Manifestations range from mild discomfort to significant disability. Joint pain is the main symptom and the typical reason the patient seeks medical attention. Pain generally gets worse with joint use. In early stages of OA, joint pain is relieved by rest. However, the patient with advanced disease may have pain at rest or have trouble sleeping due to increased joint pain. Pain may worsen as the barometric pressure falls before the onset of severe weather.

As OA progresses, increasing pain can contribute greatly to disability and loss of function. The pain of OA may be referred to the groin, buttock, or outside of the thigh or knee. Sitting down becomes hard, as does rising from a chair when the hips are lower than the knees. As OA develops in the intervertebral *(apophyseal)* joints of the spine, local pain and stiffness are common.

Unlike pain, which typically worsens with activity, joint stiffness occurs after periods of rest or an unchanged position. Early morning stiffness is common. It generally resolves within 30 minutes. This distinguishes OA from inflammatory joint disorders, such as RA. Overactivity can cause a mild joint swelling that temporarily increases stiffness. *Crepitation,* a grating sensation caused by loose cartilage

particles in the joint cavity, can cause stiffness. Crepitation is common in patients with knee OA.

OA usually affects joints on 1 side of the body *(asymmetrically)* rather than in pairs. For example, the left knee may be affected and the right knee unchanged. The distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the fingers, and the metacarpophalangeal (MCP) joint of the thumb are often affected. Weight-bearing joints (hips, knees), the metatarsophalangeal (MTP) joint of the foot, and the cervical and lower lumbar vertebrae are often involved (Fig. 64.2).

Deformity

Deformity or instability associated with OA is specific to the involved joint. For example, *Heberden's nodes* occur on the DIP joints due to osteophyte formation and loss of joint space (Fig. 64.1, *D*). They can appear as early as age 40 and tend to be seen in family members. *Bouchard's nodes* on the PIP joints indicate similar disease involvement. Heberden's and Bouchard's nodes are often red, swollen, and tender. Although they usually do not cause significant loss of function, the visible deformity may bother the patient.

Knee OA often leads to obvious joint deformity due to cartilage loss in 1 joint compartment. For example, the patient becomes bowlegged *(varus deformity)* in response to medial joint arthritis. Lateral joint arthritis causes a knock-kneed appearance *(valgus deformity).* In advanced hip OA, 1 leg may become shorter as the joint space narrows.

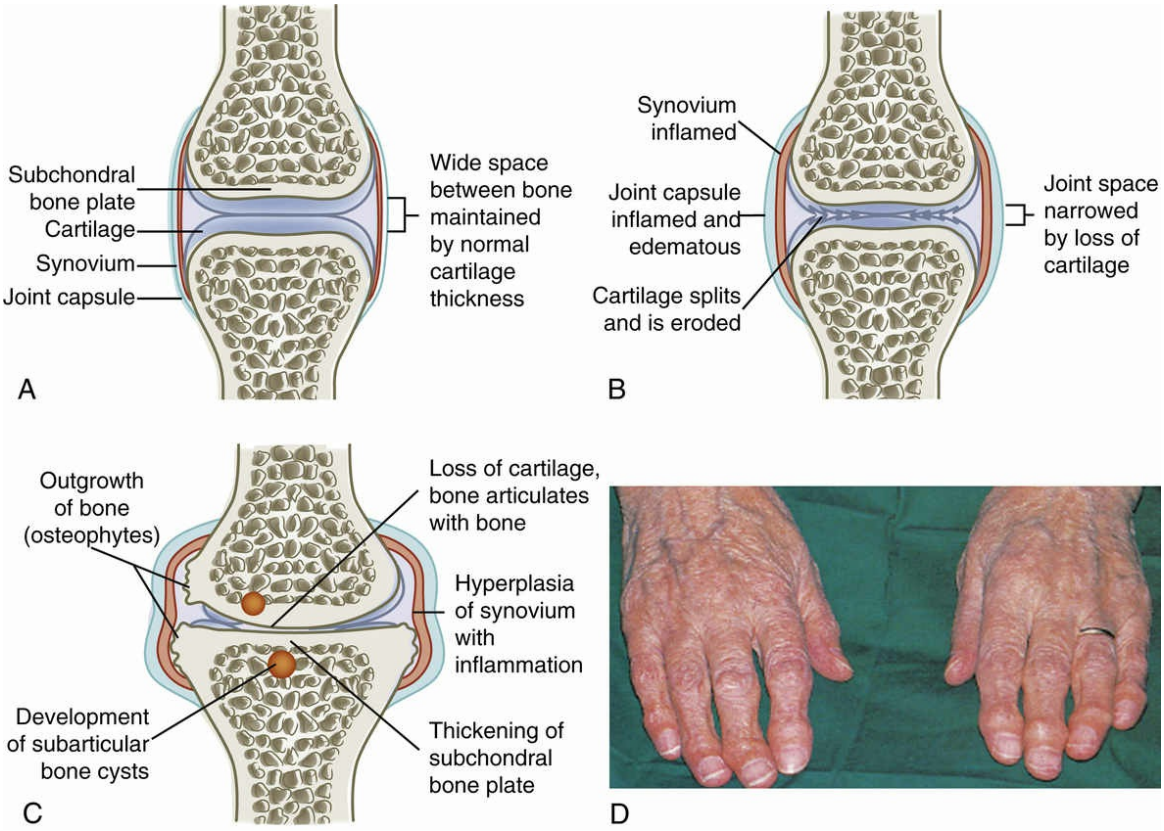

FIG. 64.1 Pathologic changes in osteoarthritis. **A,** Normal synovial joint. **B,** Early change in osteoarthritis is destruction of articular cartilage and narrowing of the joint space. There is inflammation and thickening of the joint capsule and synovium. **C,** With time, thickening of subarticular bone occurs, caused by constant friction of the 2 bone surfaces. Osteophytes form around the periphery of the joint by irregular overgrowths of bone. **D,** In osteoarthritis of the hands, osteophytes on the distal interphalangeal joints of the fingers, termed *Heberden's nodes,* appear as small nodules.
D, From Forbes CD, Jackson WF: *Color atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.

Systemic

Fatigue, fever, and organ involvement are not present in OA. This is an important distinction between OA and inflammatory joint disorders, such as rheumatoid arthritis.

Diagnostic Studies

A bone scan, CT scan, or MRI may be used to diagnose OA. These

tests can detect early joint changes. X-rays help confirm disease and stage joint damage. As OA progresses, x-rays often show joint space narrowing and increasingly dense bone. Osteophytes may be visible. However, these changes do not always reflect the degree of pain the patient has. Despite strong x-ray evidence of disease, the patient may be relatively free of symptoms. Another patient may have severe pain with only slight x-ray changes.

No laboratory tests or biomarkers can be used to diagnose OA. The erythrocyte sedimentation rate (ESR) is normal except for slight increases during acute inflammation. Other routine blood tests (e.g., CBC, renal and liver function tests) are useful only in screening for related conditions or for establishing baseline values before starting treatment. Synovial fluid analysis helps distinguish OA from other types of inflammatory arthritis. In OA, the fluid is clear yellow with little or no sign of inflammation.

Interprofessional Care

OA has no cure. Interprofessional care focuses on managing pain and inflammation, preventing disability, and maintaining and improving joint function (Table 64.2). Nondrug interventions are the basis of OA management. They should be maintained throughout the patient's treatment. Drug therapy supplements nondrug treatments.

Rest and Joint Protection

Teach the patient with OA to balance rest and activity. Encourage rest of the affected joint during periods of acute inflammation. Keep joints in a functional position with splints or braces if needed. Avoid immobilization for more than 1 week because of the risk for joint stiffness with inactivity. Review how to modify usual activities to decrease stress on affected joints. Teach the patient with knee OA to avoid standing, kneeling, or squatting for long periods. Using an assistive device, such as a cane, walker, or crutches, can decrease joint stress.

Heat and Cold Applications

Apply heat and cold to help reduce pain and stiffness. Ice is not used as often as heat in OA treatment. Ice can be helpful if the patient has acute inflammation. Heat therapy is especially useful for stiffness. Treatments include hot packs, whirlpool baths, ultrasound, and paraffin wax baths.

Nutritional Therapy and Exercise

If the patient is overweight, a weight-reduction program is a critical part of the treatment plan. Help the patient evaluate the current diet to make needed changes. (Chapter 40 discusses ways to help the patient attain and maintain a healthy body weight.) Since mobilizing the joint preserves articular cartilage health, exercise is an important part of OA management. Aerobic conditioning, range-of-motion (ROM) exercises, and programs to strengthen muscles around the affected joint help many patients.

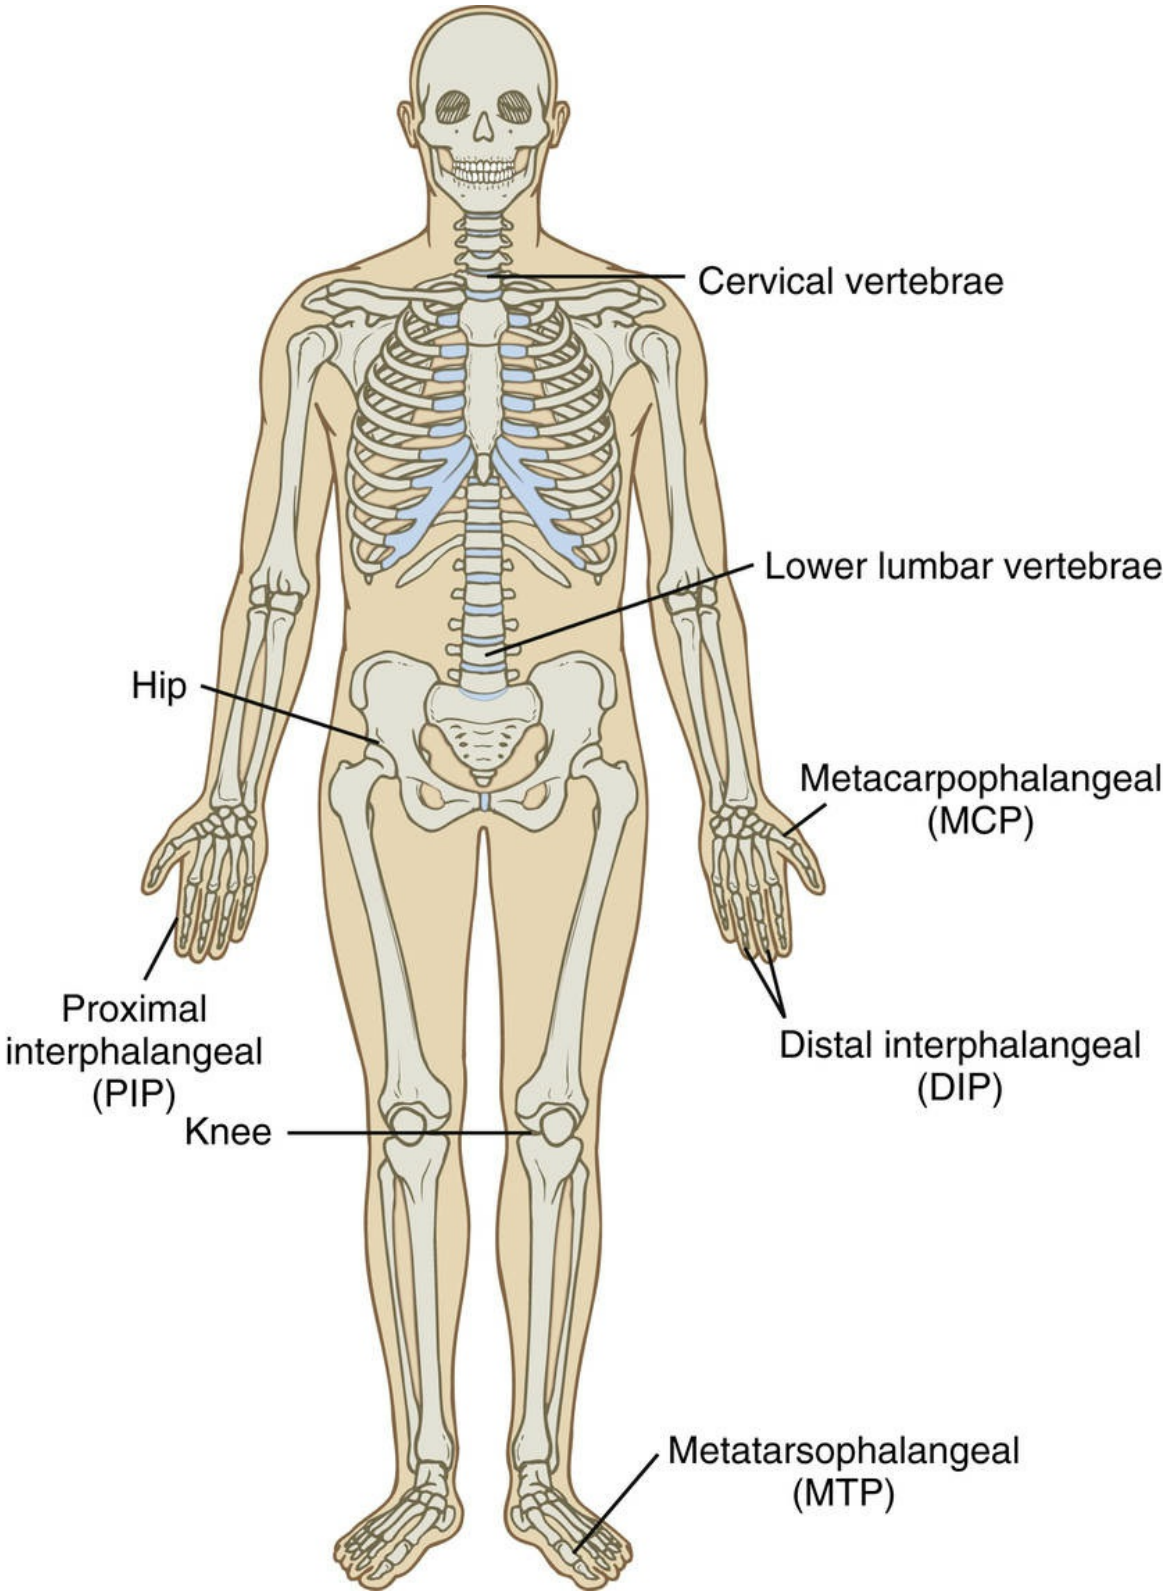

FIG. 64.2 Joints most often involved in osteoarthritis.

Complementary and Alternative Therapies

Complementary and alternative therapies for OA symptom management are popular with patients who have not found relief through traditional medical care. Teach the patient to carefully research any alternative therapies and avoid replacing conventional OA treatments with unproven complementary approaches. Acupuncture, massage, and Tai Chi may reduce arthritis pain and improve joint mobility.

Some nutritional supplements may have antiinflammatory effects (e.g., fish oil, ginger, SAM-e). However, results of studies on glucosamine and chondroitin are mixed. The American College of Rheumatology (ACR) and American Academy of Orthopaedic Surgeons (AAOS) does not recommend their use.[4] Teach patients to discuss any supplement use with their HCP to identify possible interactions with prescribed medications.

Drug Therapy

Drug therapy is based on the severity of the patient's symptoms (Table 64.3). The patient with mild to moderate joint pain may get relief from acetaminophen (Tylenol).

A topical agent, such as capsaicin cream, may be helpful, alone or with acetaminophen. It blocks pain by locally interfering with substance P. It is responsible for the transmission of pain impulses. A concentrated product is available by prescription. Creams of 0.025% to 0.075% capsaicin are available over the counter (OTC). OTC products that contain camphor, eucalyptus oil, and menthol (e.g., Bengay, Arthricare) may provide

Complementary & Alternative Therapies

Tai Chi

Scientific Evidence

- Tai Chi brought short-term improvements in pain and stiffness in knee OA.
- Some studies found improved balance or decreased depression.
- In a study comparing Tai Chi to physical therapy, patients in both groups had improved pain for a full year.
- Temporary increase of knee pain may occur in patients with knee OA.

Nursing Implications

- Generally considered to be safe practices.
- Avoid overuse of affected joints.

Source: National Center for Complementary and Alternative Medicine: Osteoarthritis: in depth. Retrieved from *www.nccih.nih.gov/health/arthritis/osteoarthritis#hed3*.

temporary pain relief. Topical salicylates (e.g., Aspercreme) may be an option for patients who cannot take aspirin-containing medication. Several applications may be needed daily because topical agents have short-acting effects.

TABLE 64.2 Interprofessional CareOsteoarthritis

Diagnostic Assessment

- History and physical examination
- Radiologic studies of involved joints (e.g., x-ray, CT scan, MRI, bone scan)
- Possible synovial fluid analysis

Management

- Nutritional and weight management counseling
- Rest and joint protection, use of assistive devices
- Therapeutic exercise
- Heat and cold applications
- Complementary and alternative therapies
    - Herbs and nutritional supplements (e.g., fish oil, ginger, SAM-e)
    - Movement therapies (e.g., yoga, Tai Chi)
    - Acupuncture
    - Massage
- Transcutaneous electrical nerve stimulation (TENS)
- Reconstructive joint surgery

Drug Therapy (Table 64.3)

- acetaminophen
- NSAIDs
- Intraarticular corticosteroids

If a patient does not get adequate pain management with acetaminophen, has moderate to severe OA pain, or has signs of joint inflammation, a nonsteroidal antiinflammatory drug (NSAID) may be more effective. NSAID therapy typically is started in low-dose OTC strengths (e.g., ibuprofen 200 mg up to 4 times daily). The dose may be increased if needed. If the patient is at risk for or develops gastrointestinal (GI) side effects with an NSAID, adding a protective agent, such as misoprostol (Cytotec), may be needed. Arthrotec, a combination of misoprostol and the NSAID diclofenac, is available. Diclofenac gel may be applied to the affected joint. Teach the patient who is taking an oral NSAID to avoid use of a topical NSAID because

of increased risk for adverse effects.

TABLE 64.3 Drug TherapyOsteoarthritis

Drug	Mechanism of Action	Nursing Considerations
Corticosteroids		
Intraarticular Injections		
methylprednisolone acetate (Depo-Medrol) **triamcinolone (Aristospan)**	Antiinflammatory Analgesic Act by inhibiting synthesis and/or release of inflammatory mediators	Use strict aseptic technique for corticosteroid injection. Tell patient that joint may temporarily feel worse right after injection. Teach patient to avoid overusing affected joint right after injection. Tell patient improvement lasts weeks to months after injection.
Systemic		
dexamethasone **hydrocortisone (Solu-Cortef)** **methylprednisolone (Solu-Medrol)** **prednisone** **triamcinolone**	Antiinflammatory Analgesic Act by inhibiting synthesis and/or release of inflammatory mediators	Use only in life-threatening exacerbation or when symptoms persist after treatment with less potent antiinflammatory drugs. Give for limited time only, tapering dose slowly. Be aware that worsening of symptoms occurs with abrupt withdrawal of drug. Monitor BP, weight, CBC, and serum potassium. Limit sodium intake. Report signs of infection.
Nonsteroidal Antiinflammatory Drugs (NSAIDs)		
celecoxib (Celebrex) **diclofenac** **ibuprofen (Advil)** **indomethacin** **ketoprofen** **meclofenamate** **meloxicam (Mobic)** **nabumetone** **naproxen (Aleve)** **oxaprozin (Daypro)** **piroxicam (Feldene)** **sulindac** **tolmetin**	Antiinflammatory Analgesic Fever reducer (antipyretic) Act by inhibiting prostaglandin synthesis	Give drug with food, milk, or antacids (as prescribed). Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds), edema, skin rashes, persistent headaches, visual problems. Monitor BP for elevations related to fluid retention. Must be used regularly for maximal effect.
Salicylate		
aspirin, salicylate (salsalate)	Antiinflammatory Analgesic Fever reducer (antipyretic) Act by inhibiting prostaglandin synthesis	Give with food, milk, antacids (as prescribed), or full glass of water. May use enteric-coated aspirin. Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds).
Topical Analgesics		
capsaicin cream	Depletes substance P from nerve endings, interrupting pain signals to the brain	Must be used at regular intervals for maximal effect. Aloe vera cream may decrease burning sensation. Teach patient not to use cream with external heat source (heating pad) because of risk for burns. Available in OTC and prescriptive strengths.
diclofenac sodium (Voltaren gel)	Antiinflammatory Analgesic	Teach patient to avoid sun and ultraviolet (UV) light exposure. Should not be used in combination with oral NSAIDs or aspirin due to risk for increased side effects.

All NSAIDs inhibit the production of cyclooxygenase-1 (COX-1)

and cyclooxygenase-2 (COX-2). These enzymes convert arachidonic acid into prostaglandins (see Fig. 8.5). Inhibiting COX-1 causes many of the untoward effects of NSAIDs, including the risk for bleeding and GI irritation.[5] Patients taking an anticoagulant (e.g., warfarin [Coumadin]) and an NSAID are at high risk for bleeding. Long-term NSAID treatment may affect cartilage metabolism, especially in older patients who may have poor cartilage integrity. As an alternative to traditional NSAIDs, the COX-2 inhibitor celecoxib (Celebrex) may be considered in selected patients.

When given in equivalent doses, all NSAIDs are comparably effective but vary widely in cost. Individual responses to NSAIDs also vary. Some patients still prefer aspirin, but it is no longer a common treatment. It should be used cautiously with NSAIDs because both inhibit platelet function and prolong bleeding time. Intraarticular injections of corticosteroids may be needed for those with local inflammation and swelling. Four or more injections without relief suggest the need for more intervention. Systemic corticosteroids are not used as they may actually hasten the disease process.

Injection of hyaluronic acid *(viscosupplementation)* has been a common treatment for knee OA. However, its effectiveness is not clear. Neither the ACR nor the AAOS recommends against using hyaluronates.[6] Research on the long-term effects continues.

Drugs thought to slow the progression of OA or support joint healing are known as *disease-modifying osteoarthritis drugs (DMOADs).* To date, no drugs have been approved to modify OA progression despite many clinical trials. Strontium ranelate, an approved treatment for osteoporosis, is being researched for effects on OA. Because it reduces levels of a cartilage turnover marker, it may be helpful in OA treatment.[5]

Surgical Therapy

Symptoms of disease are often managed conservatively for many years. However, the patient's loss of joint function, unmanaged pain, and decreased independence in self-care may lead to consideration of surgery. Patients with knee OA used to undergo arthroscopy to

remove loose bodies from the joint. However, it does not have any benefit over physical therapy and medical treatment.[7] Reconstructive surgical procedures (e.g., hip and knee replacements) are discussed in Chapter 62.

Nursing Management: Osteoarthritis

Nursing Assessment

Carefully assess and document the type, location, severity, frequency, and duration of the patient's joint pain and stiffness. Determine what makes the pain better or worse. Ask the patient how these symptoms affect the ability to perform activities of daily living (ADLs). Review the patient's pain management practices. Ask about success of each treatment. Assess tenderness, swelling, limitation of movement, and crepitation of affected joints. Compare an involved joint with the opposite joint if it is not affected.

Nursing Diagnoses

Nursing diagnoses for the patient with OA may include:

- Acute and chronic pain
- Impaired physical mobility
- Difficulty coping

Planning

Overall goals are that the patient with OA will (1) maintain or improve joint function through a balance of rest and activity, (2) use joint protection measures (Table 64.4) to improve activity tolerance, (3) achieve independence in self-care and maintain optimal role function, and (4) use drug and nondrug strategies to manage pain satisfactorily.

Nursing Implementation

Health Promotion

Prevention of OA is possible in some cases. Focus community education on altering modifiable risk factors. For example, encourage the patient to lose weight and reduce occupational or recreational hazards. For athletic instruction and physical fitness programs, include safety measures that protect and reduce trauma to the joints. Prompt treatment of traumatic joint injuries decreases the risk for OA.

Promoting Population Health

Preventing Osteoarthritis

- Avoid cigarette smoking.
- Promptly treat any joint injury.
- Maintain healthy weight and eat a balanced diet.
- Use safety measures to protect and decrease risk for joint injury.
- Exercise regularly, including strength and endurance training.

Acute Care

The patient with OA usually is treated as an outpatient. The interprofessional team involved may include an internal medicine physician or family HCP, a rheumatologist, a nurse, an occupational therapist, and a physical therapist. Health assessment questionnaires can pinpoint areas of decreased function. They are completed at regular intervals to document disease and treatment progression. Treatment goals can be based on data from the questionnaires and physical examination, with specific interventions for identified problems. The patient is usually hospitalized only if having joint surgery (see Chapter 62).

TABLE 64.4 Patient & Caregiver TeachingJoint Protection and Energy Conservation

Include the following instructions when teaching patients with arthritis to protect joints and conserve energy:

- Maintain healthy weight.
- Use assistive devices, if needed.
- Avoid forceful repetitive joint movements.
- Avoid awkward positions that stress joints.
- Use good posture and body mechanics.
- Seek help with needed tasks that may cause pain.
- Organize routine tasks and pace yourself to decrease fatigue and joint pain.
- Modify home and work environment to perform tasks in less stressful ways.

Drugs are given for the treatment of pain and inflammation. Nondrug strategies to decrease pain and disability may include massage, use of heat (thermal packs) or cold (ice packs), meditation, and yoga.[8] Splints may be prescribed to rest and stabilize painful or inflamed joints.

Once an acute flare has subsided, a physical therapist can give valuable assistance in planning an exercise program. The therapist may recommend Tai Chi as a low-impact form of exercise. Tai Chi can be done by patients of all ages and may be done in a wheelchair. Stress the importance of warming up before any exercise to decrease risk for injury.

Patient and caregiver teaching related to OA is an important nursing responsibility. Provide information about the nature and treatment of the disease, pain management, body mechanics, correct use of assistive devices (e.g., cane, walker), principles of joint protection and energy conservation (Table 64.4), nutritional choices, weight and stress management, and an exercise program.

Assure the patient that OA is a localized disease and severe deforming arthritis is not the usual course. The patient may gain support and understanding of the disease process through community resources, such as the Arthritis Foundation's self-help course *(www.arthritis.org)*.

Check Your Practice

A 54-yr-old woman has OA of the left knee. She received an intraarticular corticosteroid injection in the left knee and a prescription for diclofenac 50 mg twice daily. She receives a prescription for physical therapy.

- What information will you provide about diclofenac to ensure the patient's safe, effective use?
- What type of exercises will be appropriate for this patient?
- The patient asks about complementary therapies for osteoarthritis. What will you tell her?

Ambulatory Care

Adjust home management goals to meet the patient's needs. Include the caregiver, family members, and significant others in goal setting and teaching. Discuss home and work environment modification for patient safety, accessibility, and self-care. Measures include removing throw rugs, placing rails at the stairs and bathtub, using night-lights, and wearing well-fitting supportive shoes. Assistive devices, such as canes, walkers, elevated toilet seats, and grab bars, reduce the load on an affected joint and promote safety. Urge the patient to continue all prescribed therapies at home and be open to new approaches to symptom management.

Sexual counseling may help the patient and significant other to enjoy physical closeness by introducing the idea of alternative positions and timing for sexual activity. Discussion also increases

awareness of each partner's needs. Encourage the patient to take analgesics or a warm bath to decrease joint stiffness before sexual activity.

Evaluation

The expected outcomes are that the patient with OA will

- Have adequate rest and activity
- Achieve acceptable pain management
- Maintain joint flexibility and muscle strength through joint protection and therapeutic exercise

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints. RA is typically marked by periods of remission and exacerbation. RA often has extraarticular manifestations. RA has long been considered one of the most disabling forms of arthritis. Symptoms and outcomes can vary greatly. Without adequate treatment, patients may need mobility aids or joint reconstruction. They may have loss of independence and self-care ability.

RA occurs globally, affecting all ethnic groups. It can occur at any time of life. However, incidence increases with age, peaking between ages 30 and 50 years. RA affects around 1.5 million adult Americans. Almost 3 times as many women have the disease as men.[9]

Etiology and Pathophysiology

We do not know the exact cause of RA. It likely results from a combination of genetics and environmental triggers. An autoimmune cause is currently the most widely accepted theory. This theory suggests changes of RA begin when a genetically susceptible person has an initial immune response to an antigen. Although a bacterium

or virus could be the possible antigen, no infection or organism has been found to date.

Promoting Health Equity

Arthritis and Connective Tissue Disorders

- Arthritis is most common in whites and blacks.
- Hispanics and blacks have the highest incidence of arthritis-related activity limitations.
- Some Native Americans (e.g., Pima, Chippewa, Yakima) have a higher incidence of RA than other ethnic groups in North America.
- Ankylosing spondylitis is most common in whites and certain Native American groups.
- SLE is more common and more severe among black, Hispanic, Asian American, and Native American women than white women.
- Black and Hispanic women are at greater risk than white women for developing scleroderma.

The antigen, which is probably not the same in all patients, triggers formation of an abnormal immunoglobulin G (IgG). RA is marked by autoantibodies to this abnormal IgG. The autoantibodies are known as *rheumatoid factor (RF).* They combine with IgG to form immune complexes that initially deposit on synovial membranes or superficial articular cartilage in the joints. Immune complex formation leads to the activation of complement and an inflammatory response. (Complement activation is discussed in Chapter 11. Immune complex formation is discussed in Chapter 13.)

Neutrophils are attracted to the site of inflammation, where they release proteolytic enzymes that damage articular cartilage and cause the synovial lining to thicken (Fig. 64.3). Other inflammatory cells

include T helper (CD4) cells, which stimulate cell-mediated immune responses. Activated CD4 cells cause monocytes, macrophages, and synovial fibroblasts to secrete the proinflammatory cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). These cytokines drive the inflammatory response in RA.

Some patients report a precipitating stressful event, such as infection, work stress, physical exertion, childbirth, surgery, or emotional upset. However, research has been unable to directly correlate such events with RA onset.

Genetic Link

Genetic predisposition is important in the development of RA. The strongest evidence for a genetic influence is the role of human leukocyte antigens (HLA), especially the HLA-DR4 and HLA-DR1 antigens. (HLA is discussed in Chapter 13.) Smoking increases the risk for RA for persons who are genetically predisposed to the disease. It may interfere with treatment for diagnosed persons.[10]

Clinical Manifestations

Joints

The onset of RA is typically subtle. Nonspecific manifestations, such as fatigue, anorexia, weight loss, and generalized stiffness, may precede the onset of joint symptoms. Stiffness becomes more localized in the following weeks to months.

Specific joint involvement is marked by pain, stiffness, limited motion, and signs of inflammation (e.g., heat, swelling, tenderness). Joint symptoms occur symmetrically and often affect the small joints of the hands (PIP and MCP) and feet (MTP). Larger peripheral joints such as wrists, elbows, shoulders, knees, hips, ankles, and jaw may be involved. The cervical spine may be affected, but the axial skeleton (spine and bones connected to it) is generally spared. Table 64.5 compares RA and OA.

The patient typically has joint stiffness after periods of inactivity.

Morning stiffness may last from 60 minutes to several hours or more, depending on disease activity. MCP and PIP joints are typically swollen. In early disease, the fingers may become spindle shaped from synovial hypertrophy and thickening of the joint capsule. Joints are tender, painful, and warm to the touch. Joint pain increases with motion. It varies in intensity. It may not be related to the degree of inflammation. Tenosynovitis often affects the extensor and flexor tendons around the wrists. This causes symptoms of carpal tunnel syndrome and makes it hard for the patient to grasp objects.

As the disease progresses, inflammation and fibrosis of the joint capsule and supporting structures may cause deformity and disability. Muscle atrophy and tendon destruction cause 1 joint surface to slip past the other *(subluxation).* Metatarsal head dislocation and subluxation in the feet may cause pain and walking disability (Fig. 64.3, *D*). Ulnar drift ("zig-zag deformity"), swan neck, and boutonnière deformities are common in the hands (Fig. 64.4).

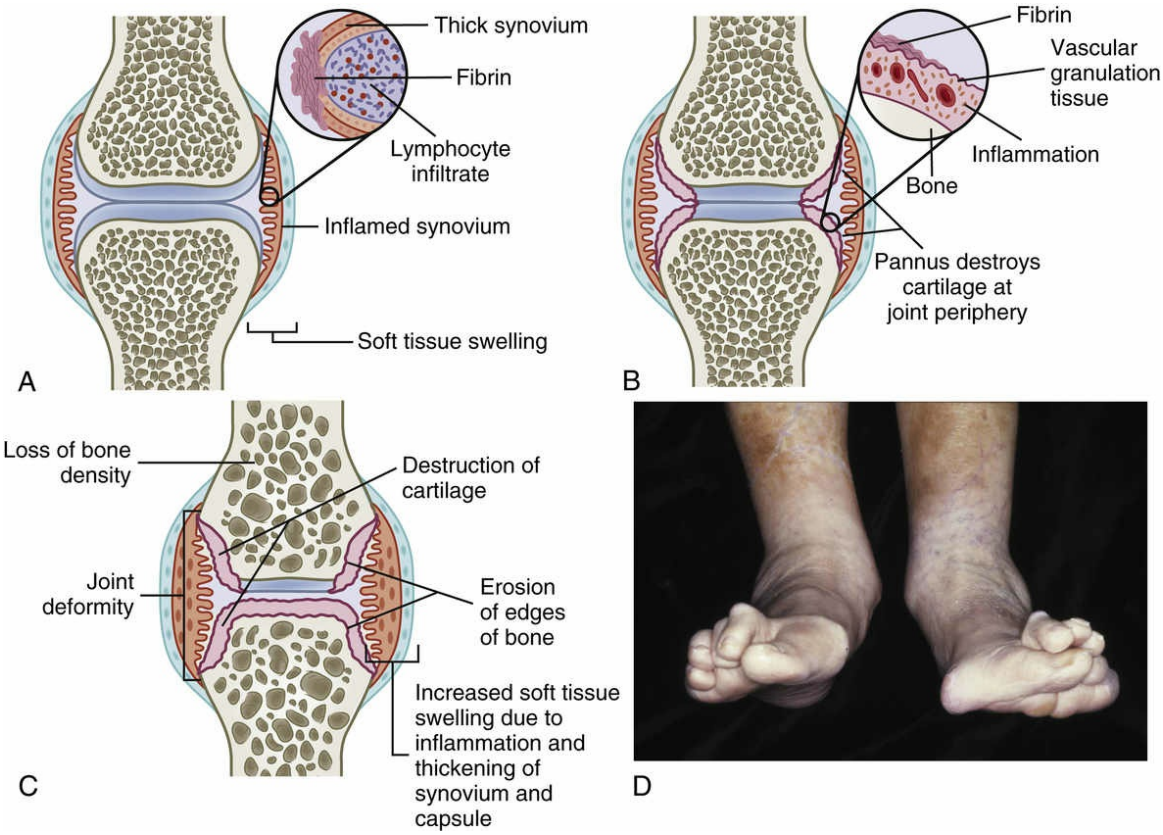

FIG. 64.3 RA. **A,** Early pathologic change is rheumatoid synovitis. Synovium becomes inflamed. Lymphocytes and plasma cells increase greatly. **B,** Over time, articular cartilage destruction occurs, and vascular granulation tissue grows across the cartilage surface (pannus) from the edges of the joint. Joint surface shows loss of cartilage beneath the extending pannus, most marked at joint margins. **C,** Inflammatory pannus causes focal destruction of bone. Osteolytic destruction of bone occurs at joint edges, causing erosions seen on x-rays. This phase is associated with joint deformity. **D,** Multiple deformities of the foot from rheumatoid arthritis.
D, From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.

TABLE 64.5 Comparison of Rheumatoid Arthritis and Osteoarthritis

Parameter	Rheumatoid Arthritis	Osteoarthritis
Age at onset	Young to middle age.	Usually older than 40 years.
Gender	Female-to-male ratio is 2:1 or 3:1. Less marked sex difference after age 60.	Females 2:1 after age 60; except for traumatic arthritis, men less affected until age 70 or 80.
Weight	Lost or maintained weight.	Often overweight or obese.
Disease	Systemic disease with exacerbations and remissions.	Localized disease with variable, progressive course.
Affected joints	Small joints typically affected first (PIPs, MCPs, MTPs), wrists, elbows, shoulders, knees. Usually bilateral, symmetric joint involvement.	Weight-bearing joints of knees and hips, small joints (MCPs, DIPs, PIPs), cervical and lumbar spine. Often asymmetric.
Pain characteristics	Stiffness lasts 1 hr to all day and may ↓ with use. Pain is variable, may disrupt sleep.	Stiffness occurs on arising but usually subsides after 30 min. Pain gradually worsens with joint use and disease progression, relieved with joint rest but may disrupt sleep.
Effusions	Common.	Uncommon.
Nodules	Present, especially on extensor surfaces.	Heberden's (DIPs) and Bouchard's (PIPs) nodes.
Synovial fluid	WBC count 5000–60,000/μL with mostly neutrophils; ↓ viscosity.	WBC count < 2000/μL (mild leukocytosis); normal viscosity.
X-rays	Joint space narrowing and erosion with bony overgrowths, subluxation with advanced disease. Osteoporosis related to decreased activity, corticosteroid use.	Joint space narrowing, osteophytes, subchondral cysts, sclerosis.
Laboratory findings	Rheumatoid factor positive in 70%–90% of patients; negative titers in early disease for about 25% of patients.	Rheumatoid factor negative.
	↑ In ANA titer likely.	ANA negative.
	Positive anti-CCP in 60%–80% of patients	Anti-CCP negative.
	↑ ESR, CRP indicative of active inflammation.	Transient elevation in ESR related to synovitis.

ANA, Antinuclear antibodies; *anti-CCP*, anti-citrullinated peptide; *DIPs,* distal interphalangeal; *MCPs,* metacarpophalangeals; *MTPs,* metatarsophalangeals; *PIPs,* proximal interphalangeals.

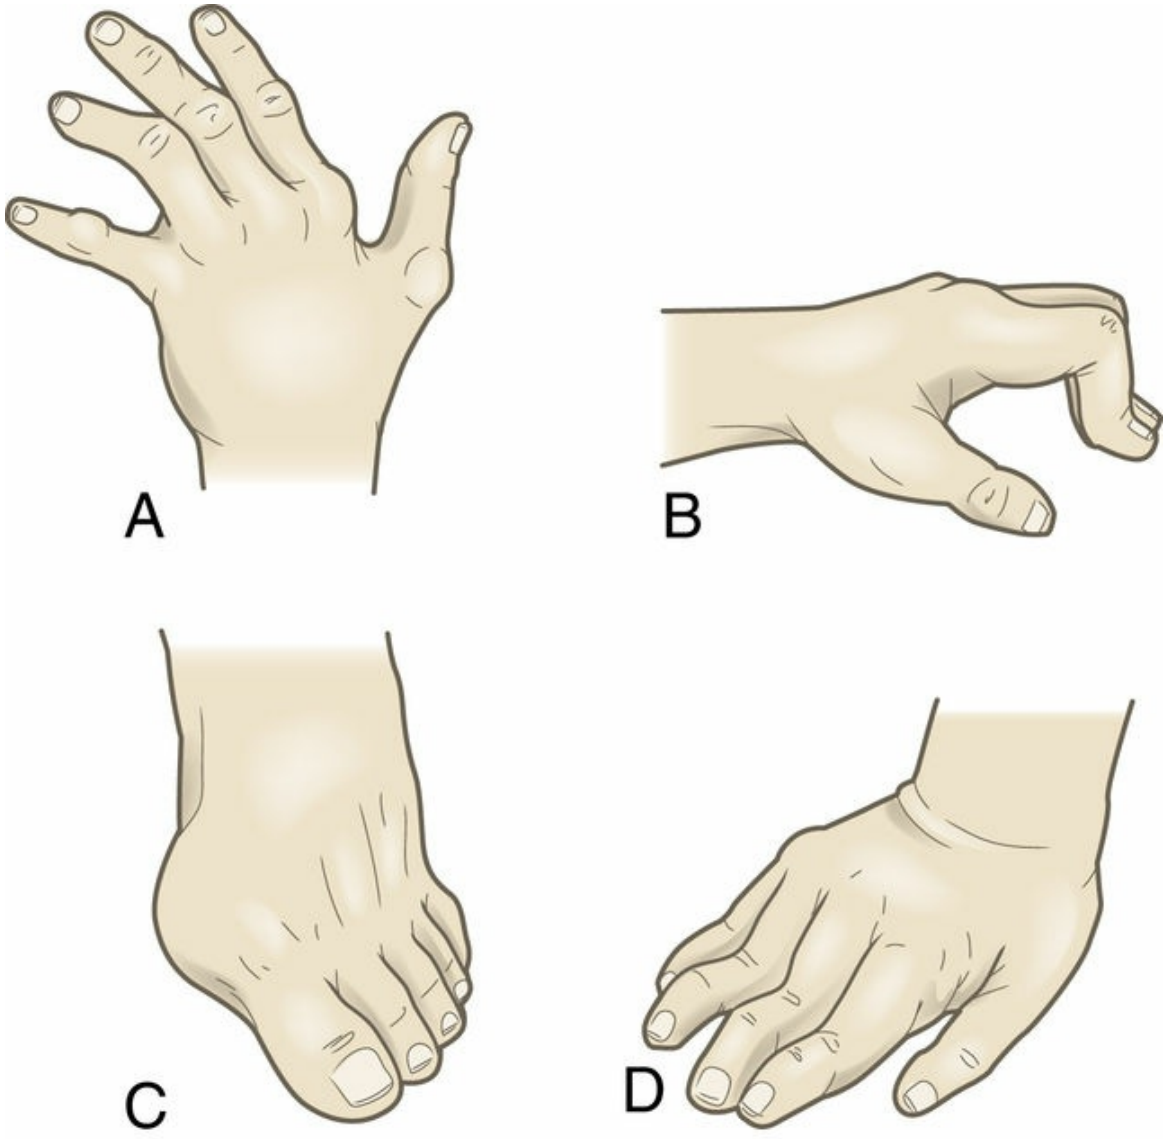

FIG. 64.4 Typical deformities of RA. **A,** Ulnar drift. **B,** Boutonnière deformity. **C,** Hallux valgus. **D,** Swan neck deformity.

Extraarticular Manifestations

RA can affect nearly every body system (Fig. 64.5). Extraarticular manifestations are more likely to occur in the person with high levels of biomarkers, such as RF.

Rheumatoid nodules develop in about half the patients with RA.[11] Rheumatoid nodules appear under the skin as firm, nontender masses. They are often found on bony areas exposed to pressure, such as the fingers and elbows. Nodules at the base of the spine and back of

the head are common in older adults. Treatment is usually not needed. However, these nodules can break down, like pressure injuries. Cataracts and vision loss can result from scleral nodules. Nodular myositis and muscle fiber degeneration can cause pain like that of vascular insufficiency. In later disease, nodules in the heart and lungs can cause pleurisy, pleural effusion, pericarditis, pericardial effusion, and cardiomyopathy.

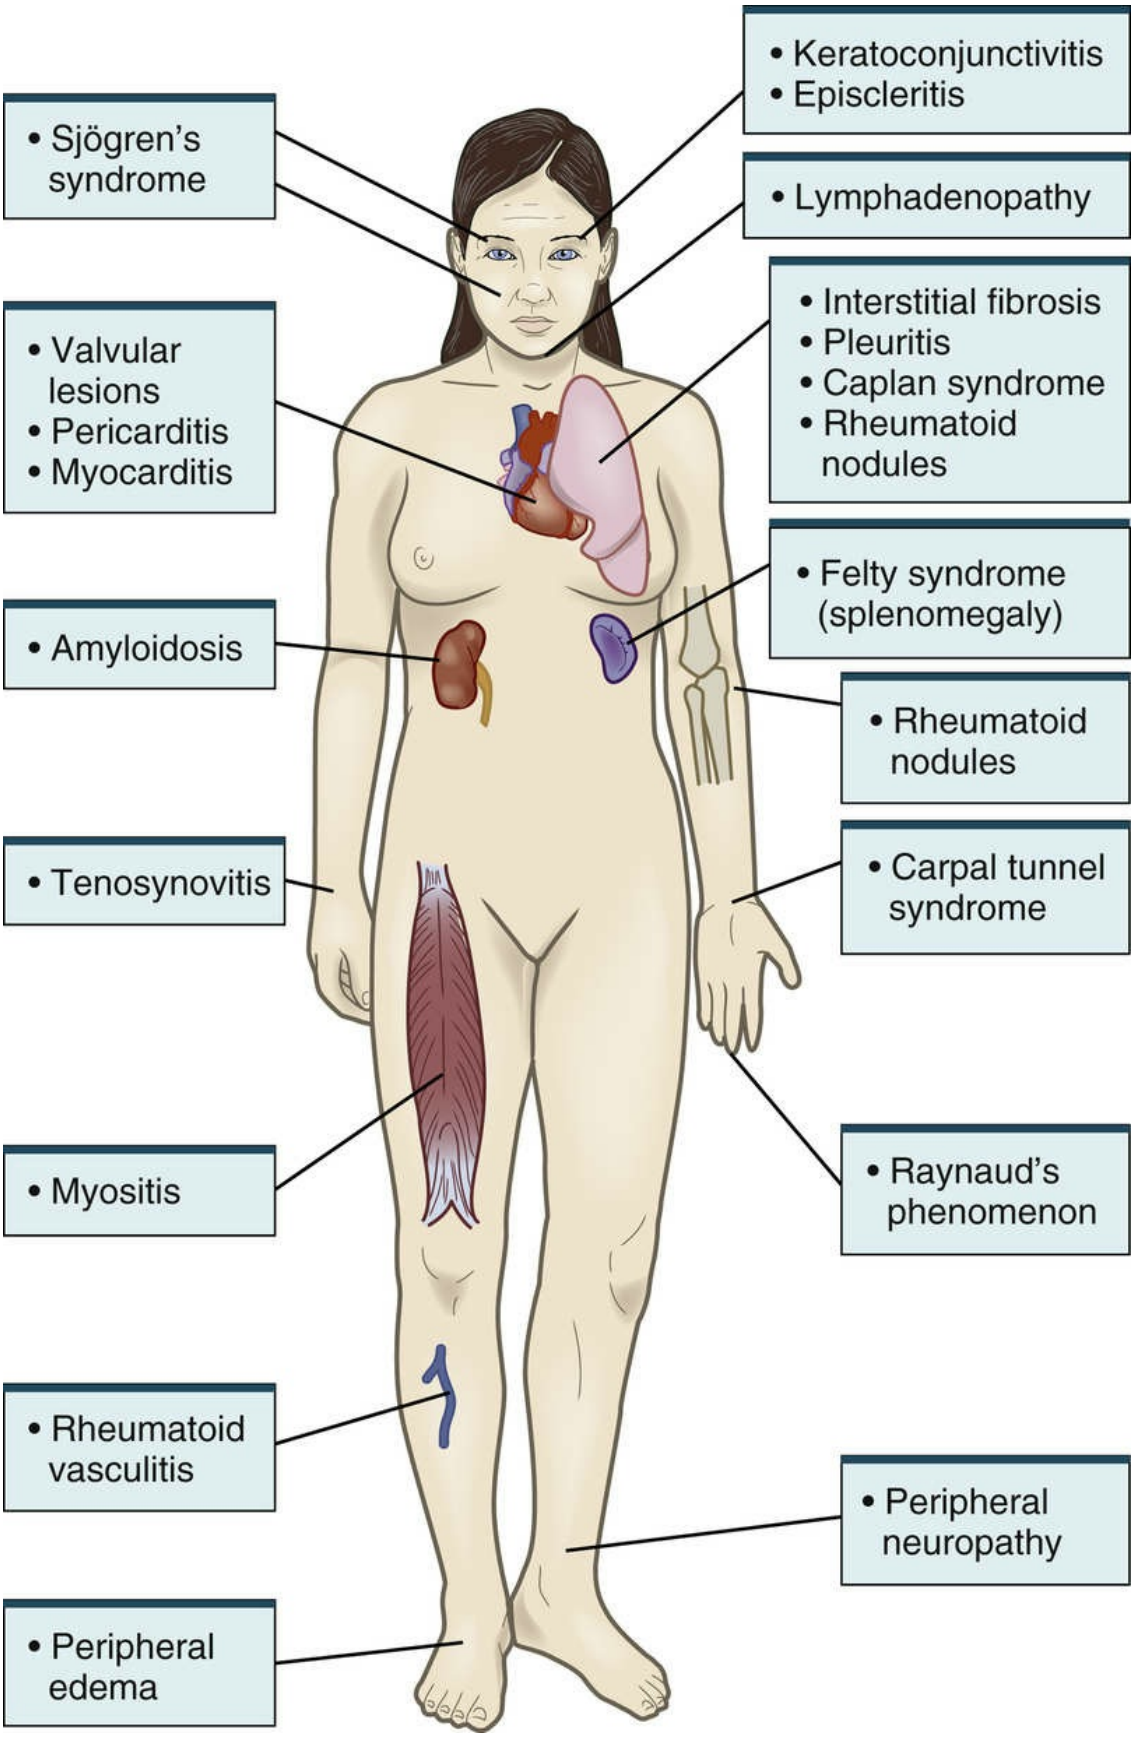
Sjögren's syndrome can occur by itself or with other arthritic disorders, such as RA and SLE. The inflammation of RA can damage the tear-producing (lacrimal) glands, making the eyes feel dry and gritty.[11] Affected patients may have photosensitivity. (Sjögren's syndrome is discussed later in this chapter on p. 1526.)

Felty syndrome is rare but can occur in those with long-standing RA. It is characterized by an enlarged spleen and low white blood cell (WBC) count. Patients with Felty syndrome are at increased risk for infection and lymphoma.

Flexion contractures and hand deformities cause decreased grasp strength and affect the patient's ability to perform self-care tasks. Depression may occur. However, it is unclear if the patient becomes depressed from struggling with chronic pain and disability or if depression is part of the autoimmune disease process. Levels of C-reactive protein (CRP), a marker of inflammation, are higher in patients with depression compared to those with no symptoms of depression.[12]

Diagnostic Studies

Accurate diagnosis is critical to prompt initiation of treatment to decrease the risk for disability. A diagnosis is often made based on history and physical findings. Criteria for diagnosis of RA in a newly presenting patient are described in Table 64.6. Laboratory tests are used to confirm diagnosis and monitor disease progression (Tables 64.7 and 64.8).



• Sjögren's syndrome
• Keratoconjunctivitis
• Episcleritis
• Lymphadenopathy
• Valvular lesions
• Pericarditis
• Myocarditis
• Interstitial fibrosis
• Pleuritis
• Caplan syndrome
• Rheumatoid nodules
• Amyloidosis
• Felty syndrome (splenomegaly)
• Rheumatoid nodules
• Tenosynovitis
• Carpal tunnel syndrome
• Myositis
• Raynaud's phenomenon
• Rheumatoid vasculitis
• Peripheral neuropathy
• Peripheral edema

FIG. 64.5 Extraarticular manifestations of RA.

Positive RF occurs in 80% of adults with RA. Titers rise during active disease. ESR and CRP are increased as general indicators of active inflammation. Testing for the antibodies to citrullinated peptide (anti-CCP) is more specific than RF for RA. Anti-CCP is present in 60% to 80% of patients with RA. It can be found in patients' blood 5 to 10 years before they have symptoms of RA. If the patient's symptoms are consistent with RA, the presence of anti-CCP and RF makes a strong case for early, accurate diagnosis. An increase in antinuclear antibody (ANA) titers is an indicator of autoimmune reaction.

Synovial fluid analysis in early disease often shows slightly cloudy, straw-colored fluid with many fibrin flecks. The enzyme MMP-3 is increased in the synovial fluid. It may be a marker of progressive joint damage. The WBC count of synovial fluid is increased. Tissue biopsy can confirm inflammatory changes in the synovial membrane.

X-rays alone are not diagnostic of RA. They may show only soft tissue swelling and possible bone demineralization in early disease. A narrowed joint space, articular cartilage destruction, erosion, subluxation, and deformity are seen in later disease. Poor alignment and fusion may be seen in advanced disease. Baseline x-rays may be used to monitor disease progression and treatment effectiveness. Bone scans are more useful in detecting early joint changes and confirming diagnosis so that RA treatment can be started.

TABLE 64.6 Diagnostic Criteria for Rheumatoid Arthritis*

Patients should be tested for RA who initially are seen with:

- At least 1 joint with definite clinical synovitis
- Synovitis not better explained by another disease

A. Joint Involvement	Score
• 1 large joint	0
• 2–10 large joints	1
• 1–3 small joints (with or without large joint involvement)	2
• 4–10 small joints (with or without large joint involvement)	3
• >10 joints (at least 1 small joint)	5
B. Serology (at least 1 test result needed for classification)	
• Negative RF *and* negative anti-CCP	0
• Low-positive RF *or* low-positive anti-CCP	2
• High-positive RF *or* high-positive anti-CCP	3
C. Acute Phase Reactants (at least 1 test needed)	
• Normal CRP *and* normal ESR	0
• Abnormal CRP *or* abnormal ESR	1
D. Duration of Symptoms	
• <6 wk	0
• ≥6 wk	1
Scoring: Add score of categories A–D. Scores range from 0–10. A score of ≥6 indicates the definitive presence of RA.	

* Used for newly diagnosed patients.

From Aletaha D, Neogi T, Silman AJ, et al: 2010 Rheumatoid arthritis classification criteria: An American College of Rheumatology/European League Against Rheumatism Collaborative Initiative, *Arthr Rheum* 62:2569, 2010. TABLE 64.7 Stages of Rheumatoid Arthritis

Stage	Characteristics
I	• Synovitis marked by: • Synovial membrane swelling with excess blood • Membrane containing small areas of lymphocyte infiltration • High WBC counts in synovial fluid (5000–60,000/μL) • X-ray results: soft tissue swelling, possible osteoporosis; no evidence of joint destruction
II	• ↑ Joint inflammation, spreading across cartilage into joint cavity • Signs of gradual destruction in joint cartilage • Narrowing joint space from loss of cartilage
III	• Formation of synovial pannus • Joint cartilage becomes eroded, bone exposed • X-ray results: extensive cartilage loss, erosion at joint margins, possible deformity
IV	• End-stage: inflammatory process subsides • Loss of joint function • Formation of subcutaneous nodules

Interprofessional Care

An individualized treatment plan considers disease activity, joint function, age, sex, family and social roles, and response to previous treatment (Table 64.8). Treatment advances have improved the prognosis for patients with newly diagnosed RA. The progression of joint damage can be slowed or stopped with aggressive, early treatment.[13] A caring, long-term relationship with an interprofessional health care team can promote the patient's self-esteem and positive coping.

TABLE 64.8 Interprofessional CareRheumatoid Arthritis

Diagnostic Assessment

- History and physical examination
- Complete blood count (CBC)
- ESR
- C-reactive protein (CRP)
- Rheumatoid factor (RF)
- Antibodies to citrullinated peptide (anti-CCP)
- Antinuclear antibody (ANA)
- X-rays of involved joints
- Possible synovial fluid analysis

Management

- Nutritional and weight management counseling
- Therapeutic exercise
- Psychologic support
- Rest and joint protection, use of assistive devices
- Heat and cold applications
- Complementary and alternative therapies
    - Herbal products and nutritional supplements
    - Acupuncture
- Reconstructive surgery

Drug Therapy

- Disease-modifying antirheumatic drugs (DMARDs) (Table 64.9)
- Biologic response modifiers (BRMs) (Table 64.9)
- NSAIDs (Table 64.3)
- Intraarticular or systemic corticosteroids (Table 64.3)

Drug Therapy

Disease-Modifying Antirheumatic Drugs

Drugs are the cornerstone of RA treatment (Table 64.9). Because irreversible joint changes can occur as early as the first year of RA, HCPs aggressively prescribe disease-modifying antirheumatic drugs (DMARDs). These drugs may slow disease progression and decrease risk for joint erosion and deformity. The choice of drug is based on disease activity, the patient's functional level, and lifestyle considerations, such as the wish to become pregnant.

Methotrexate is preferred for early treatment of patients diagnosed with RA.[13] It has a lower risk for toxicity than other drugs. Rare but serious side effects include bone marrow suppression and hepatotoxicity. Methotrexate therapy requires frequent laboratory monitoring, including CBC and blood chemistry. The patient begins to

see therapeutic effects within 4 to 6 weeks. However, not everyone gets adequate relief from methotrexate alone. It can be given with other DMARDs or biologic response modifiers.

Sulfasalazine (Azulfidine) and the antimalarial drug hydroxychloroquine (Plaquenil) may be effective DMARDs for mild to moderate disease. They are rapidly absorbed, relatively safe, and well-tolerated. Teach the patient taking sulfasalazine to drink adequate fluids to avoid crystal formation in the urine. Urge the patient to wear sunscreen with sun exposure. For those taking hydroxychloroquine, a baseline eye examination with follow-up every 6 to 12 months is needed because of the risk for vision loss.

The synthetic DMARD leflunomide (Arava) blocks immune cell overproduction. Its efficacy and side effects are similar to those of methotrexate and sulfasalazine. Because the drug is teratogenic, pregnancy in women of childbearing age must be excluded before therapy is started. Using 2 kinds of birth control is recommended during treatment.

Tofacitinib (Xeljanz), a JAK (Janus kinase) inhibitor, is used to treat moderate to severe active RA. The drug interferes with JAK enzymes that contribute to joint inflammation in RA. Live vaccinations should not be given to the patient receiving tofacitinib.

Biologic Response Modifiers

Biologic response modifiers (BRMs) (also called *biologics* or *immunotherapy*) are used to slow disease progression in RA. BRMs are classified based on their mechanism of action (Table 64.9). They can be used to treat patients with moderate to severe RA who have not responded to DMARDs. They can be used alone or in combination therapy with a DMARD, such as methotrexate.[13]

TNF inhibitors include etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), certolizumab (Cimzia), and golimumab (Simponi). Etanercept is a biologically engineered copy of the TNF cell receptor. It binds to TNF in circulation before TNF can bind to the cell surface receptor. Thus it inhibits the inflammatory response. This drug is given as a subcutaneous injection.

Infliximab and adalimumab are monoclonal antibodies that bind to TNF, preventing it from binding to TNF receptors on cells. Infliximab is given IV in combination with methotrexate. Adalimumab is given subcutaneously.

Certolizumab and golimumab are TNF inhibitors that improve symptoms in patients with moderate to severe RA. Both drugs are given in combination with methotrexate.

Drug Alert

Tumor Necrosis Factor Inhibitors

- Perform tuberculin test and chest x-ray before starting therapy.
- Monitor for signs of infection. Stop the drug temporarily and notify HCP if acute infection develops.
- Teach patients to avoid live vaccination while taking drug.
- Report bruising, bleeding, or persistent fever and other signs of infection.

Anakinra (Kineret) is an IL-1 receptor antagonist (IL-1Ra) created from new combinations of genetic material. It blocks the biologic activity of IL-1 by competitively inhibiting its ability to bind to the IL-1 receptor. Anakinra is given as a subcutaneous injection. It is used to reduce pain and swelling of moderate to severe RA. It can be used in combination with DMARDs but not with other TNF inhibitors. Using these agents together can lead to serious infection and neutropenia.

Tocilizumab (Actemra) and sarilumab (Kevzara) block the action of IL-6, a cytokine that contributes to inflammation. They are used to treat patients with moderate to severe RA who have not responded to or cannot tolerate other drugs for the disease.

Abatacept (Orencia) blocks T-cell activation. It is recommended for patients who have inadequate response to DMARDs or TNF inhibitors. It is given IV. Like anakinra, it should not be used with

TNF inhibitors.

Rituximab (Rituxan) is a monoclonal antibody that targets B cells. It may be used in combination with methotrexate for patients with moderate to severe RA not responding to TNF inhibitors. It is given IV.

Other Drug Therapy

Other DMARDS include immunosuppressants (azathioprine), penicillamine (Cuprimine), and gold preparations. These medications are used less often because they are weak treatments compared to other DMARDs and biologics.

Corticosteroid therapy can be used to manage symptoms during disease flares. Intraarticular injections may temporarily reduce acute pain and inflammation. Low-dose oral corticosteroids may be used for a limited time to decrease disease activity until the effects of DMARDs or biologics are seen. However, they are inadequate as a sole therapy because they do not affect disease progression. Their long-term use should not be a mainstay of RA treatment. Complications include osteoporosis and avascular necrosis.

Various NSAIDs and salicylates are used to treat arthritis pain and inflammation. Aspirin may be used in dosages of 3 to 4 g/day in 3 to 4 doses. Blood salicylate levels should be monitored in a patient taking more than 3600 mg daily. NSAIDs have antiinflammatory and analgesic effects. Some relief may be seen within days of starting treatment with NSAIDs. Full effect may take 2 to 3 weeks. NSAIDs may be used when the patient cannot tolerate aspirin. The patient may be able to better follow the treatment plan if using an antiinflammatory drug that can be taken only once or twice a day (Table 64.3). Celecoxib (Celebrex), the only available COX-2 inhibitor, is effective in RA as well as OA. All nonaspirin NSAIDs can increase the risk for blood clots, heart attack, and stroke.

Nutritional Therapy

Although no special diet is needed for RA, balanced nutrition is important. Fatigue, pain, and depression may cause a loss of appetite.

Limited endurance and mobility may make it hard to shop for and prepare food. Weight loss may result. The occupational therapist can help the patient modify the home environment and use assistive devices for easier food preparation.

Corticosteroid therapy and decreased mobility due to pain may cause unwanted weight gain. Corticosteroids increase the appetite, leading to higher caloric intake. A sensible weight loss program with balanced nutrition and exercise reduces stress on affected joints. The patient taking corticosteroids may become distressed as signs and symptoms of Cushing syndrome (e.g., moon face, redistribution of fatty tissue to the trunk) change the physical appearance. Encourage the patient not to change the dose or stop therapy abruptly. Weight will return to normal several months after treatment ends. Remind the patient to continue to eat a balanced diet.

Surgical Therapy

Surgery may be needed to relieve severe pain and improve the function of severely deformed joints. Removal of the joint lining *(synovectomy)* is one type of surgery. Total joint replacement *(arthroplasty)* can be done for many different joints in the body. Joint surgery is discussed in Chapter 62.

Nursing Management: Rheumatoid Arthritis

Nursing Assessment

Subjective and objective data to obtain from the patient with RA are outlined in Table 64.10. Begin with a careful physical assessment (e.g., joint pain, swelling, ROM, general health status). Assess psychosocial needs (e.g., family support, sexual satisfaction, emotional stress, financial constraints, vocational and career limitations). Assess for environmental concerns (e.g., transportation, home or work modifications). After identifying the patient's problems, carefully plan

a program for rehabilitation and education with the interprofessional care team.

Nursing Diagnoses

Nursing diagnoses for the patient with RA may include:

- Impaired physical mobility
- Chronic pain
- Disturbed body image

Additional information on nursing diagnoses and interventions for the patient with RA is provided in eNursing Care Plan 64.1 (available on the website for this chapter).

TABLE 64.9 Drug TherapyRheumatoid Arthritis

Drug	Mechanism of Action	Nursing Considerations
Disease-Modifying Antirheumatic Drugs (DMARDs)		
Antimalarial		
hydroxychloroquine (Plaquenil)	Exact mechanism unknown but may suppress formation of antigens	Monitor CBC and liver function. Tell patient therapeutic response may not occur for up to 6 mo. Teach patient to report visual changes, muscular weakness, and ↓ hearing or tinnitus.
Gold Compounds		
***Oral*: auranofin (Ridaura)** ***Parenteral:* gold sodium thiomalate, myochrysine, aurothioglucose**	Alter immune responses, suppressing synovitis of active RA	Rule out pregnancy before beginning treatment. Monitor CBC, urinalysis, and liver and renal function. Tell patient therapeutic response may not occur for 3–6 mo. Teach patient to report pruritus, rash, sore mouth, indigestion, or metallic taste.
Immunosuppressants		
azathioprine (Imuran) **cyclophosphamide**	Inhibit DNA, RNA, protein synthesis	Assess for ↓ pain, swelling, stiffness, and ↑ joint mobility. Teach patient to report unusual bleeding or bruising. Tell patient therapeutic response may take up to 12 wk. Teach women of childbearing age to avoid pregnancy. Encourage ↑ fluid intake to ↓ risk for hemorrhagic cystitis.
mycophenolate mofetil (CellCept)	Inhibits DNA synthesis	Monitor blood count and liver function tests every 2–4 wk for first 3 mo of treatment, thereafter every 1–3 mo. Teach patient about ↑ infection risk. Tell patients not to take antacids at same time because they may interfere with drug absorption.
JAK (Janus Kinase) Inhibitor		
tofacitinib (Xeljanz)	Inhibits action of JAK enzymes, signaling pathways inside the cell with a key role in inflammation of RA	Tell patient of ↑ infection risk, including opportunistic infections. Monitor patient for any sign or symptom of infection for early treatment.
Miscellaneous		
leflunomide (Arava)	Antiinflammatory Immunomodulatory agent that inhibits proliferation of lymphocytes	Monitor liver function. Assess for ↓ pain, swelling, stiffness, and ↑ joint mobility. Teach women of childbearing age to avoid pregnancy.
methotrexate (Trexall)	Antimetabolite Inhibits DNA, RNA, protein synthesis	Monitor CBC and liver and renal function. Teach patient to report signs of anemia (fatigue, weakness). Keep patient well hydrated. Due to teratogenic effects, have female patient use effective contraception during and 3 mo after treatment.
penicillamine (Cuprimine, Depen)	Antiinflammatory Exact mechanism unknown but may suppress cell-mediated immune response	Monitor WBC count, platelets, urinalysis. Tell patient to take medication 1 hr before or 2 hr after meals, and at least 1 hr away from any other drug, food, or milk.
sulfasalazine (Azulfidine)	Sulfonamide Antiinflammatory Blocks prostaglandin synthesis	Tell patient drug may cause orange-yellow discoloration of urine or skin. Space doses evenly around the clock, taking drug after food with 8 oz water. Treatment may be continued even after symptoms are relieved. Monitor CBC.
Biologic Response Modifiers (Biologics, Immunotherapy)		
B-Cell Depleting Agent		
rituximab (Rituxan)	Monoclonal antibody that binds to CD20, an antigen on B cells, destroying B cells and suppressing immune response	Monitor for infection and bleeding. Tell patient to not receive live virus vaccines with treatment. Monitor for low BP if taking BP medication. Teach patient fatigue is common.
Interleukin-1 Receptor Antagonist		
anakinra (Kineret)	Blocks the action of interleukin-1, ↓ inflammatory response	Assess for ↓ pain, swelling, stiffness, and ↑ joint mobility. Injection site reaction generally occurs in first month of treatment and decreases with continued therapy. Assess renal function. Monitor for infection. Tell patient to not take drug with TNF inhibitors.
Interleukin-6 Receptor Antagonist		
sarilumab (Kevzara) **tocilizumab (Actemra)**	Blocks action of interleukin-6, thus ↓ inflammatory response	Given to patients with RA for whom other therapies have failed. Monitor BP and for infection. Tell patient of GI effects (e.g., perforation). Monitor liver enzyme and serum low-density lipoprotein (LDL).
T-Cell Activation Inhibitor		
abatacept (Orencia)	Inhibits T-cell activation, thus suppressing immune response	Not recommended for concomitant use with TNF inhibitors. Assess for ↓ pain, swelling, stiffness, and ↑ joint mobility.

Table Continued

Drug	Mechanism of Action	Nursing Considerations
Tumor Necrosis Factor (TNF) Inhibitors		
adalimumab (Humira) **certolizumab (Cimzia)** **etanercept (Enbrel)** **golimumab (Simponi)** **infliximab (Remicade)**	Bind to TNF, blocking its interaction with cell surface receptors. Decrease inflammatory and immune responses	Assess for ↓ pain, swelling, stiffness, and ↑ joint mobility. Tell patient of ↑ risk for tuberculosis. Teach patient to have yearly PPD. Monitor for infection, bleeding, and emergence of cancers. Injection site reaction generally occurs in first month of treatment and ↓ with continued therapy. Teach patient to not receive live virus vaccines during treatment.
Other Agents		
Antibiotics		
doxycycline (Vibramycin)	↓ Action of enzymes on cartilage degradation	Possible treatment alternative for mild disease.
minocycline (Minocin)	Antirheumatic effect possibly related to immunomodulatory/antiinflammatory properties	

TABLE 64.10 Nursing AssessmentRheumatoid Arthritis

Subjective Data

Important Health Information

Past health history: Recent infections. Precipitating factors, such as emotional upset, infections, overwork, childbirth, surgery. Pattern of remissions and exacerbations
Medications: Aspirin, NSAIDs, corticosteroids, DMARDs, BRMs
Surgery or other treatments: Any joint surgery

Functional Health Patterns

Health perception–health management: Positive family history for RA or other autoimmune disorders. Malaise, ability to take part in treatment plan. Impact of disease on functional ability
Nutritional-metabolic: Anorexia, weight loss, dry mucous membranes of mouth and pharynx
Activity-exercise: Stiffness and joint swelling, muscle weakness,

difficulty walking, fatigue

Cognitive-perceptual: Paresthesia of hands and feet, loss of sensation; symmetric joint pain and aching that ↑ with motion or stress on joint, may interfere with rest

Objective Data

General

Lymphadenopathy, fever

Integumentary

Scleritis, uveitis, Sjögren's syndrome. Subcutaneous rheumatoid nodules on forearms, elbows. Skin ulcers. Shiny, taut skin over involved joints. Peripheral edema

Cardiovascular

Symmetric pallor and cyanosis of fingers (Raynaud's phenomenon). Distant heart sounds, murmurs, dysrhythmias

Respiratory

Bronchiectasis, pleural effusion, tuberculosis, interstitial lung disease

Gastrointestinal

Splenomegaly (Felty syndrome)

Musculoskeletal

Symmetric joint involvement with swelling, erythema, heat, tenderness. Deformities (with later disease). Enlargement of PIP and MCP joints. Limitation of joint movement, muscle contractures, muscle atrophy

Possible Diagnostic Findings

Positive RF, ANA, Anti-CCP. ↑ ESR; anemia. ↑ WBCs in synovial fluid. On x-ray evidence of joint space narrowing, bony erosion, deformity, possible osteoporosis

ANA, Antinuclear antibody; *anti-CCP,* antibodies to citrullinated peptide; *BRMs,* biologic response modifiers; *DMARDs,* disease-modifying antirheumatic drugs; *MCP,* metacarpophalangeal; *PIP,* proximal interphalangeal; *RF,* rheumatoid factor.

Planning

The overall goals are that the patient with RA will (1) have acceptable pain management, (2) have minimal loss of function of affected joints, (3) take part in planning and implementing the treatment plan, (4) maintain a positive self-image, and (5) perform self-care to the maximum amount possible.

Nursing Implementation

Health Promotion

Prevention of RA is not possible. Early treatment can help prevent further joint damage. Community education programs should focus on symptom recognition to promote early diagnosis and treatment. The Arthritis Foundation offers many publications, classes, and support activities to help persons with RA.

Acute Care

The patient newly diagnosed with RA is usually treated on an outpatient basis. Hospitalization may be needed for the patient who has systemic complications or needs surgery for decreased functional ability. Work closely with the HCP, physical and occupational therapists, and social worker to help the patient regain function and adjust to chronic illness.

Nursing Management

Caring for the Patient With Rheumatoid Arthritis

- Give drug therapy as ordered.
- Teach patient and caregiver about drug therapy, including increased risk for infection with disease-modifying agents.
- Assess disease impact on quality of life and joint function.
- Assess pain intensity and give analgesics as ordered. Assess patient response.
- Develop program for rehabilitation and education with the interprofessional team.
- Teach patient about need for balance of rest and activity, with use of joint protective strategies.
- Oversee UAP
    - Aid patient with passive ROM of affected joints.
    - Help patient with self-care needs.

Collaborate With Interprofessional Team Members

Physical Therapist

- Assess patient's current mobility and need for assistance (e.g., walker).

- Develop exercise plan and teach patient to perform exercises safely.
- Coordinate PT with RN so that patient can receive timely analgesia.
- Recommend and apply thermal therapies.

Occupational Therapist

- Assess impact of patient's condition on ability to perform ADLs.
- Teach patient in use of assistive devices (e.g., long-handled reacher, long-handled shoe horn) to improve self-care ability without increasing stress on joints.
- Identify modifications to improve role performance (e.g., kitchen modifications for meal preparation).

Social Worker

- Assist with obtaining durable medical equipment (e.g., walker).
- Assess psychosocial and financial impact of disease. Arrange vocational retraining if needed.

Ambulatory Care

Care of the patient with RA includes a broad program of drug therapy, balance of rest and activity with joint protection, use of heat and cold applications, exercise, and patient and caregiver teaching. Nondrug management may include the use of therapeutic heat and cold, rest, relaxation techniques, joint protection (Tables 64.4 and 64.11), biofeedback, transcutaneous electrical nerve stimulation (see Chapter 8), and hypnosis. Allow the patient and caregiver to choose therapies that promote optimal comfort and fit their lifestyle.

Rest

Alternating scheduled rest periods with activity throughout the day helps relieve fatigue and pain. The amount of rest needed varies based on disease severity and the patient's limitations. The patient should rest before becoming exhausted. Total bed rest is rarely necessary. It should be avoided to prevent stiffness and other effects of immobility. A patient with mild disease may need daytime rest plus 8 to 10 hours of sleep at night.

Help the patient find ways to change daily activities to avoid overexertion and fatigue, which can worsen disease activity. For example, the patient may be able to prepare meals more easily while sitting on a high stool in front of the sink.

Teach the patient to maintain good body alignment during rest through use of a firm mattress or bed board. Encourage positions of extension. Teach the patient to avoid positions of flexion. To decrease the risk for joint contracture, never place pillows under the knees. Use a small, flat pillow under the head and shoulders if needed.

TABLE 64.11 Patient & Caregiver TeachingProtection of Small Joints

Include the following instructions when teaching the patient with arthritis how to protect small joints:

1. Maintain joint in neutral position to minimize deformity.
    - Press water from a sponge instead of wringing.
2. Use strongest joint available for any task.
    - When rising from chair, push with palms rather than fingers.
    - Carry laundry basket in both arms rather than with fingers.
3. Distribute weight over many joints instead of stressing a few.
    - Slide objects instead of lifting them.
    - Hold packages close to body for support.
4. Change positions often.

- Do not hold book or grip steering wheel for long periods without resting.
- Avoid grasping pencil or cutting vegetables with knife for extended periods.

5. Avoid repetitious movements.
   - Do not knit or sew for long periods.
   - Rest between rooms when vacuuming.
   - Use faucets and doorknobs that are pushed rather than turned.
6. Modify chores to avoid stress on joints.
   - Avoid heavy lifting.
   - Sit on stool instead of standing during meal preparation.

Joint Protection

Protecting joints from stress is important. Help the patient find ways to alter routine tasks to put less stress on joints (Table 64.11). Energy conservation requires careful planning. The emphasis is on work simplification. Work for short periods with scheduled rest breaks to avoid fatigue (pacing). Organize activities to avoid going up and down stairs repeatedly. Use carts to carry supplies. Store frequently used materials in a convenient, easy-to-reach area. Use joint-protective devices (e.g., electric can opener) whenever possible. Teach patients to delegate tasks to other family members.

An occupational therapist helps the patient maintain upper extremity function and encourages use of splints or other assistive devices for joint protection. Lightweight splints may be prescribed to rest an inflamed joint and prevent deformity from muscle spasms and contractures. Remove the splints regularly to assess skin and perform ROM exercises. After assessment and supportive care, reapply splints as prescribed.

Occupational therapy may increase patient independence with assistive devices that simplify tasks (e.g., built-up utensils, buttonhooks, modified drawer handles, lightweight plastic dishes, raised toilet seats). Encourage the patient to make dressing easier by

wearing shoes with Velcro fasteners and clothing with buttons or a zipper in the front instead of the back. Use a cane or a walker for support and decreased pain when walking.

Cold and Heat Therapy and Exercise

Cold and heat applications can help relieve stiffness, pain, and muscle spasm. Heat and cold can be used several times a day as needed. Ice is especially helpful during periods of increased disease activity. Cold application should not exceed 10 to 15 minutes at a time. Plastic bags of small frozen vegetables (peas or kernel corn) can easily mold around the shoulder, wrists, or knees to be an effective home treatment. The patient can use ice cubes or small paper cups of frozen water to massage areas on either side of a painful joint. Moist heat offers better relief for chronic stiffness. However, heat application should not exceed 20 minutes at a time.

Heating pads, moist hot packs, paraffin baths, and warm baths or showers can relieve stiffness to allow the patient to take part in therapeutic exercise. Alert the patient to the risk for a burn and the need to avoid using a heat-producing cream (e.g., capsaicin) with an external heat device. Sitting or standing in a warm shower, sitting in a tub with warm towels around the shoulders, or simply soaking the hands in a basin of warm water may relieve joint stiffness and allow the patient to perform ADLs more comfortably.

Individualized exercise is an important part of the treatment plan. A physical therapist may develop a therapeutic exercise program to improve flexibility and strength of affected joints and increase the patient's endurance. Encourage program participation and reinforce correct performance of the exercises. Progressive joint immobility and muscle weakness can occur if the patient does not move the joints. Overaggressive exercise can cause increased pain, inflammation, and joint damage. Emphasize that taking part in a recreational exercise program (e.g., walking, swimming) or doing usual daily activities does not take the place of therapeutic exercise to maintain adequate joint motion.

Gentle ROM exercises are usually done daily to keep joints

functional. The patient should practice exercises with supervision. Exercising in warm water (78° to 86° F [25° to 30° C]) allows easier joint movement because of the buoyancy and warmth of the water. Although movement seems easier, water provides 2-way resistance that makes muscles work harder than they would on land. During acute inflammation, limit exercise to 1 or 2 repetitions.

Patient and Caregiver Teaching

Care of the patient with RA begins with a thorough program of education and drug therapy. Teach the patient and caregiver about the disease process and home management strategies. Inflammation may be managed through administration of NSAIDs, DMARDs, and BRMs. Careful timing of drug administration is critical to maintain a therapeutic drug level and reduce early morning stiffness. Discuss the action and side effects of each prescribed drug and any needed laboratory monitoring. Many patients with RA take several different drugs, so make the drug regimen as understandable as possible. Encourage patients to develop a way to remember to take their medications (e.g., pill containers).

Psychologic Support

For effective self-management and adherence to an individualized home treatment program, help the patient understand the nature and course of RA and the goals of therapy. Consider the patient's value system and perception of the disease.

Discuss changes in sexuality. Chronic pain or loss of function may make the patient vulnerable to claims of false advertising about unproven or even dangerous remedies. Help the patient recognize fears and concerns faced by all people who live with chronic illness.

Evaluate the family support system. Financial planning may be needed. Consider community resources, such as a home care nurse, homemaker services, and vocational rehabilitation. Self-help groups are helpful for some patients.

Living with chronic pain may lead to depression. To decrease depressive symptoms, suggest activities such as listening to music,

reading, exercising, and counseling. Hypnosis and biofeedback may be useful.

Gerontologic Considerations: Arthritis

The prevalence of arthritis in older adults is high. The disease is accompanied by problems unique to this age-group. Areas of concern for older adults include:

- The high incidence of OA in older adults may keep the HCP from considering other types of arthritis.
- Age alone causes changes that make interpretation of laboratory values, such as RF and ESR, more difficult. Drugs taken for co-morbid conditions can affect laboratory values.
- Musculoskeletal pain syndromes and weakness may have no physical cause. Instead, they may be related to depression and physical inactivity.
- Diseases such as SLE, which often occur in younger adults, can develop in a milder form in older adults.

Physical and metabolic changes of aging may increase the older patient's sensitivity to both therapeutic and toxic effects of some drugs. The older adult who takes NSAIDs has an increased risk for side effects, especially GI bleeding and renal toxicity. Using NSAIDs with a shorter half-life may need more frequent dosing and have fewer side effects in the older patient with altered drug metabolism.

Polypharmacy in the older adult is a concern. Use of drugs in RA treatment may increase the chance of unexpected drug interactions. The drug regimen should be as simple as possible to increase adherence (e.g., limited number of drugs with decreased frequency of administration). This is especially important for those who lack regular assistance.

Osteopenia from corticosteroid use can worsen the problem of decreased bone density from aging and inactivity. The risk for pathologic fractures is increased, especially vertebral compression

fractures. Myopathy related to corticosteroid use can be minimized by an age-appropriate exercise program. An adequate support system for the older adult is critical to the ability to follow a treatment plan.

Gout

Gout is a type of arthritis characterized by elevation of uric acid *(hyperuricemia)* and the deposit of uric acid crystals in 1 or more joints. Sodium urate crystals may be found in articular, periarticular, and subcutaneous tissues. Unlike other forms of arthritis, gout is marked by painful flares lasting days to weeks followed by long periods without symptoms. More than 8 million Americans have gout. Blacks have a higher incidence compared to whites.[14]

Gender Differences

Gout

Men

- Occurs 3 times more often in men than in women until age 60.
- Usually develops in men ages 30 to 50.

Women

- Rarely develop gout before menopause.

Etiology and Pathophysiology

Uric acid is the major end product of purine catabolism. It is primarily excreted by the kidneys. Gout occurs when either the kidneys cannot excrete enough uric acid or there is too much being made for the kidneys to handle effectively.

We classify hyperuricemia as primary or secondary. *Primary hyperuricemia* is genetic. A hereditary error of purine metabolism leads to the overproduction or retention of uric acid. *Secondary hyperuricemia* may be caused by conditions that increase uric acid production or decrease uric acid excretion or drugs that inhibit uric acid excretion (e.g., loop diuretics, β-blockers). Organ transplant recipients receiving immunosuppressive agents are at risk for hyperuricemia (Table 64.12).

TABLE 64.12 Causes of Hyperuricemia

- Acidosis or ketosis
- Alcohol use, especially beer and red wine
- Cancer
- Chemotherapy drugs
- Diabetes
- Drug-induced renal impairment
- Hyperlipidemia
- Hypertension
- Lead exposure
- Metabolic syndrome
- Myeloproliferative disorders
- Obesity
- Renal insufficiency
- Sickle cell anemia
- Starvation
- Use of certain common drugs (aspirin, ACE inhibitors, β-blockers, loop or thiazide diuretics, niacin)

Gout is likely caused by the interaction of several factors. The most important is metabolic syndrome (obesity, insulin resistance, hypertension, hyperlipidemia). Increased intake of foods containing

purines (e.g., red and organ meat, shellfish, fructose drinks) can trigger gout. High uric acid may result from prolonged fasting or excessive alcohol use because they increase the production of keto acids, which inhibit uric acid excretion.

Not everyone with high uric acid levels develops gout. Two processes are essential for a person to develop gout: crystallization and inflammation. As urate levels increase and saturate the synovial fluid or soft tissues, the excess urate coalesces into crystals. These trigger inflammation. Monocytes and macrophages try to remove the crystals through phagocytosis. This causes the release of inflammatory mediators into the surrounding area, causing more inflammation and tissue damage.[15]

Clinical Manifestations and Complications

Gout may occur acutely in 1 or more joints (usually less than 4). Inflammation of the great toe *(podagra)* is the most common initial problem. Other affected joints may include wrists, knees, ankles, and the midfoot. Olecranon bursae may be involved. Affected joints may appear dusky or cyanotic and are extremely tender. Acute gout arthritis is usually triggered by events such as trauma, surgery, alcohol use, or systemic infection. Symptom onset typically occurs at night with sudden swelling and severe pain peaking within several hours. The painful area is highly sensitive to light touch. Low-grade fever is common.

An attack usually ends in 2 to 10 days with or without treatment. The affected joint returns to normal, and patients have no symptoms between attacks.

Chronic gout is characterized by multiple joint involvement and visible deposits of sodium urate crystals called tophi. Tophi are hard white nodules. They are typically seen in subcutaneous tissue, synovial membranes, tendons, and soft tissues (Fig. 64.6). Tophi generally occur many years after the onset of disease.

The severity of gout arthritis varies. The clinical course may involve infrequent mild attacks or multiple severe episodes (up to 12 per year)

marked by slowly progressive disability. In general, tophi appear earlier, and the patient has more frequent, severe episodes of gout if serum uric acid is high. Chronic inflammation may cause joint deformity, and cartilage destruction may lead to secondary OA. Large urate crystal deposits may pierce overlying skin, producing draining sinuses that often become infected.

FIG. 64.6 Tophi associated with chronic gout. Painless nodules are filled with uric acid crystals.
Courtesy John Cook, MD. From Goldstein BG, Goldstein AE: *Practical dermatology,* ed 2, St Louis, 1997, Mosby.

Excessive uric acid excretion may lead to stone formation in the kidneys or urinary tract. Pyelonephritis related to sodium urate deposits and obstruction contributes to kidney disease.

Diagnostic Studies

In gout, serum uric acid is usually increased above 6 mg/dL. However, hyperuricemia is not specifically diagnostic of gout because serum values may be normal during an acute gout attack.[15] Increased uric acid may be related to various drugs or an asymptomatic abnormality in the general population A 24-hour urine uric acid can

determine if the disease is caused by decreased renal excretion or overproduction of uric acid.

The gold standard for diagnosis of gout is synovial fluid aspiration. Affected fluid contains needle-like monosodium urate crystals. This procedure is done in only a small number of patients because diagnosis can typically be made on clinical symptoms alone. However, it is the only reliable way to tell gout from septic arthritis or *pseudogout* (calcium phosphate crystal formation). Aspiration may decrease pain by relieving pressure in a swollen joint capsule.

X-rays appear normal in the early stages of gout. In chronic disease, tophi may appear as eroded areas in the bone.

Interprofessional and Nursing Management: Gout

Goals for the care of the patient with gout (Table 64.13) include ending an acute attack with an antiinflammatory agent, such as colchicine. Hyperuricemia and gout are chronic problems that can be controlled with effective patient education and careful adherence to a treatment program. Drug therapy is the primary way to treat acute and chronic gout.

Drug Therapy

Acute gout is treated with oral colchicine (Colcrys, Mitigare) and NSAIDs. Because colchicine has antiinflammatory effects but is not an analgesic, an NSAID is added for pain management. Colchicine generally produces dramatic pain relief when given within 12 hours of an attack. This helps in diagnosis because good response to this drug is further evidence of gout.

TABLE 64.13 Interprofessional CareGout

Diagnostic Assessment

- History and physical examination
- Family history of gout
- Sodium urate crystals in synovial fluid
- Increased serum uric acid
- Increased uric acid in 24-hr urine
- X-ray of affected joints

Management

- Joint immobilization
- Local application of heat and cold
- Joint aspiration and intraarticular corticosteroids
- Avoid food and fluids with high purine content (e.g., anchovies, liver, wine, beer)

Drug Therapy

- colchicine
- NSAIDs (e.g., naproxen [Naprosyn])
- Xanthine oxidase inhibitors: allopurinol (Zyloprim), febuxostat (Uloric)
- Uricosurics: probenecid, lesinurad (Zurampic)
- pegloticase (Krystexxa)
- Corticosteroids (e.g., prednisone)
- Intraarticular corticosteroids (methylprednisolone)
- Adrenocorticotropic hormone (ACTH)

Corticosteroids (orally or by intraarticular injection) can be helpful in treating an acute attack. Systemic corticosteroids may be used only

if routine therapies are contraindicated or ineffective. Adrenocorticotropic hormone (ACTH) may be used for acute treatment of patients for whom NSAIDs, colchicine, or steroids may be problematic.

Future attacks of gout are prevented in part by a maintenance dose of a xanthine oxidase inhibitor. These drugs decrease the production of uric acid. Allopurinol is the most commonly used drug and the first choice for therapy. It is used for patients with uric acid kidney stones or renal impairment. Serious adverse effects limit the use of febuxostat (Uloric).

Drug Alert

Febuxostat

- May cause heart-related death and liver failure.
- Encourage patient with cardiovascular disease to take low-dose aspirin therapy.
- Monitor liver function tests before starting therapy and during treatment.
- Teach patient to notify HCP if symptoms of liver or heart problems occur.

The ACR recommends therapy with probenecid if allopurinol or febuxostat are contraindicated or the patient has intolerance to either.[15] Probenecid is a uricosuric, increasing uric acid excretion in the urine. Aspirin inactivates its effect, resulting in urate retention, and must be avoided during treatment. Acetaminophen can be used safely if analgesia is needed. Lesinurad (Zurampic), a new uricosuric agent, can be taken with a xanthine oxidase inhibitor for those with persistent, increased uric acid levels. Duzallo, a fixed-dose combination of lesinurad and allopurinol, is taken once daily.

Uricosurics can cause renal impairment. They are ineffective when

creatinine clearance is reduced, as can occur in patients over age 60 years or with renal impairment. They should be taken in the morning with food and water. Teach patients to stay well hydrated and to drink about 2 L of liquid a day when taking the drug.

Patients who cannot take or do not respond to drugs that lower serum uric acid may be given pegloticase (Krystexxa). This drug is an enzyme that metabolizes uric acid into a harmless chemical excreted in the urine. It is given IV, usually for at least 6 months. Life-threatening anaphylactic and infusion reactions can occur.

The angiotensin II receptor antagonist losartan (Cozaar) may be effective for treating older patients with gout and hypertension. Losartan promotes urate excretion and may normalize serum urate. Combination therapy with losartan and allopurinol may be used.

Serum uric acid must be checked regularly to monitor treatment effectiveness. Explain the importance of drug therapy and the need for regular assessment of serum uric acid. Dietary restrictions that limit alcohol and foods high in purine help minimize uric acid production (see Table 45.12). Adequate urine volume with normal renal function (2 to 3 L/day) must be maintained to prevent precipitation of uric acid in the renal tubules. Teach obese patients in a carefully planned weight-reduction program (see Chapter 40). Teach the patient about other factors that may cause an attack, including fasting, drug use (e.g., diuretics), and major medical events (e.g., surgery, heart attack).

Nursing interventions for the patient with acute gout include supportive care of the inflamed joints. Avoid causing pain by careless handling of an inflamed joint. Bed rest may be appropriate to immobilize affected joints as needed. Use a cradle or footboard to protect a painful lower extremity from the weight of bed linens. Assess motion limitations and degree of pain.

Check Your Practice

A patient is admitted to the medical unit with acute gout. The right great toe is swollen, red, and painful. He is prescribed colchicine.

- What nursing interventions will you use to protect the foot and decrease pain?
- What will you discuss with the patient about possible dietary changes to decrease risk for future attacks?

Lyme Disease

Lyme disease is an infection caused by the spirochete *Borrelia burgdorferi.* It is transmitted by the bite of an infected deer tick. It was first identified in 1975 in Lyme, Connecticut, after an unusual occurrence of arthritis in children. It is the most common vector-borne disease in the United States, with 7.9 cases per 100,000 persons.[16] The tick typically feeds on mice, dogs, cats, cows, horses, deer, and humans. Person-to-person transmission does not occur.

The summer months are the peak season for human infection. Most U.S. cases occur in 3 areas: along the northeastern states from Maryland to northern Massachusetts, in the midwestern states of Wisconsin and Minnesota, and along the northwestern coast of California and Oregon.[16] Reinfection is common.

Symptoms mimic those of other diseases, such as multiple sclerosis, mononucleosis, and meningitis. The most characteristic clinical symptom of early localized disease is *erythema migrans* (EM). This "bull's-eye rash" occurs in about 80% of infected persons. It appears at the site of the tick bite within 1 month after exposure (Fig. 64.7). It may occur anywhere else on the body as the disease progresses. The EM lesion begins as a central red macule or papule that slowly expands to include a red outer ring of up to 12 in, resembling a bull's eye. It may be warm to the touch but is not itchy or painful. The rash often occurs with acute flu-like symptoms: (1) low-grade fever, (2) headache, (3) neck stiffness, (4) fatigue, (5) loss of appetite, and (6) migratory joint and muscle pain. Flu-like symptoms generally resolve over weeks or months, even if untreated.

FIG. 64.7 Erythema migrans. Typical skin lesion of Lyme disease occurs at the site of tick bite.
From Marx J, Hockberger R, Walls R: *Rosen's emergency medicine,* ed 7, Philadelphia, 2009, Mosby.

If not treated, the spirochete can spread within several weeks or months to the heart, joints, heart, and central nervous system (CNS). Arthritis is the second most common manifestation of Lyme disease. About 60% of persons with untreated infection develop chronic arthritic pain and swelling in the large joints, mainly the knee. Cardiac symptoms, such as heart block and pericarditis, may require hospitalization.[16] Bell's palsy is the most common neurologic effect. Other problems include short-term memory loss, cognitive impairment, shooting pains, and numbness and tingling in the feet.

Diagnosis is often based on the manifestations, especially EM, and a history of exposure in an at-risk area. The CDC recommends a 2-step laboratory testing process to confirm the diagnosis.[17] The first step is the enzyme immunoassay (EIA). It will be positive for most people with Lyme disease. If the EIA is positive or inconclusive, then a Western blot test is done. Results are diagnostic of Lyme disease only if both tests are positive. The CDC does not recommend the Western blot test alone. False-positive results lead to incorrect diagnosis and treatment. In those with neurologic involvement, cerebrospinal fluid should be examined.

Active lesions are treated with oral antibiotics. Doxycycline (Vibramycin), cefuroxime, and amoxicillin are often effective in

treating early-stage infection and preventing later stages of the disease. Short-term therapy of 10 to 21 days of doxycycline is preferred. It treats both Lyme disease and human granulocytic anaplasmosis, which can be transmitted as a co-infection with a single tick bite. While other antibiotics can be used for those who cannot tolerate any of these drugs, they all are less effective. Patients with certain neurologic or cardiac complications may need IV therapy with ceftriaxone or penicillin.

A small number of persons treated with antibiotics may have lingering fatigue or joint and muscle pain. Antibiotic treatment should be extended as needed because the risks of untreated Lyme disease outweigh those of long-term antibiotic therapy.[18]

Reducing exposure to ticks is the best way to prevent Lyme disease. Patient and caregiver teaching for people living in endemic areas is outlined in Table 64.14. No vaccine is available for Lyme disease.

TABLE 64.14 Patient & Caregiver TeachingPrevention and Early Treatment of Lyme Disease

Include the following instructions when teaching patients how to prevent Lyme disease:

- Do not walk through tall grasses and low brush or sit on logs.
- Mow grass. Remove brush around paths, buildings, and campsites to create tick-safe zones.
- Move woodpiles and bird feeders away from your house. Discourage deer (main source of food for adult ticks) from being in the area.
- Wear long pants or nylon tights of tightly woven, light-colored fabric so that you can easily see ticks.
- Tuck pants into boots or long socks, wear long-sleeved shirts tucked into pants, and wear closed toed shoes when hiking.

- Check often for ticks crawling from pant legs to open skin.
- Thoroughly inspect and wash clothes. Placing clothing in dryer on high heat kills ticks.
- Spray insect repellent containing DEET sparingly on skin or clothing. Apply permethrin to clothing and camping gear; protects for several hours.
- Have pets wear tick collars and inspect them often. Do not allow pets on furniture or beds.

Include the following instructions when teaching patients and caregivers living in endemic areas:

- Remove attached ticks with fine-tipped tweezers (not fingers). Grasp tick's mouth parts as close to skin as possible and pull straight out with steady, even pressure. Do not twist or jerk. Avoid folk solutions, such as painting the tick with nail polish or petroleum jelly (see Fig. 68.5).
- Save the tick in a bottle of alcohol (if you need it later for identification). Never crush a tick with your fingers.
- Wash bitten area with soap and water, iodine scrub, or rubbing alcohol. Apply antiseptic. Wash hands.
- See an HCP if flu-like symptoms or a bull's-eye rash appears within 2–30 days after removal of tick.

DEET, N,N-diethyl-m-toluamide.

Septic Arthritis

Septic arthritis (infectious or bacterial arthritis) is caused by microorganisms invading the joint cavity. Bacteria can travel through

the bloodstream from another site of active infection, resulting in seeding of the joint. Organisms also can be introduced directly through trauma or surgical incision.

Any infectious agent can cause septic arthritis (bacteria, viruses, mycobacteria, fungi), especially in the immunocompromised patient. *Staphylococcus aureus* is the most common causative organism. Factors that increase the risk for infection include (1) diseases with decreased host resistance (e.g., RA, SLE), (2) treatment with corticosteroids or immunosuppressive drugs, and (3) debilitating chronic illness (e.g., diabetes).

Large joints, such as the knee and hip, are most often affected. Inflammation of the joint cavity causes severe pain, redness, and swelling. Septic arthritis of the hip can cause avascular necrosis. Because infection has often spread from a primary site elsewhere in the body, fever or shaking chills often accompany joint problems. Diagnosis may be made by joint aspiration *(arthrocentesis)* and synovial fluid culture. WBC count may be low early in the infectious process, especially in those who are immunosuppressed, so diagnosis is not possible solely based on WBC count. Blood cultures for aerobic and anaerobic organisms should be obtained.

Emergent aspiration or surgical drainage is a cornerstone of successful treatment. Irreversible joint damage can occur without rapid, appropriate treatment of septic arthritis. In some cases, damage can occur despite treatment. Broad-spectrum antibiotics are typically started before culture results have been received. Once the organism is identified, more specific treatment can be determined. IV antibiotics are typically transitioned to oral antibiotics, with total treatment of 4 to 6 weeks.

Assess and monitor joint inflammation, pain, and fever. To manage pain, use resting splints or traction to immobilize affected joints. Local hot compresses can decrease pain. Start gentle ROM exercises as soon as tolerated to prevent muscle atrophy and joint contractures. Explain the need for antibiotics and the importance of their continued use until the infection is resolved. Support the patient who needs joint drainage. Use strict aseptic technique when assisting with joint

aspiration.

Spondyloarthropathies

The **spondyloarthropathies** are a group of multisystem inflammatory disorders that affect the spine, peripheral joints, and periarticular structures. These disorders include ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. They are all negative for RF so we call them *seronegative arthropathies.*

Inheritance of human leukocyte antigen (HLA) B27 is strongly associated with these diseases. Both genetic and environmental factors play a role in their development. (HLAs and their relationship to autoimmune diseases are discussed in Chapter 13.)

The spondyloarthropathies share clinical and laboratory characteristics that may make it hard to distinguish among them in early disease. These include absence of antibodies in the serum, peripheral joint involvement (mainly of the lower extremities), low back pain *(sacroiliitis),* pain and redness of the eyes *(uveitis),* intestinal inflammation, and psoriasis.[19]

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a chronic inflammatory disease that primarily affects the axial skeleton, including the sacroiliac joints, intervertebral disc spaces, and costovertebral articulations. Onset of AS is usually in the third decade of life, but onset in adolescence is fairly common. Men are 3 times more likely to develop AS. The disease may go undetected in women because of a milder course.

Etiology and Pathophysiology

We do not know the exact cause of AS. HLA-B27 antigen is found in about 90% of whites with AS, but only 8% of whites without the disease.[20] This suggests genes play a key role in AS. Along with whites, Asians and Hispanics are more likely to have AS than other

ethnic groups. Inflammation in the joints and adjacent tissue causes the formation of granulation tissue *(pannus)* and dense fibrous scars that can cause joint fusion. Inflammation can affect the eyes, lungs, heart, kidneys, and peripheral nervous system.

Clinical Manifestations and Complications

AS is characterized by symmetric sacroiliitis and progressive inflammatory arthritis of the axial skeleton. Symptoms of inflammatory spine pain are the first clues to AS. The patient often has low back pain, stiffness, and limitation of motion that

FIG. 64.8 Advanced ankylosing spondylitis. Kyphotic posture causes many patients to have a bulging abdomen due to pulmonary restriction.
From Kim DH, Henn J, Vaccaro AR, Dickman C: *Surgical anatomy and techniques to the spine,* Philadelphia, 2006, Saunders.

Genetics in Clinical Practice

Ankylosing Spondylitis

Genetic Basis

- Inheritance of HLA-B27 increases susceptibility to developing AS.
- We do not know how HLA-B27 increases the risk for AS.

Incidence

- HLA-B27 antigen is found in about 90% of whites with AS.
- Inheriting HLA-B27 does not mean a person will develop AS.
- 80% of those who inherit HLA-B27 from a parent do not develop the disease.

Genetic Testing

- Testing for HLA-B27 antigen is available.

Clinical Implications

- Diagnosis of AS usually occurs in the third decade of life.
- Multiple genetic and environmental factors play a role in pathogenesis of disease.

is worse during the night and in the morning but improves with mild activity. In women, early symptoms may include pain and stiffness in the neck rather than the lower back. Uveitis is the most common

nonskeletal symptom. It can appear as an initial presentation of the disease years before arthritic symptoms develop. Patients with AS may have distressing chest pain and sternal/costal cartilage tenderness.

Severe postural abnormalities and deformity can cause significant disability (Fig. 64.8). Impaired spinal ROM and fusion, along with vision problems, raise concerns about safe ambulation. Aortic insufficiency and pulmonary fibrosis are common complications. Cauda equina syndrome (compression of the nerves at the end of the spinal cord) can occur. This contributes to lower extremity weakness and bladder dysfunction. The patient is at risk for spinal fracture from associated osteoporosis.

Diagnostic Studies

X-rays are the most important radiographic technique for the diagnosis and follow up of AS. However, x-rays are limited in detecting early sacroiliitis or subtle changes in posterior vertebrae. MRI is useful in assessing early cartilage abnormalities. CT scan is appropriate in specific situations (e.g., cases with subtle x-ray changes). Changes on later spinal films include the appearance of "bamboo spine," the result of calcifications *(syndesmophytes)* that bridge from one vertebra to another. An increased ESR and mild anemia may be seen. When the suspicion for AS is high, the presence of the HLA-B27 antigen improves the likelihood of the diagnosis.

Interprofessional and Nursing Care

Prevention of AS is not possible. Families with other diagnosed HLA-B27–positive rheumatic diseases (e.g., psoriatic arthritis, juvenile spondyloarthritis) should be alert to signs of low back pain for early identification and treatment of AS.

Care of the patient with AS is aimed at maintaining maximal skeletal mobility while decreasing pain and inflammation. Heat applications can help relieve local symptoms. NSAIDs and salicylates are often prescribed. DMARDs, such as sulfasalazine or methotrexate,

have little effect on spinal disease but help with peripheral joint disease. Local corticosteroid injections may be helpful in relieving symptoms.

TNF, which promotes inflammation, is increased in the blood and certain tissues of patients with AS. Etanercept, a BRM, binds TNF and inhibits its action. Etanercept reduces active inflammation and improves spinal mobility. Other anti-TNF inhibitors (infliximab, adalimumab, golimumab) may be effective.

Once pain and stiffness are managed, exercise is essential. Good posture is important to minimize spinal deformity. The exercise plan should include back, neck, and chest stretches. Hydrotherapy (e.g., sauna, steam bath) can decrease pain and facilitate spinal extension. Surgery may be needed for severe deformity and mobility impairment. Spinal osteotomy and total joint replacement are the most common procedures (see Chapter 62).

A key nursing responsibility is to teach the patient with AS about the disease and principles of therapy. The home management program should include regular exercise and attention to posture, local moist heat applications, and informed use of drugs.

Assess chest expansion (using breathing exercises) as part of baseline ROM assessment. Encourage smoking cessation to decrease the risk for lung complications in persons with reduced chest expansion. Ongoing PT includes gentle, graded stretching and strengthening exercises. These preserve ROM and improve thoracolumbar flexion and extension.

Discourage excessive physical exertion during periods of increased disease activity. Proper positioning at rest is essential. Encourage the patient to use a firm mattress. They should sleep on the back with a flat pillow, avoiding positions that encourage flexion deformity. Emphasize the need to avoid spinal flexion (e.g., leaning over a desk); heavy lifting; and prolonged walking, standing, or sitting. Encourage sports that involve natural stretching, such as swimming and racquet games. Family counseling and vocational rehabilitation are important.

Psoriatic Arthritis

Psoriatic arthritis (PsA) is a progressive inflammatory disease that affects about 30% of people with psoriasis.[21] *Psoriasis* is a common, benign, inflammatory skin disorder characterized by red, irritated, and scaly patches. Both PsA and psoriasis appear to have a genetic link with HLA antigens in many patients. Although the exact cause of PsA is unknown, we suspect a combination of immune, genetic, and environmental factors.

PsA can occur in different forms. *Distal arthritis* mainly involves the ends of the fingers and toes, with pitting and color changes in the fingernails and toenails. *Asymmetric arthritis* involves different joints on each side of the body. *Symmetric psoriatic arthritis* resembles RA. It affects joints on both sides of the body at the same time. It accounts for about 50% of cases. *Psoriatic spondylitis* is marked by pain and stiffness in the spine and neck. *Arthritis mutilans* affects only 5% of people with PsA. It is the most severe form of the disease, causing complete destruction of small joints.[21]

On x-ray, the cartilage loss and erosion are similar to RA. Advanced cases often show widened joint spaces. A "pencil in cup" deformity is common in the DIP joints due to thinning, weakened bone. In this deformity, the narrowed ends of the metacarpals or phalanges insert into the expanded end of the other bone sharing the joint. Increased ESR, mild anemia, and increased serum uric acid can be seen in some patients. Thus the diagnosis of gout must be excluded.

Treatment includes splinting, joint protection, and PT. NSAIDs given early in the course of the disease may help with inflammation. Drug therapy includes the DMARDs, such as methotrexate, which is effective for both articular and cutaneous manifestations. Sulfasalazine, cyclosporine, and BRMs (e.g., etanercept, golimumab, adalimumab, infliximab) may be used. Apremilast (Otezla), an inhibitor of the enzyme phosphodiesterase-4, can treat adults with active PsA.

Reactive Arthritis

Reactive arthritis (Reiter's syndrome) occurs more often in young men. It is associated with a symptom complex that includes urethritis, conjunctivitis, and mucocutaneous lesions. Although we do not know the exact cause, it appears to be a reaction triggered in the body after exposure to specific genitourinary or GI tract infections. *Chlamydia trachomatis* spreads by sexual contact. Reactive arthritis is associated with GI infections from *Shigella, Salmonella, Campylobacter,* or *Yersinia* species and other pathogens.[22]

Those who are positive for HLA-B27 are at increased risk for developing reactive arthritis after sexual contact or exposure to certain GI pathogens. This finding supports the suggestion of genetic predisposition.

Urethritis develops within 1 to 2 weeks after sexual contact or GI infection. In women, symptoms include cervicitis. Low-grade fever, conjunctivitis, and arthritis may occur over the next several weeks. This type of arthritis tends to be asymmetric. It often involves the toes and the large joints of the lower extremities. Lower back pain may occur with severe disease. Lesions involving the skin and mucous membranes often occur as small, painless, superficial ulcerations on the tongue, oral mucosa, and glans penis. Soft tissue manifestations include Achilles tendinitis or plantar fasciitis. Few laboratory abnormalities occur, although the ESR may be increased.

Most patients recover within a few months of initial symptoms. Because reactive arthritis is often associated with *C. trachomatis* infection, treatment with doxycycline is widely recommended for patients and their sexual partners. Antibiotics have no effect on arthritis or other symptoms. Topical ophthalmic corticosteroids may be prescribed for treatment of uveitis. Conjunctivitis and lesions generally do not need treatment. NSAIDs and DMARDs may be used if joint symptoms do not resolve. PT may be helpful during recovery.

Most patients have complete remission with return of full joint function. Some patients may develop chronic arthritis, but the condition is often mild. X-ray changes in chronic reactive arthritis

closely resemble those of AS. Treatment is based on symptoms.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem inflammatory autoimmune disease. It is a complex disorder of multifactorial origin resulting from interactions among genetic, hormonal, environmental, and immunologic factors. SLE typically affects the skin, joints, and serous membranes (pleura, pericardium). Renal, hematologic, and neurologic systems are also affected. SLE is marked by a chronic unpredictable course with alternating periods of remission and exacerbation.

About 1.5 million people in the United States have SLE. Blacks, Asian Americans, Hispanics, and Native Americans are more likely than whites to develop the disease. While SLE can affect anyone, 90% of those with SLE are women ages 15 to 45 years.[23]

Etiology and Pathophysiology

The cause of the abnormal immune response in SLE is unknown. Based on the high prevalence of SLE among family members, we suspect a genetic influence. Multiple genes from the HLA complex, including *HLA-DR2* and *HLA-DR3,* are associated with SLE.

Hormones are known to play a role in SLE. Onset or worsening of disease symptoms may occur after the start of menses, with the use of oral contraceptives, and during and after pregnancy. The disease tends to become worse in the immediate postpartum period.

Environmental factors are thought to contribute to SLE. These include sun or ultraviolet light exposure, stress, and exposure to some chemicals and toxins. Infectious agents, such as viruses, may stimulate immune hyperactivity. More than 45 drugs currently in use may trigger SLE. Most cases have been related to procainamide, hydralazine, and quinidine. Drug-induced SLE should not be confused with medication side effects, which typically occur within a few hours or days of short-term drug use. SLE generally occurs

months to years after continuous therapy with a causative drug.[24]

In SLE, varied autoantibodies are made against nucleic acids (e.g., single- and double-stranded DNA), erythrocytes, coagulation proteins, lymphocytes, platelets, and many other self-proteins. Autoimmune reactions (antinuclear antibodies [ANA]) are typically directed against elements of the cell nucleus, especially DNA.

Circulating immune complexes with antibodies against DNA are deposited in the basement membranes of capillaries in the kidneys, heart, skin, brain, and joints. These complexes trigger inflammation that causes tissue destruction. Overaggressive autoimmune responses are related to activation of B and T cells. Specific disease effects depend on the involved cell types or organs. SLE is a type III hypersensitivity response (see Chapter 13).

Clinical Manifestations and Complications

Severity of SLE is extremely variable. It ranges from a relatively mild disorder to a rapidly progressive disease affecting many body systems (Fig. 64.9). No characteristic pattern occurs in the progression of SLE. The circulating immune complexes can affect any organ. The most commonly involved tissues are the skin and muscle, lining of the lungs, heart, nervous tissue, and kidneys. General complaints, such as fever, weight loss, joint pain, and excessive fatigue, may precede worsened disease activity.

Dermatologic Problems

Vascular skin lesions can appear anywhere. They are most likely to develop on sun-exposed areas. Severe skin reactions can occur in people who are sensitive to sunlight *(photosensitivity).* The classic butterfly rash over the cheeks and bridge of the nose occurs in about half of patients at some time during the disease (Fig. 64.10). SLE-specific skin disease can occur in people who do not have full-blown SLE, but the presence of skin disease increases the risk for developing SLE later in life. Some patients have *chronic cutaneous lupus* (CCLE) with discoid (round, coin-shaped) lesions. About 10% of patients have

subacute cutaneous lupus (SCLE). Lesions in SCLE usually do not scar or itch and are not thick and scaly.[25]

Oral or nasopharyngeal ulcers occur in one third of patients with SLE. Alopecia is common, with or without related scalp lesions. The hair may grow back during remission, but hair loss may be permanent over lesions. The scalp becomes dry, scaly, and atrophied.

Musculoskeletal Problems

Arthritis occurs in many patients with SLE. Pain in multiple joints *(polyarthralgia)* with morning stiffness is often the first complaint. It may precede the onset of multisystem disease by many years. Diffuse swelling occurs with joint and muscle pain and some stiffness. SLE-related arthritis is generally nonerosive but may cause deformities (e.g., swan neck deformity of the fingers [Fig. 64.4, *D*], ulnar deviation, subluxation with joint laxity). Patients have increased risk for bone loss and fracture.

Cardiopulmonary Problems

Tachypnea and cough suggest the presence of lung disease. Pleurisy is possible. Cardiac involvement may include dysrhythmias due to fibrosis of the sinoatrial and atrioventricular nodes. This shows advanced disease and is the leading cause of death among patients with SLE. Inflammation can lead to pericarditis, myocarditis, and endocarditis. Hypertension and hypercholesterolemia from steroid use need aggressive treatment and careful monitoring. People with SLE are at risk for secondary *antiphospholipid syndrome*. This coagulation disorder causes clots in the arteries and veins. It increases the risk for stroke, gangrene, and heart attack.

Renal Problems

About 40% of persons with SLE develop kidney problems that need medical evaluation and treatment. Renal involvement is usually present within the first 5 years after diagnosis.[26] Manifestations vary from mild proteinuria to rapidly progressive glomerulonephritis.

Scarring and permanent damage can lead to end-stage renal disease (ESRD).

The main goal is to slow the progression of nephropathy and preserve renal function by managing the underlying disease. The need for a renal biopsy is controversial, but findings can help guide treatment. Effective treatments include corticosteroids, cytotoxic agents (cyclophosphamide), and immunosuppressive agents (azathioprine, cyclosporine, mycophenolate mofetil [CellCept]). Oral prednisone or pulsed IV methylprednisolone may be used, especially in the initial treatment period when cytotoxic agents have not yet taken effect.

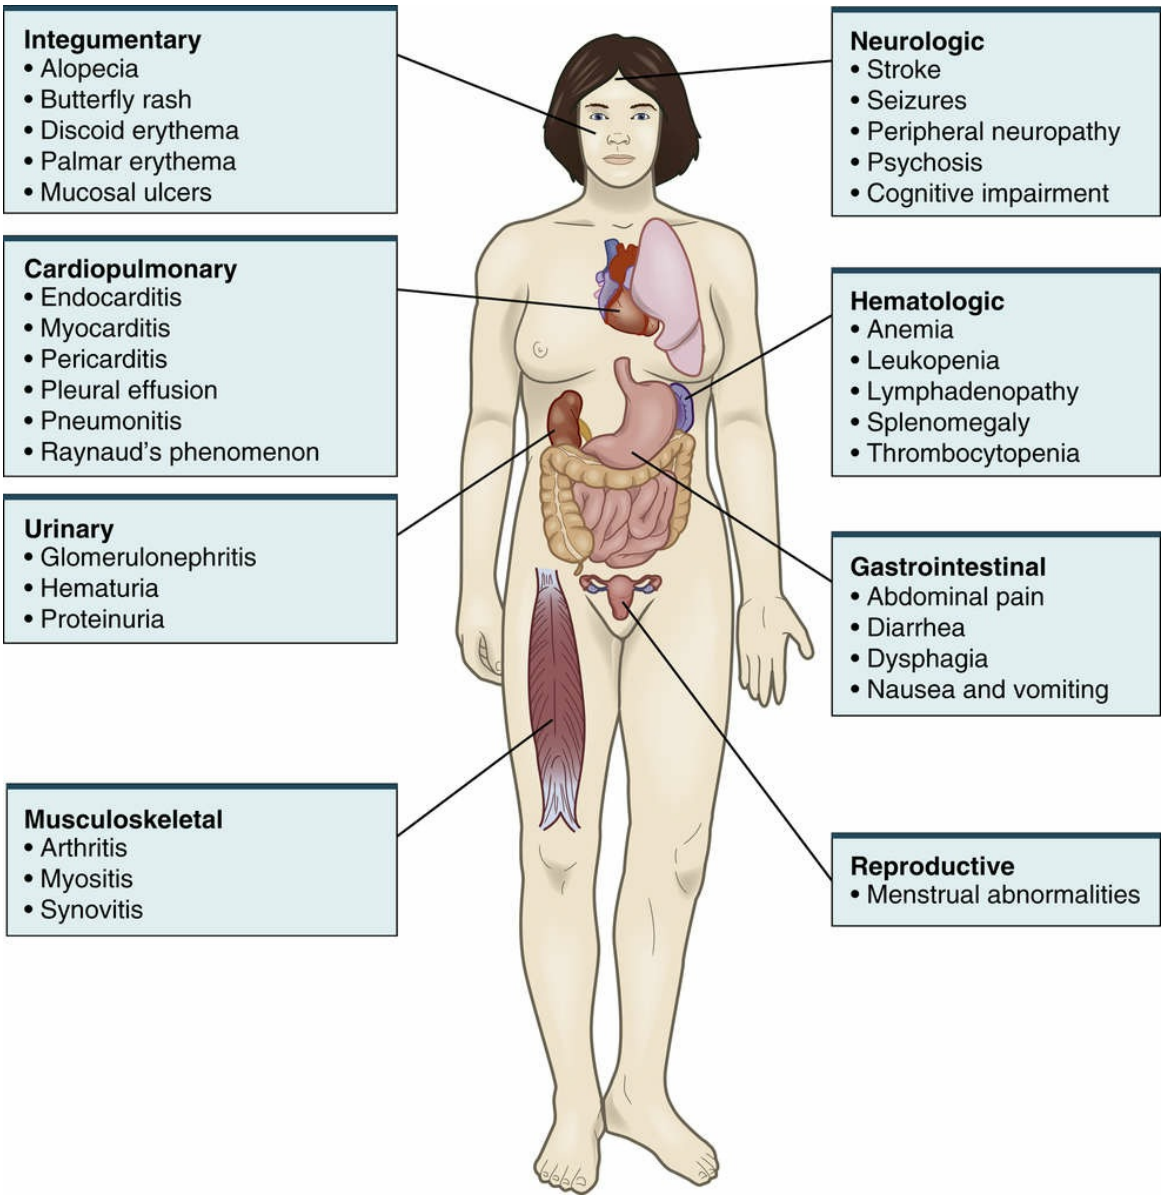

FIG. 64.9 Multisystem involvement in SLE.

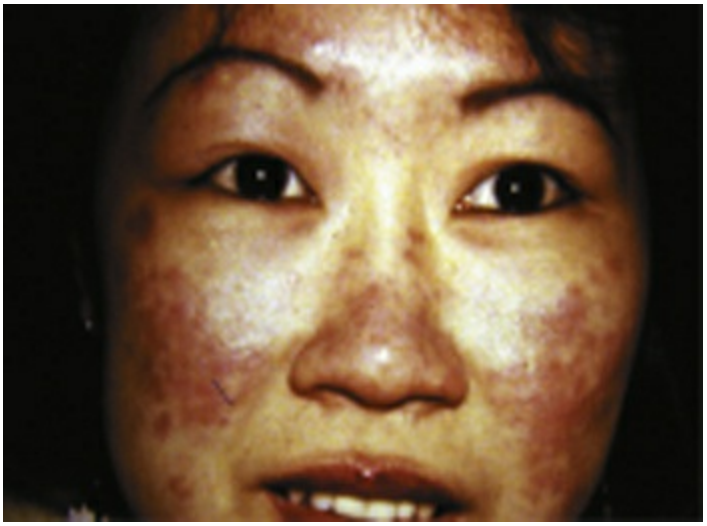

FIG. 64.10 Butterfly rash of SLE.
From Firestein GS, Budd RC, Gabriel SE, McInnes IB: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders.

Nervous System Problems

Neuropsychiatric manifestations are common in SLE. About 15% of patients with SLE have generalized-onset or focal-onset seizures. Seizures are generally controlled by corticosteroids or antiseizure drugs. Peripheral neuropathy can occur, leading to sensory and motor deficits.

Cognitive problems may result from the deposit of immune complexes within the brain. There may be disordered thinking, disorientation, and memory deficits. Various psychiatric problems may occur, including depression, mood disorders, anxiety, and psychosis. However, they may be related to the stress of having a major illness or to associated drug therapies. Sometimes SLE may cause a stroke or aseptic meningitis. Headaches are common and can become severe during a disease flare.

Hematologic Problems

Blood problems are common due to formation of antibodies against blood cells. Anemia, leukopenia, thrombocytopenia, and coagulation disorders (excess bleeding or clotting) are often present.[27] Many patients benefit from high-intensity treatment with warfarin.

Infection

Patients with SLE appear to have increased susceptibility to infection. Risk may be due to impaired ability to eliminate invading bacteria, deficient antibody production, and immunosuppressive effects of many antiinflammatory drugs. Pneumonia is the most common infection. Fever may indicate an underlying infection rather than SLE activity alone. Vaccinations are generally safe for patients with SLE. Patients receiving corticosteroids or cytotoxic drugs must avoid live virus vaccines.

Diagnostic Studies

Diagnosis of SLE is based on distinct criteria (Table 64.15). No specific test is diagnostic for SLE, but a variety of abnormalities may be present in the blood. SLE is marked by the presence of ANA in 97% of persons with the disease.[28]

TABLE 64.15 Diagnostic Criteria for Systemic Lupus Erythematosus

A person is classified as having SLE if 4 or more of the criteria are present, serially or simultaneously, during any interval of observation:

- Antinuclear antibody: abnormal titer
- Discoid rash: raised patches with scaling follicular plugging; scarring in older lesions
- Hematologic disorder: hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
- Immunologic disorder: anti-DNA antibody or antibody to Sm (Smith) nuclear antigen or positive antiphospholipid antibodies
- Malar rash: fixed erythema, flat or raised (butterfly rash)
- Oral ulcers: usually painless
- Nonerosive arthritis: 2 or more peripheral joints with tenderness,

swelling, effusion
- Pleuritis or pericarditis
- Neurologic disorder: seizures or psychosis (in the absence of causative drugs or known metabolic disorders)
- Photosensitivity: skin rash as unusual reaction to light
- Renal disorder: persistent proteinuria or cellular casts in urine

Source: American College of Rheumatology: 1997 Update of the 1982 American College of Rheumatology revised criteria for classification of systemic lupus erythematosus. Retrieved from *www.rheumatology.org/Portals/0/Files/1997%20Update%20of%201982%20*

Anti-DNA antibodies are found in half the persons with SLE. Anti-Smith (Sm) antibodies are found in 30% to 40% of persons with SLE and are almost always considered diagnostic. Nearly 30% of people with SLE will have antiphospholipid antibodies. Antibodies to histone are most often seen in people with drug-induced SLE. Increased ESR and CRP indicate inflammation but are not diagnostic of SLE. They may be used to monitor disease activity and treatment effectiveness.[28]

Interprofessional Care

A major challenge in the treatment of SLE is managing active disease while preventing complications of treatment. Age, race, sex, socioeconomic status, co-morbid conditions, and disease severity influence survival. Prognosis can be improved with early diagnosis, ongoing assessment and prompt recognition of serious organ involvement, and effective treatment plans.

Drug Therapy

NSAIDs continue to be an important intervention, especially for patients with mild joint pain. Monitor the patient on long-term NSAID therapy for GI and renal effects.

Antimalarial agents, such as hydroxychloroquine and chloroquine,

are often used to treat fatigue and skin and joint problems. They repress the immune system but do not cause immunosuppression. These drugs may reduce occurrence of flares. Patients taking hydroxychloroquine should have eye examinations by an ophthalmologist every 6 to 12 months. Retinopathy can develop with high doses of these drugs. It generally reverses when they are stopped. If the patient cannot tolerate an antimalarial agent, an antileprosy drug, such as dapsone, may be used.

Use of corticosteroids should be limited to the lowest dose for the shortest possible time. For example, steroids can be used for a few weeks until a slower acting medication becomes effective. Taper the patient's dose of steroid slowly rather than stopping the medication abruptly. High doses of corticosteroids may be especially appropriate for the patient with severe cutaneous SLE.

TABLE 64.16 Interprofessional CareSystemic Lupus Erythematosus

Diagnostic Assessment

- History and physical examination
- Antibodies (e.g., ANA, anti-DNA, anti-Sm, antiphospholipid)
- CBC count
- Serum complement
- Urinalysis
- X-ray of affected joints
- Chest x-ray
- ECG to determine cardiac involvement

Management

Drug Therapy

- NSAIDs for mild disease
- Steroid-sparing drugs (e.g., methotrexate)
- Antimalarials (e.g., hydroxychloroquine [Plaquenil])
- Corticosteroids for flares and severe disease
- Immunosuppressive drugs (e.g., cyclophosphamide, mycophenolate mofetil [CellCept])

Immunosuppressive drugs, such as azathioprine and cyclophosphamide, may be used to suppress the immune system and reduce end-organ damage. Monitor closely to decrease the risk for drug toxicity and side effects. Because blood clots can be a life-threatening complication of SLE, anticoagulants, such as warfarin, may be prescribed. Belimumab (Benlysta) is a B-lymphocyte stimulator that inhibits the inflammation of SLE.

Topical immunomodulators can be used instead of corticosteroids to treat serious skin conditions. Tacrolimus (Protopic, Prograf) and pimecrolimus (Elidel) suppress immune activity in the skin, affecting the butterfly rash and discoid lesions.

Disease management is appropriately monitored by serial anti-DNA titers and serum complement (Table 64.16). Simpler, less costly tests, such as ESR or CRP, may be helpful.

Nursing Management: Systemic Lupus Erythematosus

Nursing Assessment

Subjective and objective data to obtain from the patient with SLE are outlined in Table 64.17. In particular, assess the effect of pain and fatigue on ability to perform ADLs.

Nursing Diagnoses

Nursing diagnoses for the patient with SLE may include:

- Fatigue
- Impaired tissue integrity
- Difficulty coping

Additional information on nursing diagnoses and interventions for the patient with SLE is presented in eNursing Care Plan 64.2 (available on the website for this chapter).

Planning

Overall goals are that the patient with SLE will (1) have acceptable pain management, (2) show awareness of and avoid activities that worsen the disease, and (3) maintain optimal role function and positive self-image.

Nursing Implementation

The unpredictable nature of SLE presents many challenges for the patient and caregiver. Physical, psychologic, and sociocultural problems linked to long-term management require varied approaches and skills from the interprofessional team.

TABLE 64.17 Nursing AssessmentSystemic Lupus Erythematosus

Subjective Data

Important Health Information

Past health history: Exposure to ultraviolet light, drugs, chemicals, viral infections. Physical or psychologic stress. States of ↑ estrogen activity, including early onset of menses, pregnancy, and postpartum period. Pattern of remissions and flares

Medications: Oral contraceptives, procainamide, hydralazine,

isoniazid, antiseizure drugs, antibiotics, corticosteroids, NSAIDs

Functional Health Patterns

Health perception–health management: Family history of autoimmune disorders, frequent infections, malaise, impact of disease on functional ability
Nutritional-metabolic: Weight loss, oral and nasal ulcers, nausea and vomiting, dry mouth *(xerostomia),* dysphagia, photosensitivity with rash, frequent infections
Elimination: ↓ Urine output, diarrhea or constipation
Activity-exercise: Morning stiffness, joint swelling and deformity, shortness of breath *(dyspnea),* excessive fatigue
Sleep-rest: Insomnia
Cognitive-perceptual: Vision problems, vertigo, headache, arthralgia, chest pain (pericardial, pleuritic), abdominal pain. Painful, throbbing, cold fingers with numbness and tingling
Sexuality-reproductive: Amenorrhea, irregular menstrual periods
Coping–stress tolerance: Depression, withdrawal

Objective Data
General

Fever, lymphadenopathy, periorbital edema

Integumentary

Alopecia. Dry, scaly scalp. Keratoconjunctivitis, butterfly rash, palmar or discoid erythema, hives (urticaria), erythema at fingernails or toenails, purpura, or petechiae. Leg ulcers

Respiratory

Pleural friction rub, ↓ breath sounds

Cardiovascular

Vasculitis, pericardial friction rub, hypertension, edema, dysrhythmias, murmurs. Bilateral, symmetric pallor and cyanosis of fingers (Raynaud's phenomenon)

Gastrointestinal

Oral and pharyngeal ulcers; splenomegaly

Neurologic

Facial weakness, peripheral neuropathies, papilledema, dysarthria, confusion, hallucination, disorientation, psychosis, seizures, aphasia, hemiparesis

Musculoskeletal

Myopathy, myositis, arthritis

Urinary

Proteinuria

Possible Diagnostic Findings

	Presence of anti-DNA, anti-Sm, and antinuclear antibodies. Anemia, leukopenia, thrombocytopenia. ↑ ESR, ↑ serum creatinine. Microscopic hematuria, cellular casts in urine. Pericarditis or pleural effusion on chest x-ray

During a disease flare, the patient may quickly become very ill. Assess fever pattern, joint inflammation, limitation of motion, location and degree of discomfort, and fatigue. Monitor the patient's weight and fluid intake and output. This is especially important if corticosteroids are prescribed because of related fluid retention and possible renal failure. Collect 24-hour urine samples for protein and creatinine clearance as ordered. Observe for signs of bleeding due to drug therapy (e.g., pallor, skin bruising, petechiae, tarry stools).

Carefully assess neurologic function. Observe for vision problems, headaches, personality changes, seizures, and memory loss. Psychosis may result from CNS disease or be an effect of corticosteroid therapy. Nerve irritation of the extremities *(peripheral neuropathy)* may cause numbness, tingling, and weakness of the hands and feet.

Explain the nature of the disease, treatments, and all diagnostic procedures. When teaching patients about their prescribed drugs, include indications for use, proper administration, and side effects. Help patients understand that abruptly stopping a medication may worsen disease activity. Provide emotional support for the patient and caregiver, especially during a disease flare.

Emphasize the importance of patient involvement for successful home management. Help the patient understand that even strong adherence to the treatment plan is no guarantee against flares in this unpredictable disease. Several factors may increase disease activity, such as fatigue, sun exposure, emotional stress, infection, drugs, and surgery. Help the patient and caregiver eliminate or reduce exposure to such factors (Table 64.18).

TABLE 64.18 Patient & Caregiver

TeachingSystemic Lupus Erythematosus

Include the following information in the teaching plan for a patient with SLE and the caregiver:

- Disease process
- Names of drugs, actions, side effects, dosage, administration
- Pain management strategies
- Energy conservation and pacing techniques
- Therapeutic exercise, heat therapy for arthralgia
- Relaxation therapy
- Avoid physical and emotional stress
- Avoid exposure to those with infection
- Avoid drying soaps, powders, household chemicals
- Use sunscreen protection (at least SPF 15) and protective clothing, with minimal sun exposure from 11:00 AM to 3:00 PM
- Regular medical and laboratory follow-up
- Marital and pregnancy counseling as needed
- Community resources and health care agencies

SPF, Sun protection factor.

SLE and Pregnancy

Because SLE is most common in women of childbearing age, treatment during pregnancy must be considered. The HCP and obstetrician should discuss with the woman her desire to become pregnant. Infertility may have resulted from renal involvement and use of high-dose corticosteroids and immunosuppressive drugs. The patient should understand spontaneous abortion, stillbirth, and intrauterine growth restriction are common problems. They occur because immune complexes are deposited in the placenta and inflammation occurs in placental blood vessels.

Renal, cardiovascular, lung, and central nervous systems may be

affected during pregnancy. Women who already show serious effects in these systems should be counseled against pregnancy. For the best outcome, pregnancy should be planned when disease activity is minimal. Flares are common during the postpartum period. Therapeutic abortion offers the same risk for postdelivery exacerbation as carrying the fetus to term.

Psychosocial Issues

The patient with SLE may face many psychosocial issues. Disease onset and symptoms may be vague, and SLE may be undiagnosed for a long time. Supportive therapies may be as important as medical treatment in helping the patient cope with the disease. Tell the patient and caregiver that SLE has a good prognosis for most people.

Stress the importance of planning both recreational and work activities. The young adult may find sun restrictions and physical limitations hard to follow. Help the patient develop and achieve reasonable goals for improving or maintaining mobility, energy, and self-esteem.

Families worry about hereditary aspects and want to know if their children will have SLE. Many couples need pregnancy and sexual counseling. Those making decisions about marriage and careers worry how SLE will interfere with their plans. Teach employers, teachers, and co-workers as needed about the impact of SLE.

Evaluation

The expected outcomes are that the patient with SLE will

- Use energy-conservation techniques
- Adapt lifestyle to current energy
- Maintain skin integrity with use of topical treatments
- Prevent disease flare with use of sunscreens and limited sun exposure

Scleroderma

Scleroderma *(systemic sclerosis)* is a disorder of connective tissue characterized by fibrotic, degenerative, and, sometimes, inflammatory changes in the skin, blood vessels, synovium, skeletal muscle, and internal organs.

Scleroderma occurs in all ethnic groups. It is more common in blacks, Native Americans, and persons of Japanese descent. Although symptoms may begin at any age, the usual age at onset is between 30 and 50 years. Scleroderma is relatively rare. Only about 300,000 Americans have the disease. Incidence in women is 4 times more common than in men.[3]

Two types of disease exist: *localized scleroderma,* which is the more common form, and *systemic scleroderma*. Skin changes of localized disease are usually limited to a few places on the skin or muscle without involvement of the trunk or internal organs. The prognosis of patients with limited disease is better than for those with systemic disease. Skin and connective tissue changes progress rapidly during the first months of systemic scleroderma, which is associated with internal organ involvement.[29]

Etiology and Pathophysiology

The exact cause of scleroderma is unknown. We think immunologic and vascular abnormalities play a role in the development of systemic disease. Risk factors include environmental or occupational exposure to coal, plastics, and silica dust.

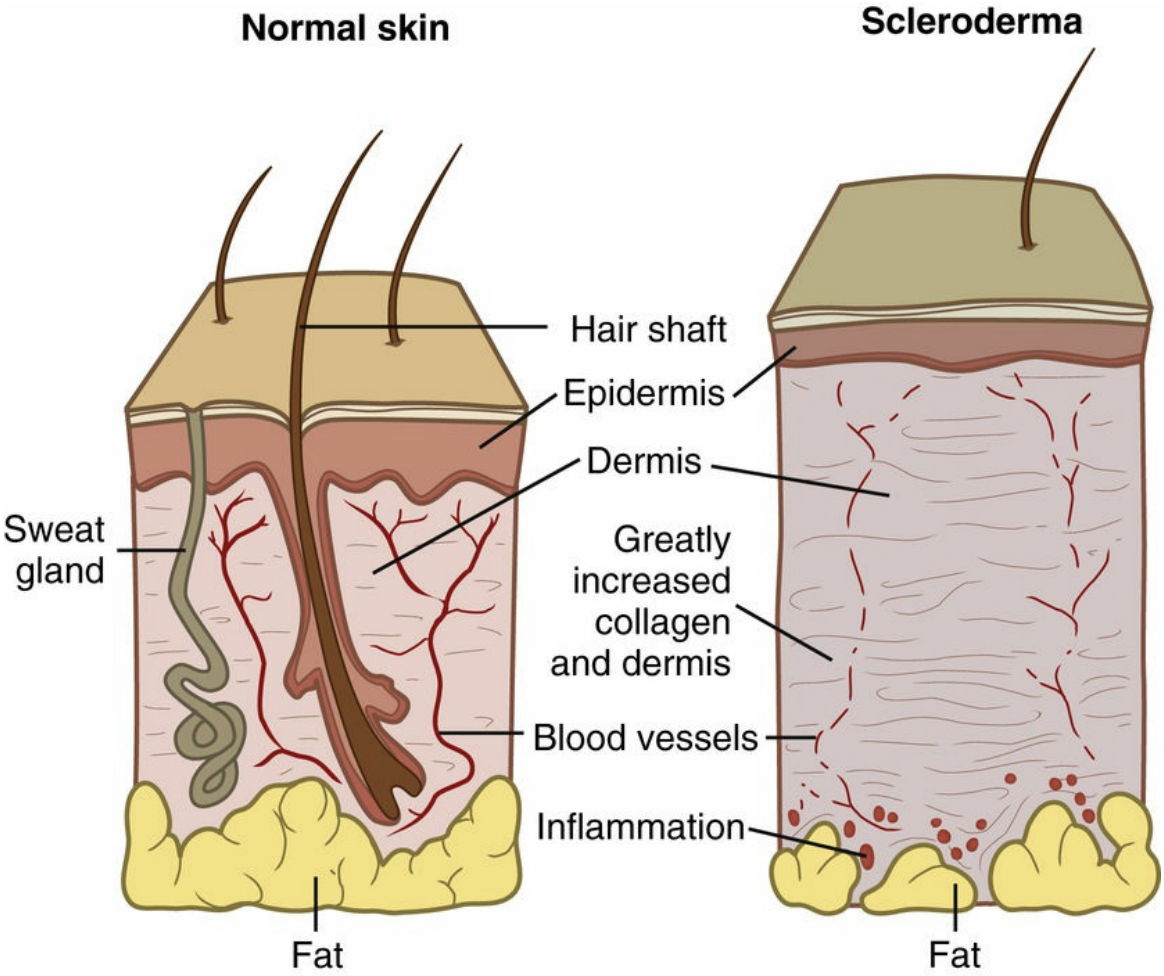

FIG. 64.11 Skin changes in scleroderma.

In scleroderma, the body makes too much collagen (protein that gives normal skin its strength and elasticity) (Fig. 64.11). This leads to progressive tissue fibrosis and occlusion of blood vessels. Collagen overproduction also disrupts normal function of internal organs, such as the lungs, kidney, heart, and GI tract.

Vascular problems, which mainly involve the small arteries and arterioles, are almost always present. These changes are some of the earliest changes in scleroderma.

Clinical Manifestations

Manifestations of scleroderma range from benign limited skin disease to diffuse skin thickening with rapidly progressive and widespread

organ involvement. Localized disease is often marked by the **CREST syndrome**:

Calcinosis: painful deposits of calcium in skin of fingers, forearms, pressure points
Raynaud's phenomenon: intermittent vasospasm of fingertips in response to cold or stress
Esophageal dysfunction: difficulty swallowing due to internal scarring
Sclerodactyly: tightening of skin on fingers and toes
Telangiectasia: red spots on hands, forearms, palms, face, and lips from capillary dilation

Raynaud's Phenomenon

Raynaud's phenomenon (sudden vasospasm of the digits) is the most common first complaint in localized scleroderma. Patients have decreased blood flow to the fingers and toes when exposed to cold *(blanching or white phase).* This is followed by cyanosis as hemoglobin releases O_2 to the tissues *(blue phase),* then erythema during rewarming *(red phase).* Numbness and tingling often occur. Raynaud's phenomenon may precede the onset of systemic disease by months, years, or even decades. Raynaud's phenomenon is described in detail in Chapter 37.

Skin and Joint Changes

Symmetric painless swelling or thickening of the skin of the fingers and hands may progress to diffuse scleroderma of the trunk. In localized disease, skin thickening generally does not extend above the elbow or knee, although the face may be affected. In diffuse disease, the skin loses elasticity and becomes taut and shiny. This causes the typical expressionless face with tightly pursed lips. Skin changes in the face may contribute to reduced ROM in the temporomandibular joint. The fingers may stay in a semiflexed position *(sclerodactyly),* with tightened skin to the wrist (Fig. 64.12). Reduced peripheral joint

function may be an early symptom of arthritis.

FIG. 64.12 Sclerodactyly in the hand of a patient with scleroderma. From Zitelli BJ, Davis HW: *Atlas of pediatric physical diagnosis,* ed 4, St Louis, 2002, Mosby.

Internal Organ Involvement

About 20% of people with systemic scleroderma and a few with localized disease develop secondary Sjögren's syndrome, a condition associated with dry eyes and dry mouth. Dysphagia, gum disease, and dental decay can result. Frequent reflux of gastric acid can occur due to esophageal fibrosis. If swallowing becomes difficult, the patient is likely to decrease food intake and lose weight. GI effects include constipation from colonic hypomotility and diarrhea due to malabsorption from bacterial overgrowth.

Lung problems include pleural thickening, pulmonary fibrosis, and abnormal pulmonary function. The patient develops a cough and dyspnea. Pulmonary arterial hypertension and interstitial lung disease may occur. Lung disease is the main cause of death in scleroderma.

Heart disease includes pericarditis, pericardial effusion, and dysrhythmias. Heart failure from myocardial fibrosis occurs most

often in patients with systemic disease.

Renal disease was a major cause of death in systemic scleroderma. Because malignant hypertension associated with rapidly progressive, irreversible renal insufficiency can occur, early recognition of renal involvement and initiation of therapy are critical. Recent improvements in dialysis, bilateral nephrectomy in patients with uncontrollable hypertension, and kidney transplant have offered hope to patients with renal failure. Use of angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril [Prinivil]) has had a marked effect on the ability to treat renal disease.

Diagnostic Studies

Laboratory results in scleroderma are relatively normal. Blood studies may show mild hemolytic anemia from RBC damage in diseased small vessels. Anticentromere antibodies related to CREST syndrome are found in about 45% to 50% of people with localized scleroderma. They are rare in people with systemic disease. Antibodies to topoisomerase-1 are present in about 30% of people with diffuse disease.[30] Presence of either antibody is highly specific for diagnosis. If renal involvement is present, urinalysis may show proteinuria, microscopic hematuria, and casts. Serum creatinine may be increased. X-ray evidence of subcutaneous calcification, distal esophageal hypomotility, or bibasilar pulmonary fibrosis is diagnostic of scleroderma. Pulmonary function studies show decreased vital capacity and lung compliance.

TABLE 64.19 Interprofessional CareScleroderma

Diagnostic Assessment

- History and physical examination
- Antibodies to topoisomerase-1

- Anticentromere antibody
- Nail bed capillary microscopy
- Chest x-ray
- Skin or organ biopsy
- Urinalysis (proteinuria, hematuria, casts)
- Pulmonary function tests
- ECG

Management

- Physical therapy
- Occupational therapy

Drug Therapy

- Vasoactive agents: reserpine, bosentan, epoprostenol
- Calcium channel blockers: diltiazem, nifedipine
- ACE inhibitors: lisinopril (Prinivil)
- Immunosuppressive drugs: cyclophosphamide, mycophenolate mofetil (CellCept)

Interprofessional Care

There is no specific treatment (Table 64.19). Supportive care is directed toward preventing or treating secondary complications of involved organs. PT helps to maintain joint mobility and preserve muscle strength. Occupational therapy assists the patient in maintaining functional abilities.

Drug Therapy

Vasoactive agents are often prescribed in early disease. Calcium channel blockers (nifedipine [Procardia], diltiazem [Cardizem]) and

the angiotensin II blocker losartan are common treatments for Raynaud's phenomenon. Reserpine, an α-adrenergic blocking agent, increases blood flow to the fingers. Bosentan (Tracleer), an endothelin-receptor antagonist, and the vasodilator epoprostenol (Flolan) may improve blood flow to the lung.[31]

NSAIDs and topical agents may give some relief from joint pain. Capsaicin cream may be useful, not only as a local analgesic but also as a vasodilator. Other therapies prescribed to treat specific systemic problems include (1) tetracycline for diarrhea caused by bacterial overgrowth, (2) histamine (H_2) receptor blockers (e.g., cimetidine) and proton pump inhibitors (e.g., omeprazole) for esophageal symptoms, and (3) antihypertensive agent (e.g., captopril, propranolol, methyldopa) for hypertension with renal involvement. Immunosuppressive drugs (e.g., cyclophosphamide, mycophenolate mofetil) are used in severe cases.

Nursing Management: Scleroderma

Nursing interventions often begin during hospitalization for diagnosis. Assess vital signs, weight, intake and output, respiratory and bowel function, and joint ROM regularly to plan appropriate care. Emotional stress and cold ambient temperatures may aggravate Raynaud's phenomenon. Teach patients with scleroderma to avoid finger-stick blood testing because of compromised circulation and poor healing.

Teaching is an important nursing intervention throughout the disease. Obvious changes in the face and hands often lead to poor self-image and loss of mobility and function. Teach the patient to regularly take part in therapeutic exercises at home to prevent skin retraction and promote vascularization. Mouth excursion (yawning with an open mouth) is a good exercise to help with temporomandibular joint function. Isometric exercises are best if the patient has arthropathy because no joint movement occurs. Encourage the use of moist heat applications or paraffin baths to promote skin flexibility in the hands and feet. Teach the patient to use assistive devices as needed and

organize activities to preserve strength and reduce disability.

Teach the patient to protect the hands and feet from cold exposure. Protect against burns or cuts that may heal slowly. Encourage the patient to avoid smoking because of its vasoconstricting effect. Report signs of infection promptly. Use alcohol-free lotions to improve skin dryness and cracking. They must be rubbed in for a long time to be absorbed through the thick skin.

Remind the patient to reduce dysphagia by eating small, frequent meals, chewing carefully and slowly, and drinking fluids. A consultation with a dietitian is helpful. Decrease risk for heartburn by using antacids 45 to 60 minutes after each meal and sitting upright for at least 2 hours after eating. Using extra pillows or raising the head of the bed on blocks may reduce gastroesophageal reflux during the night.

Job alterations are often needed due to problems with climbing stairs, using a computer, writing, and being exposed to cold. The patient may be socially withdrawn as skin tightening changes the appearance of the face and hands. Dining out may become socially embarrassing because of the patient's small mouth, swallowing difficulty, and reflux. Some persons with scleroderma wear gloves to protect fingertip ulcers and provide extra warmth. Emphasize daily oral hygiene to avoid increased tooth and gum problems. The patient needs a dentist who is familiar with scleroderma and able to adapt care to a small mouth.

Psychologic support, biofeedback training, and relaxation can reduce stress and improve sleeping habits. Sexual problems from body changes, pain, muscular weakness, limited mobility, decreased self-esteem, erectile dysfunction, and decreased vaginal secretions may require sensitive counseling.

Check Your Practice

A 34-yr-old woman hospitalized for aspiration pneumonia has a 5-year history of scleroderma.

- How could scleroderma have contributed to the aspiration pneumonia?
- What strategies will you suggest to decrease the risk for pneumonia recurrence?
- What other self-care strategies will you reinforce with this patient?

Polymyositis and Dermatomyositis

Polymyositis (PM) is diffuse, idiopathic, inflammatory myopathy of striated muscle. It causes bilateral weakness, usually most severe in the proximal or limb girdle muscles. When muscle changes associated with PM are accompanied by distinctive skin changes, the disorder is called **dermatomyositis (DM)**.

These relatively rare disorders can be similar in signs, symptoms, and treatment, but they are 2 distinct diseases. They typically affect adults age 20 years and older. They rarely occur in people under age 18 years. PM and DM occur twice as often in women as in men. Patients with PM generally have more severe disease than those with DM.

FIG. 64.13 Dermatomyositis skin changes indicating Gottron's papules.
From Firestein GS, Budd RC, Gabriel SE, McInnes IB: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2012, Saunders.

Etiology and Pathophysiology

The exact cause of PM and DM is unknown. Evidence suggests an autoimmune origin with T cell–mediated destruction of unidentified muscle antigens. Environmental factors are likely, including viral and bacterial infection, certain drugs, supplements, vaccines, medical implants, and occupational exposure.

Clinical Manifestations and Complications

Muscular

The patient with PM and DM has weight loss and increasing fatigue, with gradually developing muscle weakness that causes difficulty in performing ADLs. The most commonly affected muscles are in the shoulders, legs, arms, and pelvic girdle. The patient may have difficulty rising from a chair or bathtub, climbing stairs, combing hair, or reaching into a high cupboard. Repetitive movements are more

likely to cause trouble than a single strength exercise. The patient may be unable to raise the head from a pillow as neck muscles weaken. Muscle discomfort or tenderness is uncommon. Muscle examination shows an inability to move against resistance or even gravity. Weak pharyngeal muscles may cause dysphagia and dysphonia (nasal or hoarse voice).

Dermal

Rashes are typical with DM. They usually prompt earlier recognition of DM than PM, which has no rashes. Skin changes of DM include a classic red or purple symmetric rash *(heliotrope)* with edema around the eyelids. The typical skin rash is not often found with other disorders. A scaly, smooth, or raised rash may be seen on the knuckles and sides of the hands *(Gottron's papules)* (Fig. 64.13). Reddened, smooth, or scaly patches appear with the same symmetric distribution but sparing the interphalangeal spaces *(Gottron's sign)*. The rash can be confused with psoriasis or seborrheic dermatitis. A red, scaling rash *(poikiloderma)* may develop as a late finding on the back, buttocks, and a V-shaped area of the anterior neck and chest.

Hyperemia and telangiectasia are often present at the nail beds. Calcium nodules *(calcinosis cutis)* can develop throughout the skin and are especially common in long-standing DM.

Other Manifestations

Joint redness, pain, and inflammation often occur. They contribute to limited joint ROM in PM and DM. Contractures and muscle atrophy may occur with advanced disease. Weakened pharyngeal muscles can lead to poor cough effort, difficulty swallowing, and increased risk for aspiration pneumonia. Interstitial lung disease is a common complication. All patients should be evaluated routinely with a chest x-ray and pulmonary function tests. People with DM have increased risk for cancer and should receive age- and gender-appropriate screenings. PM and DM may be associated with other connective tissue disorders (e.g., scleroderma).

Diagnostic Studies

Biopsy is the gold standard for diagnosis of PM or DM after other neuromuscular diseases are excluded. Muscle biopsy shows necrosis, degeneration, regeneration, and fibrosis with pathologic findings distinct for DM or PM. MRI can identify areas of inflammation and guide the biopsy site selection.[32] Laboratory tests are helpful, but not diagnostic of either disease. Increased muscle enzymes (e.g., creatine kinase, myoglobin) reflect muscle damage but will decrease to normal or near normal with treatment. An EMG suggestive of PM shows bizarre high-frequency discharges and spontaneous fibrillation, with positive spikes at rest. Increased ESR or CRP occurs with active disease.

Interprofessional and Nursing Care

PM and DM are treated initially with high-dose oral corticosteroids, with the dose tapered based on patient response. Most patients respond well to treatment. Long-term corticosteroid therapy may be needed because relapses are common when the drug is withdrawn.

Immunosuppressive drugs (methotrexate, azathioprine, tacrolimus, cyclophosphamide) may be used in combination with steroids or as a second-line therapy if the patient does not respond to steroids. IV immunoglobulin (IVIG) may be given with corticosteroids or immunosuppressants, but it is not a first-line treatment.

Drug Alert

IV Immunoglobulin (IVIG)

- Give by slow infusion to decrease risk for thromboembolic complications.
- Hydrate patient well during infusion to decrease risk for renal

failure.

- Treat transient adverse effects, such as headache.

Injection of synthetic ACTH (repository corticotropin injection [Acthar]) helps with muscle spasms. The exact mechanism of action is unknown. Limited data are available on its effectiveness.[32]

PT can be helpful and is tailored to disease activity. Use massage and passive movement during active disease. Delay more aggressive exercises until disease activity is minimal based on low serum muscle enzymes.

Teach the patient about the disease, prescribed therapies, diagnostic tests, and the need for regular medical care. Help the patient understand that the benefits of therapy are often delayed. For example, weakness may increase during the first few weeks of corticosteroid therapy. Encourage the use of assistive devices to decrease risk for falls. To prevent aspiration, encourage the patient to rest before meals, maintain an upright position when eating, and choose easily swallowed foods.

Help the patient to organize activities and use pacing techniques to conserve energy. Encourage daily ROM exercises to prevent contractures. When inflammation is decreased, start muscle-strengthening (repetitive) exercises. Home care and bed rest may be needed during acute PM, when the patient may not be able to complete ADLs because of profound muscle weakness.

Mixed Connective Tissue Disease

Patients having a combination of clinical features of several rheumatic diseases are described as having *mixed connective tissue disease.* The term describes a disorder with features primarily of SLE, scleroderma, and PM. This disease occurs most often in women in their 20s and 30s.

About 25% of persons with a connective tissue disease develop another related disease over the course of several years, which is known as *overlap syndrome*.[33]

Sjögren's Syndrome

Sjögren's syndrome is a relatively common autoimmune disease that targets the moisture-producing exocrine glands. This leads to *xerostomia* (dry mouth) and *keratoconjunctivitis sicca* (dry eyes).[34] The nose, throat, airways, and skin can become dry. The disease may affect other glands, including those in the stomach, pancreas, and intestines (extraglandular involvement). The disease is usually diagnosed in people over age 40 but can be found in all age-groups. Women are 10 times more likely than men to have Sjögren's syndrome.

In primary Sjögren's syndrome, problems occur with lacrimal and salivary glands. However, up to 40% of patients have extended disease affecting the lungs, liver, kidneys, and skin. This occurrence increases the risk for non-Hodgkin's lymphoma.[34]

Sjögren's syndrome appears to be caused by genetic and environmental factors. A particular gene predisposes whites to the disease. Other genes are linked to the disease in people of Japanese, Chinese, and African-American ethnicity. The trigger may be a viral or bacterial infection that adversely stimulates the immune system. In Sjögren's syndrome, lymphocytes attack and damage the lacrimal and salivary glands.

Decreased tearing causes dry eyes, which leads to a gritty sensation in the eyes, burning, blurred vision, and photosensitivity. Dry mouth causes buccal membrane fissures, changes in taste, dysphagia, and increased mouth infection or dental decay. Dry skin and rashes, joint and muscle pain, and thyroid problems may be present. Other exocrine glands can be affected. For example, vaginal dryness may lead to painful intercourse *(dyspareunia).*

Autoimmune thyroid disorders, including Graves' disease and Hashimoto's thyroiditis, are common with Sjögren's syndrome. Histologic study shows lymphocyte infiltration of salivary and lacrimal glands. The disease may become more generalized and involve the lymph nodes, bone marrow, and visceral organs (pseudolymphoma).

Ophthalmologic examination (Schirmer's test for tear production),

measures of salivary gland function, and lower lip biopsy of minor salivary glands aid in diagnosis. Treatment is symptomatic, including (1) instillation of preservative-free artificial tears or ophthalmic antiinflammatory drops (e.g., cyclosporine [Restasis]) as needed for adequate hydration and lubrication, (2) surgical punctal occlusion, and (3) increased fluids with meals. Dental hygiene is important.

Pilocarpine (Salagen) and cevimeline (Evoxac) can ease the dry mouth. Increased humidity at home may reduce respiratory tract infections. Vaginal lubrication with a water-soluble product, such as K-Y Jelly, may increase comfort during intercourse.

Safety Alert

Sjögren's Syndrome

To help with chewing and swallowing:

- Moisten food with mayonnaise, sauces, gravy, or yogurt.
- Thin foods with skim milk or broth.
- Use a food processor or blender to finely chop or liquefy foods.
- Try soft, creamy foods (e.g., mashed potatoes, macaroni and cheese).
- Drink high-calorie cold liquids (e.g., breakfast drinks).
- Avoid salty, acidic, or spicy foods.

Myofascial Pain Syndrome

Myofascial pain syndrome is a chronic form of muscle pain and tenderness, typically in the chest, neck, shoulders, hips, and lower back. Referred pain from these muscle groups can travel to the buttocks, hands, and head, causing severe headaches. Temporomandibular joint pain may originate in myofascial pain. Regions of pain are often within the connective tissue *(fascia)* that

covers skeletal muscles. Trigger or tender points are thought to activate a characteristic pattern of pain that worsens with activity or stress.

Myofascial pain syndrome occurs more often in middle-aged adults and in women. Patients report deep, aching pain with a sensation of burning, stinging, and stiffness.

A typical PT treatment is the "spray and stretch" method. The painful area is iced or sprayed with a coolant, such as ethyl chloride and then stretched. Positive results have been seen with topical patches and injection of the trigger points with a local anesthetic (e.g., 1% lidocaine). Massage, dry needling, and ultrasound therapy have helped some patients.[35]

Fibromyalgia

Fibromyalgia is a chronic central pain syndrome marked by widespread, nonarticular musculoskeletal pain and fatigue with multiple tender points. Fibromyalgia is a common musculoskeletal disorder and a major cause of disability. It affects more than 3.7 million Americans. Most are women ages 40 to 75 years.[36] Fibromyalgia and systemic exertion intolerance disease (SEID) (formerly called chronic fatigue syndrome) share many common features (Table 64.20).

Etiology and Pathophysiology

Fibromyalgia involves abnormal central processing of nociceptive pain input. The increased pain is due to abnormal sensory processing in the CNS. Multiple physiologic abnormalities have been found. They include (1) increased levels of substance P in the spinal fluid, (2) low blood flow to the thalamus, (3) dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis, (4) low serotonin and tryptophan, and (5) abnormal cytokine function. Serotonin and substance P play a role in mood regulation, sleep, and pain perception. Changes in the HPA axis can negatively affect a person's physical and mental health. An

increased incidence of depression and decreased response to stress occur. Genetic factors contribute to the development of fibromyalgia, as a familial tendency exists. Recent illness or trauma may be a trigger in susceptible people.

TABLE 64.20 Common Features of Fibromyalgia and Systemic Exertion Intolerance Disease (SEID)

Occurrence

Previously healthy, young and middle-aged women

Etiology (Theories)

Infectious trigger, dysfunction in HPA axis, CNS problem

Clinical Manifestations

Generalized musculoskeletal pain, malaise and fatigue, cognitive problems, headaches, sleep problems, depression, anxiety, fever

Disease Course

Variable intensity of symptoms, fluctuates over time

Diagnosis

No definitive laboratory tests or joint and muscle examinations
Mainly a diagnosis of exclusion

Management

Symptomatic treatment may include antidepressant drugs, such as amitriptyline and fluoxetine (Prozac).
Nondrug measures include heat, massage, regular stretching, biofeedback, stress management, and relaxation training

HPA, Hypothalamic-pituitary-adrenal.

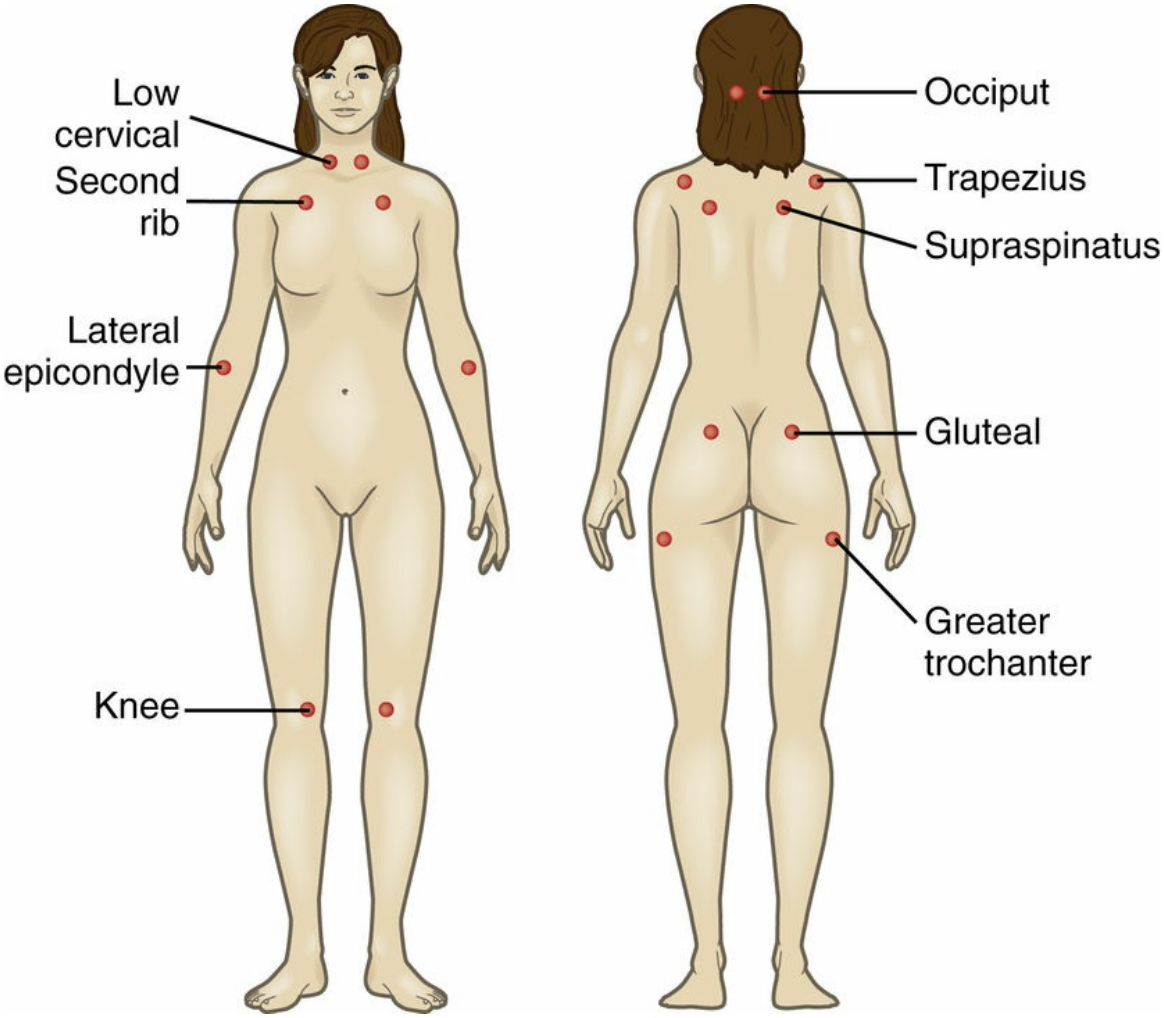

FIG. 64.14 Tender points in fibromyalgia.

Clinical Manifestations and Complications

The patient reports widespread burning pain that fluctuates through the course of a day. The patient often cannot determine if pain occurs in the muscles, joints, or soft tissues. Head or facial pain often results from stiff or painful neck and shoulder muscles. The pain can accompany temporomandibular joint dysfunction, which affects about one third of patients with fibromyalgia.

Physical examination typically shows point tenderness at 11 or more of 18 identified sites (Fig. 64.14). Patients with fibromyalgia are sensitive to painful stimuli throughout the body, not just at the identified tender sites. They may have pain in response to a stimulus that does not typically cause pain *(allodynia).* Point tenderness can vary from day to day. Sometimes, the patient may respond to fewer than 11 tender points. At other times, palpation of all sites may cause pain.

Cognitive effects range from difficulty concentrating to memory lapses and a feeling of being overwhelmed when dealing with multiple tasks. Many report migraine headaches. Depression and anxiety often occur and may require drug therapy. Stiffness, nonrefreshing sleep, fatigue, and numbness or tingling in the hands or feet often accompany fibromyalgia. Restless legs syndrome is typical. Some describe an irresistible urge to move the legs when at rest or lying down.

Irritable bowel syndrome with constipation and/or diarrhea, abdominal pain, and bloating is common. Patients may have difficulty swallowing, perhaps because of problems in esophageal smooth muscle function. Increased frequency of urination and urinary urgency, in the absence of a bladder infection, may occur. Women with fibromyalgia may have more difficult menstruation, with disease symptoms worse during this time.

Diagnostic Studies

A definitive diagnosis of fibromyalgia is often hard to establish. Lack of knowledge about the disease and its manifestations among HCPs

may cause delays in diagnosis and treatment.

Laboratory results in most cases help rule out other suspected disorders. Muscle biopsy may show a nonspecific moth-eaten appearance or fiber atrophy.

The ACR classifies a person as having fibromyalgia if 2 criteria are met: (1) pain is experienced in 11 of the 18 tender points on palpation (Fig. 64.14) and (2) a history of widespread pain is noted for at least 3 months.[37] Widespread pain is defined as pain that occurs on both sides of the body and above and below the waist. Fatigue, cognitive symptoms, and extensive somatic symptoms are considered in establishing a diagnosis.

A more recent ACR classification uses non–tender point diagnostic criteria as an alternative method of diagnosis. A symptom severity scale and a widespread pain index are used to identify disease characteristics.[38] This classification should be used with the earlier ACR criteria.

Interprofessional and Nursing Care

Treatment is symptomatic and requires a high level of patient motivation. Teach the patient to be an active participant in treatment. Rest can help the pain, aching, and tenderness.

Drug therapy for the chronic widespread pain includes pregabalin (Lyrica), duloxetine (Cymbalta), and milnacipran (Savella). Low-dose tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), or benzodiazepines (e.g., diazepam) may be prescribed. SSRI antidepressants (e.g., sertraline [Zoloft], paroxetine [Paxil]) tend to be reserved for patients who also have depression. SSRIs may have to be prescribed at higher doses than when used to treat depression. Antidepressants and muscle relaxants (e.g., baclofen) have sedative effects that can improve nighttime rest for the patient with fibromyalgia.

Long-acting opioids are not recommended unless other therapies are not successful. In some patients, pain may be managed with OTC analgesics, such as acetaminophen, ibuprofen, or naproxen (Aleve).

Nonopioids, such as tramadol (Ultram), may be used. Zolpidem (Ambien) or trazodone is sometimes given for short-term intervention in patients with severe sleep problems.

Because of the chronic nature of fibromyalgia, the patient needs consistent support from interprofessional team members. Massage is often combined with ultrasound or use of alternating heat and cold packs to soothe tense, sore muscles and increase blood circulation. Gentle stretching to relieve muscle tension and spasm can be done by a physical therapist or practiced by the patient at home. Yoga and Tai Chi are often helpful. Low-impact aerobic exercise, such as walking, can help prevent muscle atrophy.

Patients may consider limiting intake of sugar, caffeine, and alcohol because they may be muscle irritants. Vitamin and mineral supplements may help combat stress, correct deficiencies, and support the immune system. However, unproven miracle diets or supplements should be carefully investigated by the patient and discussed with the HCP before using them. Teach the patient that some foods and supplements can cause serious or even dangerous side effects when mixed with certain drugs.

Pain and the related symptoms of fibromyalgia can cause significant stress. Patients with fibromyalgia may not cope well with stress. Effective relaxation strategies include biofeedback, imagery, meditation, and cognitive-behavioral therapy. Patients need initial training for these interventions, but they can continue to practice in their own homes. (Stress management is discussed in Chapter 6.) Psychologic counseling (individual or group) and a support group may be helpful.

Systemic Exertion Intolerance Disease (SEID)

Systemic exertion intolerance disease (SEID), formerly called *chronic fatigue syndrome*, is a serious, complex, multisystem disease in which exertion of any sort (physical, emotional, cognitive) is impaired and

accompanied by profound fatigue.[39] SEID is a poorly understood condition that can have a devastating impact on the lives of patients and their families.

SEID affects at least 1 million people in the United States. The condition is 3 to 4 times more common in women than men. SEID occurs in all ethnic and socioeconomic groups, but the illness is more common in minorities and socioeconomically disadvantaged groups. The true prevalence of SEID is unknown because many people with the disease have not been diagnosed.[39]

Etiology and Pathophysiology

Despite efforts to determine the cause and pathology of SEID, we do not know the cause. Many theories exist about the cause of SEID. Neuroendocrine abnormalities have been implicated involving a hypofunction of the HPA axis and hypothalamic-pituitary-gonadal (HPG) axis, which together regulate the stress response and reproductive hormone levels. Several microorganisms have been investigated as causative agents, including herpes viruses (e.g., Epstein-Barr virus [EBV], cytomegalovirus [CMV]), retroviruses, enteroviruses, *Candida albicans,* and mycoplasma. Because many patients have cognitive deficits (e.g., decreased memory, attention, concentration), changes in the CNS have been suggested as the cause of SEID.

Clinical Manifestations

Diagnosis of SEID requires that the patient have the following 3 symptoms

1. Impaired function with profound fatigue lasting at least 6 months
2. Malaise after exertion: total exhaustion after even minor physical or mental exertion that the patient sometimes describes as a “crash”

3. Unrefreshing sleep

At least 1 of the following manifestations is also required:

1. Cognitive impairment ("brain fog," confusion)
2. *Orthostatic intolerance* (lightheadedness, dizziness, imbalance, fainting)

Severe fatigue is the most common symptom and the problem that causes the patient to seek health care.

SEID is often hard to distinguish from fibromyalgia because many clinical features are similar (Table 64.20). In about half the cases, SEID develops slowly, or the patient may have periodic episodes that gradually become chronic. SEID can arise suddenly in a previously active, healthy person. An unremarkable flu-like illness or other acute stress is often identified as a trigger. Associated symptoms may vary in intensity over time.

The patient may become angry and frustrated with HCPs who cannot diagnose a problem. The disorder may have a major impact on work and family responsibilities. Some people may need help with ADLs.

Diagnostic Studies

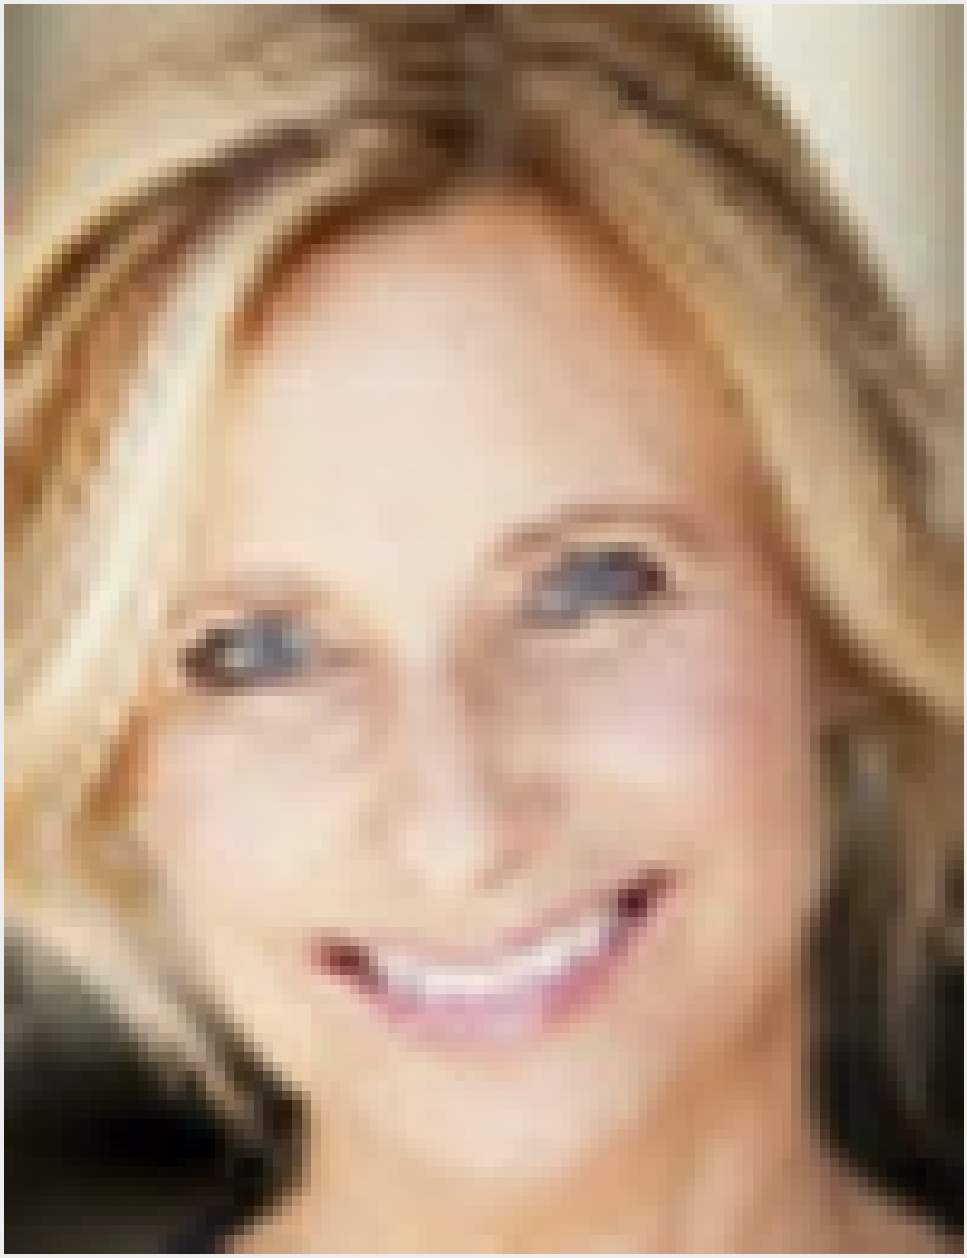
Physical examination and diagnostic studies can be used to rule out other possible causes of the patient's symptoms. No laboratory test can diagnose SEID or measure its severity. SEID is a diagnosis of exclusion.

Interprofessional and Nursing Care

Because no definitive treatment exists for SEID, supportive management is essential. Tell the patient what we know about the disease.

NSAIDs can be used to treat headaches, muscle and joint aches, and

fever. Because many patients with SEID have allergies and sinusitis, antihistamines and decongestants can be used to treat allergic symptoms. Tricyclic antidepressants (e.g., doxepin, amitriptyline) and SSRIs (e.g., fluoxetine, paroxetine) can improve mood and sleep. Clonazepam (Klonopin) can be used to treat sleep problems and panic disorders. Use of low-dose hydrocortisone to decrease fatigue and disability is being studied.



Teach the patient to avoid total rest because it can create a self-image of the patient as an invalid. On the other hand, strenuous exertion can worsen the exhaustion. Urge the patient to plan a carefully graduated exercise program. Encourage a well-balanced diet, including fiber and fresh dark-colored fruits and vegetables for antioxidant action. Behavioral therapy may be used to promote a positive outlook and improve overall disability and fatigue.

One major problem facing many patients is loss of livelihood and economic security. When the illness strikes, they cannot work or must decrease the amount of work. Loss of a job often leads to loss of medical insurance. Obtaining disability benefits can be frustrating because of the difficulty of establishing a definitive diagnosis of SEID. Patients with SEID may have severe psychosocial losses, including social pressure and isolation from being labelled as lazy or crazy.

SEID does not appear to progress. Although most patients recover or at least gradually improve, some do not show substantial improvement. Recovery is more common in persons with a sudden onset of SEID.

Case Study

Rheumatoid Arthritis

© iStockphoto/Thinkstock.

Patient Profile

K.R., a 42-yr-old married white woman, comes to the rheumatology clinic with tenderness and pain in the small joints of her hands.

Subjective Data

- Reports tenderness, joint pain, and stiffness in her hands for the last 3 mo

- Having fatigue, anorexia, and morning stiffness
- Mother diagnosed with ankylosing spondylitis 8 yr ago
- Expresses doubt about her ability to manage the disease

Objective Data
Physical Examination

- Swelling, warmth, and tenderness of third and fourth metacarpophalangeal joints of both hands
- Mild pain with neck motion
- Tenosynovitis

Diagnostic Studies

- Positive ESR, RF, and anti-CCP
- Mild bone demineralization present bilaterally in hand x-rays

Interprofessional Care

- Diagnosed with RA
- Started on methotrexate 7.5 mg PO once per week, etanercept (Enbrel) 50 mg subcutaneously once per week, prednisone 10 mg/day

Discussion Questions

1. How will you explain the pathophysiology of RA to K.R.?
2. K.R. asks you if genetic factors are related to a diagnosis of RA. How will you respond?
3. ***Safety:*** What are some home and work modifications you can suggest to K.R. to reduce her symptoms?

4. ***Patient-Centered Care:*** What suggestions can you make to K.R. about coping with fatigue?
5. ***Collaboration:*** What referrals may be needed for K.R.?
6. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
7. ***Quality Improvement***: What outcomes would indicate interprofessional care was effective?
8. ***Evidence-Based Practice:*** Why is an exercise program important in the treatment plan for K.R.?
9. Develop a conceptual care map for K.R.

Answers and a corresponding conceptual care map are available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In assessing the joints of a patient with osteoarthritis, the nurse understands that Bouchard's nodes
   a. are often red, swollen, and tender.
   b. indicate osteophyte formation at the PIP joints.
   c. are the result of pannus formation at the DIP joints.
   d. occur from deterioration of cartilage by proteolytic enzymes.
2. A patient with rheumatoid arthritis has articular involvement. The nurse recognizes these characteristic changes include *(select all that apply)*
   a. bamboo-shaped fingers.
   b. metatarsal head dislocation in feet.

c. noninflammatory pain in large joints.

d. asymmetric involvement of small joints.

e. morning stiffness lasting 60 minutes or more.

3. When administering medications to the patient with chronic gout, the nurse recognizes which drug is used as a treatment for this disease?

a. Colchicine

b. Allopurinol

c. Sulfasalazine

d. Cyclosporine

4. The nurse should teach the patient with ankylosing spondylitis the importance of

a. avoiding extremes in environmental temperatures

b. regularly exercising and maintaining proper posture.

c. maintaining patient's usual physical activity during flares.

d. applying hot and cool compresses for relief of local symptoms.

5. In teaching a patient with systemic lupus erythematosus about the disorder, the nurse knows the pathophysiology includes

a. circulating immune complexes formed from IgG autoantibodies reacting with IgG.

b. an autoimmune T-cell reaction that results in destruction of the deep dermal skin layer.

c. immunologic dysfunction leading to chronic inflammation in the cartilage and muscles.

d. the production of a variety of autoantibodies directed against components of the cell nucleus.

6. In teaching a patient with Sjögren's syndrome about drug therapy for this disorder, the nurse includes instruction about the use of which drug?
   a. Pregabalin (Lyrica)
   b. Etanercept (Enbrel)
   c. Cyclosporine (Restasis)
   d. Cyclobenzaprine (Flexeril)

7. Teach the patient with fibromyalgia the importance of limiting intake of which foods? *(select all that apply)*
   a. Sugar
   b. Alcohol
   c. Caffeine
   d. Red meat
   e. Root vegetables

1. b, 2. b, e, 3. b, 4. b, 5. d, 6. c, 7. a, b, c

Case Study

Managing Care of Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 5 patients. You have 1 LPN/VN and 1 UAP on your team to help you.

Patients	
 © iStockphoto/Thinkstock.	J.K. is a 57-yr-old white woman who had debulking surgery for a temporal-parietal glioblastoma. Her MRI/MRA showed a temporal-parietal glioblastoma that extended into the occipital lobes. 4 days ago, she had a hemorrhagic stroke into the site of the tumor bed extending into the thalamus. She now has left homonymous hemianopsia and left-sided weakness.
 © Purestock/Thinkstock.	J.P. is a 24-yr-old woman who fell and hit her head during a tonic-clonic seizure. Her boyfriend found her lying unconscious on the floor of her apartment. She had an emergency evacuation of a subdural hematoma and was initially in the ICU. She was transferred to the medical-surgical unit yesterday and is scheduled for a rehabilitation evaluation. She is oriented to person only and is somewhat restless. A safety sitter is at the bedside at all times.
 © iStockphoto/Thinkstock.	M.Y., an 78-yr-old Asian American man, had an ORIF 2 days ago for a fractured left hip. He has a 3-yr history of Alzheimer's disease and is confused to place and time. He has been pleasant and cooperative. He has a personal alarm and bed alarm on for safety. His hip dressing is dry and intact and the drainage in the Hemovac drain is minimal.
 © iStockphoto/Thinkstock.	S.W., an 18-yr-old woman, sustained a C5 cervical spinal cord injury when she dove into the shallow end of a pool and struck her head on the bottom. She was initially placed in cervical traction, intubated, and mechanically ventilated. She has since undergone surgical stabilization and the traction was removed. After spending 1 week in an inpatient SCI rehabilitation facility, she was transferred to the medical-surgical unit this morning with severe headache, blurred vision, and nausea.
 © aronaze/iStock.com.	M.C. is a 64-yr-old white man who had a right femoral fracture of the greater trochanter after falling while gardening. He previously had both hips replaced. He had surgery 4 days ago to repair the femoral component of his right total hip replacement. Discharge home is planned today.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale.
2. ***Collaboration:*** Which tasks could you delegate to UAP? *(select all that apply)*
   a. Explain discharge instructions to M.C.
   b. Change the dressing on M.Y.'s left hip.
   c. Obtain vital signs on M.C. before discharge.

d. Sit with J.P. while the safety sitter takes a break.

e. Assess J.K.'s ability to swallow before feeding her breakfast.

3. ***Priority and Collaboration:*** When you enter the room to assess S.W., you find her diaphoretic with a flushed face and pale extremities. Her BP is 200/102 mm Hg. Which 2 initial actions would be *most* appropriate?

a. Ask the UAP to obtain a stat bladder scan.

b. Have the LPN administer her oral antihypertensive meds stat.

c. Elevate the head of the bed while assessing for any noxious stimuli.

d. Ask the LPN to stay with S.W. while you stat page S.W.'s provider.

e. Insert rectal suppository after applying lidocaine to the area around the rectum.

Case Study Progression

S.W.'s bladder scan showed 700 mL of urine. After you have the LPN catheterize her using a local anesthetic gel, her symptoms subside. You take this time to further teach S.W. about the manifestations of autonomic dysreflexia and the need to report any symptom as soon as it appears. You discuss bladder training strategies and how to avoid bladder distention. S.W. is grateful for the information and your caring attitude. Just as you are finishing, the UAP tells you that M.Y. has pulled out his Hemovac drain.

4. What should be your *initial* intervention for M.Y.?

a. Reinsert the Hemovac drain.

b. Assess the incision site for a hematoma.

c. Notify M.Y.'s provider that the drain was removed.

d. Apply pressure to the incisional site where the drain had been placed.

5. Which intervention would be *most* appropriate in caring for J.K.?
   a. Place her left arm in a sling for support.
   b. Arrange the food tray so that all foods are on the right side.
   c. Position her left leg so that the ankle is lower than the knee.
   d. Call the provider to get an order of warfarin to prevent VTE.

6. When teaching J.P.'s boyfriend about what to expect during recovery from a head injury, which statement is *most* accurate?
   a. "You can tell by how great she looks physically that she will ultimately function well at the home."
   b. "One good thing that will come out of this injury is that her seizures should occur less frequently."
   c. "Most patients are transferred out of the hospital for acute rehabilitation management to prepare them for going home."
   d. "She can expect a full recovery without any chronic problems, but it may take a few months to achieve that goal."

7. ***Priority Decision:*** You receive the morning laboratory data. Which finding should you report to the provider immediately?
   a. J.K. has a platelet level of 170,000 μ/L.

b. M.C.'s INR after his first dose of warfarin is 1.4.

c. M.Y.'s WBC has increased from 7000 yesterday to 10,800.

d. S.W. who is receiving enteral nutrition, has a glucose level of 142 mg/dL.

8. ***Management Decision:*** As you enter M.C.'s room to discuss his discharge plans, you find him all packed up and ready to go. He tells you the UAP already told him what he needed to do. What is your *best* initial action?

a. Ask M.C. if he has any further questions.

b. Call the UAP to M.C.'s room to find out what she told him.

c. Review discharge instructions with M.C. to ascertain correct understanding.

d. Give M.C. a telephone number to call in case he has any concerns when he gets home.

Critical Care

Megan Ann Brissie

LEARNING OUTCOMES

1. Discuss the various certification opportunities for critical care registered nurses.
2. Select appropriate nursing interventions to manage common problems and needs of critically ill patients.
3. Develop strategies to manage issues related to caregivers of critically ill patients.
4. Apply the principles of hemodynamic monitoring to the nursing and interprofessional management of patients receiving monitoring.
5. Discern the purpose of, indications for, and function of circulatory assist devices and related nursing and interprofessional management.
6. Distinguish the indications for and modes of mechanical ventilation.
7. Select appropriate nursing interventions related to the care of an intubated patient.
8. Relate the principles of mechanical ventilation to the nursing and interprofessional management of patients receiving this intervention.

Conceptual Focus

Cognition
Gas Exchange

Nutrition
Perfusion
Sensory Perception
Sleep
Technology and Informatics

This chapter focuses on the role of the critical care registered nurse (RN) in the management of critically ill patients in an intensive care setting. The chapter reviews concepts related to cardiovascular and respiratory dynamics that support perfusion and gas exchange. We emphasize the interprofessional care and nursing management of ill patients requiring advanced care modalities. These include hemodynamic monitoring, circulatory assist devices (CADs), artificial airways, and mechanical ventilation.

Critical Care Nursing

The American Association of Critical-Care Nurses (AACN) defines *critical care nursing* as a specialty that manages human responses to life-threatening problems.[1] Critical care RNs care for patients with acute and unstable physiologic problems and their caregivers. This involves assessing life-threatening conditions, starting appropriate interventions, evaluating the outcomes of interventions, and providing teaching and emotional support to caregivers.

Critical Care Units

Critical care units (CCUs) or *intensive care units* (ICUs) are designed to meet the special needs of acutely and critically ill patients. In many hospitals, the concept of ICU care has expanded from delivering care in a standard unit to bringing care to patients wherever they may be. For example, the *electronic* or *teleICU* helps the bedside ICU team by monitoring the patient from a remote location (Fig. 65.1).

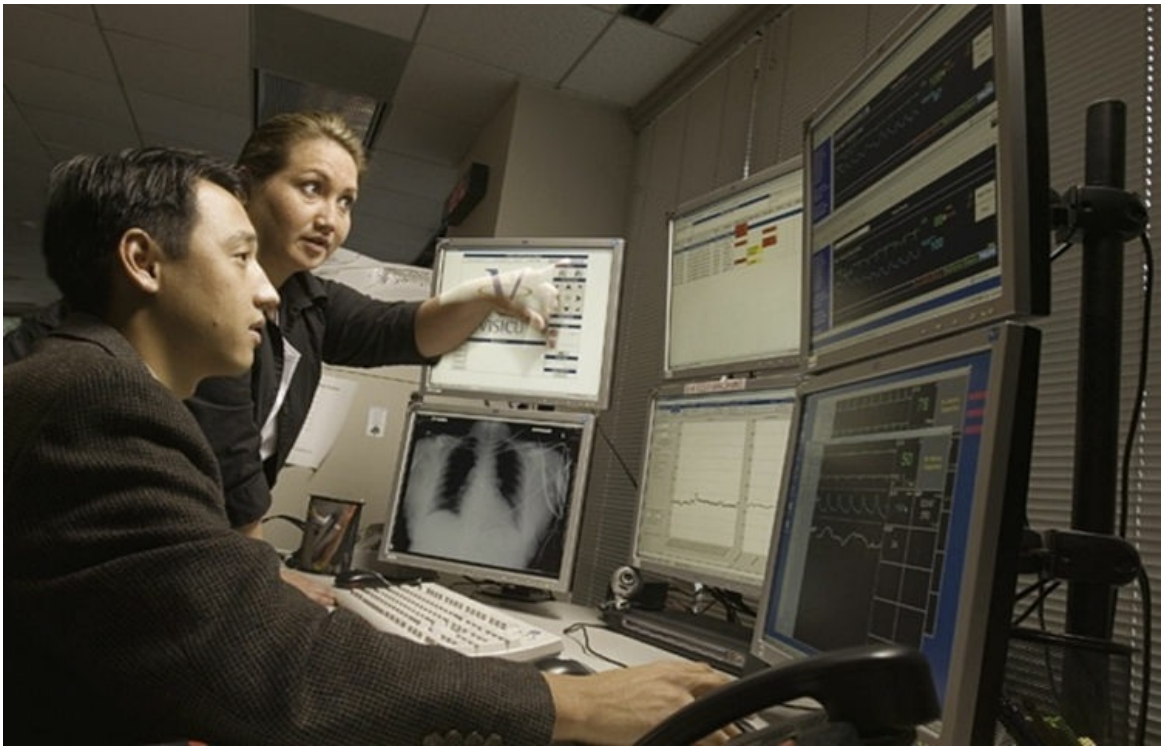

FIG. 65.1 eICU team members monitor patients from a remote site. From Amelung PJ, Doerfler, ME: VISICU and the e ICU Program. In Le Roux PD, Levine J, Kofke WA: *Monitoring in neurocritical care,* St Louis, 2013, Elsevier

Similarly, *rapid response teams* (RRTs) deliver advanced care by an interprofessional team. The team is usually composed of a critical care RN, critical care physician or an advanced practice registered nurse (APRN), and a respiratory therapist (RT). RRTs bring rapid and immediate care to unstable patients in noncritical care settings. Patients often show early and subtle signs of deterioration (e.g., mild confusion, tachypnea, vital sign changes) 6 to 8 hours before cardiac or respiratory arrest. RRT intervention has made significant advances in reducing mortality rates in these patients.[2]

The technology available in the ICU is extensive and always evolving. It is possible to continuously monitor a patient's electrocardiogram (ECG), BP, O_2 saturation, cardiac output (CO), intracranial pressure (ICP), and temperature. Advanced monitoring devices can measure cardiac index (CI), stroke volume (SV), stroke volume variation (SVV), ejection fraction (EF), end-tidal carbon dioxide ($EtCO_2$), and O_2 consumption. Patients may receive ongoing

support from mechanical ventilators, intraaortic balloon pumps (IABPs), CADs, or dialysis machines.

Progressive care units (PCUs), also called *intermediate care* or *step-down units,* are a transition between the ICU and the general unit. Generally, PCU patients are at risk for serious complications, but their risk is lower than that of ICU patients. Examples of patients in PCUs include those scheduled for interventional heart procedures (e.g., stent placement), awaiting heart transplant, receiving stable doses of vasoactive IV drugs (e.g., diltiazem [Cardizem]), being weaned from prolonged mechanical ventilation, or who recently had tracheostomy placement. Monitoring capabilities in PCUs may include continuous ECG, arterial BP, O_2 saturation, and $EtCO_2$.

Critical Care Registered Nurse

A critical care RN has in-depth knowledge of anatomy, physiology, pathophysiology, and pharmacology; advanced assessment skills; and the ability to use advanced technology. As a critical care RN, you perform frequent assessments to monitor trends in the patient's physiologic parameters (e.g., BP, ECG, O_2 saturation). This allows you to rapidly recognize and manage complications while aiding healing and recovery. You provide psychologic support to the patient and/or caregiver. To be effective, you must be able to communicate and collaborate with all interprofessional team members.

As a critical care RN, you will face ethical dilemmas related to the care of your patients. Moral distress over perceived issues of delivering futile or nonbeneficial care can lead to emotional exhaustion or burnout. Consequently, it is important that all members of the interprofessional care team coexist in a healthy work environment.

Specialization in critical care nursing requires a preceptored clinical orientation, often over several months. The AACN Certification Corporation offers (1) critical care certification (CCRN) in direct care adult, pediatric, and neonatal critical care nursing; (2) progressive care certification (PCCN); (3) critical care certification knowledge (CCRN-

K) or progressive care certification knowledge (PCCN-K) for those who do not provide direct care but influence care delivery in their role; and (4) teleICU certification (CCRN-E). Other certifications are available in cardiac medicine (CMC) and cardiac surgery (CSC). Certification requires RN licensure, practice experience in the related area, and successful completion of a written test. It validates basic knowledge of critical or progressive care nursing.

APRNs in critical care function in a variety of roles: patient and staff educators, consultants, administrators, researchers, or expert practitioners.[3] The APRN who is a clinical nurse specialist (CNS) typically provides advanced nursing care to meet the needs of adult-gerontology, pediatric, or neonatal patient populations. Certification for the CNS in acute and critical care is available through the AACN.

Another APRN role is the adult-gerontology acute care nurse practitioner (AG-ACNP). This APRN provides comprehensive care to select critically ill patients and their caregivers. The AG-ACNP conducts comprehensive assessments, orders and interprets diagnostic tests, manages health problems, prescribes treatments, and coordinates care among interprofessional care teams and during transitions in care settings. Certification as an AG-ACNP is available through the AACN. Prescriptive authority and licensure regulations for APRNs vary by state.

Critical Care Patient

A critically ill patient is one whose need for care is acute in nature, requiring intense and vigilant nursing care. A patient is generally admitted to the ICU for 1 of 3 reasons. First, the patient may be physiologically unstable, requiring advanced clinical judgments by you or another HCP. Second, the patient may be at risk for serious complications and need frequent assessments and often invasive interventions. Third, the patient may need intensive and complicated nursing support related to the use of IV medications (e.g., sedation, drugs requiring titration [e.g., vasopressors], or thrombolytics) and advanced technology (e.g., hemodynamic monitoring, mechanical

ventilation, continuous renal replacement therapy [CRRT], ICP monitoring). The incidence of death is higher in ICU patients than in non-ICU patients. In general, nonsurvivors are older, have co-morbidities (e.g., liver disease, obesity), and have longer ICU stays.

ICU patients may be clustered by disease condition (e.g., cardiology, burns, neurology) or age-group (e.g., neonatal, pediatrics, adult). Those with medical emergencies (e.g., sepsis, diabetic ketoacidosis, drug overdoses) are treated in a medical ICU. Sometimes we cluster patients by acuity (e.g., critical and unstable versus chronic but technology dependent and stable). Patients commonly treated in the ICU include those with respiratory failure, myocardial infarction (MI), or acute neurologic impairment or those requiring care after major surgery (e.g., heart or brain surgery, organ transplantation). Fig. 65.2 shows a typical ICU bed with monitors.

FIG. 65.2 Typical ICU bed with monitors.
© danutela/iStock.com.

The patient who we do not expect to recover from an illness is usually not admitted to an ICU. For example, the ICU is not typically used to care for the patient in a persistent, vegetative state or to prolong the natural process of death. ICUs will manage patients who have brain death or who meet criteria for donation after cardiac death to optimize the opportunity for organ donation. Sometimes patients may be managed in the ICU to allow for end-of-life decisions or transitions of care to occur in a private, dignified setting. So, it is important that critical care RNs are skilled in palliative and end-of-life care (see Chapter 9).

Common Problems of Critical Care Patients

The patient in the ICU is at risk for many complications and special problems. Critically ill patients are often intubated and mechanically ventilated, immobile, and at high risk for skin problems (see Chapter 23) and venous thromboembolism (VTE) (see Chapter 37). The use of multiple, invasive devices predisposes the patient to health care–associated infections (HAIs). Sepsis and multiple organ dysfunction syndrome (MODS) may follow (see Chapter 66). Other special problems relate to anxiety, pain, impaired communication, sensory-perceptual problems, sleep, and nutrition.

Anxiety

Anxiety is a common problem for ICU patients. The main sources of anxiety include the perceived or expected threat to health or life, loss of control of body functions, and a foreign environment. Many patients and caregivers feel uncomfortable in the ICU with its complex equipment, high noise and light levels, and intense pace of activity. Pain, impaired communication, sleeplessness, immobilization, and loss of control all enhance anxiety.

To help reduce anxiety, have patients and caregivers express concerns, ask questions, and state their needs. Include them in all

conversations and explain the purpose of equipment and procedures. Structure the patient's environment in a way that decreases anxiety. For example, encourage caregivers to bring in photographs and personal items. Antianxiety drugs (e.g., lorazepam [Ativan]) and relaxation techniques (e.g., music therapy) may reduce the stress response that anxiety can trigger.

Pain

The control of pain in the ICU patient is very important. Unrelieved pain is common among ICU patients and can lead to poor outcomes.[4] Inadequate pain control is linked with agitation, fear, and anxiety and adds to the stress response. ICU patients at high risk for pain include those who (1) have medical conditions that include ischemic, infectious, or inflammatory processes; (2) are immobilized; (3) have invasive monitoring devices, including endotracheal tubes (ETs); and (4) undergo procedures.

For many critically ill patients (e.g., those intubated), continuous IV sedation (e.g., propofol [Diprivan]) and an analgesic agent (e.g., fentanyl) are used for sedation and pain control. However, patients getting deep sedation are often unresponsive. This prevents you and other HCPs from fully assessing the patient's neurologic status. To address this issue, all patients who can safely tolerate an interruption in sedation usually receive a daily, scheduled interruption of sedation, or "sedation holiday." These allow you to awaken the patient to conduct a neurologic examination.[5] Pain management is discussed in Chapter 8.

Impaired Communication

Inability to communicate is distressing for patients who cannot speak because of sedative and paralyzing drugs, an ET, or the inability to communicate from a neurologic impairment. As part of every procedure, explain what will happen or is happening to the patient. When the patient cannot speak, explore other methods of communication, such as picture boards, notepads, magic slates, or computers. When speaking with the patient, look directly at the

patient and use hand gestures when appropriate. For those who do not speak English, you must use an approved interpreter or interpreter phone service when providing care or instructions (see Chapter 2).

Nonverbal communication is important. High levels of procedure-related touch and lower levels of comfort-related touch often characterize the ICU environment. Patients have different levels of tolerance for being touched, usually related to culture and personal history. If appropriate, use comforting touch with ongoing evaluation of the patient's response. Encourage the caregiver to talk to the patient, even if the patient is intubated, is sedated, or appears comatose. Hearing is often the last sense to decrease. Even if the patient cannot respond, they may still be able to hear.

Sleep

Nearly all ICU patients have sleep problems. Patients may have difficulty falling asleep or have disrupted sleep because of noise, anxiety, pain, frequent monitoring, treatments, or care needs. Sleep problems can cause delirium and delayed recovery.

Arrange the environment to promote the patient's sleep-wake cycle. Measures include scheduling rest periods, bundling care, limiting noise and visitors, getting physiologic measurements without disturbing the patient, opening curtains during the daytime and dimming lights at nighttime, providing eye masks/ear plugs to encourage sleep, and providing comfort measures (e.g., massage).[6] If needed, use benzodiazepines (e.g., temazepam), benzodiazepine-like drugs (e.g., zolpidem [Ambien]), or natural hormones (e.g., melatonin), especially for an older adult, to aid and maintain sleep. Promoting sleep is discussed in Chapter 7.

Sensory-Perceptual Problems

Acute and reversible sensory-perceptual changes are common in ICU patients. We used to call the combination of changes in mentation (e.g., delusions, short attention span, loss of recent memory), psychomotor behavior (e.g., restlessness, lethargy), and sleep-wake

cycle (e.g., daytime sleepiness, nighttime agitation) *ICU psychosis*. The patient with these changes is not psychotic but has *delirium*. Delirium is an acute change in mental status. The prevalence of delirium in ICU patients is as high as 87%.[7] It is associated with longer hospital stays and higher mortality rates.

Major risk factors for delirium include increased age, preexisting dementia, hypertension, alcohol use, and severe illness on admission. Environmental factors that can contribute to delirium include sleep deprivation, anxiety, sensory overload, and immobilization. Physical conditions such as hemodynamic instability, hypoxemia, electrolyte imbalances, and severe infections can lead to delirium. Last, certain drugs (e.g., sedatives [benzodiazepines], analgesics [opioids], vasopressors) are linked with delirium. Chapter 59 discusses delirium.

Monitor all ICU patients for delirium using a valid tool and initiate prevention strategies. Assessment tools for adult ICU patients include the Confusion Assessment Method for the ICU (CAM-ICU) (see Table 59.18) and the Intensive Care Delirium Screening Checklist (ICDSC). It is critical to address physiologic factors (e.g., correction of oxygenation, perfusion, electrolyte problems). Clocks and calendars can help orient the patient. Reorient patients who are confused during assessments to provide comfort and direction. The presence of a caregiver may help. Removing lines no longer needed and early mobility are effective.[8] If the patient has hyperactivity, insomnia, or delusions, treatment with sedative drugs with anxiolytic effects (e.g., dexmedetomidine [Precedex]) can be used.

Sensory overload can result in patient distress and anxiety. Environmental noise levels are high in the ICU. Help the patient understand we cannot prevent noise. Conversation is an especially stressful noise, especially when the discussion concerns the patient and is held in the presence of, but without participation from, the patient. Reduce this source of stress by finding suitable places for patient-related discussions. Whenever possible, include the patient and caregiver in the discussion.

You can limit noise levels by muting phones, setting alarms based on the patient's condition, and reducing unnecessary alarms. For

example, silence the BP alarm when handling invasive lines and then reset the alarm when done. Similarly, silence ventilator alarms when suctioning. Last, limit overhead paging and all unnecessary noise in patient care areas.

Nutrition

Patients often arrive at ICUs with conditions that result in either hypermetabolic states (e.g., burns, sepsis) or catabolic states (e.g., acute kidney injury). Other times, patients are in severely malnourished states (e.g., chronic heart, lung, or liver disease). In general, inadequate nutrition increases mortality and morbidity rates. Determining whom to feed, what to feed, when to feed, and how to feed (e.g., route of administration) is crucial when caring for critically ill patients.[9] Collaborate with the HCP and dietitian to decide how best to meet the nutritional needs of the ICU patient.

The main goal of nutritional support is to prevent or correct nutritional deficiencies. We usually do this through the early provision of enteral or parenteral nutrition. Enteral nutrition (EN) preserves the structure and function of the gut mucosa and stops the movement of gut bacteria across the intestinal wall and into the bloodstream. Early EN is associated with fewer complications and shorter hospital stays. It is less expensive than parenteral nutrition.[9] A contributing factor to underfeeding with EN is the frequent interruptions to give drugs and for tests and procedures.

Parenteral nutrition (PN) is used when the enteral route cannot provide adequate nutrition or is contraindicated.[9] Examples include paralytic ileus, diffuse peritonitis, intestinal obstruction, pancreatitis, GI ischemia, abdominal trauma or surgery, and severe diarrhea. EN and PN are discussed in Chapter 39.

Supporting Caregivers

When someone is critically ill, care extends beyond the patient to the patient's caregivers. Caregivers play a valuable role in the patient's recovery and are members of the interprofessional care team. They

contribute to the patient's well-being by (1) linking the patient to the outside world (e.g., news of family, job); (2) facilitating decision making and advising the patient; (3) helping with activities of daily living; (4) acting as liaisons to advise the health care team of the patient's wishes for care; and (5) providing safe, caring, familiar relationships for the patient.

Having a friend or relative in the ICU is physically and emotionally difficult, often to the point of exhaustion. Anxiety and concerns about the patient's condition, prognosis, and pain are common. Caregivers may have concern about financial issues related to hospital stay. They often disrupt their daily routines to support the patient. Caregivers may be far from their own home, friends, and relatives. Consulting with the case manager or social worker is helpful in these instances.

Caregivers of the critically ill are in crisis, and family-centered care is essential. Caregivers need your guidance and support. You must be skilled in crisis intervention to provide effective family-centered care. Conduct a family assessment and intervene as needed. Strategies include active listening, reduction of anxiety, and support for those who become upset or angry. Recognize the caregivers' feelings, listen to them openly and without being judgmental, and acknowledge their decisions. Consult other team members (e.g., chaplains, psychologists, patient representatives) as needed to help caregivers cope.

The major needs of caregivers of critically ill patients include information, communication, and access.[10] Lack of information is a major source of anxiety. Assess their understanding of the patient's status, treatment plan, and prognosis and provide information as appropriate. Identify a spokesperson to help coordinate information exchange between the interprofessional care team and caregivers.

Holding routine interprofessional conferences with caregivers improves satisfaction with communication and trust in clinicians and reduces conflict between clinicians and family members.[10] Have them meet the interprofessional care team. Include them in rounds and patient care conferences. It helps caregivers accept and cope with problems when they see that the team is caring and competent, decisions are deliberate, and their input is valued. If the patient has an

advance directive, the caregiver needs to see that the patient's wishes are followed. If the patient has a durable power of attorney for health care, this person must be involved in the patient's plan of care.

Caregivers need access to the patient. The AACN strongly recommends less restrictive and more individualized visiting policies. Achieve this goal by assessing the patient's and caregiver's needs and preferences and incorporating these into the patient's plan of care.

Ethical/Legal Dilemmas

Visitation and Caregiver Presence in the Adult ICU

Situation

B.W., a new RN, is undergoing orientation in the surgical ICU. He asks his preceptor why the patients' families are allowed on the unit throughout the day and even the night. B.W. states that, in his last position, visiting hours in the ICU were 10 AM to 12 PM and 4 PM to 6 PM. He adds that families make him nervous when they watch what he is doing and ask him many questions. B.W. says that he plans to tell the visitors to leave the patient's room when he is giving care.

Ethical/Legal Points for Consideration

- We used to think that visitation caused the patient stress, interfered with care, was mentally exhausting to patients and caregivers, and contributed to increased infection rates. Evidence does not support any of these beliefs.[1,2]
- Evidence suggests several positive benefits of flexible visitation for the patient: decreased anxiety, confusion, and agitation; fewer cardiovascular complications; shorter ICU length of stay; and reports that patients feel more secure and satisfied with care.[1]
- Similar evidence exists for the benefits of flexible visitation for caregivers: increased satisfaction, decreased anxiety, better communication, and increased opportunities for patient and

caregiver teaching as caregivers are more involved in care.[1]

- Some conditions may require restricting visitation: a documented legal reason; visitor behavior presents a risk to the patient, staff, or others; visitor behavior disrupts the functioning of the unit; visitor has a contagious illness or has been exposed to a contagious disease that could endanger the patient's health; or the patient requests fewer or no visitors.

Discussion Questions

1. How should the preceptor respond to B.W.'s statement of his intentions?
2. Does B.W. have an ethical or legal obligation to allow visitation regardless of his personal concerns? Defend your position.

2. Clark A.P, Guzzetta C.E. A paradigm shift for patient/family-centered care in intensive care units: Bring in the family. *Crit Care Nurse*. 2017;37(96).

The first time that caregivers visit, it is important for you to prepare them for the experience. Briefly describe the patient's appearance and physical environment (e.g., equipment, noise). Join caregivers as they enter the room. Observe the responses of the patient and caregivers. Invite the caregivers to take part in the patient's care if they want. Be prepared that people may respond differently to seeing their loved one in the ICU for the first time.

In some ICUs, visitation includes animal-assisted therapy or pet visitation, most often therapy dogs. The positive benefits (e.g.,

decreases in BP and anxiety) far outweigh the risks (e.g., transmission of infection from animal to patient). Pet therapy should be a part of the ICUs visitation policy.

Caregivers should also have the option to be present at the bedside when patients are undergoing invasive procedures (e.g., central line insertion) or cardiopulmonary resuscitation (CPR). Even when the outcomes are not favorable, being present helps caregivers to (1) overcome doubts about the patient's condition, (2) reduce their anxiety and fear, (3) meet their need to be together with and to support their loved one, and (4) begin the grief process if death occurs. Be a part of initiatives to develop policies and procedures that offer the option of caregiver presence during invasive procedures and CPR.[11]

Culturally Competent Care: Critical Care Patients

Providing culturally competent care to critically ill patients and caregivers can be challenging. Often, meeting the patient's physiologic needs is a priority and overshadows the influence of the patient's culture on the illness experience. It is important to consider the cultural aspects of the meaning of sickness and health, pain, dying and death, and grief when caring for critically ill patients and their caregivers (see Chapter 2).

Cultural perspectives on dying and death are complex. Some view a discussion about advance directives as a legal way to withhold, withdraw, or deny care. Customs surrounding dying and death vary. Caregiver requests may range from asking you to leave a window open so that the spirit of the deceased can leave to giving the final bath for the deceased. Ask caregivers about their cultural traditions when caring for the dying patient.

Several variables influence the expressions of grief that follow the loss of a loved one. These include the relationship between the grieving person and the deceased, whether the loss is sudden or expected, the support systems available to the grieving person, past

experiences with loss, and the person's religious and cultural beliefs. Proceed cautiously when approaching patients facing death and their caregivers. Asking patients, "What do you want to know?" and "Who do you want with you when discussing options?" are good starting points. Chapter 9 provides detailed information about end-of-life care.

Hemodynamic Monitoring

Hemodynamic monitoring is the measurement of pressure, flow, and oxygenation within the cardiovascular system. The purpose of hemodynamic monitoring is to assess heart function, fluid balance, and the effects of fluids and drugs on CO. Both invasive (internally placed devices) and noninvasive (externally placed devices) obtain hemodynamic parameters (values). These include systemic and pulmonary arterial pressures, central venous pressure (CVP), pulmonary artery wedge pressure (PAWP) (also known as pulmonary artery occlusive pressure [PAOP]), CO/CI, SV/SV index (SVI), SVV, O_2 saturation of the hemoglobin of arterial blood (SaO_2), and mixed venous O_2 saturation (SvO_2).

From these measurements, you can calculate several values. These include the resistance of the systemic and pulmonary arterial vasculature and O_2 content, delivery, and consumption. When you combine these data, you get a picture of the patient's hemodynamic status and the effect of therapy over time (trends). Take all measurements with attention to accuracy. Inaccurate data can result in unnecessary or inappropriate treatment.

Informatics in Practice

Smart Infusion Pumps

- Smart infusion pumps, with preprogrammed drug libraries and wireless technology, calculate drug dose and delivery rates to

help prevent IV drug errors and reduce the risk for patient harm.

- Smart pumps give information used to provide safe care, such as the total number of infusions programmed using the drug library, how many times pumps were manually overridden, or how often an alert resulted in reprogramming an infusion.
- Remember, if you make an error and enter incorrect data, you will get incorrect results. Some high-risk drugs (e.g., insulin, heparin) require that a second RN confirm pump settings.
- Always use your best nursing judgment when using smart infusion pumps and follow agency policy.

Hemodynamic Terminology

Cardiac Output and Cardiac Index

Cardiac output (CO) is the volume of blood in liters pumped by the heart in 1 minute. *Cardiac index* (CI) is the measurement of CO adjusted for body surface area (BSA). It is a more precise measurement of the efficiency of the heart's pumping action. Although minor beat-to-beat variations may occur, the left and right ventricles pump the same volume. The volume ejected with each heartbeat is the SV. Like CI, *stroke volume index* (SVI) is the measurement of SV adjusted for BSA.

CO and the forces opposing blood flow determine BP. *Systemic vascular resistance* (SVR) (opposition encountered by the left ventricle) or *pulmonary vascular resistance* (PVR) (opposition encountered by the right ventricle) is the resistance to blood flow by the vessels. Preload, afterload, and contractility determine SV, and thus CO (see Chapter 31). It is essential that you understand these concepts and the physiologic effects of manipulating each of these variables. Table 65.1 presents the formulas and values for common hemodynamic parameters.

Preload

Preload is the volume within the ventricle at the end of diastole.

Unfortunately, chamber volume measurements are hard to obtain. Instead, we use various pressures to estimate the volume. Left ventricular preload is called *left ventricular end-diastolic pressure.* PAWP, a measurement of pulmonary capillary pressure, reflects left ventricular end-diastolic pressure under normal conditions (i.e., when there is no mitral valve dysfunction, intracardiac defect, or dysrhythmia). CVP is measured in the right atrium or in the vena cava close to the heart. It is the right ventricular preload or right ventricular end-diastolic pressure when there is no tricuspid valve dysfunction, intracardiac defect, or dysrhythmia.

Frank-Starling's law explains the effects of preload. It says that the more a myocardial fiber is stretched during filling, the more it shortens during systole and the greater the force of the contraction. As preload increases, force generated in the subsequent contraction increases and SV and CO increase. The greater the preload, the greater the myocardial stretch and the greater the myocardial O_2 requirement. Thus increases in CO from increased preload require increased delivery of O_2 to the myocardium. The clinical measurement made is not a direct measurement of the muscle length. The measurement is of the pressure at the time of the peak stretch (end diastole) (Table 65.1). This pressure indirectly indicates the amount of stretch and the volume. It is also important because it indicates pressure in the blood vessels of the lungs or in the blood returning to the heart. Diuresis and vasodilation decrease preload. Fluid administration increases preload.

Afterload

Afterload refers to the forces opposing ventricular ejection. These forces include systemic arterial pressure, the resistance offered by the aortic valve, and the mass and density of the blood. SVR and arterial pressure are indices of left ventricular afterload, though clinically they do not include all the components of afterload. Similarly, PVR and pulmonary arterial pressure are indices of right ventricular afterload. Increased afterload often results in a decreased CO and increased O_2 demand. CO can be improved and myocardial O_2 needs reduced by decreasing afterload (i.e., decreasing forces opposing contraction). For

example, vasodilator drug therapy (e.g., milrinone) can reduce afterload.

Vascular Resistance

SVR is the resistance of the systemic vascular bed. PVR is the resistance of the pulmonary vascular bed. Both these measures reflect afterload as described earlier and can be adjusted for body size (Table 65.1).

Contractility

Contractility describes the strength of contraction. Contractility increases when preload is unchanged and the heart contracts more forcefully. Epinephrine, norepinephrine, isoproterenol (Isuprel), dopamine, dobutamine, digitalis-like drugs, calcium, and milrinone increase or improve contractility. We call these drugs *positive inotropes.* Increased contractility results in increased SV and increased myocardial O_2 requirements. *Negative inotropes* reduce contractility. These include certain drugs (e.g., calcium channel blockers, β-adrenergic blockers) and clinical conditions (e.g., acidosis).

There are no direct clinical measures of cardiac contractility. Measuring the patient's preload (PAWP) and CO and graphing the results indirectly indicate contractility. If preload, heart rate (HR), and afterload remain constant and CO changes, contractility is changed. Contractility is reduced in the failing heart.

Principles of Invasive Pressure Monitoring

Invasive lines are used in the ICU to measure systemic and pulmonary BPs. Fig. 65.3 shows the parts of a typical invasive arterial BP monitoring system. The catheter, pressure tubing, flush system, and transducer are disposable.

Pressure monitoring equipment is referenced and zero balanced to the environment, and dynamic response characteristics are optimized for accuracy.[12] *Referencing* means placing the transducer so that the zero-reference point is at the level of the atria of the heart. The

stopcock nearest the transducer is used for the zero reference. To place this level with the atria, use an external landmark, the phlebostatic axis. To find the *phlebostatic axis,* draw 2 imaginary lines with the patient supine (Fig. 65.4, *A*). Draw a horizontal line down from the axilla, midway between the anterior and posterior chest walls. Draw a vertical line laterally through the fourth intercostal space along the chest wall. The phlebostatic axis is the intersection of the 2 imaginary lines. Mark this location on the patient's chest with a permanent marker. Position the port of the stopcock nearest the transducer level at the phlebostatic axis. Tape the transducer to the patient's chest at the phlebostatic axis or ideally mount it on a bedside pole (Fig. 65.4, *B*).

Zeroing confirms that when pressure within the system is zero, the monitor reads 0. To do this, open the reference stopcock to room air (off to the patient) and observe the monitor for a reading of 0. This allows the monitor to use the atmospheric pressure as a reference for 0. Zero the transducer during the initial setup, immediately after insertion of the arterial line, when the transducer has been disconnected from the pressure cable or the pressure cable has been disconnected from the monitor and when the accuracy of the measurements is questioned. Always follow the manufacturer's guidelines.

TABLE 65.1 Resting Hemodynamic Parameters

Indicators	Normal Range
Preload	
Pulmonary artery diastolic pressure (PADP)	4–12 mm Hg
Pulmonary artery wedge pressure (PAWP) or left atrial pressure (LAP)	6–12 mm Hg
Right atrial pressure (RAP) or central venous pressure (CVP)	2–8 mm Hg
	100–160 mL
Afterload	
	70–105 mm Hg
	10–20 mm Hg
	<250 dynes/sec/cm^{-5}
	160–380 dynes/sec/cm^{-5}/m^2
	800–1200 dynes/sec/cm^{-5}
	1970–2390 dynes/sec/cm^{-5}/m^2
Other	
	2.2–4 L/min/m^2
	4–8 L/min
Heart rate	60–100 beats/min
	40%–60%
	60–150 mL/beat
	30–65 mL/beat/m^2
	<13%
Oxygenation	
Arterial hemoglobin O_2 saturation	95%–100%
Mixed venous hemoglobin O_2 saturation	60%–80%
Venous hemoglobin O_2 saturation	70%

*This formula is an approximation because it does not take into consideration the heart rate. The monitor looks at the area under the pressure curve, as well as the heart rate, to calculate MAP and PAMP.

Optimizing dynamic response characteristics involves checking that the equipment reproduces, without distortion, a signal that changes rapidly. Perform a *dynamic response test (square wave test)* every 8 to 12 hours, when the system is opened to air, or when you question the accuracy of the measurements. It involves activating the fast flush and checking that the equipment reproduces a distortion-free signal (Fig. 65.5).

Safety Alert

Positioning the Zero Reference Stopcock

- Mark the location of the phlebostatic axis on the patient's chest with a permanent marker.
- Recheck the leveling of the zero-reference stopcock to the phlebostatic axis with any change in the patient's position.
- Transducers placed higher than the phlebostatic axis will produce falsely low BP readings.
- Transducers placed lower than the phlebostatic axis will produce falsely high BP readings.

Types of Invasive Pressure Monitoring

Arterial BP

Continuous arterial BP monitoring is indicated for patients in many situations, including acute hypotension and hypertension, respiratory failure, shock, neurologic injury, coronary interventional procedures, continuous infusion of vasoactive drugs (e.g., norepinephrine), and frequent arterial blood gas (ABG) sampling.[12] A nontapered Teflon catheter is typically used to cannulate an artery (e.g., radial, femoral) using a percutaneous approach. After insertion, the HCP usually sutures the catheter in place. You should immobilize the insertion site to prevent dislodging or kinking the catheter line.

FIG. 65.3 Parts of a pressure monitoring system. The cannula, shown entering the radial artery, is connected via pressure (nondistensible) tubing to the transducer. The transducer converts the pressure wave into an electronic signal. The transducer is wired to the electronic monitoring system, which amplifies, conditions, displays, and records the signal. Stopcocks are inserted into the line for specimen withdrawal and for referencing and zero-balancing procedures. A flush system, consisting of a pressurized bag of IV fluid, tubing, and a flush device, is connected to the system. The flush system provides continuous slow (about 3 mL/hr) flushing and a mechanism for fast flushing of lines.

Measurements

Use the arterial line to obtain systolic, diastolic, and mean arterial pressure (MAP) (Fig. 65.6). Table 65.2 outlines the steps in obtaining BP measurements with an invasive line. Obtain measurements from both digital and printed analog outputs. Readings from a printed pressure tracing at the end of expiration (to limit the effect of the respiratory cycle on arterial BP) are most accurate. When possible, position the patient supine for initial readings. Values with the head of the bed elevated up to 45 degrees are generally equal to measurements with the patient supine unless the patient's BP is extremely sensitive to orthostatic changes. It is important to keep the zero-reference stopcock level with the phlebostatic axis to ensure accurate continuous measurements.

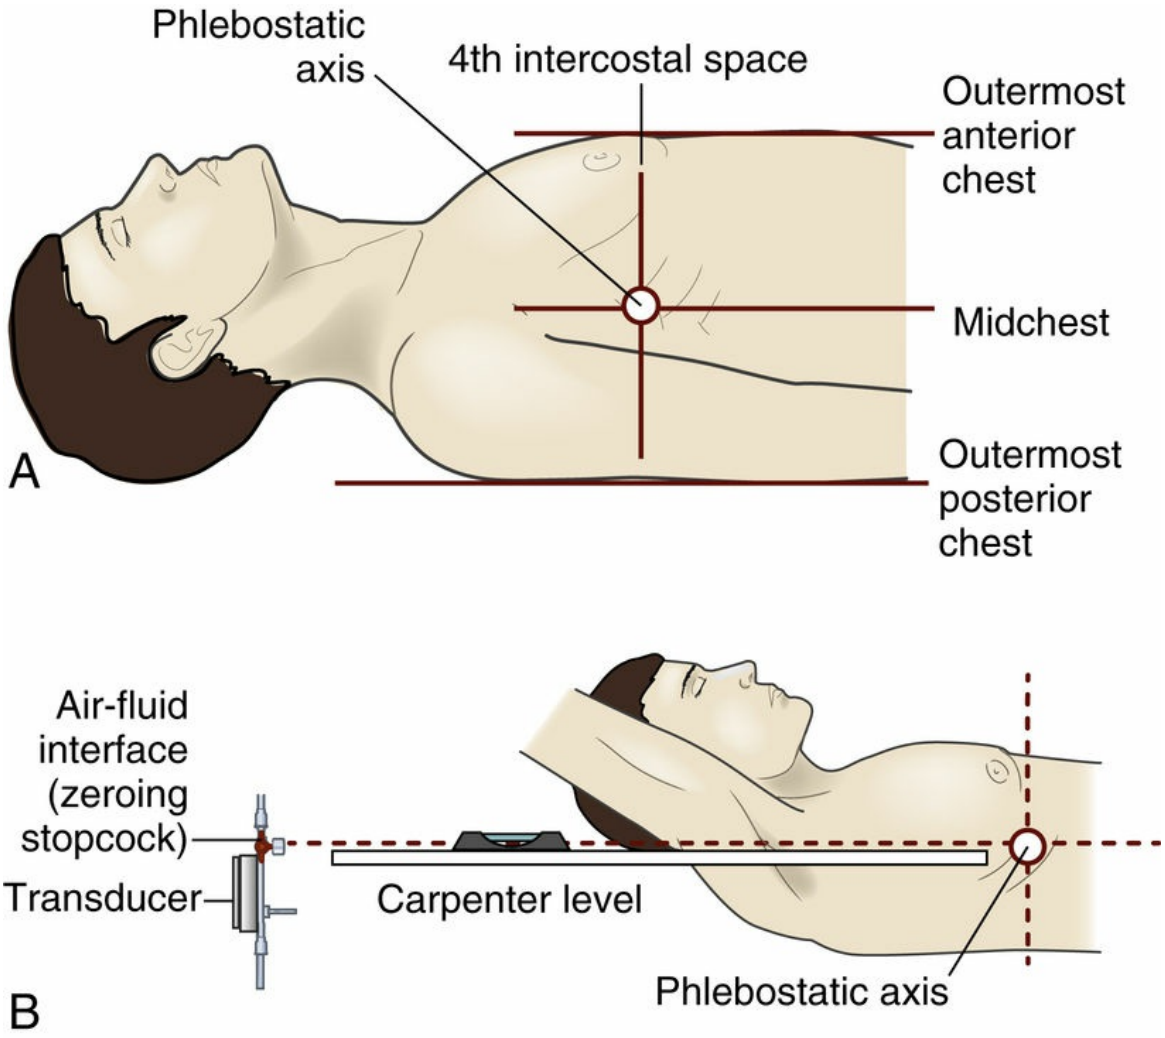

FIG. 65.4 Identification of the phlebostatic axis. **A,** Phlebostatic axis is an external landmark used to identify the level of the atria in the supine patient. It is defined as the intersection of 2 imaginary lines: 1 drawn horizontally from the axilla, midway between the anterior and posterior chest walls, and the other drawn vertically through the 4th intercostal space along the lateral chest wall. **B,** Air-fluid interface (zeroing the stopcock) is level with the phlebostatic axis using a carpenter's or laser level.

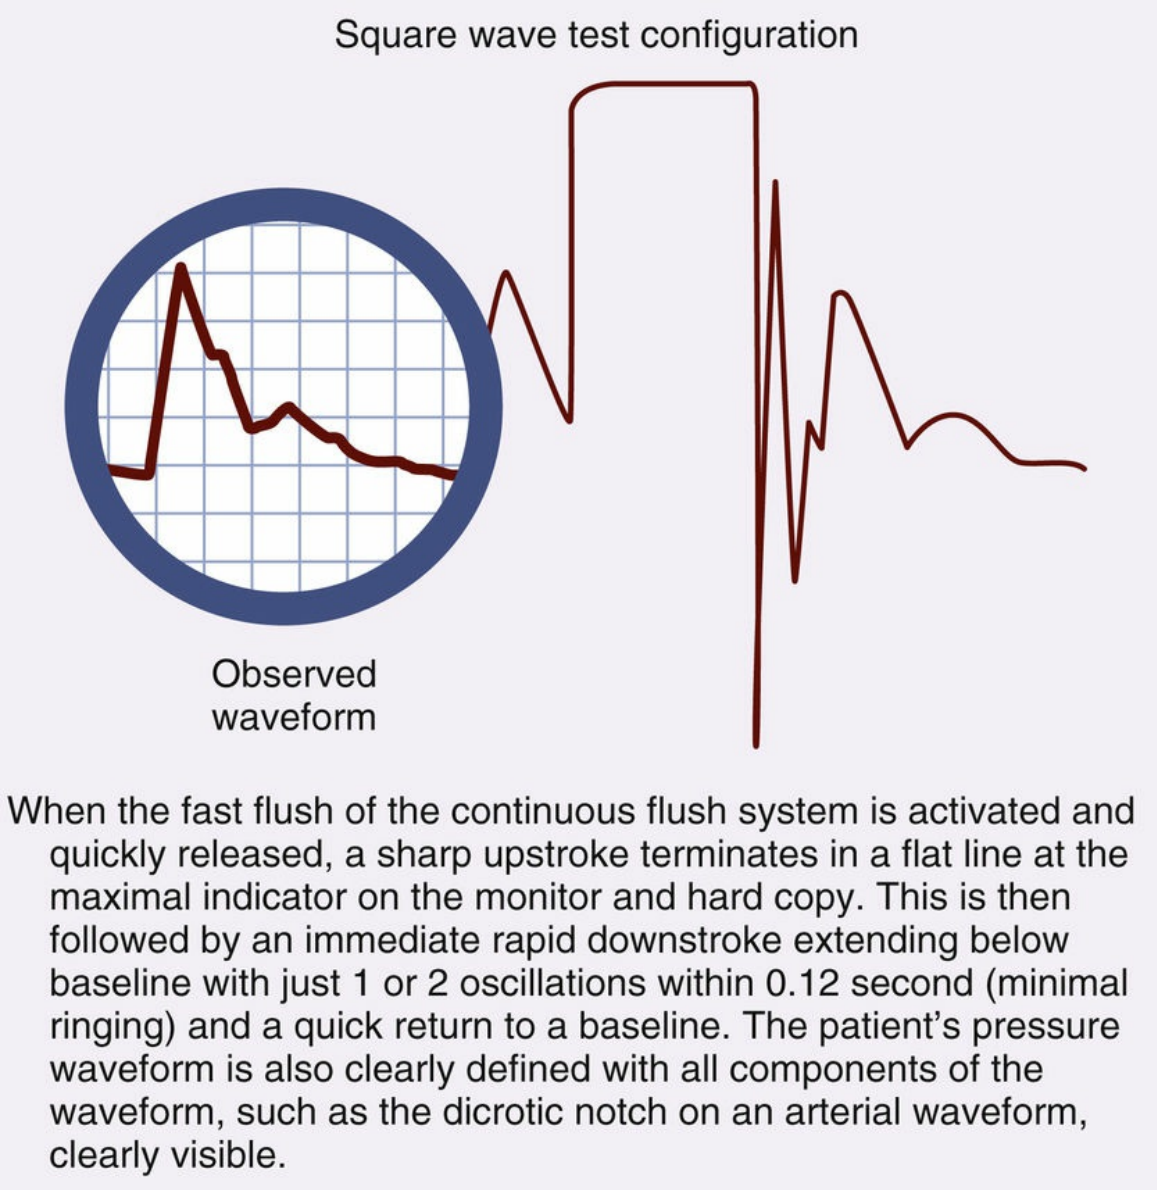

FIG. 65.5 Optimally damped system. Dynamic response test (square wave test) using the fast flush system: normal response. No adjustment in the monitoring system is needed.
From Darovic GO, Vanriper S, Vanriper J: Fluid-filled monitoring systems. In Darovic GO: *Hemodynamic monitoring,* ed 2, Philadelphia, 1995, Saunders.

The high- and low-pressure alarms are set based on the patient's status. Various patient conditions will change the pressure tracings. In heart failure (HF), the systolic upstroke may be slower. In volume depletion, systolic pressure varies with mechanical ventilation, decreasing during inspiration. Observe simultaneous ECG and

pressure tracings with dysrhythmias. Dysrhythmias that significantly decrease arterial BP are more urgent than those that cause only a slight decrease in systolic amplitude.

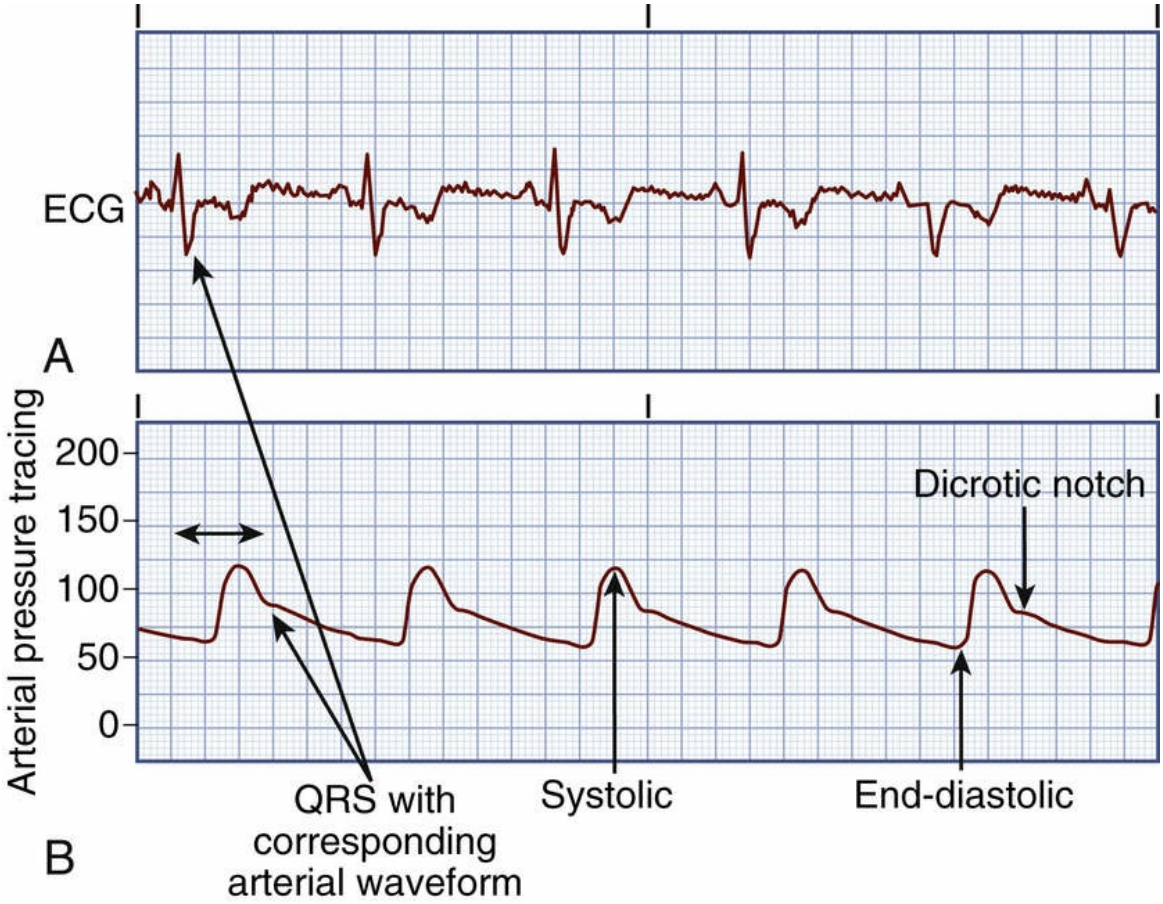

FIG. 65.6 **A,** Simultaneously recorded ECG tracing. **B,** Systemic arterial pressure tracing. Systolic pressure is the peak pressure. The *dicrotic notch* indicates aortic valve closure. Diastolic pressure is the lowest value before contraction. Mean pressure is the average pressure over time calculated by the monitoring equipment. Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

TABLE 65.2 Invasive Arterial Blood Pressure Measurement

1. Explain the procedure to the patient.
2. Position the patient supine and flat or (if appropriate) with the head of the bed less than 45 degrees or prone.
3. Confirm that the zero reference (port of the stopcock nearest the transducer) is at the level of the phlebostatic axis (Fig. 65.4). If the reference stopcock is not taped to the patient's chest, use a leveling device to position the stopcock on a bedside pole at the point level with the phlebostatic axis.
4. Observe the monitor tracing and assess the quality of the tracing. Perform a dynamic response test (Fig. 65.5).
5. Obtain an analog printout (if available) and measure the systolic and diastolic pressures at end expiration (Fig. 65.6). If no printout is available, freeze the tracing on the oscilloscope screen and use the cursor to measure the pressures at end expiration.
6. Record the pressure measurements promptly, including (if available) the printout marked to identify the points read.

Complications

Arterial lines carry the risk for hemorrhage, infection, thrombus formation, neurovascular impairment, and loss of limb. Hemorrhage is most likely to occur if the catheter dislodges or the line disconnects. To avoid this complication, use Luer-Lok connections, always check the arterial waveform, and activate alarms. If the pressure in the line falls (e.g., when the line is disconnected), the low-pressure alarm sounds immediately, allowing you to promptly correct the problem.

To limit the risk for catheter-related infection, inspect the insertion site for local signs of inflammation. Monitor the patient for signs of systemic infection. Change the pressure tubing, flush bag, and transducer every 96 hours or according to agency policy. If you suspect infection, notify the HCP, remove the catheter, and replace the equipment.

FIG. 65.7 FloTrac sensor and Vigileo monitor.
Courtesy Edwards Lifesciences, Irvine, CA.

Circulatory impairment can result from formation of a thrombus around the catheter, release of an embolus, spasm, or occlusion of the circulation by the catheter. Before inserting a line into the radial artery, perform an *Allen test* to confirm that ulnar circulation to the hand is adequate. Apply pressure to the radial and ulnar arteries simultaneously. If the patient is able, ask the patient to open and close the hand repeatedly. The hand should blanch. Release the pressure on

the ulnar artery while maintaining pressure on the radial artery. If pinkness does not return within 6 seconds, the ulnar artery is not adequate. You should not use the radial artery on that limb for line insertion.

Once the catheter is inserted, assess the neurovascular status distal to the arterial insertion site hourly. The limb with compromised arterial flow will be cool and pale, with capillary refill time longer than 3 seconds. The patient may have symptoms of neurovascular impairment (e.g., paresthesia, pain, paralysis). If present, it can result in the loss of a limb. This, this is an emergency and must be reported to the HCP at once.

To maintain line patency and limit thrombus formation, assess the flush system every 1 to 4 hours to determine that the (1) pressure bag is inflated to 300 mm Hg, (2) flush bag contains fluid, and (3) system is delivering a continuous slow (1 to 3 mL/hr) flush. Follow agency policy for adding heparin to the flush solution.[13]

Arterial Pressure–Based Cardiac Output

Arterial pressure–based cardiac output (APCO) measurement is a minimally invasive technique to determine *continuous CO* (CCO)/*continuous CI* (CCI). This technology uses a specialized sensor that attaches to a standard arterial pressure line and a monitor (Fig. 65.7).

APCO can assess a patient's ability to respond to fluids by increasing SV *(preload responsiveness)* (Table 65.1). This is determined by using SVV or by measuring the percent increase in SV after a fluid bolus.[14] SVV is the variation of the arterial pulsation caused by the heart-lung interaction. It is a sensitive indicator of preload responsiveness in certain patients. SVV helps predict whether a patient would benefit from an IV fluid challenge that may help optimize hemodynamic status.

APCO is only used with adult patients. It cannot be used in patients who are on IABP therapy. The APCO monitor may not be able to filter certain dysrhythmias, specifically atrial fibrillation, thus limiting the use of SVV in these patients.[14] SVV is used only with patients on

controlled mechanical ventilation with a fixed respiratory rate and a tidal volume (V_T).

Measurements

Arterial pressure is the force generated by the ejection of blood from the left ventricle into the arterial circulation. The heart's contractions (systole) produce pulsatile pressure waves. The sensor measures the arterial pulse pressure, which is proportional to SV. APCO monitoring uses the arterial waveform characteristics, along with demographic data (e.g., gender, age, height, weight) to calculate SV, and HR to calculate CCO/CCI and SV/SVI every 20 seconds. CO is calculated by multiplying the HR and calculated SV. It is displayed on a continuous basis. APCO monitoring is often used with a central venous oximetry catheter. Together, these allow for continuous monitoring of central venous O_2 saturation ($ScvO_2$) and SVR that is derived from the CVP.

TABLE 65.3 Common Indications and Contraindications for Pulmonary Artery Catheterization

Indications

- Assessment of response to therapy in patients with pulmonary hypertension and mixed types of shock
- Cardiogenic shock
- Differential diagnosis of pulmonary hypertension
- MI with complications (e.g., HF, cardiogenic shock)
- Potentially reversible systolic HF (e.g., fulminant myocarditis)
- Severe chronic HF requiring inotropic, vasopressor, and vasodilator therapy
- Transplantation workup

Contraindications

- Coagulopathy (may be overlooked in emergency situations)
- Endocardial pacemaker
- Endocarditis
- Mechanical tricuspid or pulmonic valve
- Right heart mass (e.g., thrombus, tumor)

Pulmonary Artery Flow-Directed Catheter

Pulmonary artery (PA) pressure monitoring guides the management of patients with select complicated heart and lung problems (Table 65.3). Pulmonary artery diastolic pressure (PADP) and PAWP are sensitive indicators of heart function and fluid volume status. PADP and PAWP increase in HF and fluid volume overload. They decrease with volume depletion. Fluid therapy based on PA pressures can restore fluid balance while limiting overcorrection or undercorrection of the problem.

A PA flow-directed catheter (e.g., Swan-Ganz) is used to measure PA pressures, including PAWP. The standard PA catheter has multiple lumens (Fig. 65.8). When properly positioned, the distal lumen port (catheter tip) is within the PA. We use this port to monitor PA pressures and sample mixed venous blood (e.g., to monitor O_2 saturation).

A balloon connected to an external valve surrounds the distal lumen port. Balloon inflation has 2 purposes: (1) to allow blood to "float" the catheter forward and (2) to allow PAWP measurement. There are 1 or 2 proximal lumens, with exit ports in the right atrium or right atrium and right ventricle (if 2). The right atrium port is used for CVP measurement, injecting fluid for CO measurement, and withdrawing blood specimens. The second proximal port (if available) is for infusing fluids and drugs or for blood sampling. A temperature sensor is near the distal tip. It monitors core temperature and is used for the thermodilution method of measuring CO.[13]

An advanced technology PA catheter can continuously monitor the patient's SvO_2. CCO and right ventricular ejection fraction (RVEF) can be measured using advanced thermodilution technology. RVEF gives information about RV function and helps to assess right heart contractility. RV end-diastolic volume is assessed by dividing SV by RVEF (Table 65.1). This is a key indicator of preload.

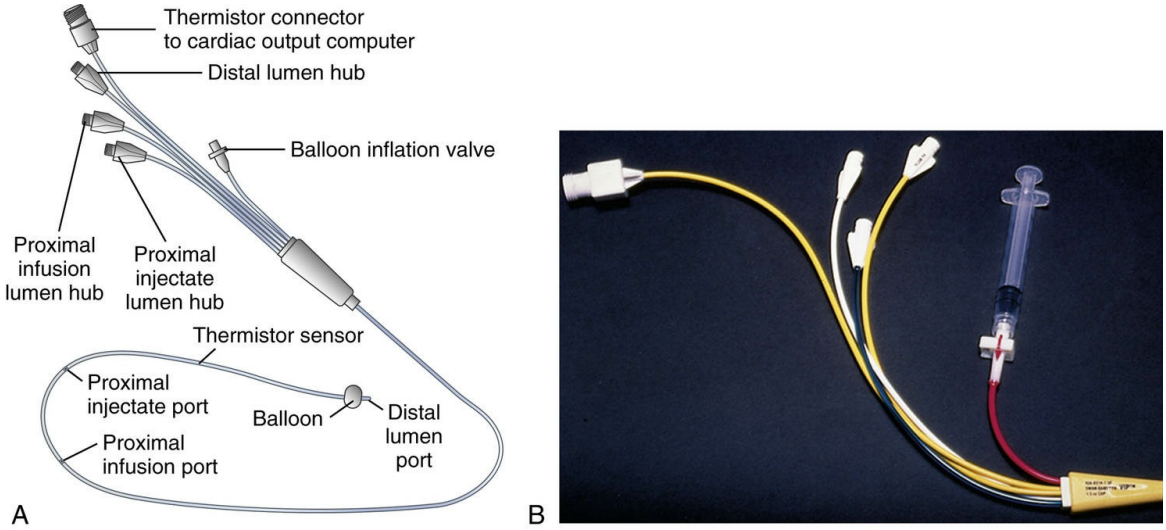

FIG. 65.8 Pulmonary artery (PA) catheter. **A,** Illustrated catheter has 5 lumens. When properly positioned, the distal lumen exit port is in the PA and the proximal lumen ports are in the right atrium and right ventricle. The distal and 1 of the proximal ports are used to measure PA and CVP, respectively. A balloon surrounds the catheter near the distal end. The balloon inflation valve is used to inflate the balloon with air to allow reading of the PAWP. A thermistor near the distal tip senses PA temperature and measures thermodilution cardiac output when solution cooler than body temperature is injected into a proximal port. **B,** Photo of an actual catheter.
B, Courtesy Edwards Critical Care Division, Baxter Healthcare Corporation, Santa Ana, CA.

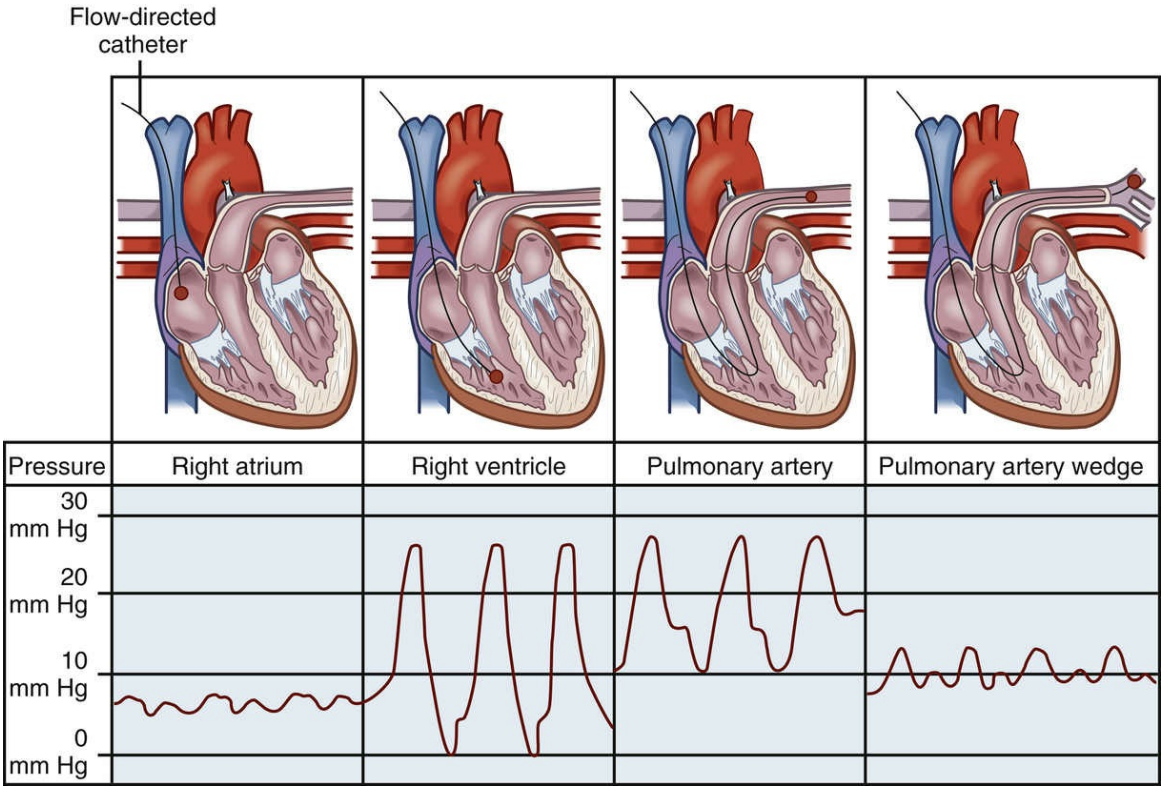

FIG. 65.9 Position of the pulmonary artery flow-directed catheter during progressive stages of insertion with corresponding pressure waveforms.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

The use of PA pressure monitoring has decreased dramatically. This is due, in part, to risks associated with this invasive technology (e.g., dysrhythmias, infection) and the development of less invasive techniques (e.g., APCO monitoring, bedside echocardiography).

The HCP often inserts a PA catheter at the bedside. Preparation includes arranging the monitor, cables, and infusion and pressurized flush solutions. The system is leveled and zero-referenced to the phlebostatic axis. Note the patient's electrolyte, acid-base, oxygenation, and coagulation status. Imbalances such as hypokalemia, hypomagnesemia, hypoxemia, or acidosis can make the heart more irritable. This can increase the risk for ventricular dysrhythmia during catheter insertion. Coagulopathy increases the risk for hemorrhage.

During insertion, a key nursing role is to observe the characteristic waveforms on the monitor as the HCP moves the catheter through the

heart to the PA (Fig. 65.9). Monitor the ECG continuously because of the risk for dysrhythmias, especially when the catheter reaches the right ventricle. After insertion and before using the PA catheter, obtain a chest x-ray to confirm catheter placement. Note and record the measurement at the exit point. Apply an occlusive sterile dressing and change it according to agency policy.

Central Venous or Right Atrial Pressure Measurement

CVP is a measurement of right ventricular preload and reflects fluid volume status. We most often measure it with a central venous catheter placed in the internal jugular or subclavian vein. It can be measured with a PA catheter using the proximal lumen in the right atrium. CVP waveforms (Fig. 65.10) are similar to PAWP waveforms. CVP is measured as a mean pressure at the end of expiration.[13] A high CVP indicates right ventricular failure or volume overload. A low CVP indicates hypovolemia.

Venous Oxygen Saturation Monitoring

In critically ill patients, measuring the O_2 saturation of hemoglobin in venous blood helps to determine the adequacy of tissue oxygenation. The O_2 saturation of venous blood from the CVP catheter is called *central venous O_2 saturation* ($ScvO_2$). Similarly, the O_2 saturation of blood from the PA catheter is the *mixed venous O_2 saturation* (SvO_2). $ScvO_2$ and SvO_2 reflect the balance among oxygenation of the arterial blood, tissue perfusion, and tissue O_2 consumption.[13] This gives a global indicator of the balance between O_2 delivery and O_2 consumption. $ScvO_2$ and SvO_2 are useful in assessing hemodynamic status and response to treatments or activities when considered in conjunction with arterial O_2 saturation (Table 65.4). Normal $ScvO_2$ or SvO_2 at rest is 60% to 80%.

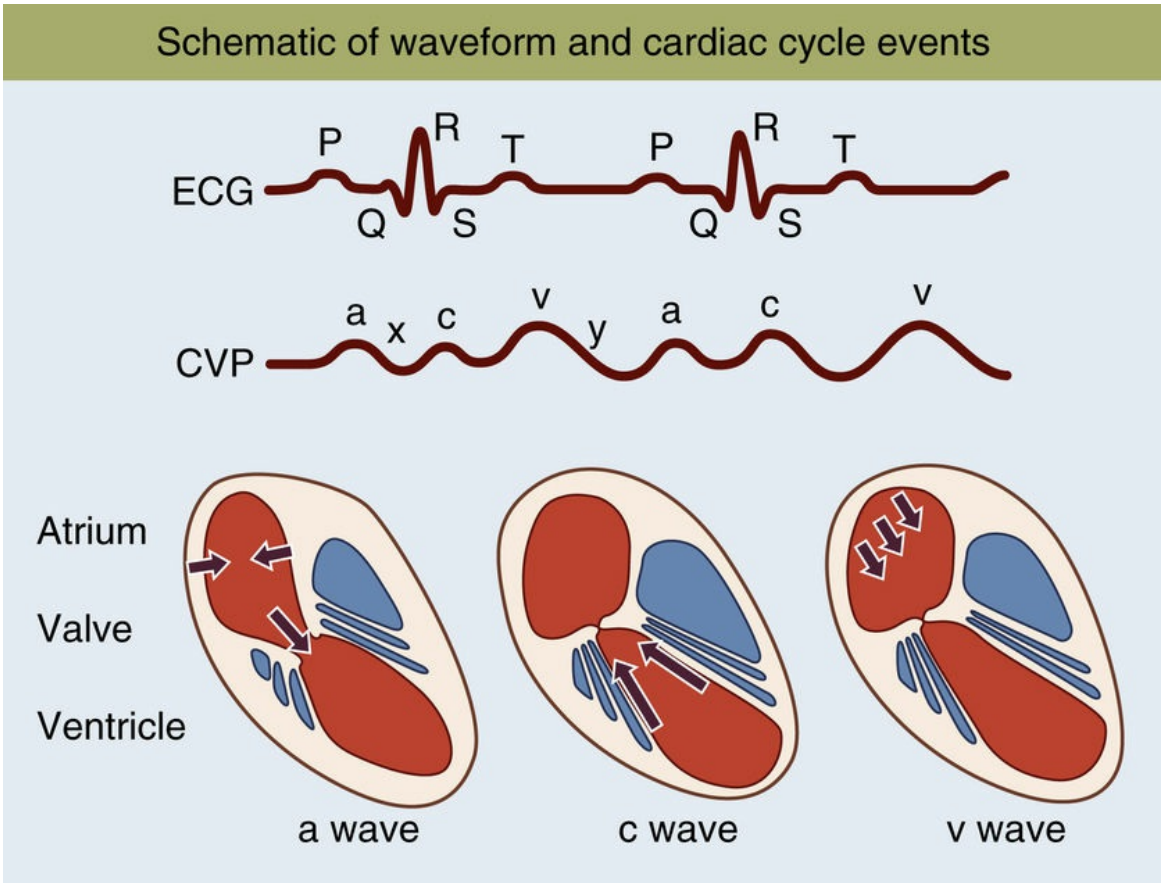

FIG. 65.10 Cardiac events that produce the CVP waveform with *a, c,* and *v* waves. The *a* wave represents atrial contraction. The *x* descent represents atrial relaxation. The *c* wave represents the bulging of the closed tricuspid valve into the right atrium during ventricular systole. The *v* wave represents atrial filling. The *y* descent represents opening of the tricuspid valve and filling of the ventricle.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

TABLE 65.4 Interpreting $ScvO_2$ and SvO_2* Measurements

$ScvO_2$ and SvO_2 Measurement	Physiologic Basis for Change in $ScvO_2$ or SvO_2	Clinical Diagnosis and Rationale
High $ScvO_2$ or SvO_2 (80%–95%)	↑ O_2 supply ↓ O_2 demand	• Patient receiving more O_2 than needed by clinical condition • Anesthesia, which causes sedation and ↓ muscle movement • Hypothermia, which ↓ metabolic demand (e.g., with cardiopulmonary bypass) • Sepsis caused by ↓ ability of tissues to use O_2 at the cellular level • False high positive because pulmonary artery catheter is wedged in a pulmonary capillary (SvO_2 only)
Normal $ScvO_2$ or SvO_2 (60%–80%)	Normal O_2 supply and metabolic demand	• Balanced O_2 supply and demand
Low $ScvO_2$ or SvO_2 (<60%)	↓ O_2 supply caused by • Low hemoglobin • Low arterial saturation (SaO_2) • Low cardiac output • ↑ O_2 demand	• Anemia or bleeding with compromised cardiopulmonary system • Hypoxemia resulting from ↓ O_2 supply or lung disease • Cardiogenic shock caused by left ventricular pump failure • Metabolic demand exceeds O_2 supply in conditions that ↑ muscle movement and metabolic rate (e.g., seizures, fever)

* $ScvO_2$ values are generally slightly higher than SvO_2 values.

Source: Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 8, St Louis, 2018, Elsevier.

Carefully review sustained decreases and increases in $ScvO_2$ or SvO_2. Decreased $ScvO_2$ or SvO_2 may indicate decreased arterial oxygenation, low CO, low hemoglobin level, or increased O_2 consumption or extraction. If the $ScvO_2$ or SvO_2 falls below 60%, determine which of these factors has changed. Observe for changes in arterial oxygenation (e.g., monitor pulse oximetry, ABGs) and indirectly assess CO and tissue perfusion. This is done by noting any changes in mental status, strength and quality of peripheral pulses, capillary refill, urine output, and skin color and temperature. If arterial oxygenation, CO, and hemoglobin level are unchanged, a fall in $ScvO_2$ or SvO_2 indicates increased O_2 consumption or extraction. This could represent an increased metabolic rate, pain, movement, fever, or shivering. If O_2 consumption increases without a comparable increase in O_2 delivery, more O_2 is extracted from the blood, and $ScvO_2$ and SvO_2 will continue to fall.[13]

Increased $ScvO_2$ or SvO_2 may indicate a clinical improvement (e.g., increased arterial O_2 saturation, improved perfusion, decreased metabolic rate) or problem (e.g., sepsis). In sepsis, O_2 is not extracted properly at the tissue level, resulting in increased $ScvO_2$ or SvO_2.

Changes in $ScvO_2$ or SvO_2 guide your interventions. For example,

you may note that the patient's HR increased slightly during repositioning but that the $ScvO_2$ remained stable. In this case, you would conclude that the patient tolerated the position change. If the $ScvO_2$ dropped, this would be a sign to stop the activity until the $ScvO_2$ returned to baseline.

In many cases, as activity or metabolism increases, HR and CO increase, and $ScvO_2$ or SvO_2 stays constant or varies slightly. However, critically ill patients often have conditions (e.g., HF, shock) that prevent substantial increases in CO. In these cases, $ScvO_2$ or SvO_2 can be a useful indicator of the balance between O_2 delivery and consumption.

Check Your Practice

You are caring for a 38-yr-old woman admitted with sepsis due to a ruptured ectopic pregnancy. She has CVP and $ScvO_2$ monitoring in place. Trends in $ScvO_2$ have shown a slow, steady decline, with the most recent reading being 55%.

- What assessment data would you obtain to explain this change?

Noninvasive Monitoring

Pulse Oximetry

Pulse oximetry is a noninvasive, continuous method of determining the O_2 saturation of hemoglobin (SpO_2). Monitoring SpO_2 may reduce the frequency of ABG sampling (see Chapter 25). SpO_2 is normally 95% to 100%. Accurate SpO_2 measurements may be hard to obtain on patients who are hypothermic, are receiving IV vasopressor therapy (e.g., norepinephrine), or have hypoperfusion or vasoconstriction (e.g., shock).

A common use for pulse oximetry is to assess the effectiveness of O_2

therapy. Decreased SpO_2 indicates inadequate oxygenation of the blood in the pulmonary capillaries. You can correct this by increasing the fraction of inspired O_2 (FIO_2) and evaluating the patient's response. Similarly, use SpO_2 to monitor how the patient tolerates decreases in FIO_2 and responds to interventions. For example, if SpO_2 falls when you place the patient in a left lateral recumbent position, plan position changes that pose less risk for the patient.

Impedance Cardiography

Impedance cardiography (ICG) is a continuous or intermittent, noninvasive method of obtaining CO and assessing thoracic fluid status. Based on the concepts of *impedance* (the resistance to the flow of electric current [Ω]), ICG uses 4 sets of external electrodes to deliver a high-frequency, low-amplitude current that is like that used in apnea monitors. Blood is an excellent conductor of electricity (lower impedance), and pulsatile blood flow generates electrical impedance changes. ICG measures the change in impedance (dΩ) in the ascending aorta and left ventricle over time (dt). It is represented as dΩ/dt. Ωo is the measurement of the average impedance of the fluid in the thorax. We can calculate impedance-based hemodynamic parameters (CO, SV, SVR) from Ωo, dΩ/dt, MAP, CVP, and ECG.

Major uses of ICG include (1) detecting early signs and symptoms of pulmonary or cardiac problems, (2) determining cardiac or pulmonary cause of shortness of breath, (3) evaluating the cause and managing hypotension, (4) monitoring after removing a PA catheter or justifying insertion of a PA catheter, (5) evaluating drug therapy, and (6) diagnosing rejection after heart transplantation. ICG is not accurate in patients who have generalized edema or third spacing because the excess volume interferes with the signals.

Nursing Management: Hemodynamic Monitoring

Assessment of hemodynamic status requires integrating data from

many sources and trending data over time. Comprehensive nursing observations give important clues about the patient's hemodynamic status.

Begin by obtaining baseline data about the patient's general appearance, level of consciousness, skin color and temperature, vital signs, peripheral pulses, capillary refill, and urine output. Does the patient appear tired, weak, exhausted? There may be too little cardiac reserve to sustain even minimum activity. Pallor, cool skin, and decreased pulses may indicate decreased CO. Changes in mental status may reflect problems with cerebral perfusion or oxygenation. Monitor urine output to determine the adequacy of perfusion to the kidneys. The patient with decreased perfusion to the GI tract may develop hypoactive or absent bowel sounds. If the patient is bleeding and developing shock, the BP may be stable at first. The patient may become increasingly pale and cool from peripheral vasoconstriction. Conversely, the patient with septic shock may be warm and pink yet have tachycardia and BP instability. Increased HRs are common in stressed, compromised, critically ill patients. However, sustained tachycardia increases myocardial O_2 demand and can result in decreased CO.

Always correlate observational data with data obtained from technology (e.g., ECG, arterial and PA pressures, $ScvO_2$, SvO_2). Single hemodynamic values are rarely helpful. You must monitor trends in these values over time and evaluate the whole clinical picture with the goals of recognizing early clues and intervening before problems escalate.

Circulatory Assist Devices

Mechanical **circulatory assist devices (CADs)** are used to decrease cardiac work and improve organ perfusion in patients with HF when conventional drug therapy is no longer adequate. CADs include **intraaortic balloon pumps (IABPs)** and left or right ventricular assist devices (VADs).

The type of device used depends on the extent and nature of the

heart problem. CADs provide support in 3 situations: (1) the left, right, or both ventricles require support while recovering from acute injury (e.g., postcardiotomy); (2) the patient must be stabilized before surgical repair of the heart (e.g., a ruptured septum); and (3) the heart has failed, and the patient is awaiting heart transplantation. All CADs decrease cardiac workload, increase myocardial perfusion, and augment circulation.

Intraaortic Balloon Pump

The IABP provides temporary circulatory assistance by reducing afterload (through reducing systolic pressure) and augmenting the aortic diastolic pressure. This improves coronary blood flow. Table 65.5 lists common indications for an IABP.

The IABP consists of a sausage-shaped balloon, a pump that inflates and deflates the balloon, a control panel for synchronizing the balloon inflation to the cardiac cycle, and fail-safe features. The balloon is inserted percutaneously or surgically into the femoral artery. It is moved toward the heart and placed in the descending thoracic aorta just below the left subclavian artery and above the renal arteries (Fig. 65.11). After placement, an x-ray confirms the position.

A pneumatic device fills the balloon with helium at the start of diastole (immediately after aortic valve closure) and deflates it just before the next systole. The ECG is the trigger used to start the deflation on the upstroke of the R wave (of the QRS) and inflation on the T wave. The dicrotic notch of the arterial pressure tracing is used to refine timing (Fig. 65.12).

TABLE 65.5 Common Indications and Contraindications for IABP Therapy

Indications

- Acute MI with any of the following*:

    - Ventricular aneurysm accompanied by ventricular dysrhythmias
    - Acute ventricular septal defect
    - Acute mitral valve dysfunction
    - Cardiogenic shock
    - Refractory chest pain with or without ventricular dysrhythmias
- High-risk interventional cardiology procedures
- Preoperative, intraoperative, and postoperative cardiac surgery (e.g., prophylaxis before surgery, failure to wean from cardiopulmonary bypass, left ventricular failure after cardiopulmonary bypass)
- Unstable angina unresponsive to drug therapy
- Short-term bridge to heart transplantation

Contraindications

- Abdominal aortic and thoracic aneurysms
- Generalized peripheral vascular disease (e.g., aortoiliac disease)[†]
- Irreversible brain damage
- Major coagulopathy (e.g., disseminated intravascular coagulation [DIC])
- Moderate to severe aortic insufficiency
- Terminal or untreatable diseases of any major organ system

---

[*] Allows time for emergent angiography and corrective heart surgery to be done.

[†] May inhibit placement of balloon and is considered a relative contraindication; sheathless insertion may be used.

IABP therapy is known as *counterpulsation* because the timing of

balloon inflation is opposite the ventricular contraction. The IABP assist ratio is 1:1 in the acute phase of treatment, meaning that 1 IABP cycle of inflation and deflation occurs for every heartbeat.

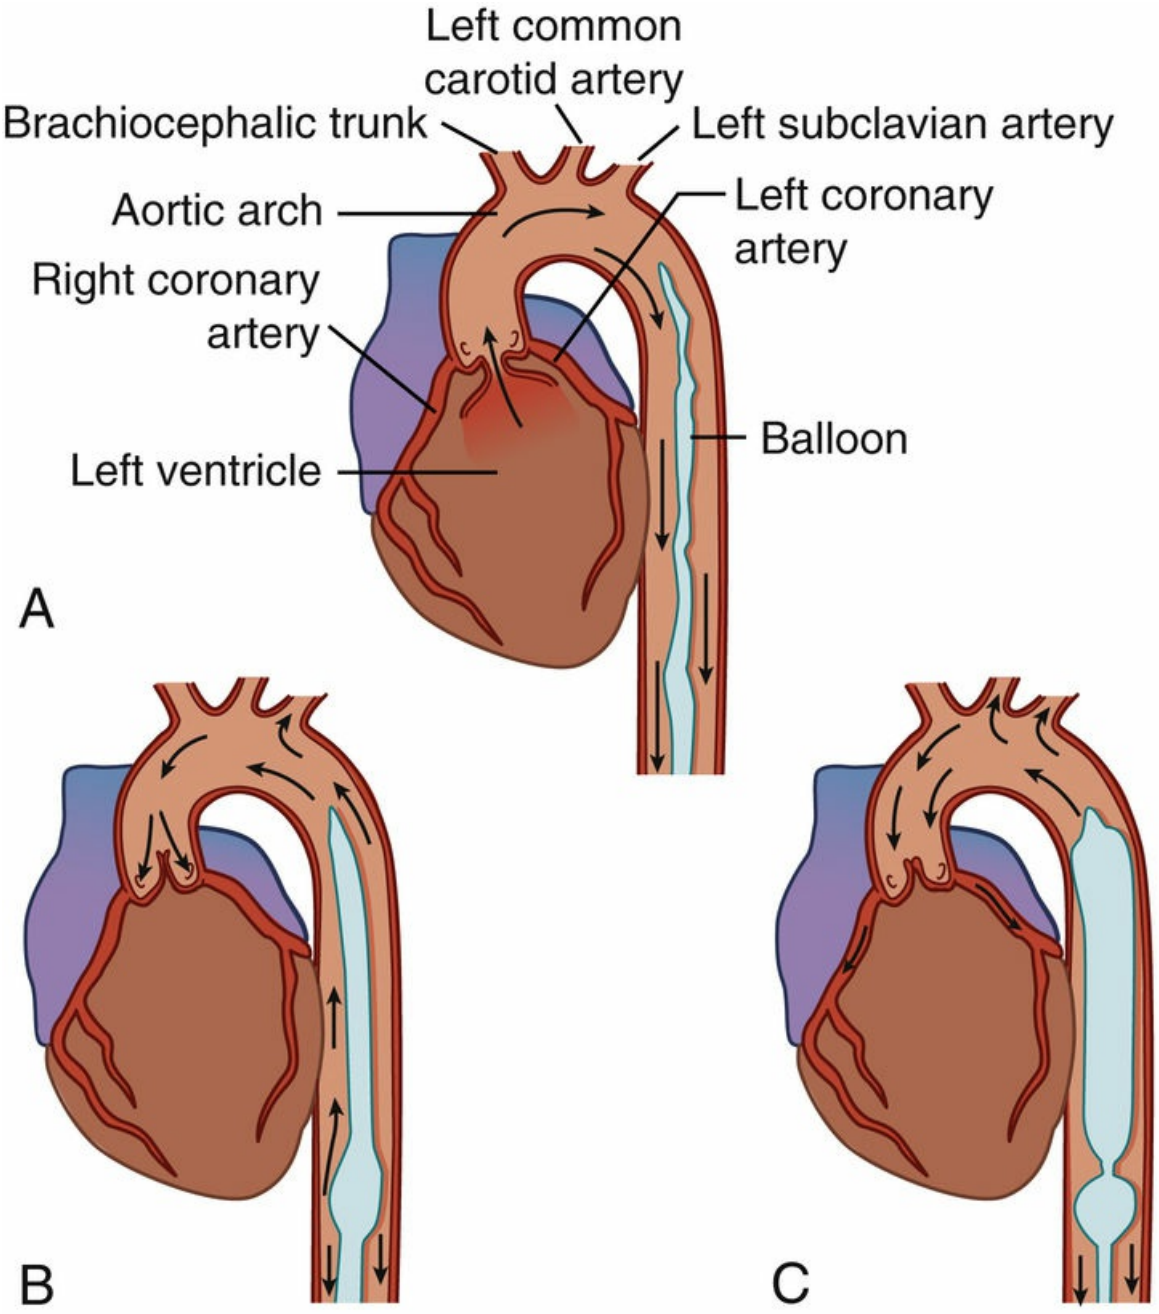

FIG. 65.11 IABP. **A,** During systole the balloon is deflated, which helps with ejection of blood into the periphery. **B,** In early diastole, the balloon begins to inflate. **C,** In late diastole, the balloon is totally

inflated, which augments aortic pressure and increases the coronary perfusion pressure. This increases coronary and cerebral blood flow.

Effects of Counterpulsation

In late diastole when the balloon is totally inflated, blood is forcibly displaced distal to the extremities and proximal to the coronary arteries and main branches of the aortic arch. Diastolic arterial pressure rises (diastolic augmentation). This increases coronary artery perfusion pressure and perfusion of vital organs. The rise in coronary artery perfusion pressure increases blood flow to the myocardium. The balloon is rapidly deflated just before systole. This creates a vacuum that causes aortic pressure to drop. When aortic resistance to left ventricular ejection is reduced (reduced afterload), the left ventricle empties more easily and completely. SV increases while myocardial O_2 consumption decreases. Table 65.6 describes the hemodynamic effects of IABP therapy.

FIG 65.12 Monitoring on an IABP machine.
© beerkoff/iStock.com.

TABLE 65.6 Hemodynamic Effects of Counterpulsation

Effects of Inflation During Diastole

- ↑ Diastolic pressure (may exceed systolic pressure)
- ↑ Pressure in the aortic root during diastole

- ↑ Coronary artery perfusion pressure
- Improved O_2 delivery to the myocardium
    - ↓ Angina
    - ↓ ECG evidence of ischemia
    - ↓ Ventricular ectopy

Effects of Deflation During Systole

- ↓ Afterload
- ↓ Peak systolic pressure
- ↓ Myocardial O_2 consumption
- ↑ Stroke volume, possibly associated with:
    - Improved mentation
    - Warm skin
    - ↑ Urine output
    - ↓ HR
- ↑ Forward flow of blood, ↓ preload
    - ↓ Pulmonary artery pressures, including PAWP
    - ↓ Crackles

Complications With IABP Therapy

Vascular injuries, such as aortic dissection and compromised distal circulation, are common with IABP therapy. Thrombus and embolus formation add to the risk for circulatory compromise to the extremity. The action of the IABP can destroy platelets and cause thrombocytopenia. Movement of the balloon can block the left subclavian, renal, or mesenteric arteries. This can result in a weak or absent radial pulse, decreased urine output, and reduced or absent bowel sounds. Patients receiving IABP therapy are prone to infection. Local or systemic signs of infection require catheter removal. To reduce these complications, perform cardiovascular, neurovascular, and hemodynamic assessments every 15 to 60 minutes, depending on

the patient's status (Table 65.7).[13]

TABLE 65.7 Managing Complications of IABP Therapy

Potential Complications	Nursing Interventions
Balloon leak or rupture	• Prepare for emergent removal and possible reinsertion.
Arterial trauma caused by insertion or displacement of balloon	• Assess and mark peripheral pulses before inserting balloon to use as baseline for assessing pulses after insertion. • Assess perfusion to both upper and lower extremities at least every hour. • Measure urine output at least every hour (occlusion of renal arteries causes severe ↓ in urine output). • Observe arterial waveforms for sudden changes. • Keep head of bed no higher than 45 degrees. • Do not flex cannulated leg at the hip. • Immobilize cannulated leg to prevent flexion using a draw sheet tucked under the mattress, soft ankle restraint, or knee immobilizer.
Hematologic problems due to platelet aggregation along the balloon (e.g., thrombocytopenia)	• Monitor coagulation profiles, hematocrit, and platelet count.
Hemorrhage from insertion site	• Check site for bleeding at least every hour. • Monitor vital signs for signs of hypovolemia with each check.
Infection at site	• Use strict aseptic technique for insertion and dressing changes for all lines. • Cover all insertion sites with occlusive dressings. • Give prescribed prophylactic antibiotic for entire course of therapy.
Issues related to immobilization (e.g., pressure injuries)	• Reposition patient at least q2hr, being careful to maintain proper positioning. • Use appropriate pressure-relieving devices.
VTE caused by trauma, balloon obstruction of blood flow distal to catheter	• Give prophylactic heparin therapy (if ordered). • Assess pulses, urine output, and level of consciousness at least every hour. • Check circulation, sensation, and movement in both legs at least every hour.

Mechanical complications from IABP are rare but can occur. Improper timing of balloon inflation may cause increased afterload, decreased CO, myocardial ischemia, and increased myocardial O_2 demand. If the balloon develops a leak, the pump will automatically stop. The catheter needs to be promptly removed to avoid an embolus. Signs of a leak include less effective augmentation, repeated alarms for gas loss, and blood backing up into the catheter. A malfunction of the balloon or console triggers fail-safe alarms and automatically shuts down the unit. You must be able to recognize complications immediately and report them to the HCP.

The patient with an IABP is relatively immobile, limited to side-lying or supine positions with the head of bed (HOB) elevated less

than 45 degrees. The patient may be receiving mechanical ventilation and will likely have multiple invasive lines. All of this increases the risk for pressure injury and makes it hard to find comfortable positioning. The patient may have sleep problems and anxiety. Adequate sedation, pain relief, skin care, and comfort measures are essential.

As the patient improves, circulatory support provided by the IABP is gradually reduced. Weaning involves reducing the IABP assist ratio from 1:1 to 1:2 and assessing the patient's response. If the patient remains stable, the ratio is changed from 1:2 to 1:3 until the IABP catheter is removed. Pumping must continue until the line is removed even if the patient is stable. This reduces the risk for clot formation around the catheter.

Ventricular Assist Devices

A **ventricular assist device (VAD)** provides short- and long-term support for the failing heart and allows more mobility than the IABP. VADs are inserted into the path of flowing blood to augment or replace the action of the ventricle. Some VADs are implanted internally (e.g., peritoneum). Others are positioned externally. A typical VAD shunts blood from the left atrium or ventricle to the device and then to the aorta. Some VADs provide right or biventricular support (Fig. 65.13).

Failure to wean from cardiopulmonary bypass (CPB) after surgery is a key indicator for VAD support. VADs can support patients with HF caused by MI and patients awaiting heart transplantation. A VAD is a temporary device that can partially or totally support circulation until the heart recovers or a donor heart is found.

Appropriate patient selection for VAD therapy is critical. Indications include (1) failure to wean from CPB or postcardiotomy cardiogenic shock, (2) a bridge to recovery or heart transplantation, and (3) patients with New York Heart Association Class IV heart disease (see Table 34.3) who have failed medical therapy. Relative contraindications for VAD therapy include (1) BSA less than

manufacturer's limit (e.g., 1.2 m^2), (2) irreversible end-stage organ damage, and (3) co-morbidities that would limit life expectancy to less than 3 years.[13]

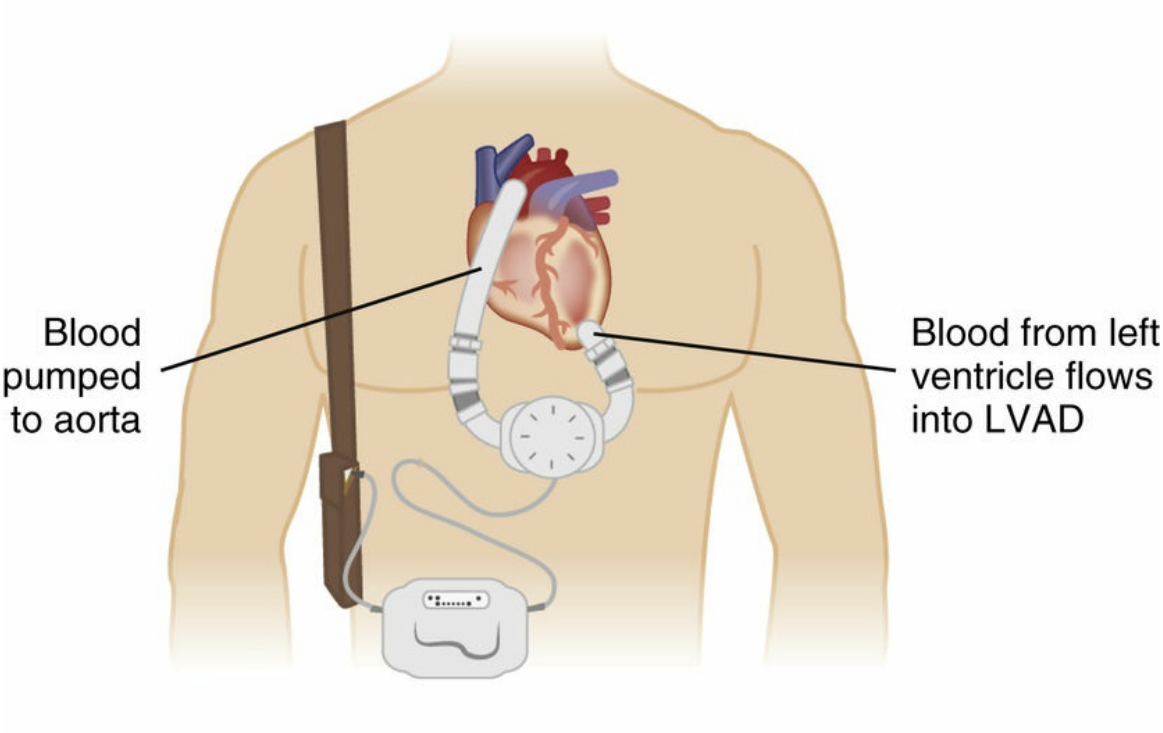

FIG. 65.13 Schematic diagram of a biventricular assist device (BVAD).
From Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 8, St Louis, 2018, Mosby.

Implantable Artificial Heart

Every year, about 2200 patients receive heart transplants, yet the demand for donor hearts far exceeds the supply. Research on mechanical CADs has led to the development of a fully implantable artificial heart that can sustain the body's circulatory system. This device can provide a bridge to transplantation or replace the hearts of patients who are not eligible for a transplant and have no other treatment options. A major advantage of the artificial heart is that patients do not need immunosuppression therapy and thus avoid its

inevitable, long-term effects. Risks include infection, thrombus, and stroke. Patients need lifelong anticoagulation and ongoing care from the interprofessional team.[15]

Nursing and Interprofessional Management: Circulatory Assist Devices

The patient with an IABP needs highly skilled care. Perform frequent and thorough cardiovascular assessments. These include measuring hemodynamic parameters (e.g., arterial BP, CO/CI, SVR), auscultating the heart and lungs, and evaluating the ECG (e.g., rate, rhythm). Assess for adequate tissue perfusion (e.g., skin color and temperature, mental status, capillary refill, peripheral pulses, urine output, bowel sounds) at regular intervals. IABP therapy should improve these findings.

Nursing care of the patient with a VAD is like that of the patient with an IABP. Observe the patient for bleeding, cardiac tamponade, ventricular failure, infection, dysrhythmias, renal failure, hemolysis, and VTE. The patient with VAD may be mobile and need an activity plan. In some cases, patients with VADs may go home. Preparation for discharge is complex and needs in-depth teaching about the device and support equipment (e.g., battery chargers). A competent caregiver must always be present.

Ideally, patients with CADs will recover, receive an artificial heart, or undergo heart transplantation. However, many patients die, or the decision is made to no longer seek treatment and death follows. Both the patient and caregiver need emotional support. Consult other team members, such as social workers or clergy, as needed.

Noninvasive Ventilation

At times, patients may need ventilator support, without the placement

of an ET tube. Noninvasive ventilation (NIV) uses a mask, instead of an ET tube, to oxygenate and ventilate a patient. These masks can be full face or a nasal piece. There are 2 common modes used for NIV.

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) restores functional residual capacity (FRC) and is similar to positive end-expiratory pressure (PEEP). However, the pressure in CPAP is delivered continuously during spontaneous breathing, preventing the patient's airway pressure from falling to 0. For example, if CPAP is 5 cm H_2O, airway pressure during expiration is 5 cm H_2O. During inspiration, we generate 1 to 2 cm H_2O of negative pressure. This reduces airway pressure to 3 or 4 cm H_2O. CPAP is often used to treat obstructive sleep apnea. It is a noninvasive modality, delivered through a tight-fitting face mask, nasal mask, or nasal pillows. CPAP increases *work of breathing* (WOB) because the patient must forcibly exhale against the CPAP. Therefore it must be used with caution in patients with myocardial compromise. The patient must be able to remove a mask independently due to the risk for vomiting. Those with increased secretions or the inability to control their airway are not good candidates for CPAP due to the risk for aspiration.[13]

Bilevel Positive Airway Pressure

In addition to O_2, *bilevel positive airway pressure (BiPAP)* provides 2 levels of positive pressure support: higher inspiratory positive airway pressure and lower expiratory positive airway pressure.[13] Like CPAP, the patient must be able to spontaneously breathe and cooperate with this treatment (Fig. 65.14).

BiPAP is used for COPD patients with HF and acute respiratory failure and for patients with sleep apnea. Its use after extubation can help prevent reintubation. Patients with shock, altered mental status, or increased airway secretions cannot use BiPAP because of the risk for aspiration and the inability to remove the mask.

FIG. 65.14 BiPAP delivered through a face mask.
Courtesy Respironics Inc., Murrysville, PA.

Artificial Airways

Patients in the ICU often need mechanical assistance to maintain airway patency. Inserting a tube into the trachea, bypassing upper airway and laryngeal structures, creates an artificial airway. The tube is placed into the trachea via the mouth or nose past the larynx (**endotracheal [ET] intubation**) or through a stoma in the neck *(tracheostomy)*. Fig. 65.15 shows the parts of an ET tube.

ET intubation is common in ICU patients requiring mechanical ventilation for short periods of time (e.g., less than 2 weeks). Other indications for intubation include (1) upper airway obstruction (e.g.,

burns, tumor, bleeding), (2) apnea, (3) high risk for aspiration, (4) ineffective clearance of secretions, and (5) respiratory distress. ET intubation is done quickly and safely at the bedside by an HCP or RT.

A *tracheotomy* is a surgical procedure that is done when the need for an artificial airway is expected to be prolonged. Early tracheotomy (done within 10 days) appears to have advantages over delayed tracheotomy. These include fewer ventilator dependent days, reduced length of stays, decreased pain, and improved communication.[16] Chapter 26 discusses tracheostomy tubes and related nursing management.

Endotracheal Tubes

In *oral intubation,* the ET tube is passed through the mouth and vocal cords and into the trachea with the aid of a laryngoscope or a bronchoscope. Oral ET intubation is preferred for most emergencies because the airway can be secured rapidly. A larger diameter tube is used. A larger tube reduces the WOB because of less airway resistance. It is easier to remove secretions and perform bronchoscopy, if needed. In *nasal ET intubation,* the ET is placed blindly (i.e., without seeing the larynx) through the nose, nasopharynx, and vocal cords. We rarely use nasal ET intubation. It may be done when oral intubation is not possible (e.g., unstable cervical spine injury, dental abscess, epiglottitis).

There are risks associated with oral ET intubation. It is hard to place the tube with limited head and neck mobility (e.g., spinal cord injury). Teeth can be chipped or accidentally removed during the procedure. Salivation increases, and swallowing is difficult. Patients can obstruct the ET tube by biting down on the tube. Sedation, along with a bite block or oropharyngeal airway, may be used to prevent obstruction. Mouth care is a challenge because of limited space in the oral cavity.

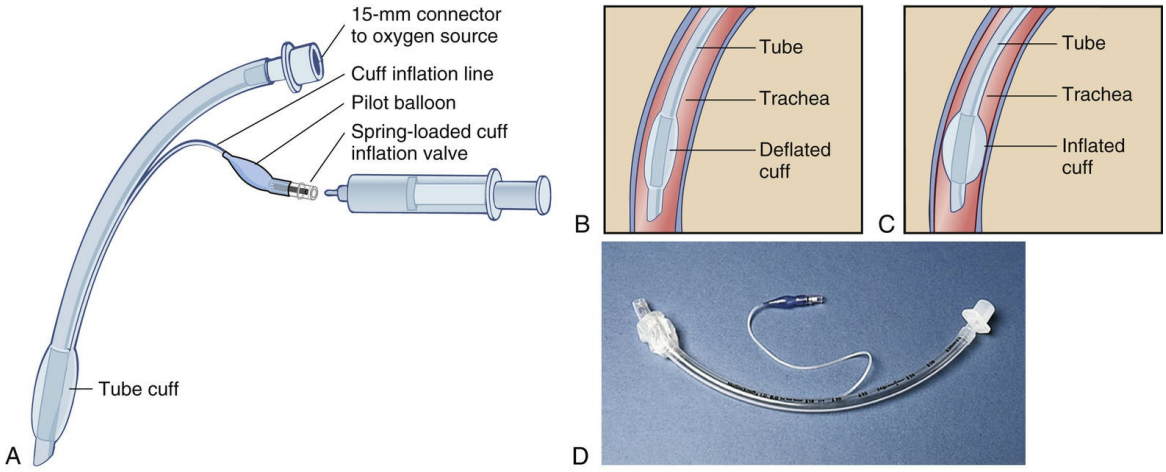

FIG. 65.15 Endotracheal tube. **A,** Parts of an endotracheal tube. **B,** Tube in place with cuff deflated. **C,** Tube in place with the cuff inflated. **D,** Photo of tube before placement.
A, From Beare PG, Myers JL: *Adult health nursing,* ed 3, St Louis, 1998, Mosby.

Endotracheal Intubation Procedure

Unless ET intubation is emergent, consent for the procedure is obtained. Tell the patient and caregiver the reason for ET intubation and steps in the procedure. Explain that, while intubated, the patient will not be able to speak, but that you will provide other means of communication. Tell them that the patient's hands may have removable mitts placed or wrists may have soft restraints placed to remind them not to touch the airway.

Have a self-inflating *bag-valve-mask* (BVM) (e.g., *Ambu bag*) attached to O_2, suctioning equipment ready at the bedside, and IV access. The BVM has a reservoir that is filled with O_2 so that it delivers concentrations of 90% to 95%. The slower the bag is deflated and inflated, the higher the O_2 concentration that is delivered. Assemble and check the equipment, remove the patient's dentures or partial plates (for oral intubation), and give medications as ordered. Premedication varies depending on the patient's level of consciousness (e.g., awake, obtunded), urgency (e.g., emergent, nonemergent), and the HCP's preferences.

For oral intubation, place the patient supine with the head extended

and the neck flexed ("sniffing position"). This position allows the HCP to better see the vocal cords. For nasal intubation, the nasal passages may be sprayed with a local anesthetic and vasoconstrictor (e.g., lidocaine with epinephrine) to reduce trauma and bleeding. Before intubation is started, preoxygenate the patient using the BVM and 100% O_2 for 3 to 5 minutes. Each intubation attempt is limited to less than 30 seconds. Ventilate the patient between successive attempts using the BVM and 100% O_2.

Rapid-sequence intubation (RSI) is the rapid, concurrent administration of both a sedative and a paralytic drug during emergency airway management to induce unconsciousness for intubation. It decreases the risks for aspiration and injury to the patient. RSI is not indicated in patients who are in cardiac arrest or have a known difficult airway. A sedative-hypnotic-amnesic (e.g., propofol, etomidate [Amidate]) is given to induce unconsciousness, along with a rapid-onset opioid (e.g., fentanyl) to blunt the pain of the procedure. This is followed with a drug (e.g., rocuronium) to produce skeletal muscle paralysis.[17] Monitor the patient's O_2 status during the procedure with pulse oximetry. Adhere to the agency policy about RSI medication administration.

After intubation, inflate the cuff. Confirm the placement of the ET tube while continuing to manually ventilate the patient using the BVM with 100% O_2. Use an $EtCO_2$ detector to confirm proper placement by noting the presence of exhaled CO_2 from the lungs (Fig. 65.16). Place the detector between the BVM and ET tube and look for a color change (indicating the presence of CO_2) or a number. At least 5 or 6 exhalations with a consistent CO_2 level must be present to confirm tube placement in the trachea.[13] Auscultate the lungs for bilateral breath sounds and the epigastrium for the absence of air sounds. Observe the chest for symmetric chest wall movement. SpO_2 should be stable or improved.

If the findings support proper ET tube placement, connect the ET tube to a mechanical ventilator and secure the tube per agency policy (Fig. 65.17). Suction the ET tube and pharynx. Insert a bite block, if

needed, and secure it separately from the ET tube to the face. Obtain a chest x-ray to confirm tube location (2 to 6 cm above the carina in the adult). This position allows the patient to move the neck without moving the tube or causing it to enter the right mainstem bronchus. Once proper positioning is confirmed with x-ray, record and mark the position of the tube at the lip or teeth or nose.

FIG. 65.16 Use an $EtCO_2$ detector to confirm proper placement of an endotracheal tube.
From Thomsen TW, Setnik GS: Orotracheal intubation, *Procedures Consult ,* 2017.

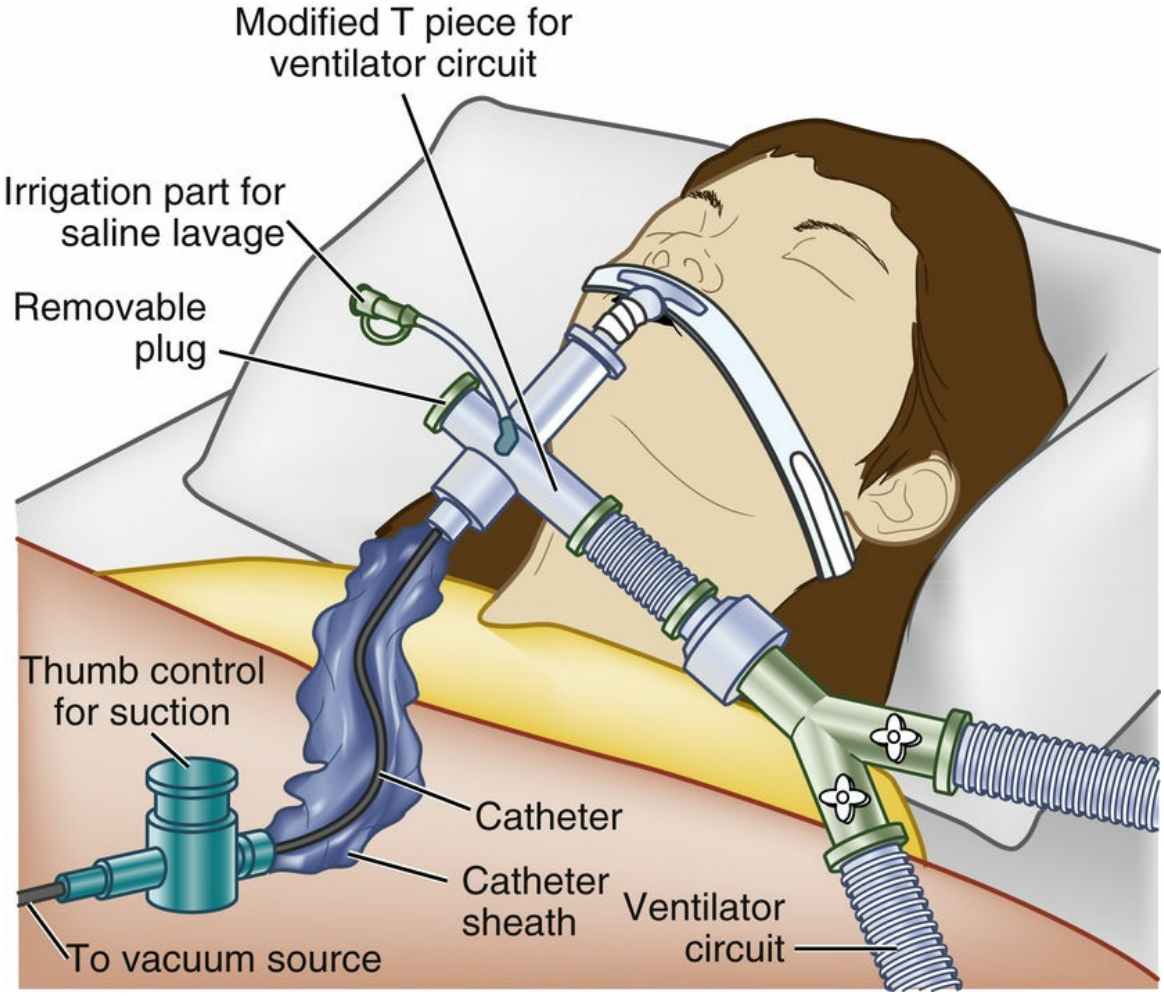

FIG. 65.17 Endotracheal tube secured to a closed tracheal suction system.

Obtain ABGs 15 to 30 minutes after intubation to determine baseline oxygenation and ventilation status. ABG values are used to guide oxygenation and ventilation changes. Continuous pulse oximetry gives data about arterial oxygenation. $EtCO_2$ monitoring provides data related to ventilation.

Nursing and Interprofessional Management: Artificial Airway

Managing a patient with an artificial airway is often a shared responsibility between you and the RT. Agency policy dictates specific

management tasks. Nursing responsibilities for the patient with an artificial airway may include: (1) maintaining correct tube placement, (2) maintaining proper cuff inflation, (3) monitoring oxygenation and ventilation, (4) maintaining tube patency, (5) providing oral care and maintaining skin integrity, (6) fostering comfort and communication, and (7) assessing for complications. See eNursing Care Plan 65.1 for the patient on a mechanical ventilator (available on the website for this chapter).

Maintaining Correct Tube Placement

Continuously monitor the patient with an ET tube for proper placement. If the tube moves or is dislodged, it could end up in the pharynx or enter the esophagus or right mainstem bronchus (thus ventilating only the right lung).

Safety Alert

Endotracheal Tube Placement

- Maintain proper ET tube position by recording and marking the position of the tube at the lip or teeth (usually 21 cm for women, 23 cm for men).
- Confirm that the mark stays constant while at rest and during patient care, repositioning, and transport.

Observe for symmetric chest wall movement. Auscultate to confirm bilateral breath sounds. If the ET tube is not positioned properly, it is an airway emergency. Stay with the patient and try to maintain the airway. Support ventilation with a BVM and 100% O_2 and call for the appropriate help to immediately assess or reposition the tube. If a dislodged tube is not repositioned, minimal or no O_2 is delivered to the lungs or the entire V_T is being delivered to 1 lung. This places the

patient at risk for pneumothorax.

Maintaining Proper Cuff Inflation

The cuff is an inflatable, pliable sleeve encircling the lower, outer wall of the ET tube (Fig. 65.15). The high-volume, low-pressure cuff stabilizes and "seals" the ET tube within the trachea and prevents escape of ventilating gases. However, excess volume in the cuff can damage the tracheal mucosa. To prevent this, inflate the cuff with air and measure and monitor the cuff pressure. To ensure adequate tracheal perfusion, maintain cuff pressure at 20 to 25 cm H_2O.[13] Measure and record cuff pressure after intubation and on a routine basis (e.g., every 8 hours) using the *minimal occluding volume* (MOV) *technique* or *the minimal leak technique* (MLT).

To perform the MOV technique, first, in the mechanically ventilated patient, place a stethoscope over the trachea and inflate the cuff to MOV by adding air until you hear no air at peak inspiratory pressure (end of ventilator inspiration). For the spontaneously breathing intubated patient, you inflate until you hear no sound after a deep breath or after inhalation with a BVM. Second, use a manometer to verify that cuff pressure is between 20 and 25 cm H_2O and record cuff pressure in the chart. If adequate cuff pressure cannot be maintained or larger volumes of air are needed to keep the cuff inflated, there could be a leak in the cuff or tracheal dilation at the cuff site. In these situations, notify the HCP. The procedure for MLT is similar with 1 exception. You remove a small amount of air from the cuff until you hear a slight air leak at peak inflation.

Monitoring Oxygenation and Ventilation

Closely monitor the patient with an ET tube for adequate oxygenation by assessing clinical findings, ABGs, SpO_2, and, if available, $ScvO_2$ or SvO_2. Assess for signs of hypoxemia, such as a change in mental status (e.g., confusion), dusky skin, and dysrhythmias. Periodic ABGs and continuous SpO_2 provide objective data about oxygenation.

Lower PaO_2 values are expected in patients with some disease states, such as chronic obstructive pulmonary disease (COPD). CVP or PA catheters with $ScvO_2$ or SvO_2 capability provide an indirect measure of the patient's tissue oxygenation status (Table 65.4).

Indicators of ventilation include clinical findings, $PaCO_2$, and continuous partial pressure of $EtCO_2$ ($PETCO_2$). Assess the patient's respirations for rate, rhythm, and use of accessory muscles. The patient who is hyperventilating will be breathing rapidly and deeply and may have circumoral and peripheral numbness and tingling. The patient who is hypoventilating will be breathing shallowly or slowly and may appear dusky. $PaCO_2$ is the best indicator of alveolar hyperventilation (e.g., decreased $PaCO_2$, increased pH indicates respiratory alkalosis) or hypoventilation (e.g., increased $PaCO_2$, decreased pH indicates respiratory acidosis).

$PETCO_2$ monitoring *(capnography)* is done by analyzing exhaled gas directly at the patient-ventilator circuit *(mainstream sampling)* or by transporting a sample of gas via a small-bore tubing to a bedside monitor *(sidestream sampling).* Continuous $PETCO_2$ monitoring can assess the patency of the airway and presence of breathing. Gradual changes in $PETCO_2$ values may accompany an increase in CO_2 production (e.g., sepsis, hypoventilation, neuromuscular blockade) or a decrease in CO_2 production (e.g., hypothermia, decreased CO, metabolic acidosis). In patients with normal ventilation-to-perfusion ratios (see Chapter 67), we can use $PETCO_2$ to estimate $PaCO_2$. $PETCO_2$ is generally 2 to 5 mm Hg lower than $PaCO_2$.[13] However, in patients with unusually large dead air space or serious mismatch between ventilation and perfusion (e.g., COPD, pulmonary embolism), $PETCO_2$ is not a reliable estimate of $PaCO_2$.

Maintaining Tube Patency

Do not routinely suction a patient.[13] Regularly assess the patient to determine if suctioning is needed. Indications for suctioning include (1) visible secretions in the ET tube, (2) sudden onset of respiratory

distress, (3) suspected aspiration of secretions, (4) increase in respiratory rate or frequent coughing, and (5) sudden decrease in SpO_2. Other signs that indicate the patient needs suctioning include an increase in peak airway pressure and auscultating adventitious breath sounds over the trachea or bronchi.[13]

Table 65.8 describes 2 recommended suctioning methods, the *closed-suction technique* (CST) and the *open-suction technique* (OST). The CST uses a suction catheter that is enclosed in a plastic sleeve connected directly to the patient-ventilator circuit (Fig. 65.17). With the CST, oxygenation and ventilation are maintained during suctioning, and exposure to the patient's secretions and infection is reduced for the patient's and HCP's safety. The CST should be used for patients who (1) require PEEP, (2) have high levels of FIO_2, (3) have bloody or infected pulmonary secretions, (4) require frequent suctioning, and (5) have clinical instability with the OST.[13]

Potential complications associated with suctioning include hypoxemia, bronchospasm, increased ICP, dysrhythmias, hypertension, hypotension, mucosal damage, pulmonary bleeding, pain, and infection. Closely assess the patient before, during, and after suctioning. If the patient does not tolerate suctioning (e.g., decreased SpO_2, increased or decreased BP, sustained coughing, development of dysrhythmias), stop at once. Continue to reassess the patient until hemodynamic stability is achieved, the patient recovers, and/or the situation resolves before trying to suction again. Prevent hypoxemia by hyperoxygenating the patient before and after each suctioning pass and limiting each pass to 10 seconds or less (Table 65.8). Assess both the ECG and SpO_2 before, during, and after suctioning.

TABLE 65.8 Suctioning Procedures for Patient on Mechanical Ventilator

General Measures for Open- and Closed-Suction Techniques

1. Gather all equipment.
2. Wash hands and don personal protective equipment and gloves.
3. Explain procedure and patient's role in assisting with secretion removal by coughing.
4. Monitor patient's cardiopulmonary status (e.g., vital signs, SpO_2, SvO_2 or $ScvO_2$, ECG, level of consciousness) before, during, and after suctioning.
5. Turn on suction and set vacuum to 100–120 mm Hg.
6. Pause ventilator alarms.

Open-Suction Technique

7. Open sterile catheter package using the inside of the package as a sterile field. NOTE: Suction catheter should be no wider than half the diameter of the ET tube (e.g., for a 7-mm ET tube, select a 10F suction catheter).
8. Fill the sterile solution container with sterile normal saline or water.
9. Don sterile gloves.
10. Pick up sterile suction catheter with dominant hand. Using nondominant hand, secure the connecting tube (to suction) to the suction catheter.
11. Check equipment for proper functioning by suctioning a small volume of sterile saline solution from the container. **(Go to step 13.)**

Closed-Suction Technique

12. Connect the suction tubing to the closed suction port.
13. Hyperoxygenate the patient for 30 seconds using 1 of the following methods:
    - Activate the suction hyperoxygenation setting on the ventilator using nondominant hand. This is the safest method to hyperoxygenate the patient and should be

used when available.
- Increase FIO_2 to 100%. NOTE: Remember to return FIO_2 to baseline level when done suctioning, if not done automatically after preset time by ventilator.
- Disconnect the ventilator tubing from the ET tube and provide manual ventilation to the patient with 100% O_2 using a BVM device. Attach a PEEP valve to the BVM for patients on >5 cm H_2O PEEP. Give 5 or 6 breaths over 30 seconds. Having a second person deliver the manual breaths significantly increases the V_T delivered.

14. With suction off, gently and quickly insert the catheter using the dominant hand. When you meet resistance, pull back ½ in.
15. Apply continuous or intermittent suction using the nondominant thumb. Withdraw the catheter over 10 seconds or less.
16. Hyperoxygenate once more for another 30 seconds as described in step 13.
17. If secretions remain and the patient has tolerated suctioning, perform 2 or 3 suction passes as described in steps 14 and 15. NOTE: Rinse the suction catheter with sterile saline solution between suctioning passes as needed. Maintaining a closed circuit at all times is best to reduce the risk for infection.
18. Reconnect patient to ventilator (open-suction technique).
19. Rinse the catheter and connecting tubing with the sterile saline solution.
20. Suction oral pharynx. NOTE: Use a separate catheter for this step when using the closed-suction technique.
21. Discard the suction catheter and rinse the connecting tubing with the sterile saline solution (open-suction technique).
22. Reset FIO_2 (if needed) and ventilator alarms.
23. Reassess patient for signs of effective suctioning.

Adapted from Wiegand DL: *AACN procedure manual for high acuity, progressive, and critical care*, ed 7, St Louis, 2017, Elsevier.

Causes of dysrhythmias during suctioning include (1) hypoxemia resulting in myocardial ischemia; (2) vagal stimulation caused by tracheal irritation; and (3) sympathetic nervous system stimulation caused by anxiety, discomfort, or pain. Dysrhythmias include tachydysrhythmias and bradydysrhythmias, premature beats, and asystole. Stop suctioning if any new dysrhythmias develop. Avoid excessive suctioning in patients with severe hypoxemia or bradycardia.

Tracheal mucosal damage may occur due to excessive suction pressures (greater than 120 mm Hg), overly vigorous catheter insertion, and the suction catheter itself. Blood streaks or tissue shreds in aspirated secretions may indicate mucosal damage. This increases the risk for infection and bleeding, especially if the patient is receiving anticoagulants. We can prevent trauma to the mucosa by following the steps described in Table 65.8.

Secretions may be thick and hard to suction because of inadequate hydration or humidification, infection, or inaccessibility of the lower airways. Maintain adequate hydration when clinically indicated (e.g., IV fluids) and provide supplemental humidification of inspired gases through the mechanical ventilator to help thin secretions. Mobilize and turn the patient (e.g., every 2 hours) to help move secretions into larger airways. If infection is the cause of thick secretions, give the patient appropriate antibiotics.

Providing Oral Care and Maintaining Skin Integrity

When an oral ET tube is in place, the patient's mouth is always open. Moisten the lips, tongue, and gums with saline or water swabs to prevent mucosal drying. Proper oral care provides comfort and prevents injury to the gums and plaque formation (Table 65.9). If space is limited in the oral cavity, use smaller or pediatric-sized oral products for providing oral care.

Frequent assessment and meticulous care are needed to prevent skin breakdown on the face, lips, tongue, and nares because of

pressure from the ET tube or the method used to secure the ET tube to the patient's face. Ongoing assessment is shared between the RN and RT. Reposition and re-tape the ET tube (per agency policy) and as needed to prevent skin breakdown. Repositioning the ET tube may be limited to the RT. Two staff members should always perform repositioning to prevent accidental ET tube dislodgment. Monitor the patient for any signs of respiratory distress throughout the procedure.

TABLE 65.9 Oral Care for Patient on Mechanical Ventilator

General Measures

1. Gather all equipment.
2. Wash hands and don personal protective equipment and gloves.
3. Explain procedure to the patient and caregiver (if present).
4. Perform oral care every 2–4 hours using a suction toothbrush and toothpaste or gel for 1–2 minutes, suctioning often. Assess for plaque buildup and any potential infection.
5. Use 0.12% chlorhexidine oral rinse twice daily.
6. Apply a mouth moisturizer to oral mucosa and lips with each cleaning.
7. Suction oral cavity and pharynx when needed. Fig. 65.18 shows an endotracheal tube that can provide continuous or intermittent subglottic suctioning.

NOTE:

- Change all oral suction equipment and suction tubing every 24 hr.
- Rinse nondisposable oral suction apparatus with sterile normal saline after each use and place on a dry paper towel.

Adapted from Wiegand DL *AACN procedure manual for high acuity, progressive, and critical care*, ed 7, St Louis, 2017, Elsevier.

For the nasally intubated patient, remove the old tape and clean the skin around the ET tube with saline-soaked gauze. For the orally intubated patient, remove the bite block (if present) and the old tape. Provide oral hygiene, then reposition the ET tube to the opposite side of the mouth. Replace the bite block (if appropriate) and reconfirm proper cuff inflation and tube placement. Secure the ET tube again (per agency policy).

We often use commercial ET holders. These may increase the risk for skin breakdown compared to tape.[18] If one is used, follow the manufacturer's directions for maintaining tube position, providing skin care, and preventing skin breakdown.

Fostering Comfort and Communication

Intubation is a major stressor for the patient.[19] Intubated patients have stress from not being able to talk and communicate their needs. This can be frustrating for the patient, caregiver, and interprofessional care team. To communicate more effectively, use a variety of methods. (See Common Problems of Critical Care Patients earlier in this chapter on p. 1535.)

The physical discomfort associated with ET intubation and mechanical ventilation often requires sedating the patient and giving an analgesic until the ET tube is removed. Assess the drugs' effectiveness in achieving an acceptable level of patient comfort by using a valid pain scale, sedation scale (e.g., Richmond Agitation and Sedation Scale [RASS], Sedation Agitation Scale [SAS]), and/or delirium scale.[20] Consider using relaxation techniques (e.g., music therapy) to complement drug therapy.

Complications of Endotracheal Intubation

Two major complications of ET intubation are unplanned extubation

and aspiration. Unplanned *extubation* (i.e., removal of the ET tube from the trachea) may complicate the patient's recovery. Unplanned extubation can be due to patient removal of the ET tube or accidental removal during movement or a procedure. Usually, the unplanned extubation is obvious (i.e., the patient is holding the ET tube). Other times, the tip of the ET tube is in the hypopharynx or esophagus and the extubation is not obvious. You are responsible for preventing unplanned extubation by ensuring that the ET tube is secured and observing and supporting the ET tube during repositioning, procedures, and patient transfers. Giving adequate sedation and analgesia and using standardized weaning protocols decrease the incidence of self-extubation.[21]

The use of restraints to immobilize the patient's hands is a deterrent to self-extubation.[21] Be sure to explain to the patient and caregiver when you use short-term restraints for patient safety and discuss the use of alternatives. Reassess for the continued need of restraints (per agency policy) and limit restraint use when possible.

Should an unplanned extubation occur, stay with the patient and call for help. Interventions are aimed at maintaining the patient's airway, supporting ventilation (e.g., manually ventilating the patient with a BVM and 100% O_2), securing the appropriate help to reintubate the patient (if needed), and providing psychologic support to the patient.

Safety Alert

Unplanned Extubation

Observe for signs of unplanned extubation:

- Activation of the low-pressure ventilator alarm
- Decreased or absent breath sounds
- Respiratory distress
- Auditory cuff leak

What to do during an unplanned extubation:

- Stay with the patient
- Support the patient's oxygenation as needed by applying an adjunct therapy, such as a nasal cannula or manually ventilating the patient with a BVM and 100% O_2
- Notify the HCP and RT
- Assess for respiratory distress and listen for stridor
- Assess the patient's ability to cough and/or vocalize
- Assess the patient's ability to maintain secretions
- Assess the patient's need for reintubation
- If the patient is unable to protect their airway or is in respiratory distress, prepare for reintubation

Aspiration is another potential hazard for the patient with an ET tube. The ET tube passes through the epiglottis, splinting it in an open position. Thus the intubated patient cannot protect the airway from aspiration. The high-volume, low-pressure ET cuff cannot totally prevent the trickle of oral or gastric secretions into the trachea.[22] Further, secretions collect above the cuff. When the cuff is deflated, those secretions can move into the lungs. Some ET tubes provide continuous suctioning of secretions above the cuff (Fig. 65.18).

Oral intubation increases salivation, yet swallowing is difficult, so suction the patient's mouth often. Use a Yankauer (tonsil-tip) suction catheter or a sterile single-use catheter. Other factors contributing to aspiration include improper cuff inflation, patient positioning, and decreased gastric mobility and bowel function if receiving EN. The patient with an ET tube is at risk for aspiration of gastric contents. Even when the cuff is properly inflated, take precautions to prevent vomiting, which can lead to aspiration.

Often, a nasogastric (NG) or an orogastric (OG) tube is inserted and connected to low, intermittent suction when a patient is first intubated. An OG tube is preferred over an NG tube to reduce the risk for sinusitis. All intubated patients who are receiving EN should have

the HOB elevated a minimum of 30 to 45 degrees, unless medically contraindicated.

FIG. 65.18 Continuous subglottal suctioning can be provided by the Hi Lo Evac Tube. A dorsal lumen above the cuff allows for suctioning of secretions from the subglottic area.

Mechanical Ventilation

Mechanical ventilation is the process by which the FIO_2 (21% [room air] or more) is moved in and out of the lungs by a mechanical ventilator. Mechanical ventilation is not curative. It is a means of supporting patients until they recover the ability to breathe independently. It can also serve as a bridge to long-term mechanical ventilation or until a decision is made to stop ventilatory support.

Indications for mechanical ventilation include (1) apnea, (2) inability to breathe or protect the airway, (3) acute respiratory failure (see Chapter 67), (4) severe hypoxia, and (5) respiratory muscle fatigue. Patients with chronic lung disease and their caregivers should be given the opportunity to discuss mechanical ventilation before end-stage respiratory failure develops. Encourage all patients, especially those with chronic illnesses, to discuss the subject of life-sustaining measures, including mechanical ventilation, with their families and HCPs. The patient's wishes about end-of-life treatment should be recorded in an advance directive.

The decision to use, withhold, or stop mechanical ventilation must be made carefully, respecting the wishes of the patient. When the interprofessional care team, patient, and/or caregiver disagree over the treatment plan that the patient desires, conferences are essential to keep the lines of communication open and discuss options. You may need to consult the agency's ethics committee for assistance.

Types of Mechanical Ventilation

The 2 major types of mechanical ventilation are negative pressure and positive pressure ventilation.

Negative Pressure Ventilation

Negative pressure ventilation involves the use of chambers that encase the chest or body and surround it with intermittent subatmospheric (or negative) pressure. The "iron lung" was the first form of negative pressure ventilation. It was developed during the

polio epidemic. Intermittent negative pressure around the chest wall pulls the chest outward, reducing intrathoracic pressure. Air rushes in via the upper airway, which is outside the sealed chamber. Expiration is passive. The machine cycles off, allowing chest retraction. This type of ventilation is like normal ventilation in that decreased intrathoracic pressures produce inspiration, and expiration is passive. Negative pressure ventilation is noninvasive and does not need an artificial airway.

Several portable negative pressure ventilators are available for home use. They are mainly for patients with neuromuscular diseases, central nervous system disorders, diseases and injuries of the spinal cord, and severe COPD. They are not routinely used for acutely ill patients.

Drug Alert

Oxygen

- O_2 is considered a drug, and overexposure can lead to O_2 toxicity.
- Mechanically ventilated patients receiving high levels of FIO_2 for prolonged periods of time (e.g., 60% FIO_2 for >24 hours) are at risk for O_2 toxicity.
- Target FIO_2 levels are to maintain SpO_2 >92% and PaO_2 between 60 and 80 mm Hg.
- Assess ABGs for evidence of excess O_2.
- Monitor patient for signs of O_2 toxicity: uncontrolled coughing, chest pain, and dyspnea.

Positive Pressure Ventilation

Positive pressure ventilation (PPV) is the main method used with acutely ill patients (Fig. 65.19). During inspiration the ventilator pushes air into the lungs under positive pressure. Unlike spontaneous

ventilation, intrathoracic pressure is raised during lung inflation rather than lowered. Expiration occurs passively as in normal expiration. There are 2 categories of PPV: volume and pressure ventilation.[13]

Volume Ventilation

With **volume ventilation**, a predetermined V_T is delivered with each inspiration. The amount of pressure needed to deliver the breath varies based on compliance and resistance factors of the patient-ventilator system. So, the V_T is consistent from breath to breath, but airway pressures vary.

Pressure Ventilation

With *pressure ventilation,* the peak inspiratory pressure is predetermined. The V_T delivered to the patient varies based on the selected pressure and compliance and resistance factors of the patient-ventilator system. Careful attention must be given to the V_T to prevent unplanned hyperventilation or hypoventilation. For example, when the patient breathes out of synchrony with the ventilator, the pressure limit may be reached quickly, and the volume of gas delivered may be small.

Settings of Mechanical Ventilators

Mechanical ventilator settings regulate rate, V_T, O_2 concentration, and other characteristics of ventilation (Table 65.10, Fig. 65.20). Settings are based on the patient's status (e.g., ABGs, ideal body weight, current physiologic state, level of consciousness, respiratory muscle strength). Settings are evaluated and adjusted until oxygenation and ventilation targets have been reached.

It is important that you check that all ventilator alarms are always on. Alarms alert the staff to potentially dangerous situations, such as mechanical malfunction, apnea, unplanned extubation, or patient asynchrony with the ventilator (Table 65.11). On many ventilators, the

alarms can be temporarily suspended or silenced for up to 2 minutes for suctioning or testing while a staff member is in the room. After that time, the alarm system automatically turns back on.

Safety Alert

Alarm Fatigue

- Alarm fatigue can develop in those who hear an excess number of alarms, resulting in sensory overload.
- This can cause a delayed response to alarms or dismissing them altogether and can lead to serious adverse events (e.g., patient death).
- One way to reduce alarm fatigue includes customizing alarm parameters based on patient specific needs.[23]

FIG. 65.19 Patient receiving mechanical ventilation.
Courtesy Draeger Medical, Houston, TX.

TABLE 65.10 Settings of Mechanical Ventilation

Parameter	Description
Respiratory rate (f)	Number of breaths the ventilator delivers per minute. *Usual setting:* 12–20 breaths/min
Tidal volume (V_T)	Volume of gas delivered to patient during each ventilator breath. *Usual volume:* 6–8 mL/kg, 4–8 mL/kg in ARDS
O_2 concentration (FIO_2)	Fraction of inspired O_2 (FIO_2) delivered to patient. May be set between 21% (essentially room air) and 100%. *Usually adjusted* to maintain PaO_2 level >60–80 mm Hg or SpO_2 level >92%
Positive end-expiratory pressure (PEEP)	Positive pressure applied at the end of expiration of ventilator breaths. *Usual setting:* 5 cm H_2O
Pressure support	Positive pressure used to augment patient's inspiratory pressure. *Usual setting:* 5–10 cm H_2O
I/E ratio	Duration of inspiration (I) to duration of expiration (E). *Usual setting:* 1:2 to 1:1.5 unless inverse ratio ventilation is desired
Inspiratory flow rate and time	Speed with which the V_T is delivered. *Usual setting:* 40–80 L/min and time is 0.8–1.2 sec
Sensitivity	Determines the amount of effort the patient must generate to initiate a ventilator breath. It may be set for pressure triggering or flow triggering. *Usual setting:* A pressure trigger is set 0.5–1.5 cm H_2O below baseline pressure and a flow trigger is set 1–3 L/min below baseline flow
High-pressure limit	Regulates the maximal pressure the ventilator can generate to deliver the V_T. When the pressure limit is reached, the ventilator ends the breath and spills the undelivered volume into the atmosphere. *Usual setting:* 10–20 cm H_2O above peak inspiratory pressure

Ventilator Alarms

Mechanical ventilators may become disconnected or malfunction. Most deaths from accidental ventilator disconnection occur while the alarm is off. Most accidental disconnections are discovered by low-pressure alarms. The most frequent site for disconnection is between the tracheal tube and the adapter. Push connections together and then twist to secure more tightly. Be certain that alarms are always set and activated. Chart that this is the case. You can pause alarms (not inactivate) during suctioning or removal from the ventilator, but you must reactivate them before leaving the patient's bedside.

Ventilator malfunction may occur. Although most agencies have emergency generators in case of a power failure and newer ventilators may have battery backup, power failure is always a possibility. Have a plan for manually ventilating all patients who depend on a ventilator. If, at any time, you decide the ventilator is malfunctioning (e.g., failure of O_2 supply), disconnect the patient from the machine and manually ventilate with a BVM and 100% O_2 until the ventilator is fixed or replaced.

Modes of Volume Ventilation

The ways by which the patient and ventilator interact to deliver effective ventilation are called *ventilator modes.* The selected ventilator mode is based on how much WOB the patient should or can perform.

WOB is the inspiratory effort needed to overcome the elasticity and viscosity of the lungs along with the airway resistance. The mode is determined by the patient's ventilatory status, respiratory drive, and ABGs. Generally, ventilator modes are controlled or assisted.

With controlled ventilatory support, the ventilator does all the WOB for the patient. With assisted ventilatory support, the ventilator and patient share the WOB. Historically, volume modes, such as controlled mandatory ventilation (CMV), assist-control ventilation (ACV), and synchronized intermittent mandatory ventilation (SIMV), have been used to treat critically ill patients. Pressure modes, such as pressure support ventilation (PSV), pressure-control ventilation (PCV), and inverse ratio ventilation (PC-IRV) are becoming more common.[24] Table 65.12 describes ventilator modes.

Assist-Control Ventilation

With **assist-control ventilation (ACV)**, the ventilator delivers a preset V_T at a preset frequency. When the patient initiates a spontaneous breath, the ventilator senses a decrease in intrathoracic pressure and then delivers the preset V_T. The patient can breathe faster than the preset rate but not slower. ACV has the advantage of allowing the patient some control over ventilation while providing some assistance. It is used in patients with a variety of conditions, including neuromuscular disorders (e.g., Guillain-Barré syndrome), pulmonary edema, and acute respiratory failure.

With ACV, the patient has the potential for hyperventilation. The spontaneously breathing patient can easily be overventilated, resulting in hyperventilation. If the volume or minimum rate is set too low and the patient is apneic or weak, the patient can be hypoventilated. Thus these patients need vigilant assessment and monitoring of ventilatory status, including respiratory rate, ABGs, SpO_2, and $ScvO_2$ or SvO_2. It is important that the sensitivity, or amount of negative pressure needed to start a breath, is appropriate to the patient's condition. For example, if it is too hard for the patient to begin a breath, the WOB is increased and the patient may tire (i.e., the patient "rides" the ventilator) or develop ventilator dyssynchrony

(i.e., the patient "fights" the ventilator).

TABLE 65.11 Managing Mechanical Ventilation Alarms

Alarm	Possible Causes	Interventions
High-pressure limit	• Secretions, coughing, or gagging • Patient fighting ventilator (ventilator asynchrony) • Condensate (water) in tubing • Kinked or compressed tubing (e.g., patient biting on ET tube) • ↑ Resistance (e.g., bronchospasm) • ↓ Compliance (e.g., pulmonary edema, ARDS, tension pneumothorax, atelectasis, pneumonia) • Improper alarm setting • ET tube inserted too far (e.g., right mainstem bronchus or carina)	• Clear secretions and ↑ sedation • Reassure patient • Remove water from ventilator tubing • Unkink tubing, insert bite block, or reposition patient • Give bronchodilator • Assess breath sounds, obtain chest x-ray • Adjust ET tube
Low-pressure limit	• Total or partial ventilator disconnect • Loss of airway (e.g., total or partial extubation) • ET tube or tracheotomy cuff leak (e.g., patient speaking, grunting)	• Check connections • Confirm adequate tidal volume and ET tube position with chest x-ray • Reinflate cuff
Apnea	• Respiratory arrest • Oversedation • Change in patient condition • Loss of airway (e.g., total or partial extubation)	• ↓ Sedation • ↓ Analgesia • Reverse sedation or analgesia • Confirm ET tube placement or reintubate
High V_T, minute ventilation, or respiratory rate	• Pain, anxiety • Change in patient condition (e.g., ↑ metabolic demand, fever, hypoxia, hypercapnia) • Excess condensate or secretions in tubing (i.e., false reading)	• Treat pain • Assess patient for change in condition • Obtain an ABG • Remove water or secretions from tubing
Low V_T or minute ventilation	• Change in patient's breathing efforts (e.g., rate and volume) • Patient disconnection, loose connection, or leak in circuit • ET tube or tracheotomy cuff leak (e.g., air leak) • Insufficient gas flow	• Assess patients respiratory and neurologic status. Reduce sedation. • Assess ventilator circuit for leaks • Reassess cuff to ensure cuff is adequately inflated • Check ventilator settings
Ventilator inoperative or low battery	• Machine malfunction • Unplugged, power failure, or internal battery not charged	• Ensure mechanical ventilator is plugged into right power source • Disconnect patient from mechanical ventilator and use bag- valve-mask to ventilate until machine is properly functioning

Adapted from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 8, St Louis, 2018, Elsevier.

TABLE 65.12 Modes of Mechanical Ventilation

Mode of Ventilation	Ventilator Settings	Nursing Implications
Volume Modes		
Assist-control (AC) or assisted mandatory ventilation (AMV)	• Requires rate, V_T, inspiratory time, and PEEP set for the patient • The ventilator sensitivity is set, so when the patient initiates a spontaneous breath, a full-volume breath is delivered	• Hyperventilation can occur • To limit spontaneous breaths, sedation may be needed
Intermittent mandatory ventilation (IMV) and synchronized intermittent mandatory ventilation (SIMV)	• Requires rate, V_T, inspiratory time, sensitivity, and PEEP set for the patient • Between "mandatory breaths," patients spontaneously breathe at their own rates and V_T • With SIMV, the ventilator synchronizes the mandatory breaths with the patient's own inspirations	• Muscle fatigue may occur due to ↑ work of breathing
Pressure Modes		
Pressure support ventilation (PSV)	• Provides an augmented inspiration to a spontaneously breathing patient • HCP selects inspiratory pressure level, PEEP, and sensitivity • When the patient initiates a breath, a high flow of gas is delivered to the preselected pressure level, and pressure is maintained throughout inspiration • Patient determines V_T, rate, and inspiratory time	• Reduces patients work of breathing and ↑ ventilator synchrony • Monitor patient for hypercapnia
Pressure-control inverse ratio ventilation (PC-IRV)	• Combines pressure-limited ventilation with an inverse ratio of inspiration to expiration • HCP selects the pressure level, rate, inspiratory time (1:, 2:1, 3:1, 4:1), and PEEP level • With the prolonged inspiratory times, auto-PEEP may result • Auto-PEEP may be a desirable outcome of the inverse ratios	• Requires sedation and/or pharmacologic paralysis to oxygenate and ventilate patient due to discomfort • Air trapping can occur due to ↑ intrathoracic pressure, leading to a ↓ cardiac output
Airway pressure release ventilation (APRV)	• Provides 2 levels of continuous positive airway pressure (CPAP) with timed releases • Permits spontaneous breathing throughout the respiratory cycle • HCP selects both pressure (high, low) and time (high, low). V_T is not a set variable and depends on the CPAP level, the patient's compliance and resistance, and spontaneous breathing effort	• Monitor for hypercapnia

Modified from Wiegand DL: *AACN procedure manual for high acuity, progressive, and critical care*, ed 7, St Louis, 2017, Elsevier; and Urden LD, Stacy, KM, Lough ME: *Critical care nursing: Diagnosis and management*, ed 8, St Louis, 2018, Elsevier.

Synchronized Intermittent Mandatory Ventilation

With **synchronized intermittent mandatory ventilation (SIMV)**, the ventilator delivers a preset V_T at a preset frequency in synchrony with the patient's spontaneous breathing. Between ventilator-delivered breaths, the patient can breathe spontaneously through the ventilator circuit. Thus the patient receives the preset FIO_2 during the spontaneous breaths but self-regulates the rate and V_T of those breaths. SIMV is used during continuous ventilation and during weaning from the ventilator. It may be combined with PSV (described later). Potential benefits of SIMV include improved patient-ventilator synchrony, lower mean airway pressure, and prevention of muscle atrophy as the patient takes on more of the WOB.

SIMV has disadvantages. If spontaneous breathing decreases when

the preset rate is low, ventilation may not be adequately supported. Only patients with regular, spontaneous breathing should use low-rate SIMV. Weaning with SIMV demands close monitoring and may take longer because the rate of breathing is gradually reduced. Patients being weaned with SIMV may have increased muscle fatigue associated with spontaneous breathing efforts.

Modes of Pressure Ventilation

Pressure Support Ventilation

With **pressure support ventilation (PSV)**, positive pressure is applied to the airway only during inspiration and is used with the patient's spontaneous respirations. The patient must be able to initiate a breath in this modality. The level of positive airway pressure is preset so that the gas flow rate is greater than the patient's inspiratory flow rate. As the patient starts a breath, the machine senses the spontaneous effort and supplies a rapid flow of gas at the initiation of the breath and variable flow throughout the breath. With PSV, the patient determines inspiratory length, V_T, and respiratory rate. V_T depends on the pressure level and airway compliance.

PSV is used with continuous ventilation and during weaning. It also may be used with SIMV during weaning. PSV is not often used as ventilatory support during acute respiratory failure because of the risk for hypoventilation and apnea. Advantages include increased patient comfort, decreased WOB (because inspiratory efforts are augmented), decreased O_2 consumption (because inspiratory work is reduced), and increased endurance conditioning (because the patient is exercising respiratory muscles).

Pressure-Control and Pressure-Control Inverse Ratio Ventilation

Pressure-control ventilation (PCV) provides a pressure-limited breath delivered at a set rate. It may permit spontaneous breathing. The V_T is not set. It is determined by the pressure limit set. *Pressure-control*

inverse ratio ventilation (PC-IRV) combines pressure-limited ventilation with an inverse ratio of inspiration (I) to expiration (E). Some HCPs use PC without IRV.

The *I/E ratio* is the ratio of duration of inspiration to the duration of expiration. This ratio is normally 1:2 or 1:3. With IRV, the I/E ratio begins at 1:1 and may progress to 4:1. Prolonged positive pressure is applied, increasing inspiratory time. IRV gradually expands collapsed alveoli. The short expiratory time has a PEEP-like effect, preventing alveolar collapse. Because IRV imposes a nonphysiologic breathing pattern, the patient needs sedation and often paralysis.

PC-IRV is used for patients with acute respiratory distress syndrome (ARDS) who continue to have hypoxemia despite high levels of PEEP. Not all patients with poor oxygenation respond to PC-IRV.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) permits spontaneous breathing at any point during the respiratory cycle with a preset CPAP with short timed pressure releases. The CPAP level (pressure high, pressure low) is adjusted to keep oxygenation goals while the timed releases (time high, time low) are increased or decreased to meet ventilation goals.[25] V_T is not set. It varies depending on the CPAP level, the patient's compliance and resistance, and spontaneous breathing effort. This mode is best for patients who need high pressure levels for alveolar recruitment (open collapsed alveoli). An advantage is that it allows for spontaneous respirations. This may reduce the need for deep sedation or paralytics.

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) is a ventilatory maneuver, or mechanical ventilator setting, in which positive pressure is applied to the airway during exhalation. Normally during exhalation, airway pressure drops to near 0, and exhalation occurs passively. With PEEP, exhalation is passive but pressure falls to a preset level, often 3 to 20

cm H_2O. Lung volume during expiration and between breaths is greater than normal with PEEP. This increases FRC and often improves oxygenation by restoring the lung volume that normally remains at the end of passive exhalation. The mechanisms by which PEEP increases FRC and oxygenation include increased aeration of patent alveoli, aeration of previously collapsed alveoli, and prevention of alveolar collapse throughout the respiratory cycle.

PEEP is titrated to the point that oxygenation improves without compromising hemodynamics. We call this *optimal PEEP.* Often 5 cm H_2O PEEP (referred to as *physiologic PEEP*) is used prophylactically to replace the glottic mechanism, help maintain a normal FRC, and prevent alveolar collapse. PEEP of 5 cm H_2O is used for patients with a history of alveolar collapse during weaning. PEEP improves gas exchange, vital capacity, and inspiratory force when used during weaning.

In contrast, *auto-PEEP* is not purposely set on the ventilator but is a result of inadequate exhalation time. Auto-PEEP is more PEEP over what is set by the HCP. This added PEEP may result in increased WOB, barotrauma, and hemodynamic instability. Interventions to limit auto-PEEP include sedation and analgesia, large-diameter ET tube, bronchodilators, short inspiratory times, and decreased respiratory rates. Reducing water accumulation in the ventilator circuit by frequent emptying or use of heated circuits also limits auto-PEEP. In patients with short exhalation times and early airway closure (e.g., asthma), setting PEEP above auto-PEEP can offset auto-PEEP effects by splinting the airway open during exhalation and preventing "air trapping."

FIO_2 often can be reduced when PEEP is used. PEEP is generally indicated in all patients who are mechanically ventilated. The classic indication for PEEP therapy is ARDS (see Chapter 67). PEEP is used with caution in patients with increased ICP, low CO, and hypovolemia. In these cases, the adverse effects of high PEEP may outweigh the benefits.

Other Modes

Advances in ventilator technology have led to the development of other pressure modes. However, the names and features of these other options are manufacturer specific. The superiority of these modes has not been proven. Some examples include *volume-assured pressure ventilation* and *adaptive support ventilation.*

Check Your Practice

You are caring for a 75-yr-old woman who was orally intubated yesterday for respiratory distress due to pneumonia and placed on ACV. Her ventilator settings are: V_T 400, RR 14 (set), PEEP 5, and FIO_2 40%. You respond to the ventilator alarm sounding and note audible air movement heard around her ET tube cuff as you suction her. The alarm panel shows "low exhaled tidal volume." She appears anxious, with the following vital signs: HR 112, RR 26, and SpO_2 89%.

- What would be your next steps?

Other Methods to Improve Oxygenation and Ventilation

Automatic Tube Compensation

Automatic tube compensation (ATC) is an adjunct designed to overcome WOB through an artificial airway. It is currently available on many ventilators. ATC is increased during inspiration and decreased during expiration. It is set by entering the internal diameter of the patient's airway and the desired number for compensation. ATC may be less effective in patients with excess secretions or who need longer term ventilation.

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation (HFOV) involves delivery of a small V_T (usually 1 to 5 mL/kg of body weight) at rapid respiratory

rates (100 to 300 breaths/min). The goals are to recruit (e.g., alveolar expansion) and maintain lung volume and reduce intrapulmonary shunting. While HFOV may be a useful mode for patients with life-threatening hypoxia, it has not improved survival of patients with ARDS.[26] Patients receiving HFOV must be sedated and may need to be paralyzed to suppress spontaneous respiration.

Nitric Oxide

Nitric oxide (NO) is a gaseous molecule that is made intravascularly and takes part in the regulation of pulmonary vascular tone. Inhibiting NO production results in pulmonary vasoconstriction. Administering continuous inhaled NO results in pulmonary vasodilation. NO may be given through an ET tube, a tracheostomy, or a face mask. Currently, NO is used as a diagnostic screening tool for pulmonary hypertension and to improve oxygenation during mechanical ventilation in this patient population. The use of NO does not reduce mortality in patients with ARDS and may cause kidney injury.[27]

Prone Positioning

Prone positioning is the repositioning of a patient from a supine or lateral position to a prone (on the stomach, face down) position. This repositioning improves lung recruitment through various mechanisms. Gravity reverses the effects of fluid in the dependent parts of the lungs as the patient is moved from supine to prone. The heart rests on the sternum, away from the lungs, contributing to an overall uniformity of pleural pressures. The prone position requires increased sedation and is nurse-intensive. It is an effective supportive therapy used in critically ill patients with severe ARDS to improve oxygenation.[28]

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an alternative form of pulmonary support for the patient with severe respiratory failure (Fig.

65.21).[13] It is used most often in the pediatric and neonatal populations but is increasingly being used in adults. ECMO is a modification of cardiac bypass. It involves partially removing blood from a patient with large-bore catheters, infusing O_2, removing CO_2, and returning the blood to the patient. This intensive therapy requires systemic anticoagulation and is a time-limited intervention. A skilled team of specialists, including a perfusionist, must be continuously at the bedside.

Informatics in Practice

Importing Monitor and Ventilator Data

- In many ICUs, monitor data (e.g., vital signs, hemodynamic pressures, core temperature, pulse oximetry) are directly imported into the electronic health record (EHR). Ventilator data also may be sent to the EHR.
- Depending on the information technology system, this connectivity of monitoring devices and ventilators can help drive evidence-based practice. Trends can be readily noted, and prompts can link the user to protocols.
- Some systems can send alarms or notifications to the HCP from the EHR.
- Always verify that correct patient data were imported into the EHR when documenting. Delete artifact or false data according to your agency's policy.

Complications of Positive Pressure Ventilation

Although PPV may be essential to maintain ventilation and oxygenation, it can cause adverse effects. It may be hard to distinguish complications of mechanical ventilation from the underlying disease.

Cardiovascular System

PPV can affect circulation because of the transmission of increased mean airway pressure to various structures in the thorax. Increased intrathoracic pressure compresses the thoracic vessels. This

compression causes decreased venous return to the heart, left ventricular end-diastolic volume (preload), and CO, resulting in hypotension. Mean airway pressure is further increased if PEEP is being titrated (greater than 5 cm H_2O) to improve oxygenation.

If the lungs are noncompliant (e.g., ARDS), airway pressures are not as easily transmitted to the heart and blood vessels. Thus effects of PPV on CO are reduced. Conversely, with compliant lungs (e.g., COPD), there is increased danger of transmission of high airway pressures and negative effects on hemodynamics.

Hypovolemia (e.g., hemorrhage) and decreased venous tone (e.g., sepsis, spinal shock) can further compromise venous return. Restoring and maintaining the circulating blood volume are important in minimizing cardiovascular complications.

Pulmonary System

Barotrauma

As lung inflation pressures increase, risk for *barotrauma* increases. Barotrauma results when the increased airway pressure distends the lungs and possibly ruptures fragile alveoli or emphysematous blebs. Patients with noncompliant lungs (e.g., COPD) are at greatest risk for barotrauma. Patients with stiff lungs (e.g., ARDS) who are given high inspiratory pressures and high levels of PEEP (greater than 5 cm H_2O) or have a lung abscess from necrotizing organisms (e.g., staphylococci) are also at risk.

Air can escape into the pleural space from alveoli or the interstitium and become trapped. Pleural pressure increases and collapses the lung, causing a pneumothorax (see Chapter 27 for more about pneumothorax.) The lungs receive air during inspiration but cannot expel it during expiration. Respiratory bronchioles are larger on inspiration than expiration. They may close on expiration, and air becomes trapped. With PPV, a simple pneumothorax can become a life-threatening tension pneumothorax. The mediastinum and contralateral lung are compressed, reducing CO. Immediate treatment of the pneumothorax is required.

Pneumomediastinum usually begins with rupture of alveoli into the lung interstitium. Progressive air movement occurs into the mediastinum and subcutaneous neck tissue, and a pneumothorax often follows. New, unexplained subcutaneous emphysema is an indication for immediate chest x-ray. Pneumomediastinum and subcutaneous emphysema may be too small to detect on x-ray or clinically before the development of a pneumothorax.

Volutrauma

The concept of *volutrauma* in PPV relates to the lung injury that occurs when a large V_T is used to ventilate noncompliant lungs. Volutrauma results in alveolar rupture and movement of fluids and proteins into the alveolar spaces. Low-volume ventilation should be used in patients with ARDS to protect the lungs.

Alveolar Hypoventilation

Alveolar hypoventilation can be caused by inappropriate ventilator settings, leakage of air from the ventilator tubing or around the ET tube or tracheostomy cuff, lung secretions or obstruction, and low ventilation/perfusion ratio. A low V_T or respiratory rate decreases minute ventilation. This results in hypoventilation, atelectasis, and respiratory acidosis. A leaking cuff or tubing that is not secured may cause air leakage and lower V_T. Mobilizing the patient, turning the patient at least every 2 hours, encouraging deep breathing and coughing, and suctioning (as needed) may limit lung secretions. Increasing the V_T, adding small increments of PEEP, and adding a preset number of *sighs* to the ventilator settings (i.e., a deeper than normal breath incorporated into the respiratory cycle) can help reduce the risk for atelectasis.

Alveolar Hyperventilation

Respiratory alkalosis can occur if the respiratory rate or V_T is set too high *(mechanical overventilation)* or if the patient receiving assisted ventilation is *hyperventilating.* It is easy to overventilate a patient on

PPV. Especially at risk are patients with chronic alveolar hypoventilation and CO_2 retention. For example, the patient with COPD may have a chronic $PaCO_2$ elevation (acidosis) and compensatory bicarbonate retention by the kidneys. When the patient is ventilated, the patient's "normal baseline" rather than the standard normal values is the therapeutic goal. If the COPD patient is returned to a standard normal $PaCO_2$, the patient will develop alkalosis because of the retained bicarbonate. Such a patient could move from compensated respiratory acidosis to serious metabolic alkalosis.

The presence of alkalosis makes weaning from the ventilator difficult. Alkalosis, especially if the onset is abrupt, can have serious consequences, including hypokalemia, hypocalcemia, and dysrhythmias. Usually the patient with COPD who is supported on the ventilator does better with a short inspiratory and longer expiratory time.

If hyperventilation is spontaneous, it is important to determine the cause and treat it. Common causes include hypoxemia, pain, fear, anxiety, or compensation for metabolic acidosis. Patients who fight the ventilator or breathe out of synchrony may be anxious or in pain. If the patient is anxious and fearful, sitting with the patient and verbally coaching the patient to breathe with the ventilator or weaning the ventilator to a more appropriate setting may help. If these measures fail, manually ventilating the patient slowly with a BVM and 100% O_2 may slow breathing enough to bring it in synchrony with the ventilator.

Ventilator-Associated Pneumonia

The risk for HAI pneumonia is highest in patients requiring mechanical ventilation because the ET or tracheostomy tube bypasses normal upper airway defenses. Poor nutrition, immobility, and the underlying disease process (e.g., immunosuppression, organ failure) make the patient more prone to infection. *Ventilator-associated pneumonia* (VAP) is pneumonia that occurs 48 hours or more after ET intubation.[29] It occurs in as many as 27% of all intubated patients.

Patients who develop VAP have significantly longer hospital stays and higher mortality rates than those who do not. Half of the patients develop early VAP (VAP that occurs within 96 hours of mechanical ventilation).

In those with early VAP, sputum cultures often grow gram-negative bacteria (e.g., *E coli, Klebsiella, Streptococcus pneumoniae, H influenzae*). Organisms associated with late VAP include antibiotic-resistant organisms, such as *Pseudomonas aeruginosa* and oxacillin-resistant *Staphylococcus aureus.* These organisms are abundant in the hospital environment and the patient's GI tract. They can spread in a number of ways, including contaminated respiratory equipment, inadequate hand washing, adverse environmental factors (e.g., poor room ventilation, high traffic flow), and decreased patient ability to cough and clear secretions. Colonization of the oropharynx tract by gram-negative organisms predisposes the patient to gram-negative pneumonia.

Clinical signs that suggest VAP include fever, high white blood cell count, purulent or odorous sputum, crackles or wheezes on auscultation, and pulmonary infiltrates noted on chest x-ray. The patient is given antibiotics after appropriate cultures are taken by tracheal suctioning or bronchoscopy and when infection is evident.

Guidelines for VAP prevention include (1) minimizing sedation, including daily spontaneous awakening trials (SATs) and daily spontaneous breathing trials (SBTs), (2) early exercise and mobilization, (3) use of ET tubes with subglottic secretion drainage ports for patients likely to be intubated greater than 48 to 72 hours, (4) HOB elevation at a minimum of 30 to 45 degrees unless medically contraindicated, (5) oral care with chlorhexidine, and (6) no routine changes of the patient's ventilator circuit tubing.[30]

Other preventive measures include strict hand washing before and after suctioning, whenever ventilator equipment is touched, and after contact with any respiratory secretions (see Nursing Management: Artificial Airway earlier in this chapter). Always wear gloves when in contact with the patient and change gloves between activities (e.g., emptying urinary catheter drainage, hanging an IV drug). Last,

always drain the water that collects in the ventilator tubing away from the patient as it collects.

Safety Alert

VAP Prevention Strategies

- Practice good hand hygiene techniques before and after suctioning.
- Wear gloves when providing oral hygiene.
- Suction patients as needed for comfort.
- Keep the HOB elevated >30 to 45 degrees.
- Turn patient according to agency policy (e.g., side to side every 2 hours).
- Initiate early mobilization.
- Follow agency policy for limiting sedation with SAT.
- Perform daily SBT unless contraindicated.[31]

Psychosocial Needs

The patient receiving mechanical ventilation often has physical and emotional stress. In addition to the problems related to critical care patients discussed at the beginning of this chapter, the patient supported by a mechanical ventilator is unable to speak, eat, move, or breathe normally. Tubes and machines cause pain, fear, and anxiety. Usual activities, such as eating, elimination, and coughing, are extremely complicated.

The ABCDEF Bundle is an evidence-based practice of providing care that strives to attain an environment in which all patients receiving mechanical ventilation are calm, delirium free, and able to express their needs for pain control, positioning, and reassurance. The ABCDEF Bundle ensures (1) **A**ssessment, (2) **B**oth SATs and SBTs are done, (3) correct **C**hoice of analgesia and sedation, (4) **D**elirium

prevention and management, (5) **E**arly mobility, and (6) **F**amily engagement.[32]

Feeling safe is an overpowering need of patients on mechanical ventilation. Work to strengthen the various factors that affect feeling safe. Encourage hope, as appropriate, and build trusting relationships with both the patient and caregiver. Involve them in decision making as much as possible.[19]

Sedation and Analgesia

Patients receiving PPV may need sedation (e.g., propofol) and/or analgesia (e.g., fentanyl) to help with optimal ventilation. Before starting sedation or analgesia in the mechanically ventilated patient who is agitated or anxious, identify the cause of distress. Common problems that can result in patient agitation or anxiety include PPV, nutritional deficits, pain, hypoxemia, hypercapnia, drugs, and environmental stressors (e.g., sleep deprivation).

At times, the decision is made to paralyze the patient with a neuromuscular blocking agent (e.g., cisatracurium [Nimbex]) to provide more effective synchrony with the ventilator and improve oxygenation. Remember that the paralyzed patient can hear, see, and feel. It is essential to give IV sedation and analgesia concurrently when the patient is paralyzed. **S**edated or paralyzed patients may be aware of their surroundings. You should always address them as if they were awake and alert.

Monitoring patients receiving these drugs is challenging. Assess the patient using train-of-four (TOF) peripheral nerve stimulation, physiologic signs of pain or anxiety (e.g., changes in HR and BP), and ventilator synchrony. The TOF assessment involves using a peripheral nerve stimulator to deliver 4 successive stimulating currents to elicit muscle twitches (Fig. 65.22).[33] The number of twitches varies with the amount of neuromuscular blockade. The usual goal is 1 or 2 twitches out of 4 currents.

Noninvasive electroencephalogram technology (e.g., bispectral index monitoring [BIS]) can be used to guide sedative and analgesic therapy.[34] Excess administration of neuromuscular blocking agents

may predispose the patient to prolonged paralysis and muscle weakness even after these agents are stopped.

Neurologic System

In patients with head injury, PPV, especially with PEEP, can impair cerebral blood flow. The increased intrathoracic positive pressure impedes venous drainage from the brain. This results in jugular venous distention. The patient may have increases in ICP due to the impaired venous return and subsequent increase in cerebral volume. Elevating the HOB and keeping the patient's head in alignment may reduce the harmful effects of PPV on ICP.

Sodium and Water Imbalance

Progressive fluid retention often occurs after 48 to 72 hours of PPV, especially PPV with PEEP. Fluid retention is associated with decreased urine output and increased sodium retention. Fluid balance changes may be due to decreased CO, which causes decreased renal perfusion. This stimulates the release of renin with the subsequent production of angiotensin and aldosterone (see Chapter 44, Fig. 44.4). This results in sodium and water retention. It is possible that pressure changes within the thorax are associated with decreased release of atrial natriuretic peptide, which also causes sodium retention. Less insensible water loss occurs via the airway because ventilated delivered gases are humidified with body-temperature water. As a part of the stress response, release of antidiuretic hormone (ADH) and cortisol contributes to sodium and water retention.

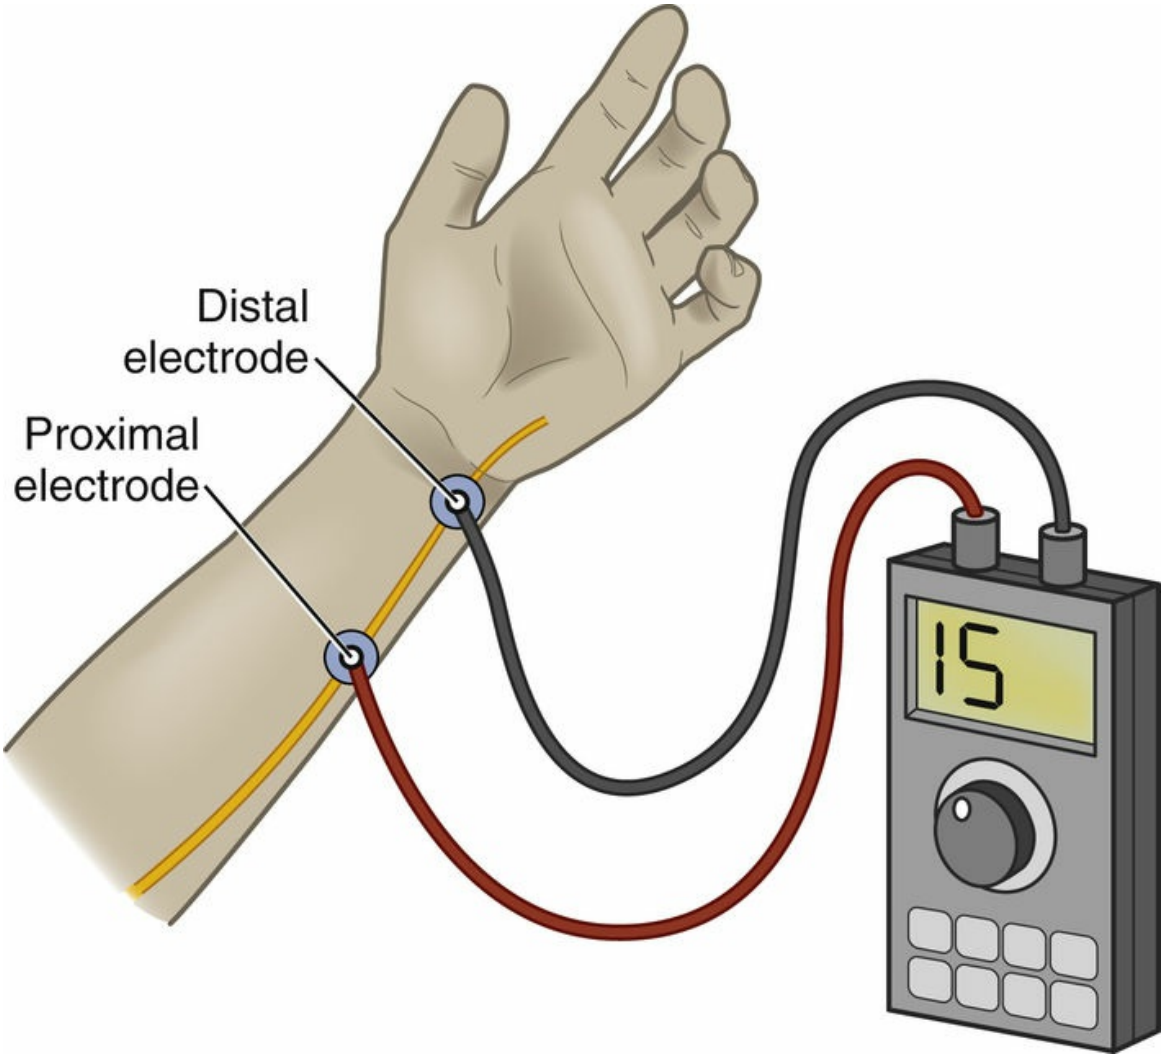

FIG. 65.22 Placement of electrodes along ulnar nerve.

Gastrointestinal System

Patients receiving PPV are stressed because of the serious illness, immobility, or discomforts associated with the ventilator. This places the patient at risk for developing stress ulcers and GI bleeding. Patients with a preexisting ulcer or those receiving corticosteroids have a higher risk. Any circulatory compromise, including reduced CO caused by PPV, may contribute to ischemia of the gastric and intestinal mucosa and increase the risk for translocation of GI bacteria.

Stress ulcer prophylaxis includes giving histamine (H_2)-receptor blockers (e.g., ranitidine), proton pump inhibitors (PPIs) (e.g.,

esomeprazole), or EN to decrease gastric acidity and reduce the risk for stress ulcer and hemorrhage. PPIs may increase the risk for *Clostridium difficile infection*.[35] (This is discussed in Chapter 41 on p. 898.)

Gastric and bowel dilation may occur because of gas accumulation in the GI tract from swallowed air. The irritation of an artificial airway may cause excessive air swallowing and gastric dilation. Gastric or bowel dilation may put pressure on the vena cava, decrease CO, and prohibit adequate diaphragmatic excursion during spontaneous breathing. Elevation of the diaphragm from a paralytic ileus or bowel dilation leads to compression of the lower lobes of the lungs. This may cause atelectasis and compromise respiratory function. Decompression of the stomach is done by inserting an OG or NG tube.

Immobility, sedation, circulatory impairment, decreased oral intake, use of opioid pain medicines, and stress contribute to decreased peristalsis. The patient's inability to exhale against a closed glottis may make defecation difficult. As a result, the ventilated patient is at risk for constipation. A bowel regimen should be started to help with motility.

Musculoskeletal System

Maintaining muscle strength and preventing complications associated with immobility are important. Adequate analgesia and nutrition can enhance exercise tolerance. Plan for early and progressive mobility of appropriate patients receiving PPV.[8] In collaboration with physical and occupational therapy, perform passive and active exercises to maintain muscle tone in the upper and lower extremities. Simple maneuvers, such as leg lifts, knee bends, or arm circles, are appropriate. Prevent contractures, pressure injuries, footdrop, and external rotation of the hip and legs by proper positioning and using specialized mattresses or beds. Use a portable ventilator or provide manual ventilation with a BVM and 100% O_2 when ambulating patients who are mechanically ventilated.

Nutritional Therapy: Patient Receiving Positive Pressure Ventilation

PPV and the hypermetabolism associated with critical illness can contribute to inadequate nutrition. Critical illness, trauma, and surgery are associated with hypermetabolism, anxiety, pain, and increased WOB, which greatly increase caloric expenditure. The presence of an ET tube eliminates the normal route for eating. Inadequate nutrition makes the patient receiving prolonged mechanical ventilation prone to poor O_2 transport from anemia and to poor tolerance of minimal exercise. It can delay mechanical ventilation weaning, decrease resistance to infection, and slow recovery. Critically ill patients have frequent EN interruptions. We often hold feedings due to procedures and during routine nursing care. Poor nutrition and the disuse of respiratory muscles contribute to decreased respiratory muscle strength. Serum protein levels (e.g., albumin, prealbumin, transferrin, total protein) are usually decreased.

Patients unlikely to be able to eat independently for 3 to 5 days should have a nutritional assessment and EN started within 24 to 48 hours of admission.[9] EN is the preferred method to meet caloric needs of mechanically ventilated patients (see Chapter 39 for discussion of EN). Consult the dietitian to determine the caloric and nutrient needs of these patients.

When eating with a tracheostomy tube in place, the patient should tilt the head slightly forward to assist with swallowing and to prevent aspiration. The diet may be restricted to soft foods (e.g., puddings, ice cream) and thickened liquids. Patients with a long-term tracheostomy will likely have a tube placed in the stomach (gastrostomy) or small bowel (jejunostomy) for nutritional support (see Chapter 39). Patients may be able to eat normally once the tracheostomy site heals and they meet criteria that will allow them to take oral intake. Swallowing studies and a speech therapy consultation are done to assess the patient's readiness for oral intake.

Nursing Management

Caring for the Patient Requiring Mechanical Ventilation

In the critically ill patient who requires mechanical ventilation, the RN and RT provide most of the care. Some patients who need chronic mechanical ventilation may be in long-term care settings or at home. In these settings, the RN and RT assess the patient and plan and evaluate care, but implementation of some activities may be delegated.

- Develop plan for communication with the patient who has an ET tube or tracheostomy.
- Give sedatives, analgesics, and paralytic drugs as needed.
- Teach patient and caregiver about mechanical ventilation and weaning procedures.
- Auscultate breath sounds and respiratory effort, assessing for decreased ventilation or adventitious sounds.
- Monitor ventilator settings and alarms.
- Determine need for ET tube suctioning and suction patients as needed.
- Reposition and secure ET tube (based on agency policy).
- Monitor oxygenation level and signs of respiratory fatigue during weaning procedure.
- Provide enteral nutrition.
- Oversee UAP:
    - Obtain vital signs and report to the RN.
    - Provide personal hygiene, skin care, and oral care, as directed by RN.
    - Assist with frequent position changes, including ambulation, as directed by the RN.
    - Help to perform passive or active range-of-motion (ROM) exercises.

Collaborate With Respiratory Therapist (RT)

- Auscultate breath sounds and respiratory effort, assessing for decreased ventilation or adventitious sounds.
- Monitor ventilator settings and alarms.
- Change ventilator settings as needed or ordered by HCP.
- Maintain appropriate cuff inflation on ET tube.
- Determine need for ET tube suctioning and suction patients as needed.
- Reposition and secure ET tube (based on agency policy).
- Monitor oxygenation level and signs of respiratory fatigue during weaning procedure.

Collaborate With Physical and Occupational Therapist

- Perform ROM exercises.
- Assist with early and progressive ambulation as directed by the RN.

Collaborate With Dietitian

- Assess and monitor patient's nutritional status.
- Recommend formulations for enteral and/or parenteral nutrition as needed.

Collaborate With Speech Therapist

- Perform swallowing studies.
- Assess patient's cognitive function and assist with communication.

- Provide teaching for patient with a long-term tracheostomy.

Collaborate With Social Worker

- Work with the patient and caregiver to identify care needs.
- Help the patient with transitions through the health care system.
- Teach the patient the various levels of care and seek to optimize outcomes in a cost-effective manner.

Weaning From Positive Pressure Ventilation and Extubation

Weaning is the process of reducing ventilator support and resuming spontaneous breathing. The weaning process differs for patients on short-term ventilation (up to 3 days) versus long-term ventilation (longer than 3 days). Those with short-term ventilation (e.g., after heart surgery) have a linear weaning process. Patients with prolonged PPV (e.g., patients with COPD who develop respiratory failure) often have a weaning process that consists of alternating gains and losses. Preparation for weaning begins when PPV is started and involves a team approach (e.g., HCP, RT, RN, patient).

Weaning consists of 3 phases: the *preweaning phase,* the *weaning process,* and the *outcome phase.* The preweaning, or assessment phase, looks at the patient's ability to breathe spontaneously. Assessment depends on a combination of respiratory and nonrespiratory factors (Table 65.13). Note the resolution of the primary problem that prompted patient admission. The patient's lungs should be reasonably clear on auscultation and chest x-ray. Weaning assessment parameters should include criteria to assess muscle strength (negative inspiratory force) and endurance (spontaneous V_T, vital capacity, minute ventilation, rapid shallow breathing index). There should be minimal secretions, the ability to cough and gag, and a cuff leak when the ET tube cuff is deflated.

Nonrespiratory factors include the patient's neurologic status;

hemodynamics; fluid, electrolytes, and acid-base balance; nutrition; and hemoglobin. It is important to have an alert, well-rested, and well-informed patient relatively free from pain and anxiety who can cooperate with the weaning plan. This does not mean complete withdrawal from sedatives or analgesics. Instead, drugs should be titrated to achieve comfort without causing excessive drowsiness.

TABLE 65.13 Indicators for Weaning

Weaning Readiness

Patients receiving mechanical ventilation for respiratory failure should undergo a formal assessment of weaning potential if the following are satisfied[*]:

1. Reversal of the underlying cause of respiratory failure
2. Adequate oxygenation
    - PaO_2/FIO_2 >150–200
    - SpO_2 ≥90%
    - PEEP ≤5–7 cm H_2O
    - FIO_2 ≤40%–50%
    - pH ≥7.25
3. Hemodynamically stabile
    - Absence of myocardial ischemia
    - Absence of clinically significant hypotension (low dose or no vasopressor therapy)
4. Patient ability to initiate respirations
5. Optional criteria
    - Hemoglobin ≥7–10 g/dL
    - Core temperature ≤100.4° F (38° C) to 101.3° F (38.5° C)
    - Mental status awake and alert or easily arousable

Weaning Assessment			
Measurement	**Significance**	**Normal Values**	**Indices for Weaning**
Spontaneous respiratory rate (RR)	Respiratory rate/frequency over 1 min.	12–20 breaths/min	<35 breaths/min
Spontaneous tidal volume (V_T)	Amount of air exchanged during normal breathing at rest. Measure of muscle endurance.	>5–7 mL/kg	≥5 mL/kg
Minute ventilation (V_E)	V_T multiplied by respiratory rate over 1 min. *For example:* 0.350 (V_T) × 28 (f) = 9.8 L/min.	>10 L/min	>10 L/min
Negative inspiratory force or pressure (NIF, NIP)	Amount of negative pressure that a patient can generate to initiate spontaneous respirations. *Measured by clinician:* After complete occlusion of inspiratory valve, a pressure manometer is attached to airway or mouth for 10–20 sec while negative inspiratory efforts are noted.	< −50 cm H_2O	< −20 cm H_2O The more negative the number, the better indication for weaning.
Positive expiratory pressure (PEP)	Measure of expiratory muscle strength and ability to cough. *Measured by clinician*: After complete occlusion of expiratory valve, a pressure manometer is attached to the airway or mouth for 10–20 sec while positive expiratory efforts are noted.	60–85 cm H_2O	≥30 cm H_2O
Rapid shallow breathing index RSBI (f/V_T)	Spontaneous respiratory rate over 1 min divided by V_T (in liters). *For example:* 30 (f)/0.400 (V_T) = 75/L	<40/L	<105/L
Spontaneous breathing trial (SBT)	If patient passes daily weaning screen, assess patient during SBT with little or no ventilator assistance. Trial should be at least 30 min to a maximum of 120 min.		Successful completion of trial is based on an integrated patient assessment.
Vital capacity (VC)	Maximum inspiration and then measurement of air during maximal forced expiration. Measure of respiratory muscle endurance or reserve or both. Requires patient cooperation.	65–75 mL/kg	≥10–15 mL/kg

* The decision to use these criteria are personalized to the patient.

Adapted from Urden LD, Stacy, KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 8, St Louis, 2018, Elsevier.

A SAT and an SBT are recommended in patients who meet a daily safety screen. A SAT should be done by stopping all sedatives and, in patients without active pain, all opioids. Sedation should be restarted at 50% of the previous dose in patients who "fail" the SAT and remain off in patients who "pass."

Evidence-Based Practice

Early Mobilization and Critically Ill Patients

W.R. is a 68-yr-old man who has been in the ICU for 2 days. He is receiving mechanical ventilation, and weaning trials are planned. You have started passive exercises and dangling with W.R. You prepare to

discuss early mobilization with him and his partner.

Making Clinical Decisions

Best Available Evidence. Implementing an early exercise and mobilization protocol for stable, mechanically ventilated patients is safe and well tolerated. Early mobilization improves patient outcomes (e.g., prevention of ICU-acquired weakness, maintenance of long-term function, preservation of quality of life) and reduces the length of hospital stays. Involving patients and families in decision-making around care (e.g., early mobilization) is an identified priority among this group.

Clinician Expertise. Your unit has successfully implemented AACN's **ABCDEF** bundle related to delirium, immobility, sedation/analgesia, and ventilator management in the ICU. You know that patients and their families often worry about ambulating with complex equipment attached to them.

Patient Preferences and Values. W.R. writes on the computer that he does not want to get out of bed until his "breathing tube is out." His partner tells you he is "afraid of falling."

Implications for Nursing Practice

1. What will you tell W.R. and his partner about the benefits of and protocol for early mobilization?
2. How will you involve them in the decision to take part in the program?

Reference for Evidence

McKenzie E, Potestio M.L, Boyd J.M, et al. Reconciling patient and provider priorities for improving the care of critically ill patients: a consensus method and qualitative analysis of decision making. *Health Expect*. 2017;20:1367.

An SBT should last at least 30 minutes but no more than 120 minutes.[13] It may be done with low levels of PEEP, low levels of PSV, or FIO_2. Tolerance of the trial may lead to extubation. Failure to tolerate an SBT should prompt a search for reversible or complicating factors and a return to a nonfatiguing ventilator modality. The SBT should be tried daily, unless contraindicated.

All health care team members should be familiar with the weaning plan. The use of a weaning protocol decreases ventilator days.[13] The ventilator settings are not as important as the use of a daily protocol to prevent delays in weaning. The patient receiving SIMV can have the ventilator breaths gradually reduced as ventilatory status permits. PEEP or PSV can be added to SIMV. PSV is thought to provide gentle, slow respiratory muscle conditioning. It may be especially beneficial for patients who are deconditioned or have heart problems.

Weaning may be tried at any time of day. It is usually done after a period of time when the patient has been ventilated in a rest mode. The rest mode should be a stable, nonfatiguing, and comfortable form of support for the patient. It is important to allow the patient's respiratory muscles to rest between weaning trials. Once the respiratory muscles become fatigued, they may need 12 to 24 hours to recover.

The patient and caregiver need ongoing emotional support. Explain the weaning process to them to keep them informed of progress. Place the patient in a comfortable sitting or semirecumbent position. Obtain baseline vital signs and respiratory parameters. During the weaning trial, closely monitor the patient for signs and symptoms that may signal a need to end the trial (e.g., tachypnea, dyspnea, tachycardia, dysrhythmias, sustained desaturation [SpO_2 less than 90%], hypertension or hypotension, agitation, diaphoresis, anxiety, sustained V_T less than 5 mL/kg, changes in mental status). Record the patient's tolerance throughout the weaning process. Include statements about the patient's and the caregiver's feelings.

The weaning outcome phase is the period when the patient is ready for extubation or weaning is stopped because progress is not being made. The patient who is ready for extubation should receive

hyperoxygenation and suctioning (e.g., oropharynx, ET tube) prior to extubation. Loosen the ET tapes or commercial holder. Have the patient take a deep breath, and at the peak of inspiration, deflate the ET tube cuff and remove the tube in one motion. After removal, encourage the patient to deep breath and cough. Suction the oropharynx as needed. Have the patient say their name to assess vocalization. Give supplemental O_2 and provide naso-oral care. Carefully monitor vital signs, respiratory status, and oxygenation immediately after extubation, within 1 hour, and per agency policy. If the patient does not tolerate extubation (e.g., decreased SpO_2 levels, tachypnea or bradypnea, tachycardia, decreased level of consciousness, decrease in PaO_2, increase in $PaCO_2$), immediate reintubation or a trial of noninvasive ventilation may be needed.

Chronic Mechanical Ventilation

Mechanical ventilators are now a part of long-term and home care. In some instances, terminally ill, ventilated patients may be discharged to hospice. The emphasis on controlling hospital costs has increased the number of patients discharged early from the acute care setting and the need to provide highly technical care, such as mechanical ventilation, in home settings. The success of home mechanical ventilation depends, in part, on careful predischarge assessment and planning for the patient and caregivers. Patients must first meet criteria to be discharged on mechanical ventilation (e.g., tracheostomy, stabile mechanical ventilator settings).

Both negative pressure and positive pressure ventilators can be used in the home. Negative pressure ventilators do not require an artificial airway and are less complicated to use. Several types of small, portable (battery-powered) positive pressure ventilators are available. They can be attached to a wheelchair or placed on a bedside table. Settings and alarms on these ventilators are simpler to use than on the standard ICU ventilators.

Home mechanical ventilation has advantages and disadvantages. Having the patient in the home eliminates the strain that the hospital

setting imposes on family dynamics. Caregivers may feel helpless when they first hear about the need for long-term mechanical ventilation. However, these feelings are often balanced by the opportunity to take part in the patient's care in the home setting. At home, the patient may be able to take part in more activities of daily living around a personalized schedule. Because of the smaller size of the home ventilator, the patient may be more mobile. Another advantage is a lower risk for HAIs.

Disadvantages include problems related to equipment, reimbursement, caregiver stress and fatigue, and the patient's complex needs. Ventilated patients are usually dependent, requiring extensive nursing care, at least initially. Disposable products may not be reimbursable. Carefully assess financial resources when arranging home ventilation. Schedule a meeting with the interprofessional care team (e.g., social worker, home health care RN, RT) before starting a discharge teaching plan. Caregivers may seem enthusiastic about caring for their loved one in the home but may not understand the sacrifices they may have to make financially and in personal time and commitment. Encourage caregivers to consider respite care to periodically relieve their stress and fatigue.

Case Study

Critical Care and Mechanical Ventilation

(© Thinkstock.)

Patient Profile

R.K. is a 72-yr-old white man who collapsed in his home. He was found by his daughter, and she activated the emergency response

system. He was unresponsive on admission to the emergency department and is still unresponsive on arrival to the ICU. He has an oral ET tube in place and is receiving mechanical ventilation. A large-bore, peripheral IV has been placed and fluids are infusing.

Subjective Data

None. Patient has no eye opening. He is intubated and is unresponsive to painful stimuli.

Objective Data

Physical Examination

- Noninvasive BP 100/75 mm Hg; apical-radial HR 128; temperature 102° F (38.8° C); SpO_2 is 98%
- ECG: atrial fibrillation with a rapid ventricular response
- Purulent secretions suctioned from ET tube
- Breath sounds: coarse crackles bilaterally, decreased breath sounds on the right
- Weight: 168 lb. (76 kg)

Diagnostic Studies

- Chest x-ray shows right lower lung consolidation
- ABGs: pH 7.48; PaO_2 94 mm Hg; $PaCO_2$ 30 mm Hg; HCO_3 34 mEq/L
- CT scan is positive for a hemorrhagic stroke

Interprofessional Care

- Positive pressure ventilation settings: assist-control mode
- Settings: FIO_2 70%, V_T 700 mL, respiratory rate 16 breaths/min,

PEEP 5 cm H_2O

- Orogastric tube. EN at 25 mL/hr, increase by 20 mL/hr every 2 hr with a goal of 80 mL/hr to start on day 2
- External condom catheter for urinary drainage and measurement
- HOB elevated at 40 degrees
- Reposition at least every 2 hr
- Azithromycin (Zithromax) 500 mg IV q24hr
- Cefotaxime 2 gram IV q6hr
- NS at 75 mL/hr

Discussion Questions

1. Identify 2 reasons for intubating and providing mechanical ventilation for R.K.
2. What does R.K.'s ABG indicate, and which ventilator setting(s) should be changed to prevent barotrauma?
3. R.K.'s BP drops to 80 mm Hg. Despite increasing doses of vasopressors and fluid challenges, his BP is still low. A central venous catheter and an arterial line are inserted. Arterial pressure–based cardiac output (APCO) monitoring is started. What would be the purpose of hemodynamic monitoring in this patient?
4. ***Priority Decision:*** What are 2 priority nursing considerations for a patient with invasive monitoring?
5. R.K.'s pulmonary condition deteriorates. PaO_2 drops to 60 mm Hg, and SpO_2 is 89%. PEEP is increased to 7.5 cm H_2O. What implications does this have for R.K. given his hemodynamic status? What other intervention could be done to improve oxygenation?
6. ***Collaboration:*** What patient care activities can you delegate to unlicensed assistive personnel?
7. ***Evidence-Based Practice:*** R.K.'s caregivers want to know why he is to receive tube feedings. What would you tell them? What

is the evidence to support the use of EN?

8. ***Patient-Centered Care:*** After 4 days, R.K. is still unresponsive and has developed renal failure. The HCP thinks the patient will not recover from his neurologic injury and wishes to discuss goals of care with the patient's caregivers. What would be your role in this meeting?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Certification in critical care nursing (CCRN) by the American Association of Critical-Care Nurses indicates that the nurse
   a. is an advanced practice nurse who cares for acutely and critically ill patients.
   b. may practice independently to provide symptom management for the critically ill.
   c. has earned a master's degree in the field of advanced acute and critical care nursing.
   d. has practiced in critical care and successfully completed a test of critical care knowledge.
2. What are appropriate nursing interventions for the patient with delirium in the ICU? *(select all that apply)*
   a. Use clocks and calendars to maintain orientation.
   b. Encourage round-the-clock presence of caregivers at the bedside.
   c. Silence all alarms, reduce overhead paging, and avoid

conversations around the patient.

d. Sedate the patient with appropriate drugs to protect the patient from harmful behaviors.

e. Identify physiologic factors that may be contributing to the patient's confusion and irritability.

3. The critical care nurse recognizes that an ideal plan for caregiver involvement includes

a. having a caregiver at the bedside at all times.

b. allowing caregivers at the bedside at preset, brief intervals.

c. a personally devised plan to involve caregivers with care and patient needs.

d. restriction of visiting in the ICU because the environment is overwhelming to caregivers.

4. To establish hemodynamic monitoring for a patient, the nurse zeros the

a. cardiac output monitoring system to the level of the left ventricle.

b. pressure monitoring system to the level of the catheter tip in the patient.

c. pressure monitoring system to the level of the atrium, or the phlebostatic axis.

d. pressure monitoring system to the level of the atrium, or the midclavicular line.

5. The hemodynamic changes the nurse expects to find after successful initiation of intraaortic balloon pump therapy in a patient with cardiogenic shock include *(select all that apply)*

a. decreased SV.

b. decreased SVR.

c. decreased PAWP.

d. increased diastolic BP.

e. decreased myocardial O_2 consumption.

6. The purpose of adding PEEP to positive pressure ventilation is to

a. increase functional residual capacity and improve oxygenation.

b. increase FIO_2 to try to help wean the patient and avoid O_2 toxicity.

c. determine if the patient can be weaned and avoid pneumomediastinum.

d. determine if the patient is in synchrony with the ventilator or needs to be paralyzed.

7. The nursing management of a patient with an artificial airway includes

a. maintaining ET tube cuff pressure at 35 cm H_2O.

b. routine suctioning of the tube at least every 2 hours.

c. observing for cardiac dysrhythmias during suctioning.

d. preventing tube dislodgment by limiting mouth care to lubrication of the lips.

8. The nurse monitors the patient with positive pressure mechanical ventilation for

a. paralytic ileus because pressure on the abdominal contents affects bowel motility.

b. diuresis and sodium depletion because of increased

release of atrial natriuretic peptide.

c. signs of cardiovascular insufficiency because pressure in the chest impedes venous return.

d. respiratory acidosis in a patient with COPD because of alveolar hyperventilation and increased PaO_2 levels.

1. d, 2. a, d, e, 3. c, 4. c, 5. b, c, d, e, 6. a, 7. c, 8. c

Shock, Sepsis, and Multiple Organ Dysfunction Syndrome

Helen Miley

LEARNING OUTCOMES

1. Relate the pathophysiology to the clinical manifestations of the different types of shock: cardiogenic, hypovolemic, distributive, and obstructive.
2. Compare the effects of shock, sepsis, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome on the major body systems.
3. Compare the interprofessional care, drug therapy, and nursing management of patients with different types of shock.
4. Describe the interprofessional care and nursing management of a patient experiencing multiple organ dysfunction syndrome.

KEY TERMS

anaphylactic shock, p. 1569

cardiogenic shock, p. 1566

hypovolemic shock, p. 1568

multiple organ dysfunction syndrome (MODS), p. 1584

Conceptual Focus

Anxiety
Fluids and Electrolytes
Gas Exchange
Immunity
Perfusion

Shock, systemic inflammatory response syndrome (SIRS), sepsis, and multiple organ dysfunction syndrome (MODS) are serious and interrelated problems (Fig. 66.1). **Shock** is a syndrome characterized by decreased tissue perfusion and impaired cellular metabolism. This results in an imbalance between the supply of and demand for O_2 and nutrients. The exchange of O_2 and nutrients at the cellular level is essential to life. When cells are hypoperfused, the demand for O_2 and nutrients exceeds the supply at the microcirculatory level. Ischemia can occur, leading to cell injury and death. Thus shock of any cause is life-threatening. This chapter gives an overview of the different types of shock, SIRS, sepsis, and MODS and the related management of

each.

Shock

Classification of Shock

The 4 main categories of shock are cardiogenic, hypovolemic, distributive, and obstructive (Table 66.1). Although the cause, initial presentation, and management vary for each type, the physiologic responses of the cells to hypoperfusion are similar.

Cardiogenic Shock

Cardiogenic shock occurs when either systolic or diastolic dysfunction of the heart's pumping action results in reduced cardiac output (CO), stroke volume (SV), and BP. These changes compromise myocardial perfusion, further depress myocardial function, and decrease CO and perfusion. Causes of cardiogenic shock are shown in Table 66.1. Mortality rates for patients with cardiogenic shock are around 50%.[1] It is the leading cause of death from acute myocardial infarction (MI).[1]

The heart's inability to pump the blood forward is called *systolic dysfunction.* This inability results in a low CO (less than 4 L/min) and *cardiac index* (less than 2.5 L/min/m^2). Systolic dysfunction primarily affects the left ventricle since systolic pressure is greater on the left side of the heart. The most common cause of systolic dysfunction is acute MI. When systolic dysfunction affects the right side of the heart, blood flow through the pulmonary circulation is reduced. Decreased filling of the heart results in decreased SV. Causes of diastolic dysfunction are shown in Table 66.1.

Fig. 66.2 describes the pathophysiology of cardiogenic shock. Whether the first event is myocardial ischemia, a structural problem (e.g., valvular disorder, ventricular septal rupture), or dysrhythmias, the physiologic responses are similar. The patient has impaired tissue perfusion and cellular metabolism.

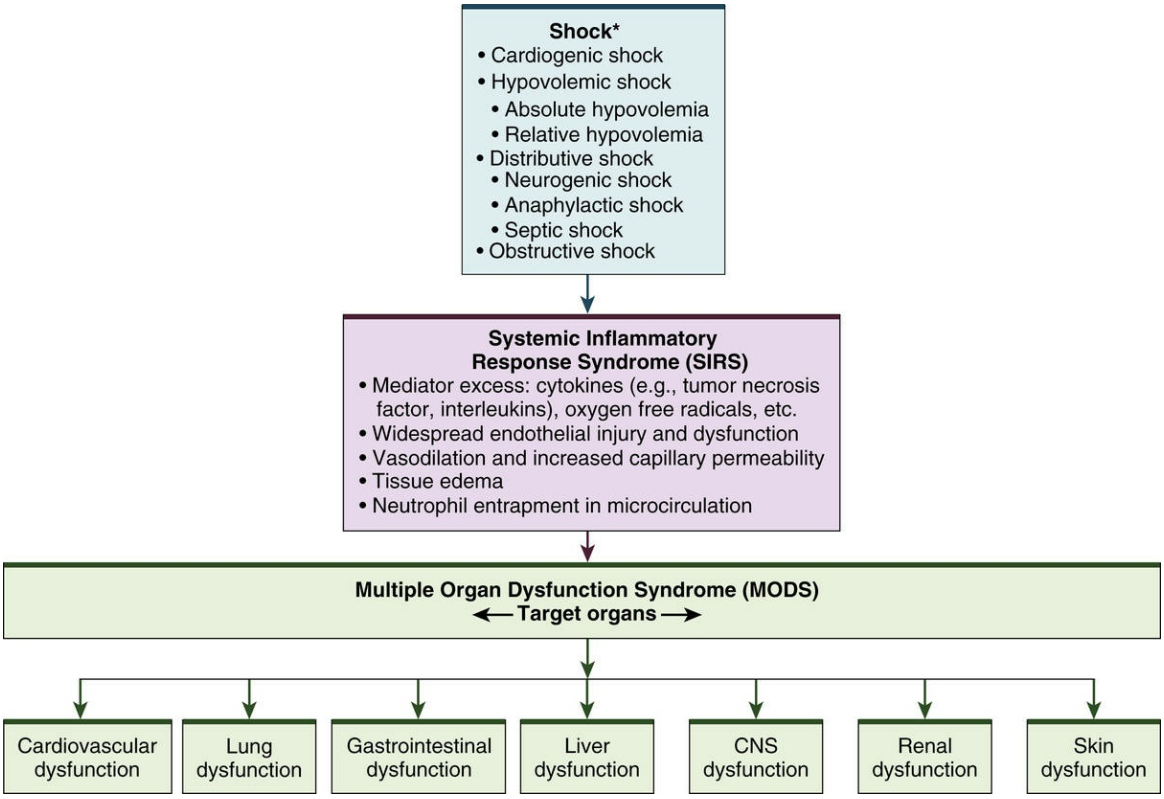

FIG. 66.1 Relationship of shock, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome. (*See Table 66.1 for causes of shock states.)

TABLE 66.1 Classification of Shock States

Types and Causes	Associated Conditions
Cardiogenic Shock	
• **Diastolic dysfunction: inability of the heart to fill**	Cardiac tamponade, ventricular hypertrophy, cardiomyopathy
• **Dysrhythmias**	Bradydysrhythmias, tachydysrhythmias
• **Structural factors**	Valvular stenosis or regurgitation, ventricular septal rupture, tension pneumothorax
• **Systolic dysfunction: inability of the heart to pump blood forward**	MI, cardiomyopathy, blunt cardiac injury, severe systemic or pulmonary hypertension, myocardial depression from metabolic problems
Hypovolemic Shock	
Absolute Hypovolemia	
• **External loss of whole blood**	Hemorrhage from trauma, surgery, GI bleeding
• **Loss of other body fluids**	Vomiting, diarrhea, excessive diuresis, diabetes insipidus, diabetes
Relative Hypovolemia	
• **Fluid shifts**	Burn injuries, ascites
• **Internal bleeding**	Fracture of long bones, ruptured spleen, hemothorax, severe pancreatitis
• **Massive vasodilation**	Sepsis
• **Pooling of blood or fluids**	Bowel obstruction
Distributive Shock	
Anaphylactic Shock	
• **Hypersensitivity (allergic) reaction to a sensitizing substance**	Contrast media, blood or blood products, drugs, insect bites, anesthetic agents, food or food additives, vaccines, environmental agents, latex
Neurogenic Shock	
• **Hemodynamic consequence of spinal cord injury and/or disease at or above T5** • **Spinal anesthesia** • **Vasomotor center depression**	Severe pain, drugs, hypoglycemia, injury
Septic Shock	
• **Infection**	Pneumonia, peritonitis, urinary tract, invasive procedures, indwelling lines and catheters
• **At-risk patients**	Older adults, patients with chronic diseases (e.g., diabetes, chronic kidney disease, HF), patients receiving immunosuppressive therapy or who are malnourished or debilitated
Obstructive Shock	
• **Physical obstruction impeding the filling or outflow of blood resulting in reduced CO**	Cardiac tamponade, tension pneumothorax, superior vena cava syndrome, abdominal compartment syndrome, pulmonary embolism

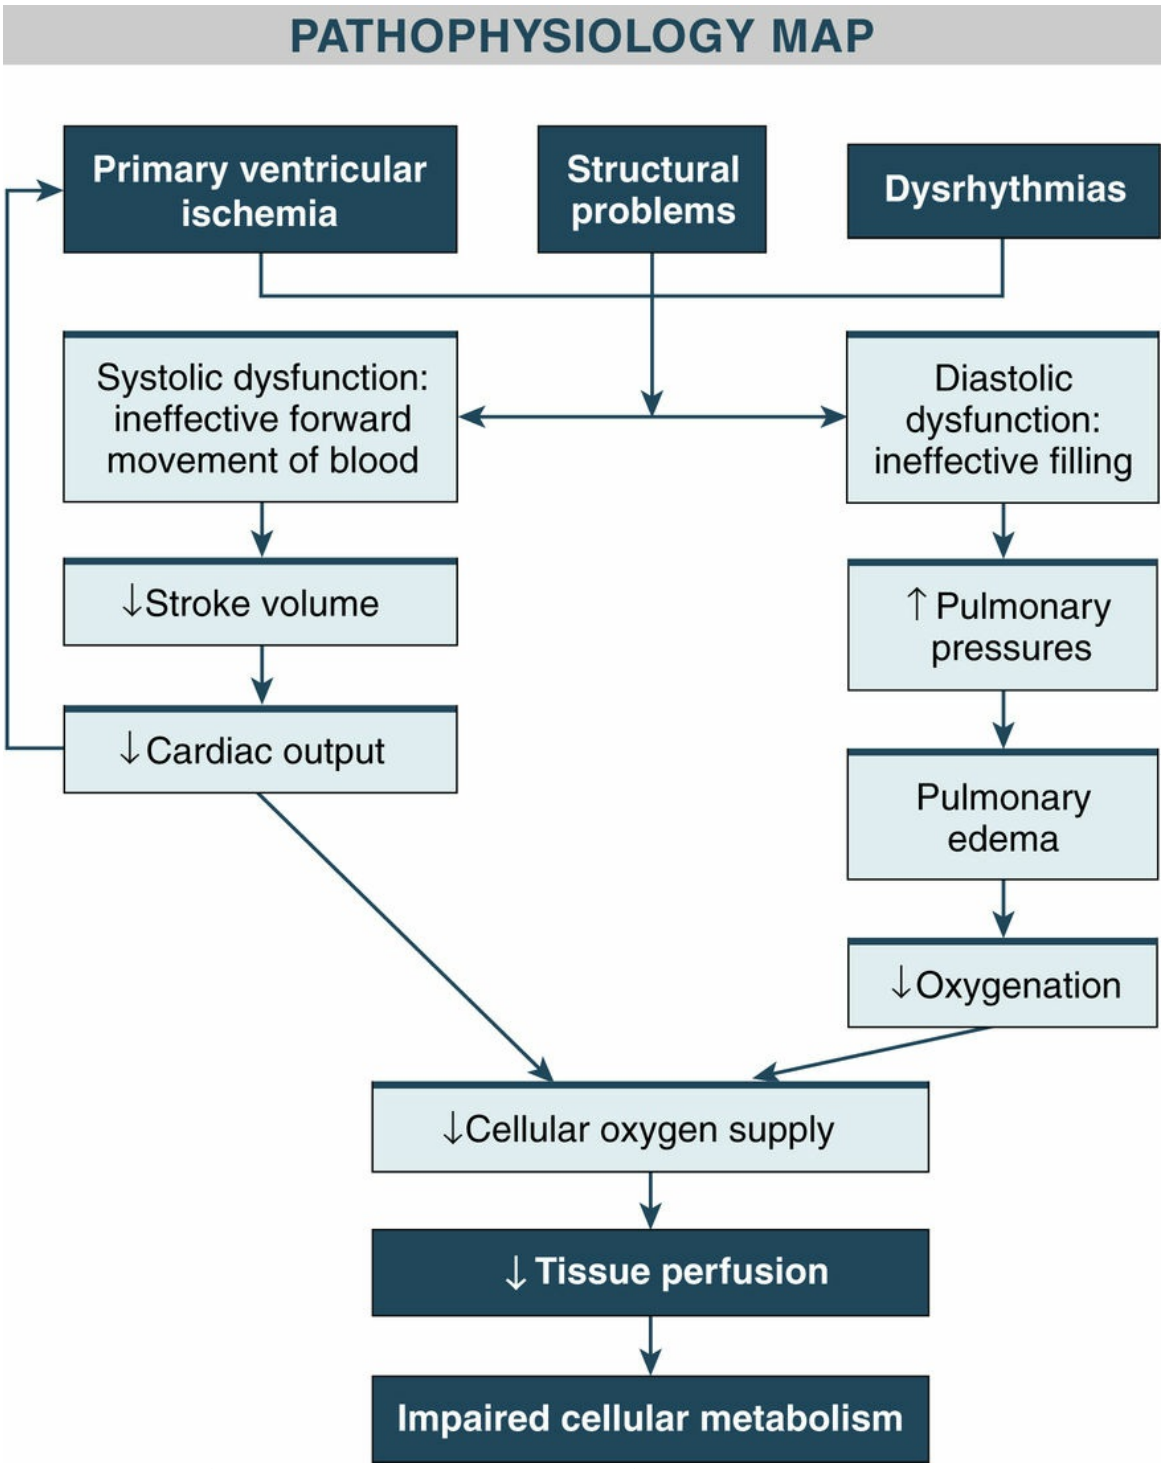

FIG. 66.2 The pathophysiology of cardiogenic shock.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

The early presentation of a patient with cardiogenic shock is similar to that of a patient with acute decompensated heart failure (HF) (see

Chapter 34). The patient may have tachycardia and hypotension. Pulse pressure may be narrowed due to the heart's inability to pump blood forward during systole and increased volume during diastole. An increase in systemic vascular resistance (SVR) increases the workload of the heart. This increases myocardial O_2 consumption.

On assessment, the patient is tachypneic and has crackles on auscultation of breath sounds because of pulmonary congestion. The hemodynamic profile shows an increase in the pulmonary artery wedge pressure (PAWP), stroke volume variation (SVV), and pulmonary vascular resistance.

Signs of peripheral hypoperfusion (e.g., cyanosis, pallor, diaphoresis, weak peripheral pulses, cool and clammy skin, delayed capillary refill) occur. Decreased renal blood flow results in sodium and water retention and decreased urine output. Anxiety, confusion, and agitation may develop with impaired cerebral perfusion. Tables 66.2 and 66.3 describe the laboratory findings and clinical presentation of a patient with cardiogenic shock.

Hypovolemic Shock

Hypovolemic shock occurs from inadequate fluid volume in the intravascular space to support adequate perfusion (Table 66.1).[2] The volume loss may be either an absolute or a relative volume loss. *Absolute hypovolemia* results when fluid is lost through hemorrhage, gastrointestinal (GI) loss (e.g., vomiting, diarrhea), fistula drainage, diabetes insipidus, or diuresis. In *relative hypovolemia,* fluid volume moves out of the vascular space into the extravascular space (e.g., intracavitary space). We call this type of fluid shift *third spacing.* One example of relative volume loss is fluid leaking from the vascular space to the interstitial space from increased capillary permeability, as seen in burns (see Chapter 24).

Whether the loss of intravascular volume is absolute or relative, the physiologic consequences are similar. The reduced intravascular volume results in a decreased venous return to the heart, decreased preload, decreased SV, and decreased CO. A cascade of events results in decreased tissue perfusion and impaired cellular metabolism, the

hallmarks of shock (Fig. 66.3).

The patient's response to acute volume loss depends on several factors, including extent of injury, age, and general state of health. The clinical presentation of hypovolemic shock is consistent (Table 66.3). An overall assessment of physiologic reserves may indicate the patient's ability to compensate. A patient may compensate for a loss of up to 15% of the total blood volume (around 750 mL). Further loss of volume (15% to 30%) results in a sympathetic nervous system (SNS)–mediated response.[2] This response results in an increase in heart rate, CO, and respiratory rate and depth. The decreased circulating blood volume causes decreases in SV, central venous pressure (CVP), and PAWP.[3]

The patient may appear anxious. Urine output begins to decrease. If hypovolemia is corrected by crystalloid fluid replacement at this time, tissue dysfunction is generally reversible. If volume loss is greater than 30%, compensatory mechanisms may fail and immediate replacement with blood products should be started. Loss of autoregulation in the microcirculation and irreversible tissue destruction occur with loss of more than 40% of the total blood volume. Common laboratory studies and assessments that are done include serial measurements of hemoglobin and hematocrit levels, electrolytes, lactate, blood gases, mixed central venous O_2 saturation (SvO_2), and hourly urine outputs (Table 66.2).

Distributive Shock

Neurogenic Shock

Neurogenic shock is a hemodynamic phenomenon that can occur within 30 minutes of a spinal cord injury and last up to 6 weeks. Neurogenic shock related to spinal cord injuries is generally associated with a cervical or high thoracic injury. The injury results in a massive vasodilation without compensation because of the loss of SNS vasoconstrictor tone.[4] This massive vasodilation leads to a pooling of blood in the blood vessels, tissue hypoperfusion, and

impaired cellular metabolism (Fig. 66.4).

In addition to spinal cord injury, spinal anesthesia can block transmission of impulses from the SNS. Depression of the vasomotor center of the medulla from drugs (e.g., opioids, benzodiazepines) can decrease the vasoconstrictor tone of the peripheral blood vessels, resulting in neurogenic shock (Table 66.1).

The classic manifestations are hypotension (from the massive vasodilation) and bradycardia (from unopposed parasympathetic stimulation).[4] The patient may not be able to regulate body temperature. Combined with massive vasodilation, the inability to regulate temperature promotes heat loss. At first, the patient's skin is warm due to the massive vasodilation. As the heat disperses, the patient is at risk for hypothermia. Later, the patient's skin may be cool or warm depending on the ambient temperature (*poikilothermia,* taking on the temperature of the environment). In either case, the skin is usually dry. Tables 66.2 and 66.3 further describe the laboratory findings and clinical presentation of a patient with neurogenic shock.

TABLE 66.2 Diagnostic StudiesShock

Study	Finding	Significance of Finding
Arterial blood gasses	Respiratory alkalosis	Found in early shock due to hyperventilation
	Metabolic acidosis	Occurs later in shock when lactate accumulates in blood from anaerobic metabolism
Base deficit	> −6	Acid production due to hypoxia
Blood cultures	Growth of organisms	May grow organisms in patients who are in septic shock
BUN	↑	Impaired kidney function caused by hypoperfusion from severe vasoconstriction, or occurs due to cell catabolism (e.g., trauma, infection)
Creatine kinase	↑	Trauma, MI in response to cellular damage and/or hypoxia
Creatinine	↑	Impaired kidney function caused by hypoperfusion because of severe vasoconstriction
DIC screen		Acute DIC can develop within hours to days after an initial assault on the body (e.g., shock)
• Fibrin split products (FSP)	↑	
• Fibrinogen level	↓	
• Platelet count	↓	
• PTT and PT	↑	
• INR	↑	
• Thrombin time	↑	
• D-dimer	↑	
Glucose	↑	Found in early shock because of release of liver glycogen stores in response to sympathetic nervous system stimulation and cortisol. Insulin insensitivity develops
	↓	Depleted glycogen stores with liver dysfunction possible as shock progresses
Electrolytes (serum)		
• Sodium	↑	Found in early shock because of ↑ secretion of aldosterone, causing renal retention of sodium
	↓	May be iatrogenic if excess hypotonic fluid is given after fluid loss
• Potassium	↑	Results when dead cells release potassium. Occurs in acute kidney injury and acidosis
	↓	Found in early shock because of ↑ secretion of aldosterone, causing renal excretion of potassium
Lactate level	↑	Usually ↑ once significant hypoperfusion and impaired O_2 use at the cellular level have occurred. By-product of anaerobic metabolism
Liver enzymes (ALT, AST, GGT)	↑	Liver cell destruction in progressive stage of shock
Procalcitonin (PCT)	↑	Biomarker released in response to bacterial infections
RBC count, hematocrit, hemoglobin	Normal	Remains within normal limits in shock because of relative hypovolemia and pump failure and in hemorrhagic shock before fluid resuscitation
	↓	Hemorrhagic shock after fluid resuscitation when fluids other than blood are used
	↑	Nonhemorrhagic shock caused by actual hypovolemia and hemoconcentration
Troponin	↑	MI
White blood cell count	↑, ↓	Infection, septic shock

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *GGT,* γ-glutamyl transferase; *INR,* international normalized ratio; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

Although spinal shock and neurogenic shock often occur in the same patient, they are not the same disorder. *Spinal shock* is a transient condition that is present after an acute spinal cord injury (see Chapter 60). The patient with spinal shock has an absence of all voluntary and reflex neurologic activity below the level of the injury.

Anaphylactic Shock

Anaphylactic shock is an acute, life-threatening hypersensitivity (allergic) reaction to a sensitizing substance (e.g., drug, chemical, vaccine, food, insect venom).[5] The reaction quickly causes massive vasodilation, release of vasoactive mediators, and an increase in capillary permeability. As capillary permeability increases, fluid leaks from the vascular space into the interstitial space.

Anaphylactic shock can lead to respiratory distress due to laryngeal edema or severe bronchospasm and circulatory failure from the massive vasodilation. The patient has a sudden onset of symptoms, including dizziness, chest pain, incontinence, swelling of the lips and tongue, wheezing, and stridor. Skin changes include flushing, pruritus, urticaria, and angioedema. The patient may be anxious and confused and have a sense of impending doom.

A patient can have a severe allergic reaction, possibly leading to anaphylactic shock, after contact, inhalation, ingestion, or injection with an antigen (allergen) to which the person has previously been sensitized (Table 66.1). IV administration of the antigen (allergen) is the route most likely to cause anaphylaxis. However, oral, topical, and inhalation routes can cause anaphylactic reactions. Tables 66.2 and 66.3 describe the laboratory findings and clinical presentation of a patient in anaphylactic shock. Quick and decisive action is critical to prevent an allergic reaction from progressing to anaphylactic shock. (Anaphylaxis is discussed in Chapter 13.)

Septic Shock

Sepsis is a life-threatening syndrome in response to an infection. It is characterized by a dysregulated patient response along with new organ dysfunction related to the infection (Table 66.4).[6] In as many as 30% of patients with sepsis, the causative organism is not identified. Sepsis and septic shock have a high incidence worldwide, with a mortality rate of 25% or higher.[7]

Septic shock is a subset of sepsis. It has an increased mortality risk due to profound circulatory, cellular, and metabolic abnormalities.

Septic shock is characterized by persistent hypotension, despite adequate fluid resuscitation, and inadequate tissue perfusion that results in tissue hypoxia.[6,7] The main organisms that cause sepsis are gram-negative and gram-positive bacteria. Parasites, fungi, and viruses can also cause sepsis and septic shock.[6] Fig. 66.5 presents the pathophysiology of septic shock.

TABLE 66.3 Clinical Presentation of Types of Shock

Distributive Shock					
Cardiogenic Shock	**Hypovolemic Shock**	**Neurogenic Shock**	**Anaphylactic Shock**	**Septic Shock**	**Obstructive Shock**
Cardiovascular System					
Tachycardia **↓ BP** **↓ SV, CO** **↑ SVR, PAWP, CVP** **↓ Capillary refill**	Tachycardia ↓ Preload ↓ CO, CVP, PAWP ↑ SVR ↓ Capillary refill	Bradycardia ↓ BP ↓ CO, CVP, SVR ↓/↑ Temperature	Tachycardia ↑ CO ↓ CVP, PAWP Chest pain Third spacing of fluid	Tachycardia ↓/↑ Temperature Myocardial dysfunction Biventricular dilation ↓ Ejection fraction	Tachycardia ↓ BP ↓ Preload ↓ CO ↑ SVR, CVP
Respiratory System					
Tachypnea **Crackles** **Cyanosis**	Tachypnea → bradypnea (late)	Dysfunction related to level of injury	Shortness of breath Edema of larynx and epiglottis Wheezing Stridor Rhinitis	Hyperventilation Crackles Respiratory alkalosis → respiratory acidosis Hypoxemia Respiratory failure ARDS Pulmonary hypertension	Tachypnea → bradypnea (late) Shortness of breath

* Also see Table 66.2.

When a microorganism enters the body, the normal immune or inflammatory responses are triggered. However, in sepsis and septic shock the body's response to the microorganism is exaggerated. Both proinflammatory and antiinflammatory responses are activated,

coagulation increases, and fibrinolysis decreases.[6] Endotoxins from the microorganism cell wall stimulate the release of cytokines. These include tumor necrosis factor (TNF), interleukin-1 (IL-1), and other proinflammatory mediators that act through secondary mediators, such as platelet-activating factor, IL-6, and IL-8.[6] (See Chapter 11 for discussion of the inflammatory response.) The release of platelet-activating factor results in the formation of microthrombi and obstruction of the microvasculature. The combined effects of the mediators result in damage to the endothelium, vasodilation, increased capillary permeability, and neutrophil and platelet aggregation and adhesion to the endothelium.

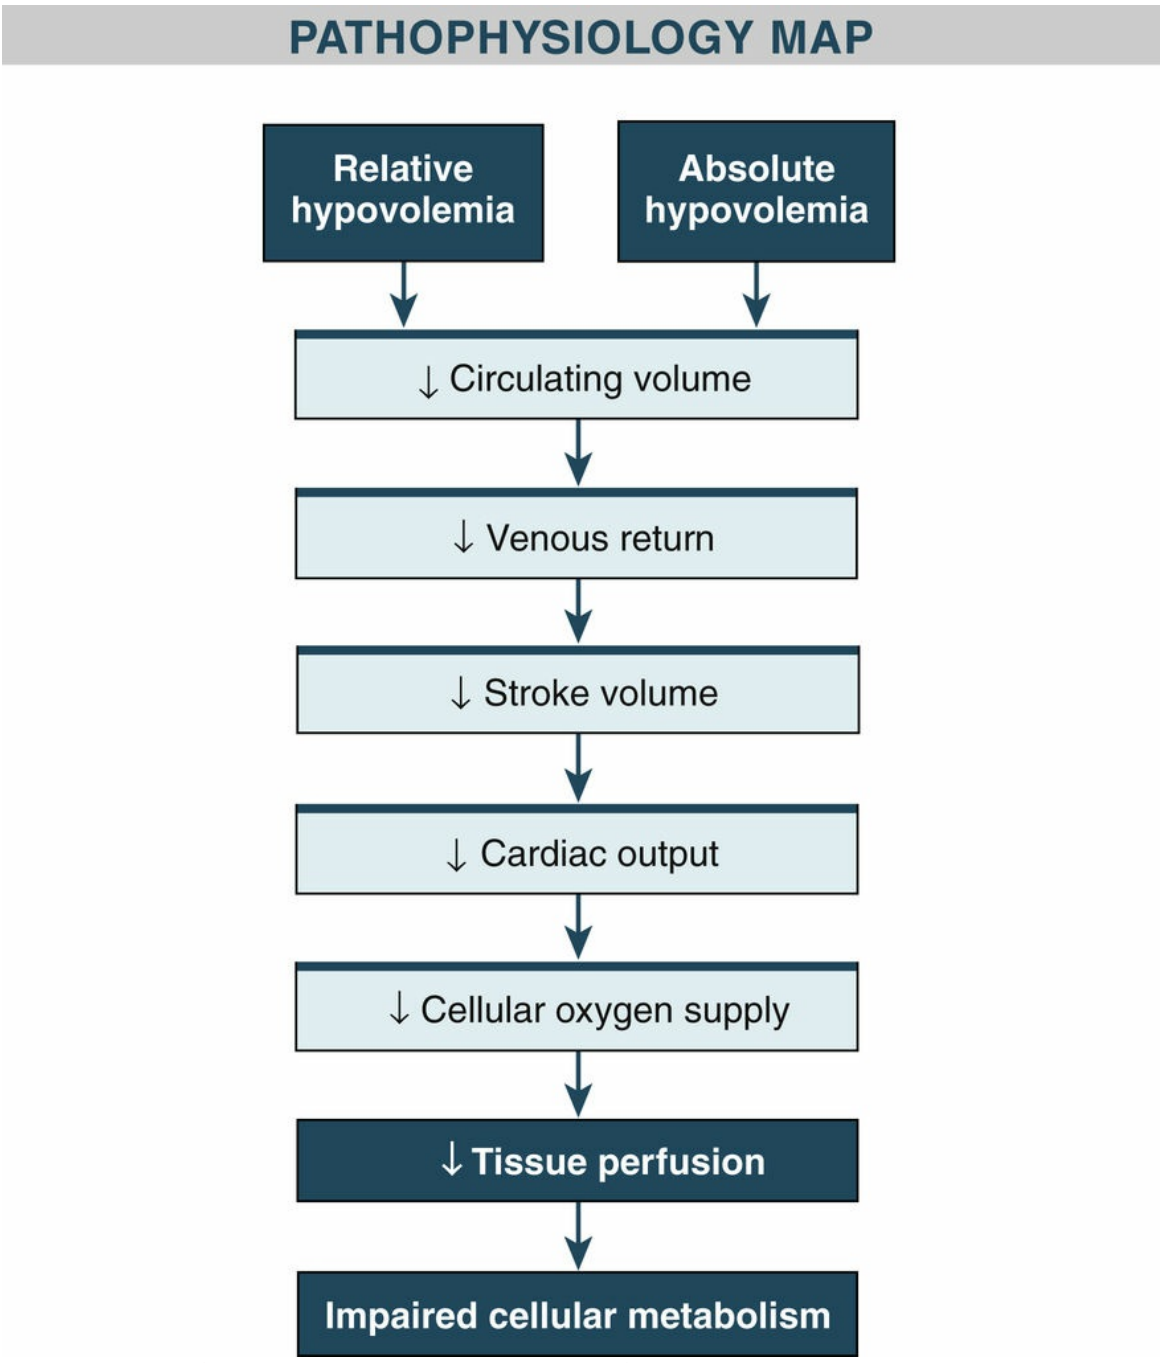

FIG. 66.3 The pathophysiology of hypovolemic shock.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

Septic shock has 3 major pathophysiologic effects: vasodilation, maldistribution of blood flow, and myocardial depression. Patients may be euvolemic, but because of acute vasodilation and shifting of fluids out of the intravascular space, relative hypovolemia and

hypotension occur. Blood flow in the microcirculation is decreased, causing poor O_2 delivery and tissue hypoxia. We think the combination of TNF and IL-1 has a role in sepsis-induced myocardial dysfunction. The ejection fraction (EF) is decreased for the first few days after the initial insult. Because of a decreased EF, the ventricles dilate to maintain the SV. The EF typically improves, and ventricular dilation resolves over 7 to 10 days. Persistent high CO and a low SVR beyond 24 hours is an ominous finding. It is often associated with an increased development of hypotension and MODS. Coronary artery perfusion and myocardial O_2 metabolism are not primarily altered in septic shock.

Respiratory failure is common. The patient initially hyperventilates as a compensatory mechanism, causing respiratory alkalosis. Once the patient can no longer compensate, respiratory acidosis develops. Respiratory failure develops in 85% of patients with sepsis, and 40% develop acute respiratory distress syndrome (ARDS) (see Chapter 67). These patients may need to be intubated and mechanically ventilated.

Other signs of septic shock include changes in neurologic status, decreased urine output, and GI dysfunction, such as GI bleeding and paralytic ileus. Table 66.3 gives the clinical presentation of a patient with septic shock.

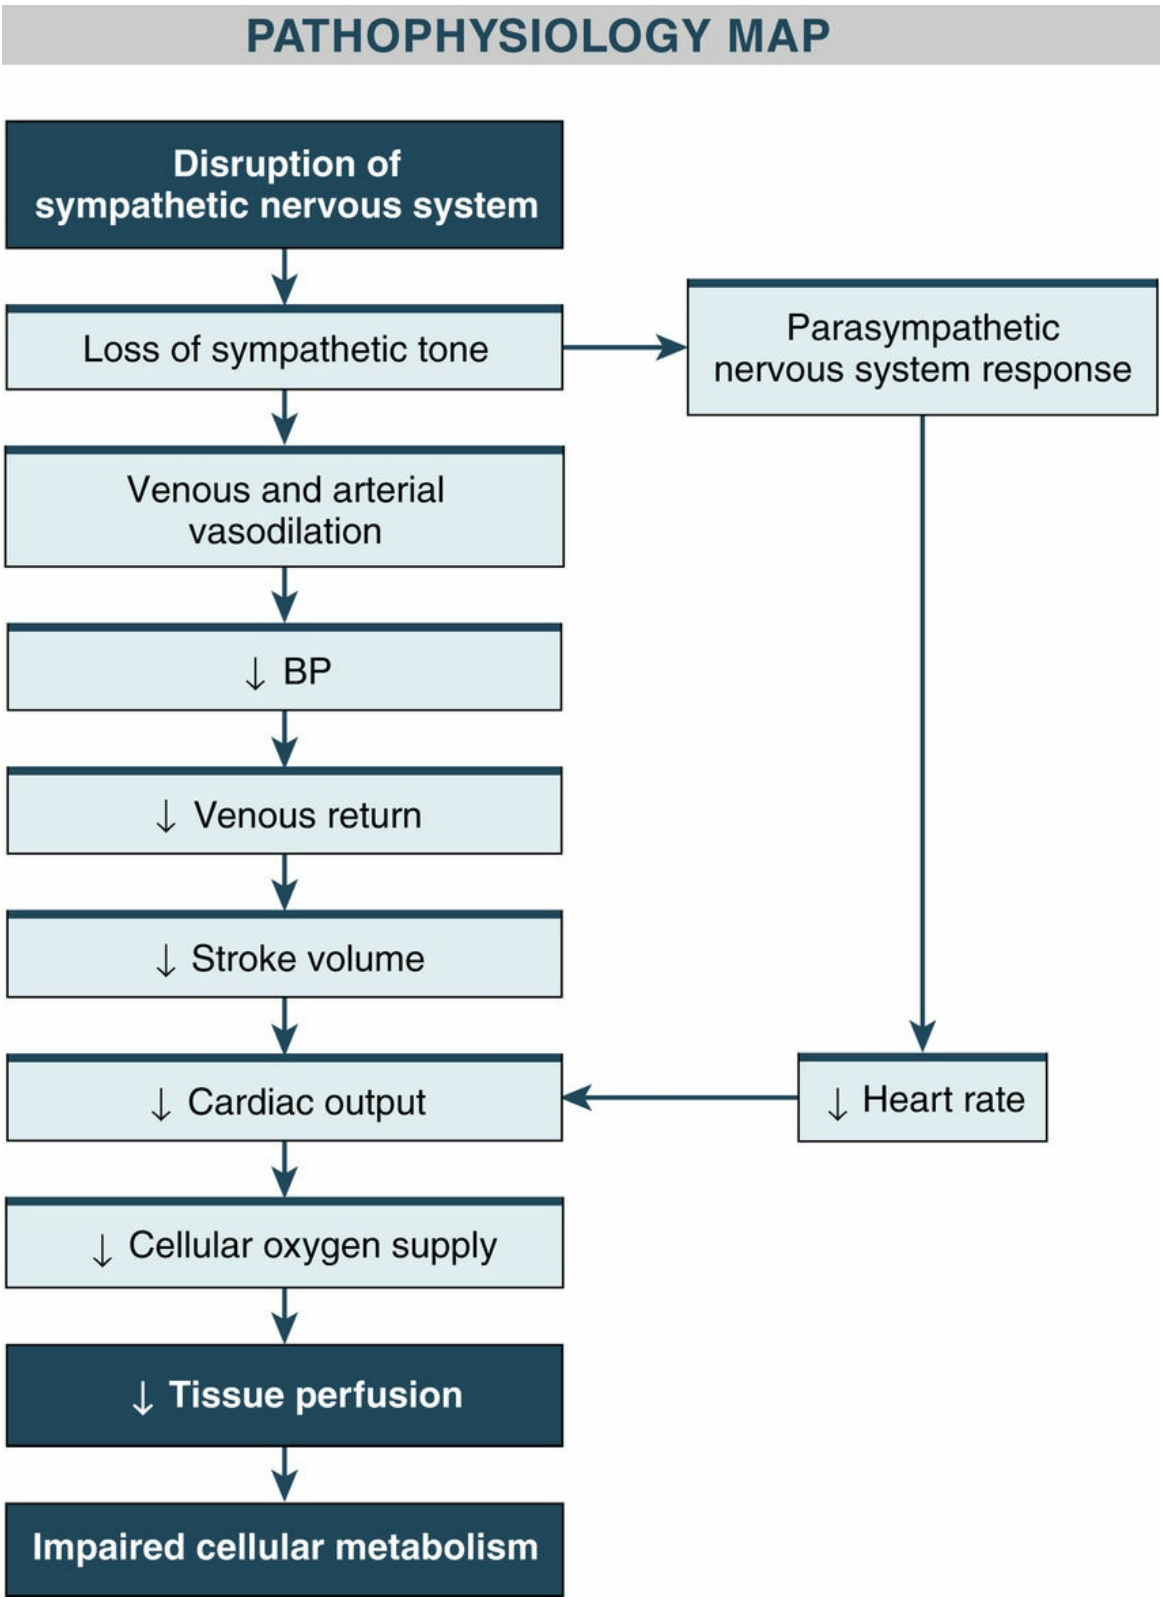

FIG. 66.4 The pathophysiology of neurogenic shock.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

Obstructive Shock

Obstructive shock develops when a physical obstruction to blood flow occurs with a decreased CO (Fig. 66.6). This can be caused by restricted diastolic filling of the right ventricle from compression (e.g., cardiac tamponade, tension pneumothorax, superior vena cava syndrome). Other causes include *abdominal compartment syndrome,* in which increased abdominal pressures compress the inferior vena cava. This decreases venous return to the heart. Pulmonary embolism and right ventricular thrombi cause an outflow obstruction as blood leaves the right ventricle through the pulmonary artery. This leads to decreased blood flow to the lungs and decreased blood return to the left atrium.

Patients have a decreased CO, increased afterload, and variable left ventricular filling pressures depending on the obstruction. Other signs include jugular venous distention and pulsus paradoxus. Rapid assessment and treatment are important to prevent further hemodynamic compromise and possible cardiac arrest (Fig. 66.6).

Stages of Shock

In addition to understanding the underlying pathogenesis of the type of shock the patient has, management is guided by knowing where the patient is on the shock "continuum." We categorize shock into 4 overlapping stages: (1) initial stage, (2) compensatory stage, (3) progressive stage, and (4) refractory stage.[6]

TABLE 66.4 Diagnostic Criteria for Sepsis

Infection, documented or suspected, and some of the following:

General Variables

- Altered mental status

- Fever (temperature >100.9°F [38.3°C])
- Heart rate >90 beats/min
- Hyperglycemia (blood glucose >140 mg/dL) in the absence of diabetes
- Hypothermia (core temperature <97.0°F [36°C])
- Systolic BP ≤100 mm Hg
- Significant edema or positive fluid balance (>20 mL/kg over 24 hr)
- Tachypnea (respiratory rate ≥22/min)

Inflammatory Variables

- Leukocytosis (WBC count >12,000/μL)
- Leukopenia (WBC count <4000/μL)
- Normal WBC count with >10% immature forms (bands)
- Elevated C-reactive protein
- Elevated procalcitonin

Hemodynamic Variables

- Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or a decrease in SBP >40 mm Hg)

Organ Dysfunction Variables

- Acute oliguria (urine output <0.5 mL/kg/hr for at least 2 hr despite adequate fluid resuscitation)
- Arterial hypoxemia (PaO_2/FIO_2 <300)
- Coagulation abnormalities (INR >1.5 or PTT >60 sec)
- Hyperbilirubinemia (total bilirubin >4 mg/dL)
- Ileus (absent bowel sounds)

- Serum creatinine increase >0.5 mg/dL
- Thrombocytopenia (platelet count <100,000/μL)

Tissue Perfusion Variables

- Hyperlactatemia (>1 mmol/L)
- Mottling or decreased capillary refill

FIO_2, Fraction of inspired O_2; *INR,* international normalized ratio; *PaO_2,* partial pressure of arterial O_2; *PTT,* partial thromboplastin time.

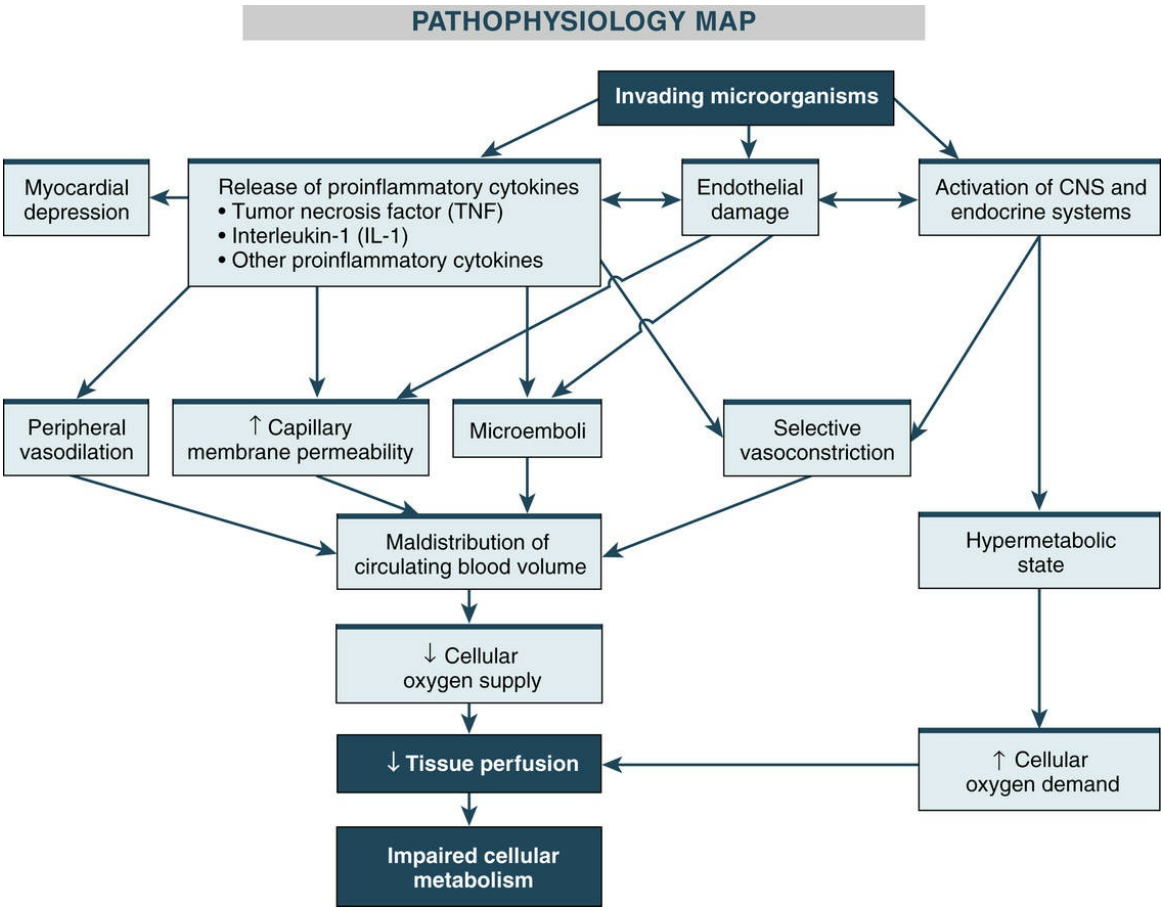

FIG. 66.5 The pathophysiology of septic shock.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

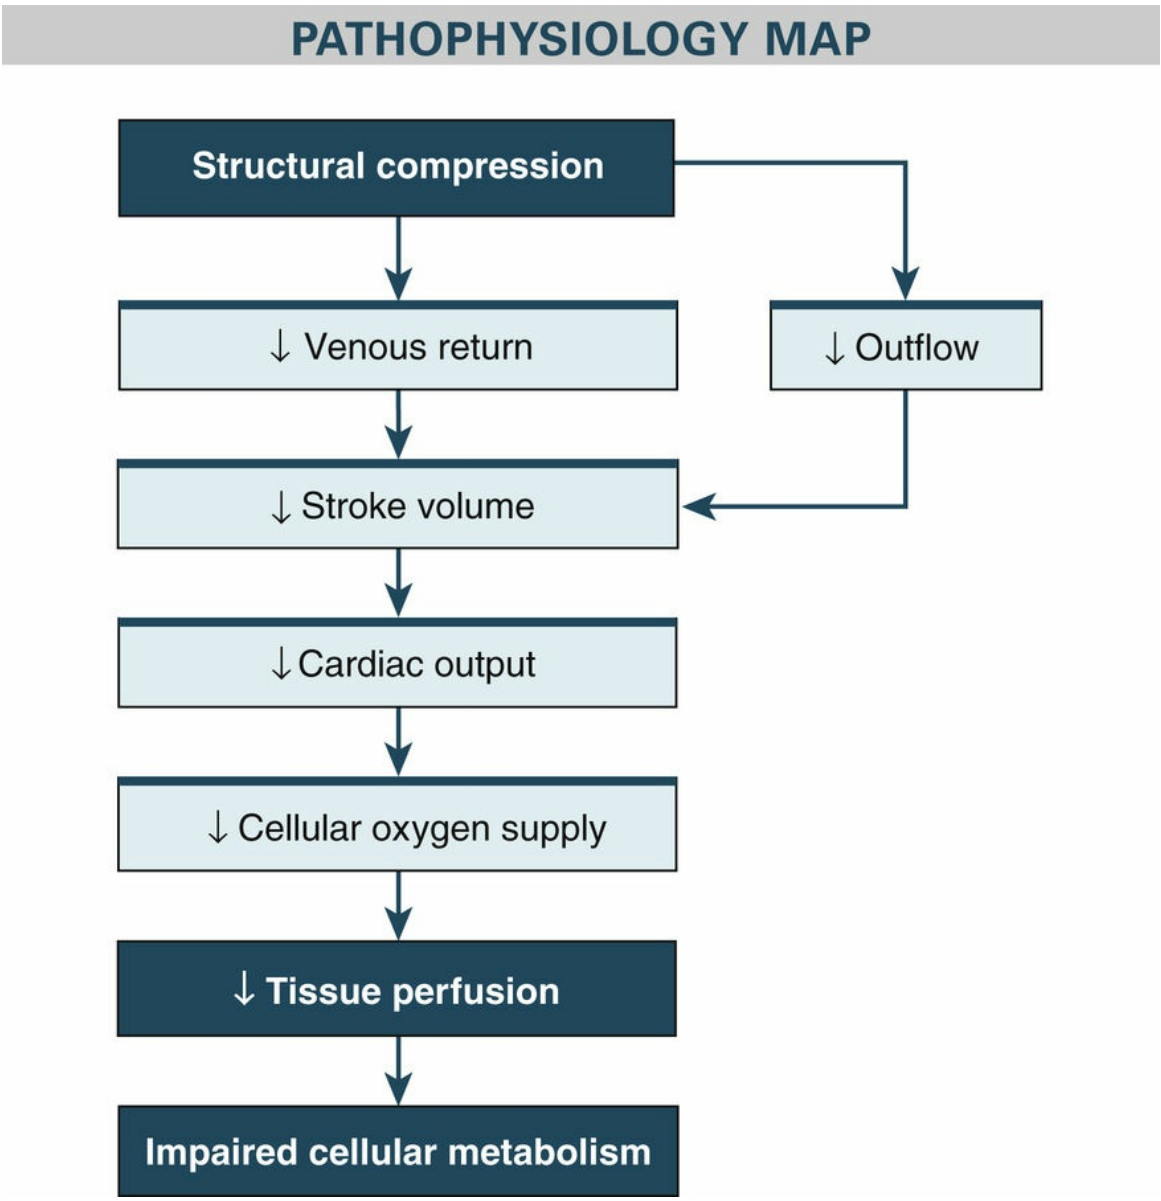

FIG. 66.6 The pathophysiology of obstructive shock.

Initial Stage

The continuum begins with the *initial stage* of shock that occurs at a cellular level. This stage is usually not clinically apparent. Metabolism changes at the cellular level from aerobic to anaerobic, causing lactic acid buildup. Lactic acid is a waste product that is removed by the liver. However, this process requires O_2, which is unavailable because of the decrease in tissue perfusion.

Compensatory Stage

In the *compensatory stage* the body activates neural, hormonal, and biochemical compensatory mechanisms to try to overcome the increasing consequences of anaerobic metabolism and maintain homeostasis. The patient's clinical presentation begins to reflect the body's responses to the imbalance in O_2 supply and demand (Table 66.5).

A classic sign of shock is a drop in BP. This occurs because of a decrease in CO and a narrowing of the pulse pressure. The baroreceptors in the carotid and aortic bodies immediately respond by activating the SNS. The SNS stimulates vasoconstriction and the release of the potent vasoconstrictors epinephrine and norepinephrine. Blood flow to the heart and brain is maintained. Blood flow to the nonvital organs, such as kidneys, GI tract, skin, and lungs, is diverted or shunted.

The myocardium responds to the SNS stimulation and the increase in O_2 demand by increasing the heart rate and contractility. Increased contractility increases myocardial O_2 consumption. The coronary arteries dilate to try to meet the increased O_2 demands of the myocardium.

Shunting blood away from the lungs has an important clinical effect in the patient in shock. Decreased blood flow to the lungs increases the patient's physiologic dead space. *Physiologic dead space* is the anatomic dead space (the amount of air that will not reach gas-exchanging units) and any inspired air that cannot take part in gas exchange. The clinical result of an increase in dead space ventilation is a *ventilation-perfusion mismatch.* Some areas of the lungs that are being ventilated will not be perfused because of the decreased blood flow to the lungs. Arterial O_2 levels will decrease, and the patient will have a compensatory increase in the rate and depth of respirations (see Chapter 67).

The shunting of blood from other organ systems results in clinically important changes. The decrease in blood flow to the GI tract results in impaired motility and a slowing of peristalsis. This increases the

risk for a paralytic ileus.

Decreased blood flow to the skin results in the patient feeling cool and clammy. The exception is the patient in early septic shock who may feel warm and flushed because of a hyperdynamic state. Decreased blood flow to the kidneys activates the renin-angiotensin system. Renin stimulates angiotensinogen to make angiotensin I, which is then converted to angiotensin II (see Fig. 44.4). Angiotensin II is a potent vasoconstrictor that causes both arterial and venous vasoconstriction. The net result is an increase in venous return to the heart and an increase in BP. Angiotensin II stimulates the adrenal cortex to release aldosterone. This results in sodium and water reabsorption and potassium excretion by the kidneys. The increase in sodium reabsorption raises the serum osmolality and stimulates the release of antidiuretic hormone (ADH) from the posterior pituitary gland. ADH increases water reabsorption by the kidneys, further increasing blood volume. The increase in total circulating volume results in an increase in CO and BP.

A multisystem response to decreasing tissue perfusion starts during the compensatory stage of shock. At this stage, the body can compensate for the changes in tissue perfusion. If the cause of the shock is corrected, the patient will recover with little or no residual effects. If the cause of the shock is not corrected and the body is unable to compensate, the patient enters the progressive stage of shock.

Progressive Stage

The *progressive stage* of shock begins as compensatory mechanisms fail. Changes in the patient's mental status are important findings in this stage. Patients must be moved to the intensive care unit (ICU), if not already there, for advanced monitoring and treatment.

The cardiovascular system is profoundly affected in the progressive stage of shock. CO begins to fall, resulting in a decrease in BP and coronary artery, cerebral, and peripheral perfusion. Continued decreased cellular perfusion and resulting altered capillary permeability are the distinguishing features of this stage. Altered

capillary permeability allows fluid and protein to leak out of the vascular space into the surrounding interstitial space. In addition to the decrease in circulating volume, there is an increase in systemic interstitial edema. The patient may have *anasarca* (diffuse profound edema). Fluid leakage from the vascular space affects the solid organs (e.g., liver, spleen, GI tract, lungs) and peripheral tissues by further decreasing perfusion.

Sustained hypoperfusion results in weak peripheral pulses, and ischemia of the distal extremities eventually occurs. Myocardial dysfunction from decreased perfusion results in dysrhythmias, myocardial ischemia, and possibly MI. The result is a complete deterioration of the cardiovascular system.

The pulmonary system is often the first system to display signs of critical dysfunction. During the compensatory stage, blood flow to the lungs is already reduced. In response to the decreased blood flow and SNS stimulation, the pulmonary arterioles constrict, resulting in increased pulmonary artery (PA) pressure. As the pressure within the pulmonary vasculature increases, blood flow to the pulmonary capillaries decreases and ventilation-perfusion mismatch worsens.

TABLE 66.5 Manifestations of Stages of Shock*

Compensatory Stage	Progressive Stage	Refractory Stage
Neurologic System		
Oriented to person, place, time **Restless, apprehensive, confused** **Change in level of consciousness**	↓ Cerebral perfusion pressure ↓ Cerebral blood flow ↓ Responsiveness to stimuli Delirium	Unresponsive Areflexia (loss of reflexes) Pupils nonreactive and dilated
Cardiovascular System		
Sympathetic nervous system response: • **Release of epinephrine/norepinephrine (vasoconstriction)** • **↑ MVO_2** • **↑ Contractility** • **↑ HR** **Coronary artery dilation** **Narrowed pulse pressure** **↓ BP**	↑ Capillary permeability → systemic interstitial edema ↓ CO → ↓ BP and ↑ HR MAP <60 mm Hg (or 40 mm Hg drop in BP from baseline) ↓ Coronary perfusion → dysrhythmias, myocardial ischemia, MI ↓ Peripheral perfusion → ischemia of distal extremities, ↓ pulses, ↓ capillary refill	Profound hypotension ↓ CO Bradycardia, irregular rhythm ↓ BP inadequate to perfuse vital organs
Respiratory System		
↓ Blood flow to the lungs: • **↑ Physiologic dead space** • **↑ Ventilation-perfusion mismatch** • **Hyperventilation** • **↑ Minute ventilation (V_E)** • **Tachypnea**	ARDS: • ↑ Capillary permeability • Pulmonary vasoconstriction • Pulmonary interstitial edema • Alveolar edema • Diffuse infiltrates • Tachypnea • ↓ Compliance • Moist crackles	Severe refractory hypoxemia Respiratory failure
Gastrointestinal System		
↓ Blood supply **↓ GI motility** **Hypoactive bowel sounds** **↑ Risk for paralytic ileus**	Vasoconstriction and ↓ perfusion → ischemic gut (e.g., stomach, small and large intestines, gallbladder, pancreas): • Erosive ulcers • GI bleeding • Translocation of GI bacteria • Impaired absorption of nutrients	Ischemic gut
Renal System		
↓ Renal blood flow **↑ Renin resulting in release of angiotensin (vasoconstrictor)** **↑ Aldosterone resulting in Na^+ and H_2O reabsorption** **↑ Antidiuretic hormone resulting in H_2O reabsorption**	Renal tubules become ischemic → acute tubular necrosis ↓ Urine output ↑ BUN-to-creatinine ratio ↑ Urine sodium ↓ Urine osmolality and specific gravity ↓ Urine potassium Metabolic acidosis	Anuria
Hepatic System		
	Failure to metabolize drugs and waste products Cell death (↑ liver enzymes) Jaundice (↓ clearance of bilirubin) ↑ NH_3 (ammonia) and lactate	Metabolic changes from accumulation of waste products (e.g., NH_3, lactate, CO_2)
Hematologic System		
	DIC: • Thrombin clots in microcirculation • Consumption of platelets and clotting factors	DIC progresses
Temperature		
Normal or abnormal	Hypothermia or hyperthermia	Hypothermia
Skin		
Pale and cool **Warm and flushed**	Cold and clammy	Mottled, cyanotic

MVO_2, myocardial O_2 consumption.

* The shock continuum begins with the *initial stage* of shock. This stage occurs at the cellular level and is usually not clinically apparent. Also see Table 66.2 and Table 66.3.

Another key response in the lungs is the movement of fluid from the pulmonary vasculature into the interstitial space. As capillary permeability increases, the movement of fluid to the interstitial spaces results in interstitial edema, bronchoconstriction, and a decrease in functional residual capacity. With further increases in capillary permeability, fluid moves into the alveoli, causing alveolar edema and a decrease in surfactant production. The combined effects of pulmonary vasoconstriction and bronchoconstriction are impaired gas exchange, decreased compliance, and worsening ventilation-perfusion mismatch. Clinically, the patient has tachypnea, crackles, and an overall increased work of breathing.

The GI system is affected by prolonged decreased tissue perfusion. As the blood supply to the GI tract is decreased, the normally protective mucosal barrier becomes ischemic. This ischemia predisposes the patient to ulcers and GI bleeding (see Chapter 41). It increases the risk for bacterial migration from the GI tract to the blood and lungs. The decreased perfusion to the GI tract leads to a decreased ability to absorb nutrients.

The effect of prolonged hypoperfusion on the kidneys is renal tubular ischemia. The resulting acute tubular necrosis may lead to acute kidney injury (AKI). This can be worsened by nephrotoxic drugs (e.g., certain antibiotics, anesthetics, diuretics) (see Chapter 46). The patient has decreased urine output and increased blood urea nitrogen (BUN) and serum creatinine. Metabolic acidosis occurs from the kidneys' inability to excrete acids (especially lactic acid) and reabsorb bicarbonate.

The sustained hypoperfusion in the progressive stage of shock greatly affects other organs. The loss of the functional ability of the liver leads to a failure of the liver to metabolize drugs and waste products (e.g., lactate, ammonia). Jaundice results from an accumulation of bilirubin. As the liver cells die, liver enzymes

increase. The liver loses its ability to function as an immune organ. Kupffer cells no longer destroy bacteria from the GI tract. Instead, they are released into the bloodstream, increasing the possibility of bacteremia.

Dysfunction of the hematologic system adds to the complexity of the clinical picture. The patient is at risk for disseminated intravascular coagulation (DIC). The consumption of the platelets and clotting factors with secondary fibrinolysis results in clinically significant bleeding from many orifices. These include the GI tract, lungs, and puncture sites (see Chapter 30). Altered laboratory values in DIC are shown in Table 66.3.

In this stage, aggressive interventions are needed to prevent the development of MODS.

Refractory Stage

In the last stage of shock, the *refractory stage,* decreased perfusion from peripheral vasoconstriction and decreased CO worsen anaerobic metabolism. The accumulation of lactic acid contributes to increased capillary permeability and dilation. Increased capillary permeability allows fluid and plasma proteins to leave the vascular space and move to the interstitial space. Blood pools in the capillary beds due to the constricted venules and dilated arterioles. The loss of intravascular volume worsens hypotension and tachycardia and decreases coronary blood flow. Decreased coronary blood flow leads to worsening myocardial depression and a further decline in CO. Cerebral blood flow cannot be maintained and cerebral ischemia results.

The patient in this stage of shock has profound hypotension and hypoxemia. The failure of the liver, lungs, and kidneys results in an accumulation of waste products, such as lactate, urea, ammonia, and CO_2. The failure of 1 organ system affects several other organ systems. Recovery is unlikely in this stage. The organs are in failure and the body's compensatory mechanisms are overwhelmed (Table 66.5).

Diagnostic Studies

There is no single diagnostic study to determine whether a patient is in shock. The diagnosis starts with a history and physical examination. Obtaining a thorough medical and surgical history and a history of recent events (e.g., surgery, chest pain, trauma) gives valuable data.

Decreased tissue perfusion in shock leads to an increased lactate with a base deficit (the amount needed to bring the pH back to normal). These laboratory changes reflect an increase in anaerobic metabolism.[8] Table 66.2 outlines laboratory findings seen in shock.

Other diagnostic studies include a 12-lead electrocardiogram (ECG), continuous ECG monitoring, chest x-ray, continuous pulse oximetry, and invasive and noninvasive hemodynamic monitoring. Chapter 65 discusses hemodynamic monitoring)

Interprofessional Care

Critical factors in the successful management of a patient in shock relate to the early recognition and treatment of the shock state. Prompt intervention in the early stages of shock may prevent the decline to the progressive or irreversible stage. Successful management of the patient in shock includes (1) identification of patients at risk for the development of shock; (2) integration of the patient's history, physical examination, and clinical findings to establish a diagnosis; (3) interventions to control or eliminate the cause of the decreased perfusion; (4) protecting target and distal organs from dysfunction; and (5) providing multisystem supportive care.

Table 66.6 provides an overview of the initial assessment findings and interventions for the emergency care of patients in shock. General management strategies begin with ensuring that the patient is responsive and has a patent airway. Once the airway is established, either naturally or with an endotracheal tube, O_2 delivery must be optimized. Supplemental O_2 and mechanical ventilation may be needed to maintain an arterial O_2 saturation of 90% or more (PaO_2 greater than 60 mm Hg) to avoid hypoxemia (see Chapter 65). The mean arterial pressure (MAP) and circulating blood volume are

optimized with fluid replacement and drug therapy.

Oxygen and Ventilation

O_2 delivery depends on CO, available hemoglobin, and arterial O_2 saturation (SaO_2). Methods to optimize O_2 delivery are directed at increasing supply and decreasing demand. Supply is increased by (1) optimizing the CO with fluid replacement and/or drug therapy, (2) increasing the hemoglobin through transfusion of whole blood or packed red blood cells (RBCs), and/or (3) increasing the arterial O_2 saturation with supplemental O_2 and mechanical ventilation.

Plan care to avoid disrupting the balance of O_2 supply and demand. Space activities that increase O_2 consumption (e.g., endotracheal suctioning, position changes) appropriately for O_2 conservation. Intermittent or continuous monitoring of $ScvO_2$ by a central venous catheter or mixed venous O_2 saturation (SvO_2) may be helpful. Both reflect the dynamic balance between O_2 supply and demand. Assess these values along with related hemodynamic measures (e.g., arterial pressure–based cardiac output [APCO], O_2 consumption, hemoglobin) to evaluate the patient's response to treatments and activities (see Chapter 65).

TABLE 66.6 Emergency ManagementShock

Etiology*	Assessment Findings	Interventions
Surgical • **Aortic dissection** • **GI bleeding** • **Postoperative bleeding** • **Ruptured ectopic pregnancy or ovarian cyst** • **Ruptured organ or vessel** • **Vaginal bleeding** **Medical** • **Addisonian crisis** • **Dehydration** • **Diabetes** • **Diabetes insipidus** • **MI** • **Pulmonary embolus** • **Sepsis** **Trauma** • **Fractures, spinal injury** • **Multiorgan injury** • **Ruptured or lacerated vessel or organ (e.g., spleen)**	• Anxiety • Chills • Confusion • Cool, clammy skin (warm skin in early onset of septic and neurogenic shock) • Cyanosis • Decreased level of consciousness • Decreased O_2 saturation • Dysrhythmias • Extreme thirst • Feeling of impending doom • Hypotension • Narrowed pulse pressure • Nausea and vomiting • Obvious hemorrhage or injury • Pallor • Rapid, weak, thready pulses • Restlessness • Tachypnea, dyspnea, or shallow, irregular respirations • Temperature dysregulation • Weakness	**Initial** • If unresponsive, assess circulation, airway, and breathing (CAB). • If responsive, monitor airway, breathing, and circulation (ABC). • Stabilize cervical spine as appropriate. • Control any external bleeding with direct pressure or pressure dressing. • Give high-flow O_2 (100%) by nonrebreather mask or bag-valve-mask. • Anticipate need for intubation and mechanical ventilation. • Establish IV access with 2 large-bore catheters (14- to 16-gauge) or an intraosseous access device; aid with central line insertion. • Begin fluid resuscitation with crystalloids (e.g., 30 mL/kg repeated until hemodynamic improvement is seen). • Draw blood for laboratory studies (e.g., blood cultures, lactate, WBC). • Assess for life-threatening injuries (e.g., cardiac tamponade, liver laceration, tension pneumothorax). • Consider vasopressor therapy if hypotension persists after fluid resuscitation. • Insert an indwelling urinary catheter and nasogastric tube. • Start antibiotic therapy after blood cultures if sepsis is suspected. • Obtain 12-lead ECG and treat dysrhythmias. **Ongoing Monitoring** • ABCs • Level of consciousness • Vital signs, including pulse oximetry; peripheral pulses, capillary refill, skin color and temperature • Respiratory status • Heart rate and rhythm • Urine output

* See Table 66.1 for other causes of shock.

Fluid Resuscitation

The cornerstone of therapy for septic, hypovolemic, and anaphylactic shock is volume expansion with administration of the appropriate fluid (Table 66.7). Fluid resuscitation should start using 1 or 2 large-bore (e.g., 14- to 16-gauge) IV catheters, an intraosseous (IO) access device, or a central venous catheter.

Safety Alert

Intraosseous (IO) Access

- Use an IO access device for emergency resuscitation when IV access cannot be obtained.
- Insertion sites include the sternum, proximal and distal tibia, and proximal and distal humerus.
- Remove IO devices within 24 hours of insertion or as soon as

possible after peripheral or central IV access is obtained.
- Monitor for complications: extravasation of drugs and fluids into the soft tissue, fractures caused during insertion, and osteomyelitis.

The choice of resuscitation fluid is based on the type and volume of fluid lost and the patient's clinical status. The ideal choice of fluid is controversial. Currently, normal saline is most often used in the initial resuscitation of shock. Large-volume resuscitation with normal saline can lead to hyperchloremic metabolic acidosis. Lactated Ringer's solution can cause serum lactate levels to increase because the failing liver cannot convert lactate to bicarbonate.[9] Transfusions of RBCs may be given to treat hypovolemic shock due to bleeding. Colloids (4% to 5%) have not been shown to improve patient outcomes.[9]

Fluid responsiveness is determined by clinical assessment. This includes vital signs, cerebral and abdominal perfusion pressures, capillary refill, skin temperature, and urine output. Hemodynamic parameters, such as SVV or CO, are also used. Monitor trends in BP with an automatic BP cuff or an arterial catheter to assess the patient's response. Use an indwelling urinary catheter to monitor urine output during resuscitation.

The goal for fluid resuscitation is to restore tissue perfusion. Although BP helps determine whether the patient's CO is adequate, an assessment of end-organ perfusion (e.g., urine output, neurologic function, peripheral pulses) provides more relevant data.

Safety Alert

Complications of Fluid Resuscitation

- Warm crystalloid and colloid solutions during massive fluid resuscitation to prevent hypothermia.
- When giving large volumes of packed RBCs, remember that they

do not contain clotting factors.

- Replace clotting factors based on the clinical situation and laboratory studies.

Drug Therapy

The goal of drug therapy for shock is to correct decreased tissue perfusion. Decisions on which drug to use should be based on the physiologic goal. Drugs used to improve perfusion in shock are given IV via an infusion pump and central venous line. Many of these drugs have vasoconstrictor properties that are harmful if the drug leaks into the tissues while being infused peripherally (Table 66.8).

TABLE 66.7 Fluid Therapy in Shock

Fluid Type	Mechanism of Action	Type of Shock	Nursing Implications
Crystalloids			
Isotonic			
• **0.9% NaCl, normal saline solution (NSS)** • **Lactated Ringer's (LR) solution**	Fluid primarily stays in the intravascular space, ↑ intravascular volume.	Used for initial volume replacement in most types of shock.	Monitor patient closely for circulatory overload.Do not use LR in patients with liver failure.LR may be used if hyperchloremic acidosis develops from use of NSS in fluid resuscitation.
Hypertonic			
• **1.8%, 3%, 5% NaCl**	Fluid stays in the intravascular space, increases serum osmolarity, shifts fluid volume from intracellular space to extracellular space to intravascular space.	May be used for initial volume expansion in hypovolemic shock.	Monitor patient closely for signs of hypernatremia (e.g., disorientation, seizures). Central line preferred for infusing saline solutions ≥ 3%, since these may damage veins.
Blood or Blood Products			
Packed red blood cells **Fresh frozen plasma** **Platelets**	Replaces blood loss, increases O_2-carrying capability. Replaces coagulation factors. Helps control bleeding caused by thrombocytopenia.	All types.	Same precautions as any blood administration (see Chapter 30).
Colloids			
Human serum albumin (5% or 25%)	Can increase plasma colloid osmotic pressure. Rapid volume expansion.	All types except cardiogenic and neurogenic shock.	Use 5% solution in hypovolemic patients. Use 25% solution in patients with fluid and sodium restrictions. Monitor for circulatory overload. Mild side effects of chills, fever, and urticaria may develop. More expensive than crystalloids.
dextran (dextran 40)	Hyperosmotic glucose polymer.	Limited use because of side effects, including reducing platelet adhesion, diluting clotting factors.	Increases risk for bleeding. Monitor patient for allergic reactions and AKI. Has maximum volume recommendations per manufacturer.

Sympathomimetic Drugs

Many of the drugs used in the treatment of shock influence the SNS. Drugs that mimic the action of the SNS are called *sympathomimetic.* The effects of these drugs are mediated through their binding to α- or β-adrenergic receptors. The various drugs differ in their relative α- and β-adrenergic effects.[10]

Many of these drugs cause peripheral vasoconstriction and are called *vasopressor drugs* (e.g., norepinephrine, dopamine, phenylephrine). These drugs can cause severe peripheral vasoconstriction and an increase in SVR, further risking tissue perfusion. The increased SVR increases the workload of the heart and myocardial O_2 demand. It can harm a patient in cardiogenic shock by causing further myocardial damage and increasing the risk for

dysrhythmias.[1] Use of vasopressor drugs is limited to patients who do not respond to fluid resuscitation. Adequate fluid resuscitation must be achieved before starting vasopressors because the vasoconstrictor effects in patients with low blood volume will cause further reduction in tissue perfusion. Typically, if the patient has persistent hypotension after adequate fluid resuscitation, a vasopressor (e.g., norepinephrine, dopamine) and/or an inotrope (e.g., dobutamine) is given.

The goal of vasopressor therapy is to achieve and maintain a MAP of greater than 65 mm Hg.[10] Continuously monitor end-organ perfusion (e.g., urine output, level of consciousness) and serum lactate levels (e.g., every 3 hours for the first 6 hours) to ensure that tissue perfusion is adequate.

Vasodilator Drugs

Patients in cardiogenic shock have decreased myocardial contractility, and vasodilators may be needed to decrease afterload. This reduces myocardial workload and O_2 requirements. Although generalized sympathetic vasoconstriction is a useful compensatory mechanism for maintaining BP, excessive constriction can reduce tissue blood flow and increase the workload of the heart. The reason for using vasodilator therapy for a patient in shock is to break the harmful cycle of widespread vasoconstriction causing a decrease in CO and BP, resulting in further sympathetic-induced vasoconstriction.

The goal of vasodilator therapy, as in vasopressor therapy, is to maintain the MAP greater than 65 mm Hg. Monitor hemodynamic parameters (e.g., CVP, CO, $ScvO_2$/SvO_2, SV, PA pressures) and assessment findings so that fluids can be increased or vasodilator therapy decreased if a serious fall in CO or BP occurs. The vasodilator agent most often used for the patient in cardiogenic shock is nitroglycerin. Vasodilation may be enhanced with nitroprusside or nitroglycerin in noncardiogenic shock.

Nutritional Therapy

Protein-calorie malnutrition is common because of hypermetabolism.

Nutrition is vital to reducing mortality. Enteral nutrition (EN) should be started within the first 24 hours. However, full calorie replacement is not recommended for previously well-nourished adults early in a critical illness.[11] Start the patient on a *trophic feeding*. This is a small amount of EN (e.g., 10 mL/hr). Early EN enhances the perfusion of the GI tract and helps maintain the integrity of the gut mucosa. Advance feedings as tolerated and as prescribed. Parenteral nutrition (PN) is used only if EN is contraindicated. Chapter 39 discusses enteral and parenteral nutrition.

TABLE 66.8 Drug TherapyShock

Drug*	Mechanism of Action	Type of Shock	Nursing Implications
angiotensin II (Giapreza)	↑ BP, ↑ MAP ↑SVR	Septic and other distributive shock	Give via central line. Monitor for thromboembolic events. VTE prophylaxis is recommended.
dobutamine	↑ Myocardial contractility ↓ Ventricular filling pressures ↓ SVR, PAWP ↑ CO, SV, CVP ↑/↓ HR	Used in cardiogenic shock with severe systolic dysfunction Used in septic shock to increase O_2 delivery and raise $ScvO_2$ or SvO_2 to 70% if Hgb >7 g/dL or Hct ≥30%	Give via central line (infiltration leads to tissue sloughing). Do not give in same line with $NaHCO_3$. Monitor HR, BP (hypotension may worsen, requiring addition of a vasopressor). Stop infusion if tachydysrhythmias develop.
Dopamine	Positive inotropic effects: ↑ Myocardial contractility ↑ Automaticity ↑ Atrioventricular conduction ↑ HR, CO ↑ BP, ↑ MAP ↑ MVO_2 Can cause progressive vasoconstriction at high doses	Cardiogenic shock	Give via central line (infiltration leads to tissue sloughing). Do not give in same line with $NaHCO_3$. Monitor for tachydysrhythmias. Monitor for peripheral vasoconstriction (e.g., paresthesias, coldness in extremities) at moderate to high doses.
epinephrine (Adrenalin)	*Low doses:* β-Adrenergic agonist (cardiac stimulation, bronchodilation, peripheral vasodilation) ↑ HR, contractility, CO ↓ SVR	Cardiogenic shock Anaphylactic shock Septic shock, if 2nd agent needed after norepinephrine	Monitor for HR >110 beats/min. Monitor for dyspnea, pulmonary edema. Monitor for chest pain, dysrhythmias from ↑ MVO_2. Monitor for renal failure due to ischemia.
	***High doses:* α-Adrenergic agonist (peripheral vasoconstriction)** **↑ SV, SVR** **↑ Systolic/↓ diastolic BP, widened pulse pressure** **↑ CVP, PAWP**	Cardiac arrest, pulseless ventricular tachycardia, ventricular fibrillation, asystole	
hydrocortisone (Solu-Cortef)	↓ Inflammation, reverses ↑ capillary permeability ↑ BP, HR	Septic shock requiring vasopressor therapy (despite fluid resuscitation) to maintain adequate BP Anaphylactic shock if hypotension persists after initial therapy	Monitor for hypokalemia, hyperglycemia. Consider use as continuous infusion.
nitroglycerin	Venous dilation Dilates coronary arteries ↓ Preload, MVO_2, SVR, BP	Cardiogenic shock	Continuously monitor BP and HR, since reflex tachycardia may occur. Glass bottle recommended for infusion.
norepinephrine (Levophed)	β_1-Adrenergic agonist (cardiac stimulation) α-Adrenergic agonist (peripheral vasoconstriction) Renal and splanchnic vasoconstriction ↑ BP, MAP, CVP, PAWP, SVR ↑/↓ CO	Cardiogenic shock after MI Septic shock—first drug of choice for BP unresponsive to adequate fluid resuscitation	Give via central line (infiltration leads to tissue sloughing). Monitor for dysrhythmias due to ↑ MVO_2 requirements.
phenylephrine	α-Adrenergic agonist (peripheral vasoconstriction) Renal, mesenteric, splanchnic, cutaneous, and pulmonary blood vessel constriction ↑ HR, BP, SVR ↑/↓ CO	Neurogenic shock	Monitor for reflex bradycardia, headache, restlessness. Monitor for renal failure from ↓ renal blood flow. Give via central line (infiltration leads to tissue sloughing).
sodium nitroprusside	Arterial and venous vasodilation ↓ Preload, afterload ↓ CVP, PAWP ↑/↓ CO ↓ BP	Cardiogenic shock with ↑ SVR	Continuously monitor BP. Protect solution from light. Wrap infusion bottle with opaque covering. Give with D_5W only. Monitor serum cyanide levels and for signs of cyanide toxicity (e.g., metabolic acidosis, tachycardia, altered level of consciousness, seizures, coma, almond smell on breath).
vasopressin	Antidiuretic hormone Nonadrenergic vasoconstrictor ↑ MAP ↑ Urine output	Shock states (most often septic shock) refractory to other vasopressors	Given with norepinephrine and in low doses. Infusions are not titrated. Monitor hemodynamic pressures and urine output.

CVP, Central venous pressure; *MVO_2,* myocardial O_2 consumption; *PAWP,* pulmonary artery wedge pressure; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *SVR,* systemic vascular resistance.

* Consult agency guidelines, pharmacist, pharmacology references, and drug manufacturer's materials for more information and dosing recommendations.

Weigh the patient daily on the same scale (usually the bed scale) at the same time of day. If the patient has a significant weight loss, rule out dehydration before adding more calories. Large weight gains are common because of third spacing of fluids. Therefore daily weights serve as a better indicator of fluid status than caloric needs. Serum protein, total albumin, prealbumin, BUN, serum glucose, and serum electrolytes are all used to assess nutritional status.

Measures Specific to Type of Shock

Cardiogenic Shock

For a patient in cardiogenic shock, the overall goal is to restore heart function and the balance between O_2 supply and demand in the myocardium. Cardiac catheterization is done as soon as possible after the initial insult.[1] Specific measures to restore blood flow include angioplasty with stenting, emergency revascularization, and valve replacement (see Chapter 33). Until these interventions are done, we must support the heart to optimize SV and CO to achieve optimal perfusion (Tables 66.8 and 66.9).

Hemodynamic management of a patient in cardiogenic shock aims to reduce the workload of the heart through drug therapy and/or mechanical interventions. Drug choice is based on the clinical goal and a thorough understanding of each drug's mechanism of action. Drugs can be used to decrease the workload of the heart by dilating coronary arteries (e.g., nitrates), reducing preload (e.g., diuretics), afterload (e.g., vasodilators), and heart rate and contractility (e.g., β-adrenergic blockers).

The patient may benefit from a circulatory assist device (e.g., intraaortic balloon pump, ventricular assist device [VAD]) (see

Chapter 65). The goals of this intervention are to decrease SVR and left ventricular workload so that the heart can heal.[12] A VAD may be used as a temporary measure for the patient in cardiogenic shock who is awaiting heart transplantation. Heart transplantation is an option for a small, select group of patients with cardiogenic shock.

Hypovolemic Shock

The underlying principles of managing patients with hypovolemic shock focus on stopping the loss of fluid and restoring the circulating volume. We often calculate the initial fluid resuscitation using a 3:1 rule (3 mL of isotonic crystalloid for every 1 mL of estimated blood loss). Table 66.7 describes types of fluid used for volume resuscitation, the mechanisms of action, and specific nursing implications for each fluid type.

Septic Shock

Patients in septic shock need large amounts of fluid replacement. The overall goal of fluid resuscitation is to restore the intravascular volume and organ perfusion. Initial volume resuscitation is achieved by giving 30 mL/kg of an isotonic crystalloid solution. Albumin 4% to 5% may be added when patients need substantial volumes.

A fluid challenge technique (e.g., a minimum of 30 mL/kg of crystalloids) may be used and repeated until hemodynamic improvement (e.g., increase in MAP and/or CVP, change in SVV) is seen. Table 66.9 shows predetermined end points of fluid resuscitation along with methods to reassess volume status.

One of these methods is a *passive leg raise* (PLR) challenge along with hemodynamic measures to monitor response.[13] A PLR challenge provides a transient increase in fluid volume of 150 to 500 mL by placing the patient supine and raising the legs to 45 degrees (Fig. 66.7). Response is monitored within 1 to 2 minutes by measuring CO, CI, SV, SVV, or other parameters for improvement. If the response is positive, the patient is fluid responsive and should receive more fluids. To optimize and evaluate large-volume fluid resuscitation, hemodynamic monitoring with various noninvasive or invasive

monitors is needed.

If the patient is hypotensive after initial volume resuscitation and no longer fluid responsive, vasopressors may be added. The first drug of choice is norepinephrine.[14] Vasodilation and low CO, or vasodilation alone, can cause low BP despite adequate fluid resuscitation. Vasopressin may be added for those who are refractory to initial vasopressor therapy.[14] Exogenous vasopressin can replace the stores of physiologic vasopressin that are often depleted in septic shock.

Drug Alert

Vasopressin

- Given along with norepinephrine.
- Infuse at low doses (e.g., 0.03 units/min) using an IV pump.
- Do not titrate infusion.
- Use cautiously in patients with coronary artery disease.

Vasopressor drugs may increase BP but can decrease SV. An inotropic agent (e.g., dobutamine) may be added to offset the decrease in SV and increase tissue perfusion (Table 66.8). IV corticosteroids may be considered for patients in septic shock who cannot maintain an adequate BP despite vasopressor therapy and fluid resuscitation.

To try to meet the increasing tissue demands coupled with a low SVR, the patient initially has a normal or high CO. If the patient is unable to achieve and maintain an adequate CO and has unmet tissue O_2 demands, CO may have to be increased using drug therapy (e.g., dopamine). $ScvO_2$ or SvO_2 monitoring is used to assess the balance between O_2 delivery and consumption, and the adequacy of the CO (see Chapter 65). If balance is maintained, the tissue demands will be met.

Broad-spectrum antibiotics are an important and early part of therapy. They should be started within the first hour of sepsis or septic shock.[15] Obtain cultures (e.g., blood, wound, urine, stool, sputum) before antibiotics are started. However, this should not delay the start of antibiotics within the first hour. Specific antibiotics may be ordered once the organism has been identified.

Glucose levels should be maintained below 180 mg/dL (10.0 mmol/L) for patients in shock.[16] Monitor glucose levels in all patients in septic shock according to agency policy. Stress ulcer prophylaxis with proton pump inhibitors (e.g., pantoprazole) and VTE prophylaxis (e.g., heparin, enoxaparin [Lovenox]) are recommended.[17]

Neurogenic Shock

The specific treatment of neurogenic shock is based on the cause. If the cause is spinal cord injury, general measures to promote spinal stability (e.g., spinal precautions, cervical stabilization with a collar) are initially used. Once the spine is stabilized, treatment of the hypotension and bradycardia is essential to prevent further spinal cord damage. Treatment involves the use of vasopressors (e.g., phenylephrine) to maintain BP and organ perfusion (Table 66.8). Bradycardia may be treated with atropine. Infuse fluids cautiously as the cause of the hypotension is not related to fluid loss. The patient with a spinal cord injury is monitored for hypothermia caused by hypothalamic dysfunction (Table 66.9).

Anaphylactic Shock

The first strategy in managing patients at risk for anaphylactic shock is prevention. A thorough history is key to avoiding risk factors for anaphylaxis (Table 66.1). The clinical presentation of anaphylactic shock is dramatic, and immediate intervention is required. Epinephrine is the first drug of choice to treat anaphylactic shock.[5] It causes peripheral vasoconstriction and bronchodilation and opposes the effect of histamine. Diphenhydramine and histamine receptor blockers (e.g., famotidine) are given as adjunctive therapies to block

the ongoing release of histamine from the allergic reaction.

TABLE 66.9 Interprofessional CareShock

Oxygenation	Circulation	Drug Therapies	Supportive Therapies
Cardiogenic Shock			
• **Provide supplemental O_2 (e.g., nasal cannula, nonrebreather mask)** • **Intubation and mechanical ventilation, if needed** • **Monitor $ScvO_2$ or SvO_2**	• Restore blood flow with angioplasty with stenting, emergent coronary revascularization • Reduce workload of heart with circulatory assist devices: IABP, VAD	• Nitrates (e.g., nitroglycerin) • Inotropes (e.g., dobutamine) • Diuretics (e.g., furosemide) • β-Adrenergic blockers (contraindicated with ↓ ejection fraction)	• Treat dysrhythmias
Hypovolemic Shock			

• **Provide supplemental O_2**
• **Monitor $ScvO_2$ or $ScvO_2$**
	• Rapid fluid replacement using 2 large-bore (14–16 gauge) peripheral IV lines, an intraosseous access device, or central venous catheter
	• Restore fluid volume (e.g., blood or blood products, crystalloids)
	• End points of fluid resuscitation:
	  • CVP 15 mm Hg
	  • PAWP 10–12 mm Hg
		• No specific drug therapy	• Correct the cause (e.g., stop bleeding, GI losses)
			• Use warmed IV fluids, including blood products (if appropriate)

Septic Shock			

• **Provide supplemental O_2**
• **Intubation and mechanical ventilation, if needed**
• **Monitor $ScvO_2$ or SvO_2**
	• Aggressive fluid resuscitation (e.g., 30 mL/kg of crystalloids repeated if hemodynamic improvement is noted)
	• End points of fluid resuscitation are based on:
	  • Focused physical examination including vital signs, cardiopulmonary assessment, capillary refill, peripheral pulses, and skin or any 2 of the following:
	  • $ScvO_2$ >70 or SvO_2 >65
	  • CVP 8–12 mm Hg
	  • Cardiovascular ultrasound
	  • Assessment of fluid responsiveness with passive leg raise or fluid challenge
		• Antibiotics as ordered
		• Vasopressors (e.g., norepinephrine)
		• Inotropes (e.g., dobutamine)
		• Anticoagulants (e.g., low-molecular-weight heparin)
			• Obtain cultures (e.g., blood, wound) before beginning antibiotics
			• Monitor temperature
			• Control blood glucose
			• Stress ulcer prophylaxis

Neurogenic Shock			
• **Maintain patent airway** • **Provide supplemental O_2** • **Intubation and mechanical ventilation (if needed)**	• Cautious administration of fluids	• Vasopressors (e.g., phenylephrine) • Atropine (for bradycardia)	• Minimize spinal cord trauma with stabilization • Monitor temperature
Anaphylactic Shock			
• **Maintain patent airway** • **Optimize oxygenation with supplemental O_2** • **Intubation and mechanical ventilation, if needed**	• Aggressive fluid resuscitation with colloids	• Epinephrine (IM or IV) • Antihistamines (e.g., diphenhydramine) • Histamine (H_2)-receptor blockers (e.g., ranitidine [Zantac]) • Bronchodilators: nebulized (e.g., albuterol) • Corticosteroids (if hypotension persists)	• Identify and remove offending cause • Prevent via avoidance of known allergens • Premedicate with history of prior sensitivity (e.g., contrast media)
Obstructive Shock			

Oxygenation	Circulation	Drug Therapies	Supportive Therapies
• **Maintain patent airway** • **Provide supplemental O_2** • **Intubation and mechanical ventilation, if needed**	• Restore circulation by treating cause of obstruction • Fluid resuscitation may provide temporary improvement in CO and BP	• No specific drug therapy	• Treat cause of obstruction (e.g., pericardiocentesis for cardiac tamponade, needle decompression or chest tube insertion for tension pneumothorax, embolectomy for pulmonary embolism)

CVP, central venous pressure; *PAWP,* pulmonary artery wedge pressure.

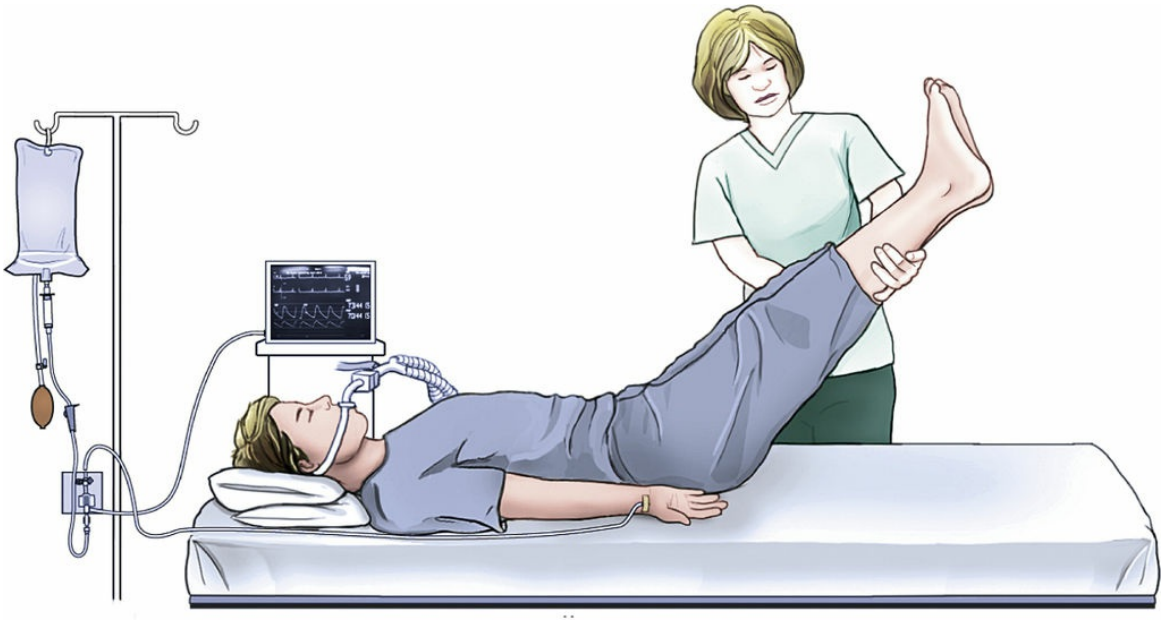

FIG. 66.7 Passive leg raise challenge in a patient with septic shock. From Lough, M.E. *Hemodynamic monitoring: Evolving technologies and clinical practice*, Philadelphia, 2016, Elsevier.

Maintaining a patent airway is important because the patient can quickly develop airway compromise from laryngeal edema or bronchoconstriction. Nebulized bronchodilators are highly effective. Aerosolized epinephrine can reduce treat laryngeal edema. Endotracheal intubation may be needed to secure and maintain a patent airway.

Hypotension results from leakage of fluid out of the intravascular space into the interstitial space because of increased vascular permeability and vasodilation. Aggressive fluid resuscitation, usually with crystalloids, is needed. IV corticosteroids may be helpful in

anaphylactic shock if significant hypotension persists after 1 to 2 hours of aggressive therapy (Tables 66.8 and 66.9).

Obstructive Shock

The main strategy in treating obstructive shock is early recognition and treatment to relieve or manage the obstruction (Table 66.1). Mechanical decompression for pericardial tamponade, tension pneumothorax, and hemopneumothorax may be done by needle or tube insertion. Obstructive shock from a pulmonary embolism requires immediate anticoagulation therapy or pulmonary embolectomy. Superior vena cava syndrome, a compression or obstruction of the outflow tract of the mediastinum, may be treated by radiation, debulking, or removal of the mass or cause. A decompressive laparotomy may be done for abdominal compartment syndrome for patients with high intraabdominal pressures and hemodynamic instability.

Nursing Management: Shock

Nursing Assessment

Your role is vital in caring for patients who are at risk for developing shock or are in a state of shock. Focus your assessment on the ABCs: airway, breathing, and circulation. Next, assess for tissue perfusion. This includes evaluating vital signs, level of consciousness, peripheral pulses, capillary refill, skin (e.g., temperature, color, moisture), and urine output. As shock progresses, the patient's neurologic status declines, urine output decreases, skin becomes cooler and mottled, and peripheral pulses decrease.

To understand the complexity of the patient's clinical status, integrate all the assessment data. It is essential to obtain a brief history from the patient or caregiver, including a description of the events leading to the shock state, time of onset and duration of symptoms, and health history (e.g., medications, allergies). In addition, obtain details about any care the patient received before hospitalization.

Nursing Diagnoses

Nursing diagnoses for the patient in shock may include:

- Impaired cardiac output
- Ineffective tissue perfusion
- Anxiety

Additional information on nursing diagnoses and interventions for the patient with shock is presented in eNursing Care Plan 66.1 (available on the website for this chapter).

Planning

The overall goals for a patient in shock include (1) evidence of adequate tissue perfusion, (2) restoration of normal or baseline BP, (3) recovery of organ function, (4) avoiding complications from prolonged states of hypoperfusion, and (5) preventing health care–associated complications of disease management and care.

Nursing Implementation

Health Promotion

You have a vital role in the prevention of shock, beginning with the identification of patients at risk. In general, patients who are older, are immunocompromised, or have chronic illnesses are at an increased risk. Any person who has surgery or trauma is at risk for shock resulting from hemorrhage, spinal cord injury, sepsis, and other problems (Table 66.1).

Planning is essential to help prevent shock after you identify an at-risk person. For example, a person with an acute anterior wall MI is at high risk for cardiogenic shock.[1] The main goal for this patient is to limit the infarct size. This is done by restoring coronary blood flow through percutaneous coronary intervention, thrombolytic therapy, or surgical revascularization. Rest, analgesics, and sedation can reduce

the myocardial demand for O_2. Modify the ICU environment to provide care at intervals that will not increase the patient's O_2 demand. For example, if the patient becomes tired with bathing, perform this care at a time that does not interfere with tests or other activities that may also increase O_2 demand.

A person with certain severe allergies, such as to drugs, shellfish, insect bites, and latex, is at increased risk for anaphylactic shock. This risk can be decreased if the patient is carefully assessed for allergies.

Safety Alert

Preventing Allergic Reactions

- Always confirm the patient's allergies before giving drugs or starting diagnostic procedures (e.g., CT scan with contrast media).
- Premedicate (e.g., diphenhydramine, methylprednisolone) patients who need a drug to which they are at high risk for an allergic reaction (e.g., contrast media).
- Encourage patients with allergies to obtain and wear a medical alert device and report their allergies to their HCPs.
- Tell patients about the availability of kits that contain equipment and drugs (e.g., epinephrine [EpiPen]) for the treatment of acute allergic reactions.

Careful monitoring of fluid balance can help prevent hypovolemic shock. Ongoing monitoring of intake and output and daily weights is important. Identifying trends in the patient's condition is more meaningful than any single piece of clinical information.

Carefully monitor all patients for infection. Progression from an infection to sepsis and septic shock depends on the patient's defense mechanisms. Patients who are immunocompromised are at high risk for opportunistic infections. Strategies to decrease the risk for health

care–associated infections (HAIs) include decreasing the number of invasive catheters (e.g., central lines, bladder catheters), using aseptic technique during invasive procedures, and paying strict attention to hand washing. Change equipment per agency policy. Thoroughly sanitize or discard (if disposable) equipment between patient use.

Evidence-based guidelines are available to reduce the risk for HAIs (e.g., ventilator-associated pneumonia, central line infections, catheter-associated urinary tract infections). These guidelines, called *care bundles,* outline key interventions aimed at reducing infections.[18]

Acute Care

Your role in shock involves (1) monitoring the patient's ongoing physical and emotional status, (2) identifying trends to detect changes in the patient's condition, (3) planning and implementing nursing interventions and therapy, (4) evaluating the patient's response to therapy, (5) providing emotional support to the patient and caregiver, and (6) collaborating with other members of the interprofessional team to coordinate care.

Neurologic Status

Assess the patient's neurologic status, including orientation and level of consciousness using a valid tool, at least every 1 to 2 hours. The patient's neurologic status is the best indicator of cerebral blood flow. Be aware of the clinical manifestations of neurologic involvement (e.g., changes in behavior, restlessness, blurred vision, confusion, paresthesias). Note any subtle changes in the patient's mental status (e.g., mild agitation) and report them to the HCP.

Orient the patient to person, place, time, and events on a regular basis. Orientation to the ICU environment is especially important. Reduce noise and light levels to control sensory input. Keep a day-night cycle of activity and rest as much as possible. Sensory overload and disruption of the patient's diurnal cycle may contribute to delirium (see Chapter 59).

Cardiovascular Status

Most of the therapy for shock is based on information about the patient's cardiovascular status. If the patient is unstable, continuously assess heart rate and rhythm, BP, CVP, and PA pressures, including CO, SVR, SV, and SVV (if available). Monitoring trends in hemodynamic parameters provides more important information than single values. Integration of hemodynamic data with physical assessment data is essential in planning strategies to manage the patient with shock. Chapter 65 discusses hemodynamic monitoring.

Continuously monitor the patient's ECG to detect dysrhythmias that may result from the cardiovascular and metabolic abnormalities associated with shock. Assess heart sounds for an S_3 or S_4 sound or new murmurs. An S_3 sound usually indicates HF. Monitor the patient's skin (e.g., upper and lower extremities) for signs of adequate perfusion. Changes in temperature, pallor, flushing, cyanosis, diaphoresis, and piloerection may indicate hypoperfusion.

Give the prescribed therapy to correct cardiovascular system problems. Assess the patient's response to fluid and drug administration as often as every 5 to 10 minutes. Make appropriate adjustments (e.g., drug titration) as needed. Once tissue perfusion is restored and the patient is stabilized, you can decrease the frequency of monitoring and slowly wean the patient off drugs to support BP and tissue perfusion.

Check Your Practice

A 69-yr-old male patient has just been admitted to the ICU with a diagnosis of sepsis. Your assessment shows that he is confused, with weak peripheral pulses and a BP of 84/50.

- What fluids would you expect to be ordered?
- How much fluid would you expect to infuse to improve his BP?
- Despite aggressive fluid resuscitation, the patient is still hypotensive. What drug would you expect to be given to improve tissue perfusion?

Respiratory Status

Frequently assess the respiratory status of the patient in shock to ensure adequate oxygenation, detect complications early, and provide data about the patient's acid-base status. At first, monitor the rate, depth, and rhythm of respirations as often as every 15 to 30 minutes. Increased rate and depth provide information about the patient's attempts to correct metabolic acidosis. Assess breath sounds every 1 to 2 hours and as needed for any changes that may indicate fluid overload or accumulation of secretions.

Use pulse oximetry to continuously monitor O_2 saturation. Pulse oximetry using a patient's finger may not be accurate in a shock state because of poor peripheral circulation. Instead, attach the probe to the ear, nose, or forehead (according to the manufacturer's guidelines). Arterial blood gases (ABGs) give definitive information on ventilation and oxygenation status and acid-base balance. Initial interpretation of ABGs is often your responsibility. A PaO_2 below 60 mm Hg (in the absence of chronic lung disease) indicates hypoxemia and the need for higher O_2 concentrations or for a different mode of O_2 administration. Low $PaCO_2$ with a low pH and low bicarbonate level may mean that the patient is trying to compensate for metabolic acidosis from increasing lactate levels.

A rising $PaCO_2$ with a persistently low pH and PaO_2 indicates the need for advanced pulmonary management. Many patients in shock are intubated and on mechanical ventilation. Maintaining a patent airway and monitoring for ventilator-related complications are critical. Chapter 65 discusses artificial airways and mechanical ventilation.

Renal Status

At first, measure urine output every 1 to 2 hours to assess the adequacy of renal perfusion. Inserting an indwelling urinary catheter helps measure during resuscitation. Urine output below 0.5 mL/kg/hr may indicate inadequate perfusion of the kidneys. Use trends in serum creatinine values to assess renal function. Serum creatinine is a

better indicator of renal function than BUN levels, since BUN is affected by the patient's catabolic state.

Body Temperature

Monitor temperature every 4 hours if normal. In the presence of a high or subnormal temperature, obtain hourly core temperatures (e.g., urinary, esophageal, PA catheter). Use light covers and control the room temperature to keep the patient comfortably warm. If the patient's temperature rises above 101.5°F (38.6°C) and the patient becomes uncomfortable or shows cardiovascular compromise, treat the fever with antipyretic drugs (e.g., ibuprofen, acetaminophen) and remove some of the patient's covers. Consider a cooling device if fever persists despite treatment.

Gastrointestinal Status

Auscultate bowel sounds at least every 4 hours. Monitor for abdominal distention. If a nasogastric tube is present, measure drainage and check for occult blood. Check all stools for occult blood.

Skin Integrity

Hygiene is especially important for the patient in shock because impaired tissue perfusion predisposes the patient to skin breakdown and infection. Perform bathing and other nursing measures carefully because a patient in shock has problems with O_2 delivery to tissues. Use clinical judgment in determining priorities of care to limit the demands for increased O_2. Monitor trends in O_2 consumption (e.g., SpO_2, $ScvO_2/SvO_2$) during all nursing interventions to assess the patient's tolerance of activity.

The increased O_2 demand that occurs during bathing and repositioning of patients with limited O_2 reserves makes the prevention of pressure injuries challenging. Turn the patient at least every 1 to 2 hours. Maintain good body alignment. Use a pressure-relieving or pressure-reducing mattress or a specialty bed as needed. Perform passive range of motion 3 or 4 times a day to maintain joint

mobility and help prevent breakdown.

Oral care is essential because mucous membranes may become dry and fragile in the volume-depleted patient. The intubated patient usually has difficulty swallowing, resulting in pooled secretions in the mouth. Apply a water-soluble lubricant to the lips to prevent drying and cracking. Brush the patient's teeth or gums with a soft toothbrush every 12 hours. Swab the lips and oral mucosa with a moisturizing solution every 2 to 4 hours.

Emotional Support and Comfort

Do not underestimate the effects of fear and anxiety when the patient and caregiver are faced with a critical, life-threatening situation (see Chapter 65). Fear, anxiety, and pain may worsen respiratory distress and increase the release of catecholamines. When implementing care, monitor the patient's mental state and level of pain using valid assessment tools. Give drugs to decrease anxiety and pain as needed. Continuous infusions of a benzodiazepine (e.g., lorazepam) and an opioid or sedative (e.g., morphine, propofol [Diprivan]) are extremely helpful in decreasing anxiety and pain.[19]

Do not overlook the patient's spiritual needs. Patients may want a visit from a chaplain, priest, rabbi, or minister. One way to provide support is to offer to call a member of the clergy rather than wait for the patient or caregiver to express a wish for spiritual counseling.

Check Your Practice

Your patient is a 74-yr-old man recovering from septic shock after a perforated diverticulum. He has been in the ICU for 7 days, and his condition has finally stabilized. His wife has been at his bedside for the duration of his ICU stay. While caring for him, you suggest that she could take a brief walk and get some coffee. She bursts out with tears, "I can't leave him. You know that he almost died."

- How can you support this caregiver?

Caregivers need to be kept informed of the patient's condition. Give the patient and caregiver simple explanations of all procedures before you carry them out and information about the plan of care. If they ask questions about progress and prognosis, give simple and honest answers.

If possible, the same nurses should continually care for the patient. This decreases anxiety, limits conflicting information, and increases trust. If the prognosis becomes grave, support the patient's caregiver when making tough decisions, such as withdrawing life support. The interprofessional care team must promote realistic expectations and outcomes. Remember, compassion is as essential as scientific and technical expertise in the total care of the patient and caregiver.

Ensure that the caregiver can spend time with the patient, provided the patient perceives this time as comforting.[20] Explain in simple terms the purpose of any tubes and equipment attached to or surrounding the patient. Tell them what they may and may not touch. If possible, place the patient's hands and arms outside the sheets to encourage therapeutic touch. Encourage caregivers to perform simple comfort measures if desired. Provide privacy as much as possible while assuring the patient and caregiver that help is readily available should it be needed. Always position the call light in reach of the patient or caregiver.

Ambulatory Care

Rehabilitation of the patient who had a critical illness requires (1) correction of the precipitating cause, (2) prevention or early treatment of complications, and (3) teaching focused on disease management or prevention of recurrence based on the initial cause of shock. Continue to monitor the patient for complications throughout the recovery period. These may include decreased range of motion, muscle weakness, decreased physical endurance, AKI (see Chapter 46), and fibrotic lung disease (from ARDS) (see Chapter 67). Patients recovering from shock often need diverse services after discharge. These can include admission to transitional care units (e.g., for mechanical ventilation weaning), rehabilitation centers (inpatient or

outpatient), or home health care agencies. Start planning for a safe transition from hospital to home as soon as the patient is admitted to the hospital.

Evaluation

The expected outcomes are that the patient who has shock will have:

- Adequate tissue perfusion with restoration of normal or baseline BP
- Normal organ function with no complications from hypoperfusion
- Decreased fear and anxiety and increased psychologic comfort

Systemic Inflammatory Response Syndrome and Multiple Organ Dysfunction Syndrome

Etiology and Pathophysiology

Systemic inflammatory response syndrome (SIRS) is a systemic inflammatory response to a variety of insults, including infection (referred to as *sepsis*), ischemia, infarction, and injury.[21] Generalized inflammation in organs remote from the initial insult characterizes SIRS. Many different mechanisms can trigger SIRS. These include:

- Mechanical tissue trauma: burns, crush injuries, surgical procedures
- Abscess formation: intraabdominal, extremities
- Ischemic or necrotic tissue: pancreatitis, vascular disease, MI
- Microbial invasion: bacteria, viruses, fungi, parasites
- Endotoxin release: gram-negative and gram-positive bacteria
- Global perfusion deficits: postcardiac resuscitation, shock states

- Regional perfusion deficits: distal perfusion deficits

Multiple organ dysfunction syndrome (MODS) is the failure of 2 or more organ systems in an acutely ill patient such that homeostasis cannot be maintained without intervention.[22] MODS results from SIRS. These 2 syndromes represent the ends of a continuum. Transition from SIRS to MODS does not occur in a clear-cut manner (Fig. 66.1).

Organ and Metabolic Dysfunction

When the inflammatory response is activated, consequences include the release of mediators, direct damage to the endothelium, and hypermetabolism. Vascular permeability increases. This allows mediators and protein to leak out of the endothelium and into the interstitial space. White blood cells begin to digest the foreign debris, and the coagulation cascade is activated (see Chapter 29). Hypotension, decreased perfusion, microemboli, and redistributed or shunted blood flow eventually compromise organ perfusion.

The respiratory system is often the first system to show signs of dysfunction in SIRS and MODS.[22] Inflammatory mediators have a direct effect on the pulmonary vasculature. The endothelial damage from the release of inflammatory mediators causes increased capillary permeability. This causes movement of fluid from the pulmonary vasculature into the pulmonary interstitial spaces. The fluid then moves to the alveoli, causing alveolar edema. Type I pneumocytes (alveolar cells) are destroyed. Type II pneumocytes are damaged, and surfactant production is decreased. The alveoli collapse. This creates an increase in *shunt* (blood flow to the lungs that does not take part in gas exchange) and worsening ventilation-perfusion mismatch. The result is ARDS. Patients with ARDS need aggressive pulmonary management with mechanical ventilation. See Chapter 67 for a complete discussion of ARDS.

Cardiovascular changes include myocardial depression and massive vasodilation in response to increasing tissue demands. Vasodilation results in decreased SVR and BP. The baroreceptor reflex

causes release of *inotropic* (increasing force of contraction) and *chronotropic* (increasing heart rate) factors that enhance CO. To compensate for hypotension, CO increases by an increase in heart rate and SV. Increases in capillary permeability cause a shift of albumin and fluid out of the vascular space. This further reduces venous return and thus preload. The patient becomes warm and tachycardic with a high CO and a low SVR. Other signs include decreased capillary refill, skin mottling, increased CVP and PAWP, and dysrhythmias. $ScvO_2$ or SvO_2 may be abnormally high because the patient is perfusing areas not consuming much O_2 (e.g., skin, nonworking muscle). Other areas may have blood shunted away from them. Eventually, either perfusion of vital organs becomes insufficient or the cells are unable to use O_2 and their function is further compromised.

Neurologic dysfunction in SIRS and MODS often presents as mental status changes. These acute changes can be an early sign of SIRS or MODS. The patient may be confused and agitated, combative, disoriented, lethargic, or comatose. These changes are due to hypoxemia, the effects of inflammatory mediators, and impaired perfusion.

AKI is common in SIRS and MODS. Hypoperfusion and the effects of the mediators can cause AKI. Decreased perfusion to the kidneys activates the SNS and the renin-angiotensin system.[22] Stimulation of the renin-angiotensin system causes systemic vasoconstriction and aldosterone-mediated sodium and water reabsorption. Another risk factor for the development of AKI is the use of nephrotoxic drugs. Many antibiotics used to treat gram-negative bacteria (e.g., aminoglycosides) can be nephrotoxic. Careful monitoring of drug levels is essential to avoid the nephrotoxic effects.

The GI tract plays a key role in the development of MODS. GI motility is often decreased in critical illness, causing abdominal distention and paralytic ileus. In the early stages of SIRS and MODS, blood is shunted away from the GI mucosa, making it highly vulnerable to ischemic injury. Decreased perfusion leads to a breakdown of this normally protective mucosal barrier. This increases the risk for ulceration, GI bleeding, and bacterial movement from the

GI tract into circulation.[21]

Metabolic changes are pronounced in SIRS and MODS. Both syndromes trigger a hypermetabolic response. Glycogen stores are rapidly converted to glucose (glycogenolysis). Once glycogen is depleted, amino acids are converted to glucose (gluconeogenesis), reducing protein stores. Fatty acids are mobilized for fuel. Catecholamines and glucocorticoids are released and cause hyperglycemia and insulin resistance. The net result is a catabolic state with a loss of lean body mass (muscle).

The hypermetabolism associated with SIRS and MODS may last for several days and cause liver dysfunction. Liver dysfunction in MODS may begin long before clinical evidence of it is present. Protein synthesis is impaired. The liver cannot make albumin, one of the key proteins in maintaining plasma oncotic pressure. This changes plasma oncotic pressure, causing fluid and protein to leak from the vascular spaces to the interstitial space. At this point, giving albumin does not normalize oncotic pressure in these patients.

As the state of hypermetabolism persists, the patient cannot convert lactate to glucose and lactate accumulates (lactic acidosis). Despite increases in glycogenolysis and gluconeogenesis, eventually the liver cannot maintain an adequate glucose level and the patient becomes hypoglycemic. Hypoglycemia can also develop due to acute adrenal insufficiency.

DIC may result from dysfunction of the coagulation system. DIC causes microvascular clotting and bleeding at the same time because of the depletion of clotting factors and excessive fibrinolysis. (Chapter 30 discusses DIC.)

Electrolyte imbalances are common and result from the hormonal and metabolic changes and fluid shifts. These changes worsen mental status changes, neuromuscular dysfunction, and dysrhythmias. The release of ADH and aldosterone results in sodium and water retention. Aldosterone increases urinary potassium loss, and catecholamines cause potassium to move into the cell, resulting in hypokalemia. Hypokalemia is associated with dysrhythmias and muscle weakness. Metabolic acidosis results from impaired tissue

perfusion, hypoxia, and the shift to anaerobic metabolism. This increases lactate levels. Progressive renal dysfunction also contributes to metabolic acidosis. Hypocalcemia, hypomagnesemia, and hypophosphatemia are common.

Clinical Manifestations of SIRS and MODS

The clinical manifestations of SIRS and MODS are described in Table 66.10.

Nursing and Interprofessional Management: Sirs and Mods

The prognosis for the patient with MODS is poor, with mortality rates of 40% to 60%.[22] Mortality increases as more organ systems fail. The most common cause of death continues to be sepsis. Survival improves with early, goal-directed therapy. So, the most important goal is to prevent SIRS from progressing to MODS.

A critical part of your role is vigilant assessment and ongoing monitoring to detect early signs of deterioration or organ dysfunction. Interprofessional care for patients with SIRS and MODS focuses on (1) prevention and treatment of infection, (2) maintaining tissue oxygenation, (3) nutritional and metabolic support, and (4) appropriate support of individual failing organs. Table 66.10 outlines the management for patients with SIRS and MODS.

TABLE 66.10 Manifestations and Management of SIRS and MODS

Manifestations	Management
Respiratory System	
Development of ARDS (see Chapter 67): • **Bilateral fluffy infiltrates on chest x-ray** • **Decreased compliance** • **Dyspnea (severe)** • **Increased minute ventilation** • **PaO_2/FIO_2 ratio <200** • **PAWP <18 mm Hg** • **Pulmonary hypertension** • **Refractory hypoxemia** • **Tachypnea** • **Ventilation-perfusion (V/Q) mismatch**	Optimize O_2 delivery and minimize O_2 consumption Mechanical ventilation (see Chapter 65) • Positive end-expiratory pressure • Lung protective modes (e.g., pressure-control inverse ratio ventilation, low tidal volumes) • Permissive hypercapnia • Positioning (e.g., continuous lateral rotation therapy, prone positioning)
Cardiovascular System	
Biventricular failure **↓ BP, MAP, SVR** **↑ HR, CO, SV** **Massive vasodilation** **Myocardial depression** **Systolic, diastolic dysfunction**	Volume management to ↑ preload Hemodynamic monitoring Arterial pressure monitoring to maintain MAP >65 mm Hg Vasopressors Intermittent or continuous $ScvO_2$ or SvO_2 monitoring Balance O_2 supply and demand Continuous ECG monitoring Circulatory assist devices VTE prophylaxis
Central Nervous System	
Acute change in neurologic status **Confusion, disorientation, delirium** **Fever** **Hepatic encephalopathy** **Seizures**	Evaluate for hepatic or metabolic encephalopathy Optimize cerebral blood flow ↓ Cerebral O_2 requirements Prevent secondary tissue ischemia Calcium channel blockers (reduce cerebral vasospasm)
Endocrine System	
Hyperglycemia → hypoglycemia	Provide continuous infusion of insulin and glucose to maintain blood glucose 140–180 mg/dL (7.77–10.0 mmol/L)
Renal System	
***Prerenal:* renal hypoperfusion** • **BUN/creatinine ratio >20:1** • **↓ Urine Na^+ <20 mEq/L** • **↑ Urine osmolality** • **Urine specific gravity >1.020**	Diuretics • Loop diuretics (e.g., furosemide [Lasix]) • May need to ↑ dosage due to ↓ glomerular filtration rate
***Intrarenal:* acute tubular necrosis** • **BUN/creatinine ratio <10:1–15:1** • **↑ Urine Na^+ >20 mEq/L** • **↓ Urine osmolality** • **Urine specific gravity ~1.010**	Continuous renal replacement therapy (see Chapter 46)
GI System	
GI bleeding **Hypoperfusion → ↓ peristalsis, paralytic ileus** **Mucosal ischemia** • **↓ Intramucosal pH** • **Potential translocation of gut bacteria** • **Potential abdominal compartment syndrome** **Mucosal ulceration on endoscopy**	Stress ulcer prophylaxis • Antacids (e.g., Maalox) • Proton pump inhibitors (e.g., omeprazole [Prilosec]) • sucralfate (Carafate) Monitor abdominal distention, intraabdominal pressures Dietitian consult Enteral nutrition Stimulate mucosal activity Provide essential nutrients and optimal calories
Hepatic System	
Bilirubin >2 mg/dL (34 µmol/L) **Hepatic encephalopathy** **Jaundice** **↑ Liver enzymes (ALT, AST, GGT)** **↓ Serum albumin, prealbumin, transferrin** **↑ Serum NH_3 (ammonia)**	Maintain adequate tissue perfusion Provide nutritional support (e.g., enteral nutrition) Careful use of drugs metabolized by liver
Hematologic System	
↑ Bleeding times, ↑ PT, ↑ PTT **↑ D-dimer** **↑ Fibrin split products** **↓ Platelet count (thrombocytopenia)**	Observe for bleeding from obvious and/or occult sites Replace factors being lost (e.g., platelets) Minimize traumatic interventions (e.g., IM injections, multiple venipunctures)

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *GGT,* γ-glutamyl transferase; *PA,* pulmonary artery; *PAWP,* pulmonary artery wedge pressure; *PT,* prothrombin time; *PTT,* partial thromboplastin time; $ScvO_2$, O_2 saturation in venous blood; SvO_2, O_2 saturation in mixed venous blood; *SVR,* systemic vascular resistance.

Prevention and Treatment of Infection

Aggressive infection control strategies are essential to decrease the risk for HAIs. Early, aggressive surgery is recommended to remove

necrotic tissue (e.g., early debridement of burn tissue) that can provide a culture medium for microorganisms. Aggressive pulmonary management, including early mobilization, can reduce the risk for infection. Strict asepsis can decrease infections related to intraarterial lines, endotracheal tubes, indwelling urinary catheters, IV lines, and other invasive devices or procedures. Daily assessment of the ongoing need for invasive lines and other devices is an important strategy to prevent or limit HAIs.

Despite aggressive strategies, infection may develop. Once an infection is suspected, begin interventions to treat the cause. Send appropriate cultures and start broad-spectrum antibiotic therapy, as ordered. Adjust therapy based on the culture results, if needed.

Maintenance of Tissue Oxygenation

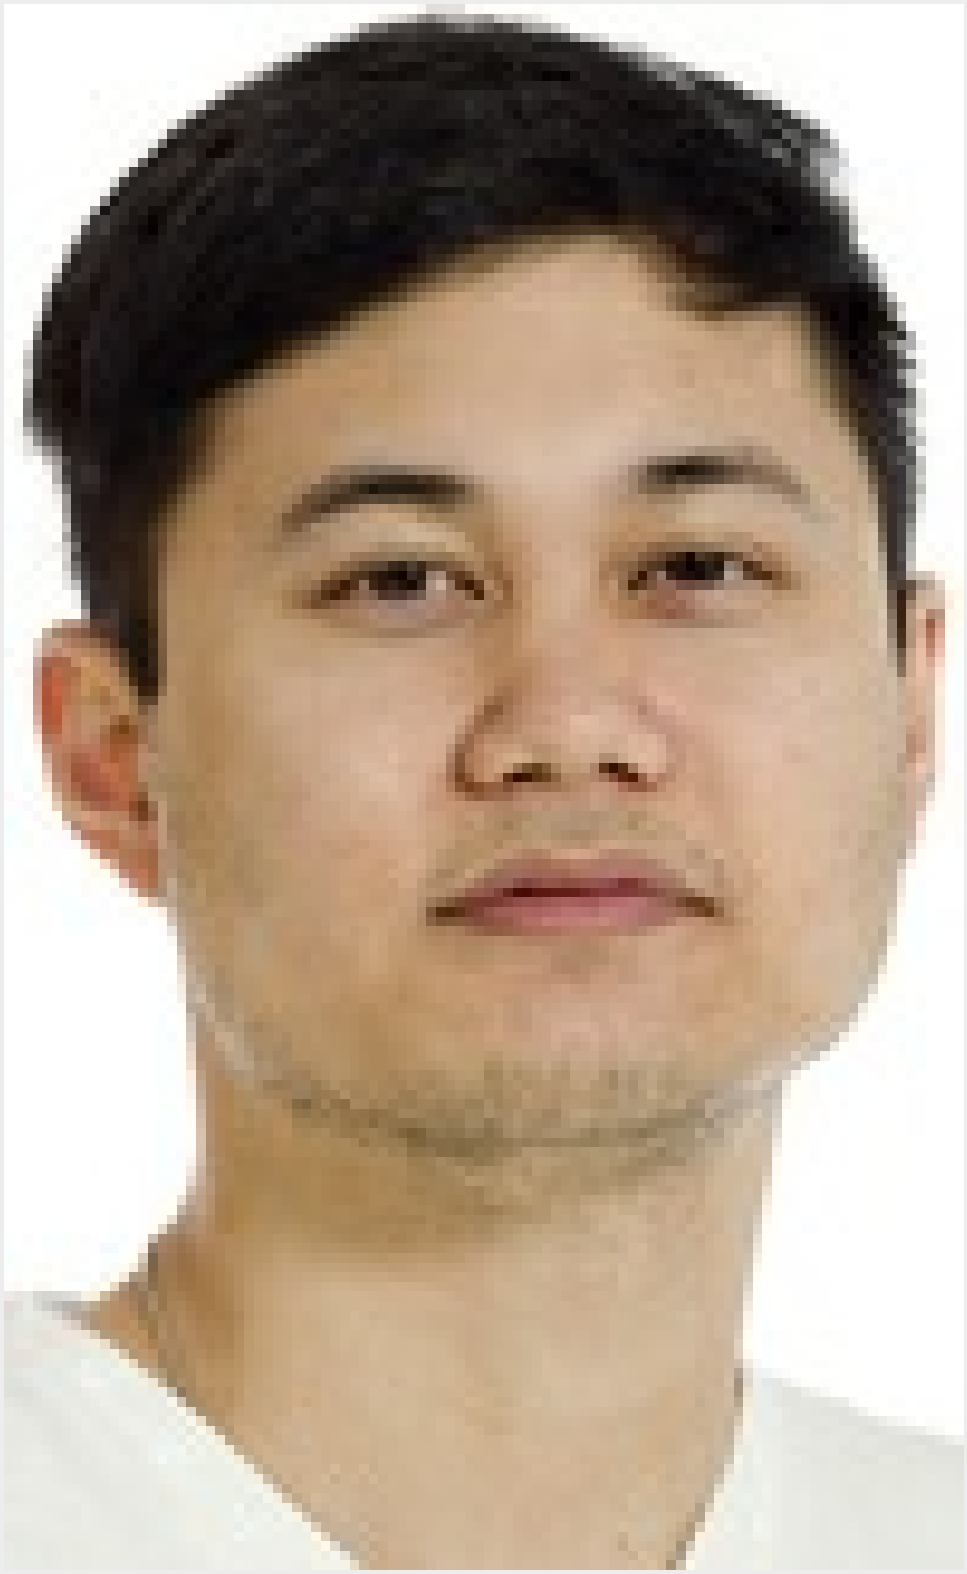
Hypoxemia often occurs because patients have greater O_2 needs and decreased O_2 supply to the tissues. Interventions that decrease O_2 demand and increase O_2 delivery are essential. Sedation, mechanical ventilation, analgesia, and rest may decrease O_2 demand and should be considered. Treating fever, chills, and pain decrease O_2 demand. O_2 delivery may be optimized by using individualized tidal volumes with positive end-expiratory pressure, increasing preload (e.g., fluids) or myocardial contractility to enhance CO, or reducing afterload to increase CO.

Nutritional and Metabolic Needs

Hypermetabolism can result in profound weight loss, cachexia, and further organ failure. Protein-calorie malnutrition is a key sign of hypermetabolism. Total energy expenditure is often increased 1.5 to 2.0 times the normal metabolic rate. Because of their short half-life, monitor plasma transferrin and prealbumin levels to assess hepatic protein synthesis.

The goal of nutritional support is to preserve organ function. Providing early and optimal nutrition decreases morbidity and

mortality rates. EN is preferred. If it cannot be used, PN should be considered. (Chapter 39 discusses EN and PN.) Provide glycemic control with a goal of ≤180 mg/dL with insulin infusions in these patients.[21]



Support of Failing Organs

Support of any failing organ is a goal of therapy. For example, the patient with ARDS requires aggressive O_2 therapy and mechanical ventilation (see Chapter 67). DIC should be treated appropriately (e.g., blood products) (see Chapter 30). Renal failure may require dialysis. Continuous renal replacement therapy is better tolerated than hemodialysis, especially in a patient with hemodynamic instability (see Chapter 46).

A final consideration may be that further interventions are futile. It is important to maintain communication between the health care team and the patient's caregiver about realistic goals and likely outcomes for the patient with MODS. Withdrawal of life support and starting end-of-life care may be the best options for the patient.

Case Study

Shock

© Thinkstock.

Patient Profile

K.L., a 25-yr-old Korean American, was not wearing his seat belt when he was driving a motor vehicle involved in a crash. The windshield was broken, and K.L. was found 10 ft from his car. He was face down, conscious, and moaning. His wife and daughter were in the car with their seat belts on. They sustained minor injuries and were very frightened and upset. All passengers were taken to the ED. This information pertains to K.L.

Subjective Data

- States, "I can't breathe"
- Cries out when abdomen is palpated

Objective Data

Physical Examination

- *Cardiovascular:* BP 80/56 mm Hg; apical pulse 138 but no palpable radial or pedal pulses; carotid pulse 1+. ECG is below:

- *Respiratory:* respiratory rate 35 breaths/min; labored breathing with shallow respirations; asymmetric chest wall movement; absence of breath sounds on left side. Trachea deviated slightly to the right
- *Abdomen:* slightly distended and left upper quadrant painful on

palpation
- *Musculoskeletal:* open compound fracture of the lower left leg

Diagnostic Studies

- Chest x-ray: hemothorax and 6 rib fractures on left side
- Hematocrit: 28%

Interprofessional Care (in the ED)

- Intraosseous access in right proximal tibia placed prehospital
- Left chest tube placed, draining bright red blood
- Fluid resuscitation started with crystalloids
- High-flow O_2 via nonrebreather mask

Emergency Surgical Procedures

- Splenectomy
- Repair of torn intercostal artery
- Repair of compound fracture

Discussion Questions

1. What types of shock is K.L. experiencing? What clinical manifestations did he display that support your answer?
2. What were the causes of K.L.'s shock states? What are other causes of these types of shock?
3. ***Priority Decision:*** What are the priority nursing responsibilities for K.L.?
4. ***Priority Decision:*** What ongoing nursing assessment parameters are essential for this patient?

5. What are his potential complications?
6. ***Patient-Centered Care:*** K.L.'s parents arrive. English is their second language. They are very anxious and asking about their son. What can you do to provide culturally competent family-centered care?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
8. ***Collaboration:*** Identify the tasks that could be delegated to unlicensed assistive personnel (UAP).
9. ***Evidence-Based Practice:*** You are orienting a new graduate RN. He asks you why crystalloids are used for fluid resuscitation. What is your response?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient has a spinal cord injury at T4. Vital signs include falling blood pressure with bradycardia. The nurse recognizes that the patient is experiencing

   a. a relative hypervolemia.

   b. an absolute hypovolemia.

   c. neurogenic shock from low blood flow.

   d. neurogenic shock from massive vasodilation.

2. A 78-yr-old man with a history of diabetes has confusion and temperature of 104°F (40°C). There is a wound on his right heel with purulent drainage. After an infusion of 3 L of normal saline solution, his assessment findings are BP 84/40 mm Hg; heart rate 110; respiratory rate 42 and

shallow; CO 8 L/min; and PAWP 4 mm Hg. This patient's symptoms are *most* likely indicative of

a. sepsis.

b. septic shock.

c. multiple organ dysfunction syndrome.

d. systemic inflammatory response syndrome.

3. Treatment modalities for the management of cardiogenic shock include *(select all that apply)*

a. dobutamine to increase myocardial contractility.

b. vasopressors to increase systemic vascular resistance.

c. circulatory assist devices such as an intraaortic balloon pump.

d. corticosteroids to stabilize the cell wall in the infarcted myocardium.

e. Trendelenburg positioning to facilitate venous return and increase preload.

4. The *most* accurate assessment parameters for the nurse to use to determine adequate tissue perfusion in the patient with MODS are

a. blood pressure, pulse, and respirations.

b. breath sounds, blood pressure, and body temperature.

c. pulse pressure, level of consciousness, and pupillary response.

d. level of consciousness, urine output, and skin color and temperature.

1. d, 2. b, 3. a, c, 4. d

Acute Respiratory Failure and Acute Respiratory Distress Syndrome

Eugene Mondor

LEARNING OUTCOMES

1. Discuss the etiology, pathophysiology, and clinical manifestations of hypoxemic and hypercapnic acute respiratory failure.
2. Describe the nursing and interprofessional management of hypoxemic or hypercapnic respiratory failure.
3. Discuss the pathophysiology and clinical manifestations of acute respiratory distress syndrome (ARDS).
4. Describe the nursing and interprofessional management of ARDS.
5. Select measures to prevent and manage complications of acute respiratory failure and ARDS.

Conceptual Focus

Acid-Base Balance
Anxiety
Gas Exchange

This chapter discusses acute respiratory failure (ARF) and acute respiratory distress syndrome (ARDS). Nursing and interprofessional management of patients with ARF and ARDS focus on interventions to promote adequate oxygenation, ensure effective ventilation, identify and treat the underlying causes, and prevent complications. When respiratory function is insufficient, all body systems are affected

Acute Respiratory Failure

The major function of the respiratory system is gas exchange. **Acute respiratory failure (ARF)** occurs when oxygenation, ventilation, or both are inadequate. ARF is not a disease. It is a symptom that reflects lung function. For example, not enough O_2 is transferred to the blood or inadequate CO_2 is removed from the lungs (Fig. 67.1). ARF occurs because of disorders involving the lungs or other body systems (Table 67.1).

Conditions that interfere with adequate O_2 transfer result in **hypoxemia**. This causes a decrease in arterial O_2 (PaO_2) and saturation (SaO_2) to less than the normal values. Insufficient CO_2 removal results in hypercapnia. It causes an increase in arterial CO_2 ($PaCO_2$). Arterial blood gases (ABGs) are used to assess changes in pH, PaO_2, $PaCO_2$, bicarbonate, and SaO_2. We use pulse oximetry to assess arterial O_2 saturation (SpO_2).

We classify ARF as hypoxemic or hypercapnic (Fig. 67.2). **Hypoxemic respiratory failure** is a PaO_2 less than 60 mm Hg when the patient is receiving an inspired O_2 concentration of 60% or more.[1] In hypoxemic respiratory failure (also called *oxygenation failure*), the main problem is inadequate exchange of O_2 between the alveoli and pulmonary capillaries. The PaO_2 level shows inadequate O_2 saturation. A less than optimal PaO_2 level exists despite supplemental O_2.

Hypercapnic respiratory failure (or *ventilatory failure*) is a $PaCO_2$ greater than 50 mm Hg with acidemia (arterial pH less than 7.35).[2] The main problem is insufficient CO_2 removal. This causes the $PaCO_2$ to be higher than normal. For whatever reason, the body is unable to compensate for the increase. This allows acidemia to occur.

Patients may have both types of respiratory failure at the same time. For example, a patient with chronic obstructive pulmonary disease (COPD) who has pneumonia could have "acute-on-chronic" respiratory failure. In other words, the patient has an underlying

chronic respiratory problem. The new infection, in addition to the chronic problem, results in the "acute-on-chronic" clinical picture.

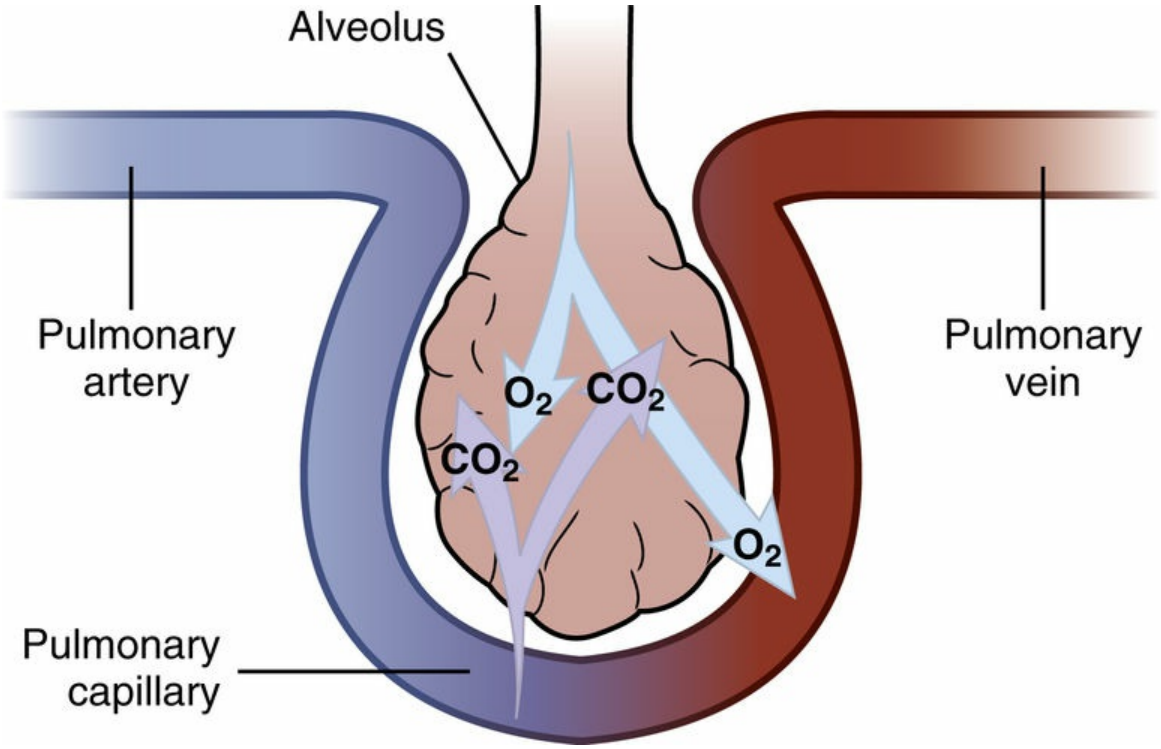

FIG. 67.1 Normal gas exchange unit in the lung.

TABLE 67.1 Common Causes of Respiratory Failure

Hypoxemic Respiratory Failure	Hypercapnic Respiratory Failure
Respiratory System • **ARDS** • **Hepatopulmonary syndrome (e.g., low-resistance flow state, V/Q mismatch)** • **Massive pulmonary embolism (e.g., thrombus emboli, fat emboli)** • **Pneumonia** • **Pulmonary artery laceration and hemorrhage** • **Toxic inhalation (e.g., smoke inhalation)** **Cardiac System** • **Anatomic shunt (e.g., ventricular septal defect)** • **Cardiogenic pulmonary edema** • **Cardiogenic shock (decreasing blood flow through pulmonary vasculature)** • **High cardiac output states: diffusion limitation**	Respiratory System • Asthma • COPD • Cystic fibrosis Central Nervous System • Brainstem injury or infarction • Sedative and opioid overdose • Spinal cord injury • Severe head injury Chest Wall • Kyphoscoliosis • Pain • Severe obesity • Thoracic trauma (e.g., flail chest) Neuromuscular System • Amyotrophic lateral sclerosis • Critical illness polyneuropathy • Guillain-Barré syndrome • Muscular dystrophy • Multiple sclerosis • Myasthenia gravis • Phrenic nerve injury • Poliomyelitis • Toxin exposure or ingestion (e.g., tree tobacco, acetylcholinesterase inhibitors, carbamate or organophosphate poisoning)

Significant changes in PaO_2 and $PaCO_2$ occur with ARF. These may develop over several minutes to a few hours to 1 or 2 days. The patient may have hemodynamic instability (e.g. tachycardia, hypotension), increased respiratory effort, and decreased level of consciousness. Urgent intervention is required. **Chronic respiratory failure** develops more slowly, over days to weeks. The patient is usually more stable as the body had time to compensate for the small, but subtle, changes that have occurred.

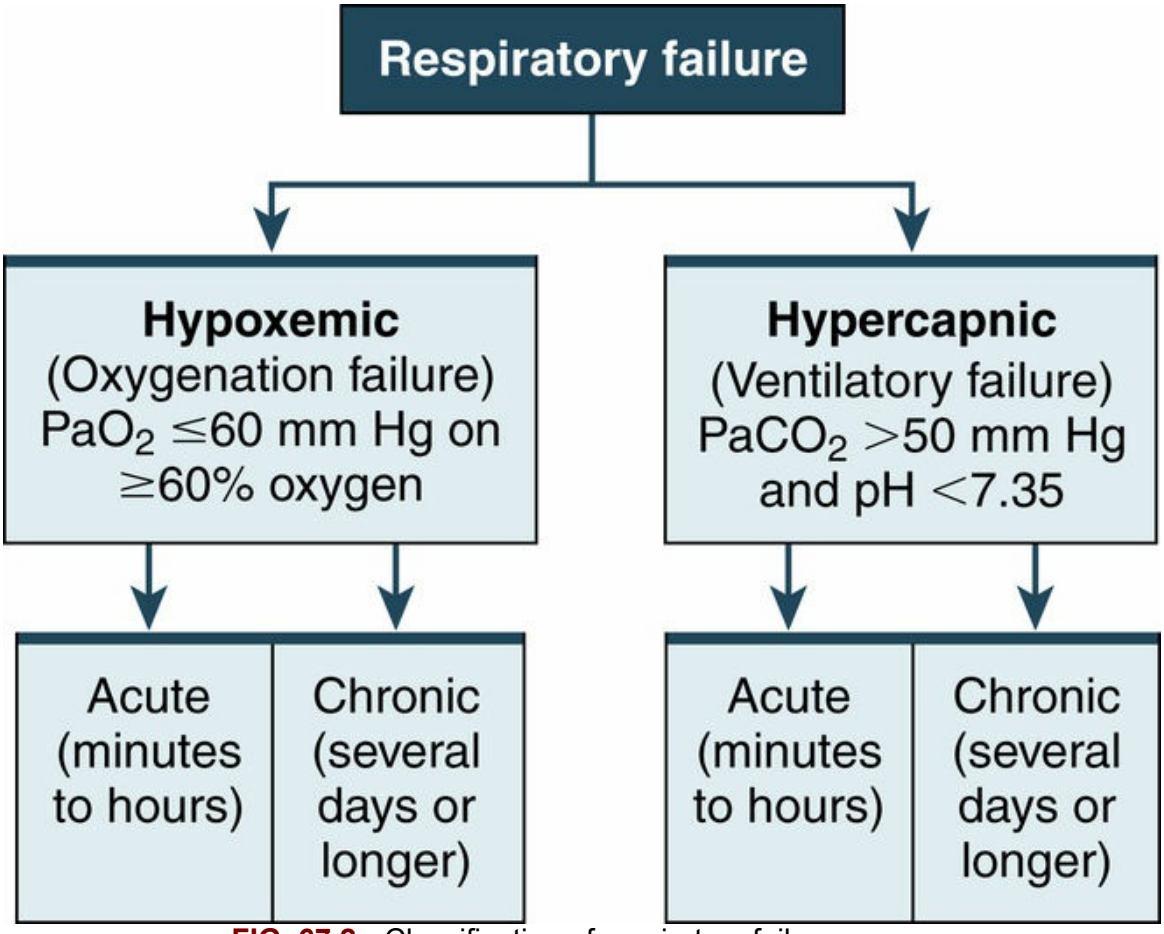

FIG. 67.2 Classification of respiratory failure.

Etiology and Pathophysiology

Hypoxemic Respiratory Failure

Four physiologic mechanisms may cause hypoxemia and hypoxemic respiratory failure: (1) mismatch between ventilation (V) and perfusion (Q), often referred to as **V/Q mismatch**; (2) shunt; (3) diffusion limitation; and (4) alveolar hypoventilation. The most common causes are V/Q mismatch and shunt.

Ventilation-Perfusion Mismatch

In normal lungs, the volume of blood perfusing the lungs and the amount of gas reaching the alveoli are almost identical. So, when you compare normal alveolar ventilation (4 to 6 L/min) to pulmonary

blood flow (4 to 6 L/min), you have a V/Q ratio of 0.8 to 1.2.[3] In a perfect match, ventilation and perfusion would yield a V/Q ratio of 1:1, expressed as V/Q = 1. When the match is not 1:1, a V/Q mismatch occurs.

This example implies that ventilation and perfusion are perfectly matched in all areas of the lung. This situation does not normally exist. In reality, some regional mismatch occurs. For example, at the apex of the lung, V/Q ratios are greater than 1 (more ventilation than perfusion). At the base of the lung, V/Q ratios are less than 1 (less ventilation than perfusion). Because changes at the lung apex balance changes at the base, the net effect is a close overall match (Fig. 67.3).

Many diseases and conditions cause a V/Q mismatch (Fig. 67.4). The most common are those in which increased secretions are present in the airways (e.g., COPD) or alveoli (e.g., pneumonia) or bronchospasm is present (e.g., asthma). V/Q mismatch may result from pain, alveolar collapse (atelectasis), or pulmonary emboli.

Pain interferes with chest and abdominal wall movement and increases muscle tension. This often compromises ventilation. The patient is often unwilling to take big, deep breaths. As a result, short, shallow respirations contribute to the development of atelectasis. This worsens V/Q mismatch.

Pain activates the stress response, increasing baseline metabolic state. This increases O_2 consumption and CO_2 production (as a by-product of cellular and tissue metabolism). The increased O_2 demand, increased CO_2, and decreased O_2 supply increase ventilation demands. Since there is no effect on blood flow to the lungs, the result is V/Q mismatch.

Pulmonary emboli affect the perfusion part of the V/Q relationship. When a pulmonary embolus occurs, it limits blood flow distal to the occlusion. Areas of normal lung ventilation remain, but there is decreased perfusion due to the vessel occlusion. This results in a V/Q mismatch. If the embolus is large, it can cause hemodynamic instability due to blockage of a large pulmonary artery.

V/Q	PaO_2	$PaCO_2$
3.3	132	28
1.0	108	39
0.63	89	42

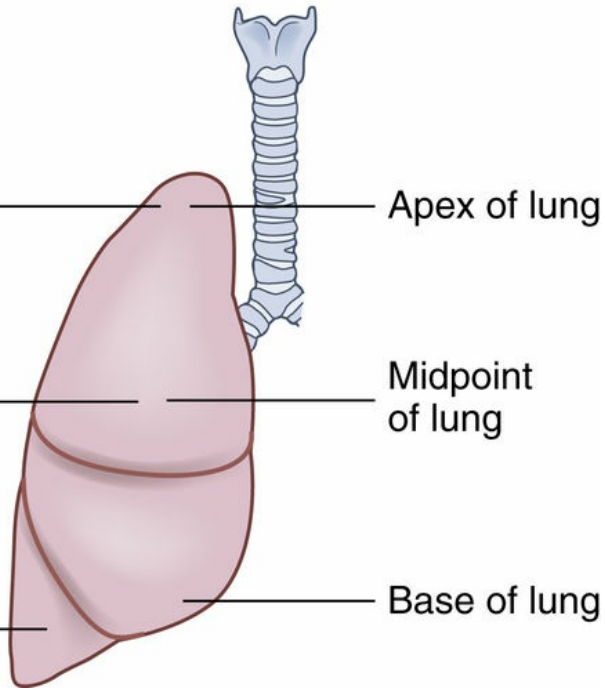

FIG. 67.3 Regional V/Q differences in the normal lung. This difference causes the PaO_2 to be higher at the apex of the lung and lower at the base. Values for $PaCO_2$ are the opposite (i.e., lower at the apex and higher at the base). Blood that exits the lung is a mixture of these values.

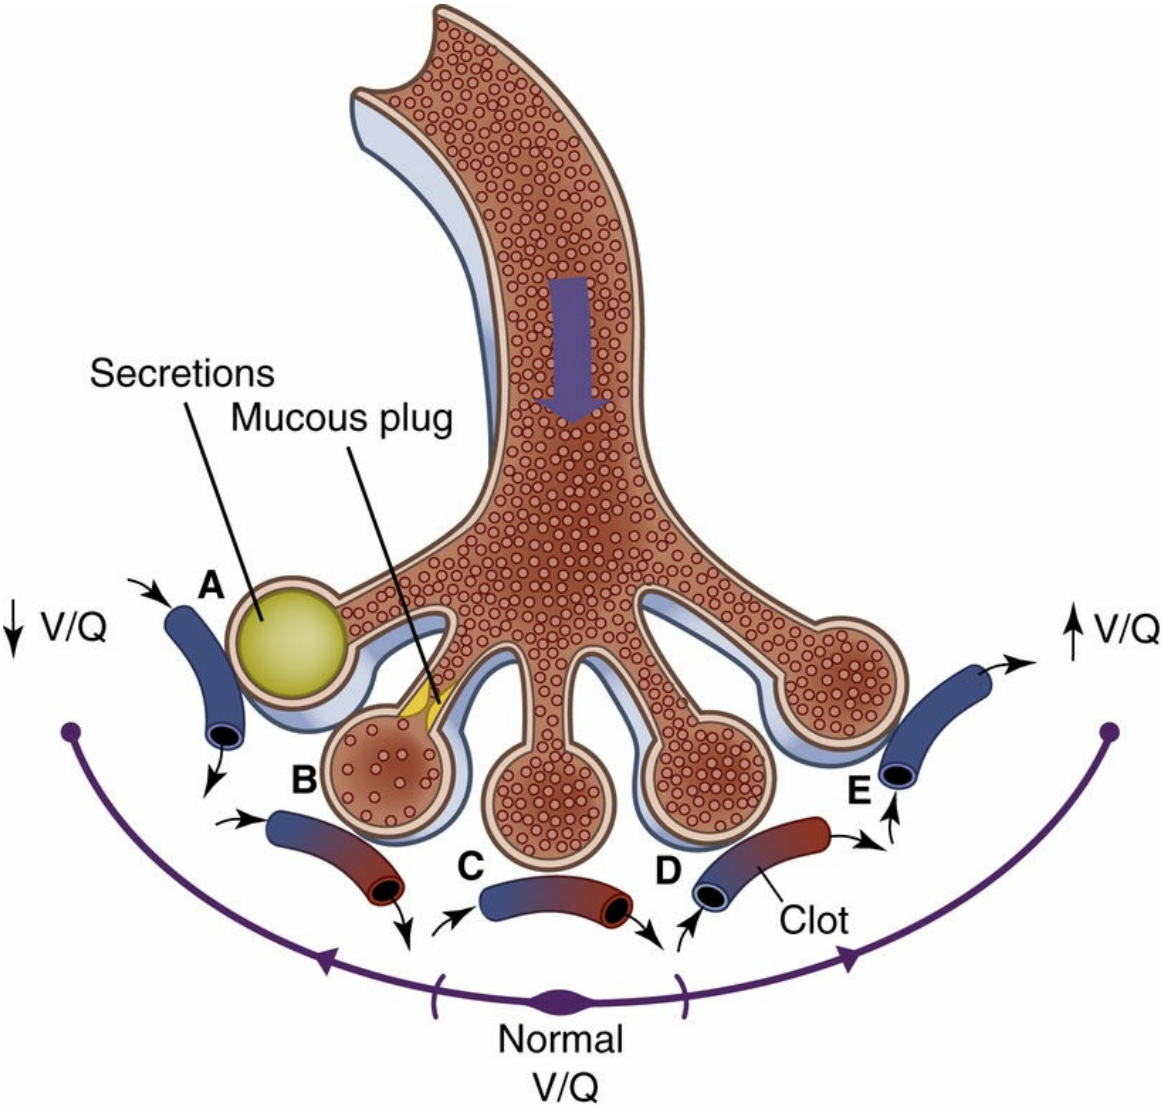

FIG. 67.4 Range of ventilation to perfusion (V/Q) relationships. *A,* Absolute shunt, no ventilation because of fluid filling the alveoli. *B,* V/Q mismatch, ventilation partially compromised by secretions in the airway. *C,* Normal lung unit. *D,* V/Q mismatch, perfusion partially compromised by emboli obstructing blood flow. *E,* Dead space, no perfusion because of obstruction of the pulmonary capillary.

O_2 therapy is an appropriate first step to reverse hypoxemia caused by V/Q mismatch. O_2 therapy increases the PaO_2 in the blood leaving normal gas exchange units, causing a higher-than-normal PaO_2. This blood mixes with the poorly oxygenated blood from damaged areas, raising the overall PaO_2 level in the blood leaving the lungs. The best way to treat hypoxemia caused by a V/Q mismatch is to treat the

cause.

Shunt

A **shunt** occurs when blood exits the heart without having taken part in gas exchange. A shunt is an extreme V/Q mismatch. There are 2 types of shunt: anatomic and intrapulmonary. An *anatomic shunt* occurs when blood passes through an anatomic channel in the heart (e.g., a ventricular septal defect) and bypasses the lungs.[4] An *intrapulmonary shunt* occurs when blood flows through the pulmonary capillaries without taking part in gas exchange.[4] It is seen in conditions in which the alveoli fill with fluid (e.g., pneumonia) and gas exchange is severely impaired at the alveolar-capillary membrane.

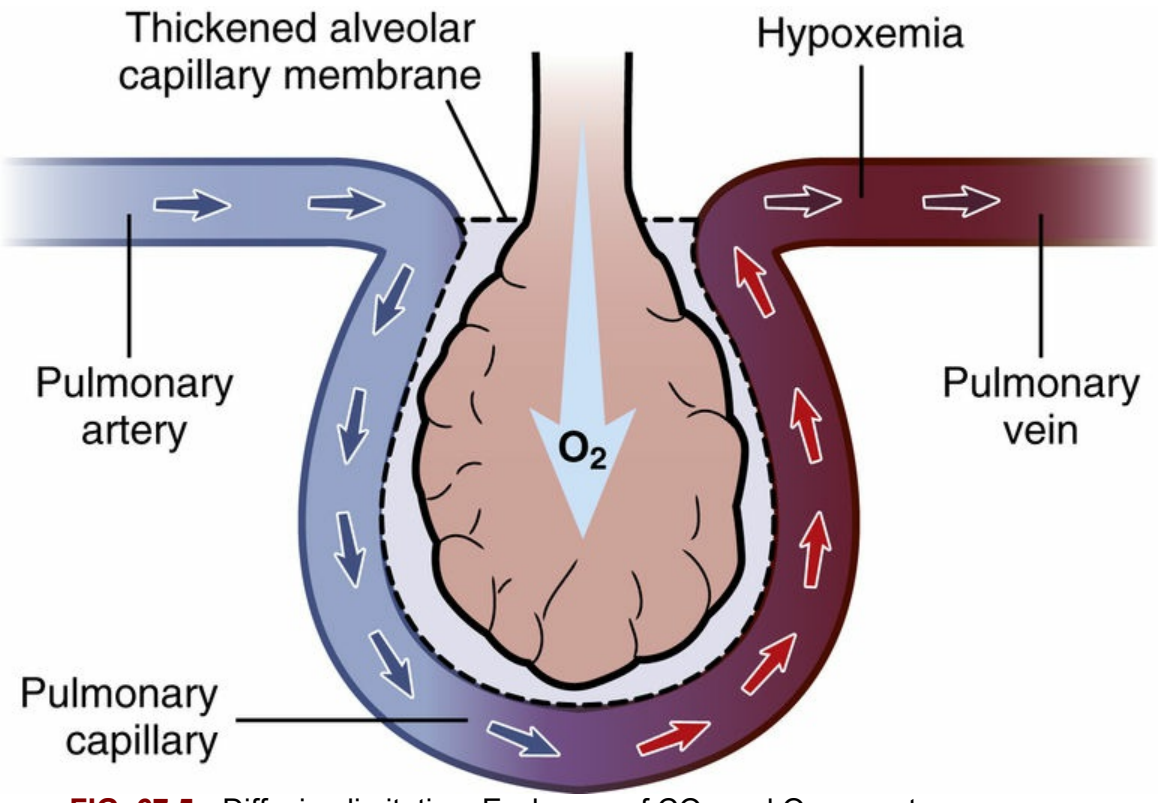

FIG. 67.5 Diffusion limitation. Exchange of CO_2 and O_2 cannot occur because of the thickened alveolar-capillary membrane.

O_2 therapy alone is not effective at increasing the PaO_2 if

hypoxemia is due to shunt. Patients with a shunt are usually more hypoxemic than patients with V/Q mismatch. They often need mechanical ventilation with a high fraction of inspired O_2 (FIO_2) to improve gas exchange.

Diffusion Limitation

Diffusion limitation occurs when gas exchange across the alveolar-capillary membrane is compromised by a process that damages or destroys the alveolar membrane or affects blood flow through the pulmonary capillaries (Fig. 67.5).[5] Conditions that cause the alveolar-capillary membrane to become thicker (fibrotic) slow gas transport. These include pulmonary fibrosis, interstitial lung disease, and ARDS. The accumulation of fluid, white blood cells, or protein in the alveoli can decrease gas exchange between the alveolus and the capillary bed. A common example is pulmonary edema.

The classic sign of diffusion limitation is hypoxemia that is present during exercise but not at rest. During exercise, blood moves more quickly through the lungs. This decreases the time for diffusion of O_2 across the alveolar-capillary membrane. Diffusion limitation can occur in conditions in which CO is markedly increased (e.g., high-output heart failure [HF], severe traumatic brain injury [TBI]). As blood circulates rapidly through the pulmonary capillary bed, there is less time for gas exchange to occur.

Alveolar Hypoventilation

Alveolar hypoventilation is a decrease in ventilation that results in an increase in the $PaCO_2$. It may be caused by central nervous system (CNS) conditions, chest wall dysfunction, acute asthma, or restrictive lung diseases. Although alveolar hypoventilation is mainly a mechanism of hypercapnic respiratory failure, it contributes to hypoxemia.

Interrelationship of Mechanisms

Rarely is acute hypoxemic respiratory failure caused by a single

factor. More often, it is a combination of 2 or more factors. For example, the patient with ARF from pneumonia may have a V/Q mismatch and shunt. Inflammation, edema, and exudate obstruct the airways (V/Q mismatch) and fill the alveoli with exudate (shunt). Other contributing factors include increases in O_2 demand with anxiety and unrelieved pain.

Consequences of Hypoxemia

Hypoxemia can lead to hypoxia if not corrected. occurs when the PaO_2 falls enough to cause signs and symptoms of inadequate oxygenation. If hypoxia or hypoxemia is severe, the cells shift from aerobic to anaerobic metabolism. Anaerobic metabolism uses more fuel, produces less energy, and is less efficient than aerobic metabolism. The waste product of anaerobic metabolism is lactic acid. Lactic acid is harder to remove from the body than CO_2, because it must be buffered with sodium bicarbonate. When the body does not have enough sodium bicarbonate to buffer the lactic acid, metabolic acidosis occurs. Left uncorrected, tissue and cell dysfunction, and ultimately cell death, occurs.

Hypercapnic Respiratory Failure

In acute hypercapnic respiratory failure, sometimes referred to as *ventilatory failure,* the lungs are often normal. In this situation, the respiratory system cannot keep CO_2 levels maintained within normal limits. This often occurs from an increase in CO_2 production or a decrease in alveolar ventilation. Hypercapnic respiratory failure can be acute or chronic. It often reflects significant problems with the respiratory system.

Many conditions can cause impaired ventilation. We group into 4 categories: (1) CNS problems, (2) neuromuscular conditions, (3) chest wall abnormalities, and (4) problems affecting the airways and/or alveoli. Acute hypercapnic respiratory failure can occur with CNS problems, neuromuscular conditions, and chest wall abnormalities in the presence of normal lungs.

Central Nervous System Problems

A number of CNS problems can suppress the drive to breathe. A common example is an overdose of a respiratory depressant drug (e.g., opioids). In a dose-related manner, CNS depressants decrease CO_2 reactivity in the brainstem. This allows arterial CO_2 levels to rise. A brainstem infarction or TBI may interfere with normal function of the respiratory center in the medulla. Patients are then at risk for acute hypercapnic respiratory failure because the medulla does not change the respiratory rate in response to a change in $PaCO_2$.

High-level spinal cord injuries can affect nerve supply to the respiratory muscles of the chest wall and diaphragm. Brain injury with a decreased level of consciousness can hinder the patient's ability to protect the airway, breathe, or manage secretions.

Neuromuscular Conditions

Various neuromuscular problems place patients at risk for respiratory failure. For example, patients with Guillain-Barré syndrome and multiple sclerosis have respiratory muscle weakness or paralysis. As a result, they cannot eliminate CO_2 and maintain normal $PaCO_2$ levels. Exposure to toxins (e.g., carbamate/organophosphate pesticides, chemical nerve agents) can interfere with the nerve supply to muscles and lung ventilation. Respiratory muscle weakness can occur from muscle wasting during a critical illness or peripheral nerve damage.

Chest Wall Abnormalities

Several conditions can prevent normal movement of the chest wall or diaphragm and limit lung expansion. In patients with flail chest, fractures prevent the rib cage from expanding normally. With kyphoscoliosis, the change in spinal configuration compresses the lungs and prevents normal expansion of the chest wall. In those with severe obesity, the weight of the chest and abdominal contents limit lung expansion.

Problems of the Airway and Alveoli

Patients with asthma, COPD, and cystic fibrosis have a high risk for hypercapnic respiratory failure because the underlying pathophysiology results in airflow obstruction and air trapping. Respiratory muscle fatigue and ventilatory failure occur from the added work of breathing needed to inspire air against increased airway resistance and air trapped within the alveoli.

Consequences of Hypercapnia

The body can tolerate increased CO_2 levels far better than low O_2 levels. This is because with slow changes in $PaCO_2$, the body may have time for compensation to occur. For example, consider the patient with COPD who has a slow increase in $PaCO_2$ after an upper respiratory tract infection. Because the change occurred over several days, there is time for the kidneys to compensate (e.g., by retaining bicarbonate). This will initially minimize the change in arterial pH. Unless the primary cause is identified and corrected, the patient's condition will likely get worse. (See Chapter 16 for a discussion of renal compensation for acid-base disorders.)

Clinical Manifestations

Respiratory failure may develop suddenly (acute, minutes or hours) or gradually (chronic, several days or weeks). A sudden decrease in PaO_2 and/or a rapid rise in $PaCO_2$ implies a serious respiratory condition, which can rapidly become a life-threatening emergency. An example is the patient with asthma who develops severe bronchospasm and a marked decrease in airflow, resulting in respiratory muscle fatigue, acidemia, and ARF.

Signs of respiratory failure are related to the extent of change in PaO_2 or $PaCO_2$, the speed of change (acute versus chronic), and the patient's ability to compensate for this change. When the patient's compensatory mechanisms fail, respiratory failure occurs. Because clinical signs vary, frequent patient assessment is a priority.

A lack of O_2 affects all body systems (Table 67.2). For example, a

decreased level of consciousness may occur without enough blood, O_2, and glucose supplied to the brain. Permanent brain damage can result if hypoxia is severe and prolonged. Gastrointestinal (GI) system changes include tissue ischemia and increased intestinal wall permeability. Bacteria can migrate from the GI tract into systemic circulation. Renal function may be impaired. Sodium retention, peripheral edema, and acute kidney injury may occur.

One of the first signs of acute hypoxemic respiratory failure is a change in mental status. Mental status changes occur early because the brain is extremely sensitive to changes in O_2 (and to a lesser degree CO_2) levels and acid-base balance. Restlessness, confusion, and agitation suggest inadequate O_2 delivery to the brain. On the other hand, a morning headache and slow respiratory rate with decreased level of consciousness may indicate problems with CO_2 removal.

Tachycardia, tachypnea, slight diaphoresis, and mild hypertension are early signs of ARF.[6] These changes indicate attempts by the heart and lungs to compensate for decreased O_2 delivery and rising CO_2 levels. It is important to understand that cyanosis is an unreliable indicator of hypoxemia. It is a late sign in ARF. It often does not occur until hypoxemia is severe (PaO_2 45 mm Hg or less).[7]

The priority for the patient with ARF is immediate assessment of the patient's ability to breathe and providing any assistive measures needed. Depending on the severity of the respiratory failure and hemodynamic status, this may involve intubation and starting mechanical ventilation.

Observing the patient's position helps assess the effort associated with the **work of breathing (WOB)**. WOB is the effort needed by the respiratory muscles to inhale air into the lungs. Patients with mild distress may be able to lie down. In moderate distress, patients may be able to lie down but prefer to sit. With severe distress they may be unable to breathe unless sitting upright. The tripod position helps decrease the WOB in patients with moderate to severe COPD and ARF. The patients sit with the arms propped on the overbed table or on the knees. Propping the arms increases the anteroposterior

diameter of the chest and changes pressure in the thorax.

TABLE 67.2 Common Manifestations of Hypoxemia and Hypercapnia

Specific	Nonspecific
Hypoxemia	
Respiratory	***Central Nervous***
Dyspnea	Agitation

	Dysrhythmias
	Hypertension
	Tachycardia
	Bounding pulse
	Neuromuscular
	Muscle weakness
	↓ Deep tendon reflexes
	Tremors, seizures (late)

The patient in ARF may have a rapid, shallow breathing pattern (hypoxemia) or a slower respiratory rate (hypercapnia). Both changes predispose the patient to insufficient O_2 delivery and CO_2 removal. Increased respiratory rates require a substantial amount of work and can lead to respiratory muscle fatigue. A change from a rapid rate to a slower rate in a patient in respiratory distress, such as that seen with

acute asthma, suggests severe respiratory muscle fatigue. There is an increased chance for respiratory arrest.

The patient's ability to speak is related to the severity of dyspnea. The dyspneic patient may be able to speak only a few words at a time between breaths. For example, the patient may have "2-word" or "3-word" dyspnea. This means the patient can say only 2 or 3 words before pausing to breathe.

You may see dyspneic patients using pursed-lip breathing (see Table 28.12). This technique increases SaO_2 by slowing respirations, increasing time for expiration, and preventing small bronchioles from collapsing. You may see *retraction* (inward movement) of the intercostal spaces or supraclavicular area and use of the accessory muscles (e.g., sternocleidomastoid) during inspiration or expiration. Use of the accessory muscles often signifies a moderate degree of respiratory distress.

Paradoxical breathing occurs with severe respiratory distress. Normally, the thorax and abdomen move outward on inspiration and inward on exhalation. With paradoxical breathing, the abdomen and chest move in the opposite manner—outward during exhalation and inward during inspiration. Paradoxical breathing results from maximal use of the accessory muscles of respiration. The patient may be extremely diaphoretic from the increased WOB.

Auscultate breath sounds. Note the presence and location of any abnormal breath sounds. Fine crackles may occur with pulmonary edema. Coarse crackles heard on expiration indicate fluid in the airways. This may be a sign of pneumonia or a degree of HF. Absent or decreased breath sounds occur with atelectasis, pleural effusion, or hypoventilation. Bronchial breath sounds over the lung periphery occur with lung consolidation from pneumonia. You may hear a pleural friction rub if pneumonia involves the pleura.

Diagnostic Studies

The most common diagnostic studies used to evaluate ARF are chest x-ray and ABG analysis. A chest x-ray helps identify possible causes

of respiratory failure (e.g., atelectasis, pneumonia). ABGs evaluate oxygenation (PaO_2) and ventilation ($PaCO_2$) status and acid-base (pH, bicarbonate) balance. Pulse oximetry monitors oxygenation status indirectly.

Other diagnostic studies that may be done include a complete blood cell count, serum electrolytes, urinalysis, and 12-lead ECG. Blood and sputum cultures (Gram stain, culture and sensitivity) may reveal infection. A CT scan or V/Q lung scan may be done if a pulmonary embolus is suspected. For the patient in severe ARF who needs intubation, end-tidal CO_2 ($EtCO_2$) may be used during ventilator management to assess trends in lung ventilation.[8]

Nursing and Interprofessional Management: Acute Respiratory Failure

Because many different problems cause ARF, initial management and specific care varies. Factors taken into consideration include patient age, severity of onset of respiratory failure, underlying co-morbidities, and suspected or most likely cause of the respiratory failure. We then tailor management strategies to what best meets the patient's unique needs. This section discusses general assessment and interventions most commonly used for patients with ARF. In acute care settings, collaboration between nursing and the interprofessional team (e.g., ICU physicians, respiratory therapists, pharmacists) is essential.

In severe ARF, the patient will be cared for in an intensive care unit (ICU). ICU care will include central venous pressure (CVP) and arterial BP monitoring. Arterial BP will be monitored at least hourly. Central or mixed venous O_2 saturation [$ScvO_2$ or SvO_2] data help determine the adequacy of tissue perfusion and the patient's response to treatment. The patient may need advanced hemodynamic monitoring to evaluate parameters such as CO and pulmonary capillary wedge pressure (PCWP). Chapter 65 discusses hemodynamic monitoring.

Nursing Assessment

Table 67.3 presents subjective and objective data that you should obtain from the patient with ARF. A thorough assessment may result in early detection of respiratory insufficiency. This allows us to intervene sooner and can prevent worsening respiratory failure. Monitor patients with preexisting cardiac and/or respiratory disease closely. A slight change in their overall condition can cause significant decompensation.

It is important to observe trends in ABGs, pulse oximetry, and assessment findings. You must identify the changes that are occurring from hypoxemia or hypercarbia. Your ability to detect problems, notify the HCP, implement appropriate treatment, and evaluate response to therapy is essential.

Nursing Diagnoses

Nursing diagnoses for the patient with ARF may include:

- Impaired gas exchange
- Impaired respiratory system function

Additional information on nursing diagnoses and interventions for the patient with ARF is presented in eNursing Care Plan 67.1 (available on the website for this chapter).

Planning

The overall goals for the patient with ARF include (1) independently maintain a patent airway, (2) absence of dyspnea or recovery to baseline breathing patterns, (3) effectively cough and able to clear secretions, (4) normal ABG values or values within the patient's baseline, and (5) breath sounds within the patient's baseline.

Nursing Implementation

Prevention

For the patient at risk for ARF, prevention and early recognition of respiratory distress are important. This is especially important for patients with neuromuscular diseases, cardiac problems, or respiratory problems (e.g., COPD). Do a thorough history and physical assessment to identify risk factors, then start appropriate interventions. Early strategies may include teaching patients about deep breathing and coughing, use of incentive spirometry, and early ambulation.

Preventing atelectasis, pneumonia, and complications of immobility, and optimizing hydration and nutrition, can decrease the risk for ARF. Those patients at high risk should be assessed more often with attention given to preventive measures.

Respiratory Therapy

The goals of respiratory care include maintaining adequate oxygenation and ventilation and correcting acid-base imbalance. Interventions include O_2 therapy, mobilization of secretions, and positive pressure ventilation (PPV) (Table 67.4).

Subjective Data

Important Health Information

Past health history: Age, weight, altered level of consciousness, tobacco use (pack-years), alcohol or drug use, hospitalizations related to either acute or chronic lung disease, thoracic or spinal cord trauma, occupational exposures to lung toxins

Medications: Use of home O_2, inhalers (bronchodilators), home nebulization, over-the-counter drugs; immunosuppressant (e.g.,

corticosteroid) therapy, CNS depressants, illicit substances
Surgery or other treatments: Intubation and mechanical ventilation, recent thoracic or abdominal surgery

Functional Health Patterns

Health perception–health management: Exercise, self-care activities, immunizations (flu, pneumonia, hepatitis)
Nutritional-metabolic: Eating habits, bloating, indigestion; recent weight gain or loss, change in appetite. Use of vitamins or herbal supplements
Activity-exercise: Fatigue, dizziness, dyspnea at rest or with activity, wheezing, cough (productive or nonproductive), sputum (volume, color, viscosity), palpitations, swollen feet, change in exercise tolerance
Sleep-rest: Changes in sleep pattern, use of CPAP
Cognitive-perceptual: Headache, chest pain or tightness, chronic pain
Coping–stress tolerance: Anxiety, depression, feelings of hopelessness. Risk for drug and/or alcohol use, nicotine withdrawal

Objective Data
General

Restlessness, agitation

Integumentary

Pale, cool, clammy skin or warm, flushed skin. Peripheral and central cyanosis. Peripheral dependent edema

Respiratory

Shallow, increased respiratory rate progressing to decreased rate. Use of accessory muscles with evidence of retractions, increased diaphragmatic excursion or asymmetric chest expansion, paradoxical chest and abdominal wall movement. Tactile fremitus, crepitus, or deviated trachea on palpation. Absent, decreased, or adventitious breath sounds. Pleural friction rub. Bronchial or bronchovesicular sounds heard in other than normal location, inspiratory stridor

Cardiovascular

Tachycardia progressing to bradycardia, dysrhythmias, extra heart sounds (S_3, S_4). Bounding pulse. Hypertension progressing to hypotension. Pulsus paradoxus, jugular venous distention, pedal edema

Gastrointestinal

Abdominal distention, ascites, epigastric tenderness, hepatojugular reflex

Neurologic

Somnolence, confusion, slurred speech, restlessness, delirium, agitation, tremors, seizures, coma, asterixis, ↓ deep tendon reflexes, papilledema

Possible Diagnostic Findings

↓/↑ pH, ↑/↓ $PaCO_2$, ↑/↓ bicarbonate, ↓ PaO_2, ↓ SaO_2, abnormal

hemoglobin, ↑ WBC count, changes in serum electrolytes. Abnormal findings on chest x-ray. Abnormal central venous or pulmonary artery pressures. Initially cardiac output may be ↑ due to the stress response. As hypoxemia, hypercapnia, and acidosis become more severe, cardiac output will ↓.

TABLE 67.4 Interprofessional CareAcute Respiratory Failure

Diagnostic Assessment

- Vital signs
- History and physical examination
- Arterial blood gases (ABGs)
- Pulse oximetry
- Chest x-ray
- CBC and differential
- Serum electrolytes
- 12-Lead ECG
- Blood, sputum, and/or urine cultures (if indicated)
- Hemodynamic monitoring: CVP, SVV, PAWP (if indicated)

Management

Respiratory Therapy

- O_2 therapy
- Mobilization of secretions
    - Positioning
    - Effective coughing
    - Chest physiotherapy
    - Suctioning of the airway

- Oral and/or IV hydration
- Humidification (of O_2)
- Ambulation (early mobility)
- Positioning: head of bed elevated

- Positive pressure ventilation (PPV)
  - Noninvasive positive pressure ventilation (e.g. CPAP, BiPAP)
  - Intubation with positive pressure ventilation

Drug Therapy

- Reduce airway inflammation (e.g., corticosteroids)
- Relief of bronchospasm (e.g., albuterol)
- Reduce pulmonary congestion (e.g., furosemide [Lasix], morphine)
- Treat pulmonary infections (e.g., antibiotics)
- Reduce anxiety, pain, and restlessness (e.g., lorazepam, fentanyl, morphine)

Supportive Therapy

- Management of the underlying cause of respiratory failure
- Monitor hemodynamic status
- Optimize balance between activity and rest
- Monitor for deterioration in patient condition

CVP, Central venous pressure; *SVV,* stroke volume variation; *PAWP,* pulmonary artery wedge pressure.

Oxygen Therapy

The primary goal of O_2 therapy is to correct hypoxemia. This requires

O_2 administration. Always administer O_2 at the lowest possible FIO_2 (O_2 concentration) needed to keep SpO_2 and PaO_2 within patient-specific goals. Never withhold O_2 from a patient. It is essential to observe the patient's response to O_2 therapy. Closely monitor patients for changes in mental status, respiratory rate, and ABGs, until their PaO_2 level has reached their baseline normal value.

Several methods are available to provide O_2 to patients in ARF. Chapter 28 and Table 28.19 discuss O_2 delivery devices. The device selected depends upon the patient's overall condition, degree of respiratory failure, ability to maintain a patent airway, the amount of FIO_2 that the device can deliver, and, most importantly, the patient's ability to breathe spontaneously. Ideally, the selected O_2 delivery device must maintain PaO_2 at 60 mm Hg or higher and SaO_2 at 90% or higher.

The patient is often agitated, disoriented, and restless. A face mask, though appropriate, may cause anxiety from feelings of claustrophobia. Anxiety can cause dyspnea and increase O_2 consumption and CO_2 production. The patient may try to remove the mask. In this case, you need to explore other O_2 therapy options.

Breathing high O_2 concentrations for prolonged periods is not without potential adverse effects. Exposure to higher FIO_2 (greater than 60%) for longer than 48 hours poses a risk for *O_2 toxicity*. In this situation, oxygen free radicals from the high O_2 levels cause inflammation and cell death, by disrupting the alveolar-capillary membrane. *Absorption atelectasis* is another risk. O_2 has the ability to replace nitrogen and other gases normally present in the alveoli. Without nitrogen to help maintain size and shape of the alveolus, structural support is lost and the alveolus collapses. Other effects of prolonged exposure to high levels of O_2 include increased pulmonary capillary permeability, decreased surfactant production, surfactant inactivation, and fibrotic changes in the alveoli.[9]

Another risk of O_2 therapy is specific to patients with chronic hypercapnia (e.g., patient with COPD). Chronic hypercapnia blunts

the response of chemoreceptors to high CO_2 levels as a respiratory stimulant. Initial O_2 therapy may be provided to patients with chronic hypercapnia through a low-flow device, such as a nasal cannula at 1 to 2 L/min or a Venturi mask at 24% to 28%. The patient with COPD who does not respond to O_2 therapy or other interventions may need mechanical ventilation with higher FIO_2.

Mobilization of Secretions

Retained pulmonary secretions may cause or worsen ARF. This occurs because the movement of O_2 into the alveoli and removal of CO_2 is severely limited or blocked. Secretions can be mobilized by proper positioning, effective coughing, chest physiotherapy, suctioning, humidification, hydration, and, when possible, early ambulation.

Patient Positioning

Position the patient upright, either by elevating the head of the bed at least 30 degrees or by using a reclining chair or chair bed. This helps maximize respiratory expansion, decrease dyspnea, and mobilize secretions. A sitting position improves pulmonary function by promoting downward movement of the lungs. When lungs are upright, ventilation and perfusion are best in the lung bases. If there is a chance for aspiration, position the patient side-lying.

Patients with one-sided lung disorders may be placed in a lateral or side-lying position. This position, called *good lung down,* allows for improved V/Q matching in the affected lung. Pulmonary blood flow and ventilation are better in dependent lung areas. This position allows secretions to drain out of the affected lung so they can be removed with suctioning. For example, place a patient with right-sided pneumonia on the left side. This will maximize ventilation and perfusion in the "good" lung and aid in secretion removal from the affected lung (postural drainage). Patients with ARF often have problems with both lungs. They may need repositioning at regular intervals on both sides to optimize air movement and drainage of secretions.

Effective Coughing

When secretions are present, encourage the patient to cough. Unfortunately, not all patients will have enough strength or force to produce a cough that will clear the airway of secretions. *Augmented coughing (quad coughing)* may benefit some patients. To aid with augmented coughing, place 1 or both hands at the anterolateral base of the patient's lungs (Fig. 67.6). As you observe deep inspiration end and expiration begin, move your hands forcefully upward. This increases abdominal pressure and helps the patient cough. It increases expiratory flow and promotes secretion clearance.

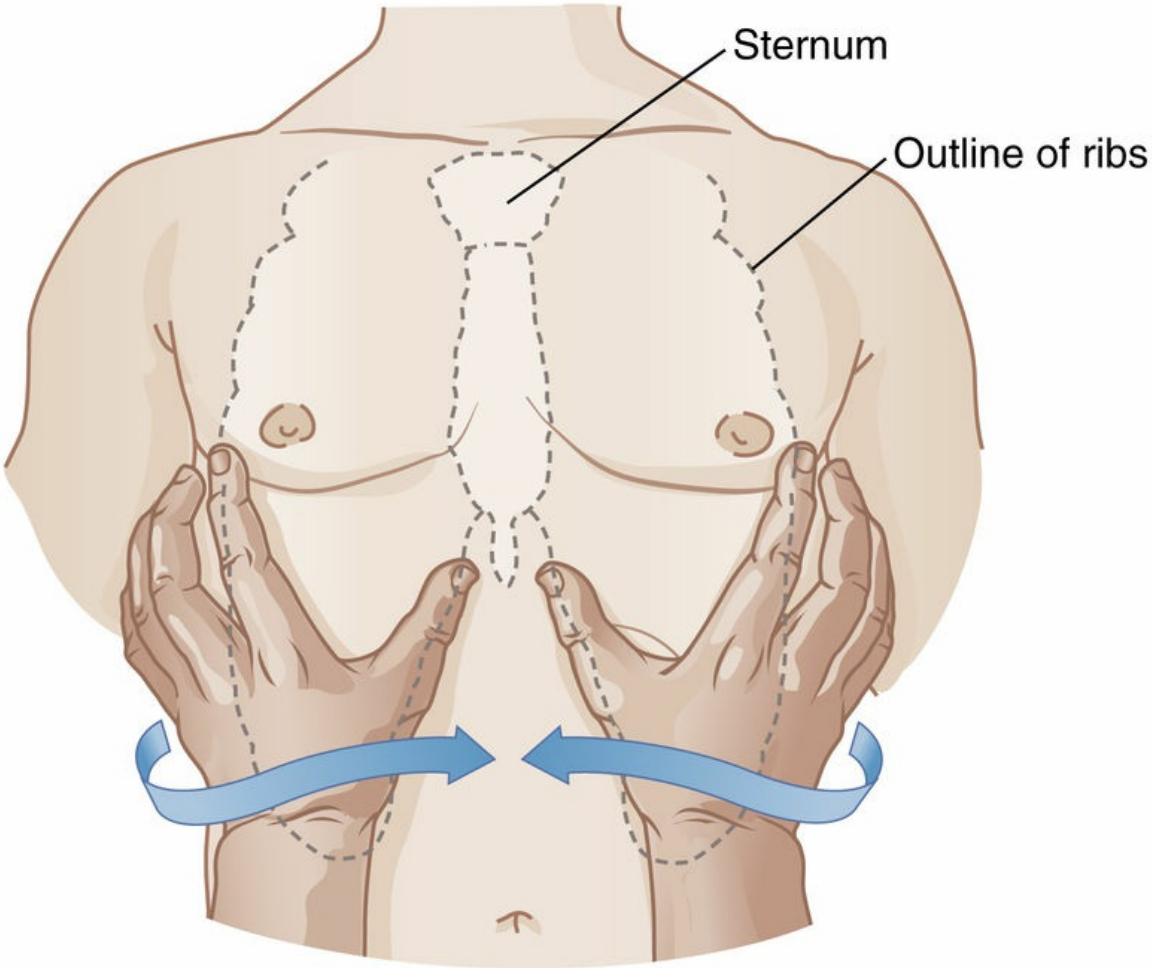

FIG. 67.6 Augmented coughing is performed by placing 1 or both hands on the anterolateral base of the lungs. After the patient takes a deep inspiration and at the beginning of expiration, move the hand(s)

forcefully upward. This increases abdominal pressure and helps produce a forceful cough.
From American Association of Critical Care Nurses: *AACN advanced critical care nursing,* St Louis, 2009, Mosby.

Huff coughing is a series of coughs performed while saying the word "huff" (see Table 28.21).[10] This technique prevents the glottis from closing during the cough. The patient takes a deep breath, holds the breath for 2 or 3 seconds, and then exhales. The huff cough is effective in clearing central airways. It may help move secretions upward. COPD patients generate higher flow rates with a huff cough than with a normal cough, and it is less tiring.

The *staged cough* also helps clear secretions. To perform a staged cough, the patient assumes a sitting position, breathes in and out 3 or 4 times through the mouth, then coughs while bending forward and pressing a pillow inward against the diaphragm.

Chest Physiotherapy

Chest physiotherapy is indicated for all patients who are producing sputum or have evidence of severe atelectasis or pulmonary infiltrates on chest x-ray. Postural drainage, percussion, and vibration to the affected lung segments help move secretions to the larger airways. Then, they can be removed by coughing or suctioning. Chest physiotherapy is discussed in Chapter 28.

Contraindications include TBI and increased intracranial pressure (ICP), unstable orthopedic injuries (e.g., spinal fractures, fractured ribs, fractured sternum), and recent hemoptysis.[11]

Suctioning

Suctioning may be needed if the patient is unable to expectorate secretions. Suctioning through an artificial airway (e.g., endotracheal tube [ET], tracheostomy) is done only as needed (see Chapters 26 and 65). Perform suctioning beyond the posterior oropharynx with caution, while monitoring the patient for complications. These include hypoxia, increased ICP, dysrhythmias, hypotension (from sudden elevation in intrathoracic pressure), hypertension and tachycardia

(from noxious stimulation), and bradycardia (possible vasovagal response).

Humidification

Humidification is an adjunct in secretion management. We can thin secretions with aerosols of sterile normal saline or mucolytic drugs (e.g., acetylcysteine mixed with a bronchodilator) given by nebulizer. O_2 given by aerosol mask can thin secretions and promote their removal. Aerosol therapy may cause bronchospasm and severe coughing, causing a decrease in PaO_2. Frequent assessment of the patient's tolerance to therapy is critical. Closely monitor the patient's respiratory status.

Hydration

Thick, viscous secretions are hard to expel. Unless contraindicated, adequate fluid intake (2 to 3 L/day) keeps secretions thin and easier to remove. The patient who is unable to take enough fluids orally needs IV hydration. Assess cardiac and renal status to determine whether the patient can tolerate the IV fluid volume and avoid HF and pulmonary edema. Regularly assess for signs of fluid overload (e.g., crackles, dyspnea, increased CVP).

Check Your Practice

You are caring for a 72-yr-old male patient admitted with acute hypoxemic respiratory failure. He has a history of atrial flutter and COPD. A chest x-ray shows left-sided pneumonia. Your patient is awake but mildly confused. He has a productive cough (thick, yellow-green purulent sputum).

- What respiratory interventions would you expect to be ordered?

Positive Pressure Ventilation

If initial measures do not improve oxygenation and ventilation, enhanced ventilatory assistance may be needed. Noninvasive positive pressure ventilation (NIPPV) is one option for patients with acute or chronic respiratory failure. During NIPPV, a mask is placed tightly over the patient's nose or nose and mouth (Fig. 67.7). When the patient breathes spontaneously, a mechanical ventilator or table-top unit delivers PPV to the patient. With NIPPV, it is possible to provide O_2 and decrease WOB, avoiding the need for endotracheal intubation.

NIPPV is most useful in managing chronic respiratory failure in those with chest wall or neuromuscular problems. It may be used with patients with a chronic respiratory problem that is worse due to cardiac problems or infection. It is an option for patients who refuse intubation, but still want some degree of ventilatory support (e.g., patients with end-stage COPD). NIPPV is not appropriate for patients who have a decreased level of consciousness, high O_2 requirements, facial trauma, hemodynamic instability, or excessive secretions. NIPPV used after extubation can help avoid reintubation.

There are 2 forms of NIPPV used for patients with ARF. Continuous positive airway pressure (CPAP) delivers 1 level of pressure—a constant pressure—to the patient's airway during inspiration and expiration. Bilevel positive airway pressure (BiPAP) uses 2 different levels of positive pressure (one on inspiration, another on expiration) (Fig. 67.8). With both CPAP and BiPAP, the patient must be awake and alert, have stable vital signs, and be able to support spontaneous ventilation.

The most often used NIPPV for ARF is BiPAP.[12] BiPAP provides O_2 therapy and humidification, decreases WOB, and reduces respiratory muscle fatigue. It helps open collapsed airways and decrease shunt. If respiratory status worsens with NIPPV, PPV via mechanical ventilation and higher O_2 concentrations is needed. Chapter 65 discusses mechanical ventilation.

Drug Therapy

Drug therapy depends on several factors. These include the cause of

ARF, the patient's preexisting medical condition, and whether infection is present. Goals of drug therapy include to (1) reduce airway inflammation and bronchospasm, (2) relieve pulmonary congestion; (3) treat infection; and (4) reduce anxiety, pain, and restlessness.

FIG. 67.7 Noninvasive bilevel positive airway pressure ventilation. A mask is placed over the nose or nose and mouth. Positive pressure from a mechanical ventilator aids the patient's breathing efforts,

decreasing the work of breathing.

FIG. 67.8 Stages of edema formation in ARDS. **A,** Normal alveolus and pulmonary capillary. **B,** Interstitial edema occurs with increased flow of fluid into the interstitial space. **C,** Alveolar edema occurs when the fluid crosses the alveolar-capillary membrane.

Reduce Airway Inflammation and Bronchospasm

Corticosteroids (e.g., IV methylprednisolone [Solu-Medrol]) are often used in combination with other drugs, such as bronchodilators, for relief of inflammation and bronchospasm. It may take several hours to see their effects. Inhaled corticosteroids require 4 to 5 days for optimum therapeutic effects, so they will not relieve ARF.

Drug Alert

IV Corticosteroids

- Monitor potassium levels. Corticosteroids worsen hypokalemia caused by diuretics.
- Prolonged use causes adrenal insufficiency.

Relief of bronchospasm increases alveolar ventilation. In acute bronchospasm, short-acting bronchodilators (e.g., albuterol), may be given at 15- to 30-minute intervals until a response occurs. Give these drugs using a hand-held nebulizer or a metered-dose inhaler with a spacer. Side effects include tachycardia and hypertension. Prolonged use can increase the risk for dysrhythmias and cardiac ischemia. It is important to monitor the patient's vital signs and ECG for any changes.

Relieve Pulmonary Congestion

Interstitial fluid can accumulate in the lungs because of direct or indirect injury to the alveolar capillary membrane from HF or fluid overload. Use of IV diuretics (e.g., furosemide [Lasix]), morphine, or

nitroglycerin can decrease pulmonary congestion caused by HF. Use extreme caution when giving these drugs. Changes in heart rate and rhythm and significant decreases in BP are common. (Chapter 34 discusses HF.)

Treat Infection

Lung infections (e.g., pneumonia, acute bronchitis) can result in excessive mucus production, fever, increased O_2 consumption, and inflamed, fluid-filled, and/or collapsed alveoli. Alveoli that are fluid filled or collapsed cannot take part in gas exchange. Consequently, pulmonary infections can either cause or worsen ARF. IV antibiotics are often given to treat infection. Chest x-rays can show the location and extent of an infection. Sputum cultures help identify the organisms causing the infection and their sensitivity to antimicrobial drugs.

Reduce Anxiety, Pain, and Restlessness

Anxiety, pain, and restlessness may result from hypoxia. They increase O_2 consumption and CO_2 production (from an increased metabolic rate) and increase WOB. For the nonintubated patient, this may cause tachypnea and ineffective ventilation. For the intubated patient, this may cause ventilator dyssynchrony and increase the risk for unplanned extubation. We promote patient comfort in several ways.

Benzodiazepines (e.g., lorazepam, midazolam), and opioids (e.g., morphine, fentanyl) may decrease anxiety, restlessness, and pain. They are often given IV. For the nonintubated patient, they should be started at the lowest dose possible. Address treatable causes of restlessness (e.g., hypoxemia, pain, delirium). Often, restlessness and mental status changes are the first signs of hypoxemia or ventilator dyssynchrony. You should address the causes and not depend solely on the use of analgesics and sedatives.

Safety Alert

Managing Restlessness and Sedation

- Pain, hypoxemia, electrolyte imbalance, TBI, and drug reactions can cause restlessness.
- Assess and aggressively treat all reversible causes of restlessness.
- Monitor patients closely for CNS, cardiac, and respiratory depression when giving sedative and analgesic drugs, especially in the nonintubated patient.
- Sedative and analgesic drugs may have a prolonged effect in critically ill patients. This can delay weaning from mechanical ventilation and increase length of stay.

Medical Supportive Therapy

Goals and interventions targeted to improving the patient's oxygenation and ventilation status are essential to improve O_2 delivery. The primary goal is to treat the underlying cause of the ARF. Patients with V/Q mismatch, shunting, or diffusion limitation are managed differently, depending on the underlying cause. Patients are continuously monitored for their response to therapy, including changes in respiratory status, trends in ABGs, and signs of clinical improvement.

Nutritional Therapy

Maintaining protein and energy stores is especially important in patients with ARF. The hypermetabolic state in critical illness increases the caloric requirements needed to maintain a stable body weight and muscle mass. Nutritional depletion causes a loss of muscle mass, including the respiratory muscles, which may delay recovery. The dietitian often determines the best method of feeding and optimal caloric and fluid requirements. Ideally, enteral or parenteral nutrition should be started within 24 to 48 hours (see Chapter 39).

Evaluation

The expected outcomes are that the patient with ARF will

- Independently maintain a patent airway
- Achieve normal or baseline respiratory system function
- Maintain adequate oxygenation as shown by normal or baseline ABGs
- Have normal hemodynamic status

Gerontologic Considerations: Acute Respiratory Failure

Many factors contribute to an increased risk for respiratory failure in older adults. The reduced ventilatory capacity that accompanies aging places the older adult at risk for ARF. Physiologic changes in the lungs include alveolar dilation, larger air spaces, and loss of surface area for gas exchange. Decreased elastic recoil within the airways, decreased chest wall compliance, and decreased respiratory muscle strength occur.[13]

In older adults, the PaO_2 falls further and the $PaCO_2$ rises to a higher level before the respiratory system is stimulated to change the rate and depth of breathing. This delayed response contributes to the development of respiratory insufficiency. A history of tobacco use is a major risk factor that can accelerate age-related respiratory changes. Poor nutritional status and less physiologic reserve in the cardiopulmonary system increases the risk for further compromising respiratory function and leading to ARF.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a sudden and progressive form of ARF in which the alveolar-capillary membrane becomes damaged and more permeable to intravascular fluid (Fig. 67.8). Next to septic shock, ARDS is one of the most common

conditions seen in the adult ICU. ARDS accounts for about 10% of all adult ICU admissions.[14] The incidence of ARDS in the United States is estimated at more than 200,000 cases each year.[14] Despite supportive therapy, the mortality rate from ARDS is around 50%.

Etiology

Table 67.5 lists conditions that predispose patients to developing ARDS. The most common cause is sepsis. ARDS may also develop because of multiple organ dysfunction syndrome (MODS). Patients with multiple risk factors are 3 or 4 times more likely to develop ARDS.

Either a direct or indirect lung injury causes ARDS. In direct lung injury, the pathogen comes into contact with the tissue of the lung. For example, aspiration of gastric contents into the lung will immediately initiate the inflammatory response. In an indirect injury, ARDS develops due to a problem somewhere else in the body. For example, necrotizing pancreatitis or bowel obstruction with perforation cause widespread inflammation and infection. As a result, septic mediators gain entrance to the bloodstream and often move toward the lungs, which provide a favorable, dark, moist environment for their proliferation. This is the beginning of acute lung injury.

TABLE 67.5 Predisposing Conditions to ARDS

Direct Lung Injury	Indirect Lung Injury
Common Causes	
• **Aspiration of gastric contents or other substances** • **Bacterial or viral pneumonia** • **Sepsis**	• Sepsis (especially gram-negative infection) • Severe massive trauma • Severe TBI • Shock states (hypovolemic, cardiogenic, septic)
Less Common Causes	
• **Chest trauma (blunt or penetrating)** • **Embolism: fat, air, amniotic fluid, thrombus** • **Inhalation of toxic substances** • **Near-drowning** • **O_2 toxicity** • **Radiation pneumonitis**	• Acute pancreatitis • Cardiopulmonary bypass • Disseminated intravascular coagulation • Opioid drug overdose (e.g., heroin) • Transfusion-related acute lung injury (e.g., multiple blood transfusions) • Urosepsis

Pathophysiology

The pathophysiologic changes in ARDS are divided into 3 phases: (1) injury or exudative phase, (2) reparative or proliferative phase, and (3) fibrotic or fibroproliferative phase. The pathophysiology of ARDS is shown in Fig. 67.9.

Injury or Exudative Phase

The *injury or exudative phase* usually occurs 24 to 72 hours after the initial insult (direct or indirect).[15] It generally lasts up to 7 days. Engorgement of the peribronchial and perivascular interstitial space causes interstitial edema. Fluid in the parenchyma of the lung surrounding the alveoli crosses the alveolar membrane and enters the alveolar space. V/Q mismatch and intrapulmonary shunt develop because the alveoli fill with fluid. Blood in the capillary network cannot be oxygenated.

The exact cause for the damage to the alveolar-capillary membrane is not known. Some think it is caused by stimulation of the inflammatory and immune systems. This stimulation attracts neutrophils to the pulmonary interstitium. The neutrophils release biochemical, humoral, and cellular mediators that produce changes in the lung. These changes include increased pulmonary capillary membrane permeability, destruction of collagen, formation of pulmonary microemboli, and pulmonary artery vasoconstriction.

Hypoxemia and the stimulation of juxtacapillary receptors in the stiff lung parenchyma *(J reflex)* initially cause an increase in respiratory rate and a decrease in tidal volume (V_T). This breathing pattern increases CO_2 removal, producing respiratory alkalosis. CO increases in response to hypoxemia, a compensatory effort to increase pulmonary blood flow. However, as atelectasis, pulmonary edema, and pulmonary shunt increase, compensation fails and hypoventilation, decreased CO, and decreased tissue O_2 perfusion occur.

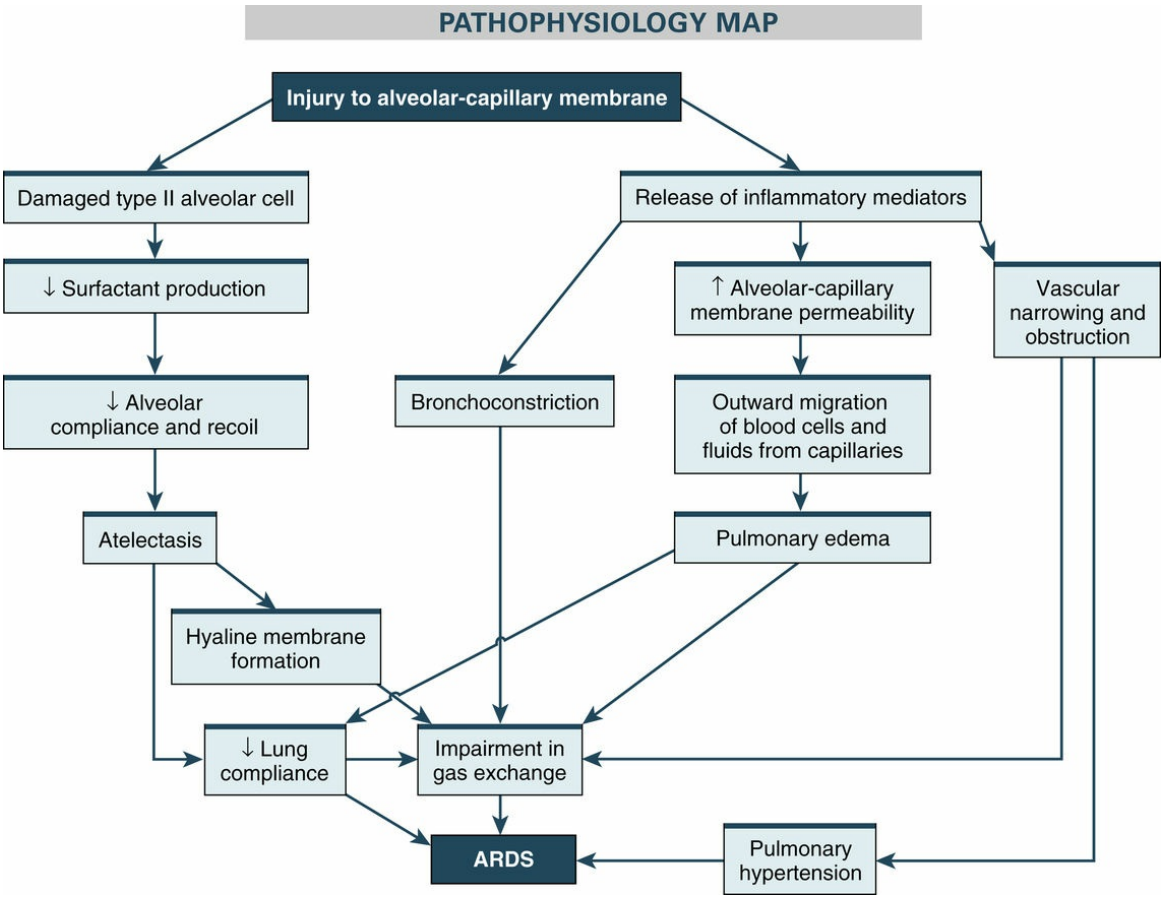

FIG. 67.9 Pathophysiology of ARDS.

The changes caused by ARDS damage both alveolar type I cells and alveolar type II cells (which make surfactant). This damage, in addition to fluid and protein accumulation, results in surfactant dysfunction. The function of *surfactant* is to maintain alveolar stability and prevent alveolar collapse. When surfactant synthesis is decreased or surfactant becomes inactivated, alveoli become unstable and collapse *(atelectasis).* Widespread atelectasis further decreases lung compliance, compromises gas exchange, and contributes to hypoxemia.

Necrotic cells, protein, and fibrin form hyaline membranes that line the inside of each alveolus. These thick hyaline membranes contribute to the development of fibrosis and atelectasis, leading to a further decrease in gas exchange capability and reduced lung compliance.

Severe V/Q mismatch and shunting of pulmonary capillary blood result in hypoxemia unresponsive to increasing concentrations of O_2.

This is the classic signs of ARDS, called **refractory hypoxemia**. In other words, despite receiving higher concentrations of O_2, the patient's condition does not improve but continues to get worse. Diffusion limitation, caused by hyaline membrane formation, contributes to and worsens hypoxemia. As the lungs become less compliant because of decreased surfactant, pulmonary edema, and atelectasis, the patient must generate higher airway pressures to inflate "stiff" lungs. Reduced lung compliance increases the patient's WOB. At this point, the patient needs mechanical ventilation.

Reparative or Proliferative Phase

The *reparative* or *proliferative phase* of ARDS begins 1 to 2 weeks after the initial lung injury.[16] During this phase, there continues to be an influx of neutrophils, monocytes, lymphocytes, and fibroblasts as part of the inflammatory response. Increased pulmonary vascular resistance and pulmonary hypertension may occur because fibroblasts and inflammatory cells destroy the pulmonary vasculature. Lung compliance continues to decrease due to interstitial fibrosis. Hypoxemia worsens because of the thickened alveolar membrane. This causes V/Q mismatch, diffusion limitation, and shunting. Airway resistance is severely increased from fluid in the lungs and secretions in the airways. The proliferative phase is complete when the diseased lung is replaced by dense, fibrous tissue. If the reparative phase persists, widespread fibrosis results. If the reparative phase stops, the lesions will often resolve.

Fibrotic or Fibroproliferative Phase

The *fibrotic phase* (*chronic* or *late phase*) of ARDS occurs 2 to 3 weeks after the initial lung injury. Not all patients who develop ARDS enter the fibrotic stage. For those who never fully recover from ARDS, the lung is completely remodeled by collagenous and fibrous tissues. Diffuse scarring of the lungs, interstitial fibrosis, and alveolar duct fibrosis result in decreased lung compliance.[17] This reduces the surface area for gas exchange because the interstitium is fibrotic, and

hypoxemia continues. Varying degrees of pulmonary hypertension may result from pulmonary vascular destruction and fibrosis.

Clinical Progression

Progression of ARDS varies among patients. Some survive the acute phase of lung injury. Pulmonary edema resolves, and complete recovery occurs within a week or so. The chance for survival is poorer in those who enter the fibrotic stage. Patients may need several weeks of long-term mechanical ventilation. It is not known why injured lungs repair and recover in some patients and in others ARDS progresses. Several factors are important in determining the course of ARDS. These include the nature of the initial injury, extent and severity of comorbidities, and pulmonary complications (e.g., pneumothorax). Genetics may account for a person's predisposition to developing ARDS.[18]

Clinical Manifestations and Diagnostic Studies

The initial presentation of ARDS is often subtle. At the time of the initial injury, and for 24 to 72 hours, the patient may not have respiratory symptoms or may have only mild dyspnea, tachypnea, cough, and restlessness. Lung auscultation may be normal or reveal fine, scattered crackles. ABGs may show mild hypoxemia and respiratory alkalosis caused by hyperventilation. The chest x-ray may be normal or reveal diffusely scattered, but minimal, interstitial infiltrates.

As ARDS progresses, symptoms worsen because of fluid in the lung parenchyma and alveoli and increased secretion accumulation in the airways. Respiratory distress becomes evident as WOB increases. Tachypnea and intercostal and suprasternal retractions may be present. Tachycardia, diaphoresis, changes in mental status, cyanosis, and pallor may occur. Lung auscultation usually reveals scattered to diffuse crackles and coarse crackles on expiration. After 72 hours, the chest x-ray often shows diffuse and extensive bilateral interstitial and alveolar infiltrates (Fig. 67.10).

As ARDS progresses, ABGs reflect changes in oxygenation and ventilation. Refractory hypoxemia is the hallmark characteristic of ARDS. Hypercapnia often signifies that respiratory muscle fatigue and hypoventilation have severely affected gas exchange, and respiratory failure is imminent.

To help evaluate the severity of hypoxemia in ARDS, we can calculate the **PaO_2/FIO_2** (P/F) ratio . This measure reflects the ratio of the patient's PaO_2 to the FIO_2 that the patient is receiving. Under normal circumstances (e.g., PaO_2 80 to 100 mm Hg; FIO_2 0.21 [room air]), the P/F ratio is greater than 400 (e.g., 95/0.21 = 452). With the onset and progression of lung injury and impairment in O_2 delivery through the alveolar-capillary membrane, the PaO_2 may remain lower than expected despite increased FIO_2. The P/F ratio distinguishes among mild (<300), moderate (<200), and severe (<100) ARDS (Table 67.6).

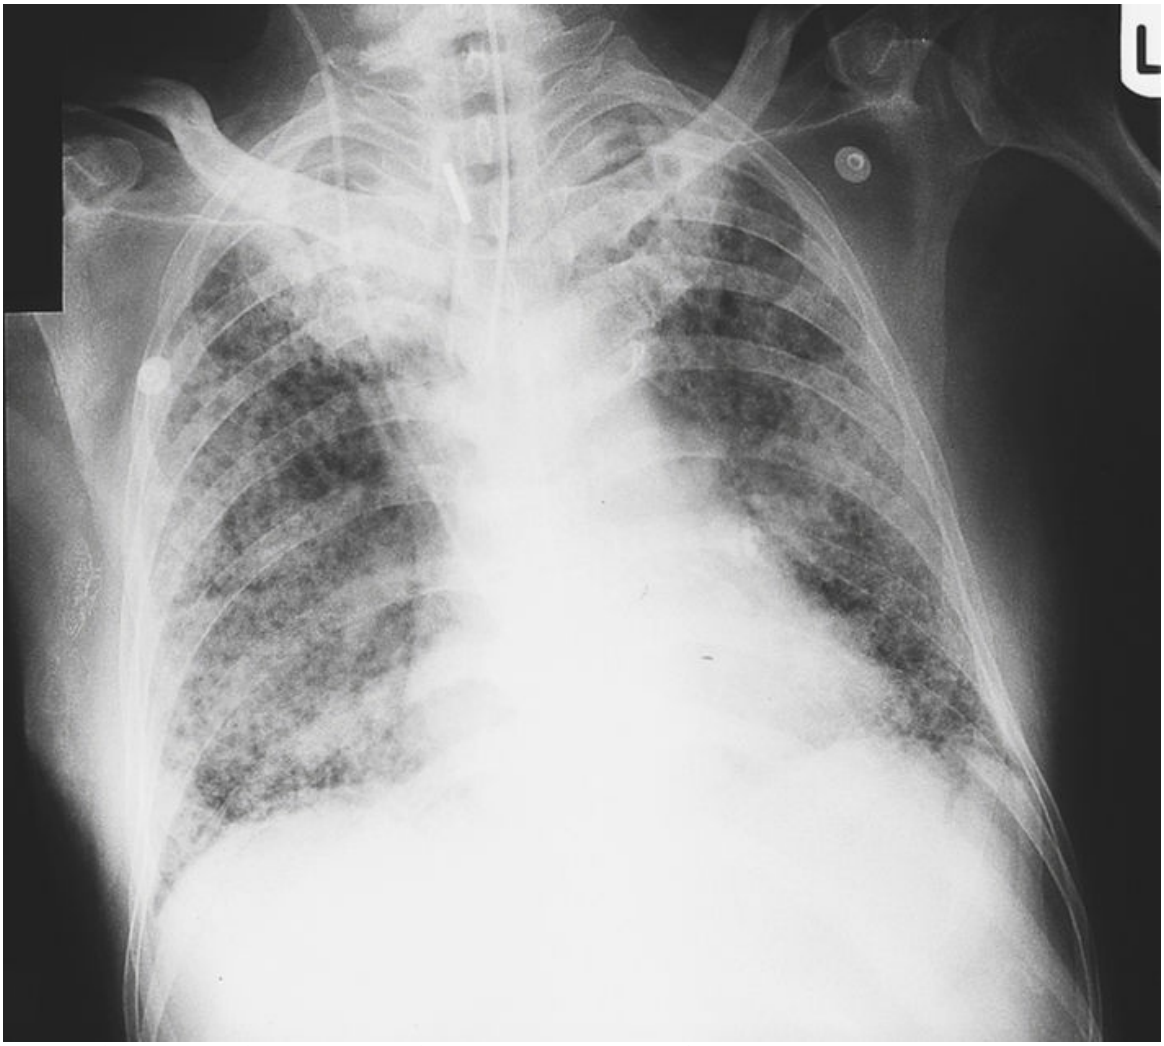

FIG. 67.10 Chest x-ray of a patient with ARDS. The x-ray shows new, bilateral, diffuse, homogeneous pulmonary infiltrates without cardiac failure, fluid overload, chest infection, or chronic lung disease. From Cohen J, Powderly WG: *Infectious diseases,* ed 2, St Louis, 2004, Mosby.

Check Your Practice

You are caring for a 26-yr-old woman with ARDS who experienced near-drowning 4 days ago. She is mechanically ventilated and receiving continuous IV infusions of analgesia and sedation. The ventilator settings are: full support (control mode), FIO_2 = 90%, PEEP = 15 cm H_2O, V_T = 350 mL, respiratory rate 12 breaths/min (patient

taking no breaths above the set rate on the ventilator), peak pressure = 35 cm H_2O. The patient's PaO_2 is 83 mm Hg.

- Calculate and interpret the PaO_2/FIO_2 (P/F) ratio.

As ARDS progresses, it is associated with profound dyspnea, hypoxemia, increased WOB, and respiratory distress, which require endotracheal intubation and PPV. The chest x-ray is often called "whiteout" (or white lung) because consolidation and infiltrates are widespread throughout the lungs, leaving few recognizable air spaces. Pleural effusions may be present. Severe hypoxemia, hypercapnia, metabolic acidosis, and organ dysfunction often accompany ARDS and provide additional challenges.

Complications

Complications may develop because of ARDS itself or its treatment (Table 67.7). Besides the lungs, the vital organs most often involved are the kidneys, liver, and heart. The main cause of death in ARDS is MODS, often accompanied by sepsis.

Abnormal Lung Function

Most patients will recover from ARDS within 6 months. Many will have normal to near normal lung function. However, not all patients regain normal lung function. Sometimes, abnormal lung function can persist for years. The severity of scarring and changes within the lungs are key factors. Mechanical ventilation, the duration of time ventilated, and use of extracorporeal life support (ECLS) may be contributing factors.[19] Patients may report extreme tiredness, chest pain, shortness of breath after minimal activity, and persistent dyspnea post-ARDS.

Ventilator-Associated Pneumonia

Risk factors for ventilator-associated pneumonia (VAP) include

impaired host defenses, invasive monitoring devices, aspiration of GI contents (especially in patients receiving enteral nutrition), and prolonged mechanical ventilation. Implement a ventilator bundle protocol (Table 67.8).

TABLE 67.6 Berlin Definition of ARDS

Timing

Within 1 week of a known clinical insult or new or worsening respiratory symptoms

Chest X-Ray

Bilateral opacities: not fully explained by effusions, lobar/lung collapse, or nodules

Oxygenation

Mild ARDS: PaO_2/FIO_2 ratio ≤300 with PEEP or CPAP ≥5 cm H_2O

Moderate ARDS: PaO_2/FIO_2 ratio ≤200 with PEEP or CPAP ≥5 cm H_2O

Severe ARDS: PaO_2/FIO_2 ratio <100 with PEEP or CPAP ≥5 cm H_2O

Modified from Pneumatikos L, Papaioannou VE: The new Berlin definition: What is, finally, the ARDS? *Pneumon* 25:365, 2012.

Common strategies to prevent VAP include elevating the head of bed 30 to 45 degrees, strict infection control measures (e.g., hand washing, sterile technique during endotracheal suctioning) and frequent oral care.

Barotrauma

Barotrauma occurs when fragile alveoli are overdistended with excess pressure during mechanical ventilation. The high peak airway pressures needed to ventilate the lungs predispose patients with ARDS to this complication. Barotrauma results in alveolar air escaping from ruptured alveoli. This can lead to pulmonary interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumopericardium, and tension pneumothorax. Providing ventilation with a smaller V_T (e.g., 4 to 8 mL/kg) and varying amounts of PEEP minimizes the risk for barotrauma.

TABLE 67.7 Complications Associated With ARDS

Cardiac

- ↓ Cardiac output
- Dysrhythmias

Central Nervous System and Psychologic

- Delirium
- PTSD

Gastrointestinal

- Hypermetabolic state, dramatically ↑ nutrition requirements

- Paralytic ileus
- Pneumoperitoneum
- Stress ulceration and hemorrhage

Hematologic

- Anemia
- Disseminated intravascular coagulation
- Thrombocytopenia
- VTE

Infection

- Catheter-related infection (e.g., central and peripheral IV catheters, urinary catheters)
- Sepsis

Renal

- AKI

Respiratory

- Pulmonary emboli
- Pulmonary fibrosis
- Ventilator associated: volutrauma, barotrauma
- VAP

TABLE 67.8 Components of a Ventilator Bundle

- Good hand washing before, during (as needed), and after delivery of patient care
- Elevate head of the bed 30 to 45 degrees
- Daily assessment of readiness for extubation (see Chapter 65)
- Stress ulcer prophylaxis (see Chapter 41)
- VTE prophylaxis (see Chapter 37)
- Daily oral care with chlorhexidine (0.12%) solution (see Table 65.9)

Stress Ulcers

Patients with ARF and ARDS are at high risk for stress ulcers because of blood being diverted from the GI to respiratory system to help meet the body's demand for O_2. Management strategies include correcting predisposing conditions, such as hypotension, shock, and acidosis. Prophylactic management includes antiulcer drugs, such as proton pump inhibitors (e.g., pantoprazole [Protonix]) and mucosal-protecting drugs (e.g., sucralfate [Carafate]). Early initiation of enteral nutrition helps prevent mucosal damage.

Venous Thromboembolism (VTE)

ARDS patients are susceptible to the effects of immobility and venous stasis. They are at risk for deep vein thrombosis (DVT) and pulmonary emboli. Prophylactic management may include intermittent pneumatic compression stockings, anticoagulation (e.g. low-molecular-weight heparin), and, when possible, early ambulation.

Acute Kidney Injury

Acute kidney injury (AKI) can occur from decreased renal perfusion and subsequent decreased delivery of O_2 to the kidneys. This most

often occurs in ARDS because of hypotension in septic shock. It may also result from hypoxemia or nephrotoxic drugs (e.g., vancomycin) used to treat ARDS-related infections. Management strategies for AKI include careful monitoring of intake and output, obtaining daily creatinine and urea levels, and, when needed, dialysis therapy.

Continuous renal replacement therapy (CRRT) is often used. Patients with ARDS are often hemodynamically unstable and need vasopressors and/or inotropes to maintain heart rate and BP. They cannot tolerate the large volumes of fluid that would be removed during traditional hemodialysis. CRRT is slow, gentle, and continuous. The patient can receive CRRT 24 hours a day. The overall mortality rate for ARDS patients is higher in those who need CRRT.[20]

Psychological Issues

Recovery is far from complete for the patient who survives ARDS. Survivors may have anxiety, issues with memory and attention, inability to focus, nightmares, depression, and in some instances, various degrees of posttraumatic stress disorder (PTSD). PTSD can occur in ARDS survivors up to 5 years later.[21]

Nursing and Interprofessional Management: ARDS

Management of a patient with ARF (Table 67.4) and the nursing care plan for ARF (eNursing Care Plan 67.1 [available on the website for this chapter]) apply to patients with ARDS. The next section discusses additional interprofessional care for the patient with ARDS (Table 67.9).

Nursing Assessment

Because ARDS causes ARF, the subjective and objective data that you should obtain from someone with ARDS are the same as those for ARF (Table 67.3). Patient information may not be possible to obtain on

admission due to the urgent need to protect the airway (intubation), initiate mechanical ventilation, monitor vital signs, and assist with urgent treatments and procedures (e.g., insertion of an arterial and central line).

Planning

With appropriate therapy, overall goals include a PaO_2 of 60 mm Hg or higher and adequate lung ventilation to maintain normal pH. Specific goals for a patient with ARDS include (1) PaO_2 within normal limits for age or at baseline on room air, (2) SaO_2 greater than 90%, (3) resolution of the precipitating factor(s), and (4) clear lungs on auscultation.

TABLE 67.9 Interprofessional CareAcute Respiratory Distress Syndrome

Diagnostic Assessment

See Table 67.6.

Management

General Care

- Identify and treat underlying cause
- Hemodynamic monitoring
- Proper patient positioning

Respiratory Therapy

- O_2 administration
- Mechanical ventilation (see Chapter 65)
- Low V_T ventilation

- Permissive hypercapnia
- PEEP
- Positioning strategies (e.g., prone)
- Extracorporeal membrane oxygenation (ECMO)

Supportive Care

- Nutrition therapy
- VTE prophylaxis
- VAP prophylaxis
- Inotropic and vasopressor drugs
    - norepinephrine (Levophed)
    - dopamine
    - dobutamine
- IV fluid administration
- Analgesia and sedation
- Neuromuscular blocking agents

Implementation

Patients with moderate to severe ARDS receive care in an ICU. Even with appropriate therapy, the clinical course of ARDS is complex and unpredictable. Patients with ARDS often need several days of mechanical ventilation to allow time for the overwhelming inflammation and fluid accumulation in the lungs to begin resolving. Best practices for care of the patient with ARDS include (1) O_2 administration, (2) mechanical ventilation, (3) low V_T ventilation, (4) permissive hypercapnia, (5) PEEP, (6) prone positioning, and (7) extracorporeal membrane oxygenation (ECMO). Many of these practices are detailed in the *Acute Respiratory Distress Syndrome Clinical Network (ARDSNet) protocol*.[22]

Respiratory Therapy

Oxygen Administration

The primary goal of O_2 therapy is to correct hypoxemia. Initially, the use of a high-flow system that delivers higher O_2 concentrations to maximize O_2 delivery may be all that is needed. Continuously monitor SpO_2 to assess the effectiveness of O_2 therapy. However, for most patients diagnosed with ARDS, high-flow O_2 delivery, including BiPAP, is only a temporary measure. As respiratory failure worsens, high-flow O_2 will be not be able to keep the PaO_2 within acceptable ranges. Patients with moderate to severe ARDS and refractory hypoxemia need mechanical ventilation to keep the PaO_2 at or close to near-normal levels. However, even with mechanical ventilation, the patient may need an FIO_2 of 70%, 80%, or higher to keep the PaO_2 at least 60 mm Hg. Most HCPs agree that in the injury and reparative phases, they may have to accept a lower than normal PaO_2 (e.g. PaO_2 55 to 80 mm Hg) and SpO_2 (88% to 95%).

Mechanical Ventilation

Mechanical ventilation is often delivered via a pressure-control type of ventilation. Pressure-control ventilation helps to keep the inspiratory and plateau pressures from becoming too high. This prevents alveolar overdistention and rupture. By reducing the amount of pressure going into the stiff, noncompliant lungs, we can help prevent further lung injury. However, no mode of mechanical ventilation is superior to the others.[23] Chapter 65 provides additional information on mechanical ventilation.

Low Tidal Volume (V_T) Ventilation

Patients with ARDS are ventilated with a low V_T of 4 to 8 mL/kg.[22] The delivery of a large V_T into stiff lungs is associated with volutrauma and barotrauma. Volutrauma causes *alveolar fractures* (damage or tears in the alveoli) and movement of fluids and protein into the alveolar spaces. Low V_T ventilation has reduced mortality and the risk for volutrauma.

Permissive Hypercapnia

As a result of delivering a lower than normal V_T to the patient with ARDS, the $PaCO_2$ level will slowly rise above normal limits. This is known as **permissive hypercapnia**. A $PaCO_2$ of up to 60 mm Hg is acceptable in the early phase of ARDS. The patient usually tolerates this rise in $PaCO_2$ if it is gradual, allowing the brain and systemic circulation to compensate. Permissive hypercapnia is not used for the patient with TBI or increased ICP.

Frequent ABG samples are needed, with careful monitoring of the pH, PaO_2, and $PaCO_2$ values. As per the ARDSNet protocol, the pH is kept between 7.30 and 7.45. CO_2 is a powerful stimulant to breathe. When permissive hypercapnia is used, the patient is usually given continuous IV analgesia and sedation.

Positive End-Expiratory Pressure (PEEP)

During PPV, it is common to apply PEEP at 5 cm H_2O to compensate for loss of glottic function caused by the ET. PEEP increases functional residual capacity, or the volume of air left in the lungs at the end of a normal expiration. PEEP also helps open up ("recruit") collapsed alveoli.

We typically apply PEEP in increments of 3 to 5 cm H_2O until oxygenation is adequate, with an FIO_2 of 60% or less (if possible). PEEP may improve ventilation in respiratory units that collapse at low airway pressures, thus allowing the FIO_2 to be lowered. Patients with ARDS may need higher levels of PEEP (e.g., 10 to 20 cm H_2O). There is no identified optimal level of PEEP for patients with ARDS.

PEEP is not without complications. The added intrathoracic and intrapulmonic pressures generated by positive pressure remaining in the lungs and transmitted to surrounding structures (e.g., inferior vena cava, heart) at end expiration can compromise venous return. This in turn has the potential to decrease the amount of blood returning to both the right and left sides of the heart. Dramatic reductions in preload, CO, and BP can occur. High levels of PEEP or

excess inspiratory pressures can cause barotrauma and volutrauma.

Prone Positioning

In the early phases of ARDS, fluid moves freely throughout the lung. Because of gravity, fluid pools in dependent regions of the lung. As a result, some alveoli are fluid filled (dependent areas) while others are air filled (nondependent areas). When the patient is supine, the heart and mediastinal contents place added pressure on the lungs. Consequently, the supine position predisposes all patients, including those with ARDS, to atelectasis.

Prone positioning is an option for patients with refractory hypoxemia who do not respond to other strategies to increase PaO_2. By turning the patient prone, perfusion may be better matched to ventilation. Air-filled alveoli in the anterior part of the lung become dependent. Alveoli in the posterior part of the lungs are "recruited" (given the opportunity to reexpand), improving oxygenation.

Some patients will have a big improvement in PaO_2 when prone with no change in FIO_2. The improvement in ventilation may be enough to allow a reduction in FIO_2 or PEEP. You may see hemodynamic instability (dysrhythmias, a decrease in BP) from fluid shifts when the patient is prone. There may be more need for airway suctioning as secretions are mobilized. Best practice suggests that patients be positioned prone early in the course of ARDS. They can stay in the prone position for up to 16 hours per day.[24] Placing a patient prone requires the presence of an ICU intensivist, respiratory therapist, and at least 3 to 4 nurses. Special attention must be given to securing the airway. Once prone, the patient should be positioned in a side-lying position.

Extracorporeal Membrane Oxygenation (ECMO)

Extracorporeal membrane oxygenation (ECMO) is used most often in specialized ICUs in major cities. Like hemodialysis, a large blood vessel is cannulated (most often the internal jugular, femoral artery, or femoral vein) and a catheter is inserted. The catheter is then connected

to a device that allows the blood to exit the patient and pass across a gas-exchanging membrane outside the body. Within the ECMO unit, O_2 is delivered into the blood and CO_2 removed. Oxygenated blood is returned back to the patient. $ECCO_2R$ is like ECMO. It does not require as high of blood flow rates. It is only used to enhance oxygenation. Both ECMO and $ECCO_2R$ are expensive and require specially trained nurses and other personnel.

Medical Supportive Therapy

The entire interprofessional team have important roles in the care of the patient with ARDS. All mechanically ventilated patients with ARDS in the ICU will have continuous heart rate, respiratory rate, BP, MAP, and SpO_2 monitoring. $EtCO_2$ monitoring is standard in the care of ARDS patients.[8]

Other positioning strategies for patients with ARDS include continuous lateral rotation therapy (CLRT) and kinetic therapy. CLRT provides continuous, slow, side-to-side turning of the patient by rotating the actual bed frame less than 40 degrees. The bed's lateral movement is maintained for 18 of every 24 hours to simulate postural drainage and help mobilize pulmonary secretions. The bed may contain a vibrator pack that provides chest physiotherapy. This feature assists with secretion mobilization and removal (Fig. 67.11). Kinetic therapy is like CLRT in that patients are rotated side-to-side 40 degrees or more. It is important to obtain baseline assessments of the patient's pulmonary status (e.g., respiratory rate and rhythm, breath sounds, ABGs, SpO_2) and continue to monitor the patient throughout the therapy.

Analgesia and Sedation

Analgesia and sedation, either by direct IV or continuous IV infusion, are important. Analgesia and sedation decrease the discomfort associated with the presence of an ET tube, help reduce WOB, and prevent ventilator dyssynchrony.

Patients who breathe asynchronously with mechanical ventilation

may benefit from an adjustment of ventilator inspiratory flow rates or other settings. Patients who stay asynchronous with mechanical ventilation despite aggressive analgesia and sedation may need a neuromuscular blocking agent (NMBA). These drugs, such as vecuronium, pancuronium (Pavulon) or cisatracurium (Nimbex), relax skeletal muscles and promote synchrony with mechanical ventilation. Remember that a patient receiving neuromuscular blockade can appear to be asleep, but still be awake and in pain. For this reason, simultaneous administration of analgesia and sedation with NMBAs is essential.

FIG. 67.11 TotalCare SpO2RT Bed System offers continuous lateral

rotation therapy and percussion and vibration therapies. Patients can easily and quickly be repositioned.

Safety Alert

Neuromuscular Blockade

- Always give concurrent analgesia and sedation to patients receiving a NMBA. This eliminates patient awareness, ensures patient comfort, and avoids the terrifying experience of being awake and in pain while paralyzed.
- Use a NMBA for the shortest duration and at the lowest dose possible to avoid complications.

Monitoring levels of sedation in patients receiving NMBA is challenging. Levels of drug paralysis are monitored primarily by clinical assessment, including heart rate and BP, but more importantly, respiratory rate and whether the patient is taking breaths above the set rate on the ventilator.

Promoting Tissue Perfusion

Patients with ARDS are at risk for hemodynamic compromise. Those on PPV and PEEP often have decreased CO. One cause is decreased venous return from the PEEP-induced increase in intrathoracic pressure. Impaired contractility and decreased preload can decrease CO. Changes in intrathoracic or intrapulmonary pressures from PPV can also decrease CO. Patients with an exacerbation of COPD or asthma and those receiving PPV are at risk for alveolar hyperinflation, increased right ventricular afterload, and excess intrathoracic pressures. These changes can limit blood flow from the right side of the heart, through the pulmonary vasculature, to the left side of the

heart, and cause hemodynamic compromise (e.g., decreased CO). Blood return from the systemic circulation to the right side of the heart may be impaired, decreasing preload and CO.

Hemodynamic monitoring (e.g., CVP, CO, $ScvO_2$, SvO_2) is essential. This allows you to see trends, detect changes, and adjust therapy as needed. BP and mean arterial pressure (MAP) are important indicators of the adequacy of CO. Closely monitor BP and indicators of CO and tissue perfusion (SaO_2, mixed venous O_2 saturation) with the start of or changes in mechanical ventilation. A decrease in CO is treated by giving IV fluids, drugs, or both. (Chapter 66 discusses drugs used to treat decreased CO and shock.)

Maintaining Fluid Balance and Nutrition

Maintaining fluid balance and nutrition is challenging. Increasing pulmonary capillary permeability results in fluid in the lungs and causes pulmonary edema. At the same time, the patient may be intravascularly volume depleted and at risk for hypotension and decreased CO from mechanical ventilation and PEEP.

Monitor hemodynamic parameters (e.g., CVP, stroke volume variation) and daily weights to assess the patient's fluid volume status. Monitor intake and output hourly. Keep the ARDS patient on the "dry" side. In other words, avoid aggressive resuscitation with IV fluids. ARDS patients typically have increased WOB because the alveoli, lungs, and spaces between the alveoli are partially or completely fluid filled. Since ARDS is an inflammatory process, diuretics play a minimal role.

Maintaining protein and energy stores is important. Nutritional depletion causes a loss of muscle mass, including the respiratory muscles, which may prolong mechanical ventilation and delay recovery. Ideally, enteral or parenteral nutrition should be started within 24 to 48 hours.

Evaluation

The expected outcomes for the patient with ARDS are similar to those

for a patient with ARF (see p. 1597). It is essential that the patient with ARDS be able to maintain and sustain adequate oxygenation and ventilation with decreasing amounts of O_2, be hemodynamically stable, and be free of complications.

Case Study

Acute Respiratory Distress Syndrome

© Thinkstock.

Patient Profile

J.N. is a 58-yr-old white man who was admitted 36 hours ago to the surgical ICU after emergent surgery for a small-bowel obstruction,

acute ischemic bowel, and perforated colon.

Past Medical History

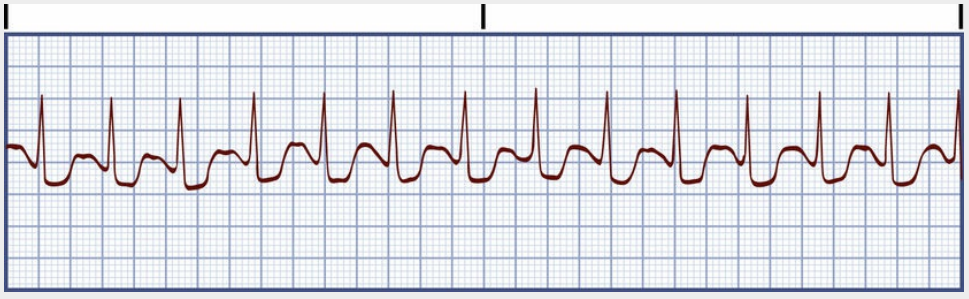
- Mild obesity, hypertension, type 2 diabetes
- Lumbar spine surgery 5 years ago
- Chronic back pain controlled with oxycodone (OxyContin) 15 mg PO 3 times daily

Operative Procedure

- Surgical procedure relieved small bowel obstruction, resected 2 feet of intestine, repaired the perforated colon, irrigated the abdominal cavity
- HR was 102 to 135, BP dropped to 70 mm Hg for 6 minutes, SpO_2 was greater than 90% for the duration of surgery
- Received 6 units of packed red blood cells and 4 L of 0.9% saline

Postoperative Status

J.N.'s pulmonary status worsened over the first 24 hours in the ICU. He required progressively higher FIO_2 via the mechanical ventilator. J.N. continued to have declining SaO_2 levels, increased WOB, and worsening hemodynamic status. He became more tachycardic. Despite direct IV analgesia and sedation, his respiratory rate increased and he was often "out-of-sync" with the ventilator. A chest x-ray showed bilateral pleural effusions and a right-sided pneumothorax, requiring chest tube placement. Immediately after chest tube placement, his SpO_2 decreased to 80% for 4 minutes. J.N. stayed dyssynchronous with the ventilator so continuous IV analgesia and sedation infusions were ordered. Neuromuscular blockade was started to decrease his WOB and achieve ventilator synchrony.



Current Status

J.N.'s oxygenation continues to worsen. He is still mechanically ventilated and is receiving 100% FIO_2 with PEEP 15 cm H_2O. Urine output has greatly decreased over the past 6 hours. He was diagnosed with AKI. His wife has brought in a copy of his advance directives. They state he does not want to be kept alive by artificial means. His wife and 2 adult children are at the bedside and voicing concerns about his status.

Objective Data

Physical Examination

- *General:* Sedated, paralyzed. Head of bed elevated 30 degrees. Skin cool, temperature 101° F (38.3° C) rectally
- *Respiratory:* ET tube in place with PPV. No accessory muscle use, retractions, or paradoxical breathing. Respiratory rate 18 breaths/min and in sync with ventilator. SpO_2 88%, coarse crackles bilaterally throughout all lung fields. Ventilator settings: V_T 350 mL, FIO_2 100%, rate 18/min, PEEP 15 cm H_2O, peak inspiratory pressure 35 cm H_2O
- *Cardiovascular:*
- Apical-radial pulse equal, BP 96/54 mm Hg. 2+ carotid, radial, and femoral pulses; 1+ dorsalis pedis pulses. ECG is below:

- *Gastrointestinal:* Surgical dressing dry and intact; colostomy draining a moderate amount of serosanguineous drainage

- *Urologic:* Indwelling bladder catheter draining concentrated, dark amber urine less than 30 mL/hr

Diagnostic Findings

- Current ABG: pH 7.23, PaO_2 59 mm Hg, $PaCO_2$ 57 mm Hg, HCO_3 16 mEq/L, O_2 saturation 88%.
- Hemoglobin 6.9 g/dL (69g/L), WBC 20.6/μL (20.6×10^9/L)
- BUN and creatinine values are increased
- Chest x-ray: Bilateral, scattered interstitial infiltrates compatible with ARDS

Discussion Questions

1. What is the cause of ARDS for J.N? Is this a direct or indirect cause?
2. How does the pathophysiology of ARDS predispose him to refractory hypoxemia?
3. What manifestations does J.N. have that support a diagnosis of ARDS?
4. Calculate the PaO_2/FIO_2 ratio. What does this value tell you about the seriousness of his condition?
5. What other complications is J.N. at risk for developing from ARDS?
6. ***Evidence-Based Practice:*** You are orienting a new nurse, who asks you why you allowed J.N.'s family to stay at the bedside during your physical assessment and morning rounds with the ICU team. How would you respond?
7. ***Priority Decision:*** What priority interventions should be implemented to improve J.N.'s respiratory status and hypoxemia?
8. ***Patient-Centered Care:*** What information would you give to J.N.'s family about his status?

9. ***Patient-Centered Care:*** Given the guidelines in the patient's advance directive, what ethical/legal issues could you encounter?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which signs and symptoms distinguish hypoxemic from hypercapnic respiratory failure? *(select all that apply)*
   a. Cyanosis
   b. Tachypnea
   c. Morning headache
   d. Paradoxical breathing
   e. Use of pursed-lip breathing
2. An important consideration in selecting an O_2 delivery device for the patient with acute hypoxemic respiratory failure is to
   a. always start with noninvasive positive pressure ventilation.
   b. apply a low-flow device, such as a nasal cannula or face mask.
   c. be able to correct the PaO_2 to a normal level as quickly as possible.
   d. base the selection on the patient's condition and amount of FIO_2 needed.

3. The *most* common early clinical manifestations of ARDS that the nurse may see are
   a. dyspnea and tachypnea.
   b. cyanosis and apprehension.
   c. respiratory distress and frothy sputum.
   d. bradycardia and increased work of breathing
4. Interventions used in managing the patient with ARDS include *(select all that apply)*
   a. IV injection of surfactant.
   b. aggressive IV fluid resuscitation.
   c. giving adequate analgesia and sedation.
   d. elevating the head of bed 30 to 45 degrees when supine.
   e. monitoring hemodynamic parameters and daily weights.
5. Which intervention is *most* likely to prevent or limit volutrauma in the patient with ARDS who is mechanically ventilated?
   a. Increasing PEEP
   b. Increasing the inspiratory flow rate
   c. Use of low tidal volume ventilation
   d. Suctioning the patient via endotracheal tube hourly

1. a, b, d, 2. d, 3. a, 4. c, d, e, 5. c

Emergency and Disaster Nursing

Cathy Edson, and Amy Meredith

LEARNING OUTCOMES

1. Apply the steps in triage, the primary survey, and the secondary survey to a patient with a medical, surgical, or traumatic emergency.
2. Relate the pathophysiology to the assessment and interprofessional care of select environmental emergencies.
3. Relate the pathophysiology to the assessment and interprofessional care of select toxicologic emergencies.
4. Select appropriate nursing interventions for victims of violence.
5. Distinguish among the responsibilities of health care providers, the community, and select federal agencies in emergency and mass casualty incident preparedness.

Conceptual Focus

Gas Exchange
Interpersonal Violence

Perfusion
Thermoregulation

Entire books are dedicated to the nursing care of emergency patients. It is a unique specialty that requires a solid understanding of basic nursing concepts and specific approaches to patient problems. Nurses unaccustomed to the emergency department (ED) often describe the flow as "chaotic" and uncertain. Certainly, it may have this appearance. The challenge of the ED is that the nurse does not know what patient will come through the doors. The trained ED nurse

must be prepared to meet this challenge. This chapter presents an overview of the triage process and care of select emergency patients. Common emergency situations discussed include heat- and cold-related emergencies, submersion injuries, bites and stings, and various types of poisonings. The chapter concludes with a discussion of terrorism, mass casualty incidents, and the methods of response.

The emergency management of various medical, surgical, and traumatic emergencies is discussed throughout this book. Tables outline the emergency management of specific problems. Table 68.1 lists these emergency management tables by title, chapter number, and page.

More than 141 million people visit EDs each year.[1] Of these, 11.2 million patients are admitted to the hospital. This number is increasing for several reasons. These include (1) the inability to see a HCP, (2) an aging population, (3) shorter hospital stays resulting in frequent readmissions, (4) acute mental health crises, (5) ED and hospital closures, and (6) lack of or inadequate health insurance or a HCP. These factors result in overcrowding and long wait times.[2]

ED nurses care for patients of all ages with a variety of problems. However, some EDs specialize in certain patient populations or conditions, such as pediatric ED or trauma ED. The Emergency Nurses Association (ENA) is the specialty organization aimed at advancing emergency nursing practice. The ENA provides standards of care for nurses working in the ED. They offer a certification process that allows nurses to become certified emergency nurses (CENs).[3]

Care of Emergency Patient

Recognizing life-threatening illness or injury is one of the most important goals of emergency nursing. Initiating interventions to reverse or prevent a crisis is often a priority before making a medical diagnosis. This process begins with your first contact with a patient. Prompt identification of patients who need immediate treatment and determining appropriate interventions are essential nurse competencies.

Triage

Triage, a French word meaning "to sort," refers to the process of rapidly determining patient acuity.[4] It is one of the most important assessment skills needed by ED nurses. Most often you will confront multiple patients who have a variety of problems. The triage process works on the premise that we must treat patients who have a threat to life before other patients.

A *triage system* identifies and categorizes patients so that the most critically ill are treated first. The ENA and American College of Emergency Physicians support the use of a 5-level triage system.[5] The *Emergency Severity Index* (ESI) is a 5-level triage system that incorporates concepts of illness severity and resource use (e.g., electrocardiogram [ECG], laboratory tests, radiology studies, IV fluids) to determine who should be treated first (Table 68.2). The ESI includes a triage algorithm that directs you to assign an ESI level to patients coming into the ED. The triage algorithm can be found in the ESI Implementation Handbook.[5]

First, assess the patient for any threats to life (ESI-1). Ask "Is the patient in imminent danger of dying?" Or, for ESI-2, is this a high-risk patient who should not wait to be seen? Next, evaluate patients who do not meet the criteria for ESI-1 or ESI-2 for the number of anticipated resources they may need. Assign patients to ESI-3, ESI-4, or ESI-5 based on this determination. Vital signs are important. Patients assigned to ESI-3 must have normal vital signs. Patients with abnormal vital signs may be reassigned to ESI-2.[5]

Check your Practice

You are working in the ED with your preceptor, who is a triage nurse.

A 24-yr-old man arrives and states, “I think I have food poisoning. I’ve been vomiting all night and now I have diarrhea.” The patient reports abdominal cramping that he rates as 6/10. He denies fever or chills. Vital signs: T = 97.8°F (36.6°C), HR = 94, RR = 16, BP = 121/74 mm Hg.

- Assign a triage acuity rating using the ESI.

After you complete the initial focused assessment to determine the presence of actual or potential threats to life, proceed with a more detailed assessment. A systematic approach to this assessment decreases the time needed to identify potential threats to life and limits the risk for overlooking a life-threatening condition. A primary and secondary survey is the approach used for all trauma patients. For nontrauma patients, the primary survey is followed by a focused assessment. Focused assessments are discussed in Chapter 3.

TABLE 68.2 Five-Level Emergency Severity Index (ESI)

	Level				
Definition	**ESI-1**	**ESI-2**	**ESI-3**	**ESI-4**	**ESI-5**
Stability of vital functions (ABCs)	Unstable	Threatened	Stable	Stable	Stable
Life threat or organ threat	Obvious	Likely but not always obvious	Unlikely but possible	No	No
How soon should the HCP see the patient	Immediately	Within 10 min	Up to 1 hr	Could be delayed	Could be delayed
Expected resource intensity	High resource intensity Staff at bedside continuously Often mobilization of team response	High resource intensity Multiple, often complex diagnostic studies Frequent consultation Continuous monitoring	Medium to high resource intensity Multiple diagnostic studies (e.g., multiple laboratory studies, x-rays) or brief observation Complex procedure (e.g., IV fluids, drugs)	Low resource intensity 1 simple diagnostic study (e.g., x-ray) or simple procedure (e.g., sutures)	Low resource intensity Examination only
Examples	Cardiac arrest, intubated trauma patient, overdose with bradypnea, severe respiratory distress	Chest pain from ischemia, multiple trauma unless responsive	Abdominal pain or gynecologic disorders unless in severe distress, hip fracture in older patient	Closed extremity trauma, simple laceration, cystitis	Cold symptoms, minor burn, recheck (e.g., wound), prescription refill

Primary Survey

The **primary survey** (Table 68.3) focuses on airway, breathing, circulation (ABC), disability, exposure, facilitation of adjuncts and family, and other resuscitation aids. If uncontrolled external hemorrhage is noted, the usual ABC assessment format may be reprioritized to <C>ABC. The <C> stands for catastrophic hemorrhage. If present, it must be controlled first.[6] Apply direct pressure with a sterile dressing followed by a pressure dressing to any obvious bleeding sites.

The primary survey aims to identify life-threatening conditions so that appropriate interventions can be started (Table 68.4). You may identify life-threatening conditions related to ABCs at any point during the primary survey. When this occurs, start interventions immediately, before moving to the next step of the survey.

A = Alertness and Airway

Nearly all immediate trauma deaths occur because of airway obstruction. Saliva, bloody secretions, vomitus, laryngeal trauma, dentures, facial trauma, fractures, and the tongue can obstruct the airway. Patients at risk for airway compromise include those who drown or have seizures, anaphylaxis, foreign body obstruction, or cardiopulmonary arrest. If an airway is not maintained, obstruction of airflow, hypoxia, and death will result. Signs and symptoms in a patient with a compromised airway include dyspnea, inability to speak, gasping (agonal) breaths, foreign body in the airway, and trauma to the face or neck. The patient's alertness level is a crucial factor for choosing the right airway interventions. Determine level of consciousness (LOC) by assessing the patient's response to verbal and/or painful stimuli. A simple mnemonic to remember is *AVPU: A* = alert, *V* = responsive to voice, *P* = responsive to pain, and *U* = unresponsive.[6]

Airway maintenance should progress rapidly from the least to the most invasive method. Treatment includes opening the airway using the **jaw-thrust maneuver** (avoiding hyperextension of the neck) (Fig. 68.1), suctioning and/or removal of foreign body, inserting a nasopharyngeal or oropharyngeal airway (in unconscious patients only), and endotracheal intubation. If intubation is impossible because of airway obstruction, an emergency cricothyroidotomy or tracheotomy is done (see Chapter 26). Ventilate patients with 100% O_2 using a bag-valve-mask (BVM) device before intubation or cricothyroidotomy.[6]

Rapid-sequence intubation is the preferred procedure for securing an unprotected airway in the ED. It involves the use of sedatives and paralytic drugs. These drugs aid in intubation and reduce the risk for aspiration and airway trauma. (See Chapter 65 for more information on intubation.)

If the patient has a suspected spinal cord injury and is not already immobilized, the cervical spine must be stabilized at the same time as the assessment of the airway. This can be done with manual stabilization or the use of a rigid cervical collar (C collar). Keep the bed flat and continue to monitor airway patency and breathing

effectiveness.

B = Breathing

Adequate airflow through the upper airway does not ensure adequate ventilation. Many problems cause breathing changes. Common ones include fractured ribs, pneumothorax, penetrating injury, allergic reactions, pulmonary emboli, and asthma attacks. Patients with these conditions may have a variety of signs and symptoms. The patient may have dyspnea, paradoxical or asymmetric chest wall movement, decreased or absent breath sounds on the affected side, visible wounds to the chest wall, cyanosis, tachycardia, and hypotension.

Every critically injured or ill patient has an increased metabolic and O_2 demand and should receive supplemental O_2. Give high-flow O_2 (100%) via a nonrebreather mask and monitor the patient's response. Life-threatening conditions (e.g., flail chest, tension pneumothorax) can severely and quickly compromise ventilation. Interventions may include BVM ventilation with 100% O_2, needle decompression, intubation, and treatment of the underlying cause.

C = Circulation

An effective circulatory system includes the heart, intact blood vessels, and adequate blood volume. Uncontrolled internal or external bleeding places a person at risk for hemorrhagic shock (see Chapter 66). Check either a femoral or carotid pulse. Peripheral pulses may be absent due to direct injury or vasoconstriction. Assess the quality and rate of the pulse if found. Assess the skin for color, temperature, and moisture. Altered mental status and delayed capillary refill (longer than 3 seconds) are common signs of shock. When evaluating capillary refill in cold environments, remember that a cold temperature delays refill.

Insert IV lines into veins in the upper extremities unless contraindicated, such as in an open fracture or an injury that affects limb circulation. Insert 2 large-bore (14- to 16-gauge) IV catheters. Start aggressive fluid resuscitation using normal saline or lactated Ringer's solution. Consider intraosseous or central venous access if

unable to rapidly obtain venous access. (See Chapter 66 for more information on hypovolemic shock and fluid resuscitation.)

The HCP may order type-specific packed red blood cells if needed. In an emergency (life-threatening) situation, give blood that is not cross-matched (e.g., O negative) if immediate transfusion is needed.

D = Disability

Conduct a brief neurologic examination as part of the primary survey. The patient's LOC is a measure of the degree of disability. Use the Glasgow Coma Scale (GCS) to determine the LOC (see Table 56.5).[7] This allows for consistent communication among the interprofessional care team. Remember! The GCS is not accurate for intubated or aphasic patients. Last, assess the pupils for size, shape, equality, and reactivity.

E = Exposure and Environmental Control

Remove clothing from all trauma patients to perform a thorough physical assessment. This often requires cutting off the patient's clothing. Be careful not to cut through any area that is forensic evidence (e.g., bullet hole). Do not remove any impaled objects (e.g., knife). Removing these could result in serious bleeding and further injury. Once the patient is exposed, use warming blankets, overhead warmers, and warmed IV fluids to limit heat loss, prevent hypothermia, and maintain privacy.

Obtain a full set of vital signs, including BP, heart rate, respiratory rate, O_2 saturation, and temperature after the patient is exposed. If the patient has sustained or is suspected of having sustained chest trauma, or if the BP is abnormally high or low, obtain a BP in both arms.

F = Facilitate Adjuncts and Family

Research supports the benefits for patients, caregivers, and staff of allowing ***family presence*** during resuscitation and invasive procedures.[8] Patients report that caregivers provide comfort, serve as

advocates for them, and help remind the care team of their "personhood." Caregivers who wish to be present during invasive procedures and resuscitation view themselves as active participants in the care process. They believe that they comfort the patient and that it is their right to be with the patient. Nurses report that family members serve as "patient helpers" and "staff helpers." It is essential to assign an interprofessional team member to explain the care being delivered and answer questions if a caregiver is present during resuscitation or invasive procedures.

TABLE 68.3 Emergency AssessmentPrimary Survey

Assessment	Interventions
Alertness and Airway With Cervical Spine Stabilization and/or Immobilization	
• **Assess for catastrophic external bleeding.** • **Assess alertness (e.g., AVPU).** • **Assess for respiratory distress.** • **Determine airway patency.** • **Check for loose teeth or foreign bodies.** • **Assess for bleeding, vomitus, or edema.**	• Control bleeding with direct pressure and pressure dressings. • Open airway using jaw-thrust maneuver. • Remove or suction any foreign bodies. • Insert oropharyngeal or nasopharyngeal airway, tracheostomy. • Initiate rapid sequence intubation. • Immobilize cervical spine using rigid cervical collar and cervical immobilization device.
Breathing	
• **Assess ventilation.** • **Scan chest for signs of breathing.** • **Look for paradoxical movement of the chest wall during inspiration and expiration.** • **Note use of accessory muscles or abdominal muscles.** • **Observe and count respiratory rate.** • **Note color of nail beds, mucous membranes.** • **Auscultate lungs.** • **Assess for jugular venous distention and trachea position.**	• Give supplemental O_2 via appropriate delivery system (e.g., nonrebreather mask). • Ventilate with bag-valve-mask with 100% O_2 if respirations are inadequate or absent. • Prepare to intubate if severe respiratory distress (e.g., agonal breaths) or arrest. • Have suction available. • If absent breath sounds, prepare for needle thoracostomy and chest tube insertion.
Circulation	
• **Check carotid or femoral pulse.** • **Palpate pulse for quality and rate.** • **Assess skin color, temperature, moisture.** • **Check capillary refill.**	• If absent pulse, start cardiopulmonary resuscitation and advanced life support measures. • If shock symptoms or hypotensive, start 2 large-bore (14- to 16-gauge) IVs and start infusions of normal saline or lactated Ringer's solution. • Consider intraosseous or central venous access if IV access cannot be rapidly obtained. • Give blood products if ordered.
Disability	
• **Assess level of consciousness by determining response to verbal and/or painful stimuli (e.g., Glasgow Coma Scale).** • **Assess pupils for size, shape, equality, and reactivity.**	• Periodically reassess level of consciousness, mental status, and pupil size and reactivity.
Exposure and Environmental Control	
• **Assess full body for determination of additional or related injuries.** • **Assess environment.**	• Remove clothing for adequate examination. • Stabilize any impaled objects. • Keep patient warm with blankets, warmed IV fluids, overhead lights to prevent heat loss, if appropriate. • Maintain privacy.
Facilitate Adjuncts and Family	
• **Assess vital signs and pulse oximetry.** • **Determine caregiver's desire to be present during invasive procedures and/or cardiopulmonary resuscitation.**	• Obtain bilateral blood pressures if patient has sustained or is suspected of having sustained chest trauma, or if the BP is abnormal. • Assign health team member to support caregiver(s). • Provide emotional support to patient and caregiver.
Get Resuscitation Adjuncts	
• **Determine need for adjunct measures for monitoring the patient's condition.**	• Obtain laboratory tests, such as type and crossmatch, CBC and metabolic panel, blood alcohol, toxicology screening, ABGs, coagulation profile, cardiac biomarkers, pregnancy. • Continuously monitor ECG. • Insert NG tube; insert orogastric tube in a patient with significant head or facial trauma. • Monitor oxygenation and ventilation (e.g., continuous pulse oximetry, capnography). • Manage pain with pharmacologic (e.g., NSAIDs, IV opioids) and nonpharmacologic (e.g., distraction, positioning, music) pain management strategies. • Provide comfort measures as appropriate (e.g., ice, position of comfort, warm blanket).

AVPU, A = alert, V = responsive to voice, P= responsive to pain, and U = unresponsive.

TABLE 68.4 Potential Life-Threatening Conditions Found During Primary Survey*

Airway

- Inhalation injury (e.g., fire victim)
- Obstruction (partial or complete) from foreign bodies, debris (e.g., vomitus), or tongue
- Penetrating wounds and/or blunt trauma to upper airway structures

Breathing

- Anaphylaxis
- Flail chest with pulmonary contusion
- Hemothorax
- Pneumothorax (e.g., open, tension)

Circulation

- Direct cardiac injury (e.g., myocardial infarction, trauma)
- Pericardial tamponade
- Shock (e.g., massive burns, hypovolemia)
- Uncontrolled external hemorrhage
- Hypothermia

Disability

- Head injury
- Stroke

---

* List is not all-inclusive.

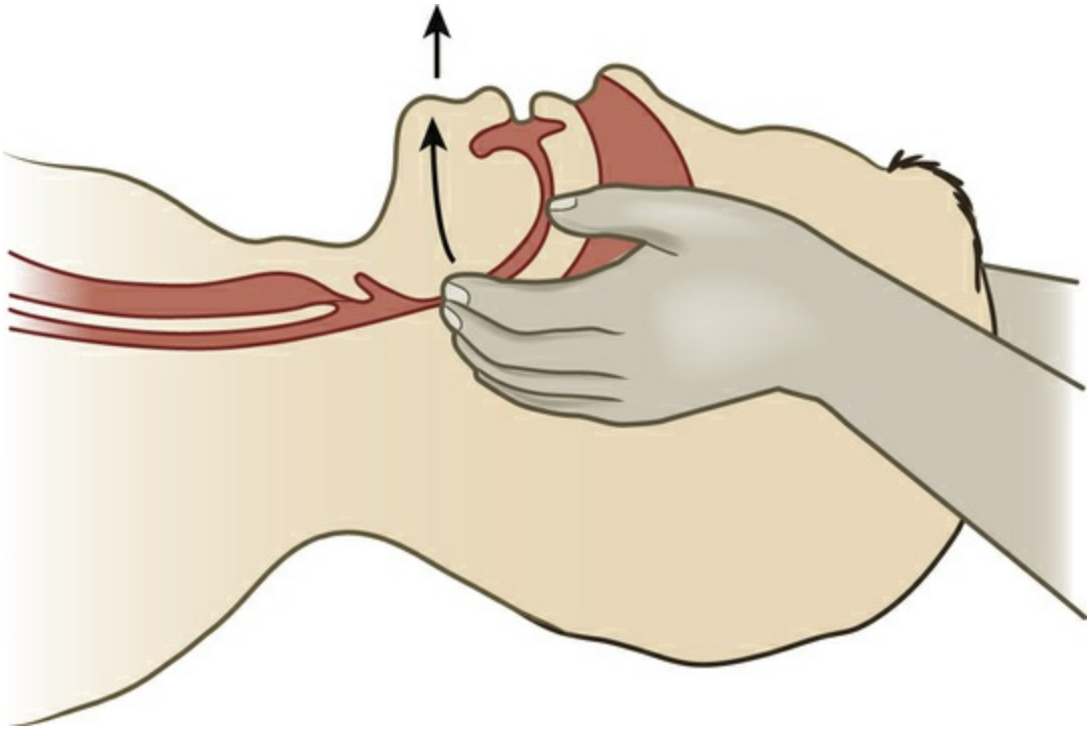

FIG. 68.1 Jaw-thrust maneuver is the recommended procedure for opening the airway of an unconscious patient with a possible neck or spinal injury. With the patient lying supine, kneel at the top of the head. Place 1 hand on each side of the patient's head, resting your elbows on the surface. Grasp the angles of the patient's lower jaw and lift the jaw forward with both hands without tilting the head.

G = Get Resuscitation Adjuncts

Start adjunct measures for monitoring the patient's condition, if not already done. Use the mnemonic "LMNOP" to remember these resuscitation aids:

L: Laboratory tests, such as type and crossmatch, complete blood count (CBC) and metabolic panel, blood alcohol, toxicology screening, arterial blood gases (ABGs), coagulation profile, cardiac biomarkers, pregnancy test, and urinalysis.

M: Monitor ECG for heart rate and rhythm.

N: Nasogastric (NG) tube to decompress and empty the stomach, reduce the risk for aspiration, and test the contents for blood. Place an orogastric tube in a patient with significant head or

facial trauma since an NG tube could enter the brain.

O: Oxygenation and ventilation assessment. Continuously monitor O_2 saturation and end-tidal CO_2 ($EtCO_2$) if the patient is intubated (see Chapter 65).

P: Pain assessment and management

Most patients who come to the ED report pain.[9] Providing comfort measures is critical when caring for patients in the ED. Many EDs have pain management protocols for nurses to use to treat pain early, beginning at triage. Pain management strategies should include a combination of pharmacologic and nonpharmacologic measures. You are the advocate in ensuring comfort measures for the patient.

Secondary Survey

The secondary survey begins after addressing each step of the primary survey and starting any lifesaving interventions. The **secondary survey** is a brief, systematic process that aims to identify *all* injuries (Table 68.5). It is valuable for discovering unknown problems in patients with a poor or confusing history.[6]

H = History and Head-to-Toe Assessment

Obtain a history and mechanism of the injury or illness. These details provide clues to the cause and guide specific assessment and interventions. The patient may not be able to give a history. However, caregivers, friends, bystanders, and prehospital personnel can often give necessary information.

SAMPLE is a memory aid that prompts you to ask about:

S: Symptoms associated with the injury or illness

A: Allergies (e.g., drugs, food, latex, environment) and tetanus status

M: Medication history

P: Past health history (e.g., preexisting medical or psychiatric

conditions, surgeries, smoking history, recent use of drugs or alcohol, last menstrual period, baseline mental status)

L: Last meal/oral intake

E: Events or environmental factors leading to the illness or injury

Details of the incident are important because the mechanism of injury and injury patterns can predict specific injuries. For example, a restrained front-seat passenger may have knee or femur fractures from hitting the dashboard and a chest injury from the airbag. Those who fell off a ladder or roof may have fractures, spinal cord injury, or head trauma.

Head, Neck, and Face

Check eyes for extraocular movements. A disconjugate gaze is a sign of neurologic damage. Battle's sign, or bruising directly behind the ears, may indicate a fracture of the base or posterior part of the skull. "Raccoon eyes," or periorbital bruising, usually occurs with a fracture of the base of the frontal part of the skull. Check the ears for blood and cerebrospinal fluid. Do not block clear drainage from the ear or nose.

Chest

Inspection and palpation of the chest will clue the nurse for heart and lung injuries. These may be life threatening and need immediate intervention.

Abdomen and Flanks

Frequent evaluation for subtle changes in the abdomen is essential. Motor vehicle crashes and assaults can cause blunt trauma. Penetrating trauma tends to injure specific organs. Stabilize, but do not remove, any impaled objects. They must be removed in a controlled environment, such as the operating room.

If the patient has blunt abdominal trauma or you suspect intraabdominal hemorrhage, perform a *focused abdominal sonography for trauma* (FAST).[6] This procedure can identify blood in the peritoneal

space and assess cardiac function. It is noninvasive and done quickly at the bedside. However, a FAST cannot rule out a retroperitoneal bleed. If one is suspected, a CT scan is usually done.

Pelvis and Perineum

Inspect and gently palpate the pelvis. Do not rock the pelvis. Pain may indicate a pelvic fracture and the need for imaging. Assess for bladder distention, hematuria, dysuria, or inability to void. The HCP may perform a rectal examination to check for blood, prostate gland problems, and loss of sphincter tone (e.g., spinal cord injury).

Extremities

Assess the upper and lower extremities for point tenderness, crepitus, and deformities. If not done prehospital, splint injured extremities above and below the injury to decrease further soft tissue injury and pain. The HCP should realign grossly deformed, pulseless extremities before splinting. Check pulses before and after movement or splinting of an extremity. A pulseless extremity is a time-critical emergency. Immobilize and elevate injured extremities and apply ice packs. Antibiotics are given for open fractures to prevent infection.

TABLE 68.5 Emergency AssessmentSecondary Survey

Assessment	Interventions
History and Head-to-Toe Assessment	
History	• Obtain details of the incident/illness, mechanism and pattern of injury, length of time since incident occurred, injuries suspected, treatment provided and patient's response, level of consciousness. • Use the mnemonic **SAMPLE** to determine **S**ymptoms associated with injury or illness; **A**llergies, including tetanus status; **M**edication history; **P**ast health history (e.g., preexisting medical/psychiatric conditions, last menstrual period); **L**ast meal/oral intake; and **E**vents/Environment preceding illness or injury.
Head, neck, and face	• Note general appearance, including skin color. • Assess face and scalp for lacerations, bone or soft tissue deformity, tenderness, bleeding, foreign bodies. • Inspect eyes, ears, nose, and mouth for bleeding, foreign bodies, drainage, pain, deformity, bruising, lacerations. • Palpate head for depressions of cranial or facial bones, contusions, hematomas, areas of softness, bony crepitus. • Assess neck for stiffness, pain in cervical vertebrae, tracheal deviation, distended neck veins, bleeding, edema, difficulty swallowing, bruising, subcutaneous emphysema, bony crepitus.
Chest	• Observe rate, depth, and effort of breathing, including chest wall movement and use of accessory muscles. • Palpate for bony crepitus and subcutaneous emphysema. • Auscultate breath sounds. • Obtain 12-lead ECG and chest x-ray. • Inspect for external signs of injury: petechiae, bleeding, cyanosis, bruises, abrasions, lacerations, old scars.
Abdomen and flanks	• Look for symmetry of abdominal wall and bony structures. • Inspect for external signs of injury: bruises, abrasions, lacerations, punctures, old scars. • Auscultate for bowel sounds. • Palpate for masses, guarding, femoral pulses. • Note type and location of pain, rigidity, or distention of abdomen.
Pelvis and perineum	• Gently palpate pelvis. • Assess genitalia for blood at the meatus, priapism, bruising, rectal bleeding, anal sphincter tone. • Determine ability to void.
Extremities	• Inspect for signs of external injury: deformity, bruising, abrasions, lacerations, swelling. • Observe skin color and palpate skin for pain, tenderness, temperature, and crepitus. • Evaluate movement, strength, and sensation in arms and legs. • Assess quality and symmetry of peripheral pulses.
Inspect posterior surfaces	• Logroll and inspect and palpate back for deformity, bleeding, lacerations, bruises. Maintain cervical spine immobilization, if appropriate.

Assess extremities for *compartment syndrome.* This occurs over several hours as pressure and swelling increase inside a muscle compartment of an extremity. This compromises the viability of the muscles, nerves, and arteries. Potential causes include crush injuries, fractures, edema, and hemorrhage.

I = Inspect Posterior Surfaces

An often overlooked part of the assessment is the back of the patient. Logroll the trauma patient while protecting the cervical spine. Up to 4 or more people with 1 person supporting the head may be needed to complete this assessment.

Acute Care and Evaluation

Once the secondary survey is complete, record all findings. Give tetanus prophylaxis based on vaccination history and the condition of

any wounds (Table 68.6).[10]

Ongoing monitoring and evaluation are critical. Provide appropriate care and assess the patient's response. The evaluation of airway patency and the effectiveness of breathing is always the highest priority. Monitor respiratory rate and rhythm, O_2 saturation, and ABGs (if ordered) to evaluate the patient's respiratory status. A portable chest x-ray is done to confirm exact placement of tubes.

Closely monitor LOC; vital signs; quality of peripheral pulses; and skin temperature, color, and moisture for key information about circulation and perfusion. When indicated, insert an indwelling catheter to decompress the bladder, monitor urine output, and check for hematuria. Notify the HCP for any changes that may occur to the patient during this ongoing assessment process.

Depending on the patient's injuries or illness, the patient may be (1) transported for diagnostic tests (e.g., CT scan, angiography) or to the operating room for immediate surgery; (2) admitted; or (3) transferred to another facility. You may go with critically ill patients on transports. You are responsible for monitoring the patient during transport, notifying the HCP should the patient's condition become unstable, and starting life-support measures as needed.

Cardiac Arrest and Targeted Temperature Management

Many patients arrive at the ED in cardiac arrest. Patients with nontraumatic, out-of-hospital cardiac arrest benefit from a combination of good chest compressions and rapid defibrillation (see Appendix A), targeted temperature management (TTM), and supportive care. TTM for at least 24 hours after the return of spontaneous circulation (ROSC) decreases mortality rates and improves neurologic outcomes in many patients.[11] It is recommended for all patients who are comatose or who do not follow commands after ROSC.

TTM, also called therapeutic hypothermia, involves 3 phases: induction, maintenance, and rewarming. The induction phase begins

in the ED. The goal core temperature is 89.6° to 96.8°F (32° to 36°C). We use a variety of methods to cool patients. These include cold saline infusions and surface cooling devices (e.g., Arctic Sun).[12] Patients need intubation, mechanical ventilation, and invasive monitoring and require continuous assessment.[12] Protocols often direct the care of these patients.

TABLE 68.6 Tetanus Vaccines and TIG for Wound Management

	Type of Wound	
Vaccination History	**Clean, Minor Wounds**	**All Other Wound**
Age 11 and Older*		
Unknown or <3 doses of tetanus toxoid-containing vaccine	Tdap and recommend catch-up vaccination	Tdap and recommend catch-up vaccination TIG
≥3 doses of tetanus toxoid-containing vaccine *and* <5 yr since last dose	No indication	No indication
≥3 doses of tetanus toxoid-containing vaccine *and* 5–10 yr since last dose	No indication	Tdap preferred (if not yet received) or Td
≥3 doses of tetanus toxoid–containing vaccine *and* >10 yr since last dose	Tdap preferred (if not yet received) or Td	Tdap preferred (if not yet received) or Td

Td, Tetanus-diphtheria toxoid absorbed; *Tdap,* tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; *TIG,* tetanus immune globulin (human).

* Pregnant women: As part of standard wound management care to prevent tetanus, a tetanus toxoid–containing vaccine might be recommended for wound management in a pregnant woman if ≥5 yr have elapsed since previous Td booster. If a Td booster is indicated for a pregnant woman, Tdap should be given.

Death in the Emergency Department

The loss of life in the ED is a stressful event. Many times, death is sudden and happens after an accident or unexpected illness (e.g.,

myocardial infarction [MI]). Sudden death is by its nature unexpected and thus shocking for family and friends.[13] It is important for you to identify and manage your feelings about sudden death so you can help them begin the grieving process (see Chapter 9).

You play a key role in providing comfort. Provide a private area for them to say goodbye, and, if appropriate, arrange for a visit from a chaplain. Assist the family by collecting the personal belongings and making mortuary arrangements. At times, you may need to contact the medical examiner or coroner. An autopsy may be done at the family's request, or if death occurred within 24 hours of ED admission, from suspected trauma or violence, or in an unusual way.

Many patients who die in the ED could potentially be candidates for *non–heart-beating donation*. We can harvest certain tissues and organs (e.g., corneas, heart valves, skin, bone, and kidneys) from patients after death. *Organ procurement organizations* aid in screening potential donors, counseling donor families, obtaining informed consent, and harvesting organs from patients who are on life support or who die in the ED.[14] Approaching caregivers about donation after an unexpected death can be distressing to both the staff and caregivers. However, for many, the act of donation may be the first positive step in the grieving process.

Gerontologic Considerations: Emergency Care

People older than 65 account for 16% of all ED visits.[15] Regardless of a patient's age, aggressive interventions are provided for all injuries or illnesses unless the patient has a preexisting terminal illness, an extremely low chance for survival, or an advance directive indicating a different course of action.

Understanding the physiologic and psychosocial aspects of aging will improve the care delivered to older adults in the ED (see Chapter 5). Many older adults dismiss their symptoms as simply "normal for their age." It is important to fully explore any complaint by an older adult.

The older population is at high risk for injury because of the many changes that occur with aging. Falls are the leading cause of injury.[16] The most common causes of falls in older adults are generalized weakness, environmental hazards, syncope, and orthostatic hypotension. When assessing a patient who has fallen, determine whether the physical findings may have caused the fall or are due to the fall itself. For example, a patient may come to the ED with acute confusion. The confusion may be due to a stroke that caused the patient to fall. Or, the patient may have a head injury because of a fall from tripping on a rug.

Environmental Emergencies

Increased interest in outdoor activities, such as running, cycling, skiing, and swimming, has increased the number of environmental emergencies seen in the ED. Illness or injury may be caused by the activity, exposure to weather, or attack from various animals or humans. Specific environmental emergencies discussed in this section include heat-related emergencies, cold-related emergencies, submersion injuries, bites, stings, and envenomation.

Heat-Related Emergencies

Brief exposure to intense heat or prolonged exposure to less intense heat leads to heat stress. This occurs when thermoregulatory mechanisms, such as sweating, vasodilation, and increased respirations, cannot compensate for exposure to increased ambient temperatures. Ambient temperature is a product of environmental temperature and humidity. Strenuous activities in hot or humid environments, clothing that interferes with perspiration, high fevers, and preexisting illnesses predispose people to heat stress (Table 68.7). Table 68.8 presents the management of heat-related emergencies.

Heat Cramps

Heat cramps are severe cramps in large muscle groups fatigued by heavy work. Cramps are brief and intense and tend to occur during rest after exercise or heavy labor. Nausea, tachycardia, pallor, weakness, and profuse diaphoresis are often present. The condition is seen most often in healthy, acclimated athletes with inadequate fluid intake. Cramps resolve rapidly with rest and oral or parenteral replacement of sodium and water. Elevation, gentle massage, and analgesia minimize pain associated with heat cramps. Tell the patient to avoid strenuous activity for at least 12 hours. Discharge teaching should emphasize salt replacement during strenuous exercise in hot, humid environments. You can recommend the use of commercially prepared electrolyte solutions.

Heat Exhaustion

Prolonged exposure to heat over hours or days leads to **heat exhaustion**. This is a clinical syndrome characterized by fatigue, nausea, vomiting, extreme thirst, and feelings of anxiety. Hypotension, tachycardia, elevated body temperature, dilated pupils, mild confusion, ashen color, and profuse diaphoresis are present. Heat exhaustion usually occurs in people engaged in strenuous activity in hot, humid weather.

Always correlate fluid replacement to clinical and laboratory findings. Place a moist sheet over the patient to decrease core temperature through evaporative heat loss. Consider hospital admission for older adults, the chronically ill, or those who do not improve within 3 to 4 hours.

TABLE 68.7 Risk Factors for Heat-Related Emergencies

Alcohol

Age

- Infants
- Older adults

Environmental Conditions

- High environmental temperatures
- High relative humidity

Preexisting Illness

- Cardiovascular disease
- Cystic fibrosis
- Dehydration
- Diabetes
- Obesity
- Skin disorders (e.g., large burn scars)
- Stroke or other CNS lesion

Prescription Drugs

- Anticholinergics
- Antihistamines
- Antiparkinsonian drugs
- Antispasmodics
- β-Adrenergic blockers
- Butyrophenones
- Diuretics
- Phenothiazines
- Tricyclic antidepressants

Street Drugs

- Amphetamines
- Jimson weed
- Lysergic acid diethylamide (LSD)
- Phencyclidine (PCP)
- 3,4-Methylenedioxymethamphetamine (MDMA, Ecstasy)

Adapted from Howard PK, Steinmann RA, eds: *Sheehy's emergency nursing*, ed 6, St Louis, 2010, Mosby.

Heatstroke

Heatstroke is the most serious form of heat stress and is a medical emergency. It results from failure of the hypothalamic thermoregulatory processes. Increased sweating, vasodilation, and increased respiratory rate deplete fluids and electrolytes, specifically sodium. Eventually, sweat glands stop functioning. Core temperature increases rapidly, within 10 to 15 minutes. The brain is extremely sensitive to thermal injuries. Cerebral edema and hemorrhage may occur from direct thermal injury to the brain and decreased cerebral blood flow. Death from heatstroke is directly related to the amount of time that the patient's body temperature is high.[6] Prognosis is related to age, baseline health status, and length of exposure. Older adults and those with diabetes, chronic kidney disease, heart disease, pulmonary disease, or other physiologic compromise are particularly prone.

Interprofessional Care

Treatment focuses on stabilizing the patient's ABCs, rapidly reducing the core temperature, and monitoring for dysrhythmias. Give 100% O_2 to compensate for the patient's hypermetabolic state. Ventilation with a BVM or intubation and mechanical ventilation may be needed. Place the patient on continuous ECG monitoring and pulse oximetry.

Monitor laboratory findings. Correcting electrolyte imbalances and coagulation abnormalities is critical.

Place the patient in a cool environment. Promote evaporative cooling by removing clothing and spraying the patient with lukewarm water in front of a large fan.[6] Other cooling methods include conductive cooling (e.g., immersing the patient in a cool water bath); applying ice packs to the groins and axillae; and, in refractory cases, peritoneal or rectal lavage with iced fluids.

Table 68.8 Emergency ManagementHyperthermia

Etiology	Assessment Findings	Interventions
Environmental • **Lack of acclimatization** • **Physical exertion, especially during hot weather** • **Prolonged exposure to extreme temperatures** **Trauma** • **Head injury** • **Spinal cord injury** **Metabolic** • **Dehydration** • **Diabetes** • **Thyrotoxicosis** **Drugs** • **Amphetamines** • **Antihistamines** • **β-Adrenergic blockers** • **Diuretics** • **Phenothiazines** • **Tricyclic antidepressants** **Other** • **Alcohol** • **Cardiovascular disease** • **CNS disorders**	**Heat Cramps** • Severe muscle contractions in exerted muscles • Thirst **Heat Exhaustion** • Altered mental status (e.g., anxiety) • Ashen, pale skin • Extreme thirst • Fatigue, weakness • Hypotension • Profuse sweating • Tachycardia • Temperature (99.6° to 105.8°F [37.5° to 41°C]) • Weak, thready pulse Heatstroke • Altered mental status (ranging from confusion to coma) • Hot, dry skin • Hypotension • Tachycardia • Tachypnea • Temperature >105.8°F (41°C) • Weakness	**Initial** • Manage and maintain ABCs. • Provide high-flow O_2 via nonrebreather mask or BVM. • Establish IV access and begin fluid replacement for significant heat injury. • Place patient in a cool environment. • For patient with heatstroke, start rapid cooling measures: remove patient's clothing, place wet sheets over patient, and place in front of fan; immerse in a cool water bath; give cool IV fluids or lavage with cool fluids. • Obtain 12-lead ECG. • Obtain blood for electrolytes and CBC. • Insert urinary catheter. Ongoing Monitoring • Monitor ABCs, temperature and vital signs, level of consciousness. • Monitor heart rhythm, O_2 saturation, and urine output. • Replace electrolytes as needed. • Monitor urine for development of myoglobinuria. • Monitor clotting studies for development of disseminated intravascular coagulation.

Closely monitor the patient's temperature and control shivering. Shivering increases core temperature due to the heat generated by muscle activity. This complicates cooling efforts. The HCP may order

drugs to control shivering.

Heat stroke places the patient at risk for kidney injury due to *rhabdomyolysis*. It is a serious syndrome caused by the breakdown of skeletal muscle. Carefully monitor the urine for color, amount, pH, and myoglobin.

Patient and caregiver teaching focuses on how to avoid future problems. Stress the importance of proper hydration during hot weather and physical exercise. Teach patients the early signs of and interventions for heat-related stress.

Cold-Related Emergencies

Cold injuries may be localized (e.g., frostbite) or systemic (e.g., hypothermia). Contributing factors include age, duration of exposure, environmental temperature, homelessness, preexisting conditions, drugs that suppress shivering, and alcohol intoxication. Smokers have an increased risk for cold-related injury because of the vasoconstrictive effects of nicotine.

Frostbite

Frostbite is true tissue freezing that results in the formation of ice crystals in the tissues and cells. Peripheral vasoconstriction is the first response to cold stress and results in a decrease in blood flow and vascular stasis. As cell temperature decreases, and ice crystals form in intracellular spaces, the organelles are damaged, and the cell membrane destroyed. This results in edema.

Depth of frostbite depends on ambient temperature, length of exposure, type and condition (wet or dry) of clothing, and contact with metal surfaces. Other factors that affect severity include skin color (those with dark skin are more prone to frostbite), lack of acclimatization, previous episodes, exhaustion, and poor peripheral vascular status.

Superficial frostbite involves the skin and subcutaneous tissue, usually the ears, nose, fingers, and toes. The skin appearance ranges

from waxy pale yellow to blue to mottled. The skin feels crunchy and frozen. The patient may report tingling, numbness, or a burning sensation. Handle the area carefully and never squeeze, massage, or scrub the injured tissue because it is easily damaged. Swelling will occur with thawing. So, remove clothing and jewelry as they may constrict the extremity and decrease circulation.

Immerse the affected area in circulating water that is temperature controlled (98.6° to 104°F) [37° to 40°C]). Use warm soaks for the face. The patient often has a warm, stinging sensation as tissue thaws. Blisters form within a few hours (Fig. 68.2). The blisters should be debrided, and a sterile dressing applied.[17] Avoid heavy blankets and clothing because friction and weight can lead to sloughing of damaged tissue. Rewarming is extremely painful. Residual pain may last weeks or even years. Give analgesia and tetanus prophylaxis as appropriate. Evaluate the patient with superficial frostbite for systemic hypothermia.

Deep frostbite involves muscle, bone, and tendon. The skin is white, hard, and insensitive to touch. The area has the appearance of deep thermal injury with mottling gradually progressing to gangrene (Fig. 68.3). Immerse the affected extremity in a temperature-controlled, circulating water bath (98.6° to 104°F [37° to 40°C]) until flushing occurs distal to the injured area.

FIG. 68.2 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitted boot.

FIG. 68.3 Gangrenous necrosis 6 weeks after the frostbite injury shown in Fig. 68.2.
Courtesy Cameron Bangs, MD. From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine,* ed 2, St Louis, 2003, Mosby.

After rewarming, elevate the extremity to reduce edema. Significant edema may begin within 3 hours, with blistering in 6 hours to days. IV analgesia is needed in severe frostbite because of the pain associated with tissue thawing. All patients should start on nonsteroidal antiinflammatory drugs (NSAIDs) because of their dual affect as an analgesic and antiinflammatory. Give tetanus prophylaxis and evaluate the patient for systemic hypothermia.

Amputation may be needed if the injured area is untreated or treatment is unsuccessful. It may take as long as 90 days to determine the final necrotic area. The patient may be admitted to the hospital for observation with bed rest, elevation of the injured part, and prophylactic antibiotics if the wound is at risk for infection.

Hypothermia

Hypothermia is a core temperature below 95°F (35°C).[6] It occurs when heat produced by the body cannot compensate for heat lost to the environment. Most body heat is lost as radiant energy, with the greatest loss from the head, thorax, and lungs (with each breath). Wet clothing increases evaporative heat loss to 5 times greater than normal. Immersion in cold water (e.g., drowning) increases evaporative heat loss to 25 times greater than normal. Environmental exposure to freezing temperatures, cold winds, and wet terrain plus physical exhaustion, inadequate clothing, and inexperience predisposes people to hypothermia. Older adults are prone to hypothermia because of decreased body fat, decreased energy reserves, decreased basal metabolic rate, decreased shivering response, chronic medical conditions, and drugs that alter body defenses. Peripheral vasoconstriction is the body's first attempt to conserve heat. As cold temperatures persist, shivering and movement are the body's only mechanisms for producing heat.

TABLE 68.9 Emergency ManagementHypothermia

Etiology	Assessment Findings	Interventions
Environmental • **Inadequate clothing for environmental temperature** • **Prolonged exposure to cold** • **Prolonged immersion or near-drowning** **Metabolic** • **Hypoglycemia** • **Hypothyroidism** **Health Care Associated** • **Administration of neuromuscular blocking agents** • **Blood administration** • **Cold IV fluids** • **Inadequate warming or rewarming in the ED or operating room** **Other** • **Alcohol** • **Barbiturates** • **Phenothiazines** • **Shock** • **Trauma**	• Core body temperature: • *Mild hypothermia:* 93° to 95°F (33.9° to 35°C) • *Moderate hypothermia:* 86° to 93°F (30° to 33.9°C) • *Severe hypothermia:* <86°F (30°C) • Shivering, decreased or absent at core body temperatures ≤86°F (30°C) • Altered mental status (ranging from confusion to coma) • Areflexia (absence of reflexes) • Blue, white, or frozen extremities • Cyanotic, pale skin • Dysrhythmias: bradycardia, atrial fibrillation, ventricular fibrillation, asystole • Fixed, dilated pupils • Hypotension • Hypoventilation	Initial • Remove patient from cold environment. • Manage and maintain ABCs. • Provide high-flow O_2 via nonrebreather mask or BVM. • Anticipate intubation for decreased or absent gag reflex. • Establish IV access with 2 large-bore catheters for fluid resuscitation. • Rewarm patient: • *Passive:* Remove wet clothing, apply dry clothing and warm blankets, use radiant lights. • *Active external:* Apply heating devices (e.g., air or fluid-filled warming blankets), use warm water immersion. • *Active internal:* Provide warmed IV fluids; heated, humidified O_2. Peritoneal lavage with warmed fluids. Extracorporeal circulation (e.g., cardiopulmonary bypass, rapid fluid infuser, hemodialysis). • Obtain 12-lead ECG. • Anticipate need for defibrillation. • Warm central trunk first in patients with severe hypothermia to limit rewarming shock. • Assess for other injuries. • Keep patient's head covered with warm, dry towels or stocking cap to limit loss of heat. • Treat patient gently to avoid increased cardiac irritability. Ongoing Monitoring • Monitor ABCs, temperature, level of consciousness, vital signs • Monitor O_2 saturation, heart rate and rhythm. • Monitor electrolytes, glucose.

Assessment findings are variable and depend on core temperature (Table 68.9). Patients with *mild hypothermia* (93° to 95°F [33.9° to 35°C]) have shivering, lethargy, confusion, rational to irrational behavior, and minor heart rate changes. *Moderate hypothermia* (86° to 93°F [30° to 33.9°C]) causes rigidity, bradycardia, slowed respiratory rate, BP obtainable only by Doppler, metabolic and respiratory acidosis, and hypovolemia. Shivering decreases or disappears at core temperatures of 86°F (30°C).[6]

As core temperature drops, metabolic rate decreases 2 to 3 times. The cold myocardium is extremely irritable, making it vulnerable to dysrhythmias (e.g., atrial and ventricular fibrillation). Decreased renal blood flow decreases glomerular filtration rate, which impairs water reabsorption and leads to dehydration. The hematocrit increases as intravascular volume decreases. Cold blood becomes thick and acts as a thrombus, placing the patient at risk for stroke, MI, pulmonary emboli, and renal failure. Decreased blood flow leads to hypoxia, anaerobic metabolism, lactic acid accumulation, and metabolic acidosis.

Severe hypothermia (below 86°F [30°C]) makes the person appear dead and is a potentially life-threatening situation. Metabolic rate,

heart rate, and respirations are so slow that they may be hard to detect. Reflexes are absent, and the pupils fixed and dilated. Profound bradycardia, ventricular fibrillation, or pulseless electrical activity may be present. Effort is made to try to warm the patient to at least 86°F (30°C) before the person is pronounced dead. The cause of death is usually refractory ventricular fibrillation.

Interprofessional Care

Treatment focuses on managing and maintaining ABCs, rewarming the patient, correcting dehydration and acidosis, and treating dysrhythmias. Mildly hypothermic patients may be rewarmed with passive and active external measures since their risk for dysrhythmia is low. Those with more severe hypothermia need active internal rewarming measures.

Carefully monitor core temperature during rewarming procedures. Rewarming places the patient at risk for *afterdrop,* a further drop in core temperature. This occurs when cold peripheral blood returns to the central circulation. Rewarming shock can produce hypotension and dysrhythmias. Thus patients with moderate to severe hypothermia should have the core warmed before the extremities. Discontinue active rewarming once the core temperature reaches 90° to 95° F (32.2° to 35° C).

Patient teaching focuses on how to avoid future cold-related problems. Essential information includes dressing in layers for cold weather, covering the head, carrying high-carbohydrate foods for extra calories, and developing a plan for survival should an injury occur when in an extreme environment.

Check Your Practice

You are working in the ED when the paramedics arrive with a patient who was found lying on the sidewalk outside the downtown bus station. He is wearing only a lightweight shirt and pants. The outdoor temperature is 12°F (–11.1°C). The patient is unresponsive. Initial

vital signs are as follows: rectal temperature = 89.5°F (31.9°C), HR = 38, RR = 8, BP (by Doppler) = 86 mm Hg.

- What are your priority interventions for this patient?

Submersion Injuries

Submersion injury results when a person becomes hypoxic from submersion in a liquid, usually water.[6] Around 3500 deaths from drowning occur each year in the United States. Most of the victims are children younger than 5 years of age or boys and men between ages 15 and 25.[18] The main risk factors for submersion injury include inability to swim, use of alcohol or drugs, trauma, seizures, hypothermia, stroke, and child neglect. Aggressive resuscitation efforts (e.g., airway and ventilation management), especially in the prehospital phase, improve survival of drowning victims.

Drowning is the process of experiencing respiratory impairment after submersion in water or other fluid. Submersion in cold water (below 32°F [0°C]) may slow the progression of hypoxic brain injury.

Most drowning victims do not aspirate any liquid due to laryngospasm. If liquid is aspirated, it is in small amounts. Drowning victims who do aspirate water develop pulmonary edema, which can cause acute respiratory distress syndrome (see Chapter 67).

The osmotic gradient caused by aspirated fluid leads to fluid imbalances in the body (Fig. 68.4). Hypotonic fresh water is rapidly absorbed into the circulatory system through the alveoli. Fresh water is often contaminated with chlorine, mud, or algae. This causes the breakdown of lung surfactant, fluid seepage, and pulmonary edema.

Hypertonic saltwater draws fluid from the vascular space into the alveoli, impairing alveolar ventilation and causing hypoxia. The body tries to compensate for hypoxia by shunting blood to the lungs. This results in increased pulmonary pressures and deteriorating respiratory status. More and more blood is shunted through the alveoli. Since the blood is not adequately oxygenated, and hypoxemia worsens. This can result in cerebral injury, edema, and brain death.

Interprofessional Care

Treatment focuses on correcting hypoxia and fluid imbalances, supporting basic physiologic functions, and rewarming when hypothermia is present. Initial evaluation involves assessment of airway, cervical spine, breathing, and circulation (Table 68.10). Mechanical ventilation with positive end-expiratory pressure or continuous positive airway pressure can improve gas exchange across the alveolar-capillary membrane when significant pulmonary edema is present. Ventilation and oxygenation are the main techniques for treating respiratory failure (see Chapters 65 and 67).

Deterioration in neurologic status suggests cerebral edema, worsening hypoxia, or profound acidosis. Drowning victims may have head and neck injuries that cause changes in the LOC. Complications can develop in patients who are free of symptoms immediately after the drowning episode. Consequently, observe all victims of drowning in a hospital for a minimum of 23 hours. Additional observation is needed for patients with co-morbidities.

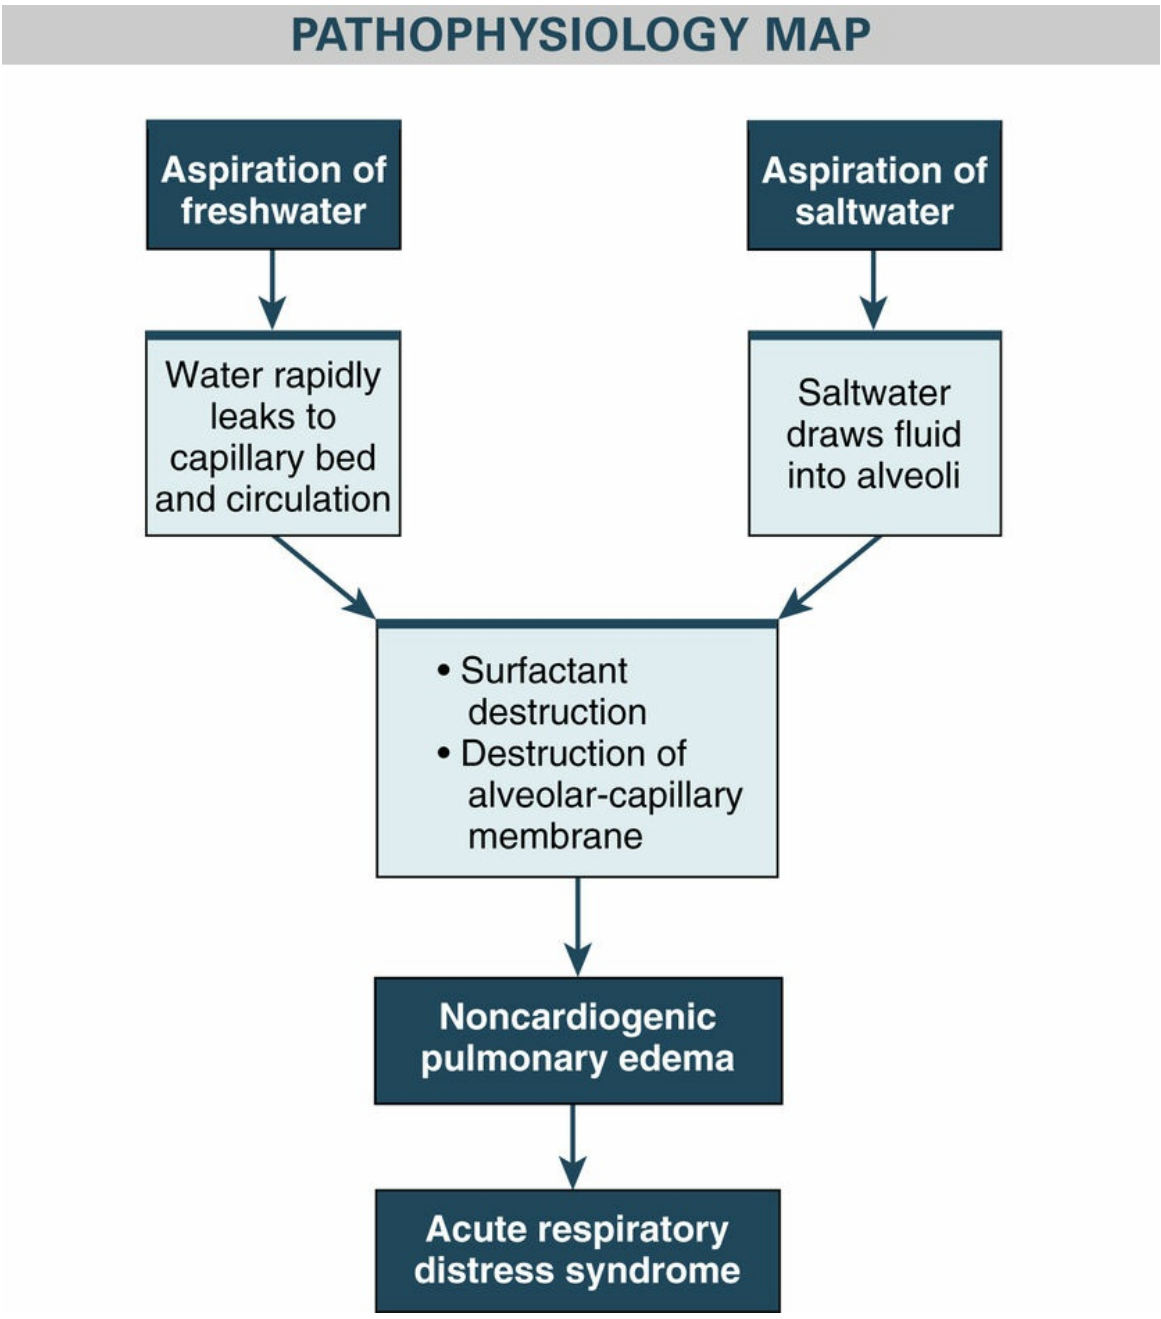

FIG. 68.4 Pathophysiology of submersion injury.

Patient teaching focuses on water safety and how to reduce the risks for drowning. Remind patients and caregivers to lock all swimming pool gates; use life jackets on all watercrafts, including inner tubes and rafts; and learn water survival skills. Emphasize the dangers of combining alcohol and drugs with swimming and other water sports.

Stings and Bites

Animals, spiders, snakes, and insects cause injury and even death by biting or stinging. Morbidity is a result of either direct tissue damage or lethal toxins. Direct tissue damage is a product of animal size, characteristics of the animal's teeth, and strength of the jaw. Tissue is lacerated, crushed, or chewed, while teeth, fangs, stingers, spines, or tentacles release toxins that have local or systemic effects. Death associated with animal bites is due to blood loss, allergic reactions, or lethal toxins. Injuries caused by select insects, ticks, animals, and humans are described here.

Hymenopteran Stings

The *Hymenoptera* family includes bees, yellow jackets, hornets, wasps, and fire ants. Stings can cause mild discomfort or life-threatening anaphylaxis (see Chapter 66). Venom may be cytotoxic, hemolytic, allergenic, or vasoactive. Symptoms may begin immediately or be delayed up to 48 hours. Reactions are more severe with multiple stings. Most hymenopterans sting repeatedly. However, the domestic honey bee stings only once, usually leaving a barbed stinger with an attached venom sac in the skin so that venom release continues.

African honey bees (killer bees) look like domestic bees. If threatened, these bees aggressively swarm and can repeatedly sting their victims. These attacks can be fatal.

TABLE 68.10 Emergency ManagementSubmersion Injuries

Etiology	Assessment Findings	Interventions
• **Entrapment or entanglement with objects in water** • **Inability to swim or exhaustion while swimming** • **Loss of ability to move secondary to trauma, stroke, hypothermia, MI** • **Poor judgment due to alcohol or drugs** • **Seizure while in water**	**Respiratory** • Cough with pink-frothy sputum • Crackles, rhonchi • Cyanosis • Dyspnea • Respiratory distress • Respiratory arrest **Cardiac** • Bradycardia • Dysrhythmia • Hypotension • Tachycardia • Cardiac arrest **Other** • Exhaustion • Coma • Coexisting illness (e.g., MI) or injury (e.g., cervical spine injury) • Core temperature slightly elevated or below normal, depending on water temperature and length of submersion • Panic	Initial • Manage and maintain ABCs. • Assume cervical spine injury in all drowning victims and stabilize or immobilize cervical spine. • Provide 100% O_2 via nonrebreather mask or BVM. • Anticipate need for intubation and mechanical ventilation if airway is compromised (e.g., absent gag reflex). • Establish IV access with 2 large-bore catheters for fluid resuscitation and infuse warmed fluids, if appropriate. • Obtain 12-lead ECG. • Assess for other injuries. • Remove wet clothing and cover with warm blankets. • Obtain temperature and begin rewarming, if needed. • Obtain cervical spine and chest x-rays. • Insert gastric tube and urinary catheter. **Ongoing Monitoring** • Monitor ABCs, vital signs, level of consciousness. • Monitor O_2 saturation, heart rate and rhythm. • Monitor temperature and maintain normothermia. • Monitor for signs of acute respiratory failure.

BVM, Bag-valve-mask.

Safety Alert

Hymenopteran Stings

- Remove the stinger using a scraping motion with thin, flat object, like a fingernail, knife, or credit card.
- Do not use tweezers because they may squeeze the stinger and release more venom.
- Remove rings, watches, or any restrictive clothing around the sting site.

Manifestations of mild reactions include stinging, burning, swelling, and itching. More severe reactions may present with edema, headache, fever, syncope, malaise, nausea, vomiting, wheezing, bronchospasm, laryngeal edema, and hypotension. Treatment depends on the severity of the reaction. Treat mild reactions with elevation, cool compresses, antipruritic lotions, and oral antihistamines. More severe reactions require IM or IV antihistamines, subcutaneous epinephrine, and corticosteroids. Chapter 13 discusses

allergic reactions and related patient teaching.

Snake Bites

There are more than 45,000 snakebites each year in the United States. *Envenomation* (poisoning by venom) occurs in only 8000 cases, with only 5 to 10 deaths each year.[19] The 2 families of venomous snakes found in the United States are Crotalidae or pit vipers (rattlesnakes, copperheads, cottonmouths) and Elapidae (coral snakes). Almost all the venomous bites are from pit vipers.

Snake venom may be hemolytic, neurotoxic, vascular toxic, or any combination of these. When bites occur, you will see fang or puncture marks. The patient often has severe pain at the site. There may be swelling, discoloration and blistering. If moderate envenomation has occurred, the patient will have paresthesias, lymphadenopathy, and nausea and vomiting. Treatment includes wound care and tetanus prophylaxis. Immobilize the affected extremity. Remove potentially constricting clothing. Most bites are minor and resolve without antivenom therapy. Patients with suspected envenomation are observed for at least 8 hours to ensure no life- or limb-threatening symptoms develop.

Manifestations of severe envenomation include profound edema, tachycardia, blurred vision, headache, chills, paresthesias, hypotension, and muscle twitching. The patient may report a metallic taste in the mouth. As symptoms progress, pulmonary edema, coagulopathy, thrombocytopenia, and hemorrhage may develop. Treatment of severe envenomation requires close patient monitoring. The ABCs are the most vital part of nursing management. Limb circumference and the advancing edema should be marked and monitored every 30 minutes. Anticipate fluid resuscitation, respiratory support, monitoring of laboratory results, and antivenom therapy. On rare occasions, the patient will need a fasciotomy.[6] The need to give antivenom is made in conjunction with a snake venom expert. Antivenom is given only if symptom progression occurs and platelet and coagulation studies are abnormal.

Snakebites from exotic snake species are primarily neurotoxic. They result in autonomic dysfunction, paralysis, and dysrhythmias. The bite should be discussed with your regional poison control center as there is specific antivenom therapy, often obtained from a zoo, for each species.

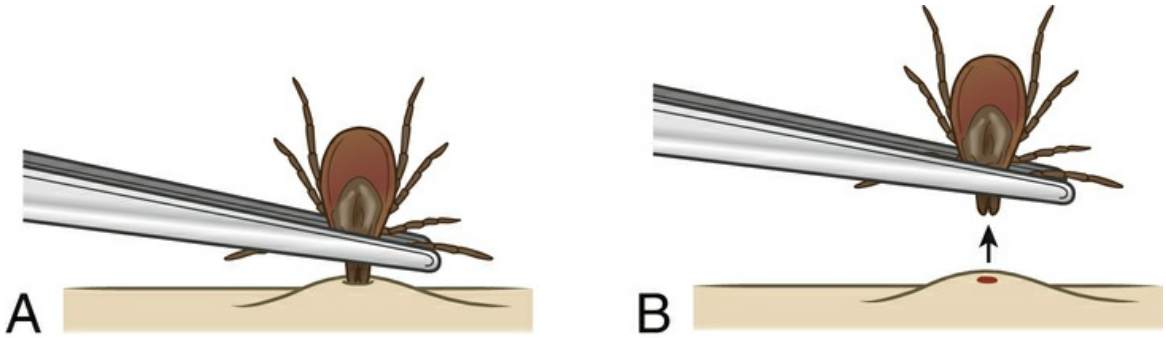

FIG. 68.5 Tick removal. **A,** Use tweezers to grasp the tick close to the skin. **B,** With a steady motion, pull the tick's body up and away from the skin. Do not be alarmed if the tick's mouthparts stay in the skin. Once the mouthparts are removed from the rest of the tick, it can no longer transmit disease.

Tick Bites

Ticks live throughout the United States. Specific types are more prevalent in certain regions. Tick-borne pathogens can be passed to humans by the bite of an infected tick. Common tick-borne illnesses include Lyme disease, Rocky Mountain spotted fever, anaplasmosis, Southern tick-associated rash illness, tick-borne relapsing fever, and tularemia.

Ticks transmit pathogens that cause disease through their feeding process. The infected tick attaches to its host and can slowly feed for up to several days. During this time, saliva from the tick can be transferred to the host. Tick saliva may harbor pathogens acquired by the tick from a prior host. The tick should be removed as soon as possible to stop the flow of saliva. Use forceps or tweezers to grasp the tick close to the point of attachment and pull upward in a steady

motion (Fig. 68.5). After you remove the tick, clean the skin with soap and water. Do not use a hot match, petroleum jelly, nail polish, or other products to remove the tick. These measures may cause a tick to salivate, thus increasing the risk for infection.[20]

Lyme disease is the most common tick-borne disease in the United States. In 2016, more than 22,500 confirmed and 37,000 probable cases were reported to the CDC.[20] It is caused by the bacterium *Borrelia burgdorferi* that lives on the tick. In most cases, the tick must be attached for at least 36 hours to transmit the bacterium. Symptoms usually appear in about 7 days. The first stage begins with flu-like symptoms (e.g., headache, stiff neck, fatigue). Some patients may develop a characteristic bull's-eye rash. This is a circular area of redness 5 cm or more in diameter. Treatment at this stage includes doxycycline, cefuroxime, or amoxicillin.[20] The rash, if it develops, will disappear even if the patient is not treated.

Monoarticular arthritis, meningitis, and neuropathies occur days or weeks after the initial manifestations. Treatment at this stage involves IV ceftriaxone or penicillin. Chronic arthritis, heart disease, and peripheral nerve problems occur with the later stage of the disease. These illnesses can last several months to years after the initial skin lesion. (Chapter 64 discusses Lyme disease.)

Rocky Mountain spotted fever is caused by *Rickettsia rickettsia*. It is a bacterium that is spread to humans by the ixodid tick. The incubation period is 2 to 14 days. A pink, macular rash appears on the palms, wrists, soles, feet, and ankles within 10 days of exposure. Other symptoms include fever, chills, malaise, muscle pain, and headache. It is hard to diagnosis in the early stages. Without treatment, the disease can be fatal. Antibiotic therapy with doxycycline is the treatment of choice.

Animal and Human Bites

Every year more than 5 million animal bites are reported in the United States. Animal bites from dogs and cats are most common. Wild or domestic rodents (e.g., squirrels, hamsters) follow as the third most

common offenders. The few bite deaths (15 to 20) are mostly from dogs. The greatest problems associated with animal bites are infection and mechanical destruction of skin, muscle, tendons, blood vessels, and bone. The bite may cause a simple laceration or be associated with crush injury, puncture wound, or tearing of multiple layers of tissue (Fig 68.6). The severity of injury depends on animal size, victim size, and anatomic location of the bite. Children are at greatest risk.

FIG. 68.6 Dog bite wound.
From Mannion C, Kanatas A, Telfer MR: One dog bite too far, *Brit J Oral Max Surg* 49:159, 2011.

Dog bites usually occur on the extremities. Facial bites are common in small children. Cat bites result in deep puncture wounds. They can involve tendons and joint capsules. There is a greater risk for infection than with dog bites. Septic arthritis, osteomyelitis, and tenosynovitis can occur. The most common infectious organisms from dog and cat bites are the *Pasteurella* species (e.g., *Pasteurella multocida*). Most healthy cats and dogs carry this organism in their mouths.

The human jaw has great crushing ability, causing laceration, puncture, crush injury, soft tissue tearing, and even amputation (Fig. 68.7). Hands, fingers, ears, nose, vagina, and penis are the most common sites of human bites. Often these injuries are due to violence or sexual activity. There is a high risk for infection from oral bacterial flora, most often *Staphylococcus aureus, Streptococcus* organisms, and hepatitis virus. Infection rates are as high as 50% when victims do not seek medical care within 24 hours of injury.

Interprofessional Care

Initial treatment for animal and human bites includes cleaning, copious irrigation, debridement, tetanus prophylaxis, and analgesics as needed. Prophylactic antibiotics are used for animal and human bites at risk for infection, such as wounds over joints, those older than 6 to 12 hours, puncture wounds, and bites of the hand or foot. People at greatest risk for infection are infants, older adults, immunosuppressed patients, patients with substance or alcohol use disorder, people living with diabetes, or those taking corticosteroids.

Leave puncture wounds open. Splint wounds over joints. Lacerations may be loosely sutured. Plastic surgery consultation may be needed for disfiguring facial wounds. The patient often receives prophylactic antibiotics. Report animal and human bites to the police as required.

FIG. 68.7 Human bite injury.
From Stevens MR, Emam HA, Cunningham L: *Oral & maxillofacial trauma,* ed 4, St Louis, 2013, Elsevier.

Consider *rabies postexposure prophylaxis* in the management of all animal bites. Rabies is caused by a neurotoxic virus in the saliva of an infected animal. Most rabies carriers are wild animals, like raccoons, skunks, bats, foxes, and coyotes. Rabies is usually transmitted through the saliva via a bite by the infected animal. If the saliva from the infected animal has come in contact with its claws, theoretically rabies may be transmitted through a scratch. The virus spreads through the central nervous system (CNS) via peripheral nerves. People who develop rabies may have flu-like symptoms, confusion, paresthesias, or numbness resulting in death.

Consider rabies exposure if an animal attack was not provoked, involves a wild animal, or involves a domestic animal not immunized against rabies. Always provide postexposure vaccinations when the animal is not found or a wild animal causes the bite. The series of 4

injections of rabies vaccine (human diploid cell rabies vaccine [HDCV, Imovax Rabies]) are given on days 0, 3, 7, and 14 to provide active immunity.[21] Give an initial, weight-based dose of rabies immune globulin (RIG [HyperRab S/D]) to provide passive immunity at the same time as the first dose of vaccine.

Since rabies is nearly always fatal, management efforts are directed at preventing the transmission and onset of the disease. Although death from rabies is significant worldwide, it is rare in the United States. Rabies vaccine is encouraged for persons who travel globally, since it is a serious world health concern. Notify your local health department for any suspected cases.

Drug Alert

Rabies Postexposure Prophylaxis

- If possible, give the calculated dose of RIG via infiltration around the wound edges.
- Give any remaining volume of RIG IM at a site distant from the vaccine site (e.g., gluteal site for bite wounds on the arm).
- Give the HDCV IM in the deltoid.

Poisonings

A poison is any chemical that harms the body. More than 5 million cases of human poisonings occur each year in the United States. Poisonings can be accidental, occupational, recreational, or intentional. Natural or manufactured toxins can be ingested, inhaled, injected, splashed in the eye, or absorbed through the skin. Chapter 10 discusses other poisonings related to the use of drugs, such as amphetamines, opioids, and hallucinogens. Poisoning also may be due to toxic plants or contaminated foods. (Chapter 41 discusses food poisoning.)

Severity of the poisoning depends on type, concentration, and route of exposure (Table 68.11). Toxins can affect every tissue of the body, so symptoms can be seen in any body system. Specific management of toxins involves decreasing absorption, enhancing elimination, and implementing toxin-specific interventions. Consult the local poison control center (available 24 hours a day) for the most current treatment protocols for specific poisons.[22]

Decontamination takes priority over all interventions except those needed for life support. Wear *personal protective equipment (PPE)* for decontamination to prevent secondary exposure. In some cases, decontamination is done by those specially trained in hazardous material decontamination before the patient arrives at the hospital and again at the hospital, if needed.

Skin and ocular decontamination involves removing the toxins from skin and eyes using copious amounts of water or saline. Most toxins can be safely removed with water or saline. As a rule, brush dry substances from the skin and clothing before using water. Do not remove powdered lime or mustard gas with water. Lime should just be brushed off. Water mixes with mustard gas and releases chlorine gas.

Under the guidance of the Poison Control Center, binding agents, such as activated charcoal, cathartics, whole-bowel irrigation, hemodialysis, urine alkalinization, chelating agents, and antidotes, may be given to increase the elimination of poisons.[22] Focus patient teaching for toxic emergencies on how the poisoning occurred. Arrange for an evaluation and follow-up by a mental health professional for all patients who have poisoning because of a suicide attempt or substance use.

Many health care workers (e.g., nurses, housekeepers) are at risk for exposure to hazardous materials (e.g., antineoplastic drugs, cleaning agents). Always consult the Material Safety Data Sheet (required by the Occupational Health and Safety Administration [OSHA]) for specific information about hazardous agents in the workplace. OSHA should evaluate all poisoning related to a workplace hazard.

Violence

Violence is the acting out of the emotions of fear and/or anger to cause harm to someone or something. It may be the result of organic disease (e.g., temporal lobe epilepsy), psychosis (e.g., schizophrenia), or criminal behavior (e.g., assault, murder). The patient cared for in the ED may be the victim or the perpetrator of violence. Violence can take place in a variety of settings, including the home, community, and workplace.

EDs are high-risk areas for *workplace violence*.[23] Measures to protect staff include the use of on-site security personnel and police officers, metal detectors, surveillance cameras, self-defense training, and locked access doors. The ENA recommends comprehensive workplace violence prevention plans be in place in every ED.[24]

Awareness of *family and intimate partner violence* (IPV) along with the possibility of a patient being a victim or perpetrator of human trafficking is a critical part of the ED nurse's role. IPV and human trafficking are patterns of coercive behavior in relationships that involve fear, humiliation, intimidation, neglect, or intentional physical, emotional, financial, or sexual injury (see Chapter 53 for information on sexual assault). Trafficking can involve being kidnapped or even being sold by family. It may also involve coercion of runaways into a "safe" situation that results in anything but safety.

TABLE 68.11 Common Poisons

Poison	Manifestations	Treatment
acetaminophen (Tylenol)	*Phase 1* (within 24 hr of ingestion): Malaise, diaphoresis, nausea and vomiting *Phase 2* (24–28 hr after ingestion): Right upper quadrant pain, ↓ urine output, ↓ nausea, increase in LFTs *Phase 3* (72–96 hr after ingestion): Nausea and vomiting, malaise, jaundice, hypoglycemia, enlarged liver, possible coagulopathies, including DIC *Phase 4* (7-8 days after ingestion): Recovery, resolution of symptoms or permanent liver damage, LFT results remain high	Activated charcoal, *N*-acetylcysteine (oral form may cause vomiting, IV form can be used)
Acids and Alkalis		
• ***Acids:*** **Toilet bowl cleaners, antirust compounds** • ***Alkalis:*** **Drain cleaners, dishwashing detergents, ammonia**	Excess salivation, dysphagia, epigastric pain, pneumonitis; burns of mouth, esophagus, and stomach	Immediate dilution (water, milk), corticosteroids (for alkali burns), induced vomiting is contraindicated
• **Aspirin and aspirin-containing drugs**	Tachypnea, tachycardia, fever, seizures, pulmonary edema, occult bleeding or hemorrhage, metabolic acidosis	Activated charcoal, gastric lavage, urine alkalinization, hemodialysis for severe acute ingestion, intubation and mechanical ventilation, supportive care
Bleaches	Irritation of lips, mouth, and eyes, superficial injury to esophagus; chemical pneumonia and pulmonary edema	Washing of exposed skin and eyes, dilution with water and milk, gastric lavage, prevention of vomiting and aspiration
Carbon monoxide	Dyspnea, headache, tachypnea, confusion, impaired judgment, cyanosis, respiratory depression	Remove from source, apply 100% O_2 via nonrebreather mask, BVM, or intubation and mechanical ventilation; consider hyperbaric O_2 therapy
Cyanide	Almond odor to breath, headache, dizziness, nausea, confusion, hypertension, bradycardia followed by hypotension and tachycardia, tachypnea followed by bradypnea and respiratory arrest	Amyl nitrate (nasally), IV sodium nitrate, IV sodium thiosulfate, supportive care
Ethylene glycol	Sweet aromatic odor to breath, nausea and vomiting, slurred speech, ataxia, lethargy, respiratory depression	Activated charcoal, gastric lavage, supportive care
Iron	Vomiting (often bloody), diarrhea (often bloody), fever, hyperglycemia, lethargy, hypotension, seizures, coma	Gastric lavage, chelation therapy (deferoxamine [Desferal])
NSAIDs	Gastroenteritis, abdominal pain, drowsiness, nystagmus, hepatic and renal damage	Activated charcoal, gastric lavage, supportive care
Tricyclic antidepressants (e.g., amitriptyline)	*In low doses:* Anticholinergic effects, agitation, hypertension, tachycardia *In high doses:* CNS depression, dysrhythmias, hypotension, respiratory depression	Multidose activated charcoal, gastric lavage, serum alkalinization with sodium bicarbonate, intubation and mechanical ventilation, supportive care; never induce vomiting
Alcohol, barbiturates, benzodiazepines, cocaine, hallucinogens, stimulants	See Chapter 10	See Chapter 10

BVM, Bag-valve-mask; *DIC*, disseminated intravascular coagulation; *LFT*, liver function test.

IPV is found in all cultures, socioeconomic groups, age-groups, and genders. Although men can be victims of family violence and IPV, most victims are women, children, and older adults. Each year, more than 5 million women and 3 million men are treated in EDs for *battery* (assault) by spouses, caregivers, or persons known to them. IPV is most common among women of reproductive age.[25]

In the ED, screening for family violence and IPV (e.g., Do you feel safe at home? Is anyone hurting you?) is required. Barriers to effective screening include lack of privacy, fear of offending the patient, lack of

time, and discomfort with the topic. Developing and implementing policies, procedures, and staff education programs improve screening practices.

With over 100 million people worldwide affected by human trafficking, it is likely that the ED nurse will come in contact with either a victim or perpetrator of human trafficking. Interviews with former victims suggest that over 85% had come in contact with the health care system at some time during their captivity.[26] ED nurses are uniquely positioned to help identify and report a trafficking victim or perpetrator to the appropriate authorities.

Be sensitive when gathering information about suspected abuse and trafficking as it may have potential for increasing the patient's risk. Start appropriate interventions for patients who you suspect or find are victims of abuse or trafficking. This includes making referrals, notifying appropriate agencies, providing emotional support, and informing victims about their options. The ENA encourages ED nurses to become certified *sexual assault nurse examiners* (SANEs). SANEs provide expert emergency care, collect and document evidence, take part in staff and community education, and advocate for sexual assault and rape victims.[27]

Agents of Terrorism

Terrorism involves overt actions, such as the dispensing of nuclear, biologic, or chemical (NBC) agents as weapons, for the express purpose of causing harm. Prompt recognition and identification of potential health hazards are essential in the preparedness of health care professionals.

Biologic agents most often used in terrorist attacks include anthrax, smallpox, botulism, plague, tularemia, and hemorrhagic fever. Anthrax, plague, and tularemia are treated effectively with antibiotics if enough supplies are available and the organisms are not resistant.[28] Vaccines are available for most of these agents.

Chemicals used as agents of terrorism are categorized by their target organ or effect. For example, sarin is a highly toxic nerve gas

that can cause death within minutes of exposure.[29] The radioactive dust and smoke can spread and cause illness if inhaled. Since radiation cannot be seen, smelled, felt, or tasted, you should start measures to limit contamination and provide for decontamination. *Ionizing radiation,* such as that from a nuclear bomb or damage to a nuclear reactor, is a serious threat to the safety of victims and the environment. Exposure to ionizing radiation may include skin contamination with radioactive material. Begin decontamination procedures immediately if external radioactive contaminants are present.

Explosive devices cause blast, crush, and/or penetrating injuries. Blast injuries result from the supersonic pressurization shock wave caused by the explosion. This shock wave primarily damages the lungs, GI tract, and middle ear. Crush injuries often result from explosions in confined spaces causing structural collapse. Some explosive devices contain materials that are projected during the explosion, leading to penetrating injuries.

Penetrating Trauma

Penetrating trauma is an injury that occurs when an object pierces the skin and enters the body creating an open wound. When the object goes all the way through, creating and entry and exit wound, it is a perforating injury. The most common causes of penetrating and perforating injuries in the United States are gunshot and stab wounds. The severity of the injury largely depends on the body part involved. Patients with penetrating trauma have the best outcome when they are thoroughly evaluated and promptly treated. All victims must first have a primary assessment to maintain airway, breathing, and circulation; control bleeding; and evaluate neurologic status.

Penetrating head trauma is a traumatic brain injury (TBI) that has a high mortality rate. Most deaths from TBI are from gunshot wounds. Other causes include stab wounds, motor vehicle accidents, or occupational accidents. Those who survive penetrating head trauma often have permanent neurologic deficits.

Patients with penetrating neck trauma are at risk for injury to major blood vessels, airway, and spinal cord. Anticipate bleeding, respiratory, and neurologic problems. Chest wounds can damage the heart, lungs, esophagus, diaphragm, or trachea. Penetrating wounds to the heart are almost 80% fatal. Lung injury can cause pneumothorax or hemothorax requiring emergent decompression and chest tube insertion.

Penetrating wounds to the abdomen often result from gunshot wounds. Severity and prognosis depend on the organs injured. Mortality from abdominal wounds is about 5%. Death usually occurs later due to hemorrhage or infection.

FIG. 68.8 American Red Cross.
Photo used with the permission of the American Red Cross.

Extremity trauma is usually not life threatening but can cause permanent disability. Blood vessels may be affected, leading to hemorrhage. Angulated fractures can cause penetrating trauma. Nerves, tendons, ligaments, and muscles can be injured. Early interventions include control of bleeding and stabilization of the

injured extremity.

Emergency and Mass Casualty Incident Preparedness

The term **emergency** usually refers to any extraordinary event that requires a rapid and skilled response and that the community's existing resources can manage. An emergency is different from a **mass casualty incident (MCI)** in that an MCI is a human-made (e.g., involving NBC agents) or natural (e.g., hurricane) event or disaster that overwhelms a community's ability to respond with existing resources. MCIs usually involve large numbers of victims, physical and emotional suffering, and permanent changes within a community. MCIs always require assistance from resources outside the affected community (Fig. 68.8).

When an emergency or an MCI occurs, first responders are sent to the scene. Triage of victims of an emergency or an MCI differs from the usual ED triage. Several systems exist. Many use colored tags to designate both the seriousness of the injury and the chance for survival. One system uses green for minor injuries and yellow for urgent but not life-threatening injuries. Red means a life-threatening injury requiring immediate intervention. Blue indicates those who are expected to die, and black identifies the dead.[30]

Triage of victims of an emergency or an MCI must be done in less than 15 seconds. Victims need to be treated and stabilized and, if there is known or suspected contamination, decontaminated at the scene. After this, they are moved to hospitals. Many other victims arrive at hospitals on their own. The total number of victims a hospital can expect is estimated by doubling the number of victims who arrive in the first hour.

Ethical/Legal Dilemmas

Good Samaritan

Situation

You are a registered nurse, employed as a charge nurse at a subacute rehabilitation facility. It is midnight, and you are driving home from work when you see a motor vehicle crash with a person at the side of the road waving and yelling for help. You stop and call 911 to report the incident. What do you do next?

Ethical/Legal Points for Consideration

- As a licensed health care professional, you are under no legal obligation to stop and give aid.
- If you do stop, you assume an obligation not to leave the scene until sufficiently trained first responders arrive and assume control.
- Many states encourage health care professionals to stop and give aid by having "Good Samaritan" laws. These laws, which vary somewhat from state to state, offer immunity from lawsuit for bystanders who offer aid in emergencies except in the case of gross negligence.
- A Good Samaritan must not be in the place of employment or under employment conditions.
- An example of gross negligence may be refusing to help someone who obviously had a serious hemorrhage in favor of a person with a minor injury because the bleeding person looked old or disheveled.
- Immunity covers only the scene of the accident and not later care under the supervision of HCPs.
- If there is a national disaster, an act of terrorism, or a major emergent need for HCPs, you may be required to go to an assigned site to offer aid. You would not be covered by the Good Samaritan Act under these circumstances.

Discussion Questions

1. What factors do you think contribute to a health care professional's decision whether to stop to provide aid?
2. What basic aid would you feel comfortable providing if you do not have an emergency or trauma background?
3. Would your professional liability (malpractice) insurance cover you if someone claimed that you acted negligently while giving aid?

In addition to the services provided by first responders, many communities have developed *community emergency response teams* (CERTs). CERTs are recognized by the Federal Emergency Management Agency (FEMA) as important partners in emergency preparedness. The CERT training helps citizens understand their personal responsibility in preparing for a natural or human-made disaster. Participants learn what to expect after a disaster and how to safely help themselves, their family, and their neighbors. Training includes lifesaving skills with emphasis on decision making and rescuer safety. CERTs are an extension of the first responder services. They can offer immediate help to victims and organize untrained volunteers to assist until professional services arrive.[31]

All HCPs have a role in emergency and MCI preparedness. Knowledge of the hospital's *emergency response plan* is essential. This includes individual roles and responsibilities of the members of the response team plus participation in emergency/MCI preparedness drills on a regular basis. Several types of drills can assess a hospital's level of emergency preparedness. These include hospital disaster drills, computer simulations, and table-top exercises. Drills allow HCPs to become familiar with the emergency response procedures.

Response to MCIs often requires the aid of a federal agency. The National Incident Management System (NIMS), American Red Cross, FEMA, and National Disaster Medical System (NDMS) are examples of federal resources.

All disasters result in psychologic stress to those involved. This

stress can persist for an extended period. It is influenced, in part, by the nature of the event, the person's age, preexisting coping mechanisms, role in the event, and medical and mental health history. Many hospitals have a *critical incident stress management unit.* This unit arranges group discussions to allow participants to share their feelings about the experience. This is important for emotional recovery.

Case Study

Trauma

© Thinkstock.

Patient Profile

D.F., a 20-yr-old Hispanic female trauma victim, is brought to the ED in an ambulance. She was the driver in a motor vehicle crash and was not wearing a seat belt. Two unrestrained children in the car were pronounced dead at the scene. The paramedics said there was significant damage to the car on the driver's side.

Subjective Data

- Patient asks, "What happened? Where am I?"
- Reports of shortness of breath and leg pain

Objective Data
Physical Examination

- Vital signs: BP = 85/40 mm Hg, HR = 140 beats/min, RR = 36 breaths/min; O_2 saturation = 85% with 100% nonrebreather mask
- Decreased breath sounds on left side of chest
- Asymmetric chest wall movement
- Glasgow Coma Score = 14; pupils slightly unequal
- Badly deformed left lower leg with significant swelling and a pedal pulse by Doppler only
- 4-cm head laceration, bleeding controlled

Discussion Questions

1. What are D.F.'s most likely life-threatening injuries?
2. ***Priority Decision:*** What is the priority of care for D.F.?
3. ***Priority Decision:*** What interventions does this patient need immediately?
4. What other interventions should you consider?

5. ***Collaboration:*** What activities could you delegate to unlicensed assistive personnel (UAP)?
6. ***Patient-Centered Care:*** Several family members have arrived in the ED, including the mother of 1 of the children who died. The second child who died was the patient's child. How should you approach the family?
7. ***Priority Decision:*** Based on assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-Based Practice:*** What are the best practice guidelines for fluid resuscitation in patients with hypovolemic shock?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are working in a 12-bed ICU and have been assigned to care for the following 2 patients. There is 1 UAP available to help as needed.

Patients	
 © Thinkstock.	R.K. is a 72-yr-old white man who was admitted with a massive stroke after collapsing at his home. He is unresponsive, even to painful stimuli. He has an oral endotracheal (ET) tube in place and is receiving mechanical ventilation (assist-control mode, FIO_2 70%, V_T 700 mL, respiratory rate 16 breaths/min, PEEP 7.5 cm H_2O). His chest x-ray shows right lower lung consolidation. A subclavian central line was placed to monitor central venous pressure (CVP) and give fluids and IV antibiotics. His cardiac rhythm on admission was atrial fibrillation with a rapid ventricular response. He is receiving IV diltiazem (Cardizem), and his ventricular response has slowed to 84 bpm. His temperature is increased despite receiving acetaminophen (Tylenol) q4hr. Enteral nutrition is running at 25 mL/hr via orogastric feeding tube. R.K. has a catheter for urinary drainage.
 © Thinkstock.	J.N. is a 58-yr-old white man who was admitted 24 hours ago after emergent surgery for an acutely ischemic bowel. The surgical procedure involved extensive abdominal surgery to repair a perforated colon, irrigate the abdominal cavity, and provide hemostasis. During surgery, his systolic BP dropped to 70 mm Hg and is still in the low 90s. He is in sinus tachycardia at a rate of 128 bpm. His pulmonary status worsened over the first 24 hr in ICU. He developed a right-sided pneumothorax and a chest tube was placed at that time. His hypoxemia has rapidly progressed and is now refractory to 100% FIO_2 and 15 cm H_2O PEEP. His laboratory tests show kidney and liver failure. He has an advance directive that states he does not want to be kept alive by artificial means, but he currently is full code status. He is sedated, paralyzed, and unable to communicate. His urinary catheter is draining concentrated urine <30 mL/hr. He has a central line in place with 0.9% saline running at 125 mL/hr. His most recent ABGs are as follows: pH 7.12, PaO_2 59 mm Hg, $PaCO_2$ 62 mm Hg, HCO_3^- 17 mEq/L, and O_2 saturation 84%, and his chest x-ray shows worsening bilateral interstitial infiltrates compatible with an ARDS pattern.

Answers and rationales available at *http://evolve.elsevier.com/Lewis*.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide rationale.
2. ***Collaboration:*** Which tasks could you delegate to the UAP? *(select all that apply)*
    a. Record vital signs on R.K. and J.N.
    b. Drain the water from J.N.'s ventilator tubing.
    c. Change suction tubing on R.K.'s ET tubes as needed.
    d. Titrate the diltiazem IV drip based on R.K.'s heart rate.
    e. Talk to J.N.'s family about his advance directive and current code status.
3. ***Priority Decision and Collaboration:*** As you are assessing J.N., the UAP informs you that R.K. just vomited all over his bed. Which *initial* action would be *most* appropriate?
    a. Ask the UAP to give R.K. a bath while you finish assessing J.N.
    b. Turn off R.K.'s enteral nutrition pump and auscultate his breath sounds.
    c. Ask the UAP to inform the HCP about J.N.'s ABG results while you assess R.K.
    d. Finish assessing R.K., then suction R.K.'s endotracheal tube to remove any emesis.

Case Study Progression

R.K.'s lungs are clear to auscultation. Evaluation of his GI status reveals minimal bowel sounds and a gastric residual of 200 mL even after his emesis. You elevate the head of his bed to 60 degrees, place the enteral nutrition on hold, and notify his HCP.

4. Which intervention would you expect the HCP to order for R.K.?
    a. Morphine sulfate 2 mg IV stat

b. Metoclopramide (Reglan) 10 mg IV every 6 hr
c. Restart enteral nutrition and maintain HOB elevation at 90 degrees
d. Hold enteral nutrition for 1 hour and restart with half-strength fluid at same rate

5. J.N.'s ABG results reflect a worsening of his ARDS. You correctly identify that these results demonstrate
   a. uncompensated respiratory acidosis.
   b. uncompensated respiratory alkalosis.
   c. partially compensated respiratory acidosis.
   d. partially compensated respiratory alkalosis.
6. Calculate and interpret J.N.'s PaO_2/FIO_2 ratio.
7. What aspects of care would be the same for J.N. and R.K. since they are both receiving mechanical ventilation? *(select all that apply)*
   a. Obtaining daily arterial blood gasses.
   b. Monitoring pulse oximetry continuously.
   c. Administering an IV proton-pump inhibitor.
   d. Suctioning the endotracheal tube every 2 hours.
   e. Applying intermittent pneumatic compression stockings.
8. ***Management Decision:*** You walk into J.N.'s room and find his wife whispering in his ear with her hand on the ventilator tubing, appearing to be ready to disconnect him from life support. What is your *best* initial action?
   a. Ask J.N.'s wife to leave the room immediately.
   b. Report the incident to the charge nurse and security at once.
   c. Ask J.N.'s wife if you could talk to her about her husband's condition.
   d. Report the incident to J.N.'s health care provider to address J.N.'s code status.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. An older man arrives in triage disoriented and dyspneic. His skin is hot and dry. His wife states that he was fine earlier today. The nurse's next *priority* would be to
   a. assess his vital signs.
   b. obtain a brief medical history from his wife.
   c. start supplemental O_2 and have the provider see him.
   d. determine the kind of insurance he has before treating him.
2. A patient has a core temperature of 90°F (32.2°C). The *most* appropriate rewarming technique would be
   a. passive rewarming with warm blankets.
   b. active internal rewarming using warmed IV fluids.
   c. passive rewarming using air-filled warming blankets.
   d. active external rewarming by submersing in a warm bath.
3. What are effective interventions to decrease absorption or increase elimination of an ingested poison? *(select all that apply)*
   a. Hemodialysis
   b. Eye irrigation
   c. Hyperbaric O_2
   d. Gastric lavage
   e. Activated charcoal
4. An older woman arrives in the ED reporting severe pain in her right shoulder. The nurse notes her clothes are soiled

with urine and feces. She tells the nurse that she lives with her son and that she "fell." She is tearful and asks you if she can be admitted. What possibility should the nurse consider?

a. Dementia

b. Possible cancer

c. Family violence

d. Orthostatic hypotension

5. A chemical explosion occurs at a nearby industrial site. First responders report that victims are being decontaminated at the scene and about 125 workers will need medical evaluation and care. The first action of the nurse receiving this report should be to

a. issue a code blue alert.

b. activate the hospital's emergency response plan.

c. notify the Federal Emergency Management Agency (FEMA).

d. arrange for the American Red Cross to provide aid to victims.

1. a, 2. b, 3. a, d, e, 4. c, 5. b

APPENDIX A

Basic Life Support for Health Care Providers

Mariann M. Harding

Basic life support (BLS) for health care professionals consists of a series of actions and skills performed by the rescuer(s) based on assessment findings. The first action the rescuer performs upon finding an adult victim is assessing for responsiveness. This is done by tapping or shaking the victim's shoulder and asking, "Are you all right?" If the victim does not respond, simultaneously scan the victim's chest for signs of breathing and perform a pulse check (described later).

If the rescuer is alone, the rescuer shouts for help. If someone responds, the rescuer asks him or her to activate the *emergency response system* (ERS) (e.g., through the use of a mobile phone) and get an *automatic external defibrillator* (AED) (if available). If no one responds and the rescuer does not have a mobile phone, the rescuer should leave to activate the ERS, get an AED (if available), and return to the victim before beginning *cardiopulmonary resuscitation* (CPR) and defibrillation if necessary.[1]

Cardiopulmonary Resuscitation

Cardiac arrest is characterized by the absence of a pulse and breathing in an unconscious victim. The current approach for CPR is the chest *compressions-airway-breathing* (CAB) sequence.[1]

The first step in CPR is to perform a pulse check by palpating the carotid pulse for at least 5 but no more than 10 seconds. While maintaining a head-tilt position with 1 hand on the victim's forehead,

locate the victim's trachea using 2 or 3 fingers of your other hand. Slide these fingers into the groove between the trachea and neck muscles where the carotid pulse can be felt. The technique is more easily performed on the side nearest you.

If a pulse is felt, give 1 rescue breath every 5 to 6 seconds (10 to 12 breaths/min) and recheck the pulse every 2 minutes (Fig. A.1). If no pulse is felt, start CAB.[1,2]

Chest Compressions

The proper technique for providing chest compressions is shown in Fig. A.2. Chest compression technique consists of fast and deep applications of pressure on the lower half of the sternum. The victim must be in the supine position when compressions are performed. The victim must be lying on a flat, hard surface, such as a CPR board (specially designed for use in CPR), a headboard from a unit bed, or, if necessary, the floor. Position yourself close to the side of the victim's chest. More frequently, mechanical chest compression devices are being used to provide chest compressions both prehospital and in the emergency department.

Chest compressions are combined with rescue breathing for an effective resuscitation effort of the adult victim of cardiac arrest. The compression-to-ventilation ratio for 1- or 2-rescuer CPR is 30 compressions to 2 breaths (Table A.1). However, if the patient has an advanced airway (e.g., endotracheal tube, laryngeal mask airway), do not pause between compressions for breaths and deliver 1 breath every 6 seconds (10 breaths/min).[1]

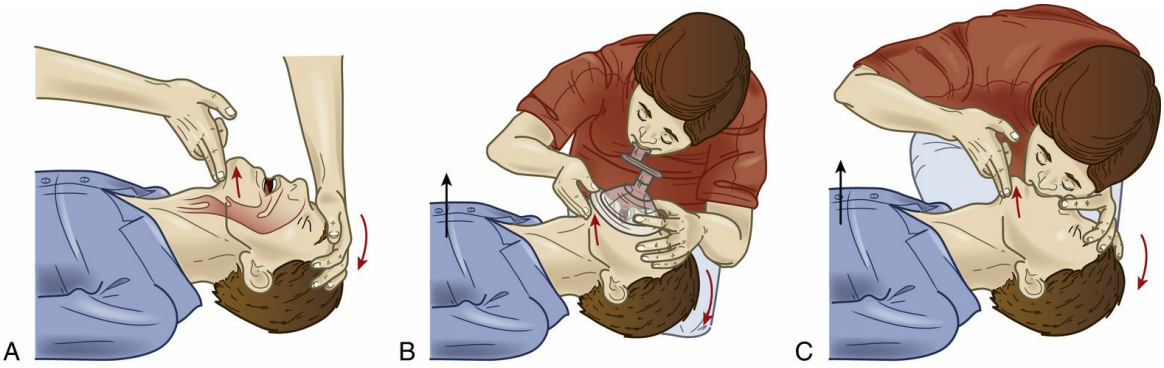

FIG. A.1 The head tilt–chin lift maneuver is used to open the victim's airway to give rescue breaths. **A,** Rescuer places 1 hand on the victim's forehead and applies firm, backward pressure with the palm to tilt the head back. The chin is lifted and brought forward with the fingers of the other hand. **B,** Mouth-to-barrier device: Rescuer places the device tightly over the victim's mouth and nose and delivers a regular breath. **C,** Mouth-to-mouth technique: Rescuer pinches the victim's nostrils, tightly seals mouth over victim's mouth, and delivers a regular breath. *Note:* Rescuer should observe for a rise in the victim's chest *(black arrows).*

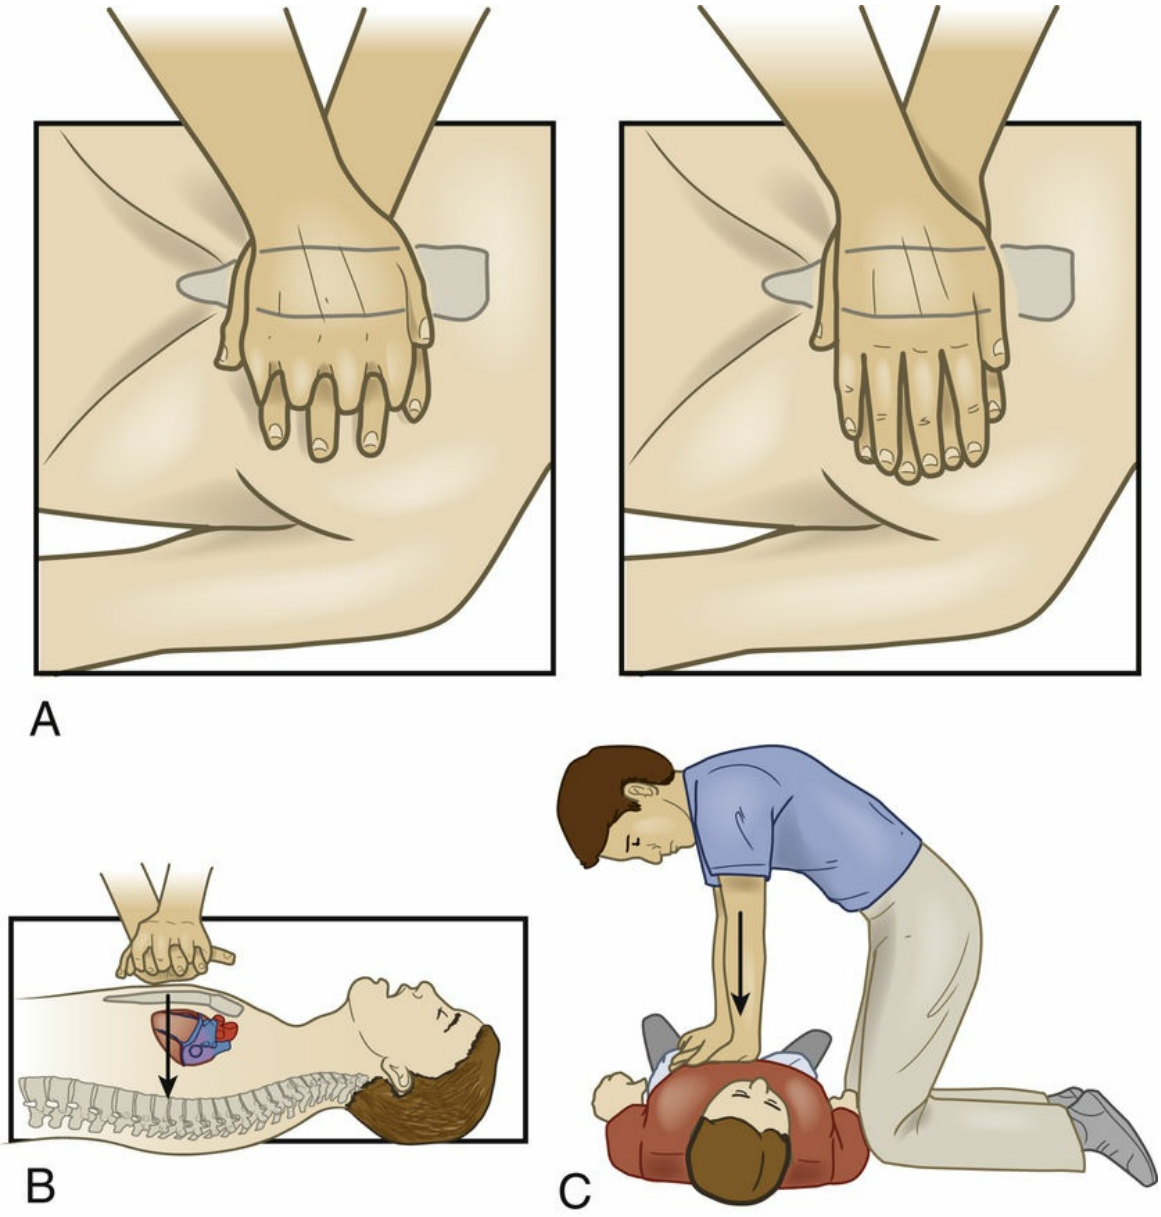

FIG. A.2 CPR. **A,** Position of the hands on the lower half of the sternum during chest compressions. **B,** When pressure is applied, the sternum is displaced posteriorly with the heel of the hand. **C,** Arms are kept straight, and the rescuer pushes deep (at least 2 in [5 cm]) and fast (a rate of 100 to 120 compressions per minute).

If a mechanical chest compression device is not used, it is preferable to have 2 persons performing CPR. One rescuer, positioned at the victim's side, performs chest compressions while the second rescuer, positioned at the victim's head, maintains an open airway and performs ventilations. To maintain the quality and rate of compressions, rescuers should change roles every 2 minutes.[2]

Interruptions in CPR should be limited.

Defibrillation

When the AED or advanced cardiovascular life support (ACLS) team arrives, assess the victim's rhythm. If the victim has a shockable rhythm (e.g., ventricular tachycardia, ventricular fibrillation), deliver 1 shock and immediately resume CPR for about 2 minutes before checking the rhythm again. If the rhythm is not a shockable rhythm, immediately resume CPR and recheck the rhythm after 2 minutes. CPR should continue between rhythm checks and shocks and until the ACLS team arrives or the victim shows signs of movement.[1]

The American Heart Association includes training in the use of AEDs with BLS instruction of HCPs and laypersons. Survival from cardiac arrest is the highest when immediate CPR is provided and defibrillation occurs within 3 to 5 minutes.[2] AEDs are found in many out-of-hospital, public settings (Fig. A.3).

Airway and Breathing

If a victim has a pulse but is gasping (e.g., agonal breathing) or not breathing, establish an open airway and begin rescue breathing. Open an adult's airway by hyperextending the head (Fig. A.1). Use the *head tilt–chin lift maneuver.* This involves tilting the head back with 1 hand and lifting the chin forward with the fingers of the other hand. Use the *jaw-thrust maneuver* if you suspect a cervical spine injury (see Fig. 68.1). Try to provide ventilation to the victim using a mouth-to-barrier (recommended) device (e.g., face mask or bag-valve-mask) or mouth-to-mouth resuscitation (Fig. A.1, *B, C*).[2]

Table A.1 Adult 1- and 2-Rescuer Basic Life Support With Automatic External Defibrillator (AED)

Assess

- Determine unresponsiveness: tap or shake victim's shoulder; shout, "Are you all right?"
- Check for no breathing or abnormal breathing (e.g., gasping) while simultaneously performing a pulse check (5–10 sec).

Activate Emergency Response System (ERS)

- Activate ERS (e.g., call 911) and get the AED (if available) (outside of hospital).
- Call a code and ask for the AED or crash cart (in hospital).

Begin High-Quality CPR

- If victim has a pulse but is not breathing or not breathing adequately, begin rescue breathing at a rate of 1 breath every 3–5 sec, or about 12–20/min (Fig. A.1). Recheck the pulse every 2 min.*
- If there is no pulse, expose the victim's chest and immediately begin chest compressions (Fig. A.2).
- Deliver compressions at a rate of 100–120/min.
- Compress the chest at least 2 in (5 cm) but not greater than 2.4 in (6 cm).
- Allow for complete chest recoil after each compression.
- Deliver a compression-ventilation ratio of 30 compressions to 2 breaths.†
- Minimize interruptions in compressions by delivering the 2 breaths in <10 sec.

Deliver Effective Breaths

- Open airway adequately (Fig. A.1, *A*).
- Deliver breath to produce a visible chest rise (Fig. A.1, *B, C*).
- Avoid excessive ventilation.

Integrate Prompt Use of the AED

- Use AED as soon as possible.
- If rhythm is shockable, deliver 1 shock and then resume chest compressions immediately after delivery of shock.
- If the rhythm is not shockable, resume CPR and recheck rhythm every 5 cycles.

Continue CPR

- Continue CPR between rhythm checks and shocks, and until ACLS providers arrive or the victim shows signs of movement.

ACLS, Advanced cardiovascular life support.

---

* If possible opioid overdose, give naloxone if available and per protocol.

† For patients with ongoing CPR and an advanced airway in place, a ventilation rate of 1 breath every 6 seconds (10 breaths per minute) with no interruption in compressions is recommended.

Source: American Heart Association: *BLS for healthcare providers: student manual,* Dallas, 2015, The Association.

For mouth-to-mouth resuscitation give ventilations with the victim's nostrils pinched. Take a regular (not deep) breath and tightly seal your lips around the victim's mouth. Give 1 breath and watch for a rise in the victim's chest. Continue rescue breaths at a rate of 10 to 12

per minute. When the victim has a tracheostomy, give ventilations through the stoma.

If the victim cannot be ventilated, proceed with CPR. When providing the next rescue breaths, look for any objects in the victim's mouth. If any objects are visible, remove them (Table A.2).

Table A.2 Management of the Adult Choking Victim

Conscious Adult Choking Victim

Assess Victim for Severe Airway Obstruction

Look for any of the following signs:

- Poor or no air exchange
- Clutching the neck with the hands, making the universal choking sign
- Weak, ineffective cough or no cough at all
- High-pitched noise while inhaling or no noise at all
- Increased respiratory difficulty
- Possible cyanosis

Ask the victim if he or she is choking. If the victim nods yes and cannot talk or has any of the symptoms noted above, severe airway obstruction is present and you must take immediate action.

Abdominal Thrusts (Heimlich Maneuver) With Standing or Sitting Victim (Fig. A.4)

1. Stand or kneel behind victim and wrap arms around the victim's waist.
2. Make fist with 1 hand.
3. Place thumb side of fist against victim's abdomen. Position fist

midline, slightly above navel and well below breastbone.
4. Grasp fist with other hand and press fist into victim's abdomen with a quick, forceful upward thrust.
5. Give each new thrust with a separate, distinct movement to relieve the obstruction. *Caution:* If victim is pregnant or obese, give chest thrusts instead of abdominal thrusts. Position hands (as described) over lower portion of the breastbone and apply quick backward thrusts.
6. Repeat thrusts until object is expelled or victim becomes unresponsive.

Unconscious Adult Choking Victim

If you see a choking victim collapse and become unresponsive:

1. Activate the emergency response system.
2. Lower the victim to the ground and begin CPR, starting with compressions (do not check for a pulse).
3. Open the victim's mouth wide each time you prepare to give breaths. Look for the object. If you see the object and can easily remove it, do so with your fingers. If you do not see the object, continue with CPR using the chest compression–airway-breathing sequence (Table A.1).
4. If efforts to ventilate are unsuccessful, continue with CPR.

Source: American Heart Association: *BLS for healthcare providers: Student manual,* Dallas, 2015, The Association.

Hands-Only Cpr

Hands-only CPR can be used to help adult victims who suddenly collapse from cardiac arrest outside of a health care setting. If an untrained person witnesses the event, the person should provide compression-only CPR. If you are trained and witness the event (as a bystander), you should provide conventional CPR (described

previously). If you are unable to do so, provide chest compressions only (push fast and deep in the center of the chest). Both methods are effective when done in the first few minutes of an out-of-hospital cardiac arrest.[1]

APPENDIX B

Nursing Diagnoses

1. Activity Intolerance: Lack of ability or energy to endure or complete daily activities.
2. Acute Confusion: Confusion occurring abruptly, over a short time interval.
3. Acute Pain: Pain occurring abruptly, over a short time interval.
4. Altered Blood Pressure: Any change in the systolic or diastolic BP.
5. Altered Perception: Change in the response to sensory stimuli, awareness of objects, or other data through the senses.
6. Anxiety: Feelings of threat, fear, apprehension, danger, or distress.
7. Chronic Pain: Pain occurring over time, long-standing.
8. Confusion: Memory impairment with disorientation in relation to person, place, or time.
9. Constipation: Decrease in the frequency of defecation accompanied by difficult or incomplete passage of stool; passage of excessively hard, dry stool.
10. Death Anxiety: Anxiety associated with the awareness of death.
11. Decreased Intracranial Adaptive Capacity: Compromised intracranial fluid volumes.
12. Diarrhea: Passage of loose, liquid, unformed stools, increased frequency of elimination accompanied by increased bowel sounds, cramping, and urgency of defecation.
13. Difficulty Coping: Inadequate personal ability to manage problems, stress, or responsibilities.
14. Disturbed Body Image: Disturbance in the mental picture of one's own body or physical appearance.

15. Electrolyte Imbalance: High or low serum electrolyte levels.
16. Fatigue: Feelings of decreased strength or endurance, weariness, mental or physical tiredness, and listlessness with lower capacity for physical or mental work.
17. Fluid Imbalance: Any change in or modification of body fluid balance.
18. Hyperglycemia: Increased serum glucose levels.
19. Hyperthermia: Increased body temperature.
20. Hypoglycemia: Decreased serum glucose levels.
21. Hypothermia: Reduced body temperature.
22. Impaired Airway Clearance: Impaired ability to keep air passage open from mouth to lung alveoli due to inability to clear secretions or obstructions from the respiratory tract.
23. Impaired Breathing: Inadequate inhalation or exhalation.
24. Impaired Cardiac Output: Any change in or modification of the pumping action of the heart.
25. Impaired Communication: Impediment or blockage to exchanging thoughts, messages, or information.
26. Impaired Gas Exchange: Impairment of the alveolar exchange of oxygen and carbon dioxide.
27. Impaired Hearing: Change in the ability to hear.
28. Impaired Nutritional Intake: Impaired ability to take in nutrients necessary for growth, normal functioning, and maintaining of life.
29. Impaired Nutritional Status: Impairment of weight and body mass in relation to intake of nutrition and specific nutrients estimated according to height, body build, and age.
30. Impaired Peripheral Neurovascular Function: Change in or modification of neurovascularization of the extremities.
31. Impaired Mobility: Diminished ability to perform independent movement.
32. Impaired Respiratory System Function: Any change in respiratory system function that influences oxygenation and breathing.
33. Impaired Sexual Functioning: Change negatively affecting a

person's sexual response and the ability to participate in intercourse.
34. Impaired Sleep Pattern: Imbalance in the normal sleep/wake cycle.
35. Impaired Tissue Integrity: Damage, inflammation, or lesion to the skin or underlying structures.
36. Ineffective Tissue Perfusion: Change in the movement of blood through periphery tissues resulting in ineffective delivery of oxygen, fluids, and nutrients at the cellular level.
37. Impaired Urinary System Function: Any change in urinary system function that affects the ability to excrete waste.
38. Lack of Knowledge: Lack of information, understanding, skills, or comprehension.
39. Nausea: Sensation of feeling sick with an inclination to vomit.
40. Obesity: Condition of high body weight and body mass usually of more than 20% over ideal weight, abnormal increase in proportion of fat cells mainly in viscera and subcutaneous tissues.
41. Risk for Aspiration: Risk for inhaling gastric or external substances into the trachea or lungs.
42. Risk for Bleeding: Risk for loss of blood, externally or internally.
43. Risk for Fall-Related Injury: Risk for injury from the descent of a body from higher to lower level.
44. Risk for Infection: Risk for invasion of the body by pathogenic microorganisms that cause disease.
45. Risk for Injury: Risk for intentional or accidental physical harm or damage to tissues.
46. Sleep Deprivation: Lack of a normal sleep/wake cycle.
47. Substance Abuse: Misuse of chemically active substance for a nontherapeutic effect that may be harmful to health and cause addiction.
48. Surgical Wound: Cut of tissue made by sharp surgical instrument to create an opening into a body space or an organ.
49. Urinary Retention: Involuntary accumulation of urine in the

bladder or incomplete emptying of the bladder.

50. Vomiting: Expulsion of stomach contents through the esophagus and out of mouth.

APPENDIX C

Laboratory Reference Intervals

The tables in this appendix list some of the most common tests, their reference intervals (formally referred to as *normal values*), and possible etiologies of abnormal results. Laboratory results may vary depending on different techniques or different laboratories. Abbreviations appearing in the tables are defined as follows:

mEq = milliequivalent
mm Hg = millimeter of mercury
mm = millimeter
mOsm = milliosmole
L = liter
dL = deciliter (10^{-1} liter)
mL = milliliter (10^{-3} liter)
μL = microliter (10^{-6} liter, 10^{-3} milliliter)
fL = femtoliter (10^{-15} liter, 10^{-12} milliliter)
g = gram
mg = milligram (10^{-3} gram)
mcg = microgram (10^{-6} gram)
ng = nanogram (10^{-9} gram)
pg = picogram (10^{-12} gram)
U = unit
μU = microunit
IU = international unit
mU= milliunit
mmol = millimole (10^{-3} mole)
μmol = micromole (10^{-6} mole)
nmol = nanomole (10^{-9} mole)

pmol = picomole (10^{-12} mole)
kPa = kilopascal
μkat = microkatal

Table C.1 Serum, Plasma, and Whole Blood Chemistries

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
Aldolase	22–59 mU/L	22–59 mU/L	Skeletal muscle disease	Muscle-wasting disease
α_1-Antitrypsin	85–213 mg/dL	0. 85–2.13 g/L	Acute and chronic inflammation, arthritis	Early-onset emphysema, malnutrition, nephrotic syndrome
α_1-Fetoprotein	<40 ng/mL	<40 mcg/L	Cancer of testes, ovaries, and liver	
Ammonia	10–80 mcg/dL	6–47 µmol/L	Severe liver disease	
Amylase	60–120 Somogyi U/dL	30–220 U/L	Acute and chronic pancreatitis, salivary gland disease, perforated ulcers	Acute alcoholism, cirrhosis of liver, extensive destruction of pancreas
Bicarbonate	21–28 mEq/L	21–28 mmol/L	Compensated respiratory acidosis, metabolic alkalosis	Compensated respiratory alkalosis, metabolic acidosis
b-Type natriuretic peptide (BNP)	<100 pg/mL	<100 pmol/L	Heart failure	
Bilirubin			Biliary obstruction, hemolytic anemia, impaired liver function, pernicious anemia	
• Total	0.3–1.0 mg/dL	5.1–17 µmol/L		
• Indirect	0.2–0.8 mg/dL	3.4–12.0 µmol/L		
• Direct	0.1–0.3 mg/dL	1.7–5.1 µmol/L		
Blood gases*				
• Arterial pH	7.35–7.45	7.35–7.45	Alkalosis	Acidosis
• Venous pH	7.31–7.41	7.31–7.41		
• $PaCO_2$	35–45 mm Hg	4.66–5.98 kPa	Compensated metabolic alkalosis	Compensated metabolic acidosis
• $PvCO_2$	40–50 mm Hg	5.06–7.32 kPa	Respiratory acidosis	Respiratory alkalosis
• PaO_2	80–100 mm Hg	10.6–13.33 kPa	Administration of high concentration of O_2	Chronic lung disease, decreased cardiac output
• PvO_2	40–50 mm Hg	5.04–5.57 kPa		
Calcium (total)	9.0–10.5 mg/dL	2.25–2.62 mmol/L	Hyperthyroidism, hyperparathyroidism, vitamin D intoxication, multiple myeloma	Pancreatitis, hypoparathyroidism, malabsorption syndrome, renal failure, vitamin D deficiency
Calcium (ionized)	4.5–5.6 mg/dL	1.05–1.3 mmol/L	Acidosis	Alkalosis
Chloride	98–106 mEq/L	98–106 mmol/L	Metabolic acidosis, respiratory alkalosis, corticosteroid therapy, uremia	Addison's disease, vomiting, metabolic alkalosis, respiratory acidosis

Table Continued

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
Cholesterol	<200 mg/dL	<5.2 mmol/L	Biliary obstruction, hypothyroidism, idiopathic hypercholesterolemia, renal disease, uncontrolled diabetes	Extensive liver disease, hyperthyroidism, malnutrition, malabsorption
• **High-density lipoproteins (HDLs)**	*Male:* >45 mg/dL	*Male:* >0.75 mmol/L	Excessive exercise	Metabolic syndrome, liver disease
	Female: >55 mg/dL	*Female:* >0.91 mmol/L		
• **Low-density lipoproteins (LDLs)**	*Recommended:* <130 mg/dL		Chronic liver disease, familial hypercholesterolemia, nephrotic syndrome	Hyperthyroidism
• **Very low-density lipoproteins (VLDLs)**	7–32 mg/dL		Familial hypercholesterolemia, nephrotic syndrome	Hyperthyroidism
Cortisol	8 AM: 5–23 mcg/dL 4 PM: 3–13 mcg/dL	8 AM: 138–635 nmol/L 4 PM: 83–359 nmol/L	Cushing syndrome, hyperthyroidism	Adrenal insufficiency, panhypopituitary states
Creatine kinase (CK)	*Male:* 55–170 U/L	*Male*: 55–170 U/L	Musculoskeletal injury or disease, myocardial infarction, severe myocarditis, exercise, numerous IM injections	
	***Female:* 30–135 U/L**	*Female*: 30–135 U/L		
• **CK-MB**	<4%–6% of total CK	<0.4–0.6	Acute myocardial infarction	
Creatinine	*Male*: 0.6–1.2 mg/dL	*Male*: 53–106 µmol/L	Severe renal disease	Decreased muscle mass, dehabilitation
	***Female:* 0.5–1.1 mg/dL**	*Female:* 44–97 µmol/L		
Ferritin	*Male*: 12-300 ng/mL	*Male:* 12–300 mcg/L	Anemia of chronic disease, sideroblastic anemia	Iron-deficiency anemia
	***Female*: 10-150 ng/mL**	*Female*: 10-150 mcg/L		
Folic acid (folate)	5–25 ng/mL	11–57 nmol/L	Hypothyroidism, pernicious anemia	Alcoholism, hemolytic anemia, inadequate diet, malabsorption syndrome, megaloblastic anemia
γ-Glutamyl transferase (GGT)	*Male and Female >45*: 8–38 U/L *Female <45*: 5–27 U/L	*Male and Female >45*: 8–38 U/L *Female <45*: 5–27 U/L	Liver disease, infectious myocardial infarction, pancreatitis, hyperthyroidism	Hypothyroidism
Glucose (fasting)	74–106 mg/dL	4.1–5.9 mmol/L	Acute stress, Cushing disease, diabetes, hyperthyroidism, pancreatic insufficiency	Addison's disease, hepatic disease, hypothyroidism, insulin overdosage, pancreatic tumor, pituitary hypofunction
Haptoglobin	50–220 mg/dL	0.5–2.2 g/L	Infectious and inflammatory processes, cancer	Hemolytic anemia, malnutrition, chronic liver disease
Insulin (fasting)	6–26 µU/mL	43–186 pmol/L	Acromegaly, adenoma of pancreatic islet cells, Cushing syndrome	Diabetes, hypopituitarism
Iron, total	*Male:* 80–180 mcg/dL	*Male:* 14–32 µmol/L	Excess RBC destruction, hepatitis, massive blood transfusion	Anemia of chronic disease, iron-deficiency anemia, cancer
	***Female:* 60-160 mcg/dL**	*Female:* 11-29 µmol/L		
(Total) iron-binding capacity	250–460 mcg/dL	45–82 µmol/L	Iron-deficient state, polycythemia	Cirrhosis, chronic infections, pernicious anemia

Table Continued

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
Lactic acid (L-Lactate), venous	5–20 mg/dL	0.6–2.2 mmol/L	Acidosis, liver disease, sepsis, shock	
Lactic dehydrogenase (LDH)	100–190 U/L	100–190 U/L	Heart failure, hemolytic disorders, hepatitis, metastatic cancer of liver, myocardial infarction, pernicious anemia, pulmonary embolus, skeletal muscle damage	
Lactic dehydrogenase isoenzymes				
• LDH_1	17%–27%	0.17–0.27	Myocardial infarction, pernicious anemia	
• LDH_2	27%–37%	0.27–0.37	Pulmonary embolus, sickle cell crisis	
• LDH_3	18%–25%	0.18–0.25	Malignant lymphoma, pulmonary embolus	
• LDH_4	3%–8%	0.03–0.08	Systemic lupus erythematosus, pulmonary infarction	
• LDH_5	0%–5%	0.00–0.05	Heart failure, hepatitis, pulmonary embolus and infarction, skeletal muscle damage	
Lipase	0–160 U/L	0–160 U/L	Acute pancreatitis, hepatic disorders, perforated peptic ulcer	
Magnesium	1.3–2.1 mEq/L	0.65–1.05 mmol/L	Addison's disease, hypothyroidism, renal failure	Chronic alcoholism, severe malabsorption
Osmolality	285–295 mOsm/kg	285–295 mmol/kg	Chronic renal disease, diabetes, diabetes insipidus	Addison's disease, diuretic therapy, SIADH, hypervolemia
O_2 saturation (arterial) (SaO_2)	>95%	>0.95	Polycythemia	Anemia, cardiac decompensation, respiratory disorders
Phosphatase, alkaline	30–120 U/L	0.5–2.0 μkat/L	Biliary system obstruction, bone diseases, marked hyperparathyroidism, rickets	Excess vitamin D ingestion, hypothyroidism
Phosphorus (phosphate)	3.0–4.5 mg/dL	0.97–1.45 mmol/L	Bone cancer, hypoparathyroidism, renal disease, vitamin D intoxication, hypocalcemia	Diabetes, hyperparathyroidism, vitamin D deficiency
Potassium	3.5–5.0 mEq/L	3.5–5.0 mmol/L	Addison's disease, diabetic ketosis, massive tissue destruction, renal failure, infection, dehydration	Cushing syndrome, diarrhea (severe), diuretic therapy, gastrointestinal fistula, starvation, vomiting
Progesterone (Female)				
• Follicular phase	<50 ng/dL	0.5–2.2 nmol/L	Adrenal hyperplasia, choriocarcinoma of ovary, pregnancy, cysts of ovary	Threatened abortion, hypogonadism, amenorrhea, ovarian tumor
• Luteal phase	300-2500 ng/dL	6.4-79.5 nmol/L		
• Postmenopause	<40 ng/dL	1.28 nmol/L		
Prostate-specific antigen (PSA)	<4.0 ng/mL	<4.0 mcg/L	Prostate cancer, prostatitis, benign prostatic hypertrophy	
Proteins			Burns, cirrhosis (globulin fraction), dehydration	Liver disease, malabsorption
• Total	6.4–8.3 g/dL	64–83 g/L		
• Albumin	3.5–5.0 g/dL	35–50 g/L		
• Globulin	2.3–3.4 g/dL	23–34 g/L		
• Albumin/globulin ratio	1.5:1–2.5:1	1.5:1–2.5:1	Multiple myeloma (globulin fraction), shock, vomiting	Malnutrition, nephrotic syndrome, proteinuria, renal disease, severe burns
Sodium	136–145 mEq/L	136–145 mmol/L	Dehydration, impaired renal function, primary aldosteronism, corticosteroid therapy	Addison's disease, diabetic ketoacidosis, diuretic therapy, excessive loss from GI tract, excessive perspiration, water intoxication
Testosterone (total)	*Male*: 280–1080 ng/dL	*Male*: 280–1080 ng/dL	Hyperthyroidism	Hypofunction of testes, hypogonadism
	***Female*: <70 ng/dL**	*Female*: <70 ng/dL	Polycystic ovary, virilizing tumors	
T_4 (thyroxine), total	*Male*: 4–12 mcg/dL	*Male*: 59–135 nmol/L	Hyperthyroidism, thyroiditis, hepatitis, Graves' disease, thyroid cancer	Cretinism, hypothyroidism, myxedema, Cushing syndrome, renal failure
	***Female*: 5–12 mcg/dL**	*Female*: 71–142 nmol/L		

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
T_4 (thyroxine), free	0.8–2.8 ng/dL	10–36 pmol/L		
T_3 uptake	24%–34%	0.24–0.34	Hyperthyroidism	Hypothyroidism
T_3 (triiodothyronine), total	*Age 20–50:* 70–205 ng/dL	1.2–3.4 nmol/L	Hyperthyroidism	Hypothyroidism
	***Age >50:* 40–180 ng/dL**	0.60–2.8 nmol/L		
Thyroid-stimulating hormone (TSH)	2.0–10 μU/mL	2.0–10 mU/L	Myxedema, primary hypothyroidism	Secondary hypothyroidism, hyperthyroidism
Transaminases				
• Aspartate aminotransferase (AST)	0–35 U/L	0–0.58 μkat/L	Liver disease, myocardial infarction, pulmonary infarction, acute hepatitis	Acute renal disease, diabetic ketoacidosis
• Alanine aminotransferase (ALT)	4–36 U/L	4–36 U/L	Liver disease, shock	
Transferrin	*Male*: 215–365 mg/dL	*Male*: 2.15–3.65 g/L	Iron-deficiency anemia, polycythemia vera	Cirrhosis, pernicious anemia, sickle cell disease
	***Female*: 250–380 mg/dL**	*Female*: 2.5–3.8 g/L		
Transferrin saturation (%)	*Male*: 20%–50%	*Male*: 20%–50%	Hemolytic anemia, iron overdose	Malnutrition
	***Female*: 15%–50%**	*Female*: 15%–50%		
Triglycerides	*Male*: 40–160 mg/dL	*Male*: 0.45–1.81 g/L	Diabetes, hyperlipidemia, hypothyroidism, liver disease	Malnutrition
	***Female*: 35–135 mg/dL**	*Female*: 0.40–1.52 g/L		
Troponins (cardiac)			Myocardial infarction, myocardial injury	
				Table Continued

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
• Troponin T (cTnT)	<0.1 ng/mL	<0.1 mcg/L		
• Troponin I (cTnI)	<0.03 ng/mL	<0.03 mcg/L		
Urea nitrogen (BUN)	10–20 mg/dL	3.6–7.1 mmol/L	Increase in protein catabolism (fever, sepsis, stress), renal disease, heart failure, myocardial infarction	Malnutrition, severe liver damage
Uric acid	*Male:* 4.0–8.5 mg/dL	*Male:* 0.24–0.51 mmol/L	Gout, gross tissue destruction, high-protein weight reduction diet, leukemia, renal failure	Administration of uricosuric drugs
	***Female:* 2.7–7.3 mg/dL**	*Female:* 0.16–0.43 mmol/L		
Vitamin B_{12} (cobalamin)	160–950 pg/mL	118–701 pmol/L	Chronic myeloid leukemia	Strict vegetarianism, malabsorption syndrome, pernicious anemia, total or partial gastrectomy
Vitamin C (ascorbic acid)	0.4–2.0 mg/dL	23–114 µmol/L	Excessive ingestion of vitamin C	Connective tissue disorders, hepatic disease, renal disease, rheumatic fever, vitamin C deficiency
Vitamin D	25–80 ng/dL	25–80 ng/dL	Excess dietary supplement	Liver disease, malabsorption syndromes, osteoporosis, renal disease

$PaCO_2$, Partial pressure of CO_2 in arterial blood; *PaO_2,* partial pressure of oxygen in arterial blood; *$PvCO_2$,* partial pressure of CO_2 in venous blood; *PvO_2,* partial pressure of oxygen in venous blood; *RBC,* red blood cell; *SaO_2,* arterial oxygen saturation.

* Because arterial blood gases are influenced by altitude, the value for PaO_2 decreases as altitude increases. The lower value is normal for an altitude of 1 mile.

Table C.2 Hematology

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
Bleeding time	1–9 min	60–540 sec	Aspirin ingestion, ineffective platelet function, thrombocytopenia, vascular disease, von Willebrand disease	
Activated partial thromboplastin time (aPTT)	30–40 sec*	30–40 sec*	Deficiency of factors I, II, V, VIII, IX, X, XI, XII; hemophilia, heparin therapy, liver disease	Early DIC, extensive cancer
Prothrombin time (protime, PT)	11–12.5 sec*	11–12.5 sec*	Deficiency of factors I, II, V, VII, and X; liver disease; vitamin K deficiency; warfarin therapy	
Fibrinogen	200–400 mg/dL	2–4 g/L	Burns (after first 36 hr), inflammatory disease, stroke, myocardial infarction	Burns (during first 36 hr), DIC, severe liver disease, malnutrition
Fibrin split (degradation) products	<10 mcg/mL	<10 mg/L	Acute DIC, massive hemorrhage, primary fibrinolysis	
D-Dimer	<250 ng/mL	<250 mcg/L	DIC, myocardial infarction, VTE, unstable angina, cancer	
Erythrocyte count† (altitude dependent)	*Male:* 4.7–6.1 × 10^6/μL	*Male:* 4.7–6.1 × 10^{12}/L	Dehydration, high altitudes, polycythemia vera, severe COPD	Anemia, leukemia, hemorrhage, cancer, chronic illness, kidney disease
	Female: 4.2–5.4 × 10^6/μL	*Female:* 4.2–5.4 × 10^{12}/L		
Red blood indices				
• **Mean corpuscular volume (MCV)**	80–95 fL	80–95 fL	Alcoholism, liver disease, macrocytic anemia	Microcytic anemia, thalassemia
• **Mean corpuscular hemoglobin (MCH)**	27–31 pg	27–31 pg	Macrocytic anemia	Microcytic anemia
• **Mean corpuscular hemoglobin concentration (MCHC)**	32%–36%	32–36 g/dL	Spherocytosis	Iron deficiency anemia, thalassemia
Erythrocyte sedimentation rate (ESR)	<20 mm/hr (some gender variation)	<20 mm/hr (some gender variation)	*Moderate increase:* acute hepatitis, myocardial infarction, rheumatoid arthritis *Marked increase:* acute and severe bacterial infections, cancer, pelvic inflammatory disease	Malaria, severe liver disease, sickle cell anemia
Hematocrit† (altitude dependent)	*Male:* 42%–52% *Female:* 37%–47%	*Male:* 0.42–0.52 *Female:* 0.37–0.47	Dehydration, high altitudes, polycythemia, COPD	Anemia, hemorrhage, overhydration, cirrhosis, kidney disease
Hemoglobin† (altitude dependent)	*Male:* 14– 18 g/dL *Female:* 12–16 g/dL	*Male:* 140–180 g/L*Female:* 120–160 g/L	COPD, high altitudes, polycythemia, dehydration, burns	Anemia, hemorrhage, kidney disease, cancer
Hemoglobin, glycosylated (A1C)	4.0%–5.6%	4.0%–5.6%	Diabetes, pre–diabetes	Sickle cell anemia, chronic renal failure, pregnancy
Platelets (thrombocytes)	150–400 × 10^3/μL	150–400 × 10^9/L	Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, postsplenectomy	Acute leukemia, DIC, thrombocytopenic purpura
Reticulocyte count	0.5%–2.0% of RBC	0.5%–2.0% of RBC	Hemolytic anemia, polycythemia vera	Hypoproliferative anemia, macrocytic anemia, microcytic anemia
White blood cell count†	5000–10000/mm^3	5.0–10.0 × 10^9/L	Inflammatory and infectious processes, leukemia	Aplastic anemia, side effects of chemotherapy and irradiation
WBC differential				
• **Segmented neutrophils**	55%–70%	0.55–0.70	Bacterial infections, collagen diseases, Hodgkin's lymphoma	Aplastic anemia, viral infections
• **Band neutrophils**	0–8%	0–0.08	Acute infections	
• **Lymphocytes**	20%–40%	0.20–0.40	Chronic infections, lymphocytic leukemia, mononucleosis, viral infections	Corticosteroid therapy, whole body irradiation
• **Monocytes**	2%–8%	0.02–0.08	Chronic inflammatory disorders, malaria, monocytic leukemia, acute infections, Hodgkin's lymphoma	
• **Eosinophils**	1%–4%	0.01–0.04	Allergic reactions, eosinophilic and chronic granulocytic leukemia, parasitic disorders, Hodgkin's lymphoma	Corticosteroid therapy
• **Basophils**	0.5%–1%	0.005–0.01	Hypothyroidism, ulcerative colitis, myeloproliferative diseases	Hyperthyroidism, stress

COPD, Chronic obstructive pulmonary disease; *DIC,* disseminated intravascular coagulation.

* Values depend on reagent and instrumentation used.

† Components of complete blood count (CBC).

Table C.3 Serology-Immunology

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High/Positive	Low
Antinuclear antibody (ANA)	Negative at 1:40 dilution	Negative at 1:40 dilution	Chronic hepatitis, rheumatoid arthritis, scleroderma, systemic lupus erythematosus	
Anti-DNA antibody	<5 IU/mL	<5 IU/mL	Systemic lupus erythematosus	
Anti-Sm (Smith)	Negative	Negative	Systemic lupus erythematosus	
C-reactive protein (CRP)	<1.0 mg/dL	<10.0 mg/L	Acute infections, any inflammatory condition, widespread cancer	
Carcinoembryonic antigen (CEA)	*Nonsmoker:* <3 ng/mL	*Nonsmoker:* <3 mcg/L	Cancer of colon, liver, pancreas; cigarette smoking; inflammatory bowel disease	
	Smoker: <5 ng/mL	*Smoker:* <5 mcg/L		
Complement, total hemolytic (CH_{50})	30–75 U/mL	30–75 U/mL	Cancer, ulcerative colitis	Bacterial endocarditis, glomerulonephritis, rheumatoid arthritis, systemic lupus erythematosus
Direct Coombs or direct antihuman globulin test (DAT)	Negative	Negative	Acquired hemolytic anemia, drug reactions, transfusion reactions	
Fluorescent treponemal antibody absorption (FTA-Abs)	Negative or nonreactive	Negative or nonreactive	Syphilis	
Hepatitis A antibody	Negative	Negative	Hepatitis A	
Hepatitis B surface antigen (HB_sAg)	Negative	Negative	Hepatitis B	
Hepatitis C antibody	Negative	Negative	Hepatitis C	
Monospot or monotest	Negative	Negative	Infectious mononucleosis	
Rheumatoid factor (RF)	Negative or titer <1:17	Negative or titer <1:17	Rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus	
RPR	Negative or nonreactive	Negative or nonreactive	Leprosy, malaria, rheumatoid arthritis, systemic lupus erythematosus, syphilis,	
VDRL	Negative or nonreactive	Negative or nonreactive	Syphilis	

RPR, Rapid plasma reagin test; *VDRL,* Venereal Disease Research Laboratory test.

Table C.4 Urine Chemistry

Test	Reference Intervals			Possible Etiology	
	Specimen	Units	SI Units	High	Low
Acetone	Random	Negative	Negative	Diabetes, high-fat and low-carbohydrate diets, starvation	
Aldosterone	24 hr	2–26 mcg/day	6–72 nmol/day	*Primary aldosteronism:* adrenocortical tumors *Secondary aldosteronism:* cirrhosis, heart failure hyperkalemia, hyponatremia	ACTH deficiency, Addison's disease, corticosteroid therapy, hypokalemia
Amylase	24 hr	<5000 Somogyi U/day	6.5–48.1 U/hr	Acute pancreatitis	
Bence Jones protein	Random	<0.68 mg/dL	<0.68 mg/dL	Multiple myeloma	
Bilirubin	Random	Negative	Negative	Liver disorders	
Catecholamines	24 hr			Heart failure, pheochromocytoma, progressive muscular dystrophy	
• Epinephrine		<20 mcg/day	<109 nmol/day		
• Norepinephrine		<100 mcg/day	<590 nmol/day		
Cortisol	24 hr	<100 mcg/day	<276 nmol/day	Adrenal cancer, Cushing syndrome, hyperthyroidism, obesity, stress	Addison's disease, hypothyroidism, liver disease
Creatinine clearance	24 hr	*Male:* 107–139 mL/min	*Male:* 1.78–2.32 mL/sec	Exercise, pregnancy	Cirrhosis, heart failure, renal disease
		***Female:* 87–107 mL/min**	*Female:* 1.45–1.78 mL/sec		
Estrogens	24 hr				
• Female				Gonadal or adrenal tumor	Endocrine disturbance, ovarian dysfunction, menopause
• Nonpregnant		4–60 mcg/day	4–60 mcg/day		
• Postmenopause		<20 mcg/day	<20 mcg/day		
• Male		4–25 mcg/day	4–25 mcg/day		
Glucose	Random	Negative	Negative	Diabetes, pituitary disorders	
Hemoglobin	Random	Negative	Negative	Extensive burns, glomerulonephritis, hemolytic anemia, hemolytic transfusion reaction	
5-Hydroxyindole acetic acid (5-HIAA)	24 hr	2–8 mg/day	10–40 µmol/day	Malignant carcinoid syndrome	
Ketones	Random	Negative	Negative	Diabetes, starvation, dehydration	
Metanephrine	24 hr	<1.3 mg/day	<7 µmol/day	Pheochromocytoma	
Myoglobin	Random	Negative	Negative	Crushing injuries, electric injuries, extreme physical exertion	
Osmolality	Random	50–1200 mOsm/kg	50–1200 mmol/kg	Heart failure, liver disease, shock, SIADH	Aldosteronism, diabetes insipidus, hypokalemia, pyelonephritis
pH	Random	4.6–8.0	4.6–8.0	Urinary tract infection, urine allowed to stand at room temperature	Respiratory or metabolic acidosis
Protein	Random	0–8 mg/dL	0–8 mg/dL	Acute and chronic renal disease, heart failure	
Protein (quantitative)	24 hr	50–80 mg/day	50–80 mg/day	Heart failure, inflammatory process of urinary tract, nephritis, nephrosis, strenuous exercise	
Sodium	24 hr	40–220 mEq/day	40–220 mmol/day	Acute tubular necrosis	Hyponatremia
Specific gravity	Random	1.005–1.030	1.005–1.030	Albuminuria, dehydration, glycosuria, fever	Diabetes insipidus, hypothermia, diuresis
Uric acid	24 hr	250–750 mg/day	1.48–4.43 mmol/day	Gout, leukemia	Nephritis
Urobilinogen	Random	Negative	Negative	Hemolytic disease, hepatic parenchymal cell damage, liver disease	Complete bile duct obstruction
Vanillylmandelic acid	24 hr	<6.8 mg/day	<35 µmol/day	Pheochromocytoma	

ACTH, Adrenocorticotropic hormone.

Table C.5 Fecal Analysis

Test	Reference Intervals		Possible Etiology
	Conventional Units	SI Units	High
Fecal fat	2–6 g/24 hr	7–21 mmol/day	Common bile duct obstruction, malabsorption syndrome, pancreatic disease
Mucus	Negative	Negative	Mucous colitis, spastic constipation
Pus	Negative	Negative	Chronic bacillary dysentery, chronic ulcerative colitis, localized abscesses
Blood*	Negative	Negative	Anal fissures, gastrointestinal cancer, hemorrhoids, inflammatory bowel disease, peptic ulcer disease
Color			
• **Brown**			Various color depending on diet
• **Clay**			Biliary obstruction, presence of barium sulfate
• **Tarry**			More than 100 mL of blood in gastrointestinal tract
• **Red**			Blood in large intestine
• **Black**			Blood in upper gastrointestinal tract, iron medication

* Ingestion of meat may produce false-positive results. Patient may be placed on a meat-free diet for 3 days before the test.

Table C.6 Cerebrospinal Fluid Analysis

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	High	Low
Pressure	<20 mm H_2O	<20 mm H_2O	Hemorrhage, intracranial tumor, meningitis	Head injury, spinal tumor, subdural hematoma
Blood	Negative	Negative	Intracranial hemorrhage	
Cell count (age dependent)			CNS infection or inflammation	
• **WBC**	0–5 cells/μL	0–5 × 10^6 cells/L		
• **RBC**	Negative	Negative		
Chloride	700–750 mg/dL	118–132 mmol/L	Uremia	CNS bacterial infection
Glucose	50–75 mg/dL	2.2–3.9 mmol/L	CNS viral infection, diabetes	Bacterial infection, CNS tuberculosis
Protein				
• **Lumbar**	15–45 mg/dL	0.15–0.45 g/L	Guillain-Barré syndrome, poliomyelitis, trauma	
• **Cisternal**	15–25 mg/dL	0.15–0.25 g/L	CNS syphilis	
• **Ventricular**	5–15 mg/dL	0.05–0.15 g/L	Acute meningitis, brain tumor, chronic CNS infection, multiple sclerosis	

CNS, Central nervous system.

Index

Note: Disorder names and key terms are in **boldface.** Page numbers in **boldface** indicate main discussions. Page numbers followed by *f* or *b* indicate figures or boxes/tables, respectively.

clinical manifestations of, 1061–1062
diagnostic studies in, 1062–1063
diuretic phase, 1062
etiology and pathophysiology of, 1060–1061
health promotion for, 1064
interprofessional care for, 1063–1064, 1063b
nursing diagnoses for, 1064
nursing management of, **1064–1065**
nutritional therapy for, 1064
in older adults, 1065
oliguric phase, 1061–1062
recovery phase, 1062
RIFLE classification of, 1061, 1061b
Acute laryngitis, **487**

Acute liver failure, 989–990
Acute low back pain, **1484**
Acute lymphocytic leukemia (ALL), **636**, 636b, 638b
Acute marginal gingivitis, 841b–842b
Acute marijuana toxicity, 150
Acute myelogenous leukemia (AML), **635–636**, 636b, 638b
Acute necrotizing ulcerative gingivitis, 893b
Acute osteomyelitis, 1479
Acute otitis media, 384
Acute pain, 103b, **107**, 107b
Acute pancreatitis, **992–995**
acute care for, 995–996
ambulatory care for, 996
clinical manifestations of, 993
complications of, 993
diagnostic studies for, 993–994, 994b
drug therapy for, 994, 995b
etiology and pathophysiology of, 992, 993f
health promotion for, 995
interprofessional care for, 994–995, 994b
nursing assessment for, 995, 995b
nursing diagnoses for, 995
nursing management for, **995–996**
nutritional therapy, 995
respiratory distress in, 996b

surgical therapy for, 994
Acute pericarditis, **782–784**
clinical manifestations, 782–783
complications, 783, 783b
diagnostic studies, 783, 783f
etiology and pathophysiology, 782, 782f, 782b
interprofessional care, 783–784, 784f, 784b
nursing management, **784**, 784b
Acute pharyngitis, **486–487**
clinical manifestations of, 486–487
interprofessional and nursing care for, **487**
Acute poststreptococcal glomerulonephritis, 1033
Acute pulmonary embolism, 533b
Acute pyelonephritis, **1028–1029**, 1029f
drug therapy for, 1029b
interprofessional care for, 1029, 1029b
nursing management for, **1029–1030**
Acute respiratory distress syndrome, **1597–1600**
Berlin definition of, 1599b
case study, 1603b
chronic or late phase, 1598
clinical manifestations of, 1599, 1599f, 1599b
clinical progression of, 1598–1599
complications of, 1599–1600, 1600b
diagnostic studies in, 1599

X

Xalatan (latanoprost), 371b

Xalkori (crizotinib), 184b

Xarelto (rivaroxaban), 817b

Xeljanz, *See* Tofacitinib

Xenical (orlistat), 880b

Xerostomia, **497**

X-linked disorders, 178

X-linked gene, 176b

X-linked recessive disorders, 178b, 179

Xolair (omalizumab), 551b–552b

Xopenex (levalbuterol), 551b–552b

X-rays, 1440

- basic, 1440b–1441b
- chest, 472b–473b, 669b–671b, 673, 673f
  - in TB, 512
- kidneys, ureters, bladder (KUB), 1019b–1022b
- lower gastrointestinal series, 841, 842b–845b, 846f
- skeletal, 601b–602b
- skull, 1296b–1297b
- small bowel series, 842b–845b
- spine, 1296b–1297b
- upper gastrointestinal series, 841, 842b–845b

Xtandi (enzalutamide), 1267b

Xyzal (levocetirizine), 481b–482b

Y

Yeast infections, 1235–1236

Y-linked disorders, 178

Yoga, 82b

Young men, 1220b

Young-old adult, 62

Z

Zafirlukast (Accolate), 481b–482b, 551b–552b, 552–553

Zanaflex (tizanidine), 116b, 1370b

Zantac (ranitidine), 899b

Zaroxolyn (metolazone), 689b

Zebeta (bisoprolol), 687b–688b

Zegerid (omeprazole and sodium bicarbonate), 899b

Zenker's diverticulum, 903

Zestril (lisinopril), 687b–688b, 713b

Zetia (ezetimibe), 707b

Ziagen (abacavir), 184b

Zileuton (Zyflo), 481b–482b, 551b–552b, 552–553

Zinbryta (daclizumab), 1362b

Zinc, 483b

Zinc deficiency, 164b

Zocor (simvastatin), 706b

Zofran (ondansetron), 323b, 891b

Zoladex (goserelin), 1267b

Zoledronic acid (Reclast, Zometa), 645–646, 646b, 1495

Zollinger-Ellison syndrome, 906

Zontivity (vorapaxar), 713b

Zonule, 351

Zutripro oral solution (hydrocodone, chlorpheniramine, and pseudoephedrine), 481b–482b

Zyban (bupropion), 144–145, 145b–146b
Zyflo (zileuton), 481b–482b, 551b–552b, 552–553
Zygomatic arch fracture, 1468b
Zyrtec (cetirizine), 481b–482b
Zytiga (abiraterone), 1267b

IBC

Abbreviations

ABG	arterial blood gas
ACE	angiotensin-converting enzyme
ACLS	advanced cardiac life support
ACS	acute coronary syndrome
ACTH	adrenocorticotropic hormone
ADH	antidiuretic hormone
AED	automatic external defibrillator
AIDS	acquired immunodeficiency syndrome
AKA	above-knee amputation
AKI	acute kidney injury
ALI	acute lung injury
ALL	acute lymphocytic leukemia
ALS	amyotrophic lateral sclerosis
AMI	acute myocardial infarction
ANA	antinuclear antibody
ANS	autonomic nervous system
AORN	Association of periOperative Room Nurses
APD	automated peritoneal dialysis
aPTT	activated partial thromboplastin time
ARDS	acute respiratory distress syndrome
ATN	acute tubular necrosis
BCLS	basic cardiac life support
BKA	below-knee amputation
BMI	body mass index
BMR	basal metabolic rate
BMT	bone marrow transplantation
BPH	benign prostatic hyperplasia
BSE	breast self-examination
BUN	blood urea nitrogen
CABG	coronary artery bypass graft
CAD	coronary artery disease; circulatory assist device
CAPD	continuous ambulatory peritoneal dialysis
CAVH	continuous arteriovenous hemofiltration
CBC	complete blood count
CCU	coronary care unit; critical care unit
CDC	Centers for Disease Control and Prevention
CIS	carcinoma in situ
CKD	chronic kidney disease
CLL	chronic lymphocytic leukemia
CML	chronic myelocytic leukemia
CMP	cardiomyopathy
CN	cranial nerve
CNS	central nervous system
CO	cardiac output
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPR	cardiopulmonary resuscitation
CRRT	continuous renal replacement therapy
CRNA	certified registered nurse anesthetist
CSF	cerebrospinal fluid
CT	computed tomography
CVA	cerebrovascular accident; costovertebral angle
CVAD	central venous access device

CVI	chronic venous insufficiency
CVP	central venous pressure
D&C	dilation and curettage
DDD	degenerative disk disease
DI	diabetes insipidus
DIC	disseminated intravascular coagulation
DJD	degenerative joint disease
DKA	diabetic ketoacidosis
DM	diabetes mellitus; diastolic murmur
DRE	digital rectal examination
DVT	deep vein thrombosis
ECF	extracellular fluid
ECG	electrocardiogram
ED	emergency department; erectile dysfunction
EEG	electroencephalogram
EMG	electromyogram
EMS	emergency medical services
ENT	ear, nose, and throat
ERCP	endoscopic retrograde cholangiopancreatography
ERT	estrogen replacement therapy
ESKD	end-stage kidney disease
ESR	erythrocyte sedimentation rate
ET	endotracheal
FEV	forced expiratory volume
FRC	functional residual capacity
FUO	fever of unknown origin
GCS	Glasgow Coma Scale
GERD	gastroesophageal reflux disease
GFR	glomerular filtration rate
GH	growth hormone
GI	glycemic index
GTT	glucose tolerance test
GU	genitourinary
GYN, Gyn	gynecologic
HAI	health care–associated infection
HAV	hepatitis A virus
Hb, Hgb	hemoglobin
HBV	hepatitis B virus
Hct	hematocrit
HCV	hepatitis C virus
HD	hemodialysis, Huntington's disease
HDL	high-density lipoprotein
HF	heart failure
HIV	human immunodeficiency virus
H&P	history and physical examination
HPV	human papillomavirus
HSCT	hematopoietic stem cell transplantation
IABP	intraaortic balloon pump
IBS	irritable bowel syndrome
ICP	intracranial pressure
I&D	incision and drainage
IE	infective endocarditis
IFG	impaired fasting glucose
