypotension [38]. Clinically, increased driving pressure and inspiratory time can result in impedance in expiratory gas flow, gas trapping, development of auto-PEEP, and impaired CO_2 elimination [39].

When HFJV is used in the intensive care unit, the ventilating catheter is advanced through an orotracheal tube; however the optimum position of the catheter tip is the subject of considerable debate [40]. During airway surgery, the ventilating catheter is advanced across a stenosis or surgically created defect; catheter position is therefore dictated by the nature of the procedure. The use of HFJV via a catheter placed through an LMA has been described for the resection of a high tracheal stenosis either with [41] or without addition cross-field IPPV [32]. Catheters may be advanced through an orotracheal tube into the mid- or distal trachea for

Fig. 13.8 The basket tip of the Hunsaker MonJet ventilation catheter. The collapsible basket is designed to center the catheter in the airway and to reduce catheter-whip injuries to the walls of the airway during jet ventilation. The catheter had a second lumen for monitoring distal airway pressure and presence of CO_2

resection of tracheal segments [42, 43], into the distal bronchus for carinal or sleeve resection [42], and bilateral bronchial catheters have been reported in carinal resection in a patient with limited respiratory reserve, when desaturation occurred during HFJV of one lung [44]. These reports emphasize that ventilator frequency and driving pressure must be adjusted to the patient's respiratory compliance and the proportion of lung segments being ventilated at the time.

"Whip motion" of the distal catheter tip possibly causing tracheal laceration and pneumothorax is a concern with all jet catheter ventilation techniques. The Hunsaker jet ventilation catheter (MonJet, Medtronic Xomed, Jacksonville FL) has a distal, collapsible basket-like support to maintain the jet port tip in the center of the airway and reduce whip injuries. It has been used extensively for endoscopic laryngeal surgery and has been used in some centers for airway resection [32] (see Fig. 13.8). A recent review describes commercially available high-frequency ventilators and catheters [45].

High-Frequency Positive Pressure Ventilation (HFPPV)

High-frequency positive pressure ventilation (HFPPV) of small tidal volumes (3–5 ml/kg breaths at 60 breaths/min) may be delivered using a conventional ventilator of low internal volume and negligible internal compliance; known volumes and gas mixtures are delivered. External PEEP may be added and there is little hemodynamic derangement described. HFPPV is applied via an insufflation catheter placed at the tip of an endotracheal tube. An injection catheter with multiple side holes is recommended to both increase turbulence, thereby reducing airway injury from the jet of gas, and to minimize gas entrainment [36]. Eriksson [46] first described tracheal resection using HFPPV with gas delivery via a rigid bronchoscope during examination of the lesion and via a 5 mm diameter insufflation catheter threaded into the distal trachea during resection and anastomosis. El-Baz [47] described the use of HFPPV during complex tracheal reconstruction using a 2 mm insufflation catheter via a Montgomery T-tube. The same type of catheter inserted down the endotracheal tube and across the resected airway for HFPPV during sleeve resection and carinal resection was further reported [48, 49]. Excellent surgical conditions with minimal motion of the field and uninterrupted access to the circumference of the anastomosis were described; continuous outflow of gas through the open bronchus was felt to minimize soiling with blood. Placement of a sterile ventilation catheter in the distal airway across the surgical field has also been used to deliver HFPPV [17]. It should be noted that the use of the high-frequency oscillation ventilation, which is used in intensive care units to treat hypoxia, is not useful for airway surgery due to excessive movement of the airways produced by this modality [37].

Disadvantages of the use of high-frequency techniques include requirement for specialized ventilator equipment and technical difficulty in monitoring ventilation parameters. The variable positioning of ventilation catheters during airway surgery precludes the use of optimal sites for airway pressure monitoring. Peripheral airway pressures may be markedly different from those in the large airways due to gas trapping inherent to the use of high respiratory rates, short expiratory times, and expiratory flow limitation. Delivered breath volumes are nearly impossible to quantify with an open airway; therefore serial blood gas analysis is essential to detect hypoventilation. Provision for humidification of gases must be made for longer procedures to avoid drying of the airway mucosa and desiccation of secretions; this is a particular problem when jet techniques are used. All modes of high-frequency ventilation require that the delivery circuit have minimal compliance. Review of the HFV literature is notable for the variation in devices used in different clinical reports. Many ventilators and breathing circuits are institution specific, having been built in a hospital laboratory. A description of operating conditions is often lacking. Many devices are in fact hybrids, superimposing a high-frequency mode on conventional IPPV or displaying features of two forms of high-frequency ventilation [40]. Similarly, many catheters used for the delivery of high-frequency jet ventilation are either institution specific or intended for other purposes such as urethral catheters or airway suction catheters, for example. There is inherent risk in the use of high flow, high-pressure gas pulses in the airway, even more so when delivered at rapid rates. Catheter position and alignment within the tracheobronchial tree must be known at all times and are made more difficult by

manipulation of the airway during surgery. Free egress of expired gas and adequate expiratory time must be maintained in order to avoid inadvertent hyperinflation and barotrauma. Whereas continuous positive airway pressure is expected in HFV and is beneficial in maintaining lung recruitment, the use of higher ventilation rates and higher volumes may result in occult PEEP [35]. The resulting lung hyperinflation can lead to impedance of venous return and hemodynamic compromise, particularly if the chest is closed. Barotrauma and volutrauma in the form of pneumothorax, pneumomediastinum, and subcutaneous emphysema have been reported with all forms of high-frequency ventilation and with LFJV. The use of not only distal airway pressure monitoring but automatic shut-off mechanisms to prevent further gas flow into the lungs in the event of high airway pressure is recommended [40].

While there are many reports of the adaptation of volatile agent vaporizers for use with high-frequency ventilation [46, 50], this is unnecessary as current practice offers ideal total intravenous anesthetic regimens. The use of short-acting volatile agent using the high flows required of HFV would be wasteful and difficult to scavenge.

Extraordinary Ventilation Strategies

Cardiopulmonary Bypass (CPB) and Extracorporeal Oxygenation (ECMO)

Cardiopulmonary bypass without circulatory arrest was first used for resection of a carinal tumor in 1959 followed by reports of small series in both adults and children [51]. Then as now, systemic anticoagulation required for CPB may introduce formidable problems, notably intrapulmonary hemorrhage [4]. Currently, CPB is considered only under specific circumstances: tracheoplasty of long segments in small children in whom small airway caliber precludes other options [52], combined cardiac and pulmonary procedures for malignant disease in adults [53], the repair of complex tracheobronchial injuries [54], or when tracheal occlusion is imminent from a lesion unlikely to be bypassed by tracheotomy or rigid bronchoscopy [55]. Recently, reports of tracheal reconstruction in pediatric [56] and adult patients [56, 57] using extracorporeal membrane oxygenation (ECMO) have emphasized that this form of lung assist is amenable to peripheral rather than central vascular cannulation and reduced levels of anticoagulation (see also Chap. 27). The practice of performing particularly complex tracheal reconstruction only in centers where extracorporeal support is available can be justified.

Spontaneous Ventilation

A departure from the use of neuromuscular relaxants and positive pressure ventilation are case reports of a small number of patients allowed to breathe spontaneously throughout tracheal resection [58] and tracheoesophageal fistula repair [59]. Total intravenous anesthesia was provided with endotracheal oxygen insufflation. Some aspiration of blood and debris from the surgical field was noted. The reported patients were well oxygenated and stable despite moderate respiratory acidosis; however it is unlikely that patients with significant limitation of pulmonary reserve would tolerate this approach. A pilot study in 20 patients of the feasibility performing upper tracheal resection awake using cervical epidural anesthesia and remifentanil sedation reported that surgical conditions were facilitated by the absence of any tube or catheters within the airway and the opportunity to assess vocal cord motion. The authors did not discuss what they would have done if a patient has suffered complete airway obstruction [60]. Since that time there have been single cases described of upper tracheal resection under cervical plexus block, and VATS assisted mid-tracheal and carinal resection under thoracic epidural block supplemented by vagus nerve block to suppress coughing. All patients received intravenous anesthesia (propofol, remifentanil +/− dexmedetomidine) and had an LMA placed to secure the supraglottic airway, spontaneous breathing oxygen-enriched air. Anesthetic infusions were titrated to electroencephalogram bispectral index. These cases were reported by a multidisciplinary group with an interest and expertise in non-intubated thoracic surgery; they suggest that their approach leads to accelerated recovery. They have developed exclusion criteria for patients unsuitable for the technique. Contingency plans for rescue tracheal intubation were described but not required [61, 62, 63].

Hyperbaric Oxygenation

The use of hyperbaric oxygenation has been reported to supplement differential lung ventilation by conventional and HFV modes when these methods failed in the repair of a large tracheal tear [64]. Hyperbaric conditions enhance oxygen delivery via increased oxygen dissolved in the plasma. This approach requires the performance of surgery within a hyperbaric chamber with compression of the entire surgical team and must be considered experimental.

Anesthesia Induction and Maintenance

Careful questioning of the patient will reveal position-dependent increase in airway obstruction, particularly intolerance to lying supine. Anesthetic induction may be performed in a sitting or semi-sitting position. Any difficulty encountered at previous intubation or bronchoscopy should be known to the team. All team members should be present. A clear, coordinated plan is required and ongoing communication is essential. All equipment anticipated for airway management should be ready and confirmed to be working.

When there is little or no tracheal obstruction, the induction of anesthesia, neuromuscular relaxation, and intubation is performed as per the anesthesiologist's usual practice. In the presence of significant airway obstruction or stenosis, induction is followed by rigid bronchoscopy, dilation of tracheal stenosis, or debridement of tumor prior to placement of an orotracheal tube. A variety of anesthetic strategies have been described including airway topicalization and awake intubation, inhalational induction with volatile anesthetics, and intravenous induction agents with and without the use of neuromuscular relaxants [23]. Awake intubation is of questionable value in this circumstance; in patients with high stenosis, endotracheal tube placement is not possible, and in those with lower lesions, the tube must shortly be removed for rigid bronchoscopy after the induction of general anesthesia. When an inhalation induction is chosen, currently sevoflurane is most often used. Complete preoxygenation/denitrogenation will take more than the usual time, often more than 5 min, due to restriction of tidal volumes. In the setting of airway compromise, inhalation induction with a slowly increasing concentration of a volatile anesthetic in 100% oxygen will also take increased time. Patients often require some ongoing continuous positive airway pressure via the anesthetic circuit to maintain even modest tidal volumes. When a deep plane of anesthesia is achieved, a local anesthetic (often lidocaine) is applied to the vocal cords and upper airway prior to instrumentation. While this approach attempts to maintain the ability to turn off the anesthetic and to wake up the patient if difficulties are encountered, it is not without drawbacks. The decision to attempt airway dilation without the use of relaxant may make placement of the rigid bronchoscope considerably more difficult. Coughing can result in profound desaturation. If the patient forcefully breathes against a nearly obstructed airway as a very small bronchoscope fills the remaining lumen, the patient is put at risk of negative-pressure pulmonary edema. Another option after inhalation induction is to use a rapid-acting muscle relaxant (such as succinylcholine) to facilitate the introduction of the bronchoscope. Intravenous induction of anesthesia, with the use of short- or intermediate-acting muscle relaxant to facilitate rigid bronchoscopy, is described in many reports and is particularly appropriate when prior rigid bronchoscopy has been uneventful. This is the approach most often used in the author's center. Spirometric studies before and after the induction of anesthesia in patients undergoing upper tracheal reconstruction surgery showed that intravenous induction of anesthesia with muscle relaxation, placement of a LMA, and initiation of IPPV resulted in improvement in airflow across even severe intraluminal, extra-thoracic stenosis as compared to the patients' awake spontaneous efforts [65]. However it is clear that the decision of what induction agent to use and when to give muscle relaxant and control the patient's ventilation must be made by the anesthesiologist and surgeon based on their assessment of the patient and their level of experience.

The sympathetic response to airway instrumentation may be reduced by the use of intravenous lidocaine (1–1.5 mg/kg) bolus prior to induction. The intravenous induction may be with propofol or a combination of propofol and an opioid; fentanyl or remifentanil infusion is frequently used. Another choice of induction agent is ketamine, an *N*-methyl-D-aspartate receptor antagonist that produces dissociative anesthesia. Ketamine depresses ventilation less than many other sedative or general anesthetic drugs. It has the additional advantage of having bronchodilator and sympathomimetic effects and may contribute to the prevention of post-incisional pain. After induction patient may be mask ventilated until the introduction of the rigid bronchoscope, or a laryngeal mask airway may be placed. When the tracheal obstruction is relieved, the trachea is intubated and positive pressure ventilation usually instituted, a dose of an intermediate-acting muscle relaxant is usually given, and provision is made for ventilation during the period of open airway.

Anesthesia may be maintained with an inhalational agent while the trachea is intact, but during cross-field ventilation, where there are frequent periods where the endotracheal tube is out of the airway and the inhaled anesthetic is not delivered to the patient. Many anesthesiologists will convert to a total intravenous technique with propofol and an opioid, often a remifentanil infusion. Similarly, intravenous anesthesia is used when high-frequency jet ventilation techniques are required. The α-2 adrenergic agonist dexmedetomidine has several desirable properties for sedation while securing a critically compromised airway including anxiolysis, analgesia, and amnesia with minimal respiratory depression [66]. It is likely the sole intravenous agent that can replace inhalational induction when a spontaneous breathing technique is chosen for airway manipulation and may prove to be particularly useful in obese patients [67]. Dexmedetomidine may facilitate controlled emergence and has been used as a prolonged infusion for patients requiring a few days of mechanical support following tracheal reconstruction [68].

Reconstruction of the Airway

When the airway is open, the surgeon is able to manipulate the endotracheal tube within the trachea. During distal cross-field ventilation, in order to easily retrieve the distal tip of the orotracheal tube, the surgeon may affix a suture to the Murphy eye which remains in the surgical field and can be used to reposition the orotracheal tube. If the orotracheal tube is damaged, specifically if the cuff is ruptured, it may be replaced if the trachea is still open. After removal of the connector of the new tube, the surgeon can insert the pilot balloon within the lumen tube and pass the tube retrograde up

the trachea into the oropharynx where it is retrieved by the anesthesiologist. During airway reconstruction, the use of uncut endotracheal tubes is recommended, as positioning distal to surgical anastomoses is frequently required. When the airway is closed, conventional positive pressure ventilation through the orotracheal tube is resumed.

When a Montgomery T-tube is left in the trachea, there are several ways to maintain ventilation. An inflated Fogarty catheter can remain in the proximal limb, while positive pressure ventilation is provided by the tracheotomy limb. This can be facilitated by the use of a multiport ventilation of the type used for insertion of a bronchial blocker. The multiport adaptor is connected to the tracheal limb of the T-tube via an endotracheal tube connector (from a 5.0 or 6.0 endotracheal tube), and the Fogarty catheter is placed in the proximal limb of the Montgomery T-tube via the side port [69]. Alternately, the surgeon will fit a small (usually 6.0 mm) endotracheal tube into the proximal limb. This press fit permits positive pressure ventilation via the proximal limb with the tracheotomy limb corked. With spontaneous ventilation reestablished, the endotracheal tube is removed by steady traction while the surgeon maintains the position of the T-tube with a clamp.

In upper and mid-tracheal resections, the head is flexed as the anastomosis is created to reduce anastomotic tension. The guardian stitch is placed after skin closure, between the skin of the chin and the anterior chest (Fig. 13.2d). Patients should be warned of this positioning that their head will be flexed at the time of emergence, and all efforts should be made to maintain the flexed position during the postoperative period to avoid traction on the new repair.

Emergence After Airway Surgery

The resumption of sustained spontaneous ventilation is highly desirable. Prompt extubation is a priority after airway reconstruction to avoid positive pressure or endotracheal tube cuff trauma to the new anastomosis, which might predispose to dehiscence. Most patients breathe more comfortably in a sitting position, removing the weight of abdominal contents from the diaphragm and increasing the patient's functional lung capacity. The oropharynx is thoroughly suctioned, neuromuscular blockade is fully reversed, and the patient is extubated when awake, able to maintain patency of their upper airway and to mobilize secretions. Intravenous anesthesia by infusion for the final stages of the procedure is useful, which permits rapid emergence to a wakeful state without agitation in most cases. It is important to avoid abrupt neck extension with possible traction injury to the anastomosis. The patient should be warned in advance of the need to maintain head flexion and the presence of the guardian stitch. Alternatively, the tracheal may be extubated when the patient is still anesthetized, breathing spontaneously, and a laryngeal mask placed. This permits fiber-optic bronchoscopy and assessment of both the anastomosis and vocal cord function. Emergence with the LMA in place provokes minimal airway irritation and coughing; the patient will often atraumatically remove the device themselves. A drawback of this approach is that the laryngeal mask is not always easily seated in the supraglottis; this technique is best reserved for patients who were easy to bag-mask ventilate.

Maintenance of normothermia is important; shivering increases oxygen consumption, which is particularly problematic if the patient's airway is compromised. Humidification of inhaled gases minimizes the inspissated airway secretions.

Re-intubation after tracheal reconstruction may be difficult. After subglottic resection the patient's neck may be positioned in extreme flexion, the airway may be edematous and bloody, and there is potential for mechanical injury to new anastomosis. If required, endotracheal tube repositioning is best accomplished under direct vision with a fiber-optic bronchoscope. When an airway stent is left in place, the trachea should not be blindly intubated from above. Telescoping of a small endotracheal tube into the stent may be possible using a bronchoscope. This technique should be applied with great care when a self-expanding metal stent has been placed for airway stenosis; the stents require several hours to completely expand. Insertion of an endotracheal tube may distort or dislodge the stent, especially if the balloon cuff becomes snagged. An LMA may be positioned above the stented airway, particularly if a short period of ventilatory assistance is required, to facilitate emergence from anesthesia. The airway with a Montgomery T-tube can be ventilated in several ways. The side arm protruding via a tracheal stoma will accommodate an endotracheal tube connector (from a 5.0 to 6.0 mm ETT), permitting connection to standard ventilation circuits. If positive pressure is required, the open upper limb must be obstructed to prevent loss of ventilating gas. The patient's mouth and nose may be manually held shut, packing may be placed in the pharynx, or a bronchial blocker or an embolectomy catheter (Fogarty #14) may be directed into to upper limb via the side arm of the stent and the balloon inflated [70]. Low-frequency jet ventilation may also be initiated via the side arm [71].

Immediate Postoperative Complications Specific to Airway Surgery

In all surgical patients, residual anesthetics, analgesics, and neuromuscular blockade may contribute to hypoventilation, atelectasis, and poor mobilization of secretions, leading to postoperative respiratory compromise. Additional pulmonary complications may be a direct result of surgery to the

airway. Airway obstruction should be suspected if the patient is in respiratory distress particularly if stridor is evident. Prior to emergence the tracheobronchial tree should be examined and any residual blood in the airway should be carefully removed; despite this, bleeding may be ongoing, or old clot may be mobilized from the lung periphery. Airway caliber may be further compromised by edema. Diuresis and steroids are used empirically; however controlled studies of their use in airway surgery are entirely lacking. Dexamethasone is frequently chosen for its long duration of action; however several hours may be required after dosing (4–10 mg intravenously) for edema to subside. For many years, nebulized racemic epinephrine has been recommended for treatment of post-intubation edema. The racemic form which is an equal mixture of the dextro- and levo-isomers of epinephrine is increasingly unavailable. The more commonly available 1% levo-epinephrine is proposed to be equally effective. In our institution, 5 ml of 1:1000 epinephrine is administered by nebulizer unless limited by tachycardia. Helium and oxygen mixtures provided by non-rebreathing facemask may permit increased ventilation in patients with narrowed conducting airway and are useful as a supportive measure while definitive therapy is pursued. Breathing with airway obstruction may be viewed as breathing through an orifice, which creates turbulent flow. Under turbulent conditions, gas flow varies with inverse square root of density. The low density of helium permits a 1.5 fold increase in relative flow of the commercially available heliox (70% helium/30% oxygen) over air and oxygen mixtures [72]. The high helium fraction required to significantly reduce the work of breathing precludes a high delivered oxygen concentrations which may be undesirable if the patient has low oxygen saturation. When airway compromise is refractory to medical therapy, reintubation may be required.

Pulmonary parenchymal injury may occur. In a review of cases of pulmonary edema associated with airway obstruction after surgery, more than 20% of cases were in adults that were being treated for airway tumor [73]. Spontaneous inspiratory efforts against an obstructed upper airway result in marked negative intrapleural and transpulmonary pressures, causing edema formation, usually within minutes. Laryngospasm is a frequent precursor. Bronchoscopic findings include pink frothy secretions and punctate hemorrhagic lesions throughout tracheobronchial tree [74]. Treatment is supportive and includes re-establishment of airway patency, oxygen supplementation, and diuresis; 85% of patients require reintubation, usually of short duration [73].

Pulmonary aspiration of acidic stomach contents is a particular concern during and after airway surgery where the trachea is not consistently protected by an endotracheal tube. Aspiration may occur at the time of airway manipulation or after completion of the airway procedure. Patients with newly placed T-tubes may have difficulty closing their glottis. Laryngeal dysfunction can occur after suprahyoid release but is less common than after previously used thyrohyoid release procedures [74]. Swallowing dysfunction usually improves after a few days. Recurrent laryngeal nerve paralysis is possible after tracheal surgery [16]. Chemoprophylaxis with antacids, H2 blockers, and gastric propulsants remains unproven in the prevention of the secondary lung injury of acid aspiration. Once aspiration has occured treatment is supportive: bronchoscopy for removal of particulate matter and ventilation with positive end-expiratory pressure if indicated.

Tracheal Procedures with Specific Considerations

Two clinical scenarios present the challenge of a pre-existing defect in the trachea prior to the induction of anesthesia: traumatic injury to the airway and tracheoesophageal fistula.

Airway Trauma

Iatrogenic airway injury may occur during airway instrumentation, most often the posterior membranous portion of the trachea. This may occur during intubation with a single-lumen endotracheal tube or advancement of a bougie, bronchoscope, or other inflexible devices. Injury during placement of a double-lumen tube is most frequently located in the membranous trachea near the carina. If not noted intraoperatively, most injuries become apparent immediately after extubation. While small tears may be managed conservatively, urgent repair is required when significant clinical manifestations hemoptysis, dyspnea, or pneumomediastinum or if bronchoscopic examination reveals gaping of the edges of the tear during respiratory flow. Repair of injuries in the upper trachea may be possible via an extended cervicotomy, whereas thoracotomy is required for tears that extend lower in the airway [75]. Preoperative assessment is limited by the urgency of the procedure. Pulmonary function testing with spirometry is contraindicated as positive airway pressure will increase subcutaneous emphysema. Intubation of the patient for surgery is best accomplished under bronchoscopic guidance while the patient is breathing spontaneously, either awake with upper airway topicalization or after inhalation induction, until the lesion is bypassed. When a transtracheal approach is used, the surgeon will make an anterior tracheotomy and pass a small endotracheal tube distally to be used intermittently for ventilation. The repair is performed during periods of apnea when the cross-field tube is withdrawn. Repairs via thoracotomy may be repaired with a small diameter single-lumen endobronchial tube guided under direct vision to the side contralateral to the tear.

A double-lumen tube may be used but has a larger diameter which may make placement more difficult and may impede the surgical repair.

Injury to the conducting airways may be a result of blunt or penetrating trauma; often other injuries are present. Respiratory distress and subcutaneous emphysema are the most common physical findings [76]. Approximately 6% of penetrating neck injuries involve tracheal trauma as compared to less than 1% of patients with penetrating chest injuries. Most patients with blunt trauma severe enough to cause a tracheal tear do not survive long enough to present to the hospital. But in those who do, cervical spine injury is common and must be considered in securing the airway. The disruption of the trachea is most likely to occur within 2 cm of the carina. Airway control beyond the injury is required, and intubation with the aid of fiber-optic bronchoscopy in the spontaneously ventilating awake patient is recommended both to inspect the injury and to secure ventilation. When lower airway injury is identified, endobronchial intubation of side contralateral to the injury may be desirable. Trauma cases are particularly fraught with technical difficulties, patient agitation, and competing medical concerns. If the initial plan for securing the airway fails, an alternate plan should be identified. A surgical tracheostomy is useful in injuries of the cervical trachea, but if the tear is intrathoracic, then it is of no value. Cardiopulmonary bypass via femoral cannula has been described to provide lifesaving oxygenation and ventilation in such scenarios but is certainly not available in all trauma centers and has the significant drawback of the requirement for full anticoagulation of a polytrauma patient [77]. ECMO has been described for multiday support for both conservative treatment of airway trauma and for surgical repair [78] (see also Chap. 27).

Tracheoesophageal Fistula

Congenital TE fistula is recognized in the neonatal period; adults may acquire such a lesion from trauma, neoplasia, or radiotherapy of the trachea. In cases of TE fistula, contamination of the airway with gastric contents and pre-existing pulmonary injury likely will have occurred, resulting in preoperative pneumonitis. Positive pressure ventilation is avoided prior to securing the airway as gastric insufflation may result in increased intrathoracic pressure, difficult ventilation, and impaired venous return [79]. Placement of an endotracheal tube beyond the fistula while maintaining spontaneous ventilation is recommended. A novel variation of this strategy was described in an adult who presented for resection of a large carinal tracheoesophageal fistula. To independently isolate each lung, two 5.0 mm microlaryngoscopy endotracheal tubes were place sequentially in each bronchus following inhalation induction of anesthesia using sevoflurane. Conventional IPPV was then initiated [80].

Pediatrics

Congenital tracheal stenosis in infants and children typically occur in the presence of complete tracheal rings and may involve significant lengths of the trachea. Not infrequently these lesions are associated with cardiovascular anomalies which also require repair, most often a pulmonary artery sling. Surgical reconstruction of long-segment tracheal stenoses has been described with a number of techniques including simple resection, incision and patching with pericardium, rib cartilage or tracheal autograft, and slide tracheoplasty all performed via median sternotomy [81, 82]. Slide tracheoplasty is performed by dividing the stenotic trachea at midpoint, incising the proximal and distal narrowed segments vertically on opposite anterior and posterior surfaces and sliding these together. The advantage of this approach is that only fully vascularized, cartilage-supported tissue is used which permits early extubation of many patients. There remains some debate among surgeons which procedure should be performed, whether CPB is always required when only airway reconstruction is performed and if cardiovascular repair is required if the procedures should be staged or performed as a single operation. These surgeries are performed in highly specialized centers, and early referral is recommended to avoid complications associated with lengthy preoperative periods of mechanical ventilation (see also Chap. 50).

Management of the Patient with a T-Tube

A T-tube may be placed for a finite period of time to allow an upper airway prone to malacia or scarring to heal and stabilize or in some cases becomes essentially permanent airway support. Patients with T-tubes may require airway examination, replacement, or adjustment of their T-tube or surgery unrelated to their airway. They present a significant challenge to the anesthesiologist. When a patient with a T-tube in situ required a general anesthetic, the risk of aspiration should be considered. If the procedure is elective, the upper airway can be controlled by a laryngeal mask airway either with spontaneous or controlled ventilation, in which the tracheostomy limb is capped. Alternately the use of a well-seated LMA which is then capped to block the escape from the proximal tracheal limb while ventilating the patient via the tracheostomy limb has been described [11]. Other methods of ventilation through the T-tube offer only partial airway protection from aspiration such as the placement of a Fogarty catheter through the tracheotomy limb into the proximal limb to block egress of gas into the upper airway, with simultaneous ventilation through the tracheotomy limb. Awake fiber-optic telescoping of a small endotracheal tube into the proximal tracheal limb of the T-tube has been

described, but aspiration around the T-tube is still possible. One report of airway management of a patient with a full stomach described awake fiber-optic placement of a 5mm microlaryngoscopy tube through both the proximal and distal limbs of the T-tube with the inflation of the cuff in the trachea [83]. Adult T-tube sizes vary from 8 to 16 mm external diameter. This approach may only be possible with the larger sizes. Finally, the T-tube can be removed, ideally with the help of the patient's surgeon, and replaced by a tracheotomy tube. If the tracheotomy is left for any length of time, the patient could suffer a recurrence of their airway compromise. They would require another general anesthetic for replacement of a T-tube.

Part V

Diagnostic and Therapeutic Procedures of the Mediastinum

Anesthesia for Patients with Mediastinal Masses

14

Lorraine Chow

Key Points

- Patients with mediastinal masses can develop major airway and cardiovascular compression under general anesthesia, which could be fatal.
- High-risk features include supine symptoms (orthopnea, increased cough), SVC syndrome, pericardial effusion, and evidence of airway or cardiovascular compression on CT imaging.
- Knowledge of the anatomical location of the mass as well as its relationship to vital cardiorespiratory structures should be obtained through imaging modalities.
- Diagnostic procedures should be performed under local anesthesia whenever feasible.
- Induction of general anesthesia should proceed in a stepwise fashion.
- Airway management techniques may include awake fiber-optic assessment, intubation distal to airway compression, maintenance of spontaneous ventilation, and avoidance of muscle relaxation.
- Perioperative planning should be made in conjunction with the surgical team, with inclusion of management plans for potential acute airway obstruction or cardiovascular collapse.
- Preinduction CPB or ECMO cannulation should be considered in extremely high-risk patients.

Introduction

Mediastinal masses are a group of heterogeneous tumors, cysts, or aneurysms that may be benign or malignant in nature. The anesthesiologist is required to provide perioperative care to patients undergoing diagnostic or therapeutic procedures of these masses. The type of mass encountered will depend on the location as well as the age of the patient. In adults, the most commonly encountered diagnoses are lymphoma, thymoma, germ cell tumor, and bronchogenic carcinoma [1]. In children, lymphoma, primitive neuroectodermal tumor (PNET), and neuroblastoma are more common [2]. Perioperative morbidity and mortality are due to compression of tracheobronchial tree or cardiovascular structures and can lead to hypoxia or hemodynamic collapse. Improved knowledge, better preparation, and vigilance have led to decreased morbidity in this population since the early case reports in the 1970s and 1980s [3–7]. Key to successful management of patients with mediastinal masses relies on:

1. Knowledge of mass anatomy, including its location and relationship to other vital structures (tracheobronchial tree, heart, major vessels), and knowledge of the pathophysiology of the mass
2. Careful preoperative assessment
3. Discussion and collaborative perioperative planning with surgeon
4. Preparation to manage cardiorespiratory complications

Surgical procedures encountered may include biopsy of extra-thoracic mass, biopsy of mediastinal mass via cervical mediastinoscopy, anterior parasternal mediastinoscopy/mediastinotomy (Chamberlain procedure), video-assisted thoracoscopic biopsy or excision of mass, thoracotomy, and sternotomy [1]. These patients can also present for an unrelated surgical procedure (e.g., staging laparotomy) or be an incidental diagnosis at the time of another procedure [8, 9].

Anatomy and Pathophysiology

The mediastinum is bound by the sternum anteriorly and the vertebral bodies posteriorly and extends from the thoracic inlet to the diaphragm (Fig. 14.1) [11]. It is divided into superior and inferior regions, which is further subdivided into the anterior, middle, and posterior mediastinum. Table 14.1 shows the typical masses in the various mediastinal compartments [11, 12].

Because of the proximity to other airway and cardiovascular structures, mediastinal masses can lead to complications under anesthetic due to compression or encroachment of these structures. Although the majority of complications are described for masses in the anterior mediastinum, masses in the middle mediastinum [13] and posterior mediastinum [14] have also been associated with hemodynamic and respiratory collapse with general anesthesia (GA).

During normal spontaneous ventilation, there is preferential perfusion to dependent areas of the lung and distribution of ventilation controlled mainly by lung compliance [15]. Most studies evaluating ventilation changes under anesthesia have shown a decrease in functional reserve capacity (FRC) [15]. With muscle paralysis and supine positioning, there is cephalad shift of the diaphragm that further contributes to impaired gas exchange under anesthesia. Neuman stated three reasons for the dangers of general anesthesia: (1) the reduction of lung volume by as much as 500–1500 ml under GA, (2) relaxation of bronchial smooth muscle leading to greater compressibility, and (3) loss of spontaneous diaphragmatic movement with paralysis, which reduces the normal transpleural pressure gradient that helps dilate the airways [16]. These normal changes that occur under general anesthesia are especially pronounced in patients with mediastinal masses who may have limited reserve or further alteration of ventilation-perfusion matching due to extrinsic airway compression.

Induction of general anesthesia is a sequence of events, and complications can occur at any of these stages, including (1) changing patient position from upright to supine, (2) transitioning from awake to anesthetized state, (3) moving from spontaneous negative pressure ventilation to positive pressure ventilation, and (4) changing of muscle tone from

Table 14.1 Masses in the mediastinal compartments

	Adult	Children

unparalyzed to paralyzed state. Furthermore, complications do not occur solely at the time of induction and intubation but can extend into the maintenance phase, at extubation, or even into the postoperative period [17].

Numerous case studies documenting airway collapse [3, 6, 18] and cardiovascular collapse [5, 7, 18, 19] under anesthesia have been described. Most anesthetic deaths have been described in the pediatric population, possibly due to increased compressibility of pediatric airways or the lack of awareness of the extent of airway involvement [3–5], as well as the intolerance of any cardiovascular insult.

Hemodynamic decompensation may occur if there is compression of the heart or great vessels such as the pulmonary artery (PA) and superior vena cava (SVC). If the PA is compressed, decreased pulmonary perfusion can lead to hypoxemia, acute right ventricular dysfunction, and even cardiac arrest [17]. Compression of SVC leads predominantly to a reduction in venous return and the subsequent reduction in cardiac output [20]. Direct compression of the heart is rare but can lead to arrhythmias, pericardial effusion, or reduction in preload from mechanical compression [17].

Preanesthetic Assessment

Clinical Signs and Symptoms

Common symptoms include dyspnea, cough, hoarseness, new-onset wheezing, syncope, chest pain, night sweats, weight loss, dysphagia, and superior vena cava (SVC) obstruction [1, 17]. These symptoms are especially worrisome if it worsens in the supine position.

SVC syndrome can present with edema of the upper body (face, neck, larynx, upper limbs), plethora, dilation of veins (neck and thorax), and development of collateral veins if slowly evolving [11, 17, 20]. Patients can also present with CNS symptoms including headache, visual distortion, or altered mentation [11]. Respiratory symptoms can accompany SVC obstruction due to concurrent compression of the airway by tumor or engorged veins [7].

Clinical signs may include tachypnea, stridor, rhonchi, or decreased breath sounds. Severity of respiratory symptoms may not correlate with degree of airway obstruction, especially in the pediatric population [6, 21, 22].

Coexisting systemic syndromes such as myasthenia gravis or thyroid dysfunction may be present, and their concurrent optimization needs to be considered, but the specific management of these conditions will not be discussed here.

Mediastinal masses may also be asymptomatic and found incidentally through work-up being performed for other indications. Occasionally these masses come to light due to perioperative complications for an unrelated surgical procedure, and patients are subsequently found to have a mediastinal mass [8, 9].

Investigations

Following chest radiography, computed tomography (CT) is often the next choice of imaging modality as it can provide exact anatomical detail of the mass, including size and relation to adjacent structures [1, 23]. CT can provide useful information regarding the location and extent of airway compression, as well as cardiovascular involvement [17]. Unfortunately, CT scans are static images that only assess one time-point and do not provide information about dynamic compression or position-related changes [16]. MRI may provide more details regarding soft tissue but is not routinely performed. However, it may be useful for neurogenic and vascular lesions, especially when the use of contrast is contraindicated [24].

Azizkhan examined a series of 50 children with anterior mediastinal mass and found that the severity of pulmonary symptoms is not a reliable indicator of the degree of compression in children [25]. Rather, those who had decreases in cross-sectional area of the trachea of at least 50% had the highest association of complications under general anesthetic. Retrospective analysis by Shamberger confirmed the absence of major complications in pediatric patients with a tracheal diameter greater than 50% predicted who underwent general anesthesia [26]. A follow-up prospective study confirmed that GA was well tolerated in children with tracheal area and peak expired flow rate (PEFR) greater than 50% predicted. It was, however, unable to conclude whether impaired pulmonary function as measured by PEFR would be predictive of respiratory collapse during GA as the highest-risk patients were all operated on under local anesthesia [27].

Neuman et al. first advocated for pulmonary function testing and flow-volume loops in 1984, and it soon became widespread recommendation as part of the preoperative work-up of anterior mediastinal masses despite being based on anecdotal recommendations [16, 28]. Subsequent studies have failed to correlate degree of changes in spirometry with perioperative airway complication rates [29]. Hnatiuk et al. assessed upright and supine spirometry and showed no correlation between abnormal spirometry results and respiratory symptoms, abnormal CT results, and anesthetic complications [30]. Spirometry and flow-volume loops do not predict intraoperative morbidity and mortality beyond the information obtained on imaging studies [1, 28].

Transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) are indicated if clinical or CT information suggests cardiac or great vessel involvement.

They provide additional information about encroachment or compression of cardiac structures [23]. These exams can also be performed in recumbent and lateral positions to determine any positional changes in tumor compression effects [17]. As some masses can enlarge and progress rapidly, imaging should be performed as close to the time of surgery as possible.

Other modalities that are sometimes employed include fluorodeoxyglucose positron emission tomography (FDG-PET), which may provide additional information for staging, diagnosis, and prognosis, as it evaluates the metabolic activity of the tumor to predict its response to neoadjuvant therapy [23].

An awake fiber-optic bronchoscopic exam assessing any dynamic airway compression, especially with positional changes, is a useful adjunct to preoperative evaluation and planning.

Anesthetic Risks

Risk Stratification (Fig. 14.2)

Risk assessment in this patient population depends on clinical signs and symptoms (with emphasis on presence of supine symptoms), radiologic studies (CXR and CT chest), and possibly echocardiography (if cardiac or vascular compression is suspected). Table 14.2 outlines several high-risk criteria that are useful for risk stratification of these patients.

Neuman et al. presented a flowchart of suggested management of anterior mediastinal masses [16]. Since then, there have been modifications on this flowchart with continued emphasis on maintaining spontaneous ventilation and avoidance of muscle relaxation if possible.

Knowledge and documentation of "position of comfort" for patient in terms of respiration and circulation may be useful [17].

Risk of complications in the pediatric population has been reported to be 7–20% [4, 25, 31, 32]. Bechard examined 105 anesthetics in the adult population and had an incidence of airway obstruction of 0% during the intraoperative period. However, some patients with the most worrisome features received preoperative chemotherapy or had their tissue biopsy obtained by other means [33]. The overall intraoperative cardiorespiratory complication rate was 3.8%, and postoperative respiratory complication rate was 10.5% [33]. This study found a correlation between the presence of cardiorespiratory symptoms and perioperative complications, with no perioperative complications seen in asymptomatic patients. Although an abnormal pulmonary function test (PEFR <40% predicted) did not predict intraoperative complications, it was associated with a tenfold increase in postoperative complications. Also, a combination of obstruction/restrictive pattern was also associated with a higher rate of postoperative complications [33].

Preoperative Treatment

Preoperative chemotherapy, steroids, or radiation therapy may reduce the size of the tumor and reduce intraoperative risk but may distort histological diagnosis. However, the recommendation of preoperative radiation may be warranted in cases of SVC syndrome as massive hemorrhage, respiratory obstruction, or fatal exacerbation of the SVC obstruction can occur with induction of general anesthesia [7].

Piro recommended preoperative radiation based on their series of 139 patients, where all 5 acute life-threatening complications were encountered in patients with untreated AMM [4]. This recommendation is echoed by other authors [3, 18], while others [12, 31] feel that in the absence of tissue diagnosis, empiric treatment with radiation therapy may delay diagnosis or lead to inappropriate treatment of the mediastinal mass.

Tracheobronchial stenting can also be performed either via flexible or rigid bronchoscopy. This may provide a bridge to chemotherapy or radiation, used to maintain adequate airway prior to excision of mediastinal mass, or for palliation [12]. Spontaneous ventilation maintained with the use of an LMA has been successfully described for placement of a self-expanding metallic stent [34]. There is however a small chance that airway stenting may worsen patient hemodynamics by displacing the mass into adjacent cardiovascular structures.

Anesthetic Management

The choice of anesthetic is based on preoperative risk stratification. For those with high-risk criteria (Table 14.2), the avoidance of general anesthesia and utilization of local or regional anesthesia is advocated if feasible, but this is less practical in the pediatric population.

The ability to rapidly change patient's position should be considered prior to the initiation of anesthesia or surgery.

Sedation

Judicious use (or avoidance) of sedation in the highest-risk population is recommended as respiratory depression, upper airway obstruction, and any amount of muscle relaxation may worsen compressive symptoms exerted by the mediastinal mass [17].

Dexmedetomidine has been used successfully in this population as a sole anesthetic without the use of muscle relaxant, with the ability to maintain spontaneous respirations with minimal respiratory depression [35].

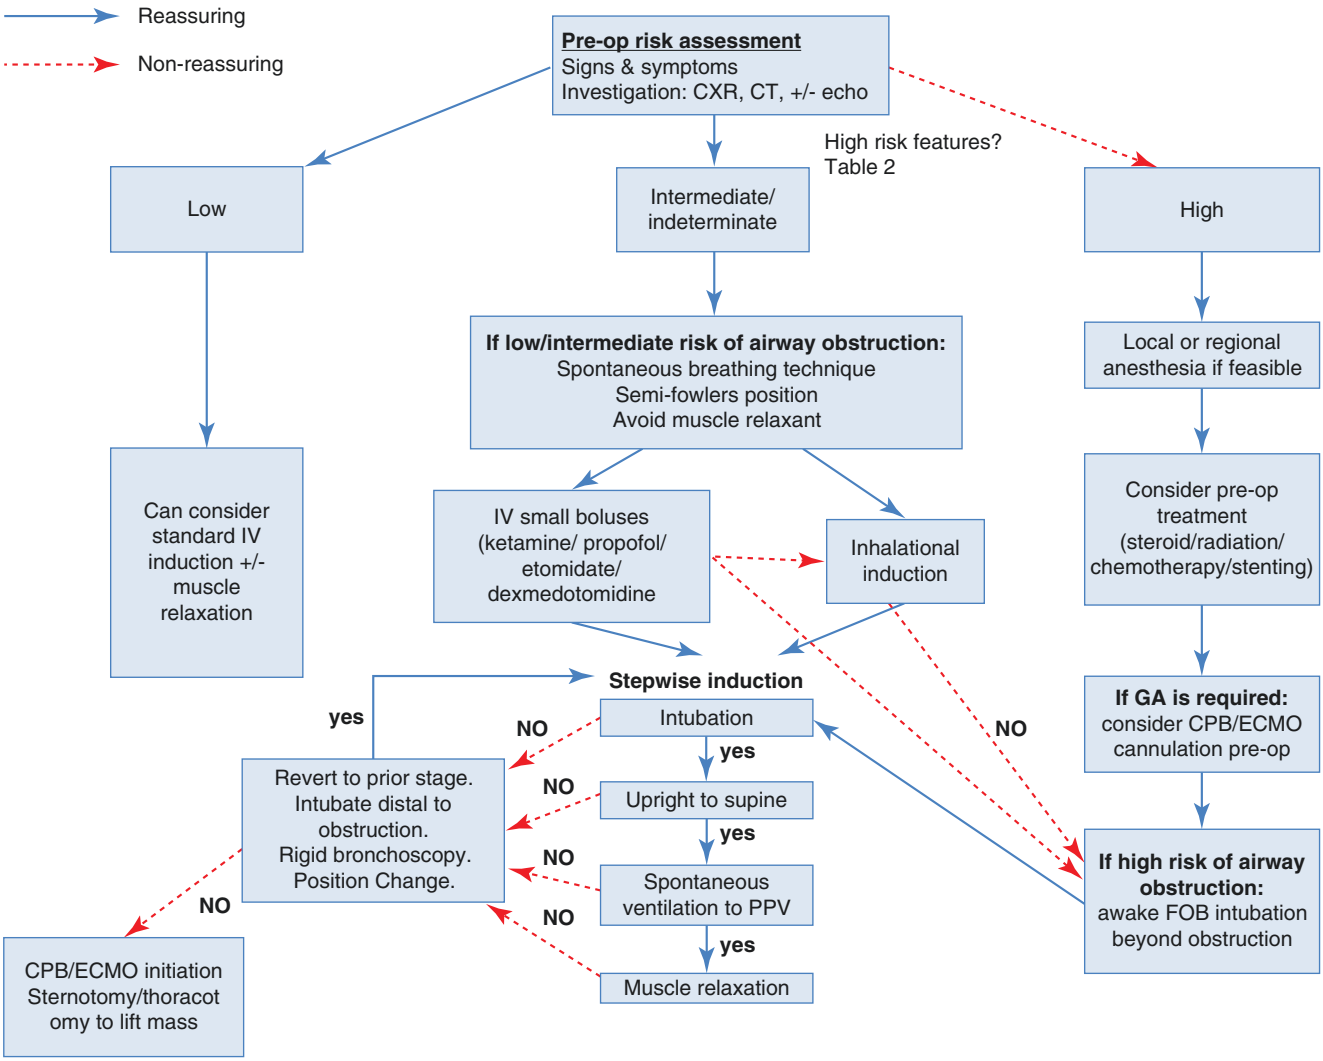

Fig. 14.2 Flowchart of potential management strategies of patients with anterior mediastinal mass based on preoperative risk stratification

Table 14.2 Preoperative high-risk criteria

High-risk criteria
Dyspnea when supine (orthopnea)
Increased cough when supine
Syncope
SVC syndrome
Pericardial effusion
Tracheal compression to <50% of predicted cross-sectional area (pediatric)

Induction and Intubation

This should be performed in a stepwise approach, with verification of adequate ventilation and circulation at each step prior to proceeding [1, 17]. The use of short-acting medications allows for the resumption of the previously tolerated state (e.g., spontaneous ventilation).

Options for induction include:

1. No induction (local vs. regional, with or without sedation).
2. Awake fiber-optic intubation with placement of ETT beyond area of compression or stenosis; then proceed with induction.
3. Maintenance of spontaneous ventilation using small boluses of IV anesthetic (e.g., Ketamine [36], propofol, or etomidate) or inhalational induction.
4. Standard IV induction (with or without muscle relaxation).

Maintenance of spontaneous ventilation has been advocated. However, cases of airway collapse have also been documented despite maintenance of spontaneous respirations [37].

Prior to induction of anesthesia, alternative airway management and rescue for hemodynamic complications should be laid out. This may include long endotracheal tubes of

varying diameters (e.g., endobronchial tubes, microlaryngeal tubes [MLT]), double-lumen tubes or bronchial blockers, flexible fiber-optic bronchoscope, rigid bronchoscope, (and an experienced bronchoscopist), and potential equipment and personnel to initiate extracorporeal circulation (ECC) if cannulation is planned prior to induction. Glycopyrrolate is useful in this population to reduce airway secretions prior to awake bronchoscopic airway assessments, as well as lessening any vagal responses to airway manipulation.

Muscle relaxation should be avoided whenever possible. If muscle relaxation is required for surgical reasons, a small dose of short-acting muscle relaxant such as succinylcholine should be given and mechanical ventilation attempted. If mechanical ventilation can proceed without any significant increase in airway pressure or hemodynamic compromise, subsequent doses of muscle relaxant can be considered [17].

The use of ECC including full cardiopulmonary bypass (CPB) and extracorporeal membrane oxygenation (ECMO) in high-risk patients may be considered. This will be discussed in more detail below.

Maintenance of Anesthesia and Intraoperative Monitoring

Intraoperative transesophageal echocardiography (TEE) may play an increasing role during tumor resection, as it is an invaluable tool in the monitoring and diagnosis of hemodynamically unstable patients [28]. It provides real-time imaging of the heart and nearby structures and can help establish anatomical and functional involvement of the tumor during resection [37–40]. TEE can also provide information regarding contractility, degree of right ventricular outflow tract (RVOT) obstruction or compression [14], volume status, and presence of pericardial effusion [39, 41]. The American Society of Anesthesiologist and Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography supports the use of TEE in noncardiac surgical patients with known or suspected cardiovascular pathology that might result in hemodynamic, pulmonary, or neurologic compromise [42]. Furthermore, its use should be considered in those with unexplained persistent hypotension as well as unexplained hypoxemia [42].

Emergence and Postoperative Care

Complications related to mediastinal masses have been reported in the postoperative periods; therefore increased vigilance must continue during this time. Transitioning from the anesthetized state to the awake state can pose an issue if pain, anxiety, or coughing leads to increased airflow and turbulence through a compromised airway [31]. Tracheomalacia can occur with prolonged compression of airway by enlarging masses. Furthermore, upper airway obstruction and decreased muscle tone will further aggravate airway collapse during high inspiratory pressure exerted against a closed glottis. Patients with SVC obstruction may encounter post-extubation breathing issues due to airway edema [43].

Most of these patients will require intensive postoperative monitoring especially after diagnostic procedures where the cause of obstruction has not been addressed [17, 43].

Complications

Mediastinal mass syndrome (MMS) is a term describing the clinical picture caused by mediastinal mass in anesthetized patients, encompassing acute respiratory and hemodynamic decompensation [17].

Airway Compression

Respiratory decompensation is caused by mechanical compression of the trachea, main bronchi, or both [17]. Table 14.3 outlines rescue options for acute airway obstruction.

Even asymptomatic patients can develop life-threatening obstruction at induction and maintenance of anesthetic [24, 37, 44]. Preoperative chest CT can provide accurate measurement of airway diameter, and it is important to determine the precise level and extension of compression [25, 44]. Any indication of tracheal or bronchial compression may be associated with airway complications under anesthetic.

Azizkhan et al. examined 50 consecutive cases of children with anterior mediastinal mass and found that all 5 cases of life-threatening complications occurred in those with tracheal compression >50% [25].

Spontaneous ventilation with the avoidance of muscle relaxant has often been advocated for this patient population, but this is not a failsafe option as airway collapse has been described in a case of anterior mediastinal mass despite spontaneous ventilation and avoidance of muscle relaxation [37].

Alternative airway management may include wire-reinforced endotracheal tubes, long endotracheal tubes, flexible

Table 14.3 Rescue options for airway obstruction

Rescue options for airway obstruction
Double-lumen tube or long endotracheal tube advanced beyond obstruction or compression [24]
Reposition patient to position of comfort (if known), lateral or prone (to decrease the weight of tumor on airway)
Resumption of previous tolerated state (e.g., upright position, spontaneous ventilation, awaken from anesthetic)
Rigid bronchoscopy beyond stenosis
Initiation of cardiopulmonary bypass or ECMO

Table 14.4 Management of SVC syndrome

Management of SVC syndrome
Augmentation of preload
Positioning to minimize compression of heart or major vessels (e.g., lateral position)
Lower extremity IV access
Spontaneous ventilation to augment venous return
Sternotomy and lifting of mass to relieve compression

fiber-optic bronchoscope, and rigid bronchoscope. Lee describes a case of airway obstruction on induction that was relieved with rigid bronchoscopy and subsequent placement of a double-lumen tube to act as an endobronchial stent [24].

Aggressive ventilation through a partially obstructed airway may lead to dynamic hyperinflation and worsened hemodynamics. These patients may benefit from transient disconnection from airway circuit or utilization of zero end-expiratory pressure (ZEEP).

Cardiovascular Compression

SVC compression and obstruction can lead to excessive bleeding, insufficient drug delivery, and possible airway swelling. These patients may require postoperative ventilation as airway edema can extend into the postoperative period. If worsening of SVC syndrome is suspected, optimization of preload and attempt to relieve compression from the mediastinal mass should be made (Table 14.4).

Compression of the pulmonary trunk or main pulmonary artery (PA) can also occur [19]. Unlike the SVC, PA is relatively protected by the aortic arch, making it less vulnerable to external compression. If cyanosis does occur; the possibility of RVOT obstruction and subsequent hypoxemia, hypotension, or cardiac arrest should be considered [11, 19].

Extracorporeal Circulation (ECC)

Preinduction femoral cannulation for CPB can be considered in extremely high-risk patients as the use of CPB as an emergency rescue can take 10–20 min to initiate and can lead to anoxic brain injury [14, 28, 37]. Patient positioning, inadequate access to femoral vessels, and near-arrest conditions may further complicate vessel cannulation once the surgical procedure has commenced [45].

Femoral-femoral cardiopulmonary bypass (CPB) initiated in an awake patient under local anesthesia has been utilized in patients at high risk of airway or hemodynamic collapse with general anesthesia in which awake fiber-optic intubation may not always be feasible or successful [46–49].

Increasingly, extracorporeal membrane oxygenation (ECMO) is being initiated prior to intubation as part of the airway plan in patients with mediastinal tumors with evidence of airway compromise [50, 51].

On the other hand, preinduction initiation of CPB carries with it the risks of anticoagulation and potentially unnecessary access to vessels. Occasionally, the patient may not tolerate attempts at awake cannulation, as they cannot endure supine positioning [52]. Some authors have advocated for the placement of wires in femoral vessels without full commencement of CPB as a compromise [28].

Anesthesia for Mediastinoscopy

Mediastinoscopy can be performed for staging of lung cancer, for evaluation of mediastinal lymph nodes, or for obtaining tissues biopsy samples for diagnosis of mediastinal masses [53]. The more common procedure is the cervical mediastinoscopy, where the mediastinoscope is inserted toward the carina through a small transverse incision in the suprasternal notch [53] and requires general anesthesia. The less commonly performed anterior mediastinoscopy is performed through the interchondral space along the second rib. This procedure can be performed under local anesthesia or general anesthesia while maintaining spontaneous respiration [54, 55], but coughing or movement can lead to catastrophic surgical complications.

Monitoring of the pulse in the right arm is recommended (either through pulse oximeter or arterial line in the right arm) as compression of the innominate artery by the mediastinoscope can occur and lead to decreased cerebral perfusion and ischemia [53] (Fig. 14.3). Noninvasive blood pressure monitoring in the left arm will provide information regarding systemic perfusion pressures.

The most significant immediate complication of mediastinoscopy is major hemorrhage. Adequate IV access in a lower extremity and availability of blood products should be considered. In a retrospective review of over 300 mediastinoscopies, Park et al. had a major hemorrhage rate of 0.4% [56]. Ninety-three percent of the patients had control of hemorrhage through packing, and only one patient required emergency sternotomy. Once local tamponade was in place, all patients eventually underwent surgical exploration and management of bleeding. The most commonly injured vessels were the azygos vein and the innominate and pulmonary arteries [56]. Lower limb IV access may be required if SVC injury is suspected. Principles of massive transfusion should be utilized until control of hemorrhage has occurred.

Pneumothorax is an uncommon complication but can lead to increased airway pressures, tracheal shift, hypotension, and cyanosis [53]. Other rare complications include injury to

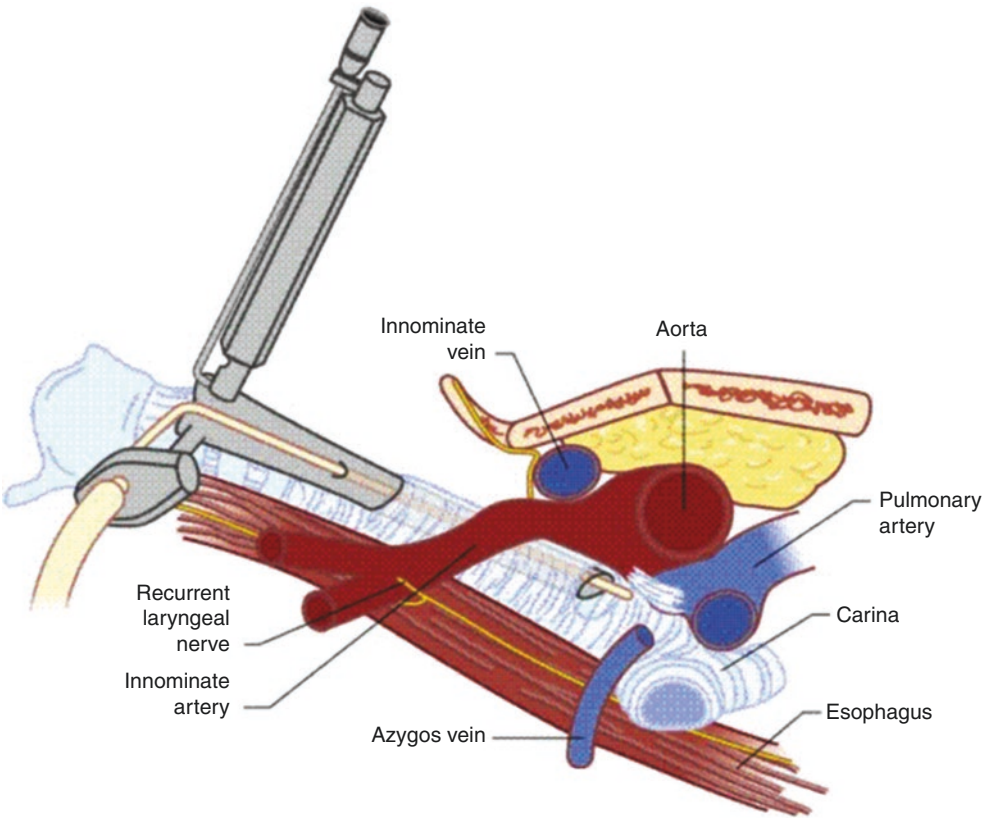

Fig. 14.3 Diagram of a mediastinoscope in the pretracheal fascia along with relevant surrounding structures. Note the innominate artery immediately anterior to the mediastinoscope. The azygos vein drains into the superior vena cava, which has been omitted from the drawing because it would cover the location of the mediastinoscope. (Reprinted from Slinger and Campos [53] with permission)

the recurrent laryngeal nerve, which can cause vocal cord dysfunction, vagus nerve, and thoracic duct and compression of the aorta, which may lead to reflex bradycardia [56].

Summary

Improved understanding of the pathophysiology of mediastinal masses has improved the perioperative morbidity, and mortality has been reduced in this patient population. Careful preoperative assessment and knowledge of the location of the mass and its relationship to adjacent structures are paramount for anesthesia planning. Diagnostic procedures should be performed under local or regional anesthesia whenever possible. Close communication with the surgical team thorough risk assessment and devising a plan for intraoperative airway or hemodynamic complications all contribute to the successful management of these cases.

Clinical Case Discussion

A 24-year-old female presented with a 1-week history of progression of dry cough and increased facial and neck swelling (especially in the morning on awakening). She also notes increasing shortness of breath, especially when lying flat. Chest X-ray (Fig. 14.4 a, b) demonstrates a large anterior mediastinal mass as well as a right pleural effusion. CT scan demonstrates a 6.3 x 8.7 x 8.0 cm soft tissues mediastinal mass that is encasing the superior vena cava, both brachiocephalic veins, and the right pulmonary artery (Fig. 14.5 a–d). The trachea and mainstem bronchi are compressed. Percutaneous CT-guided biopsy was nondiagnostic (Fig. 14.6 a–c).

Question 1

Anterior mediastinoscopy is planned to obtain tissue biopsy samples. What are your options for induction of anesthesia?

Answer

This patient has several high-risk features (increased shortness of breath and cough when supine as well as SVC syndrome). Options include local anesthesia (if feasible), awake fiber-optic intubation, and inhalational induction with avoidance of muscle relaxation. Discussion with the surgical team should also include the possibility of preinduction CPB or

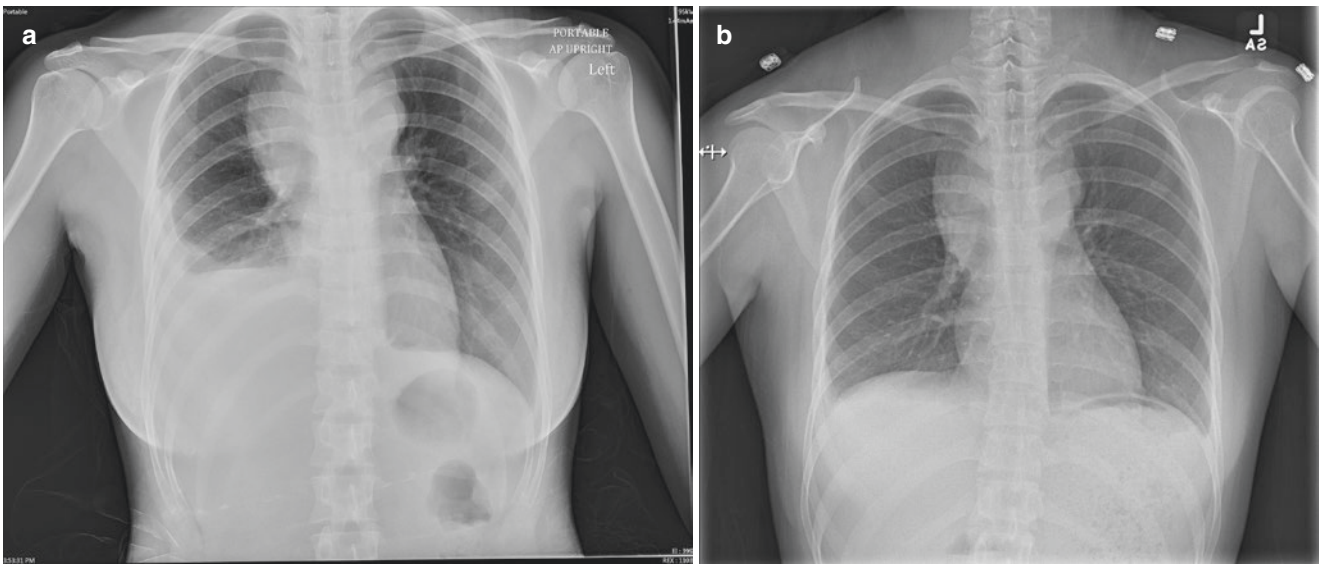

Fig. 14.4 Chest X-ray of a 24-year-old female patient with a large anterior mediastinal mass presenting for biopsy of the mass under GA. (**a**) CXR shows presence of a right-sided pleural effusion. (**b**) Repeat CXR after pleural effusion was drained. Recent percutaneous CT-guided biopsies were nondiagnostic. She presented with symptoms of SVC obstruction. The trachea appears midline and patent on CXR

ECMO with the encasement of SVC. If local anesthesia is not feasible, awake fiber-optic assessment of the airway, followed by passage of endotracheal tube distal to obstruction, may be the safest technique. This also allows for assessment of any dynamic airway obstruction during spontaneous ventilation, association with any positional changes, and identification of the least obstructed bronchus.

Question 2

You successfully performed an awake fiber-optic intubation of this patient. There is moderate mid-tracheal compression and mild compression of bilateral bronchi on examination. A long endotracheal tube (ETT) is placed beyond the area of tracheal compression. Soon after administration of a muscle relaxant, ventilation becomes more difficult, and patient begins to desaturate. BP is 60/42. What do you suspect?

Answer

The differential diagnosis includes acute airway obstruction as well as potential compression of major cardiovascular structures.

Increase in airway pressure may suggest obstruction distal to the ETT. A quick check with the bronchoscopy may help verify this, and the ETT can be advanced beyond the obstruction (endobronchial intubation may be required).

SVC compression will lead to decreased venous return and subsequent reduction in cardiac output. The cessation of spontaneous ventilation will also augment the decrease in venous return. Profound hypotension will lead to insufficient pulmonary perfusion and hypoxemia.

Cyanosis and hypoxemia can also occur with RVOT obstruction and should be considered in this patient.

Question 3

The patient begins to desaturate despite attempts at bronchoscopic adjustment of the endotracheal tube and adjustment of patient position from supine to upright. The surgeons are scrubbing. What should you do?

Answer

Immediately alert the surgeon. The plan may be to proceed immediately to sternotomy to lift the mediastinal mass to relieve its compressive effects. CPB and ECMO may be considered but may not be achieved quickly enough if preinduction cannulation of vessels was not performed.

The surgeons quickly perform a sternotomy, and upon lifting the mass off the trachea and right pulmonary artery, the airway pressure, saturation, and blood pressure improved dramatically.

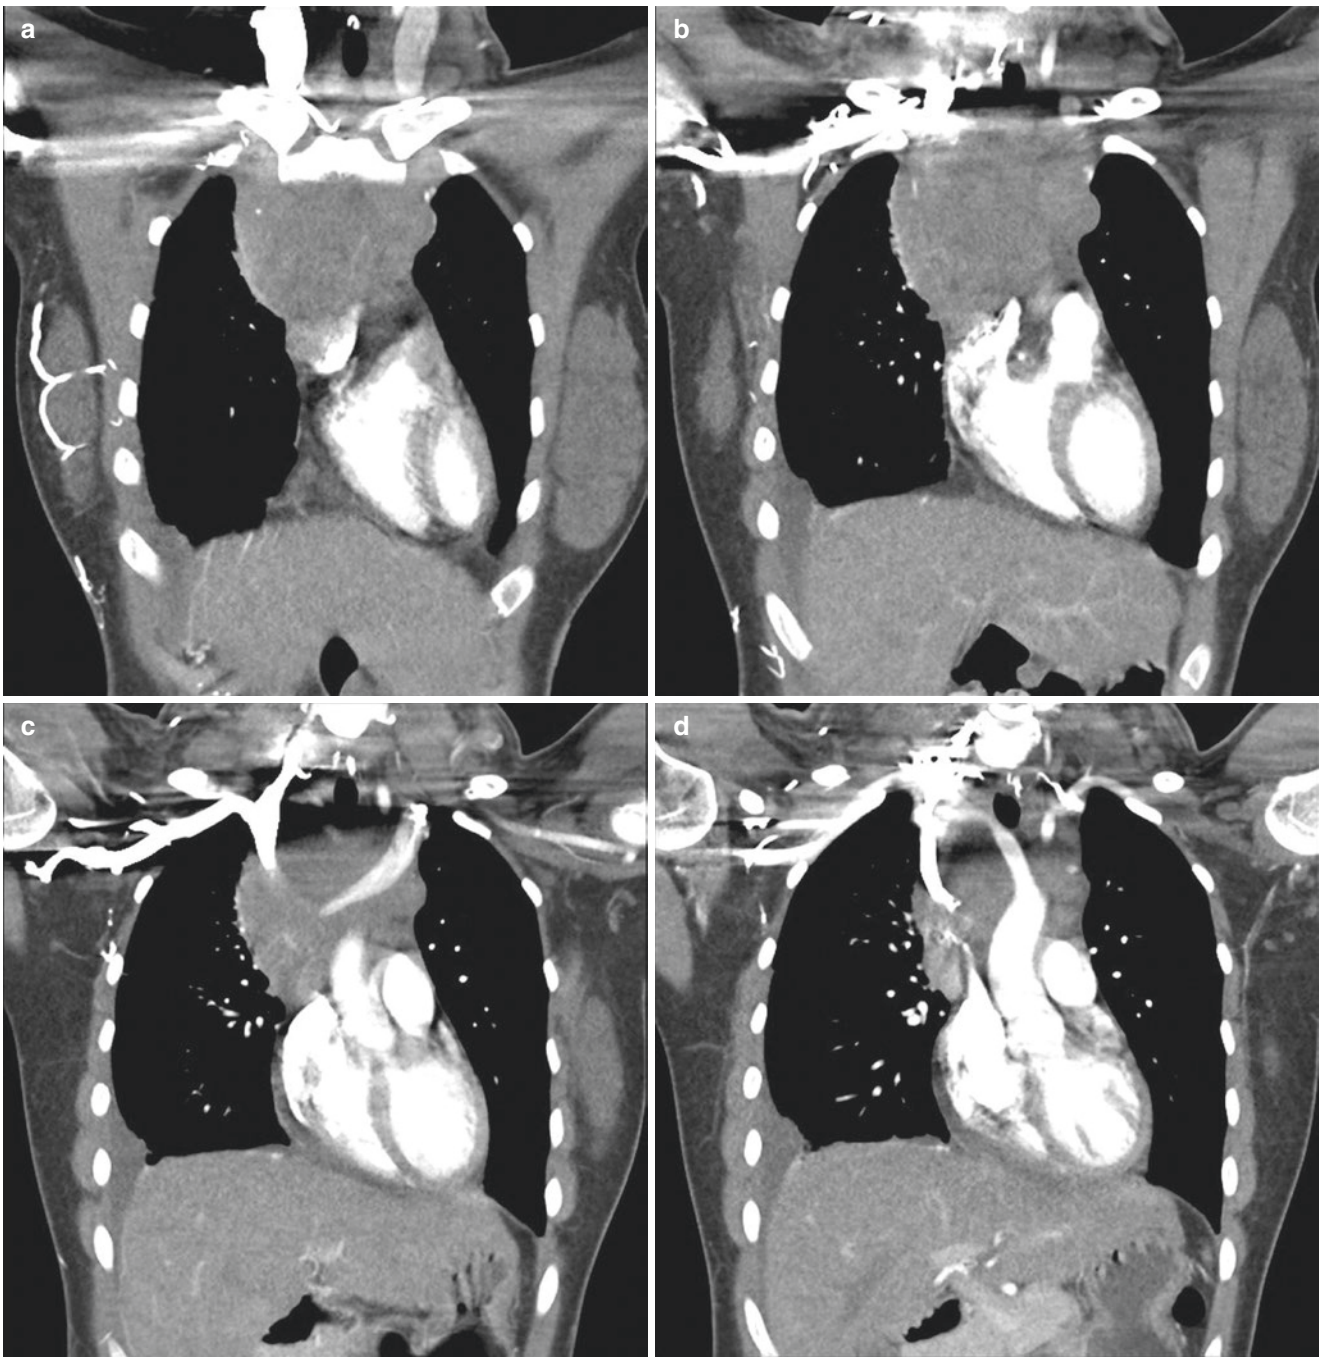

Fig. 14.5 (**a**–**d**) CT scan (sagittal views) of the same patient shows a large anterior mediastinal mass measuring 6.3 × 8.7 × 8.0 cm. There is encasement and compression of the SVC, both brachiocephalic veins, and the right pulmonary artery

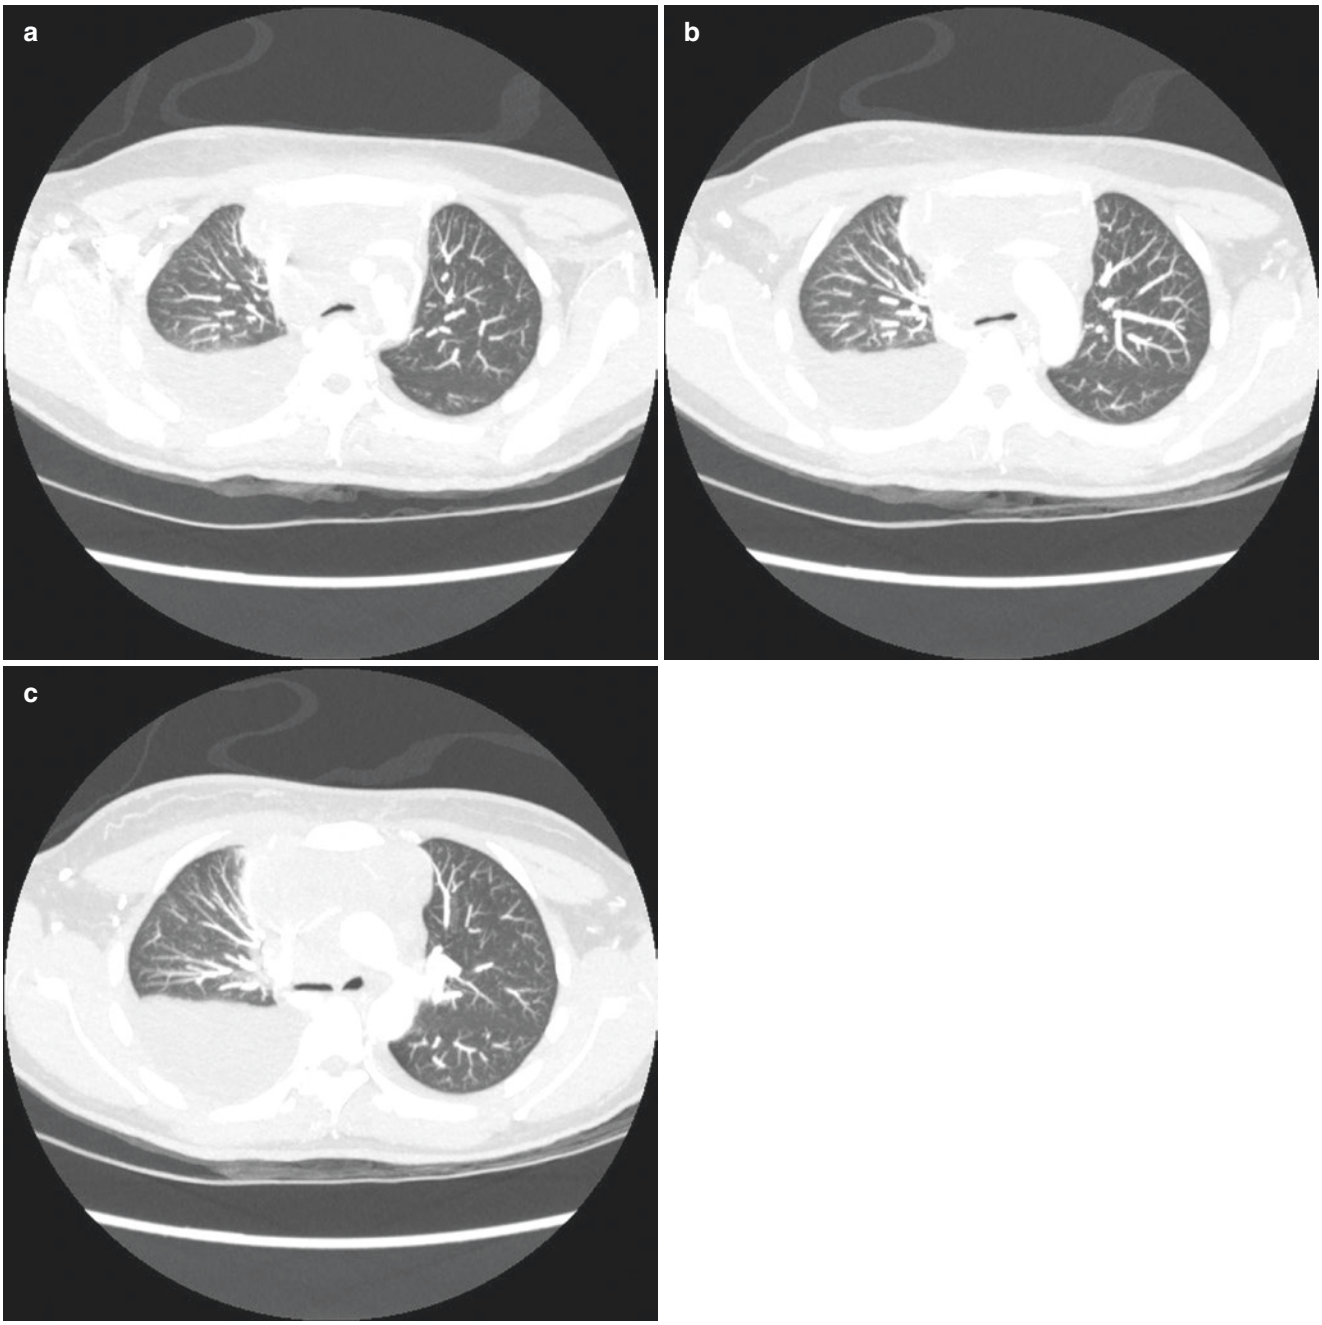

Fig. 14.6 (**a**–**c**) CT scan (coronal views) of the same patient shows tracheal and bilateral mainstem bronchi compression by anterior mediastinal mass to almost a slit. The patient was intubated awake beyond the area of maximal tracheal compression

Abbreviations

ACTH	Adrenocorticotrophic hormone
CRH	Corticotrophin-releasing hormone
CT	Computed tomography
CVP	Central venous pressure
ECG	Electrocardiogram
GHRH	Growth-hormone-releasing hormone
IVIG	Intravenous immunoglobulin
LES	Lambert-Eaton syndrome
LRP-4	Lipoprotein receptor-related protein 4
MEN	Multiple endocrine neoplasia
MG	Myasthenia gravis
MGFA	Myasthenia Gravis Foundation of America
MuSK	Muscle-specific kinase
NDMR	Nondepolarizing muscle relaxants
NMJ	Neuromuscular junction
SCLC	Small cell lung cancer
SIADH	Syndrome of inappropriate release of antidiuretic hormone
TEA	Thoracic epidural anesthesia
TIVA	Total intravenous anesthesia
TSH	Thyroid-stimulating hormone
VATS	Video-assisted thoracic surgery

Key Points

- Indications for thymic surgery typically include thymic mass or nonthymomatous myasthenia gravis (MG).
- Considerations for a patient with a thymic mass include potential for invasion or compression of cardiopulmonary structures causing life-threatening compromise particularly at induction of general anesthesia.
- Thymectomy for MG is never an emergency procedure and should not proceed without preoperative optimization by a multidisciplinary team specializing in the care of myasthenic patients.
- Anesthetic considerations for a patient with MG focus on preventing an exacerbation and minimizing the effect of surgical pain and residual anesthetics on postoperative respiratory function.
- Muscle relaxants and their reversal agents should be avoided in patients with MG whenever possible. Other principles include the use of short-acting agents, use of regional anesthesia for opioid-sparing effects, and proper perioperative management of anticholinesterases.
- Despite repeated efforts to determine what clinical features predict the need for postoperative ventilation, no criteria have been proven to be universally applicable in the myasthenic population.
- Many thoracic malignancies have commonly associated paraneoplastic syndromes with important implications for the anesthesiologist.
- The most common extraintestinal location of carcinoid tumors is the lungs; however, unlike their gastrointestinal counterparts, bronchial carcinoids are rarely secretory.

- Carcinoid syndrome must be optimized with at least 24 h of preoperative octreotide to minimize the life-threatening cardiopulmonary instability that can occur during a carcinoid crisis.
- Advanced carcinoid disease is associated with fibrosis which can lead to pulmonary hypertension or significant valvulopathy with progressive, severe, right-sided heart failure. For these reasons, patients presenting with carcinoid syndrome must have a preoperative echocardiogram.

Introduction

The thymus gland is situated in the anterior mediastinum; protected by the sternum and ribcage, it is nestled amid vital cardiopulmonary structures. Its function is primarily as a site for maturation of T cells from hemopoietic progenitors and as such is a critical part of the development of the adaptive immune system. It is largest in childhood, becomes quiescent in early adolescence, and after puberty is increasingly replaced by fat. Its autoimmune function gives rise to pathology with which the thoracic anesthesiologist must be familiar, myasthenia gravis (MG) in particular. The implications of acquired myasthenia are essential material for the anesthesiologist, and therefore, much of this chapter is devoted to this important neuromuscular condition. Other paraneoplastic and paraendocrine syndromes with important perioperative implications include Lambert-Eaton syndrome (LES) and other endocrine derangements commonly associated with malignancies. The final part of this chapter deals with this.

Thymic Surgery

Common indications for thymectomy include MG and the presence of thymic masses. Thymectomy for MG is covered in the following section. Here, the common masses of the thymus are briefly reviewed along with general anesthetic considerations. As an anterior mediastinal structure, the reader is also referred to Chap. 14 which addresses anterior mediastinal masses and the potential for compressive effects.

The most common tumor of the thymus and the anterior mediastinum is thymoma. Thymoma may be invasive or noninvasive, and 40% have associated paraneoplastic syndromes [1]. The most commonly associated paraneoplastic syndrome is MG (30%), but systemic lupus erythematosus, Cushing's syndrome, syndrome of inappropriate antidiuretic hormone secretion, and pure red cell aplasia may be associated [2].

Thymic carcinomas are much more rare than thymoma, and in contrast, they are always invasive and often present with symptoms reflective of their aggressive nature [3]. Paraneoplastic syndromes are possible but are much less common [4].

Thymic carcinoid is the most common member of the rare group of thymic neuroendocrine neoplasms. It is a potentially secretory tumor, commonly manifesting as Cushing's syndrome rather than the typical carcinoid syndrome [5]. At least 15% of thymic carcinoids present as part of multiple endocrine neoplasia (MEN-1) syndrome [1]. Surgery plays an important role in the management of thymic masses. Removal of all thymic tissue and perithymic fat is the current standard of care [6, 7] for malignant masses for optimal oncological clearance. The anesthesia considerations for non-myasthenia thymic surgery are similar to those for any anterior mediastinal mass. The anesthetist must maintain suspicion of compression of the major cardiopulmonary structures [8–10]. A history of cough, chest discomfort, dyspnea, palpitations, and syncope should be sought including any change associated with assuming the supine position. Symptoms may also occur due to paraneoplastic and paraendocrine syndromes, as detailed later in this chapter. Clinicians should screen for MG by inquiring about blurring vision, difficulty swallowing, or difficulty with speech. Invasive thymoma and thymic carcinoma tend to invade surrounding structure including major airways, pericardium, and great vessels; therefore imaging should be reviewed and resection of major structures discussed with the surgeon preoperatively [11]. A history of any preceding treatment should also be sought. Radiation to the chest can result in pulmonary fibrosis, coronary artery disease, valvular heart disease, and pericarditis [12]. Many chemotherapeutic agents have known implications for perioperative management, particularly cisplatin (a potential nephrotoxin) which is one of the most common chemotherapeutic drugs used in the treatment of thymoma; doxorubicin (with potential for decreased left ventricular function), vincristine (which causes neuropathy), and others may also be used [13, 14].

Myasthenia Gravis

First described in the seventeenth century, MG did not become a recognized entity until over 200 years later when Dr Friedrich Jolly titled the syndrome "myasthenia gravis pseudoparalytica" [15, 16]. At that time, MG almost uniformly caused death by respiratory failure within 1–2 years of illness. With a prevalence of 1:17,000 [17] and an established role for surgery in its management, the anesthesiologist must know how to optimize and safely manage these patients perioperatively.

Pathophysiology

MG is an autoimmune disease due to antibody-mediated destruction of nicotinic acetylcholine receptors [18] or other related proteins such as muscle-specific kinase (MuSK) or lipoprotein receptor-related protein 4 (LRP-4). As a result, the neuromuscular junctions (NMJs) of all muscles, even clinically unaffected muscles, have a reduced number of acetylcholine receptors [19, 20]. In addition to a reduced number of acetylcholine receptors, other abnormalities of the NMJ include reduced number and depth of the junctional folds in the postsynaptic membrane [21]. Autoantibodies are detectable in most cases, and the 10–20% of patients once considered "sero-negative" actually have AChR antibodies which are detectable through more advanced laboratory techniques or antibodies to MuSK or LRP-4.

Patients present with fluctuating skeletal muscle weakness which is made worse by activity and improves with rest. The reduction in postsynaptic acetylcholine receptors results in generation of fewer motor end-plate potentials; therefore fewer muscle fibers contract. With repeated or continued stimulation, even less motor end-plate potentials reach threshold, and weakness becomes more pronounced.

The cause of the immune reaction leading to MG is unknown. A very strong link exists between MG and thymic pathology. Most patients with MG exhibit thymic abnormalities which can range from hyperplasia (70–80%) to the presence of thymoma (10–15%), and 15% of patients with thymoma have MG. Furthermore, removal of the thymus results in clinical improvement in the majority of cases of MG [20, 22, 23].

MG is often associated with other conditions which share an underlying autoimmune tendency [17]. Diabetes and thyroid disorders (hyperthyroid or hypothyroid) are present in 5–6%, and 1–2% have rheumatoid arthritis. Systemic lupus erythematosus, leukemia, scleroderma, and polymyositis have also been found in higher numbers in the myasthenic population than in the general population [24].

Presentation

The majority of patients initially present due to diplopia (leading to blurring vision) or ptosis. Other presentations include difficulty swallowing or speaking due to bulbar dysfunction, dyspnea due to respiratory muscle compromise, or weakness of the neck or limbs. Symptoms always worsen with the use of the affected muscles, and strength returns after rest [16, 17]. The muscle groups affected can vary according to the serological profile: patients with AChR antibodies tend to have ocular involvement which progresses through limb weakness to bulbar symptoms, whereas MuSK antibodies tend to be ocular-sparing, and LRP-4 antibodies cause very mild generalized disease [25].

Acetylcholine receptor antibodies in MG are specific to the neuromuscular junction, so MG does not cause hemodynamic instability directly; however cardiac antibodies (such as anti-$\beta_1\beta_2$, ryanodine, and Kv1.4) are commonly also found, which can cause palpitations, dyspnea, mild hypertension, first-degree atrioventricular block, atrial fibrillation, and myocarditis. Diastolic dysfunction has also been noted [26–31].

Diagnosis

Since 1952, the first-line diagnostic test for MG has been the "Tensilon test" [32]. As an anticholinesterase of rapid onset (30 s) and offset (5 min), edrophonium (Tensilon™) is ideal for diagnostic testing. The inhibition of acetylcholine breakdown allows acetylcholine to accumulate and stimulate the reduced number of postjunctional receptors. Intravenous edrophonium is administered, and muscle performance is assessed within 30–90s. Clear improvement in the affected muscles, as measured qualitatively and quantitatively, is found in of MG [20, 24]. However, this test has a significant false-positive rate, and current guidelines [33–35] advise AChR antibody assay, with MuSK antibody assay if negative, in conjunction with thyroid function tests and CT of the chest as first-line investigations. In cases of diagnostic dilemma, referral for formal neurophysiological testing, including Tensilon test, as well as MRI brain is made.

Classification

In 1971, Dr. Osserman based a classification scheme on the observation of over 1200 patients at the Myasthenia Gravis Clinic in New York [24]. In its modified form, this continues to be of use today (see Table 15.1). Patients are placed into a grade based on their weakest muscle group. More recently, a task force put together by the Myasthenia Gravis Foundation of America (MGFA) developed a clinical classification scheme to facilitate standardization of reporting (see Table 15.2).

Medical Management

Pyridostigmine is the anticholinesterase of choice for management of MG. Others are available for oral use; however, the effectiveness, kinetics, and tolerability of pyridostigmine are the most favorable [38]. Side effects, usually uncommon or mild, include diarrhea, bronchorrhea, and abdominal cramping.

After an oral dose of pyridostigmine, an effect may be seen as early as 30 min later, and the peak effect is reached

Table 15.1 Modified Osserman grades

Type I	Disease localized to ocular muscles Tends not to progress if remains confined to ocular muscles for first 2 years
Type IIA	Mild generalized myasthenia Slowly progressive often from ocular muscles to skeletal and bulbar muscles, however spares muscles of respiration Good response to drug therapy and low mortality
Type IIB	Moderate generalized myasthenia Gradual onset, usually ocular, progressing to more generalized bulbar and skeletal muscle involvement Respiratory muscles are not involved More bulbar symptoms than IIA Less responsive to medical therapy than IIA
Type III	Severe disease Progression may be gradual or sudden deterioration Poor response to drug therapy High mortality
Type IV	Myasthenic crisis with respiratory failure Require intubation

Based on data from Refs. [24, 36]

Table 15.2 MGFA clinical classification

Class	Description	Subclassification (where applicable)
I	Isolated ocular weakness	–
II	Mild weakness of extraocular muscles	(a) Predominantly affecting limb, axial muscles, or both (b) Predominantly affecting oropharyngeal, respiratory muscles, or both
III	Moderate weakness of extraocular muscles	
IV	Severe weakness of extraocular muscles	(a) Swallowing unaffected (b) Requiring feeding tube without intubation
V	Intubation	

Adapted from Ref. [37]

1 to 2 h later. The duration of action is usually between 3 and 6 h. The nonsustained release formulation can be crushed and given via nasogastric tube. If required, pyridostigmine can also be given intravenously with an oral to intravenous conversion ratio of 30:1.

There is great interindividual variability in the kinetics of oral pyridostigmine; therefore the dose and frequency are titrated to reach optimum effect for each individual [38, 39]. The symptomatic control provided by anticholinesterases is often incomplete, so most patients find themselves on additional medication in the form of immunosuppression.

Corticosteroids are commonly used to treat MG; however, the considerable side effect profile (see Table 15.3) of long-term corticosteroids makes them undesirable as an immunosuppressant. Once a patient has achieved remission, corticosteroids are usually tapered to their lowest effective dose. Frequently, corticosteroids are helpful to gain more control of the disease process, while other immunosuppressants are being initiated [40].

Table 15.3 Adverse effects of corticosteroids

Gastrointestinal	Dyspepsia Peptic ulcers
Body habitus	Truncal obesity
Skin and musculoskeletal	Acne Easy bruising Delayed wound healing Aseptic necrosis of the femoral head Osteoporosis
Metabolic, fluid, and electrolyte	Hypertension Peripheral edema Hypokalemia Hyperglycemia/glucose intolerance Adrenal suppression
Muscle	Myopathy
Behavior	Anxiety Psychosis

Azathioprine is one such alternative immunosuppressant which may take months to have an effect. A maximal benefit may take up to 24 months; however its use allows corticosteroids to be minimized [38]. Adverse effects include bone marrow suppression, hepatotoxicity (usually mild and reversible), and gastrointestinal upset.

Cyclosporine is a potent immunosuppressant agent with onset much sooner than azathioprine. Greater risks of toxicity limit its use. Common and severe adverse side effects include hypertension, nephrotoxicity, hepatotoxicity, and bone marrow suppression. Levels must be monitored regularly [38, 40].

First reported in 1976 [41], the role of plasmapheresis for the treatment of MG has grown substantially. Treatments occur over 1–2 weeks and consist of three to five exchanges of plasma via a temporarily placed dialysis catheter. Each treatment removes 1–3 L. There is a reduction in acetylcholine receptor antibody titers in patients who have measurable antibodies. Benefits are usually seen after one or two exchanges, and, once a course is completed, the improvement can last for 2 weeks to 2 months. Indications for treatment include bulbar symptoms, myasthenic crisis, or preoperative optimization in patients who are at high risk of postoperative respiratory failure [42].

Intravenous immunoglobulin (IVIG) represents a similar immune-mediating therapy for MG. Its role is not as extensively studied as plasmapheresis, and a Cochrane review based on six randomized controlled trials found limited evidence for its use in chronic MG [42]. However, it is recommended as a first-line treatment in patients with acute relapse requiring hospital admission, in particular requiring intensive care [33]. IVIG is preferred to plasmapheresis as its efficacy is similar and it is more easily applied [43]. As a blood product pooled from a large volume of donor plasma, it carries with it risks inherent to any blood product. The dose is given intravenously over 2–5 days, and adverse reactions are

mild and tolerable (fever, nausea, headache). Benefit is seen within 4 days and peaks by 2 weeks; it may last 40–100 days. The mechanism of action remains unknown.

Surgical Management

In 1939, the first thymectomy was performed by Dr. Blalock and resulted in remission of MG [44]. Dr Blalock followed this success with a series of thymectomies with similarly positive results [45, 46]. Today, thymectomy remains an important part of the management of MG although there remains controversy regarding its indications, timing, and preferred surgical approach [47–52]. Despite the first thymectomy for MG being reported in 1939, a randomized trial demonstrating effectiveness has only just been completed, which demonstrated that patients who received thymectomy in addition to immunosuppression required lower prednisolone doses (44 vs 60 mg, $P < 0.001$), were less likely to need supplemental immunosuppression with azathioprine (17 vs 48%, $P < 0.001$), and were less likely to be hospitalized for exacerbations (9 vs 37%, $P < 0.001$) [53]. Thymectomy for MG, while already established in clinical practice, is now backed by high-quality evidence. Remission does not immediately follow removal of the thymus gland. It may take months to years for remission or significant improvement in the disease to occur. By 5 years, 34–46% of patients have complete remission, and another 33–40% are significantly improved [38]. The other indication for thymectomy is the presence of a thymoma or thymic carcinoma, for relief or mass effect and oncological clearance [38, 39].

The preferred surgical approach for removal of thymoma remains median sternotomy, as this provides optimal surgical access to facilitate a full oncological clearance.

However, a wide range of minimally invasive approaches are practiced for nonthymomatous MG, including transcervical, subxiphoid, ministernotomy, and both right and left VATS [54]. The rarity of MG makes performing randomized controlled trials of these surgical approaches difficult, but published case series demonstrate similar long-term outcomes in terms of reduction of MG symptoms [48, 55]. The anesthesiologist may encounter any combination of different approaches, depending on surgical and institutional preference.

Myasthenic vs Cholinergic Crisis

A myasthenic crisis refers to rapidly deteriorating strength which threatens the life of the patient. The most common causes of crisis are infection, surgery, and drugs (see Table 15.4); however, in many cases no underlying precipitant can be found.

Table 15.4 Precipitants of myasthenic crisis

Stress
Surgery
Infection
Drugs
Aminoglycosides
Quinolones
Macrolides
Beta-blockers
Calcium channel blockers
Magnesium salts
Iodinated contrast agents
Phenytoin
Procainamide

Based on data from Ref. [56]

Table 15.5 Manifestations of cholinergic crisis

Motor: fasciculations, weakness
Cardiac: bradycardia
Respiratory: bronchorrhea
Ocular: miosis
Gastrointestinal: salivation, nausea, vomiting, colic, diarrhea
General: pallor, diaphoresis

Patients with myasthenic crisis will be in respiratory failure due to weakness of the diaphragm and other muscles of respiration. Management requires intubation and admission to and intensive care unit for respiratory care [57]. Correctable causes should be sought and treated, high-dose prednisolone reinstituted, and IVIG given as first-line treatment. Patients who have not recovered at 5 days may require second dose of IVIG or plasmapheresis.

In contrast to myasthenic crisis, a cholinergic crisis is caused by too much acetylcholine at the cholinergic receptors. It is most often caused by a relative overdose of anticholinesterase. This syndrome has become uncommon with present-day management because the use of immunosuppressants has meant that smaller doses of anticholinesterases are used [56]. The high levels of acetylcholine at all cholinergic receptors have multi-system effects. At the NMJ, it creates an endogenous depolarization type of phenomenon causing fasciculations and muscle weakness [58]. The respiratory distress due to muscle weakness may be further compounded by bronchorrhea. Other manifestations are attributable to muscarinic stimulation (Table 15.5).

Differentiating a cholinergic vs myasthenic crisis can be difficult as both can present with weakness and respiratory distress. In addition to a history of recent events, pupil size, muscarinic signs, and Tensilon test may be helpful, but should be applied with caution in acutely ill patients, as it may precipitate complete respiratory failure. The pupils are constricted in a cholinergic crisis and dilated in a myasthenic crisis (due to sympathetic activation). Treatment includes intubation, antimuscarinics, and supportive care.

Anesthetic Considerations

The anesthesiologist will be confronted with myasthenic patients coming for thymectomy as well as those coming for surgery unrelated to their disease. Whenever possible, surgery should never be undertaken without preoperative stabilization and optimization of MG.

Anesthetic considerations include minimizing the risk of a myasthenic crisis and facilitating sustained extubation at the end of a general anesthetic. If a thymectomy is planned, then considerations of thymoma and anterior mediastinal mass may also apply (see earlier).

Preoperatively, it is important to ask about the duration of disease and its severity, particularly with respect to ocular, bulbar, respiratory, and generalized symptoms. Many attempts have been made to delineate preoperative characteristics which predict the need for postoperative ventilation. The Leventhal criteria are often cited for this purpose [59] and are based on a retrospective review of 24 patients who underwent transsternal thymectomy (see Table 15.6). The criteria have been evaluated in other settings and have been found inaccurate in predicting the need for postoperative ventilation in patients undergoing other types of thymectomy as well as nonthymectomy surgery [60, 61]. Despite continued attempts to develop a model predictive of the need for postoperative ventilation, no such model has been consistently reliable. Anesthesiologists may use a series of preoperative factors examined in the literature which have been suggested to be predictive in various settings (see Table 15.7)

Patients should be questioned for any cardiac symptoms of palpitations, syncope, dyspnea, and any manifestations of congestive heart failure. A history of associated autoimmune conditions, particularly thyroid dysfunction, should be sought. In order to plan perioperative medical management, detailed history of current medications should be noted on the chart. Use of corticosteroids is usually tapered or discontinued preoperatively where possible, but ongoing use may necessitate a stress dose of steroids preoperatively. Use of other immunosuppressants should also prompt a search for signs of toxicity or adverse effects. Table 15.8 lists suggested preoperative investigations

Preoperative optimization should be undertaken in cooperation with a neurologist familiar with the care of myasthenia. Plasmapheresis or IVIG may be arranged to reduce the chances of perioperative respiratory failure. As these treatments are not without adverse effects, their routine use may expose patients to unnecessary risk [64]. In general, patients with advanced disease, bulbar symptoms, or poor pulmonary function receive these immune-modulating therapies [28, 65]. It should be noted that preoperative plasmapheresis depletes plasma cholinesterase, so the duration of some neuromuscular-blocking drugs (e.g., succinylcholine, mivacurium, and remifentanil) will be prolonged [36].

There are different approaches to perioperative dosing of anticholinesterases. Some advocate the complete omission of anticholinesterase medications on the day of surgery in order to reduce the need for muscle relaxants [66]. Anticholinesterases may be given intraoperatively near the end of the procedure to facilitate extubation with this approach. See Table 15.9 for useful conversion factors of

Table 15.6 Leventhal criteria

Disease duration >6 years
Pyridostigmine dose >750 mg/day
Preoperative vital capacity <2.9 L
Presence of other respiratory disease

Based on data from Ref. [59]

Table 15.7 Prediction of myasthenia gravis patients at high risk of prolonged postoperative ventilator support

Advanced disease
Myasthenia Gravis Foundation class II or higher
Myasthenia gravis for >6 years
History of steroid requirement for myasthenia gravis
History of myasthenia gravis-induced respiratory insufficiency
Vital capacity <2.9 L
Pyridostigmine dose >750 mg/day
Maximum respiratory force <40–50 cmH20

Based on data from Refs. [28, 59, 60, 62, 63]

Table 15.8 Suggested preoperative investigations for the patient with myasthenia gravis

Complete blood count	May have pernicious anemia, red cell aplasia, bone marrow suppression from immunosuppressants
Electrolytes, creatinine, liver function	As required depending on immunosuppressants
TSH	Commonly have thyroid dysfunction
Chest X-ray	Rule out thymoma/mediastinal mass, pneumonia (particularly aspiration if bulbar symptoms)
ECG	Arrhythmias, atrial fibrillation
Echo	If signs or symptoms of cardiac involvement
Pulmonary function tests	Useful to compare to previous for baseline

Table 15.9 Conversion between anticholinesterases for management of myasthenia gravis

Drug and formulation	Dose equivalent	Onset	Time to maximum response	Duration of action
Pyridostigmine oral	60 mg	40 min	1 h	4 h
Neostigmine oral	15 mg	1 h	1.5 h	30 min
Neostigmine IM	1.5 mg	30 min	1 h	30 min
Neostigmine IV	0.5 mg	5–10 min	20 min	30 min

anticholinesterase drugs. Another approach is to give half the usual morning dose for patients with grade I or II disease and the full dose for more severe cases [68]. Still others advocate giving patients their full dose at their usual schedule [69].

The approach followed at our institution, as well as others, is to give patients their usual dose of pyridostigmine preoperatively. Ideally, the patient delays their morning dose until immediately preoperatively when it is given with a sip of water. Patients are scheduled as early in the day as possible to facilitate this approach. The goal is optimal strength at the time of extubation. While myasthenics have intact respiratory drive in response to arterial CO_2 and are not at greater risk of respiratory depression caused by opioids or benzodiazepines, it is conceivable that preoperative sedation may act synergistically with respiratory muscle weakness to cause respiratory compromise, so these drugs should be used cautiously if at all. Monitors and invasive lines are dictated by the individual patient and the planned surgery; however, regardless of whether neuromuscular-blocking drugs are used, the use of nerve monitoring is essential.

Myasthenic patients are exquisitely sensitive to all nondepolarizing muscle relaxants (NDMR) [70–72]. The underlying muscle weakness due to the disease combined with the muscle-relaxing properties of intravenous and volatile anesthetics often makes the use of muscle relaxants unnecessary. The use of remifentanil can reduce the response to airway manipulation and allow intubation without NMDRs; however Fujita et al. report a rate of postoperative respiratory failure of 28% with this technique [73], so it cannot be regarded as fail-safe.

Circumstances may rise when paralysis becomes necessary. For intermediate-acting neuromuscular-blocking agents, a dose reduction to one-fifth the usual is recommended. Long-acting neuromuscular blockade should be avoided [74, 75]. Patients who have received their pyridostigmine preoperatively may have a prolonged action of mivacurium due to the interaction with plasma cholinesterase [76].

The reversal of neuromuscular blockade is another area of controversy. The safest recommendation is to choose a minimal dose of short-acting NDMR and ensure that the effect has completely terminated spontaneously [69]. Sugammadex, a cyclodextrin which rapidly and completely terminates the action of rocuronium and vecuronium, is a very attractive option for NMDR reversal in MG. There are a number of case reports [77, 78] and case series [79, 80] which support this as a strategy. However, it may not always be successful [81], as other intraoperative factors and drugs can affect the NMJ (see Table 15.4). In addition, if a patient appears weak and in respiratory distress postoperatively, differentiating between insufficient reversal and cholinergic crisis is very difficult. If such a situation is encountered, supportive care with appropriate ventilation is recommended until the diagnosis becomes clear, and appropriate anticholinesterase levels are re-established.

In contrast to the response to NDMR, myasthenic patients show resistance to succinylcholine due to the loss of nicotinic receptors [82, 83]. Eisenkraft et al. have demonstrated that the ED50 is twice normal and recommend using a dose of 1.5–2 mg/kg if rapid sequence induction conditions are required [82]. The onset of the depolarizing block may take longer than expected [69]. Myasthenics are also more likely to develop a phase II block, particularly with repeated doses [84], and the duration of action may be prolonged if cholinesterase inhibitors have been taken that day.

Volatile anesthetics (halothane and particularly sevoflurane and isoflurane) have potent muscle relaxation effects in normal patients and have been shown to reduce neuromuscular transmission by close to 50% [85–87]. The dose of volatile required to achieve this depth may lead to hemodynamic instability. To minimize inhalational agents, they have been combined with regional anesthesia [88] or remifentanil infusion. Desflurane's lower blood-gas partition coefficient has a theoretical advantage and has been used with good results [89, 90].

The use of total intravenous anesthesia (TIVA) for patients with MG has grown, particularly with the widespread use of remifentanil [89, 91, 92]. Propofol, etomidate, and ketamine have also been used uneventfully, and effects on neuromuscular transmission are minimal [93]. Opioids should be minimized because of the central respiratory depression as described earlier. For pain management perioperatively, consideration should be given to opioid-sparing techniques such as regional anesthesia or multimodal analgesia plans.

The use of regional anesthesia for myasthenics has many advantages; however, possible drug interactions must be kept in mind [94]. Local anesthetics (ester and amide) have some inhibitory effect on neuromuscular transmission, and this can be potentiated further in the presence of NDMR [95]. If regional anesthesia is used, it is recommended to reduce the maximum dose of local anesthetic [39, 74]. However, modern ultrasound-guided regional anesthesia practice allows much lower volumes of local anesthetic to be used, much reducing the risk of this rare interaction.

The place of thoracic epidural anesthesia (TEA) in the perioperative management of MG has changed dramatically. Traditionally, concern over blockade of intercostal muscles causing respiratory distress precluded the use of TEA [69]. Many examples now exist of the successful use of TEA intraoperatively as well as postoperatively [92, 96–98]. The benefits of excellent analgesia, muscle relaxation, and opioid sparing have translated into earlier extubation and a reduced need for postoperative ventilator support [92, 97]. Intrathecal opioids have similarly proven beneficial in terms of analgesia and optimizing respiratory function postoperatively [99, 100].

The perioperative management of patients with MG coming for surgery requires a team of experts in neurology,

surgery, and anesthesia. No anesthetic technique has been shown to be superior in MG. The individualization of a perioperative plan encompassing the principles presented here is suggested.

Paraendocrine and Paraneoplastic Syndromes

Paraendocrine and paraneoplastic syndromes must be kept in mind when patients present with malignancy. Table 15.10 contains the most common paraneoplastic syndromes that may be encountered. The remainder of this chapter will be devoted to the discussion of the carcinoid syndrome (a paraendocrine syndrome) and LES (a paraneoplastic syndrome). Although not common, both have important implications for the anesthesiologist.

Carcinoid Tumors

Carcinoid tumors are most commonly found in the gastrointestinal tract where they often present due to bowel obstruction or are discovered due to symptoms of carcinoid syndrome. Primary carcinoids outside of the GI tract have originated in the ovary [102], liver [103, 104], and thymus [105, 106], but the most common extraintestinal location is the lung [107].

Bronchial carcinoids account for 2–5% of primary lung tumors; however, this makes up 20–30% of all carcinoids [107]. Seventy-five percent of bronchial carcinoids are centrally located therefore present with symptoms of postobstructive pneumonia, hemoptysis, and dyspnea [108]. The remaining one-quarter occur peripherally in the lung, are asymptomatic, and are usually detected on routine chest radiography [108].

It is estimated that 15–20% of all carcinoids give rise to paraendocrine syndromes, most notable the "carcinoid syndrome" [107]. Carcinoid tumors may secrete well over a dozen compounds, including serotonin, histamine, catecholamines (norepinephrine and dopamine), bradykinins, ACTH, GHRH, and others [109]. The secretory behavior of the tumor as well as the exposure to the systemic circulation determines whether a paraendocrine syndrome will develop. Enzymes capable of metabolizing the secretory products are present in the liver and lung. Tumor products secreted from gastrointestinal carcinoids travel to the liver via the portal circulation and are inactivated before a paraendocrine syndrome can be manifested. If metastases to the liver occur, secretory products may enter the systemic circulation via the hepatic vein and exert their systemic effects.

The carcinoid syndrome is classically described as the triad of flushing, diarrhea, and bronchospasm. In addition, patients complain of sweating, tachycardia, and dyspnea. Diarrhea can be particularly troublesome, occurring up to 30 times per day and causing fluid and electrolyte disturbances as well as weight loss [110]. The limerick below aptly describes the classic patient with carcinoid syndrome:

This man was addicted to moanin'
Confusion, edema and groanin'
Intestinal rushes
Great tricolored blushes
And died from too much serotonin
Samuel A. Wells [111]

Carcinoid crises are life-threatening, severe episodes of profound flushing, hypertension or hypotension, arrhythmia, bronchoconstriction, and alteration of mental status [110, 112]. Crisis may be triggered by emotional stress, heat, cold, ingestion of certain foods (such as alcohol, chocolate), straining, as well as physical manipulation of the tumor (abdominal palpation or biopsy) [109, 113].

A significant proportion of carcinoid syndromes occur in the bronchus and, less commonly, in the thymus [106] and therefore will be encountered by the thoracic anesthesiologist. In contrast to gastrointestinal carcinoids, bronchial and thymic carcinoids are seldom secretory. Less than 5% of

Table 15.10 Common paraneoplastic syndromes

	Humoral hypercalcemia	SIADH	Cushing's syndrome
Associated malignancy	Squamous cell cancers of the lung, esophagus, head, and neck. Breast cancer, more rarely ovarian cancer	Small cell lung cancer and squamous cell cancer of the head and neck	Small cell lung cancer bronchial carcinoid, medullary thyroid cancer, pancreatic islet cell tumors, pheochromocytoma
Presentation	Muscle weakness, cardiac arrhythmias, nausea and vomiting, renal failure	Hyponatremia, decreased serum osmolarity, inappropriately increased urine osmolarity, euvolemia, normal thyroid, and adrenal function	Hypokalemia, alkalosis, hypertension, psychosis
Etiology	Increased release of parathyroid-related peptides and other cytokines	Production of arginine vasopressin by tumor	Abnormally high secretion of ACTH or CRH
Management	Treat malignancy, hydrate, diuresis, calcitonin, steroids, bisphosphonates	Treat malignancy, fluid restriction, demeclocycline	Dexamethasone suppression (for some tumors), bromocriptine, ketoconazole

Based on data from Ref. [101]
ACTH adrenocorticotrophic hormone, *CRH* corticotrophin-releasing hormone

bronchial carcinoids exhibit paraendocrine syndromes [108]. When the rare secretory bronchial carcinoid is encountered, the symptoms described above may be unusually severe and prolonged. In addition to the classical carcinoid syndrome, bronchial and thymic carcinoids may secrete exclusively ACTH (causing Cushing's syndrome) or even GHRH (causing acromegaly) [114–118]. In fact, bronchial and thymic carcinoids are the most common causes of ectopic ACTH outside the pituitary and adrenal glands [105]. Therefore, although the lung is the most common location of extraintestinal carcinoids, secretion of metabolically active compounds is rare. Although often nonsecretory, the vascularity of these tumors should be kept in mind in the cases of bronchoscopy and particularly biopsy. Severe hemorrhage can result and may require emergency thoracotomy [119].

Advanced carcinoid disease is associated with fibrosis which is attributed to the mitogenic effect of serotonin on smooth muscle and connective tissue. In the abdomen, this may present as retroperitoneal or omental fibrosis, but in the cardiopulmonary system, this can lead to pulmonary hypertension and carcinoid heart disease [109, 120].

Carcinoid heart disease manifests as right-sided valvulopathy, most notably with severe tricuspid regurgitation with progressive volume overload of the right-sided heart chambers. Its onset is usually preceded by a history of carcinoid syndrome indicating passage of secretory products into the systemic circulation and therefore into the chambers of the right heart [121]. Although most often attributed to serotonin, the reduction of serotonin levels by medical management does not alter progression of heart disease indicating that other secretory products are involved in the pathophysiology [122]. The left-sided cardiac chambers are considered to be "protected" by the pulmonary circulation which metabolizes carcinoid products; however, in the presence of a secretory bronchial carcinoid or a right to left shunt, left-sided carcinoid heart disease is seen and manifests as regurgitant mitral and aortic valve lesions [122]. With time, the right ventricle becomes hypokinetic, and right-sided heart failure develops with severe dyspnea, ascites, and peripheral edema. Management options are limited. Medical therapies used for left-sided heart failure often have limited effect or may even worsen right-sided heart failure [121, 122]. Surgical management is the only option and carries a 35% mortality rate [119].

Medical management of carcinoid syndrome was revolutionized by the discovery that the tumor cells often possess somatostatin receptors. Somatostatin, or its longer-acting analog octreotide, is able to suppress tumor secretion and alleviate the symptoms of carcinoid syndrome in most patients [123]. Prior to the introduction of octreotide, management of the carcinoid syndrome involved a variety of antihistamine and antiserotonergic drugs with limited efficacy. Despite the ability to control symptoms of carcinoid disease, octreotide has no effect on tumor growth. Use of chemotherapeutic agents has had limited success in carcinoid tumors making surgical resection the definitive therapy.

Preoperative assessment of patients with carcinoid tumors is influenced by whether the tumor is secretory or not. This is determined by history or by urinary levels of 5-HIAA (a serotonin metabolite) in the case of asymptomatic patients. A nonsecretory tumor has less significance for the anesthesiologist. In the case of carcinoid syndrome, the history should ascertain the severity of symptoms as well as how well they are controlled with medical therapy. The severity of symptoms does not predict the intraoperative course; however, it is helpful to know that the tumor is responsive to octreotide [124]. Physical examination should look for signs of right-sided valvulopathy and heart failure. Preoperative investigations should include complete blood count, electrolytes, liver function tests, and creatinine as well as measurement of blood glucose. All patients should have an electrocardiogram and chest X-ray to screen for cardiac disease; however, an echocardiogram is the definitive test for carcinoid heart disease.

Perioperative care of the patient with carcinoid syndrome involves avoidance of triggers and preparation to manage crisis, particularly at times of tumor manipulation.

Preoperative optimization should correct hypovolemia and electrolyte imbalances. Preoperative sedation with benzodiazepine (lorazepam sublingual 2 mg, 90 min preoperatively) is highly recommended, and consideration may be given to use of cyproheptadine (4 mg; antihistamine and antiserotonergic) as well. Patients should receive octreotide 50–100 mcg sc BID for at least 24 h prior to induction with an additional 100mcg sc 1 h preoperatively [119, 121, 124].

Intraoperatively, monitors should be placed while the patient is awake. In addition to standard monitors, invasive blood pressure monitoring is required, and central access is indicated for CVP monitoring, rapid administration of drugs, fluids, and blood if required. Temperature monitoring and body warmers should be used as hypothermia is a trigger of crises. In the presence of cardiac disease, transesophageal echocardiography should be readily available. Octreotide infusion at 100–250mcg/h is recommended [112, 119] and may be started once in the operating room. A smooth induction and blunting of airway reflexes for intubation are ideal. Nonhistamine-releasing opioids such as fentanyl or remifentanil may be used with good results [125]. The use of NDMR is safe provided histamine release is avoided. Succinylcholine use is controversial. Some practitioners strictly avoid it due to concern over histamine release and concern over precipitating a crisis secondary to fasciculations [112, 119]. In a review of 21 patients with carcinoid syndrome, Veall et al. [126] used succinylcholine in half of patients uneventfully. Therefore, in optimized patients, the use of succinylcholine

should not be considered contraindicated when airway or other concerns make it the best choice of muscle relaxant.

Intraoperatively, electrolytes and glucose should be monitored, and hyperglycemia may require insulin infusion. Octreotide, diluted to 10–50 mcg/mL, should be readily available for emergency use in doses of 50–100mcg iv titrated to response.

Carcinoid crisis may manifest as profound hypertension or hypotension accompanied by bronchospasm. Hypertension may be treated by increasing anesthetic depth, administering a bolus of short-acting opioid [126], using β-blockade (metoprolol or esmolol) [124], or administering octreotide. Kataserin, a selective serotonin antagonist with α-1 blocking effects, has also been described as useful (dose 5–10 mg) but has Vaughn-Williams class I and III antiarrhythmic effects and may prolong QT interval [121, 124]. Cyproheptadine (1 mg) and methotrimeprazine (2.5 mg) are serotonin antagonists which have also been described for the management of hypertensive carcinoid crisis.

Profound hypotension is a more common manifestation of crisis intraoperatively and may be severe. The treatment of choice is octreotide boluses as described above. Intravenous octreotide reaches peak effect after 4 min; there are no significant side effects, and doses may need to be escalated until a response is seen [126]. Vasopressin or phenylephrine has also been described as an additional therapy if hypotension is refractory [124, 127]. Additional management of hypotension includes fluid resuscitation, reduction of anesthetic depth, and cessation of surgical manipulation. Catecholamines are usually avoided in the treatment of hypotension as they may precipitate further crisis; however recent data suggest they may be used in patients who have been optimized with somatostatin analogs [122]. If necessary, small boluses should be administered and the response observed carefully. In addition to the above, calcium, angiotensin, and milrinone are also considered safe [112, 126].

The management of bronchospasm with salbutamol is another area of controversy. Noncatecholamine bronchodilators (ipratropium bromide), steroids, antihistamines, and octreotide have been suggested as effective for crisis-associated bronchospasm [124]. Others describe the safe and effective use of salbutamol and advocate its use despite sympathomimetic activity [102, 126]. While noncatecholamine bronchodilators should be considered first, salbutamol is not contraindicated particularly in the optimized patient with bronchospasm.

Neuraxial anesthesia is controversial in a patient population at risk for acute hemodynamic instability; however both epidural [125, 128] and spinal anesthesias [129] have been described even in the presence of severe carcinoid heart disease. Keys to this approach noted by all authors included fluid loading, and minimization of hemodynamic changes with careful drug selection.

Postoperatively, delayed awakening has been described and attributed to the high serotonin levels. Patients require an intensive care environment where hemodynamic monitoring and continuation of drug infusions are possible. Manifestations of carcinoid syndrome may continue due to residual tumor or unresected metastases. Octreotide infusions should be continued or weaned slowly while monitoring for manifestations of secretory activity. Postoperative analgesia is imperative to avoid triggering crisis, and for this reason, the benefits of a carefully titrated epidural infusion may outweigh the risks.

Lambert-Eaton Myasthenic Syndrome (LEMS)

LEMS is a common paraneoplastic neurological syndrome associated with lung cancer [130]. Fifty to sixty percent of patients with LEMS will subsequently be diagnosed with a malignancy, most commonly small cell lung cancer (SCLC), within 2 years [131].

LEMS bears a striking resemblance to MG at first glance, but there are many important differences (Table 15.11). While MG is a disease affecting the postsynaptic membrane, LEMS is due to a reduction in acetylcholine release from the presynaptic nerve terminal [132–134]. An autoimmune attack directed against the voltage-gated calcium channels of the presynaptic nerve terminal reduces calcium entry into the presynaptic nerve terminal. As a result of reduced calcium influx, there is markedly reduced acetylcholine release leading to symptoms of LEMS.

The most common symptom of LEMS is proximal lower extremity weakness. Many also experience autonomic symptoms such as dry mouth, impotence, constipation, and orthostatic hypotension. Ocular and bulbar muscle involvement may be present, but it is often mild and usually not the presenting feature. Respiratory muscle weakness can occur but usually as a late complication [135].

Table 15.11 Myasthenia gravis vs. Lambert-Eaton syndrome

Feature	Myasthenia gravis	Lambert-Eaton syndrome
Most common malignancy	Thymoma (40%)	Small cell lung cancer (1–3%)
Antibody target	Post synaptic acetylcholine, MuSK, LRP-4 receptors	Presynaptic voltage-gated calcium channels
Common presenting feature	Ocular progressing to limb and then bulbar weakness	Limb weakness, ocular and bulbar sparing
Autonomic dysfunction	Rare	Common
Deep tendon reflexes	Normal	Reduced
Exercise effect	Weakness exacerbated	Weakness reduced

Management of LEMS is usually medical as patients with SCLC are often not operative candidates for resection of their malignancy. 3,4-Diaminopyridine is a potassium channel-blocking drug which causes the depolarization of the presynaptic nerve terminal to be prolonged. This allows time for increased calcium influx which results in increased acetylcholine release and greater clinical strength [131]. There may also be a role for IVIG and plasmapheresis in some cases [102].

Patients with LEMS presenting for anesthesia are very sensitive to both succinylcholine and NDMR [131]. Therapy with 3,4-diaminopyridine should be continued up to the time of surgery. The use of paralytics should be minimized and, if necessary, should be titrated in very small doses and monitored closely. Reversal of neuromuscular blockade by usual means is seldom effective. The administration of 3,4-diaminopyridine concomitantly with reversal agents has met with some success [136, 137]. Additional consideration should be given to the potential for autonomic disturbances, and provision should be made preoperatively for postoperative ventilation if required.

Case Discussion

Case A 32-year-old female presents for preoperative assessment. She is booked for a transcervical thymectomy for MG. In addition to the usual preoperative assessment, consider:

- What additional information, specific to this patient, should be gathered at the preoperative anesthesia consultation?
- Appropriate investigations
- How will you optimize her for her upcoming surgery?
- What premedication will she require including dosing of her current medication?
- Appropriate preoperative disposition
- Your anesthetic technique of choice including acute postoperative pain management

What Additional Information, Specific to This Patient, Should Be Gathered at the Preoperative Anesthesia Consultation?

In addition to the usual elements of a preoperative consultation, the preoperative visit should serve to characterize the severity of MG in this patient as well as determine if there are any mediastinal compressive symptoms. A history of associated autoimmune disorders should also be sought.

Determine when the patient was diagnosed with MG and how the disease has progressed. Determine if the symptoms have been purely ocular or if they have involved bulbar muscles (putting the patient at risk for dysphagia and aspiration), axial or limb muscles, or if the patient has had any episodes of respiratory failure requiring ventilator support. Determine the management history, particularly the dose and frequency of pyridostigmine and what consequences are of delaying a dose. Is there a history of steroid requirements or the use of any other immunosuppressant drugs?

A history of palpitations, chest pain, or dyspnea on exertion as well as findings consistent with heart failure should be sought due to the possibility of cardiac involvement. The association with thyroid dysfunction, rheumatoid arthritis, and lupus should prompt screening questions which may or may not require additional medical consultation and optimization.

To screen for a thymoma with mass effect, a history of orthopnea, supine dyspnea, or cough should be sought. Changes in voice (dysphonia, hoarseness), palpitations, syncope, edema of the face or tongue, and dysphagia are other signs of mediastinal compression; however, dysphagia and dysphonia may also be due to MG.

This patient has been diagnosed with MG for 5 years. She initially presented with oculobulbar symptoms which were well controlled with pyridostigmine. Over the last few years, increasing doses have been required eventually prompting referral for surgical treatment. She does not have any associated autoimmune disorders and denies all symptoms of mass compression. To her knowledge, there is no thymoma present. She takes 80 mg of pyridostigmine every 4 h and feels weakness if she is more than an hour later with her dose. Her usual first dose is around 6 o'clock in the morning.

Appropriate Investigations

Bloodwork: CBC (pernicious anemia) and crossmatch are mandatory. Strongly consider electrolytes and creatinine, coagulation profile, and TSH as well.

Imaging must be reviewed, CXR and chest CT for the presence of thymoma. Bloodwork in this patient is all within normal limits. Her TSH is normal. The radiologist's reports do not mention any sign of aspiration pneumonia nor any thymoma causing compression of cardiopulmonary structures.

How Will You Optimize Her for Her Upcoming Surgery?

Confirm that the patient's neurologist is aware of the upcoming surgery and discuss possible plasmapheresis or IVIG to optimize the patient's muscle strength and minimize the chances of postoperative respiratory failure and the need for postoperative ventilation. Pyridostigmine should be continued up to the day of surgery, and the surgery should be scheduled first thing in the morning. The patient should be instructed to take their morning dose of pyridostigmine as close to the time of surgery as possible. If surgery takes longer than expected, an intravenous supplemental anticholinesterase may be given or an additional dose of oral pyridostigmine may be given via nasogastric tube. No premedication with sedating effects should be ordered.

What Is the Anesthetic Technique of Choice Including Postoperative Pain Management?

General anesthesia with endotracheal intubation is the technique of choice under these circumstances. Induction with propofol and remifentanil is recommended (no neuromuscular blockade). Maintenance may be achieved with a volatile such as desflurane or with a propofol infusion. Remifentanil may be used as an analgesic infusion. Pre- or intraoperative acetaminophen and nonsteroidal anti-inflammatory (such as Naprosyn or ketorolac) should also be used and continued postoperatively. The surgeon should also be asked to infiltrate the wound with local anesthetic solution at closure.

What Is the Most Appropriate Postoperative Disposition?

Patients undergoing transcervical thymectomy for nonthymomatous MG have significantly less pain and respiratory dysfunction than patients undergoing transsternal thymectomy. Provided that the patient can be optimized preoperatively with plasmapheresis or equivalent, an overnight stay in a regular ward is appropriate. Pain is likely to be manageable with oral opioids, and multimodal analgesia with acetaminophen and anti-inflammatories will be beneficial. Based on the history, optimization, and low analgesic requirements, the risk of postoperative respiratory failure is low. Pyridostigmine dosing must be continued, and ongoing collaboration with neurology and the postoperative care team is important.

Part VI

Anesthetic Management for Intra-Thoracic Surgery

Lung Isolation

16

Javier Campos

Key Points

- During the preoperative period, review of the posteroanterior chest radiograph is necessary to measure the tracheal width and also appreciate the pattern of the tracheobronchial anatomy to determine what device and size to use.
- The left-sided DLT is the most common device used for lung isolation because of its greater margin of safety.
- The use of bronchial blockers is indicated in patients who present with difficult airways and require lung isolation.
- Patients with a tracheostomy in place requiring lung isolation are best managed with the use of an independent bronchial blocker and flexible fiberoptic bronchoscopy.
- Flexible fiberoptic bronchoscopy is the recommended method to achieve optimal position of lung isolation devices, first in supine position, later in lateral decubitus, or whenever a malposition occurs.

Introduction

Lung separation techniques are used to provide one-lung ventilation (OLV) in patients undergoing thoracic, mediastinal, cardiac, vascular, or esophageal procedures [1, 2]. Lung separation can be achieved with two different techniques. The first involves a device made of disposable polyvinylchloride material, the double-lumen endotracheal tube (DLT) [3]. The DLT is a bifurcated tube with both an endotracheal and an endobronchial lumen and can be used to achieve isolation of either the right or left lung. In addition the newly designed VivaSight® DLT has an integrated camera, allowing continuous visualization of its position within the trachea [4]. The second technique involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion [5]. Currently, there are different bronchial blockers available to facilitate lung separation collapse; these devices are either attached to a single-lumen endotracheal tube with an enclosed bronchial blocker (Torque Control Blocker Univent) (Vitaid, Lewiston, NY) [6] or are used independently over a standard single-lumen endotracheal tube, as with the wire-guided endobronchial blocker (Arndt® blocker) [7] (Cook Critical Care, Bloomington, IN), the Cohen tip-deflecting endobronchial blocker [8] (Cook Critical Care, Bloomington, IN), the Fuji Uniblocker® [9] (Fuji Corp, Tokyo, Japan], or the EZ-blocker® [10] (Teleflex Medical, Morrisville, NC). There are a number of recognized indications for OLV. In practice, the most common indications for lung separation are (1) for surgical exposure, (2) for prevention of contamination to the contralateral lung from bleeding pus material or saline lavage (abscess, hemoptysis, bronchiectasis, and lung lavage), and (3) during differential lung ventilation or for continuity of the airway gas exchange such as with bronchopleural fistula. Table 16.1 describes common indications for lung isolation with a DLT or a bronchial blocker.

Double-Lumen Endotracheal Tubes

Currently, all DLTs are based on a design suggested by Carlens and Björk [11]. There are two versions of DLTs, left-sided and a right-sided, which are designed to accommodate the unique anatomy of each mainstem bronchus [12]. DLTs are available from different manufacturers: Mallinckrodt Broncho-Cath (St. Louis, MO) is the most common brand name in North America; there are also the Sheridan Sher-I-Bronch (Argyle, NY) and DLTs from

Table 16.1 Indications for lung isolation with a double-lumen endotracheal tube (DLT) or a bronchial blocker

A. *Indications for lung isolation with the use of a DLT*
Protection of one lung from a contralateral contamination
Lung abscess
Lung cyst
Pulmonary hemorrhage
Bronchopulmonary lavage
Pulmonary alveolar proteinosis
Control and continuity of the airway gas exchange
Bronchopleural fistula
Bronchial disruption (i.e., laceration with a knife)
Pneumonectomy
B. *Indication for lung isolation with the use of a DLT or a bronchial blocker*
Any operation that requires surgical exposure through the chest cavity with lung collapse
Video-assisted thoracoscopic surgery
Lobectomy and bilobectomy
Mediastinal mass resection through the chest (selective cases)
Esophageal surgery
Orthopedic procedures (spine surgery involving chest)
Minimally invasive cardiac surgery
C. *Specific indications for bronchial blockers*
Difficult airways
Limited mouth opening
Nasotracheal intubation
Awake orotracheal intubation
Already intubated patient requiring lung isolation
Tracheostomy patient requiring lung isolation
Selective lobar blockade
Potential for mechanical ventilation in the postoperative period

Table 16.2 Displays the external and internal diameters of the different sizes of DLTs and the size of the flexible fiberoptic bronchoscope recommended

DLT French size (F)

Rüsch (Duluth, GA) and Portex (Keene, NH) and the VivaSight® DLT from Teleflex (St. Louis, MO). The sizes of the DLTs vary among manufacturers; the smallest available is 26 French (F) followed by 28, 32, 35, 37, 39, and 41 F. Table 16.2 displays the external and internal diameters of the different sizes of DLTs and the size of the flexible fiberoptic bronchoscope recommended (of note, the size of the DLTs varies among manufacturers). The ones described in this table are Mallinckrodt Broncho-Cath, Sher-I-Bronch, and Rüsch.

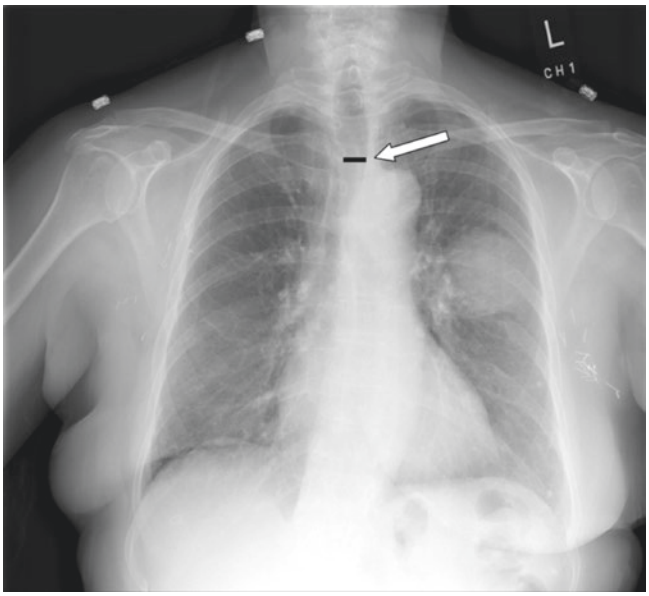
Size Selection

Regarding selection of the proper size of a DLT, all studies have focused on the left-sided DLT in part because the right-sided DLT is used infrequently. A common problem with the left-sided DLT is the lack of objective guidelines to properly choose the correct or approximate size of DLT.

A left-sided DLT that is too small requires a large endobronchial cuff volume, which might increase the incidence of malposition. In addition, a small DLT does not readily allow fiberoptic bronchoscope placement and can make suction difficult. A properly sized DLT is one in which the main body of the tube passes without resistance through the glottis and advances easily within the trachea and in which the bronchial component passes into the intended bronchus without difficulty. In a study performed in adult cadavers, it was shown that the cricoid ring diameter never exceeds the diameter of the glottis. If a DLT encounters resistance when passing the glottis, it is likely that the DLT would encounter resistance while passing the cricoid ring [13].

There are reports of complications related to the use of an undersized DLT. A tension pneumothorax and pneumomediastinum occurred after the endobronchial tip of an undersized DLT had migrated too far into the left lower bronchus, and the entire tidal volume was delivered into a single lobe [14]. Also, smaller DLTs might present with more resistance to gas flow and more intrinsic auto-positive end-expiratory pressure compared with the wider lumen of larger DLTs [15]. Airway-related complications have been reported with undersized left-sided DLTs. A rupture of the left mainstem bronchus by tracheal portion of a DLT has been reported [16]. A longitudinal laceration of the left mainstem bronchus occurred. The cause of this complication was believed to be an undersized DLT, which allowed the endotracheal portion of the DLT to enter the left mainstem bronchus. In addition, an oversized DLT also can be associated with bronchial rupture in a small adult patient [17].

Brodsky et al. [18] reported that measurement of tracheal diameter at the level of the clavicle on the preoperative posteroanterior chest radiograph can be used to determine proper left-sided DLT size. These methods lead to a 90% increase in the use of larger left-sided DLTs (i.e., 41 F DLT in men and 39 F and 41 F DLT in women). However, a study involving Asian patients by Chow et al. [19], using the methodology of Brodsky et al. [18], found this approach less reliable. In the Chow et al. [19] study, the overall positive predictive value for the proper left size of a left-sided DLT was 77% for men and 45% for women. This method seems to have limited use in patients of smaller stature, such as women and people of Asian descent, and an alternative method should be sought, including placement of a different lung isolation device such as an independent bronchial blocker through a single-lumen endotracheal tube. Figure 16.1 shows the guidelines to pre-



Measured Tracheal Width (mm)	Predicted Left Bronchus Width (mm)	Recommended DLT size (F)
≥**18**	≥12.2	**41**
≥**16**	≥10.9	**39**
≥**15**	≥10.2	**37**
≥**14**	≥9.5	**35**

dict the proper left-sided DLT based upon measurements of the tracheal width from the chest X-ray according to Brodsky et al. [18].

A study involving thoracic anesthesiologists by Amar et al. [20] has shown that the use of a smaller DLT (i.e., 35 or 37 F left-sided DLT) rather than a conventionally large-sized DLT (i.e., 39 or 41 F) was not associated with any difference in clinical intraoperative outcomes, regardless of patient size or gender in 300 patients undergoing thoracic surgery requiring lung isolation. However, in their study, only 51 (35%) of the patients who received a 35 F DLT were males, and 92 (65%) were females. In practice, women usually receive a 35 F DLT; therefore, the question of whether or not a 35 F for all patients is favorable remains unclear.

Another alternative that has been suggested in order to predict the proper size of a right-sided or left-sided DLT is a three-dimensional image reconstruction of tracheobronchial anatomy generated from spiral computed tomography (CT) scans combined with superimposed transparencies of DLTs [21]. Taken together, these studies suggest that chest radiographs and CT scans are valuable tools for selection of proper DLT size, in addition to their proven value in assessment of any abnormal tracheobronchial anatomy. These images should be reviewed before placement of a DLT. Particular emphasis should be made in viewing a posteroanterior chest radiograph in order to assess the shadow of tracheobronchial anatomy along with bronchial bifurcation. It is estimated that in 75% of the films, the left mainstem bronchus shadow is seen. The trachea is located in the midline position, but often can be deviated to the right at the level of the aortic arch, with a greater degree of displacement in the setting of an atherosclerotic aorta, advanced age, or in the presence of severe chronic obstructive pulmonary disease (COPD). With COPD or aging, the lateral diameter of the trachea may decrease with an increase in the anteroposterior diameter. Conversely, COPD may also lead to softening of the tracheal rings with a decrease in the anteroposterior diameter of the trachea. The cricoid cartilage is the narrowest part of the trachea with an average diameter of 17 mm in men and 13 mm in women.

Figure 16.2a shows a multidetector three-dimensional CT scan of the chest displaying the trachea and bronchial anatomy in a 25-year-old healthy volunteer; Fig. 16.2b shows the changes that occur in a 60-year-old man with severe COPD, which shows a deviated trachea and narrow bronchus. Points of importance include the recognition of any distorted anatomy identified in the films prior to placement of DLTs.

Methods of Insertion

Two techniques are used most commonly by anesthesiologists when inserting and placing a DLT. The first is the blind technique, that is, when the DLT is passed with direct laryngoscopy, then it is turned to the left (for a left-sided DLT) or right (for a right-sided DLT) after the endobronchial cuff has passed beyond the vocal cords. The DLT then is advanced until the depth of insertion at the teeth is approximately 29 cm for both men and women if the patient's height is at least 170 cm [23].

The second technique employs fiberoptic bronchoscopy guidance, where the tip of the endobronchial lumen is guided after the DLT passes the vocal cords; direction is sought with the aid of a flexible fiberoptic bronchoscope. A study by Boucek et al. [24] comparing the blind technique versus the fiberoptic bronchoscopy-guided technique showed that of the 32 patients who underwent the blind technique approach, primary success occurred in 30 patients. In contrast, in the 27 patients receiving the bronchoscopy-guided technique, primary success was achieved only in 21 patients and eventual success in 25 patients. This study also showed that the time spent placing a DLT was an average of 88 s for the blind technique and 181 s for the directed bronchoscopic approach. Although both methods resulted in successful left mainstem bronchus placement in most patients, more time was required when the fiberoptic bronchoscopy guidance technique was used. In addition, two patients in each group required an alternative method for tube placement. Either method may

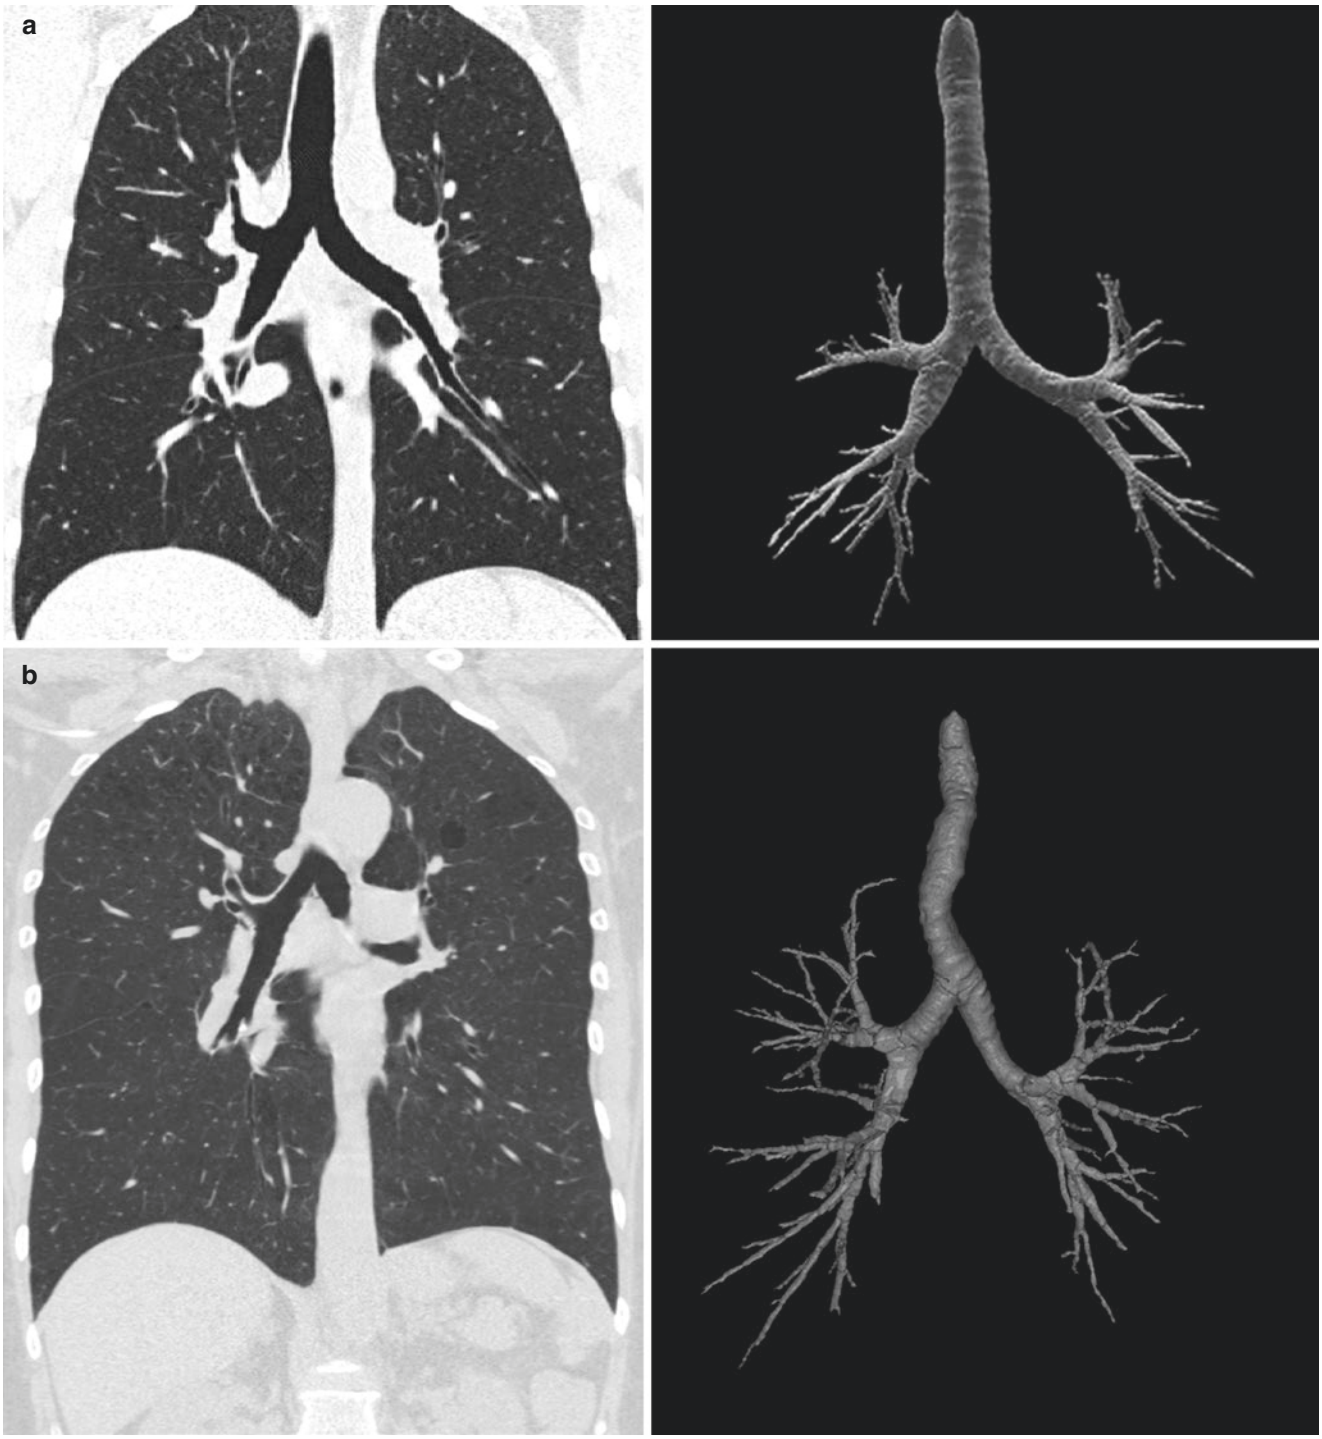

Fig. 16.2 (**a**) Male tracheobronchial tree via multidetector three-dimensional computer tomography scan in a healthy 25-year-old. (**b**) Male tracheobronchial tree via multidetector three-dimensional computer tomography scan in a 60-year-old with chronic obstructive pulmonary disease (COPD) [22]

fail when used alone. Figure 16.3 shows the blind method technique and Fig. 16.4 shows a fiberoptic bronchoscopy guidance technique for placement of a left-sided DLT.

In recent years video laryngoscopy has been introduced as an important tool in the management of patients with expected or unexpected difficult airways. Clinical studies have shown that video laryngoscopes improve visualization of laryngeal structures and facilitate insertion of a single-lumen endotracheal tube [26]. The use of the C-MAC video laryngoscope has been compared with the Macintosh blade (most common

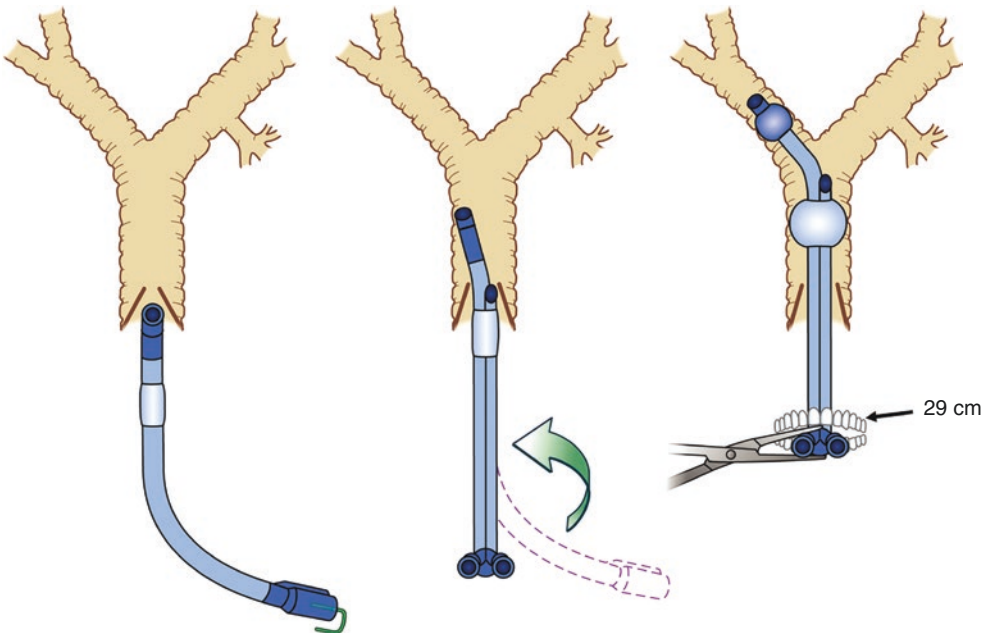

Fig. 16.3 Blind technique for placement of a left-sided DLT [25]

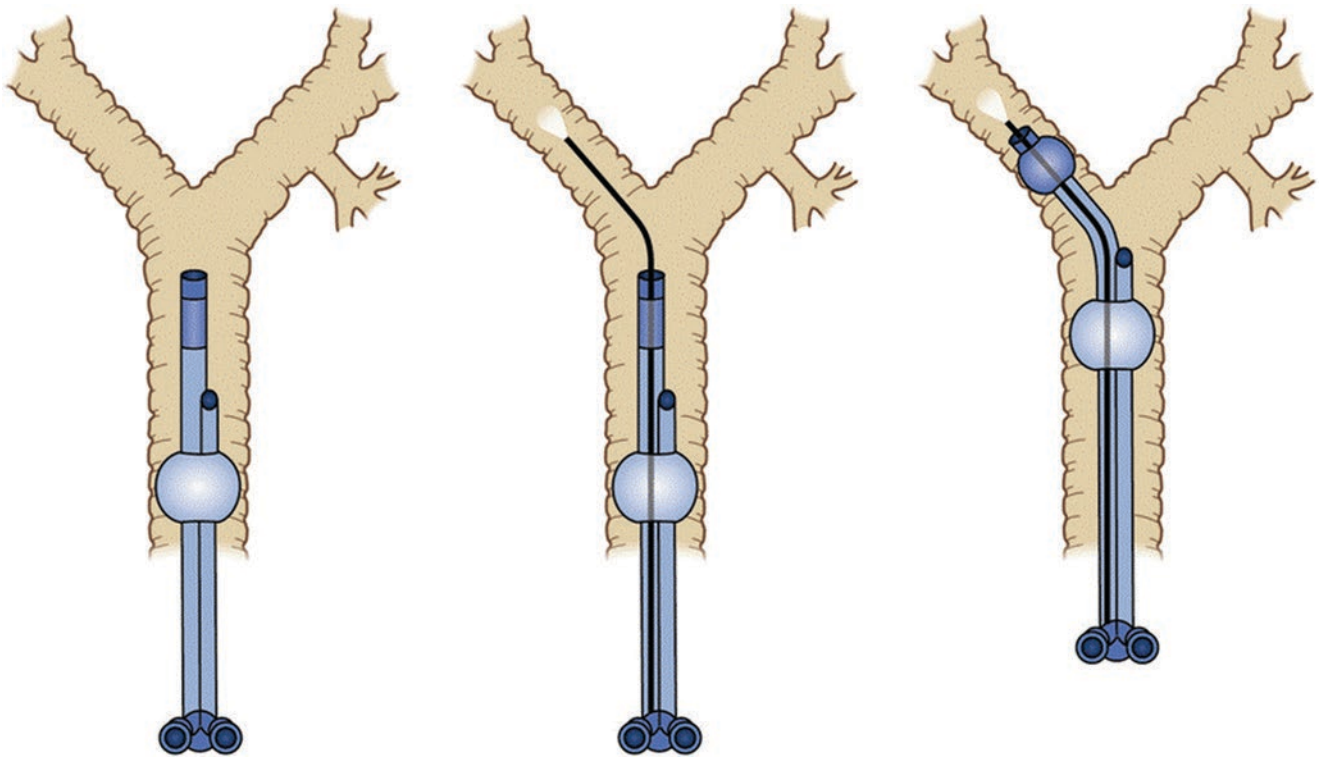

Fig. 16.4 A fiberoptic bronchoscopy guidance technique for placing a left-sided DLT [25]

device used during laryngoscopy while using a DLT) and the Miller blade during DLT intubation in patients with normal airways. The authors of this retrospective study [27] showed that video laryngoscopy was similar to the views obtained with a Miller blade while passing a DLT. In contrast the group that used a Macintosh blade had reported higher difficult intubations with the DLTs. Another study [28], comparing the GlideScope® and the Macintosh laryngoscope for a DLT intubation, showed that the overall rate of successful endobronchial intubation was easier with the Macintosh blade compared with the GlideScope; also voice changes were less common in the Macintosh group. Therefore the authors do not recommend the routine use of the GlideScope in patients who have normal airways while using a DLT.

Table 16.3 Indications for a right-sided DLT

Any contraindication to placement of a left-sided DLT
Distorted anatomy of the entrance of left mainstem bronchus by an intrabronchial or external compression
Compression of the entrance of the left mainstem bronchus due to a descending thoracic aortic aneurysm
Left lung transplantation
Left-sided sleeve resection
Left-sided pneumonectomy

In contrast a recent study [29] using the Airtraq DL® video laryngoscope during placement of DLT showed an improvement exposure of the supraglottis during insertion of the DLT in patients with normal airways. Using the Airtraq DL® video laryngoscope, patients were graded Cormack and Lehane I as compared to the Macintosh laryngoscopy. Overall the use of a video laryngoscope while inserting a DLT will depend on the experience of the operator and the clinical necessity at laryngoscopy

Right-Sided Double-Lumen Endotracheal Tubes

Although a left-sided DLT is used more commonly for most elective thoracic procedures [30], there are specific clinical situations in which the use of a right-sided DLT is indicated. Table 16.3 displays the indications for use of a right-sided DLT.

The anatomic differences between the right and left mainstem bronchus are reflected in fundamentally different designs of the right-sided and left-sided DLTs. Because the right mainstem bronchus is shorter than the left bronchus and because the right upper lobe bronchus originates at a distance of 1.5–2 cm from the carina, techniques using right endobronchial intubation must take into account the location and potential obstruction of the orifice of the right upper lobe bronchus. The right-sided DLT incorporates a modified cuff, or slot, on the endobronchial side that allows ventilation of the right upper lobe. Figure 16.5 displays the Sheridan and the Mallinckrodt right-sided DLTs.

Safety

In theory, the left-sided DLT and right-sided DLT should be equally safe and efficacious for collapse of either the right or the left lung. In practice, however, use of the right-sided DLT has become controversial. An early study showed that because of bronchial anatomy, the left-sided DLT is simpler to use and has a greater margin of safety than the right-sided DLT [31]. Another study [32] has shown failure to ventilate the right upper lobe in 11% of patients and obstruction of the right upper bronchus in 89% of patients after right-sided DLT placement; studies relying on fiberoptic bronchoscopy guidance techniques have shown no increased risk of obstruction of the right upper lobe orifice [33]. A right-sided DLT from the Mallinckrodt brand has been modified to increase the margin of safety. In this right-sided Broncho-Cath® DLT, the opening slot of the ventilating orifice for the right upper bronchus lobe has been widened and consists of an enlarged area of the lateral orifice; this modification has increased the alignment between the opening slot and the right upper lobe bronchus [34]. A contraindication for right-sided DLT use is the presence of an anomalous right upper lobe takeoff from the trachea, which has been estimated to be present in 1 of 250 otherwise normal subjects [35]. A recent study involving the use of right- or left-sided DLTs has shown that these have identical clinical performances. In this study, the authors hypothesized that by placing a left-sided DLT for a right-sided lung isolation, the tubes will have similar performance. This retrospective study reported no difference in the incidence of duration of hypoxemia hypercarbia or high airway pressures [36]. Unfortunately, this study was retrospective in nature, and also the authors showed greater than 35 cm H_2O of peak inspiratory pressure in over 65% of the cases reported in both groups during OLV.

Placement Technique

The preferred technique for placement of a right-sided DLT is with the fiberoptic bronchoscopy guidance technique. After the right-sided DLT is passed beyond the vocal cords under direct laryngoscopy, the fiberoptic bronchoscope is advanced through the endobronchial lumen. Before advancing the DLT, the tracheal carina, the entrance of the right mainstem bronchus, and the entrance of the right upper lobe bronchus are identified. Then the DLT is rotated 90° to the right and advanced with the aid of the fiberoptic bronchoscope. The optimal position of a right-sided DLT is one that provides good alignment between the opening slot of the endobronchial lumen in relationship to the entrance of the right upper lobe bronchus and, distally, a clear view of the bronchus intermedius and the right lower lobe bronchus seen from the endobronchial lumen. From the tracheal view, the optimal position for a right-sided DLT provides a view of the edge of the blue cuff of the endobronchial balloon when inflated just below tracheal carina and a view of the entrance of the right mainstem bronchus [22]. Figure 16.6 shows the optimal position of a right-sided DLT seen from the endobronchial or endotracheal view with a fiberoptic bronchoscope.

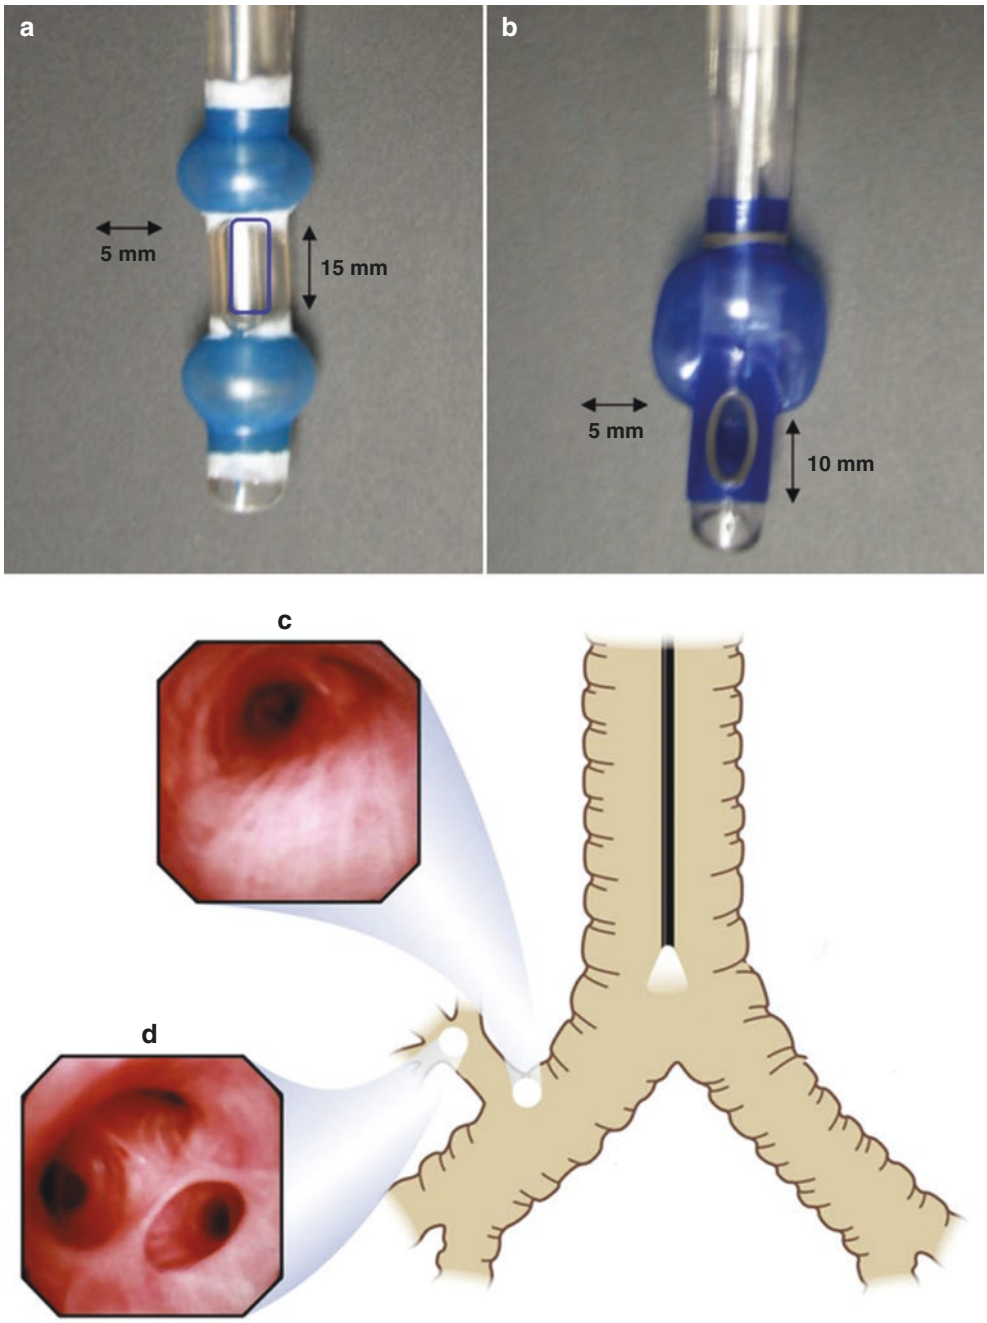

Fig. 16.5 (**a**) Sheridan right-sided DLT. (**b**) Mallinckrodt right-sided DLT. (**c**) View of the right mainstem bronchus showing the bronchus intermedius toward the center of the photo and the smaller right upper lobe orifice to the right. (**d**) The three segments of the right upper lobe (the "cloverleaf" view)

Left-Sided Double-Lumen Endotracheal Tubes

Placement Technique

Placement and positioning of a left-sided DLT can be accomplished with either technique discussed earlier, the blind technique in which the left-sided DLT is passed beyond the vocal cords (endobronchial cuff) and the tube is rotated 90° counterclockwise and advances until the tip of the tube enters the left mainstem bronchus, or the bronchoscopy guidance technique, in which the endobronchial tip is passed beyond the vocal cords and guided through the trachea with the aid of the fiberoptic bronchoscope until the entrance of the left mainstem bronchus is identified and the tube is introduced into the left bronchus. The optimal position for a left-sided DLT as seen with the fiberoptic bronchoscope is the one that allows, from the tracheal lumen view, observation of a fully inflated endobronchial cuff with no more than 3 mL of air located 5–10 mm below the tracheal carina inside the left mainstem

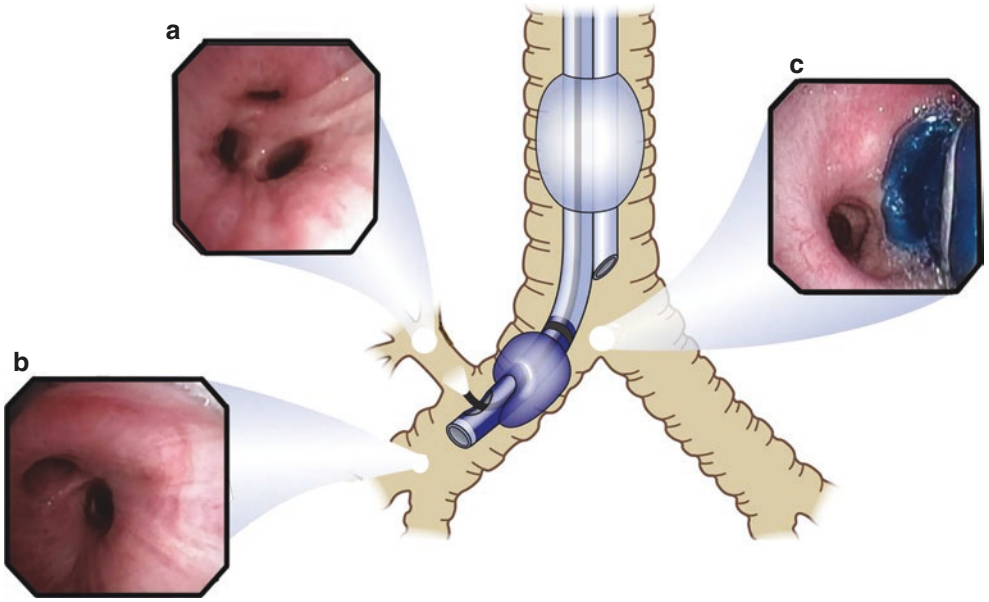

Fig. 16.6 The optimal position of a right-sided double-lumen endotracheal tube. (**a**) Shows the takeoff of the right upper bronchus with three segments (apical, anterior, and posterior) when the fiberoptic bronchoscope emerges from the opening slot located in the endobronchial lumen. (**b**) Shows an unobstructed view of the entrance of the right middle and right lower lobe bronchus when the fiberscope is passed through the endobronchial lumen. (**c**) Shows a view of tracheal carina to the right edge of the blue balloon fully inflated, to the left unobstructed view of the entrance of the left-mainstem bronchus when the fiberscope is advanced through the tracheal lumen

bronchus. The second important view is the endobronchial bronchoscopy view. Two observations are relevant: first, the fiberoptic bronchoscope is advanced inside the endobronchial lumen, and the patency of the lumen is observed before advancing the bronchoscope through the blue portion of the tube; the second view is at the distal end of the endobronchial tip of the tube, where a clear and unobstructed view of the left upper and lower lobe bronchus entrance orifices is visualized distally. In order to recognize the right mainstem bronchus while placing a left-sided DLT, the fiberoptic bronchoscope is advanced through the tracheal lumen below the main tracheal carina to the right side approximately 1–2 cm at which point the orifice of the right upper lobe bronchus is seen at 3–4 o'clock on the lateral wall. Advancing the fiberoptic bronchoscope inside this orifice should provide a clear view of the apical, anterior, and posterior segments (the "cloverleaf" view). This is the only structure in the tracheobronchial tree that has three orifices. Figure 16.7 shows the optimal position of a left-sided DLT as seen with a fiberoptic bronchoscope.

VivaSight Double-Lumen Tube

ET View Medical has designed a new device called the VivaSight DLT with an integrated high-resolution camera. This camera is embedded at the end of the endotracheal lumen, so that when connected to a screen monitor via a cable, it allows a continuous view of the tracheal carina. In addition, this DLT device has an integrated flushing system that allows for in situ camera lens cleaning [37]. Some of the advantages of the VivaSight DLT are that it allows continuous airway monitoring and its view facilitates immediate corrections of DLT malpositions at the level of the tracheal carina [38]. In order to maintain a good visualization with the VivaSight camera, it is recommended that a defogging solution be used prior to insertion [39]. Figure 16.8 shows the VivaSight DLT and monitor. In a prospective single-center study [40], the 76 patients included in the study (99%) had correct position of the VivaSight DLT after intubation; however malposition was present in 40 patients (53%) intraoperatively, although the malpositions were easily corrected while using the embedded camera of the VivaSight DLT without the need of the use of the flexible fiberoptic bronchoscope.

Another study [41] comparing the VivaSight DLT with a conventional DLT in patients undergoing video-assisted thoracoscopic surgery showed that the VivaSight DLT enables significantly more rapid intubation when compared with the conventional DLT. Also in this study the group that received the VivaSight DLT did not require flexible fiberoptic bronchoscopy during intubation and positioning or surgery.

One of the limitations of the VivaSight is the presence of secretions on the tip of the camera; using a suction channel and flushing it with normal saline will in part alleviate the problems. Unfortunately all previous studies have shown more hoarseness and discomfort with the use of the VivaSight DLT. Also, be aware that connecting the camera for prolonged periods of time in vitro will lead to melting the portion of the tube near the light source [41]. The VivaSight DL DLT is only available for a left-sided DLT version. The placement is similar to a conventional DLT with the exception that the tube can be connected through the camera to allow visualization of the vocal cords or tracheal carina while in use.

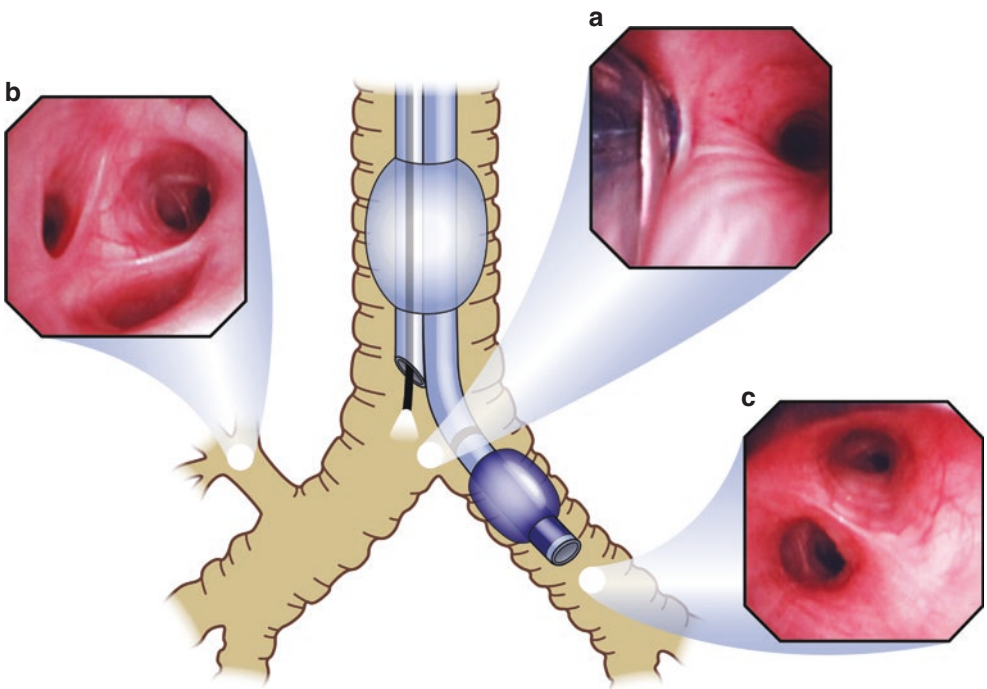

Fig. 16.7 The optimal position of a left-sided DLT. (**a**) View from the tracheal lumen of the unobstructed entrance of the right mainstem bronchus. (**b**) View from the tracheal lumen of the right upper bronchus. (**c**) View from the bronchial lumen of the left upper (above) and left lower (below) lobe bronchi [22]

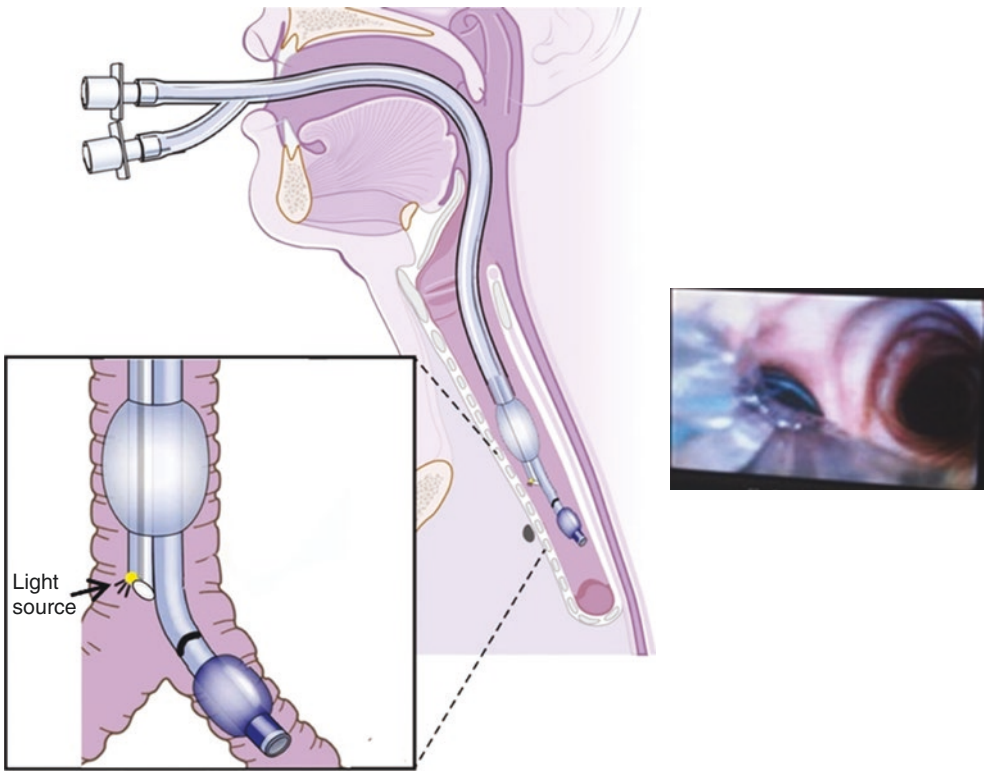

Fig. 16.8 The VivaSight DLT and monitor

Auscultation and Fiberoptic Bronchoscopy when Placing Double-Lumen Endotracheal Tubes

Evidence strongly suggests that auscultation alone is unreliable for confirmation of proper DLT placement. However, the basic principle of auscultation and clamping maneuvers while testing the proper placement of a DLT must be routinely applied prior to the use of fiberoptic bronchoscopy. For a left-sided DLT, the endobronchial lumen should be placed below the tracheal carina into the left mainstem bronchus, and the depth of the tube in a 170-cm-tall subject should be approximately 29 cm at the level of the teeth. Clamping the limb connector of the tracheal lumen should reveal the absence of breath sounds on the right side of the chest (right hemithorax). After this maneuver is completed, the next step is to ventilate both lungs; then to clamp the limb connector of the endobronchial lumen should reveal the absence of breath sounds on the

left side of the chest (left hemithorax). If none of these maneuvers are successful, or confusion ensues with breath sounds and the location of the DLT, a fiberoptic bronchoscopy exam takes precedent. In a study involving 200 patients who were intubated by the blind technique in whom confirmation of placement of DLTs was done first with auscultation and clamping, one of the ports of the connector of the DLT and with a second anesthesiologist with expertise in fiberoptic bronchoscopy reconfirming the placement of the DLT showed that 35% of the tubes placed were malpositioned when auscultation was used alone. All detected malpositions were eventually corrected [42]. A study by Brodsky and Lemmens [30] reported their clinical experience with the use of left-sided DLTs. Using auscultation and clinical signs, they reported 98% efficacy in lung collapse, yet in only 58 instances they used fiberoptic bronchoscopy to attempt to place the DLTs correctly. In this study, there were 71 patients (6.2%) in whom the DLT was found not to be in a satisfactory position, requiring readjustment after initial placement. What is important from the Brodsky study [30] is the fact that in 56 patients the DLT was considered too deep into the left bronchus, and indirectly this was a cause of hypoxemia in 21 of 56 patients who had a malpositioned tube. Anesthesiologists should be able to avoid this complication with the use of fiberoptic bronchoscope. In a report related to the national confidential inquiry into perioperative deaths in Great Britain [43], which detailed the management of patients undergoing esophagogastrectomy, it was shown that 30% of deaths reported were associated with malposition of DLTs. The problems ranged from use of multiple DLTs to prolonged periods of hypoxia and hypoventilation. The anesthesiologists did not use a fiberoptic bronchoscope to confirm DLT position before surgery, during surgery, or when the DLT was placed incorrectly [44].

In another report from Great Britain, Seymour [45] reported a survey among anesthesiologists in a single institution, in which they participated in 506 placements of left- or right-sided DLTs; in their report, only 56% of the cases managed used fiberoptic bronchoscopy to confirm the proper placement of the DLTs. In more than 10% of their cases, hypoxemia was present in the intraoperative period. An editorial by Slinger [46] pointed out the importance of using fiberoptic bronchoscopy to confirm placement of DLTs.

A study involving nonthoracic anesthesiologists with very limited experience in lung separation techniques showed that when placing lung isolation devices (DLTs or bronchial blockers), there was a 38% incidence in unrecognized malpositions when these devices were placed with the fiberoptic bronchoscope. The possible causes were lack of skill with fiberoptic bronchoscopy and lack of recognition of the tracheobronchial anatomy [47]. It is the author's opinion that fiberoptic bronchoscopy is essential and mandatory to achieve 100% success in placement and positioning of DLTs as long as the anesthesiologist is able to recognize proper tracheobronchial anatomy and has skills with flexible fiberoptic bronchoscopy. Table 16.4 displays the findings and outcomes when auscultation, clamping maneuvers, and or fiberoptic bronchoscopy were used to position and achieve optimal position of the DLTs.

In another study involving thoracic anesthesiologist [48], 104 patients were intubated with a left-sided DLT, and auscultation and clamping maneuver technique were used to confirm the optimal position of the DLT. An endoscopist with experience in flexible fiberoptic bronchoscopy was asked to confirm the optimal and proper position after auscultation, and it showed that in 37% of the patients, there were unrecognized malpositions while placing the DLT and all malpositions were easily corrected with the use of flexible fiberoptic bronchoscopy. This study clearly demonstrates that even experienced thoracic anesthesiologists can't rely on the optimal position of the DLT with just auscultation; therefore flexible fiberoptic bronchoscopy must be used to obtain optimal position.

Table 16.4 Role of auscultation, fiberoptic bronchoscopy, and/or both during lung isolation

References	Number of patients	Method	Outcome
Brodsky and Lemmens [30]	1170 DLTs (retrospective study)	Clinical experience over 8-year period (1993–2001)	Successful lung isolation 98%
		Auscultation and clinical signs	56 DLT too deep in the left bronchus ($n = 21$ hypoxemia)
			Fiberoptic bronchoscopy was used $n = 58$
Klein et al. [42]	200 L-R DLTs (prospective study)	Auscultation/clamping/followed by a fiberoptic bronchoscopy with a second anesthesiologist	35% malpositions
			Optimal position achieved with the use of fiberoptic bronchoscopy in all cases
Seymour et al. [45]	506 L-R DLTs (survey)	Audit of DLT	56% used fiberoptic bronchoscopy
		Auscultation/clamping maneuvers or fiberoptic bronchoscopy	>10% hypoxemia ($SpO_2 < 88\%$)

DLT double-lumen endotracheal tube; *R* right; *L* left

New Technology with Double-Lumen Endotracheal Tubes

Fuji Systems in Tokyo, Japan, has introduced the Silbroncho DLT, which is made of silicone. The unique characteristic of this device relies on the wire-reinforced endobronchial tip. Also, the short bronchial tip and reduced bronchial cuff should increase the margin of safety when compared with a Broncho-Cath left-sided DLT. At the present time, only a left-sided Silbroncho DLT is available on the market [49]. Its effectiveness has not been reported.

Also, there is a newly designed right-sided DLT, the Cliny® (Create Medic Co., Ltd., Yokohama, Japan). This device has a long oblique bronchial cuff and two ventilation slots for the right upper lobe. The proximal part of the bronchial cuff is located immediately opposite the tracheal orifice. This device can be useful in patients with a very short right mainstem bronchus [50]. Figure 16.9 (a) displays the Silbroncho left-sided DLT and (b) displays the Cliny® right-sided DLT (c) VivaSight DLT® left-sided.

Another newly designed DLT has been designed to enable rapid and reliable lung isolation using a bronchial blocker. The Papworth BiVent Tube [51, 52] is a DLT with two D-shaped lumens arranged in a side-by-side configuration, separated by a central position. The tube characteristics include a preformed single posterior concavity and a single inflatable, low-volume, high-pressure tracheal cuff. At the distal end, there are two pliable crescent-shaped flanges arising from the central position to form a forked tip. The purpose of the forked tip is to seat at the tracheal carina. A bronchial blocker can be advanced blindly through either lumen and is guided into a bronchus. The size available for the Papworth BiVent tube at the present time is 43 F. According to the developers, the Papworth BiVent tube

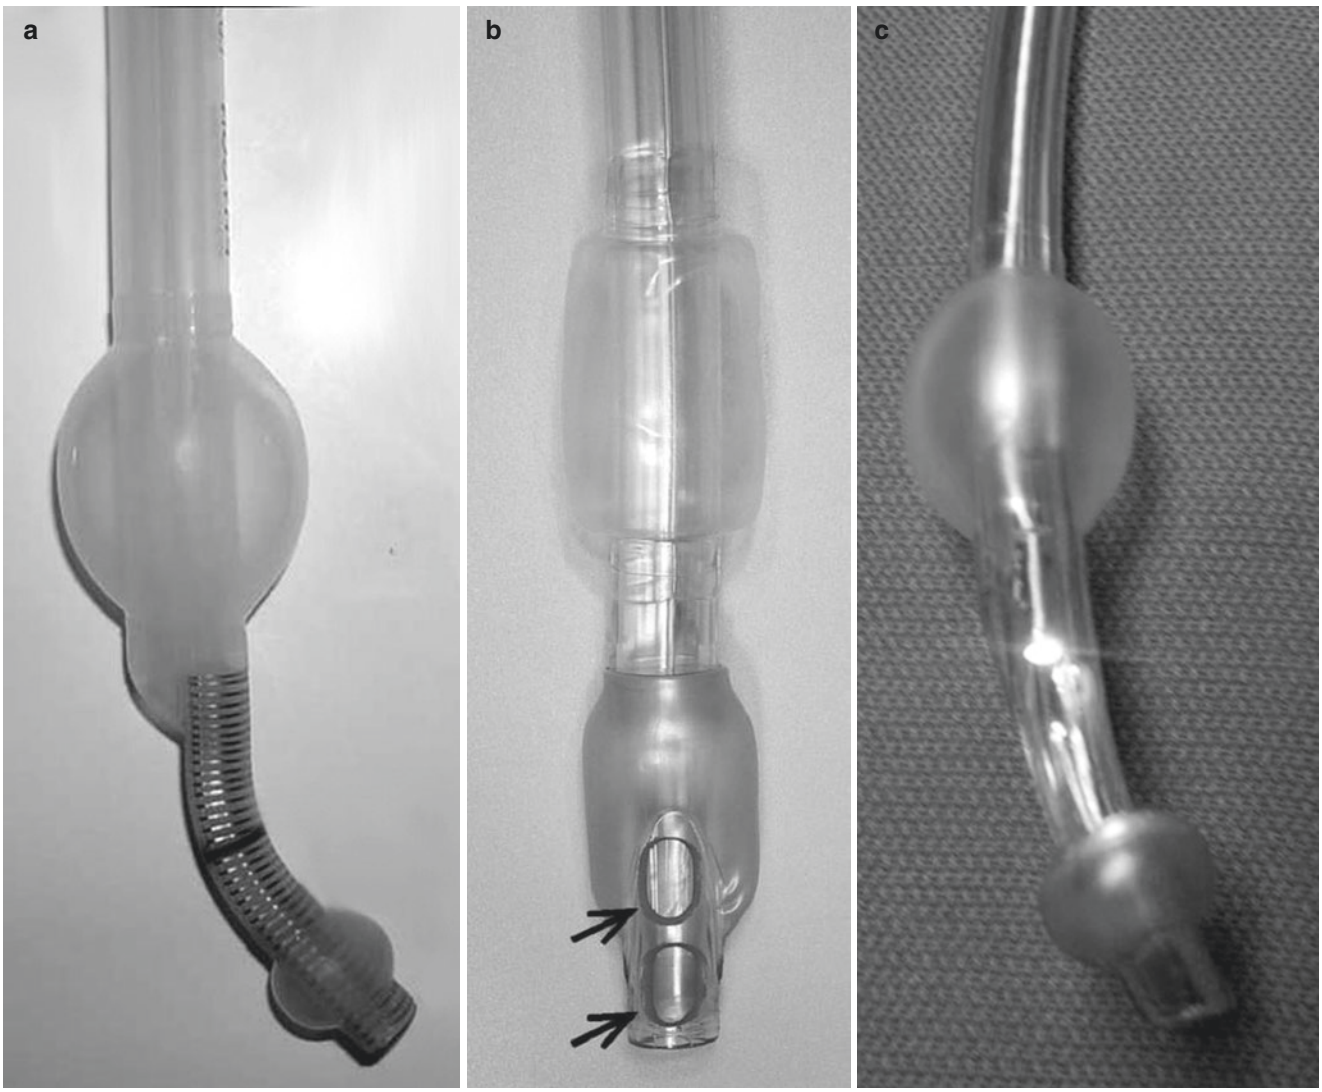

Fig. 16.9 (**a**) Silbroncho left-sided DLT. (**b**) Cliny® right-sided DLT. (**c**) VivaSight DLT® left-sided

can be used without the requirement for endoscopic guidance. Unfortunately, at the present time, there are no studies in humans to confirm its clinical use during lung separation.

A new DLT called the VivaSight DL® has an integrated high-resolution camera. The camera is embedded at the right end of the endotracheal lumen; when connected through a cable, the camera allows continuous visualization of the tracheal carina and blue cuff of the endobronchial lumen of the DLT [37]. The advantage of this device is the real-time image of the position of the DLT.

Complications Associated with Double-Lumen Endotracheal Tube Placement

The most common problems and complications from the use of DLTs are malpositions and airway trauma. A malpositioned DLT fails to allow collapse of the lung, causing gas trapping during positive pressure ventilation, or it may partially collapse the ventilated or dependant lung, producing hypoxemia. A common cause of malposition is dislodgement of the endobronchial cuff because of overinflation, surgical manipulation of the bronchus, or extension of the head and neck during or after patient positioning [53].

Airway trauma and rupture of the membranous part of the trachea or the bronchus continue to be infrequent problems with the use of DLTs [15, 17]. These complications can occur during insertion and placement, while the case is in progress, or during extubation [54–56]. Another problem that has been reported is the development of bilateral pneumothoraces or a tension pneumothorax in the dependent, ventilated lung [57, 58]. A 25-year review of the literature by Fitzmaurice and Brodsky [59] found that most airway injuries were associated with undersized DLTs, particularly in women who received a 35 or 37 F disposable DLT. It is likely that airway damage occurs when an undersized DLT migrates distally into the bronchus and the main tracheal body of the DLT advances into the bronchus, producing lacerations or rupture of the airway. Airway damage during the use of DLTs can present as unexpected air leaks, subcutaneous emphysema, massive bleeding into the lumen of the DLT, or protrusion of the endotracheal or endobronchial cuff into the surgical field, with visualization of this by the surgeon. If any of the aforementioned problems occur, a bronchoscopic examination should be performed and surgical repair performed.

Benign complications with the use of the DLT have been reported by Knoll et al. [60]. In their comparative study between the DLT and the endobronchial blocker, the development of postoperative hoarseness occurred significantly more commonly in the DLT group when compared to the endobronchial blocker group; however, the incidence of bronchial injuries was comparable between groups. A meta-analysis of a randomized controlled trial comparing the efficiency and adverse effects of DLT when compared with bronchial blockers showed that the DLTs were associated with more patients having a sore throat and hoarseness and more minor airway injuries [61].

Also, a recent review on lung isolation for thoracic surgery reiterated that DLTs are quicker and more reliable to place but are associated with a higher incidence of airway injuries when compared to bronchial blocker [62]. A prospective randomized study [63] has shown that the use of dexamethasone 0.1 or 0.2 mg·kg is beneficial prior to the use of the DLT in order to reduce the incidence of sore throat and hoarseness up to 24 h.

Bronchial Blockers

An alternative method to achieve lung separation involves blockade of a mainstem bronchus to allow lung collapse distal to the occlusion [5]. Bronchial blockers also can be used selectively to achieve lobar collapse, if needed [64–70]. Currently, there are different bronchial blockers available to facilitate lung separation collapse; these devices either are attached to a single-lumen endotracheal tube with an enclosed bronchial blocker (Torque Control Blocker Univent) [5] or are used independently through or alongside a conventional single-lumen endotracheal tube, such as the wire-guided endobronchial blocker Arndt® blocker [6], the Cohen tip-deflecting endobronchial blocker [8], the Fuji Uniblocker® [9, 71], or the EZ-blocker® (Teleflex Medical, Morrisville, NC) [72, 73]. See Fig. 16.10.

Torque Control Blocker Univent

The Univent® tube consists of a single-lumen endotracheal tube with an enclosed and movable bronchial blocker made of flexible, nonlatex material, and it includes a flexible shaft that is easier to guide into a bronchus [6]. The bronchial balloon has a high-pressure, low-volume cuff that requires approximately 2 mL of air to produce an airtight seal if selective lobar blockade is used or 4–8 mL of air if the total blockade of the bronchus is desired. The bronchial blocker has a 2-mm-diameter lumen that can be used for suctioning or for oxygen administration and it should be closed before insertion. One of the advantages of the Univent® blocker is its utility in patients in whom the airway is considered difficult for direct laryngoscopy and during unanticipated difficult endotracheal intubation [74–80].

Placement of the Univent® blocker is straightforward. First the bronchial blocker is lubricated to facilitate passage. The enclosed bronchial blocker is fully retracted into the lumen of the tube. Conventional endotracheal tube placement is performed via direct laryngoscopy, and then a fiberoptic bronchoscope is passed through a Portex swivel adaptor into the endotracheal tube. Under direct vision, the enclosed bronchial blocker is advanced into the targeted bronchus. All bronchial blockers must be directed into the bronchus of the surgical side, where the lung collapse is to occur.

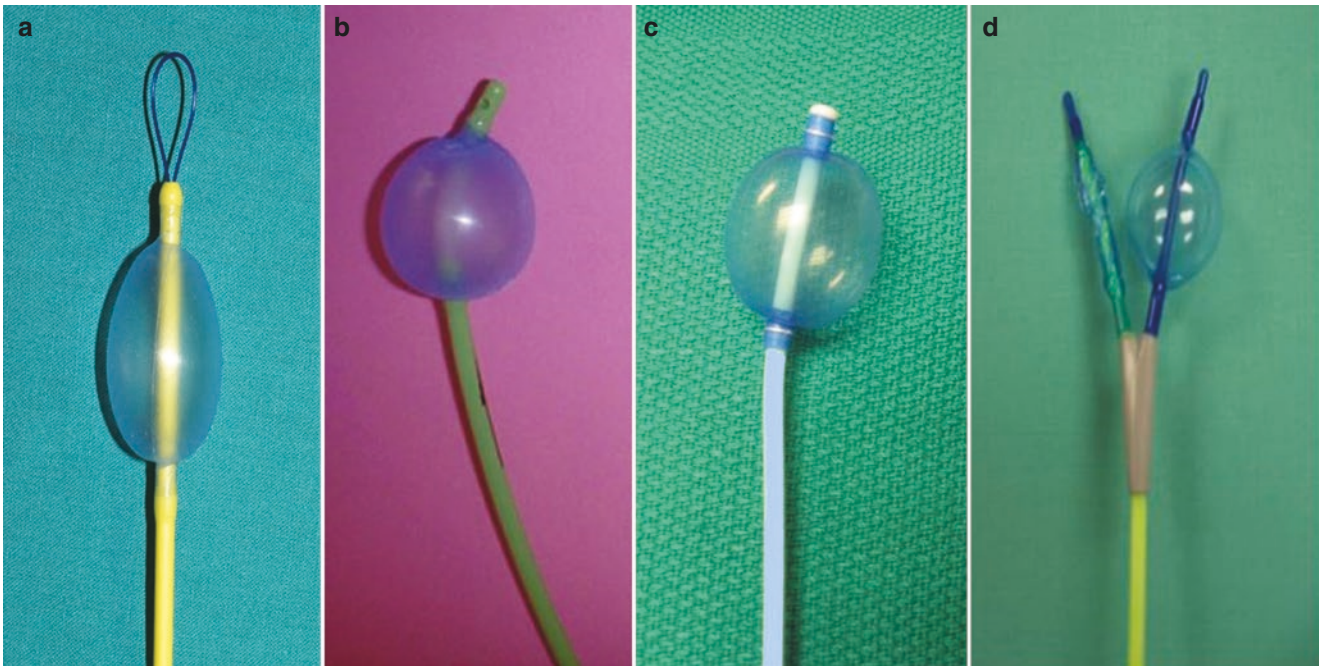

Fig. 16.10 Four independent bronchial blockers currently available in North America (see Table 16.6 for details). (**a**) The Arndt wire-guided endobronchial blocker (Arndt® Cook Critical Care), (**b**) the Cohen® tip-deflecting endobronchial blocker 9F (Cook Critical Care, Bloomington, IN), (**c**) the Fuji Uniblocker®, 9F (Fuji Corp., Tokyo, Japan), (**d**) EZ-blocker (Teleflex Medical, Morrisville, NC)

Independent Bronchial Blockers During Lung Isolation

Another alternative to achieve lung separation is by using an independent blocker passed through an in situ single-lumen endotracheal tube. The various devices considered to be independent blockers include the wire-guided endobronchial blocker (Arndt® blocker), the Cohen tip-deflecting endobronchial blocker, the Fuji Uniblocker®, and the EZ-blocker [9, 71].

Arndt® Wire-Guided Endobronchial Blocker

The Arndt® blocker [7] is an independent blocker attached to a 5 F, 7 F, or 9 F catheter that is available in 65- and 78-cm lengths with an inner lumen that measures 1.4 mm in diameter. Near the distal end of the catheter, side holes are incorporated to facilitate lung deflation. These side holes are present only in the 9 F Arndt® block. The Arndt® blocker has a high-volume, low-pressure cuff with either an elliptical or spherical shape (see Fig. 16.11). A unique feature of the Arndt® blocker compared with other blockers is that the inner lumen contains a flexible nylon wire passing through the proximal end of the catheter and extending to the distal end, which exits as a small flexible wire loop. This blocker comes with a multiport connector. The wire loop of the Arndt® blocker is coupled with the fiberoptic bronchoscope and serves as a guide wire to introduce the blocker into the bronchus [25]. For the Arndt® blocker to function properly and allow manipulation with the adult fiberoptic broncho-

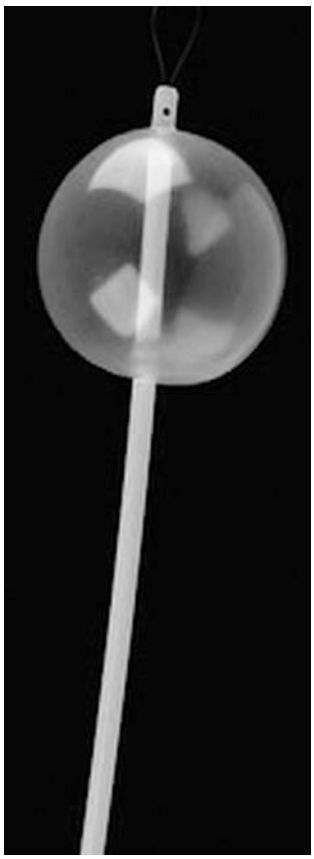

Fig. 16.11 The recently introduced Arndt® spherical bronchial blocker cuff (Cook Critical Care, Bloomington, IN). Some clinicians prefer to use this spherical cuff for right-sided surgery versus the original elliptical cuff because of the short length of the right mainstem bronchus

scope, the proper size endotracheal tube must be used. For a 7 F blocker which can be used for a 40-kg patient, a 7.5-mm internal diameter (ID) single-lumen endotracheal tube is used, and for the larger 9 F Arndt® blocker, at least an 8.0-mm ID single-lumen endotracheal tube is used. Figure 16.12a displays the placement of an Arndt® blocker through a single-lumen endotracheal tube with the fiberoptic bronchoscope advanced through the guide wire loop. Figure 16.12b displays the optimal position of the Arndt® blocker.

The advantages of the Arndt® blocker include its use in patients who are already tracheally intubated [81], who present a difficult airway and require an awake orotracheal or nasotracheal intubation [82], or who require OLV during acute trauma to the chest [83, 84]. In addition, an Arndt® blocker can be used as a selective lobar blocker in patients with previous pneumonectomy who require selective one-lobe ventilation [85] or as a selective blocker during severe pulmonary bleeding [86]. Figure 16.13a displays the use of a bronchial blocker for selective lobar blockade. Figure 16.13b displays the use of the Arndt® blocker in a patient with previous contralateral pneumonectomy and segmental lobar blockade.

Methods of Placement

The Arndt® blocker is an independent endobronchial blocker that is passed through an existing single-lumen endotracheal tube. To facilitate insertion through the endotracheal tube, the blocker and the fiberoptic bronchoscope are lubricated. For a right-sided mainstem bronchus intubation, the spherically shaped blocker is recommended; for the left mainstem bronchus intubation, the elliptical or the spherical blocker is used.

The placement of the Arndt® blocker involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope and wire-guided loop to direct the blocker into a mainstem bronchus. The fiberoptic bronchoscope has to be advanced distally enough so that the Arndt® blocker enters the bronchus while it is being advanced. When the deflated cuff is beyond the entrance of the bronchus, the fiberoptic bronchoscope is withdrawn, and the cuff is fully inflated with fiberoptic visualization with 4–8 mL of air to obtain total bronchial blockade.

For right mainstem bronchus blockade, the Arndt® blocker can be advanced independently of the wire loop by observing its entrance into the right mainstem bronchus under fiberoptic visualization. Before turning the patient into a lateral decubitus position, the cuff of the blocker should be deflated and then advanced 1 cm deeper to avoid proximal dislodgement while changing the patient's position; the placement again is confirmed in the lateral decubitus position. The wire loop can be withdrawn to convert the 1.4-mm channel into a suction port to expedite lung collapse. The newest version of the Arndt® blocker has a cone-shaped device that is attached

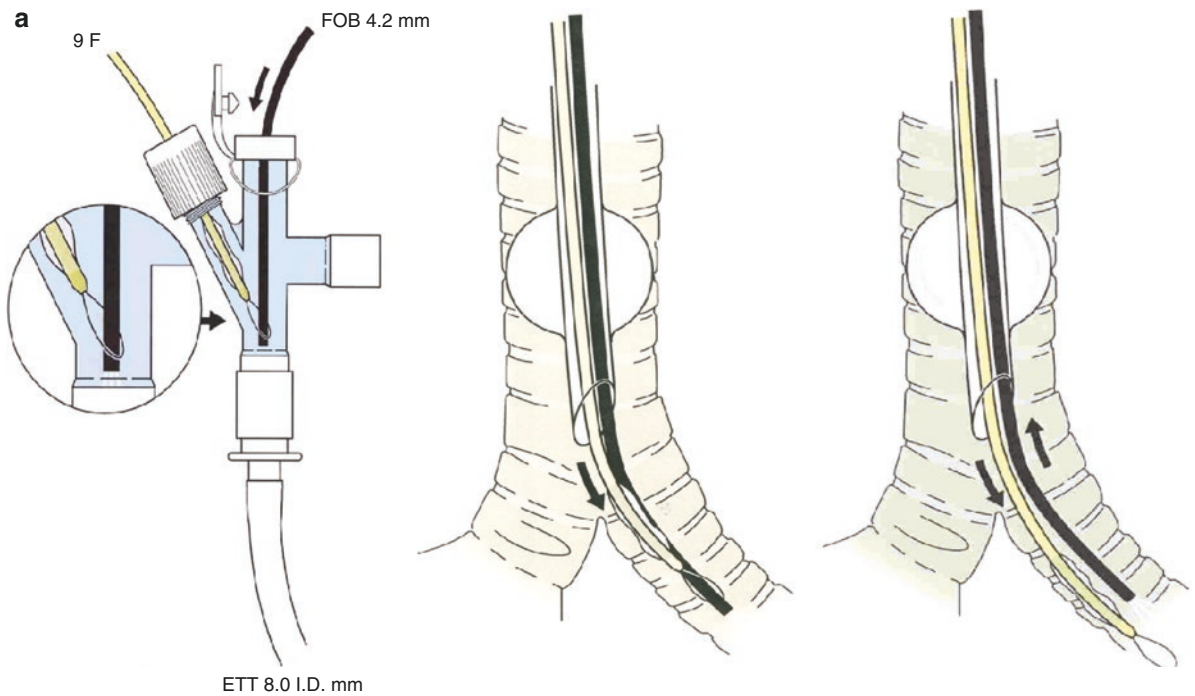

Fig. 16.12 (**a**) Placement of an Arndt® blocker through a single-lumen endotracheal tube with the fiberoptic bronchoscope advanced through the guide wire loop. (**b**) Optimal position of a bronchial blocker in the right or left mainstem bronchus as seen with a fiberoptic bronchoscope. (**A**) Right mainstem blocker; (**B**) Left mainstem blocker [25]

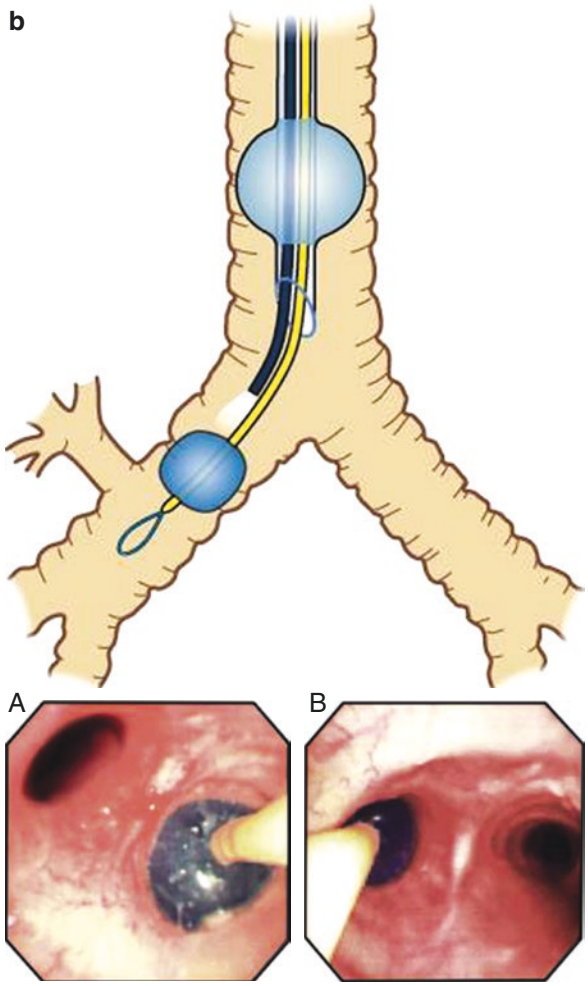

Fig. 16.12 (continued)

to the center channel to connect and facilitate suction [87, 88]. It is important to remove the wire loop to avoid inclusion in the stapling line of the bronchus [89]. The optimal position of the Arndt® blocker in the left or in the right bronchus is achieved when the blocker balloon's outer surface is seen with the fiberoptic bronchoscope at least 5 mm below the tracheal carina on the targeted bronchus and the proper seal is obtained.

Cohen® Flexitip Endobronchial Blocker

The Cohen® blocker is an independent endobronchial blocker that is available only in size 9 F and 65-cm length with an inner lumen measuring 1.4 mm in diameter. This device comes with a spherically shaped balloon. Near the distal end of the catheter, there are side holes incorporated to facilitate lung deflation. This bronchial blocker has a high-volume, low-pressure cuff. The Cohen® blocker relies on a wheel-turning device located in the most proximal part of the unit that allows deflection of the tip of the distal part of the blocker into the desired bronchus [2, 8, 73]. This device has been purposely preangled at the distal tip to facilitate insertion into a target bronchus. Also, there is a torque grip located at the 55-cm mark to allow rotating the blocker. In the distal tip above the balloon, there is an arrow that when seen with the fiberoptic bronchoscope indicates in which direction the tip deflects. This Cohen® blocker also comes with a multiport adaptor to facilitate an airtight seal when in place. The indications for use of the Cohen® blocker are the same as for the Arndt® blocker. Figure 16.14 displays the Cohen® blocker.

Methods of Placement

The Cohen® blocker is advanced through an 8.0-mm ID single-lumen endotracheal tube; before insertion, the blocker balloon is tested and then fully deflated. This blocker needs

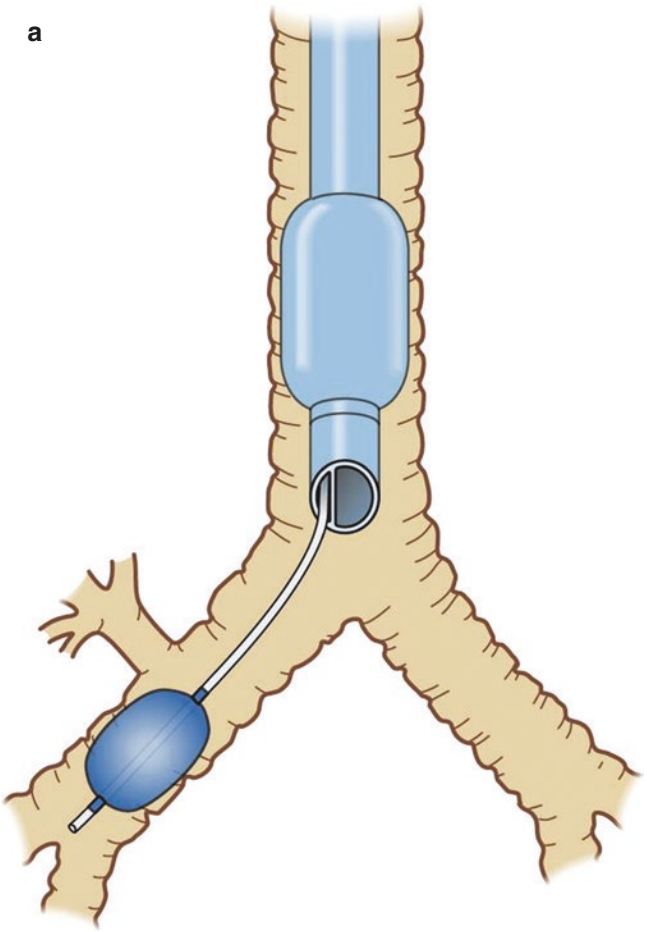

Fig. 16.13 (**a**) Selective lobar blockade where the blocker is sealing the right bronchus intermedius. (**b**) Patient with a previous right pneumonectomy where selective lobar blockade is used to occlude the left upper lobe. *R* stump of right mainstem bronchus; *C* main carina; *L* left mainstem bronchus; *LUL* left upper lobe; *LLL* left lower lobe [70]

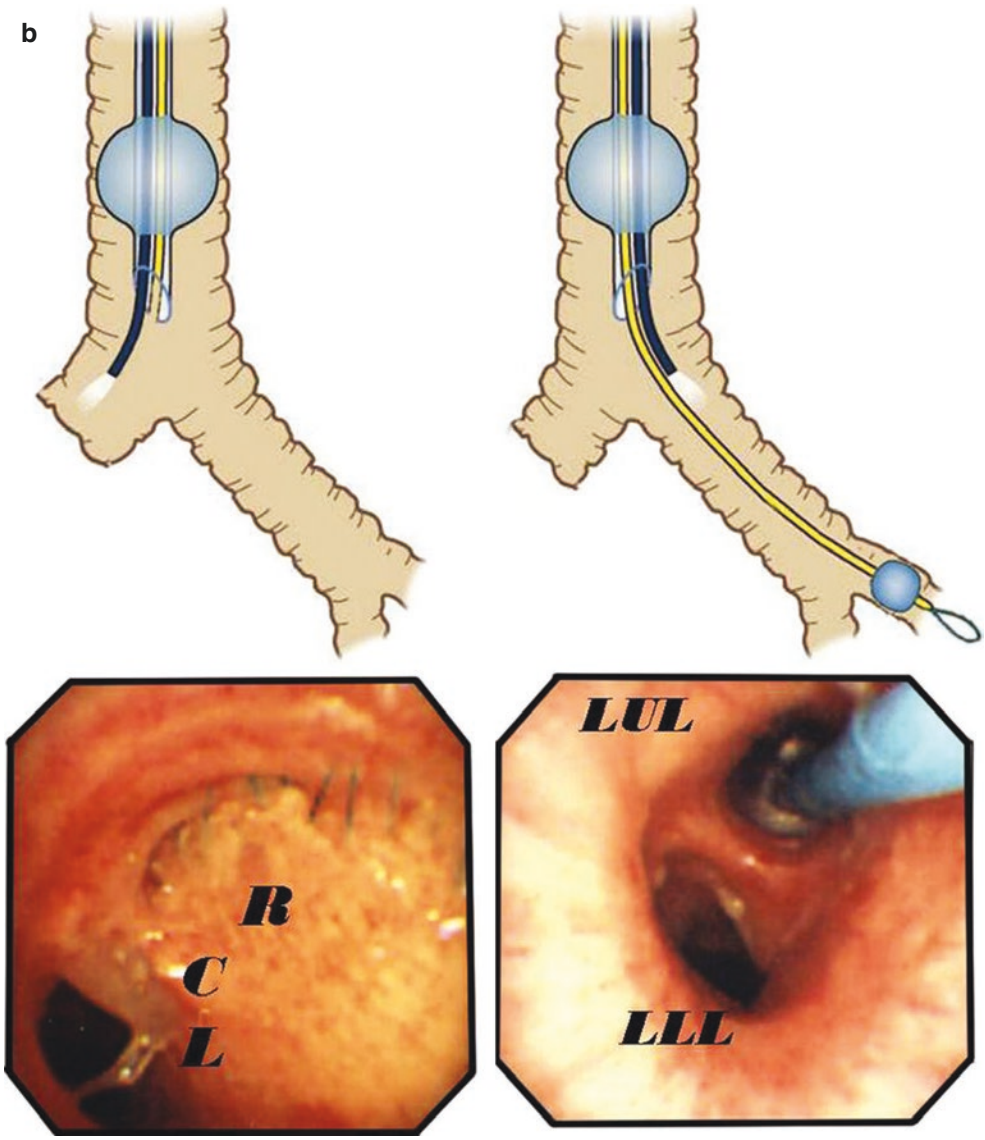

Fig. 16.13 (continued)

to be lubricated to facilitate insertion and passage through the single-lumen endotracheal tube.

The placement of the Cohen® blocker involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope to observe the direction of the blocker into a mainstem bronchus. For blocking the right mainstem bronchus, the optimal position is the one that provides a view of the outer surface of the fully inflated balloon (4–8 mL of air) with the fiberoptic bronchoscope at least 5 mm below the tracheal carina on the right mainstem bronchus.

Intubation of the left mainstem bronchus can be facilitated by allowing the tip of the single-lumen endotracheal tube to be near the entrance of the left bronchus and then twisting the Cohen® blocker to the left side. After the blocker is seen inside the left bronchus, the single-lumen endotracheal tube is withdrawn a few centimeters. A different alternative is to turn the head toward the right allowing the left main bronchus to displace to the midline. This maneuver will facilitate the placement of a Cohen® blocker into the left mainstem bronchus. The optimal position in the left mainstem bronchus is achieved when the blocker balloon's outer surface is seen with the fiberoptic bronchoscope at least 5 mm below the trachea carina inside the left mainstem bronchus.

Fuji Uniblocker®

The Fuji Uniblocker® is an independent bronchial blocker that is available in 4.5 and 9 F size and is 65 cm in length that has a high-volume balloon made of silicone with a gas barrier property to reduce diffusion of gas into or out of the cuff. Also, with its maximal cuff inflation of 6 mL of air, this new bronchial blocker's transmitted pressure tested in vitro was

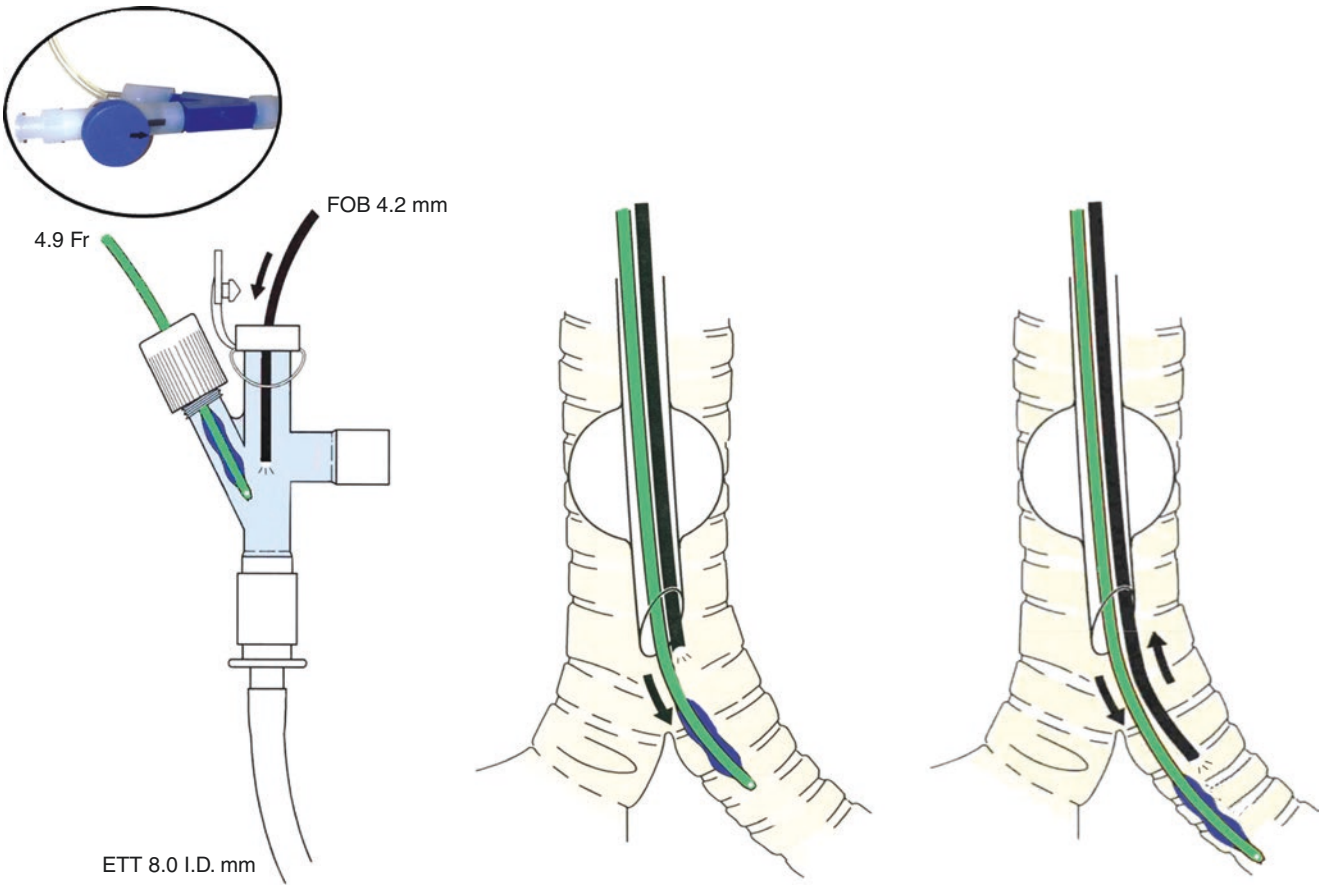

Fig. 16.14 The Cohen flexitip bronchial blocker with a multiport connector [90]

<30 mmHg, which does not exceed the recommended safety limit in relationship to bronchial mucosa [91]. In addition, the Fuji Uniblocker® is equipped with a swivel connector. The swivel connector allows easy insertion of the fiberoptic bronchoscope. The Fuji Uniblocker® has a torque control blocker with an incorporated shaft that allows the guidance through the desired bronchus. A recent study [9] involving the use of the Fuji Uniblocker® compared with the Arndt® and Cohen® blocker showed that surgical exposure was clinically equivalent to left-sided DLTs for thoracoscopic or open thoracotomies; however, the bronchial blockers including the Fuji Uniblocker® took a longer time to position and required more intraoperative repositioning when compared to left-sided DLTs. Another report [92], this one examining the use Fuji Uniblocker® in patients undergoing thoracoscopic surgery, showed a better quality of lung collapse with left-sided procedures than right-sided procedures. The indications for use of the Fuji Uniblocker® are the same as for the Arndt® blocker. Table 16.5 displays the characteristics of the Arndt® blocker, the Cohen® flexitip endobronchial blocker, the Fuji Uniblocker®, and the EZ-blocker. The Cohen® and Fuji® blockers can be easily placed through the glottis or tracheostomy external to an endotracheal tube, if required in small patients, and the blocker position confirmed with a FOB passed through the endotracheal tube.

Methods of Placement

The Fuji Uniblocker® size 9 F is advanced through an 8.0-mm ID single-lumen endotracheal tube; before insertion the blocker balloon is tested and then fully deflated. This blocker needs to be lubricated to facilitate insertion and passage through the single-lumen endotracheal tube.

The placement of the Fuji Uniblocker® involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope to observe the direction of the blocker into a mainstem bronchus. The torque control shaft with the blocker allows guidance into the desired target bronchus. For blocking the right mainstem bronchus, the optimal position is the one that provides a view of the outer surface of the fully inflated balloon (4–8 mL of air) with the fiberoptic bronchoscope at least 5 mm below the tracheal carina on the right mainstem bronchus. The optimal position in the left mainstem bronchus is achieved when the blocker balloon's outer surface is seen with the fiberoptic bronchoscope at least 5–10 mm below

Table 16.5 Characteristics of the Arndt® blocker, the Cohen® flexitip endobronchial blocker, the Fuji Uniblocker®, and the EZ-Blocker

	Cohen blocker	Arndt® blocker	Fuji Uniblocker®	EZ-blocker
Size	9 F	5 F, 7 F, and 9 F	4.5 F, 9 F	7 F

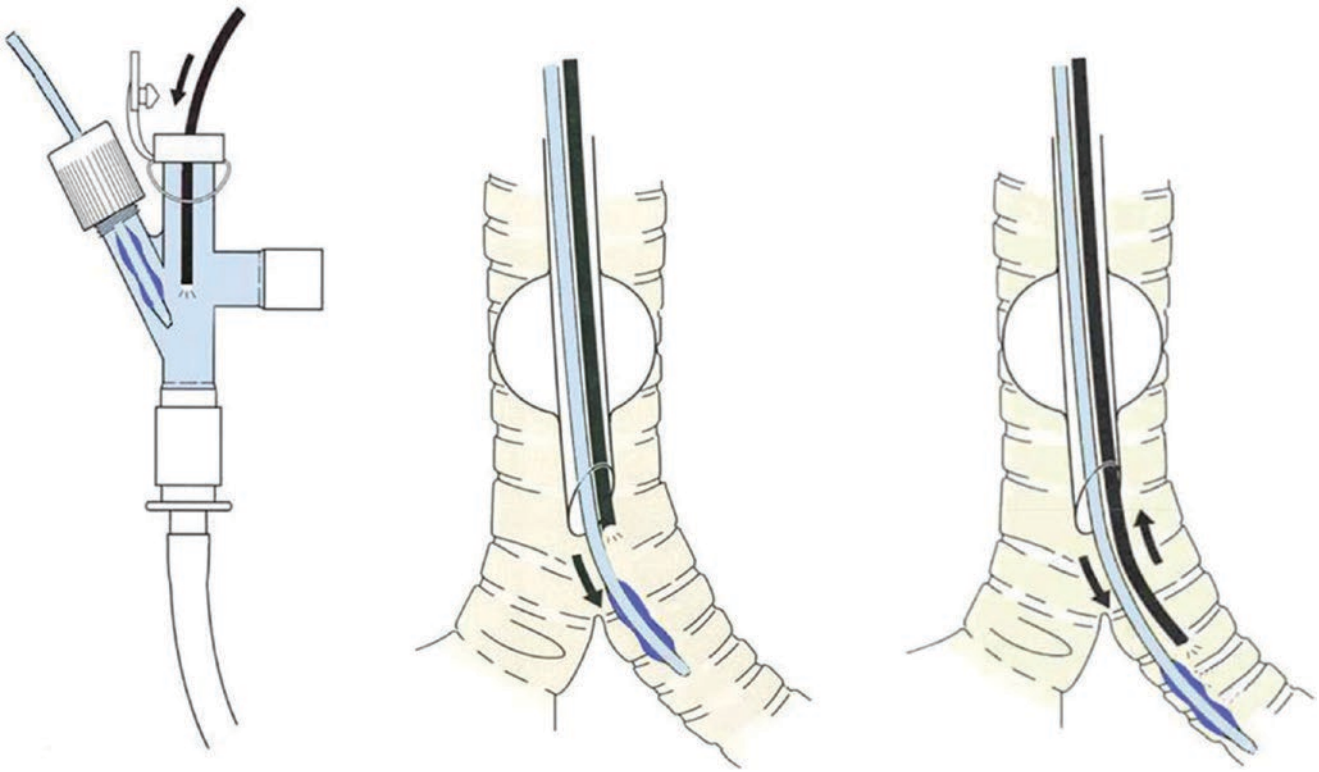

Fig. 16.15 Placement of the Fuji blocker

the trachea carina inside the left mainstem bronchus. Figure 16.15 displays the Fuji blocker and placement.

The EZ-Blocker

The EZ-blocker is an independent bronchial blocker that is available in a 7.0 F size and made of polyurethane material. The EZ-blocker is manufactured with a Y-shaped distal end. Both limbs of the distal end are fitted with an inflatable balloon and a central channel in each to allow suction. Also, each limb is color coded (yellow or blue) for easy identification with the matching pilot balloon. The EZ-blocker is inserted through a port on the enclosed multiport adapter that is attached to a single-lumen endotracheal tube. The optimal size of the single-lumen endotracheal tube should be 7.5 or 8.0 mm internal diameter so it allows the blocker and the fiberoptic bronchoscope to navigate together.

The multiport adaptor of the EZ-blocker is designed to connect to a connector of the single-lumen endotracheal tube and it contains two additional ports, one to allow advancement of the blocker and the other port for passing the flexible fiberoptic bronchoscope.

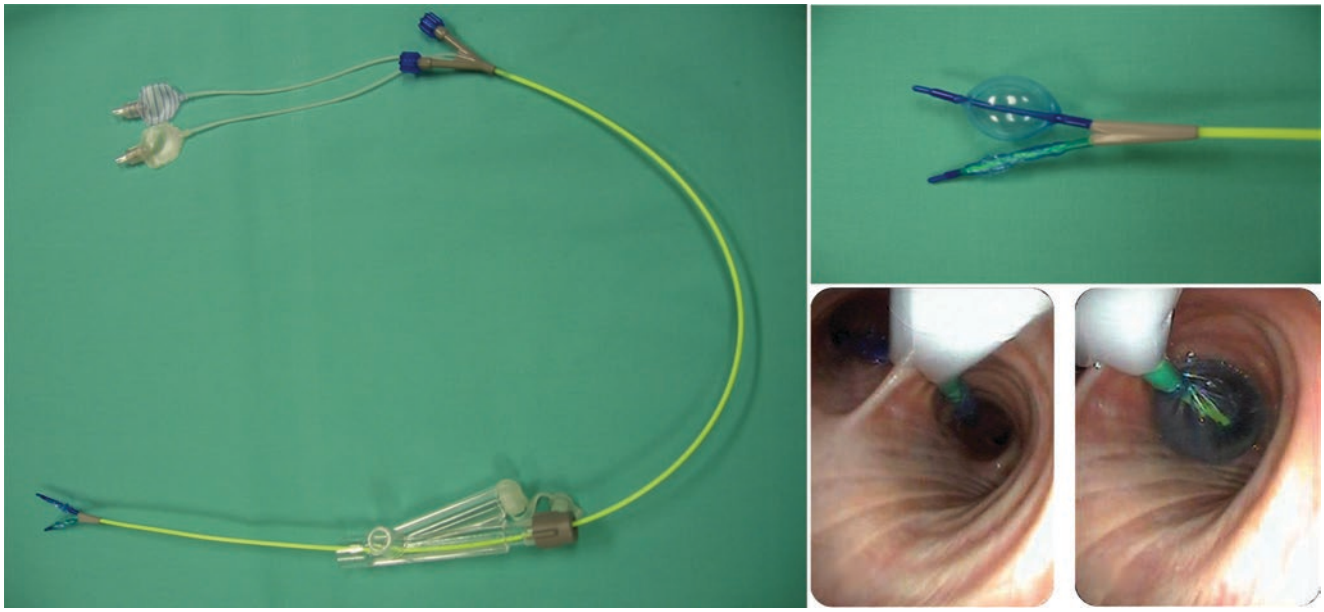

Fig. 16.16 Placement of the EZ-Blocker

Methods of Placement

The EZ-blocker is tested and lubricated prior to passing into the lumen of the single-lumen endotracheal tube and the multiport connector. After advancing the blocker, the Y-shaped end should be seated in the tracheal carina and each independent tip should be located in the entrance of right and left bronchus. Only the balloon where lung isolation occurs should be inflated under direct fiberoptic bronchoscopy. The pilot of the cuff is color coded to allow identification of the respective balloon (one is yellow and the other one is blue). After the tip of the deflated balloon is in the bronchus, inflation of the balloon should be performed with flexible fiberoptic bronchoscopy. Unfortunately the balloon of the EZ-blocker sometimes requires between 10 and 14 cc of air to block the left or right bronchus [72]. Proper and optimal position is when the outer surface of the balloon is seen 5–10 mm below the entrance of the bronchus. A common problem with the EZ blocker is that both limbs initially enter the right mainstem bronchus. This requires withdrawing the blocker above the carina and readvancement under direct vision with the bronchoscope. The distal end of the single-lumen ETT should be at least 4 cm above the carina to minimize this problem. The distal Y-junction of the two limbs of the blocker must be firmly seated on the carina to minimize displacement of the blocker during surgery. Figure 16.16 displays the optimal position of the EZ-blocker.

Complications with the Use of Bronchial Blockers

Although serious complications have been reported with the use of current bronchial blockers, these complications appear to be more benign than those involving DLTs. A structural complication has been reported in the torque control Univent blocker in which a fracture of the blocker cap connector occurred in 2 of the first 50 tubes used [93]. Failure to achieve lung separation because of abnormal anatomy, in which the entrance of the right upper lobe bronchus was located above the tracheal carina, or lack of seal within the bronchus also has been reported [94, 95]. Inclusion of the enclosed bronchial blocker into the stapling line has been reported during a right upper lobectomy [96]. Communication with the surgical team regarding the presence of a bronchial blocker in the surgical side is crucial. Another potential and dangerous complication with the bronchial cuff of the Univent has been reported: the cuff of the bronchial blocker was inflated mistakenly near the tracheal lumen, precluding all airflow and producing respiratory arrest [97].

Complications with the Arndt® blocker include a report of a sheared balloon of the Arndt® blocker that occurred when the blocker was removed through the multiport blocker side [98]. It is advised that when an independent bronchial blocker is not in use, it needs to be removed with the multiport connector in place rather than through the connector to prevent shredded material into the single-lumen endotracheal tube. Another near-fatal complication reported with the use of the

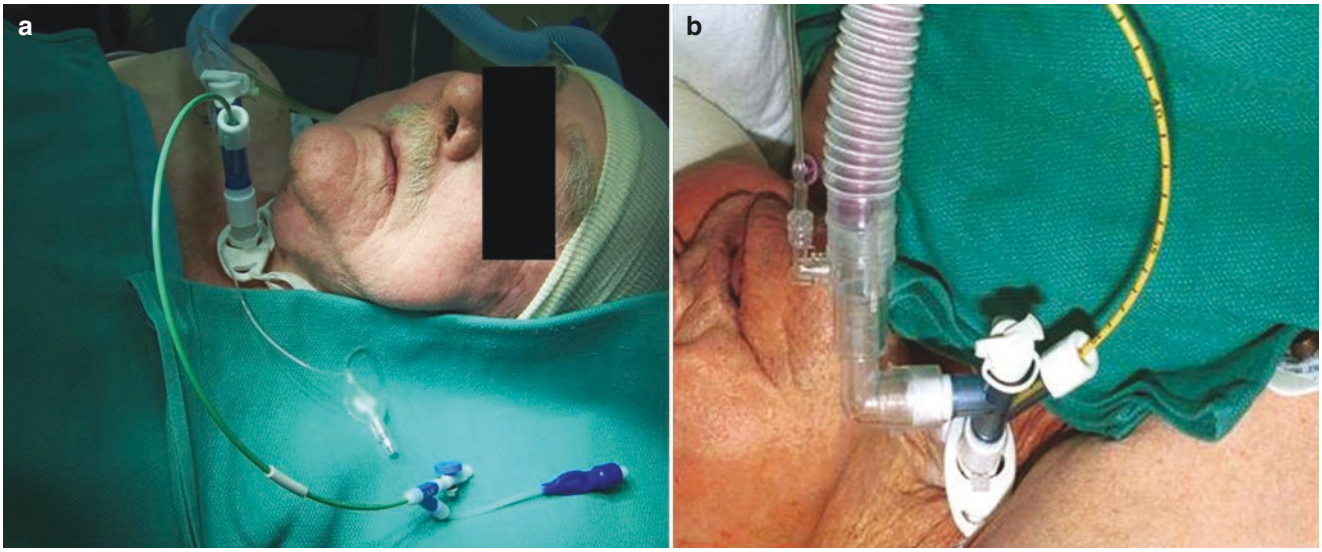

Fig. 16.17 (**a**) Cohen® blocker in a patient with a tracheostomy. (**b**) Use of an Arndt® blocker via a tracheostomy

Arndt® blocker occurred when the fully inflated balloon of the blocker dislodged into the patient's trachea, leading to a complete airway obstruction. Severe air trapping led to pulseless activity in the patient, who was undergoing a rupture descending thoracic aortic aneurysm. A prompt deflation of the bronchial blocker cuff resolved the problem [99].

Another complication reported with the Arndt® blocker involved inadvertent resection of the guide wire and part of the tip of the bronchial blocker during stapler resection of the left lower lobe; this complication required surgical reexploration after unsuccessful removal of the bronchial blocker after extubation [89].

In a retrospective review of 302 consecutive cases from a single institution, no major complications were found with the use of different bronchial blockers during lung isolation [100]. A recent report involving three cases where the balloon of the Fuji blocker failed to deflate at the conclusion of the surgery. In two of the cases, the already inflated bronchial blocker had to be removed along with the single-lumen endotracheal tube during extubation [101]. It is recommended to test the pilot and the balloon prior to use to ensure that the air that is injected is aspirated and the balloon completely deflates. When compared the complications the DLTs outnumber the reported complications with the bronchial blockers.

Lung Isolation in Patients with Tracheostomy in Place

OLV can be a challenge in patients with a tracheostomy in place because the airway has been shortened and the stoma can be small and restrictive. Although a shortened version of a DLT for tracheostomy patients has been used [102, 103], there is no shortened DLT available for tracheostomy patients in the United States. An alternative to achieve successful lung separation through a tracheostomized patient involves the use of a bronchial blocker, either attached to a single-lumen endotracheal tube such as the Univent® blocker [104, 105], or passed independently through a Shiley 8.0-mm ID tracheostomy tube (Mallinckrodt, St. Louis, MO) with the Arndt® bronchial blocker [69], or placed independently through a single-lumen endotracheal tube [106]. An alternative way to manage these cases is with the Cohen® Blocker [8] or the Fuji Uniblocker® [9]; when passing a 9 F bronchial blocker through a tracheostomy tube, the recommended flexible fiberoptic bronchoscope should be 3.5-mm ID so the independent blocker and the fiberscope can navigate together to achieve optimal position of these devices into the designed bronchus. In some instances when using a Shiley tracheostomy tube, the multiport connector is attached to the ventilating port of the Shiley cannula to maintain the bronchial blocker in place. Optimal position is achieved with the fiberoptic bronchoscope. Figure 16.17 displays the use of an independent blocker through a tracheostomy stoma.

Lung Collapse During Lung Isolation

A challenge for every anesthesiologist is to properly position a lung isolation device and make it work by allowing the lung to collapse. In a study [6] comparing the Broncho-Cath left-sided DLT with the Univent® torque control blocker and the Arndt® wire-guided blocker, it was shown that the average time for lung collapse is 17 min for a DLT (spontaneous lung collapse without suction) versus 19–26 min for the Univent® or Arndt® bronchial blocker (assisted with suction). Once lung isolation was achieved, however, the overall clinical performance was similar for the three devices studied.

Another study [9] involving left-sided DLTs and comparing it with the Arndt®, the Cohen®, or the Fuji® blocker showed that the surgical exposure was equivalent among the devices studied. However, the bronchial blockers required longer time to position and were more prone to intraoperative reposition. It is important to emphasize that these two studies involved at least one senior thoracic anesthesiologist with broad experience with lung isolation devices.

A study [107] has shown that denitrogenation of the lung which is to be collapsed with a FiO_2 1.0 is a useful strategy to improve surgical conditions during OLV; in contrast, the use of air in the inspired gas mixture during two-lung ventilation and prior to OLV delays lung collapse during OLV. A recent study involving the use of a bronchial blocker showed that the use of nitrous oxide in a mixture of N_2O/O_2 ($FiO_2 = 0.5$) facilitated lung collapse after opening the chest compared with a comparative group using 100% oxygen. Both groups also have a suction assisted in place during one-lung ventilation [108]. Another study involving morbidly obese patients undergoing one-lung ventilation where a left-sided DLT was compared with the Arndt wire-guided blocker reported that there was no overall advantage of one device over the other during intubation or the success of lung collapse both devices were very comparable [109].

A recent study comparing the Fuji blocker with a left-sided DLT in video-assisted thoracoscopic surgery reported that the bronchial blocker had a faster time to obtain lung collapse and overall superior quality of lung deflation when compared to a left-sided DLT [110].

Combining all studies my recommendation is that all anesthesiologists should be familiar with the use of bronchial blockers and DLTs during lung isolation techniques. Editorial reports, scientific evidence, and topic of debates support this recommendation [6, 111, 112].

Table 16.6 displays the advantages and disadvantages of DLTs and bronchial blockers.

Table 16.6 Advantages and disadvantages of DLTs and bronchial blockers

Double-lumen endotracheal tubes	Bronchial blockers (Arndt®, Cohen®, Fuji®)
Advantages	
Large lumen facilitates suctioning Best device for absolute indications for lung separation, to protect the lung from soiling Conversion from two- to one-lung ventilation and back easy and reliable	Easy recognition of anatomy if the tip of a single tube is above carina Best device for patients with difficult airways Cuff damage during intubation rare No need to replace a tube if mechanical ventilation is needed
Disadvantages	
Difficulties in selecting proper size More difficult to place during laryngoscopy Potential damage to tracheal cuff during intubation Rare major tracheobronchial injuries	Small channel for suctioning Conversion from one- to two- and then to one-lung ventilation problematic more complicated High maintenance device (frequent dislodgement or loss of seal during surgery)

Modified from Campos [71]

Future Trends in Lung Isolation

With the advances in thoracic, cardiac, esophageal surgery, and minimally invasive surgery, it has led to an increased need for lung isolation techniques among anesthesiologists. A previous study [47] has shown that anesthesiologists with limited thoracic experience often fail to correctly place lung isolation devices. Increased clinical experience would likely reduce this failure rate, but greater experienced may not be possible, particularly for anesthesiologists working in centers that perform relatively few thoracic cases. Therefore, improved nonclinical training methods are needed.

Anesthesia simulators have been used to enhance learning and to improve performance [113–115], usually under the personal direction of an experienced clinician. Therefore, one educational approach to lung isolation techniques might involve training on an airway simulator mentored by an experienced thoracic anesthesiologist. An alternative is to train in a fiberoptic bronchoscopy simulator [116] on lung isolation techniques particularly for the occasional anesthesiologist who does not perform thoracic cases on a regular basis. In a study involving anesthesiologists with limited thoracic experience comparing the simulator intubation model versus computer didactic-based material in how to place a left-sided DLT, it showed that both teaching methods had similar outcomes when this group of anesthesiologists placed the DLTs after their training [117].

Another study involving high-fidelity simulation of lung isolation with double-lumen endotracheal tubes and bronchial blockers in anesthesiology residents showed that their performance to place lung isolation devices was very successful [118]. A similar model/study was performed involving senior medical students to teach basic lung isolation skills on a simulator, and it showed that video-didactic and simulation-based methods were very comparable and successful in training novices for lung isolation techniques [119]. This study also reported that the acquired skills particularly decreased without practice. Regardless of the method to teach lung isolation techniques, it should be used periodically in anesthesiologist with limited thoracic experience in order to retain their level of skills.

It is the author's personal opinion that every surgical center that performs lung isolation techniques must consider the

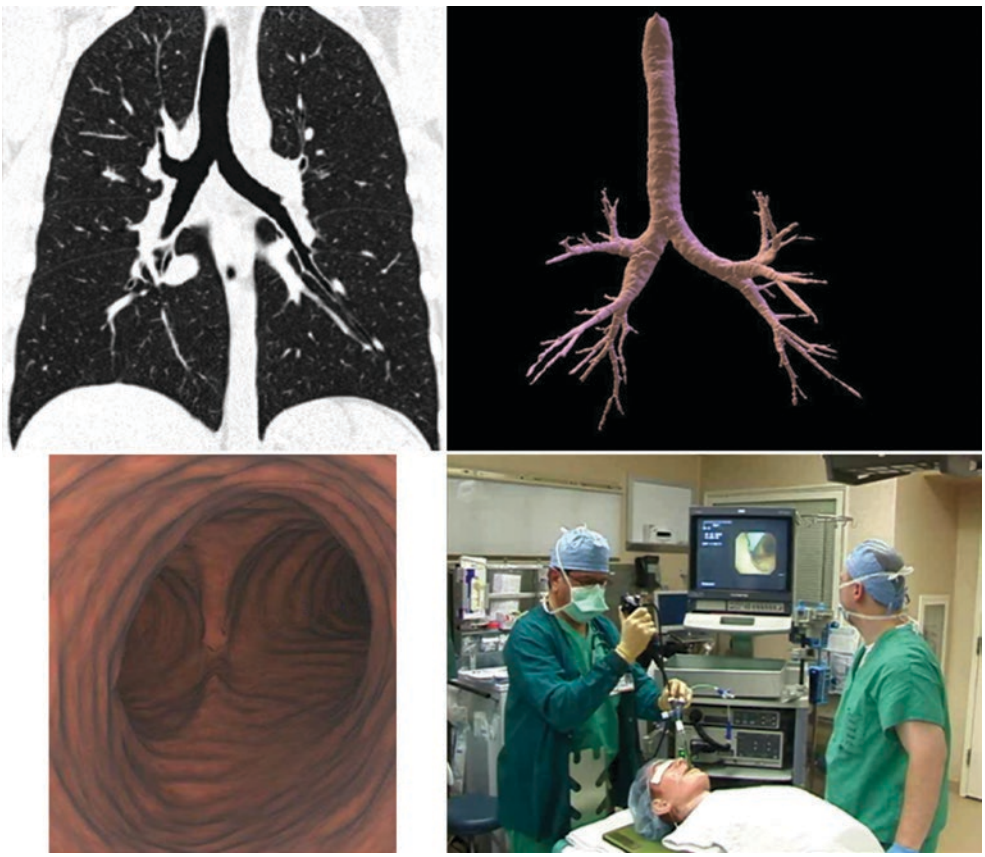

Fig. 16.18 Ideal teaching facility with a pulmonary work station for placement of lung isolation devices by trainees

development of a pulmonary workstation along with simulator training facility to enhance teaching to residents, fellows, and staff anesthesiologists [117–119]. Figure 16.18 displays a pulmonary workstation including simulator. Also, a free online bronchoscopy simulator is available on the website www.thoracicanesthesia.com to teach anesthesiologists tracheobronchial anatomy (see Fig. 16.19).

Summary

The basic principle of successful lung separation requires (1) recognition of tracheobronchial anatomy with a posteroanterior chest radiograph in the preoperative evaluation and with flexible fiberoptic bronchoscopy in the perioperative period, (2) familiarity and skills with flexible fiberoptic bronchoscopy, and (3) familiarity and expertise with DLTs and bronchial blockers.

Because of its greater margin of safety, a left-sided DLT is the more common and easiest device used during lung separation. A right-sided DLT is recommended for a left-sided pneumonectomy or any contraindication to placement of a left-sided DLT. For patients with a difficult abnormal airway or a tracheostomy in place, the use of a bronchial blocker is indicated. Bronchial blockers require more time for placement and are more prone to intraoperative dislodgement. Lung collapse is facilitated with a denitrogenation technique using FiO_2 1.0 during two-lung ventilation prior to lung collapse. Every lung isolation device placement requires auscultation and clamping maneuvers followed by a fiberoptic bronchoscopy to obtain 100% success during lung separation techniques. The optimal position of these devices (DLTs and bronchial blockers) is achieved best with the use of fiberoptic bronchoscopy techniques with the patient first in the supine and then in the lateral decubitus position or whenever repositioning of the device is needed.

Clinical Case Discussion

Case: A 60-year-old female, weight 61 kg and is 161 cm tall, has a left lower lobe mass and is scheduled for a left lower lobectomy (Fig. 16.17a, b). She is a former smoker and the predicted value of forced expiratory volume in 1 s (FEV_1) is 75% of the predicted value. She has no significant known comorbidities and past history otherwise unremarkable (see Fig. 16.20).

Questions

- What lung isolation device will be indicated?
- What side and size of lung isolation device will be indicated?
- What anatomical structures in the chest radiograph are relevant while planning the use of lung isolation devices?

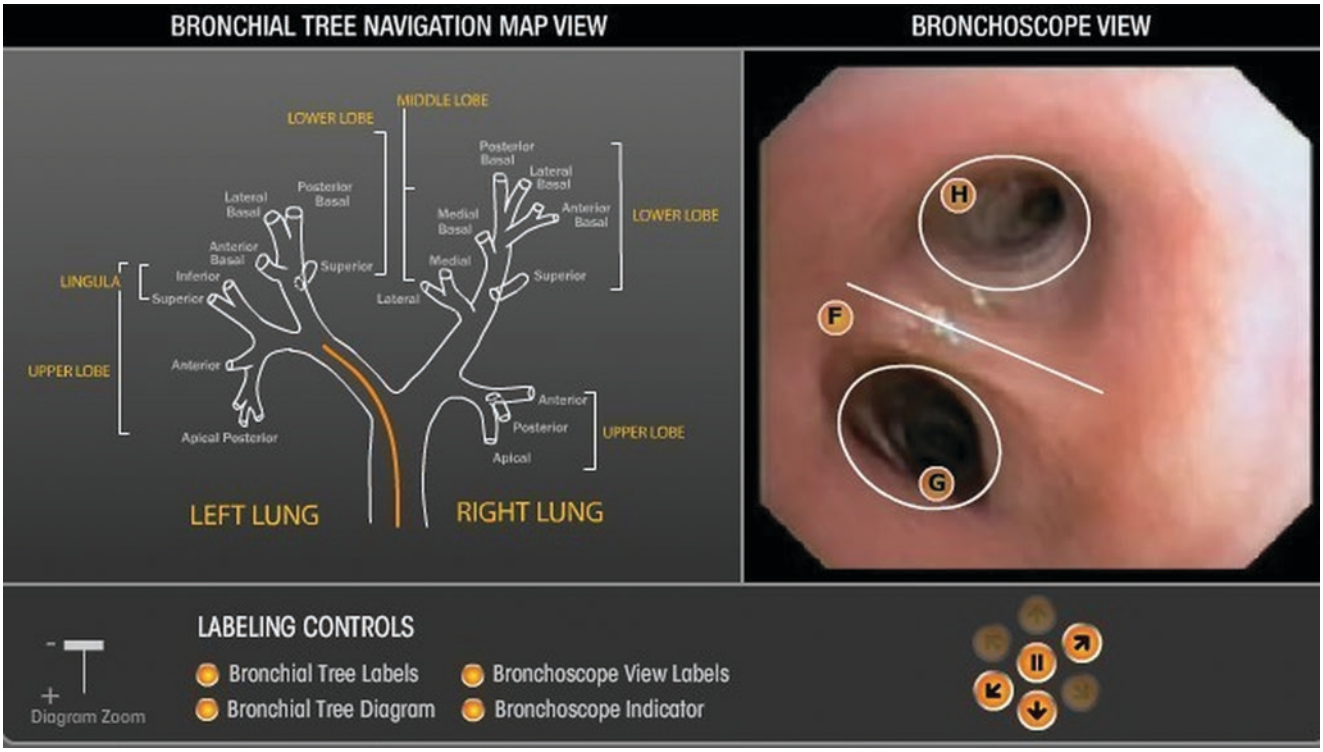

Fig. 16.19 The free online bronchoscopy simulator at www.thoracic-anesthesia.com. The user can navigate the tracheobronchial tree using real-time video by clicking on the lighted directional arrows under the "Bronchoscopic view" (right). Clicking on the labels on the "Bronchoscopic view" gives details of the anatomy seen. The process is aided by the "Bronchial Tree Navigational Map" (left), which shows the simultaneous location of the bronchoscope as the orange line in the airway

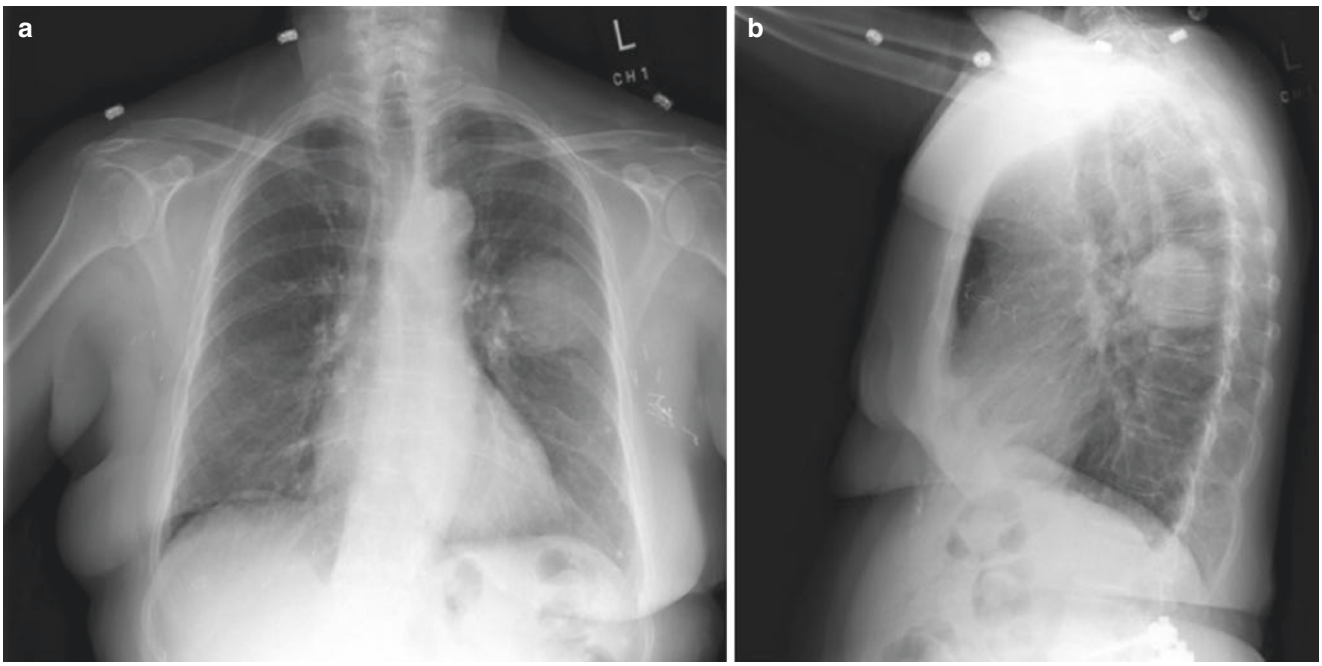

Fig. 16.20 (**a**, **b**) Chest X-ray of a female patient with a carcinoma of the left lower lobe undergoing a lobectomy

- What are the different alternatives for lung isolation devices?
- What technique should be used to achieve optimal position of lung isolation devices?
- What are the common problems in the intraoperative period with lung isolation devices?
- What are the complications associated with lung isolation devices?

Focus on the Patient's Gender, Size, Height, and Preoperative Chest Radiograph

- To determine the lung isolation device.
- Focus on the use of left-sided DLT for routine, uncomplicated cases or a right-sided DLT for selective cases.
- Focus on the indication of lung isolation.
- Knowledge of tracheobronchial anatomy and the use of flexible fiberoptic bronchoscopy to confirm device placement are essential for success on lung isolation.
- Alternative devices for lung isolation such as bronchial blockers should be considered in specific cases.

Choice of Lung Isolation Device

- If there is nothing in the patient's history or physical examination to suggest the possibility of difficult airway in a left- or right-sided DLT, depending on the clinician's preference, would be equivalent first choices to manage this case.
- The patient's sex and height suggest that either a 35 or 37 F DLT would be appropriate and the choice can be further refined by measuring the tracheal width on the PA chest X-ray (see Fig. 16.1).
- In the absence of a difficult airway, the problem of intraoperative displacement with bronchial blockers makes them a second choice for lung isolation in this patient.
- Correct positioning of the device for lung isolation should be confirmed with fiberoptic bronchoscopy.

Expected Intraoperative Problems During Lung Isolation

- Malpositions and the potential for tracheobronchial injuries

Fiberoptic Bronchoscopy for Positioning Double-Lumen Tubes and Bronchial Blockers

17

Javier Campos

Key Points

- Recognition of tracheobronchial anatomy structures is a key component during flexible fiberoptic bronchoscopy.
- Flexible fiberoptic bronchoscopy is the recommended method to achieve optimal position of lung isolation devices, first in supine position, later in lateral decubitus, or whenever a malposition occurs.
- The preferred technique for placement of a right-sided double-lumen endotracheal tube is with the fiberoptic bronchoscopy guidance technique.
- Any suspicion of airway trauma, unexpected air leaks, subcutaneous emphysema, massive bleeding, or protrusion of the cuff balloon into the surgical field, a flexible fiberoptic bronchoscopy examination should be performed followed by surgical repair if needed.
- The use of flexible fiberoptic bronchoscopy should be considered an art in thoracic anesthesia.

Introduction

Flexible fiberoptic bronchoscopy is a diagnostic and therapeutic procedure of great value in the clinical practice of thoracic anesthesia [1]. The most common method to perform flexible fiberoptic bronchoscopy is with the use of a single-lumen endotracheal tube. Once the tube is advanced beyond the vocal cords and inside the trachea, the tip of the endotracheal tube should come to rest 3–4 cm above the tracheal carina. A Portex fiberoptic bronchoscope (SSL American, Inc. Norcross, Georgia, USA) swivel adapter with a self-sealing valve is used to facilitate ventilation and manipulation of the bronchoscope at the same time. When using a large single-lumen endotracheal tube, an adult fiberoptic bronchoscope should be used (i.e., 4.1 mm inner diameter). Another alternative to perform fiberoptic bronchoscopy is with the use of a laryngeal mask airway (LMA). This technique allows visualization of the vocal cords and subglottic structures with lower resistance than a single-lumen endotracheal tube when the bronchoscope is inserted.

A systematic and complete fiberoptic bronchoscopy examination (refer to Fig. 17.1) includes a clear view of the anterior wall (tracheal cartilage) and posterior wall (membranous portion) of the trachea below the vocal cords and of the tracheal carina. When advancing the bronchoscope through the right mainstem bronchus, a clear view of the bronchus intermedius should be seen, and at 3 o'clock the orifice of the right upper bronchus should also be seen. The distance from the tracheal carina to the takeoff of the right upper lobe is between 1.0 and 2.0 cm as the fiberscope is advanced inside the takeoff of the right upper bronchus; a clear view of three orifices is found in 98% of the population, and four orifices are found in less than 2%. These orifices are apical anterior and posterior segments. This is the only structure in the tracheobronchial tree that has three orifices. After withdrawing the bronchoscope from the right upper bronchus, it is advanced distally into the bronchus intermedius in order to identify the middle and lower right lobe bronchi. The right middle bronchus has the shape of a letter D. Infrequently seen is the takeoff of the right upper bronchus that emerges above the tracheal carina on the right side [2–4]. Once the complete examination has been performed on the right mainstem bronchus, the flexible bronchoscope is withdrawn until the tracheal carina is seen again, and then the bronchoscope is readvanced into the left mainstem bronchus in which the bifurcation into the left upper and lower lobe is visualized. The anatomical distance from the tracheal carina to the bifurcation on the left-sided bronchus is approximately 4–5 cm in length. Also in a very limited occurrences

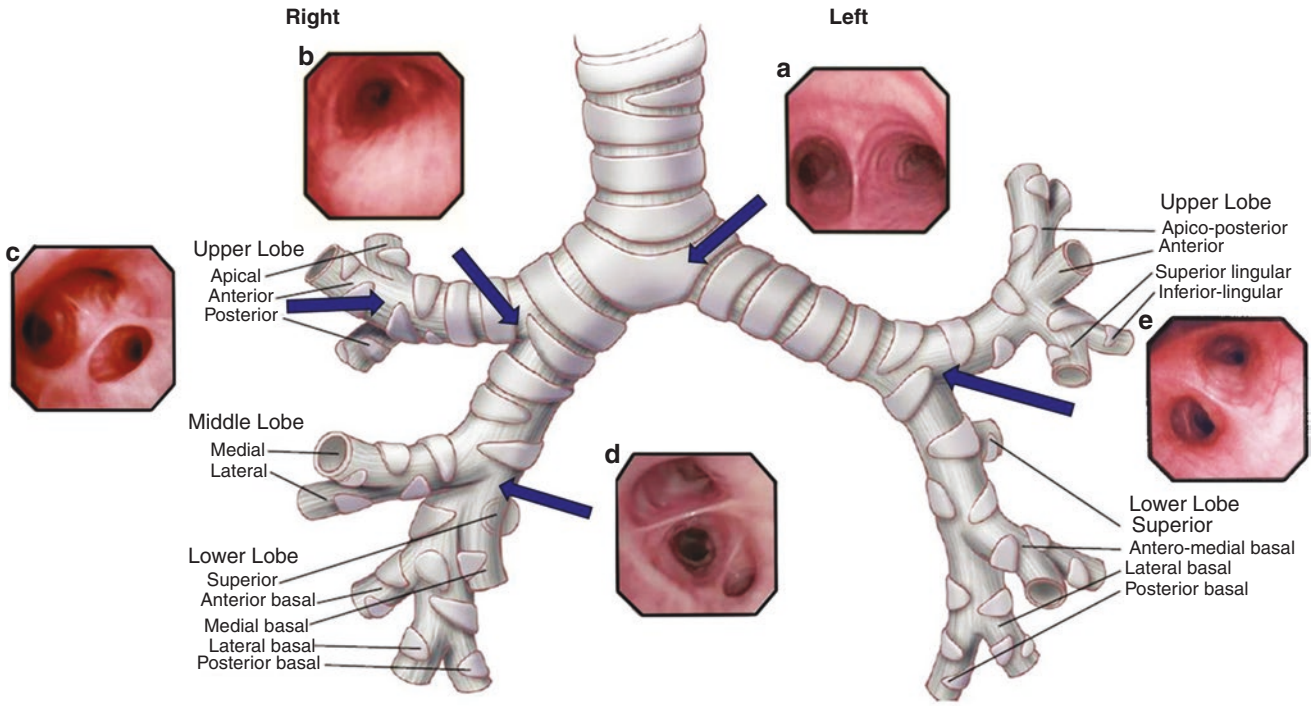

Fig. 17.1 Tracheobronchial anatomy and fiberoptic bronchoscopy exam with the view of the trachea and right and left bronchus. (**a**) shows a clear view of the tracheal carina with the flexible fiberoptic bronchoscope, (**b**) shows the takeoff of the right upper bronchus, (**c**) shows the apical upper (center) anterior toward the left and posterior segment toward the right of the right upper lobe bronchus, (**d**) shows the right middle (D shaped) and the right lower lobe bronchus (middle) and the superior segment of right lower lobe, and (**e**) shows a view of the left upper lobe and left lower lobe bronchus

an observant left upper or left lower bronchus can emerge above the tracheal carina [5]. Fig. 17.1 shows tracheobronchial anatomy [6] and fiberoptic bronchoscopy exam with the view of the trachea and right and left bronchus.

Flexible Fiberoptic Bronchoscopy and Double–Lumen Endotracheal Tube Placement

Placement and positioning of a left-sided DLT can be accomplished with the flexible fiberoptic bronchoscopy guidance technique, in which the endobronchial tip is passed beyond the vocal cords and guided through the trachea with the aid of the fiberoptic bronchoscope until the entrance of the left mainstem bronchus is identified and the tube is introduced into the left bronchus.

Optimal Position of the Left-Sided Double-Lumen Tube with Flexible Bronchoscopy

Flexible fiberoptic bronchoscopy is the recommended method to confirm the optimal position of the DLT [7–9]. Recognition of tracheobronchial anatomy and familiarity with the use of flexible fiberoptic bronchoscopy are mandatory in order to successfully achieve optimal position of the DLT. Previous studies [10, 11] involving non-thoracic anesthesiologist with very limited experience in lung separation techniques showed up to 38% incidence of unrecognized malpositions when DLTs were placed with fiberoptic bronchoscope.

The optimal position for a left-sided DLT as seen with the fiberoptic bronchoscope is completed in two steps: First the flexible fiberscope is advanced to the tracheal lumen, after the tracheal carina is identified the fiberscope is guided towards the entrance of the right mainstem bronchus, in a distance of approximately 1.0–2.0 cm to the takeoff of the right upper bronchus is seen at 3–4 o'clock on the lateral wall. Advancing the fiberoptic bronchoscope inside this orifice should provide a clear view of the apical, anterior, and posterior segments (the "cloverleaf" view). This is the only structure in the tracheobronchial tree that has tree orifices. In addition, in less than 2% of the population, a quadrivial pattern (four orifices) can be seen inside the right upper lobe bronchus [5]. Figure 17.2 shows a trifurcated and quadrivial view of the apical, anterior, and posterior segments.

After the right bronchus is identified, the endobronchial cuff of the DLT is fully inflated with no more than 3 ml of air. The blue edge of the endobronchial balloon should be posi-

tioned at least 1 cm below the trachea carina into the entrance of the left mainstem bronchus. During inspection with the fiberscope, the fully inflated balloon should not show air bubbles (leak).

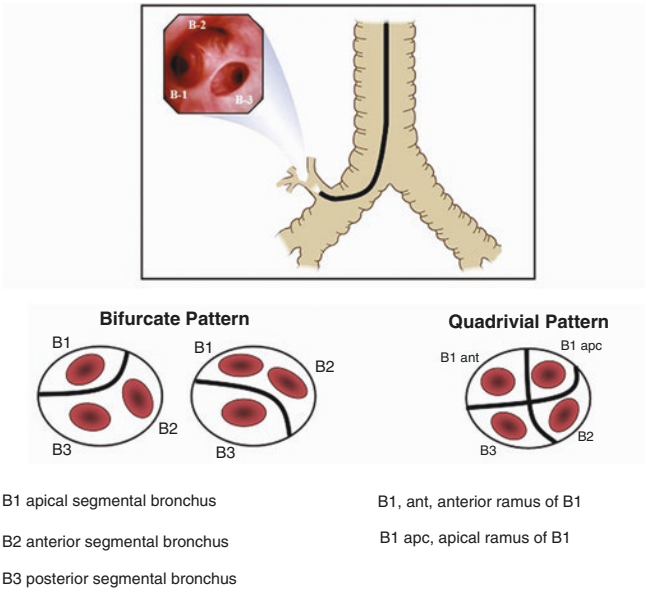

Fig. 17.2 A trifurcated and quadrivial view of the apical, anterior, and posterior segments

After the fiberoptic bronchoscopic inspection is completed from the tracheal lumen, the patient is ventilated, and then the next view is from the endobronchial lumen. Two observations are relevant: First the fiberoptic bronchoscope is advanced inside the endobronchial lumen, and the patency of the lumen is observed before advancing the bronchoscope through the blue inside portion of the tube; the second view is at the distal end of the endobronchial tip of the tube, where a clear and unobstructed view of the left upper and lower lobe bronchus entrance orifices is visualized distally. This view provides the margin of safety for a left-sided DLT [12]. Figure 17.3 shows the optimal position of a left-sided DLT seen with the flexible fiberoptic bronchoscope. This examination should be done in supine and after the patient is turned into lateral decubitus position.

A variation of the left-sided DLT is a newly designed DLT named VivaSight DLT that includes an integrated camera near to the tracheal lumen (distal) to allow a continuous view of the tracheal carina [13, 14]. A systematic review of randomized controlled trials comparing the VivaSight double-lumen tubes with a conventional double-lumen tubes showed that for optimal position of the VivaSight DLT, a flexible fiberoptic bronchoscopy is needed when this device is used [15]. Therefore, the optimal position of the VivaSight DLT is no different than placing a conventional left-sided DLT with the fiberoptic bronchoscope to achieve optimal position.

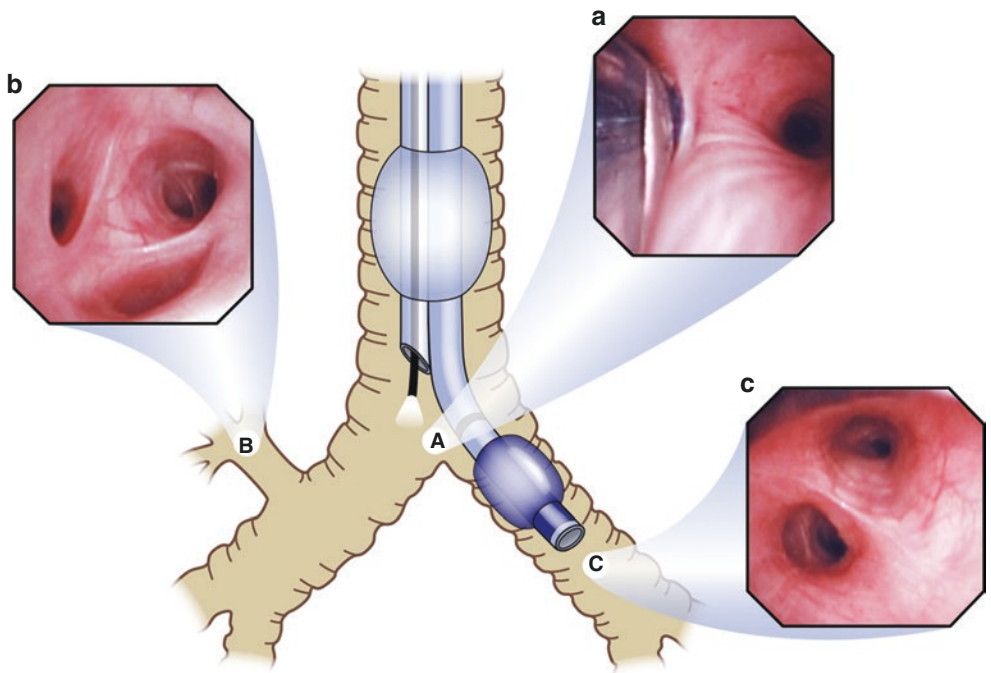

Fig. 17.3 The optimal position of a left-sided DLT seen with the flexible fiberoptic bronchoscope. This examination should be done in supine and after the patient is turned into lateral decubitus position. (**a**) shows an unobstructed view of the entrance of the right mainstem bronchus when the fiberscope is passed through the tracheal lumen and the edge of the fully inflated endobronchial cuff is below the tracheal carina in the left bronchus. (**b**) shows the takeoff of the right upper bronchus with the three segments (apical, anterior, and posterior); this is a landmark to reconfirm a right bronchus. (**c**) shows an unobstructed view of the left upper and left lower bronchus when the fiberoptic bronchoscope is advanced through the endobronchial lumen. (Campos [1])

Optimal Position of a Right-Sided Double-Lumen Tube with Flexible Bronchoscopy

The preferred technique for placement of a right-sided DLT is with the fiberoptic bronchoscopy guidance technique [16]. After the right-sided DLT is passed beyond the vocal cords under direct laryngoscopy, the fiberoptic bronchoscope is advanced through the endobronchial lumen. Before advancing the DLT, the tracheal carina, the entrance of the right mainstem bronchus, and the entrance of the right upper lobe bronchus are identified. Then the right-sided DLT is rotated toward the right and advanced with the aid of the fiberoptic bronchoscope. The optimal position of a right-sided DLT is one that provides good alignment between the opening slot of the endobronchial lumen in relationship to the entrance of the right upper lobe bronchus and, distally, a clear view of the bronchus intermedius and the right lower lobe bronchus seen from the endobronchial lumen. After the endobronchial inspection is completed and after ventilation is re-established, the next step is to inspect the DLT from the tracheal view; the optimal position for a right-sided DLT provides a view of the edge of the blue cuff just below the tracheal carina and a view of the entrance of the right mainstem bronchus. Figure 17.4 shows the optimal position of a right-sided DLT seen from the endobronchial or endotracheal view with a fiberoptic bronchoscope.

Flexible Fiberoptic Bronchoscopy and Bronchial Blockers

Another alternative to achieve lung separation is with the use of bronchial blockers passed through an in situ single-lumen endotracheal tube [17]. The various devices available at the present time include the wire-guided endobronchial blocker (Arndt® blocker), the Cohen tip-deflecting endobronchial blocker, the Fuji Uniblocker®, and the EZ-blocker [18, 19].

Placement of the Arndt® Blocker with Fiberoptic Bronchoscopy

The placement of the Arndt® blocker involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope and wire-guided loop to direct the blocker into a mainstem bronchus (Fig. 17.5). The fiberoptic bronchoscope has to be advanced distally enough so that the Arndt® blocker enters the bronchus while it is advanced. When the deflated cuff is beyond the entrance of the bronchus, the fiberoptic bronchoscope is withdrawn, and the cuff is fully inflated with fiberoptic visualization with 4–8 mL of air to obtain a total bronchial blockade. The optimal position of the Arndt® blocker in the left or in the right

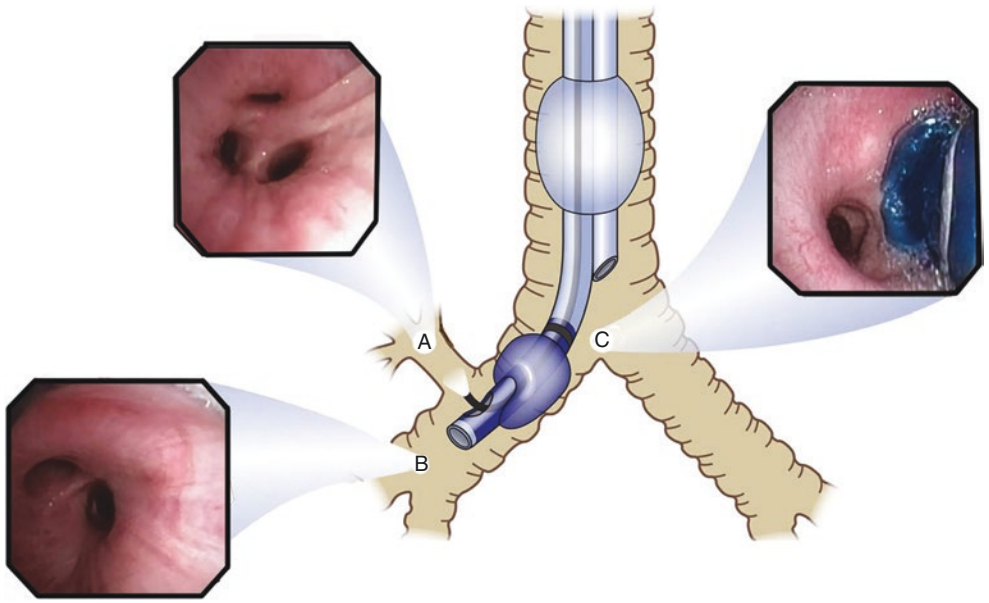

Fig. 17.4 The optimal position of a right-sided DLT seen from the endobronchial or endotracheal view with a fiberoptic bronchoscope. (**a**) shows the takeoff of the right upper bronchus with three segments (apical, anterior, and posterior) when the fiberoptic bronchoscope emerges from the opening slot located in the endobronchial lumen. (**b**) shows an unobstructed view of the entrance of the right middle and right lower lobe bronchus when the fiberscope is passed through the endobronchial lumen. (**c**) shows a view of the tracheal carina to the right edge of the blue balloon fully inflated, to the left unobstructed view of the entrance of the left mainstem bronchus when the fiberscope is advanced through the tracheal lumen. (Campos [1])

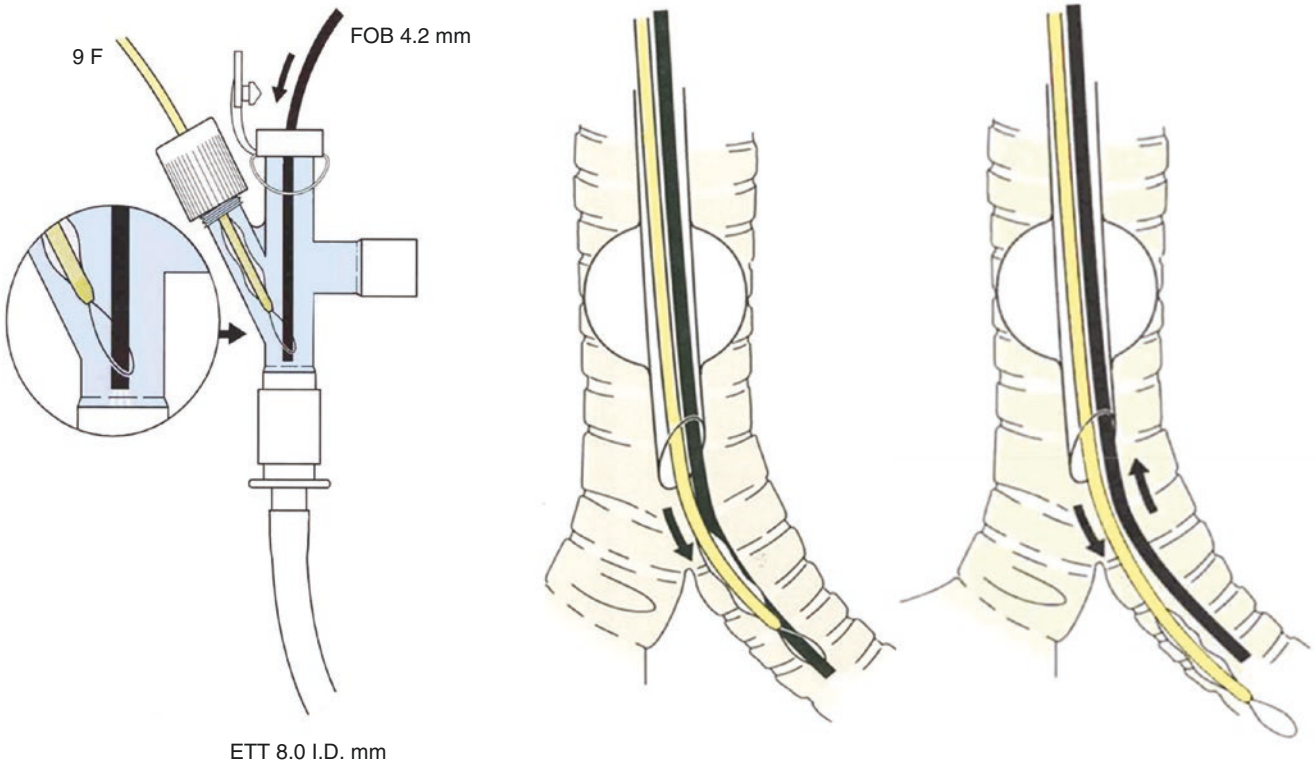

Fig. 17.5 (**a**) The placement of an Arndt® blocker through a single-lumen endotracheal tube with the fiberoptic bronchoscope advanced through the guide-wire loop into the left mainstem bronchus. Abbreviations: FOB fiberoptic bronchoscopy, ETT single-lumen endotracheal tube. (Campos [20])

bronchus is achieved when the blocker balloon's outer surface is seen with the fiberoptic bronchoscope at least 5–10 mm below the tracheal carina on the targeted bronchus and the proper real is obtained (Fig. 17.6).

Placement of the Cohen® Blocker with Fiberoptic Bronchoscopy

The Cohen® blocker relies on a wheel-turning device located in the most proximal part of the unit that allows deflection of the tip of the distal part of the blocker into the designated bronchus. This device has been purposely pre-angulated at the distal tip to facilitate insertion into a targeted bronchus. The Cohen® blocker is advanced through an 8.0 mmID single-lumen endotracheal tube. The placement of the Cohen® blocker involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope to observe the direction of the blocker into a mainstem bronchus. The advantage of the Cohen® blocker is that the tip of the blocker can be seen as it is advanced when the fiberoptic bronchoscope tip is placed a few centimeters from the tip of the blocker (Fig. 17.7).

The optimal position for the right of mainstem bronchus if the one that provides a view of the outer surface of the

(**a**) shows a bronchial blocker in the right mainstem bronchus, and (**b**) shows a bronchial blocker in the left mainstem bronchus. (Campos [20])

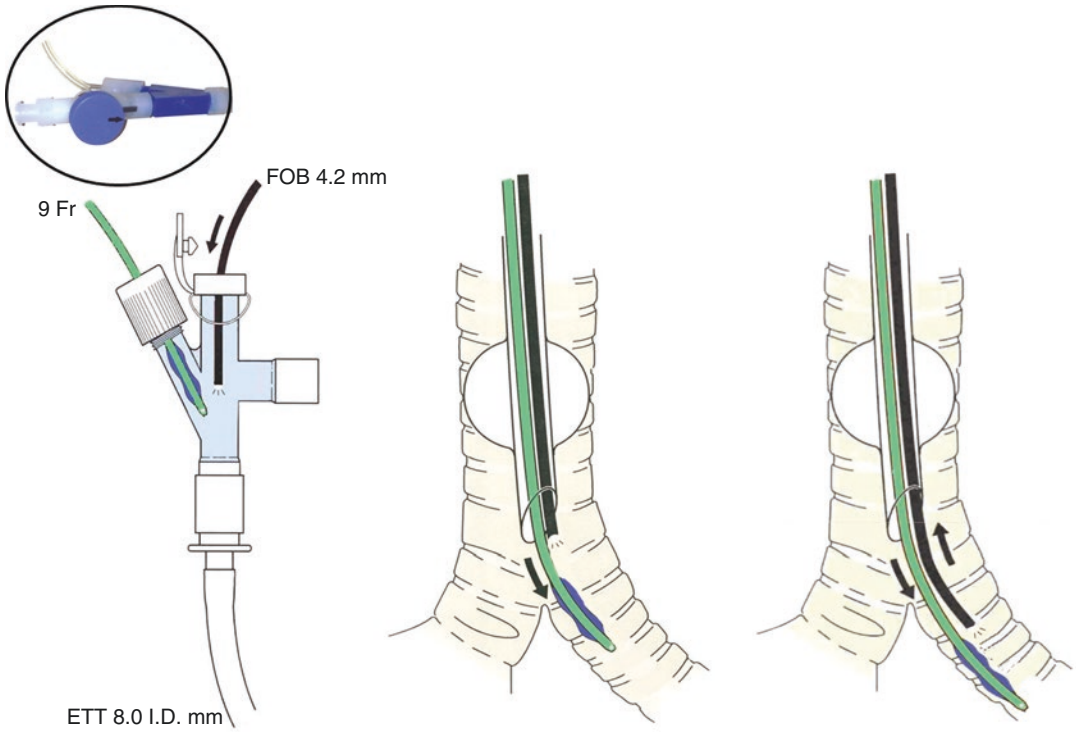

Fig. 17.7 The Cohen® blocker going into the left mainstem bronchus with the fiberoptic bronchoscope

fully inflated balloon (4–8 mL of air) with the fiberoptic bronchoscope at least 5–10 mm below the tracheal carina on the respective bronchus (Fig. 17.8).

Placement of the Fuji Uniblocker® with the Fiberoptic Bronchoscopy

The Fuji Uniblocker® is another independent bronchial blocker; the unique characteristic of this blocker is that the balloon is made of silicone with a gas barrier property to reduce diffusion of gas into or out of the cuff. The Fuji Uniblocker® size 9F (adult size) is advanced through an 8.0 mmID single-lumen endotracheal tube; before insertion, the blocker balloon is tested and then fully deflated. The tip of this blocker has a pre-angulated tip (hockey stick shape) to facilitate insertion into a targeted bronchus. The placement of the Fuji Uniblocker® involves placing the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope to observe the direction of the blocker into a mainstem bronchus. For blocking the right mainstem bronchus, the optimal position is the one that provides a view of the outer surface of the fully inflated balloon (4–8 mL of air) with the fiberoptic bronchoscope at least 10 mm below the tracheal carina on the right mainstem bronchus (Fig. 17.9a, b). The optimal position in the left mainstem bronchus is achieved when the blocker balloon's outer surface is seen with the fiberoptic bronchoscope at least 10 mm below the trachea carina inside the left mainstem bronchus.

Placement of the EZ-Blocker with Fiberoptic Bronchoscopy

The EZ-blocker is an independent bronchial blocker that is available only in a 7.0F size (adult size) (Fig. 17.10a). The EZ-blocker is manufactured with a y-shaped distal end (Fig. 17.10b). Both limbs of the distal end are fitted with an inflatable balloon (Fig. 17.10c). Each limb is color-coded (yellow or blue) for easy identification with a matching pilot balloon. The optimal size of the single-lumen endotracheal tube should be 7.5 or 8.0 mmID so it allows the blocker and the fiberoptic bronchoscope to navigate together. The multiport adaptor of the EZ-blocker is designated to connect to the connector of the single-lumen

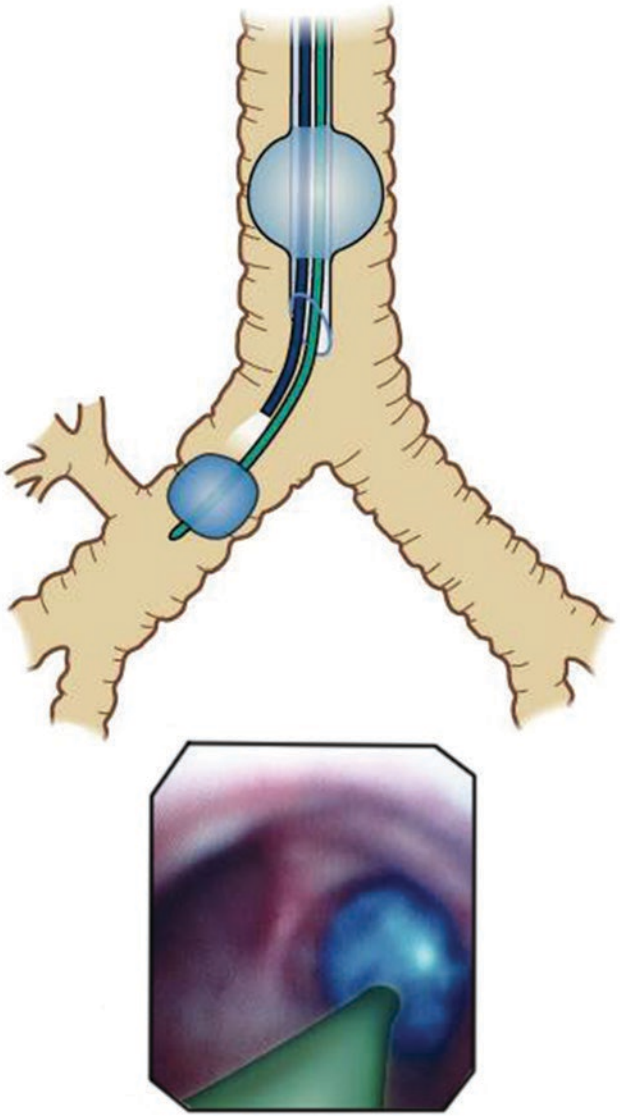

Fig. 17.8 The optimal position of the Cohen® blocker in the right mainstem bronchus with the bronchial balloon fully inflated

endotracheal tube, and it contains two additional ports, one to allow advancement of the blocker and the other port for passing the flexible fiberoptic bronchoscope. The EZ-blocker is tested and lubricated prior to passing into the lumen of the single endotracheal tube and the multiport connector. After advancing the blocker, the y-shaped end should be seated in the tracheal carina, and each independent tip should be located in the entrance of the right or left bronchus. Only the balloon where lung isolation occurs should be inflated under direct fiberoptic bronchoscopy. The pilot of the cuff is color-coded to allow identification of the respective balloon (one is yellow and the other one is blue). After the tip of the deflated balloon is in the bronchus, inflation of the balloon should be performed with flexible fiberoptic bronchoscopy. The balloon inflation requires between 8 and 14 mL of air to block a bronchus [21]. Proper and optimal position is when the outer surface of the balloon is seen at least 5–10 mm below the entrance of the bronchus. The distal end of the single-lumen endotracheal tube should be at least 4 cm above the carina to allow easy placement of the blocker into the bronchus. The distal y-junction of the two limbs of the blocker must be firmly seated on the carina to minimize displacement of the blocker during surgery. Optimal position with the fiberscope should be obtained in supine and lateral decubitus position.

Selective Lobar Blockade with Bronchial Blocker and Flexible Fiberoptic Bronchoscopy

Selective lobar blockade is a specific technique that allows one-lobe ventilation (OLV), while the operated lobe is collapsed during thoracic surgery in patients with previous pulmonary resection requiring subsequent resection or in patients with limited pulmonary reserve resulting from severe pulmonary disease [22–24]. During selective lobar blockade techniques, it is mandatory for the anesthesiologist to recognize the tracheobronchial anatomy with special emphasis on the previous bronchial resection. For instance, a patient who has previous right upper lobectomy lacks the right upper bronchus, which may contribute to difficulties in recognizing the right mainstem bronchus versus the left mainstem bronchus (Fig. 17.11). Owing to this loss of an anatomical landmark (right upper bronchus), the anesthesiologist may not be able to recognize the apical, anterior, and posterior segments seen inside the right upper bronchus with the fiberoptic bronchoscope.

Patients with previous lobectomy requiring another surgery in the contralateral lung may be at risk of developing hypoxemia during total lung collapse, barotrauma, or pulmonary hyperinflation of the remaining lung, which can lead to the development of acute lung injury. One alternative is to use a bronchial blocker to achieve selective lobar blockade to facilitate surgical exposure and improve oxygenation (Fig. 17.12).

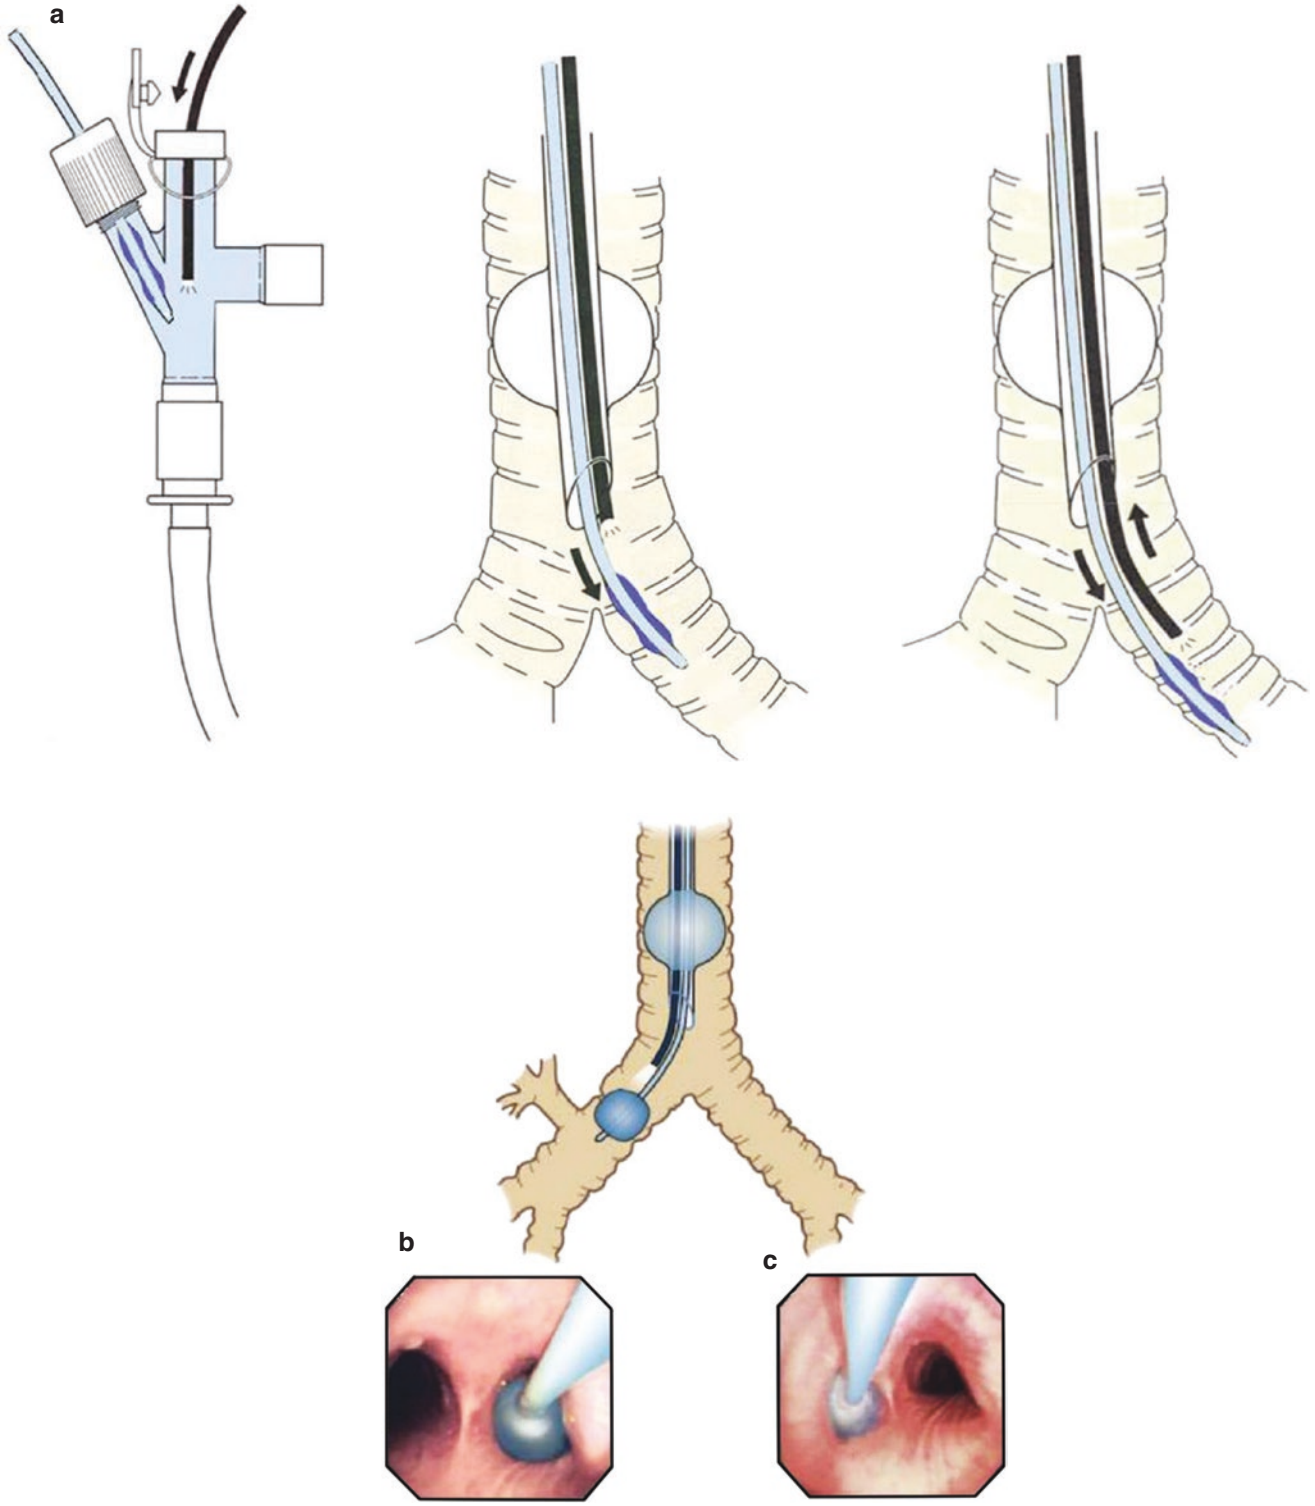

Fig. 17.9 (**a**) The Fuji Uniblocker® and placement into the right mainstem bronchus. (**b**)**.** The fully inflated balloon of the Fuji Uniblocker® in the right mainstem bronchus and (**c**) the fully inflated balloon of the Fuji Uniblocker® in the left mainstem bronchus. (Campos [1])

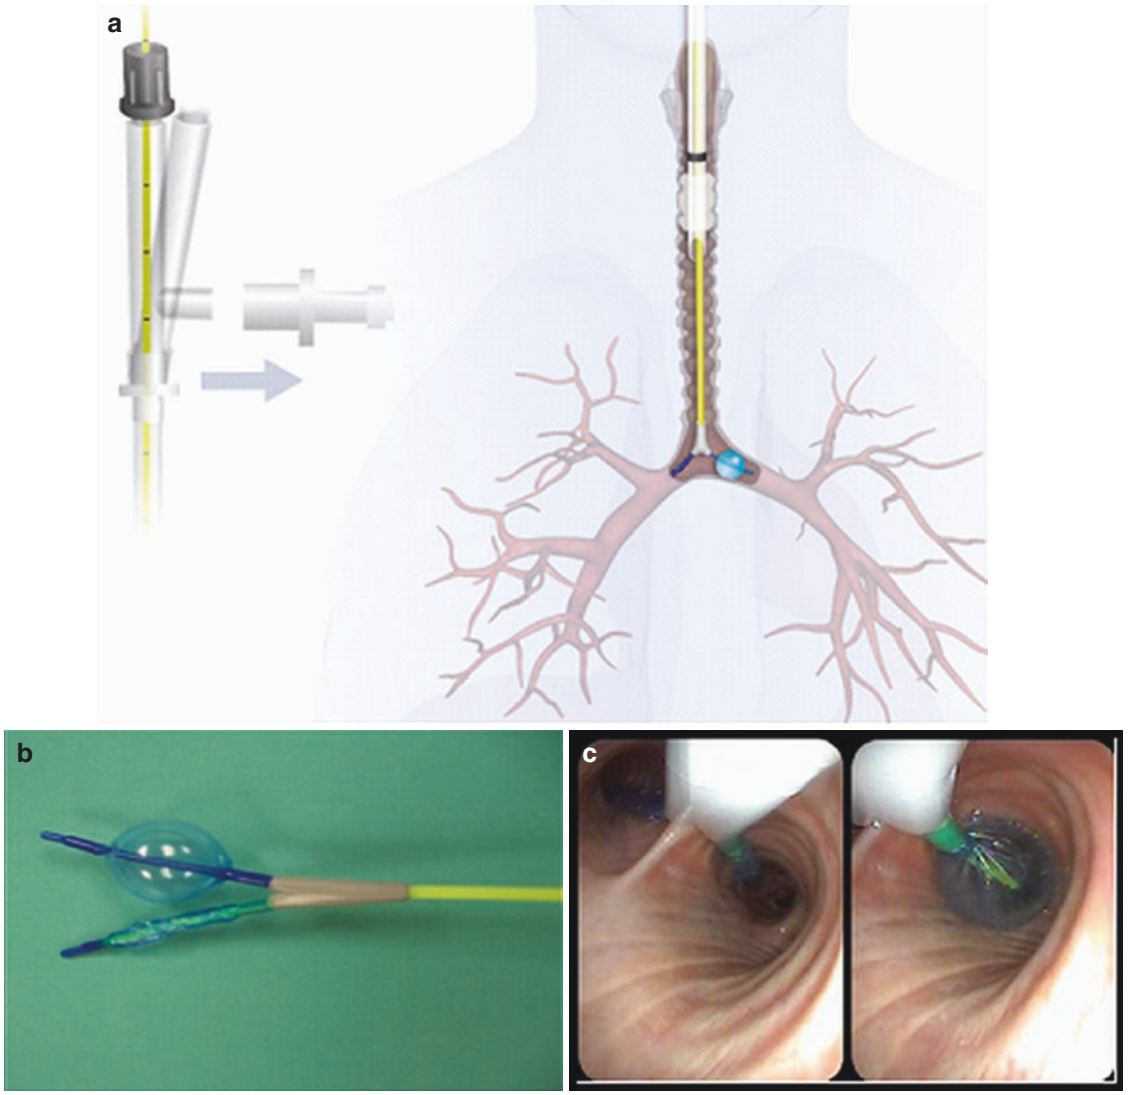

Fig. 17.10 (**a**) The EZ-blocker, (**b**) a close up of the y-shaped end, (**c**) the deflated blocker to the left and inflated blocker to the right

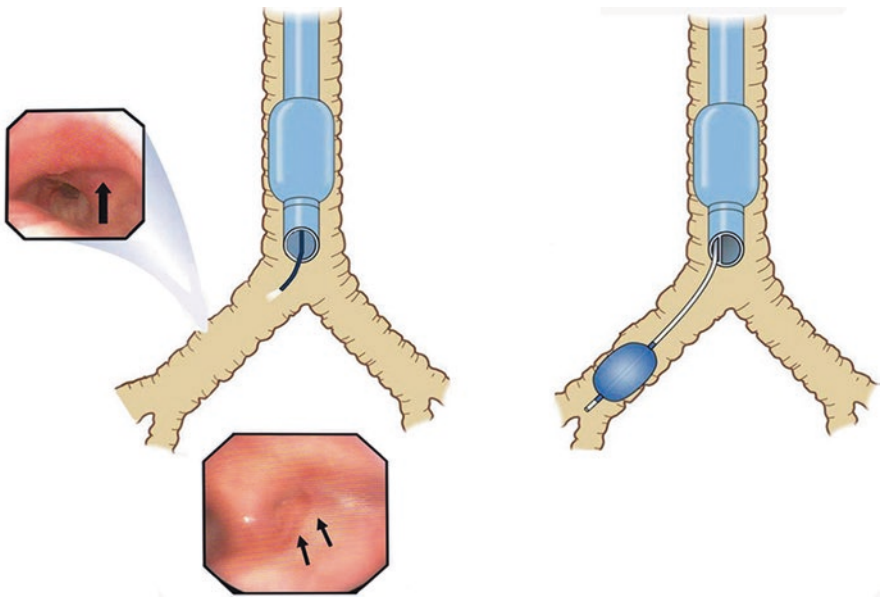

Fig. 17.11 The fiberoptic bronchoscopy view in a patient with previous right upper lobectomy

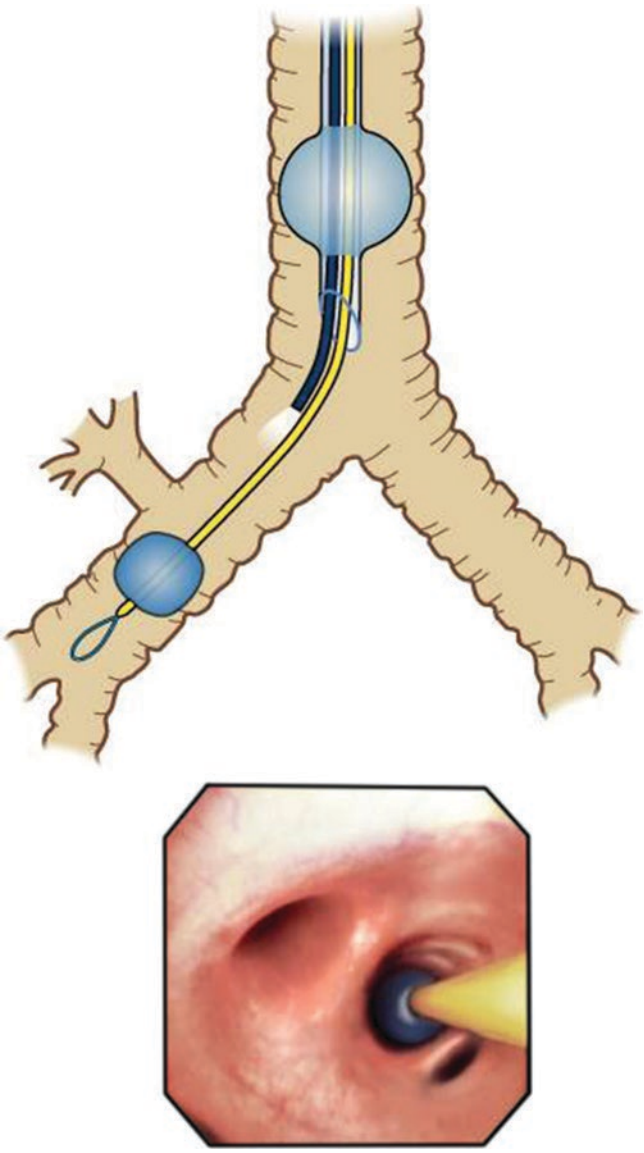

Fig. 17.12 A bronchial blocker placed in the bronchus intermedius. The fully inflated balloon is blocking the right middle and right lower lobe bronchus while the right upper lobe is being ventilated (selective lobar blockade). (Campos [24])

A bronchial blocker can be used through a single-lumen endotracheal tube. In order to achieve a bronchial blockade, it must be advanced and positioned with the aid of a fiberoptic bronchoscope into a selective bronchus (Fig. 17.13a). The amount of air required to inflate a bronchial blocker balloon to achieve selective lobar blockage ranges between 2 and 4 mL (Fig. 17.13b).

Other Uses of Flexible Fiberoptic Bronchoscopy During Double-Lumen Tubes or Bronchial Blockers

Common problems and limited number of complications can occur with the use of DLTs and bronchial blockers, particularly malpositions and airway trauma. Therefore it is essential to keep the flexible fiberoptic bronchoscope during the entire case and remove it (after the patient leaves the operating room). Malpositions of lung isolation devices are easily corrected with the use of flexible fiberoptic bronchoscope. Airway trauma and rupture of the membranous part of the trachea or bronchus continue to be an infrequent problem with the use of DLTs, and this can occur during insertion, placement, while the case is in progress, or during extubation [25, 26]. Airway damage during the use of DLTs can present as unexpected air leaks, subcutaneous emphysema, massive bleeding, or protrusion of the cuff balloon into the surgical fields. If any of the aforementioned problems occur, a flexible fiberoptic bronchoscopic examination should be performed and surgical repair performed. Another use of flexible fiberoptic bronchoscopy is to inspect the airway after removal of a fully inflated blocker [27] after failure in the device to achieve deflation at the conclusion of surgery. Inspection with the fiberscope allows to identify any trauma to the airway.

Summary

The use of flexible fiberoptic bronchoscopy should be considered an art in thoracic anesthesia. To master this art, one must be able to recognize tracheobronchial anatomy and changes that occur with age, understand the anatomical distances of the airway, recognize the takeoff of the right upper lobe bronchus and its variants, and have familiarity and expertise with the use of the flexible fiberoptic bronchoscopy. This will lead to a successful placement of a right- or left-sided DLT as well as bronchial blocker during lung isolation techniques.

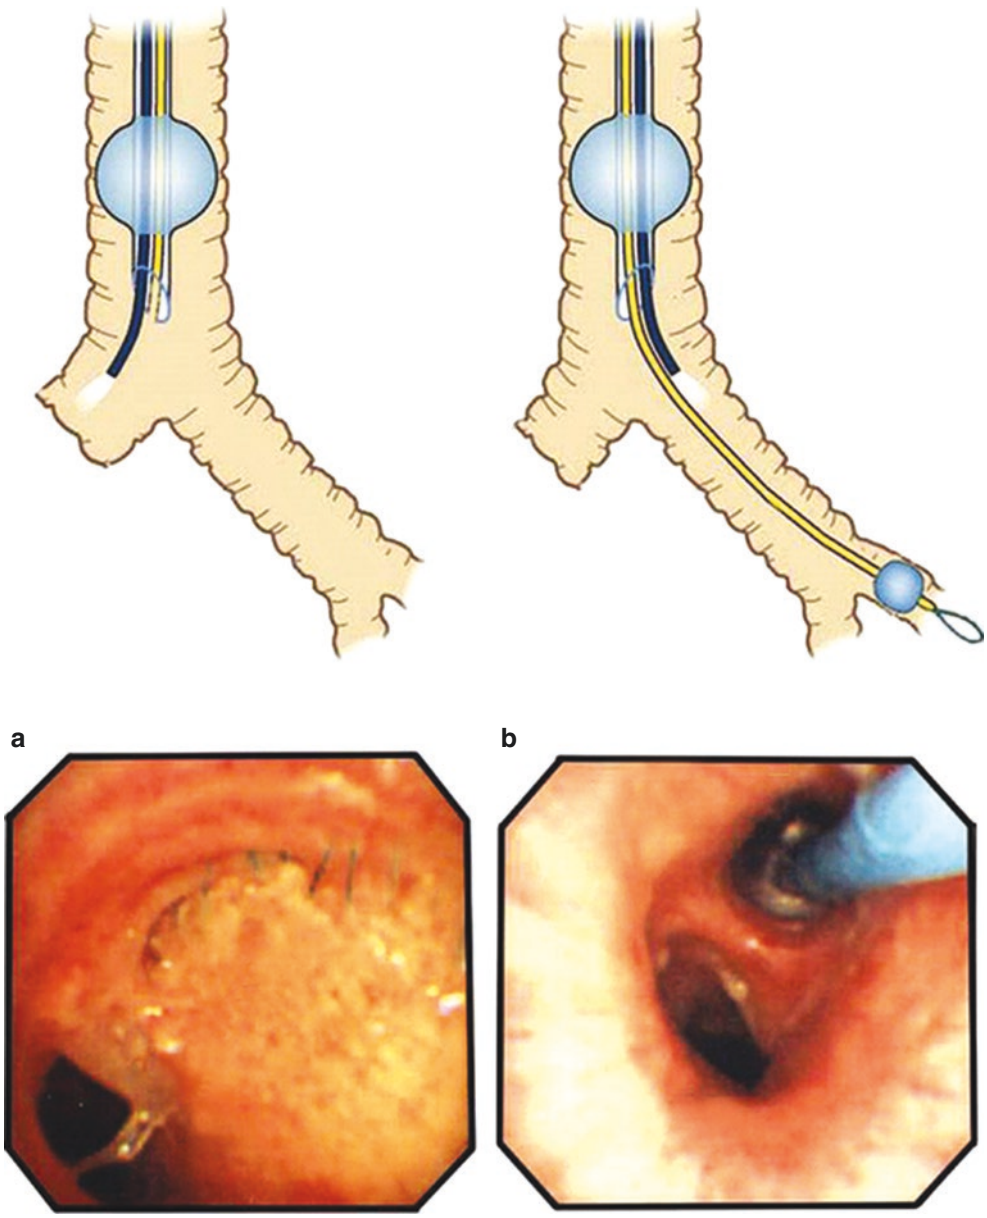

Fig. 17.13 (**a**) displays a fiberoptic bronchoscopy view of tracheal carina in a patient with a right-sided pneumonectomy. (**b**) displays an Arndt® blocker blocking the entrance of the left upper lobe in a patient that required left upper segmentectomy. (Campos [24])

Lung Isolation in Patients with Difficult Airways

18

Daniel Tran and Wanda M. Popescu

Key Points

- Recognition of a difficult airway prior to the use of lung isolation devices is essential.
- Securing the airway is the primary task in patients with difficult airways requiring lung isolation.
- The use of bronchial blocker is the first-line choice in patients with difficult airway who require lung isolation.
- In patients with difficult airways, the use of airway exchange catheters is recommended when changing single-lumen tubes to double-lumen tubes and vice versa.

Introduction

One-lung ventilation (OLV) in the thoracic surgical patient can be achieved with the use of a double-lumen endotracheal tube (DLT) or an independent bronchial blocker [1]. A number of patients requiring lung isolation may present as potentially difficult airways due to abnormalities of either the upper or lower airway [2]. In order to optimally manage these patients, it is important to understand the normal anatomy of the tracheobronchial tree, including the anatomical distances of the airway [3].

Patients with a potentially difficult airway who require OLV may be identified during the preoperative evaluation. However, others will present with airways that are unexpectedly difficult to intubate after induction of anesthesia. It is estimated that between 5% and 8% of patients with primary lung carcinoma also have a carcinoma of the pharynx, usually in the epiglottic area [2]. Many of these patients may have had previous airway surgery or radiation therapy to the neck, making intubation and achievement of OLV difficult due to distorted upper airway anatomy. In addition, a patient who requires OLV might have distorted anatomy at or beyond the tracheal carina due to a descending thoracic aortic aneurysm compressing the entrance of the left mainstem bronchus or an extraluminal tumor compressing the tracheobronchial bifurcation, making the insertion of a left-sided DLT relatively difficult or impossible.

Preoperative Evaluation of the Difficult Airway and Lung Isolation Techniques

According to the ASA practice guideline for management of the difficult airway [4], an airway is termed difficult when conventional laryngoscopy reveals a grade III view (just the epiglottis is seen) or a grade IV view (just part of the soft palate is seen). However, in patients requiring OLV, the definition of a difficult airway is more comprehensive. It includes not only issues pertaining to the the upper airway, which could render a laryngoscopic grade III or IV view, but also problems with the lower airway (tracheobronchial tree). If the upper airway is recognized as being potentially difficult, a careful examination of the patient ensues. Previous anesthesia records should be examined for a history of airway management. Patients should be asked to open their mouths as widely as possible and extend their tongues. The mandibular opening should be assessed and the pharyngeal anatomy observed. The length of the submental space should also be noted. Patients should be evaluated from side to side to assess any degree of maxillary overbite and their ability to assume the sniffing position. Also, the patency of the nostrils must be assessed in patients who cannot open their mouths, as a nasotracheal approach might be considered. In patients

with previous radiation therapy to the neck, the external surface of the neck should be palpated to determine if the presence of very hard, rigid tissue could make intubation challenging. Similarly, patients with limited neck mobility can make laryngoscopy difficult. For patients who have a tracheostomy cannula in place and require OLV, it is important to determine if the cannula is cuffed or uncuffed and to assess the inlet of the stoma as well as the circumferential diameter in order to establish what type and size of lung isolation device can be used.

Another group of patients considered to have difficult airways during OLV are those who have distorted anatomy at the entrance of the mainstem bronchus. Such anomalies can be found by reviewing the chest radiographs and by reviewing the computer tomography scans of the chest regarding the mainstem bronchus diameter and anatomy, which can be distorted or compressed (see Fig. 18.1). Also, in specific patients, an examination with a flexible bronchoscope under local anesthesia and sedation prior to the selection of a specific OLV device could be useful to assess a distorted area of the airway. Table 18.1 displays the patients at risk of having a difficult intubation during OLV [5].

Difficult Airway and Lung Isolation: Securing the Airway First

In patients who require OLV and present with a difficult airway, the primary goal is to establish a secure airway. This task may be easier when using a single-lumen endotracheal tube placed orally. In selected patients who seem easy to ventilate, placing the endotracheal tube may be performed after induction of anesthesia with the use of a flexible bronchoscope or with a video laryngoscope [6–8]. Alternatively, a single-lumen endotracheal tube can be placed with flexible bronchoscopic guidance through a laryngeal mask airway.

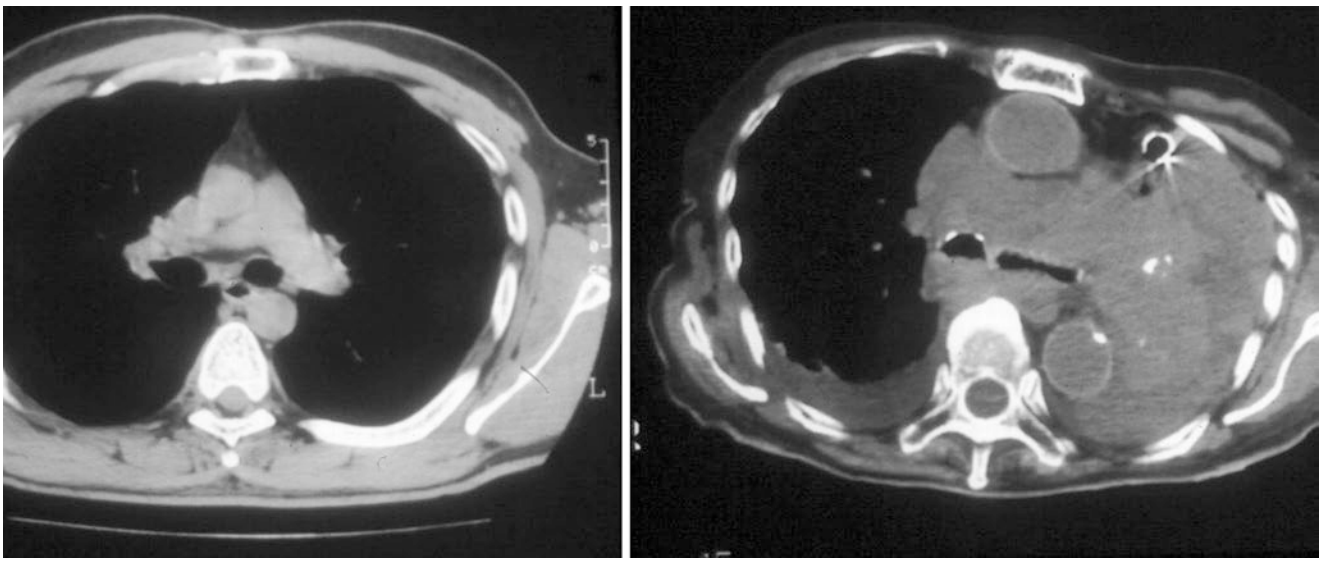

Fig. 18.1 Computed tomography (CT) scans from just below the level of the carinal bifurcation. *Left*: CT from a patient with no compression of the airway. *Right*: CT from patient scheduled for left lung biopsy. The patient has a left-sided lung tumor and effusion, which compresses the left mainstem bronchus. This bronchial compression was not evident on the chest X-ray. It may be difficult to place a left-sided double-lumen endobronchial tube (DLT) in this patient. A right-sided DLT or a bronchial blocker would be the preferred method of lung isolation for this patient under flexible bronchoscopy guidance

Table 18.1 Characteristics of patients at risk of having a difficult intubation during one-lung ventilation

Upper airway	Lower airway
Short neck and increased neck circumference	Existing tracheostomy in place
Prominent upper incisors with a receding mandible	Distorted anatomy of the trachea or bronchus
Limited cervical mobility	Compression at the entrance of left mainstem bronchus by a tumor, descending thoracic aortic aneurysm, previous surgery, or radiation
Limited jaw opening	Previous lobectomy
Radiation therapy of the neck	Congenital abnormalities of the tracheobronchial tree (bronchus suis)
Hemiglossectomy/hemimandibulectomy	Tracheoesophageal fistula
Tumors (mouth, tongue, epiglottis)	

Use of a Flexible Bronchoscope During Awake Intubation

The administration of supplemental oxygen via nasal cannula as well as an antisialog medication such as glycopyrrolate is highly advisable during awake flexible bronchoscopic intubations. All local anesthetics used via spray or aerosolizer should be quantified to avoid overdose or complications, such as seizures or methemoglobinemia. A simple approach to anesthetize the posterior part of the tongue is to apply lidocaine 5% ointment to a tongue blade depressor and let the patient hold this in his or her mouth for about 5 min. After the tongue blade depressor is removed, the next step is to use a mucosal atomization device (MAD®) to spray the local anesthetic (lidocaine 4%, 10 mL) directly to the pharynx, larynx, and vocal cords. When the patient experiences a cough reflex, it is very likely that the anesthetic has entered the vocal cords. Before proceeding, all residual secretions accumulated in the airway should be suctioned. In order to test that the gag reflex is abolished, an intubating pharyngeal airway impregnated with lidocaine 5% ointment at the posterior tip can be advanced until it is completely inserted in the oral cavity. The oral intubating airway guides the bronchoscope toward the airway and prevents contact between the device and the patient's teeth.

The flexible bronchoscope is positioned in the midline such that the single-lumen endotracheal tube faces posteriorly during the intubation attempt. In some cases, retraction of the single-lumen endotracheal tube and 90° counterclockwise rotation will facilitate passage of the tube through the vocal cords. Sometimes it is necessary to complement the local anesthetic with an additional dose of lidocaine 4% (3 mL) through the suction channel of the bronchoscope to abolish the cough reflex during manipulation of the airway. The best indicator of proper placement of the bronchoscope and the endotracheal tube within the patient's trachea is the direct visualization of the tracheal rings and tracheal carina [9]. Once the patient is intubated with an endotracheal tube, then an independent bronchial blocker can be considered to achieve OLV.

Common independent bronchial blockers used through a single-lumen endotracheal tube include the following: a wire-guided endobronchial Arndt® blocker sizes 5.0, 7.0, and 9.0 F [10], the Cohen® Flex-Tip blocker size 9.0 F [11], and the Fuji Uniblocker® sizes 4.5 and 9.0 F [12, 13] (see Chap. 16).

The EZ-Blocker (IQ Medical Ventures BV, Rotterdam, Netherlands) is a new Y-shaped, symmetrical, bronchial blocker with two distal extensions, each with its own inflatable spherical cuff and central lumen. It is intended for use with a conventional endotracheal tube to provide lung isolation by inflation of either the left or right cuff while the distal extensions are located in the left and right mainstem bronchi. The design of the EZ-Blocker resembles the anatomic structure of the tracheobronchial tree which gives the device stability as it sits atop the carina, resulting in fewer dislodgements when compared to the Cohen Flex-Tip blocker [14]. The EZ-Blocker's polyurethane cuffs are "high pressure-low volume"; therefore the lowest required volumes should be used for inflation to avoid trauma to the bronchial mucosa. It is best to inflate the cuff of the bronchial blocker under direct visualization of the flexible bronchoscope in order to assure that the lowest amount of air is used while the entire bronchus is occluded. Limitations of the EZ-Blocker include the inability to perform selective lobar blockade, endobronchial suctioning, or lavage [15, 16].

If a patient cannot open his/her mouth and cannot be intubated orally, then an awake nasotracheal intubation can be performed. All precautions of a nasal intubation, including the application of a vasoconstrictor and a local anesthetic, should be taken. Once the airway is established with a nasal endotracheal tube, then an independent bronchial blocker can be advanced [17, 18]. Figure 18.2 shows a patient with previous hemimandibulectomy requiring nasotracheal intubation with an 8.0 mm internal diameter endotracheal tube and an Arndt® blocker passed through the multiport connector.

When a bronchial blocker is used, the smallest acceptable endotracheal tube size is 8.0-mm internal diameter to allow enough space between the bronchial blocker and the flexible bronchoscope. Once the endotracheal tube is secured in the patient's trachea, a bronchial blocker can be advanced with the aid of a flexible bronchoscope. An advantage of the Cohen® or the Fuji Uniblocker® over the Arndt® wire-guided endobronchial blocker is that while advancing it to a desired bronchus, the distal tip of the blocker can be seen while entering a bronchus. With the Arndt® blocker, the distal tip is looped into the fiberscope and cannot be seen until disengagement occurs. One of the advantages of bronchial

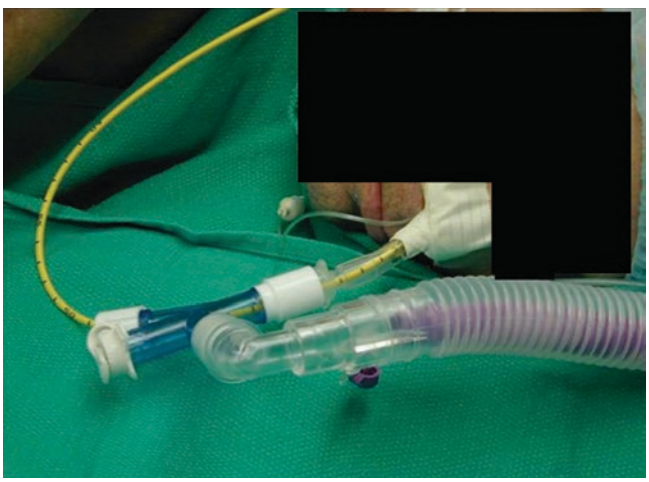

Fig. 18.2 A patient with previous hemimandibulectomy requiring nasotracheal intubation with an 8.0-mm internal diameter single-lumen endotracheal tube and an Arndt® blocker

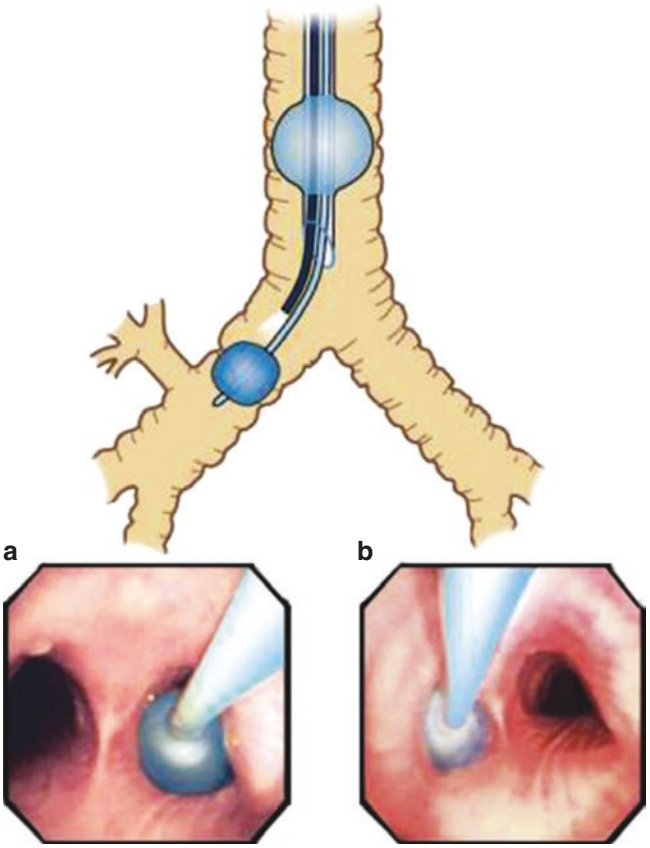

Fig. 18.3 The optimal position of an independent bronchial blocker through a single-lumen endotracheal tube. (**a**) The bronchial blocker balloon fully inflated into the right mainstem bronchus. (**b**) Fully inflated balloon in the entrance of the left mainstem bronchus [9]

blocker for lung isolation in a patient with a difficult airway is that at the end of the procedure, if postoperative ventilatory support is needed, the blocker is simply removed and the patient remains intubated with a single-lumen endotracheal tube [19].

In an adult the amount of air needed to achieve a complete seal within the bronchus varies significantly depending on the type of blocker utilized as well as on the size of the bronchi. The optimal position of a bronchial blocker is when the blocker balloon's outer surface is seen at least 10 mm below the tracheal carina inside the blocked bronchus and a proper seal is achieved. In order to identify an appropriate seal of the bronchus, the balloon should be inflated under bronchoscopic guidance. Figure 18.3 shows the optimal position of an independent bronchial blocker through a single-lumen endotracheal tube.

Special Consideration for Patients with High Aspiration Risk

Patients with difficult airways and high aspiration risk presenting for thoracic surgery require additional care given the need to quickly and safely secure the airway. NPO guidelines should be strictly followed prior to surgery. The safest approach for securing the airway for this patient group is by performing an awake oral or nasal fiberoptic intubation with a single-lumen endotracheal tube, following proper airway topicalization. If lung isolation is required, an independent bronchial blocker is placed after the airway is safely secured. Alternatively, an awake DLT intubation can be done with the flexible bronchoscope inserted into the bronchial lumen of the DLT, then advanced into the correct mainstem bronchus under direct visualization. Awake DLT placement is more challenging due to the larger size of the tube which may not easily pass through the glottic opening. Intraoperatively, periodic suctioning of the oropharynx and gastric tubes before emergence and extubation is important to prevent reflux of contents from the esophagus. At the end of the procedure, patients should be extubated after being positioned with the head of the bed elevated and when fully awake [20].

Use of Laryngeal Mask Airway and a Bronchial Blocker During Difficult Airways

An alternative to achieve OLV in a patient with a difficult airway is with the use of a laryngeal mask airway in conjunction with the use of an independent bronchial blocker. A laryngeal mask airway can be modified by removing the aperture bar in order to facilitate the insertion of a flexible bronchoscope and bronchial blocker [21]. The ProSeal laryngeal mask airway has been used with a bronchial blocker in patients in whom the airway was deemed difficult and who required OLV during thoracoscopic surgery [22, 23].

Use of a Double-Lumen Endotracheal Tube in Patients with Difficult Airways

Intubation with a DLT can be more difficult than intubation with a single-lumen endotracheal tube. The larger size, the rigidity, and the shape of the DLT, without a bevel at the tip of the tube, can obscure the view of the glottis. In practice there are several different ways to place a DLT in patients with difficult airways. The first involves the use of airway topical anesthesia and awake bronchoscopy with passage of the flexible bronchoscope through the bronchial lumen of the DLT. The tube is advanced under bronchoscopic guidance while the patient is breathing spontaneously [24] (see Fig. 18.4). The second technique involves the use of ancillary lighted devices or video laryngoscopes that increase the visualization field of the epiglottis and vocal cords and aid the passage of the tube. The use of a malleable, lighted stylet

Fig. 18.4 (**a**) Pediatric fiberoptic bronchoscope passed through the endobronchial lumen of a double-lumen endotracheal tube (DLT) for fiberoptic intubation. Note that the actual working length of the DLT beyond the distal bronchial orifice is only approximately 20–25 cm. (**b**) Fiberoptic intubation of a mannequin with a left-sided DLT

(Mercury Medical, Clearwater, FL, USA) has been reported. The lighted stylet is placed via the endobronchial lumen of the DLT, where the tip of the bulb is positioned distally at the tip of the DLT [25]. Others have reported the use of a fiberoptic laryngoscope, the WuScope (Pentax Precision Instruments, Orangeburg, NJ, USA), during placement of a DLT in patients with abnormal airway anatomy [26]. One of the advantages of the fiberoptic laryngoscope is that it protects against rupture of the endotracheal cuff during laryngoscopy because the DLT is enclosed with the laryngoscope blade. A disadvantage of this device is the need for smaller-sized DLTs, such as 35–37 F.

Another option is the use of the VivaSight-DL. This is a new, single-use DLT with an integrated high-resolution camera embedded at the tip of the endotracheal lumen that allows for continuous visualization of the carina and position of the endobronchial balloon [27]. When used in a patient with a difficult airway, this device is placed in a similar manner as a standard DLT, with the advantage that the VivaSight-DL is connected to a screen monitor to provide a live view while the tube navigates the airway. In addition, after the VivaSight-DL is correctly positioned in the left mainstem bronchus, the continuous display of the carina and its position relative to the endobronchial balloon makes it easy to detect tube malposition in real time [28].

The Glidescope® video laryngoscope (Saturn Biomedical Systems, Burnaby, British Columbia, Canada) has been used in patients with a difficult airway during placement of a DLT [29]. Video-directed laryngoscopy may facilitate DLT intubation when direct laryngoscopy does not yield a clear view of the glottic opening for easy intubation. The Glidescope® technique offers several advantages including faster speed (in experienced hands), increased rate of first-pass success, and reduced risk of upper airway trauma. However, for patients with small oral apertures, the Glidescope® has limited utility.

The Glidescope® should be used with a dedicated semi-rigid intubating stylet (GlideRite DLT Stylet) while inserting a DLT, which maintains optimal curvature of the DLT and aligns the tip of the DLT with the tip of the Glidescope® blade

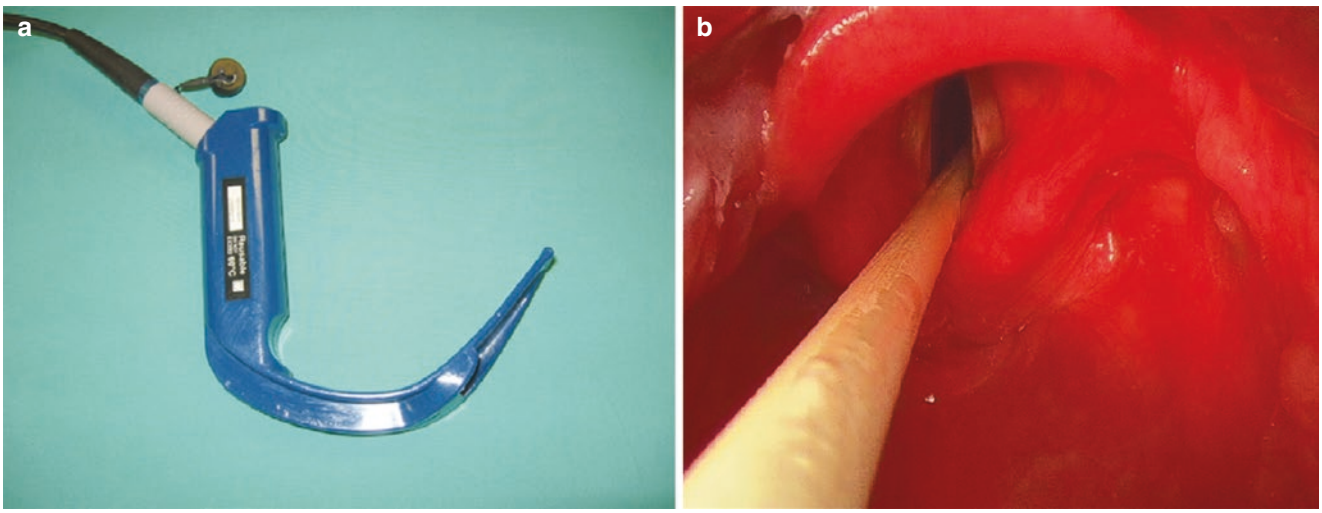

Fig. 18.5 (**a**) GlideScope® (Verathon Corp., Bothell, WA) video laryngoscope. Note the acute flexion of the laryngoscope blade. (**b**) View of the glottis from a GlideScope® during a tube exchange. A tube exchange catheter can be seen passing through the vocal cords. This clear view of the glottis facilitates manipulation of the airway device during replacement of a single-lumen endotracheal tube with a DLT or vice versa

[30]. Alternatively, the stylet of the DLT can be used; however, bending the tip of the DLT is recommended to facilitate insertion using the Glidescope®.

Another alternative is to intubate the patient's trachea with a single-lumen endotracheal tube during an awake or asleep flexible bronchoscopy. After induction of anesthesia, a DLT-specific Cook airway catheter can be used to exchange out the existing tube for a DLT [31] (see Fig. 18.5). The flexible beveled distal tip of the bronchial lumen of the Fuji Silbroncho doube-lumen tube is specifically designed for this purpose and facilitates this tube exchange [31] (see Fig. 18.6a–d).

The airway exchange catheter, single-lumen endotracheal tube, and the DLT combination should be tested in vitro before the exchange [32]. A sniffing position will facilitate tube exchange. After the airway exchange catheter is lubricated, it is advanced through a single-lumen endotracheal tube. The airway catheter should not be inserted deeper than 24 cm from the lips to avoid accidental rupture or laceration of the trachea, bronchi, or lung [33, 34]. After cuff deflation, the single-lumen endotracheal tube is withdrawn. The endobronchial lumen of the DLT is then advanced over the exchange catheter. It is optimal to use a video laryngoscope during the tube exchange to guide the DLT through the glottis under direct vision [35]. If a video laryngoscope is not available, then having an assistant perform a standard laryngoscopy during tube exchange partially straightens out the alignment of the oropharynx and glottis and facilitates the exchange. Proper final position of the DLT is then achieved with bronchoscopic examination. Replacement of a DLT for a single-lumen endotracheal tube can be done at the conclusion of surgery with the use of either a single or a double airway exchange catheter. One study using two airway exchange catheters to exchange a DLT for a single-lumen endotracheal tube showed that there was a reduction in the incidence of glottis impingement of the tracheal tube and that there was a higher success rate of passage of the single-lumen endotracheal tube when compared with the use of a single airway exchange catheter [36]. The use of a double airway exchange catheter involves the following techniques: two 11 F, 83-cm-long airway exchange catheters from Cook® Critical Care are used. One catheter is passed through the endobronchial lumen of the DLT, making sure that the tip of the airway exchanger does not protrude distally in the tip of the DLT. A second exchange catheter is passed through the tracheal lumen; both catheters provide easy placement of the new single-lumen endotracheal tube because of the increase rigidity with the two tube exchangers. For this technique to work, an 8.0-mm internal diameter single-lumen endotracheal tube must be used. Another variation of the tube exchanger technique is using a double-diameter coaxial airway exchange

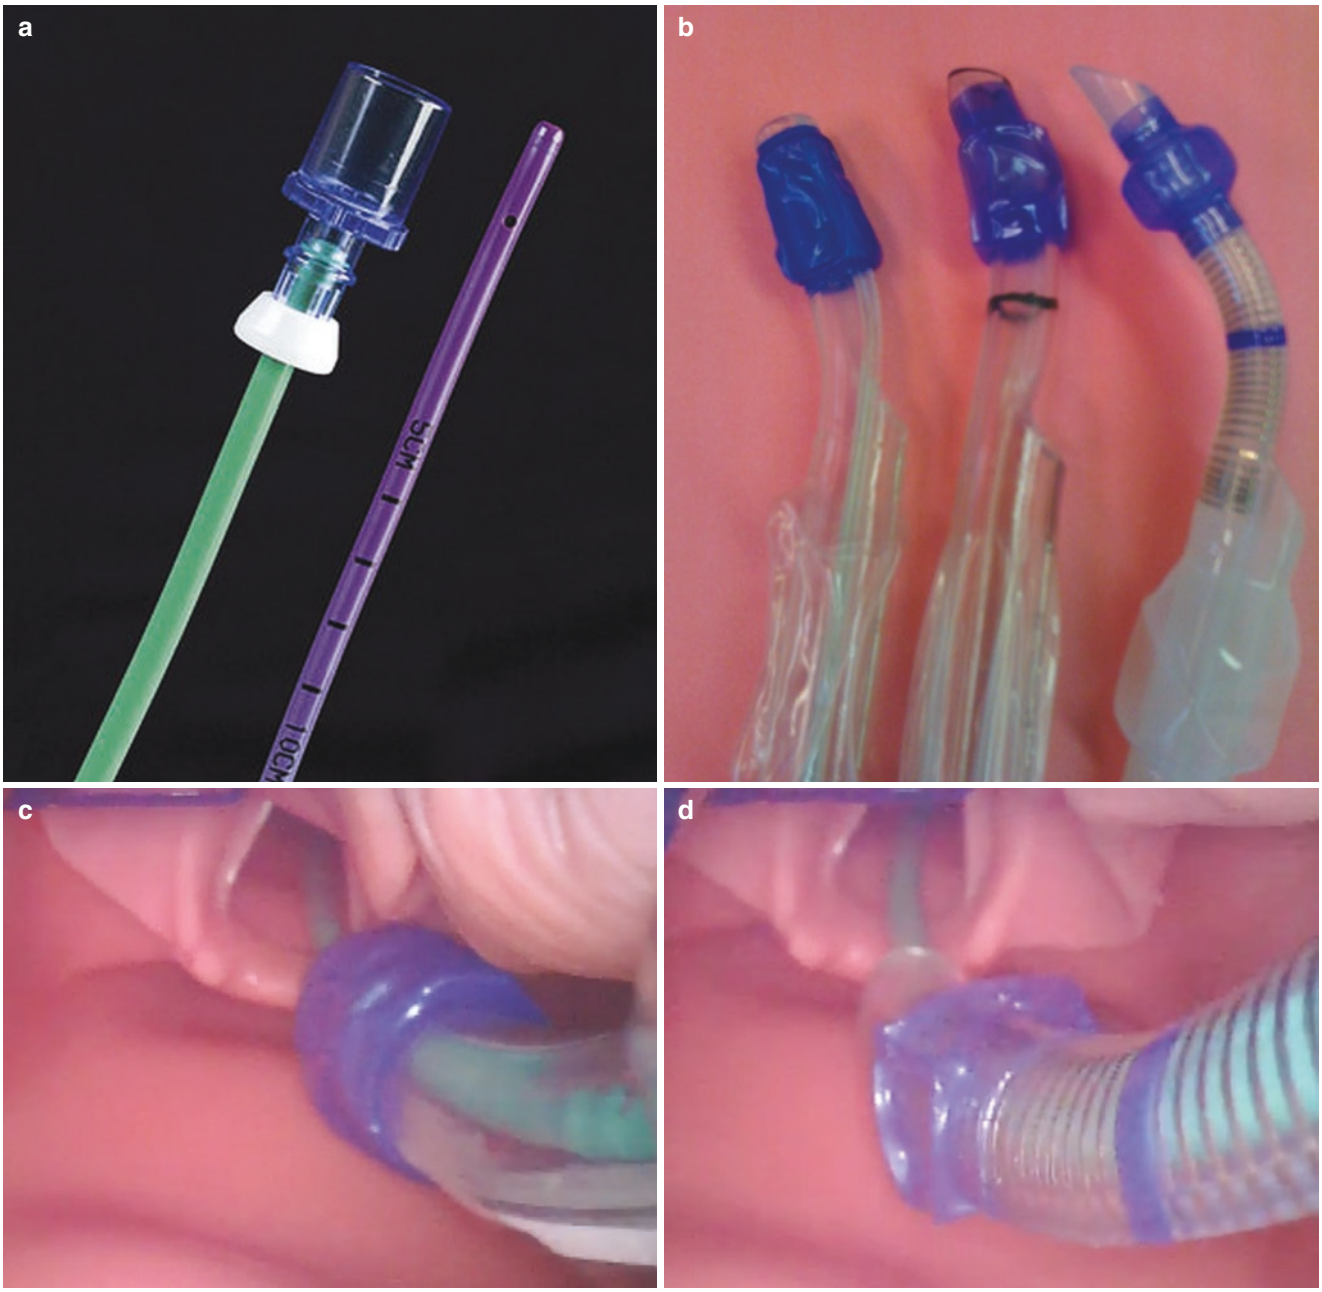

Fig. 18.6 (**a**) The Cook® airway catheter (Cook Critical Care, Bloomington, IN) for exchange between DLTs and a single-lumen endotracheal tube. This catheter has a soft distal (*purple*) tip to attempt to decrease the risk of distal airway injury during tube exchange (*right*). The proximal stiffer *green* end (*left*) has detachable connectors for emergency ventilation. Shown is the standard 15-mm outside diameter breathing circuit connector. The exchange catheter also comes with a jet ventilation connector (not shown). (**b**) Double-lumen tube manufacturers' designs of the distal tip of the bronchial lumen. From left to right: Rusch Brochopart, Teleflex, Research Triangle Park, NC; Mallinckrodt, Broncho-Cath, Covidien, Mansfield, MA; and Fuji, Silbroncho, Fuji Systems, Tokyo. (**c**) Single- to double-lumen tube exchange over a Cook catheter with a Rusch double-lumen tube seen via a video laryngoscope. The distal bronchial lumen of the tube is impacted on the right arytenoid. (**d**) Single- to double-lumen tube exchange over a Cook catheter with a Fuji double-lumen tube seen via a video laryngoscope. The bevel of the distal bronchial lumen of the tube facilitates entry into the glottis. (Figures reproduced from Ref. [31] with permission)

catheter. This consists of a 4.0-mm outer diameter exchanger inside a 7.0-mm outer diameter exchanger. This device allows for a more rigid guide wire for replacing DLT with a single-lumen endotracheal tube. During tube exchanger techniques, it is recommended to use a video laryngoscope to visualize the proper exchange and move the tongue away from the tube. Figure 18.7 displays the different techniques to manage the patient who has a difficult airway and requires lung isolation. Several other manufacturers have introduced different designs of video laryngoscopes that are also useful for lung isolation with difficult airways (see Fig. 18.8).

Lung Isolation Techniques in Patients with Tracheostomies

Before placing any lung isolation devices through a tracheostomy stoma, it is important to consider whether it is a fresh stoma (i.e., few days old, when the airway can be lost immediately or decannulation can occur) versus an old tracheostomy. A standard DLT placed through a tracheostomy stoma can be prone to malposition because the upper airway has been shortened and a conventional DLT is too long.

When selecting a DLT as a replacement of the tracheostomy cannula, a specially designed short version of a DLT, such as the Naruke DLT, can be used. In a report involving six patients with permanent tracheostomies, the Naruke tube was used with satisfactory results in patients requiring thoracic surgery and OLV [37].

An alternative to achieve lung isolation in a tracheostomized patient includes the placement of a single-lumen endotracheal tube through the tracheostomy followed by insertion of a bronchial blocker [38] [see Video 18.1]. If possible the airway could be accessed orally for standard placement of a single-lumen endotracheal tube followed by a bronchial blocker. Another option is the use of a disposable cuff tracheostomy cannula with an independent bronchial blocker passed coaxially. In these cases, a small-size flexible bronchoscope (i.e., 3.5-mm outer diameter) is recommended. Figure 18.9 shows lung isolation in a patient with a small tracheal stoma. The tracheostomy device has been replaced; a small laryngeal mask airway LMA #3 has been used to ventilate the patient through the stoma. Also shown in the picture is a patient with a tracheostomy stoma where a 7.0-mm internal diameter single-lumen endotracheal tube has been advanced through the stoma followed by an Arndt® bronchial blocker.

Lower Airway Abnormalities and Lung Isolation

Patients with lower airway abnormalities, specifically distal tracheal or bronchial lesions, require special attention when OLV is required. A right-sided DLT is indicated when the lumen of the left mainstem bronchus is either constricted or compressed (e.g., by intraluminal tumor or descending thoracic aortic aneurysm), absent or stenosed due to previous

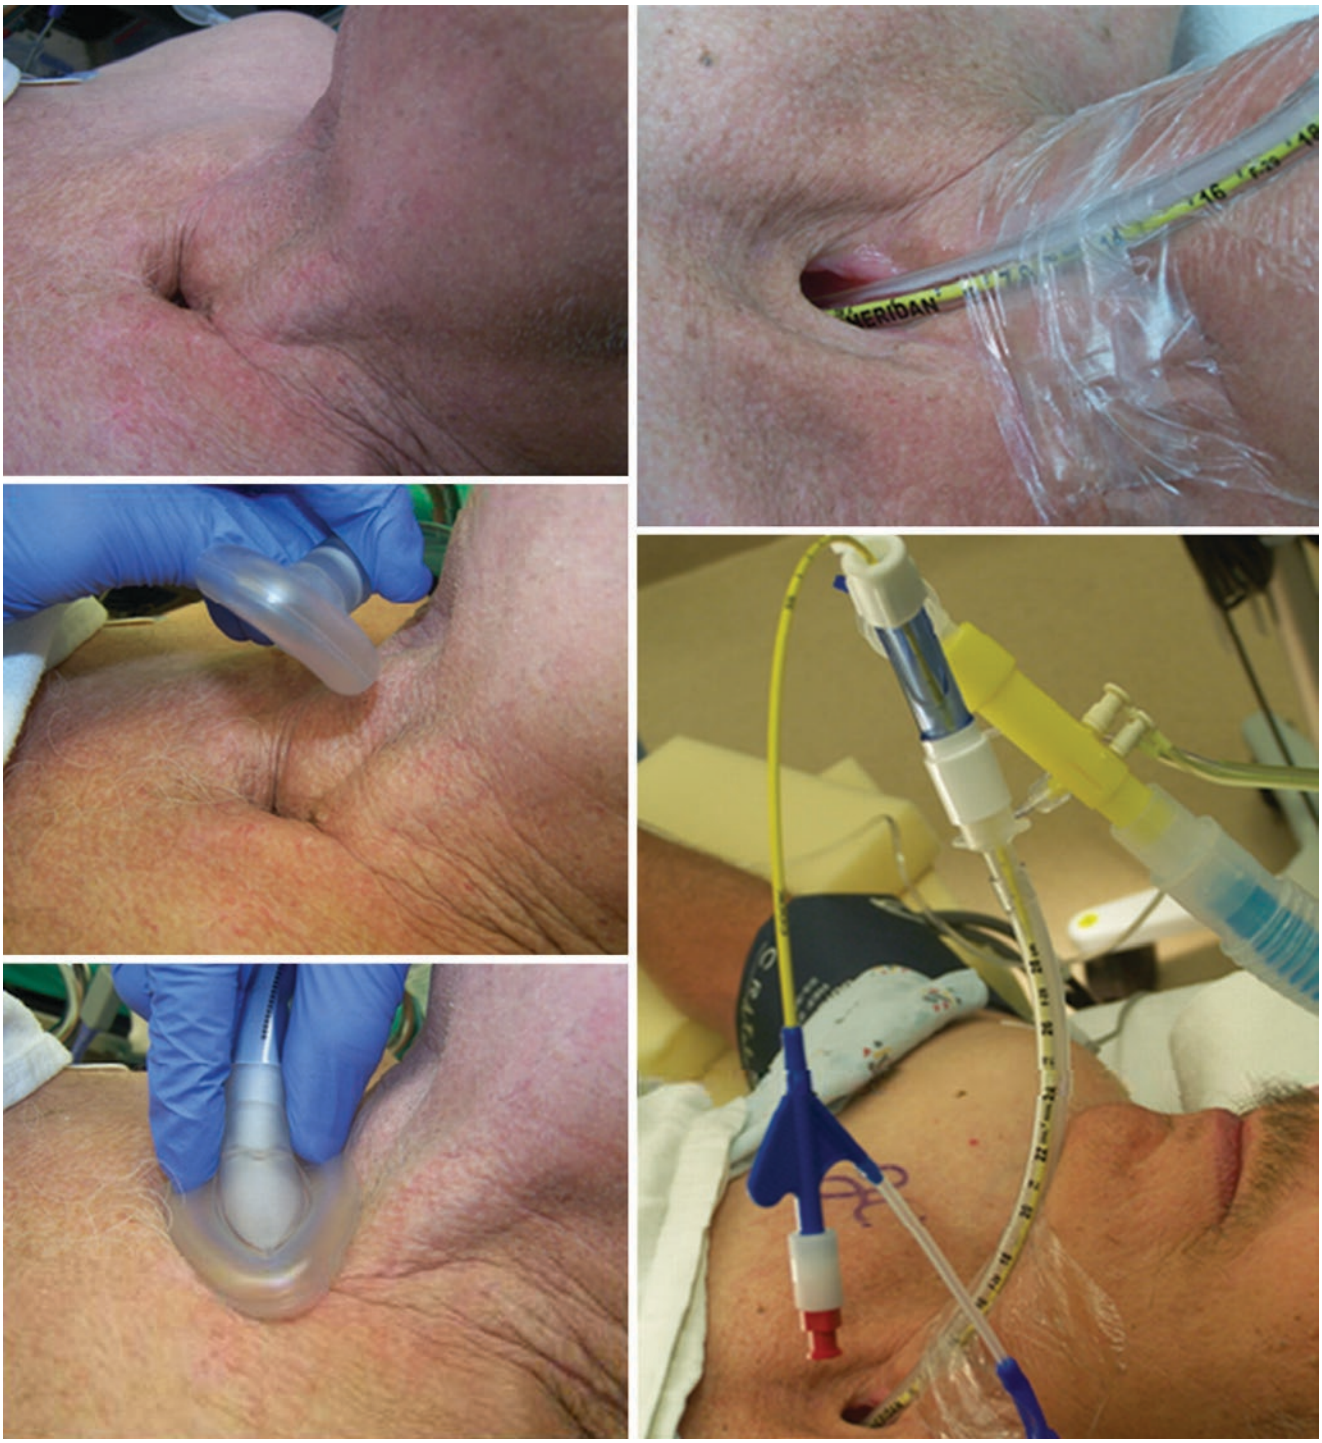

Fig. 18.9 Lung isolation in a patient with a small tracheal stoma. The tracheostomy device has been replaced; to the *left* a small laryngeal mask airway LMA #3 has been used to ventilate the patient through the stoma. To the *right* is shown a patient with a stoma where a 7.0-mm internal diameter single-lumen endotracheal tube has been advanced through the stoma followed by an Arndt® bronchial blocker

surgeries (e.g., pneumonectomy or lung transplantation), or when surgical repair involves the left mainstem bronchus [39]. Following endotracheal tube placement, flexible bronchoscopy should be used to verify the proper alignment between the right upper lobe bronchus and the ventilation slot of the right-sided DLT to avoid right upper lobe obstruction; also, the right lower and middle lobes should be unobstructed by the bronchial lumen. Studies have shown that there is no clinical ventilatory advantage between a left-sided and a right-sided DLT [40].

Patients who have undergone previous lobectomy surgery may present with distorted anatomy. Identifying the right and left bronchi may be difficult because of the loss of anatomical landmarks [41]. In order to properly identify the

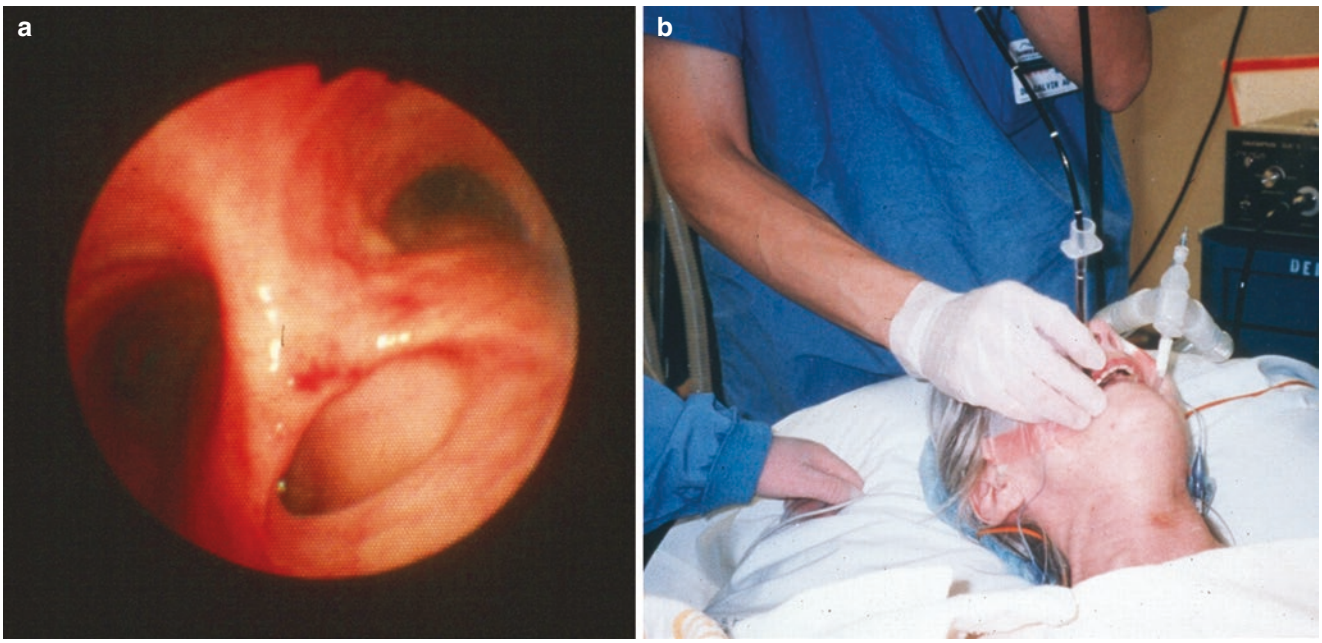

Fig. 18.10 (**a**) Flexible bronchoscopy view of a tracheoesophageal fistula caused by esophageal cancer. The fistula is seen posteriorly at the level of the carina at 5 o'clock. The left mainstem bronchus is at 9 o'clock, and the right mainstem bronchus is at 2 o'clock. (**b**) Fiberoptic-guided placement of bilateral endobronchial tubes (5-mm internal diameter microlaryngoscopy tubes) for repair of tracheoesophageal fistula in the same patient. (Photos are courtesy of Dr. R Grant)

anatomy of the tracheobronchial tree, a complete bronchoscopic exam of the lower airway prior to placement of the lung isolation device is required.

Another lower airway abnormality to consider is the tracheoesophageal fistula (TEF). Improper positioning of the endotracheal tube in patients with TEF can lead to serious complications. Ultimately, the location and size of the fistula and surgical approach will dictate how the airway should be secured to facilitate lung isolation and exposure for repair. Generally, if a single-lumen endotracheal tube is employed, for instance, to facilitate the repair of a TEF that is located high in the trachea, it should be secured so that its tip is above the carina and its cuff is below the fistula in order to provide adequate ventilation while avoiding gastric insufflation which may lead to an unwanted aspiration event. Flexible bronchoscopy is an indispensable tool for TEF assessment prior to repair but also for quick confirmation of endotracheal tube migration and malposition, especially in cases where the fistula is large and located near the carina ("large and low-lying"). For TEF repair via a right thoracotomy incision, lung isolation with a left-sided DLT can be achieved effectively when the fistula is positioned above the cuff of the tracheal lumen. Alternatively, isolation of the right lung and fistula can be achieved simultaneously by inserting a single-lumen endotracheal tube down the left mainstem bronchus [42, 43]. Also, the use of two microlaryngeal endotracheal tubes as endobronchial tubes placed under flexible bronchoscopy guidance can help secure the airway under these circumstances as shown in Fig. 18.10.

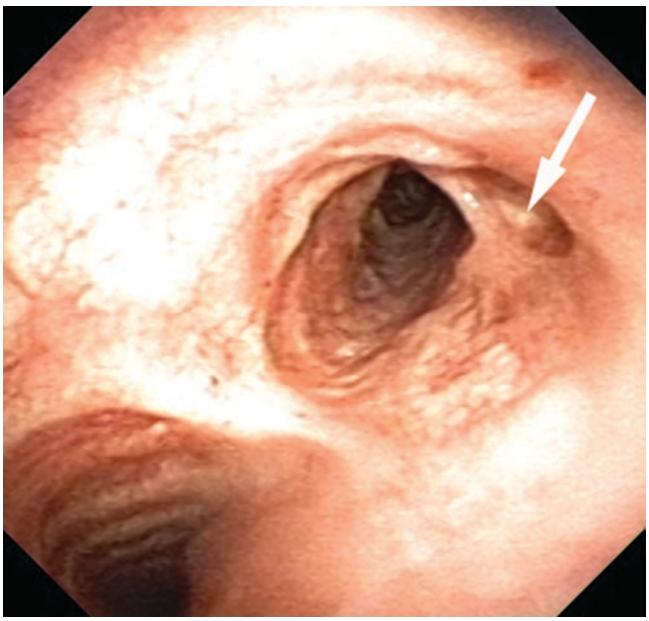

Fig. 18.11 Bronchoscopic view of the bronchus suis. White arrow indicates the supracarinal takeoff of the right upper lobe

Tracheal bronchus, also called bronchus suis or pig bronchus, is a congenital anatomical variant where the right upper lobe bronchus originates directly from the supracarinal trachea [see Fig. 18.11]. The incidence ranges from 0.1% to 5%, with the right tracheal bronchus being the more common presentation. Tracheal bronchi can be classified as

supernumerary (the normal segmental bronchus is also present, in addition to the supernumerary bronchus) or displaced (the normal segmental bronchus is absent). Most patients with this condition are asymptomatic, but some may experience recurrent pneumonia, stridor, or chronic bronchitis due to retained secretions [44, 45].

Several challenges arise in the management of patients with tracheal bronchus undergoing surgery requiring lung isolation. Whether a single-lumen endotracheal tube or DLT is used, proper positioning of the endotracheal tube above the bronchial takeoff must be confirmed to ensure adequate ventilation of the anomalous bronchus. Additionally, care should be taken to avoid insertion of the endotracheal tube into the tracheal bronchus which could lead to injury from overventilation. Lung isolation for right-sided lung surgery in the setting of the tracheal bronchus can be achieved using a single-lumen endotracheal tube, DLT, and in certain situations a bronchial blocker. A left-sided DLT is the best option for tracheal bronchus with carinal takeoff. However, if the right upper lobe bronchus takeoff is supracarinal, then a single-lumen endotracheal tube (inserted into the left mainstem bronchus) or two bronchial blockers (one to isolate the normal and the other to isolate the anomalous bronchus) can be used. Close communication with the surgical team and a thorough bronchoscopic examination of the airway are recommended prior to formulating a complete anesthetic plan for patients with this congenital condition.

Lung Isolation in Patients with Cervical Spine Abnormalities

Injuries to the cervical spine occur in only 2–3% of all patients with blunt trauma but are significant because of their high level of associated mortality and morbidity [46, 47]. Some of these patients have experienced trauma to the chest with an injury to the descending thoracic aorta. In these trauma patients, the atlantoaxial region is the most common site of injury, and the sixth and seventh vertebrae are involved in over one third of all injuries [48]. In these patients, all precautions must be taken with regard to cervical spine injury [49].

Close communication with the surgical team is paramount in managing patients presenting after acute chest trauma with possible multiple injuries to intrathoracic structures. In a stable and cooperative patient, an approach which preserves spontaneous ventilation (e.g., awake flexible bronchoscopy-guided intubation) is ideal. In most cases, however, it is important to immediately and safely secure the airway to facilitate surgical treatment of injuries and for protection against aspiration of blood and gastric contents. Following thoracic trauma, a single-lumen endotracheal tube is recommended for rapidly securing an airway with questionable integrity. Videolaryngoscopy and flexible bronchoscopy approaches may be challenging due to the presence of blood in the airway. A bronchoscopic exam should immediately be performed after intubation to assess the extent of damage to the airway. After the integrity of the lower airway is confirmed, lung isolation can be achieved with a bronchial blocker [50].

Patients who present with cervical spine instability require additional care aimed at minimizing excessive force to the cervical spine which may lead to further injury. Manual in-line stabilization (MILS) is a standard practice performed during intubation with the goal of preventing cervical spine movement by the application of equal and opposite forces to those generated by the intubator. Rigid MILS, however, may cause problems during intubation by limiting the view for laryngoscopy and potentially increasing subluxation of unstable cervical segments. It is important to consider the application of additional intubating tools (e.g., stylet or bougie) for securing the airway [51]. If lung isolation is desired, a bronchial blocker can be placed under flexible bronchoscopic guidance only after the integrity of the lower airway has been established. A similar approach can be used in patients with cervical spine instability due to rheumatoid arthritis (see Fig. 18.12).

Fig. 18.12 This patient with rheumatoid arthritis has a retroflexed odontoid process and associated inflammatory mass (pseudogout) causing compression of the cervical spinal cord just inferior to the foramen magnum. The patient also had intervertebral subluxations and osteophytes from C3 to C5 that cause cord compression. The anesthetic plan included an awake fiberoptic intubation with a single-lumen endotracheal tube

Extubation or Mechanical Ventilation After Surgery

Extubation at the completion of surgery in a patient who has a difficult airway represents a challenge. Factors to consider prior to extubation include any mucosal edema, bleeding or lacerations to the airway during intubation, the length of surgery, and the amount of fluid administered during the intraoperative period. Continuous access to the airway should be maintained in case reintubation is needed. The single-lumen endotracheal tube or the DLT can be removed with an airway catheter exchanger left in place after extubation [52].

In some instances a patient with a difficult airway who has a DLT in place may require mechanical ventilation in the postoperative period. One option is to deflate both cuffs, withdraw the bronchial lumen above the carina, and then reinflate the tracheal cuff to effectively convert the DLT to a "single" lumen tube [53], particularly if the conversion to exchange a DLT for a single-lumen endotracheal tube is considered too risky.

An alternative technique is to exchange a DLT for a single-lumen endotracheal tube using an airway catheter exchanger under direct vision with a laryngoscope [54] or video laryngoscope [55–57].

Summary

In patients who require OLV, a key element during the preoperative assessment is the recognition and identification of the potentially difficult airway. The safest way to establish an airway is by securing the airway with a single-lumen endotracheal tube placed orally or nasotracheally with the aid of a flexible bronchoscope. Lung isolation in these patients is best achieved with the use of an independent bronchial blocker. An alternative can be the use of a DLT placed with an airway catheter exchange technique. For the patient who has a tracheostomy in place, the use of an independent bronchial blocker through a single-lumen endotracheal tube or through a tracheotomy cannula in place is recommended. For all these devices, a flexible bronchoscopic examination is recommended prior, during placement, and at the conclusion of the use of lung isolation devices.

Clinical Case Discussion

Case: A 61-year-old male with a right upper lobe lung mass is scheduled for a right upper lobectomy. He is 175 cm tall and weights 73 kg. Relevant history includes right manidibular mass resection and radiation therapy to the neck. He smoked two packs of cigarettes per day for 40 years.

Airway exam reveals the following: normal dentition, Mallampati score III, thyromental distance of two finger breadths, very limited neck range of motion, and scarring from previous surgery and radiation. Palpation of the anterior neck shows hard and rigid consistency of the tissue.

Questions

- What technique would you select to intubate this patient?
- What potential problems do you expect during an awake fiberoptic bronchoscopy in a patient with a previous neck resection and extensive surgery?
- What device and size would you use to provide lung isolation?
- What are the common problems in the intraoperative period with the use of bronchial blockers?
- What are the complications associated with the bronchial blocker?
- What are the advantages and disadvantages of using a bronchial blocker during a case with a difficult airway that requires lung isolation?

The Key Is to Focus on Patient's Anatomy in Order to Select the Lung Isolation Device

- Review the chest radiograph to appreciate the distorted tracheobronchial anatomy.
- Focus on lung isolation devices during difficult airways.
- Familiarity with the use of independent blockers is mandatory.
- Skills with flexible bronchoscopy during awake intubation, as well as during placement of bronchial blockers, are essential.

Expected Intraoperative Problems with the Use of Bronchial Blockers

- Possible malposition/dislodgement of bronchial blocker.
- The balloon of the bronchial blocker can occlude the trachea and impede ventilation.

Suggested Management

In patients requiring OLV who are identified during the preoperative evaluation to have difficult airway as in the case presented here, the main challenges include (1) to safely secure the airway and (2) to select the proper bronchial blocker to achieve lung isolation during OLV. Because of previous neck surgery with airway anatomy distortion, the main problem in this case is to safely establish an airway. An awake flexible bronchoscopy can be used. After nasal and

oral airway topical anesthesia is achieved, a flexible bronchoscope is passed orally with an 8.5-mm internal diameter single-lumen endotracheal tube loaded on it.

The single-lumen endotracheal tube is advanced without difficulty. After the tube is secured, a complete flexible bronchoscopic exam is performed under general anesthesia. Successful lung isolation is achieved with a 9 F Fuji Uniblocker® that is passed under direct bronchoscopic view into the right mainstem bronchus. The bronchial blocker cuff is inflated under direct bronchoscopic view to confirm complete bronchial occlusion [see Video 18.2]. The optimal position is once again confirmed in the lateral decubitus position. After completion of the right upper lobectomy, two-lung ventilation is reestablished, the bronchial blocker is removed, and the patient can be extubated without any complications.

Intraoperative Patient Positioning and Neurological Injuries

19

Cara Reimer and Peter Slinger

Key Points

- Thoracic cases usually involve repositioning the patient after induction of anesthesia. Vigilance is required to avoid major displacement of airway devices, lines, and monitors during and after position changes.
- Obtaining central venous access after changing to the lateral position is extremely difficult. If a central line may be needed, it should be placed at induction.
- Prevention of peripheral nerve injuries in the lateral position requires a survey of the patient from the head and sides of the operating table prior to draping.
- A large portion of the ipsilateral shoulder pain following thoracic surgery may be due to intraoperative positioning.
- Several centers now advocate minimally invasive esophagectomy surgery in the prone position to improve surgical access.
- Post-thoracotomy paraplegia is primarily a surgical complication.

The majority of thoracic procedures are performed in the lateral position, but depending on the surgical technique, a flexed-lateral (nephrectomy), supine, semi-supine, semi-prone lateral, or prone position may be used. These positions have specific implications for the anesthesiologist.

Position Change It is awkward to induce anesthesia in the lateral position. Thus, monitors will be placed, and anesthesia will usually be induced in the supine position, and the anesthetized patient will then be repositioned for surgery. Sometimes multiple repositionings are required during a single case. It is possible to induce anesthesia in the lateral position, and this may rarely be indicated with unilateral lung diseases such as bronchiectasis or hemoptysis until lung isolation can be achieved. However, even these patients will then have to be repositioned after induction and the diseased lung turned to the non-dependent position. The operating room team, led by the anesthesiologist, needs to follow a standardized protocol to avoid injury to the patient and displacement of lines, tubes, and monitors during each position change.

Due to the loss of venous vascular tone in the anesthetized patient, it is not uncommon to see hypotension when turning the patient to or from the lateral position. All lines and monitors will have to be secured during position change and their function reassessed after repositioning. The anesthesiologist should take personal responsibility for the head, neck, and airway during position change and must be in charge of the operating team to direct repositioning. It is useful to make an initial "head-to-toe" survey of the patient after induction and intubation checking oxygenation, ventilation, hemodynamics, lines, monitors, and potential nerve injuries. This survey then must be repeated and documented after repositioning (see Table 19.1). It is nearly impossible to avoid some movement of a double-lumen tube or bronchial blocker during repositioning [1]. The patient's head, neck, and endobronchial tube should be turned "en bloc" with the patient's thoracolumbar spine. However, the margin of error in positioning endobronchial tubes or blockers is often so narrow that even very small movements can have significant clinical implications [2]. The carina and mediastinum may shift independently with repositioning, and this can lead to proximal misplacement of a previously well-positioned tube.

Table 19.1 Neurovascular injuries specific to the lateral position routine "Head-to-Toe" survey

1) Dependent eye
2) Dependent ear pinna
3) Cervical spine in-line with thoracic spine
4) Dependent arm: (i) brachial plexus, (ii) circulation
5) Non-dependent arm[a]: (i) brachial plexus, (ii) circulation
6) Dependent and non-dependent suprascapular nerves
7) Non-dependent leg sciatic nerve
8) Dependent leg: (i) peroneal nerve, (ii) circulation

[a]Neurovascular injuries of the non-dependent arm are more likely to occur if the arm is suspended or held in an independently positioned armrest.

Fig. 19.1 Patient in the lateral position on a vacuum mat. Note both arms are supported on armrests which are fixed to the operating table. This position of the arms allows good access to the head for monitoring and airway management after surgical draping. The dependent leg is straight and the non-dependent leg flexed. (From Ref. [18])

Endobronchial tube/blocker position and the adequacy of ventilation must be rechecked by auscultation and fiber-optic bronchoscopy after patient repositioning.

The Lateral Position (also referred to as the lateral decubitus position) This is the commonest position for thoracic surgical procedures. The patient may be positioned on a vacuum mat (see Fig. 19.1) or on cushions (see Fig. 19.2). The operating table headrest and pillows must be adjusted so that the cervical spine remains in-line with the thoracic spine. It is very easy after repositioning the patient in the lateral position to cause excessive lateral flexion of the cervical spine because of improper positioning of the patient's head. This malpositioning, which exacerbates brachial plexus traction, can cause a "whiplash" syndrome and is difficult to appreciate from the head of the operating table, particularly after the surgical drapes have been placed. It is useful for the anesthesiologist to survey the patient from the side of the table immediately after turning to ensure that the entire vertebral column is aligned properly. Both eyes should be visible to the anesthesiologist throughout the procedure to avoid compression on the globes by pillows or lines. The dependent ear pinna may be positioned in the center of a gel ring.

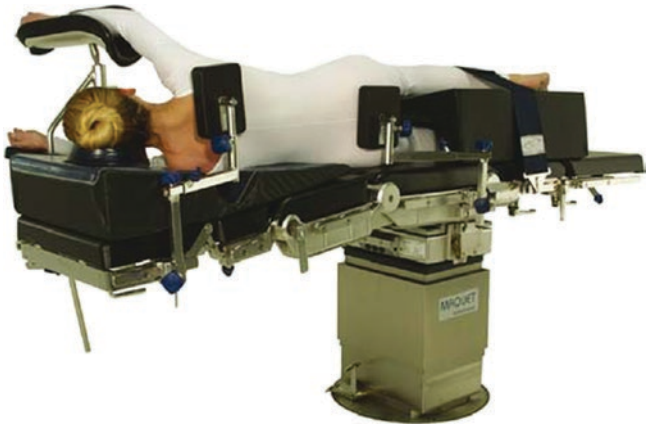

Fig. 19.2 Posterior view of a patient in the lateral view with a vacuum mat. It is very important to survey the patient from this perspective to ascertain that the cervicothoracic spine is in alignment prior to draping. After turning from the supine position, it is very easy to accidentally reposition the patient with a degree of lateral cervical flexion that is difficult to appreciate from the head of the table. Note the extra padding under the upper thorax below the axilla. Also note the gel ring preventing compression of the dependent ear pinna and the cushioning between the legs. (From Ref. [18])

The dependent arm is positioned on an armrest at 90° to the table, and the non-dependent arm is positioned on an armrest or pillows. The brachial plexus is the site of the majority of intraoperative nerve injuries related to the lateral position [3]. These are basically of two varieties: the majority are compression injuries of the brachial plexus of the dependent arm, but there is also significant risk of stretch injuries to the brachial plexus of the non-dependent arm. The brachial plexus is fixed at two points: proximally by the transverse processes of the cervical vertebrae and distally by the axillary fascia. This two-point fixation plus the extreme mobility of neighboring skeletal and muscular structures makes the brachial plexus extremely liable to injury (see Table 19.2). The patient should be positioned with padding under the dependent thorax (see Fig. 19.2) to keep the weight of the upper body off the dependent arm brachial plexus. Unfortunately this pad is called an "axillary pad" or "axillary roll" in some institutions. However, this padding will exacerbate the pressure on the brachial plexus if it migrates superiorly into the axilla.

The brachial plexus of the non-dependent arm is most at risk if it is suspended from an independently fixed arm support or "ether screen" (see Fig. 19.3). Traction on the brachial plexus in these situations is particularly likely to occur if the patient's trunk accidentally slips toward a semi-prone or semi-supine position after fixation of the non-dependent arm. Vascular compression of the non-dependent arm in this situation is also possible, and it is useful to monitor pulse oximetry in the non-dependent hand to observe for this. The arm should not be abducted beyond 90° and should not be extended posteriorly beyond the neutral position nor flexed

Table 19.2 Factors contributing to brachial plexus injury in the lateral position

a) Dependent arm (compression injuries):
1) Arm directly under thorax
2) Pressure on clavicle into retro-clavicular space
3) Cervical rib
4) Caudal migration of thorax padding into the axilla[a]
b) Non-dependent arm (stretch injuries):
1) Lateral flexion of cervical spine
2) Excessive abduction of arm (>90%)
3) Semi-prone or semi-supine repositioning after arm fixed to a support

[a]Unfortunately this padding under the thorax is misnamed an "axillary roll" in some institutions. This padding absolutely should NOT be placed in the axilla.

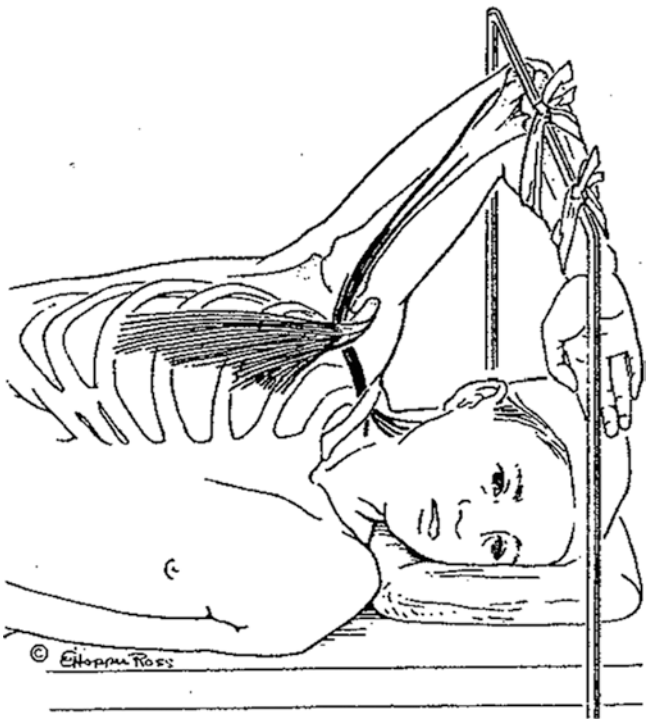

Fig. 19.3 Bilateral malpositioning of the arms in the lateral position. The non-dependent arm is hyperextended and fixed to the anesthetic screen. This causes traction of the brachial plexus as it passes under the clavicle and the tendon of the pectoralis minor muscle. This traction may increase if the patient's torso rotates during surgery, while the arm remains fixed. The dependent arm is directly under the thorax with the potential for vascular compression and/or injury to the brachial plexus. (From Ref. [3])

anteriorly greater than 90°. Fortunately, the majority of these nerve injuries resolve spontaneously over a period of months.

Anterior flexion of the non-dependent arm at the shoulder (circumduction) across the chest or lateral flexion of the neck toward the opposite side can cause a traction injury of the suprascapular nerve. Malpositioning can also cause a deep, musculoskeletal pain of the posterior and lateral

Fig. 19.4 Posterior view of the flexed-lateral position commonly used for thoracoscopic (VATS) surgery. The patient is on a vacuum mat, and a forced-air warmer has been applied to the lower body prior to draping. The flexed-lateral position is more likely to cause impairment of venous return and hypotension than the lateral position

aspects of the shoulder and is responsible for a large proportion of cases of postoperative ipsilateral shoulder pain [4]. The anesthesiologist should question the patient before surgery about any shoulder problems, and, if there is any history, the intraoperative position should be tested preinduction to find a comfortable position for the non-dependent arm.

The dependent leg should be slightly flexed with padding under the knee to protect the peroneal nerve lateral to the proximal head of the fibula. The non-dependent leg is placed in a neutral extended position and padding placed between it and the dependent leg. The dependent leg must be observed for vascular compression. Excessively tight strapping at the hip level can compress the sciatic nerve of the non-dependent leg.

The Flexed-Lateral Position To lower the non-dependent iliac crest so that it does not interfere with surgical access, most patients for VATS surgery are placed in a flexed-lateral position (see Fig. 19.4) similar to the nephrectomy position with lateral flexion of the lower thoracolumbar spine, while the upper thoracic and cervical spine is maintained in a horizontal plane. Some surgeons also use this position for thoracotomies to try and open the intercostal spaces. After repositioning and stabilization, the hemodynamics of the lateral position are not significantly different from the supine position. However, the flexed-lateral position impairs venous return and is associated with significant reductions in blood pressure and cardiac index (3.0 vs. 2.4 l/min/m^2 in one study [5]). This can particularly be a problem in the elderly, who are more liable to have clinically important falls in blood pressure with decreases in pre-load.

Positive pressure ventilation during anesthesia in the lateral position is associated with significant increases in mismatching of ventilation and perfusion. These changes are discussed in Chap. 5.

Supine Position The standard supine position with arms abducted is used for a variety of thoracic surgical procedures such as sternotomies for mediastinal tumors or bilateral wedge resections. The arms are positioned prone with careful attention to padding the ulnar nerves at the elbow to prevent pressure. The supine position with the arms abducted may be used for bilateral trans-sternal thoracotomies (the "clamshell" incision) for bilateral lung transplantation or large anterior mediastinal mass resections or for bilateral thoracoscopic procedures (see Fig. 19.5). The arms are positioned supine and not abducted more than 90°. The arms should be padded with the joints slightly flexed, so that the wrist is higher than the elbow and the elbow higher than the shoulder.

Prone Position Recently, the use of the prone position for the intrathoracic portion of minimally invasive esophagectomy procedures has been adopted in several centers because the surgical access is felt to be improved vs. the lateral position [6] (see Chap. 38). This has implications for airway management since it may be difficult to accommodate a double-lumen tube in a standard prone head rest. Some centers use a bronchial blocker for lung isolation in these cases. It has been reported that esophagectomy in the prone position can be performed with a single-lumen tube with surgical capnothorax and without one-lung ventilation [7].

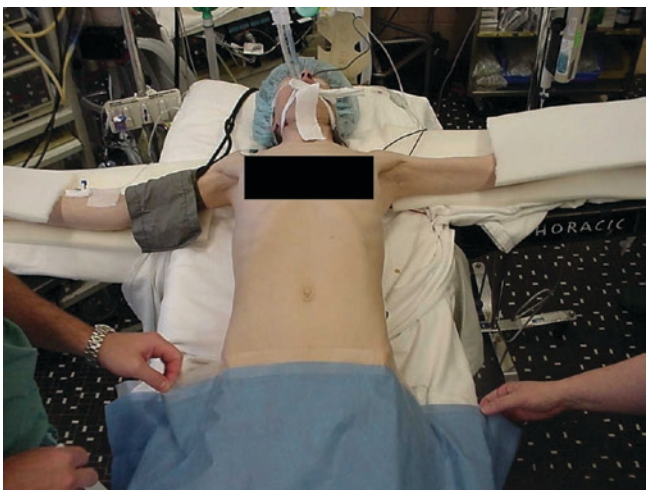

Fig. 19.5 The supine position with the arms abducted. This position is appropriate for bilateral thoracoscopic procedures or for bilateral lung transplantation

Central Neurological Injuries

Paraplegia With an estimated incidence of 0.08% [8], postthoracotomy paralysis (PTP) is a rare but devastating complication following thoracic surgery. PTP can occur as a result of spinal cord compression from an epidural hematoma or a foreign body or ligation of major arteries perfusing the vulnerable thoracic cord. Arterial embolus and perioperative hypotension have also been implicated.

Epidural hematoma (EH) is a rare but well-appreciated complication of neuraxial anesthesia. EH associated with epidural placement is estimated to occur with a frequency of 1:150000 [9]. Symptoms of EH vary but can include back pain, sensory and motor deficits, and incontinence. EH can present any time, including immediately postoperatively and after catheter removal. Prompt diagnosis, ideally with MRI scanning, can confirm the diagnosis. Immediate neurosurgical consultation should be obtained for decompression which has its best results within 12 h of onset of symptoms.

Surgical bleeding at or near the costovertebral junction with posterolateral thoracotomy incisions can be difficult to manage. There are multiple case reports [10] of oxidized cellulose polymer (Surgicel) positioned and left at or near the angle of the vertebral body to control bleeding. The material has subsequently swelled and compressed the ipsilateral nerve root or even migrated into the spinal canal, causing permanent paralysis [11]. The product monograph specifically contraindicates the use of the polymer in this situation. Neurologic deficit in this scenario presents within hours of surgery. Diagnosis is confirmed with imaging and treatment is removal.

Paralysis due to spinal cord ischemia is a commonly appreciated complication of vascular surgery, where its postoperative incidence can reach upward to 20% [12]. Nonvascular thoracic surgery can also lead to spinal cord ischemia. Anatomical considerations related to this have been reviewed [13]. The thoracic spinal cord has a less luxurious blood supply than its cervical and lumbar counterparts. The cord is supplied by the solitary anterior spinal artery (ASA) which provides blood supply to the anterior 2/3 of the cord and the paired posterior spinal (PSA) arteries which supply the posterior 1/3. In the thoracic region, the ASA receives important contributions from a few variable radicular arteries which are branches of the posterior intercostal arteries. Ligation of small but integral intercostal arteries during thoracic surgery, leading to hypoperfusion and ischemia of the spinal cord, has been implicated in PTP, both in lung resection and esophagectomy. The classic presentation of spinal cord ischemia from ASA supply interruption in the thoracic region is bilateral motor, pain, and temperature loss with maintenance of proprioception, the so-called anterior cord syndrome. There may be associated autonomic dysfunction.

Treatment of ischemia due to inadvertent surgical interruption of spinal cord blood supply is guided by interventions driven at optimizing supply and demand to the cord. Commonly used strategies include maintaining a normal to supranormal blood pressure with vaso-inopressors, an adequate hemoglobin, and a steroid administration. It should be noted that none of these interventions have been rigorously proven to improve neurologic outcome and some, in particular steroid administration, are controversial. Spinal drains are commonly placed electively in thoracic aneurysm repair to optimize spinal cord perfusion, but this treatment has not been utilized in the PTP literature.

To conclude, post-thoracotomy neurologic deficit is usually assumed to be an anesthetic complication related to epidural placement. Although anesthesiologists must always be vigilant and act quickly in these cases to image the spinal cord to rule out a hematoma, we must also remember the differential includes surgically related causes.

Blindness Postoperative visual loss (POVL) has been infrequently reported following surgery in the lateral position. Similar to the POVL more often reported after surgery in the prone position, the risk factors include prolonged surgery, hypotension, massive transfusion, diabetes, and obesity [14]. The etiology in non-cardiac surgery has been primarily due to posterior ischemic optic neuropathy. The perfusion pressure in the posterior portion of the optic nerve is directly related to mean arterial pressure and inversely related to venous drainage pressure. In one case report following spine surgery in the lateral position via VATS and open thoracotomy, the visual loss was complete in the dependent eye and partial in the non-dependent eye suggesting the potential impact of venous drainage pressure [15]. Of note, this patient also had marked facial edema after the end of the case. Since there is no monitor available to assess the perfusion pressure in the optic nerve, prevention involves avoiding the treatable associated factors (hypotension and anemia), regular intraoperative observation of the face to assure that there is no direct pressure on the eyes and careful neutral positioning of the cervical spine to avoid any compromise of venous drainage.

Ischemic optic neuropathy has been well described following orthopedic surgical procedures in the prone position. If the patient can be placed with a slight extension of the cervical spine (10° above neutral) while prone, this will decrease the intraocular pressure [16]. This may improve optic nerve perfusion but has not yet been demonstrated to have a beneficial effect on outcome. To date, there do not seem to have been any published reports of blindness following prone esophageal surgery.

Other Position-Related Injuries The lateral position has been reported to be associated with a variety of pressure-related injuries to the legs. These include myonecrosis, sciatic nerve palsy, and compartment syndromes [17]. The majority of these reports involve orthopedic procedures of long duration (>5 h). Increased vigilance for potential position-related injuries is required in long procedures.

Clinical Case Discussion

A 60-year-old woman presents for a left thoracotomy for left lower lobectomy for lung cancer. Past medical history includes a remote myocardial infarction with a preoperative ejection fraction of 40%, controlled hypertension, and diet-controlled diabetes mellitus. Regular medications are taken the morning of the OR, including metoprolol and aspirin 81 mg. A flexible epidural catheter with inner stainless steel coil wire is placed at T6/7 for postoperative analgesia. After an epidural test dose of 3 ml lidocaine 2%, an infusion of bupivacaine 0.1% plus hydromorphone 15ug/ml is started at 5 cc/h. A central line is placed after induction. The operation is remarkable for intraoperative hypotension requiring dopamine and norepinephrine and brisk bleeding near the costovertebral junction. Immediately postoperatively, blood pressure is in the patient's normal range with no support, there is no motor deficit, and pain is well-controlled. Six hours postoperatively, a nurse from the ward calls to report that the patient is complaining of bilateral lower extremity motor weakness.

1. What is the differential diagnosis?

At this point, the differential is wide and includes a motor block secondary to epidural local anesthetic solution, an intrathecal catheter, compression of the nerve roots or spinal cord from an epidural hematoma or a foreign body, arterial embolus to a radicular artery, or a hypoperfusion state.

2. What should be done immediately?

Vital signs should be taken and documented, the epidural solution should be stopped, and the catheter should be aspirated. A focused chart review should be undertaken with special note taken of any recently administered anticoagulants. The surgeon should be called and be advised of the problem. A complete neurological examination should be performed.

3. What does the initial assessment reveal?

The patient is awake and alert. Her blood pressure is 89/65 with a normal heart rate and oxygen saturation. No blood or CSF is aspirated through the catheter. She is unable to move her legs. She has loss of sensation to pain

and temperature in both legs, but proprioception is intact. Thirty minutes after the epidural solution has been turned off, there is no change in her neurological status. The last documented INR is 1.29 5 h ago. The patient received subcutaneous heparin for DVT prophylaxis 1 h ago.

4. What should be done next? What bloodwork, imaging, and consults should be ordered?

Dopamine is started through the patient's central line to keep the blood pressure in her normal range (120/80) with continuous cardiac monitoring. "STAT" complete blood count and coagulation tests are drawn. There is hesitance to remove the epidural catheter in the context of a coagulation abnormality combined with recent heparin administration and aspirin. MRI is the preferred modality to diagnose an epidural hematoma. However, the in situ epidural catheter is not permitted in the scanner. After consultation with the radiologist, the epidural is left in place, and a CT is performed. The neurosurgeon and neurologist are called and made aware of the patient.

5. What is found on additional testing?

The CT shows no epidural hematoma or mass. The hemoglobin is 90 g/L. Platelets are normal. INR is 1.21. The patient is seen by the neurologist and given a provisional diagnosis of spinal cord ischemia causing an anterior cord syndrome.

6. What else can be done?

The patient is moved to a step-down unit with continuous monitoring. Neurologic vitals are done every 4 h. Dopamine is continued, and the patient is given 100 mg methylprednisolone IV q8h × 3 doses. Hemoglobin is maintained at 100 g/L. The epidural is removed 6 h after the last subcutaneous heparin dose. An MRI is then performed and is normal. Pain is controlled with hydromorphone intravenous PCA. Over the next 4 days, the patient gradually and completely recovers.

Intraoperative Monitoring

20

Gabriel E. Mena, Karthik Raghunathan, and William T. McGee

Key Points

- Continuous automated ST-segment analysis is especially important during thoracic surgery given the potential for cardiac ischemia, arrhythmias, pneumothorax, severe hypoxemia, and hemodynamic instability.
- Oxygenation during one-lung ventilation is determined by many factors including cardiac output, blood pressure, ventilation-perfusion matching, anesthetic effects on hypoxic pulmonary vasoconstriction, airway mechanics and reactivity, oxygen consumption, and preexisting pulmonary disease. Pulse oximetry with occasional intermittent arterial blood gas analysis provides warning of significant hypoxemia.
- The typical CO_2 vs. time waveform, displayed on most anesthesia monitors, has characteristic intervals that represent different physiologic events during ventilation.
- Continuous breath-by-breath spirometry (monitoring of inspiratory and expiratory volumes, pressures, and flows) enables the early detection of a malpositioned double-lumen tube and can reduce the potential for ventilatory-induced lung injury by guiding the optimization of ventilatory settings.
- Invasive arterial pressure monitoring is commonly used to assess beat-by-beat blood pressure and can also be used to derive functional hemodynamic information such as systolic pressure variation (SPV) and pulse pressure variation (PPV).
- SPV and PPV measure related aspects of cardiorespiratory interaction in the presence of adequate tidal volume. However, these variables do not predict the ability to increase cardiac output with fluid loading when tidal volumes are <8 cc/kg, as is typically the case with one-lung ventilation during thoracic surgery.
- Minimally invasive hemodynamic monitoring (arterial pressure waveform-based devices) coupled with certain maneuvers can identify whether inadequate tissue perfusion can be improved with intravenous fluid therapy.

Introduction

The general principles of intraoperative monitoring for thoracic surgery are similar to those for any major surgery. Monitoring guides the detection of problems and helps track the response to interventions. From a practical standpoint, this translates into the rather conservative approach of invasive monitoring from the outset, with the assumption that cardiac and pulmonary complications are more prone to occur (relative to other noncardiac procedures) and that access to the patient may be restricted (especially with the patient in the lateral decubitus position during lung isolation).

Monitoring techniques have rarely been subjected to the kind of scrutiny that pharmacologic and other therapeutic

interventions are [1]. With improvements in monitoring technology and in our understanding of cardiorespiratory physiology, we hope to acquire and interpret data better, recognize errors, and generate and apply evidence-based goal-directed interventions to optimize outcomes in a cost-effective manner. Although this is self-evident, intraoperative monitoring, no matter how sophisticated, cannot *itself* improve outcomes. Monitoring coupled with physiologically derived protocol-driven care can improve outcomes by reducing unwarranted variation in practice while still allowing practitioners to use their clinical judgment [2]. For instance, protocol-driven goal-directed resuscitation in septic patients has been shown to reduce mortality [3], while invasive pulmonary artery catheter (PAC)-based monitoring during high-risk surgery has, in fact, been shown *not* to lead to better outcomes [4]. We will focus on intraoperative monitoring specifically relevant to thoracic surgical patients and will also emphasize minimally and noninvasive hemodynamic monitoring technologies.

ECG

Approximately 30% of patients exposed to anesthesia for surgical procedures in the United States have a known prior history of coronary artery disease (CAD) or coronary risk factors. Perioperative myocardial ischemia is more common in patients with poor cardiopulmonary reserve that typically present for thoracic surgery. Multivessel coronary disease is also more likely in the thoracic surgical population given their likelihood of being smokers and having related comorbidities [5]. An estimated 50,000 such patients per year, who receive noncardiac surgery, will experience a perioperative myocardial infarction, which carries a 40–70% mortality rate.

Continuous automated ST-segment analysis is fundamental during thoracic surgery due to the potential for cardiac ischemia as a result of arrhythmias, pneumothorax, the potential for severe hypoxemia from intrapulmonary shunting, and hemodynamic instability from the compression of large vessels with the potential for cardiac decompensation from pulmonary hypertension or hemorrhage [6]. The typical five-lead electrocardiographic system should be placed for thoracic surgical patients with suspected or known coronary disease undergoing thoracic surgery. Depending on the surgical site, careful positioning of leads is pivotal in order to both avoid errors in the ST-segment analysis and minimize interference with the sterile surgical field. Based on previous studies, lead II has a 90% sensitivity to detect arrhythmias, and the lateral lead V5 has 75% sensitivity to detect lateral wall ischemia. London M, et al. demonstrated that lead V4 was the second-most sensitive lead to detect intraoperative ischemia (61% sensitivity) and that the use of two lateral leads (V4 and V5) provided a combined sensitivity of 90% for the detection of lateral wall ischemia [7]. ST-segment trend analysis is pivotal for the diagnosis of myocardial ischemia caused by and characteristic of multivessel coronary disease in patients with a significant history of smoking and with poor collateral circulation [8]. Specific coronary artery territories typically implicated in ischemia or infarction can be diagnosed based on the congruence of leads showing ST-segment changes (for instance, changes in leads II, III, and aVF typically represent RCA territory supply/demand mismatch). Although the diagnosis of acute MI in the presence of a left bundle branch block (LBBB) is difficult, criteria have been developed that may be applied for early detection and timely intervention [9].

ECG can also be used to monitor for various severe electrolyte disturbances (e.g., hyperkalemia, hypocalcemia, hypomagnesaemia) and the appropriate functioning of cardiac rhythm management devices. As a result of serious underlying cardiac rhythm disturbances or congestive heart failure, many patients undergoing thoracic surgery will have pacemakers or implantable cardiac defibrillators, and monitoring these devices during the surgical procedure is critical to ensuring appropriate responses. Atrial fibrillation is also more common with thoracic surgical procedures.

Pulse Oximetry

Pulse oximetry (SpO_2) is a continuous, noninvasive method of measuring the arterial oxygen saturation (SaO_2) from a processed infrared light signal transmitted through a pulsatile vascular bed (a practical application of the Beer-Lambert law). Plethysmography, the measurement of pulsatile volume changes that occur in tissue beds, can also be performed by most pulse oximeters and may have future applications in the noninvasive assessment of fluid responsiveness.

The main goal of pulse oximetry in thoracic surgery is to provide immediate warning of hypoxemia mainly during procedures at high risk for desaturation such as one-lung ventilation (OLV). This allows for prompt treatment to be initiated before irreversible metabolic derangements occur. During OLV, significant desaturation ($SpO_2 < 90\%$) can occur despite high-inspired oxygen concentration secondary to obligate shunt (nonventilated lung) and potentially treatable intrapulmonary shunting (ventilated lung). Oxygenation during OLV (and during other thoracic surgical procedures) is determined by many factors including cardiac output, blood pressure, blood flow through nonventilated lung, ventilation-perfusion matching in ventilated lung, anesthetic effects on hypoxic pulmonary vasoconstriction (HPV), airway mechanics and reactivity, oxygen consumption, and preexisting pulmonary disease. In the 1980s, a significant study by Brodsky J, et al. revealed (based on findings from 19 patients undergoing OLV with continuous pulse oximetry monitoring and simultaneous arterial blood gas analysis) that the pulse oximetry measurements were in good agreement

with the arterial blood gas analysis [12]. The greatest discrepancy was about ±6%, and these authors concluded that the reliability of the pulse oximetry for the detection of changes in oxygenation was sufficient enough that frequent arterial blood gas analysis was not required. However, arterial blood gas analysis will always have a role in the determination of the safety margin before arterial desaturation in terms of the partial pressure of oxygen (PaO_2) measurement. Once the arterial oxygen saturation drops below 90%, the critical "steep portion" on the sigmoid oxy-hemoglobin dissociation curve, further desaturation might be drastic and need prompt evaluation and intervention. Since significant desaturation does not occur until the PaO_2 falls below 60 mmHg, the pulse oximeter (SpO_2) will not detect large changes in PaO_2. Interestingly enough, the maintenance of normocarbia is not problematic during OLV (described further in the section "Capnography"), while the inevitable intrapulmonary shunt during OLV makes desaturation likely. As most of the oxygen content in arterial blood is based largely on transportation by hemoglobin, when venous admixture occurs (with blood flow from nonventilated lung mixing with the blood flow from ventilated lung), the ability to compensate for this decrease in the oxygen content is limited. The lungs are unable to compensate for this decrease in the arterial oxygen content by increasing blood flow through ventilated lung.

During thoracotomy or thoracoscopy when the patient is placed in the lateral decubitus position, there is potential for rapid changes in SpO_2 from the compression of mediastinal great vessels in addition to intrapulmonary shunting (OLV). The manipulation of lung parenchyma and/or the mediastinum can lead to the development of cardiac arrhythmias that can affect the pulse oximetry readings as well. The use of electrocautery will also, occasionally, interfere with pulse oximetry.

Judicious perioperative fluid management is of crucial importance for thoracic surgical patients. Respiratory variations in invasive arterial pressure recordings (discussed later) such as systolic pressure variation (SPV) or pulse pressure variation (PPV) are sensitive and specific indicators of fluid responsiveness. There is growing interest in the use of variations in the pulse oximeter plethysmographic waveform amplitude as a noninvasive method of estimating fluid responsiveness. Such ventilatory variations in plethysmographic amplitude can be sensitive to changes in preload and can predict fluid responsiveness in mechanically ventilated patients [10]. The "Pleth Variability Index" (PVI, Masimo Corp., Irvine, CA) may be one such dynamic index automatically derived from pulse oximeter waveform analysis, with potential for clinical applications in the assessment of fluid responsiveness and in monitoring response to therapy. Studies showing that patients with significant dynamic plethysmographic variation will respond to a fluid bolus have been published [8]. However, since different pulse oximeters use different nonstandardized proprietary signal processing plethysmographic algorithms, measurements obtained by one specific device or method may not be applicable to similar variables from other manufacturers [11]. There are several factors other than volume status that can affect plethysmography such as local temperature, site of measurement, influence of venous pressures, etc. [13]. The future application of this plethysmographic aspect of pulse oximetry is ripe for further investigation both during and after thoracic surgery.

Capnography

Monitoring the adequacy of ventilation via CO_2 waveform analysis is usually performed continuously during thoracic surgery by infrared dispersion spectrophotometry or mass spectrometry. Patients undergoing thoracic surgery usually have significant underlying lung disease and a chronic history of smoking, so it is extremely important to recognize the different phases of the time capnograph to recognize the underlying pulmonary pathology (such as obstructive patterns of expiration) as well as distinguish artifacts and errors. The typical CO_2 vs. time waveform (time capnography) is displayed on most anesthesia monitors and has characteristic intervals that represent different physiologic events during ventilation (see Fig. 20.1).

Phase I is the expiratory baseline and represents the exhalation of CO_2-free gas from anatomic dead space. Phase II is the expiratory upstroke or fast rise phase representing the mixing of dead space gas with alveolar gas containing CO_2. Phase III or the alveolar expiratory plateau phase represents the exhalation of CO_2-rich gas from the gas-exchanging alveoli. The angle between phases II and III has been referred to as the α angle and is an indirect indication of ventilation-perfusion (V/Q) matching. Finally, phase 0 is the inspiratory

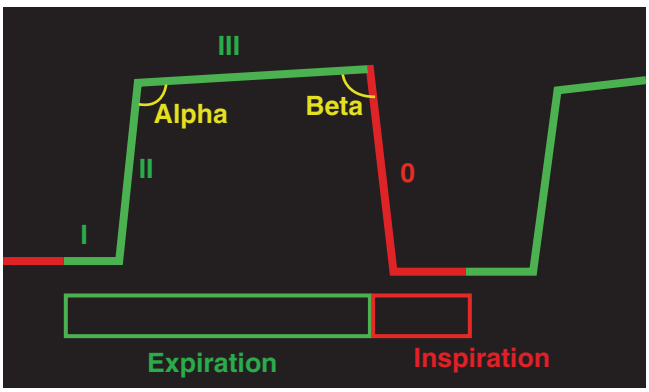

Fig. 20.1 Time capnograph. (From Bhavani Shankar Kodali MD. http://www.capnography.com Accessed 10 Feb 2010)

downslope during which time fresh gases are inhaled. The nearly 90° angle between phases III and 0 has been referred to as the β angle [14]. This β angle may increase during rebreathing. During thoracic surgery these phases are affected by cardiopulmonary conditions that need to be recognized by the anesthesiologist. A decrease in the slope of phase II may be seen in certain acute and chronic conditions that negatively impact expiratory flow (such as bronchospasm or COPD). This reduction in the slope is determined by the extent of mixing of parallel and series dead space gases with ideally well-mixed alveolar gas. An increase in the α angle appears as a prominent upsloping in phase III and signifies worsening *V*/*Q* matching. This may be due to changes in cardiac output, CO_2 production, airway resistance, and/or functional residual capacity.

In the lateral decubitus position, there are physiologic changes in ventilation and perfusion for both the dependent and nondependent lungs. Phase III of the capnograph has a characteristic biphasic appearance of the waveform. This is believed to occur because the nondependent lung will obtain significantly more ventilation relative to perfusion (high *V*/*Q* units) and will contain more alveolar dead space contributing to the earlier and lower part of an upsloping phase III. The dependent lung will receive more perfusion relative to ventilation (lower *V*/*Q* units) and less alveolar dead space consequently contributing to the later and higher part of the phase III plateau. During cross-field ventilation for procedures involving resection of main stem or tracheal masses that require jet ventilation or intermittent apnea, close monitoring and vigilance of the capnogram are pivotal because complete absence of a waveform implies no ventilation, no circulation, or a disconnected capnometer. The end-tidal CO_2 to arterial CO_2 gradient ($PaCO_2$–$PETCO_2$) is related to the extent of dead space ventilation and tends to increase during OLV. Despite occasionally significant oxygen desaturation, the maintenance of adequate ventilation or normocarbia during OLV is usually not problematic.

There is increasing acknowledgment of the similarities between adult respiratory distress syndrome (ARDS) and OLV [15]. Ventilation strategies originally developed for ARDS may have benefits during OLV. Permissive moderate hypercarbia is becoming a routine component of OLV management, and capnography (with intermittent arterial blood gas analysis) will aid in monitoring this approach to ventilation. Increasing minute ventilation to the dependent ventilated lung during OLV in the lateral position removes sufficient CO_2 to compensate for the higher CO_2 content of the pulmonary blood flow perfusing the nonventilated lung. Capnography also enables the detection of improperly placed double-lumen tubes (DLT) if the tracheal and bronchial lumens are separately and continuously monitored during tube positioning.

Intraoperative Spirometry

With the availability of real-time intraoperative spirometry in the current generation of anesthesia machines, it has become possible to continuously monitor inspiratory and expiratory volumes, pressures, and flows. During thoracic anesthesia, especially with OLV in the patient with preexisting pulmonary disease or at-risk for postoperative complications, breath-by-breath spirometry can guide the early detection of a malpositioned DLT and help minimize the potential for lung injury by guiding the optimization of ventilatory settings that are individualized to each patient [16].

With the loss of lung isolation, such as with cephalad migration of the DLT, the expired volume will, acutely, decrease significantly to well below the inspired volume (beyond the usual normal 20–30 mL/breath difference that results from the uptake of inspired oxygen) [16]. Similarly, unintentional caudad migration of the DLT can result in a readily apparent decrease in compliance as set tidal volume/pressure is delivered to a single lobe rather than the appropriate lung. The pressure-volume and flow-volume graphs can show characteristic changes. Additional uses for intraoperative spirometry include the identification of auto-PEEP (persistent end-expiratory flow) during OLV, which can be seen on the flow-volume loop. Intraoperative spirometry data (e.g., monitoring compliance and plateau pressures) can be combined with data from arterial blood gases, capnography, and oximetry to make adjustments to ventilatory parameters to optimize gas exchange [16]. The ability to accurately measure differences in inspiratory and expiratory tidal volumes can also be extremely useful to aid in the assessment and management of pulmonary air leaks during pulmonary resections.

Arterial Blood Pressure Monitoring

Given the potential for cardiovascular instability during intrathoracic procedures, the possible need for repeated blood gas analysis, and a patient population with significant underlying comorbidities, the use of invasive arterial blood pressure monitoring is common in current clinical thoracic anesthesia practice to assess beat-to-beat blood pressure and derived functional hemodynamics. Mean arterial pressure (MAP) is the most useful parameter to approximate organ perfusion pressure in noncardiac tissues provided venous or surrounding tissue pressures are not elevated [17].

Technical aspects of the invasive measurement of vascular pressures: the principles described here apply to the invasive measurement of vascular pressures (arterial blood pressure, central venous pressure (CVP), or PAC pressures). The monitoring system typically used in current clinical practice consists of a catheter connected via saline-filled,

low-compliance tubing to an electronic transducer. Signal transduction, performed by these so-called dynamic pressure transducers, involves changing either electric resistance or capacitance in response to changes in pressure on a solid-state device (Wheatstone bridge system) [18]. Pressure waves recorded through intravascular catheters should be transmitted undistorted to the transducer, processed, and then displayed. Unfortunately, there are phenomena that can interfere with the accuracy of such systems. Distortion can result from either resonance or damping and produce erroneous readings that need to be recognized. The "fast flush test" is a clinically useful method that allows for the detection of these errors. Readers are directed to comprehensive technical reviews on this topic for further information [18, 19].

Digital numeric readouts of systolic and diastolic pressures that are displayed on the monitors are the running average of values over a certain time interval. From a clinically relevant perspective, the transducer must be placed in the appropriate position relative to the patient. Correct positioning of the pressure transducer is crucial and often most prone to error. Generally, pressures are referenced against ambient atmospheric pressure by exposing the pressure transducer system to air through an open stopcock and pressing the zero-pressure button on the monitor display. The transducer must be horizontally aligned with a specific position on the patient's body that represents the upper fluid level in the chamber or vessel from which pressure is to be measured [19]. Proper positioning of the pressure transducer is especially critical for measurement of venous pressures (CVP, PAOP) because seemingly small errors in transducer height relative to the patient are amplified. Ideally, transducers should be positioned approximately 5 cm posterior to the left sternal border at the fourth intercostals space, since this point better represents the upper fluid level of the right atrium. This is especially relevant during thoracic surgery when patients are in a lateral position where errors in zeroing/referencing can easily influence therapy. For instance, in the lateral decubitus position, invasive arterial pressure recorded directly from either the right or left radial arteries will remain unchanged relative to the supine position as long as the respective pressure transducers remain at heart level. However, noninvasively measured blood pressure will be higher in the dependent arm and lower in the nondependent arm. Such differences in noninvasive blood pressure measurement are determined by the positions of the arms above and below the level of the heart and are equal to the hydrostatic pressure differences between the level of the heart and the respective arm. Blood pressure is directly related to the cardiac output (CO) and systemic vascular resistance (SVR). This is the hemodynamic corollary to Ohm's law where electricity (flow or Q) is directly proportional to the voltage (driving pressure gradient across vascular beds or MAP − CVP) and is inversely proportional to resistance (SVR). Adapted to circulation, this proportionality can be described as flow or $Q = (\text{MAP} - \text{CVP})/\text{SVR}$. While a normal blood pressure does not necessarily reflect hemodynamic stability, hypotension does represent a potential threat to adequate tissue perfusion.

As the arterial waveform is transmitted from the aortic root to the periphery, the actual pressure wave itself becomes distorted. Aging, hypertension, and atherosclerosis all relatively common in thoracic surgical patients can also influence the displayed arterial waveform. In the peripheral arterial tree, the high-frequency components (such as the dicrotic notch) disappear, the diastolic trough decreases, the systolic peak increases, and there is a transmission delay because there is decreased arterial elastance. Thus, invasive pressure waveform morphology and actual pressure values depend on the site of pressure measurement. Pulse contour analysis-based devices are, therefore, susceptible to mechanical errors in arterial pressure measurement and to such distal pulse amplification. Consequently, clinical therapy is often better guided using mean arterial pressure than systolic or diastolic blood pressure measurements. The use of arterial pressure-derived variables such as SPV, PPV, deltaDown, etc. is discussed below under noninvasive hemodynamic monitoring.

Central Venous Pressure

Technical aspects of invasive pressure measurement are described in the previous section. CVP represents the back pressure to systemic venous return and is, in effect, an estimate of right ventricular filling pressure. An appropriately inserted central venous catheter is required for actual CVP measurement, and placing a catheter on the same side as the thoracic operation (internal jugular or subclavian) allows for an unintentional pneumothorax to be treated by the pleural drainage tube that is usually inserted for most thoracic surgical procedures. Routine placement of central venous catheters are not justified, but the risks may be worth taking if it is likely that infusions of vasoactive drugs will be used, if blood products may need to be rapidly administered, or when large-bore peripheral venous access is not obtainable.

CVP might be inaccurate after the establishment of a pneumothorax during thoracic surgery, during the resection of mediastinal masses compressing the right heart chambers, and also during lateral positioning or with an open chest. Tumors invading cardiac structures can also produce erroneous CVP values. The use of isolated CVP measures to guide fluid therapy during thoracic procedures is not desirable given the evidence against the use of static hemodynamic measures. Changes in CVP over time are more clinically relevant than absolute numeric values. There are no clear CVP "cutoffs" that can reliably distinguish between

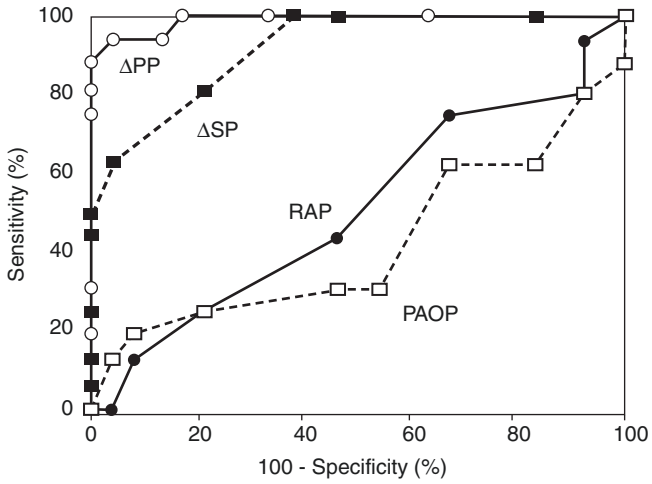

Fig. 20.2 Receiver operating curve (ROC) for right atrial pressure (RAP), pulmonary artery occlusion pressure (PAOP), delta systolic pressure (ΔSP), and delta pulse pressure (ΔPP) to predict a response to volume challenge. Only the dynamic parameters allow prediction beforehand if the patient will improve cardiac performance in response to a volume challenge. Using a cutoff value of 13% for ΔPP allows almost perfect prediction of which patients respond to a volume challenge (area under the ROC of 90%). Static parameters (CVP, PAOP) are no better than a coin toss with area under the ROC of approximately 50%

patients whose cardiac output will and will not change in response to a fluid bolus [20, 21]. A volume-responsive patient is better identified by, and fluid therapy is better titrated using dynamic or functional hemodynamic indices (see Fig. 20.2). There are several factors that can make venous pressure measurement a poor surrogate for the determination of intravascular volume status. The cardiac pressure-volume relationships are nonlinear. Ventricular compliance may change intraoperatively and dynamically based on the effects of anesthesia, drugs, and ongoing pathophysiology. Such changes in compliance produce changes in CVP without any significant changes in volume status. In addition, the physiologically relevant determinant of ventricular preload is the transmural pressure (the difference between intracardiac and intrathoracic-extracardiac pressure) [20] and not the CVP (which is referenced against the atmospheric pressure).

Positive end-expiratory pressure (PEEP) and variable intrathoracic pressures, which can both be seen during thoracic procedures, can influence preload by affecting transmural pressures. For instance, higher levels of PEEP necessary to maintain oxygenation may *raise* the CVP while *reducing* venous return. When viewed in isolation, such a CVP measure does not reflect this paradoxical effect [21]. Occasionally, the CVP waveform morphology can also provide clues to diagnosis and management [18]. Examples include the absence of the "a" wave in atrial fibrillation, cannon "a" waves during junctional rhythm, and a combined "cv" wave with an absent × descent in moderate-severe tricuspid regurgitation. The displayed digital value for CVP is influenced by such tall regurgitant waves and does not necessarily reflect the right ventricular preload.

Pulmonary Artery Catheter Monitoring

The balloon-tipped flow-directed pulmonary artery catheter (PAC) can provide an estimate of cardiac output, accurate measurement of right atrial and right ventricular pressures and pulmonary arterial pressures, and an estimate of left ventricular filling pressures (via measurement of the pulmonary artery occlusion pressure). Clinically relevant technical aspects of invasive pressure measurement are described in the previous section. Use of pulmonary artery diastolic pressures or pulmonary artery occlusion pressures as an estimate of left ventricular preload is subject to many confounding factors, including dynamic changes in ventricular compliance and juxtacardiac transmural influences. Both under- and overestimation of the left ventricular end-diastolic volumes are possible with the PAC. Variable intrathoracic pressures and PEEP during thoracic surgery can have an adverse influence on PAC-based pressure measurements. Practically, the use of the PAC has been largely limited in present-day thoracic anesthesia. Hemodynamic therapies guided by specific PAC-derived pressure "cutoff" values do not result in systematically better results. In the large rigorous RCT by Sandham et al. [4], patients with PACs did not accrue any significant improvements in outcome vs. standard care during high-risk surgery (including thoracic surgical patients). Further, the FACTT study showed that PAC-guided therapy in ARDS and acute lung injury did not improve survival relative to CVC-guided therapy [22]. This lack of benefit further discourages the use of the PAC as a monitor to guide fluid therapy for the thoracic surgical patient who is at risk for developing ARDS/ALI [22]. Other problems with PACs also include the significant potential for data misinterpretation, risks for mechanical complications like arrhythmias, pulmonary infarction, pulmonary artery rupture, thromboembolism, infectious risks, and potential for cardiac valvular/endocardial injury.

The PAC is still occasionally indicated when the accurate measurement of cardiac output is of critical importance or in the setting of severe pulmonary hypertension or right ventricular dysfunction. The air-filled PAC balloon tends to float to nondependent regions as it passes into the pulmonary vasculature. During thoracic surgery appropriate positioning of the PAC in the lateral position during lung isolation is a challenge since most of the perfusion is largely directed by HPV to the dependent lung. So for accurate estimation of cardiac output, the PAC will need to be "floated" into the correct pulmonary artery prior to surgical positioning. Thermodilution-based cardiac output monitoring, the most

widely used clinical technique, is subject to measurement errors introduced by rapid intravenous fluid administration, tricuspid valve regurgitation, and may be unreliable during OLV. "Oximetric" PACs can measure mixed venous hemoglobin oxygen saturation and continuously display a Fick principle-based cardiac output. Mixed venous hemoglobin desaturation is a reflection of the global inadequacy of cardiac output relative to global oxygen requirements and is also influenced by arterial hemoglobin oxygen desaturation and a reduction in the overall hemoglobin content. "Volumetric" PACs use a rapid-response thermistor and, by measuring residual thermal signal, can be used to estimate the right ventricular end-diastolic volume (RVEDV). Such PACs can be used to monitor RVEDV and may indicate right heart failure if the RVEDV increases as cardiac output decreases – such as may be seen in patients with cor pulmonale presenting for thoracic surgery. Pathophysiologic conditions involving left-sided cardiac structures (mitral valvular disease, LV dysfunction) can also produce characteristic changes in the PAC waveforms.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) is routine around complex cardiac surgical procedures and has multiple applications in the operating room and in the intensive care unit around thoracic (noncardiac) surgery for critically ill patients. TEE examinations around thoracic surgery can detect ischemia, help distinguish etiologies of shock, confirm right heart dysfunction, and assist in the placement of cannulae for extracorporeal membrane oxygenation (ECMO). The only absolute contraindication to the insertion of the TEE probe during thoracic surgery is a planned esophageal surgery, although there are several relative contraindications (esophageal varices, strictures, Zenker's diverticulum, undiagnosed dysphagia, etc.).

Although no randomized trials have formally examined whether postoperative outcomes are improved with the use of TEE as a routine monitor in thoracic surgery, we believe that the use of TEE is justifiable when surgery or the patient's underlying comorbidities place the patient at increased risk for severe hemodynamic compromise. Multiple studies have confirmed the sensitivity of TEE for the detection of myocardial ischemia relative to other monitoring methods (ECG-based automated ST-segment monitoring or changes in pulmonary artery-based pressures). New regional wall motion abnormalities (RWMA) on TEE is the most sensitive sign of ischemia, and the development of ST-segment changes on the ECG is a late sign of ischemia. Prompt insertion of a TEE probe in intubated, hemodynamically unstable patients can facilitate identification of the etiology of shock and help monitor responses to interventions such as fluid-loading, vasopressor, or inotrope infusions. Assessment of the right heart may be necessary when dysfunction is suspected during one-lung ventilation or with clamping of a branch of the pulmonary artery during pneumonectomy, and the TEE exam should include examination of right ventricular free wall motion, tricuspid annular plane systolic excursion, and interventricular septal function. ECMO may be used for oxygenation and carbon dioxide removal during acute respiratory failure, and circuits require placement of either venoarterial (V-A) or venovenous (V-V) cannulae. For both, a venous cannula is positioned in the right atrium, and using TEE for guidance is often a routine (with a bicaval view obtained to view both the inferior and superior vena cavae). Detection of intracardiac lesions responsible for hypoxemia (right-to-left shunts) is also facilitated by TEE. Quantitative tools such as color-flow mapping (CFM) and Doppler echocardiography allow for the evaluation of congenital cardiac lesions, vascular malformations, valvular pathology, and measurement of pressure as well as flow. Pulmonary artery systolic and diastolic pressures can be estimated with Doppler. More esoteric recent uses include the use of TEE for staging of locally advanced lung cancers [23], such as in the setting of patients with locally advanced non-small cell lung cancer with suspected involvement of cardiac structures and/or great vessels, and also the evaluation of resectability of certain lung cancers when CT imaging is suspicious for local invasion. A recent study concluded that TEE-measured diameter of the inferior vena cava at the atrio-caval junction is significantly correlated with the mean CVP [24]. Tissue Doppler imaging enables accurate assessment of diastolic dysfunction, which is important since heart failure with preserved ejection fraction is present in almost one-third of all patients with signs and symptoms of congestive heart failure. The diagnosis of impaired diastolic relaxation or restricted filling is currently made by echocardiography and is not easily accessible by other monitoring tools. In both endovascular and open surgical procedures involving the thoracic aorta, the TEE has a critical intraoperative role to play.

Minimally and Noninvasive Hemodynamic Monitoring Devices and Tissue Perfusion Monitoring

As in other intraoperative situations, in the thoracic surgical patient, the goal of hemodynamic monitoring is to identify threats to adequate tissue perfusion early, to intervene using goal-directed therapy, and to track response to such therapy. The rational use of fluids is critical, in thoracic surgical patients, given the recognition that traditional approaches to fluid therapy may result in less optimal outcomes [25–29]. For instance, fluid restriction in pulmonary resection surgery is a well-recognized approach to management with proven benefits [30].

Table 20.1 Comparison of currently clinically useful minimally invasive hemodynamic monitoring devices

Noninvasive hemodynamic device	Calibration required	Arterial waveform high fidelity	Hemodynamic parameters calculated	Requires central line insertion
FloTrac and Vigileo	No	Yes	SVV, SV, CO, SVR	No
Esophageal Doppler monitoring (EDM)	No	No	SV, CO, and FTc (flow corrected time)	No
LiDCO (lithium dilution cardiac output)	Yes (lithium)	Yes	SVV, SV, CO, SVR, DO_2	Yes
LiDCO rapid	No	Yes	SVV, SV, CO, SVR	No
PiCCO (pulse intermittent continuous cardiac output)	Yes	Yes	SVV, SV, CO, SVR, EVLW, ITTV, CI	Yes
Cheetah BioReactance	No	Not applicable	SV, change in stroke volume with PLR	No

SVV stoke volume variation, *SV* stoke volume, *SVR* systemic vascular resistance, *CO/CI* cardiac output/index, *FTc* heart rate corrected flow time, DO_2 oxygen delivery in cc/min, *EVLW* extravascular lung water, *ITTV* intrathoracic thermal volume, *PLR* passive leg raise

When compared with conventional intraoperative assessment (physical examination, fluid input and output measurements, etc.), fluid administration guided by flow monitoring can improve outcomes [28]. Furthermore, there is evidence that compared to catheter-based measurements (such as cardiac output by thermodilution or CVP), therapeutic management based on certain less invasive cardiac output monitors leads to fewer complications and shorter length of stay [26–28]. The dangers of inadequate cardiac output secondary to hypovolemia need to be balanced against the dangers of fluid overloading in these patients. Increasingly, dynamic indices of fluid responsiveness are being monitored to guide intraoperative fluid therapy [31, 32]. Functional hemodynamic monitoring is a term often used to describe the use of monitoring to evaluate treatment efficacy. The devices described below are minimally or noninvasive when compared with central venous catheters, PACs, and TEE. Table 20.1 provides a comparison of the different minimally invasive monitoring technologies.

Key functional hemodynamic questions applied to thoracic surgical patients include is flow (cardiac output) adequate to meet global tissue demands, will flow increase with fluid loading, and is hypotension a reflection of reduced flow or vascular tone or both. Therapies are consequently based on the identification of the potential for tissue hypoperfusion and the likelihood that fluid loading alone (preload responsiveness) and/or the use of inotropes or vasopressors will increase flow and mean arterial pressure. The stroke volume, systolic arterial pressure, and pulse pressure all vary in hypovolemic patients during positive-pressure ventilation with fixed tidal volumes [33, 34].

Stroke volume variation (SVV), SPV, and PPV measure different but related aspects of cardiorespiratory interaction. These variables have been shown to be superior to the conventional estimates for preload responsiveness such as CVP and PAOP. Figure 20.3 shows the receiver operating curve for SVV and PPV [26–28]. In other words, the ability to increase flow with volume loading is better predicted by the SVV, SPV, and/or PPV especially in patients undergoing surgical procedures with an expected substantial blood loss or fluid-compartment shifts (compare with Fig. 20.2). These variables are directly measured from the arterial pressure tracing and its variation with ventilation. During controlled mechanical ventilation, there are respirophasic changes in venous return and consequently subtle changes in pulse pressure and systolic pressure with each respiratory cycle. Figures 20.4 and 20.5 graphically display the physiologic mechanisms underlying these observations.

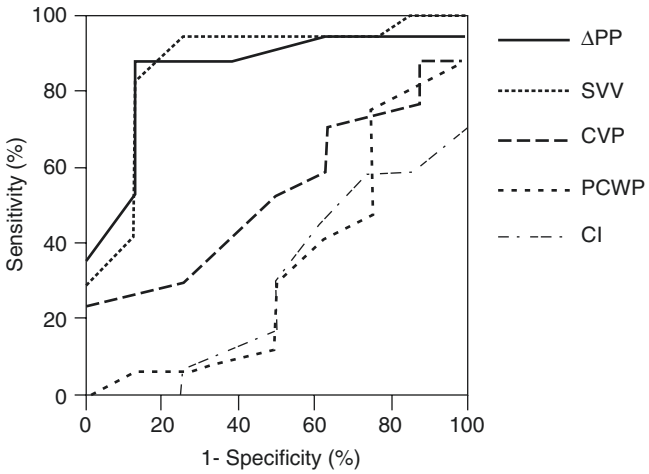

Fig. 20.3 Only the dynamic variables ΔPP (delta pulse pressure) and SVV (stroke volume variation) allow discrimination of responders from non-responders to a volume challenge, area under the ROC > 0.85. CVP central venous pressure, PCWP pulmonary capillary wedge pressure, CI cardiac input area under the ROC of 50% or less

Esophageal Doppler Monitoring

Esophageal Doppler monitoring (EDM) was first introduced in 1975. Since that time, it has been the most common minimally invasive hemodynamic monitor used and studied for

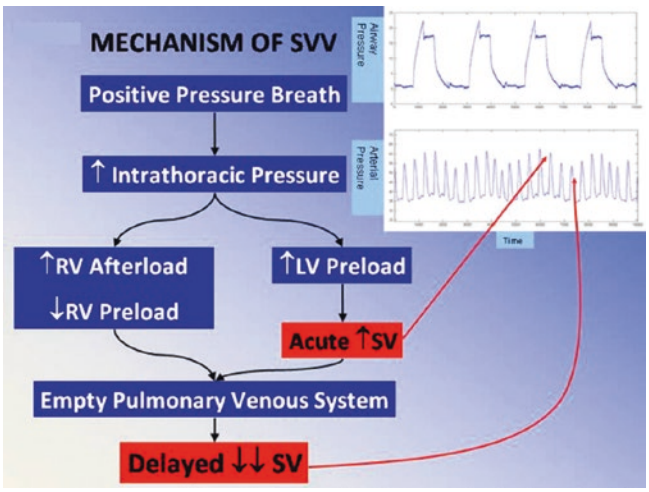

Fig. 20.4 Mechanism of stroke volume variation (SVV) from positive pressure ventilation. An acute increase in (left ventricular) LV stroke volume (SV) coincident with the inspiratory phase of positive pressure ventilation. Simultaneously displayed airway pressure and arterial pressure demonstrate that the increase in blood pressure and left ventricular stroke volume occurs during inspiration with positive pressure ventilation. This is the opposite of spontaneous breathing and is sometimes referred to as reverse pulsus paradoxus. RV right ventricular

individualized hemodynamic optimization and goal-directed therapy in thoracic surgery. Based on the Doppler principle, the probe which is inserted into the mid-esophagus transmits a continuous wave Doppler signal aligned with flow in the descending thoracic aorta at the tip of the device. The ultrasound beam is directed as parallel to the pathway of the red blood cells (traveling through the descending thoracic aorta) as possible. The constant motion of the red blood cells reflects a fraction of these ultrasound signals. The relative shift in the frequency of returned signals is called the Doppler shift, and this shift is proportional to the peak red blood cell velocity. The displayed velocity vs. time profile allows the hemodynamic calculation of stroke volume and cardiac output (based on certain assumptions). This device allows immediate real-time, comprehensive left ventricular flow-based assessment of the effects of changes in preload, afterload, contractility, and rhythm and on stroke volume. This device has been validated against the thermodilution PAC.

The caveat with this device is that it *estimates* the cross-sectional area of the descending thoracic aorta based on patients' demographics from a nomogram including age, height, and weight. Also, the angle between the direction of

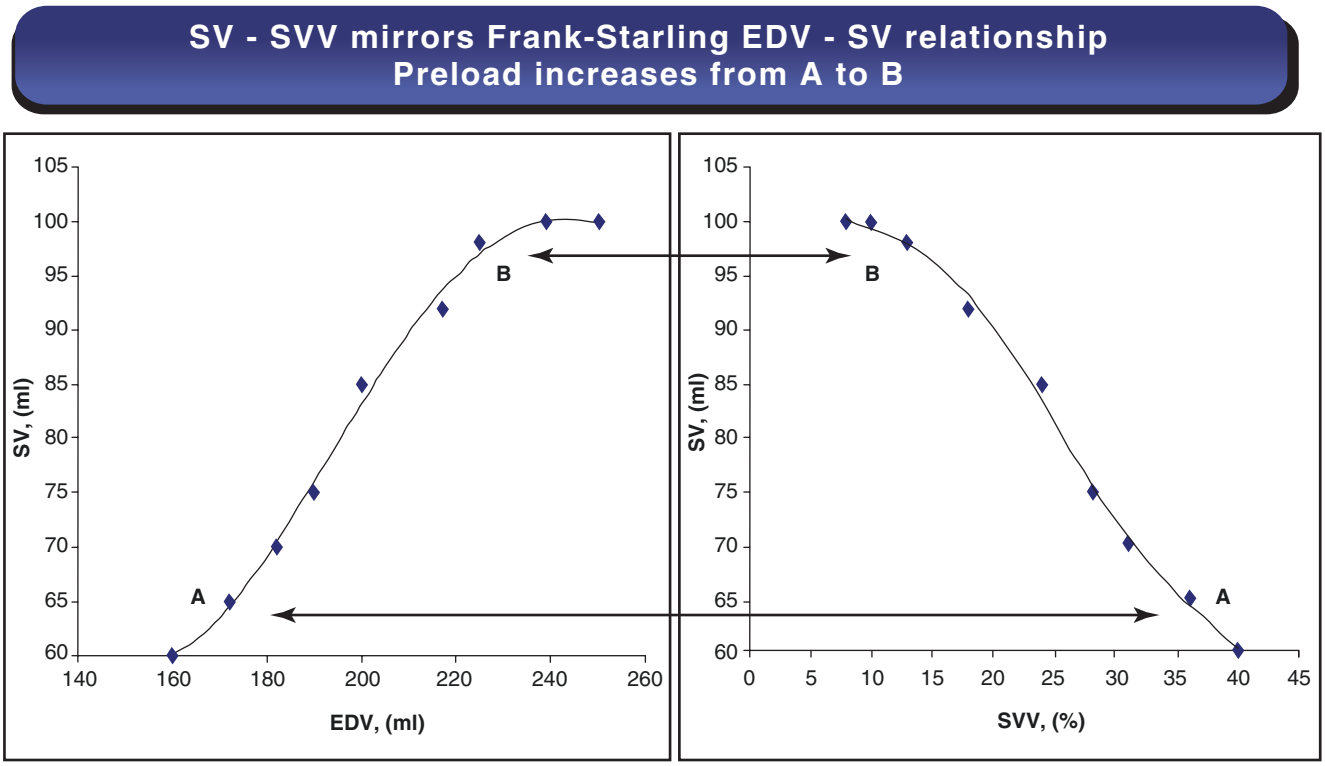

Fig. 20.5 Simultaneously developed Frank-Starling curve with the corresponding SV-SVV relationship in an individual patient undergoing volume resuscitation. The SV - SVV relationship mirrors the Frank Starling curve: as preload increases cardiac performance reaches a plateau, similarly declining SVV is associated with improved cardiac performance. SVV-SV pairs can provide information about cardiac performance similar to a Frank-Starling curve. *EDV* end diastolic volume

blood flow in the descending thoracic aorta and the Doppler signal sent by the esophageal probe is greater than the ideal 20° angle, so flow can be underestimated (although automated corrections are made for this difference). Furthermore, assumptions on the ratio of blood flow distribution to the upper vs. the lower body are also made. These correction factors can generate inaccuracies when exposed to interventions that affect blood flow distribution such as when using thoracic epidural analgesia. The esophageal Doppler device is very sensitive to positioning for the probe, leading to a need for frequent repositioning when trying to obtain accurate data. The use of electrocautery also interferes with data acquisition. The technology also allows for the calculation of flow time corrected for heart rate (FTc). This is the time that it takes for the left ventricle to eject the stroke volume or the systolic flow time in the descending thoracic aorta corrected for heart rate. The typical range for the FTc is 330–360 ms. The more volume loaded the ventricle is, the longer it takes to eject the stroke volume, conversely the more volume depleted the ventricle is, the lesser time it takes to eject the stroke volume. The FTc usually decreases to under 300 ms in volume-depleted patients. The FTc has been used in algorithms for goal-directed fluid therapy [35]; however, it remains a function of contractility, preload, and SVR, and as such, vascular impedance significantly affects this variable. In thoracic surgical patients, it has been demonstrated that this device can be used to detect and correct low-flow conditions and to guide hemodynamic support during the intraoperative period [35, 36].

Unfortunately, the EDM cannot be used during esophageal procedures where fluid management is pivotal to length of hospital stay and outcomes. The goals during these often lengthy procedures (such as esophagectomy for esophageal cancer) are to be more liberal with fluids during the abdominal portion of the surgery and more conservative during the thoracic portion of the procedure.

Continuous Pulse Contour Analysis (PiCCO)

This device estimates cardiac output using a combination of transpulmonary thermodilution and arterial contour waveform analysis. Both the thermal indicator and the pressure waveform must be measured simultaneously from a central line and an arterial line (either femoral or axillary) for calibration. This is impractical in the operating room setting, and consequently this technology is largely limited to use in Europe in the intensive care unit setting. Stroke volume is estimated from the portion of the arterial waveform that corresponds to systole. The pulsatile systolic pressure-time integral (multiplied by the heart rate to give an estimated cardiac output) is calibrated against the transpulmonary thermodilution technique of cardiac output measurement. The advantage of calibration against transpulmonary thermodilution is its independence relative to the influence of ventilation and the respiratory cycle. PiCCO has also been validated against continuous cardiac output monitoring offered by the PAC. This technology relies on a high fidelity arterial waveform and is, therefore, sensitive to damping and resonance where errors in the estimation of the cardiac output may occur. Another limitation of the PiCCO system is that conditions that interfere with the calibration process or pulse contour waveform analysis such as intracardiac shunts, severe aortic valvular disease, and the use of intraaortic balloon pump devices introduce errors [37]. As of the time that this section was written, there have been no prospective randomized controlled outcome studies published in thoracic surgery using the PiCCO system as part of goal-directed therapy (GDT).

Lithium Dilution Cardiac Output

This technology is based on the physics of pulse power analysis, which is independent of the waveform morphology, and has a correction factor incorporated to account for impedance and arterial compliance. Based on an understanding that pulse pressure measured from the arterial trace is a combination of an incident pressure wave ejected from the aorta and a reflected wave from the periphery, stroke volume calculation requires that the two waves need to be separated. The algorithm takes into consideration the fact that the arterial pressure wave changes in size depending upon the proximity of the sampling site to the heart and also on patient's age. The use of an indicator dilution method for calibration (in this case lithium since it does not naturally occur in plasma and therefore can generate a high signal-to-noise ratio) allows the measurement of blood flow, with a lithium ion-selective electrode situated in an arterial line sensing the extent of dilution. These data are used to generate a concentration vs. time curve, and the cardiac output can then be calculated from the known amount of lithium and the area under the concentration-time curve (standard indicator-dilution technique for cardiac output estimation). Multiple studies have compared continuous cardiac output measurement via PACs with the lithium dilution cardiac output (LiDCO plus) system and have found acceptable correlation (defined as agreement of measured values within 15% of each other). There have been multiple studies confirming that lithium dilution is comparable to intrapulmonary thermodilution over a range of cardiac outputs. This is very important in thoracic surgical patients with poor ventricular function and in individual patients with a fluctuating cardiac output or with a hyperdynamic circulation [38].

This device has to be calibrated because the proprietary algorithm lacks the ability to independently assess the effects

of constantly changing vascular tone on stroke volume measurement. Another limitation of this technology revolves around the use of lithium. Nondepolarizing muscle relaxants cross-react with the lithium sensor and can cause the sensor to drift. Calibration may also be unreliable in patients with severe hyponatremia. For intraoperative use, calibration needs to be performed either before induction or after the initial hemodynamic stress from airway management has had time to subside. The device can be onerous for the operating room, and it is currently mainly used in the ICU setting. The accuracy of the device is compromised in patients with severe peripheral vascular or aortic valve disease and in those requiring intraaortic balloon counter-pulsation therapy. A high fidelity arterial waveform is mandatory for accurate hemodynamic data.

The LiDCO Rapid is a recently introduced alternative designed for the operating room setting. This technology uses the same internal algorithm as the LiDCO plus but allows for the calculation of other hemodynamic parameters. The device analyzes the arterial pressure waveform and using the pulse power cardiac output algorithm converts pulse pressure into a nominal stroke volume and cardiac output. The device does not require calibration with lithium and uses a nomogram for calculation of arterial compliance. There are no published studies at the time of this review that examine the use of this technology during thoracic surgery.

Arterial Pressure Cardiac Output Device (APCO, FloTrac/Vigileo)

This technology is based on the physical principle of the relationship between pulse pressure and stroke volume. Arterial pulse pressure is directly proportional to left ventricular stroke volume and is inversely related to aortic compliance. Once stroke volume is determined by the internal algorithm, the pulse rate is counted, and cardiac output is estimated. The device does not require external calibration because the algorithm, in theory, corrects and compensates for dynamic changes in vascular tone. The device calculates cardiac output on a continuous basis (in a 20-s averaging cycle or a 5-min averaging cycle) [39–44]. With the FloTrac/Vigileo device, the arterial pressure waveform morphology is used to analyze the pulse rate and examine the variation (skewness, kurtosis, and standard deviation) of the waveform to determine changes in stroke volume. Finally, the device takes into account the multiple variables responsible for the changes in vasculature compliance (a so-called Ki factor). This constant is derived from the patient's specific vascular compliance based on biometric values (age, height, sex, and weight). The second-generation software tended to underestimate the cardiac output when the SVR was less than 800 dynes such as in sepsis and during liver transplants secondary to the hyperdynamic state typical of these situations. With the development of the third-generation software, the estimation of the cardiac output is more accurate, and newer data have demonstrated clinically acceptable precision in hyperdynamic states. Presumably, this will lead to further important studies in the near future in thoracic surgical patients. The accuracy of the device is compromised in patients with severe peripheral vascular or aortic valvular disease and in those requiring intraaortic balloon counterpulsation therapy. A high fidelity arterial line waveform is mandatory for accurate hemodynamic data. The technology has been studied during cardiac surgery and in the postoperative cardiac surgical population. Precision and bias in the estimation of cardiac output (using Bland-Altman analyses) are acceptable relative to the gold standard thermodilution PAC measurement [41–44]. Data relevant to thoracic surgical patients are sparse.

In addition, central venous oximetry can be integrated into decision-making with this device. This technology allows for the measurement of the superior vena cava oxygen saturation ($SvcO_2$) via insertion of an 8 Fr fiber-optic double-lumen catheter into the jugular or subclavian veins (using the same physical principle of spectrophotometry used for pulse oximetry). The measured value is 5–7% higher than the true mixed venous oximetry since only the upper extremity, neck, and head venous effluent is captured. With PACs, mixed venous oximetry can be performed, and coronary sinus and lower extremity effluent causes the measured value to be lower (global mixed venous effluent saturation is measured rather than central venous saturation). Despite the fact that the difference in saturation is 5–7% higher with the $SvcO_2$ than with SvO_2, it is still a very good surrogate and may be used as a sensitive marker for GDT in high-risk surgical patients undergoing elective thoracic surgery.

BioReactance (Cheetah)

The principle underlying BioReactance is that ejection of blood from the left ventricle into the thoracic aorta creates changes in injected transthoracic electric signals, i.e., phasic changes in blood flow in the thoracic aorta are detectable as changes in the "phase" of a current that is injected into the body using electrodes placed on the chest. Data have demonstrated the feasibility of using "blood flow-related phase shifts" for noninvasive measurement of cardiac output [45]. The BioReactance system consists of four dual-electrode "stickers" (two on the right side and two on the left side of the chest) placed to establish electrical contact with the body. Within each sticker, one electrode is used to inject an oscillating high-frequency sine wave into the body (by a current generator), while the other is used as a receiver (voltage input amplifier). A "phase" shift is detected and is directly

proportional to stroke volumes ejected from the left ventricle into the thoracic aorta. Stickers on a given side of the body are paired, so that the currents are passed between the outer electrodes of the pair and voltages are recorded from between the inner electrodes. Noninvasive cardiac output measurement signal is determined separately from each side of the body, and the final signal is obtained by averaging.

As with other noninvasive devices, rather than an absolute measurement of cardiac output, the utility of this device may lie in detection of relative changes when various maneuvers are instituted (passive leg raising or a fluid challenge). Volume responsiveness can be detected and fluid administered when clinically indicated. When compared with bioimpedance, which relies on measurement of changes in signal amplitude, thoracic bioreactance is based on analysis of relative phase shifts of oscillating currents. This is theoretically less impacted more by patient movement, variable environment, humidity, and sticker location (i.e., bioreactance is robust to interpatient body variance and electrode positioning) [46].

Fluid Management in Thoracic Surgery

21

Rebecca Y. Klinger

Key Points

- Excess fluid administration in the perioperative period is associated with increased risk of postoperative pulmonary injury.
- The role of the endothelial surface layer (glycocalyx) is important to understand as it relates to intraoperative injury and resultant capillary leak.
- "Goal-directed" fluid therapy using dynamic indices has been helpful in non-cardiothoracic surgery but has many limitations in thoracic surgery.
- Although the risk of acute kidney injury remains a concern with restrictive fluid regimens, there is little evidence to support an association between fluid restriction and postoperative acute kidney injury after thoracic surgery.
- Thoracic surgical patients will benefit from smaller intraoperative crystalloid maintenance infusions, judicious colloid boluses to replace blood loss, the use of inotropes/vasopressors to combat anesthesia−/neuraxial-related relative hypovolemia, and a focus on limiting postoperative positive fluid balance.

Introduction

One of the most challenging aspects of the anesthetic management of patients undergoing thoracic surgery is achieving and maintaining optimal fluid balance. Too little fluid risks hypovolemia and organ dysfunction, while too much fluid risks edema, anastomotic leakage, and lung injury. Both scenarios can profoundly impact perioperative morbidity and mortality, so achieving the appropriate fluid balance is crucial.

The Fluid Problem

Intravenous fluid therapy is integral to the practice of anesthesia, but the optimal volume and composition of fluid therapy in the perioperative setting remain debated. Both too little, but more commonly too much, intravenous fluid administration has been associated with increased postoperative complications [1]. Fluid therapy is often the first-line approach for maintaining and/or restoring intraoperative hemodynamic stability. Anesthesia decreases the effective circulating blood volume, thus reducing perfusion pressure and potentially compromising adequate oxygen delivery to tissues. However, the effectiveness with which intravenous fluid administration will improve tissue oxygen delivery is highly dependent on global cardiovascular parameters [2]. In some settings, fluid administration is beneficial, while in other settings, it is deleterious.

In patients undergoing intraabdominal surgery, excessive intraoperative fluid administration appears to be associated with multiple postoperative complications, including ileus and delayed hospital discharge [3–5]. In thoracic surgery, the consequences of fluid overload, including pulmonary edema and lung injury, are arguably far graver.

Lung Injury After Thoracic Surgery

Incidence

Lung injury occurring after pulmonary resection is a significant contributor to postoperative morbidity and mortality [6]. What had formerly been known as "acute lung injury" (ALI)

Table 21.1 Criteria for acute respiratory distress syndrome (ARDS) per the Berlin criteria [7]

ARDS severity	PaO_2/F_iO_2	Associated mortality
Mild	200–300	27%
Moderate	100–200	32%
Severe	<100	45%

now falls under the definition of mild acute respiratory distress syndrome (ARDS) as of the 2012 publication of the Berlin criteria by the ARDS Definition Task Force [7]. Mild ARDS is characterized, as acute lung injury was, by a PaO_2/F_iO_2 of 200–300 occurring within 7 days of surgery. Worse degrees of hypoxemia are associated with moderate or severe classifications of ARDS (Table 21.1). Radiographic evidence of pulmonary edema, being most commonly unilateral in the case of pulmonary surgery, is also required for the diagnosis.

The overall incidence of ALI/mild ARDS after thoracic surgery consistently ranges from 2% to 7%, with an average of around 4% [8–11]. Lung injury is less common after smaller lung resections and increases with increasingly invasive pulmonary resection, peaking with pneumonectomy. In early studies, the overall mortality with ALI after thoracic surgery was up to 70%. While the overall mortality for postoperative lung injury has improved to closer to 26% [8], it remains higher after pneumonectomy at 40% [12]. Furthermore, ALI remains the leading cause of death after surgical lung resection [13].

Factors Contributing to Postoperative Lung Injury

While lung injury following extensive lung resection has long been known [14], it is important to recognize that this syndrome also occurs after lesser degrees of lung parenchyma removal and even after intrathoracic procedures requiring one-lung ventilation but without concomitant pulmonary resection [15, 16]. The etiology of lung injury after thoracic surgery is not fully elucidated and is most likely multifactorial in nature [17]. Radionucleotide lung scans have demonstrated an increase in the pulmonary vascular permeability in the remaining lung tissue after major pulmonary resections [18]. This altered permeability is thought to be due to several perioperative factors, including surgical trauma to the lung parenchyma, lymphatic disruption, lung hyperinflation during mechanical ventilation, and release of inflammatory mediators [19]. Furthermore, surgical factors, patient characteristics, and intraoperative management all play a role in modulating the risk of postoperative lung injury.

Surgical Risk Factors

The surgical approach and extent of resection both contribute to the risk of postoperative lung injury. A right pneumonectomy has been clearly linked to increased risk for the development of acute lung injury. Zeldin et al. [14], who were the first to identify postpneumonectomy pulmonary edema, noted in their case series that nine of the ten patients who developed pulmonary edema postoperatively had undergone right pneumonectomy. The reason right pneumonectomy carries a higher risk than left pneumonectomy is likely related to the fact that more lung tissue is resected with a right pneumonectomy, thereby forcing the entire cardiac output to flow through less residual lung and thus potentially injuring the pulmonary capillary endothelium. It is likely for similar reasons that more extensive pulmonary resections in general carry a greater risk of postoperative pulmonary injury than lesser resections. Further explanation for more extensive pulmonary edema with right pneumonectomy may relate to the fact that lymphatic drainage is not the same for the right and left lungs. Greater than 90% of the lymphatic drainage of the right lung is ipsilateral, while the left lung is drained partially on the left but more than 50% by right-sided lymphatics [20]. For this reason, a right pneumonectomy will compromise more than half of the lymphatic drainage of the remaining left lung, increasing the risk for pulmonary edema, while a left pneumonectomy will do little to compromise drainage of the remaining right lung [21].

Patient-Related Risk Factors

Fernandez-Perez et al. [22] described several patient-related risk factors that significantly contribute to acute lung injury after thoracic surgery. As may be expected, American Society of Anesthesiologists (ASA) physical status class is associated with increased risk [23]. Specific comorbidities associated with a higher risk of postoperative lung injury include diabetes, smoking, chronic obstructive pulmonary disease (COPD), and daily alcohol use (defined as >60 g alcohol consumed per day). Chronic alcohol abuse has also been noted as a risk factor by others [9]. This association was described in early studies of ARDS, which identified that the incidence of ARDS in patients with a history of alcohol abuse was 43% compared to only 22% in nonalcoholic patients [24]. Importantly, alcoholics who developed ARDS had a higher mortality (65%) than nonalcoholic patients (36%). The mechanism by which chronic alcohol ingestion increases the susceptibility to acute lung injury may be related to decreases in the levels of glutathione, which is known to serve as an important antioxidant at the alveolar membrane during periods of inflammatory stress.

Risk factors for developing postpneumonectomy pulmonary edema, specifically, have been described to include predicted postoperative lung perfusion ≤55% and predicted postoperative FEV_1 < 45% of preoperative values. History of chemotherapy or radiation therapy has also been linked to the risk for postoperative pulmonary edema [25], although this association was not observed in more recent studies [26–28]. Several other risk factors have also been identified, including advanced age, blood loss, reoperation, preoperative albumin level, pulmonary metastasis, altered mental status, shortness of breath, current or past history of smoking, and low body mass index [11, 26, 28–30].

Intraoperative Management

Multiple factors related to intraoperative anesthetic management have been identified to contribute to postoperative acute lung injury. These are discussed in detail in Chap. 10 (Perioperative Lung Injury). However, two key factors are mechanical ventilation strategy [22, 31] and intravenous fluid balance. In the remainder of this chapter, we focus on the contribution of perioperative fluid management to lung injury in the setting of thoracic surgery.

Perioperative Fluid Administration and Acute Lung Injury

Acute lung injury after thoracic surgery has been linked to the administration of excessive fluid in the perioperative period by several authors [14, 17, 25]. Zeldin and colleagues were the first to propose this connection based on data from a retrospective review of ten patients who developed postpneumonectomy pulmonary edema; those who developed pulmonary edema received 4.9 ± 1.2 L of fluid, while patients who did not develop pulmonary edema received 3.5 ± 1 L of fluid [14]. Concurrently the authors reported that excessive fluid administration led to postoperative pulmonary edema in a canine model. Dogs undergoing right pneumonectomy received either "liberal" (100 mL/kg rapid bolus followed by >100 mL/kg positive fluid balance) or a more "restrictive" (50 mL/kg rapid bolus followed by <100 mL/kg positive fluid balance) crystalloid administration in the first 48 hours after surgery. All dogs who received "liberal" fluid management developed pulmonary edema postoperatively, while no dogs receiving "restrictive" fluid management developed pulmonary edema. While Zeldin and colleagues lay much of the blame for postpneumonectomy pulmonary edema on fluid administration, Turnage and colleagues [21] found no correlation between postpneumonectomy pulmonary edema and 24-h fluid balance, although their standard fluid regimen was comparatively restrictive to most. What these conflicting data do tell us is that while fluid balance clearly plays a role in pulmonary injury after surgery, it is not likely to be the only contributor.

The best human evidence to date addressing the issue of perioperative fluid management and ALI after thoracic surgery comes from a study by Licker and colleagues [8]. The authors evaluated 879 consecutive patients undergoing pulmonary resection via thoracotomy for non-small cell lung cancer. Within this cohort, only 4.2% developed lung injury (as defined by consensus guidelines); however, this acute lung injury was responsible for 43% of perioperative deaths (26–60%, depending on the etiology of the ALI). Licker et al. identified that excess fluid administration during surgery and within the first 24 h postoperatively was an independent risk factor (OR 2.9) for early acute lung injury after surgery. Those patients who developed acute lung injury received a mean cumulative intraoperative and postoperative fluid administration of 2.6 ± 1.2 mL/kg/h, while non-ALI patients received 2.0 ± 1.1 mL/kg/h (p = 0.003). This appeared to be driven primarily by intraoperative, rather than postoperative, fluid administration since fluid infusion in the first 24 h postoperatively did not differ between groups. Intraoperatively, patients who went on to develop ALI received a mean of 1.68 ± 0.60 L (9.1 ± 4.1 mL/kg/h) of crystalloid compared to 1.22 ± 0.72 L (7.2 mL/kg/h) in the non-ALI group. Interestingly, the difference in total fluid administration between ALI and non-ALI groups is rather narrow, making it difficult to define "liberal" compared to "restrictive" fluid strategies and suggesting a small margin of error in fluid administration before lung injury results.

Similar fluid volume cutoffs have been suggested by others. Parquin et al. [25] noted that intraoperative fluid administration >2 L is an independent risk factor for pulmonary edema after pneumonectomy [25]. Also in pneumonectomy patients, Blank et al. [32] found in univariate analysis that patients who suffered respiratory complications (inclusive of the need for initial mechanical ventilation for >48 h postoperatively, the need for reintubation due to respiratory insufficiency, ALI, ARDS, atelectasis requiring bronchoscopy, pneumonia, and bronchopleural fistula) received a median of 2.7 L of intravenous fluids compared to 1.8 L in patients without respiratory complications (p = 0.001). Importantly, this association was no longer seen in multivariate analysis.

The ARDS network conducted a randomized study aimed to identify the contribution of conservative vs. liberal fluid management strategies on outcomes in 1000 ALI patients in the intensive care unit (not necessarily operative patients) [33]. While this study did not address the contribution of fluid balance to the development of ALI, especially in the perioperative period, it did demonstrate a benefit to fluid

restriction in patients with established ALI [34]. This benefit was primarily a significant increase in ventilator-free days at 28 days, with a trend toward a mortality benefit.

A similar study evaluated the role of fluid balance on outcomes in critically ill surgical patients. Barmparas and colleagues [35] prospectively followed 144 non-thoracic surgical patients admitted to the intensive care unit (ICU) and stratified them by positive or negative fluid balance achieved by ICU day 5 (or ICU discharge if before day 5). The positive fluid balance group had a significantly higher mean daily fluid intake than the negative fluid balance group (3728 ± 211 mL vs. 4579 ± 263 mL, p = 0.013), as would be expected. While there was no difference in the observed rate of ALI/ARDS, the negative fluid balance group had a 70% lower in-hospital mortality than the positive fluid balance group, after adjustment for potential confounders.

Several more recent studies have been performed in thoracic surgical patients, specifically, which add to the picture described early on by Zeldin and Licker. Arslantas and colleagues [36] evaluated data on perioperative fluid management in 139 patients undergoing multiple types of thoracic surgical procedures. Patients were divided into those suffering pulmonary complications (inclusive of ARDS, need for intubation, pneumonia, need for toilet bronchoscopy, atelectasis, air leak >7 days, and failure to expand the lung) compared to those without such pulmonary complications. Those thoracic surgical patients who developed postoperative pulmonary complications received significantly greater intraoperative crystalloids, blood products, and other fluids as well as a higher infusion rate of fluids in the first 48 hours after surgery. However, in multivariate logistic regression, only intraoperative crystalloid infusion rate (and smoking history) was significantly associated with pulmonary complications. Patients with pulmonary complications received a mean intraoperative fluid infusion rate of 6.58 ± 3.64 mL/kg/h compared to 4.61 ± 2.28 mL in those without pulmonary complications.

Fluid administration has also been implicated in ALI after esophagectomy by several groups. After multivariate analysis in 45 patients undergoing esophagectomy, Casado and colleagues [16] identified that intraoperative fluid administration plus 5-day fluid balance was the only factor in their analysis that was predictive of postoperative acute lung injury. Those who developed respiratory complications received a mean of 5410 ± 810 mL of fluid intraoperatively and had a 5-day positive fluid balance of 7873 ± 954 mL (compared with 4174 ± 1033 mL and 5928 ± 1047 mL, respectively, in the group without respiratory complications). Tandon and colleagues found that ARDS, developed in 14.5% of patients after esophagectomy, was associated with intraoperative fluid and transfusion requirements, and was associated with 50% mortality (compared to only 3.5% in esophagectomy patients who did not develop ARDS) [37].

Physiologic Basis of Fluid Overload

Intraoperative fluid administration has historically been targeted by anesthesiologists to replace perceived significant fluid deficits resulting from overnight fasting, insensible losses occurring through perspiration and exposure of organ surfaces during surgery, and third-space fluid shifts. We now know that these assumptions of fluid deficit requiring treatment with intravascular volume are grossly overestimated [38–40] and that this paradigm only leads to relative hypervolemia and perioperative fluid retention. Much of the fluid load given intravascularly during surgery shifts into the extracellular space, resulting in edema.

Shifting of administered fluid out of the intravascular compartment is well documented in the perioperative period. In the setting of major surgery, the difference between intravenous fluid input and measurable output (e.g., blood loss, urine output) reveals an approximate loss of 3–6 L from the vasculature [41–43]. While this shifting begins intraoperatively, it continues into the postoperative period, extending out to 72 h in certain cases [44]. Indeed, Lowell et al. described that 40% of patients admitted to a surgical intensive care unit were 10% over their preoperative weight, presumably due to fluid accumulation [45]. This additional fluid is also not rapidly cleared. Healthy volunteers require approximately 2 days to excrete an intravenous saline load of 22 mL/kg [46, 47], and postsurgical patients would conceivably require longer in the setting of tissue trauma and possible organ dysfunction.

What remains unclear is whether surgical trauma is the primary driver of fluid shifts from the intravascular space to the interstitium (that is then treated with aggressive intraoperative fluid administration) or if inappropriately high volumes of intravenous fluid administration lead to overload of the intravascular compartment and consequent interstitial edema. In a rabbit model, surgical manipulation and trauma are alone sufficient to increase interstitial fluid by 5–10% in the complete absence of intravenous fluid administration [48]. What is even more interesting is that the resultant postsurgical interstitial edema doubled in volume with the concomitant administration of intravenous crystalloid.

Role of the Glycocalyx

Tissue and pulmonary edema are produced by increased permeability of the capillary vasculature that then allows for the egress of protein-rich fluid from the vascular compartment into the interstitial compartment. Edema has long been understood in the context of the Starling principle; however, recent understanding of the role of the endothelial surface layer (ESL), which is comprised of the endothelial

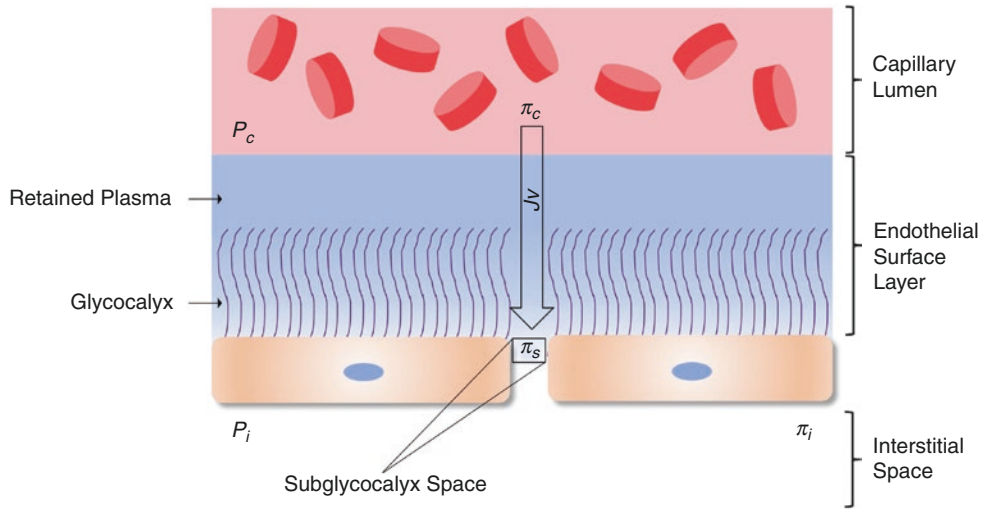

Fig. 21.1 The endothelial surface layer (ESL) is comprised of the endothelial glycocalyx and retained plasma proteins on the luminal surface of the capillary endothelium. The ESL acts as a sieve, allowing few plasma proteins to pass into the subglycocalyx space. These proteins are continuously cleared to the interstitial space; thus, the subglycocalyx space below the ESL has a very low oncotic pressure (π_s) compared to the capillary plasma oncotic pressure (π_c), creating an oncotic gradient favoring retention of fluid in the vascular lumen. The net flux of fluid across the endothelium (J_v) is driven by the balance between the capillary and interstitial hydrostatic pressures (P_c and P_i, respectively) and the oncotic gradient established between capillary lumen (π_c) and the subglyceal space (π_s). Compared to the traditional Starling principle, in this revised model, the oncotic pressure of the interstitium (π_i) does not contribute to fluid flux. (Adapted from [51, 57])

glycocalyx and bound plasma proteins, has expanded our understanding of fluid transit across the vasculature and called into question the classic Starling model.

The Starling principle [49] relies on a differential in hydrostatic and oncotic pressures between the intravascular and interstitial spaces to explain fluid transport across the capillary endothelium. However, several experiments have revealed that the calculations derived from the Startling equation are incorrect; specifically, the expected lymph flow based on calculations using the Starling principle far exceeds actual measured flow [50]. Adamson and colleagues demonstrated this phenomenon in rat mesentery. They measured trans-endothelial fluid in post-capillary venules while altering the interstitial oncotic pressure through albumin superfusion; this led to the finding that raising the interstitial oncotic pressure only increased fluid filtration by a small fraction of that predicted by the Starling model [51]. A similar study in frogs found that altering interstitial oncotic pressure had essentially no effect on fluid filtration [52].

Instead, the vascular endothelial glycocalyx appears to play a crucial role in modulating transvascular fluid flux. The glycocalyx is found on the luminal side of the vascular endothelium and is comprised of membrane-bound proteoglycans, glycoproteins, and glycolipids [53]. The glycocalyx adsorbs plasma proteins, primarily albumin, to form the ~1 μm-thick endothelial surface layer. The ESL is responsible for trapping approximately 700–1000 mL of plasma at the endothelial surface [54], thereby forming an inwardly directed oncotic force that retains plasma that would otherwise be hydrostatically forced into the interstitium (Fig. 21.1). Furthermore, it appears to be the oncotic pressure of a small area below the glycocalyx (the subglycocalyx, or subglyceal, space) that is responsible for opposing vascular oncotic pressure rather than the interstitial tissue oncotic pressure; this again is based on experimental evidence that alterations of interstitial albumin concentration had no effect on fluid filtration. This subglycocalyx oncotic pressure is developed by diffusion of plasma albumin into this space under conditions of low transcapillary fluid filtration rates [55]. Proteins in the subglycocalyx space are rapidly cleared into the interstitium by protein transport, keeping the oncotic pressure in this space extremely low and favoring retention of fluid in the vascular compartment.

It has been proposed that the endothelial glycocalyx structure serves as a passive barrier to edema formation. Increases in vascular hydrostatic pressure (i.e., during exercise) will accelerate fluid filtration into the subglycocalyx space, thereby rapidly decreasing the subglycocalyx oncotic pressure and establishing a high trans-glycocalyx oncotic pressure gradient favoring retention of fluid in the vascular lumen [51]. Similarly, low vascular hydrostatic pressure and decreased fluid filtration rates would readjust the Starling forces across the capillary endothelium to allow for more fluid filtration into the interstitium. This "revised" Starling principle, reviewed in [56, 57], can be summarized by the following equation:

$$J_v = K_f\left[\left(P_c - P_i\right) - \sigma\left(\pi_c - \pi_s\right)\right],$$

where J_v is the net fluid filtration; K_f is the filtration coefficient; P_c is the capillary hydrostatic pressure; P_i is the interstitial hydrostatic pressure; σ is the reflection coefficient; π_c is the oncotic pressure in the capillary plasma; and π_s is the oncotic pressure of the subglycocalyx space below the ESL. Note that the transvascular oncotic pressure in this revised model is entirely driven by the oncotic pressure differential across the ESL between the capillary lumen and the subglycocalyx space; in this model, the interstitial tissue oncotic pressure plays no role in driving fluid flux when the ESL is intact. Reuptake of fluid into the vascular compartment does not occur through venous capillaries, as predicted by Starling, but rather through sympathetically mediated lymph return [58].

The relevance of this concept to perioperative fluid management relates to the theory that the breakdown of the glycocalyx and the ESL has been shown to contribute to tissue edema. There is much evidence that various perioperative disturbances, including ischemia-reperfusion injury [59], inflammation/infection [60, 61], and atrial natriuretic peptide [41, 62, 63] (ANP, released in response to iatrogenic volume overload), can all disrupt the endothelial glycocalyx. In contrast, certain strategies have been shown to protect against disruption of the endothelial glycocalyx, including pretreatment with hydrocortisone and antithrombin [64] and the use of sevoflurane [65].

Relevant to the discussion of perioperative fluid management in thoracic patients, investigators have observed that the pulmonary capillary ESL is significantly thicker than that found in other organ microcirculatory systems [66]. This may help to explain the observation by several groups that the pulmonary microvasculature is less prone to leak than that in other tissues [67–69]. Inflammatory diseases that are associated with ALI (e.g., sepsis) have been noted to include increased plasma concentrations of glycosaminoglycan fragments [60, 70, 71], and glycocalyx components have been found in the bronchoalveolar lavage fluid of animals with lung injury [72, 73] suggesting that pulmonary endothelial glycocalyx degradation may play a role in lung injury. Compromise of the ESL may promote lung injury by encouraging leukocyte and platelet adhesion to the underlying endothelium and by failing to prevent pulmonary capillary leakage [74–76]. Of note, the influence of pulmonary ESL degradation may differ from that in the systemic vasculature, and animal studies investigating the role of glycocalyx destruction on pulmonary edema formation have been conflicting [66, 77, 78].

Hypervolemia and the Glycocalyx

As noted above, ANP appears to link fluid overload and tissue edema formation via destruction of the endothelial glycocalyx. ANP is released from the cardiac atria in response to wall stress created by fluid overload [79]. Furthermore, ANP has been shown to cause destruction of the endothelial glycocalyx and shifting of fluid into the interstitial space in guinea pig hearts [62]. The same authors demonstrated that an artificial infusion of ANP caused degradation of the vascular glycocalyx along with measurably increased vascular permeability and cardiac tissue edema. In patients undergoing coronary bypass surgery, increased plasma ANP has also been found to precede shedding of the endothelial glycocalyx [62]. These findings have been replicated in a recent study of 18 patients in good cardiopulmonary health undergoing elective surgery with an expected blood loss >500 mL [63]. These patients underwent a blood sparing procedure: either acute normovolemic hemodilution or 20 mL/kg volume loading, both using 6% hydroxyethyl starch. Both groups received the same volume of colloid. Patients who underwent volume loading had a significant increase in serum ANP levels, while ANP remained unchanged in the normovolemic hemodilution patients. Furthermore, patients who underwent volume loading and experienced increased ANP levels also demonstrated elevated serum levels of hyaluronan and syndecan-1, two components of the endothelial glycocalyx.

Mechanical Ventilation and the Glycocalyx

In addition to the passive barrier functions of the glycocalyx described above, there is evidence that the glycocalyx also participates in active barrier regulation through mechanotransduction [78, 80], which alters endothelial junctional integrity through various signaling molecules, including nitric oxide and reactive oxygen species (reviewed in [81]). Through this mechanism, increased intravascular hydrostatic pressure and laminar shear stress forces from blood in the vascular lumen appear to produce nonlinear (non-Starling) changes in lung capillary barrier dysfunction, leading to pulmonary edema [78, 82]. Interestingly, Dull and colleagues [77] demonstrated in whole rat lung preparations that mechanical ventilation directly affects the influence of intravascular pressure on endothelial barrier integrity. In lungs ventilated with "standard tidal volumes" (approximating 6–8 mL/kg), increases in intravascular pressure augmented lung endothelial permeability to a greater extent than when low tidal volumes (approximating 4–6 mL/kg) were used. At the highest intravascular pressures (left atrial pressure of 17 cmH_2O), permeability increased ~5-fold in the low tidal volume group but ~15-fold in the high tidal volume group. These data further support the notion that lung-protective ventilation strategies are likely as important to the discussion of preventing pulmonary edema as are fluid management strategies.

Table 21.2 summarizes many of the factors described in animals and humans to damage the endothelial surface layer

Table 21.2 Factors that damage or protect the endothelial surface layer

Damaging	Protective
Inflammation (TNF-alpha)	Antioxidants[a]
Ischemia-reperfusion	Antithrombin III
Infection/sepsis (LPS)	Glucocorticoids
Hypervolemia (ANP)	Rosuvastatin
Surgical trauma	Lidoflazine
Hyperglycemia	Sevofluorane
Low-density lipoprotein	Albumin
Cardiopulmonary bypass	Fresh frozen plasma
High tidal volumes	Lung-protective ventilation
Hypoxia	
Hypertension	

TNF tumor necrosis factor, *LPS* lipopolysaccharide, *ANP* atrial natriuretic peptide

[a]Antioxidants shown to be protective/reparative in animal studies include polyethylene glycol, nitric oxide, TNF-alpha inhibitors (e.g., etanercept), allopurinol, heparin, and hyaluronan

and increase vascular permeability and those that are protective against such damage. Of note, the clinical relevance of many of the listed protective factors remains unclear.

Fluid Composition

The ideal fluid for volume replacement in the perioperative period is not definitively known and is beyond the scope of this chapter. With regard to crystalloids, we know that normal saline (0.9% NaCl) infusions (>1.5–2 L) in noncardiac surgery and critical illness are associated with hyperchloremic acidosis [83, 84]. Furthermore, several large observational studies have found an association between non-buffered, chloride-rich crystalloids (such as 0.9% NaCl) and renal injury/renal failure, 30-day mortality, hospital length of stay, and major infection [83, 85, 86]. In particular for large-volume resuscitation, buffered crystalloid solutions that do not inflict a significant chloride load appear to be preferable; however, these solutions in excess may result in hyperlactatemia, metabolic alkalosis, and hypotonicity, depending on their exact composition [87]. Nonetheless, observational studies comparing normal saline and balanced solutions suggest a decrease in major complications, acute kidney injury, and the need for renal replacement therapy in both operative and ICU patients when balanced solutions are used [85, 86, 88]. Colloids, especially hydroxyethyl starch, are associated with renal damage (and possibly death) in sepsis, trauma, and other critical illness [89–92], although there is little data to extrapolate these findings to healthy surgical patients [93]. Considerations regarding the risk of anaphylaxis [94] and anaphylactoid reactions [95], tissue deposition [96], and effects on coagulation [97] should also be noted with the various commercially available colloid solutions.

Some authors espouse that direct head-to-head comparisons of crystalloids and colloids are unfair because one may be better than the other depending on the clinical circumstances. For example, experimental evidence derived from acute normovolemic hemodilution (which simulates a bleeding patient) revealed that crystalloids and colloids have a very different so-called volume effect [41, 42, 98, 99]. In these experiments, removal of ~1 L of blood with concomitant replacement by a three-fold amount of crystalloid, as is traditional dogma, resulted in a *decrease* in circulating blood volume of approximately 10%. The authors estimated that only 17 ± 10% of the infused crystalloid was retained in the vascular space [98]. In contrast, an approximate 1:1 replacement of lost blood with colloid resulted in a volume effect of 90 ± 18% for 6% hydroxyethyl starch and 87 ± 14% for 5% human albumin [41, 42]. Importantly, this behavior of crystalloids and colloids assumes an intact ESL and may not hold true in all perioperative situations in which ischemia, inflammation, and other factors may compromise the glycocalyx. This is bolstered by experimental evidence indicating that colloid infusions in normovolemic patients, presumably leading to iatrogenic hypervolemia, only result in ~40% retention of volume in the vasculature [41].

While no outcome benefit can be identified for colloids over crystalloids for fluid resuscitation [100], with respect to the risk of pulmonary injury, the type of fluid used appears unimportant. A study by Verheij and colleagues reported that in the absence of volume overload, the choice of fluid did not affect the incidence of pulmonary vascular permeability or postoperative pulmonary edema after cardiac and major vascular surgery [101]. Interestingly, their findings suggested that hydroxyethyl starch ameliorated increases in pulmonary vascular permeability. Similarly, Huang and colleagues reported that fluid resuscitation with hydroxyethyl starch in patients with established sepsis-related ARDS did not alter pulmonary mechanics or worsen extravascular lung water [102]. Others have found that pulmonary capillary leak increases with fluid loading in critically ill patients, but again the type of fluid used did not affect the degree of resultant pulmonary edema [103].

Based on currently available evidence, it appears prudent to primarily use crystalloids in the perioperative period. Colloids should probably be reserved for actively bleeding patients in the absence of sepsis and renal dysfunction, although there is little data at present to support their superiority over crystalloids.

Risks of Fluid Restriction in Thoracic Surgery

The primary concern with restrictive fluid management strategies is the risk of inducing or failing to prophylax against acute kidney injury (AKI). Data from the Society of Thoracic Surgeons Database indicates a low rate of renal failure after

thoracic surgery at 1.4%; notably this only reflects patients requiring renal replacement therapy [104]. The rate of renal failure after esophagectomy appears to be slightly higher at 2.0% [105]. Criteria have been devised to classify AKI, including the risk, injury, failure, loss, and end-stage disease (RIFLE) [106] and acute kidney injury network (AKIN) [107] criteria. Using these criteria, AKI after thoracic surgery appears to range around 6% and is associated with increased length of stay, morbidity, and mortality [108, 109].

In the study by Ishikawa and colleagues [108], AKI as defined by AKIN criteria occurred within the first 72 h of surgery in 5.9% of patients. Most of these cases were AKIN stage 1 (59/67), while a few were AKIN stage 2 (8/67). Using the RIFLE criteria, AKI was diagnosed in 2.3% in the same cohort of patients. As would be expected, the rate of AKI varied based on the invasiveness of the procedure, with pneumonectomy having the highest rate and wedge resection/bullectomy having the lowest rate. Several patient-related risk factors were identified in those who developed AKI. With regard to perioperative fluid management, only exposure to hydroxyethyl starch fluids was associated with AKI and in a dose-dependent manner, such that each 250 mL of hydroxyethyl starch increased the odds of AKI 1.5-fold. Rather than volume restriction, univariate analysis indicated that patients who developed AKI received *more* perioperative crystalloid than those without AKI; however, this association was not supported in multivariate analysis.

Licker and colleagues [109] identified a slightly higher rate of AKI (6.8%) after lung cancer surgery using RIFLE criteria. Again, risk was highest in patients undergoing more extensive surgery with longer operative and anesthesia times. Patients who developed AKI received higher volumes of colloids intraoperatively and had greater vasopressor requirements. However, logistic regression failed to identify any fluid-related risk factors; rather vasopressor requirement was one of the four identified independent predictors of AKI. While this observation has been noted by others in noncardiac surgical patients [110], it remains unclear whether the association between vasopressor use and AKI is reflective of arterial hypotension and uncompensated hypovolemia, as the authors suggest, or rather reflective of patient- or procedure-related comorbidity. The authors did note that AKI was more prevalent in patients who received chronic angiotensin receptor blocker therapy preoperatively. Furthermore, there was no difference in intravenous fluid administration between patients who developed AKI and those who did not.

In a more recent study, Ahn and colleagues [111] retrospectively evaluated the association between postoperative AKI, based on AKIN criteria, within 72 h after thoracic surgery in nearly 1500 patients. In their cohort, 5.1% of patients developed AKI with only 0.1% requiring renal replacement therapy. In this cohort, the highest risk of AKI was seen in esophagectomy patients (13%), followed by pneumonectomy (11%), lobectomy (5%), and finally wedge resection/segmentectomy (2%). Intraoperative crystalloid restriction was not associated with a higher incidence of AKI after thoracic surgery, even down to ≤2 mL/kg/h and in patients with preexisting abnormal renal function. However, and in support of the findings by Ishikawa et al., hydroxyethyl starch administration was associated with increased postoperative AKI, with each 500 mL increasing the odds for AKI 1.75-fold. Importantly, after multivariate adjustment, hydroxyethyl starch administration was only a risk factor for postoperative AKI in patients with preexisting abnormal renal function (odds ratio 7.6).

These findings are in line with the general surgical literature. A recent systematic review and meta-analysis evaluating a total of 1594 patients were unable to find an association between "restrictive" intraoperative fluid management and an increase in oliguria or AKI [112]. They also found no difference in AKI between studies that specifically targeted reversal of oliguria versus those that did not. In the pooled studies, intraoperative fluid administration was 1.9 L lower in the restrictive group versus the conventional fluid group when oliguria was not targeted and still 1.6 L lower in studies that targeted oliguria reversal. Similarly, the Fluids and Catheters Treatment Trial (FACCT) failed to demonstrate any difference in AKI-free days between restrictive and conventional fluid management approaches in patients with established ARDS [33].

In addition to the evidence that fluid restriction does not appear to increase the risk of AKI in thoracic surgery, there is also little support for generous hydration to improve perioperative renal function or urine output in thoracic surgical patients. In a study by Matot et al., urine output was the same (median, 300 mL) in 102 video-assisted thoracoscopic surgical patients, regardless of whether they received "high" (mean, 2131 ± 850 mL) or "low" (mean, 1035 ± 652 mL) intraoperative fluid. Serum creatinine levels decreased postoperatively from preoperative levels in both fluid groups to an equal extent, and there was no difference in postoperative creatinine between patients with urine output <1 mL/kg/h and those with urine output >1 mL/kg/h.

Based on the currently available evidence, it does not appear that intraoperative crystalloid fluid restriction is associated with an increased risk for postoperative renal injury.

Methods of Targeting Fluid Management

Maintaining dry lungs and relative normovolemia during the perioperative period has been espoused by many and appears to be a rational approach. However, the question remains as to how one can accomplish this goal without straying into either hypervolemia or hypovolemia. The general perioperative literature has proposed a conservative fluid management

strategy referred to as the "zero-balance" approach, the goal of which is to minimize perioperative weight gain due to fluid administration and salt/water retention in response to surgical stress-induced antidiuretic hormone release [57] without inducing hypovolemia.

The so-called goal-directed fluid therapy has long been an objective in anesthesia practice. As might be expected, clinicians are not good at estimating the volume status of patients; only 50% of hemodynamically unstable patients will appropriately respond (increase their stroke volume by 10–15%) to fluid challenges administered based on clinical suspicion [113]. For a fluid bolus to cause an appropriate increase in stroke volume, the following must be true: the bolus must increase the mean circulatory filling pressure above the central venous pressure, thus driving venous return to the heart, and the heart must be on the ascending portion of the Frank-Starling curve [114]. Furthermore, volume loading of patients in the steep portion of the Frank-Starling curve (preload-insensitive patients) will only increase hydrostatic pressure and resultant edema with minimal gains in cardiac output (Fig. 21.2). The resultant tissue and pulmonary edema with inappropriate fluid loading is accentuated in patients with disease processes that increase endothelial permeability/glycocalyx damage, as described above. Increased extravascular lung water specifically is known to be strong predictor of morbidity and mortality in patients with critical illness [115, 116].

Initially, invasive monitors, including central venous pressure monitoring and pulmonary artery catheters, were utilized to help guide fluid therapy. However, central venous pressure was found to be inaccurate at assessing volume status or predicting response to a volume challenge [113, 117]. Pulmonary artery catheters are also poor predictors of fluid responsiveness [118, 119] and are associated with major morbidity [120]. The use of dynamic hemodynamic parameters to predict fluid responsiveness has been advocated, including variation (generally of >13%) in systolic pressure, stroke volume, or pulse pressure [121]. These indices are based on the principle that mechanical ventilation cyclically increases intrathoracic pressure, which then has variable effects on ventricular loading depending on the volume status of the patient. Thus, these indices can theoretically predict fluid responsiveness [122, 123] and are designed to offer the clinician an estimate of the position of the patient's cardiovascular system on the Frank-Starling curve. Unfortunately, there remains a "gray zone" (between 9% and 13% variation) in which fluid responsiveness cannot be reliably predicted in many patients [124].

Particularly problematic for adoption of these dynamic indices in thoracic surgery is the fact that their predictive value varies greatly with different delivered tidal volumes [125] and substantially decreases at tidal volumes less than 7 mL/kg [126]. Furthermore, the reliability of these dynamic indices under open-chest conditions has varied in different studies, with some reporting loss of reliability [127–129] but others reporting no change [130]. Lee and colleagues interestingly reported the ability of pulse pressure variation to predict fluid responsiveness with protective one-lung ventilation (OLV) but not with non-protective OLV strategies in thoracotomy [131]. Patients were randomized to either protective strategies (OLV with tidal volumes of 6 mL/kg, FiO_2 of 0.5, and positive end-expiratory pressure [PEEP] of 5 cmH_2O) or "conventional" OLV (tidal volumes of 10 mL/kg and no PEEP). After the initiation of OLV, patients received volume loading with 7 mL/kg of 6% hydroxyethyl starch, and pulse pressure variation and cardiac index were measured. Pulse pressure variation was predictive of fluid responsiveness (cardiac index increase of at least 15%) only in the protective lung ventilation group and at a threshold of 5.8%. In contrast, a study in patients undergoing lobectomy identified that stroke volume variation was only able to predict fluid responsiveness during OLV if the tidal volume was at least 8 mL/kg [132]. Transesophageal echocardiography can be particularly useful in assessing volume responsiveness during open-chest procedures [133] but is unlikely to be used in the vast majority of thoracic surgical procedures. The various dynamic

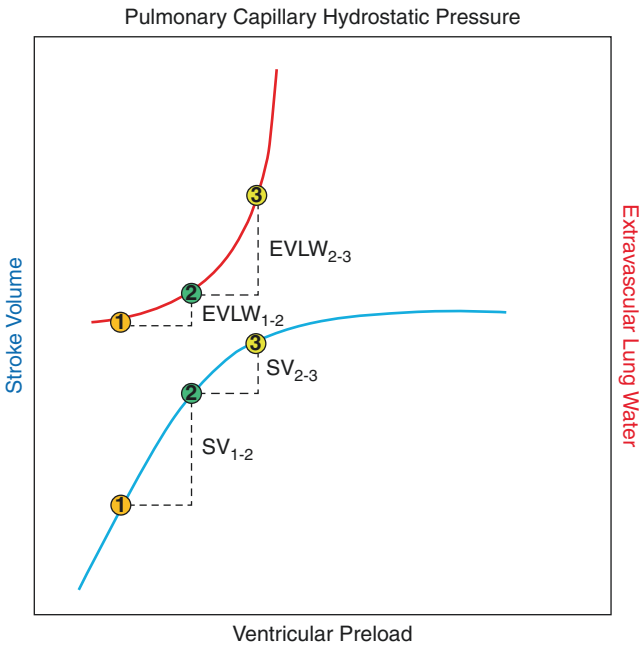

Fig. 21.2 Superimposition of the Frank-Starling curve (blue), which describes the relationship between left-ventricular preload and stroke volume/cardiac output, and the Marik-Phillips curve (red), which describes the relationship between pulmonary capillary hydrostatic pressure and extravascular lung water (EVLW). Movement from positions 1 to 2 on the curves produces a large increase in stroke volume ($SV_{1–2}$) with a relatively small increase in EVLW ($EVLW_{1–2}$); this describes a preload-dependent patient. In contrast, movement from positions 2 to 3 on the curves produces only a small gain in stroke volume ($SV_{2–3}$) but at the expense of a much larger increase in EVLW ($EVLW_{2–3}$); this describes a preload-independent patient. (Adapted from [114])

hemodynamic monitoring devices in clinical use today are reviewed elsewhere [134, 135].

While fluid challenges are known to predict fluid responsiveness [136], the actual hemodynamic response to fluid augmentation is generally fleeting and of unclear benefit. In a study of patients with shock, fluid responders experienced a 25% increase in their cardiac index following a fluid bolus; however, their cardiac index returned to baseline by 30 min after the completion of the bolus [137]. Similarly, in patients with sepsis, a fluid bolus increased the mean arterial pressure for only 1 h and did not augment urine output [138]. ARDS patients similarly experienced an augmentation of mean arterial pressure in response to a fluid bolus without any increase in urine production [139]. In the Fluid Expansion as Supportive Therapy (FEAST) trial in pediatric febrile patients, albumin and saline boluses both increased the rate of death due to cardiovascular collapse (not fluid overload) at 48 h compared to no fluid bolus, suggesting that bolus fluids may adversely impair normal neurohormonal compensatory mechanisms [140].

The currently employed paradigms for fluid administration are naturally only surrogates for the intended benefit, namely, optimizing tissue blood flow and oxygen delivery. The difficulty in monitoring the effects of fluid therapy at the intended site of action – the microcirculation – likely contributes to the ongoing controversy surrounding best practices for fluid administration. However, the use of the microcirculation as the end point of fluid resuscitation, via measures such as in vivo microscopy to identify the microvascular flow index or sublingual capnography to define the sublingual-systemic CO_2 gradient (reviewed in [141]), may bring us closer to defining optimal perioperative fluid management strategies in the future.

Approach to Fluid Management in Thoracic Surgery

Fluid management has become central to much of the literature surrounding enhanced recovery after surgery (ERAS) approaches. Careful and rational fluid management is also central to the perioperative management of thoracic surgical patients to mitigate postoperative morbidity. Borrowing from the broader ERAS literature, several recommendations may also make sense in the thoracic surgical population.

ERAS-Based Fluid Management

ERAS protocols have called into question the traditional thinking regarding *nil* per os (NPO) guidelines in the preoperative phase. Many centers and individuals still practice NPO after midnight, inclusive of any food and drink, except for small amounts of clear liquids up to 2 h prior to surgery. However, there is sufficient evidence to support the notion that fasting of solid food for 6 h and oral fluid intake until 2 h prior to surgery is safe and may improve outcomes [142, 143]. Some protocols even encourage active carbohydrate drink consumption up to 2 h prior to surgery. While this strategy has not necessarily been shown to prevent fluid overload or acute lung injury and is derived largely from the abdominal surgery literature, there appears to be a signal toward reduced length of stay and attenuation of insulin resistance [144]. Whether carbohydrate drinks are superior to clear liquid consumption and whether these findings are applicable to thoracic surgical patients remain to be investigated. Furthermore, an exact target for volume of preoperative liquid consumption also remains unclear.

The second component of an ERAS-based fluid strategy is to restrict intraoperative fluid administration to avoid overt hypervolemia. While the correct amount of fluid needed to maintain normovolemia remains elusive and the definition of a "restrictive" approach is highly variable, some sort of protocol-driven fluid management appears to reduce the incidence of complications in major surgery [145–147]. In general, replacement of fluid losses into the "third space" has largely been discounted [57]. Based on the available evidence, ERAS advocates have argued for limiting intraoperative maintenance infusions designed to replace loss of fluid through the skin and airways, evaporation from the surgical field, and bodily secretions to 1–2 mL/kg/h [148]. Additional fluid should only be administered to account for blood loss. The results of many of the trials of goal-directed fluid therapy in a myriad of surgical procedure types are reviewed by the International Fluid Optimization Group [148]. It should be noted that goal-directed approaches are not synonymous with restrictive fluid administration approaches; in many trials, goal-directed patients received more fluids, in particular colloids, than control patients [148]. This may be particularly problematic for the translation of these approaches to thoracic surgical patients.

Managing Fluids in Lung Surgery

Thoracic patients are unique in their risk for postoperative lung injury; thus stricter fluid recommendations have been put forth [149]. In addition to protective lung ventilation strategies, a more restrictive fluid administration regimen targeted to maintaining normovolemia has been advocated in thoracic surgical patients. Assaad and colleagues suggested a protocol that maintained normal renal function without increasing extravascular lung water in a small prospective observational study [150]. Their preferred fluid regimen included the following: maintenance fluids administered as a balanced salt solution at 1.5 mL/kg/h and continued until

oral intake resumed; repletion of fasting fluid deficit with a bolus equivalent to number of hours of fasting times the above maintenance rate; repletion of evaporative losses in open thoracotomy procedures at a rate of 1 mL/kg/h; and 1:1 repletion of blood loss with either a hetastarch solution or packed red blood cells if the hematocrit fell below 25%. They showed this protocol to maintain cardiac preload and tissue perfusion (as assessed by serum lactate and central venous oxygen saturation). There were no cases of ALI in this cohort, and their rate of postoperative AKI in the first 3 days was 7.5% (based on AKIN criteria). This study suffers from several limitations: the cohort size is very small, encompassing only 40 patients; arguably, the routine replacement of fasting fluid loses is outdated; and this study lacked an alternate fluid administration protocol group for comparison. Nevertheless, their results provide some guidelines as to fluid administration parameters that, in combination with lung-protective ventilation strategies, appear to be non-injurious.

Goal-directed approaches using dynamic indices have also been attempted in the thoracic surgical population with mixed results. A small study of 27 patients undergoing either lung surgery or esophagectomy by Haas and colleagues reported that a goal-directed fluid approach (an arguably aggressive maintenance crystalloid infusion of 9 mL/kg/h intraoperatively and 5 mL/kg starch colloid boluses for stroke volume variation >10%) did not result in an increase in extravascular lung water [151]. They did, however, report a decrease in the PaO_2/F_iO_2 ratio during surgery, although this value remained >300 mmHg outside of periods of OLV. A larger study of 60 patients undergoing thoracoscopic lobectomy randomized patients to receive either goal-directed fluid therapy or control therapy [152]. Control patients received a basal crystalloid infusion of 8 mL/kg/h and crystalloid or colloid boluses at the discretion of the anesthesiologist to maintain mean arterial pressure 65–90 mmHg, heart rate 60–100 beats/min, and urine output >0.5 mL/kg/h. Goal-directed patients received the same basal crystalloid infusion rate along with the following interventions: starch colloid boluses when stroke volume variation >11% to achieve stable stroke volume variation ≤9%; ephedrine boluses and continuous phenylephrine infusion of 2 mcg/min for mean arterial pressure <60 mmHg despite fluid resuscitation; and dobutamine infusion (2–5 mcg/kg/min) to maintain the cardiac index between 2.5–4 L/min/m^2. They demonstrated that the goal-directed group received significantly less colloids and overall less infused fluid volume than the control group and had fewer instances of nausea and vomiting. With regard to pulmonary outcomes, they report that the goal-directed group had a significantly higher PaO_2/F_iO_2 ratio before the end of OLV than the control group. Five of the 30 goal-directed patients required dobutamine infusions. The authors note in their discussion that stroke volume variation values became more difficult to treat and less predictably responsive to treatment in the lateral position, again highlighting that these dynamic indices may fall short given the complexities of thoracic surgery and one-lung ventilation.

In addition to focusing on the volume of fluid administered, the anesthesiologist must also remember that not all episodes of hypotension are due to hypovolemia and that hemodynamic optimization can and should include vasopressors and inotropes in addition to fluids. Several guidelines have encouraged the use of vasopressors in lieu of intravenous fluids to counteract anesthesia-induced vasodilation and accompanying relative hypovolemia. It is known from the sepsis literature that norepinephrine, for example, is quite effective in augmenting venous return to the heart, increasing stroke volume and cardiac output, and raising the mean arterial pressure; these effects should improve organ and tissue perfusion while minimizing the formation of edema [153, 154]. A randomized trial in radical cystectomy patients demonstrated that a so-called restrictive deferred hydration protocol (initial fluid therapy limited to 1 mL/kg/h with low-dose norepinephrine followed by a hydration phase at 3 mL/kg/h) resulted in a shorter hospital length of stay and lower transfusion rate compared to a liberal fluid regimen (6 mL/kg/h) without any difference in major complications [155, 156]. Finally, in a recent meta-analysis, perioperative hemodynamic optimization using a combination of fluids and inotropes was effective in reducing AKI after surgery [157].

Lastly, in addition to intraoperative fluid targets, attention should be paid to overall perioperative fluid balance and patient body weight in the early postoperative period. An excess positive fluid balance in the postoperative period should be avoided. Intravenous fluid administration should be terminated as soon as feasible, with the resumption of oral hydration and alimentation as soon after surgery as is safe.

Table 21.3 offers suggestions regarding perioperative fluid management for providers in thoracic anesthesia.

Managing Fluids in Esophagectomy

Esophagectomy deserves additional consideration, as this procedure has traditionally been approached with more aggressive fluid resuscitation. As noted above, lung injury after esophagectomy also occurs, but typically at a higher fluid threshold than for lung surgery. Regardless, excessive fluid administration should also be avoided in these patients. Both aggressive fluid resuscitation and the use of vasopressors have been feared to contribute to anastomotic complications after esophagectomy. While the data in esophagectomy is sparse, extrapolation of the abdominal surgery literature

Table 21.3 Suggestions for perioperative fluid management in thoracic surgical patients

Variable	Suggested value
Clear liquid consumption up to 2 h before surgery	Unrestricted
Fluid administration in first 24 h	≤2 mL/kg/h
Perioperative positive fluid balance	≤1.5 L
Vasopressors/inotropes	As needed for anesthesia-induced vasodilation or ongoing hypoperfusion
Mechanical ventilation	Lung-protective strategies

Based in part on Evans and Naidu [149]

suggests that avoiding excessive fluid administration may avoid anastomotic breakdown [158, 159].

A recent study evaluated the effects of goal-directed fluid therapy in 199 esophagectomy patients [160]. Control patients received crystalloids and colloids at the discretion of the anesthesiologist with the only goal to maintain mean arterial pressure >65 mmHg or <20% from baseline. Goal-directed patients received colloid boluses to reach and then maintain stroke volume within 10% below optimum. Phenylephrine, ephedrine, and norepinephrine were used in both groups to maintain mean arterial pressure. There were no differences in morbidity or mortality between the groups. The control group had a higher mean postoperative intensive care unit or post anesthesia care unit length of stay, but overall hospital length of stay did not differ. Goal-directed patients received overall less fluid intraoperatively, although they received more colloid than controls. Norepinephrine use was higher in the goal-directed group, but phenylephrine use was higher in controls. With regard to composite pulmonary complications, there was no difference between groups, although the goal-directed patients had a significantly lower incidence of pneumonia in secondary analyses. Important to esophagectomy patients, this study failed to demonstrate a benefit to goal-directed therapy in terms of anastomotic leakage.

Glatz and colleagues very recently published a retrospective study of 335 esophagectomy patients that identified an association between intra- and postoperative fluid overload and several complications, including both pulmonary (representing 53% of all complications) and anastomotic complications, along with in-hospital mortality [161]. Intraoperative fluid load (postoperative day zero fluid balance) along with ASA score were the only independent predictors of adverse outcomes (at least one complication) in multivariate analysis. The cutoff points for identifying liberal versus restrictive fluid strategies in terms of outcomes in this study were again quite large in comparison to those typically seen in lung surgery: a positive fluid balance on postoperative day zero (representative of intraoperative administration) of 6 L and on postoperative day 4 of 5.5 L. Anastomotic leakage occurred in 9% of the patients who received restrictive intraoperative fluids compared to 21% who received liberal management.

With respect to vasopressors use, earlier animal studies of esophagectomy indicated that treatment of hypotension with norepinephrine was associated with gastric conduit hypoperfusion [162]. However, small human studies have since indicated that treatment of epidural-induced hypotension during esophagectomy with epinephrine [163] or phenylephrine [164] were not detrimental and actually improved or restored compromised graft blood flow.

While larger fluid volumes appear to be tolerated in esophagectomy patients before complications occur, the available data suggests that the avoidance of an excessive (several liter) postoperative fluid balance is desirable and that the use of vasopressors and inotropes to improve intraoperative hemodynamics and offset anesthesia−/neuraxial-related hypotension is reasonable without risking overt anastomotic breakdown.

Conclusion

Lung injury after thoracic surgery remains a significant problem that is associated with postoperative morbidity and mortality. There is considerable evidence to associate postoperative lung injury with perioperative fluid administration, among other factors. While more research is required, the available evidence suggests that a more restrictive approach to fluid management along with the use of vasopressors and inotropes to offset anesthesia-related hypotension is likely beneficial to the thoracic surgical patient without significant risk of renal or other tissue injuries. Dynamic indices to guide fluid administration may be of benefit, although they are associated with many pitfalls in related to one-lung ventilation and open-chest approaches. Practitioners should pay attention to overall perioperative fluid balance in addition to limiting intraoperative fluid administration. Finally, the apparent synergism between volume status and mechanical ventilation strategies argues for the use of lung-protective ventilation along with judicious perioperative fluid management in the patient undergoing thoracic surgery.

Intraoperative Ventilation Strategies for Thoracic Surgery

22

Jennifer A. Macpherson

Key Points

- Ventilatory strategies for one-lung ventilation (OLV) should take into account preventing intraoperative hypoxemia, intraoperative alveolar stress, and postoperative ventilator-induced lung injury (VILI).
- Based on available evidence, it seems appropriate to limit tidal volumes and inflation pressures during OLV, providing high breathing frequencies are not needed and mild to moderate hypercapnia is not contraindicated.
- A lung-protective strategy utilizing low tidal volumes, ≤6 mL/kg of predicted body weight and preferable 4–5 mL/kg, and limited plateau inspiratory pressures (<25 cm H_2O) is clearly indicated for patients at high risk for postoperative pulmonary complications.
- With appropriate use of pressure and tidal volume alarms, either pressure- or volume-controlled ventilation may be used to deliver the desired tidal volume and plateau pressure.
- Intrinsic positive end-expiratory pressure (PEEP) is common with OLV (utilizing a double-lumen endotracheal tube), and caution is warranted when high respiratory rates (short exhalation times) are utilized. The addition of external PEEP does not consistently greatly improve oxygenation and has not been shown to reduce the incidence of VILI. Any PEEP used should be titrated for the individual patient.
- A lung-opening procedure (LOP) utilizing several breaths of high inspiratory and expiratory pressures may improve oxygenation, but the hemodynamic consequences of the maneuver must be considered. The use of a LOP after the institution of OLV may be warranted.

Introduction

While not all thoracic surgery requires specialized intraoperative ventilation, techniques that ventilate only a single lung are the hallmarks of anesthesia for this type of surgery. One-lung ventilation (OLV), with the collapse of the contralateral lung, greatly facilitates surgery within the thorax. With the development of video-assisted thoracoscopic surgery, the collapse of the lung on the operative side has become a necessity. OLV during these operations must ensure adequate gas exchange (arterial oxygenation and venous carbon dioxide removal), full contralateral lung deflation, and reduction of the incidence of postoperative pulmonary complications (PPC) and acute lung injury (ALI). This last concern has grown more important as it has become clear that prevention of ventilator-induced lung injury (VILI) is important in intensive care unit treatment of acute respiratory distress syndrome (ARDS) and ALI [1] (see Chaps. 10 and 42 for a discussion of the definitions and treatment of ALI and ARDS). It may not always be possible to fully achieve these three goals, and anesthesiologists' skills are required to determine the best compromise for each individual patient.

Postthoracotomy ALI, while not common, has a high mortality rate [2]. Early studies indicated a correlation with high intraoperative fluid administration [3], but subsequent

studies have not shown as strong a correlation [4]. Although the causes are multifactorial [5–7], including a possible genetic predisposition [8], recent studies have pointed to intraoperative mechanical ventilation with large tidal volumes as an important risk factor [2, 4, 9–15]. In an observational study, Licker et al. [9] used historical controls to compare outcomes from a lung-protective ventilation protocol. The protocol resulted in a decrease of ALI from 3.7% to 0.9% ($P < 0.01$) and an odds ratio of 0.34 (95% confidence interval of 0.23–0.75) adjusted for the other significant risk factors of chronic alcohol consumption, chemoradiation therapy, more advanced cancer stage, pneumonectomy, and increased fluid administration. For complications less severe than postoperative ALI, the data may not be as clear. Blank et al. [13] in a retrospective analysis of 1019 cases found, using multivariate logistic regression modeling, that higher tidal volumes were associated with a *decrease* in PPC but an increase in driving pressure was associated with an increase in complications. However, they noted that positive end-expiratory pressure (PEEP) of ≥5 cm H_2O was used in fewer than half of the patients and that 73.3% of the patients were ventilated with a tidal volume (V_T) > 5 mL/kg of predicted body weight. Liu et al. [11] performed a meta-analysis of 11 studies (657 patients) and found that a protective ventilatory strategy (tidal volume ≤ 6 mL/kg) decreases the incidence of postoperative pulmonary complications (OR 0.29 95% CI 0.15–0.57).

While the chosen ventilation strategy clearly has an immediate effect on oxygenation, the potential for opposing effects as well as many other important patient and surgical factors has made it difficult to determine the single best ventilation mode or even predict the best mode for an individual patient. Because there are so many options for ventilator parameters, e.g., tidal volume (V_T), pressure-controlled ventilation (PCV), volume-controlled ventilation (VCV), PEEP, and lung-opening procedures (LOP), few studies are directly comparable. The clinician needs a deep understanding of ventilation and gas exchange physiology and potential lung injury mechanisms [1] to place the clinical and animal studies into context and to be equipped for making appropriate clinical decisions.

Physiology of One-Lung Mechanical Ventilation (See Chap. 6 for a More Complete Discussion)

Although there is specific terminology describing certain "modes" of ventilation (e.g., pressure-controlled, volume-controlled, inverse I/E ratio, etc.), mechanical ventilation, in a fully paralyzed patient without any spontaneous ventilatory effort, fundamentally provides a time-varying pressure waveform at the interface between the lung and its external environment. For thoracic surgery, this is invariably at the proximal end of the ventilated lumen of the double-lumen endotracheal tube. The resulting movement of gas into and out of the lung depends on both this waveform and the resistance and compliance of the lung, chest wall, and endotracheal tube (the reader is referred to Chap. 7 of *Nunn's Applied Respiratory Physiology* [16] for a full discussion of the physiology). Even more germane, the flow of gas into and out of the individual gas-exchanging units depends on the relative airway resistance and alveolar compliance of each unit.

While this pressure waveform can be quite complex, obviously the key characteristic is a cyclic variation in pressure through a cycle of high (inspiration) to low (expiration). Several basic clinical measurements describe this waveform, including peak and plateau inspiratory pressure, inspiratory and expiratory times, inspiratory (tidal) volume, and end-expiratory pressure. This waveform not only determines the distribution of gas in the lung but, through changes in pulmonary vascular resistance and intrathoracic pressure, will influence regional perfusion and total cardiac output. The latter can become quite important during OLV, since the unventilated lung creates an obligate shunt and the oxygen level in the venous admixture directly determines arterial oxygenation.

While modern double-lumen endotracheal tubes and bronchial blockers, combined with the routine use of fiberoptic flexible bronchoscopy, have greatly reduced the incidence of hypoxemia during OLV [13–18], the selection of the mechanical ventilation mode clearly still plays a role. Hypoxemia during OLV is caused by venous admixture through shunts and areas of low ventilation/perfusion ratio (V/Q) gas-exchanging units. Thus, during OLV the collapsed lung is an obligate shunt, while the dependent lung also causes a venous admixture through shunt and areas of low V/Q. This is primarily through atelectatic areas of the lung seen with general anesthesia [19] and is perhaps increased with the lateral decubitus position through the weight of the mediastinum, abdominal organs, and low compliance of the chest wall in the dependent position [20, 21]. The ventilation strategy should therefore minimize perfusion to the collapsed lung and reduce areas of low V/Q in the ventilated lung. Since gas exchange not only involves providing adequate oxygenation but also adequate removal of CO_2, the total alveolar ventilation required is determined by the desired P_aCO_2. These considerations have resulted in the classic recommendation that tidal volume for OLV not be reduced (preventing atelectasis and maintaining elimination of CO_2) and the two-lung minute ventilation be maintained, often resulting in normocapnia to moderate hypocapnia with typical tidal volumes of 10 mL/kg. In this situation, the addition of PEEP causes a decrease in cardiac output and an increase in venous admixture, Fig. 22.1 [22].

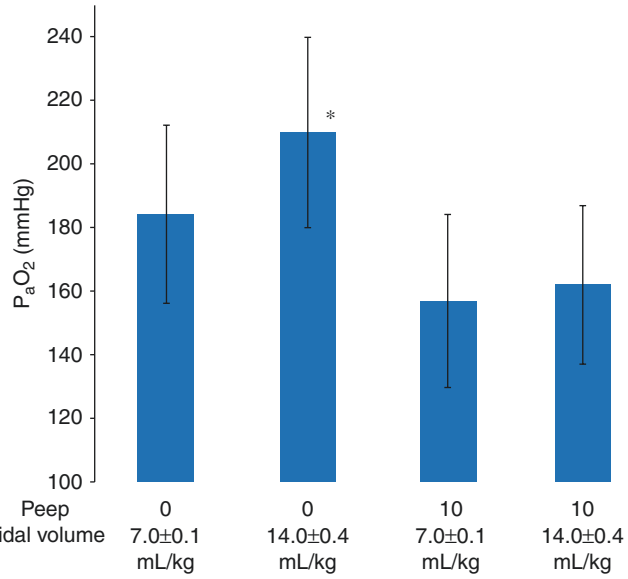

Fig. 22.1 Effect of 10 cm H_2O of positive end-expiratory pressure at tidal volumes of 8% and 16% of total lung capacity (approximately 7 and 17 mL/kg) during one-lung ventilation (OLV) (mean ± SEM, $n = 11$). Mean P_aCO_2 during all conditions was 35–38 mmHg. *$P < 0.05$ different from the other conditions by two-way ANOVA. P_aO_2 arterial oxygen partial pressure; FiO_2 fractional concentration of inspired oxygen; QT cardiac output; and QS/QT physiological shunt. (Based on data from Katz et al. [21])

Traditionally, the avoidance and treatment of arterial hypoxemia have been the essential concern of anesthesiologists during thoracic surgery with OLV [19]. Using the classic three-compartment model of gas exchange, the determinants of arterial oxygen content are hemoglobin concentration, hemoglobin dissociation curve (P_{50}), oxygen consumption, total cardiac output (Q_t) [23, 24], inspired oxygen fraction (F_iO_2) and arterial carbon dioxide (P_aCO_2) (both of which determine the alveolar oxygen level, P_AO_2), blood flow through the unventilated lung, and unventilated (or low V/Q) areas of the ventilated lung [19, 24]. The latter two factors are often lumped together as shunt (Q_s) or shunt fraction (Q_s/Q_t) [25]; however, when considering the effects of ventilation on arterial oxygenation during OLV, it is often better to consider the blood flow through the unventilated lung ($V/Q = 0$) separately from the ventilation of the low V/Q areas of the ventilated lung, since ventilation strategy may have opposing effects on these causes of venous admixture. Changes in ventilation have both direct and indirect effects on these factors (Table 22.1). The first counter to hypoxemia during OLV is to utilize an F_iO_2 of 100%, and many anesthesiologists use 100% F_iO_2 routinely for OLV. The high-inspired oxygen concentration will reduce any residual hypoxic pulmonary vasoconstriction and increase P_AO_2 in the ventilated lung [26]. While concerns have been expressed about the absorption atelectasis caused by high F_iO_2 and the possibility of oxidative damage to the lung, neither of these

Table 22.1 Effects of different ventilatory strategies on the determinants of arterial oxygenation

Determinants of arterial oxygen content	Effect of changes in ventilation
P_{50} of the hemoglobin dissociation curve	Increased ventilation will cause a respiratory alkalosis, left shifting the curve (↓ P_{50}). While this may increase arterial saturation, unloading of oxygen in the tissue may be impaired
	Decreased ventilation will cause a respiratory acidosis, right shifting the curve (↑ P_{50}). While this may decrease the arterial content when the P_aO_2 is low, this may be offset by the increased ease of unloading O_2 at the tissue (increased tissue PO_2)
Arterial carbon dioxide (P_aCO_2)	Hyperventilation lowers the P_aCO_2 and, for a given inspired oxygen tension (F_iO_2), will increase the alveolar oxygen (P_AO_2), while hypercapnia will lower the P_AO_2. These are relatively small effects except at the extremes of P_aCO_2
Total cardiac output (Q_t)	Increased ventilation requires a higher mean alveolar pressure which can reduce the cardiac output via a decreased venous return and increased right ventricular afterload
Blood flow through the unventilated lung (Q_s)	Increased ventilation and/or increased PEEP to the dependent lung (higher mean alveolar pressure) may cause more blood to be diverted away from the ventilated lung and increase the blood flow to the unventilated lung
Blood flow through the unventilated (atelectatic or low V/Q) areas of the ventilated lung	Lower tidal volumes and/or ZEEP (zero end-expiratory pressure) may result in more atelectasis and shunt in the ventilated lung

factors have been explicitly studied as a possible contributor to postoperative ALI. Utilizing continuous positive airway pressure to the unventilated lung, while not possible in many procedures, e.g., video-assisted thoracotomy (VATS), this maneuver most often will ameliorate any significant hypoxemia [19, 27]. Since selection of the F_iO_2 and the use of continuous positive airway pressure are not ventilatory strategies, they will not be discussed further in this chapter.

By not decreasing total V_T during OLV, the distension of the ventilated lung is essentially doubled. That is, if two-lung total ventilation is typically a V_T of 10 mL/kg (5 mL/kg/lung) with a rate of 8–12 breaths/minute, going to OLV would be the equivalent of increasing the total tidal volume to 20 mL/kg when still ventilating two lungs. With the increasing use of a lung-protective strategy of $V_T < 6$ mL/kg for two-lung ventilation, decreasing V_T by half for OLV may be unnecessary, as alveolar recruitment occurs without significant increase in plateau pressures [1, 12–14]. In addition, the distribution of ventilation is not uniform and is determined by regional airway resistance and alveolar; thus low-resistance, high-compliance alveoli may be greatly overdistended by

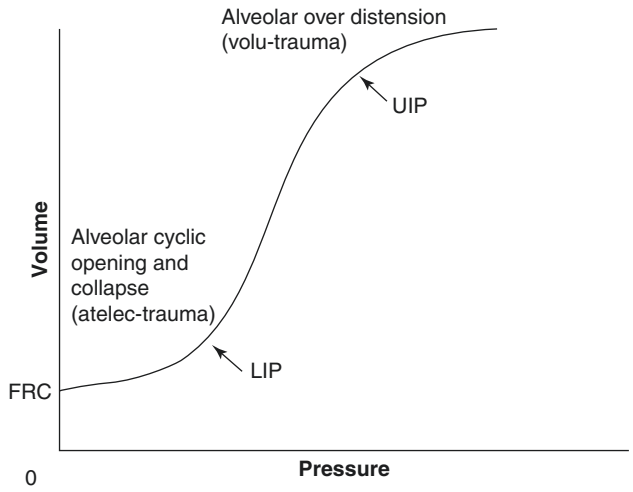

Fig. 22.2 Idealized lung pressure-volume curve. Under anesthesia, the functional residual capacity (FRC) falls too close to the residual volume, potentially causing a relatively noncompliant lung at low airway pressures as atelectatic regions of the lung are opened. At high airway pressures, the limits of distensibility may be reached. The lower inflection point (LIP) represents the pressure when the compliance increases as all atelectatic regions are opened; the upper inflection point (UIP) represents the pressure when alveoli are becoming less compliant due to overdistension

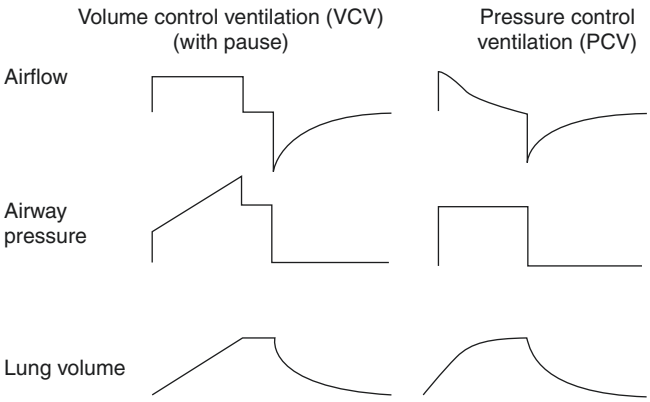

Fig. 22.3 Pressure, flow, and volume generated by constant flow or volume-controlled ventilation (VCV) (left) and constant pressure or pressure-controlled ventilation (PCV) (right). The constant flow ventilator incorporates an end-inspiratory pause, resulting in peak and plateau pressures, while the constant pressure ventilator only has a plateau pressure. With PCV, the airflow constantly declines from the initial maximum

such high tidal volumes. The pressure-volume curve for the whole lung has an idealized sigmoid shape (Fig. 22.2). The relatively low compliance at low pressures represents the pressure needed to inflate the atelectatic collapsed portions of the lung, and the flatter, less compliant portion at high pressures represents the limits of elasticity. Tidal volumes at the lower end of the curve (no PEEP) may involve opening and closing atelectatic areas of the lung (atelectrauma); tidal volumes at the upper end (high PEEP) may cause barotrauma. However, Slinger et al. [27] actually measured the single-lung compliance curve, and while approximately a quarter of their patients did not have a lower inflection point, at volumes of 1500 mL or a maximum pressure of 30 cm H_2O, there was no decrease in compliance (no upper inflection point).

Modes of Mechanical Ventilation for OLV in the Operating Room

While modern operating room ventilators have a wide range of settings, a primary variation between ventilator types is the pressure waveform generated by a constant inspiratory *pressure* vs. a waveform generated by a constant inspiratory *flow*. These types are commonly referred to as pressure-controlled ventilators (PCV) and volume-controlled ventilators (VCV). The resulting V_T may be the same, but the pressure and flow waveforms are quite different, although when the constant flow ventilator is used with an end-inspiratory pause, the differences in the change in lung volume with time are not as pronounced (Fig. 22.3). There are three main areas of controversy in selecting the ventilation mode for OLV: (1) pressure vs. volume ventilation, (2) high vs. low tidal volume, and (3) use of PEEP. Until recently, most studies focused on which mode would most improve oxygenation. However, the use of modern double-lumen tubes (DLTs) or bronchial blockers correctly positioned with bronchoscopic confirmation has actually greatly reduced the incidence of clinically significant hypoxemia [18]. Since the pulse oximeter permits continuous monitoring, saturations in the high 80s are frequently well tolerated (by both the patient and the anesthesiologist) during OLV. Current research has thus focused more on the ventilator mode, primarily high vs. low tidal volume, to prevent PPC and ALI.

Pressure- Versus Volume-Controlled Ventilation

The two primary modes of ventilation commonly used in the operating room are either PCV or VCV. Short-term effects of PCV or VCV on oxygenation during OLV as well as possible effects of VILI postoperatively are controversial. No definitive studies can conclusively provide specific recommendations. As can be seen from Fig. 22.3, the difference in the waveforms produced by the modes results from the decreasing airflow with PCV, when compared with the constant airflow with VCV. By adding an end-inspiratory pause to VCV, the volume trajectories of the two modes are not too dissimilar. Figure 22.4 illustrates the airway and average alveolar pressures that are generated by each of the two waveforms. The peak pressure generated by VCV for a given tidal volume

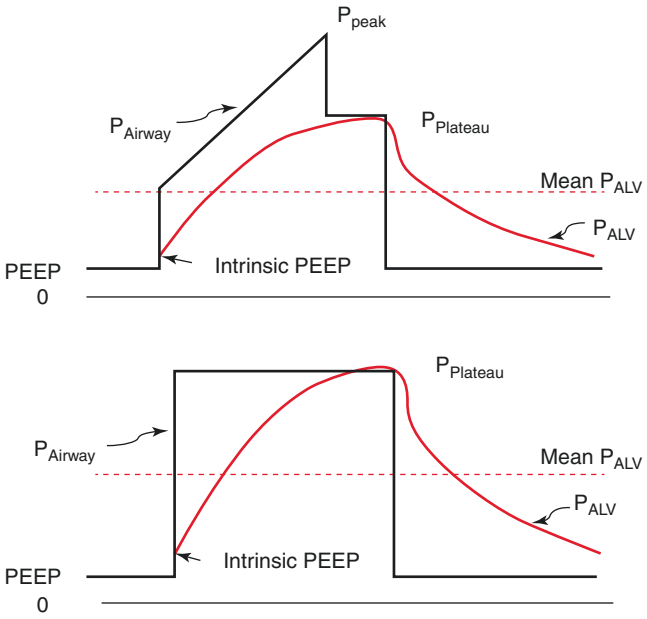

Fig. 22.4 Comparison of the airway (P_{airway}, black line) and alveolar (P_{ALV}, red line) pressures for VCV (top) and pressure-controlled ventilation (bottom). For VCV, both a peak (P_{peak}) and a plateau ($P_{Plateau}$) are observed. The difference between these pressures represents the resistance to gas flow. The PCV has only a plateau pressure

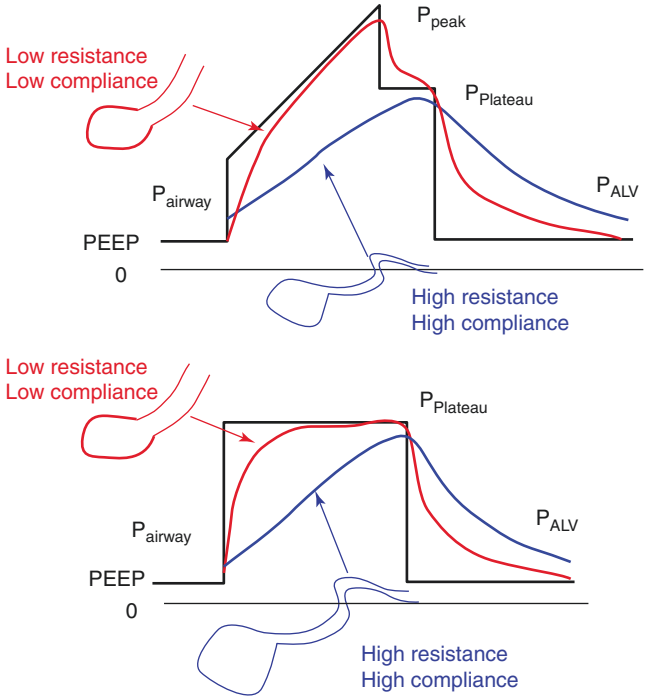

Fig. 22.5 The distribution of inspiratory pressure to different areas of the lung with different time constants for VCV (top) and PCV (bottom)

is due to both airway resistance and compliance, and the plateau pressure is due to the dynamic compliance (the difference between the peak and plateau pressure is determined by the airway resistance and flow). The plateau pressure for both modes is representative of the average maximum alveolar pressure and the resulting tidal volume. The mean airway pressure (the time-averaged pressure over the whole inspiratory-expiratory cycle) determines the average lung inflation.

Another way of looking at the two modes is that PCV has a high peak inspiratory flow, which is limited in VCV, while VCV has a high peak airway pressure that is limited in PCV. Although primarily based on animal studies, both high peak inspiratory flows [28] and high peak airway pressures [29] may contribute to VILI. By limiting the tidal volume and maintaining an adequate inspiratory time, both these factors can be minimized for either PCV or VCV. It is important to note that in acutely injured and inflamed lungs, the heterogeneity of the compliance, airflow resistance, and capillary blood flow of alveolar units result in a very uneven distribution of airflow, volume, and pressure throughout the respiratory cycle (Fig. 22.5). This may cause gross overinflation (volutrauma) of some units even though the airway pressure and total tidal volume are both limited. Both VCV with an end-inspiratory pause and PCV may permit a better distribution of the inspiration across alveolar-capillary units with different airflow time constants because of the relatively longer time at full inspiration. However, this distribution fundamentally requires an adequately long total inspiratory time. This lengthened inspiratory time may be difficult during OLV because of the conflict between the need to increase the respiratory rate (to compensate for the lower tidal volumes now recommended) and the concern about development of intrinsic PEEP as the expiratory time becomes crowded out (see next sections of this chapter).

Prella et al. [30] found that in patients with ARDS, the use of PCV permits lower peak airway pressures when tidal volumes of 9 mL/kg are used. However, no differences in blood gas values were observed. Although not commonly available in the operating room, VCV with a decreasing inspiratory flow pattern (rather than the constant inspiratory flow pattern shown in Fig. 22.3) seems to provide all the advantages of PCV but limits the possible damaging effects of the initial high peak flow seen with PCV [31–33].

There have been a few direct comparisons of VCV and PCV in laparoscopic surgery [34, 35] and in thoracic surgery [36–39]. In general, these studies have shown either no or only small improvement in oxygenation with PCV over VCV. All studies for OLV used relatively large tidal volumes (9–10 mL/kg) with resulting normocapnia to mild hypocapnia. Among the four studies, only Tugrul et al. [38] showed a significant statistical improvement in P_aO_2, and that

improvement was not clinically significant since the average S_aO_2 was above 98% with either mode. All studies used a 10% inspiratory pause during VCV. The addition of an end-inspiratory pause in this type of ventilation can help with distribution of the inspired gas and improve oxygenation, but, particularly in patients with chronic obstructive pulmonary disease undergoing OLV, a reduction in expiratory time to accommodate the end-inspiratory pause may increase intrinsic PEEP and reduce oxygenation [40]. No clinical studies have looked at PCV vs. VCV for prevention of post-thoracotomy lung injury. A meta-analysis of research about mechanical ventilation strategies during OLV published by Liu et al. [11] concluded that current data are insufficient to determine any decreased risk of postoperative lung injury when using PCV as opposed to VCV.

Monitoring for changes in airway pressure for VCV and in tidal volume for PCV can provide important early warning indicators of a malpositioned DLT. A possible advantage of PCV is that the tidal volume alarms can be set for increases or decreases from the current tidal volume. An increase in resistance or compliance (e.g., a left-sided DLT migrating into the left lower lobe during left lung ventilation) would cause a decrease in the delivered volume (for the set pressure) and would thereby sound the low-volume alarm. Alternately, a leak from the left side to right (e.g., from a leak around the bronchial cuff into the left lung when ventilating the right lung with a left DLT) would cause an increase in the delivered volume (but often a decrease in the returned volume, resulting in the bellows of the ventilator not completely filling if the fresh gas flow is low enough). For VCV, the airway pressure would increase if the left-sided DLT migrated into the left lower lobe orifice, but for a partial leak, only the loss of the full return volume would cause an alarm. Whichever mode is used, the anesthesiologist should carefully set the appropriate alarms close to the volume currently being delivered and understand the likely causes for any alarm activation. A timely response to an alarm, by repositioning the DLT under bronchoscopic guidance, can often prevent desaturation or unwanted inflation of the operative lung.

High Versus Low Tidal Volume

In a patient with ARDS, there is strong evidence that a lung-protective strategy improves outcomes [41–43] although Putensen et al. [43] have pointed out that there are still only a limited number of randomized controlled trials. This lung-protective strategy may include tidal volume of <6 mL/kg and plateau pressure below 25 cm H_2O, with the respiratory frequency adjusted to maintain CO_2 elimination (normocapnia to mild hypercapnia) and PEEP as needed to improve oxygenation without increasing the plateau pressure above 30 cm H_2O. This ventilation strategy is intended to prevent both the cyclic opening and closing of collapsed alveoli at the start of inspiration (atelectrauma) as well as the overdistension (barotrauma) of some alveoli at the end of inspiration (Fig. 22.5) [44–46]. The mild to moderate hypercapnia and respiratory acidosis induced by this strategy are not thought to be harmful [47, 48], and may even have some beneficial effects [49]. The basic mechanisms for low tidal volumes providing protection are not entirely known, but the prevention of the induction of a pulmonary and systemic inflammatory response seems to be the common pathway [30, 50–52]. Of interest, there is increasing evidence that a further reduction in tidal volume may be beneficial even when the P_{peak} is less than 30 cm H_2O [53] and a significant hypercapnia can be tolerated.

A low tidal volume protective strategy is not without drawbacks. In the PROVHILO trial [53], it was reported that the low tidal volumes in combination with high PEEP (12 cm H_2O) and LOPs led to an increased incidence of intraoperative hypotension and use of vasoactive medications without any decrease in PPC compared to low PEEP (2 cm H_2O). Although this study was not in thoracic patients, it might be expected that in OLV, with its obligate increased shunt, any decrease in cardiac output could cause significant hypoxemia. However, Ferrando and Belda [54] utilized a PEEP decrement trial to individualize PEEP (average of 10 cm H_2O) which did not decrease the cardiac index relative to the control group (fixed PEEP of 5 cm H_2O).

One point does need clarification, and that is whether the tidal volume is expressed as mL per actual or per PBW. Since lung volume is more closely related to height than body weight, using actual body weight may result in particularly large tidal volumes in short, obese individuals. It is better to set the tidal volume on the basis of PBW. PBW is calculated in males as PBW (kg) = 50 + 2.3 (height (in) −60) and in females as PBW (kg) = 45.5 + 2.3 (height (in) −60) [55]. The tidal volume recommendations in this chapter are based on PBW.

Although the anesthesiologist may be more concerned about acute intraoperative hypoxemia [19], the not infrequent rate of ARDS or ALI following thoracic surgery [4, 5, 10, 56, 57] has brought into focus the question of using a lung-protective strategy during OLV [58]. While the use of such a strategy during OLV has been controversial [59, 60], a recent large observational study [15] and other smaller clinical studies examining risk factors for ALI following OLV [3, 9] support the use of such a protective strategy. Fernández-Pérez et al. [4] found an odds ratio for postoperative respiratory failure after pneumonectomy of 1.56 (95% confidence interval of 1.12–2.23) per each mL/kg of PBW (Fig. 22.6).

However, the use of lower V_T during anesthesia has been implicated in the development of intraoperative atelectasis

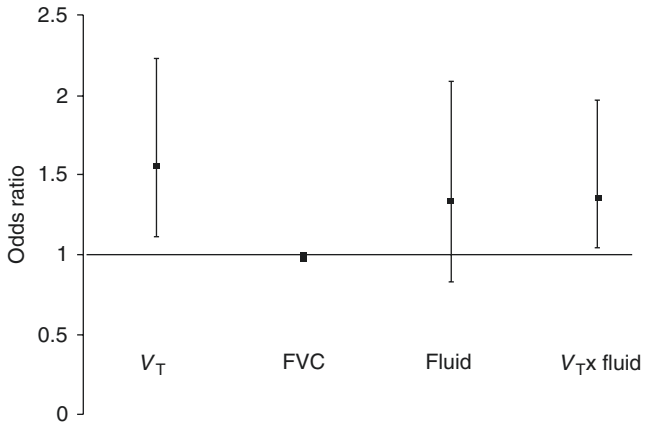

Fig. 22.6 Risk factors associated with postpneumonectomy acute lung injury. Odds ratio and 95% confidence interval from multivariate logistic regression analysis: V_T (tidal volume) is per each mL/kg predicted body weight; FVC (forced vital capacity) is for each percent decline; fluid is for each liter of fluid infused intraoperatively; and V_T × fluid is the cross product in the logistic regression model. (Based on data from Fernández-Pérez et al. [4])

which may contribute to both intraoperative hypoxemia and postoperative lung injury [60]. Levin et al. [61] in a large retrospective study found that a low tidal volume with minimal PEEP actually increased the 30-day mortality and suggested that a low tidal volume strategy is helpful only with used with PEEP.

The role of V_T in influencing the development of lung or systemic inflammatory markers in patients without ALI undergoing short-term mechanical ventilation has been investigated in several studies, with some finding a correlation [60, 62, 63] but others not finding that high tidal volumes had a pro-inflammatory effect [61]. In addition, other factors may also play a role in the development of inflammatory markers following OLV [63–66], including genetics [62, 66], the length of time of OLV [67, 68], and the patient's capacity to handle an oxidative stress [69].

The recommendations for low tidal volumes even in patients without ALI [70, 71] are based on the observed synergistic effects of high tidal volume with other lung injuries that might by themselves be subclinical ("two hit" hypothesis) [72]. This is clearest in situations where the second lung injury occurs during high tidal volume ventilation in previously healthy lungs or in a patient with developing ALI [70]. It is not as clear if the same synergism applies when the nonprotective ventilation occurs for a short period of time (intraoperative) and precedes rather than is concurrent with a second event that could cause lung injury.

Until there is a definite prospective clinical trial of sufficient size to decide the question, several factors must be considered when deciding the best strategy to use. First, as noted previously, OLV requires relatively high tidal volumes to a single lung to ensure even normocapnia to moderate hypercapnia. The recommended lung-protective ventilation of 6 mL/kg is only 3 mL/kg/lung. Thus, with two-lung ventilation, 6 mL/kg may require a frequency of 12–16 breaths/min to maintain moderate hypercapnia (P_aCO_2 40–55 mmHg); initiating OLV and maintaining the 3 mL/kg/lung tidal volume may require a frequency of over 20 breaths/min and still may result in excessive hypercapnia. This rapid rate, together with the high-resistance DLT, may not permit adequate exhale time, and excessive intrinsic positive end-expiratory pressure (PEEPi) may occur [73]. The best current recommendation is to use a lower V_T, < 6 mL/kg (PBW) and preferably 4–5 mL/kg if moderate hypercapnia can be maintained without excessively rapid ventilatory rates.

Positive End-Expiratory Pressure

The use of PEEP is a mainstay for increasing oxygenation in patients with ARDS or ALI [74]. It can also be useful in preventing cyclic opening and closing of atelectatic areas of the lung (see Figs. 22.2 and 22.7), thus potentially reducing VILI in these patients. By increasing the functional residual capacity, PEEP can prevent the closure of alveoli at the end of expiration and accomplish both an increase in oxygenation and a reduction of VILI. However, the optimal level of PEEP for both objectives is still controversial [75]. The ARDS Clinical Trials Network investigators found no difference in outcomes in patients with ARDS with either low PEEP (8.3 ± 3.2 cm H_2O) or higher PEEP (13.2 ± 3.5 cm H_2O) adjusted to maintain oxygenation [75]; subsequent studies have confirmed this finding [76, 77]. However, there is still no clear means of determining the "optimal" PEEP in ARDS/ALI [67], and there may even be subgroups that would particularly benefit from a higher level of PEEP (while maintaining the peak airway pressure below 30 cm H_2O) [77, 78].

The factors considered for selecting PEEP for the ventilated lung in OLV differ from the factors determining PEEP in ARDS/ALI patients. First is the level of intrinsic PEEP (PEEPi) that is already present; second is the fact that the presence of the large shunt fraction in OLV is due to the blocked ventilation to the nondependent lung rather than to the heterogeneous lung injury in ARDS. Intrinsic PEEP results from incomplete emptying of the lung back to its passive recoil equilibrium by the start of the next inspiration (end exhale) and can result from factors related both to the patient (lung resistance and compliance) and to the mechanical ventilation (endotracheal tube expiratory resistance, tidal volume, and exhale time). Patients undergoing thoracic surgery with OLV are at risk for developing PEEPi (Fig. 22.8a) [80, 81]. However, the magnitude of PEEPi is not correlated with P_aO_2 during OLV (Fig. 22.8b) [79, 80]. It is important to remember that the magnitude of PEEPi is not indicated on the usual airway pressure manometer, but requires a special

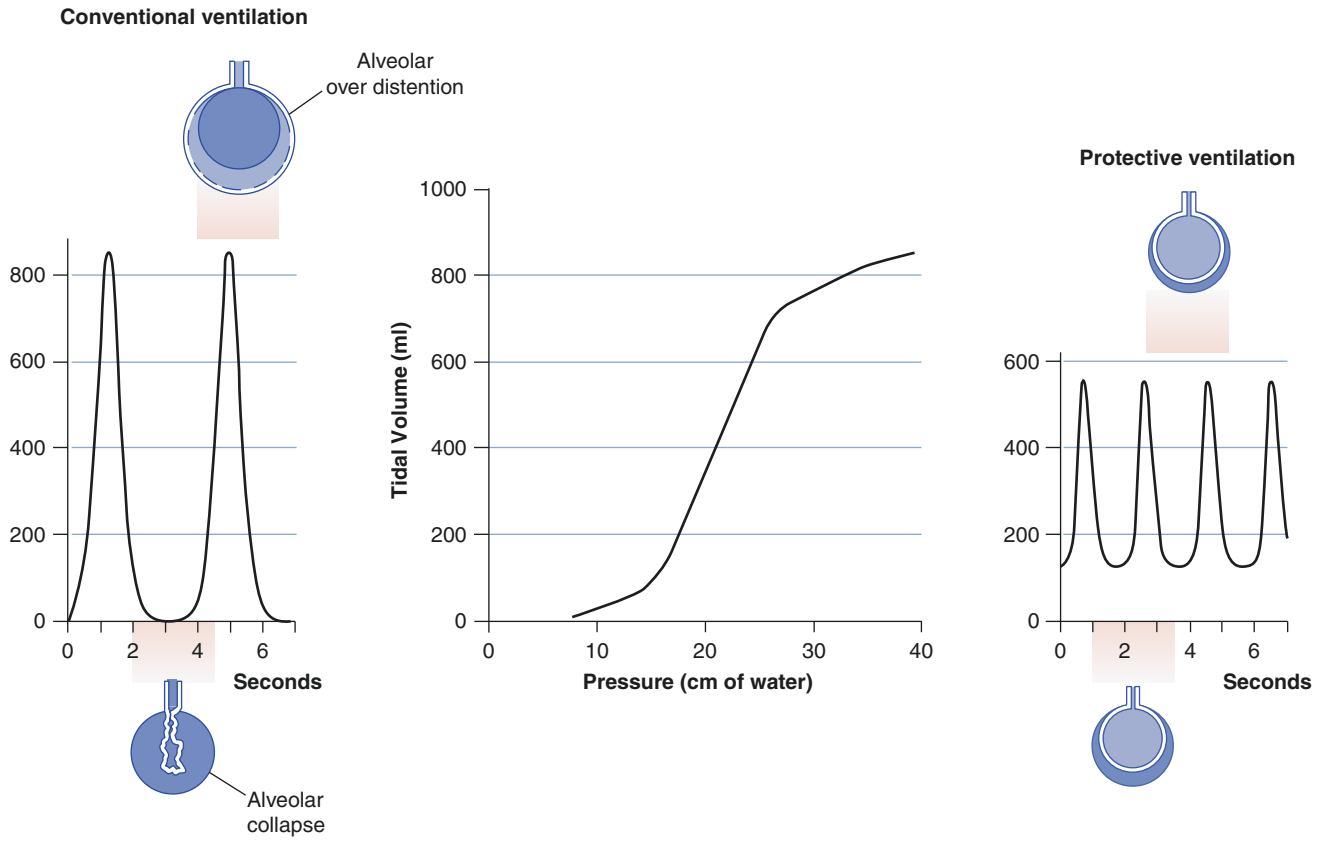

Fig. 22.7 The pressure-volume curve shown in the middle represents the compliance curve of a patient with acute respiratory distress syndrome. At low volumes, compliance is increased because of alveolar collapse, and at high volumes, it is decreased because of overdistension. In the illustration, these inflection points occur at 14 and 26 cm H_2O, respectively. With conventional high tidal volume (12 mL/kg) and no PEEP, alveoli collapse and are overdistended on every breath (left). With low tidal volumes (6 mL/kg) plus PEEP (LIP plus 2 cm H_2O), the tidal volume range stays in the nondistended, noncollapsed region (right). Note the increase in respiratory frequency with low tidal volume to maintain CO_2 elimination. (Reprinted with permission from Tobin [44]. © 2001 Massachusetts Medical Society. All rights reserved)

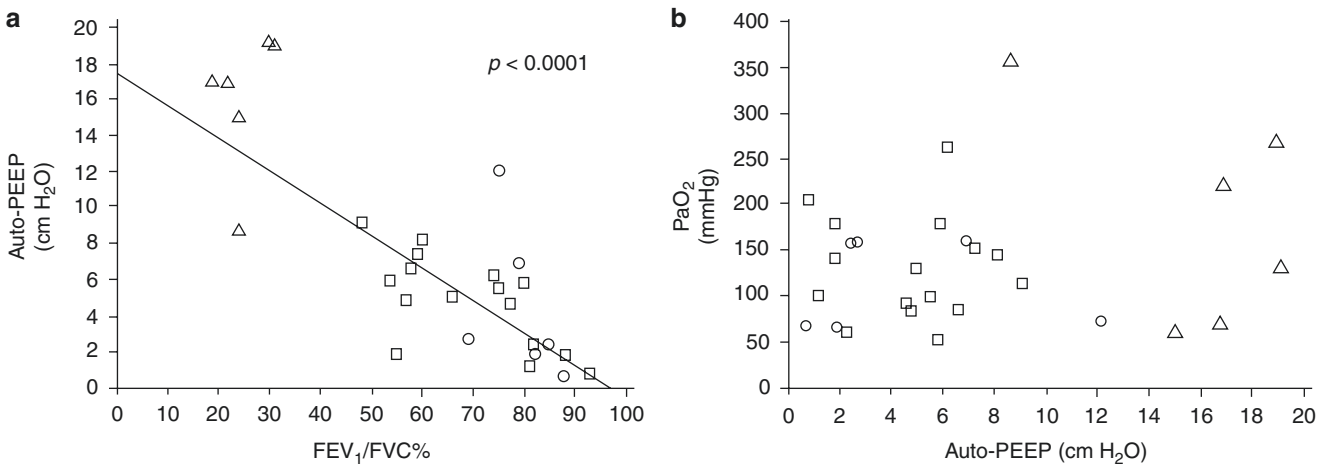

Fig. 22.8 The amount of intrinsic positive end-expiratory pressure (auto-PEEP) was measured in patients with moderate or no obstructive lung disease (open circle), severe emphysema (open triangle), or severe fibrotic lung disease (open square) during OLV with tidal volumes of 10 mL/kg and respiratory rates of 10–12. The amount of PEEPi was inversely related to FEV1/FVC% (**a**). PaO_2 was not correlated with PEEPi (**b**). (Reprinted from Ducros et al. [79]. © 1999 with permission from Elsevier)

maneuver to determine its presence [82, 83]. Additional factors to be considered include the relationship between PEEP and total cardiac output and relative blood flow between the ventilated and unventilated lungs. As PEEP is increased, the average alveolar pressure increases and causes compression of the pulmonary vasculature, increasing the pulmonary vascular resistance in the ventilated lung. This increased resistance may cause more blood to flow to the nonventilated lung, resulting in a greater venous admixture. In addition, the increased afterload on the right heart and increased intrathoracic pressure may decrease total cardiac output and reduce the mixed venous oxygen hemoglobin saturation, also resulting in an increased venous admixture. These negative effects of PEEP are countered by the improved oxygenation of the ventilated lung by assuring more open alveoli. It is not surprising that clinical studies of the effects of PEEP on arterial oxygenation during OLV have shown conflicting results [25, 79]. Current evidence does show that high tidal volume ventilation without PEEP causes injury, but low tidal volume ventilation without adequate PEEP may also [61].

Early studies of the best ventilatory pattern during OLV indicated that external PEEP tended to decrease P_aO_2; in these studies, the best ventilatory strategy was for relatively large tidal volumes and no PEEP to the ventilated lung (Fig. 22.1) [22] unless continuous positive airway pressure with oxygen was applied to the unventilated lung [27]. More recent studies have generally confirmed this finding [83, 84], although there may be subgroups in which PEEP will improve oxygenation [85–89].

Ferrando et al. [54] investigated individualizing PEEP compared to a standardized 5 cm H_2O. They utilized a LOP upon initiation of OLV with subsequent VCV adjusted to a plateau pressure of ≤25 cm H_2O in both groups. The individualized PEEP was selected by decrementing PEEP from 20 cm H_2O to determine the PEEP that yielded the maximum dynamic compliance. The resulting individualized PEEP was 10 ± 2. Oxygenation was high in the individualized PEEP group both during and after OLV without a difference in cardiac index. However, since 100% oxygen was used, no patient in either group was hypoxemic.

Since PEEPi is so common in OLV, it is important to understand the complex relationship between external PEEP and PEEPi: actual total PEEP is different from applied, measured PEEP, depending on preexisting PEEPi [80, 81]. The interaction between applied PEEP and PEEPi is not straightforward, although it is apparent from the study by Slinger and Hickey [73] that total PEEP does not increase greatly beyond PEEPi until the added PEEP approaches the value of PEEPi. It has been suggested that applying an external PEEP equal to PEEPi results in the best oxygenation [85], but PEEPi is not readily measurable in the operating room. Slinger et al. clarified the effects of PEEP on oxygenation in a study measuring the static lung compliance curve [27]. By measuring the static compliance curve, the lower inflection point (Fig. 22.2) could be identified. Without the application of external PEEP, the lower inflection point was 4.5 ± 3.5 cm H_2O, but no lower inflection point could be identified in 24% of the 42 patients studied. The value of the lower inflection point was not significantly changed by the addition of 5 cm H_2O of external PEEP. When patients were ventilated with a tidal volume of 10 mL/kg at a rate of 10 breaths/min, the measured PEEPi was 4.2 ± 3.4 cm H_2O, and the total PEEP with 5 cm H_2O added externally was 6.8 ± 1.8 cm H_2O.

Overall, no significant improvement in oxygenation was observed with the addition of PEEP. However, improvements in oxygenation were seen when total PEEP was closest to the lower inflection point. Thus, external PEEP improved oxygenation depending on the relationship between the lower inflection point, intrinsic PEEP, and total PEEP at the time external PEEP was added. The minority of patients benefiting from external PEEP had a larger lower inflection point pressure and had good elastic recoil. Presumably this good recoil resulted in an end-expiratory lung volume in the dependent lung during OLV below the normal functional residual capacity with resulting atelectasis and increased vascular resistance.

Lung Opening Procedures

Atelectasis commonly occurs even in healthy lungs under general anesthesia, and the cyclic opening and closing of atelectatic areas of the lungs (Fig. 22.7) during mechanical ventilation may contribute to VILI (atelectrauma) [60]. Even with a lung-protective ventilation strategy, it may be necessary to periodically apply higher pressures, on both inspiration and end-expiration, to open atelectatic areas of the lung [90]. Such maneuvers are often called “alveolar recruitment” or “lung opening” maneuvers [91]. While such a strategy may improve oxygenation in the heterogeneously inflamed lung of ARDS, there may not be any decrease in mortality when combined with established low-tidal volume lung-protective ventilation [76, 92].

The use of an open-lung procedure during OLV has been proposed, not to reduce VILI by prevention of atelectrauma but rather to prevent or treat intraoperative hypoxemia. As with the use of PEEP, in OLV the open-lung procedure in a noninflamed lung is quite different from its use in ARDS or ALI. However, areas of atelectasis in the dependent lung may benefit from a lung-opening procedure. While the details of the procedure vary somewhat, in essence it consists of several breaths (often 6–10) at an inspiratory pressure of 40 cm H_2O and a PEEP of 20 cm H_2O. There is also a several-breath “ramp-up” to these high pressures. Tusman et al. [92] found that such a lung recruitment procedure, when combined with a tidal volume of 6 mL/kg (peak pressures less

than 30 cm H_2O), respiratory rate of 15–18, and a PEEP of 8 cm H_2O, significantly increased P_aO_2 (see Chap. 6, Fig. 6.8). Subsequently, Cinnella et al. studied the physiological effects of a lung recruitment procedure during OLV with a tidal volume of 8 mL/kg and a respiratory rate of 12 and found a similar lasting increase in P_aO_2 [93]. They also noted a decrease in cardiac output and mean arterial pressure during the maneuver, but the hemodynamic variables returned to baseline following the maneuver.

Conclusion

Anesthesiologists have many options to consider in determining the intraoperative ventilation, and there is no definite evidence supporting a single strategy to prevent intraoperative hypoxemia, intraoperative alveolar injury, and postoperative ALI. Brassard et al. [14] has provided one "step-by-step" approach to the management of OLV. Current evidence supports a strategy to maintain end-inspiratory plateau pressures no greater than 30 cm H_2O, preferably less than 25 cm H_2O. To do so, tidal volume should be reduced to a range of ≤6 mL/kg of PBW during OLV, and respiratory rate increased to maintain normocapnia to moderate hypercapnia (P_aCO_2 in a range of 40–50 mmHg). Using the measured P_aCO_2 (the $P_{ET}CO_2$ can be used as a guide, but there is often a significant gradient between the two) greatly facilitates the adjustment of the ventilator, but an initial ventilator setting should be based on ideal or PBW, since lung volume is more closely related to height than to actual weight. Caution is warranted if the respiratory rate must be increased above the mid-teens, since excessive PEEPi may develop, causing a reduced cardiac output and hypoxemia. The initial use of low to moderate PEEP (4–8 cm H_2O) is probably unnecessary to maintain adequate oxygenation, but the use of low to moderate PEEP is often used to prevent atelectrauma and may reduce PPC. The individualization of PEEP may be necessary to optimize oxygenation. However, the actual total PEEP may not change significantly with the addition of low external PEEP because of the probable existence of PEEPi during OLV. Either PCV or VCV can be used, as long as proper monitoring for changes in airway pressure and tidal volume is maintained. This ventilation strategy should prevent intraoperative hypoxemia in most patients and may even reduce the incidence of postoperative VILI, particularly in high-risk situations (e.g., pneumonectomy, patients with a history of alcohol abuse, large intraoperative fluid requirements, men over 60 years old, longer OLV, fresh frozen plasma administration, and/or preexisting ALI). If intraoperative hypoxemia develops, then careful adjustment of PEEP and a lung-opening procedure can be tried. Of course, correct positioning of the DLT or bronchial blocker must be verified whenever there is hypoxemia during OLV, and continuous positive airway pressure with oxygen to the unventilated lung may be successful if compatible with the surgical procedure.

Clinical Case Discussion

A 72-year-old woman, with weight = 98 kg, height = 168 cm (BMI = 34.7, PBW = 60.3 kg), and a 43 pack-year smoking history (stopped smoking 2 weeks ago), presents for left upper lobectomy for small cell carcinoma via a left VATS. Past medical history includes hypertension, type 2 DM, and obstructive sleep apnea (CPAP at 10 cm H_2O nightly).

Preoperative pulmonary function testing showed:

- FVC = 2.82 L (57% predicted).
- FEV_1 = 1.58 (42% predicted).
- FEV_1/FVC = 56%.
- DLCO = 23.9 mL/min/mmHg (79% predicted).

A left 37 French DLT was placed without difficulty, and its correct position was confirmed via fiber-optic bronchoscopy. Two-lung ventilation was initiated, while the patient was supine with VCV incorporating a 10% end-inspiratory pause with a tidal volume of 550 mL and a rate of 10 breaths/min. Peak airway pressures were 22 cm H_2O and the $P_{ET}CO_2$ was 45 mmHg. SpO_2 = 98% on 100% oxygen.

(a) What mode of ventilation and inspiratory gas concentration would you use for initiating OLV? What tidal volume would you use?
   - Either PCV or VCV would be acceptable. Initial tidal volume should be set based on the PBW, typically at 4–6 mL/kg. 6 mL/kg × 60.3 kg PBW = 361 mL, so initial tidal volume should be reduced and the OLV peak and plateau pressures noted.

(b) After setting the tidal volume to 361 mL with a rate of 14 and 0 end-expiratory pressure (ZEEP), the peak inspiratory pressure is 28 cm H_2O, and the $P_{ET}CO_2$ is 49 mmHg. Is any further adjustment of the ventilator required? Would other clinical measurements be useful?
   - With the peak inspiratory pressure less than 30 mmHg (presumable if VCV is being used, the plateau pressure, which is more reflective of the alveolar distending pressure, will be less than the peak) and the end-tidal CO_2 at an acceptable level, no further adjustments are needed. Initially observing the end-tidal CO_2 ($P_{ET}CO_2$) can guide the respiratory rate setting, but a blood gas would be helpful because the increased alveolar dead space associated with this patient's COPD may result in a significant arterial to end-tidal gradient.

(c) What would your recommendation for PEEP be after making these adjustments?
- At low tidal volumes and in patients with ALI, PEEP may help reduce the opening and closing of atelectatic regions of the lung, improving oxygenation and possibly prevent further lung injury. However, a high PEEP may also reduce oxygenation during OLV by forcing more blood flow to the unventilated lung. PEEP up to 5 cm H_2O may be used but higher levels should be instituted cautiously.

(d) Thirty minutes after the start of OLV, S_pO_2 falls to 88%. What maneuvers could be employed to stabilize the S_pO_2?
- Whenever there is an acute decrease in the S_pO_2, after increasing the FiO_2, the position of the DLT must be carefully checked with a fiber-optic bronchoscopy. In this case entry of the left bronchial lumen into the left lower lobe orifice could result in the tracheal opening of the DLT to abut the carina and result in a decrease in right lung ventilation.

A lung opening procedure (LOP) with a few breaths of high PEEP and inspiratory pressure may also be of benefit, but caution must be exercised if there is any indication of hemodynamic instability.

If hypoxemia still persists after optimal positioning of the DLT and a LOP, then CPAP to the unventilated lung is the most reliable way of decreasing the venous admixture; however, this is unlikely to provide acceptable operating conditions for a VATS. Switching to PCV or increasing the end-inspiratory pause with VCV may be useful. With a large DLT and a respiratory rate of only 14, significant intrinsic PEEP is unlikely, but a reduction in the inspiratory rate (with perhaps an increase in the tidal volume) can be tried.

A blood gas should be obtained and the surgeon notified that it may be necessary to return to two-lung ventilation intermittently if the saturation falls any lower. Since a low cardiac output will cause hypoxemia during OLV, interventions to increase the cardiac output may be of value.

Anesthesia for Open Pulmonary Resection: A Systems Approach

23

E. Andrew Ochroch, Gavin Michael Wright, and Bernhard J. C. J. Riedel

Key Points

- Perioperative morbidity and mortality are common following lung resection, with most deaths (>75%) attributed to major adverse pulmonary events (MAPE; including pneumonia, acute lung injury [ALI], and acute respiratory distress syndrome [ARDS]).
- Perioperative risk can be managed by dividing risk into two broad categories: iatrogenic risk and patient-attributed risk. Clinical care pathways manage iatrogenic risk, while perioperative strategies that allow identification and optimal management of high-risk patients manage patient-attributed risk. These factors will improve outcomes and reduce hospital costs.
- Patient safety and the delivery of quality care, with emphasis on systems improvement, have emerged as central tasks for healthcare providers. In fact, benchmarking of data will increasingly allow patients to identify institutions that deliver on the value proposition – providing medical care that measures up in safety and quality and yet is delivered at significantly lower costs.

General Concepts

Perioperative morbidity and mortality are common following lung resection (Table 23.1). Importantly, while the studies summarized in Table 23.1 highlight an increasing incidence of morbidity and mortality with increased volume of lung resected [1], these studies consistently report a need for improved predictors of adverse postoperative outcome. Further, major adverse pulmonary events (MAPE; including pneumonia, acute lung injury [ALI], and acute respiratory distress syndrome [ARDS]) have a high rate of mortality and contribute singularly to most (>75%) perioperative deaths. While a decline in adverse outcome has been witnessed over the last 50 years, it is important that we continue to seek strategies to improve perioperative outcome following open lung surgery. Recent strategies that have contributed to a reduction in the incidence and the mortality associated with ALI/ARDS include surgical attempts to limit the volume of lung resected (e.g., performing a sleeve resection rather than a pneumonectomy) and protective lung ventilation strategies (tidal volume reduction proportional to the number of segments resected) [2].

Strategies to further improve surgical outcome require a global approach, with implementation of (1) clinical care pathways that reduce iatrogenic risk and (2) perioperative strategies that focus on identifying and optimally managing the high-risk patient to reduce patient-attributed risk. Clinical care paths should embrace safety and quality initiatives, which when implemented within clinical practice should encompass improvements in reliability (reduced variability), processes, and performance and be combined with cost measures to assess the value of the care delivered. With society increasingly intent on actualizing the value proposition of healthcare, we are obligated to deliver optimized quality care within the constraints of cost [7]. Driven by the unsustainable growth in healthcare expenditure – accounting for 10–16% of the gross domestic product in developed nations – the need to improve quality and reduce costs has rapidly become the mantra of the healthcare industry.

Table 23.1 Summary of key studies illustrating the incidence of perioperative morbidity and mortality associated with major lung resection

Author	Year	*N*	Morbidity	Mortality	Factors associated with mortality	Commentary
Kopec et al. [3]	1998		*All morbidities* 40–60%	*Right* vs. *left pneumonectomy* 10–12% vs. 1–3.5%		1. Review of literature on pneumonectomy. 2. Mortality has decreased significantly from 56.4% reported in www–1940.
Kutlu et al. [4]	1991–1997	1139		3.5%	*Cause of death* ALI/ARDS = 72.5%* Dysrhythmia = 12.5% Pneumonia = 5%* Pulmonary embolism = 5% Renal failure = 2.5% DIC = 2.5%	1. Review of all lung resections performed at an single institution. 2. While incidence of ALI/ARDS is low (3.9%), it is a leading cause of mortality. 3. >75%* of mortality is associated with major adverse pulmonary events.
Vaporciyan et al. [5]	2002	257	*MAPE only* 12.8%	*Overall mortality* 6.2%	*Mortality in patients without and with MAPE* 2.1% vs. 39.3%	1. Single institution review of pneumonectomy. 2. Smoking cessation within 1 month of surgery was only multivariate predictor of risk. 3. High mortality observed in patients that suffer a major adverse pulmonary event.
Dulu et al. [1]	2002–2004	2039	*Incidence of ALI/ARDS* 2.5%	*Mortality associated with ALI/ARDS* 40%	*Incidence (and mortality) of ALI/ARDS by type of lung resection* Pneumonectomy: 7.9% (50%) Lobectomy: 2.96% (42%) Segmentectomy: 0.88% (22%)	1. Review of incidence of ALI/ARDS following lung resections performed at a single institution. 2. Increased incidence of ALI/ARDS with increasing lung volume resected. 3. High mortality in patients that suffer from ALI/ARDS.
Tang et al. [2]	1991–1997 2000–2005	1376	*Incidence of ALI/ARDS* 3.2% 1.6%	*Mortality associated with ALI/ARDS* 72% 45%	Pneumonectomy rate = 17.4% of resections Pneumonectomy rate = 6.4% of resections	1. Review of incidence of ALI/ARDS following lung resections performed at a single institution over two time periods. 2. High mortality in patients that suffering ALI/ARDS. 3. Reduced incidence (and associated mortality) of ALI/ARDS after 2000 associated with two factors: (a) Aggressive strategies to avoid pneumonectomy. (b) Lung protective ventilation strategies (reduced tidal volume per number of resected segments).
Kozower et al. [6]	2002–2008	18,800		*Overall mortality 3.2%* *Composite major morbidity or mortality 8.6%*	68.3% thoracotomy 36.9% thoracoscopy Pneumonectomy rate 6%	1. STS database review. 2. 111 centers 3. Predictors of mortality include the following: Pneumonectomy ($p < 0.001$), bilobectomy ($p < 0.001$), American Society of Anesthesiology rating ($p < 0.018$), Zubrod performance status ($p < 0.001$), renal dysfunction ($p = 0.001$), induction chemoradiation therapy ($p = 0.01$), steroids ($p = 0.002$), age ($p < 0.001$), urgent procedures ($p = 0.015$), male gender ($p = 0.013$), forced expiratory volume in one second ($p < 0.001$), and body mass index ($p = 0.015$).

The Institute of Medicine's report on patient safety *To Err is Human: Building a Safer Health System* estimates that 100,000 people die each year from medical errors in US hospitals [8]. This report, a landmark study in modern medicine, is an important contributor to the current patient-safety movement, with patient safety and the delivery of quality care emerging as central issues in medicine and as central tasks for healthcare providers in the last decade. In fact, quality healthcare is now a worldwide goal. Consequently, an important paradigm shift occurred: with (1) emphasis shifting to systems improvement rather than exhortations to individual health professionals and (2) recognition that leadership in healthcare institutions is a key catalyst in improving patient safety and in the delivery of quality care. The Institute

of Medicine defines "quality" as "the degree to which health services increase the likelihood of desired health outcomes, consistent with current professional knowledge" and as such recommends six standards of care (safe, effective, patient-centered, timely, efficient, and equitable) to achieve the delivery of quality healthcare [9].

Additionally, economic factors, such as reimbursement programs, market forces, and globalization of healthcare, will continue to drive the need to deliver quality care. Hospitals will increasingly compete for patients on the grounds of quality at local, regional, and global (medical tourism) levels. In this regard, reimbursement programs, such as pay for performance (P4P) or refusal of payment for preventable "never events," will increasingly be used to link patient outcomes with reimbursement. Benchmark data will increasingly allow patients to identify institutions that deliver on the value proposition – providing medical care that measures up in safety and quality at a lower cost.

A Systems Approach

Continued improvement in patient outcome is feasible when one understands and manages the risk types found within the complexity of a patient presenting for thoracic surgery. This complexity originates in the patient's disease process and associated comorbidities (patient-attributed risk; Fig. 23.1) and within the complexity of the healthcare system (iatrogenic risk). The majority of risk is derived from the burden of disease and the comorbidities that patients present with. However, iatrogenic risk, the risk of adverse outcome associated with therapy (medical, including anesthesia, or surgical therapy, or lack thereof, imposed by a third-party, the healthcare provider), remains sizeable, with an estimated 100,000 deaths occurring each year in the USA [8]. Importantly, this risk is largely preventable.

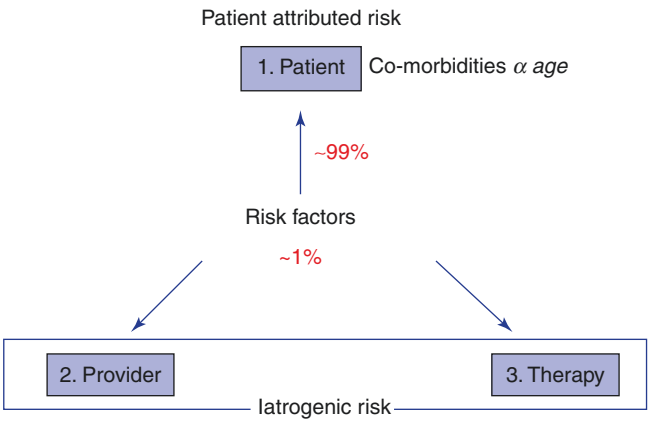

Fig. 23.1 Complexity and risk for adverse outcome originate in the patient's disease process and Associated comorbidities (patient-attributed risk) and within the complexity of the healthcare system (iatrogenic risk)

A strategy for understanding, examining, and improving care patterns, with the intended consequence of improved surgical outcome, and based on the two broad risk categories (iatrogenic and patient-attributed risk) is outlined in Fig. 23.2. This systems approach divides care into three broad areas based on decision points at Q1 and Q2.

Decision point Q1 delineates elective surgical care from emergent surgical care. While emergency procedures account for a small fraction of the thoracic surgical caseload, these patients nevertheless are often critically ill, have limited time for preoperative optimization, and are at significant risk for a protracted and costly length of hospital stay. Decision point Q2 delineates care into processes that (1) deliver the value proposition of the surgical procedure – delivering uncomplicated surgical outcome in a cost-effective manner through the implementation of clinical care pathways, thereby reducing iatrogenic risk – and (2) provide cost-effective perioperative risk stratification and optimization of high-risk patients, reducing patient-attributed risk and associated postoperative morbidity and mortality. The former processes are predominantly directed at the surgical disease and accompanying surgical procedure, while the latter are predominantly directed at the underlying disease burden and the medical comorbidities of the patient.

Patient Care Processes in Thoracic Anesthesia

The events involved between a patient presenting for thoracic surgery and having him/her discharged safely represent an extraordinarily complex system. This requires the collection, verification, and distribution of a large volume of information through multiple healthcare providers (including primary care physicians, pulmonologists, thoracic surgeons, oncologists, radiologists, cardiologists, nurse practitioners, and physiotherapists). Further complexity is added by the sophistication of the high acuity perioperative environment, with numerous perioperative physiological monitors and surgical instruments. A high volume of information must be processed in real time, communicated effectively throughout the operative team, and acted upon. Harm can originate at a multitude of levels [10]. The uncertainty and urgency inherent in the decision-making processes produce risk, which is compounded by external stressors, such as work load, fatigue, and a great degree of variability in organizational and/or environmental structures that support decision-making and physical tasks. After completion of the surgical procedure, patients then typically reside in the post-anesthesia care unit where care decisions are divided between anesthesiologists, surgeons, and the acute pain

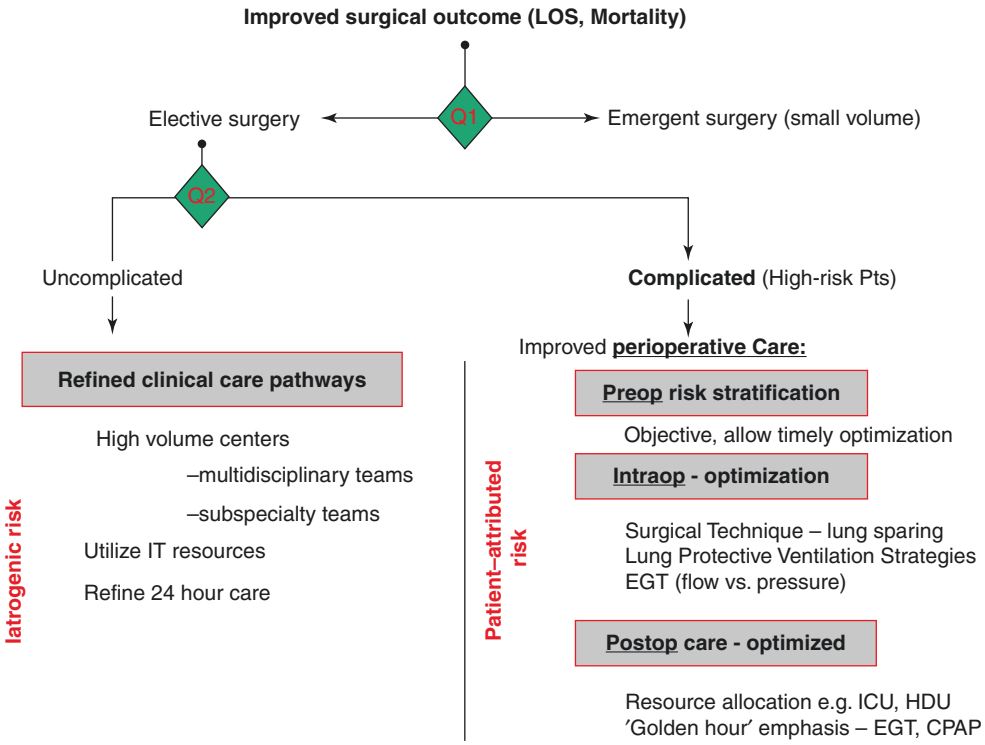

Fig. 23.2 A strategy for understanding, examining, and improving care patterns, with the intended consequence of improved surgical outcome. *CPAP* continuous positive airway pressure, *EGT* early goal-directed therapy, *HDU* high dependency unit, *ICU* intensive care unit, *IT* information technology, *LOS* length of stay, *postop* postoperative, *Q1 Q2* decision points

team, all of whom have ongoing responsibilities. Even when the patient is ensconced on the hospital ward, care for chest tubes, pulmonary toilet, X-ray follow-up, medication therapy, etc. requires a continuous flow of interactions and communication.

Recent progress in patient safety originates from the adoption of a systems analysis approach developed in other high-risk environments such as aviation. Vincent et al. [11] (among others) adopted these approaches for patient care (Table 23.2) and further modified these specifically to suite the perioperative care of the surgical patient (Table 23.3). Improved safety evolves from the study of this exhaustive list, which covers all aspects of the patient, the patient's interactions with the care team, the interaction among members of the care team, and the interactions of the patient and care team with the hospital environment. This has changed the focus of care from one of a surgeon's skill vs. the patient's disease to one of care that encompasses development of the care pathways that ensure consistent best practice regardless of the caregiver, individual performance within a team setting, optimal team coordination and communication, and the interaction of all of these aspects within the larger hospital organization/environment – all of which can help or hinder performance. Such approaches require a nonpunitive culture that promotes open dialog with a focus on improved patient outcomes.

Table 23.2 Framework of factors influencing clinical practice

Factor types	Influencing contributory factors
Institutional context	Economic and regulatory context
	National health service executive
	Clinical negligence scheme for trusts
Organizational and management factors	Financial resources and constraints
	Organizational structure
	Policy standards and goals
	Safety culture and priorities
Work environment factors	Staffing levels and skills mix
	Workload and shift patterns
	Design, availability, and maintenance of equipment
	Administrative and managerial support
Team factors	Verbal communication
	Written communication
	Supervision and seeking help
	Team structure (consistency, leadership, etc.)
Individual (staff) factors	Knowledge and skills
	Competence
	Physical and mental health
Task factors	Task design and clarity of structure
	Availability and use of protocols
	Availability and accuracy of test results
Patient factors	Condition (complexity and seriousness)
	Language and communication
	Personality and social factors

An important use of systems analysis to reduce medical errors focused on process improvement in transitions in care to decrease medical errors. In thoracic surgery the patient transitions from outpatient to preoperative holding, intraoperative care, PACU or ICU care, floor care, and then discharge/home care. Each instance of transition presents an opportunity for the failure to transfer critical information which may impact morbidity and mortality. While not yet studied in thoracic surgery, the I-PASS study focused on defining critical elements of transition of care and produced "bundles" of critical elements. The use of these bundles (a structured transition of care approach) at nine sites reduced medical error from 24.5 to 18.8 per 100 admissions $p < 0.001$ and preventable adverse events from 4.7% to 3.3% per 100 admissions $p < 0.001$ [10]. The greater acuity of thoracic surgical patients should increase the impact of such improvements in care.

While there have been few specific studies of a systems approach in thoracic surgery, clear examples abound. Although controversial, increasing data support benefits through reduced morbidity and improved survival in patients having high-risk operations performed by subspecialty-trained surgeons [12, 13]. Such results are especially evident in esophageal cancer surgery, colorectal cancer surgery, and vascular surgery [12–16]. It is unclear if this is purely a volume effect, i.e., greater numbers of surgeries produce better results. A study of 40,460 thoracic surgeries captured by the 2007 Nationwide Inpatient Sample (NIS) indicated that volume only accounted for outcomes differences if analysis was done with center volume broken down into quartiles [17]. Similarly, no differences in outcome by center volume were found in an analysis of esophageal surgeries in the General Thoracic Surgery Database – a component of the Society of Thoracic Surgeons (STS) National (US) Database [18]. While the volume effect may speak for the technical proficiency of the surgeon, it is likely to also reflect on the wider care services provided by other team members, including anesthesiologists, intensive care physicians, nurses, physiotherapists, etc. The effect of wider care services has been demonstrated in patients requiring thoracotomy for lobectomy where defined clinical care pathways both improved outcomes and reduced hospital costs [19, 20]. These pathways have the further benefit of patient education, managing patient and family expectations, educating junior house staff and new care team members, and defining points of care and team interaction with the patient where data can be collected, analyzed, and benchmarked.

Care patterns and outcomes need to be assessed and examined both for benchmarks; to track changes from trends in technology, reimbursement, or patient issues; and to seek improvement in outcomes. These outcomes need to be examined locally and against national data such as the General Thoracic Surgery Database – a component of the Society of Thoracic Surgeons (STS) National (US) Database, which collected 9470 adult thoracic procedures between July 2012 and June 2016 from its 6000 participating surgeons and allied health professionals. Potential biases in these data include the voluntary reporting process and the fact that most of the participating centers are affiliated with surgical training and/or research institutions – with the potential for such institutions to have sicker or more complicated patients and thus worse outcomes if the data are not appropriately adjusted for risk. Mandatory reporting, such as the National Surgical

Quality Improvement Program (NSQIP) in the USA, may provide more reliable comparative data due to wider data capture, incorporating more diverse patients, and thereby facilitate risk adjustment.

Once the care pathway has been defined and the internally collected data have been reviewed and examined against external benchmark data, meaningful changes can then be implemented. For example, as a result of the NSQIP program, the changes implemented in the US Veterans Affairs hospital system decreased the 30-day morbidity from major surgery by 45% and decreased 30-day mortality by 27% [21, 22]. Such improvements promise expansion into other surgical avenues and potentially into outcomes other than morbidity and mortality that include patient and provider satisfaction with the care process.

Preoperative Care

In North America and Europe, the majority of patients present for open thoracic procedures with a confirmed diagnosis of cancer or an intrathoracic process suspicious for cancer. In contrast, patients in the developing world are likely to present with trauma or pulmonary infection. Patients also often present with comorbidities, especially smoking-related comorbidities that dramatically increase their risk for perioperative pulmonary and cardiac complications. Irrespective of the underlying disease mechanism, all patients require a thorough preoperative assessment to address and improve correctable physiological problems and to assure adequate physiological reserve following surgical intervention. The preoperative evaluation needs to be focused on preoperative risk stratification, identification of reversible pathologies, and decreasing the patient's risk through preoperative optimization (see Chap. 2 for a detailed review) [23]. Beyond reducing risk, preoperative interaction with the patient allows practitioners to mentally prepare patients for the rigors of recovery.

Preoperative smoking cessation and pulmonary rehabilitation have not been consistently noted to be effective in improving outcomes [24, 25]. A study of 7990 thoracic surgeries from 1999 to 2007 indicated a small mitigation of smoking risk with duration of cessation, although this could have been due to increased focus on outpatient pulmonary toilet [26]. Consequently, practitioners should ensure continuation of bronchodilator therapy throughout the perioperative period. Patients need to understand the importance of complying with their pulmonary toilet; moreover, it should be explained that even with aggressive postoperative epidural analgesia combined with multimodal therapy, visual analog pain scores with pulmonary toilet are typically 5 out of 10 for the first 5 postoperative days [27].

For patients with cardiovascular comorbidities, the acute introduction of beta-blocker therapy may increase the risk for cardiovascular harm [28, 29]. Similarly, randomized trials of coronary revascularization before major surgery have not shown any clear benefits [30–32]. As such, it is currently recommended that the preoperative evaluation of coronary artery disease should only be addressed in those patients with acute changes in symptoms while focusing on optimized medical therapy and exploring other cardioprotective strategies (e.g., statins) for the remaining patients with stable coronary disease.

If beta-blockers are indicated for intercurrent medical conditions, then these medications should be started well before rather than at the time of surgery. In cases where coronary heart disease is only recognized at the time of admission for elective surgery, results of the POISE trial suggest that while acute perioperative administration of beta-blocker therapy may confer cardioprotection, it increases the risk of stroke and all-cause mortality [28]. Further, beta-blocked patients seem to tolerate surgical anemia less than patients who are naïve to beta-blockers, resulting in increased adverse postoperative events [33].

Studies suggest that the pleiotropic effects (nonlipid-lowering effects, including anti-inflammatory effects and endothelial modulation) of statins improve outcomes in the perioperative period in patients undergoing major cardiac and noncardiac surgery [34, 35]. The best evidence comes from vascular surgery patients where preoperative fluvastatin, commenced at least 30 days before (and continued for at least 30 days after surgery), significantly reduced postoperative myocardial ischemia and death from cardiovascular causes, without adverse skeletal muscle or hepatic injury [35]. (This study was investigated due to a co-author's – Poldermans – nonconformity with consent procedures but was found to be valid.) [29] Specific to the thoracic surgery population, preoperative statin therapy is reported to result in a threefold reduction in the incidence of postoperative atrial fibrillation [36]. These pleiotropic effects of statin therapy may translate into perioperative protection of the heart, brain, and kidney for other major surgeries, but they cannot be currently recommended [29].

Antihypertensive medications (including beta-blockers), HMG Co-A reductase inhibitor (statin) therapy, and where possible antiplatelet therapy should be continued to avoid potential cardiovascular harm associated with drug withdrawal [37–39]. Controversy, however, surrounds the preoperative management of antiplatelet therapy, with increasing data supporting the continuation of clopidogrel and aspirin in the perioperative period to reduce both stroke and myocardial infarction [40]. Factors increasing the risk for such thrombotic adverse events include poor endothelialization of drug-eluting coronary stents, hypercoagulability induced by the surgical stress response, and a rebound response from the

perioperative withdrawal of antiplatelet therapy. To prevent acute in-stent thrombosis, patients with bare metal and drug-eluting coronary stents should continue dual antiplatelet therapy for a minimum of 3 and 12 months, respectively, after stent placement, with consideration for lifelong antiplatelet monotherapy; thereafter patients at increased risk may require lifelong dual antiplatelet therapy. If possible, elective surgery should be performed beyond this 3- or 12-month window and strong consideration given to continue dual antiplatelet therapy, with a minimum of antiplatelet monotherapy with aspirin, throughout the perioperative period. This continuation protocol needs to be balanced against the risk of perioperative bleeding and the need for epidural analgesia.

Patient safety decisions need to be incorporated into the preoperative phase. There has been recent focus on a morning "huddle" in which the day's cases are discussed among surgeons, anesthesiologists, nurses, and technicians. This ensures proper equipment, identifies particular patient's risks (latex allergy), and helps to develop patient-specific multidiscipline plans. Although potentially impactful on safety, most of the data focuses on efficiency metrics. Intraoperative safety issues to be discussed include surgical site marking, surgical plan, allergies, patient-specific medical comorbidities, thromboembolic prophylaxis (sequential compression stockings or subcutaneous heparin), strategies to maintain normothermia, antibiotic administration within 1 h prior to incision, universal precautions (gown and gloves) as mandated for invasive procedures, and a type and screen for blood cross-matching sent to transfusion services.

Intraoperative Care

Operating room preparation needs to occur as with every case to ensure patient safety. In addition to a routine setup, typical airway management equipment includes methods of establishing (double lumen tubes [DLT], bronchial blockers, or Univent tubes) and verifying (pediatric fiber-optic bronchoscope) lung isolation. A circuit for delivering continuous positive airway pressure (CPAP) to the nondependent lung should be immediately available. Other devices that should be in the room include the following: a "bean bag" placed on the operating table prior to the patient's arrival; an arm holder for positioning the nondependent arm; warming devices such as intravenous fluid warmers and warm air blankets for maintaining normothermia in patients and thereby negating the adverse effect of hypothermia on hypoxic pulmonary vasoconstriction (HPV), coagulopathy, and wound healing; and mechanical compression devices to prevent thromboembolism.

Once consent is obtained and the patient has been properly identified and the surgical site marked, an intravenous catheter should ideally be placed in the hand/wrist/forearm of the operative (nondependent) side. The antecubital fossa is not ideal due to the position of the arms in the lateral decubitus position where the arms will be bent at 90° and the flow potentially inhibited. An 18-gauge intravenous catheter is sufficient for medication and fluid management since for a thoracotomy in a hemithorax that has not had previous surgery, chest tubes, trauma, or radiation therapy, the operative blood loss should be minimal. However, after induction of anesthesia, an additional intravenous cannula is typically placed in case of sudden unanticipated blood loss. This is especially mandatory in re-operative cases, cases where the patient received preoperative radiation therapy, or cases that require an extrapleural approach (e.g., extrapleural pneumonectomy for mesothelioma). If surgical dissection is required around the greater veins (vena cava or subclavian veins), contralateral access, central access, and/or lower extremity access should then be considered.

Paravertebral and epidural catheter placement is equally efficacious for postoperative analgesia [41]. Regional anesthesia is typically established in the preoperative area or in the operating room prior to induction, with the goal of establishing adequate analgesia prior to completion of the surgical procedure and emergence from anesthesia. Once the patient is positioned for regional anesthesia, noninvasive monitoring (pulse oximeter and blood pressure cuff) and nasal oxygen are applied, and sedation is then administered to facilitate regional anesthesia. Typical sedative regimens used to facilitate the induction of regional anesthesia include titrated doses of midazolam and/or fentanyl as dictated by patient anxiety and medical status. Dexmedetomidine is a viable alternative for sedation, especially if it is planned to be used as part of the general anesthetic technique or if awake fiberoptic bronchoscopy (usually for an anticipated difficult airway) is planned preceding the induction of general anesthesia.

After securing the regional anesthesia catheter, the patient is positioned in the supine position and the standard American Society of Anesthesiologists (ASA) monitors placed. The placement of the EKG leads requires an understanding of the surgical approach. For a thoracotomy, care should be taken to avoid trapping the electrodes and leads between the patient and the bed as this can lead to pressure necrosis. For a left-sided thoracotomy, the V_5 lead cannot be placed in its usual position over the fourth interspace in the anterior axillary line as this intrudes on the surgical field. It is typically placed in the V_1 position (second interspace, right of the sternum). These factors (modified lead placement and lateral decubitus positioning) are likely to reduce the sensitivity of such monitoring for ischemic events.

After all noninvasive monitors are secured, preoxygenation is commenced. Five minutes of tidal breathing preoxygenation compensates for delayed nitrogen washout in

patients with chronic obstructive pulmonary disease (COPD) [42]. During this period, a preinduction arterial line can be placed if needed; however, in primary thoracotomy it is unclear if arterial line monitoring reduces risk. Placement of the arterial line is typically preferred in the dependent arm to avoid waveform damping by compression of the nondependent wrist by the overhead arm holder.

Induction agents are chosen in relation to the patient's medical status and are intended to blunt the sympathetic stimulation associated with laryngoscopy and intubation without producing deleterious hypotension. Propofol doses of 0.5–1 mg/kg can adequately ensure unconsciousness with minimal hemodynamic impact. Etomidate doses of 0.1–0.2 mg/kg are reasonable alternatives. A reduction in the dose of the induction agent, thereby avoiding hypotension, can be achieved by incorporating analgesic agents during induction and by ensuring that the peak effect of analgesia coincides with laryngoscopy. The onset of significant analgesia following intravenous fentanyl, sufentanyl, and remifentanil is noted to be 2–5 min [43]. Doses of fentanyl would typically be 2–4 μg/kg. Lidocaine 0.5–1 mg/kg can also be used for reducing this sympathetic response.

An understanding of the physiology of one-lung ventilation (OLV), the strategies for inducing OLV, and the means to address intraoperative challenges associated with OLV is required to improve operative efficiencies and patient outcomes. Patient safety can be advanced through the use of task trainers and simulations to improve skills in the use of double lumen tubes and bronchial blockers [44]. Bronchoscopic anatomy can be learned first on online simulations.

A plan to maintain a patent airway and adequate ventilation at all times will ensure maintenance of hyperoxia and normocarbia. To this effect, mask ventilation needs to be rapidly established after loss of consciousness and neuromuscular blockade rapidly induced – to accommodate the reduction in functional residual capacity (FRC) associated with smoking-related disease, which shortens the apneic oxygenation time in these patients. Sevoflurane is initially employed in patients with reactive airway disease until sufficient depth of anesthesia is obtained. No significant outcome differences have been established in terms of maintenance of anesthesia for currently used volatile agents, such as isoflurane, sevoflurane, and desflurane (see HPV).

If the patient is scheduled for a diagnostic bronchoscopy, a laryngeal mask airway (LMA) may be placed. This allows the upper airway to also be assessed for associated smoking-related laryngeal cancers. However, if the patient is scheduled for a mediastinoscopy, a standard single-lumen endotracheal tube (preferably 8.0 mm, internal diameter) may be preferred. Once bronchoscopy and mediastinoscopy are complete, lung isolation using a DLT or bronchial blocker needs to be implemented to facilitate the thoracotomy. The endotracheal tube (DLT or single-lumen tube with bronchial blocker) should then be secured with tape to the nondependent side, allowing easy access to the tape if the tube needs to be repositioned while in the lateral decubitus position. The patient is then positioned in the lateral decubitus position, 100% FiO_2 maintained, and lung isolation then established. Proper positioning of the endotracheal tube should be reconfirmed after the patient's repositioning, because flexion or extension of the neck can potentially displace the endotracheal tube. The "tip of the tube follows the tip of the nose"; therefore, head extension causes the endotracheal tube to move proximally, and the endobronchial balloon can herniate across the main carina. Confirmation of tube position with fiber-optic bronchoscopy after placement and position change decreases the incidence of inadequate lung isolation.

The use of a left double lumen endotracheal tube for a left thoracotomy carries the increased risk of acute intraoperative hypoventilation if the endotracheal tube displaces proximally with the endobronchial balloon herniating across the carina, especially if lung retraction moves the left main stem bronchus caudad. This can also occur from overinflation of the endobronchial balloon. The astute anesthesiologist may notice decreased tidal volumes as the balloon partially obstructs the right main stem orifice. Minute ventilation alarms may be triggered if there is a partial occlusion, or the high-pressure alarms will be triggered if there is a total or near total occlusion. The anesthesiologist reacts based on the patient's oxygenation and the surgeon's flexibility. If the patient is appropriately oxygenated, then ventilation can be briefly suspended and the fiber-optic bronchoscope utilized to check tube position and the endobronchial cuff deflated prior to tube advancement. If the patient deoxygenates acutely to dangerously low levels, then quick communication should inform the surgeon of the urgent need to re-establish two-lung ventilation. This is achieved by re-establishing ventilation through both the tracheal and endobronchial lumens of the DLT and, importantly, by deflation of the endobronchial balloon. The endotracheal tube can then be repositioned and OLV re-established once oxygenation levels are satisfactory.

OLV strategies are covered in detail in Chap. 6. Briefly, the patient is maintained on 100% oxygen (or combined with nitrous oxide) during initial two-lung ventilation. This denitrogenation allows for faster deflation – through absorption atelectasis – of the nondependent (surgical) lung on the initiation of OLV. ALI increases with greater peak inspiratory pressures [45, 46]. Ventilation parameters during OLV therefore typically strive to reduce the risk of ALI associated with barotrauma or volutrauma through tidal volume reduction (<6 mL/kg), respiratory rate > 10 breaths per minute, I:E ratio of 1:2, and peak inspiratory pressure < 25 mmHg. Such a protective ventilatory strategy aims to maintain baseline

CO_2 levels or tolerate permissive hypercapnia (pH > 7.25) rather than mild hypocapnia. This protective ventilatory strategy is supported by evidence that reduced tidal volume (5 mL/kg) during OLV decreases the pro-inflammatory systemic response, improves lung function, and results in earlier extubation after esophagectomy [47]. Similarly, mechanical ventilation with lower tidal volumes (6 mL/kg and 10 cm H_2O positive end expiratory pressure; PEEP) after 5 h of two-lung mechanical ventilation is noted to induce lowered activation of bronchoalveolar coagulation, as reflected by reduced thrombin–antithrombin complexes, soluble tissue factor, and factor VIIa levels in lavage fluids when compared to higher tidal volumes (12 mL/kg ideal body weight) without PEEP [48, 49]. Inhalational agents tend to provide an inhibitory (protective) effect on inflammation during one-lung ventilation as compared to propofol [50].

In patients with significant COPD with a prolonged exhalation phase and CO_2 retention, the respiratory rate and I:E ratio need to be adjusted to avoid hyperexpansion from breath stacking. In patients with right ventricular dysfunction or pulmonary hypertension, ventilator parameters should aim to maintain hyperoxia and induce mild hypocarbia in an attempt to reduce pulmonary vasoconstriction and any further strain on the right heart.

Optimal ventilation can be achieved by maintaining an appropriate plane of anesthesia to decrease the risk of reactive airways, inducing neuromuscular blockade to prevent abdominal or chest wall contractions, suctioning the double lumen to prevent mucus plugs, and visual bronchoscopic checks of the tube placement to correct tube malposition, kinking, and misalignment.

Typically, for a patient on 100% oxygen, the initiation of OLV does not bring on any immediate changes except for changes in ventilatory pressures or parameters [51]. Oxygenation is initially maintained due to apneic oxygenation. The duration of apneic oxygenation is proportional to the FRC and dependent on oxygen utilization. This can last a few minutes in COPD patients with reduced FRC or longer (8–15 min) in healthy nonsmokers. Once the nondependent lung is bereft of oxygen, a shunt develops and hypoxemia can ensue. HPV (discussed below) is initiated by the mitochondria sensing decreased oxygen levels.

Should hypoxia develop during OLV, the first response should be to communicate this to the surgeon in case two-lung ventilation needs to be resumed. Delivery of 100% oxygen through a properly positioned endotracheal tube needs to be ensured. Assuming that the rate of descent of the saturation is not too rapid and the nadir is safe (moderate hypoxemia, 88–90% saturation), then the nadir can be tolerated for several minutes until HPV has a chance to decrease the shunt. If unsafe levels of hypoxemia are reached, then the shunt needs to be decreased. This can be achieved through the application of CPAP, with 100% O_2 delivery to the nondependent lung. PEEP to the dependent lung can eliminate atelectasis, but this typically has a lesser impact on saturation than does CPAP. Restoration of adequate cardiac output and blood pressure can also restore oxygenation by improving the blood flow (perfusion zones) and V/Q matching in the dependent lung. It is important to advise the surgeon to any changes in ventilation, particularly when they are dissecting around the hilum. Obviously, if the oxygen saturation falls to a dangerous level, then either two-lung ventilation needs to be resumed, or a temporary clamp on the pulmonary artery of the nondependent lung can be placed. While the temporary pulmonary artery clamp will significantly reduce the shunt, extreme care should be taken as it can incite right heart strain and right heart failure.

After positioning the patient, prior to surgery, the multidisciplinary (anesthesia, surgical, and nursing) team should "time out" and pause for open dialog to ensure that the correct patient, correct surgical side, sterility of instruments, and patient-safety procedures (including surgical site marking, thromboembolic prophylaxis, strategies to maintain normothermia, antibiotic administration within 1 h prior to incision, type and screen for blood cross-matching, correct surgical instruments, etc.) are verified and to provide an opportunity to address any potential concerns that need clarification or may harm the patient. In the future, computerized information technology (anesthesia information management systems, AIMS) will increasingly assist supportive decision-making, with smart alerts prompting for critical items such as timely antibiotic administration and risk prediction modeling, and allow benchmarking against national outcome databases.

At rest, the normal pulmonary vascular system is noted as a high-compliance, high-flow, low-pressure system. This contrasts the systemic circulation, which has much higher resting levels of arterial and venous tone. This difference stems partly from the anatomy because the pulmonary precapillary arterioles have a thinner media and less smooth muscle than their systemic counterparts. Furthermore, at rest, there are far more recruitable vessels in the pulmonary bed that allow dramatic increases in flow with minimal impact on pressure.

The difference between the systemic and arterial systems is also due to the way in which the pulmonary vascular endothelium responds to the challenges of hypoxia, i.e., hypoxic pulmonary vasoconstriction (HPV). This vasoconstriction is known as the Euler–Liljestrand reflex. While the basic mechanism of HPV is controversial [52], it appears that mitochondria play a key role as the primary sensors of hypoxia, with intracellular calcium levels increasing as a key response [53, 54]. Voltage-gated K^+ channels directly alter mitochondrial responses. L-type Ca^{2+} channels are facilitated by the depolarization of the K^+ channels, and they directly increase

intracellular Ca^{2+}. Classical transient receptor potential channel 6 (TRPC6) also increases intracellular Ca^{2+} as do store-operated channels (SOC) and Na^{+}/Ca^{2+} exchangers (NCX) [53]. This rise in intracellular Ca^{2+} triggers further Ca^{2+} release from the sarcoplasmic reticulum via activation of the ryanodine receptors. The end result is constriction of the smooth muscle of the precapillary sphincters and pulmonary arterioles. This calcium-dependent vasoconstriction is the primary phase of HPV and lasts 15–30 min. The calcium-independent phase (the sustained phase) of pulmonary vascular constriction starts at 15 min and can last for several hours. It is highly dependent on RhoA/Rho kinase (ROCK)-mediated Ca^{2+} sensitization [55] and may play a key role in the development of pulmonary hypertension [56]. Interestingly, NO-induced relaxation and endothelin-1-induced vasoconstriction of pulmonary arteries has been demonstrated to be due to the regulation of ROCK-mediated Ca^{2+}-sensitization, rather than altered Ca^{2+} metabolism [57, 58].

End tidal CO_2 can influence HPV. Alveolar hypercapnia, but not arterial hypercapnia, can inhibit NO synthetase [59]. This inhibition augments the increase in pulmonary vascular tone following endothelin-induced vasoconstriction. Consequently, mild hypercapnia can reduce shunt. However, hypoventilation can worsen hypoxemia, as can right heart strain and decreasing cardiac output.

Anesthetics can influence pulmonary vascular function and inhibit HPV. Inhalational agents (halothane and enflurane and, to a lesser degree, isoflurane, desflurane, and sevoflurane) will inhibit HPV but at concentrations of greater than 1 MAC [60]. Propofol may have a less profound impact on HPV than the inhalational agents [61], but this effect is not significant when a BIS of 40–60 is targeted [62]. Opioids, benzodiazepines, and epidural and paravertebral analgesics/anesthetics have minimal impact. Normothermia, mild hypercapnia, and mild acidosis may enhance HPV. Direct vasodilators such as sodium nitroprusside and nitroglycerine should be avoided as they abolish HPV, thus increasing the shunt and causing hypoxemia [55, 60]. Antihypertensives such as beta-blockers, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors may theoretically reduce HPV but have minimal impact in clinical practice [35].

It is unlikely that the routine patient would tolerate the sole use of regional anesthesia, especially during an open thoracotomy. The techniques of general and epidural or paravertebral anesthesia often are combined to utilize the benefits of each. The relative contribution of each technique to combined anesthesia can vary. The regional block may either be used for postoperative analgesia or as the major anesthetic, with light general anesthesia used for amnesia and sedation. Regional block has the advantages of reduction in afterload, improved pulmonary function [63–67], decreased incidence of venous thromboembolism [63, 68, 69], and suppression of the stress response [67, 70–73]. Potential disadvantages include the time required to establish the block, potential increased fluid requirements, relative decrease in blood pressure associated with sympathectomy, and the potential for adverse complications such as epidural hematoma.

A prospective, randomized, controlled clinical study has previously examined the effects of epidural anesthesia and postoperative analgesia on the postoperative morbidity rate in high-risk surgical patients [74]. Patients who received epidural anesthesia and analgesia had fewer overall complications and fewer cardiovascular or major infectious complications, lower urinary cortisol secretion (a marker of the stress response), and lower hospital costs [74]. Vital capacity and lung compliance are known to decrease after general anesthesia and neuromuscular blockade in patients undergoing thoracotomy. Epidural analgesia with light general anesthesia results in a comparatively lesser decrease in static compliance and fewer alterations in postoperative pulmonary function [75, 76]. The perioperative use of epidural anesthesia is also associated with fewer major postoperative infections. This may result from (1) the decreased duration of endotracheal intubation and mechanical ventilation, which diminishes many of the defense mechanisms against infection [77, 78]; (2) decreased duration of intensive care unit (ICU) stay postoperatively and reduced risks of nosocomial infection; (3) suppression of the endocrine stress response to the surgery, which has an inhibitory effect on the immune system; and (4) improved compliance with pulmonary toilet. Immune competence is better preserved postoperatively when epidural anesthesia is used compared with other anesthetic/analgesic techniques [70, 72, 73]. Epidural anesthesia is also reported to be associated with fewer cardiovascular complications, such as a lower incidence of congestive heart failure [75] and decreased size of myocardial infarctions, which are probably related to improved regional subendocardial perfusion [71, 79, 80]. Possible mechanisms for the improved function include afferent sensory blockade, decreased adrenergic tone, and coronary and systemic vasodilation with a reduction in cardiac preload and afterload [71, 79, 80].

The timing of initiation of regional anesthetic is a mildly contentious issue. There has been no consistent benefit from a preemptive analgesic approach when measuring long-term outcomes (chronic pain, survival, readmission, etc.) where the regional anesthetic is established well prior to surgical incision [27, 81]. Similarly, it remains unclear what the concentration of intraoperative local anesthetics should be, since concentrations of bupivacaine an order of magnitude apart (0.5–0.05%) have similar short- and long-term pain outcomes as well as similar morbidity and mortality [81–84]. It is considered that if an epidural is employed, a thoracic epi-

dural and a combination of local anesthetics and opioids [85] are superior to local anesthetics or opioids alone. For paravertebral blockade there is no advantage of adding opioids to local anesthetics [86]. A real advantage of utilizing a combined regional and general anesthetic approach is the ability to limit the amount of inhaled anesthetics, thereby theoretically reducing the inhibition of HPV. The risk of hypotension is reduced with a paravertebral catheter as compared to an epidural catheter [87], but even with an epidural, it can be easily managed with alpha agonists and minimal fluid therapy.

Maintenance of anesthesia during thoracic surgery requires attention to the activities of the surgeon. Given the typically long time between induction and incision, epidural or paravertebral bupivacaine loaded after incision should blunt the majority of sympathetic stimulation from the incision and retractor insertion. Manipulation of visceral pleura and the bronchi, which have vagal and phrenic afferents, is not blocked by regional anesthesia; accordingly, these may require supplemental inhalational or intravenous agents.

Volatile, halogenated anesthetic drugs have several desirable properties for use during thoracic procedures. They decrease airway irritability and obtund airway reflexes in patients who usually have reactive airways, and they maintain adequate anesthesia while allowing increased inspired oxygen concentrations. They can be eliminated rapidly, allowing tracheal extubation in the operating room with less concern for postoperative respiratory depression. While it has not been definitively been shown to alter outcome, fluorinated inhalational agents inhibit pulmonary inflammation from lung surgery as compared to propofol [88]. Although volatile anesthetics allow high inspired O_2 concentrations, they may reduce PaO_2 by increasing the shunt caused by the partial inhibition of HPV. Because large intrapulmonary shunts are anticipated with the initiation of OLV, it is prudent to increase the inspired concentration of oxygen. Nitrous oxide should be avoided in patients who have marginal preoperative oxygenation or in those with large bullae and emphysematous lungs to avoid expansion of bullae by nitrous oxide.

The management of perioperative fluid therapy remains controversial without conclusive data to guide treatment [89]. The origins of the controversy stem from the significant risk of mortality in patients who develop ALI (previously also termed "post-pneumonectomy pulmonary edema") after thoracic surgery. Retrospective reviews have highlighted the possible role of fluid management in the development of ALI, with large volumes of crystalloid and blood component therapy predicting post-pneumonectomy pulmonary edema in regression analysis [90]. Obviously, these predictors can simply represent more complex surgery on sicker patients. However, typical guidelines that are promulgated suggest minimizing crystalloid therapy by not replacing the overnight losses, utilizing alpha agonists rather than fluid boluses to compensate for vasodilatation from regional anesthesia, and disregarding low urine output and consider utilizing appropriate blood transfusion to replace lost blood [45, 91]. These guidelines appear prudent, especially given that concomitant smoking-related cardiac disease can decrease systolic function and potentiate right heart strain from surgery and associated changes in pulmonary vascular resistance.

In brief, much data has been accumulated to suggest that perioperative ALI is an inflammatory response to perioperative stress [46, 92]. Regardless of the volume of fluid, 0.9% (normal) saline appears to induce a stress response in research settings [93]. However, since there are scant data to suggest that other balanced salt solutions would result in an improved outcome, the use of colloids to reduce overall extracellular fluid gain seems reasonable. The concern over the antiplatelet/antithrombotic effect of hydroxyethyl starch results from the effects of the early high-molecular-weight compounds, the so-called HES 200/0.5, when dosed greater than 15 mL/kg [94–96]. The newer formulation with small starch particles, the HES 130/0.42, has fewer risks and may be a better alternative to older HES formulations and large-volume crystalloid therapy for blood loss that needs replacement. Albumin therapy probably has an insignificant role in perioperative fluid management unless a large volume of pleural effusion or peritoneal effusion has been drained at the time of surgery [97, 98]. HES has not been shown to decrease mortality [99, 100].

Overall, perioperative fluid management goals for a lobectomy or pneumonectomy attempt to maintain a euvolemic state – favoring fluid restriction (~1.0–1.5 L total crystalloid) and the judicious use of vasoconstrictors such as phenylephrine to provide hemodynamic stability, in an attempt to preserve renal function. Although large volumes of blood loss are rare, any blood loss should be replaced with packed red blood cells. Fresh frozen plasma should only be considered when directed by perioperative testing indicating coagulopathy. Platelet therapy is rarely indicated except in the case of severe thrombocytopenia or perioperative platelet inhibitors associated with widespread oozing, where there are few other therapeutic choices available.

With restriction of fluid therapy comes a concern about renal damage [101]. A recent review indicates that patients who developed acute kidney injury (AKI) were significantly older and had a larger body mass index, higher ASA classification, lower preoperative hemoglobin concentration, higher serum creatinine, and lower glomerular filtration rate. Further AKI was seen in patients who received larger intraoperative volumes of crystalloid [101]. Consequently, AKI seems to be related to preoperative comorbidities and difficulty/duration of surgery.

Postoperative Care

On the basis of the evidence available showing improved postoperative outcomes with aggressive postoperative management in high-risk general surgical patients [102] and thoracic surgery patients [103], a decision-making algorithm may guide the need for elective admission into a high dependency unit (HDU) or ICU postoperatively [103]. Proposed criteria include the following: age > 70 years; those at increased risk of general anesthesia, as judged by ASA risk score, performance status scores, and cardiovascular risk assessment; and those patients with preexisting fibrotic lung disease. Patients undergoing OLV, especially with a predicted postoperative forced expiratory volume in one second (FEV_1) of less than 44%, and those undergoing extensive lymphatic dissection should be monitored closely for signs of ALI in the first 5 days postoperatively. These high-risk categories, together with any indication of postoperative complications such as bronchopleural fistula (BPF) or empyema, should mandate immediate transfer to the ICU.

Early identification of high-risk individuals will allow close monitoring and early institution of therapy during the "golden hours" immediately following surgery. Such therapy may include early goal-directed therapy with hemodynamic optimization, early institution of CPAP for hypoxemia, aggressive pain management, and early mobilization. Such strategies are expected to improve postoperative outcomes and shorten length of hospital stays.

Lung Cancer

Lung cancer is currently the most common cause of cancer mortality throughout the world, with 243,820 new cases diagnosed and 158,080 deaths reported in the USA in 2015 [104]. The World Health Organization (WHO) classification of lung tumors, revised most recently in 2015 [105], remains the foundation for lung carcinoma nomenclature. Lung cancer is divided into two broad categories: small cell lung carcinoma (SCLC, ~15–20%) and non-small cell lung carcinoma (NSCLC, ~80–85%). Less common are other types of cancers, e.g., bronchial carcinoid tumors. SCLC has been demonstrated to have a strong correlation with cigarette smoking [106]. NSCLC comprises several broad categories based on histology: adenocarcinoma (38–61%), squamous cell carcinoma (SCC, 21–38%), large cell carcinoma, pleomorphic carcinoma, and adenosquamous carcinoma [107, 108].

Intrathoracic Manifestations

The clinical manifestations of lung cancer are varied. Common symptoms include shortness of breath, hemoptysis, chest pain, and increasing dyspnea on exertion. Pleural effusions are a common but nonspecific finding observed on chest radiographs. Such effusions result from obstruction of lymphatic drainage or malignant extension of the tumor to the lung surface. Chest pain associated with lung cancer is generally a dull or mild nonspecific pain occurring ipsilateral to the tumor. Metastasis to the chest wall and ribs can result in local tenderness and pleuritic chest pain. Shoulder pain may result from tumor growth at the lung apex and invasion or encroachment of the brachial plexus (such as in superior sulcus or Pancoast tumors) or invasion of the phrenic nerve. Tumor extension into the pericardium can result in pericarditis, cardiac arrhythmias, and pericardial effusions that cause tamponade. In addition, superior vena cava obstruction by direct invasion or lymphatic metastases impedes venous return from the head and upper extremities. Other manifestations of lung cancer include neurologic symptoms caused by mechanical encroachment or invasion of the nerve plexus. Involvement of the brachial plexus may result in not only shoulder pain but also upper arm pain and weakness. Involvement of the phrenic nerve can lead to unilateral diaphragmatic dysfunction, and involvement of the recurrent laryngeal nerve is characterized by hoarseness of the voice.

Extrathoracic Metastatic Manifestations

Common extrathoracic sites of metastases include the lymph nodes, brain, bone, liver, skin, and adrenal glands [109]. The neurologic manifestations of metastatic brain tumors include hemiplegia, personality changes, cerebellar disturbances, seizures, headache, and confusion. Metastases to the bone occur primarily in the ribs, vertebra, humerus, and femur. Although metastases to the spinal cord and vertebral column are less common, they have implications for positioning and postoperative management of pain.

Extrathoracic Nonmetastatic Manifestations

The extrapulmonary manifestations of lung cancer affect the metabolic, neuromuscular, skeletal, dermatologic, vascular, and hematologic systems. Although uncommon, the systemic manifestations of such paraneoplastic syndromes, especially the metabolic and neuromuscular manifestations, and other nonspecific findings such as malaise, weight loss, and cachexia, may affect perioperative management and impact the patient's recovery and survival.

Metabolic manifestations result from endocrine secretions by the tumor as follows:

- Adrenal corticotrophic hormone (ACTH, Cushing's syndrome): most often associated with small cell carcinoma [110].

- Antidiuretic hormone (syndrome of excessive ADH): associated with small cell carcinoma; it may manifest as nausea, vomiting, anorexia, hyponatremia, seizures, or other neurologic disturbances [111].
- Serotonin (carcinoid syndrome): diagnosed by elevated 5-hydroxyindoleacetic acid (5-HIAA) [110].
- Parathyroid hormone-like polypeptide: associated with bronchogenic carcinoma; results in hypercalcemia and hypophosphatemia [112].
- Ectopic gonadotropin production and hypoglycemia are rare manifestations.

Neuromuscular manifestations are the most frequent extrathoracic nonmetastatic effects of lung cancer, most often associated with small cell carcinoma of the lung [109, 113]. The paraneoplastic myopathy, Eaton-Lambert syndrome, may appear as a myasthenic-like syndrome characterized by proximal muscle weakness, particularly of the pelvic and thigh muscles. The defect in neuromuscular transmission is a result of an antibody-mediated impairment in presynaptic neurocalcium channel activity, which reduces the release of acetylcholine [113]. Patients with this syndrome do not respond as well to anticholinesterase drugs as do patients with myasthenia gravis. In contrast, these patients exhibit an increased sensitivity to succinylcholine and nondepolarizing muscle relaxants.

Other neuromuscular manifestations include subacute cerebral degeneration, encephalomyelopathy, and polymyositis. The cause and the pathogenesis of these neuropathies are not completely understood. Immunologic factors are believed to be important in the pathogenic process, because antibody and T-cell responses are directed against shared antigens that are ectopically expressed by the tumor but otherwise exclusively expressed by the nervous system [114].

In general, these extrathoracic symptoms resolve, and laboratory studies return to normal after successful tumor resection.

Treatment Options

SCLC tumors often have distant metastases at the time of diagnosis and are therefore managed primarily by chemotherapy. Only ~50% of people with SCLC survive for 4 months without chemotherapy. With chemotherapy, their survival time is increased by four to five-fold. Chemotherapy may be given alone, as an adjuvant to surgical therapy, or in combination with radiotherapy. While a number of chemotherapeutic drugs have been developed, the platinum-based class of drugs has been the most effective in the treatment of lung cancers. Chemotherapy alone is not particularly effective in treating primary NSCLC, but prolongs survival when NSCLC has metastasized [115].

Radiation therapy may be employed as a treatment for both NSCLC and SCLC. Radiation therapy may be given as curative therapy, palliative therapy (using lower doses of radiation than with curative therapy), or adjuvant therapy in combination with surgery or chemotherapy. Radiation therapy can be administered if a person refuses surgery, if a tumor has spread to areas such as lymph nodes or the trachea – making surgical removal impossible, or if a person has other conditions that disallow major surgery. Radiation therapy generally only shrinks a tumor or limits its growth when given as a sole therapy; however, in 10–15% of patients, it leads to long-term remission and palliation of the cancer. Combining radiation therapy with chemotherapy can further prolong survival.

NSCLC tumors are more localized and thus better candidates than other types of tumors for curative resection. Surgical removal of the tumor is generally performed for limited-stage NSCLC (Stage I or some Stage II; see Chap. 2) [116]. About 10–35% of lung cancers can be removed surgically, but removal does not always result in a cure, since the tumors may already have spread microscopically and can recur. Lobectomy, the surgical removal of an anatomic lobe of a lung, is generally accepted as the optimal procedure for early-stage NSCLC because of its ability to preserve pulmonary function [116]. Limited (sub-lobar, segmentectomy) resection is increasingly used to treat patients who cannot tolerate a full lobectomy because of severely compromised pulmonary function, advanced age, or extensive medical comorbidities. Among people who have an isolated, node-negative lung cancer resected, the 5-year survival is now in the range of 47–92%, depending on size and degree of invasion [117]. In addition to surgery, adjuvant chemotherapy may be administered for selected patients with Stage IB, II, and IIIA disease for a 5-year absolute survival benefit of 5.4%. There are predictors of response to adjuvant chemotherapy. The morphology of the tumor, using the new WHO classification of lung adenocarcinoma, can predict response to adjuvant chemotherapy [118]. Gene expression profiles have also been developed from randomized trials of adjuvant chemotherapy to predict which early-stage lung cancers will have a poorer prognosis and a better response to adjuvant chemotherapy [119]. Many advances have been made on companion biomarkers and therapy in NSCLC. These are vital in a disease where even apparent curative surgery has a high relapse rate. The presence of specific genomic aberrations, specifically activating EGFR mutation and ALK or ROS1 gene rearrangements, predicts very high response rates with targeted therapies such as gefitinib and erlotinib (tyrosine kinase inhibitors of EGFR) and crizotinib (tyrosine kinase inhibitor of ALK) [120, 121]. Almost invariably, the tumors eventually become resistant to these therapies with time, due to the selection pressure of resistant clones within a notoriously heterogeneous tumor. Newer-generation tyrosine kinase inhibitors

which target the common resistance mechanisms are currently in clinical trials.

The presence of PDL-1 expression and tumor-infiltrating lymphocytes (TILs) appears to predict response for the immune checkpoint inhibitors such as nivolumab and pembrolizumab, with an apparent durable remission in 15–20% of cases.

These advances and the improved surgical results over the last decade suggest that the nihilism associated with lung cancer [122] should be consigned to history and every endeavor should be made to resect lung cancers from patients with adequate physiologic reserves.

Anesthesia and Long-Term Cancer Outcomes

It is increasingly recognized that anesthetic factors (volatile agents, opioid analgesics, surgical neuroendocrine response, blood transfusion, etc.) may shift the balance toward the progression of residual disease after potentially curative cancer surgery [123, 124]. Anesthetics may inhibit both cellular and humoral immune functions through the impairment of neutrophil, macrophage, T-cell, and natural killer cell functions. Regional analgesia attenuates these adverse events by largely preventing the neuroendocrine surgical stress response and minimizing the amount of volatile anesthetic and opioids required. Preliminary animal and human data suggest that regional analgesia may reduce tumor recurrence after cancer surgery [124].

Other perioperative strategies that may impact long-term cancer outcomes seem to focus on anti-inflammatory pathways. Statins, via the inhibition of the rate-limiting step of the mevalonate pathway, have potential anticancer effects [125]. There is some evidence for the anticancer effects of statins in patients with esophageal [126] and lung cancer [127, 128]. Additionally, other agents with known anti-inflammatory effects also point to the potential for improved outcomes in cancer patients. In this regard, aspirin use is reported to be associated with prolonged survival in many types of cancer, but often only seen after many years of therapy [129], while the perioperative use of anti-inflammatory agents (Cox-II inhibitor use in lung cancer; aprotinin use in mesothelioma) [130, 131] is associated with improved postoperative survival. Moreover, the use of regional analgesia is commonly employed in the thoracic surgery population and has been associated with attenuation of metastasis and improvement in recurrence rates for some types of cancers [123, 124]. It is imperative that further research is conducted in this field as we strive to improve long-term outcomes.

Surgical Procedure

To allow anesthesiologists to function within the combined expertise of the multidisciplinary team and to ensure optimal patient safety and outcome, a thorough understanding of the salient features of procedure-specific issues is required.

Pulmonary Resection

In most thoracic surgery practices, approximately two-thirds of surgical interventions are related to the management of intrathoracic malignancy or clinical sequelae of cancer. Anatomic resections (segmentectomy, lobectomy, and pneumonectomy) are most commonly performed for lung cancer, while nonanatomic resections (wedge) are typically performed for pulmonary nodules with diagnostic or therapeutic intention. Lobectomy with mediastinal lymph node dissection remains the standard surgical recommendation for the technical management of lung cancer. Segmental resection is a sound oncological operation that is typically used in patients with smaller cancers and marginal pulmonary reserve, such as those patients with COPD [132]. Pneumonectomy offers some more unique possible challenges including a higher mortality rate. The mortality rate of pneumonectomy is 8–10% vs. 2% for lobectomy [133].

Pulmonary resections can be performed via an open, thoracoscopic, or robotic approach. The technical aspects of the resection are essentially identical regardless of the approach. Evolution of surgical technique and technical advances in electronics and instrumentation has renewed interest in thoracoscopy, especially video-assisted thoracic surgery (VATS) and robotic VATS. As such, thoracoscopy permits the visualization of the pulmonary cavity through several small portals. These portals provide access for the video camera and allow manipulation of thoracic structures and use of surgical instruments such as staplers, dissectors, coagulators, and lasers. Although initially used for only minor surgical procedures, the application of VATS and robotics has expanded considerably for both diagnostic and therapeutic procedures and increasingly utilized in anatomic (lobectomy, segmentectomy) and limited (wedge) resections in selected patients.

Data suggests that VATS procedures may offer advantages beyond open thoracotomy, including decreased postoperative pain, reduced pulmonary impairment, reduced postoperative morbidity, shortened hospital stay, and potentially improved 1-year survival [134, 135]. There is less evidence of benefit of robotic-assisted thoracic surgery, but it seems to be at least equivalent to VATS in outcomes as compared to open surgery [136]. If access is inadequate or if bleeding complications occur, a thoracoscopic approach is easily converted to a limited open thoracotomy. VATS procedures for larger resections such as lobectomy seem to derive benefit from more aggressive pain management strategies, and epidural techniques may be beneficial. As such, careful communication between surgeon, patient, anesthesiologist, and the acute pain service is warranted to determine the best pain management strategy for each patient.

A thorough physiological assessment with attention to physiological and cardiac reserve is required prior to proceeding with surgical therapy. Spirometry, quantitative ventilation-perfusion scanning, and exercise cardiopulmonary testing can be helpful to determine physiological reserve for resection considerations. When considering pulmonary resection, a postoperative predicted FEV_1 or D_LCO of greater that 40% is a general requirement for resection considerations. In this regard, for patients whose preoperative FEV_1 or D_LCO is less than 60% predicted, a quantitative lung scan is performed to determine the predicted postoperative lung function. If the predicted postoperative ppoFEV_1 or D_LCO is greater than 40%, then surgical resection is feasible. In patients with predicted postoperative FEV_1 or D_LCO less than 40%, additional workup with cardiopulmonary exercise testing is required to delineate patient risk. Adequate aerobic exercise capacity (preoperative VO_2 max > 15 mL/kg/min and predicted postoperative VO_2 max > 10 mL/kg/min or stair climb >3 flights of stairs – 54 steps) improves patients' safety of operation [137]. In those patients who fail to meet these criteria, alternatives to resection should be considered. Relative contraindications for pulmonary resection that point to inadequate pulmonary reserve include chronic oxygen use, severe hypercarbia ($PaCO_2$ > 55 mmHg), and moderate pulmonary hypertension (PA pressure greater than one-half systemic pressures).

Anesthetic management for pulmonary resection requires effective isolation of the operative lung, judicious fluid management, and an appropriate ventilation strategy of the dependent lung [138–140]. Intraoperative bleeding is not a common challenge; however, catastrophic hemorrhage can occur in association with pulmonary arterial injury. This necessitates that patients have preoperative typing and screening for potential transfusion, with good venous access and hemodynamic monitoring – typically an arterial line and two large peripheral cannulae. More central cancers generally increase the risk for an intraoperative event.

The primary cause of perioperative mortality of lung resection remains ALI which can be secondary to infection, transfusion-related, pulmonary embolism, but often there is no specific identifiable etiology. Two factors, intraoperative fluid administration and prolonged elevated airway pressures during OLV, have been consistently implicated with perioperative lung injury [138–140]. Optimal intraoperative management of these factors is thus required.

During the conduct of an anatomic pulmonary resection, three structures (the pulmonary artery, pulmonary vein, and bronchus) are identified and divided at the segmental level (segmentectomy), at the bronchial level (lobectomy), or at the main stem bronchus (pneumonectomy). Prior to division of any structure, there must be assurance that anesthetic "hardware" (endotracheal tubes, suction catheters, nasogastric tube, pulmonary arterial catheters) are absent from the site of resection. Additionally, during the conduct of a segmental resection or lobectomy, patency of the remaining airway must be confirmed prior to airway division. This requires temporary ventilation of the lung in the surgical field to ensure expansion of non-resected segments or lobes. Intraoperatively, chest drains are placed for perioperative management. During chest closure while the patient is still requiring positive-pressure ventilation, these drainage catheters should be placed to suction. Provided that postoperative air leak is minimal, most surgeons manage chest drainage tube without suction (i.e., "water seal") [141].

Regardless of the type of pulmonary resection performed, extubation should be planned following surgery. Adequate postoperative analgesia is required to optimize patient outcome by ensuring the patient can cough and has adequate tidal volumes with breathing. As a result, liberal use of thoracic epidural analgesia is encouraged. Resumption of spontaneous breathing will avoid possible lung barotrauma as well as the risk of bronchial stump disruption and resultant BPF formation. Attention to optimal analgesia, pulmonary toilet, and pleural space management is required to achieve optimal patient outcome. Regional analgesia with epidural catheter provides superior pain control and promotes effective pulmonary toilet. Early mobilization is required with ambulation initiated the first postoperative day. Most patients will have a component of underlying reactive airway disease, and regular administration of bronchodilator therapy is typically used. Awake, bedside bronchoscopy is used liberally for secretion management. Noninvasive ventilator support, such as CPAP or BiPAP, can be used, but more often, endotracheal intubation is optimal for postoperative respiratory failure so as to decrease risk of aspiration event and subsequent pneumonia.

Lobectomy

Lobectomy with mediastinal lymph node dissection remains the standard surgical recommendation for the technical management of lung cancer. Lobectomy, commonly performed via open thoracotomy or VATS, is associated with lower local tumor recurrence compared to lesser resections. An open thoracotomy is usually performed through a posterolateral thoracotomy incision, but anterolateral and muscle-sparing lateral incisions are used occasionally. In cases where the clinical staging of the lung cancer is advanced, an elective lobectomy may be converted to a bilobectomy or pneumonectomy during the operation. Potential intraoperative problems include damage to the airway while using lung isolation devices, potential for bleeding, and hypoxemia during OLV.

After the lobe and blood vessels have been dissected, a test maneuver is performed by the surgeon clamping the surgical bronchus and confirming that the correct lobe is extirpated. The anesthesiologist then unclamps the DLT on the respective side or, in the case of a bronchial blocker, deflates the blocker balloon and re-expands the lung with manual

ventilation. During VATS lobectomy, reinflating the residual lobe may interfere with the surgical field, and so the anesthesiologist may be asked to fiber-optically inspect the bronchial tree to confirm patency of the bronchus of the noninvolved lobe. Once the lobectomy has been performed, the bronchial stump is usually tested with 30 cm H_2O positive pressure in the anesthetic circuit to detect the presence of air leaks. Following an uncomplicated lobectomy, the patient is usually extubated in the operating room, provided preoperative respiratory function is adequate. Emergence of the patient in a comfortable manner with good inspiratory effort and ability to cough requires aggressive postoperative analgesia, commonly achieved through the use of either a thoracic epidural or through a paravertebral analgesia technique.

Pancoast tumors are carcinomas of the superior sulcus of the lung and can invade/compress local structures including the lower brachial plexus, subclavian blood vessels, stellate ganglion (resulting in Horner's syndrome), and vertebrae. More complicated resection may entail a two-stage procedure with an initial operation for posterior instrumentation/stabilization of the spine. During lobectomy extensive chest wall resection may be required and massive transfusion is a possibility. Peripheral lines and monitoring should be placed in the contralateral arm due to frequent compression of the ipsilateral vessels during surgery.

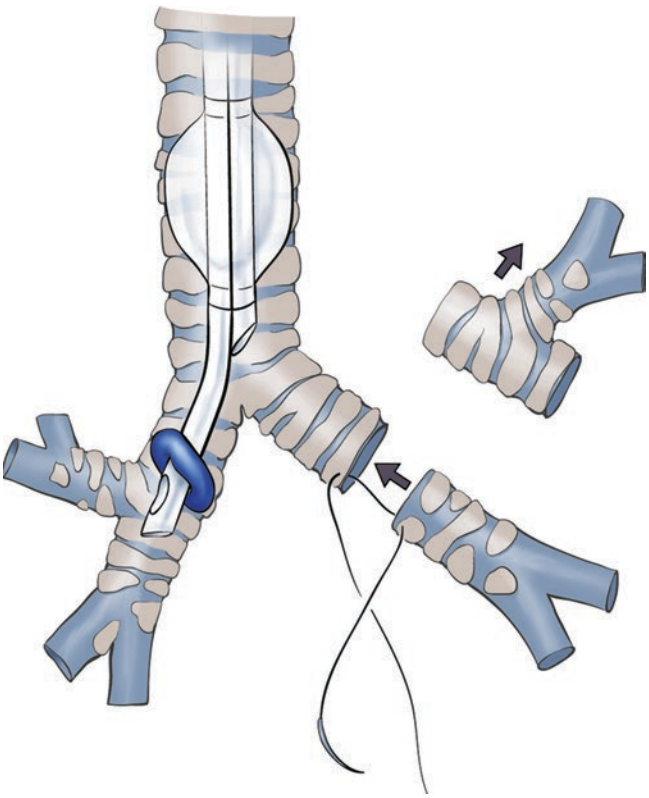

Fig. 23.3 Illustration of a sleeve resection for carcinoma of the left upper lobe, with reimplantation of the left lower lobe

Sleeve Lobectomy

Bronchogenic carcinoma is the most frequent indication for a sleeve lobectomy, followed by carcinoid tumors, endobronchial metastases, primary airway tumors, bronchial adenomas, and occasionally benign strictures. Sleeve lobectomy involving parenchyma-sparing techniques in patients with limited pulmonary reserve provides an alternative surgery for patients that cannot tolerate a pneumonectomy. The sleeve technique involves main stem bronchial resection without parenchymal involvement and possibly resection of pulmonary arteries to avoid pneumonectomy (Fig. 23.3). Sleeve resection, with reimplantation of the remaining lobe, associates with shorter periods of postoperative mechanical ventilation, shorter duration of ICU stay, fewer locoregional recurrences, and improved overall survival. Immediate and long-term survival is better after sleeve lobectomy compared with right pneumonectomy for comparable stages of right upper lobe cancer [142].

Ideally, patients undergoing sleeve lobectomy require lung isolation with a contralateral DLT or endobronchial tube, thereby improving surgical exposure for resection and reimplantation. High-frequency jet ventilation can be used for resections close to the tracheal carina. In rare cases a sleeve lobectomy may require transplant of vessels, thereby necessitating temporary heparinization. In these cases, thoracic epidural catheters should not be manipulated for 24 h following heparin administration. During pulmonary arterioplasty uncontrollable bleeding may occur. For this reason, large bore intravenous catheters should be used. Patients undergoing sleeve lobectomy are usually extubated in the operating room before transfer to the postanesthesia recovery room.

Pneumonectomy

Complete removal of the lung is required when a lobectomy or its modifications (bilobectomy or sleeve lobectomy) are not adequate to remove the local disease and/or ipsilateral lymph node metastases. However, pneumonectomy offers more unique challenges, including a higher incidence of morbidity (cardiac complications, ALI, ARDS) and mortality (8–10% for pneumonectomy vs. 2% for lobectomy) [133]. The overall operative mortality correlates inversely with the surgical case volume [143].

The technical conduct of the resection is typical as with any pulmonary resection. The pneumonectomy is usually performed through a standard posterolateral incision. Following incision of the mediastinal pleura, the pulmonary

artery, the superior and inferior pulmonary veins, and the main stem bronchus are evaluated for resectability. After all vessels are stapled, stapling of the bronchus occurs, and the entire lung is taken from the chest. A test for air leaks is generally performed at this point, and reconstruction of the bronchial stump is completed. The bronchial stump should be as short as possible to prevent a pocket for the collection of secretions.

Patients undergoing a pneumonectomy commonly receive a thoracic epidural catheter for postoperative analgesia, unless there is a contraindication. The placement of large bore intravenous lines is necessary in case blood products need to be administered. An invasive arterial line is placed for measurement of beat-to-beat blood pressure and to monitor arterial blood gases. A central venous pressure catheter is recommended to help guide intravascular fluid management, specifically in the postoperative period. Management of lung isolation in a pneumonectomy patient can be achieved with a DLT, bronchial blocker, or single-lumen endobronchial tube. When using a DLT for a pneumonectomy patient, it is preferable to use a device that does not interfere with the ipsilateral airway; however, the preference to use a left-sided DLT (or left-sided bronchial blocker) requires that during a left pneumonectomy, these devices are withdrawn prior to stapling the bronchus, in order to avoid accidental inclusion into the suture line.

Challenges can arise related to the empty hemithorax following pneumonectomy. There is no consensus among thoracic surgeons as to the best management of the post-pneumonectomy space. Some thoracic surgeons do not place a chest drain after a pneumonectomy, while others prefer a temporary drainage catheter to add or remove air. The removal of air, ranging from 0.75 to 1.5 L, is necessary to empty the chest and to keep the mediastinum and trachea "balanced" (in the midline). Some surgeons place a specifically designed post-pneumonectomy chest drainage system with both high- and low-pressure underwater relief valves to balance the mediastinum. A chest X-ray is mandatory after the patient arrives in the postanesthesia care unit or in the surgical ICU to assess for mediastinal shift. If suction is applied to an empty hemithorax or a chest drain is connected to a standard underwater seal system, it may cause mediastinal shift, impingement of venous return to the heart, and hemodynamic collapse. This requires correction with appropriate instillation or evacuation of air from the empty hemithorax. Although rare, cardiac herniation (more common following right pneumonectomy) can occur with catastrophic consequences and need for emergent correction.

The high morbidity and mortality associated with pneumonectomy are predominantly driven by ALI (also previously termed "post-pneumonectomy pulmonary edema"), culminating in respiratory failure. While the incidence of ALI after pneumonectomy is only 4%, the mortality rate associated with ALI is 30–50%.

The etiology for ALI seems multifactorial. In a retrospective report by Zeldin et al. [144], the risk factors that were identified for the development of ALI, previously termed "post-pneumonectomy pulmonary edema," were a right-sided pneumonectomy, increased perioperative intravenous fluid administration, and increased urine output in the postoperative period. However, close analysis of Zeldin's data reveals that only six out of ten cases had full intake and output data. A more recent study by Licker et al. has shown that the excessive administration of intravenous fluids in thoracic surgical patients (more than 3 L in the first 24 h) is an independent risk related to an ALI [139]. Further, the decrease in ventilatory function, increase in pulmonary artery pressure, and pulmonary vascular resistance (right ventricular afterload) may have a significant detrimental effect on right ventricular function [145].

Consequently, in an attempt to reduce high risk for perioperative morbidity and mortality following a pneumonectomy, perioperative management should focus on the judicious management of perioperative fluid therapy, tidal volumes during mechanical ventilation, and improved ICU strategies. In this regard, a retrospective review (Table 23.1) suggested that the incidence and mortality of ARDS after lung resection are declining and likely associated with more aggressive strategies to avoid pneumonectomy and greater attention to protective ventilation strategies during surgery and to improved ICU management of ARDS [2].

A retrospective report [146] involving 170 pneumonectomy patients showed that patients that received median tidal volumes greater than 8 mL/kg had a greater risk of respiratory failure in the postoperative period after pneumonectomy. In contrast, patients that received tidal volumes less than 6 mL/kg were at lower risk of respiratory failure. Schilling et al. [147] have shown that a tidal volume of 5 mL/kg during OLV significantly reduces the inflammatory response to alveolar cytokines. Considering these factors, it is prudent to use lower tidal volumes (i.e., 5–6 mL/kg, ideal body weight) in the pneumonectomy patient and limit peak and plateau inspiratory pressures (i.e., <30 and 25 cm H_2O) during OLV [138].

The presentation of ALI is biphasic, with intraoperative strategies (fluid restriction and lower tidal volumes) aimed at reducing the incidence of the primary form, which typically has a clinical onset during the first 72 h. The secondary, or late form, appears after 72 h and is usually related to other complications such as aspiration, BPF, or surgical complications. At the present time, only symptomatic management is appropriate for ALI, including fluid restrictions, diuretic administration, low ventilatory pressures and tidal volumes (if mechanical ventilation is used), and measures to decrease the pulmonary artery pressure.

Sleeve Pneumonectomy

Tumors involving the most proximal portions of the main stem bronchus and the carina may require a sleeve pneumonectomy. These are most commonly performed for right-sided tumors and can usually be performed without cardiopulmonary bypass via a right thoracotomy. A long single-lumen endobronchial tube can be advanced across into the left main stem bronchus during the period of tracheobronchial anastomosis. High-frequency positive-pressure ventilation has also been used for this procedure. Since the carina is surgically more accessible from the right side, left sleeve pneumonectomies are commonly performed as a two-stage operation, with a left thoracotomy to perform the pneumonectomy and a right thoracotomy to perform the carinal excision. The complication rate and mortality are higher, and the 5-year survival is significantly lower than for other pulmonary resections. Post-pneumonectomy pulmonary edema is particularly a problem following right sleeve pneumonectomy.

Limited Pulmonary Resections: Segmentectomy and Wedge Resection

Segmentectomy and wedge resection are limited pulmonary resections. Segmentectomy is a sound oncological operation that is typically used in patients with smaller cancers and marginal pulmonary reserve, such as those patients with COPD [132]. It entails an anatomic pulmonary resection of the pulmonary artery, vein, bronchus, and parenchyma of a particular segment of the lung. Lung cancers that are considered for limited resection are usually less than 3 cm in size, located in the periphery of the lung, and with regional lymph nodes free of metastatic cancer.

In contrast, a wedge resection is a nonanatomic removal of a portion of the lung parenchyma with a 1.5–2.0 cm margin and can be accomplished by open thoracotomy or VATS. Wedge resections are most commonly performed for diagnosis of lung lesions with unknown histology or as palliation in patients with metastatic lesions in the lungs from distant primary tumors.

A group of patients considered for limited pulmonary resection are those who develop a new primary lesion after a previous lobectomy or pneumonectomy. The patient with compromised lung function presents a greater risk in the intraoperative period (hypoxemia during OLV or prolonged intubation after surgery). Cerfolio [148] et al. reported that lung cancer patients with compromised pulmonary function can safely undergo limited pulmonary resection if selected appropriately. Segmentectomies and wedge resections can be performed with any of the standard thoracotomy or VATS incisions. Segments that are most commonly resected are the lingular and superior divisions of the left upper lobe and the superior segments of the lower lobes.

Anesthetic technique and monitoring are essentially the same as for larger pulmonary resections. In order to facilitate surgical exposure and achieve OLV, it is necessary to use either a DLT or a bronchial blocker. If the patient had a previous contralateral lobectomy or a pneumonectomy, selective lobar collapse with the use of a bronchial blocker will facilitate surgical exposure while maintaining oxygenation. In selected cases the combined use of a DLT and a bronchial blocker will allow selective lobar collapse/ventilation in the ipsilateral lung [149]. It is very important to use low tidal volumes (i.e., 3–5 mL/kg) during selective lobar ventilation, particularly in patients with previous pneumonectomy to prevent overinflation in the remaining lobes.

Segmentectomy plays a significant role in the management of patients with a second primary lung cancer. Many of these patients have previously undergone thoracic surgery; this includes previous lobectomy or pneumonectomy; therefore the potential for increased intraoperative bleeding is always a risk. In addition, because many of these patients have compromised lung function, early extubation may not be feasible. A common complication after surgery is an air leak. Chest tubes are placed to maximize postoperative expansion and minimize space complications. Suction and underwater seal chest drainage are used in the postoperative period.

Bronchopleural Fistula

BPF can result as a consequence of surgical therapy (Fig. 23.4) or from the complications of intrathoracic infection or malignancy (see also Chap. 43). The classic presentation is a patient who has undergone a resection 10–14 days previously, who feels unwell and who has developed a productive cough of "salmon-colored" sputum. Patients can succumb to the resultant soilage of the lung and pneumonitis. If surgical therapy is required for BPF, the surgeon and anesthesiologist must combine their efforts to prevent any further lung injury.

In order to achieve satisfactory and sustainable ventilation, the team must have a command of the airway options as well as knowledge of nonstandard ventilation strategies. Positive-pressure ventilation is achievable in patients with a small fistula. However, with larger fistula, the ability to ventilate without isolating the fistula may be limited, and maintaining spontaneous ventilation may be a requisite. The initial management of the fistula is indeed drainage of

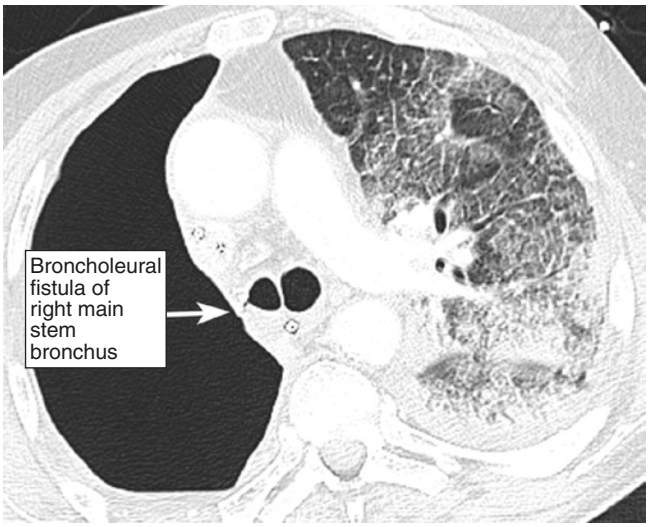

Fig. 23.4 CT image of a bronchopleural fistula in the right main stem bronchus, which developed after pneumonectomy, with accompanying pneumonitis in the contralateral lung

the infected pleural space. Patient positioning should be kept in mind, and the side of the fistula should be maintained in a dependent position. Surgical management of the fistula typically involves closure with vascularized flap coverage or window thoracostomy for drainage. Rarely, additional pulmonary parenchyma resection is required. As with tracheal surgical interventions, the use of jet ventilation and appropriate airway isolation strategies could potentially be necessary. Prompt discontinuation of positive-pressure ventilation is also required. In fact, if patients need positive-pressure ventilation in the presence of a BPF and this provides satisfactory ventilation and oxygenation, the surgical treatment of the BPF is relatively contraindicated.

Clinical Case Discussion

Case: A 68-year-old male presents for anesthesia. He has a 40-pack-year smoking history, hypertension controlled with diltiazem, and hypercholesterolemia controlled with simvastatin. He gives no history of exertional angina. The chest X-ray indicates a mass in the left upper lobe (Fig. 23.5), with absence of metastatic disease as assessed by computerized tomography and by a nuclear bone scan. Pulmonary function testing shows impaired function, characteristic of moderate COPD, with a negligible reversible component and a predicted postoperative FEV_1 of 48%.

Previous diagnostic bronchoscopy revealed encroachment of a non-small cell lung cancer onto the left main stem bronchus. Consequently, he is now scheduled for a

Fig. 23.5 Chest X-ray demonstrating a carcinoma of the left upper lobe

bronchoscopy, mediastinoscopy and left upper lobectomy with sleeve resection, and reattachment of the left lower lobe.

Questions

1. How does the mediastinoscopy alter perioperative management?
2. What airway management technique would be optimal?
3. What invasive monitoring is necessary?
4. Is there an optimal analgesic regimen?
5. Can perioperative fluid management affect outcome?
6. What ventilation strategy would promote optimal outcome?

Discussion

Given the rarity of blood loss requiring blood transfusion, an 18- or 16-gauge intravenous catheter, preferably placed in the nondependent hand, wrist, or forearm, would be appropriate. It is best to avoid the antecubital veins as the arms are bent at 90° when the patient is positioned in a lateral decubitus position, and this will hamper flow of the intravenous fluids. In anticipation of continuation to thoracotomy after mediastinoscopy, a thoracic epidural (alternatively, a paravertebral block) is placed in the T5–T8 region prior to induction. Standard noninvasive monitors will be used, with ECG leads placed as for any median sternotomy, thereby allowing

the entire chest to be prepped in a sterile fashion in case an emergent sternotomy is required due to massive bleeding resulting from the mediastinoscopy.

After induction, tailored to the patient, the airway is secured using an 8.0-mm single-lumen endotracheal tube to facilitate bronchoscopy. A LMA can be used for bronchoscopy if mediastinoscopy is not required. The endotracheal tube is usually brought out to the side of the mouth closest to the anesthesia machine once the bed is turned 90° for mediastinoscopy.

Given the absence of significant cardiac disease, invasive monitoring, with placement of an arterial line, can be deferred until after the mediastinoscopy is completed, and the decision is made to proceed to a thoracotomy – based on the absence of mediastinal lymph node involvement by the cancer. Placement of the arterial line is preferred in the dependent radial artery. This allows vigilant hemodynamic monitoring since acute hemodynamic embarrassment often occurs during surgical manipulation and due to the risk of catastrophic pulmonary vasculature injury. Significant fluctuations in blood pressure are especially seen with left-sided procedures where compression of the heart may occur during surgical manipulation.

A right-sided DLT would be of greater advantage in this case. Since a thoracotomy with sleeve resection requires surgical reimplantation of the left lower lobe bronchus (Fig. 23.3), a left-sided DLT may hamper optimal surgical exposure. If intubation is profoundly difficult, to the point where even changing the endotracheal tube over a tube changer would place the patient at significant risk, then alternative strategies including placement of a left main stem bronchial blocker or advancement of the single-lumen endotracheal tube into the right main stem bronchus should be considered.

Clear communication between the surgical and anesthetic team is essential if the pulmonary artery requires resection and reconstruction. In this case blood products should be readily available in the operating room, and steps to reduce the pulmonary artery pressure should be implemented. Such steps may include increased oxygenation (FiO_2, 100%), moderate hypocarbia (P_aCO_2, 30–35 mmHg), an appropriately "deep" level of anesthesia, minimized use of phenylephrine (consider vasopressin if blood pressure is low), and inhaled epoprostenol therapy to the ventilated lung.

Timing of initiation of the epidural and the choice of neuraxial medications remains controversial. A common practice is to initiate the epidural prior to induction so that inhalational anesthetics can be reduced to levels where HPV is not hampered. The intraoperative use of the epidural also helps to minimize the use of systemic opioids to reduce the risk of postoperative respiratory depression. Typically, more concentrated local anesthetics (± opioids) are used intraoperatively and more dilute combinations of local anesthetics and opioids used postoperatively.

The management of perioperative fluid therapy remains a controversy without conclusive data to guide treatment. The origins of the controversy stem from the significant risk of mortality from patients who develop ALI after thoracic surgery, in particular, those that develop post-pneumonectomy pulmonary edema. Typical guidelines suggest minimizing crystalloid therapy to 1.0–1.5 L, as this may help to reduce post-lobectomy pulmonary edema and facilitate early postoperative extubation.

Ventilation parameters during OLV typically strive to reduce the risk of ALI associated with barotrauma or volutrauma through tidal volume reduction (<6 mL/kg), respiratory rate > 10 breaths per minute, I:E ratio of 1:2, and peak inspiratory pressure < 25 mmHg. Such a protective ventilatory strategy aims to maintain baseline CO_2 levels or tolerate permissive hypercapnia (pH >7.25) rather than mild hypocapnia. Importantly, prolonged positive-pressure ventilation may hamper the tenuous blood supply of the sleeve anastomosis and increase the risk for a BPF and its associated complications. As such, this necessitates that the overall anesthetic technique be tailored to afford prompt and comfortable extubation of the patient.

Anesthesia for Video-Assisted Thoracoscopic Surgery (VATS)

24

Edmond Cohen and Peter Slinger

Key Points

- VATS has been shown to decrease postoperative complications compared to open thoracotomy in high-risk patients.
- Limited options to treat hypoxemia during one-lung ventilation compared to open thoracotomy. CPAP interferes with surgical exposure during VATS.
- Priority on rapid and complete lung collapse.
- Decreased postoperative analgesic requirements compared to open thoracotomy.
- Small and/or deep parenchymal lesions can be located by CT-guided micro-coil placement preoperatively
- Uniportal VATS surgery may offer improved postoperative recovery.

Historical Considerations of Video-Assisted Thoracoscopy

Thoracoscopy involves intentionally creating a pneumothorax and then introducing an instrument through the chest wall to visualize the intrathoracic structures. Recent application of video cameras to thoracoscopes for high-definition magnified viewing coupled with the development of sophisticated surgical instruments and stapling devices has greatly expanded the endoscopist's ability to do increasingly more complex procedures by thoracoscopy. It was widely believed that the first to perform a documented thoracoscopy using a Nitze cystoscope in a human patient was the Swedish internist Hans Christian Jacobaeus. Thoracoscopy, the introduction of an illuminated tube through a small incision made between the ribs, was first used in 1910 for the treatment of tuberculosis. In 1882 the tubercle bacillus was discovered by Koch, and Forlanini observed that tuberculous cavities collapsed and healed after patients developed a spontaneous pneumothorax. The technique of injecting approximately 200 cc of air under pressure to create an artificial pneumothorax became a widely used technique to treat tuberculosis [1].

Jacobaeus [2], however, was able to directly visualize pleural adhesions using thoracoscopy and described a method for cutting them to facilitate lung collapse. Closed intrapleural pneumolysis, also called the Jacobaeus operation, consisted in inserting a galvanocautery into the pleural cavity through another small opening in the chest wall and dividing the adhesions under thoracoscopic control. Thus the two-point entry technique of medical thoracoscopy was born.

After the introduction of tuberculostatic medications, this surgical approach was practically abandoned until the early 1990s when advancement in fiber-optic light transmission, image display, and instrumentation made video-assisted thoracoscopic surgery (VATS) possible. The improvements in video endoscopic surgical equipment and a growing enthusiasm for minimally invasive surgical approaches brought VATS to the practice of surgery for diagnostic and therapeutic procedures. Most of these procedures required general anesthesia and a well-collapsed lung and are an indication for one-lung ventilation (OLV).

A variety of medical and surgical procedures are performed by VATS [3] (see Table 24.1). The patient population tends to be either very healthy, undergoing diagnostic procedures, or high-risk patients who are undergoing VATS to avoid the risks of thoracotomy. Patients with advanced

Table 24.1 Spectrum of minimally invasive thoracic surgical procedures

Diagnostic
a. Pleural disease
Biopsy, thoracentesis
b. Staging
Lung, pleural, esophageal cancer
c. Parenchymal disease
Fibrosis, solitary nodules, pneumonitis
d. Mediastinal tumors
Thymoma, lymphoma, sarcoma, germ cell
e. Pericardial disease
Pericarditis, tumors
Therapeutic
a. Pleural disease
Pleurodesis, decortication
b. Parenchymal disease
Wedge resection, segmentectomy, lobectomy, pneumonectomy, bleb/bullae resection, lung volume reduction
c. Cardiovascular disease
Pericardial window, valve repair, coronary artery bypass, arrhythmia ablation
d. Mediastinal disease
Tumor excision, thymectomy, chylothorax
e. Esophageal surgery
Vagotomy, myotomy, antireflux surgery, esophagectomy
f. Sympathectomy
Hyperhidrosis, reflex sympathetic dystrophy
g. Spinal surgery

cardiopulmonary disease, malignancies, and heavy smoking history deserve an extensive preoperative evaluation and optimization since conversion to an open procedure is always a possibility. Intraoperative monitoring in these high-risk patients should be the same as for thoracotomy.

Medical Thoracoscopy This is mainly performed for diagnostic procedures. Initially it was limited to the use of a rigid thoracoscope; however with the introduction of optical fibers, it was expanded to include diagnostic procedures with flexible thoracoscopy. Unlike VATS, which consist of multiple access ports, medical thoracoscopy involves the insertion of an endoscope through a single entry port into the thoracic cavity and pleural space. Medical thoracoscopy is limited to diagnosis and biopsy of pleural disease, pleural effusions, infectious diseases, staging procedures, chemical pleurodesis, and occasionally for lung biopsy. It is often performed by the pulmonologist in the clinic rather than the operating room and is generally under local anesthesia. A small incision is made in thorough the lateral chest wall, and with the insertion of the instrument, fluid and biopsy specimens are easily obtained. Medical thoracoscopy has somewhat limited applications which are confined by the inability, in most cases, to perform more extensive therapeutic procedures such as wedge resection, lobectomy, or pneumonectomy.

Surgical Thoracoscopy VATS was introduced to thoracic surgical practice in the early 1990s and entails making multiple small incisions in the chest wall, which allow the introduction of a video camera and surgical instruments into the thoracic cavity through access ports. Most commonly, it is performed by a thoracic surgeon in the operating room under general anesthesia. In more recent years, surgical techniques, instruments, and video technology have improved to permit a wide variety of therapeutic procedures to be performed using VATS.

Indications

The proportion of thoracic procedures performed by VATS vs. thoracotomy has increased dramatically in the past decade. Currently, at one of the Author's (PS) institutions, approximately 70% of all lobectomies are performed by VATS. Previously, it was thought that survival after lung cancer surgery may be decreased with VATS due to incomplete resection. However, recently it has been shown that long-term survival is not decreased by VATS surgery vs. open thoracotomy [4].

Initially, when introduced to clinical practice, VATS was limited to diagnostics procedures of short duration and limited extension. Increased familiarity with thoracoscopic techniques, as with laparoscopic techniques, had enabled surgeons to perform almost any major thoracic surgical procedure in a minimally invasive manner. VATS operations can be used for all structures in the chest and are not limited to the lungs, pleura, and mediastinum.

Diagnostic Procedures

With VATS, diagnosis of pleural disease, thoracentesis, and pleural biopsy of a specific area under direct vision can be performed. In many cases this is indicated for an undiagnosed pleural effusion, in which the cytology is inconclusive. VATS for parenchymal lung pathology such as biopsy, wedge resection for solitary lung nodules or for diffuse interstitial lung disease is a common indication. In the past, such a diagnosis was possible only by subjecting the patient to an open thoracotomy, despite the associated morbidity, or the patient was treated empirically. VATS, which offers an extensive visualization of the entire chest cavity, essentially has replaced the traditional mini-thoracotomy particularly in cases where percutaneous needle aspiration biopsy is inconclusive. Other diagnostic procedures are performed on the mediastinum for biopsy of lymph nodes not accessible via traditional mediastinoscopy such as the subcarinal lymph nodes or for mediastinal masses, either primary or metastatic. This procedure is

essential when staging of the disease needs to be established. It is also useful for assessing resectability, to exclude direct invasion of the mediastinal structures. Lymphomas or germ-cell tumors that require a tissue diagnosis may benefit from a VATS approach. Diagnostic procedures involving the pericardium, such as a pericardial biopsy and/or drainage of a pericardial effusion can be accomplished both for diagnosis and therapy with a VATS pericardial window.

Therapeutic Procedures

Pleural disease can be managed by VATS including pleurocentesis, pleural abrasion for recurrent pleural effusion from malignancy or pneumothorax, decortication, empyectomy, and lysis of adhesions. In the past, thoracotomy was performed for formal decortication to permit re-expansion of the lung. With VATS, thoracotomy can be avoided, particularly in the early stages of empyema. Malignant pleural effusions, particularly those with multiple loculated collections, are difficult to drain with tube thoracostomy and can be effectively treated with VATS.

Lung parenchymal disease such as wedge resection of a lesion, lobectomy or pneumonectomy can routinely be performed with VATS. These are better tolerated by the compromised patient with decreased pulmonary reserve [5]. VATS offers the opportunity to both diagnose and treat parenchymal lesions at the same time. Management of bullous disease, particularly giant bullae with significant compression of the adjacent lung, is frequently managed with VATS. Often these cases present with recurrent pneumothoraces or air leaks associated with apical blebs. Lung volume reduction (LVR) performed by VATS is better tolerated by the patient with severe emphysema (see also Chap. 46). Resection of mediastinal masses such as thymoma or mediastinal cyst or resection of posterior mediastinal neurogenic tumors, treatment of chylothorax by ligation of the thoracic duct, bilateral sympathectomy are all possible with VATS.

A variety of esophageal procedures can be performed minimally invasively. Vagotomy, Heller myotomy, antireflux procedures, or staging of esophageal cancer are common procedures done with VATS. Finally, the dissection of the thoracic esophagus in cases of esophagogastrectomy is increasingly performed with a combined VATS and laparotomy.

VATS sympathectomy is usually performed for hyperhidrosis or reflux sympathetic dystrophy. The sympathetic chain is visualized as it lies along the vertebral bodies. The magnification provided by VATS facilitates the procedure, which is usually done bilaterally during the same anesthetic.

Benefits

The incisions for VATS are usually 2–4 ports to allow for the passage of a video camera stapling device and forceps. Because the ribs are not spread, patients have lower narcotic requirements for postoperative pain, reduced shoulder dysfunction, and decreased time until return to preoperative activities. There is a reduced risk of respiratory depression, reduced risk of atelectasis due to splinting, or reduced ability to sustain deep breathing and reduction in retained secretions.

A propensity score matched study has shown that fewer patients had complications after VATS vs. open lobectomies [6] (see Table 24.2). Patients who are considered high risk for lobectomy via open thoracotomy, based on preoperative pulmonary function studies, were demonstrated not to have an increased risk compared to low-risk patients when the surgery was performed by VATS (see Fig. 24.1) [7]. COPD patients have been shown to have improved outcomes after lobectomy with VATS vs. open thoracotomy (see Table 24.3) [8]. A randomized study has shown that long-term postoperative pain after lobectomy is decreased in VATS

Table 24.2 Postlobectomy complications VATS vs. open thoracotomy

Outcome	VATS (n = 122)	Open (n = 122)	p value
Length of stay (days ± SD)	4.9 ± 2.4	7.2 ± 3.8	0.001
All complications	17%	28%	0.046
Atrial fibrillation	12%	16%	0.36
Prolonged air leaks	3.8%	5.7%	0.54
Pneumonitis	1.6%	4.1%	0.28

Based on data from Bendixen et al. [9]

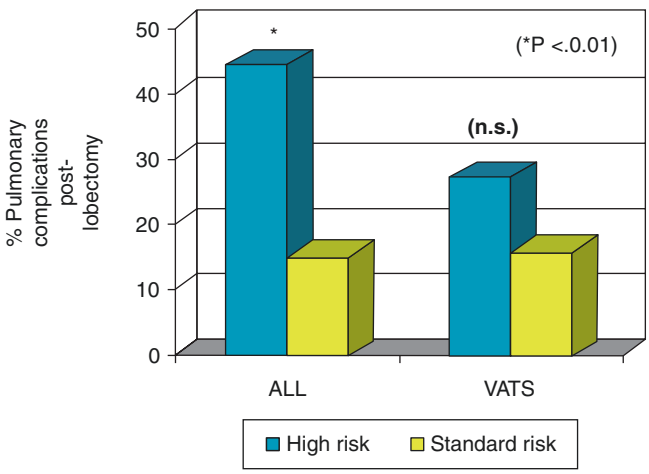

Fig. 24.1 The percentages of high-risk vs. standard-risk patients having postlobectomy pulmonary complications during the period 2002–2010. High risk was defined based on preoperative pulmonary function tests, cardiac function, and exercise performance. For VATS procedures, there was no statistically significant increase in complications for high-risk patients vs. standard-risk patients

Table 24.3 Postlobectomy complications in elderly patients

Outcome	VATS	Open	*p* value
Median length of stay (days)	5	6	0.001
No complications	72%	55%	0.04
Pulmonary	15%	33%	0.01
Cardiac	17%	23%	0.44

Based on data from Miyazaki et al. [10]

patient vs. thoracotomy patients [9]. VATS procedures seem to benefit elderly patients. A series of five nonagenarian patients has been published with successful lung cancer surgery by VATS [10]. Although decreased rates of complications are seen with lobectomies or wedge resections, this has not been evident for pneumonectomies [11].

Surgical Technique

VATS is performed usually in the lateral position through three to five entry ports created in the chest wall on the side of the pathology (see Fig. 24.2). A video camera is inserted to allow for direct visualization of the entrance of trocars into the thorax. The lung is collapsed on the ipsilateral side by passive elastic recoil equilibrium of intrapleural and atmospheric pressure occurs through the access port. If the lung is not adequately collapsed, the surgeon is not able to appreciate the surgical field and identify a lung lesion when it is not located on the surface of the lung. Additionally, placing a stapler suture on a lung that is only partially deflated may result in inadequate closure lines which may be the source of continuous air leak (see Fig. 24.3).

Although rarely used in thoracoscopic procedures, unlike laparoscopic procedures, some surgeons may elect to insufflate CO2 gas into the ipsilateral hemithorax to assist in collapsing the lung and breaking adhesions and to maintain the pneumothorax. There is no good evidence that a CO2 insufflation has any benefit. Insufflation of CO2 into the ipsilateral hemithorax can be associated with hemodynamic compromise and significant hypotension since the chest is a closed cavity, and the increase in intra-thoracic pressure by insufflation of CO2 will reduce venous return and cardiac output. The pressure inside the thorax must be measured and kept low. Keeping the intra-thoracic pressure below 10 cm of H2O should minimize the negative hemodynamic effects. This is a period when communication between surgeon and anesthesiologist is crucial.

Anesthetic Management

After appropriate anesthesia and surgical evaluation, an anesthetic plan is devised to allow the patient to be safely anesthetized for the surgical procedure and to recover. Most patients find it reassuring to have a discussion with their anesthesiologist about the anesthetic and postoperative pain relief options. The choice of anesthetic technique is variable and dependent upon the wishes of the patient and the experience of the clinician. While simple diagnostic procedures can be performed under local anesthesia by infiltrating the chest wall accompanied by light sedation, more complex procedures that require sampling of tissue are best done under regional (epidural, intercostal blocks) or general anesthesia. The main disadvantage of local and regional anesthesia is that the patient is required to breathe spontaneously. While this is generally tolerated for brief periods of time, most VATS procedures today are performed under general anesthesia utilizing one-lung ventilation (OLV) techniques, which provides better exposure and guarantees a secure airway in the lateral decubitus position.

Fig. 24.2 Video-assisted thoracoscopic surgery as viewed from the foot of the operating table. A well-collapsed lung on the side of surgery is necessary for any major procedure

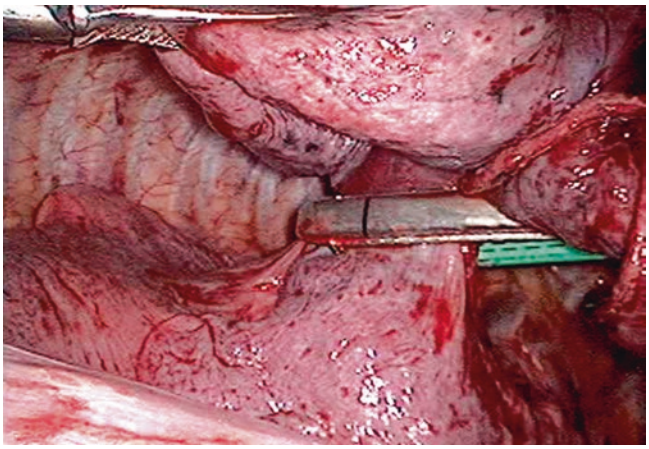

Fig. 24.3 A stapling devise is used to open the interlobar fissure as part of the initial surgical approach during a VATS lobectomy. If the lung is not well collapsed, there is an increased risk of air leaks from the staple lines

Each of the above techniques has its advantages and disadvantages. Decisions regarding postoperative pain relief should be made preoperatively. The management of an epidural vs. patient-controlled analgesia (PCA) vs. PRN medications given by the nurse with or without adjunctive agents is best evaluated on a daily basis by a specialist in the field of pain management. Additional considerations regarding postoperative pain management should be given to the likelihood of proceeding on to thoracotomy.

Local/Regional Anesthesia

The simplest technique is to use a local anesthetic to infiltrate the lateral thoracic wall and parietal pleura combined with appropriate sedation and supplemental oxygen. Preferably intercostal nerve blocks can be performed at the level of the incision(s) and at two interspaces above and below (see Chap. 59). Thoracic epidural anesthesia can also be used [12]. For VATS procedures under local or regional anesthesia, an ipsilateral stellate ganglion block is often performed to inhibit the cough reflex from manipulation of the hilum. To anesthetize the visceral pleura, topical local anesthetics can be applied. Intravenous sedation with propofol may be needed to supplement regional nerve blocks.

For VATS performed under local or regional anesthesia with the patient breathing without assistance, partial collapse of the lung on the operated side occurs when air is allowed to enter the pleural cavity. The resulting atelectasis may provide suboptimal surgical exposure. The major disadvantage to VATS under local or regional anesthesia is that the patient must breathe spontaneously. This is usually tolerated for short periods of time, but for major VATS procedures, a general anesthetic with OLV is a better choice.

The collapse of the lung provides the surgeon with a working space, and a chest tube is placed at the conclusion of the surgery. Changes in PaO2, PaCO2, and cardiac rhythm are usually minimal when the procedure is performed using local or regional anesthesia. With local anesthesia, the spontaneous pneumothorax is usually well tolerated because the skin and chest wall form a seal around the thoracoscope and limit the degree of lung collapse. Occasionally, however, the procedure is poorly tolerated, and general anesthesia must be induced. The insertion of a double-lumen tube (DLT) with the patient in the lateral position may be difficult, in which case the patient may be temporarily placed in the supine position for the intubation.

If general anesthesia is required, a DLT is preferable to a single-lumen tube because positive-pressure ventilation via a single-lumen tube would interfere with endoscopic visualization. In addition, if pleurodesis is being performed, general anesthesia through a DLT allows for re-controlled re-expansion of the lung. A regional approach is well suited to a patient who is motivated to maintain control of their environment, a surgeon who can work gently, and for a procedure that is short in duration. A benefit of regional anesthesia is that it wears off slowly over a few hours allowing for oral opioids and adjuvant analgesics to be added as needed with minimal discomfort to the patient. The risks of this approach include accidental intravenous, epidural or spinal injection with associated toxicity, or cardiopulmonary embarrassment. In experienced hands, complications are rare enough to allow for the routine use of regional anesthesia for minor VATS procedures. Because the patient is not under general anesthesia and local anesthetic has only been applied to the rib cage, the patients may complain of discomfort during manipulation of lung tissue with pain referred to the shoulder. Referred shoulder pain may be difficult to differentiate from the anginal discomfort of cardiac disease.

General Anesthesia

Indications for one-lung ventilation: "Lung isolation" includes the classical absolute indications for OLV, such as massive bleeding, pus, and alveolar proteinosis or bronchopleural fistula. The goal is to protect the non-diseased contralateral lung from contamination. "Lung separation," on the other hand, refers to cases with no risk of contamination to the dependent lung and is performed primarily to improve surgical exposure such as for VATS. The inability to completely deflate the non-dependent lung during VATS leads to poor surgical exposure, which in turn can jeopardize the success of the procedure, potentially requiring conversion to an open technique. Because of the increasing number of diagnostic and therapeutic procedures performed with VATS, the need to provide OLV has risen significantly.

Treatment of Hypoxemia During VATS The application of continuous positive airway pressure (CPAP) by oxygen insufflation to the non-ventilated lung has traditionally been accepted as the best maneuver to treat hypoxemia during OLV [13] (see also Chap. 6). This maneuver is well accepted during open thoracotomy. Unfortunately, the application of CPAP is poorly tolerated by the surgeon during VATS because of the obstruction of the surgical field by the partially inflated lung [14] (see Fig. 24.4). Since most patients will develop atelectasis in the ventilated dependent lung during general anesthesia in the lateral position (see Fig. 24.5), recruitment maneuvers [15] and the application of PEEP to the ventilated lung are useful in the majority of patients, except those with severe obstructive lung disease [16] (see Fig. 24.6). A useful method of improving oxygenation during

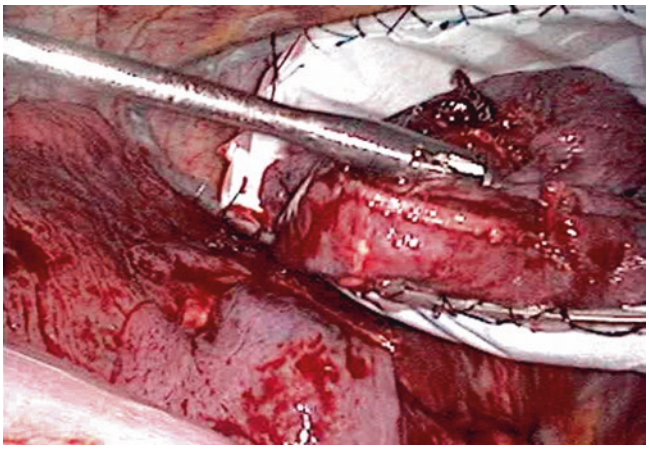

Fig. 24.4 During a VATS lobectomy, the excised lobe is placed in a retrieval bag before being removed through a small chest wall incision. Good collapse of the operative lung is required for the surgeon to perform this operation

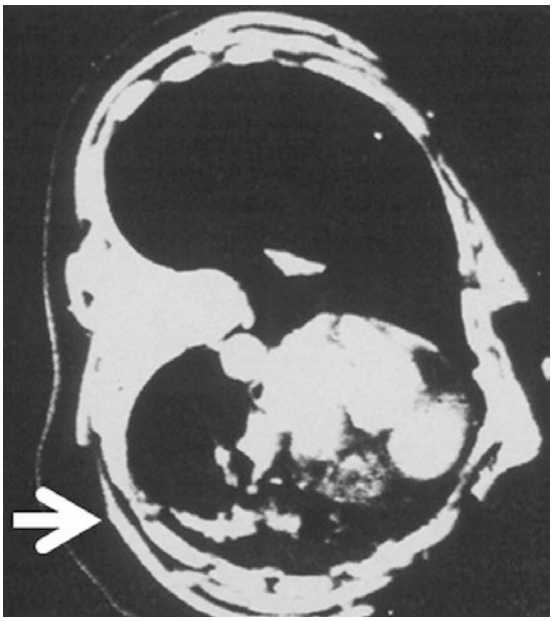

Fig. 24.5 Chest CT scan during general anesthesia in the lateral position. The white arrow points to a plaque of atelectasis in the dependent lung. Most patients develop atelectasis in the dependent lung during anesthesia

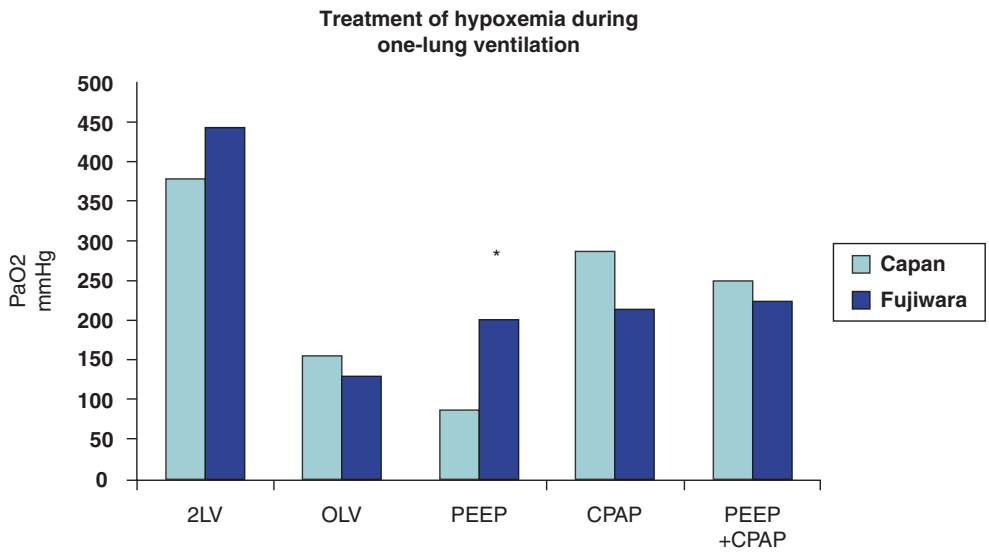

Fig. 24.6 A comparison of the effects of PEEP and CPAP on oxygenation during one-lung ventilation in patients with COPD (Capan) vs. normal pulmonary function (Fujiwara). PEEP improves PaO2 for most patients with normal pulmonary function during OLV (* significant improvement $p < 0.05$) but decreases PaO2 in patients with COPD. (Based on data from Refs. [13, 15])

OLV for VATS is the bronchoscope-guided insufflation of oxygen into segments of the non-dependent lung remote to the site of surgery [17] (see Chap. 6, Fig. 6.10).

Improving Lung Collapse During VATS Since a collapsed immobile lung on the side of surgery is fundamental to VATS for major pulmonary resections, one of the anesthesiologists' responsibilities is to facilitate collapse of the non-ventilated lung. There are three basic maneuvers that will increase the rate of lung collapse:

1. Eliminate all nitrogen from the operative lung prior to the initiation of lung collapse. The poorly-soluble nitrogen in air delays collapse in non-ventilated alveoli. Although the use of air-oxygen mixtures are desirable to prevent the development of atelectasis in the ventilated lung during one-lung anesthesia, if air is present in the non-ventilated lung at the start of OLV it will delay collapse [18] (see Chap. 6). It is best to ventilate with a FiO2 of 1.0 for a period of 3–5 min immediately prior to the start of OLV to denitrogenate the operative lung. After a recruitment maneuver of the ventilated dependent lung, air can then be reintroduced to the gas mixture after the start of OLV as tolerated, according to the arterial oxygen saturation.
2. Avoid entrainment of room air into the non-ventilated lung during closed-chest OLV. Many anesthesiologists

will begin OLV as soon as possible to encourage lung collapse prior to the start of surgery. However during closed-chest OLV, if the lumen of the DLT to the non-ventilated lung is open to atmosphere, passive paradoxical ventilation of the non-ventilated lung will occur (inspiration during the expiratory phase of the ventilated lung), and air will be drawn into the non-ventilated lung delaying collapse (see Fig. 24.7). It has been shown that these passive tidal volumes are approximately 130 ml/breath [19] which far exceeds the dead space of one side of a DLT (10–15 ml). These passive tidal volumes cease as soon as atmospheric pressure is allowed into the operative hemithorax.

3. Apply suction to the lumen of the DLT or bronchial blocker to the non-ventilated lung at the start of OLV. Low suction (−20 cmH2O) improves the rate of lung collapse for both open thoracotomy and VATS [20] (see Figs. 24.8). It is not clear whether the effect of suction is due to the negative pressure or simply due to a suction catheter preventing passive entrainment of air into the non-ventilated lung (see Fig. 24.9).

Verifying Patency of Other Bronchi During VATS Lobectomy During open thoracotomy for lobectomy, to ensure that the patency of a bronchus to a remaining lobe has not been compromised, the surgeon will often ask the anesthesiologist to temporarily re-inflate the non-ventilated lung

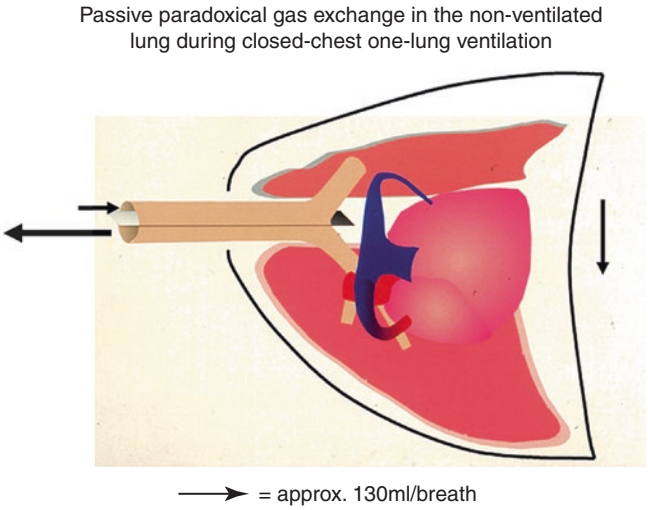

Fig. 24.7 Passive paradoxical gas exchange occurs in the non-ventilated lung during OLV if the chest is closed. As the mediastinum falls during exhalation of the ventilated lung, the resultant negative pressure in the non-ventilated hemithorax entrains room air into the non-ventilated lung if the lumen of the DLT is open to atmosphere. This air is then expired during the inspiration phase of the ventilated lung. The passive tidal volumes depend on the size of the patient and cease once the initial VATS port allows atmospheric pressure to equilibrate in the non-ventilated hemithorax. (Based on data from Ref. [19])

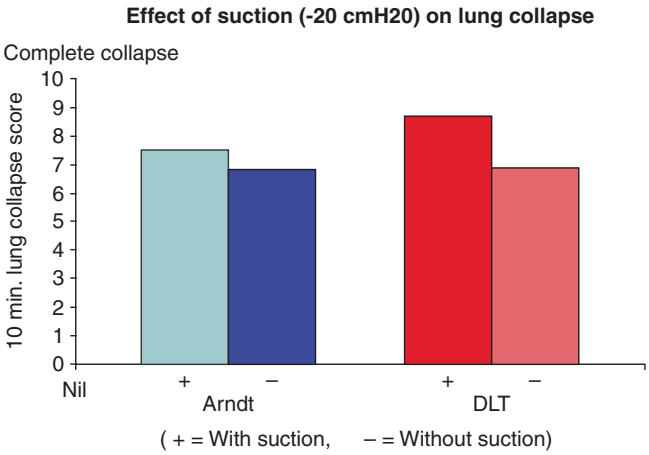

Fig. 24.8 The application of low suction to the channel of a bronchial blocker (in this case the Arndt blocker) or to the lumen of the DLT to the non-ventilated lung significantly improves the speed of lung collapse measured both 10 min (shown here) and 20 min after the start of OLV. (Based on data from Ref. [20])

Fig. 24.9 Photograph of suction being applied via a catheter to the tracheal lumen of a left-sided DLT during a right-sided VATS procedure. Low suction (–20cmH2O) should be applied from the start of OLV until the non-ventilated lung is completely collapsed

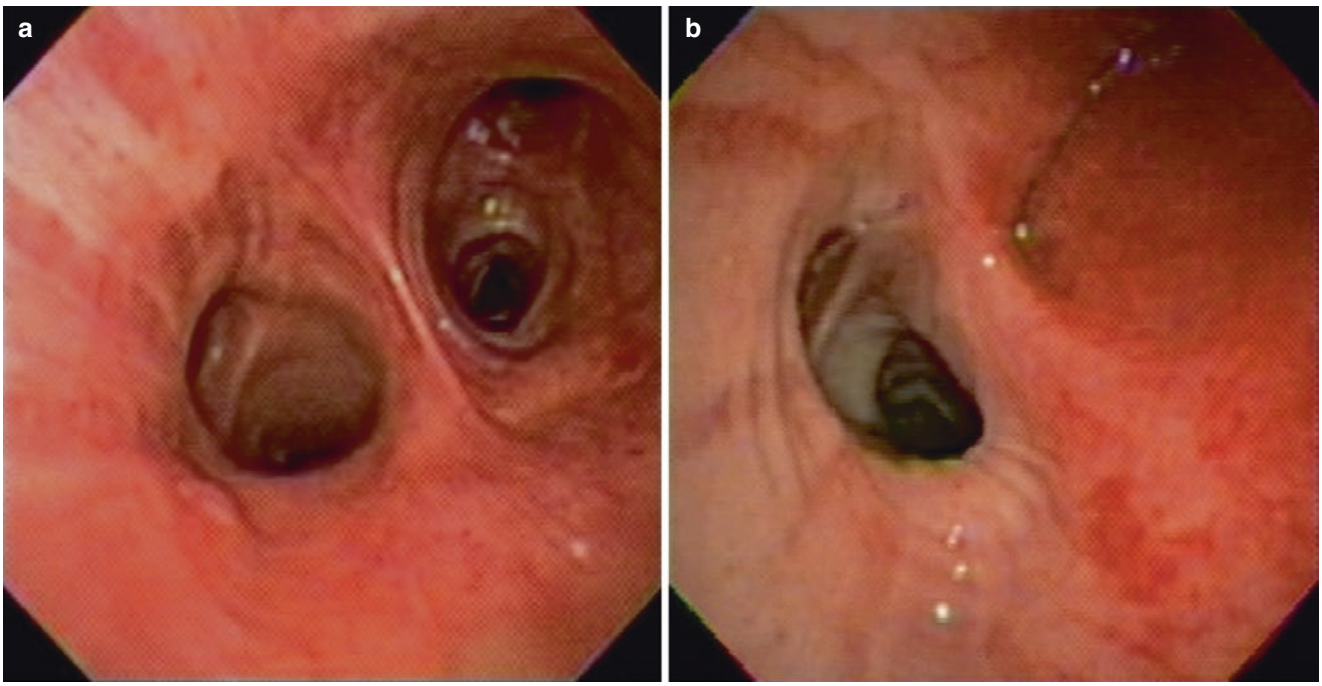

Fig. 24.10 (**a**) Normal anatomy of the secondary carina of the left lung as seen during fiber-optic bronchoscopy during VATS lobectomy. The left upper lobe orifice is at the upper right. The posterior wall of the mainstem bronchus is identified by the longitudinal elastic bundles, seen at 9 o'clock, which extend into the left lower lobe. (**b**) A surgical stapler has been applied to the left upper lobe bronchus. The anesthesiologist is asked to ensure that the bronchus to the left lower lobe remains patent, as seen in the photograph, prior to firing the stapler

after the stapling device has occluded the bronchus to the operative lobe or segment, just before the desired bronchus is cut and stapled. Re-inflation of the ipsilateral remaining lobe(s) ensures the patency of their bronchi. However, during a VATS resection, this maneuver impairs the surgeon's ability to visualize the surgical field and to proceed with the resection. To avoid this potential for compromise of non-involved bronchi during VATS, the anesthesiologist may be asked to perform fiber-optic bronchoscopy at this stage to ensure that the bronchi to the remaining ipsilateral lobe(s) are patent (see Fig. 24.10a, b). To perform this, the anesthesiologist needs a detailed knowledge endoscopic bronchial anatomy (see Chap. 17).

Lung Isolation The use of double-lumen tubes (DLT) has classically been considered the "gold standard" for achieving OLV. Proper position of the DLT or endobronchial blocker is often confirmed in the supine position, but it is when the patient has been placed in the lateral decubitus position that matters most since the surgery will take place in that position and dislocation during position changes are not uncommon. A study conducted by Narayanaswamy and colleagues [20] showed in 104 patients undergoing left-sided lung surgery that, in regards to quality of surgical exposure, there was no difference between the use of bronchial blockers (Arndt wire-guided, Cohen Flexi-tip, Fuji Uniblocker) and a left-sided DLT. However, significant differences were found favoring the use of DLTs with regard to time to initial lung deflation and amount of repositioning required after initial placement of the lung isolation device. Since most VATS procedures require lung separation and not isolation, the insertion of a bronchial blocker to obtain OLV is an attractive alternative to a DLT, especially since multiple intubations of the trachea will not be necessary when using a bronchial blocker. Additionally, a difficult intubation is even more difficult much when using a DLT.

Management of OLV

Peak airway pressure, delivered tidal volume (spirometry), and the wave-form of the capnogram should be inspected to identify obstruction or reduced end-tidal carbon dioxide tension from inadequate gas exchange subsequent to DLT malposition. A peak airway pressure of up to 35 cmH_2O during OLV is acceptable. A sudden increase in the peak airway pressure (during volume-controlled ventilation) may be from DLT or endobronchial blocker dislocation. These tube or blocker movements are often a consequence of surgical

manipulation. During pressure-controlled ventilation, this will present as a fall in tidal volume. When OLV is required, a FiO_2 of 1.0 provides the greatest margin of safety against hypoxemia. When using a FiO_2 of 1.0, assuming a typical HPV response, the expected PaO_2 during OLV should be between 150 and 210 mmHg. I typically ventilate OLV patients with a tidal volume of 6–7 ml/kg, PEEP 5 cm H_2O, and at a respiratory rate sufficient to maintain a $PaCO_2$ of 35 ± 3 mmHg. Following the initiation of OLV, PaO_2 can continue to decrease for up to 45 min; hence, a pulse oximeter is indispensable. Should hypoxia occur, proper positioning of the DLT should be reconfirmed using fiber-optic bronchoscopy.

Other Anesthetic Considerations for VATS In addition to the usual complications related to intrathoracic surgery and anesthesia, thoracoscopic procedures can be associated with massive hemorrhage and decreased inability to control large blood vessels. Maintaining stable hemodynamics can present a challenge until the surgeon gets control of the source of bleeding which may require conversion to an open thoracotomy. Therefore, large-bore intravenous catheters are even more critical for VATS procedures than open thoracotomy where the hilar blood vessels can be controlled easier. Bleeding can be from placement of trocars into the lung or great vessels

A false assumption that is made by patients coming for minimal invasive surgery is that the perioperative risk will also be "minimal." VATS is frequently described to the patient and their family as a simple entry into the chest. While VATS is associated with improved healing, lung function and shorter hospital length of stay, by no means should one be lured into thinking that the procedure is any less invasive than an open thoracotomy. Diagnostic VATS procedures are being increasingly performed on ASA III-IV patients, who historically would have been classified as inoperable using an open approach. An example would be a patient on the cardiac transplant list that needs a pre-transplant tissue diagnosis of a lung lesion seen on a preoperative chest X-ray. Consequently, very ill patients requiring flawless lung separation techniques, who expect an uneventful perioperative course, pose an increased stress for the anesthesia team.

Localization of Small Parenchymal Lesions

As imaging modalities improve, smaller lung lesions are detected at an early stage when surgical intervention may be optimal. Initially VATS procedures were considered unsuitable for small lesions deep in the parenchyma which needed to be localized by surgical palpation of the lung. A number of techniques have been developed to identify these lesions before surgery so that they could be removed by VATS. These techniques include percutaneous CT-guided injection of the lesions with dye or placement of a hookwire. Preoperative CT-guided placement of micro-coils has proven to be the most useful of these techniques [21]. A micro-coil is placed adjacent to the lesion by radiology using CT guidance in the awake patient with local anesthesia and sedation. Anesthesia is then induced with one-lung ventilation. During VATS, intraoperative fluoroscopy is used to localize the lesion for resection. This technique has been shown to have a high success rate for removal of small lesions.

The specific anesthetic concern is that a significant number of these patients develop a small pneumothorax at the time of coil placement. All these patients should be assumed to have a potential bronchopleural fistula for purposes of anesthetic induction. Positive-pressure ventilation without lung isolation could lead to an ipsilateral tension pneumothorax. This Author's (PS) management is a modified rapid-sequence induction of anesthesia with a DLT. The position of the DLT is adjusted with fiber-optic bronchoscopy immediately after intubation. One-lung ventilation of the contralateral lung is then begun after confirmation of the DLT positon and inflation of the bronchial cuff.

Uniportal VATS

Initially, VATS procedures have been performed through 2–4 surgical ports. Over the past 7 years, the use of a single port for VATS procedures has become more widespread. The uniportal technique has now been extended to include lobectomies and even pneumonectomies [22]. The possible advantages include decreased postoperative pain and shorter length of stay. The uniportal procedure is performed with the patient in the standard lateral VATS positon with general anesthesia and one-lung ventilation (see Fig. 24.11). The single VATS port is placed through a 2–4 cm muscle-sparing incision in the 4th–6th intercostal space in the anterior axillary line. Like standard VATS, the uniportal technique can be used in non-intubated, spontaneously breathing patients (see also Chap. 25) [23].

Pain Management Techniques

Extensive discussion of the management of post-thoracotomy pain can be found in Chap. 59. A commonly cited advantage of VATS when compared to open thoracotomy is a reduction in postoperative pain. While this is true in a relative sense, VATS procedures are still associated with a significant amount of postoperative pain that is not only disturbing to

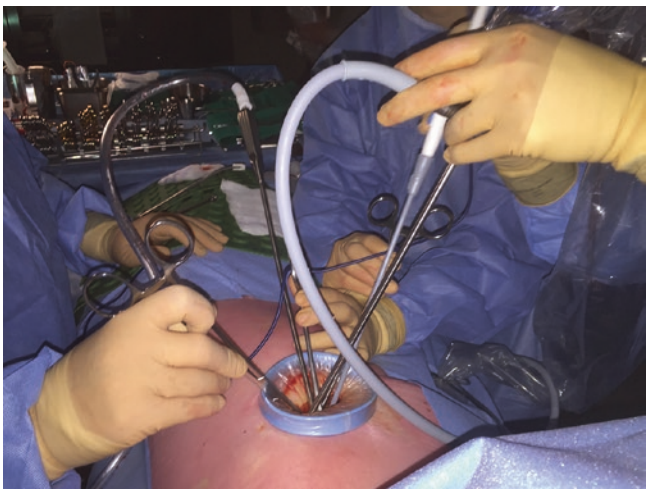

Fig. 24.11 Photograph of uniportal VATS surgery. The patient is in the right lateral position. Multiple surgical instruments can be passed through a single port. (Photograph courtesy of Dr. J Bussieres)

patients but may be associated with pain-related morbidities and prolonged hospital stays. The preponderance of literature suggests that VATS lung resection is associated with decreased postoperative pain compared with conventional thoracotomy. Sugiura and colleagues found a reduced duration of epidural catheter use, less narcotic use, decreased frequency of analgesic administration, and possibly a lower incidence of post-thoracotomy pain syndrome in patients undergoing VATS compared with those undergoing thoracotomy [20].

Thoracic epidural analgesia has a long track record of efficacy and safety and is considered by many anesthesiologists the gold standard in pain relief during the postoperative period for thoracotomy. However, the majority of VATS procedures are now performed with other types of regional block. While other forms of postoperative analgesia are possible, many are associated with unwanted side effects. Systemic opioids are respiratory depressive and inhibit the cough reflex. Nonsteroidal anti-inflammatory medication can inhibit coagulation and in isolation do not suffice to control the immediate postoperative pain experienced by this patient population. The utilization of paravertebral, serratus anterior plane, and erector spinae plane blocks has shown promise as an alternative to epidural analgesia.

The control of postoperative pain in patients after intrathoracic surgery is critical to the rehabilitation of their respiratory function. Postoperative pain in the chest wall can cause splinting which will impair couching, deep breathing leading to retention of secretions, and a decrease in FRC. These problems have been shown to be a source of great morbidity and should be managed aggressively. The options for postoperative pain management should begin preoperatively and not postoperatively. A frank discussion with the patient will allow the patient to discuss their fears of anesthesia and postoperative pain. Pain control options include cognitive/behavioral (i.e., relaxation, distraction, and imagery techniques), intravenous administration of opioids and adjuvant agents (i.e., nonsteroidal anti-inflammatory drugs, tricyclic agents) on an "around the clock" and/or PRN basis, PCA intravenous pumps, neuraxial (epidural, intrathecal) agents (local anesthetics, opioids, ketamine, clonidine, alpha agonists), intermittent neural blockade (with local anesthetics, cryoprobe, neurolytic agents) or continuous neural blockade (with an intrapleural catheter), physical application of hot and cold compresses, or TENS (transcutaneous electrical nerve stimulation). The surgical technique plays a very important part in the level of pain the patient will have postoperatively. There should be less pain associated with a VATS vs. open thoracotomy since there is less chest wall muscle damage. Controversy exists whether thoracic epidural analgesia is necessary for procedures performed with VATS since the pain experience is less dominated by the incisional component, compared to a thoracotomy. Thoracoscopy pain reflects more the visceral, pleural, and diaphragmatic nociceptive components. Multimodal techniques involving a combination of intraoperative intercostal nerve blocks, pre- and postoperative oral anti-inflammatories, and postoperative intravenous patient-controlled opioid analgesia are common strategies for the majority of VATS patients in many centers. Thoracic epidural may be reserved for patients with severe pulmonary dysfunction who are at a high risk for postoperative respiratory complications.

Clinical Case Discussion

A 67-year-old male with a right upper lobe non-small cell lung tumor is scheduled for VATS right upper lobectomy (see Fig. 24.12). He has COPD, preoperative FEV1 is 57% predicted, and DLCO is 60%. No other comorbidities. After intravenous induction of anesthesia, he is intubated with a left double-lumen tube. After turning the patient to the left lateral position and confirming the position of the double-lumen tube with fiber-optic bronchoscopy, one-lung anesthesia is begun with sevoflurane (1MAC) and a FiO2 of 1.0, pressure-control ventilation, tidal volume 6 ml/kg, and resp. rate 12/min. When the surgeon places the VATS camera in the right chest, the lung is not completely collapsed. What can be done to improve lung collapse?

Answer: The position of the double-lumen tube should be reconfirmed with bronchoscopy. The adequacy of lung isolation should be confirmed by verifying that the inspired and expired tidal volumes of the left lung match using sidestream spirometry (the expired tidal volume is often a small percentage lower than the inspired volume due to the greater uptake of oxygen than the production of CO2). The use of

Fig. 24.12 Chest X-ray of a patient with a right upper lobe non-small cell lung cancer scheduled for VATS lobectomy. The patient has moderate COPD as evidenced by the hyperinflation of the lungs and the narrow cardiac silhouette

FiO2 1.0 to the operative lung prior to the initiation of one-lung ventilation will increase the rate of lung collapse, and a low suction (20 cmH20) applied to the non-ventilated lung will also speed collapse (see text).

With the onset of one-lung ventilation, the arterial oxygen saturation begins to slowly decrease. All other vital signs are stable: HR 78, BP 130/82, and PetCO2 32 mmHg. After 20 min of surgery, the SpO2 has fallen to 89% and continues to decline. What is the most appropriate next step?

Answer: After reconfirming the FiO2 and the correct position of the double-lumen tube with bronchoscopy, a recruitment maneuver of the left lung is performed, and PEEP 5cmH2O is added to the left lung. In spite of these therapies, the SpO2 continues to fall and is now 87%. The anesthesiologist suggests applying CPAP to the operative left lung. The surgeon is adamant that he/she will not be able to complete the operation as a VATS procedure if CPAP is necessary and will have to convert to an open thoracotomy.

Is there any other therapy that can improve oxygenation and will not interfere with surgical exposure?

Answer: Guided insufflation of oxygen at 5 L/min into the basilar segments of the right lower lobe is performed for 30 sec via the suction channel of the fiber-optic bronchoscope, while the surgeon monitors the insufflation using the VATS camera (see Chap. 6, Fig. 6.10). After partial re-inflation of the anterior and lateral basal segments of the right lower lobe, the SpO2 increases to 93% and surgery continues. The bronchoscopic segmental insufflation needed to be repeated once again 20 min later when the SpO2 fell to <90%. Surgery was completed without complication or conversion to open thoracotomy. Management of hypoxemia during VATS procedures is outlined in Table 24.4.

Table 24.4 Management of hypoxemia during VATS

Severe or acute desaturation
Resume two-lung ventilation
Gradual desaturation
1. Assure FiO_2 = 1.0
2. Check double-lumen tube or bronchial blocker placement with fiber-optic bronchoscopy
3. Optimize cardiac output
4. Recruitment maneuver of the ventilated lung
5. Apply PEEP 5 cm H_2O to ventilated lung (except moderate–severe COPD patients)
6. Partial ventilation of the non-ventilated lung
(i) Segmental re-inflation (with fiber-optic bronchoscopy)
(ii) High-frequency jet ventilation

Anesthesia for Non-intubated Thoracic Surgery

25

Peter Slinger

Key Points

- The increasing use of VATS surgery has revived interest in non-intubated thoracic surgery.
- Recent advances in regional local anesthetic chest wall blocks have improved anesthesiologist's willingness to use non-intubated thoracic anesthesia.
- Improved methods of sedation have increased patients satisfaction with non-intubated thoracic anesthesia techniques.

Initial attempts at anesthesia for thoracic surgery in the late 1800s were all made with non-intubated patients breathing air-ether spontaneously through a mask. The lung collapse and pendelluft effect (see Chap. 1) when the surgeon opened the chest led to hypoxemia, hypercapnia, and hemodynamic instability [1]. The first major advance in thoracic anesthesia came in the first decade of 1900 when Sauerbruch developed the negative pressure chamber for thoracic anesthesia (see Fig. 25.1) [2]. Non-intubated patients continued to breathe air-ether spontaneously, but the negative pressure in the chamber (which excluded the patients head) prevented the lung in the open hemithorax from collapsing. However, this technique did not deal well with the problem of secretions. This was a major drawback since most of the chest surgery in the early part of the past century was for infectious causes.

As intubation, methods of lung isolation, and positive-pressure ventilation were developed, non-intubated thoracic anesthesia became very infrequent, although there were always case reports using spinal [3] or epidural [4] anesthesia. With the use of supplemental oxygen, the problem of hypoxemia is rarely an issue during non-intubated thoracic anesthesia. During traditional one-lung ventilation, the positive pressure in the ventilated hemithorax tends to divert pulmonary blood flow to the non-ventilated lung and partially opposes the redistribution of blood flow by hypoxic pulmonary vasoconstriction in the non-ventilated lung (see Chap. 5). This effect is not seen when positive-pressure ventilation is avoided and arterial oxygenation is often equivalent or better with non-intubated techniques [5]. In 2010 Katlic and Facktor described 384 consecutive cases of VATS with local anesthesia and sedation. The patients ranged in age from 21 to 100 years (mean 67 years). Operations included pleural biopsy drainage with or without talc (244), drainage of empyema (74), lung biopsy (40), evacuation of hemothorax

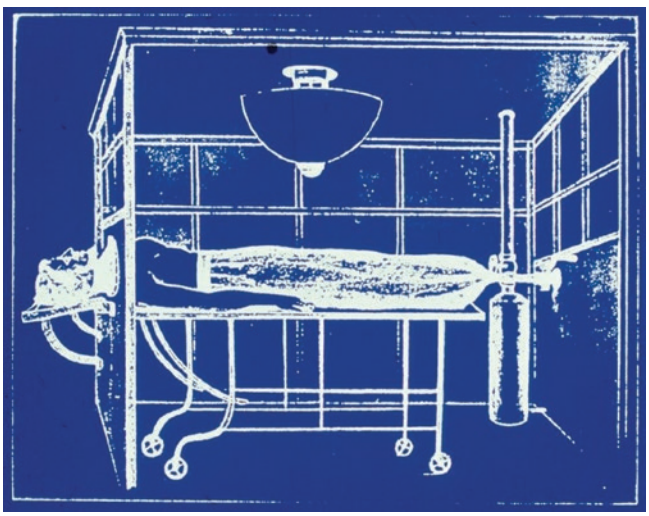

Fig. 25.1 The negative pressure chamber for thoracic anesthesia. Designed in 1900 by Sauerbruch. The patient's torso was placed in an airtight box along with the surgeon and nurse. Anesthesia was induced and maintained by breathing an air-ether mixture from a mask. The box was then evacuated to −10cmH2O pressure. When the surgeon opened the chest because of the pressure differential between the patient's lung and the box, the operative lung did not collapse. This apparatus was used in some centers until the 1930s but was replaced by endotracheal intubation and positive-pressure ventilation

(13), pericardial window (7), drainage of lung abscess (2), treatment of chylothorax (2), treatment of pneumothorax (1), and biopsy of mediastinal mass (1). No patient required intubation or conversion to thoracotomy [6].

Since then the number of different types of thoracic procedures performed on non-intubated patients has expanded to include lobectomy, segmentectomy, and lung volume reduction. Almost any common thoracic surgical procedure has now been reported using non-intubated anesthesia. A meta-analysis comparing intubated to non-intubated VATS surgery has shown shorter surgical times, shorter hospital stays, and lower rates of postoperative complications with non-intubated anesthesia [7]. However, the majority of publications on non-intubated thoracic anesthesia come from a few centers, and there may be a degree of patient selection. Also, the learning curve of the anesthesiologist-surgeon team, prior to publication, is difficult to appreciate.

The potentially harmful effects of intubation, lung isolation, and positive-pressure ventilation can be avoided using non-intubated thoracic anesthesia. This may be applicable in patients who require lung surgery but have contralateral bullae or bronchial injuries (see Fig. 25.2) [8].

Techniques of Non-intubated Thoracic Anesthesia

Techniques of non-intubated thoracic anesthesia include a variety of methods of sedation or general anesthesia maintaining spontaneous ventilation [5]. Patients should receive supplemental oxygen to avoid hypoxemia. Patients may develop hypercapnia; however, mild hypercapnia is usually well tolerated. For patients who are hypercapnic at rest, the use of high-flow nasal oxygen (see Chap. 54) may be beneficial. Dexmedetomidine has been described to provide satisfactory sedation in combination with epidural anesthesia for VATS in patients with severe respiratory dysfunction [9]. If general anesthesia is selected, with either total intravenous or volatile anesthesia, a laryngeal mask airway is useful for non-intubated procedures. Regional anesthesia is commonly provided by either intercostal, paravertebral, or epidural blocks. Either of the two ultrasound-guided chest wall blocks (serratus anterior plane and erector spinae plane) (see Chap. 59) may be appropriate in some patients. A remifentanil infusion may be helpful in patients who are tachypneic without hypoxemia. Also, remifentanil may decrease the cough reflex. But the risk of apnea must be appreciated and ventilation closely monitored. For surgical procedures that involve manipulation near the hilum, coughing may be problematic. Chen et al. describe the use of an intrathoracic vagal block with 2–3 ml of 0.25% bupivacaine injected close to the vagus nerve at the level of the lower trachea in the right hemithorax or in the aortopulmonary window on the left [10]. This resulted in abolition of coughing for 3 h.

Conversion to General Anesthesia and Endotracheal Intubation

During non-intubated thoracic surgery, conversion to general anesthesia with endotracheal intubation may become necessary if there is persistent agitation, hypoxemia, tachypnea, hemodynamic instability, or hypercarbia [5]. Surgical problems which may lead to conversion include hemorrhage and adhesions. Since the patient is in the lateral position, airway access may be awkward. There are several options. Initial airway control may be achieved with a LMA. Then a fiberoptic bronchoscope can be passed through the LMA inside an Aintree tube exchange catheter (Cook Medical, Bloomington IN) which can be left in place to guide endotracheal intubation after the LMA is removed. After securing the airway with a single-lumen endotracheal tube (ETT), the options include proceeding with surgery using two-lung ventilation or, if one-lung ventilation is required, either to use a bronchial blocker via the ETT or to exchange the ETT for a double-lumen tube using a video laryngoscope and double-lumen tube exchange catheter (see Chaps. 16, 17, and 18).

Clinical Case Discussion

A 72-year-old male has developed a bronchopleural fistula 5 days postoperatively after an uncomplicated right pneumonectomy (see Fig. 25.3). The patient has been started on anti-

Fig. 25.3 Chest X-ray of a 72-year-old patient who developed a bronchopleural fistula after a right pneumonectomy

biotics and a chest drain inserted which drained 250 ml of fluid and showed a persistent air leak. The patient is not septic. The patient is scheduled to undergo thoracoscopy, rib resection, and insertion of a large-caliber drainage tube. The surgeon has requested that the airway not be instrumented due to the possibility of injury to the precarious bronchial stump.

How would you manage the anesthetic for this surgical procedure?

After placement of standard ASA monitors and an arterial line, a thoracic epidural catheter was placed by a paramedian technique at the T5-6 level. After a test dose of 3 ml lidocaine 2%, a mixture of bupivacaine 0.2% and fentanyl 10ug/ml was titrated in 2 ml aliquots (total dose 8 ml) until a sensory block developed from T2-10. The patient was then started on an intravenous infusion of dexmedetomidine 0.7ug/kg/h and supplemental oxygen via a facemask and turned to the left lateral positon for surgery.

How would you manage this case if the patient was septic?

Because of the concern of the development of an epidural abscess in a septic patient, other types of nerve block may be optimal for this patient. Ultrasound-guided serratus anterior or erector spinae plane blocks may be considered in place of an epidural (see Chap. 59).

Troubleshooting One-Lung Ventilation

26

Danielle Sophia Shafiepour

Key Points

- The perioperative hypoxemia that can accompany thoracic surgery is likely the principal contributor to cerebral desaturations that are observed during these cases and may be linked to adverse outcomes.
- There is no accepted "safe lower limit" for oxygen saturation during one-lung ventilation.
- During one-lung ventilation, a stepwise approach to hypoxia typically allows for the surgery to progress unhindered.
- Optimal V/Q matching during OLV requires that both perfusion to the ventilated lung and pulmonary vascular resistance (PVR) to the non-ventilated lung are maximized, while atelectasis in the ventilated lung is minimized.

Introduction

The introduction of reliable methods to isolate the operative lung and achieve one-lung ventilation has allowed for drastic advances in the field of thoracic surgery. Prior to this, attempts at thoracotomy were limited by the challenges of operating on a moving surgical field in a patient experiencing respiratory distress. These phenomena are the result of disrupting the pleural interface which exposes the pleural cavity to atmospheric pressure in a spontaneously breathing patient. The patient is prevented from generating negative pressure in the operative hemithorax despite diaphragmatic contraction, resulting in mediastinal shift downward with inspiration and "Pendelluft" or paradoxical back and forth rebreathing of air from one lung to the other [1].

Prior to the use of routine fiberoscopy to confirm adequate lung isolation and the use of modern inhaled anesthetics that have less of an inhibitory action on hypoxic vasoconstriction, hypoxemia was a frequent complication of one-lung ventilation. Even with modern lung isolation and anesthetic techniques, however, significant desaturation may still occur in a proportion of patients and can prove to be quite a challenge for the anesthesia team. This chapter will discuss a stepwise approach to this problem, addressing the physiology that underlies hypoxia on one-lung ventilation. Troubleshooting the poorly deflated operative lung will also be covered.

Hypoxia

Permissive Hypoxia

Before tackling what to do about hypoxia during one-lung ventilation, it deserves to be noted that no safe lower limit of oxygen saturation (SpO_2) has been designated as an acceptable threshold during one-lung ventilation. The question is an important one, however, because unlike other clinical situations, the desaturation during one-lung ventilation is "iatrogenic" so to speak and typically entirely reversible by resuming two-lung ventilation. Naturally this is disruptive to the surgical procedure taking place, so in cases of hypoxia during one-lung ventilation, the burden remains with the anesthesiologist to decide how low is too low and at what point, when other manoeuvers fail, should one-lung ventilation be abandoned.

An evidence-based review of OLV management suggests titration of the inspired oxygen fraction (FiO_2) to target an SpO_2 of 92–96% to avoid both atelectasis and oxygen toxicity [2]. Saturations of 90% are often accepted in clinical

practice, and even desaturations to the high 80s may be tolerated, ideally in the absence of significant comorbid disease.

Hyperoxia is increasingly recognized to contribute to pulmonary morbidity both through generation of absorption atelectasis and direct pulmonary toxicity, as well as systemic morbidity, with worse outcomes demonstrated in settings such as post-myocardial infarction or cardiac arrest [3, 4]. Interest has therefore emerged in the evaluation and adoption of a conservative or restrictive approach to oxygen therapy versus the more traditional liberal approach. Studies on outcomes in this area may allow for extrapolation to the thoracic surgery population and provide some further insight into the question of acceptable lower limits. A recent international multicenter randomized pilot study of mechanically ventilated ICU patients comparing liberal (≥96%) and restrictive (88–92%) oxygen targets showed no difference in measures of organ dysfunction, ICU, or 90-day mortality between the groups despite a higher incidence of hypoxia (SpO_2 <88%) in the conservative group [5]. While these preliminary results are interesting, their extrapolation to the typical one-lung ventilation patient may be limited by the inclusion of patients with a wide variety of underlying critical illnesses including ARDS. Outcomes that are more relevant to the typical thoracic surgery population were not assessed, such as differences in postoperative neurocognitive testing scores. This approach also does not allow for an individualized management strategy, as likely the acceptable low SaO_2 differs between patients.

A small observational study exploring the cerebral oxygenation of patients undergoing thoracic procedures with one-lung ventilation demonstrated that patients spent a significant proportion of time with saturations considerably lower than their baseline on two lungs [6]. Important desaturations (>20% of baseline) occurred more frequently than those reported in non-thoracic surgery cohorts and were more common in patients who were elderly and heavier and had higher ASA scores. In other surgical populations, cerebral desaturations of this magnitude have been shown to correlate with adverse postoperative outcomes. The authors did not examine postoperative outcomes, however, and they used "baseline" values under anesthesia as opposed to preinduction which limits the validity of clinically significant desaturation cutoffs when comparing to other studies. Subsequent studies however have confirmed this observation and have found even higher rates of significantly decreased cerebral oxygenation during OLV [7–9]. In thoracic surgery patients, absolute cerebral oximetry levels of 65% have been correlated with increased postoperative organ dysfunction and complications, and the time spent at levels below 65% appears to correlate with worsened cognitive function at 24 h [8, 9]. Interestingly these cerebral desaturations are often not heralded by declines in SaO_2 or any other conventionally measured vital signs, but the authors point out that the lower PaO_2 values without frank hypoxia during OLV may put these patients at risk for cerebral desaturation. Other mechanisms particular to the thoracic surgery setting have been proposed to possibly contribute to cerebral desaturation, such as changes in cardiac output with the lateral position and mediastinal shift and even a decrease in cerebral perfusion pressure due to elevated central venous pressure resulting from elevated pulmonary vascular resistance. A review on the subject of cerebral oximetry in thoracic anesthesia suggests that perioperative hypoxemia is most likely the principal contributor to cerebral desaturations during these cases [10]. Further work in this field may allow for a more individualized and targeted approach to oxygenation during OLV.

Management of Hypoxia

Ventilation of the Dependent Lung

Debates about optimal saturation during OLV aside, significant desaturation below 90% does still occur with enough frequency that the anesthesiologist taking care of thoracic surgical patients must have an approach when faced with this challenge. The typical pattern observed during OLV consists of a PaO_2 nadir 20–30 min after the initiation of OLV followed by a stabilization or increase thereafter. This is due to the biphasic nature of the hypoxic pulmonary vasoconstriction response that commences when moderate hypoxia is sustained [11]. In the event of an abrupt profound desaturation, restoring oxygenation is a priority, and two-lung ventilation should be resumed. This should be communicated to the surgeon who may have insight into the cause if the reason is a mechanical one, e.g., tube dislodgment or decreased cardiac output due to compression of the heart. The FiO_2 should be increased to 1.0, and the bronchial cuff of the double-lumen tube or the balloon on the blocker should be deflated. Frequently in this setting, failure of appropriate device placement may be to blame, and this can be verified and corrected bronchoscopically. For example, the cuff may have herniated over the carina to obstruct the trachea when ventilating through the tracheal lumen of a DLT or with a blocker, or a left DLT may have been positioned too far excluding part of the left lung when ventilating through the bronchial lumen. If these scenarios are eliminated as potential causes for desaturation, proceeding without lung isolation may be an option in some cases but is rarely a realistic choice particularly in video-assisted thoracoscopy which requires good lung isolation. A stepwise approach to improving oxygenation during OLV allows for continuation of surgery with OLV in the majority of cases.

During OLV, the primary mechanism responsible for hypoxia is the shunting of deoxygenated blood through the pulmonary circulation of the non-ventilated lung. This is

worsened as atelectasis develops in the ventilated lung due to compression from the mediastinum and abdominal contents as well as absorption aggravated by the usually high inspired oxygen content. In order to optimize V/Q matching during OLV, both perfusion to the dependent lung and pulmonary vascular resistance (PVR) to the nondependent lung should be maximized. Lung volumes influence PVR in a hyperbolic manner with PVR at its highest at either extreme, total lung capacity (TLC) or residual volume (RV). Ideally the dependent lung should be kept as close to functional residual capacity (FRC) as possible. Any atelectasis that develops in this lung results in the end-expiratory volume trending toward RV in the absence of positive pressure to counteract this. Following lung isolation, a gentle manual recruitment maneuver is recommended, and the use of PEEP 3–10 cm H_2O has been recommended for ventilation of the dependent lung [2]. In the event of hypoxia, rerecruitment may be attempted; however there is no consensus on the optimal method to perform this maneuver. Brassard et al. recommend a gentle increase in pressure to 30 cm H_2O for at least 10 s [2]. Others have advocated cycling maneuvers with stepwise increases of PEEP and peak pressure. A rat model of acute lung injury demonstrated increased markers of injury after a continuous pressure of 30 cm H_2O maneuver vs a stepwise increase with the same time pressure product. Both methods yielded the same benefit with regard to oxygenation and pulmonary compliance [12]. During or immediately following a recruitment maneuver, it is common to see the saturation fall transiently as the perfusion is shifted momentarily to the non-ventilated lung.

The optimal level of PEEP depends on the individual patient, and it should be noted that both inadequate and excessive PEEP may worsen hypoxia. Inadequate PEEP will allow for development of atelectasis, and excessive PEEP may have adverse effects on the PVR, diverting blood to the non-ventilated lung and increasing shunt. Ideally PEEP should be titrated in order to optimize lung compliance. Ferrando et al. describe a more fine-tuned approach by performing a PEEP decrement trial at the initiation of OLV starting from 20 cm H_2O and decreasing by 2 cm H_2O each 2 min seeking the maximum dynamic compliance [13]. In their randomized comparison of this technique vs a control group with a fixed PEEP of 5 cm H2O, the study group showed improved oxygenation and compliance at the end of OLV. The average (optimal) PEEP in the decremental titration group was 10 cm H_2O.

The type of positive-pressure ventilation used appears to have little if any significant impact on hypoxia. A meta-analysis of six studies comparing VCV and PCV during OLV showed a statistically but not clinically significant difference in PaO_2/FiO_2 ratio in favor of PCV [14]. If hypoxia persists, an arterial gas should be sent to ensure ventilation is adequate as HPV in the non-ventilated lung may be impaired by respiratory alkalosis, and significant respiratory acidosis may increase the PVR disproportionately in the ventilated lung as the non-ventilated lung is already vasoconstricted. Because of the high level of V/Q mismatch in the diseased lungs of many thoracic surgical patients, $EtCO_2$ may less reliably correlate with $PaCO_2$.

Management of the Non-ventilated Lung

If these measures do not adequately improve oxygenation, consideration should be given to applying continuous positive airway pressure (CPAP) with oxygen to the nondependent lung. The use of a PEEP valve with an oxygen source allows accurate measurement of the pressure applied. If not readily available, oxygen tubing with flows around 2 L/min may be attached to a double-lumen tube suction catheter advanced down the side of the nondependent lung, with a piece of tape partially occluding the thumb-control valve to control the amount of oxygen delivered (see Fig. 26.1). The lung should be observed in the field or on the VATS screen to assess for overinflation. To be most effective, CPAP should be preceded by a recruitment maneuver of the non-ventilated lung as atelectatic alveoli have a high opening pressure (>20 cm H_2O). This requires transient interruption of the surgical procedure, and for thoracoscopic procedures, even a small amount of CPAP may impair the surgical view. CPAP of only 2 cm H_2O has been demonstrated to improve oxygenation provided that it is applied after a recruitment maneuver [15].

Another method that has been described involves attaching a standard bacterial filter to the lumen of the DLT corresponding to the non-ventilated lung and attaching oxygen flowing at 2 L/min to the gas sampling port (see Fig. 26.2). When the open end of the filter is occluded manually for 2 s, approximately 66 mL of oxygen will enter the non-ventilated lung; in a series of 26 thoracotomy patients, only in 6 cases

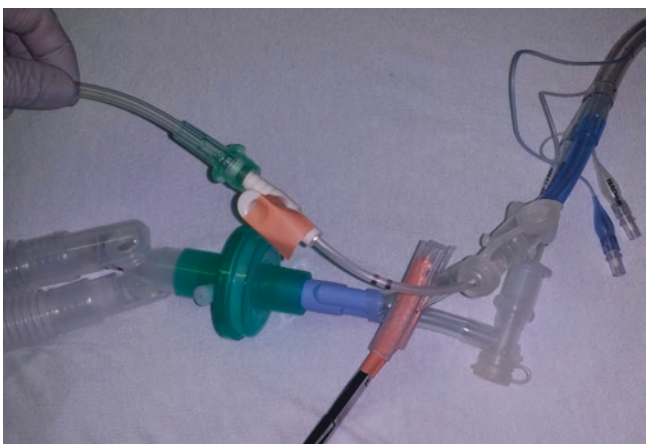

Fig. 26.1 This photograph illustrates the use of a double-lumen tube suction catheter to insufflate oxygen to the non-ventilated lung during OLV

Fig. 26.2 This photograph illustrates the use of a breathing circuit filter to transiently insufflate small volumes of oxygen to the non-ventilated lung during OLV

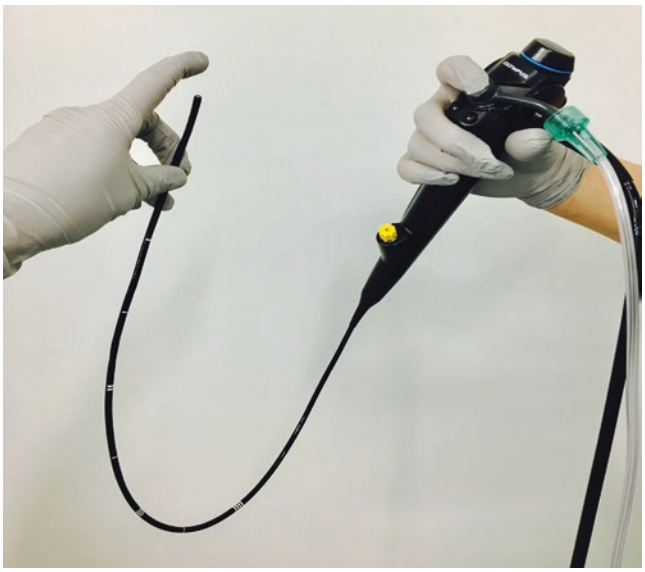

Fig. 26.3 This photograph illustrates the use of a bronchoscope with oxygen tubing attached to the suction port to selectively insufflate lobes or segments of the non-ventilated lung

did the surgeon notice the lung move, and in no cases did this negatively impact surgical exposure [16]. A case report describes successful treatment of hypoxia in a robotic VATS thymectomy using "high-frequency/small tidal volume" differential ventilation [17]. The procedure was performed in the semi-lateral position and was complicated by hypoxia that would not resolve with CPAP of 5 cm H_2O applied to the non-ventilated lung. Using a second circuit attached to the non-ventilated lung set to deliver tidal volumes of 60 mL at a rate of 35–40 breaths per minute, the authors describe successful oxygenation with no interference to the surgical procedure.

Other techniques allow for oxygen insufflation or ventilation to only part of the non-ventilated lung. Selective lobar collapse may be achieved by directing a bronchial blocker into a lobar bronchus which allows for ventilation to the remaining portions of that lung [18]. Naturally this comes at the expense of worsened surgical exposure. In some settings (patient with a previous contralateral pneumonectomy), this is the only alternative to intermittent apnea. Oxygen may also be intermittently insufflated selectively into segments or lobes of the operative lung that are remote from the surgical site [19]. This can be achieved by attaching oxygen tubing flowing at 5 L/min to the suction port of the bronchoscope and advancing the bronchoscope into, for example, the lower lobe during upper lobe surgery and pressing on the suction trigger for a couple of seconds (see Fig. 26.3). The surgeon should be warned before as the lung will move and visibility may still be impaired, but less so than with generalized CPAP. The surgeon can also direct the VATS cameras to the area being inflated and alert the anesthesiologist to any overinflation observed as there is no pressure gauge and insufflation is being performed blindly. If hypoxia recurs after the oxygen is gradually absorbed, this maneuver may be repeated.

Regulation of Perfusion

In addition to ventilation strategies, the anesthesiologist should also be aware of the interaction between the circulatory system and hypoxia during OLV. The shunt fraction can be influenced by controlling the relative flow of blood to each lung. During a pulmonary resection, exclusion of the vessels to the soon-to-be resected lobe usually coincides with an improvement in saturation because of a decrease in the amount of shunt. If issues with hypoxia are communicated to the surgeons, they may be able to assist by accomplishing this more quickly. In the case of significant hypoxia, the surgeon may be able to partially or completely occlude the pulmonary artery on the operative side, bearing in mind that this will generate a significant increase in right ventricular afterload.

Acute changes in blood pressure and cardiac output are common in thoracic surgery, due, for example, to factors such as manipulation of the heart and great vessels by the surgeon or use of thoracic epidural boluses. Such changes should be sought when dealing with hypoxia during OLV as they may be contributory. Cardiac output influences saturation during OLV in two main ways. An increase can cause dilation of the pulmonary bed and increase perfusion to the non-ventilated lung, counteracting HPV and increasing the shunt fraction, thereby worsening oxygenation. This effect is counterbalanced however by the effect of increased

cardiac output on mixed venous oxygen saturation (SvO_2). If oxygen consumption is relatively stable, an increase in CO will increase the SvO_2, and in the presence of significant shunting (as in OLV), this will have a positive effect on oxygenation. The overall effect is that both increasing and decreasing cardiac output can have detrimental effects and maintaining a normal cardiac output is optimal (see Chap. 5, Fig. 5.5).

Pharmacology

HPV is essential to minimize the degree of V/Q mismatch during OLV. Pharmacologic agents can either enhance or impair this response. Of particular relevance to the anesthetic setting, older volatile anesthetics (halothane, enflurane, and isoflurane) have been demonstrated to cause a dose-dependent reduction in the vasoconstrictive response to hypoxia with a 50% reduction at approximately 0.5 MAC units in in vitro animal studies [20]. A lesser magnitude of effect has been observed with in vivo animal studies suggesting a 21% reduction in response at 1 MAC for isoflurane [21]. Human studies of modern volatile agents do not support a large effect or a difference between agents with isoflurane, desflurane, or sevoflurane at doses up to 1 MAC [22, 23]. Previous comparisons of total intravenous anesthesia (TIVA) using propofol-narcotic combinations with sevoflurane and isoflurane have shown no significant difference in oxygenation with TIVA [24–26]. A recent RCT comparing desflurane-remifentanil and propofol-remifentanil calls this into question as the authors demonstrated a significant difference in PaO_2 values at all time points measured (15, 30, 45, and 60 min after initiation of OLV) [27]. An advantage of this study is its larger size compared to previous ones, as well as the duration of observation which suggests that a difference may have been missed before as one of the previously mentioned studies measured up to 10 min of OLV only. The study may be criticized however as the mean MAC in the desflurane group was 1.1 which seems high for a balanced anesthetic using remifentanil. The BIS target was lower in this study (30–50), and there was indeed more hypotension in the desflurane group which may have driven the difference in PaO_2 via the effect on SvO_2 as outlined above. It should be mentioned that volatiles, particularly sevoflurane, have been shown to have a protective effect during OLV, mitigating some of the alveolar and systemic inflammatory responses seen in this setting [28–30]. Taken together, the evidence to minimize volatile use to 1 MAC or less or abandon them in favor of a propofol anesthetic is not compelling. In the setting of refractory hypoxia, however, converting to a propofol-based anesthetic seems an acceptable move, but the benefit is unlikely to be large.

Conflicting results exist regarding an effect of thoracic epidural analgesia (TEA) on saturations during OLV. Two proposed mechanisms have been described to explain the potential influence of local anesthetics in the epidural space on hypoxia during OLV. First, if the cardiac output is allowed to fall with use of TEA, the SvO_2 may decrease and negatively impact oxygenation due to the presence of a large shunt as described earlier. Second, a decrease in sympathetic tone may decrease PVR in the nondependent lung therefore counteracting the HPV. In a small study where the mean blood pressure was comparable between the TEA group and the non-TEA group, there was no difference in PaO_2 [31]. Another study showed a nonsignificant trend to worsened PaO_2 with TEA, but there was also a nonsignificant trend to decreased blood pressure in the TEA group [32]. These studies would suggest that if cardiac output is maintained, TEA has little if any effect on PaO_2 during OLV. Others have found a decrease in PaO_2 and an increase in shunt fraction (Qs/Qt) with the use of TEA, which supports the second theory [33].

A recent interest has emerged in determining the effect of dexmedetomidine on oxygenation during OLV. Dexmedetomidine may potentially cause vasoconstriction through a direct peripheral alpha effect, but the central alpha-2 effect could result in vasodilation. Several groups have demonstrated a favorable effect of dexmedetomidine on oxygenation during OLV when combined with inhalational agents titrated to BIS values [34, 35]. A typical loading dose of 1 μg/kg was used followed by infusions that varied between 0.5 and 0.7 μg/kg/hr in different studies. The differences in PaO_2 were on the order of approximately 30 mm Hg at several time points in one study [34]. Interestingly another study specifically looking at patients with COPD demonstrated improved postoperative PaO_2/FiO_2 ratios and decreased ICU admission in the dexmedetomidine group [35]. Other proposed mechanisms include a reduction in inhalational agent requirement and a direct effect on pulmonary mechanics.

Another potential strategy to improve oxygenation during OLV is the selective delivery of vasodilators to the ventilated lung via the inhalational route, with or without concurrent administration of systemic vasoconstrictor drugs to enhance HPV in the non-ventilated lung. For example, the combination of 20 ppm inhaled nitric oxide (iNO), a selective pulmonary vasodilator, with almitrine, a systemic vasoconstrictor, has been demonstrated to improve oxygenation during OLV in humans [36]. The relative contribution of each drug is not certain, however, as iNO alone has not consistently been shown to improve oxygenation in this setting [37] and a small randomized study of almitrine alone did demonstrate improvement in PaO_2 during OLV [38]. Since almitrine, a respiratory stimulant, is no longer available in North America, these results are interesting more from a purely theoretical point of view; however interest in pharmacologically modulating the amount of shunt has led to research with other available medications.

In lung transplantation, use of inhaled prostaglandin E_1 (PGE_1) during implantation of the first lung (during OLV but after pulmonary artery clamping) has been demonstrated to lower pulmonary artery pressure (PAP) but also to improve the PaO_2/FiO_2 ratio by decreasing shunt wthin the ventilated lung. Presumably the drug preferentially vasodilated the better ventilated portions of the recipient's lung thereby optimizing V/Q matching [39]. Inhaled prostacyclin (PGI_2, commercially known as Flolan) is an appealing alternative to iNO for reducing PAP in heart and lung transplant patients as it can be easily delivered directly to a breathing circuit via nebulization and is much cheaper [40]. A case report describes a dramatic improvement in oxygenation observed with the combination of inhaled PGI_2 at a dose of 50 ng/kg/min and IV phenylephrine used in a hypoxic patient during OLV for a VATS procedure [41]. In my (albeit limited) experience, using this combination in hypoxic patients during OLV has led to a modest improvement in saturation shortly after initiation of the inhaled prostacyclin. Further research is needed in this area to confirm this effect and clarify the magnitude and time course.

Lung Collapse

Sometimes, despite adequate positioning of the lung isolation device, the deflation of the operative lung is suboptimal. Occasionally this may be worsened by adhesions in the chest cavity, but often it is due to the slow egress of air, particularly in patients with decreased lung elasticity as in the case of chronic obstructive pulmonary disease (COPD). This can be particularly problematic in VATS cases and may require conversion to an open technique if the surgical team is not able to fully visualize the relevant structures.

Certain strategies may be employed to avoid this issue. Prior to the initiation of OLV, the patient should be kept on an FiO_2 of 100% to ensure the elimination of nitrogen from the non-ventilated lung. After the pleural space equilibrates with atmospheric pressure on chest opening and the lung begins to collapse, the remaining gas will be absorbed much faster if the lung is filled with oxygen instead of air [42]. When using a bronchial blocker, the anesthesiologist should ensure that the blocker is inflated only after turning the ventilator to manual and allowing for a very long expiratory pause, ensuring that lung deflation is not commencing with the lung in a partially inflated state. Both of these maneuvers, the use of 100% FiO_2 and allowing for a prolonged expiration with no PEEP, will encourage atelectasis formation in the ventilated lung, so a recruitment maneuver may be performed after initiation of OLV and the FiO_2 titrated down as permitted.

In patients with significant obstructive pulmonary disease, it seems intuitive that the lung should be isolated immediately after positioning to allow time for deflation, particularly for VATS cases. An interesting consideration, however, is that prior to the chest being opened, this can lead to entrainment of nitrogen through the open end of the DLT due to cyclical changes in the pressure of the non-ventilated hemithorax that occur with ventilation of the dependent lung [43]. A proposed method to counteract this is connecting the non-ventilated lumen to an oxygen source, either via suction tubing passed down the lumen or an oxygen-filled reservoir bag.

A suction catheter on low suction (approximately −20 cm H_2O) may be applied to either a blocker or passed down the lumen of the DLT. This may serve to hasten lung collapse both by aspiration of gas from the lung and impeding the entrainment of nitrogen into the non-ventilated lung.

Case Discussion

Your next patient is a 65 year-old man awaiting a VATS right upper lobectomy for adenocarcinoma of the lung. He is 169 cm tall and weighs 74.0 kg. He has a preoperative FEV1 of 82% predicted with an obstructive FEV1/FVC ratio and a DLCO of 58%. He quit smoking 3 years ago and is on an ACE inhibitor for hypertension but has no other comorbidities. He climbs two flights of stairs without difficulty.

After a smooth induction and placement of your 39 Fr DLT, you turn the patient on his left side. Because of the obstructive lung disease, you isolate the lung early and pass a suction catheter down the tracheal lumen at 20 cm H_2O to encourage lung deflation. The ventilator is set at 15 × 380 with a PEEP of 5, and FiO_2 has been turned down to 80%. The surgery begins, and the surgeon is pleased with lung collapse. After 5 min, you notice that the saturation has fallen gradually and is now hovering at 87%.

1. Is this desaturation surprising in this case?
   - Early after lung isolation, desaturation may happen because of either tube malposition or because of the slow onset of HPV which has not kicked in fully yet. In this case risk factors include the fact that surgery is taking place on the right lung which implies a potentially larger shunt, and the poor preoperative DLCO which suggests that the PaO_2 prior to OLV may already be suboptimal. The patient is also taking a systemic vasodilator drug that can impair HPV.
2. Describe your management at this point.
   - The FiO_2 and flows should be turned up in order to deliver 100% oxygen. If it appears that the saturation is

falling precipitously, it would be prudent to notify the surgeon and resume TLV. Since the fall described here is gradual, bronchoscopy may be performed to confirm adequate tube positioning, and a stepwise approach to hypoxia on one lung can be performed.

3. The blue cuff is situated well beyond the carina but when scoping down the bronchial lumen, you note that you cannot see the left upper lobe bronchus suggesting that the tube is too far. A larger shunt is likely the cause of the hypoxia because of complete or partial exclusion of the left upper lobe which is not being ventilated due to malpositioning of the tube. You reposition the tube under bronchoscopic guidance by entering the tracheal lumen, pulling the tube back and then confirming through the bronchial lumen that the tip is well situated in the left main bronchus. What do you do next?
   - Prior to resuming ventilation to the dependent lung, a manual recruitment maneuver may be performed with a gentle sustained pressure of 30 cm H_2O for 10 s, as the poorly ventilated left upper lobe has likely developed some atelectasis during this time. You may then proceed to titrate your FiO_2 down to aim for a saturation of 92–96%.
4. The saturation improves to 96% but 10 min later has drifted down again to 88%. Bronchoscopy confirms that the DLT is well positioned. How do you proceed?
   - Initial steps may include ruling out physiologic derangements that would impair saturation such as decreased perfusion or inadequate or over-ventilation. You may check for hypotension from surgical compression, hypovolemia, or excessive anesthesia and send an ABG to assess $PaCO_2$. An optimal ventilator strategy in the dependent lung is one that avoids the development of atelectasis but doesn't over distend alveoli to the point that PVR increases in that lung. Following another manual recruitment maneuver, a PEEP decrement trial may be employed, searching for the PEEP that provides optimal compliance. If more than one MAC of volatile is being used, a balanced technique should be employed, or TIVA may be considered if it is not possible to reduce the dose of volatile.
   - If the saturation has not improved, the surgeon should be made aware and a plan agreed upon. As this case is a VATS, the surgeon will likely be very reluctant to employ CPAP to the non-ventilated lung. They may in fact prefer intermittent gentle re-expansion with 100% oxygen, repeating as needed. An alternate approach would be using a bronchoscope with oxygen attached to the suction port to selectively insufflate the lower lobe segments. This needs to be done in collaboration with the surgeons who can direct their cameras to observe the insufflated segment and avoid overdistension.

Intraoperative Extracorporeal Life Support for Thoracic and Airway Surgery

27

Daniel Sellers, Karen Lam, and Karen McRae

Abbreviations

ACT	Activated clotting time
APTT	Activated partial thromboplastin time
CPB	Cardiopulmonary bypass
ECLS	Extracorporeal life support
ECMO	Extracorporeal membrane oxygenation
FEV_1	Forced expiratory volume in 1 second
FVC	Forced vital capacity
HIT	Heparin-induced thrombocytopenia
ICU	Intensive care unit
INR	International normalised ratio
IVC	Inferior vena cava
OLV	One-lung ventilation
RA	Right atrium
SVC	Superior vena cava
SVR	Systemic vascular resistance
TEE	Transoesophageal echocardiography
TTE	Transthoracic echocardiography

Key Points

- Extracorporeal support is an established therapy in perioperative care of lung transplant recipients.
- New applications of intraoperative extracorporeal life support (ECLS) are increasingly being explored in thoracic surgery.
- In clinical scenarios which compromise oxygenation, VV-ECMO is most often used. These include procedures for patients with airway obstruction, require an open airway or have advanced lung disease.
- Surgery which will compromise cardiac function or great vessel flow is best supported by VA-ECMO. These include procedures for life-threatening mediastinal masses and locally advanced malignancies requiring resection of the atrium or great vessels.
- Unanticipated perioperative respiratory failure may require extracorporeal support.
- Meticulous and multidisciplinary preoperative assessment and planning are essential. The anaesthesiologist should understand the technical capability and limitations of the ECLS device.
- Critically ill patients may require cannulation of vessels under local anaesthesia, which may be technically challenging and uncomfortable but best done electively rather than emergently.
- ECLS applied to thoracic surgery is not as yet supported by strong medical evidence, but can be life-saving in individual cases.

Introduction

Extracorporeal life support (ECLS) encompasses a spectrum of temporary mechanical support for patients with heart or lung dysfunction that does not respond to traditional critical

care therapy. The term ECMO (extracorporeal membrane oxygenation) is often used when the primary indication for support is failure of gas exchange. The physiologic goals vary with patient needs but may include oxygenation and CO_2 removal, increased oxygen delivery via improved perfusion and the provision of lung rest and cardiac unloading. ECLS is available in an increasing number of specialised centres and may be of short duration (hours) to facilitate a surgical procedure or provide support for prolonged periods (weeks to months).

The dramatic expansion of ECLS applications during the last decade is evidenced by an ever-increasing number of annual ECLS-related publications. It is a challenge for the interested clinician to keep up with the latest literature on the topic [1]. Use of ECLS for cardiac failure and cardiac procedures is beyond the scope of this chapter. The highest level of evidence for the clinical benefit of all the ECLS technologies in both respiratory and cardiac disease are randomised controlled trials of ECMO in acute respiratory distress syndrome (ARDS); all other applications are described in case series or cohort studies [2].

This chapter endeavours to provide the anaesthesiologist with a clear understanding of the nomenclature used to describe ECLS, the configurations of ECLS circuits and their physiological effects and the applications described for support of the thoracic surgical patient population both in the critical care unit and the operating room. Most applications in thoracic surgery require some degree of gas exchange support and therefore for the purposes of this chapter will be referred to as ECMO.

Brief History

ECMO first became an established practice in neonates with hyaline membrane disease and has been used in that context since the 1970s. In adults, although it had been occasionally reported as a rescue technique for the critically ill for decades, high mortality and significant neurological complication rate prevented its widespread use. However, interest was renewed in the intensive care population during the influenza outbreak of 2009 [3]. The CESAR trial demonstrated a 6-month survival benefit with ECMO use versus optimal conventional ventilator management of ARDS [4]. Additionally, streamlined ECLS technology has improved the feasibility of transporting critically ill patients from outside facilities to specialised ECLS-capable centres. In the last decade, ECMO has become a widely accepted supportive treatment for severe respiratory failure in the ICU. Improved survival has also been observed in end-stage lung disease patients supported with ECMO as a bridge to transplant and for severe primary graft dysfunction as a bridge to recovery. The growing experience of thoracic surgical teams in operating on patients on ECMO, either from the ICU for diagnostic or therapeutic procedures or for lung transplantation, has meant that this form of support is increasingly for elective surgical situations where adequate gas exchange cannot be guaranteed. Historically, full cardiopulmonary bypass (CBP) has been the most typical form of extracorporeal mechanical and gas exchange support for complex thoracic surgery. Use of CPB has the known disadvantages of the need for full heparinisation, increased transfusion requirements, pump-related inflammatory response and the potential recirculation of tumour cells in oncology cases. Technological improvements offered by ECMO include the miniaturisation of circuits requiring lower priming volumes, limited air/blood contact by closed circuits without cardiotomy suction/reservoir and improved biocompatibility of material used in circuit components [5].

Components of the ECMO Circuit

The equipment used for mechanical cardiac or respiratory support have evolved from components of cardiopulmonary bypass for cardiac surgery. The original ECMO circuits used a CPB circuit stripped down to an oxygenator, pump, heating coil and minimal volume tubing, with no reservoir. There now exists a wide spectrum of different circuit configurations and cannulation options for mechanical support, but the basic components remain similar. It is important to understand the different components of the circuit being used, as they directly affect aspects of anaesthetic management such as oxygenation, anticoagulation, monitoring, transfusion, inotrope and volume status management (see Fig. 27.1).

Oxygenator

The oxygenator in an ECMO circuit channels blood down hollow fibres, with a counter current gas flow surrounding the fibres. Gases diffuse down concentration gradients, a similar mechanism to haemodialysis. The rate of gas exchange along the fibres can be controlled by altering the gas flow (sweep) and blood flow to change the partial pressure difference of oxygen and carbon dioxide across the membrane. Oxygenation is mainly a function of blood flow, while CO_2 removal can be modified by regulating the sweep. Modern membrane oxygenators are compact and have a very low resistance to flow. They are susceptible to fibrin clots making them first less efficient and then eventually fail; however, this usually occurs after weeks of support, and anticoagulation is used to delay this. In addition, their delicate structure makes them susceptible to trauma.

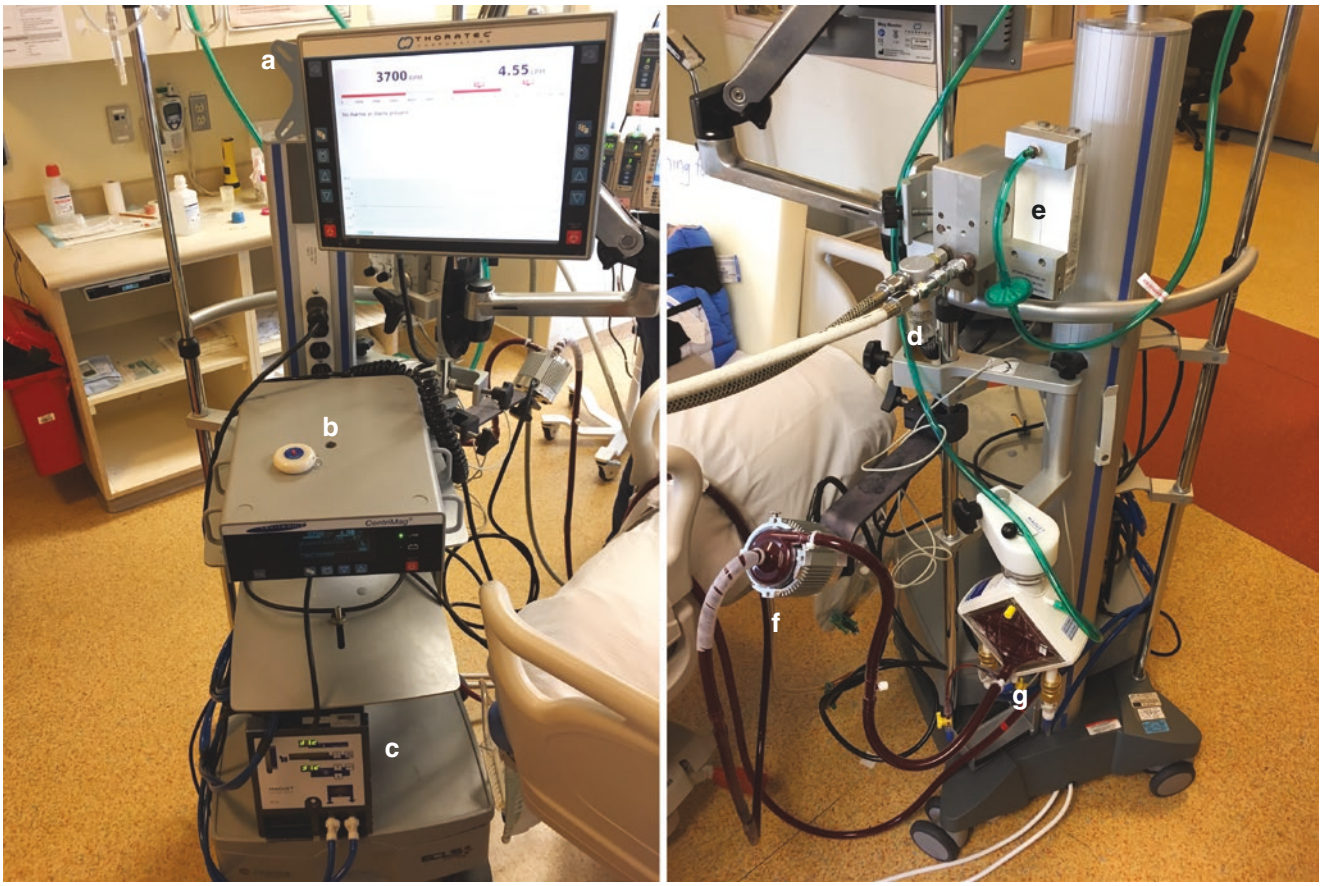

Fig. 27.1 Typical bedside ECLS circuit (back and front views shown). (**a**) Display with revolutions per minute, pump flow and resistance display (lower line). (**b**) Pump control terminal. (**c**) Oxygenator heater, (**d**) Air and oxygen wall gas inlet, (**e**) Sweep gas flowmeter, (**f**) Centrifugal pump, (**g**) Oxygenator (note oxygenated blood line marked with red tape)

Pump (When Applicable)

In CPB both roller pumps and centrifugal pumps are used. However, centrifugal pumps cause less haemolysis during long-term use, so in ECMO they are used almost exclusively. Centrifugal pumps are composed of a disposable cone which sits on top of a spinning magnet and rotate through magnetic coupling. The centrifugal force generated by this rotation causes a pressure difference across the cone which drives the blood flow. Pump flow is determined by this pressure difference, as well as preload and afterload, in a non-linear way. There is limited scope for the perfusionist to increase the cardiac output by turning up the revolutions per minute, as decoupling of the magnets can take place. Compared to CPB, the amount of flow is much more limited by technical design of the pump. Crucially, centrifugal pump flows are dependent on both preload and afterload conditions. If preload drops or the drainage line occludes, the centrifugal pump generates high negative pressures, and the cone slows down causing the flow to drop. This is seen clinically as "chugging" of the drainage line requiring restoration of patient volume to maintained desired flow. If afterload suddenly increases, the pressure difference across the pump drops and flow slows. Retrograde flow can happen, which would exsanguinate the patient or aspirate air from the reinfusion cannula site. If centrifugal pump flows drop too much, the perfusionist *must* clamp the arterial line and come off support altogether until the problem is rectified. This means that in a haemodynamic crisis, support may be suddenly terminated which can be difficult to manage.

Reservoir, Circuit and Connectors

A major step in the evolution of ECMO from CPB pumps was the removal of components such as the venous reservoir, three-way taps, stop cocks and shortening of lines. This has the effect of reducing the priming volume required for an ECMO circuit, minimising dilution. The use of heparin-bonded circuit components and removal of the large reservoir, filled with static blood often with an air/blood interface, means that the anticoagulation requirement is much lower

(activated clotting times of 160–200 s compared to >400 s for CPB [6]). Since the ECMO circuit is completely closed, the risk of accidental air entrainment is much reduced (a requirement for long-term use). Unlike a CPB circuit, there are no infusion ports meaning that all drugs, blood products and replacement volume must be delivered by direct intravenous access into the patient. Shed blood must be processed in a cell saver prior to reinfusion.

ECMO Configurations

Configurations of ECMO

Several different ECMO configurations are possible, with varying levels of gas exchange capacity and haemodynamic support (summarised in Table 27.1).

Veno-venous ECMO

VV-ECMO is used in refractory respiratory failure and requires only peripherally placed venous catheters. Blood is drained from and reinfused into central veins. In the most common configuration with early use of VV-ECMO, deoxygenated blood drained via a femoral catheter was actively pumped though the membrane oxygenator and returned via a jugular catheter (Fig. 27.2). Oxygenated blood is reinfused into the right atrium (RA) and ejected into the pulmonary circulation by the patient's own cardiac output, mixing with the deoxygenated venous return. VV-ECMO has no direct effect on cardiac function; however, myocardial dysfunction associated with hypoxia and respiratory acidosis will improve. Additionally, oxygenated blood entering the pulmonary circulation will reduce hypoxic pulmonary vasoconstriction, increasing the shunt fraction but decreasing right heart afterload. It is not unusual for depressed right ventricular function to improve after institution of VV-ECMO. In TEE assessment of the reinfusion cannula, the recommended position of the tip is in the RA just beyond the IVC/RA junction, a safe distance away from the intra-atrial septum and the tricuspid valve [9].

The development of bi-caval dual-lumen catheters allowed for inflow and outflow from a single percutaneous site, usually the right jugular vein (Fig. 27.4). Optimal cannula positioning is essential for good oxygenation; specifically, the infusion jet should be directed towards the tricuspid valve. TEE assessment of position and flow is very helpful, although fluoroscopy may also be used to guide venous catheter placement. By avoiding femoral cannulation, patient mobilisation is improved and participation in rehabilitation is possible, which is important in patients being bridged to transplant.

In VV-ECMO there is a functional dissociation of decarboxylation and oxygenation. Oxygenation varies primarily with blood flow through the membrane oxygenator, while CO2 removal is dependent on the gas sweep past the membrane. Oxygenation also varies with the ratio of the circuit blood flow to the patient's cardiac output. Blood flow of 3–6 L/min is typically required to maintain acceptable oxygenation in patients with severe lung injury. The higher range of ECMO blood flow may be required to oxygenate an

Table 27.1 Extracorporeal life support configurations, indications and applications in thoracic surgery

Mode of ECLS	Hypercapnia	Hypoxia	RV failure	RV and LV failure	Applications in thoracic surgery
Low-flow VV-ECMO	Yes	No	No	No	Bridge to LTX
High-flow VV-ECMO	Yes	Yes	Rarely, only if ASD or PFO is present	No	Bridge to LTX LTX intraoperative Post-LTX – primary graft dysfunction Airway surgery Impossible one-lung ventilation Lung lavage
VA-ECMO	Yes	Yes	Yes	Yes	Bridge to LTX LTX intraoperative Myocardial dysfunction post-LTX or HLTX Airway surgery Mediastinal mass Lung resection involving the atrium or great vessels
AV-ECMO (pumpless)	Yes	No	No	No	Bridge to LTX Airway surgery Impossible one-lung ventilation
PA-LA Novalung (pumpless)	No	No	Yes	No	Bridge to LTX for PH

ASD indicates atrial septal defect, *AV* arteriovenous, *ECLS* extracorporeal life support, *ECMO* extracorporeal membrane oxygenation, *HLTX* heart-lung transplant, *LTX* lung transplant, *LV* left ventricular, *PA-LA* pulmonary artery to left atrium, *PFO* patent foramen ovale, *PH* pulmonary hypertension, *RV* right ventricle, *VA* veno-arterial, and *VV* veno-venous

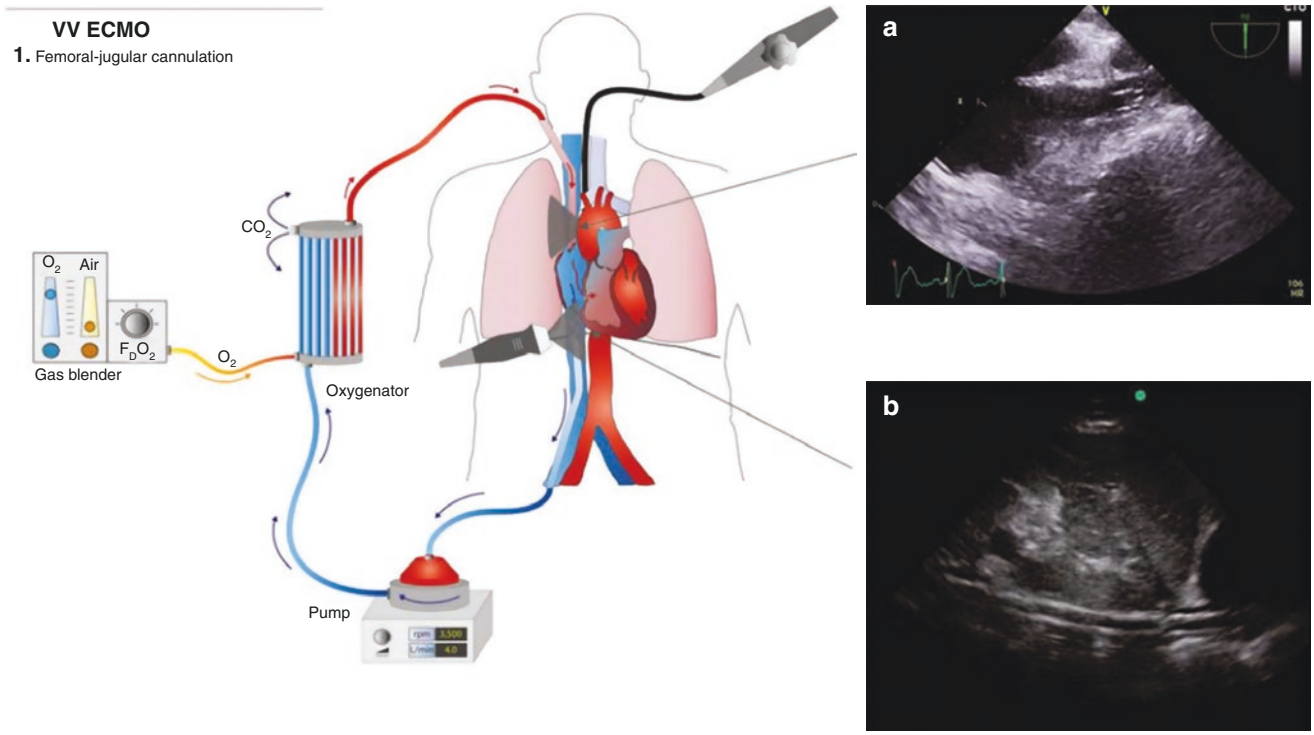

Fig. 27.2 Veno-venous (VV)-ECMO with drainage of deoxygenated blood from the inferior vena cava (IVC) via cannulation of a femoral vein and reinfusion of oxygenated blood into the superior vena cava (SVC) via cannulation of the jugular vein. Oxygenated blood is ejected into the pulmonary circulation by the patient's right heart function. (**a**) Mid-oesophageal TEE view verifies the position of the outflow cannula in the SVC. (**b**) TTE subcostal view visualises the inflow cannula within the long axis of the IVC. (Adapted with permission from Doufle et al. [8])

unventilated surgical patient with a hyperdynamic circulation. If the lungs are not severely injured and can be partially ventilated with oxygen, oxygenation can be maintained with lower flows. Low-flow VV-ECMO via small-sized cannula can achieve blood flow of up to 1.0 L/min which is sufficient for CO2 removal but provides very little oxygenation [10].

Veno-arterial ECMO

VA-ECMO is used for cardiocirculatory support with or without respiratory failure. Blood is drained from the venous side and reinfused arterially; for peripheral VA-ECMO in adults, the femoral vessels are most often used for cannulation (Fig. 27.3). Blood drained from the RA is pumped through the membrane oxygenator and reinfused in the mid-aorta. Oxygenated blood mixes with the blood ejected from the heart with direct perfusion of the central organs. Physiological effects include unloading of the RV; when ECMO blood flows are high, much of the patient's venous return bypasses the pulmonary circulation. While organ perfusion pressure is improved, left ventricular afterload is increased as blood from the ECMO circuit is reinfused at arterial pressure. The cannula chosen should be large enough to allow VA-ECMO blood flow up to 2 L/min higher than the calculated cardiac output [11]. Because of the large size of the femoral arterial cannula required, distal limb perfusion may be compromised, and a distal arterial perfusion catheter is routinely placed. Disadvantages of VA-ECMO include the risk of arterial cannulation: arterial injury, bleeding and embolism, distal limb ischemia and cardiac thrombus if low flows are maintained through the heart. TEE can be used to assessing the drainage cannula position, ideally in the lower part of the RA, and decompression of the right side of the heart, as well as overall heart function.

Central cannulation directly in the left atrium and ascending aorta enables placement of larger cannula and higher ECMO blood flows but requires an open chest and is generally reserved for operative cases that require haemodynamic support, including lung transplantation.

Patients on VV-ECMO for respiratory failure who subsequently develop haemodynamic instability can be supported by the addition of an arterial cannula for a hybrid configuration called veno-veno-arterial ECMO. Both venous catheters are used for drainage into a single ECMO circuit with reinfusion via a third (usually femoral) catheter.

AV-ECMO (Pumpless)

The Novalung interventional lung assist device (Novalung GmbH, Hechingen, Germany) is a low-resistance gas

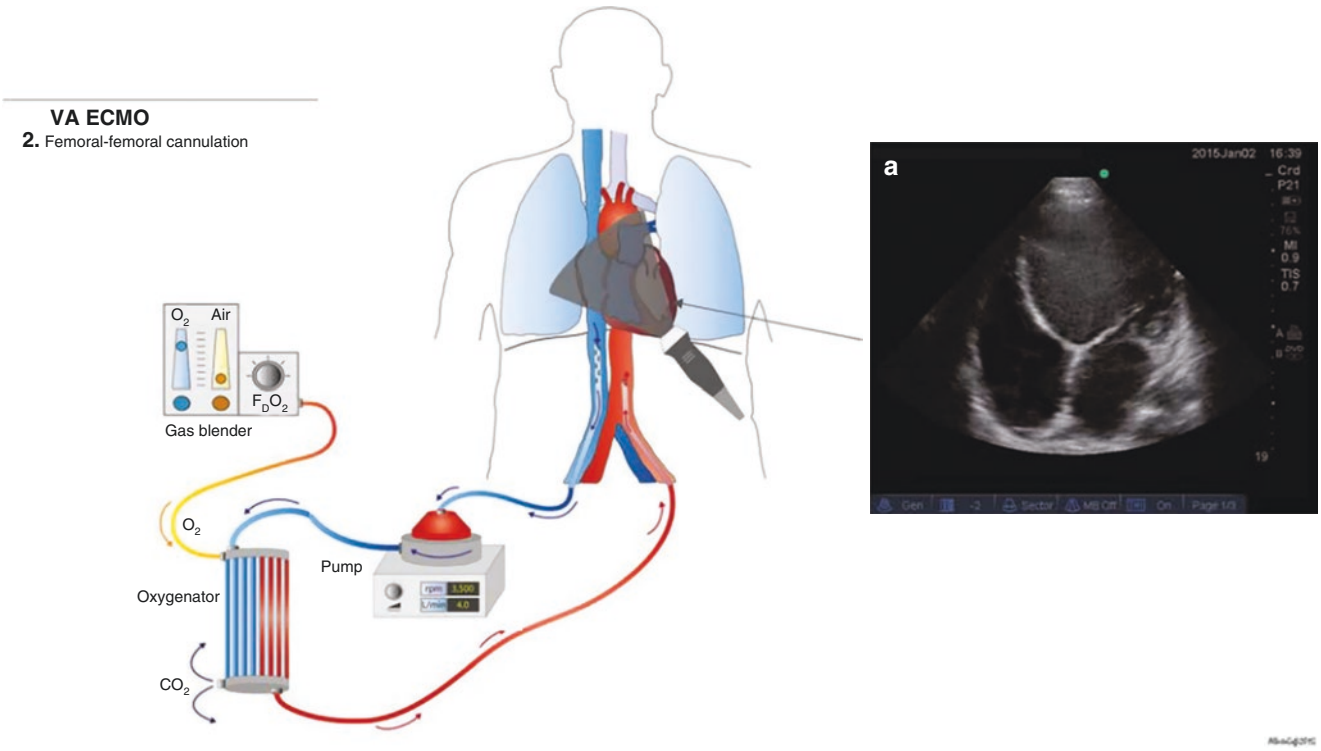

Fig. 27.3 Veno-arterial (VA)-ECMO with drainage of deoxygenated blood from the IVC via cannulation of a femoral vein and reinfusion of oxygenated blood into the ascending aorta via cannulation of a femoral artery. (**a**) Four-chamber view visualised by a TTE four-chamber view to assess cardiac function. (Adapted with permission from Doufle et al. [8])

exchanger designed for pulsatile blood flow driven by the patient's cardiac output. A drainage catheter is inserted into a femoral artery and reinfusion catheter into a femoral vein. The two are connected to the Novalung via a short, pumpless circuit. The blood flows generated are dependent on cardiac function and arterial blood pressure and are in the range of 1–2.5 L/min. This allows full decarboxylation, but only partial oxygenation, so this modality is particularly useful for treating hypercapnic respiratory failure [10].

Pumpless configurations have the advantage of greater portability and low priming volumes. They are practical for inter-hospital transport [12]. Once hypercarbia is controlled, many patients can be extubated, be mobilised and participate in rehabilitation [13].

PA-LA Novalung (Pumpless)

Another pumpless configuration is applicable only to patients with pulmonary hypertension and impending right heart failure. The Novalung is connected via a short tubing circuit between a drainage cannula placed directly into the main PA and reinfusion catheter inserted in the left atrium via the right upper pulmonary vein. High right-sided pressures drive the flow through the low-resistance Novalung. This oxygenated right to left shunt has the effect of unloading the RV, reduced septal shift, allowing better LV filling, coronary perfusion and leading to improved RV function. This modality involves central cannulation via a sternotomy; patients who are awake but haemodynamically unstable may need femoral cannulation for peripheral VA-ECMO to safely tolerate the induction of general anaesthesia, with planned weaning when the right heart is decompressed. Intraoperative TEE does not direct the cannula positioning; however, it is vital for assessing adequate unloading of the RV and the status of LV function. It is crucial to verify that the LV is able to tolerate increased blood flow without failing. In the event of LV decompensation, longer-term VA-ECMO would be required. At the end of the procedure, the PA and LA cannulas are advanced through the skin of the upper abdomen and the chest closed. Used as a bridge to transplant, many patients can be extubated and subsequently mobilised [7, 14].

Applications in Thoracic Surgery

Lung Transplantation

ECMO is being used at an increasing number of specialised centres to bridge deteriorating patients with end-stage lung disease to lung transplant surgery. ECMO-bridged patients

are at an increased risk of perioperative morbidity and mortality but do have an excellent 1-year survival (>90%) [2]. Given that without pre-transplant ECLS most of the ECMO-bridged patients would have died, this is increasingly an accepted practice. Many patients with hypercapnic respiratory failure can be bridged with pumpless AV-ECMO or preferably low-flow VV-ECMO. Those with significant hypoxia will require full-flow VV or if haemodynamically unstable peripheral VA-ECMO. In the subgroup with severe pulmonary hypertension, VA-ECMO or PA-LA Novalung is used [14].

Lung transplant surgery is characterised by dynamic haemodynamic and respiratory compromise, the most challenging being systemic hypotension, pulmonary hypertension and hypoxemia (see Chap. 47). ECMO is supplanting CBP as the favoured form of ECLS to stabilise patients. Typically, when ECMO is initiated intraoperatively, a VA-ECMO configuration via central cannulation sites is used. In a recent case-control cohort study of patients where cardiopulmonary support was used intraoperatively, those managed with ECMO had better early outcomes including duration of mechanical ventilation, ICU and hospital length of stay than patient who went on CBP. Blood product usage was significantly less in the ECMO patients [15].

VV-ECMO is the most common mode for preoperative bridging. When these patients undergo their transplant, some patients can be adequately supported with continued VV support. Many though require higher flows or increased haemodynamic support, often with a hybrid configuration. Patients who arrive in the operating room with a jugular dual-lumen catheter and with the addition of a central aortic catheter can receive veno-venous-arterial support with drainage via the bi-caval lumen and reinfusion of oxygenated blood into both the atrial lumen and into the aorta. Alternately, the VV-ECMO can be maintained unchanged via the jugular catheter, and additional central IVC and aortic cannulas can be placed as separate circuit for simultaneous VA-ECMO (personal communication Dr. Marcelo Cypel). The VV-ECMO is maintained during the surgery to avoid any thrombotic problem in the circuit and thus can be resumed postoperatively after weaning VA-ECMO if necessary.

Upon completion of the transplant, ECMO will be weaned for assessment of graft function. While desirable to decannulate the patient, the function of the allograft dictates the withdrawal of support. Some patients are decannulated of all extracorporeal support, patients with hypoxemia may be converted to VV, and those with pulmonary hypertension or severe myocardial dysfunction need continued VA-ECMO, requiring a later return to the operating room for decannulation. Any form of postoperative ECMO has the disadvantage of increased bleeding risk from continued anticoagulation after major surgery. Lung transplant recipients requiring ECMO for PGD have decreased survival as compared to those without PGD, but similar outcomes to patients with PGD managed without ECMO. Bridge to recovery support with VA-ECMO has a much higher 30-day mortality than VV-ECMO [2].

Airway Surgery

ECMO may be used to support patients with critical airway obstruction. Lesions above the larynx may be managed with awake fibre-optic intubation or tracheostomy under local anaesthesia. When severe obstruction is encountered below the larynx, while intubating the vocal cords may not be difficult, ventilation may be impossible. While some lesions may be managed by rigid bronchoscopy and debridement with intermittent ventilation (see Chaps. 11 and 13), extensive tracheal obstruction, need for prolonged debridement and significant bleeding into the airway present formidable problems. Historically, full CPB support was instituted via femoral venous and arterial catheters placed under local anaesthesia [16]. More recently, VV-ECMO support has been reported for endotracheal tumour resection [17, 18], dislodged stents [17, 19], foreign body removal [20], control of haemoptysis [21], debridement of papillomatosis [22] and relief of external compression [17, 23, 24] in adults. A variety of cannulation strategies have been reported: femoral and jugular single-lumen catheters [17, 20, 22] and bi-caval dual-lumen catheter in the right jugular vein [18, 24] have been described. Death as a result of post-resection haemoptysis has been reported likely exacerbated by anticoagulation for ECMO [17]. Relief of airway obstruction in small children has been performed with both VV- and VA-ECMO [25].

ECMO management has been reported after resuscitation from cardiopulmonary arrest due to airway obstruction; both VA [19] and VV [18] have been used. While VV support was successful in a hypoxic patient where haemodynamic stability had been restored, if there is postarrest myocardial dysfunction, VA-ECMO is a better choice. Both reports describe ECMO support during restoration of airway patency, conversion to conventional mechanical ventilation and a short period of observation for neurological sequelae, followed by successful extubation.

An additional challenge presented by tracheal resection and reconstruction is continued oxygenation and ventilation during the period with an open airway. Distal airway management often involves cross-field ventilation with an endotracheal tube or jet ventilation with a tracheal catheter, both of which may obstruct the surgical field (see Chap. 13). Complex reconstruction may be facilitated with ECMO support, as can open airway procedures in patients with limited respiratory reserve [26, 27]. Advanced tumours requiring extensive en bloc resection have been managed with VA-ECMO due to the need for vigorous retraction of the

heart and great vessels. Both central and peripheral cannulation has been described [26]. VV-ECMO support is more often reported and is suitable for tracheal and carinal resection including carinal pneumonectomy [28–30]. An unusual case of repair of a complex tracheoesophageal fistula was reported using pumpless AV-ECMO, with a low-resistance circuit placed between femoral arterial and venous catheters for CO_2 removal. Apnoeic oxygenation was provided via a small endotracheal tube at the carina, allowing 12 h of surgery under without ventilation of the lungs [31]. Tracheal resection has also been described with AV-ECMO [32]. When VV-ECMO provides insufficient oxygenation during tracheal surgery, supplemental catheter oxygen insufflation had also been used [29].

Impossible One-Lung Ventilation

Patients under consideration for thoracic surgery may have limited pulmonary reserve, making oxygenation with one-lung ventilation impossible. Successful prior management of lung cancer may result in patients who have undergone pneumonectomy presenting with contralateral disease. Post-pneumonectomy patients have undergone contralateral wedge resection and segmentectomy for second malignancies [30, 33], VATS bullectomy [34] and esophagectomy [35] with VV-ECMO support. A low-flow VV-ECMO was noted to suffice in a subgroup of 3 of these patients undergoing segmentectomy. A dual-lumen catheter inserted in a femoral artery and an average of 1.6 L/min blood flow and sweep gas flow of 5 L/min through the oxygenator maintained stable blood gases for over 45 min. Pumpless AV-ECMO has also been used to facilitate wedge resection and decortication in post-pneumonectomy patients [32].

Patients who have advanced pulmonary parenchymal lung disease may present for vital thoracic surgery procedures; however, may not tolerate OLV. There are no guidelines to determine which patients will need extracorporeal support and who will tolerate the procedure without. Arterial P_aO_2 on two-lung ventilation, FEV_1/FVC ratio and side of operation are usually good predictors of hypoxia on OLV [36]; however, this information may be limited on critically ill patients and may not reflect new pulmonary co-morbidities such as empyema or an air leak. Patients for empyema surgery frequently have necrotising pneumonia or bronchiectasis, and VV-ECMO has been instituted intraoperatively to allow aggressive decortication of empyema [37]. The bilateral decortication of critically ill, VV-ECMO-dependent patients was proposed to be a crucial step in their weaning from ECMO, followed by successful extubation [38].

Patients with emphysema are prone to ruptured bullae and prolonged air leaks, and VATS resection of bullae has been with both VV-ECMO support [30] and AV-ECMO [32]. In the late 1990s, elective intraoperative initiation of ECMO was used to support three COPD patients with severe hypercapnia undergoing LVRS, who therefore did not meet standard selection criteria for this procedure [39]. VA-ECMO was chosen due to the anticipated haemodynamic instability often seen with positive pressure of patients with pulmonary hyperinflation. This must be described as a controversial treatment plan as severe hypercapnia is a risk factor for perioperative mortality. This practice has not been reported by other groups. VV-ECMO has been used to facilitate LVRS/major bullectomy to liberate COPD patients from mechanical ventilation [40, 41].

Additionally, VV-ECMO has been used to enable patients with significant loss of lung parenchyma to tolerate resections: metastasectomy after prior extensive lung resection [30], bullectomy [42] and resection of aspergilloma [43] after scarring from tuberculosis have been reported.

Finally, patients with alveolar proteinosis with progressive hypoxia require whole lung lavage of both lungs with large volumes of saline to remove lipoprotein deposits. Classically, this has been done sequentially via a double-lumen tube, but severely affected patients may not tolerate this, and there are many case reports describing VV-ECMO support to enable lavage in this patient group [44–55].

Mediastinal Masses

Large masses occupying the anterior mediastinum have the potential to cause compression of great vessels and right atrium, causing reduction in preload and cardiac output. In the awake patient, the negative pressure generated by inspiration reduces this effect so that compression is minimal until surgical disease is advanced. However, this is abolished by muscle relaxants, and positive pressure ventilation can precipitate collapse of cardiac output and arrest. This is a particular risk for children with large anterior lymphomas. Historically, this has been treated with CPB support [56–59]. More recently, preinduction femoral VA-ECMO while maintaining spontaneous ventilation has been described in children [60] and adults [61]. The VA configuration is warranted by the potential for cardiovascular collapse. This is a well-known problem in thoracic anaesthesia, and the risk assessment for extracorporeal support is described in more detail in Chap. 14.

Advanced Surgical Resections

Late presentation of intrathoracic cancer with local invasion historically was deemed unresectable. However, tertiary

referral centres are increasingly undertaking resection of advanced lung and oesophageal malignancies as part of multimodal therapy and reporting reasonable survival [62–72]. The most common extrapleural site of invasion for lung cancer is the left atrium. Resection requires clamping the affected area of the atrial wall, which causes haemodynamic instability which can be prolonged as a patch repair or primary closure of the atrium is required before the clamp can be released. This can be achieved in some cases without extracorporeal support [63, 73]. Resection of lung malignancies with reconstruction of the superior or inferior vena cava, left atrium, distal aorta and carina has been described with VA-ECMO support [71] as have oesophageal malignancies invading carina [5]. Cannulation sites are chosen according to the planned resection and may be central or peripheral [71]. Resection of complex thoracic malignancies with extension into the pulmonary trunk, the aortic arch or the heart requiring opening a cardiac chamber is only amenable to traditional CPB [71, 74–76].

Thoracic Emergencies

ECMO has been described as a life-saving emergency treatment of massive haemoptysis [21, 77, 78]. Intraoperative iatrogenic large vessel injury with massive bleeding is most often managed with CPB, which provides the advantages of rapid infusion, autotransfusion and delivery of cardioplegia for cardiac arrest or deep hypothermic circulatory arrest if needed [5]. In the event of pulmonary artery injury, the reduction of blood flow through the pulmonary trunk enables surgical repair [5, 79], whereas ECMO has been shown to be of benefit in a wide variety of tracheal injuries to facilitate tracheal repair and healing. These include iatrogenic injury, postoperative fistulae and trauma [27, 80].

ECMO for primary graft dysfunction is frequently required after lung transplantation, to support the lungs, while reperfusion injury abates but has also been instituted emergently for other perioperative aetiologies of lung failure. These include haemodynamic stabilisation in patients with acute severe pulmonary embolism [81] to allow pulmonary embolectomy [82, 83], reperfusion injury after pulmonary thromboendarterectomy [84–86] for chronic thromboembolic pulmonary hypertension and the indications and methodology of which have recently been reviewed [7]. Support for postoperative transfusion-associated lung injury (TRALI) is also well-described [87, 88]. The importance of advanced planning for emergencies and effective multidisciplinary team-working has recently been emphasised in maintaining good patient outcomes [5]. In addition, ECMO has been used outside the thoracic operating rooms as part of resuscitation and surgical repair for thoracic trauma [37, 89–92].

The choice of VV- versus VA-ECMO in emergency circumstances is dependent on the need for primarily oxygenation versus the need for concomitant haemodynamic support. When urgent ECMO is instituted intraoperatively, available venous and arterial cannulation sites may be dictated by patient position and available vessels [5].

Preoperative Planning of ECMO

For any patient who requires extracorporeal support, the surgical checklist should include the planned ECMO configuration, cannulation sites, timing of cannulation (before or after induction of general anaesthesia) and anticipated timing of weaning and decannulation. Patient position and planned incision will influence cannulation sites [5]. If patients are transferred to the operating room already on ECMO, any required modification of support or additional cannulation should be discussed. This allows the anaesthesiologist to optimise intravenous and arterial access for monitoring and volume infusion.

Are the Proposed Vessels Big Enough?

The sizes of the cannulas currently available for ECMO are summarised in Table 27.2.

The size of the cannula required will depend on the patient's body surface area (aiming for 2.5 L/min/m^2), the achievable flow rate through the cannula without excessively high pressures (a technical property of the cannula available from the manufacturer). A large adult will need femoral vessels in the range of 8–10 mm in diameter, without atherosclerosis, stricture or tortuosity to be successful. This can be checked preoperatively with ultrasound or ultimately with angiography. Central cannulation typically allows placement of larger cannulas and consequently higher flows than peripheral ECMO.

Table 27.2 Sizes of currently available ECMO cannulas

Manufacturer	Central ECMO		Peripheral ECMO	
	Arterial Fr (mm)	Venous Fr (mm)	Arterial Fr (mm)	Venous Fr (mm)
Terumo	10–26 (3.3–8.7)	28–36 (9.3–12)	20–24 (6.7–8)	19–29 (6.3–9.7)
Medtronic	15–24 (5–8)	28–36 (9.3–12)	None	None
Maquet	20–24 (6.7–8)	32–36 (10.7–12)	15–29 (5–9.7)	19–29 (6.3–9.7)
Edwards	None	None	16–24 (5.3–8)	18–28 (6–9.3)

Note: dual-lumen cannulas are larger at 23–32 Fr (7.7–10.7 mm) [93]

Will the Patient Tolerate the Procedure?

An intrathoracic mass large enough to cause obstruction on induction may also cause positional symptoms, and such patients can often not lie flat for any length of time. Airway tumours also often cause positional dyspnoea. It is very difficult for the surgeon to insert these large cannulas into the groin with the patient in a semi-sitting position, and this must be done carefully to avoid iatrogenic vessel injury. In addition, even with meticulous local anaesthetic, the procedure can be painful for the patient as the cannulas are introduced and as the innervation of the vessels is visceral rather than somatic. Judicious sedation and analgesia may be helpful while maintaining respiratory drive and muscle strength. In the authors' experience, a vasovagal response to awake femoral cannulation can provoke cardiopulmonary arrest, so cannulation should only be done in a fully monitored setting with resuscitative drugs and equipment immediately available.

Are the Cannulas Correctly Positioned?

Malpositioned cannulas have the potential to become obstructed or create recirculation (see "Troubleshooting ECMO"), causing the patient to become hypoxic. The position can be checked with TEE or fluoroscopically. The chosen imaging modality should be in place prior to induction.

What Are the Risks of Anticoagulation, and How Should It Be Managed?

Once the cannulas are in place, the patient must be sufficiently anticoagulated to prevent thrombosis, either at the tips of the cannulas or in the circuit. This potentially has implications for neuraxial analgesia and surgical blood loss, which can be significant and rapid, so appropriate intravenous access should be gained prior to insertion.

Historically, the predominant causes of adverse outcome from ECMO on ICU patients with respiratory failure have been major bleeding requiring surgical intervention, and intracerebral haemorrhage, particularly in neonates. ICU patients on long-term ECMO have low platelet function and numbers, fibrinogen deficiency, loss of vitamin K-dependent clotting factors and acquired Von Willebrand's disease resulting in complex coagulopathy, which has been recently reviewed [94]. International guidelines from the Extracorporeal Life Support Organization (ELSO) [95] are summarised in Table 27.3. For CPB, anticoagulation practices are well-established [96], and a typical institutional protocol is given in Table 27.3 for comparison.

Table 27.3 Anticoagulation for ECMO and CPB

	ECMO (as per ELSO [95])	CPB
Unfractionated heparin bolus (units/kg)	50–100	300
Maintenance heparin	7.5–20 units/kg/hr	5000–10,000 unit boluses guided by ACT
ACT target (seconds)	180–220	480
Anti-Xa target (units/ml)	0.3–0.7	–
APTT range	1.5 x baseline	–
Fibrinogen target (mg/dl)	>150	>200
INR	<1.5	<1.5
Platelet target (1000 cells/mm^3)	>100	>75
Haematocrit (%)	35–40	24–28

It should be emphasised that the risk/benefit gained from anticoagulation in the intraoperative setting is potentially different, and these guidelines were not designed for short-term operative use. For example, the use of a heparin-bonded circuit can reduce the heparin requirement substantially for the first 6 h of its use [95]. This doesn't reduce the heparin requirement in the long term, but could substantially reduce the thrombosis risk in the intraoperative situation. Similarly, patients undergoing procedures with major blood loss will also be deficient in platelets, fibrinogen and other clotting factors, which will potentially prolong coagulation in the absence of heparin. There are multiple reports of surgical interventions with high bleeding risk using ECMO without heparin [21, 32, 33, 37, 38]. In our institution, we routinely target an ACT of 160–180 s for these reasons, checking at least every 30 min and giving small boluses of heparin as needed rather than running an infusion. We also routinely use ROTEM™ and platelet function assay, as an adjunct to ACT, to detect other potential causes of bleeding such as factor deficiency, platelet dysfunction or fibrinolysis.

Vascular Access

Two-cannula peripheral ECMO may use femoral vessels (often on both sides) or jugular and femoral vessels. A single-stage VV-ECMO cannula is usually placed in the right internal jugular, but axillary [97, 98] and supraclavicular cannulation sites have also been described [99, 100]. Placement of central lines should be planned in discussion with the surgeon, leaving the sites with the highest calibre for ECMO cannulas. If ECMO is already in place and central venous line placement is required, the potential for air entrainment is increased by the negative pressure generated by the drainage cannula. In VA-ECMO there is a risk of paradoxical arterial air embolism from venous bubbles, via the arterial return cannula (the ECMO circuit contains no bubble traps or filters).

Ventilation Strategies for ECMO

All configurations of ECMO are extremely efficient at clearing carbon dioxide, which means that in the ECMO patient the main determinant of p_aCO2 is sweep gas flow and carbon dioxide tension, not the patient's minute volume. Alveolar pO_2 is still important to preserve when possible, as it contributes to oxygenating the remaining pulmonary blood flow. Tidal volumes and respiratory rate can be reduced far beyond what is normally possible. Given the established link between mechanical ventilation and lung injury, particularly in thoracic surgery and one-lung ventilation [101, 102], it would seem prudent to adopt a lung-protective ventilation strategy even in patients without prior injury, with tidal volumes 6–8 ml/kg (ideal body weight) preventing volutrauma. Prevention of atelectasis with 5-10 mmHg of PEEP will reduce atelectotrauma. Reducing the ventilator rate to 6–10 breaths a minute will allow for reduction in ventilator mean pressures, and longer rise times, with consequent reduction in strain forces which may be associated with acute lung injury. High alveolar oxygen tensions can exacerbate perioperative lung injury, so titrating FiO2 as low as saturations allow is advisable [103].

The efficacy of ECMO means that the patient can receive little to no ventilation and remain stable – so "ultraprotective" lung ventilation has been advocated for the ARDS patient group [104]. This comprises tidal volumes of less than 4 ml/kg, with PEEP >10 mmHg and a respiratory rate of 6 breaths/minute. The degree of protection is not mandatory for the perioperative patient, but is easy to achieve with ECMO support.

Monitoring Patients on ECMO

Monitoring considerations for patients on ECMO in the ICU has recently been authoritatively reviewed, with particular emphasis on the importance of TEE for cannula positioning [9]. Arterial lines are best placed in the right arm to measure pressure and P_aO_2 downstream from the brachiocephalic artery, which correlates most closely with conditions in the right carotid artery and coronary arteries. Central venous line location most likely will be dictated by the surgical incision, but care should be taken not to advance the tip of the catheter too far into the central circulation, so that it is not aspirated into the lumen of the ECMO cannula. Once the ECMO is started, central venous pressure monitoring may not be reliable. Pulmonary artery (PA) catheters may be very difficult to insert if upper body ECMO cannulas are already in place, both in terms of passing the catheter through the occupied SVC and in floating into the right heart with ongoing drainage into the ECMO circuit. It is possible for the PA catheter balloon to be aspirated into a drainage cannula and occlude it completely. Seeing a pulsatile PA tracing is a reassuring sign that volume replacement is adequate.

Peripheral saturation probes should be placed on the right hand, to guard against diffusion hypoxia. Consideration should be given to cerebral saturation monitoring with near-infrared spectroscopy, as an indicator of cerebral hypoxia. In a short retrospective case series using this monitor, Wong et al. found a 100% rate of cerebral desaturation on initiation of ECMO, 80% of which were reversible with changes in haemodynamic management [105].

Troubleshooting ECMO

Hypoxia

Flows Are Insufficient

VV-ECMO is dependent on sufficient venous blood flow through the oxygenator before returning it to the right atrium. If flow through the oxygenator is much less than the total cardiac output, the difference will pass through the unventilated pulmonary circulation, and the arterial saturation will be reduced by this mixing. In severe respiratory failure, VV-ECMO flows of 60% of cardiac output are required to maintain an SpO_2 over 90% [106]. The solution is to oxygenate via the lungs if possible, optimise venous drainage, increase the ECMO flows if possible, increase the sweep gas to ensure full oxygenation of the return blood and if necessary reduce the cardiac output. When this problem occurs on the ICU, beta-blockers are occasionally used, but their use should only be considered carefully in the unstable patient in the operating room.

Recirculation

In VV-ECMO, recirculation of blood between the reinfusion and drainage catheters can occur. The intent is for the oxygenated return blood to pass through the tricuspid valve; therefore, the reinfusion ports should be in the right atrium. Oxygenated reinfused blood may flow into a single-lumen drainage catheter if the catheters are too close together. Recirculation can also occur with bi-caval dual-lumen catheters particularly if malpositioned and when higher flow rates are used but is less common than with two cannula configurations [107]. Echocardiography using colour Doppler can be useful for assessing ECMO cannula positions and direction of flows. The IVC cannula should be below the hepatic vein, SVC cannula should be at the SVC-RA border, and double-lumen cannulas should have the return port pointed at the tricuspid valve.

Differential Hypoxia/Watershed Phenomenon

In peripheral VA-ECMO, oxygenated arterial flow is retrograde from the femoral arterial reinfusion catheter back to

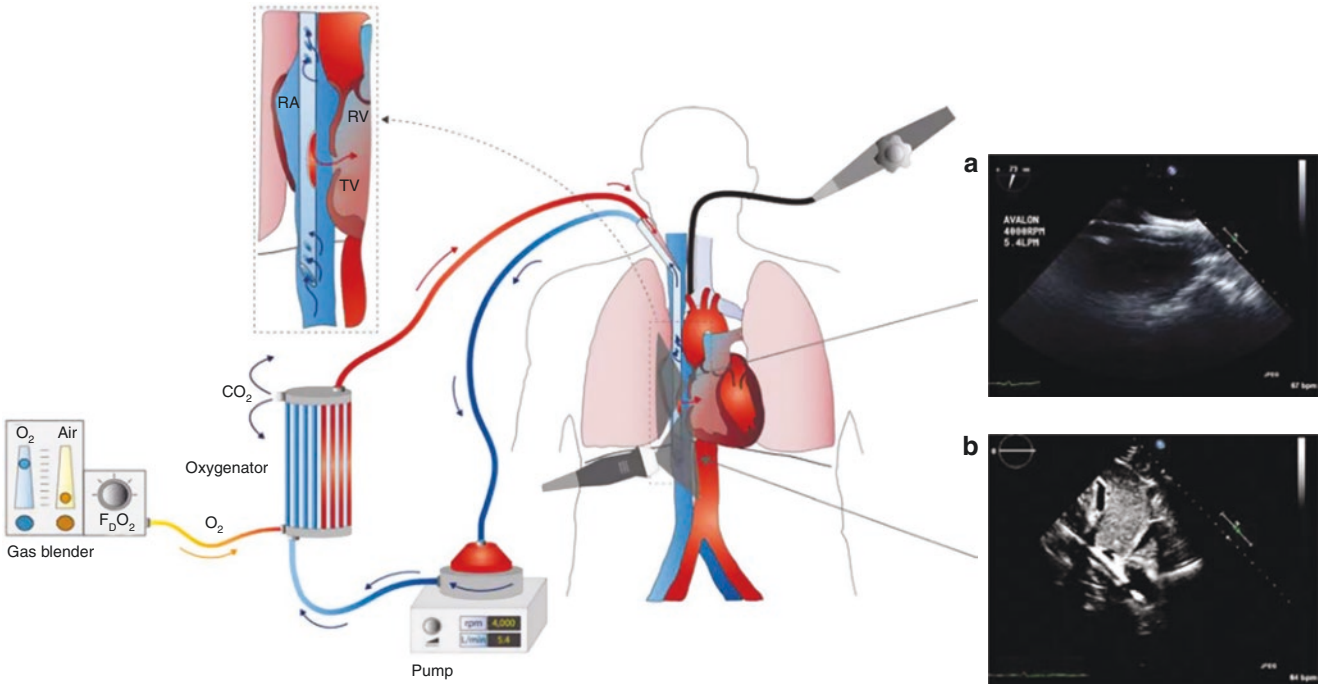

Fig. 27.4 Veno-venous (VV)-ECMO via a bi-caval dual-lumen catheter inserted via the jugular vein. Deoxygenated blood is aspirated via holes located in the drainage lumen of the catheter: proximally in the SVC and distally in the IVC. Oxygenated blood is reinfused via the atrial lumen with infusion port oriented towards the tricuspid valve (inset). (**a**) TEE mid-oesophageal bi-caval view of the cannula within the right atrium. (**b**) TTE subcostal view of the injection port facing the tricuspid valve and the tip of the cannula within the IVC. (Adapted with permission from Doufle et al. [8])

the aortic arch. Reinfused blood competes with anterograde (deoxygenated) cardiac output ejected from the left ventricle. This means that while the lower body is perfused with highly oxygenated blood, there may be ongoing upper body hypoxia (see Fig. 27.4). Importantly, this may result in deoxygenated blood flow to the brain and coronary arteries [11]. This is a particular risk in the patient with poor lung function in the presence of preserved myocardial function. The solution is to increase ECMO blood flow: the effect of this is twofold, and it will reduce pulmonary blood flow while increasing the ECMO flow itself. The replacement of inotropes by purely vasopressor medications may also be helpful (Fig. 27.5).

Hypotension

VA-ECMO Flows Are Insufficient

Check the drainage cannula: if it is chugging, flow may be obstructed (ask surgeon to check), the line may be kinked (perfusionist can check), the patient's great veins are compressed (e.g. by extrinsic pressure or retraction), or the patient may be hypovolemic. Intravascular volume status is the responsibility of the anaesthesiologist, and volume must be delivered intravenously as the perfusionist has no reservoir. Check the reinfusion cannula; low flows can occur if the line is kinked or cannula is misplaced.

The Patient's Afterload Is Too Low

Support of the patient's SVR on ECMO is the responsibility of the anaesthesiologist, requiring infusion of vasopressors via a central venous line separate from the ECLS device. In addition, the ECMO flows vary with the level of support required and surgical manipulation. Inotropy is frequently required.

Weaning ECMO

VA-ECMO

At the end of the surgical procedure, if ECMO support is not planned into the postoperative period, VA-ECMO can be weaned by sequentially dropping the flows on the pump over a period of 10–20 min, with the lungs well recruited, suctioned and ventilated at protective tidal volumes. In preparation for this, the anaesthesiologist must ensure adequate filling, afterload and inotropy and be prepared to react

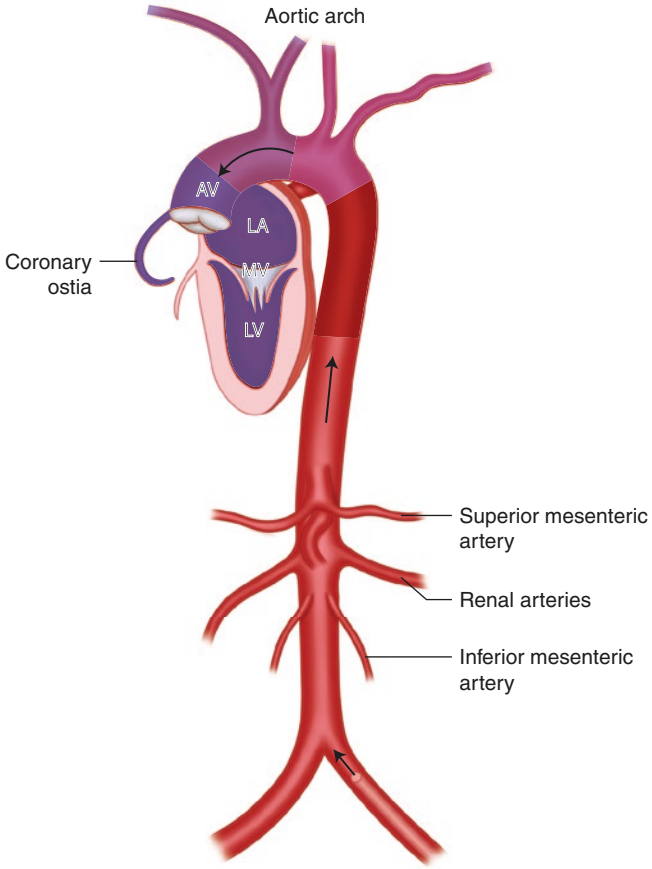

Fig. 27.5 Differential hypoxia or the watershed phenomenon. In peripheral VA-ECMO, oxygenated blood reinfused into the descending aorta mixes with blood ejected from the left ventricle. The mixing point (or watershed) is typically located at the base of the aortic root but will vary depending on the ECMO flows and the patient's cardiac output. In situations of severe lung injury with preserved myocardial function, deoxygenated blood ejected from the heart can force the watershed distally, resulting in hypoxemia of the heart and brain. The SaO2 in the right arm will be lower than the other limbs. This phenomenon is alternately called the "harlequin syndrome"

quickly to deterioration. The right heart in particular is at risk of failure, as no cardioprotection is used during ECMO, and coronary perfusion may be threatened by the watershed phenomenon as described above. Pulmonary vascular resistance may be altered by the surgical procedure, and clots can form in the relatively empty heart on ECMO. A thorough TEE evaluation prior to and during weaning ECMO, monitoring right ventricular size and function in real time as flows are reduced, should be considered. Once flows are down to around 1 L/min, the ECMO pump is stopped altogether and the arterial line clamped. This process often reveals hypovolemia, which the anaesthesiologist should be prepared to treat. If the patient remains stable and the arterial blood gas is adequate after 5 min, the patient can be decannulated.

VV-ECMO

Weaning VV-ECMO takes place with full flows running and the sweep gas speed and FiO_2 slowly being reduced. This gradually reduces the diffusion gradient of oxygen and carbon dioxide across the oxygenator membrane to zero, allowing the lungs to take over the process of gas exchange. Since flows are maintained, this process can be done slowly if necessary, with time for serial arterial blood gases, suctioning, bronchoscopy, recruitment manoeuvres and trials of high PEEP to optimise gas exchange. If blood gases remain good on low sweep flows, the pump can be stopped, and decannulation can take place.

Complications of ECLS

Most of the studies describing ECMO complications (see Table 27.4) have been in ICU populations, where ECMO use lasts for weeks rather than hours. The extent to which these risks can be extrapolated to short-term intraoperative use is unknown. Acute kidney injury, haemolysis and HIT are all

Table 27.4 Complications of long-term ECMO in adult ICU patients [98, 108–115]

Complication	Incidence	Notes
Acute kidney injury	70–85%	Very high rate due to pre-existing critical illness
Arrhythmia	15%	
Haemorrhage	Overall: 10–30% GI:4–6% Cannulation site: 15–20% Surgical site: 14–20% Intracerebral: 2–4% Pulmonary: 3–7%	
Seizure	1–2%	
Cerebral infarct	2–4%	
Systemic embolism	8%	Rate of cannula-tip thrombosis is as high as 85% but occurs after weeks of treatment
Haemolysis	6–7%	
Heparin-induced thrombocytopenia (HIT)	1–5%	Occurs 5–14 days post exposure to unfractioned heparin
Circuit clotting	2–19%	Varies according to component; may be less with heparin-bonded circuits
Air embolism	2%	
Oxygenator failure	16%	Usually chronic due to subclinical thrombosis
Vascular complications	<5%	For example, distal ischemia, dissection, pseudoaneurysm

complications of long-term ECMO use and are unlikely relevant intraoperative considerations. Incidence of infection is also correlated to the duration of ECMO [116]. In intraoperative ECMO, cannulation and surgical site haemorrhage, thrombotic events and vascular complications are probably the most relevant issues.

Neurological complications in ECMO are insidious and therefore potentially more common than Table 27.4 would suggest. For example, in a retrospective case series of adults who received ECMO for an average of 91 h, 50% suffered a variety of complications including subarachnoid haemorrhage, watershed ischemia and hypoxic-ischemic encephalopathy [117]. Overt stroke was rarely clinically diagnosed, in keeping with a rate of 2–4% as above, but nine out of ten patients who died had cerebral infarcts on autopsy. Similarly, in an autopsy study of patients who received emergency ECMO post cardiotomy, Rastan et al. [118] found an unrecognised cerebral infarct rate of 9%, unrecognised venous thromboembolism in 32% and unrecognised systemic embolism in 31%. In total 69–75% of long-term ECMO recipients were having subclinical thrombosis on autopsy [118, 119]. In addition, the rate of gaseous microembolism during ECMO support rivals that of CPB, with intravenous injections being the most common culprit, with potential for postoperative neurological morbidity [120]. For the perioperative context, simple maintenance of peripheral saturation and blood pressure are not necessarily sufficient to ensure adequate oxygen delivery to the brain – some form of active cerebral monitoring, such as near-infrared spectroscopy, should be considered [9, 105].

Fatal air embolism has been reported associated with performance of tracheostomy while on high-flow VV-ECMO with drainage via a bi-caval dual-lumen jugular catheter [121]. Inadvertent breach of the neck veins enabled the negative pressure in the SVC to aspirate air into the ECMO circuit. Suggested measures for avoiding this complication include temporary reduction of ECMO flows, performance of tracheotomy with the patient in a head down position and coverage of the puncture sites with wet compresses. The risk of air embolism by a similar mechanism could occur during placement of upper body central venous lines.

Clinical Case Discussion

A 54-year-old man with relapsing polychondritis presented for elective rigid bronchoscopy and tracheal stent repositioning. His original silicone stent was placed 3 years ago for tracheomalacia. He had stridor on forceful inhalation from suspected granulation tissue distal to the stent, but no stridor at rest. He is able to lie supine with no dyspnoea. He had a history of well-controlled hypertension and stable ankylosing spondylitis treated with prednisone and adalimumab. He had normal cardiac function and no valvular lesions. His airway examination revealed Mallampati I view with unrestricted cervical spine motion. He underwent a titrated intravenous induction and was maintained on a propofol and remifentanil infusion with muscle relaxation and intermittent jet ventilation. Rigid bronchoscopy and debridement of granulation tissue were performed. The stent was unable to be removed after multiple attempts and was ultimately pushed further distally over the area of granulation. At the end of the case, a mucosal tear of the posterior mid-trachea was noted.

On emergence, the patient had acute stridor and hypoxemia, requiring urgent reinduction and positive pressure ventilation. Repeat rigid bronchoscopy was performed and a Y-stent was inserted at the carina. The patient developed subcutaneous emphysema of the upper chest and neck. There was suspected perforation of one arm of the Y-stent through the trachea into the mediastinum. The stent was removed, and a tear could be seen from the mid-trachea extending into the left mainstem bronchus just distal to the carina.

The thoracic surgeons proposed to repair the tracheal tear via right thoracotomy.

What is your anesthetic plan for converting to thoracotomy?

During positioning and exposure of the left thorax, the goals are to provide gas exchange while avoiding high airway pressures and expansion of the mediastinal emphysema. Our patient was intubated orotracheally with an endobronchial tube with a narrow cuff placed just below the vocal cords and above the area of airway disruption to avoid pressure on the area. We maintained the patient asleep on total intravenous anaesthesia as volatile agents could not be reliably delivered during the complex lung isolation. A radial arterial line and right internal jugular central venous catheter were placed.

What are the options for oxygenating and ventilating this patient during repair of the trachea and left mainstem bronchus?

Due to the location of the tear, oxygenation via a right- or left-sided double-lumen tube or endobronchial tube would be impossible. Likewise, cross-field ventilation from an endobronchial tube placed directly into the right mainstem bronchus would be interrupted almost continuously to allow for repair of the tear. Therefore, veno-arterial extracorporeal membrane oxygenation (ECMO) was initiated via femoral cannulation to provide continuous gas exchange, allowing the surgeons full access to open and repair the trachea and bronchus. After cannulation and heparinisation, the patient's oxygenation improved on flows of 2–4 L/min. He was placed in the left lateral decubitus position, the right chest was opened and the trachea, and bronchi were repaired with both lungs collapsed. A Y-stent is inserted at the carina. The lungs

were re-expanded with positive pressure through the endotracheal tube and new stent, and water sealing test with Valsalva did not reveal any leaks. Chest tubes were placed in the right hemithorax and the chest was closed.

How will you wean ECMO support, and what are the postoperative considerations?

The ECMO flows were weaned to 1.5 L/min and the patient was decannulated after good oxygenation and blood chemistry were confirmed. The patient was transferred to the ICU intubated. He was neurologically intact, but failed extubation twice due to hospital-acquired pneumonia and difficulty clearing secretions. He eventually required tracheostomy. He left the ICU on postoperative day 18 and was discharged home on day 45 with a speaking tracheostomy.

Summary

As the technical frontiers of thoracic procedures are pushed ever forwards by our surgical colleagues, demand for intraoperative ECLS may be predicted to increase. It is unlikely that preinduction provision of mechanical support will ever become routine, and any procedure major enough to require it should not be taken lightly; however, with the help of the principles outlined in this chapter, they can at least feel within our envelope of comfort and experience.

Part VII

Applications of Ultrasound in Thoracic Anesthesia

Pulmonary Ultrasound

28

Nathan Ludwig and Ahmed F. Hegazy

Key Points

- Pulmonary ultrasound is a powerful bedside tool that anesthesiologists can use to expeditiously guide patient management decisions in the perioperative period.
- Ultrasonographic lung and pleural patterns such as A-lines, B-lines, lung sliding, and consolidation can be easily recognized by the anesthesiologist with basic ultrasound training. In the appropriate clinical setting, these can provide diagnostic evidence of pulmonary edema, atelectasis, pneumothorax, pneumonia, or normal lung aeration.
- Pulmonary ultrasound can help narrow the differential diagnosis in patients with undifferentiated respiratory failure, help assess the size and significance of pleural effusions, and aid in lung recruitment and ventilator management in the perioperative setting.
- Pulmonary ultrasound can be incorporated into a more general ultrasound assessment of the trauma or shock patient.

Introduction

The advancement of clinical ultrasound technology and reduction in costs have led to its widespread adoption in the clinical practice of anesthesiology. Most anesthesiologists have become comfortable with the use of ultrasound in vascular access. Ultrasound-based regional anesthesia has become commonplace, replacing and/or complementing landmark and nerve stimulator-based techniques. In addition, point-of-care echocardiography is becoming more commonly used by both cardiac- and noncardiac-trained anesthesiologists as a monitor of heart function, valvular performance, and fluid status. Using this experience and knowledge as a starting point, anesthesiologists can easily incorporate pulmonary ultrasound into their practice. When used in conjunction with physical examination and other imaging modalities, pulmonary ultrasound is a powerful technique that can aid in the diagnosis and management of patients in respiratory failure.

Ultrasound Physics

It can be argued that an advanced knowledge of ultrasound physics is unnecessary for the average clinician to incorporate ultrasound into their practice. A basic understanding of ultrasound physics, however, is useful in understanding how to optimize your image, interpret artifacts, as well as recognize the limitations of different ultrasound transducers. This chapter will review what the authors feel is essential knowledge for frontline clinicians to preform and interpret pulmonary ultrasound [1, 2].

Put simply, ultrasound transducers convert electrical energy into mechanical energy with the use of vibrating piezoelectric crystals. This leads to the creation of ultrasonic waves that penetrate body tissues and are reflected back to the transducer. The reflected waves are then reconverted into an electric signal that is processed and displayed as an image.

Electronic Supplementary Material The online version of this chapter (https://doi.org/10.1007/978-3-030-00859-8_28) contains supplementary material, which is available to authorized users.

Body tissues vary in the resistance they offer to ultrasound waves, described mathematically as their acoustic impedance. Bone offers very high resistance to ultrasound waves, and most of the ultrasound wave is reflected off the bone surface. It is therefore very common to see complete darkness below ribs in a phenomenon called acoustic shadowing or attenuation artifact (Video 28.1). In contrast, adipose tissue and muscle have a low impedance, and therefore ultrasound waves can easily be transmitted through these tissues, and visualization of deeper structures is often possible. Knowledge of how ultrasound waves interact with various body tissues is useful to the sonographer as it allows for an understanding of why it is critically important to position the transducer correctly in the intercostal spaces during pulmonary ultrasound.

When ultrasound waves encounter an interface between two tissue planes that vary in their acoustic impedance, reflection of waves back to the transducer occurs. It is possible for a wave to reflect back and forth between two surfaces in the body or between one surface and the transducer. Sound waves bouncing back and forth between a tissue surface and the transducer produce what is called reverberation artifact (Fig. 28.1). Reverberations can be of significant diagnostic value and produce a sonographic pattern known as A-lines (described later in this chapter). An ultrasound beam trapped in a pocket of fluid will vibrate within that pocket, causing a constant energy return to the transducer (Fig. 28.2). This constant energy return will produce what is known as a ring down or comet-tail artifact. Comet tails are also of diagnostic significance and produce a sonographic pattern called B-lines (also described later in this chapter).

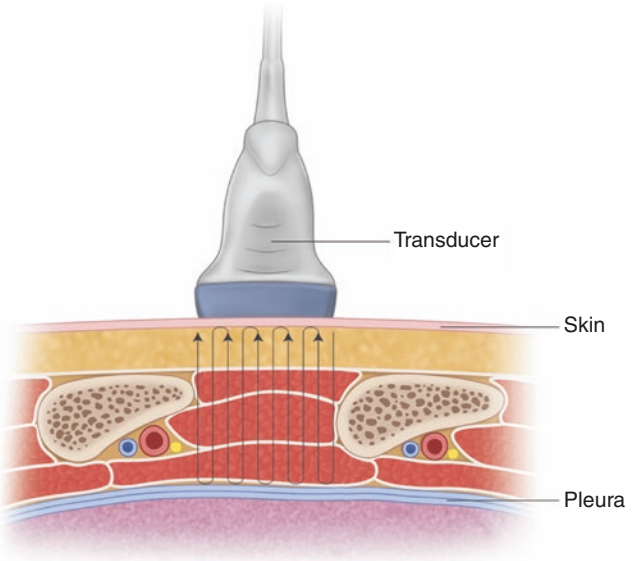

Fig. 28.1 Reverberation artifact. Reflection of ultrasound waves between the transducer and the pleural line leads to the generation of multiple horizontal lines on the screen, equidistant between the transducer and the pleura. In pulmonary ultrasound, this artifact is called A-lines

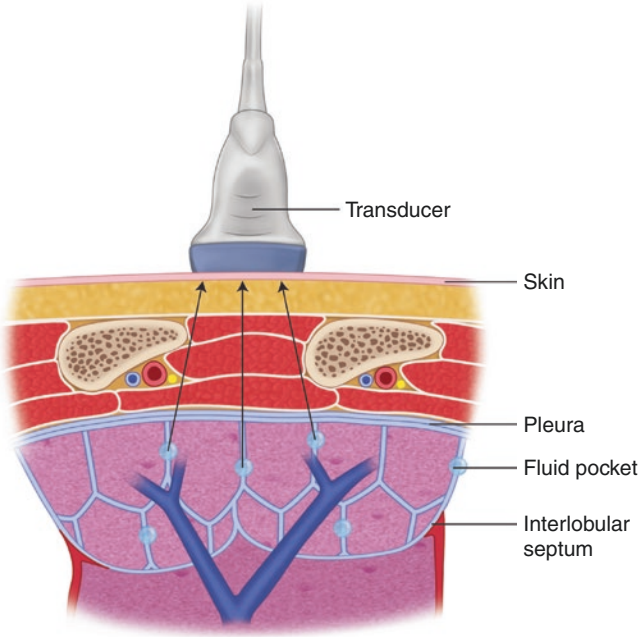

Fig. 28.2 Comet-tail artifact. An ultrasound beam trapped in a fluid pocket in the interlobular septum leads to a constant energy return to the transducer. The resultant comet-tail artifact in pulmonary ultrasound is referred to as B-lines

Transducers

In order to save costs, many clinical departments will purchase ultrasound machines with multiple transducers, commonly known as probes. This allows for the same machine to be used in a wide range of clinical uses. It is essential that the clinician understands the utility and limitations of the various transducers. Portable bedside ultrasound machines typically come with some combination of linear, curvilinear, and phased array transducers. All three of these transducer types can be used in pulmonary ultrasound.

Linear transducers are probably most familiar to anesthesiologists as they are used frequently for regional anesthesia and vascular access. These are high-frequency probes that provide excellent resolution for superficial structures like the pleural line. High-frequency ultrasound waves, however, undergo very rapid attenuation making linear probes a very poor choice when trying to visualize deeper structures. By contrast, curvilinear probes are low frequency, with less ultrasound attenuation and greater capability of visualizing deeper lung structures. They have a much larger footprint, however, and, when used for pulmonary ultrasound, will always show rib shadows within the scanning sector. Phased array probes are also low-frequency probes but with a flat and much

smaller footprint. This small footprint fits nicely between the ribs, making these probes ideal for thoracic scanning. In addition, phased array probes are capable of producing high frame rates providing good visualization of rapidly moving structures like the heart. They have therefore been the probe of choice for echocardiography applications since their inception. This fast frame rate, however, comes at a cost of a lower spatial resolution than its curvilinear counterpart. The curvilinear probe is therefore superior to the phased array probe at visualizing needles in deeper tissue planes (e.g., real-time ultrasound-guided pleural drainage). An understanding of the advantages and limitations of each transducer is essential when attempting to examine the lungs and pleura. Table 28.1 demonstrates the various transducer characteristics and their appropriate uses in pulmonary ultrasound.

Ultrasound Nomenclature

Some basic knowledge of ultrasound terminology is necessary to communicate findings effectively. The near field describes superficial structures displayed at the top of the screen. The far field describes deeper structures that are displayed at the bottom of the screen. Structures can be described based on how well they reflect or transmit ultrasound waves. Hyperechoic structures are very strong reflectors of ultrasound waves and therefore appear white on the screen (e.g., bone surface). Anechoic structures do not reflect ultrasound waves and thus appear black on the screen (e.g., fluid). Hypoechoic structures are partial reflectors of ultrasound waves and therefore appear gray on the screen (e.g., adipose tissue or muscle) [3].

Table 28.1 Transducers used in pulmonary ultrasound

Transducer	Linear transducer	Curvilinear transducer	Phased array transducer
Photo			
Image produced			Frequency	High frequency (5–15 MHz)	Low frequency (2–5 MHz)	Low frequency (2–5 MHz)
Resolution and depth of penetration	Excellent axial resolution but limited depth of penetration (up to 6 cm)	Lower axial resolution but greater depth of penetration (up to 35 cm)	Lower axial resolution but greater depth of penetration(up to 35 cm)
Scanning beam	Straight scanning beam (produces rectangular image)	Divergent scanning beam (produces a sector shaped image)	Divergent scanning beam(produces a sector shaped image)
Footprint	Small linear footprint	Large curved footprint	Small flat footprint
Frame rate	Fast frame rate	Slow frame rate but better spatial resolution	Fast frame rate at the cost of lower spatial resolution
Uses (diagnostic)	Used for imaging the pleural line	Used for pleural and lung parenchymal assessments	Used for pleural and lung parenchymal assessments
Uses (procedural)	Adequate needle visualization only in superficial tissue planes	Adequate needle visualization in deeper tissue planes (e.g., real-time ultrasound-guided pleural drainage)	Inadequate needle visualization in tissue planes

Clinical Environment

The clinician using pulmonary sonography must be self-sufficient in setting up a suitable clinical environment for examination. Typically, the clinician stands or sits on one side of the patient. It is easiest to have the machine on the same side of the bed as the sonographer as to allow for independent control of the machine settings. To the maximum extent possible, maintain privacy by exposing the patient only as necessary. It is useful to have a supply of clean towels to clean up ultrasound gel after the imaging is done. Gel is necessary to maintain good contact and to avoid air in the probe/patient interface. Donning the appropriate personal protective equipment may be necessary for patients with contact, droplet, or airborne precautions. The machine and transducers require cleaning after each patient use as per the hospital and manufacturer recommendations.

Pulmonary ultrasound is often done with the patient in the supine position, though limited scans are often done in the sitting position as well. It is often necessary to move the patient to lateral position for imaging of posterior structures. Abduction of the arm can be useful to expose the entire hemithorax for examination. Space limitations, in many clinical environments, often require the clinician to become comfortable with imaging using either hand.

Image Acquisition

For any pulmonary ultrasound, the probe index mark should always be oriented in a cephalad direction. At a minimum, a three-zone examination of each hemithorax should be performed as outlined in the seminal works of Lichtenstein [4, 5]. The authors of this chapter however recommend obtaining a four-zone examination of each hemithorax whenever possible. These images are digitally stored and labeled as shown in Table 28.2. We choose to label the images with acronyms that describe the physical location. The left ante-

Table 28.2 Scanning points in the left hemithorax. The exam is then repeated in the contralateral hemithorax with appropriate labeling. Throughout the exam, the transducer index mark is maintained in a cephalad direction

Left anterior chest wall (LACW) Transducer is placed in the midclavicular line at approximately the second or third intercostal space. This corresponds to the left (or right) upper lobe of the lung	
Left anterior axillary line (LAAXL) Transducer is moved to the fourth or fifth intercostal space in the anterior axillary line. This corresponds to the lingula on the left or the right middle lobe on the right	
Left costophrenic angle (LCOSTO) Transducer is placed in the midaxillary line along the diaphragm-lung interface. This corresponds to the left (or right) lower lobe of the lung	
Left posterolateral alveolar pleural syndrome (LPLAPS) The transducer is moved posteriorly, along the diaphragm, to the posterior axillary line. It is often necessary to rotate the patient to the opposite side for adequate examination. This point corresponds to the left (or right) posterior basal segments. In the supine patient, this is the most dependent portion of the lung	

rior chest wall is labeled LACW, which corresponds anatomically to the left upper lobe. The left anterior axillary line is labeled LAAXL, which corresponds to the lingula (left) or right middle lobe on the right. The left costophrenic angle is labeled LCOSTO, which corresponds with the left lower lobe. PLAPS (posterolateral alveolar pleural syndrome), as described by Lichtenstein et al., is the label we use for the last point [4]. The PLAPS point corresponds to the posterior basal segments and, in the supine patient, is the most dependent point in the lung. Slight tilting of the patient into the lateral position is sometimes required to image the PLAPS point.

The examination is then repeated on the contralateral side, using a similar labeling scheme for the right side. Analogous to a stethoscope examination of the chest, additional points can be examined on either side if the clinician feels there is additional information to be gained.

There is a learning curve associated with image optimization. This involves slight adjustments of the imaging hand by the sonographer as well as interaction with the machine settings. Adjusting your probe position until a certain lung aeration pattern (A-lines or B-lines) is obtained is sometimes necessary. A common language is useful in describing movements of the probe on the patient's body, especially when giving suggestions to a medical trainee new to sonography. We commonly describe three hand motions of the transducer: sliding, rotating, and tilting. Sliding describes moving the transducer in a particular direction "slide superiorly" while keeping the angle of the interaction between traducer and the patient fixed. Rotating the probe describes keeping the transducer position fixed while turning its central axis, like turning a screw "rotate clockwise." Tilting the probe describes adjustments to the angle of the interaction between the transducer and the patient both in the long and short axis of the transducer "tilt superiorly or inferiorly or tilt right or left."

Machine Settings

Adjusting the imaging settings is useful to optimize the images obtained. The first setting to consider is the exam type preset also called the machine mode. Many modern ultrasound machines have a specific lung mode. If this is unavailable, an abdominal mode is sufficient. The cardiac preset is not ideal as it sacrifices resolution, to detect fast tissue movements (as is appropriate for echocardiography).

Both lung and abdominal modes display ultrasound images using the "radiology convention." The orientation mark in the radiology convention displays on the left side of the screen. While acquiring lung and pleural images, the transducer index mark should always be directed cephalad. The orientation mark on the screen would, therefore, always represent the superior (cranial) aspect of the body. This contrasts with the cardiology convention, which displays the orientation mark on the right side of the screen. This can be quite confusing to novices as it is fairly routine to use the phased array transducer for both echocardiography (using the cardiology convention) and pulmonary ultrasound (using the radiology convention). Changing the machine preset to "lung" or "abdominal" mode is therefore necessary prior to starting a pulmonary ultrasound examination, both to optimize image quality and change the display to the standard radiology convention.

Adjustment of depth and gain is often necessary to optimize the images obtained. When examining the anterior pleural line, the required depth is usually very superficial. Setting the exam depth to 4–6 cm will optimize image resolution and make pleural sliding very apparent. When examining lung parenchyma using a low-frequency probe, however, a depth of at least 15 cm is recommended. Most images in pulmonary ultrasound are taken in 2D mode though M-mode has significant utility as well. Doppler modes are rarely needed in pulmonary ultrasound.

Lung Sliding, Lung Pulse, and Lung Point

A pulmonary ultrasound finding that is the result of the interaction between the visceral and parietal pleura during respiration is termed lung sliding. This is often visualized as a subtle to-and-fro movement (or shimmering) of the pleural line with each inspiration and expiration (Video 28.1). A positive finding of lung sliding indicates contact between the two pleural linings and rules out the presence of air or fluid between them. By examining the nondependent areas of each hemithorax and confirming the presence of lung sliding throughout, pneumothorax is ruled out with 100% sensitivity [6].

Pleural movement that is the result of a transmitted cardiac activity results in a similar interaction between the layers of the pleura. This is referred to as the lung pulse and is usually observed as a pleural shimmering of a faster rate (coinciding with the heart rate) more in the left hemithorax (Video 28.2). A pneumothorax will typically act as an air cushion, preventing transmission of these cardiac oscillations to the parietal pleura. Demonstration of a lung pulse at the pleural line therefore rules out a pneumothorax, at the site of probe application.

2D images of lung sliding can be created using either a high-frequency linear transducer or a low-frequency (phased array or curvilinear) transducer. As a matter of efficiency, a low-frequency transducer is commonly used for the entire examination – visualizing lung sliding before moving on to the deeper structures. However, more detailed images of the presence or absence of lung sliding can be created using the high-frequency linear probe.

Lung sliding can be further confirmed using M-mode (motion mode). The presence of movement below the pleural line during normal respiration gives a characteristic sand-like appearance, while the tissues above the pleural line remain relatively static and appear as straight lines. This characteristic pattern is known as the "seashore sign" (Fig. 28.3). Conversely, the absence of lung sliding or lung pulse at the pleural line results in an M-mode image of multiple static horizontal lines both above and below the pleural line. This is sometimes referred to as the "bar code" or "stratosphere sign" (Fig. 28.4).

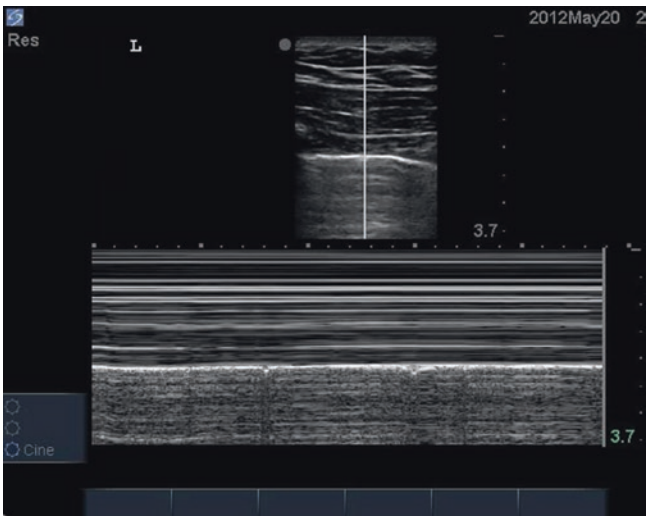

Fig. 28.3 M-mode of the pleura showing the seashore sign. The "sandy" appearance underneath the pleural line indicates the presence of lung sliding (seashore sign). Image captured using a linear transducer

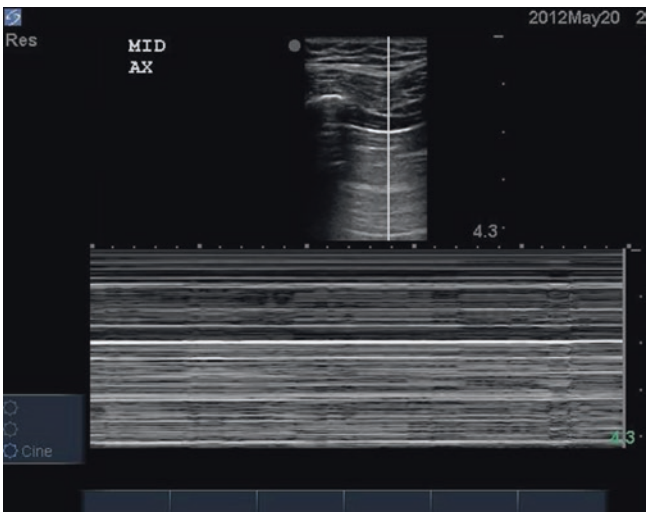

Fig. 28.4 M-mode of the pleura showing the stratosphere or bar code sign. The static appearance of straight lines underneath the pleura indicates the absence of lung sliding (stratosphere or bar code sign). Image captured using a linear transducer

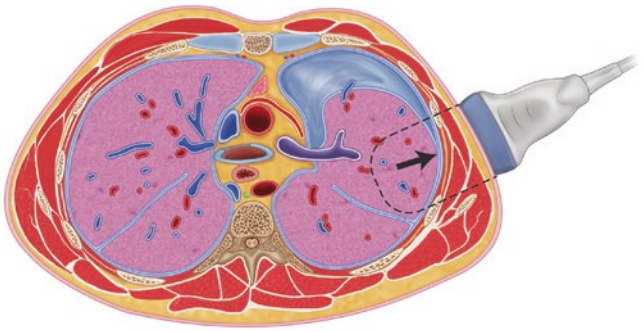

Fig. 28.5 Lung point. The point of separation between the visceral and the parietal pleura is demonstrated. Despite this finding being very specific to pneumothorax, locating this point of separation may be challenging

As mentioned, the presence of lung sliding is a very powerful finding, ruling out a pneumothorax with 100% sensitivity. The absence of lung sliding however (Video 28.3) is not specific to pneumothorax. In essence, any condition preventing movement of the visceral against the parietal pleura (as occurs with normal respiration) will cause absent lung sliding. Apnea, non-ventilated lungs with massive atelectasis, mainstem intubation, and lobar pneumonia are among the possible culprits. In addition, sliding is absent post-pleurodesis. In the right clinical context, absent lung sliding is very suggestive of a pneumothorax, but the differential diagnosis of this ultrasound finding is quite broad [7].

In the absence of lung sliding, the detection of a lung point can help diagnose a pneumothorax. A lung point is an image that captures the transition point between normal lung sliding and the absence of lung sliding (Video 28.4). Anatomically, this represents the point where the visceral and parietal pleura start separating in a pneumothorax (Fig. 28.5). As an ultrasound finding, it is 100% specific for a pneumothorax. In the setting of a significant pneumothorax, however, the lung point may be very posteriorly located or, in cases of large circumferential pneumothorax, nonexistent. In these circumstances, it may be very difficult, time-consuming, and sometimes impossible to find. The authors of this chapter, therefore, do not advocate searching for a lung point on a routine basis. In an unstable patient with clinical findings suggestive of a pneumothorax, absent lung sliding should trigger immediate decompression. Searching for a lung point in such a critical situation is not appropriate and may delay time-sensitive management.

A-Lines, B-Lines, and Consolidation Patterns

A central concept in the assessment of lung parenchyma by ultrasound is the assessment of the presence of A-lines and B-lines [8]. A-lines are the result of reverberation artifacts

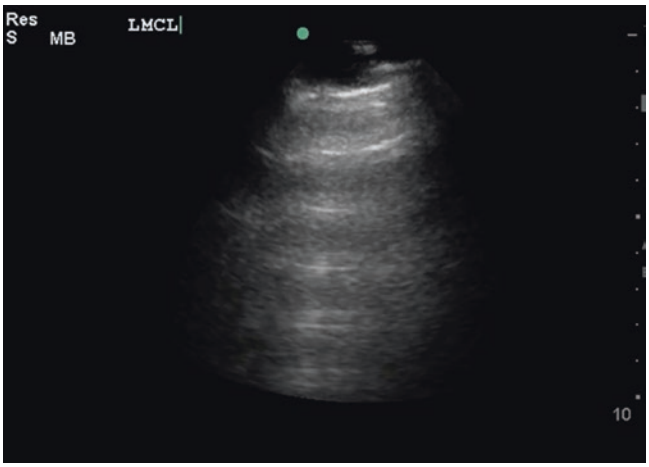

Fig. 28.6 A-line artifact. A-lines appear as horizontal, equidistant, repetitious lines parallel to the pleural surface. In the presence of lung sliding, they indicate normal lung aeration at the point of probe placement
