Diuretics reduce symptoms of fluid overload and congestion in both HFrEF and HFpEF. Diuretics reduce edema, pulmonary venous pressure, and preload (see Table 32.7). These drugs act on the kidney by promoting excretion of sodium and water. Loop diuretics (e.g., furosemide (Lasix) and bumetanide [Bumex]) act on the ascending loop of Henle to promote sodium, chloride, and water excretion. Problems in using loop diuretics include low serum potassium levels, ototoxicity, and possible allergic reaction in patients sensitive to sulfa-type drugs. Thiazide diuretics inhibit sodium reabsorption in the

distal tubule, promoting excretion of sodium and water. They also can severely lower potassium levels.

In chronic HF, the lowest effective dose of diuretic should be used. Side effects of diuretics include dehydration, hypotension, orthostasis, renal dysfunction, and electrolyte abnormalities. Diuretic resistance can occur in HF patients, necessitating dosing augmentation and the addition of different diuretic classes.

Device Therapy

Patients with HFrEF may benefit from implantable cardiac devices. HF patients must be on appropriate therapies before becoming a candidate for device therapy. Patients with an LVEF < 35% are at significant risk for SCD. An ICD is recommended for primary prevention of SCD in these patients.[1] In patients with a LVEF <35%, neurohormonal effects and cardiac remodeling can result in dyssynchronous contraction of the LV and RV, contributing to poor ventricular filling and reduced CO. CRT is recommended for these patients.[1] With CRT, an extra pacing lead is placed through the coronary sinus to a coronary vein of the LV. This lead coordinates right and left ventricular contractions (Fig. 34.4). Patients with symptomatic HFrEF often need both CRT and an ICD. Combination implantable devices are available. (Pacemakers and defibrillators are discussed in Chapter 35.) Mechanical assist devices available to sustain HF patients with deteriorating function and those awaiting cardiac transplant will be discussed later in the chapter.

Check Your Practice

Your patient is scheduled for a biventricular pacemaker for her worsening HF. She currently has a demand pacemaker and asks you why she needs this new one.

- How would you respond to her question?

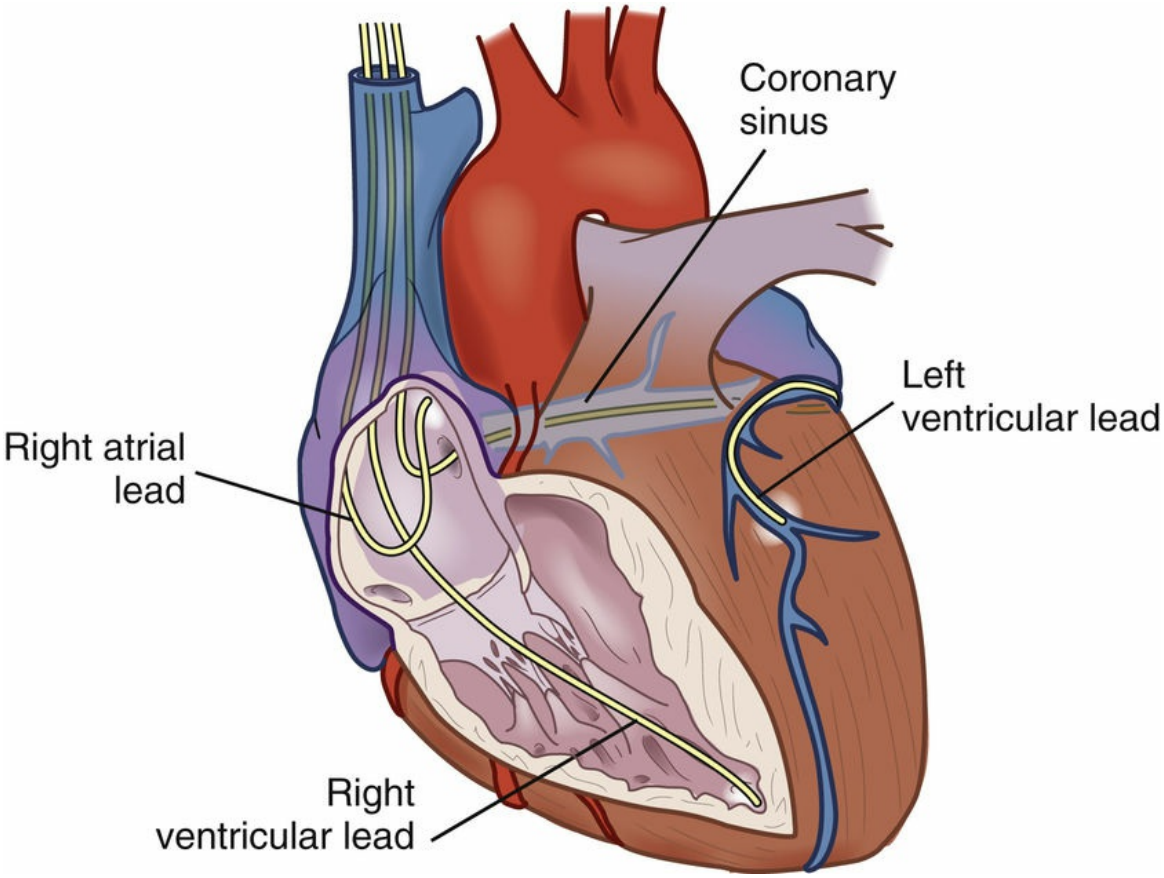

FIG. 34.4 Placement of pacing leads in cardiac resynchronization therapy.

Remote Monitoring of Physiologic Data

Implanted ICD and CRT devices can be used for remotely monitoring HF patients. Physiologic parameters of worsening HF known to change prior to symptom emergence can predict HF decompensation and help with clinical decision making. Information from these devices can be retrieved electronically via secure websites. Examples of parameters we can remotely follow are BP, weight, HR trends (can evaluate adequacy of beta blockade, increasing HR can indicate worsening HF), HR variability (HRV, a reduction is associated with higher risk for exacerbation and hospitalization), patient activity level, dysrhythmias, and intrathoracic impedance (an indicator of intrathoracic fluid level providing early detection of impending ADHF).[16] Implantable hemodynamic monitoring is also possible. A

pulmonary artery sensor can be implanted in the pulmonary artery during a right heart catheterization. It can provide information about HR, systolic, diastolic, and mean pulmonary artery pressure. Detection of early hemodynamic and fluid status changes can allow for proactive management to reduce fluid overload, which decreases hospitalizations in patients with HFrEF. [17]

Nutritional Therapy

Poor adherence to a low-sodium diet and failure to take prescribed medications as directed are the most common reasons for readmissions of HF patients to the hospital. It is critical that you accurately assess a patient's diet and teach both the patient and caregiver about the importance of diet.

Take a detailed diet history. Determine not only what foods the patient eats, but also when, where, and how often the patient dines out. Assess the cultural value of food. Use this information to help the patient in making appropriate dietary choices when developing an individualized and culturally sensitive diet plan. The AHA website has helpful dietary guidelines for HF patients.

HF guidelines vary with regard to sodium restriction in HF management. There is agreement that excess sodium may worsen HF symptoms and facilitate an exacerbation. A low sodium intake may lead to higher adverse event rates in later stages of HFrEF. The degree of sodium restriction depends on the severity of the HF and the effectiveness of diuretic therapy. Generally, sodium intake is restricted to 2 grams per day (Table 34.8). Teach the patient what foods are low and high in sodium content and how to read labels. Review how to find sodium content per serving and the number of servings per package (Fig. 34.5). Teach ways to enhance food flavors without the use of salt (e.g., substituting lemon juice, various spices). Discuss the high sodium content of most restaurant foods.

Fluid restrictions are not often prescribed for the patient with mild to moderate HF. However, fluid restrictions may be needed for stage D HF patients with persistent fluid retention despite appropriate

sodium restriction.

To monitor fluid status, tell patients to weigh themselves at the same time each day. To ensure valid trending, this should be before breakfast, using the same scale, and wearing the same type of clothing. For patients with visual limitations, suggest scales with larger numbers or an audible response. Tell patients to call the HCP about a weight gain of 3 lb (1.4 kg) over 2 days or a 3- to 5-lb (2.3-kg) gain over a week.[12]

Nursing Management: Heart Failure

Nursing Assessment

Subjective and objective data that you should obtain from a patient with HF are shown in Table 34.9. Carefully review the patient's current prescription and over-the-counter (OTC) drugs. Chronic HF patients often take multiple other medications for co-existing conditions and underlying CVD. OTC medications known to pose significant risk to people with HF include nonsteroidal antiinflammatory drugs (NSAIDs), higher-than-prescribed aspirin doses, ephedrine, pseudoephedrine, and diet pills. NSAIDs can contribute to sodium retention and an exacerbation of HF.

TABLE 34.8 Nutritional TherapyLow-Sodium Diets

General Principles

- Do not add salt or seasonings containing sodium when preparing foods.*
- Do not use salt at the table.*
- 1 tsp of salt equals 2.3 g of sodium.
- Avoid high-sodium foods (e.g., canned soups, processed meats, cheese, frozen meals).
- Limit milk products to 2 cups daily.

Sample Menu Plans for 2400-mg Sodium Diet

Breakfast	Sodium (mg)
2/3 cup bran cereal	161

(2⁄3 cup Shredded Wheat cereal)†	3
1 slice whole-wheat bread	149
1 medium banana	1
6 oz fruit yogurt, fat free	85
1 cup fat-free milk	126
2 Tbsp jelly	5
Coffee, 8 oz	5

Lunch	
Chicken breast sandwich	
2 slices (3 oz) chicken breast, skinless	65
2 slices whole wheat bread	299
1 slice (¾ oz) American cheese	328
(1 slice [¾ oz] Swiss cheese, natural)†	54
Large-leaf romaine lettuce	1
2 slices tomato	90
1 Tbsp mayonnaise, low fat	90
1 medium peach	7

Dinner	
¾ cup vegetarian spaghetti sauce	459
(6 oz no-salt-added tomato paste)†	260
1 cup spaghetti	1
3 Tbsp parmesan cheese	349
Spinach salad	
1 cup fresh spinach leaves	24
¼ cup fresh carrots (grated)	10
¼ cup fresh mushrooms (sliced)	1
2 Tbsp vinaigrette dressing	0
½ cup canned pears, juice pack	4
½ cup corn, cooked from frozen	4

Snack	
1⁄3 cup almonds	4
¼ cup dried apricots	3
6 oz fruit yogurt, fat free	85

* 1 tsp of salt equals 2.3 g of sodium.

† Substitutes to reduce to 1500-mg sodium diet.

Review the patient's dietary habits to identify issues related to an exacerbation of HF. Explore the patient's chronic health problems as they may exacerbate HF, affecting the plan of care and the timing and choice of therapies. For example, a patient with sleep apnea may not use a continuous positive airway pressure device at night. This can worsen pulmonary or systemic HTN and lead to an exacerbation of HF.

TABLE 34.9 Nursing AssessmentHeart Failure

Subjective Data
Important Health Information

Past health history: CAD (including recent MI), HTN, cardiomyopathy, valvular or congenital heart disease, diabetes, hyperlipidemia, renal disease, thyroid or lung disease, rapid or irregular heart rate

Medications: Use of and adherence with any heart drugs. Use of diuretics, estrogens, corticosteroids, NSAIDs, OTC drugs, herbal supplements

Functional Health Patterns

Health perception–health management: Fatigue, depression, anxiety

Nutritional-metabolic: Usual sodium intake. Nausea, vomiting, anorexia, stomach bloating. Weight gain, ankle swelling

Elimination: Nocturia, decreased daytime urine output, constipation

Activity-exercise: Dyspnea, orthopnea, cough (e.g., dry, productive). Palpitations, dizziness, fainting

Sleep-rest: Number of pillows used for sleeping. Paroxysmal nocturnal dyspnea, insomnia, sleep apnea

Cognitive-perceptual: Chest pain or heaviness. RUQ pain,

abdominal discomfort. Behavioral changes, visual changes

Objective Data

Integumentary

Cool, diaphoretic skin. Cyanosis or pallor. Peripheral edema (right-sided HF)

Respiratory

Tachypnea, crackles, wheezes. Frothy, blood-tinged sputum

Cardiovascular

Tachycardia, S_3, S_4, murmurs. Pulsus alternans. PMI displaced inferiorly and posteriorly, lifts and heaves, jugular venous distention

Gastrointestinal

Abdominal distention, hepatosplenomegaly, ascites

Neurologic

Restlessness, confusion, decreased attention or memory

Possible Diagnostic Findings

Altered serum electrolytes (especially Na^+ and K^+), ↑ BUN, creatinine, or liver function tests. ↑ NT-proBNP or BNP. Chest

x-ray showing cardiomegaly, pulmonary congestion, and interstitial pulmonary edema. Echocardiogram showing increased chamber size, decreased wall motion, decreased LVEF or normal LVEF with evidence of diastolic dysfunction (abnormal relaxation/filling). Atrial and ventricular enlargement on ECG. ↓ O_2 saturation

Nursing Diagnoses

Nursing diagnoses for the patient with HF include:

- Impaired gas exchange
- Impaired cardiac output
- Fluid imbalance
- Activity intolerance

Additional information on nursing diagnoses and interventions for the patient with HF is presented in eNursing Care Plan 34.1 on the website for this chapter.

Chicken Noodle Soup

Nutrition Facts

Serving Size 1/2 cup (120 mL) condensed soup
Servings Per Container about 2.5

Planning

Nursing care focuses on the priority problems of decreased CO, impaired oxygenation, fluid overload, intolerance of physical activity and managing a complex medication regimen. The overall goals for the patient with HF include (1) decrease in symptoms (e.g., shortness of breath, fatigue); (2) decrease in peripheral edema; (3) increase in exercise tolerance; (4) adherence with the treatment plan, including appropriate evidence-based medication and device therapies; and (5) no complications related to HF.

Nursing Implementation

Health Promotion

Communication and joint decision making among the patient, caregiver, and interprofessional team are integral to high-quality, patient-centered care. Currently, the emphasis is on aggressively identifying and treating risk factors in the patient with stage A HF to prevent or slow the progression to symptomatic HF.[18] By identifying patients with obesity, metabolic syndrome, diabetes, HTN, and hyperlipidemia as already having stage A HF, goals related to a heart-healthy lifestyle can be given deserved urgency. Recommended lifestyle modifications begin with weight management, diet, and regular exercise. Often, medications are needed. Encourage patients to get influenza and pneumococcal vaccinations. Patients with valvular disease that may be contributing to HF should be evaluated for valve repair or replacement procedures. Coronary revascularization procedures should be considered in patients with CAD. Antidysrhythmic drugs or pacing therapy may be indicated for patients with serious dysrhythmias or conduction disturbances.

Acute Care

Many persons with HF have 1 or more episodes of ADHF. Common precipitating factors to HF hospitalization include respiratory infections, dysrhythmias, acute coronary syndrome, uncontrolled HTN, and nonadherence to medications and/or diet. Patients with ADHF are usually admitted through the ED, stabilized, then cared for in an ICU, intermediate care unit, or specialized HF unit with continuous ECG monitoring capability.

Successful HF care depends on several important principles: (1) HF is a progressive disease; (2) treatment plans are established with QOL goals; (3) symptom management depends to a significant degree on adherence to self-management protocols (e.g., daily weights, diet, exercise, recognizing signs and symptoms of decompensation); and drug and device therapies; (4) precipitating factors, etiologies, and contributing comorbid conditions must be addressed; (5) complex care needs often require care in multiple settings, increasing risk for fragmented care; and (6) support systems are essential to the success of the entire treatment plan.

Ambulatory Care

Transitional care programs and protocols are designed to ensure coordination and continuity of health care as patients transfer between care settings. Programs that include comprehensive discharge planning, collaboration among providers, and planned, prompt follow-up with HCPs have shown reduced readmission rates.[19]

Goals of ambulatory HF care include symptom management, QOL maintenance, morbidity and mortality benefit from therapy, identifying and mitigating factors precipitating ADHF and hospitalization, and closely monitoring responses to and potential side effects of therapies. HF is a chronic and progressive condition that will require lifelong therapies. It is important to include the patient and caregiver(s) in the overall care plan. Help them develop a clear action plan for response to increased signs and symptoms of impending exacerbation. A patient and caregiver guide for the patient

with HF is shown in Table 34.10.

Effective home health (HH) care can prevent future hospitalizations by providing ongoing assessments (e.g., monitoring vital signs and weight, evaluating response to therapies) and followup.[19] HH nurses often use individualized care protocols coordinated with the patient and HCP. The protocols allow the nurse and patient to identify signs and symptoms of worsening HF (e.g., weight gain, increased dyspnea). Many agencies offer specialized HF programs. Telehealth and device remote monitoring technology (e.g., electronic scale, BP cuff, pulse oximeter) can collect physiologic and symptom data (Fig. 34.6).[15,16] Results can be sent to the HCP via telephone or secure website. In response to collected data, therapeutic interventions, such as a temporary increase in diuretic therapy, can be implemented to improve functional capacity and prevent rehospitalization.

Teach the patient the basic mechanism of action of medications and signs of drug toxicity in easily understood terms. Effective self-care includes proper technique in taking a pulse (for a full minute) and use of home BP monitor and device remote monitoring equipment. The patient should understand specific HCP instructions on when to hold heart rate–lowering medications, such as β-blockers and digoxin. If patients are taking diuretic and/or potassium supplement medications, teach them the signs and symptoms of hypokalemia and hyperkalemia, including weakness, fatigue, constipation, and muscle cramping.

Exercise training (e.g., CR) can improve symptoms of chronic HF. Exercise for patients with HF has been found to be safe and to improve overall sense of well-being. It has been associated with reduced mortality.[1,14] Tailor exercise programs based on what the patient most enjoys doing. Teach the patient about the importance of rest periods, especially after exertion, and energy-conserving behaviors. Changes may be needed if environmental conditions involve an increased cardiac workload (e.g., frequent climbing of stairs). Consultation with a physical therapist or occupational therapist may be appropriate.

TABLE 34.10 Patient & Caregiver TeachingHeart Failure

Include the following instructions when teaching the patient and caregiver about the management of heart failure:

Dietary Therapy

- Consult the diet plan and list of permitted and restricted foods.
- Adhere to specific sodium restriction guidelines outlined by your HCP.
- Examine labels to determine sodium content. Also examine the labels of over-the-counter drugs, such as laxatives, cough medicines, and antacids for sodium content.
- Avoid using salt when preparing foods or adding salt to foods.
- Weigh yourself at the same time each day, preferably in the morning, using the same scale and wearing similar clothes.
- Eat small, frequent meals.

Activity Program

- Increase walking and other activities gradually, provided they do not cause fatigue or dyspnea.
- Consider a cardiac rehabilitation program.
- Avoid extremes of heat and cold.

Ongoing Monitoring

- Know the signs and symptoms of worsening HF, including increasing dyspnea, cough, orthopnea, PND, weight gain, edema, fluid retention, fatigue, and tiredness with physical activity.
- Recall the symptoms when illness began. Reappearance of

previous symptoms may indicate a recurrence.

- Report at once any of the following to the HCP:
    - Weight gain of 3 lb (1.4 kg) in 2 days, or 3–5 lb (2.3 kg) in a week
    - Difficulty breathing, especially with activity or when lying flat
    - Waking up breathless at night
    - Frequent dry, hacking cough, especially when lying down
    - Fatigue, weakness
    - Swelling of ankles, feet, or abdomen. Swelling of face or difficulty breathing (if taking ACE inhibitors)
    - Nausea with abdominal swelling, pain, and tenderness
    - Dizziness or fainting
- Follow up with HCP on regular basis.
- Consider joining a local support group with your family members and/or caregiver(s).

Health Promotion

- Obtain annual influenza vaccination.
- Obtain pneumococcal vaccine (see Table 27.5 for guidelines on pneumococcal vaccination).
- Develop plan to reduce risk factors (e.g., BP control, tobacco cessation, blood glucose/Hb A1C control, weight reduction).

Rest

- Plan a regular daily rest and activity program.
- After exertion, such as exercise and ADLs, plan a rest period.
- Consider shorter working hours or schedule rest period during working hours.

- Avoid emotional upsets. Share any concerns, fears, feelings of depression, etc. with HCP.

Drug Therapy

- Take each drug as prescribed.
- Develop a system (e.g., daily chart, weekly pillbox) to ensure drugs are taken.
- Count pulse rate each day before taking drugs (if appropriate). Know the limits that your HCP wants for your pulse rate.
- Take BP at determined intervals (if appropriate). Know your target BP limits.
- Know signs and symptoms of orthostatic hypotension and how to prevent them (see Table 32.12).
- If taking anticoagulants, know signs and symptoms of internal bleeding (bleeding gums, increased bruises, blood in stool or urine) and what to do.
- Know your INR and target range if taking warfarin (Coumadin) and how often to have blood checked.

ACE, Angiotensin-converting enzyme; *INR,* international normalized ratio.

Mechanical Circulatory Support Devices in End-Stage Heart Failure

Therapeutic options for stage D HF patients include: (1) chronic inotropic therapy, (2) mechanical circulatory support (MCS) devices, (3) palliative care and hospice that may or may not include ICD deactivation, and (4) heart transplant. MCS devices can be beneficial to carefully selected patients for short-term management, long-term and bridge-to-transplant management, or as destination therapy.[12] Patients who are ineligible for heart transplant may be candidates for lifelong MCS. Short-term MCS include IABP, extracorporeal membrane oxygenation (ECMO), and various continual flow pumps.

The limitations of bed rest and the risk for infection and vascular complications prevent long-term use of these devices.

Long-term MCS devices include LV assist devices (VADs), including percutaneous devices (PVAD) and transplanted devices (LAVDs, BiVADs) (see Chapter 65). VADs provide highly effective long-term support and have become standard care in many heart transplant centers. The heart pump runs via a driveline that exits the abdominal wall and attaches to a system controller with patient specific settings. VADs operate on AC current or batteries (Fig. 34.7). Morbidity and mortality is significantly reduced if MCS is started before onset of severe right HF and systemic organ failure.[12]

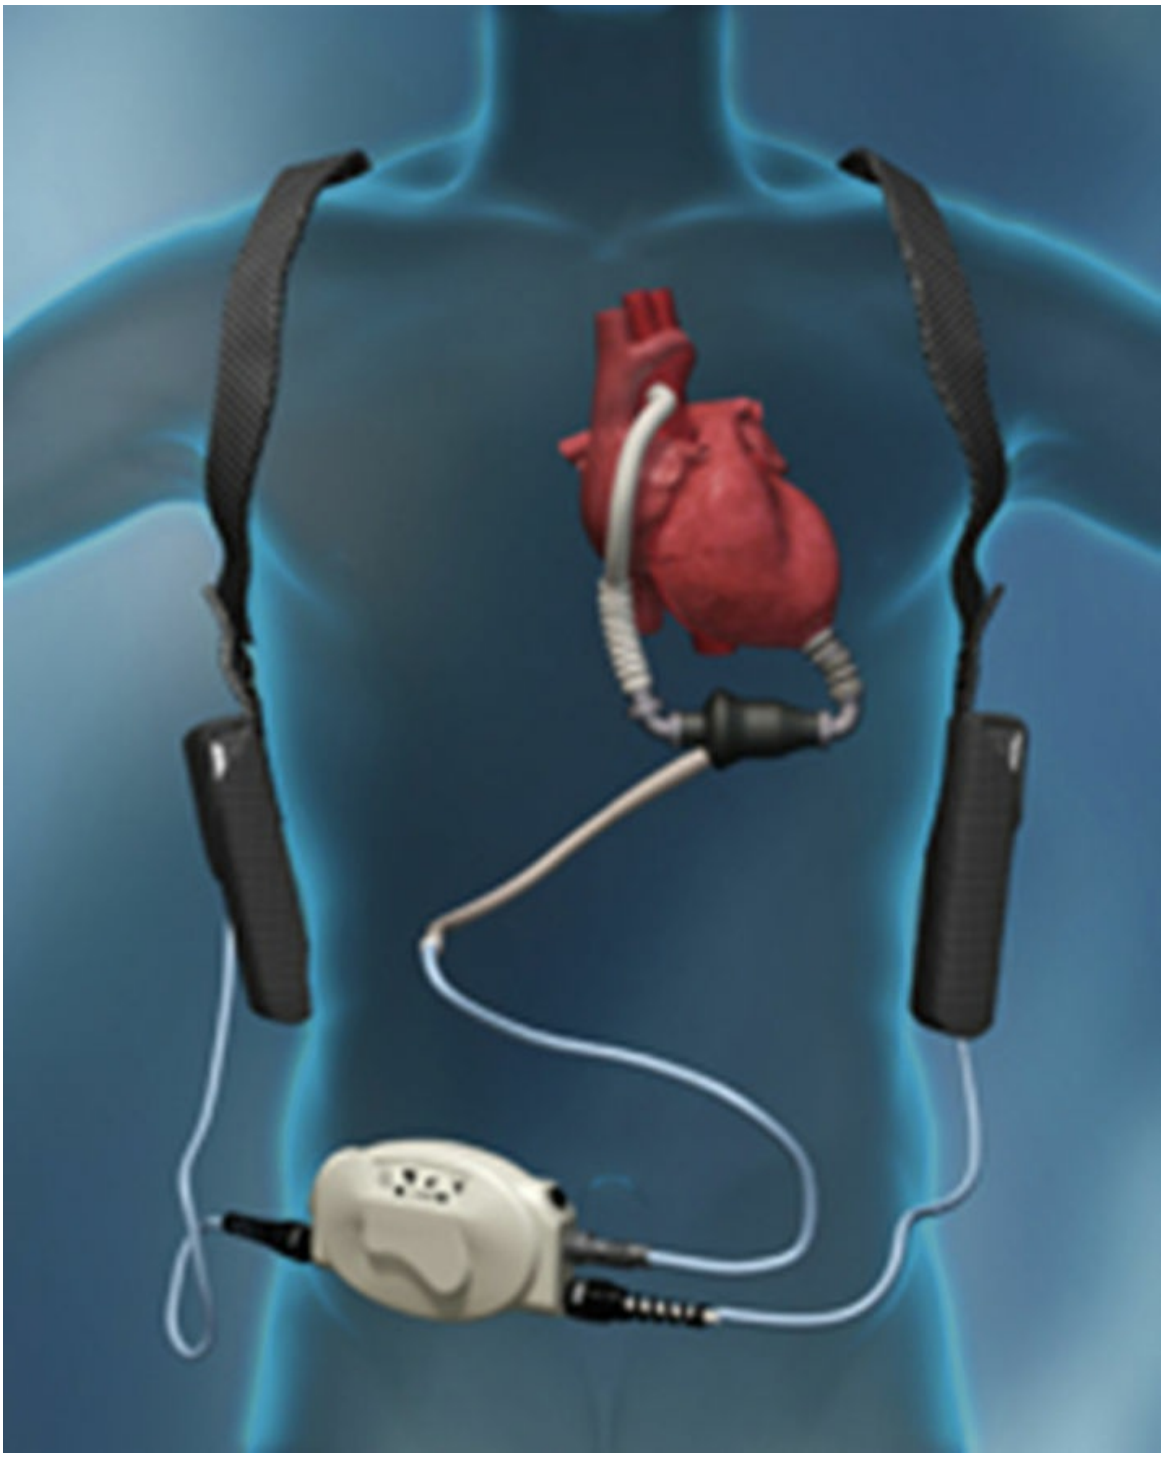

FIG. 34.7 Left ventricular assist device.
Reprinted with the permission of Thoratec Corp.

Palliative and End-of-Life Care

HF mortality rates are still high. One in 5 persons with HF die within

a year of diagnosis. The estimated 5-year survival rate is worse than for most types of cancer. Repeated hospitalizations and ED visits for ADHF can be predictive of end-stage HF.[1,15,19]

The ACCF and AHA provide guidelines for patients with end-stage HF (stage D).[1] End-of-life discussions and management are emphasized, including advanced directives and information about advanced HF therapies (e.g., VADs, heart transplants), palliative care, and hospice.

Palliative care may be appropriate earlier in the course of the illness in conjunction with other therapies intended to prolong life. Palliative nursing care of the HF patient emphasizes (1) unifying the patient, family, and health care team in formulating a plan of care; (2) aggressive symptom management; (3) avoiding therapies that are no longer appropriate or effective and may prolong suffering; (4) integrating emotional and spiritual support for patient and family; and (5) determining when a patient may be ready to consider hospice care.

Patients with advanced CVD are eligible for hospice when (1) an HCP certifies that a life expectancy of 6 months or less is expected assuming the disease takes its normal course, (2) the patient has received optimal medical treatment and is not a candidate for further invasive procedures, and (3) the patient is assessed at NYHA Class IV. End-stage HF patients who meet hospice criteria are often referred late or not at all. Challenges in referring these patients to hospice include (1) difficulties with accurate life expectancy prediction, (2) reluctance to accept a DNR order due to multiple resuscitation survivals and implantable devices, and (3) a lack of patient and family understanding as to the chronic and terminal nature of HF.[20,21]

End-of-life nursing care of HF patients includes ongoing assessment and evaluation of interventions for effectiveness. Strategies include patient and caregiver support, drug therapies, and nondrug therapies. Palliative and end-of-life care are discussed in Chapter 9.

TABLE 34.11 Common Indications and Contraindications for Heart Transplantation

Indications

- End-stage HF refractory to medical care
- Severe, decompensated, inoperable, valvular heart disease
- Recurrent life-threatening dysrhythmias not responsive to maximal interventions, including defibrillators
- Any other heart abnormalities that severely limit normal function and/or have a mortality risk of more than 50% within 2 years

Absolute Contraindications

- Chronologic age over 70 years or physiologic age over 65 years
- Life-threatening illness (e.g., cancer) that will limit survival to <5 years despite therapy
- Advanced cerebral or peripheral vascular disease not amenable to correction
- Active infection, including HIV infection
- Severe pulmonary disease that will likely result in the patient being ventilator-dependent after transplant

Relative Contraindications

- Severe obesity
- Psychologic impairment
- Active substance use (e.g., alcohol, drugs, tobacco)
- Uncontrolled diabetes with vascular and neurologic complications
- Irreversible liver or kidney dysfunction not explained by HF
- Evidence of noncompliance with accepted medical practices

- Lack of social support network that can make long-term commitment for patient's welfare
- Unrealistic expectations by the patient or caregiver about transplant, its risks, and its benefits

Evaluation

The expected outcomes are that the patient with HF will

- Maintain adequate O_2/CO_2 exchange at the alveolar-capillary membrane to meet O_2 needs of the body
- Maintain adequate blood pumped by the heart to meet metabolic demands of the body
- Reduction or absence of edema and stable baseline weight
- Achieve a realistic program of activity that balances physical activity with energy-conserving activities

Heart Transplantation

Heart transplantation is the transfer of a healthy donor heart to a patient with a diseased heart. It is done to treat a variety of terminal or end-stage heart conditions (Table 34.11). In the United States, about 3000 patients are awaiting heart transplants. However, an average of only 2000 hearts become available. The 1-year transplant survival rate is 85% to 90%, while the 3-year survival rate is about 75%.[22,23] A heart transplant is a gold standard therapy for some patients in end-stage HF.

Criteria for Selection

A careful selection process ensures that hearts are distributed fairly and to those who will benefit most from the donor heart. The United Network for Organ Sharing (UNOS) oversees a system to allocate donor organs. UNOS and transplantation are discussed in Chapter 13.

Indications and contraindications for a heart transplant are outlined

in Table 34.11. Once a person meets the criteria for a transplant, an exhaustive physical examination and diagnostic workup are done. Heart function, vascular and immune systems are assessed. The patient and caregiver undergo a comprehensive psychologic evaluation that assesses coping skills, support systems, and commitment to follow a rigorous life-long regimen. The complexity of the transplant process may be overwhelming to a patient without an adequate support system and understanding of the needed lifestyle changes.

Donor and recipient matching is based on body and heart size and an immunologic assessment. That assessment includes ABO blood type, antibody screen, panel of reactive antibody (PRA) level, and human leukocyte antigen typing.

A person accepted as a transplant candidate is placed on a transplant list. This may happen quickly during an acute illness or after a longer period. Stable patients may wait at home and receive ongoing medical care. If unstable, a patient may be hospitalized for more intensive therapy. Unfortunately, the overall waiting period for a new heart is long. Many patients die while waiting for a transplant.

Ethical/Legal Dilemmas

Competence

Situation

M.T., a 60-yr-old man, has been awaiting heart transplantation for 6 months. He has been in the ICU for 1 month since he needed a VAD for his failing heart. He recently had a stroke, which is a complication of the device. It left him paralyzed on his right side. He is only able to answer yes/no questions by shaking his head. He has needed mechanical ventilation since his stroke. For the past 2 weeks, he has needed hemodialysis because of renal failure. Recently, when you suction him, he turns his head away from you and bites down on the endotracheal tube. Although he does not have an advance directive,

his wife and daughter tell you that, on many occasions before these events, he expressed that he would not want to live if he lost his independence. His wife and daughter request to have the mechanical ventilator withdrawn.

Ethical/Legal Points for Consideration

- Decisional capacity for informed consent related to treatment decisions involves 4 elements: (1) information provided about possible treatment options must be understood by patients, (2) patients must have the capacity to deliberate about the treatment choices and their consequences, (3) patients' treatment decisions must be freely chosen and made without coercion, and (4) patients must be able to communicate their decisions.
- Legal competence, as determined by the courts, has a low threshold. The ability to respond to questions by signaling a yes or no may be enough to prove understanding of the questions, ability to discriminate between choices, and ability to communicate choices, providing that the answers make sense and are appropriate. Review how your state defines legal competence.
- Next of kin are the legal decision makers in the absence of advance directives if the patient is unable to make decisions for himself. Decisional capacity should be tested without assuming it is absent.
- Some courts have accepted past assertions of preferences, past behavior, and assertions of their parties as evidence to support end-of-life preferences in the absence of advance directives.
- Know your agency's policies and the local jurisdiction's laws and regulations about informed consent and end-of-life decision making.

Discussion Questions

1. What would you do next given M.T.'s behavior and the information you obtained from his wife?
2. What are your feelings and concerns about caring for a patient for whom withdrawal of treatment will result in death?

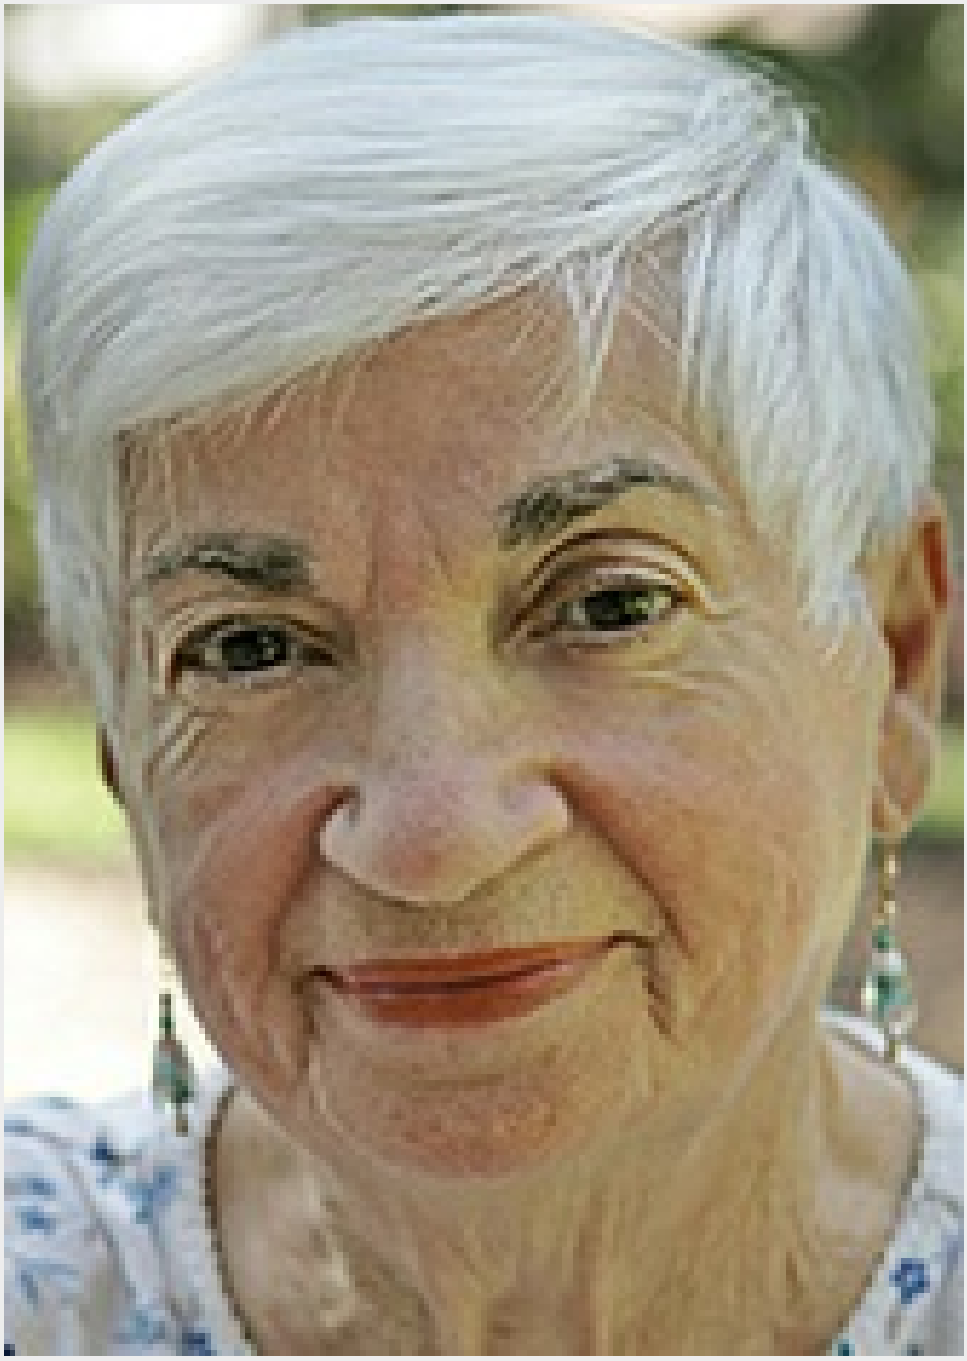
Surgical Procedure

The transplant donor is someone who has irreversible brain injury. A surgical team goes to the hospital of the donor to remove donated organs after the declaration of brain death. The retrieved organs are transported on ice until they can be implanted. For the heart, this is optimally less than 4 hours. Often the donor heart is flown to the recipient's hospital. The donor heart is then implanted into the recipient using 1 of 2 approaches. In the biatrial approach, the recipient's damaged heart is removed at the midatrial level and the donor heart connected at the LA, pulmonary artery, aorta, and RA. In the bicaval approach, the RA of the recipient's heart (with the SA node and atrial conduction intact) is preserved and then the donor heart is connected. Cardiopulmonary bypass is needed during the surgical procedure to maintain oxygenation and perfusion to vital organs.

Posttransplantation

After cardiac transplant, a variety of complications can occur, including a risk for SCD. Acute rejection is an immediate posttransplant complication, and immunosuppressive therapy is the key in posttransplant management. In the first year after transplantation, the major causes of death are infection and acute rejection.

Most immunosuppressive regimens include corticosteroids, calcineurin inhibitors (tacrolimus), and antiproliferative drugs (mycophenolate mofetil). The mechanisms of action and side effects of these and other immunosuppressants are discussed in Chapter 13 and Table 13.17. Because of the use of immunosuppressive therapy, infection is a primary concern after transplant surgery. On a long-term basis, immunosuppressive therapy increases the risk for cancers,



especially lymphomas, and cardiac vasculopathy (accelerated CAD).[23]

To detect rejection, an endomyocardial biopsy is done on a weekly basis for the first month, monthly for the next 6 months, and yearly thereafter. In this procedure, the HCP inserts a catheter into the jugular vein and moves it into the RV. The catheter uses a bioptome, a device with 2 small cups that can be closed, to remove small samples of heart muscle for analysis.[23]

Nursing management throughout the posttransplant period focuses on promoting patient adaptation to the transplant process, monitoring heart function, managing lifestyle changes, and providing ongoing teaching of the patient and caregiver.

Case Study

Heart Failure

© iStockphoto/Thinkstock.

Patient Profile

J.E. is a 70-yr-old Hispanic woman who was admitted to the intermediate care unit with a report of increasing shortness of breath, fatigue, and weight gain.

Subjective Data

- History of HTN for 20 yrs
- History of MI at 58 yrs of age
- Has increasing shortness of breath, fatigue, and an unexplained 11-lb weight gain during the past 2 wks
- Had a respiratory tract infection 2 wks ago; has persistent cough and edema in legs
- Cannot climb a flight of stairs without getting short of breath
- Sleeps with head elevated on 3 pillows
- Lives alone, does not always remember to take medication

Objective Data
Physical Examination

- Moderate respiratory distress, use of accessory muscles, respiratory rate 36 breaths/min
- Systolic heart murmur
- Bilateral crackles in all lung fields
- Cyanotic lips and extremities
- Skin cool and diaphoretic

Diagnostic Studies

- Chest x-ray results: cardiomegaly with right and left ventricular hypertrophy; fluid in lower lung fields
- Echocardiogram results: ejection fraction 20%

Interprofessional Care

- Furosemide (Lasix) 40 mg IV twice daily
- Potassium 40 mEq PO twice daily
- Enalapril (Vasotec) 5 mg/day PO

- Nesiritide (Natrecor) 2 mcg/kg IV bolus followed by a continuous infusion of 0.01 mcg/kg/min
- Continuous ECG monitoring
- Diet: 2-gram sodium diet
- Titrate O_2 to keep O_2 saturation >93%
- Monitor intake and output, and daily weights
- Serum electrolytes; cardiac biomarkers q8hr × 3

Discussion Questions

1. Explain the pathophysiology of J.E.'s heart disease and symptoms.
2. What clinical manifestations of ADHF did J.E. exhibit?
3. What is the significance of the findings of the diagnostic studies?
4. How would a serum NT-proBNP be beneficial in the diagnosis of ADHF?
5. Provide the rationale for each of the HCP's orders prescribed for J.E.
6. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Identify any collaborative problems.
7. ***Priority Decision:*** What are your priority nursing interventions for J.E.?
8. ***Collaboration:*** Which interventions could be delegated to UAP or other members of the interprofessional team?
9. ***Patient-Centered Care:*** What priority patient teaching measures should be instituted to prevent recurrence of ADHF and prepare J.E. for discharge?
10. ***Evidence-Based Practice:*** J.E. asks you why it is so important to "watch her salt." She tells you that food tastes better with salt. How would you respond to her?

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which statements accurately describe heart failure with preserved ejection fraction (HFpEF)? *(select all that apply)*
   a. Uncontrolled hypertension is the primary cause.
   b. Left ventricular ejection fraction may be within normal limits.
   c. The pathophysiology involves ventricular relaxation and filling.
   d. Multiple evidence-based therapies have been shown to decrease mortality.
   e. Therapies focus on symptom control and treatment of underlying conditions.
2. What compensatory mechanism involved in both chronic heart failure and acute decompensated heart failure leads to fluid retention and edema?
   a. Ventricular dilation
   b. Ventricular hypertrophy
   c. Increased systemic blood pressure
   d. Renin-angiotensin-aldosterone activation
3. The nurse is caring for a patient with acute decompensated heart failure who is receiving IV dobutamine. Why would this drug be prescribed? *(select all that apply)*

a. It dilates renal blood vessels.

b. It will increase the heart rate.

c. Heart contractility will improve.

d. Dobutamine is a selective β-agonist.

e. It increases systemic vascular resistance.

4. A patient with chronic heart failure and atrial fibrillation is treated with low-dose digitalis and a loop diuretic. What does the nurse need to do to prevent complications of this drug combination? *(select all that apply)*

a. Monitor serum potassium levels.

b. Teach the patient how to take a pulse rate.

c. Withhold digitalis if pulse rhythm is irregular.

d. Keep an accurate measure of intake and output.

e. Teach the patient about dietary potassium restrictions.

5. A barrier to hospice referrals for patients with stage D heart failure is

a. family member refusal.

b. scarcity of hospice facilities.

c. history of pacemaker placement.

d. difficulty in estimating prognosis.

6. Patients are at risk for which complications in the first year after heart transplantation? *(select all that apply)*

a. Cancer

b. Infection

c. Rejection

d. Vasculopathy

e. Sudden cardiac death

1. a, b, c, e, 2. d, 3. c, d, 4. a, b, 5. d, 6. b, c, e

Dysrhythmias

Kimberly Day

LEARNING OUTCOMES

1. Examine the nursing care of patients needing continuous electrocardiographic (ECG) monitoring.
2. Distinguish the clinical characteristics and ECG patterns of normal sinus rhythm, common dysrhythmias, and pacemaker rhythms.
3. Describe the nursing and interprofessional management of patients with common dysrhythmias.
4. Compare and contrast defibrillation and cardioversion, including indications for use and physiologic effects.
5. Describe the nursing and interprofessional management of patients with pacemakers and implantable cardioverter-defibrillators.
6. Select appropriate interventions for patients undergoing electrophysiologic testing and radiofrequency catheter ablation therapy.

Conceptual Focus

Fluids and Electrolytes
Perfusion

This chapter describes basic principles of electrocardiographic monitoring and the recognition and treatment of common dysrhythmias. Adequate perfusion requires the heart to generate sufficient cardiac output (CO) to distribute blood to the body tissues. Abnormal heart rhythms, called **dysrhythmias**, can directly decrease CO by changing stroke volume and heart rate (HR). For example, tachycardia from a fever may decrease CO and cause hypotension.

Your ability to recognize normal heart rhythms and dysrhythmias is an essential nursing skill.[1] Prompt recognition of a dysrhythmia and assessment of the patient's response to the rhythm is critical to maintaining adequate perfusion.

Rhythm Identification and Treatment

Conduction System

Four properties of heart cells allow the conduction system to start an electrical impulse, send it through the heart tissue, and stimulate muscle contraction (Table 35.1). The heart's conduction system consists of specialized neuromuscular tissue found throughout the heart (see Fig. 31.4, *A*). A normal impulse starts in the sinoatrial (SA) node in the upper right atrium near the entrance of the vena cava. It spreads over the atrial myocardium via interatrial and internodal pathways, causing atrial contraction. The impulse then travels to the atrioventricular (AV) node, through the bundle of His, and down the left and right bundle branches to the Purkinje fibers, which transmit the impulse to the ventricles.

Nervous Control of the Heart

The autonomic nervous system plays a vital role in the rate of impulse formation, speed of conduction, and strength of cardiac contraction. The parts of the autonomic nervous system that affect the heart are the vagus nerve fibers of the parasympathetic nervous system and the nerve fibers of the sympathetic nervous system.

Stimulation of the vagus nerve slows firing of the SA node and slows impulse conduction of the AV node. This decreases heart rate. Stimulation of the sympathetic nerves increases SA node firing, AV node impulse conduction, and cardiac contractility. This increases heart rate.[2,3]

Electrocardiographic Monitoring

The *electrocardiogram* (ECG) is a graphic tracing of the electrical impulses produced in the heart. The waveforms on the ECG represent the electrical activity of depolarization and repolarization produced by the movement of ions across the membranes of heart cells (see Fig. 31.4, *B*).

TABLE 35.1 Properties of Heart Cells

Property	Definition
Automaticity	Ability to initiate an impulse spontaneously and continuously
Excitability	Ability to be electrically stimulated
Conductivity	Ability to transmit an impulse along a membrane in an orderly manner
Contractility	Ability to respond mechanically to an impulse

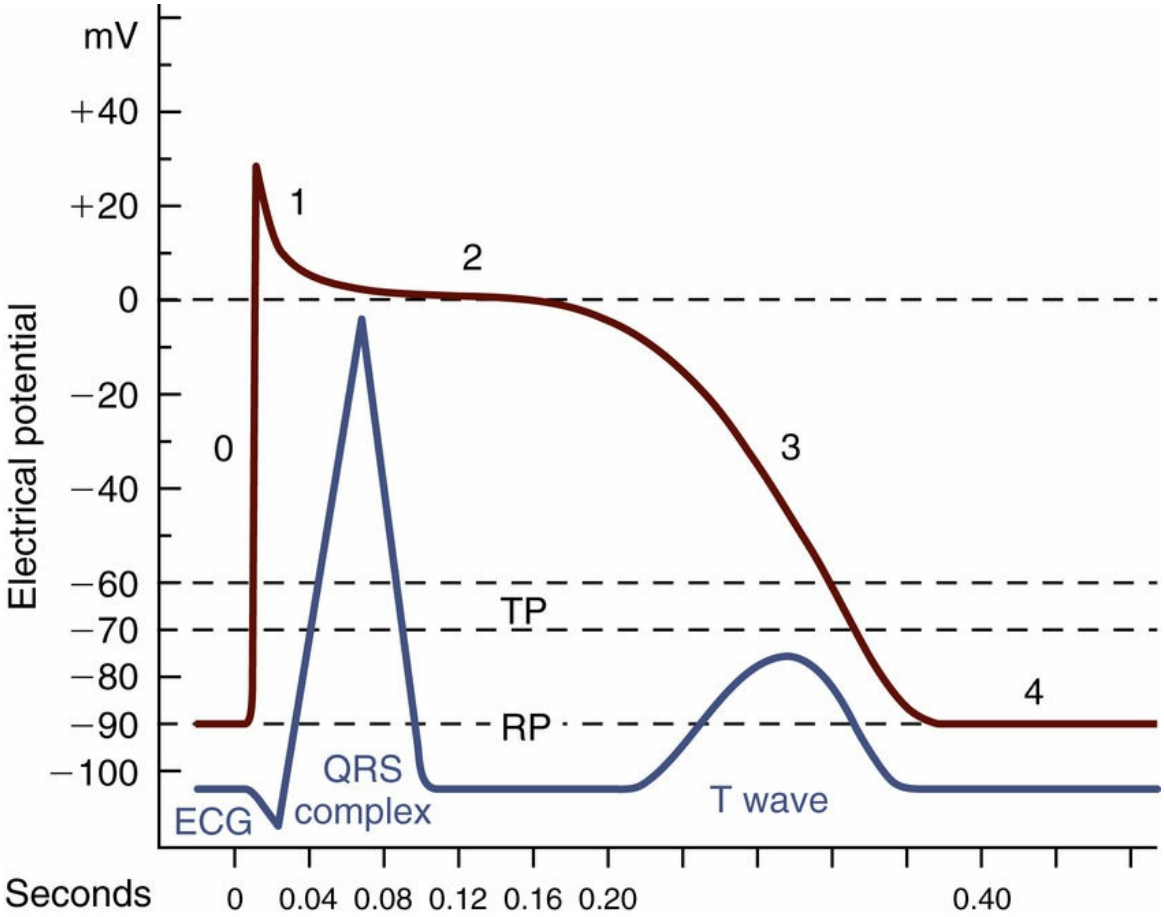

FIG. 35.1 Phases of the cardiac action potential. The electrical potential, measured in millivolts (mV), is indicated along the vertical axis of the graph. Time, measured in seconds (sec), is indicated along the horizontal axis. The action potential has 5 phases, labeled *0* through *4.* Each phase represents a specific electrical event or combination of electrical events. Phase 0 is the upstroke of rapid depolarization and corresponds with ventricular contraction. Phases 1, 2, and 3 represent repolarization. Phase 4 is known as complete repolarization (or the polarized state) and corresponds to diastole. *RP,* Resting membrane potential; *TP,* threshold membrane potential.

The membrane of a heart cell is semipermeable. This allows it to maintain a high concentration of potassium and a low concentration of sodium inside the cell. Outside the cell, a high concentration of sodium and a low concentration of potassium exist. The inside of the cell, when at rest or in the polarized state, is negative compared with the outside. When a cell or groups of cells are stimulated, the cell membrane changes its permeability. This allows sodium to move rapidly into the cell, making the inside of the cell positive compared

with the outside *(depolarization).* A slower movement of ions across the membrane restores the cell to the polarized state, called *repolarization*. Fig. 35.1 describes the phases of the cardiac action potential.[1,2]

A 12-lead ECG view of the heart is helpful in assessing dysrhythmias. Six of the leads measure electrical forces in the frontal plane. These are bipolar (positive and negative) leads I, II, and III and unipolar (positive) leads aVR, aVL, and aVF (Fig. 35.2, *A* and *B*). The remaining 6 unipolar leads (V_1 through V_6) measure the electrical forces in the horizontal plane (precordial leads) (Fig. 35.2, *C*). The 12-lead ECG may show changes suggesting structural changes, conduction changes, damage (e.g., ischemia, infarction), electrolyte imbalance, or drug toxicity. Fig. 35.3 is an example of a normal 12-lead ECG.

We can use one or more ECG leads to continuously monitor a patient. The most common leads used are leads II and V_1 (Fig. 35.4). A modified chest lead (MCL_1) is used when only 3 leads are available for monitoring. MCL_1 is similar to V_1. Accurate interpretation of an ECG depends on the correct placement of the leads on the patient. The monitoring leads used are determined by the patient's clinical status.[4,5]

The ECG monitor continuously displays the heart rhythm. Paper attached to the monitor records the ECG (i.e., rhythm strip) to provide a record of the patient's rhythm. It allows for measurement of complexes and intervals and for assessment of dysrhythmias.

To correctly interpret an ECG, measure time and voltage on the ECG paper. ECG paper consists of large (heavy lines) and small (light lines) squares (Fig. 35.5). Each large square consists of 25 smaller squares (5 horizontal and 5 vertical). Horizontally, each small square (1 mm) represents 0.04 second. This means that 1 large square equals 0.20 second and that 300 large squares equal 1 minute. Vertically, each small square (1 mm) represents 0.1 millivolt (mV). This means that 1 large square equals 0.5 mV. Use these squares to calculate the HR and measure time intervals for the different ECG complexes.

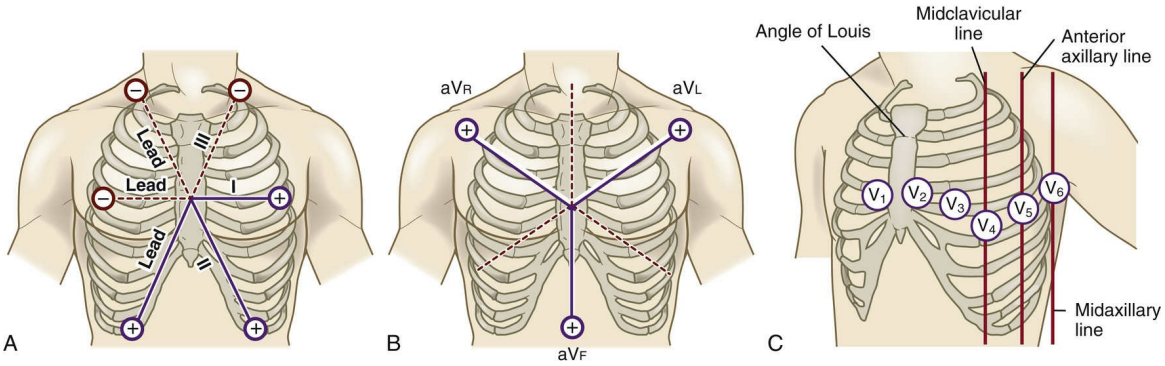

FIG. 35.2 **A,** Limb leads I, II, and III. These bipolar leads are placed on the extremities. Shown are the angles from which these leads view the heart. **B,** Limb leads aVR, aVL, and aVF. These unipolar leads use the center of the heart as their negative electrode. **C,** Placement for the unipolar chest leads: V_1, 4th intercostal space at the right sternal border; V_2, 4th intercostal space at the left sternal border; V_3, halfway between V_2 and V_4; V_4, 5th intercostal space at the left midclavicular line; V_5, 5th intercostal space at the left anterior axillary line; V_6, 5th intercostal space at the left midaxillary line.

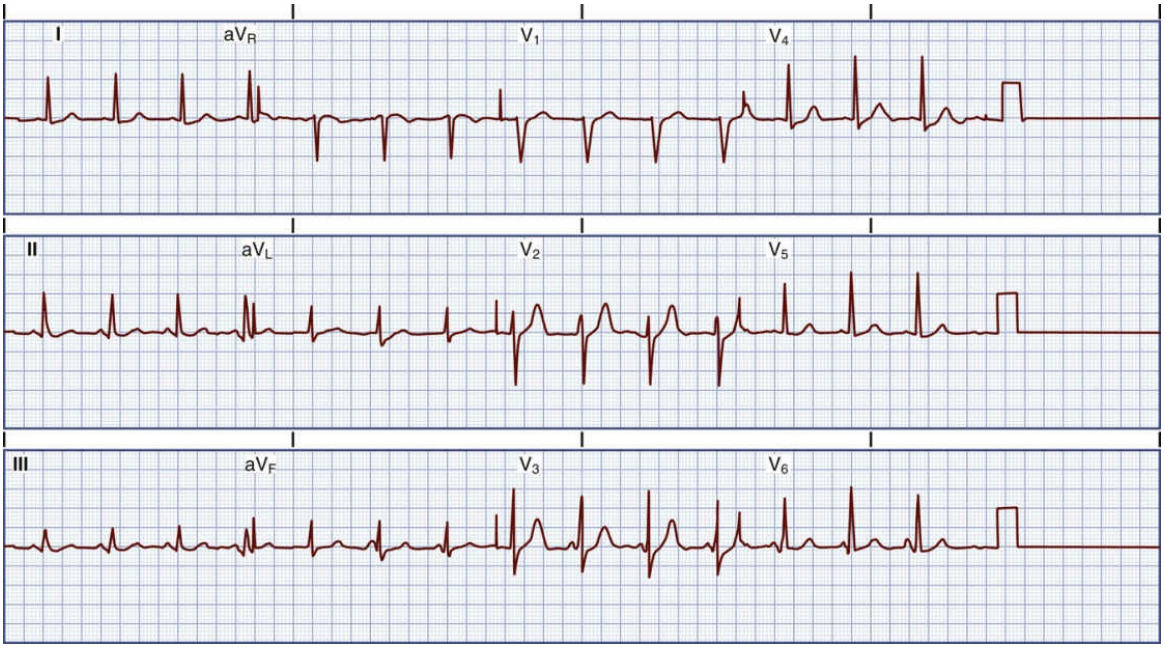

FIG. 35.3 12-lead electrocardiogram showing a normal sinus rhythm.

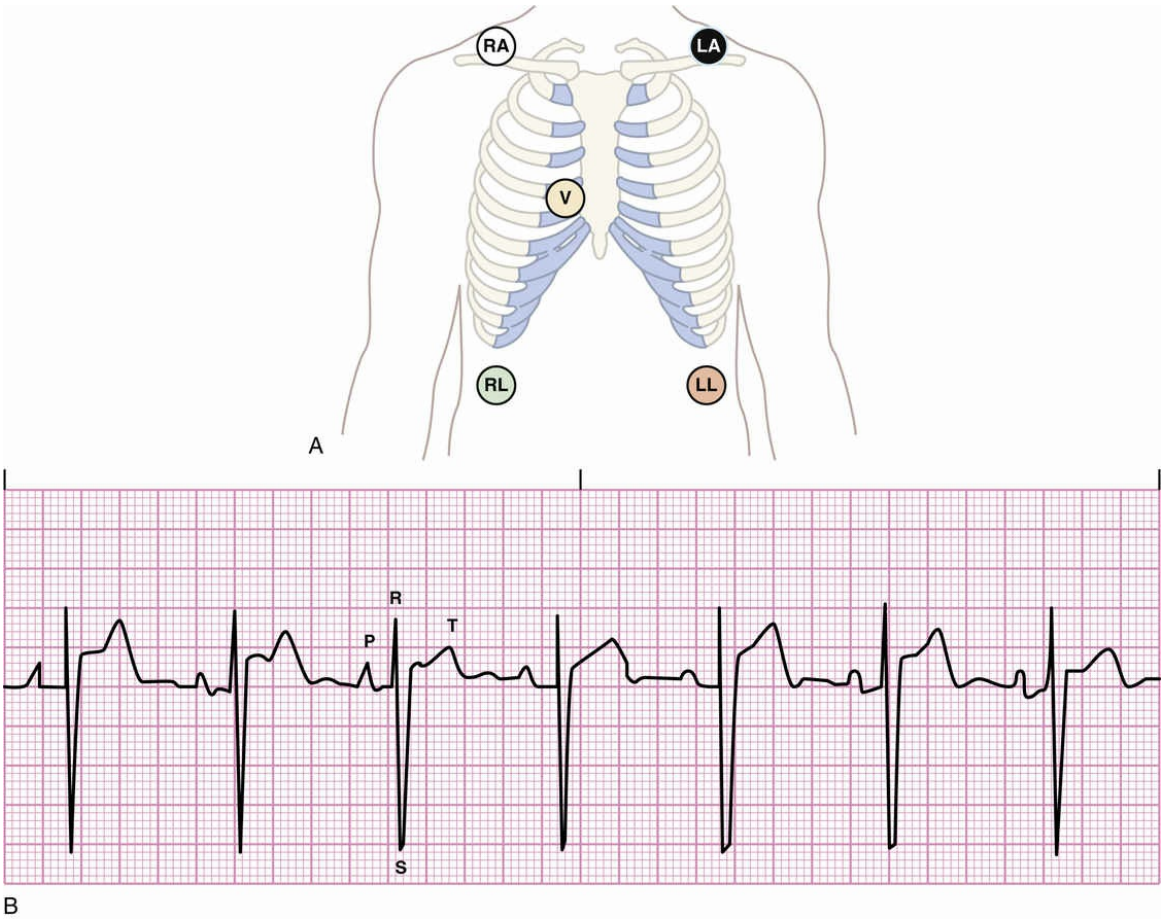

FIG. 35.4 **A,** Lead placement for V_1 using a 5-lead system. **B,** Typical ECG tracing in lead V_1. *V,* Chest lead; *LA,* left arm; *LL,* left leg; *RA,* right arm; *RL,* right leg.

You can use a variety of methods to calculate the HR from an ECG. The most accurate way is to count the number of QRS complexes in 1 minute. However, because this method is time consuming, you can use a simpler process. Note that every 3 seconds a marker appears on the ECG paper (Fig. 35.5). Count the number of QRS complexes in 6 seconds and multiply that number by 10. This is the estimated number of beats per minute (Fig. 35.6).

Another method to calculate the HR is to count the number of small squares between 1 R-R interval. Divide this number into 1500 to get the HR. Last, you can count the number of large squares between 1 R-R interval and divide this number into 300 to get the HR (Fig. 35.6). All these methods are more accurate when the rhythm is regular.[1,2]

Another way to measure distances on the ECG strip is to use

calipers. Often a P or R wave will not fall directly on a light or heavy line. Place the fine points of the calipers exactly on the parts you need to measure and then move to another part of the strip for a more precise time measurement.

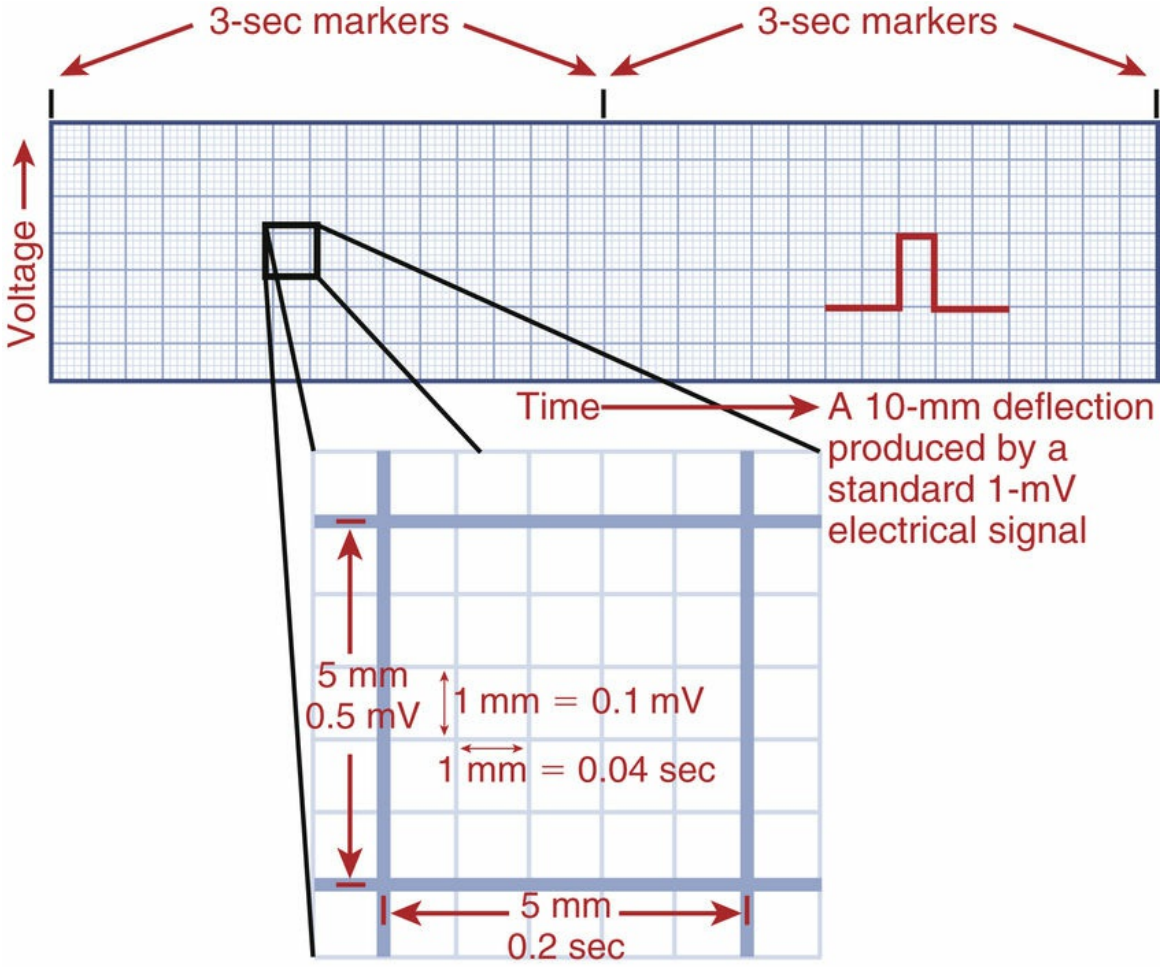

FIG. 35.5 Time and voltage on the electrocardiogram; 6-sec strip. Modified from Wesley K: *Basic dysrhythmias and acute coronary syndromes,* ed 4, St Louis, 2011, Mosby JEMS.

Fig. 35.7 shows the components of a normal ECG tracing. Table 35.2 describes ECG waveforms and intervals, normal durations, and possible sources of changes in each. Table 35.3 presents a systematic approach to assessing a heart rhythm.

ECG leads consist of an electrode pad fixed with electrical conductive gel. Before placing these on the patient, properly prepare

the skin. Clip excess hair on the chest wall with scissors. Gently rub the skin with dry gauze until slightly pink. If the skin is oily, wipe with alcohol first. If the patient is diaphoretic, apply a skin protectant before placing the electrode.

Artifact is a distortion of the baseline and waveforms seen on the ECG (Fig. 35.8). It is hard to accurately interpret heart rhythm when artifact is present. You will see artifact on the monitor when leads and electrodes are not secure, the conductive gel is becoming dry, and there is muscle activity (e.g., shivering, ambulating) or electrical interference. If artifact occurs, check the connections in the equipment. Replace the electrodes if the conductive gel has dried out.

Telemetry Monitoring

Telemetry monitoring is the observation of a patient's HR and rhythm at a site distant from the patient. This technology can help rapidly identify dysrhythmias, ischemia, or infarction. There are 2 types of systems for telemetry monitoring. The first type is a centralized monitoring system. It requires you or a telemetry technician to continuously observe a group of patients' ECGs at a central location. The second system of telemetry monitoring does not require constant surveillance. These systems have the capability of detecting and storing data. Advanced alarm systems provide different levels of detection of dysrhythmias, ischemia, or infarction.

Informatics in Practice

Wireless ECG Monitoring

- Wireless ECG monitoring systems continuously monitor and interpret the findings, sending an alert when a patient's rhythm and/or measurements fall outside of set parameters.
- Early detection of abnormal heart rhythms allows you time to assess the patient for signs of hemodynamic instability (e.g., chest

pain, hypotension, palpitations, dyspnea) and determine the need to intervene (e.g., call the rapid response team).

- These systems can automatically save the pre-event portion of the ECG while continuing to record the post-event portion and send all the information to the HCP.
- Computerized monitoring systems are not fail-proof. Frequently assess all monitored patients for signs of hemodynamic instability.

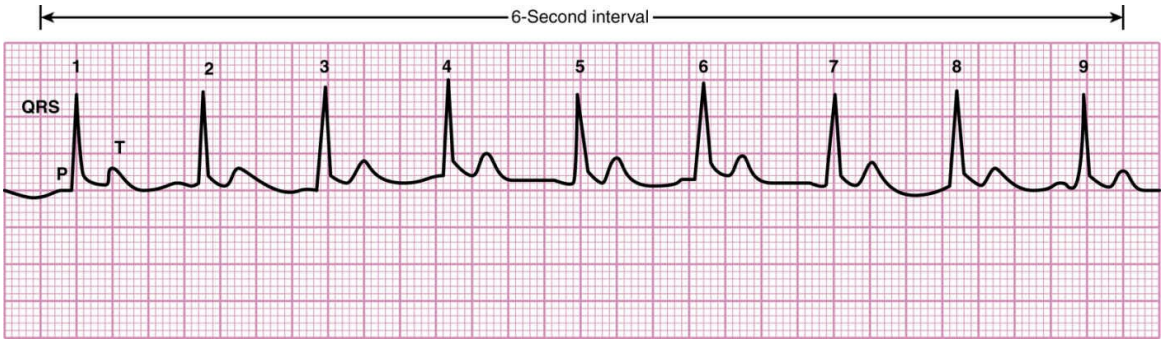

FIG. 35.6 When the rhythm is regular, heart rate can be easily determined by counting the number of "R" waves. The estimated heart rate is 90 beats/min. NOTE: Recorded from lead II.

Electrophysiologic Mechanisms of Dysrhythmias

Dysrhythmias result from disorders of impulse formation, impulse conductions, or both. The heart has specialized cells in the SA node, atria, AV node, bundle of His, and Purkinje fibers (His-Purkinje system), which can fire (discharge) spontaneously. This is termed *automaticity.* Normally, the SA node is the natural pacemaker of the heart. It spontaneously fires 60 to 100 times per minute (Table 35.4). A secondary pacemaker from another site may fire in 2 ways. If the SA node fires more slowly than a secondary pacemaker, the electrical signals from the secondary pacemaker may "escape." The secondary pacemaker will then fire automatically at its intrinsic rate. These

secondary pacemakers may start from the AV node at a rate of 40 to 60 times per minute or the His-Purkinje system at a rate of 20 to 40 times per minute.

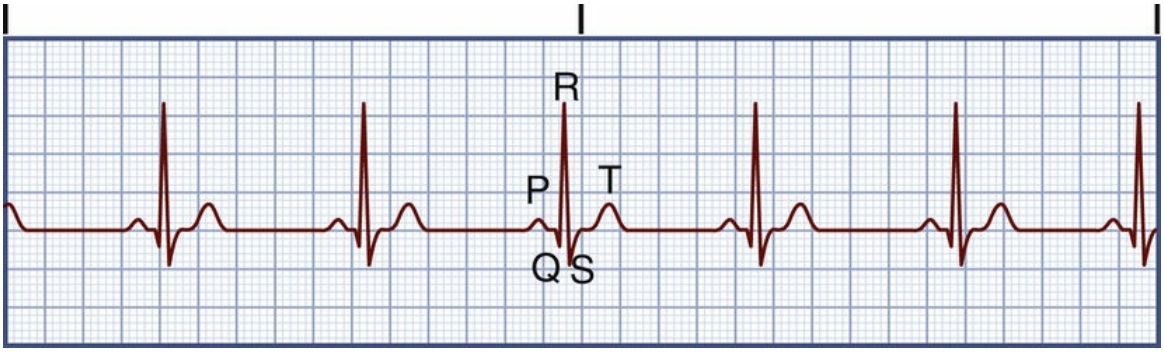

FIG. 35.7 Normal sinus rhythm. NOTE: Recorded from lead II.

Another way that secondary pacemakers can start is when they fire more rapidly than the normal pacemaker of the SA node. *Triggered beats* (early or late) may come from an *ectopic focus* or *accessory pathway* (area outside the normal conduction pathway) in the atria, AV node, or ventricles. This results in a dysrhythmia, which replaces the normal sinus rhythm.

The impulse started by the SA node or an ectopic focus is conducted to the heart cells. The property of myocardial tissue that allows it to be depolarized by a stimulus is called *excitability.* The level of excitability is determined by the length of time after depolarization before the tissues can be restimulated. The recovery period after stimulation is the *refractory phase* or period. The *absolute refractory phase* or period occurs when excitability is zero and the heart cannot be stimulated. The *relative refractory period* occurs slightly later in the cycle, and excitability is more likely. In states of *full excitability,* the heart is completely recovered. Fig. 35.9 shows the relationship between the refractory period and ECG.

If conduction is depressed and some areas of the heart are blocked (e.g., by infarction), the unblocked areas are activated earlier than the blocked areas. When the block is unidirectional, this uneven conduction may allow the initial impulse to reenter areas that were

previously not excitable but have recovered. The reentering impulse may be able to depolarize the atria and ventricles, causing a premature beat or rapid rhythm.

TABLE 35.2 ECG Waveforms and Intervals*

Description	Normal Duration (sec)	Source of Possible Variation
P Wave		
Represents time for the passage of the electrical impulse through the atrium causing atrial depolarization (contraction). Should be upright	0.06–0.12	Problem in conduction within atria
PR Interval		
Measured from beginning of P wave to beginning of QRS complex. Represents time taken for impulse to spread through the atria, AV node and bundle of His, bundle branches, and Purkinje fibers, to a point immediately before ventricular contraction	0.12–0.20	Problem in conduction usually in AV node, bundle of His, or bundle branches but can be in atria as well
QRS Complex		
Q wave: First negative (downward) deflection after the P wave, short and narrow, not present in several leads	<0.03	MI may result in development of a pathologic Q wave that is wide (≥0.03 sec) and deep (≥25% of the height of the R wave)
R wave: First positive (upward) deflection in the QRS complex	Not usually measured	
S wave: First negative (downward) deflection after the R wave	Not usually measured	
QRS Interval		
Measured from beginning to end of QRS complex. Represents time taken for depolarization (contraction) of both ventricles (systole)	<0.12	Problem in conduction in bundle branches or in ventricles
ST Segment		
Measured from the S wave of the QRS complex to the beginning of the T wave. Represents the time between ventricular depolarization and repolarization (diastole). Should be isoelectric (flat)	0.12	Changes (e.g., elevation, depression) usually caused by ischemia, injury, or infarction
T Wave		
Represents time for ventricular repolarization. Should be upright	0.16	Changes (e.g., tall, peaked; inverted) usually caused by electrolyte imbalances, ischemia, or infarction
QT Interval†		
Measured from beginning of QRS complex to end of T wave. Represents time taken for entire electrical depolarization and repolarization of the ventricles. Normal adult women have slightly longer QT intervals than men.	0.34–0.43	Problems usually affecting repolarization more than depolarization and caused by drugs, electrolyte imbalances, and changes in heart rate

* Heart rate influences the duration of these intervals, especially the PR and QT intervals (e.g., QT interval shortens in duration as heart rate increases).

† A corrected QT interval (QTc) is calculated to account for the influence of heart rate.

TABLE 35.3 Approach to Assessing Heart Rhythm

When assessing a heart rhythm, use a consistent and systematic approach. One such approach includes the following:

1. Look for the P wave. Is it upright or inverted? Is there 1 for every QRS complex or more than 1? Are atrial fibrillatory or flutter waves present?
2. Evaluate the atrial rhythm. Is it regular or irregular?
3. Calculate the atrial rate.
4. Measure the duration of the PR interval. Is it normal duration or prolonged? Is the duration consistent before each QRS?
5. Evaluate the ventricular rhythm. Is it regular or irregular?
6. Calculate the ventricular rate.
7. Measure the duration of the QRS complex. Is it normal duration or prolonged?
8. Assess the ST segment. Is it isoelectric (flat), elevated, or depressed?
9. Measure the duration of the QT interval. Correct for heart rate (cQT) to determine if it is normal or prolonged.*
10. Note the T wave. Is it upright or inverted?

Other questions to consider include:

1. What is the dominant or underlying rhythm and/or dysrhythmia?
2. What is the clinical significance of your findings?
3. What is the treatment for the particular rhythm?

---

* A website for calculating the cQT interval for heart rate can be found at *www.mdcalc.com/corrected-qt-interval-qtc*.

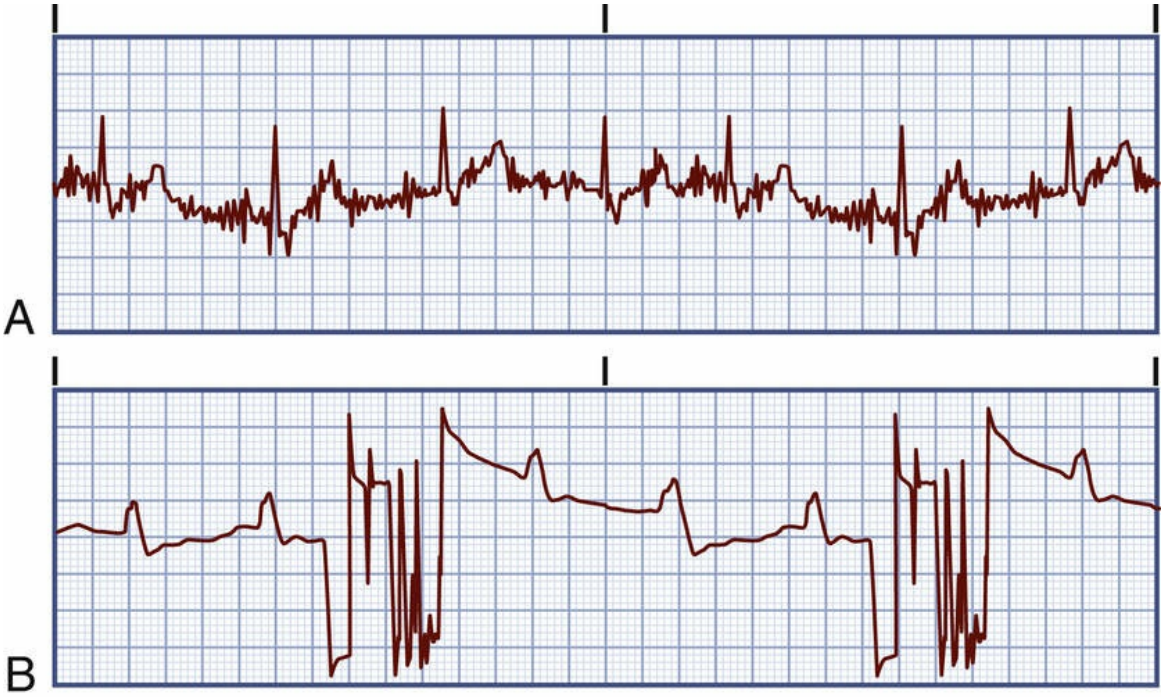

FIG. 35.8 Artifact. **A,** Muscle tremor. **B,** Loose electrodes.

TABLE 35.4 Intrinsic Rates of the Conduction System

Part of Conduction System	Rate
SA node and atria	60–100 times/min
AV node and bundle of His	40–60 times/min
Bundle branches and Purkinje fibers	20–40 times/min

Evaluation of Dysrhythmias

Dysrhythmias occur as the result of various abnormalities and disease states. Assess the heart rhythm, any changes in rhythm, and the patient's clinical status. Determining the cause of dysrhythmias is a priority. The cause influences the patient's treatment. Table 35.5 presents common causes of dysrhythmias.

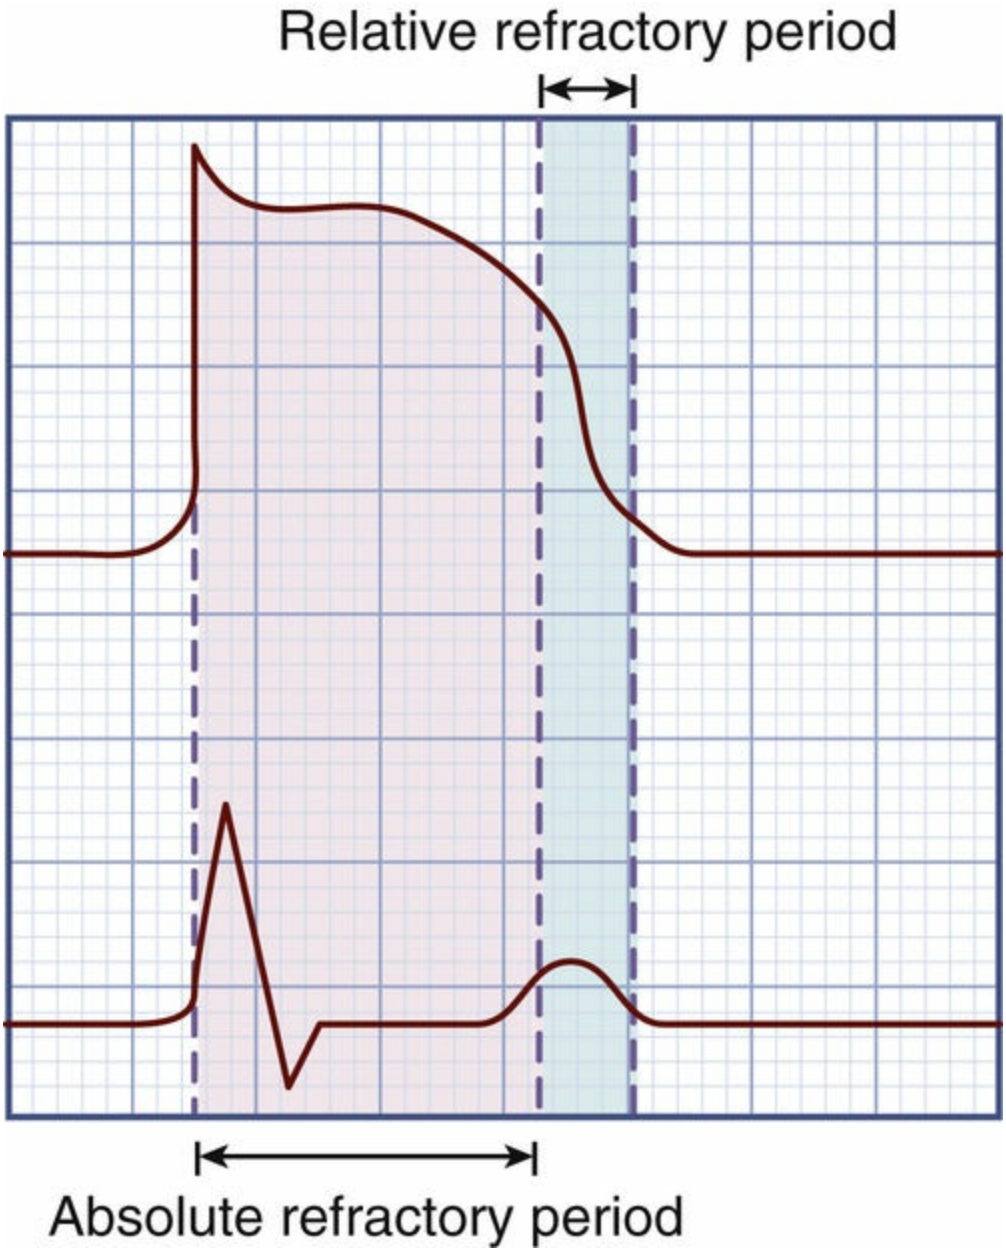

FIG. 35.9 Absolute and relative refractory periods correlated with the heart muscle's action potential and with an ECG tracing.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

TABLE 35.5 Common Causes of Dysrhythmias

Heart Conditions

- Accessory pathways
- Cardiomyopathy
- Conduction defects
- Heart failure
- Myocardial ischemia, infarction
- Valve disease

Other Conditions

- Acid-base imbalances
- Alcohol
- Caffeine, tobacco
- Connective tissue disorders
- Drowning
- Drug effects (e.g., antidysrhythmic drugs, stimulants, β-blockers) or toxicity
- Electric shock
- Electrolyte imbalances (e.g., hyperkalemia, hypocalcemia)
- Emotional crisis
- Herbal supplements (e.g., areca nut, wahoo root bark, yerba maté)
- Hypoxia
- Metabolic conditions (e.g., thyroid dysfunction)
- Sepsis, shock
- Toxins

Dysrhythmias occurring in nonmonitored settings present management challenges. If the patient becomes symptomatic (e.g., chest pain, syncope), determination of the rhythm by heart monitoring is a high priority. Activate the emergency response system (ERS). Table 35.6 outlines the emergency care of the patient with a

dysrhythmia.

In addition to continuous ECG monitoring during hospitalization, several other tests can assess dysrhythmias and the effectiveness of antidysrhythmic drug therapy. An electrophysiologic study, Holter monitoring, event monitoring (or loop recorder), exercise treadmill testing, and signal-averaged ECG can be done on an inpatient or outpatient basis (see Tables 31.7 and 31.8 for nursing care related to these tests).

An *electrophysiologic study* (EPS) can identify the causes of heart blocks, tachydysrhythmias (dysrhythmias with rates greater than 100 beats/min), bradydysrhythmias (dysrhythmias with rates less than 60 beats/min), and syncope. An EPS study can locate accessory pathways and determine the effectiveness of antidysrhythmic drugs.

TABLE 35.6 Emergency ManagementDysrhythmias

Assessment Findings	Interventions
• **Irregular rate and rhythm; tachycardia, bradycardia** • **Chest, neck, shoulder, back, jaw, or arm pain** • **Cold, clammy skin** • **Decreased level of consciousness, confusion** • **Decreased or increased BP** • **Decreased O_2 saturation** • **Decreased peripheral pulses** • **Diaphoresis** • **Dizziness, syncope** • **Dyspnea** • **Extreme restlessness, anxiety** • **Feeling of impending doom** • **Nausea and vomiting** • **Numbness, tingling of arms** • **Pallor** • **Palpitations** • **Weakness and fatigue**	Initial • If unresponsive, assess circulation, airway, and breathing (CAB). • If responsive, monitor airway, breathing, and circulation (ABC). • Apply O_2 via nasal cannula or nonrebreather mask. • Take baseline vital signs, including O_2 saturation. • Obtain 12-lead ECG. • Begin continuous ECG monitoring. • Identify underlying rate and rhythm. • Identify dysrhythmia. • Establish IV access. • Obtain baseline laboratory studies (e.g., CBC, electrolytes). Ongoing Monitoring • Monitor ABCs, vital signs, level of consciousness, O_2 saturation, and heart rhythm. • Anticipate need for antidysrhythmic drugs and analgesics. • Anticipate need for intubation if respiratory distress occurs. • Anticipate need to begin advanced cardiovascular life support (e.g., CPR, defibrillation, transcutaneous pacing).

The Holter monitor continuously records the ECG while the patient is ambulatory and performing daily activities. The patient keeps a diary and records activities and any symptoms. Events in the diary are correlated with any dysrhythmias seen on the ECG. Use of event

monitors has improved the evaluation of dysrhythmias in outpatients. Event monitors are recorders that the patient activates only when he or she has symptoms. New technology using smart phone apps can obtain and save ECG recordings and even detect some dysrhythmias (e.g., Kardia at *https://itunes.apple.com/us/app/aliveecg/id579769143?mt=8*).

Exercise treadmill testing evaluates the patient's heart rhythm during exercise. Any exercise-induced dysrhythmias or ECG changes that occur can be evaluated for treatment.

The signal-averaged ECG identifies *late potentials,* which suggest that the patient may be at risk for developing serious ventricular dysrhythmias. (See Chapter 31 for a discussion of diagnostic procedures for assessment of the cardiovascular system and related nursing care.)

Overview of Cardiac Rhythms

Figs. 35.10 to 35.21 give examples of the ECG tracings of common normal cardiac rhythms and dysrhythmias. Table 35.7 presents the characteristics of each.

Normal Cardiac Rhythms

Normal Sinus Rhythm

Normal sinus rhythm refers to a rhythm that starts in the SA node at a rate of 60 to 100 beats/min and follows the normal conduction pathway (Fig. 35.10). The P wave is normal, precedes each QRS complex, and has a normal shape and duration. The PR interval is normal. The QRS complex has a normal shape and duration. Normal sinus rhythm implies that cardiac electrical activity is normal.

Sinus Arrhythmia

In *sinus arrhythmia,* the conduction pathway is the same as that in sinus rhythm, but the SA node fires irregularly. This often results from changes in intrathoracic pressure during breathing. The HR

increases slightly during inspiration and decreases slightly during exhalation. It remains 60 to 100 beats/min. It is common in healthy adults.

Types of Dysrhythmias

Sinus Bradycardia

In *sinus bradycardia,* the conduction pathway is the same as that in sinus rhythm, but the SA node fires at a rate less than 60 beats/min (Fig. 35.11, *A*). *Symptomatic bradycardia* refers to a HR that is less than 60 beats/min and causes the patient to have symptoms of inadequate perfusion (e.g., fatigue, dizziness, chest pain, syncope).

Clinical Associations

Sinus bradycardia may be a normal sinus rhythm in aerobically trained athletes and in some people during sleep. It also occurs in response to carotid sinus massage, Valsalva maneuver, hypothermia, increased intraocular pressure, vagal stimulation, and certain drugs (e.g., β-blockers, calcium channel blockers). Common disease states associated with sinus bradycardia are hypothyroidism, increased intracranial pressure, and inferior myocardial infarction (MI).

ECG Characteristics

In sinus bradycardia, the HR is less than 60 beats/min and rhythm is regular. The P wave precedes each QRS complex and has a normal shape and duration. The PR interval is normal. The QRS complex has a normal shape and duration.

Clinical Significance

The significance of sinus bradycardia depends on how the patient tolerates it. Manifestations of symptomatic bradycardia include pale, cool skin; hypotension; weakness; angina; dizziness or syncope; confusion or disorientation; and shortness of breath.

Treatment

If bradycardia is due to drugs, these may have to be held, stopped, or reduced. For the patient with symptoms, treatment consists of giving IV atropine (anticholinergic drug). If atropine is ineffective, transcutaneous pacing or a dopamine or epinephrine infusion are options. The patient may need a permanent pacemaker.

Sinus Tachycardia

The conduction pathway is the same in *sinus tachycardia* as that in normal sinus rhythm. The discharge rate from the sinus node increases because of vagal inhibition or sympathetic stimulation. The sinus rate is 101 to 180 beats/min (Fig. 35.11, *B*).[2]

Clinical Associations

Sinus tachycardia is associated with physiologic and psychologic stressors, such as exercise, fever, pain, hypotension, hypovolemia, anemia, hypoxia, hypoglycemia, myocardial ischemia, heart failure (HF), hyperthyroidism, anxiety, and fear. It can be an effect of drugs, such as epinephrine, norepinephrine (Levophed), atropine, caffeine, theophylline, or hydralazine. In addition, many over-the-counter cold remedies have active ingredients (e.g., pseudoephedrine) that can cause tachycardia.

ECG Characteristics

In sinus tachycardia, the HR is 101 to 180 beats/min and rhythm is regular.[2] The P wave is normal and precedes each QRS complex. The PR interval is normal. The QRS complex has a normal shape and duration.

TABLE 35.7 Characteristics of Common Dysrhythmias

Pattern	Rate and Rhythm	P Wave	PR Interval	QRS Complex
Normal sinus rhythm (NSR)	60–100 beats/min and regular	Normal	Normal	Normal
Sinus bradycardia	<60 beats/min and regular	Normal	Normal	Normal
Sinus tachycardia	101–180 beats/min and regular	Normal	Normal	Normal
Premature atrial contraction (PAC)		Abnormal shape	Normal	Normal (usually)
Paroxysmal supraventricular tachycardia (PSVT)	151–220 beats/min and regular	Abnormal shape, may be hidden in the preceding T wave	Normal or shortened	Normal (usually)
Atrial flutter	*Atrial:* 200–350 beats/min and regular *Ventricular:* > or <100 beats/min and may be regular or irregular	Flutter (F) waves (sawtoothed pattern); more flutter waves than QRS complexes; may occur in a 2:1, 3:1, 4:1, etc., pattern	Not measurable	Normal (usually)
Atrial fibrillation	*Atrial:* 350–600 beats/min and irregular *Ventricular:* > or <100 beats/min and irregular	Fibrillatory (f) waves	Not measurable	Normal (usually)
Junctional dysrhythmias	40–180 beats/min and regular	Inverted, may be hidden in QRS complex, or behind the S wave	Shortened, if present	Normal (usually)
First-degree AV block	Normal and regular	Normal	>0.20 sec	Normal
Second-degree AV block				
• **Type I (Mobitz I, Wenckebach heart block)**	*Atrial:* Normal and regular *Ventricular:* Slower and irregular	Normal	Progressive lengthening (longer, longer, longer, drop, now you have a Wenckebach)	Normal QRS width, with pattern of 1 nonconducted (blocked) QRS complex
• **Type II (Mobitz II heart block)**	*Atrial:* Usually normal and regular *Ventricular:* Slower and regular or irregular	More P waves than QRS complexes (e.g., 2:1, 3:1)	Normal or prolonged but consistent for every QRS	Widened QRS, preceded by ≥2 P waves, with nonconducted (blocked) QRS complex
Third-degree AV block (complete heart block)	*Atrial:* Regular but may appear irregular due to P waves hidden in QRS complexes *Ventricular:* 20–60 beats/min and regular	Normal, but no connection with QRS complex	Inconsistent	Normal or widened, no relationship with P waves
Premature ventricular contraction (PVC)	Underlying rhythm can be any rate, regular or irregular rhythm, PVCs occur at variable rates	Not usually visible, hidden in the PVC	Not measurable	Wide and distorted
Ventricular tachycardia (VT)	150–250 beats/min and regular or irregular	Not usually visible	Not measurable	Wide and distorted
Accelerated idioventricular rhythm	40–100 beats/min and regular	Not usually visible	Not measurable	Wide and distorted
Ventricular fibrillation (VF)	Not measurable and irregular	Absent	Not measurable	Not measurable

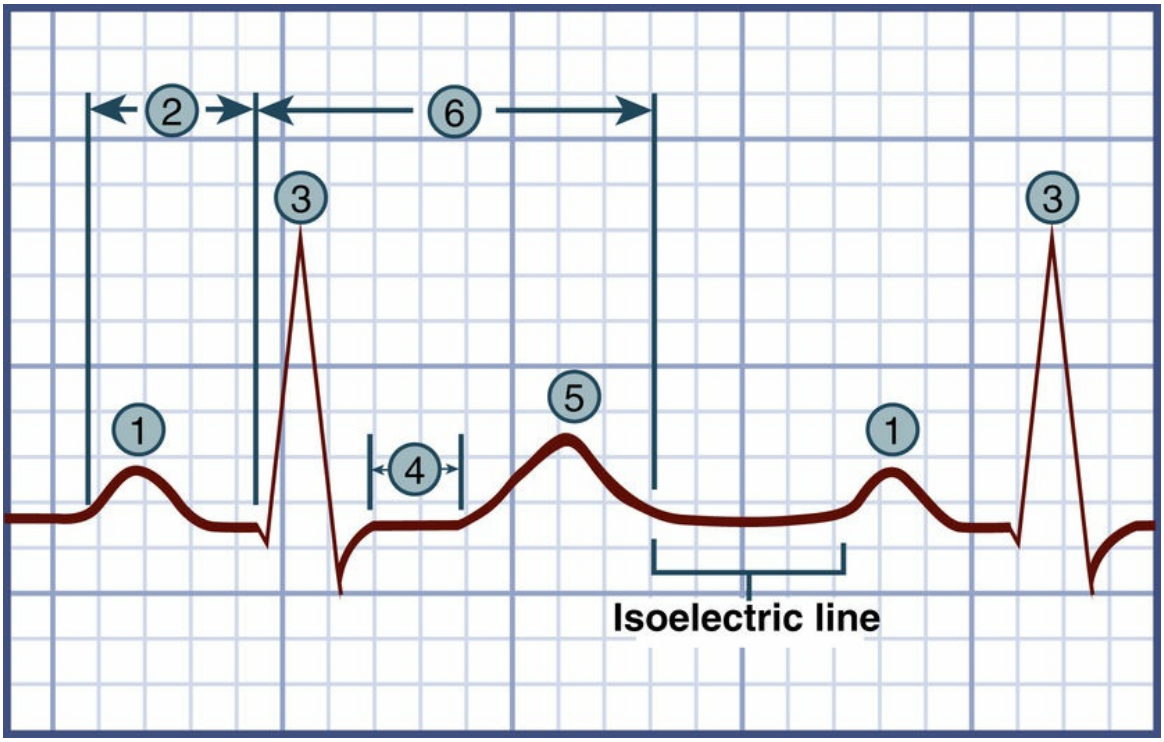

FIG. 35.10 The ECG tracing as seen in normal sinus rhythm. *1,* P wave; *2,* PR interval; *3,* QRS complex: Q wave, R wave, S wave; *4,* ST segment; *5,* T wave; *6,* QT interval. Isoelectric (flat) line or baseline represents the absence of electrical activity in the heart cells. (See Table 35.2 for timing of intervals.)

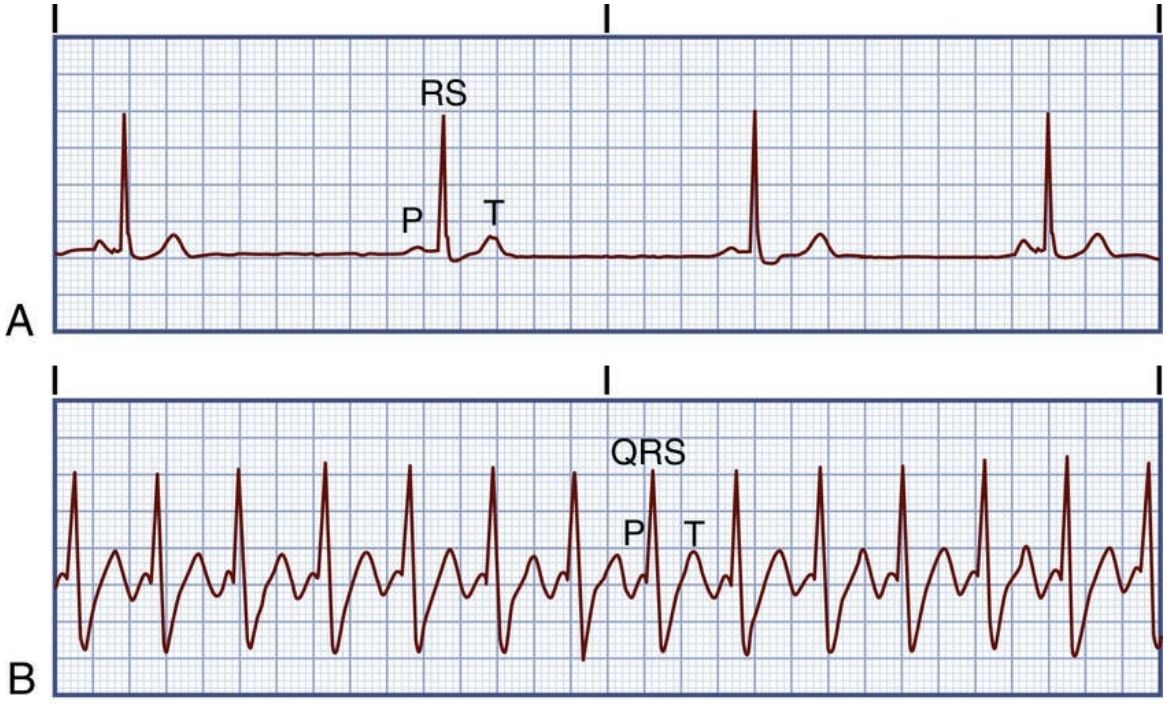

FIG. 35.11 **A,** Sinus bradycardia. **B,** Sinus tachycardia.

FIG. 35.12 Premature atrial contractions *(arrows).*

Clinical Significance

The clinical significance of sinus tachycardia depends on the patient's tolerance of the increased HR. The patient may have dizziness, dyspnea, and hypotension because of decreased CO. An increased HR increases myocardial oxygen (O_2) consumption. Angina or an increase in infarction size may occur with sinus tachycardia in those with

coronary artery disease (CAD) or an acute MI.

Treatment

The underlying cause of tachycardia guides the treatment. For example, if the patient has tachycardia from pain, effective pain management is important to treat the tachycardia. In clinically stable patients, vagal maneuvers can be tried. IV β-blockers (e.g., metoprolol), adenosine (Adenocard), or calcium channel blockers (e.g., diltiazem) can reduce HR and decrease myocardial O_2 consumption. Clinically unstable patients may need synchronized cardioversion. Cardioversion is discussed on p. 770.

Premature Atrial Contraction

A **premature atrial contraction (PAC)** is a contraction starting from an ectopic focus in the atrium (i.e., a location other than the SA node) sooner than the next expected sinus beat. The ectopic signal starts in the left or right atrium and travels across the atria by an abnormal pathway. This creates a distorted P wave (Fig. 35.12). At the AV node, it may be stopped (nonconducted PAC), delayed (lengthened PR interval), or conducted normally. If the signal moves through the AV node, in most cases it is conducted normally through the ventricles.

Clinical Associations

In a normal heart, a PAC can result from emotional stress or physical fatigue, or from caffeine, tobacco, or alcohol use. A PAC can also result from hypoxia, electrolyte imbalances, hyperthyroidism, chronic obstructive pulmonary disease (COPD), and heart disease, including CAD and valvular disease.

ECG Characteristics

HR varies with the underlying rate and frequency of the PAC. The rhythm is irregular. The P wave has a different shape from that of a P wave originating in the SA node, or it may be hidden in the preceding T wave. The PR interval may be shorter or longer than the PR interval

coming from the SA node, but it is within normal limits. The QRS complex is usually normal. If the QRS interval is 0.12 second or more, abnormal conduction through the ventricles is occurring.

Clinical Significance

In persons with healthy hearts, isolated PACs are not significant. Patients may report palpitations or a sense that the heart "skipped a beat." In persons with heart disease, frequent PACs may indicate enhanced automaticity of the atria or a reentry mechanism. Such PACs may warn of or start more serious dysrhythmias (e.g., supraventricular tachycardia).

Treatment

Treatment depends on the patient's symptoms. Withdrawal of sources of stimulation, such as caffeine or sympathomimetic drugs (e.g. epinephrine, dopamine), may be needed. β-Blockers may be used to decrease PACs.

Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT), also known as supraventricular tachycardia (SVT) or atrial tachycardia, is a dysrhythmia starting in an ectopic focus anywhere above the bifurcation of the bundle of His (Fig. 35.13). Identifying the ectopic focus is often hard even with a 12-lead ECG since it requires recording the dysrhythmia as it starts.

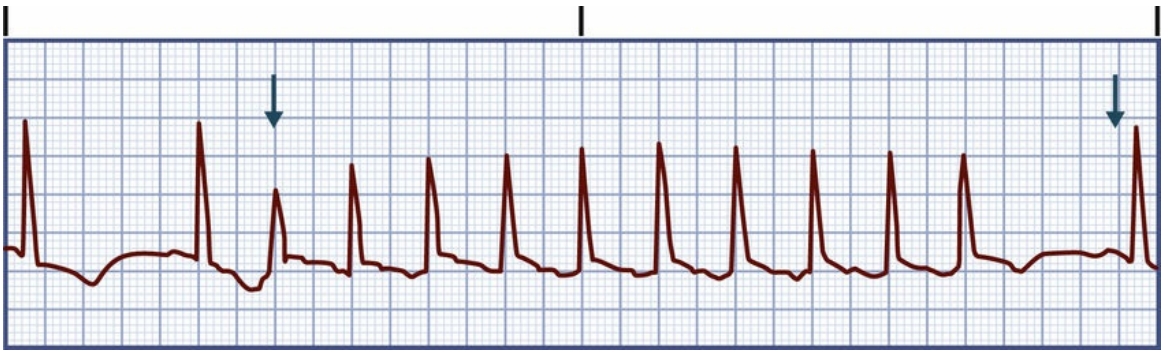

FIG. 35.13 Paroxysmal supraventricular tachycardia (PSVT). *Arrows* indicate beginning and ending of PSVT.

PSVT occurs because of a reentrant phenomenon (reexcitation of the atria when there is a 1-way block). Usually a PAC triggers a run of repeated premature beats. *Paroxysmal* refers to an abrupt onset and ending. A brief period of *asystole* (absence of all cardiac electrical activity) may follow the termination. AV block may prevent some of the impulses from being conducted to the ventricles. PSVT can occur with Wolff-Parkinson-White (WPW) syndrome or "preexcitation" with extra conduction or accessory pathways.

Clinical Associations

In the normal heart, PSVT is associated with overexertion, emotional stress, deep inspiration, and stimulants, such as caffeine and tobacco. PSVT is also associated with rheumatic heart disease, digitalis toxicity, CAD, and cor pulmonale.

ECG Characteristics

In PSVT, the HR is 151 to 220 beats/min. The rhythm is regular or slightly irregular. The P wave may have an abnormal shape or be hidden in the preceding T wave. The PR interval may be shortened or normal. The QRS complex is usually normal.

Clinical Significance

The significance of PSVT depends on the associated symptoms. A prolonged episode and HR greater than 180 beats/min will cause decreased CO because of reduced stroke volume. Manifestations include hypotension, palpitations, dyspnea, and angina.

Treatment

Treatment for PSVT includes vagal stimulation and drug therapy. Common vagal maneuvers include Valsalva, carotid massage, and coughing. IV adenosine is the drug of choice to convert PSVT to a normal sinus rhythm (Fig. 35.14). This drug has a short half-life (10

seconds) and is well tolerated.[6] IV β-blockers and calcium channel blockers (e.g., diltiazem, verapamil) are options. If the patient becomes hemodynamically unstable, synchronized cardioversion is done.[7] Cardioversion is discussed on p. 770.

Drug Alert

Adenosine (Adenocard)

- Explain that the patient may feel chest pressure after the medication is given.
- Injection site should be as close to the heart as possible (e.g., antecubital area).
- Give IV dose rapidly (over 1 to 2 sec) and follow with a rapid 20-mL normal saline flush. Use a stopcock setup to make sure adenosine gets to the heart quickly.
- Monitor patient's ECG continuously. Brief period of asystole is common (Fig. 35.14).
- Assess the patient for flushing, dizziness, chest pain, or palpitations.

Treatment of recurring PSVT and PSVT in patients with WPW syndrome includes radiofrequency catheter ablation of the accessory pathway.[7] Catheter ablation therapy is discussed on p. 773.

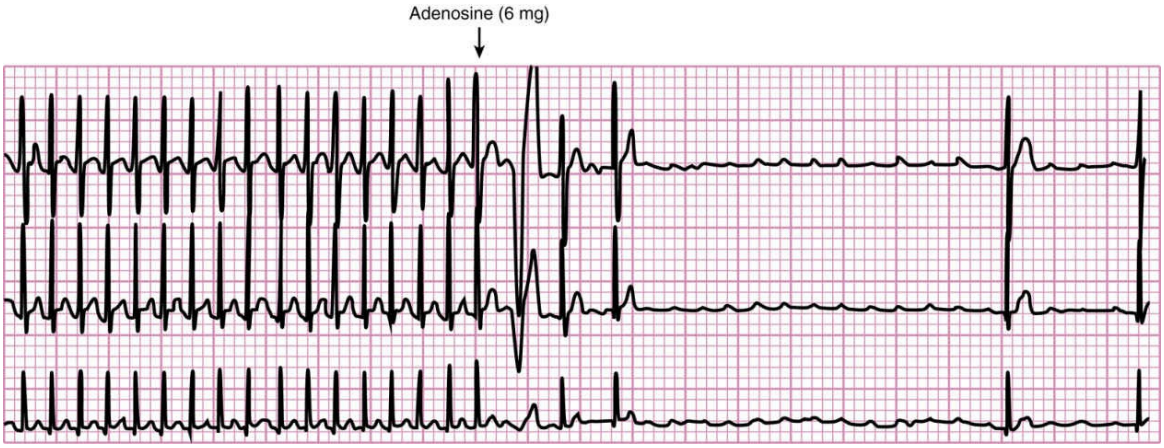

FIG. 35.14 Administration of adenosine rapid IV push. Note that SVT is followed by a brief period of asystole before the return to normal sinus rhythm. This is a common occurrence after adenosine.

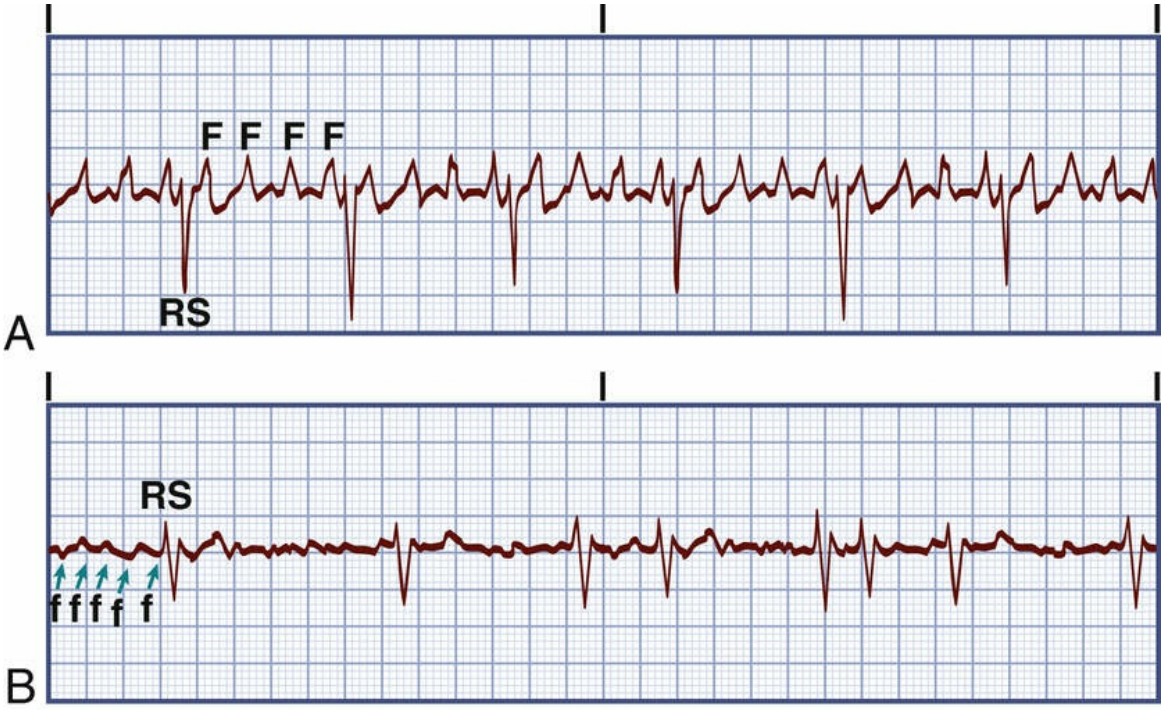

FIG. 35.15 **A,** Atrial flutter with a 4:1 conduction (4 flutter *[F]* waves to each QRS complex). **B,** Atrial fibrillation with a controlled ventricular response. Note the chaotic fibrillatory *(f)* waves *(arrows)* between the RS complexes. NOTE: Recorded from lead V_1.

Atrial Flutter

Atrial flutter is an atrial tachydysrhythmia identified by recurring, regular, sawtooth-shaped flutter waves that originate from a single ectopic focus in the right atrium or, less often, the left atrium (Fig. 35.15, *A*).

Clinical Associations

Atrial flutter rarely occurs in a healthy heart. It is associated with CAD, hypertension, mitral valve disorders, pulmonary embolus, chronic lung disease, cor pulmonale, cardiomyopathy, hyperthyroidism, and the use of drugs, such as digoxin, quinidine, and epinephrine.

ECG Characteristics

Atrial rate is 200 to 350 beats/min. The ventricular rate varies based on the conduction ratio. In 2:1 conduction, the ventricular rate is typically around 150 beats/min. Atrial and ventricular rhythms are usually regular. The atrial flutter waves represent atrial depolarization followed by repolarization. The PR interval is variable and not measurable. The QRS complex is usually normal. There is usually some AV block in a fixed ratio of flutter waves to QRS complexes because the AV node can delay signals from the atria.

Clinical Significance

The high ventricular rates (greater than 100 beats/min) and loss of the atrial "kick" (atrial contraction coordinated with ventricular contraction) that are associated with atrial flutter decrease CO. This can cause serious problems, such as HF, especially in the patient with underlying heart disease. Patients with atrial flutter have an increased risk for stroke because thrombi (clots) can form in the atria from the stasis of blood. Warfarin or another anticoagulant is given to prevent stroke in patients who have atrial flutter.[8] (See Chapter 37 for discussion of anticoagulation therapy.)

Treatment

The primary goal in treatment of atrial flutter is to slow the ventricular response by increasing AV block. Drugs used to control ventricular rate include calcium channel blockers and β-blockers. Electrical cardioversion may be done to convert the atrial flutter to sinus rhythm in an emergency (i.e., when the patient is clinically unstable) and electively. Antidysrhythmic drugs can convert atrial flutter to sinus rhythm (e.g., ibutilide [Corvert]) or to maintain sinus rhythm (e.g., amiodarone, flecainide).[6,8]

Radiofrequency catheter ablation in an EPS laboratory is the treatment of choice for atrial flutter.[8] The procedure involves placing a catheter in the right atrium. Low-voltage, high-frequency electrical energy is then used to ablate (or destroy) the ectopic foci. This should restore normal sinus rhythm. (Catheter ablation is discussed on p. 773.)

Atrial Fibrillation

Atrial fibrillation is characterized by a total disorganization of atrial electrical activity because of multiple ectopic foci. It results in loss of effective atrial contraction (Fig. 35.15, *B*). The dysrhythmia may be paroxysmal (i.e., beginning and ending spontaneously) or persistent (lasting more than 7 days).[1] Atrial fibrillation is the most common, clinically significant dysrhythmia with respect to morbidity and mortality rates and economic impact. Its prevalence increases with age.[8]

Clinical Associations

Atrial fibrillation usually occurs in a patient with underlying heart disease, such as CAD, valvular heart disease, cardiomyopathy, hypertensive heart disease, HF, and pericarditis. It often develops acutely with thyrotoxicosis, alcohol intoxication, caffeine use, electrolyte problems, stress, and heart surgery.

ECG Characteristics

During atrial fibrillation, the atrial rate may be as high as 350 to 600

beats/min. Chaotic, fibrillatory waves replace the P waves. Ventricular rate varies, and the rhythm is usually irregular. When the ventricular rate is between 60 and 100 beats/min, it is atrial fibrillation with a *controlled ventricular response.* Atrial fibrillation with a ventricular rate greater than 100 beats/min is atrial fibrillation with a *rapid (or uncontrolled) ventricular response.* The PR interval is not measurable. The QRS complex usually has a normal shape and duration. At times, atrial flutter and atrial fibrillation coexist.[1]

Clinical Significance

Atrial fibrillation results in a decrease in CO because of ineffective atrial contractions (loss of atrial kick) and/or a rapid ventricular response (RVR). Thrombi may form in the atria because of blood stasis. An embolized clot may move through arteries to the brain, causing a stroke. Atrial fibrillation accounts for as many as 20% of all strokes.[9]

Treatment

The goals of atrial fibrillation treatment are to decrease the ventricular response (to less than 100 beats/min), prevent stroke, and convert to sinus rhythm, if possible. Ventricular rate control is a priority. Drugs used for rate control include calcium channel blockers (e.g., diltiazem), β-blockers (e.g., metoprolol), amiodarone, and digoxin (Lanoxin).

Some patients need drug or electrical conversion of atrial fibrillation to a normal sinus rhythm (e.g., reduced exercise tolerance with rate control drugs, contraindications to warfarin). The most common antidysrhythmic drug used for conversion to and maintenance of sinus rhythm is amiodarone.[8]

Electrical cardioversion may convert atrial fibrillation to a normal sinus rhythm. If a patient is in atrial fibrillation for longer than 48 hours, anticoagulation therapy with warfarin is needed for 3 to 4 weeks before the cardioversion.[1,8] Anticoagulation therapy continues for several weeks after because the procedure can cause the clots to

dislodge, placing the patient at risk for stroke. A transesophageal echocardiogram may be done to rule out clots in the atria. If no clots are present, anticoagulation therapy may not be needed before the cardioversion.

If drugs or cardioversion does not convert atrial fibrillation to normal sinus rhythm, the patient needs long-term anticoagulation therapy (Table 35.8). Warfarin is often used, and we monitor for therapeutic levels (e.g., international normalized ratio [INR]). Alternatives to warfarin are available that do not require routine laboratory testing. Examples include dabigatran (Pradaxa), apixaban (Eliquis), and rivaroxaban (Xarelto).[8] See Chapter 37 for discussion of anticoagulation therapy.

For symptomatic patients with atrial fibrillation refractory to drugs or electrical conversion, radiofrequency catheter ablation (similar to procedure for atrial flutter), AV nodal ablation, and the Maze procedure are further options. AV nodal ablation involves the destruction of the AV node and insertion of a permanent ventricular pacemaker.[8]

The Maze procedure is a surgical intervention that stops atrial fibrillation by interrupting the ectopic foci that are causing the dysrhythmia. Incisions are made in both atria, and *cryoablation* (cold therapy) is used to stop the formation and conduction of ectopic signals and restore normal sinus rhythm.

Left atrial appendage occlusion

The left atrial appendage (LAA) is a pouch that extends off the left atrium. The LAA is known to trigger atrial fibrillation. It is a common source of blood clots in patients with atrial fibrillation. LAA occlusion is a treatment strategy to prevent blood clot formation in patients who have atrial fibrillation. Removing or occluding the LAA can decrease the incidence of strokes.

A special stapler can be used to remove the LAA. Or, the LAA can be occluded manually with sutures or an LAA occlusion device (e.g., Amplatzer, Lariat, Watchman). These devices are positioned around the LAA and then closed, like a clamp that is used to shut off the

blood supply. This prevents blood from flowing into and out of the LAA. LAA occlusion is an alternative for patients who cannot use oral anticoagulants.[10]

TABLE 35.8 Drug TherapyAntithrombotic Therapy for Atrial Fibrillation and Atrial Flutter

Risk Category	Recommended Therapy
Mechanical heart valve	Warfarin (target INR 2.5–3.5)
CHA_2DS_2-VASc* score of 0	No therapy recommended
CHA_2DS_2-VASc score of 1	No therapy recommended. An oral anticoagulant or aspirin (e.g., 81–325 mg/day) may be considered
CHA_2DS_2-VASc score of ≥2 or a history of prior stroke or transient ischemia attack (TIA)	Warfarin (target INR 2.0–3.0) Apixaban (Eliquis) Dabigatran (Pradaxa) Rivaroxaban (Xarelto)
CHA_2DS_2-VASc score of ≥2 and end-stage kidney disease or on hemodialysis	Warfarin

CHA_2DS_2-VASc, Congestive heart failure; hypertension; age ≥75 (doubled); diabetes; prior stroke, transient ischemic attack, thromboembolism (doubled); vascular disease; age 65–74; sex, *INR,* international normalized ratio.

* The CHA_2DS_2-VASc score for nonvalvular atrial fibrillation stroke risk can be calculated at www.mdcalc.com/cha2ds2-vasc-score-for-atrial-fibrillation-stroke-risk/.

Check Your Practice

You are caring for a 72-yr-old female patient who was admitted with chest pain. She has continuous EGG monitoring. You are concerned because you think her ECG tracing is hard to interpret and she may be in atrial fibrillation. Your preceptor tells you that there is a lot of artifact present.

- What can you do to improve the ECG tracing?

- How would you determine the patient's rhythm?

Junctional Dysrhythmias

Junctional dysrhythmias start in the area of the AV node to the bundle of His known as the AV junction. They result because the SA node does not fire or the signal is blocked. When this occurs, the AV node becomes the pacemaker of the heart. The impulse from the AV node usually moves in a retrograde (backward) fashion. This produces an abnormal P wave that occurs just before or after the QRS complex or is hidden in the QRS complex. The impulse usually moves normally through the ventricles. Junctional premature beats may occur. They are treated in a manner similar to that for PACs. Other junctional dysrhythmias include junctional escape rhythm (Fig. 35.16), accelerated junctional rhythm, and junctional tachycardia. Their treatment depends on the patient's tolerance of the rhythm and the patient's clinical condition.

Clinical Associations

Junctional dysrhythmias are often associated with CAD, HF, cardiomyopathy, electrolyte imbalances, inferior MI, and rheumatic heart disease. Certain drugs (e.g., digoxin, nicotine, amphetamines, caffeine) can also cause junctional dysrhythmias.

ECG Characteristics

In junctional escape rhythm, the HR is 40 to 60 beats/min. It is 61 to 100 beats/min in accelerated junctional rhythm and 101 to 180 beats/min in junctional tachycardia. The rhythm is regular. The P wave is abnormal in shape and inverted, or it may be hidden in the QRS complex (Fig. 35.16). The PR interval is less than 0.12 second when the P wave precedes the QRS complex. The QRS complex is usually normal.

FIG. 35.16 Junctional escape rhythm. P wave is hidden in the RS complex. NOTE: Recorded from lead V_1.

Clinical Significance

Junctional escape rhythms serve as a safety mechanism when the SA node has not been effective. Escape rhythms like this should not be suppressed. Accelerated junctional rhythm is due to sympathetic stimulation to improve CO. Junctional tachycardia indicates a more serious problem. This rhythm may reduce CO, causing the patient to become hemodynamically unstable (e.g., hypotensive).

Treatment

Treatment varies according to the type of junctional dysrhythmia. If a patient has symptoms with a junctional escape rhythm, atropine can be used. If accelerated junctional rhythm or junctional tachycardia are caused by drug toxicity, the drug is stopped. In the absence of digitalis toxicity, β-blockers, calcium channel blockers, and amiodarone are used for rate control. Cardioversion is not done.

First-Degree AV Block

First-degree AV block is a type of AV block in which every impulse is conducted to the ventricles, but the time of AV conduction is prolonged (Fig. 35.17, *A*). After the impulse moves through the AV node, the ventricles usually respond normally.

Clinical Associations

First-degree AV block is associated with increasing age, MI, CAD, rheumatic fever, hyperthyroidism, electrolyte imbalances (e.g., hypokalemia), vagal stimulation, and drugs, such as digoxin, β-blockers, calcium channel blockers, and flecainide.

ECG Characteristics

In first-degree AV block, the HR is normal. The rhythm is regular. The P wave is normal. The PR interval is prolonged (greater than 0.20 second). The QRS complex usually has a normal shape and duration.

Clinical Significance

First-degree AV block is usually not serious. Patients are asymptomatic.

Treatment

There is no treatment for first-degree AV block. Treatment of associated conditions may be considered. Monitor patients for changes in heart rhythm (e.g., more serious AV block).

Second-Degree AV Block, Type I

Type I second-degree AV block (Mobitz I or *Wenckebach heart block)* includes a gradual lengthening of the PR interval. AV conduction time is increasingly prolonged until an atrial impulse is nonconducted and a QRS complex is blocked (missing) (Fig. 35.17, *B*). Type I AV block most often occurs in the AV node, but it can occur in the His-Purkinje system.

Clinical Associations

Type I AV block may result from drugs, such as digoxin or β-blockers. It may be associated with CAD and other diseases that can slow AV conduction.

ECG Characteristics

Atrial rate is regular, but ventricular rate may be slower because of

nonconducted or blocked QRS complexes resulting in bradycardia. Once a ventricular beat is blocked, the cycle repeats itself with progressive lengthening of the PR intervals until another QRS complex is blocked. Think of the phrase, “longer, longer, longer, drop, now you have a Wenckebach.” The rhythm appears on the ECG in a pattern of grouped beats. Ventricular rhythm is irregular. The P wave has a normal shape. The QRS complex has a normal shape and duration.

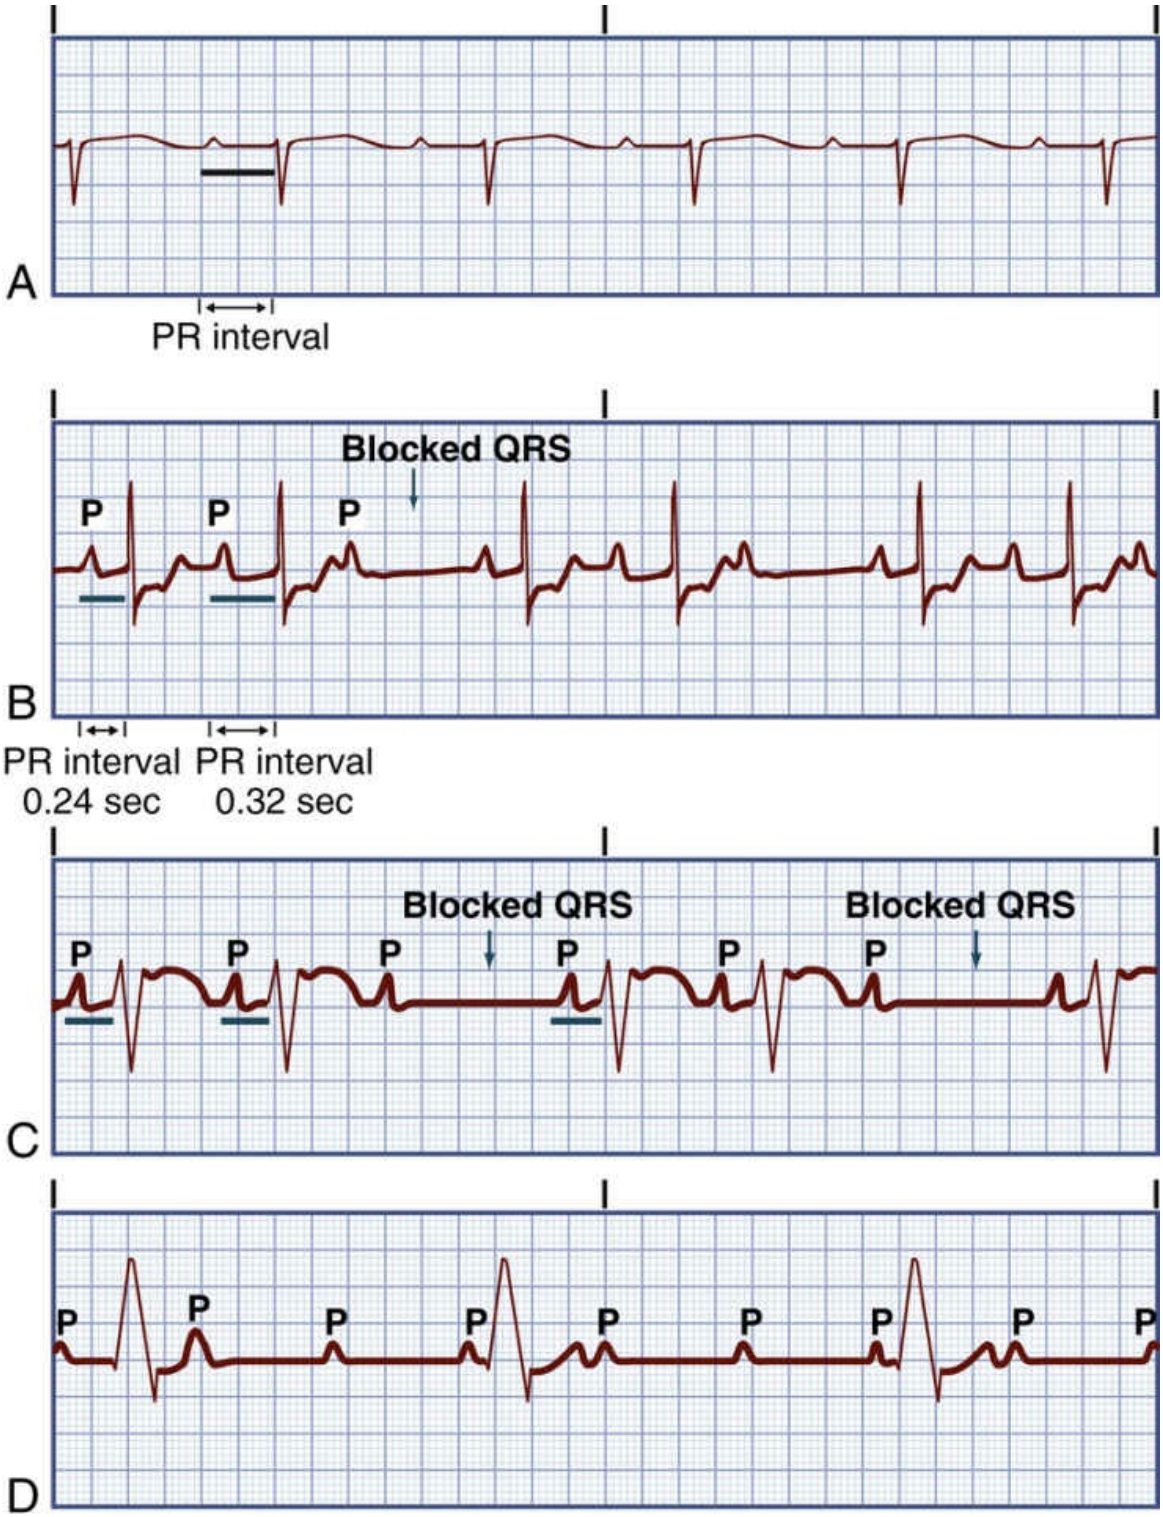

FIG. 35.17 Heart block. **A,** First-degree AV block with a PR interval of 0.40 sec. **B,** Second-degree AV block, type I, with progressive lengthening of the PR interval until a QRS complex is blocked. **C,** Second-degree AV block, type II, with constant PR intervals and variable blocked QRS complexes. **D,** Third-degree AV block. Note that there is no relationship between P waves and QRS complexes.

Clinical Significance

Type I AV block is usually a result of myocardial ischemia or inferior MI. It is generally transient and well tolerated. However, in some patients (e.g., acute MI) it may be a warning sign of a more serious AV conduction problem (e.g., complete heart block).

Treatment

A symptomatic patient may need atropine or a temporary pacemaker to increase HR, especially if the patient has had an MI. If the patient is asymptomatic, observe the rhythm closely and have a transcutaneous pacemaker on standby. Bradycardia is more likely to become symptomatic when hypotension, HF, or shock is present.

Second-Degree AV Block, Type II

In *type II second-degree AV block (Mobitz II heart block),* a P wave is nonconducted without progressive PR lengthening. This usually occurs when a block in 1 of the bundle branches is present (Fig. 35.17, *C*). On conducted beats, the PR interval is constant. Type II second-degree AV block is a more serious type of block because a certain number of impulses from the SA node are not conducted to the ventricles. This occurs in ratios of 2:1, 3:1, and so on (i.e., 2 P waves to one QRS complex, 3 P waves to 1 QRS complex). It may occur with varying ratios.

Clinical Associations

Type II AV block is associated with rheumatic heart disease, CAD, anterior MI, and drug toxicity.

ECG Characteristics

Atrial rate is usually normal. Ventricular rate depends on the degree of AV block. Atrial rhythm is regular, but ventricular rhythm may be irregular. The P wave has a normal shape. The PR interval may be

normal or prolonged in duration and remains constant on conducted beats. The QRS complex is usually greater than 0.12 second because of bundle branch block.

Clinical Significance

Type II AV block often progresses to third-degree AV block and is associated with a poor prognosis. The reduced HR often results in decreased CO with subsequent hypotension and myocardial ischemia. Type II AV block is an indication for a permanent pacemaker.

Treatment

Transcutaneous pacing or the insertion of a temporary pacemaker may be needed before inserting a permanent pacemaker if the patient becomes symptomatic (e.g., hypotension, angina).[1,11] (Temporary pacemakers are discussed on pp. 772–773.) Atropine is not an effective treatment.

Third-Degree AV Block

Third-degree AV block, or **complete heart block**, is a form of AV dissociation in which no impulses from the atria are conducted to the ventricles (Fig. 35.17, *D*). The atria are stimulated and contract independently of the ventricles. The ventricular rhythm is an escape rhythm. The ectopic pacemaker may be above or below the bifurcation of the bundle of His.

Clinical Associations

Third-degree AV block is associated with severe heart disease, including CAD, MI, myocarditis, cardiomyopathy, and some systemic diseases, such as scleroderma. Some drugs can cause third-degree AV block, such as digoxin, β-blockers, and calcium channel blockers.

ECG Characteristics

The atrial rate is usually a sinus rate of 60 to 100 beats/min. The ventricular rate depends on the site of the block. If it is in the AV

node, the rate is 40 to 60 beats/min. If it is in the His-Purkinje system, it is 20 to 40 beats/min. Atrial and ventricular rhythms are regular but unrelated to each other. The P wave has a normal shape. The PR interval is variable. There is no relationship between the P wave and the QRS complex. The QRS complex is normal if the escape rhythm starts at the bundle of His or above. It is widened if the escape rhythm starts below the bundle of His.

Clinical Significance

Third-degree AV block usually results in reduced CO with subsequent ischemia, HF, and shock. Syncope from third-degree AV block may result from severe bradycardia or even periods of asystole.

Treatment

Symptomatic patients need a transcutaneous pacemaker until a temporary transvenous pacemaker can be inserted.[1,11] (Types of temporary pacemakers are discussed on pp. 772–773.) The use of drugs such as dopamine and epinephrine is an interim measure to increase HR and support BP until temporary pacing is started.[11] Patients need a permanent pacemaker as soon as possible. Atropine is not an effective treatment.

Premature Ventricular Contractions

A **premature ventricular contraction (PVC)** is a contraction coming from an ectopic focus in the ventricles. It is the premature (early) occurrence of a QRS complex. A PVC is wide and distorted in shape compared with a QRS complex coming down the normal conduction pathway (Fig. 35.18). PVCs that have the same shape are *unifocal* PVCs. PVCs that arise from different foci appear different in shape from each other. These are *multifocal* PVCs. When every other beat is a PVC, the rhythm is called *ventricular bigeminy.* When every third beat is a PVC, it is called *ventricular trigeminy.* We call 2 consecutive PVCs a *couplet.*

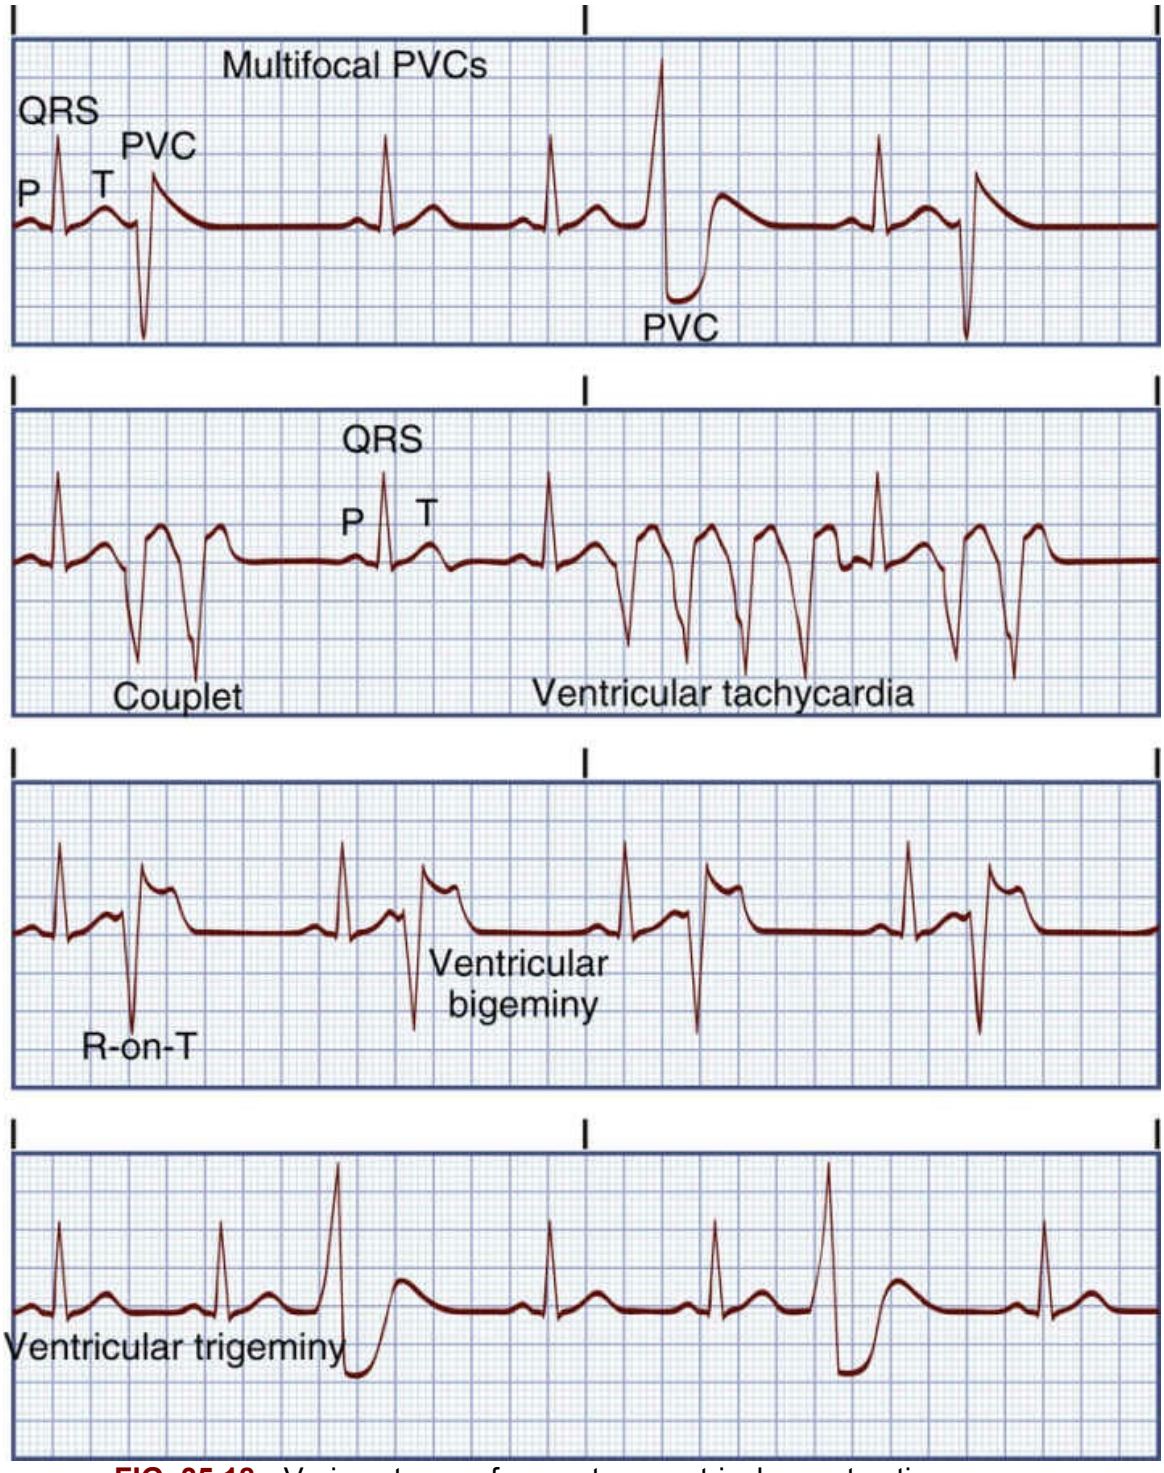

FIG. 35.18 Various types of premature ventricular contractions (PVCs).

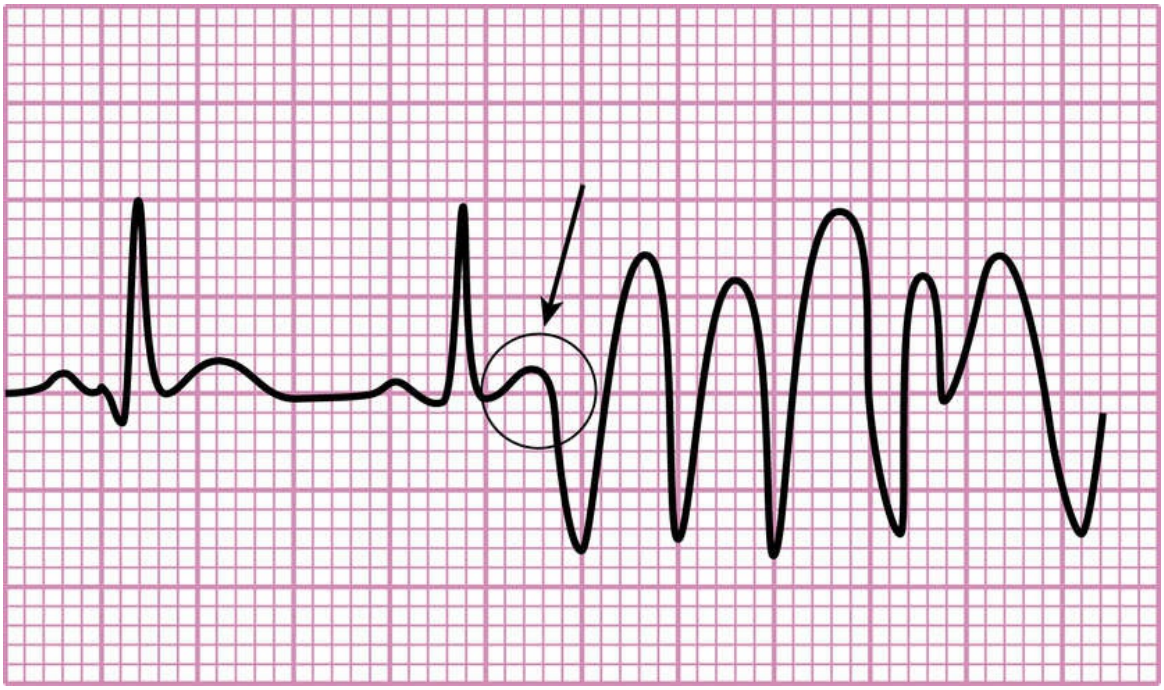

FIG. 35.19 R-on-T phenomenon. The "shock" occurred on the T wave leading to ventricular tachycardia.

Ventricular tachycardia (VT) occurs when there are 3 or more consecutive PVCs. *R-on-T phenomenon* occurs when a PVC falls on the T wave of a preceding beat (Fig. 35.19). This is especially dangerous because the PVC is firing during the relative refractory phase of ventricular repolarization. Excitability of the heart cells increases during this time, and the risk for the PVC to start VT or ventricular fibrillation (VF) is great.

Clinical Associations

PVCs are associated with stimulants, such as caffeine, alcohol, nicotine, aminophylline, epinephrine, and isoproterenol. They are also associated with electrolyte imbalances, hypoxia, fever, exercise, and emotional stress. Disease states associated with PVCs include MI, mitral valve prolapse, HF, cardiomyopathy, and CAD.

ECG Characteristics

HR varies according to intrinsic rate and number of PVCs. Rhythm is irregular because of premature beats. The P wave is rarely visible. It is

usually lost in the QRS complex of the PVC. Retrograde conduction may occur with the P wave seen after the ectopic beat. The PR interval is not measurable. The QRS complex is wide and distorted in shape, lasting more than 0.12 second. The T wave is generally large and opposite in direction to the major direction of the QRS complex.

Clinical Significance

PVCs are usually not harmful in a patient with a normal heart. PVCs in CAD or acute MI indicate ventricular irritability. PVCs may reduce the CO and lead to angina and HF for those with heart disease, so assess the patient's physiologic response. Take the patient's apical-radial pulse rate and determine the pulse deficit, since PVCs often do not generate a sufficient ventricular contraction to result in a peripheral pulse.

Treatment

Treatment relates to the cause of the PVCs (e.g., O_2 therapy for hypoxia, electrolyte replacement). Assessing the patient's hemodynamic status is important to determine if treatment with drug therapy is needed. Drug therapy includes β-blockers, lidocaine, or amiodarone.

Accelerated Idioventricular Rhythm

An *accelerated idioventricular rhythm* (AIVR) can develop when the intrinsic pacemaker (SA node or AV node) rate becomes less than that of a ventricular ectopic pacemaker. The rate is between 40 and 100 beats/min.

Clinical Associations

It is most often associated with acute MI and reperfusion of the myocardium after thrombolytic therapy or percutaneous coronary interventions (e.g., angioplasty). It can occur with digitalis toxicity.

Treatment

In the setting of acute MI, AIVR is usually self-limiting and well tolerated, and it needs no treatment. If the patient becomes symptomatic (e.g., hypotensive, chest pain), atropine is an option. Temporary pacing may be needed. Drugs that suppress ventricular rhythms (e.g., amiodarone) should not be used since they can further reduce the HR.

Ventricular Tachycardia

A run of 3 or more PVCs defines **ventricular tachycardia (VT)**. It occurs when an ectopic focus or foci fire repeatedly and the ventricle takes control as the pacemaker. Different forms of VT exist, depending on QRS configuration. *Monomorphic* VT (Fig. 35.20, *A*) has QRS complexes that are the same in shape, size, and direction. *Polymorphic* VT occurs when the QRS complexes gradually change back and forth from one shape, size, and direction to another over a series of beats. *Torsades de pointes* (French for "twisting of the points") is polymorphic VT associated with a prolonged QT interval of the underlying rhythm (Fig. 35.20, *B*).

VT may be sustained (longer than 30 seconds) or nonsustained (less than 30 seconds). The development of VT is an ominous sign. It is a life-threatening dysrhythmia because of decreased CO and the possible development of VF, which is lethal.

Clinical Associations

VT is associated with MI, CAD, significant electrolyte imbalances, cardiomyopathy, long QT syndrome, drug toxicity, and central nervous system disorders. It can occur in patients who have no evidence of heart disease.

ECG Characteristics

Ventricular rate is 150 to 250 beats/min. Rhythm may be regular or irregular. AV dissociation may be present, with P waves occurring independently of the QRS complex. The atria may be depolarized by the ventricles in a retrograde fashion. The P wave is usually buried in

the QRS complex. The PR interval is not measurable. The QRS complex appears distorted and wide (greater than 0.12 second in duration). The T wave is in the opposite direction of the QRS complex (Fig. 35.20).

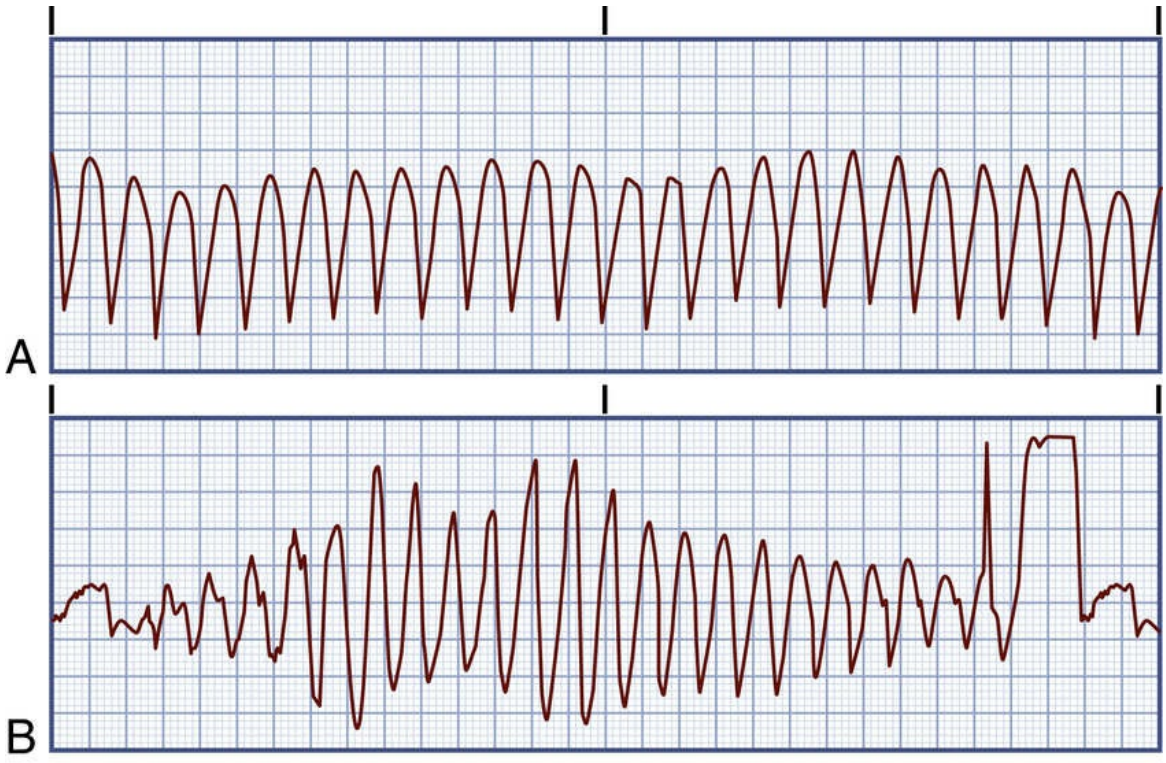

FIG. 35.20 Ventricular tachycardia. **A,** Monomorphic. **B,** Torsades de pointes (polymorphic).

Clinical Significance

VT can be stable (patient has a pulse) or unstable (patient is pulseless). Sustained VT causes a severe decrease in CO because of decreased ventricular diastolic filling times and loss of atrial contraction. This results in hypotension, pulmonary edema, decreased cerebral blood flow, and cardiopulmonary arrest. VT must be treated quickly, even if it occurs only briefly and stops abruptly. Episodes may recur if prophylactic treatment is not started. VF may develop.

Ethical/Legal Dilemmas

Scope and Standards of Practice

Situation

A young woman is admitted to the intensive care unit (ICU) after having several episodes of nonsustained VT credited to a history of viral cardiomyopathy. While she is being stabilized, she codes (pulseless VT) and needs intubation. A nurse anesthetist tries to intubate her 3 times unsuccessfully. There is an unforeseen delay in the arrival of the anesthesiologist. P.F., an ICU nurse who is a paramedic certified in advanced trauma life support (ATLS) and advanced cardiovascular life support (ACLS), tries to intubate the patient and does so successfully. The next day the nursing supervisor questions P.F. about intubating the patient since this is not within the scope of practice for an ICU nurse.

Ethical/Legal Points for Consideration

- The RN *Scope of Practice,* including rules and regulations that guide practice, are defined by individual state boards of nursing and can vary from state to state.
- Individual agencies have policies and procedures that describe the scope of practice for nurses. These can be more restrictive than those of the state.
- P.F. has had training, education, and certification beyond the usual nursing role.
- The life-threatening situation is an extenuating circumstance.
- Negligence may have been a factor if P.F., who is a nurse with training and experience, had not acted.

Discussion Questions

1. What would you have done in this situation?
2. How would you respond to the nursing supervisor?
3. What are the legal ramifications for P.F. in this situation?
4. What are the ethical issues in this situation?

Treatment

Precipitating causes (e.g., electrolyte imbalances, ischemia) must be identified and treated. If the VT is monomorphic and the patient is clinically stable (i.e., pulse is present) and has preserved left ventricular function, IV procainamide, lidocaine, or amiodarone are options. These drugs can be given if VT is polymorphic with a normal baseline QT interval.

Polymorphic VT with a prolonged baseline QT interval is treated with IV magnesium, isoproterenol, phenytoin, or antitachycardia pacing (discussed later in this chapter). Drugs that prolong the QT interval (e.g., dofetilide [Tikosyn]) should be stopped. Cardioversion is used if drug therapy is ineffective.

VT without a pulse is a life-threatening situation. It is treated the same as VF. Cardiopulmonary resuscitation (CPR) and rapid defibrillation are the first lines of treatment, followed by the administration of vasopressors (e.g., epinephrine) and antidysrhythmics (e.g., amiodarone) if defibrillation is unsuccessful.[11]

Check Your Practice

You are assigned to a 69-yr-old male patient on a telemetry unit who is recovering from colon surgery. He has a history of 2 MIs and he has 3 coronary stents in place. You hear his ECG monitor alarm and see what looks like ventricular tachycardia on the screen.

- What should you do?

Ventricular Fibrillation

Ventricular fibrillation (VF) is a severe derangement of the heart rhythm characterized on ECG by irregular waveforms of varying shapes and amplitude (Fig. 35.21). This represents the firing of multiple ectopic foci in the ventricle. Mechanically, the ventricle is simply "quivering," with no effective contraction, and so no CO occurs. VF is a lethal dysrhythmia.

Clinical Associations

VF occurs in acute MI and myocardial ischemia and in chronic diseases such as HF and cardiomyopathy. It may occur during cardiac pacing or cardiac catheterization procedures because of catheter stimulation of the ventricle. It may also occur with coronary reperfusion after thrombolytic therapy. Other causes are electric shock, hyperkalemia, hypoxemia, acidosis, and drug toxicity.

ECG Characteristics

HR is not measurable. Rhythm is irregular and chaotic. The P wave is not visible. The PR interval and the QRS interval are not measurable.

Clinical Significance

VF results in an unresponsive, pulseless, and apneic state. If VF is not treated quickly, the patient will not recover.

Treatment

Treatment consists of immediate initiation of CPR and ACLS with the use of defibrillation and definitive drug therapy (e.g., epinephrine, amiodarone). There should be no delay in starting chest compressions and using a defibrillator once available.

Asystole

Asystole is the total absence of ventricular electrical activity. Occasionally, P waves are seen. No ventricular contraction occurs because depolarization does not occur. Patients are unresponsive, pulseless, and apneic. Asystole is a lethal dysrhythmia that needs

immediate treatment. VF may masquerade as asystole. Always assess the rhythm in more than 1 lead. The prognosis of a patient with asystole is extremely poor.

Clinical Associations

Asystole is usually a result of advanced heart disease, a severe cardiac conduction system problem, or end-stage HF.

Clinical Significance

Generally, the patient with asystole has end-stage heart disease or has a prolonged arrest and cannot be resuscitated.

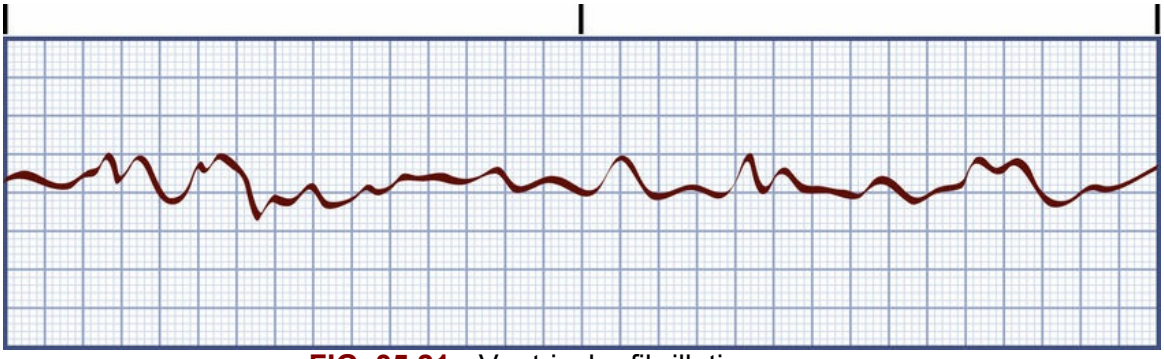

FIG. 35.21 Ventricular fibrillation.

Treatment

Treatment consists of CPR with ACLS measures. These include definitive drug therapy with epinephrine and intubation.

Pulseless Electrical Activity

Pulseless electrical activity (PEA) is a situation in which organized electrical activity is seen on the ECG, but there is no mechanical heart activity and the patient has no pulse. It is the most common dysrhythmia seen after defibrillation. Prognosis is poor unless the underlying cause is quickly identified and treated. Common causes of PEA include hypovolemia, hypoxia, metabolic acidosis, hyperkalemia,

hypokalemia, hypoglycemia, hypothermia, toxins (e.g., drug overdose), cardiac tamponade, thrombosis (e.g., MI, pulmonary embolus), tension pneumothorax, and trauma. Treatment begins with CPR, followed by drug therapy (e.g., epinephrine) and intubation. Correcting the underlying cause is critical to prognosis.

Sudden Cardiac Death

The term *sudden cardiac death* (SCD) refers to death from a cardiac cause. Most SCDs result from ventricular dysrhythmias, specifically VT or VF. SCD is discussed in Chapter 33.

Prodysrhythmia

Antidysrhythmic drugs can cause life-threatening dysrhythmias similar to those for which they are treating. We call this a *prodysrhythmia.* The patient who has severe left ventricular dysfunction is the most susceptible to prodysrhythmias. Digoxin and class IA, IC, and III antidysrhythmic drugs can cause a prodysrhythmic response.[6] The first several days of drug therapy are the vulnerable period for developing prodysrhythmias. For this reason, many patients start oral antidysrhythmic drugs in a monitored hospital setting.

Interprofessional and Nursing Care: Dysrhythmias

Antidysrhythmic Drug Therapy

Table 35.9 shows antidysrhythmic drugs by their primary effects on the heart cells and the ECG.

Before giving any *antidysrhythmic drug*, perform a thorough assessment with a complete physical assessment, health history, and medication history. Assess for contraindications, cautions, and drug interactions. Obtain a baseline ECG. Assess vital signs, heart and lung sounds, and pulse rate, rhythm, and quality. Assess for signs and symptoms associated with decreased CO because of the dysrhythmia,

such as restlessness, syncope, chest pain, dyspnea, and crackles. Review laboratory studies, including electrolytes, and liver and kidney function tests.

When giving antidysrhythmics, closely monitor the ECG and vital signs, especially BP and pulse rate. Continue to perform an ongoing physical assessment. Monitor laboratory studies as needed. Give specific instructions for each drug. Teach the patient that oral forms are often better tolerated if taken with food and fluids to help decrease GI upset. Tell patients to avoid alcohol, caffeine, and tobacco.

TABLE 35.9 Drug TherapyAntidysrhythmic Drugs

Drug	Effects on the Action Potential	Effects on ECG
Class I: Sodium Channel Blockers	Decrease impulse conduction in the atria, ventricles, and His-Purkinje system	
Class IA **disopyramide (Norpace)** **procainamide** **quinidine**	Delay repolarization	Widened QRS and prolonged QT interval
Class IB **lidocaine** **mexiletine** **phenytoin (Dilantin)**	Accelerate repolarization	Little or no effect on ECG
Class IC **flecainide** **propafenone (Rythmol)**	Decrease impulse conduction	Pronounced prodysrhythmic actions, widened QRS, prolonged QT interval
Class II: β-Adrenergic Blockers **esmolol (Brevibloc)** **metoprolol (Lopressor)** **propranolol (Inderal)**	Decrease automaticity of the SA node, slow impulse conduction in AV node, reduce atrial and ventricular contractility	Bradycardia, prolonged PR interval, AV block
Class III: Potassium	Delay repolarization, resulting in prolonged duration of action potential and refractory	Prolonged PR and QT intervals, widened QRS,

Channel Blockers **amiodarone** **dofetilide (Tikosyn)** **ibutilide (Corvert)** **sotalol* (Betapace)**	period	bradycardia
Class IV: Calcium Channel Blockers **diltiazem (Cardizem)** **verapamil**	Decrease automaticity of SA node, delay AV node conduction; reduce myocardial contractility	Bradycardia, prolonged PR interval, AV block
Other Agents		
adenosine (Adenocard) **digoxin (Lanoxin)**	Decrease conduction through AV node, reduce automaticity of SA node	Prolonged PR interval, AV block
dronedarone (Multaq)†	Suppress atrial dysrhythmias though mechanism is unknown	Prolonged QT interval
magnesium	Decrease impulse conduction through AV node	AV block

* Sotalol has both class II and class III properties.

† Dronedarone has class I through IV properties.

Defibrillation

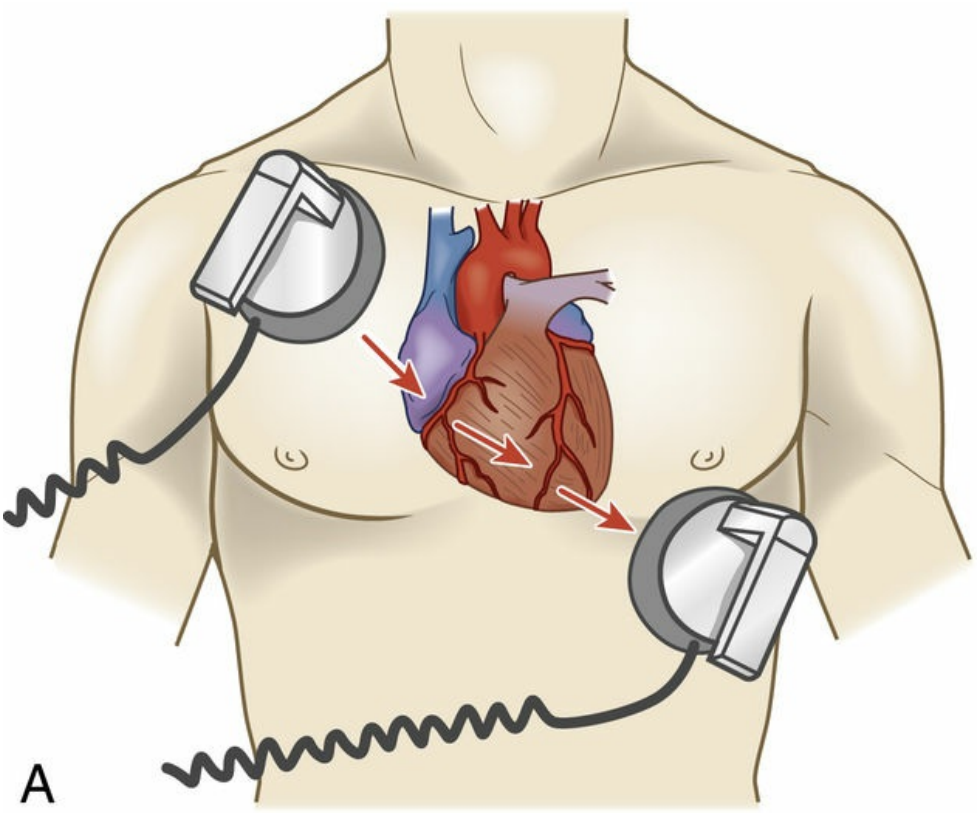
Defibrillation is the treatment of choice to end VF and pulseless VT. It is most effective when the myocardial cells are not anoxic or acidotic. Rapid defibrillation (within 2 minutes) is critical to a successful patient outcome. Defibrillation involves the passage of an electric shock through the heart to depolarize the myocardial cells. The goal is that after repolarization, the SA node will be able to resume the role of pacemaker.

Defibrillators deliver energy using a monophasic or biphasic waveform. Monophasic defibrillators deliver energy in 1 direction. Biphasic defibrillators deliver energy in 2 directions (Fig. 35.22). The shocks delivered are at lower energies and with fewer post-shock

dysrhythmias than monophasic defibrillators.

We measure the output of a defibrillator in *joules,* or watts per second. The recommended energy for initial shocks in defibrillation depends on the type of defibrillator. Biphasic defibrillators deliver the first and any successive shocks using 120 to 200 joules. Recommendations for monophasic defibrillators include an initial shock at 360 joules. After the first shock, start CPR immediately beginning with chest compressions.

We can perform rapid defibrillation using a manual or automatic device (Fig. 35.23). Manual defibrillators require you to interpret heart rhythms, determine the need for a shock, and deliver a shock. An **automatic external defibrillator (AED)** can detect heart rhythms and tell the user to deliver a shock using hands-free defibrillator pads. Proficiency in AED use is part of the basic life support course for health care professionals. Be familiar with the operation of the type of defibrillator used in your clinical setting.



The following general steps are taken for defibrillation: (1) continue CPR until the defibrillator is charged; (2) turn the defibrillator on, and select the proper energy level; (3) check to see that the synchronizer switch is turned off (discussed later); (4) apply conductive materials (e.g., defibrillator gel pads) to the chest, one to the right of the sternum just below the clavicle, and the other to the left of the apex; (5) charge the defibrillator using the button on the defibrillator or the paddles; (6) position the paddles firmly on the chest wall over the conductive material (Fig. 35.22); (7) call and look to see that everyone is "all clear" to ensure that staff are not touching the patient or the bed at the time of discharge; and (8) deliver the charge by depressing buttons on both paddles simultaneously.

Hands-free, multifunction defibrillator pads are available. We place them on the chest as described earlier. Hands-free pads decrease the risk for injury compared to paddles. Connect the cables from the pads to the defibrillator. Charge and discharge the defibrillator using buttons on the defibrillator. It is still essential to ensure that all staff are clear before discharging the defibrillator.

Safety Alert

Defibrillation and Cardioversion

- Check that the synchronizer switch is OFF for defibrillation.
- Turn the synchronizer switch ON for a cardioversion.
- Never apply defibrillator pads over a pacemaker or implantable cardioverter-defibrillator.
- Be certain that personnel are “all clear” before discharging the device.

Synchronized Cardioversion

Synchronized cardioversion is the therapy of choice for the patient with ventricular tachydysrhythmias (e.g., VT with a pulse) or supraventricular tachydysrhythmias (e.g., atrial flutter with a rapid ventricular response). A synchronized circuit in the defibrillator delivers a shock on the R wave of the QRS complex of the ECG. The synchronizer switch must be turned on when performing cardioversion.

The procedure for synchronized cardioversion is the same as for

defibrillation with a few exceptions (Table 35.10). If synchronized cardioversion is done on a nonemergency basis (i.e., the patient is awake and hemodynamically stable), we sedate the patient with IV agents (e.g., midazolam, fentanyl) beforehand. Strict attention to maintaining the patient's airway is critical. If a patient with supraventricular tachycardia or VT with a pulse becomes hemodynamically unstable, synchronized cardioversion should be done as quickly as possible. Start the initial energy for synchronized cardioversion at 50 to 100 joules (biphasic defibrillator) and 100 joules (monophasic defibrillator) and increase if needed. If the patient becomes pulseless or the rhythm changes to VF, turn the synchronizer switch off and perform defibrillation.

TABLE 35.10 Nursing ManagementAssisting With Cardioversion

Preprocedure

- Obtain 12-lead ECG and initiate ECG monitoring.
- Perform baseline assessment, including vital signs, pulse oximetry, noting any manifestations of the dysrhythmia.
- Withhold food and fluids per institution policy.
- Assess baseline laboratory values (e.g., cardiac biomarkers, electrolytes).
- Teach patient and caregiver about procedure and postprocedure care.
- Remove all metallic objects, dentures, and transdermal patches. Clipping or removing chest hair may be needed.
- Establish IV access.
- Give sedative and other drugs, as ordered.

Postprocedure

- Maintain patent airway and administer O_2 as needed.
- Monitor ECG for dysrhythmias or other changes (e.g., ST segment elevation).
- Perform assessment and compare to baseline: vital signs, pulse oximetry, and heart and breath sounds.
- Assess level of consciousness and reorient as needed.
- Administer IV dysrhythmic and analgesic medications as ordered.
- Assess for burns and provide skin care.

Implantable Cardioverter-Defibrillator

The *implantable cardioverter-defibrillator* (ICD) is an important technology for patients who (1) have survived SCD, (2) have spontaneous sustained VT, (3) have syncope with inducible VT or VF during EPS, or (4) are at high risk for future life-threatening dysrhythmias (e.g., have cardiomyopathy). The use of ICDs has significantly decreased mortality rates in these patients.[12]

The ICD consists of a lead system placed via a subclavian vein to the endocardium. A battery-powered pulse generator is implanted subcutaneously, usually over the pectoral muscle on the patient's nondominant side. The pulse generator is similar in size to a pacemaker. Most systems are single-lead systems (Fig. 35.24). The ICD sensing system monitors the HR and rhythm and identifies VT or VF. After the sensing system detects a lethal dysrhythmia, the device delivers a 25-joule or less shock to the patient's heart. If the first shock is unsuccessful, the device recycles and can continue to deliver shocks.

In addition to defibrillation capabilities, ICDs have *antitachycardia* and *antibradycardia pacing* capabilities. These devices use algorithms that detect dysrhythmias and determine the appropriate response. They can start *overdrive pacing* of supraventricular tachycardia and VT, sparing the patient painful defibrillator shocks. They can provide backup pacing for bradydysrhythmias that may occur after defibrillation. Nursing care of the patient undergoing ICD placement is similar to the care of a patient undergoing permanent pacemaker

implantation (see p. 771).

Patients with structural or congenital cardiac anomalies may receive a totally subcutaneous ICD (S-ICD).[13] The S-ICD pulse generator is placed under the skin on the left side of the chest with the electrode under the skin above the sternum. The system delivers a shock if it detects VT or VF. Since the S-ICD does not have any electrodes implanted in the heart, it has no pacing capability.[13]

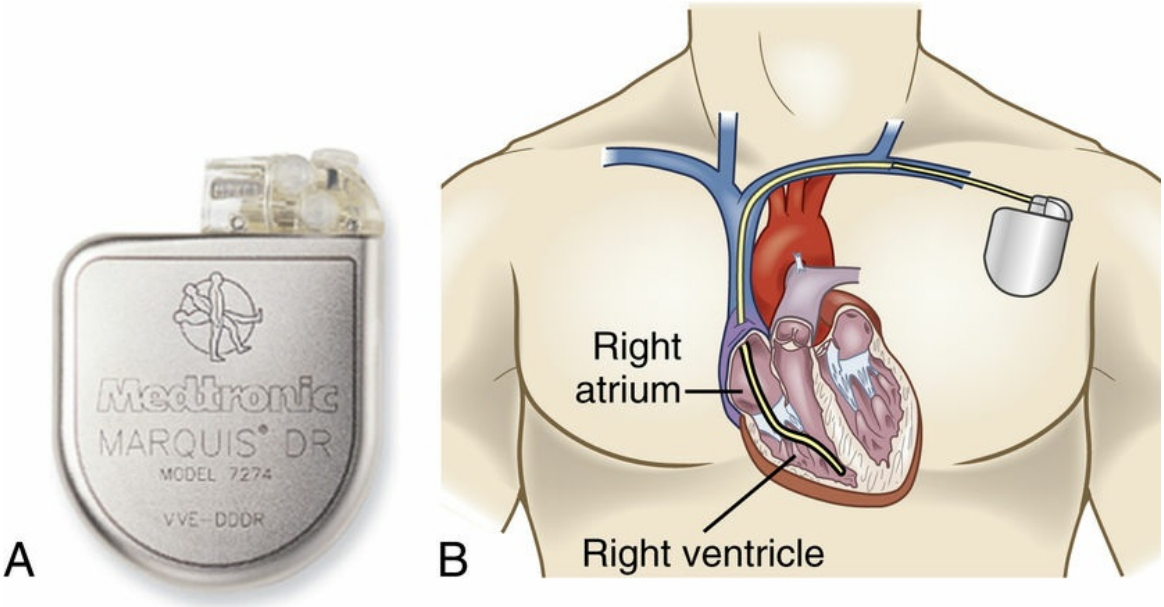

FIG. 35.24 **A,** The implantable cardioverter-defibrillator (ICD) pulse generator from Medtronic, Inc. (Courtesy Medtronic, Inc., Minneapolis, Minn.) **B,** The ICD is placed in a subcutaneous pocket over the pectoral muscle. A single-lead system is placed transvenously from the pulse generator to the endocardium. The single lead detects dysrhythmias and delivers an electric shock to the heart muscle.

Teaching the patient who is receiving an ICD and the caregiver is extremely important. Patients may have a variety of emotions, including fear of body image change, fear of recurrent dysrhythmias, expectation of pain with ICD discharge (described as a feeling of a blow to the chest), and anxiety about going home. Encourage patients and caregivers to take part in local or online ICD support groups.[14] Table 35.11 presents a teaching guide for the patient with an

ICD and the caregiver.

Pacemakers

The artificial **cardiac pacemaker** is an electronic device used to pace the heart when the normal conduction pathway is damaged. The basic pacing circuit consists of a power source (battery-powered pulse generator) with programmable circuitry, 1 or more pacing leads, and the myocardium. The electrical signal (stimulus) travels from the pulse generator, through the leads, to the wall of the myocardium. The heart muscle is "captured" and stimulated to contract (Fig. 35.25).

Current pacemakers are small, sophisticated, and physiologically precise. They pace the atrium and/or 1 or both ventricles. Most pacemakers are *demand pacemakers.* This means that they sense the heart's electrical activity and fire only when the HR drops below a preset rate. Demand pacemakers have 2 distinct features: (1) a sensing device that inhibits the pacemaker when the HR is adequate and (2) a pacing device that triggers the pacemaker when no QRS complexes occur within a preset time.[1]

In addition to antibradycardia pacing, devices now include antitachycardia and overdrive pacing. *Antitachycardia pacing* involves the delivery of a stimulus to the ventricle to end tachydysrhythmias (e.g., VT). Overdrive pacing involves pacing the atrium at rates of 200 to 500 impulses per minute to try to stop atrial tachycardias (e.g., atrial flutter with a rapid ventricular response).[15,16]

Permanent Pacemaker

A *permanent pacemaker* is totally implanted within the body (Fig. 35.26). The power source is placed subcutaneously, usually over the pectoral muscle on the patient's nondominant side. The pacing leads are placed transvenously to the right atrium and/or 1 or both ventricles and attached to the power source. Common reasons for insertion of a permanent pacemaker are found in Table 35.12.

Table 35.11 Patient & Caregiver TeachingImplantable Cardioverter-Defibrillator (ICD)

Include the following information in the teaching plan for a patient receiving an ICD and the patient's caregiver:

1. Follow up with your HCP for routine checks of the function of the ICD. This is often done by interrogating the device using a telephone.
2. Report any signs of infection at incision site (e.g., redness, swelling, drainage) or fever to your HCP at once.
3. Keep incision dry for 4 days after insertion or as instructed.
4. Avoid lifting arm on ICD side above shoulder until approved.
5. Discuss resuming sexual activity with your HCP. It is usually safe to resume sexual activity once your incision is healed.
6. Do not drive until cleared by your HCP. This decision is usually based on the ongoing presence of dysrhythmias, the frequency of ICD firings, your overall health, and state laws about drivers with ICDs.
7. Avoid direct blows to ICD site.
8. Avoid large magnets and strong electromagnetic fields because these may interfere with the device.
9. You should not have an MRI unless the ICD is approved as MRI safe or there is a protocol in place for patient safety during the procedure.
10. Travel is not restricted. Tell security (e.g., airport, train station, public buildings) of presence of ICD because it may set off the metal detector. If hand-held screening wand is used, it should not be placed directly over the ICD. Manufacturer information may vary about the effect of metal detectors on the function of the ICD.
11. Do not stand near antitheft devices in doorways of stores and public buildings. You should walk through them at a normal pace.

12. If your ICD fires once, call your HCP right away. If you feel sick or if it fires more than once, contact the emergency response system.
13. You should always wear a Medic Alert ID device.
14. Always carry the ICD identification card and a current list of your drugs.
15. Consider joining an ICD support group (e.g., *www.icdsupportgroup.org/*).
16. Caregivers should learn cardiopulmonary resuscitation (CPR).

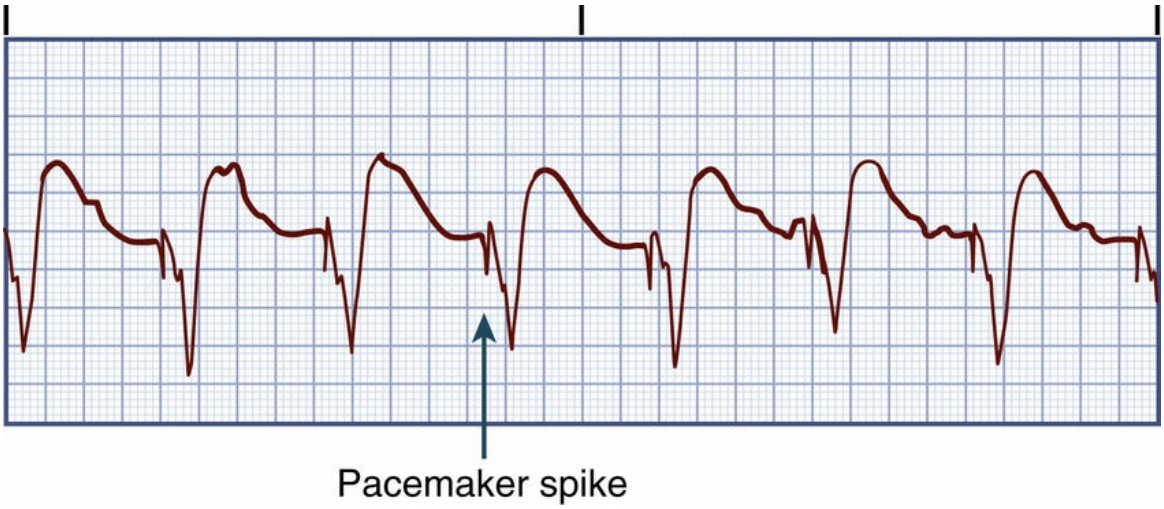

FIG. 35.25 Ventricular capture (depolarization) secondary to signal *(pacemaker spike)* from pacemaker lead in the right ventricle.

New technology and research are focused on miniaturized, leadless permanent pacemakers. Single-component devices have the battery, sensors, electronics, and stimulating electrodes in a small capsule that is placed in the ventricle using a deflatable sheath. A multicomponent device has a small "seed" that is placed in a cardiac chamber. It acts as an energy transducer while an outside piece beams ultrasound (or radio waves) to the seed. The seed converts the energy to a pacing pulse.[15] The lack of a transvenous lead and subcutaneous pulse generator is a major shift in cardiac pacing.[16] Other research is focusing on making permanent pacemakers without batteries.

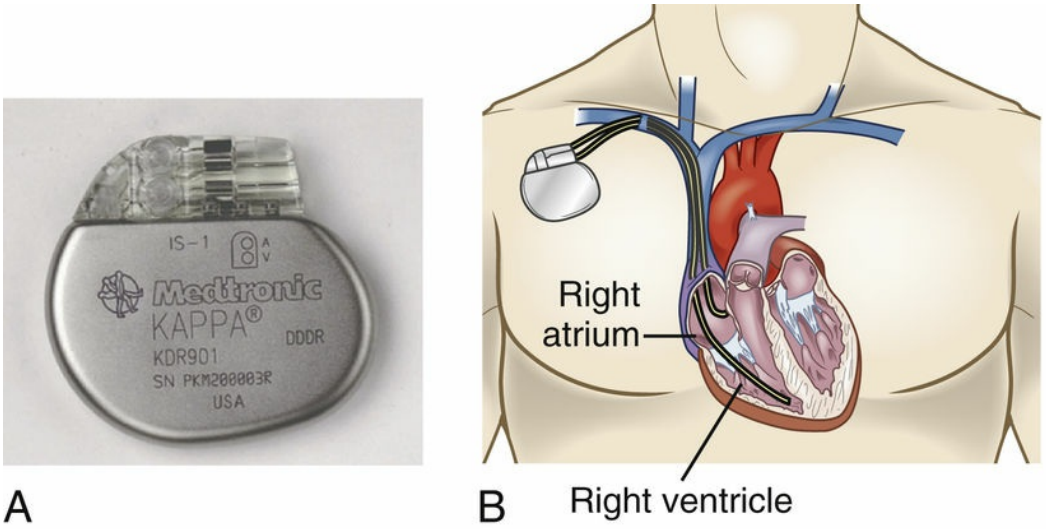

FIG. 35.26 **A,** A dual-chamber rate-responsive pacemaker from Medtronic, Inc., is designed to treat patients with chronic heart problems in which the heart beats too slowly to support the body's circulation needs. (Courtesy Medtronic, Inc., Minneapolis, Minn.) **B,** Pacing leads in both the atrium and the ventricle enable a dual-chamber pacemaker to sense and pace in both heart chambers.

TABLE 35.12 Indications for Permanent Pacemakers

- Acquired AV block
- Second-degree AV block
- Third-degree AV block
- Atrial fibrillation with a slow ventricular response
- Bundle branch block
- Cardiomyopathy
    - Dilated
    - Hypertrophic
- HF
- SA node dysfunction
- Symptomatic bradycardia with unknown cause

- Tachydysrhythmias (e.g., ventricular tachycardia)

Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CRT) is a pacing technique that resynchronizes the heart cycle by pacing both ventricles *(biventricular pacing).* This promotes improvement in ventricular function (Fig. 34.4). Most HF patients have intraventricular conduction delays causing abnormal ventricular contraction. This causes dyssynchrony between the right and left ventricles and results in reduced systolic function, pump inefficiency, and worsened HF. For patients with severe left ventricular dysfunction, devices that combine CRT with an ICD provide maximum therapy.[15,16]

Temporary Pacemaker

A *temporary pacemaker* is one that has the power source outside the body (Fig. 35.27). There are 3 types of temporary pacemakers: transvenous, epicardial, and transcutaneous. Table 35.13 lists common reasons for temporary pacing.

A *transvenous pacemaker* consists of a lead or leads that are threaded transvenously to the right atrium and/or right ventricle and attached to the external power source (Fig. 35.28). Most of these pacemakers are inserted in the ED or ICU in emergency situations. They provide a bridge to insertion of a permanent pacemaker or until the underlying cause of the dysrhythmia is resolved.

Epicardial pacing involves attaching an atrial and ventricular pacing lead to the epicardium during heart surgery. The leads are passed through the chest wall and attached to the external power source. Epicardial pacing leads are placed prophylactically in case a bradydysrhythmia or tachydysrhythmia occurs in the early postoperative period.[15,16]

FIG. 35.27 Temporary external, dual-chamber demand pacemaker. Courtesy Medtronic, Inc., Minneapolis, Minn.

TABLE 35.13 Common Indications for Temporary Pacemakers

- Maintain adequate HR and rhythm during special circumstances

    - During surgery and postoperative recovery
    - During cardiac catheterization or coronary angioplasty
    - With drug therapy that may cause bradycardia
    - Before implantation of a permanent pacemaker
- Prophylaxis after open heart surgery
- Acute anterior MI with second- or third-degree AV block or bundle branch block
- Acute inferior MI with symptomatic bradycardia and AV block
- EPS to evaluate patient with bradydysrhythmias and tachydysrhythmias

A *transcutaneous pacemaker* (TCP) can provide adequate HR and rhythm to the patient in an emergency. Placement of a TCP is a noninvasive, temporary procedure used until a transvenous pacemaker can be inserted or more definitive therapy is available.[1,11]

The TCP consists of a power source and a rate- and voltage-control device that attaches to 2 large, multifunction electrode pads. Position 1 pad on the anterior part of the chest, usually on the V_4 lead position, and the other pad on the back between the spine and left scapula at the level of the heart (Fig. 35.29). When programming the TCP, use the lowest current that results in a ventricular contraction (capture) to minimize patient discomfort.

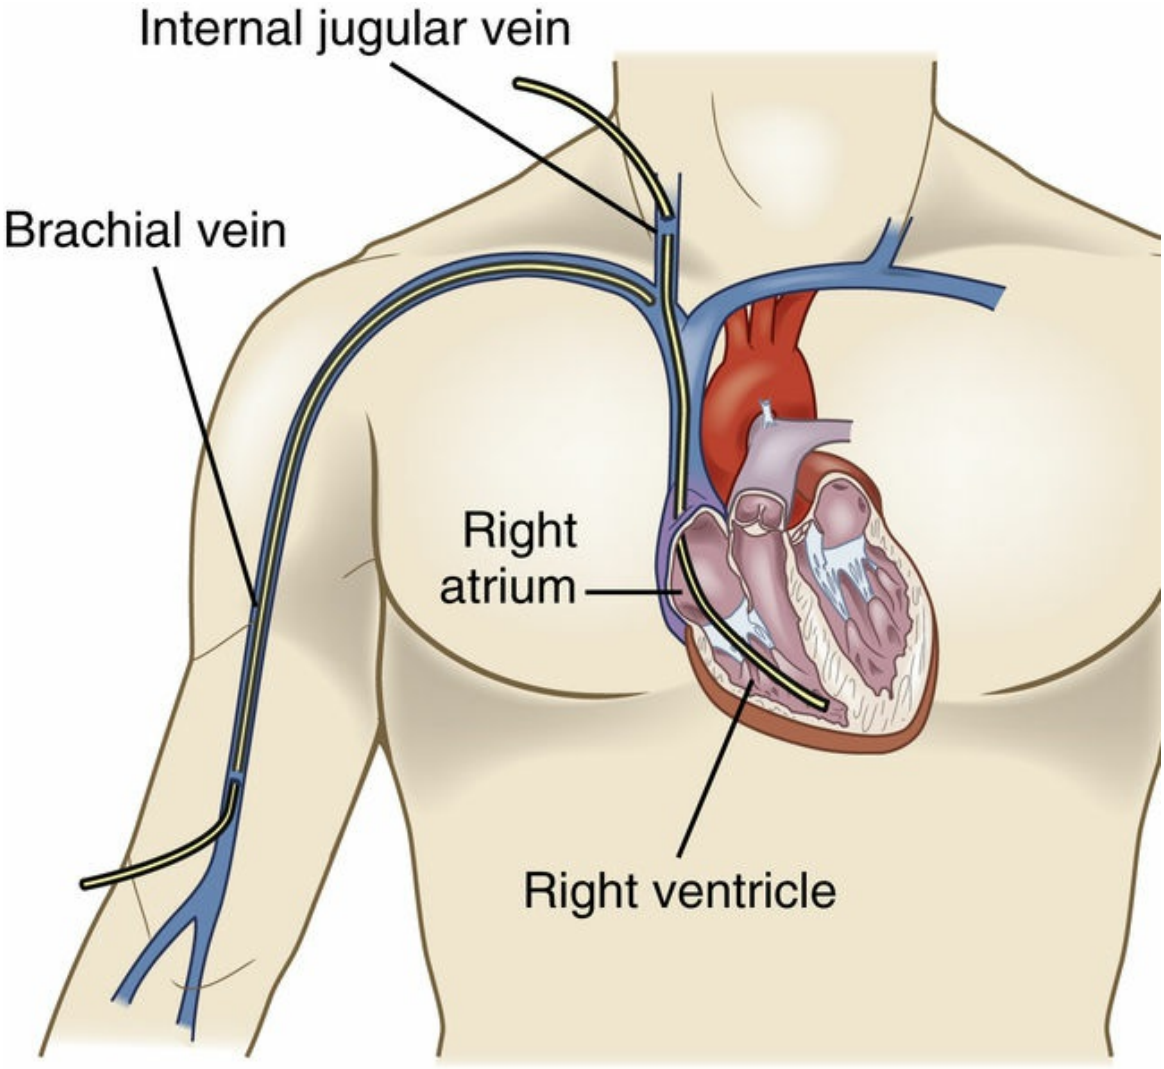

FIG. 35.28 Temporary transvenous pacemaker catheter insertion. A single lead is positioned in the right ventricle through the brachial, subclavian, jugular, or femoral vein.

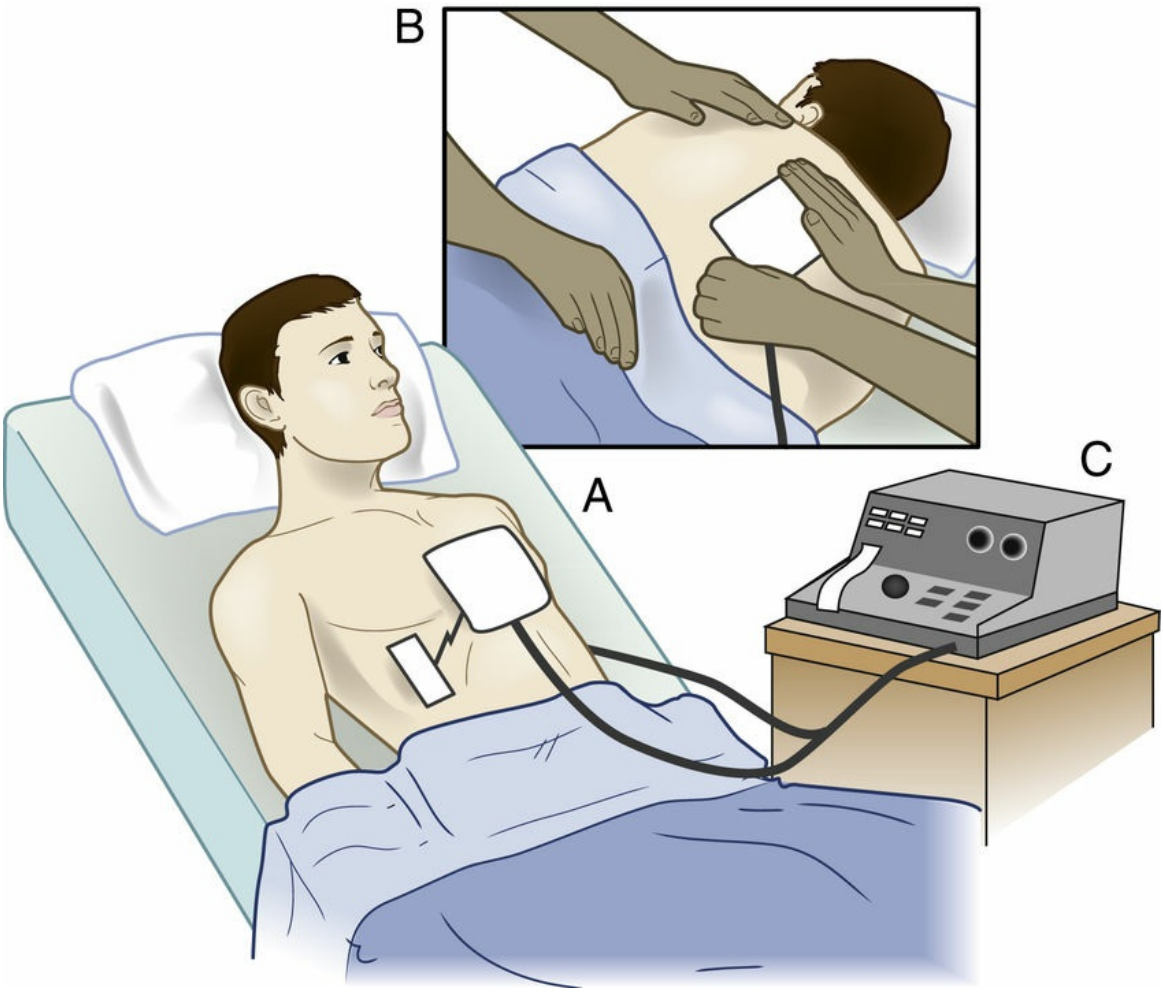

FIG. 35.29 Transcutaneous pacemaker. Pacing electrodes are placed on the patient's anterior *(A)* and posterior *(B)* chest walls and attached to an external pacing unit *(C)*.

Before starting TCP therapy, it is important to tell the patient what to expect. Explain that the muscle contractions created by the pacemaker when the current passes through the chest wall are uncomfortable. Reassure the patient that the TCP is temporary, and that it will be replaced by a transvenous pacemaker as soon as possible. Whenever possible, provide analgesia and/or sedation while the TCP is in use.

Monitoring of Patients With Pacemakers

Patients with temporary or permanent pacemakers are ECG monitored to evaluate the status of the pacemaker. Pacemaker

malfunction involves a failure to sense, a failure to capture, or a failure to pace. *Failure to sense* occurs when the pacemaker does not recognize spontaneous atrial or ventricular activity, and it fires inappropriately (Fig. 35.30, *A*). This can result in the pacemaker firing during the excitable period of the cardiac cycle, resulting in VT. Failure to sense is caused by fibrosis around the tip of the pacing lead, battery failure, sensing set too high, or dislodgment of the electrode.

Failure to capture occurs when the electrical charge to the myocardium is insufficient to produce atrial or ventricular contraction (Fig. 35.30, *B*). This can result in serious bradycardia or asystole. Failure to capture is caused by pacer lead damage, battery failure, dislodgment of the electrode, electrical charge set too low, or fibrosis at the electrode tip.

Failure to pace occurs when the pacemaker does not initiate an electrical stimulus when it should fire (Fig. 35.30, *C*). This can happen from a wire fracture, lead displacement, oversensing, or electrical interference. Table 35.14 describes pacemaker troubleshooting.

Complications of invasive temporary (i.e., transvenous) or permanent pacemaker insertion include infection and hematoma formation at the insertion site, pneumothorax, failure to sense or capture, perforation of the atrial or ventricular septum by the pacing lead, and appearance of "end-of-life" battery power on testing the pacemaker. Several measures can prevent or assess for complications. These include prophylactic IV antibiotic therapy before and after insertion, postinsertion chest x-ray to check lead placement and to rule out a pneumothorax, careful observation of insertion site, and continuous ECG monitoring of the patient's rhythm.

After pacemaker insertion, the patient can be out of bed once stable. Have the patient limit arm and shoulder activity on the operative side to prevent dislodging the newly implanted pacing leads. Observe the insertion site for signs of bleeding and check that the incision is intact. Note any temperature elevation or pain at the insertion site and treat as ordered. Most patients are discharged by the next day if stable.

Table 35.15 outlines patient and caregiver teaching for the patient with a pacemaker. The patient with a newly implanted pacemaker

and the caregiver may have questions about activity restrictions and concerns about body image. The goals of pacemaker therapy include enhancing physiologic functioning and quality of life. Emphasize this to the patient and caregiver and provide specific advice on activity restrictions.

After discharge, patients need to check pacemaker function on a regular basis. This can include outpatient visits to a pacemaker clinic or home monitoring using telephone transmitter devices. Another method to evaluate pacemaker performance is noninvasive program stimulation. This procedure is done on an outpatient basis in the EPS laboratory.

Radiofrequency Catheter Ablation Therapy

Radiofrequency catheter ablation therapy uses electrical energy to "burn" or ablate areas of the conduction system. Ablation therapy is done after EPS has identified the source of the dysrhythmia. An electrode-tipped ablation catheter ablates accessory pathways or ectopic sites in the atria, AV node, and ventricles. Catheter ablation is a definitive treatment for tachydysrhythmias. It is the nonpharmacologic treatment of choice for atrial dysrhythmias resulting in rapid ventricular rates and AV nodal reentrant tachycardia refractory to drug therapy.[8]

The ablation procedure is an effective treatment with a low complication rate. Nursing care of the patient after ablation therapy is similar to that of a patient undergoing cardiac catheterization (see Chapter 31 and Table 31.9).

Syncope

Syncope is a brief lapse in consciousness accompanied by a loss in postural tone (fainting). The causes of syncope can be cardiovascular or noncardiovascular. The most common cause of syncope is cardioneurogenic syncope, or "vasovagal" syncope (e.g., carotid sinus sensitivity). Other cardiovascular causes relate to dysrhythmias (e.g., tachycardias, bradycardias), prosthetic valve malfunction, pulmonary

emboli, and HF. Noncardiovascular causes vary and include stress, hypoglycemia, dehydration, stroke, and seizure.[17]

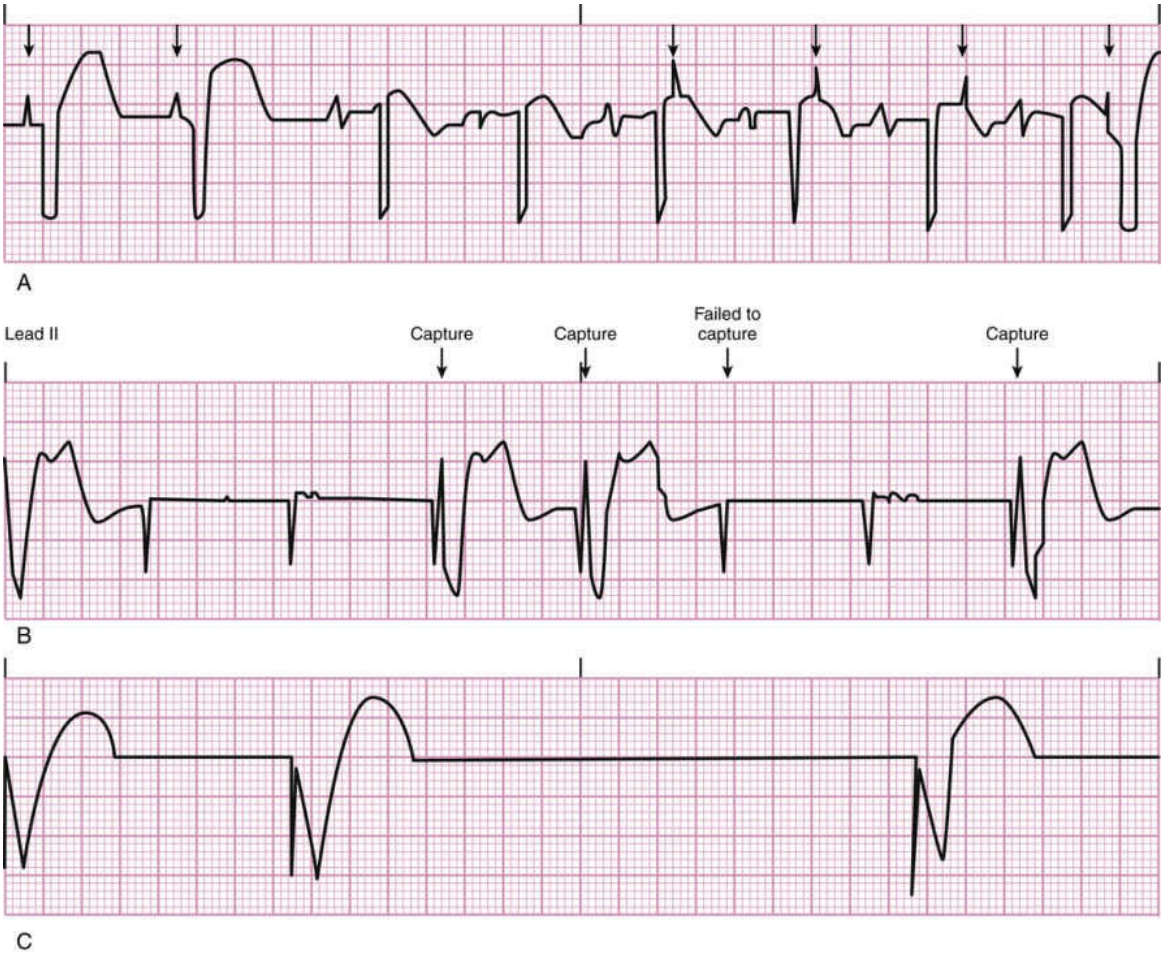

FIG. 35.30 Causes of pacemaker malfunction. **A,** Failure to sense: the pacemaker does not sense the patient's own cardiac rhythm and initiates an electrical impulse. Failure to sense manifests as pacer spikes that fall too closely to the patient's own rhythm, earlier than the programmed rate (see *arrows*). **B,** Failure to capture: a pacer spike is noted but is not followed by a P wave (atrial pacemaker) or a QRS complex (ventricular pacemaker). **C,** Failure to pace: the pacemaker fails to initiate an electrical stimulus when it should fire.

TABLE 35.14 Nursing

ManagementTroubleshooting Pacemakers

Problem	Potential Solution
Identified initial concern about pacemaker function	• Monitor continuous ECG and patient's vital signs while troubleshooting pacemaker problems • Call emergency response services if needed • Contact HCP immediately if basic troubleshooting does not work, as patient could have a lead wire displaced or a defective lead wire
Temporary pacemaker not firing	• Check to make sure all connections are hooked up correctly and tight • Ensure that hands-free pads have contact with the skin (shave excess hair, dry off perspiration) • Check that the generator has power (plug in the equipment or use a new battery each time)
Temporary pacemaker not capturing	• Check connections • Check for generator power • Turn up the milliamps on the generator, look for capture and set 10 milliamps above capture • Place patient on left side to promote contact of the transvenous pacing wire with the epicardium
Temporary pacemaker not sensing patient's underlying rhythm	• Check connections • Check for generator power • Turn up sensitivity • Place patient on left side
Permanent pacemaker not working	• Contact HCP • Contact pacemaker company for service if requested by HCP

TABLE 35.15 Patient & Caregiver TeachingPacemaker

Include the following information in the teaching plan for a patient with a pacemaker and the patient's caregiver:

1. Maintain follow-up care with your HCP to begin regular pacemaker function checks. This is often done by checking the device using a telephone.
2. Report any signs of infection at incision site (e.g., redness, swelling, drainage) or fever to your HCP at once.
3. Keep incision dry for 4 days after implantation, or as ordered.
4. Avoid lifting arm on pacemaker side above shoulder until approved by your cardiologist.
5. Avoid direct blows to pacemaker site.
6. Avoid close proximity to high-output electric generators since these can interfere with the function of the pacemaker.
7. You should not have an MRI unless the pacemaker is approved as MRI safe or there is a protocol in place for patient safety

during the procedure.
8. Microwave ovens are safe to use and do not interfere with pacemaker function.
9. Avoid standing near antitheft devices in doorways of department stores and public libraries. You should walk through them at a normal pace.
10. Travel is not restricted. Tell security (e.g., airport, train station, public buildings) of presence of pacemaker because it may set off the metal detector. If hand-held screening wand is used, it should not be placed directly over the pacemaker. Manufacturer information may vary about the effect of metal detectors on the function of the pacemaker.
11. Monitor pulse and tell your HCP if heart rate drops below predetermined rate.
12. Always carry your pacemaker information card and a current list of drugs.
13. Always wear a Medic Alert ID device.
14. Consider joining a pacemaker support group (e.g., *www.pacemakerclub.com/*).

A diagnostic workup for a patient with syncope from a suspected heart cause begins with ruling out structural and ischemic heart disease. This is done with echocardiography and stress testing. EPS is used to diagnose atrial and ventricular tachydysrhythmias and conduction problems causing bradydysrhythmias, all of which can cause syncope. These problems can be treated with antidysrhythmic drug therapy, pacemakers, ICDs, and/or catheter ablation therapy.

A patient without structural heart disease or in whom EPS testing is not diagnostic may have a *head-up tilt-test*. Normally, an upright position results in gravity displacing 300 to 800 mL of blood to the lower extremities. Specialized nerve fibers called mechanoreceptors are found throughout the vascular system. These respond to the increased blood volume by starting a reflex increase in sympathetic stimulation and decrease in parasympathetic output. The end results are a slight increase in HR and diastolic BP, and a slight decrease in

systolic BP.[17,18]

In cardioneurogenic syncope, the increase in venous pooling that occurs in the upright position reduces venous return to the heart. This results in a sudden, compensatory increase in ventricular contraction. The brain mistakenly thinks this is a hypertensive state and stops sympathetic stimulation. This produces a paradoxical vasodilation and bradycardia (vasovagal response). The end results are bradycardia, hypotension, cerebral hypoperfusion, and syncope.

In the head-up tilt-test the patient is placed on a table supported by a belt across the torso and feet. Baseline ECG, BP, and HR are obtained in the horizontal position. Next, the table is tilted 60 to 80 degrees and the patient is kept in this upright position for 20 to 60 minutes. ECG and HR are recorded continuously. BP is measured every 3 minutes throughout the test.

If the patient's BP and HR responses are abnormal and clinical symptoms occur (e.g., faintness), the test is positive. If after 30 minutes there is no response, the table is returned to the horizontal position and an IV infusion of low-dose isoproterenol may be started to try to provoke a response.

Other diagnostic tests for syncope can include various recording devices (e.g., Holter monitor or event monitor/loop recorder, discussed in Chapter 31 and Table 31.7), blood volume determination, hemodynamic testing, and autonomic reflex testing. About 30% of those who have 1 episode of syncope have a recurrence. The underlying cause of syncope and the patient's age and co-morbidities affect the patient's treatment and prognosis.[17,18]

Case Study

Dysrhythmia and Cardiac Arrest

© iStockphoto/Thinkstock.

Patient Profile

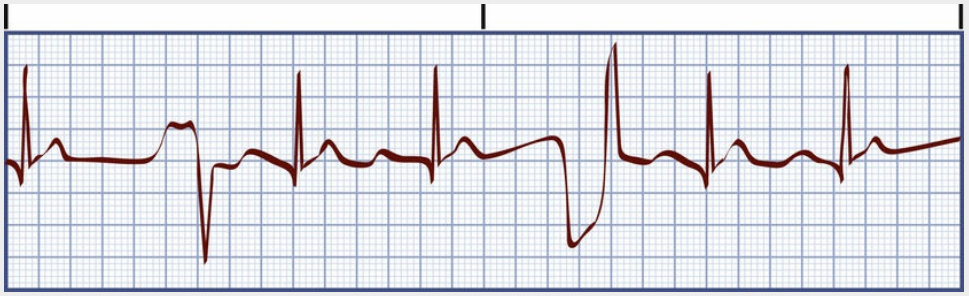
J.M., a 68-yr-old white, retired postal worker, was admitted to the telemetry unit with a diagnosis of acute decompensated heart failure (ADHF). He had a cardiac arrest (pulseless ventricular tachycardia [VT]) and was successfully defibrillated after 1 shock. He was transferred to the cardiac care unit. J.M. is awake but lethargic and

responds appropriately to questions.

Subjective Data

- History of hypertension, CAD, 2 MIs, and chronic HF
- Reports shortness of breath at rest and in an upright position

Objective Data
Physical Examination



- Appears weak, anxious
- BP 102/60 mm Hg, pulse 70/min, respirations 26/min
- Lungs: bilateral coarse crackles in the bases
- Heart: S_3 gallop at apex

Diagnostic Studies

- Echocardiogram: severe left ventricular dysfunction with ejection fraction of 24%
- Serum potassium: 2.9 mEq/L (2.9 mmol/L)
- Serum cardiac biomarkers: negative
- Serum b-type natriuretic peptide (BNP): 1852 pg/mL

Interprofessional Care

- Continuous ECG monitoring

- Amiodarone infusion
- Cardiac rehabilitation consult
- Dietary consult

Discussion Questions

1. Why is J.M. at risk for sudden cardiac death?
2. Explain the reason for using amiodarone after cardiac arrest.
3. What methods are used to assess the effectiveness of the antidysrhythmic therapy?
4. Interpret the rhythm strip.
5. Explain the significance of the diagnostic studies and other interprofessional care orders.
6. Why would J.M. be a candidate for CRT and an ICD?
7. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses?
8. ***Priority Decision:*** What are the priority nursing interventions for J.M.?
9. ***Collaboration:*** Which tasks could be delegated to UAP?
10. ***Evidence-Based Practice:*** Once J.M. is stable, he is scheduled for the insertion of a CRT/ICD. On your rounds, he asks you why he needs 2 devices. How would you respond?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient admitted with syncope has continuous ECG monitoring. An examination of the rhythm strip reveals the following: atrial rate 74 beats/min and regular; ventricular rate 62 beats/min and irregular; P wave normal shape; PR interval lengthens progressively until a P wave is not conducted; QRS normal shape. The *priority* nursing intervention would be to
   a. give epinephrine 1 mg IV push.
   b. prepare for synchronized cardioversion.
   c. observe for symptoms of hypotension or angina.
   d. apply transcutaneous pacemaker pads on the patient.
2. The ECG monitor of a patient in the cardiac care unit after an MI shows ventricular bigeminy with a rate of 50 beats/min. The nurse would
   a. perform defibrillation.
   b. administer IV amiodarone.
   c. prepare for temporary pacemaker insertion.
   d. assess the patient's response to the dysrhythmia.
3. In the patient with supraventricular tachycardia, which assessment indicates decreased cardiac output?
   a. Hypertension and dyspnea
   b. Chest pain and palpitations
   c. Abdominal distention and tachypnea
   d. Bounding pulses and a systolic murmur

4. The nurse prepares a patient for synchronized cardioversion knowing that cardioversion differs from defibrillation in that
   a. defibrillation delivers a lower dose of electrical energy.
   b. cardioversion is a treatment for atrial bradydysrhythmias.
   c. defibrillation is synchronized to deliver a shock during the QRS complex.
   d. patients should be sedated if cardioversion is done on a nonemergency basis.
5. Which patient teaching points should the nurse include when providing discharge instructions to a patient with a new permanent pacemaker and the caregiver? *(select all that apply)*
   a. Avoid or limit air travel.
   b. Take and record a daily pulse rate.
   c. Obtain and wear a Medic Alert ID device at all times.
   d. Avoid lifting arm on the side of the pacemaker above shoulder.
   e. Do not use a microwave oven because it interferes with pacemaker function.
6. Important teaching for the patient scheduled for a radiofrequency catheter ablation procedure includes explaining that
   a. ventricular bradycardia may be induced and treated during the procedure.
   b. catheter will be placed in both femoral arteries to allow double-catheter use.

c. the procedure will destroy areas of the conduction system that are causing rapid heart rhythms.

d. general anesthetic will be given to prevent the awareness of any "sudden cardiac death" experiences.

1. c, 2. d, 3. b, 4. d, 5. b, c, d, 6. c

Conceptual Focus

Fatigue
Functional Ability

Inflammation
Perfusion

This chapter describes the pathophysiology and management of patients with select inflammatory and structural heart problems. Conceptually, these problems can adversely affect perfusion. Inflammatory, infectious, and structural problems result in impaired cardiac output (CO), which leads to decreased tissue perfusion and impaired gas exchange. The patient may have pain, hyperthermia, and decreased functional and cognitive ability. The nurse plays a key role in providing patients with the education needed to manage problems and their effects.

Inflammatory Disorders of Heart

Infective Endocarditis

Infective endocarditis (IE) is a disease of the endocardial layer of the heart. The *endocardium* is the innermost layer of the heart (Fig. 36.1) and heart valves. IE most often affects the aortic and mitral valves. In the United States, there are around 40,000 to 50,000 new cases of IE per year.[1] The 1-year mortality of IE has not changed in the past 20 years.[1]

Classification

We often classify IE based on the cause (e.g., IV drug use IE [IVDA IE], fungal IE) or site of involvement (e.g., prosthetic valve endocarditis [PVE]). In the past, we have described IE as subacute or acute. The *subacute form* affects those with preexisting valve disease over a period of months. In contrast, the *acute form* affects those with healthy valves and appears as a rapidly progressive illness.

Etiology and Pathophysiology

IE occurs when blood flow allows organisms to contact and infect

previously damaged heart valves or other endothelial surfaces. About 30% of cases are caused by *Staphylococcus aureus.*[1] Other bacterial causes include *Streptococcus viridans* and coagulase-negative staphylococci. The organisms make biofilms, which protect the organisms from immune defenses and make antimicrobials less effective.[2]

Persons with a variety of underlying cardiac and noncardiac conditions can develop IE (Table 36.1). Patients are stratified into categories of high, moderate, or low risk for developing IE or having a poor outcome.[2] Rheumatic heart disease used to be the most common cause of IE. Now, it accounts for less than 20% of cases. The main risk factors for IE include (1) aging (more than 50% of older people have calcified aortic stenosis), (2) IV drug use, (3) having a prosthetic valve, (4) use of intravascular devices resulting in health care–associated infections (e.g., methicillin-resistant *S. aureus* [MRSA]), and (5) renal dialysis.[1]

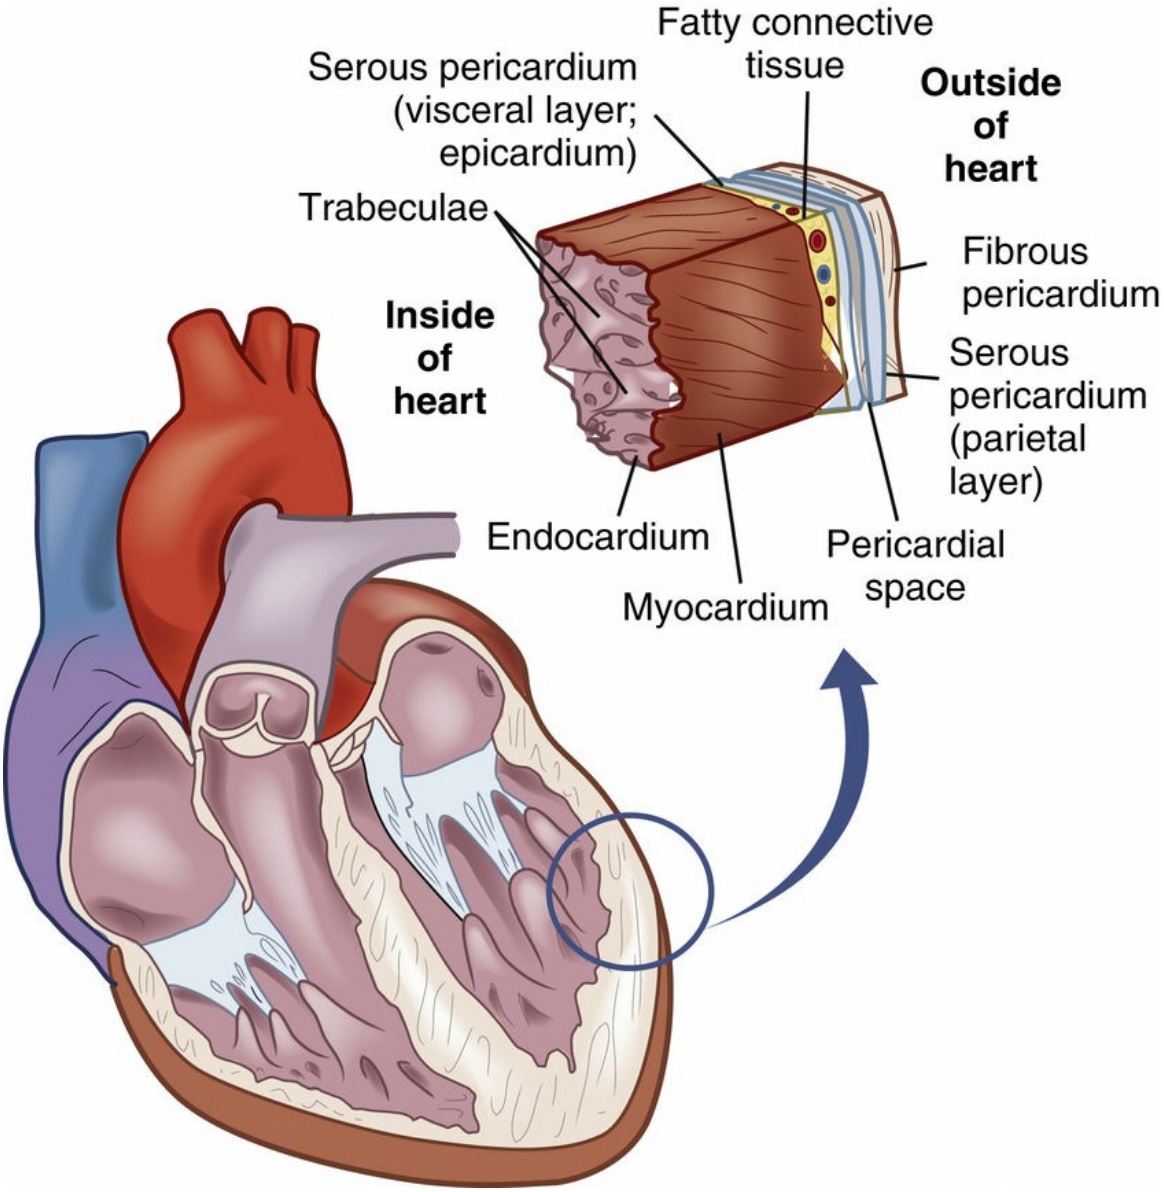

FIG. 36.1 Layers of the heart muscle and pericardium. The section of the heart wall shows the fibrous pericardium, the parietal and visceral layers of the serous pericardium (with the pericardial sac between them), the myocardium, and the endocardium.
Modified from Patton KT, Thibodeau GA: *The human body in health and disease,* ed 5, St Louis, 2010, Mosby.

TABLE 36.1 Common Risk Factors for Endocarditis

Cardiac Conditions

- Acquired valve disease (e.g., mitral valve prolapse with regurgitation, calcified aortic stenosis)
- Cardiomyopathy
- Congenital heart disease
- Heart lesions (e.g., ventricular septal defect, asymmetric septal hypertrophy)
- Marfan's syndrome
- Pacemaker
- Prior IE
- Prosthetic heart valve(s)
- Rheumatic heart disease (e.g., mitral valve regurgitation)

Noncardiac Conditions

- Hospital-acquired bacteremia
- IV drug use

Procedure-Associated Risks

- Intravascular devices (e.g., central venous catheter)
- Procedures listed in Table 36.2

IE typically develops in 3 stages: (1) bacteremia, (2) adhesion, and (3) vegetation.[1] *Vegetations,* the primary lesions of IE, consist of fibrin, leukocytes, platelets, and microbes that stick to the valve surface or endocardium (Fig. 36.2). The loss of parts of these fragile vegetations into the circulation results in *emboli.* Up to 30% of persons with IE develop embolization.[3] This occurs when left-sided heart vegetation moves to various organs (e.g., brain, kidneys, spleen) and to the

extremities, causing limb infarction. Right-sided heart lesions move to the lungs, resulting in pulmonary emboli.

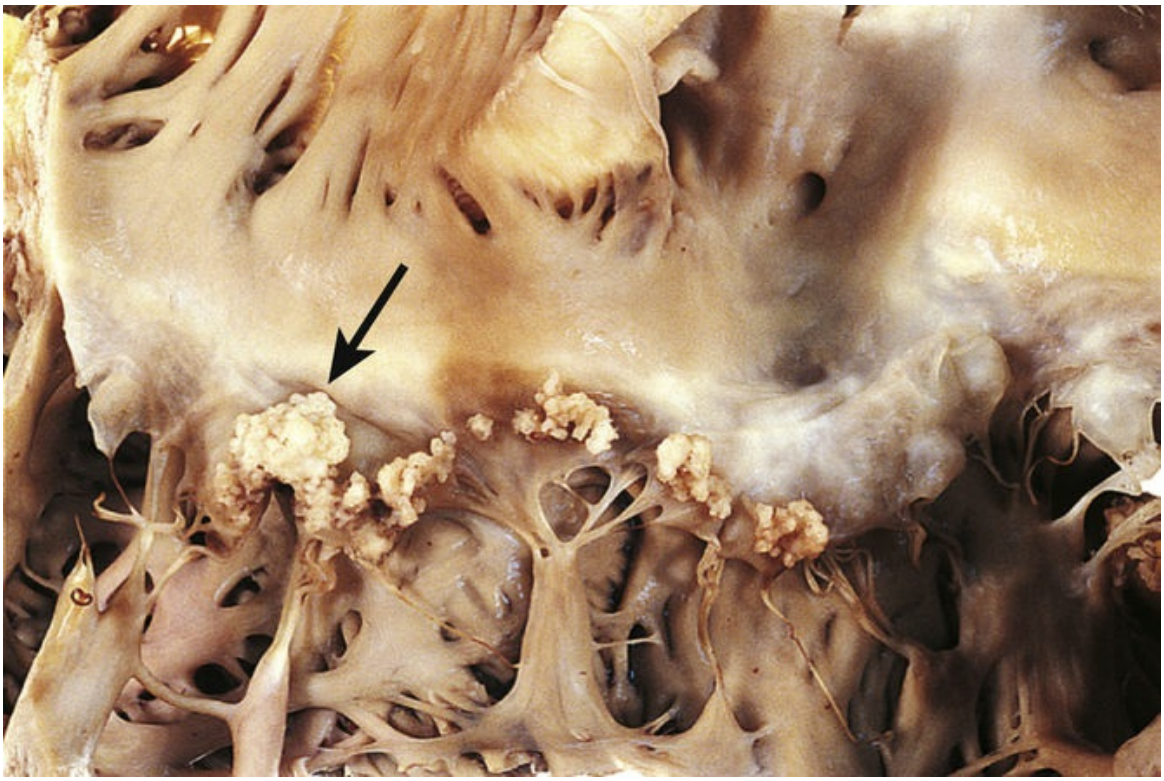

FIG. 36.2 Bacterial IE of the mitral valve. The valve is covered with large, irregular vegetations *(arrow).*
From Damjanov I, Linder J: *Pathology: A color atlas,* St Louis, 2000, Mosby.

The infection may spread locally and damage the valves or their supporting structures. This causes dysrhythmias, valve dysfunction, and invasion of the myocardium, leading to heart failure (HF), sepsis, and heart block (Fig. 36.3).

Clinical Manifestations

The manifestations of IE are nonspecific and can involve multiple organ systems. Most patients have fever.[3] Fever may be low grade or may be absent in older adults or those who are immunocompromised. Other symptoms include chills, weakness, malaise, fatigue, and

anorexia. Patients may have arthralgias, myalgias, back pain, abdominal discomfort, weight loss, headache, and clubbing of fingers in subacute forms of IE.[4]

Vascular signs include *splinter hemorrhages* (black longitudinal streaks) in the nail beds. Petechiae from microembolization of vegetative lesions can occur on the conjunctivae, lips, buccal mucosa, and palate and over the ankles, feet, and antecubital and popliteal areas. *Osler's nodes* (painful, tender, red or purple, pea-size lesions) are found on the fingertips or toes. *Janeway's lesions* (flat, painless, small, red spots) may be seen on the fingertips, palms, soles of feet, and toes. Eye examination may show hemorrhagic retinal lesions called *Roth's spots.*

Most patients have a new or worsening systolic murmur. Murmurs are usually absent in tricuspid IE because right-sided heart sounds are too low to be heard. HF is common, occurring in up to 80% of patients with aortic valve IE and 50% of those with mitral valve IE.[3]

Septic embolism is a potential complication of IE. Embolic events occur in more than half of patients.[3] The central nervous system (CNS) is the most often affected organ system, followed by extremities, spleen, and kidney.

Diagnostic Studies

The health history is important in assessing IE. Ask patients if they have had any recent (within the past 3 to 6 months) dental, urologic, surgical, or gynecologic procedures, including obstetric delivery. Note any history of IVDA, heart disease, recent heart catheterization, heart surgery, intravascular device placement, renal dialysis, or infections (e.g., skin, respiratory, urinary tract).

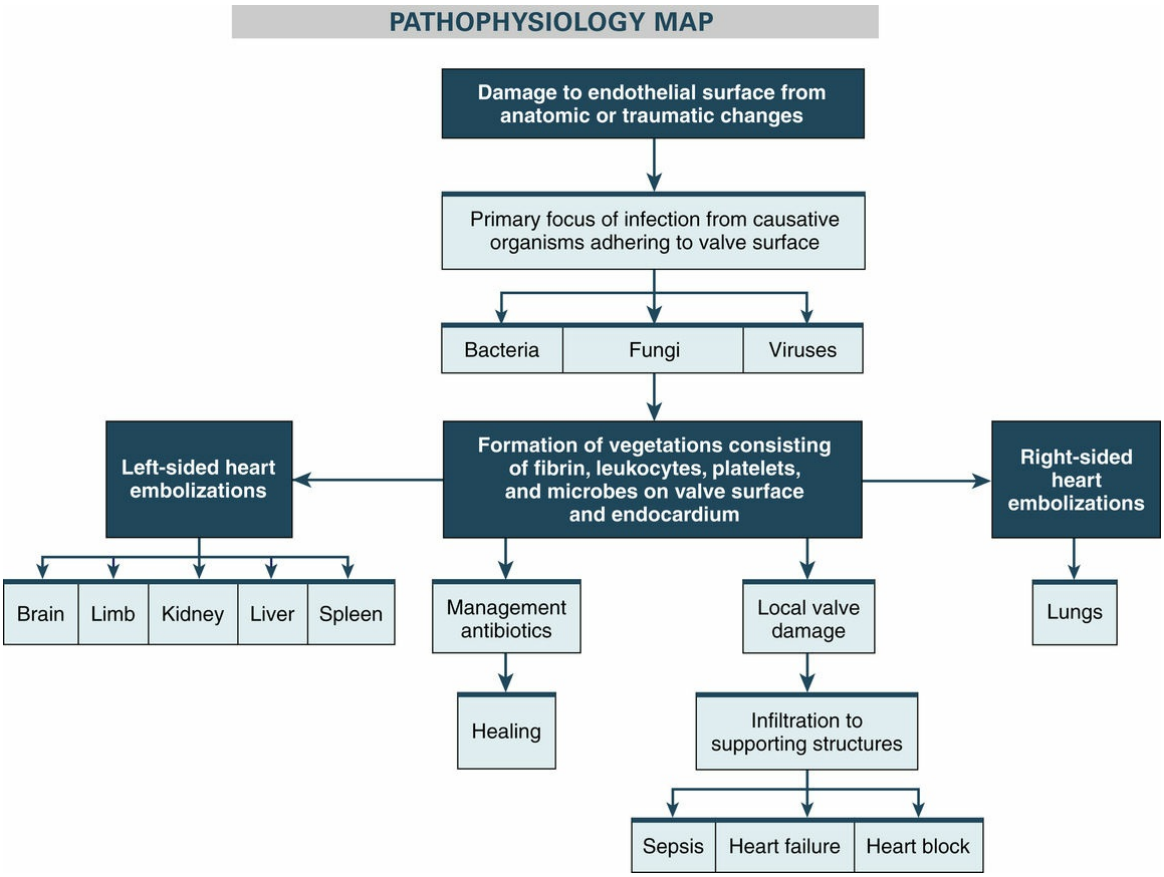

FIG. 36.3 Pathogenesis of IE.

Three blood cultures drawn over a period of 1 hour from 3 different sites will be positive in most patients with IE.[4] Culture-negative IE is associated with antibiotic usage within the previous 2 weeks or results from a pathogen not easily detected by standard cultures A mild leukocytosis occurs in acute IE. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels may be increased. Echocardiography can show vegetations.

Guidelines for the diagnosis of IE are based on the Duke Criteria. The patient must have 2 major criteria and 1 minor criterion, or 1 major and 3 minor, or 5 minor criteria. Major criteria include positive blood cultures, typical microorganism for IE from 2 separate blood cultures, evidence of endocardial involvement, and new valvular vegetation. Minor criteria include predisposing heart condition or IV drug use, vascular phenomena, immunologic phenomena, microbiologic evidence, or echocardiographic findings consistent with

IE but not meeting major criteria.[5]

A chest x-ray may show *cardiomegaly* (an enlarged heart). An electrocardiogram (ECG) may show first- or second-degree atrioventricular (AV) block because the heart valves lie close to conductive tissue, especially the AV node.

Interprofessional Care

Prophylactic Treatment

Situations and conditions that require antibiotic prophylaxis are detailed in Table 36.2.

TABLE 36.2 Antibiotic Prophylaxis to Prevent Endocarditis

Target Groups for Prophylactic Antibiotics

People with the following heart conditions should receive prophylactic antibiotics when they have the conditions or procedures listed below:

- Prosthetic heart valve or prosthetic material used to repair heart valve
- History of infectious IE
- Congenital heart disease (CHD)
    - Unrepaired cyanotic CHD (including palliative shunts and conduits)
    - Repaired congenital heart defect with prosthetic material or device for 6 mo after the procedure
    - Repaired CHD with residual defects at the site or next to the site of prosthetic patch or prosthetic device
- Heart transplant recipients who develop heart valve disease

Conditions or Procedures Requiring Antibiotic Prophylaxis

When the target groups have the following conditions or procedures, they need prophylactic antibiotics:

- Oral
    - Dental manipulation involving the gums or roots of the teeth
    - Dental manipulation involving puncture of the oral mucosa
- Respiratory
    - Respiratory tract incisions (e.g., biopsy)
    - Tonsillectomy and adenoidectomy
- Surgical procedures that involve infected skin, skin structures, or musculoskeletal tissue

Source: Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guidelines for the management of patients with valvular heart disease: executive summary—A report of the American College of Cardiology/AHA Task Force on Practice Guidelines, *Circulation* 129:2440, 2014.

Drug Therapy

Accurately identifying the causative organism is the key to successful treatment of IE. Long-term treatment is needed to kill dormant bacteria within the valvular vegetations. Complete removal of the organism generally takes weeks. Relapses are common.[5]

Antibiotic therapy is based on blood culture results. The effectiveness of therapy is assessed with subsequent blood cultures. Cultures that stay positive indicate inadequate or inappropriate antibiotics, an aortic root or myocardial abscess, or the wrong diagnosis (e.g., an infection elsewhere). It is reasonable to obtain 2 sets

of blood cultures every 24 to 48 hours until the infection is cleared.[3] After completion of antibiotics, follow-up echocardiogram and inflammatory markers are done at 1, 3, 6, and 12 months.[4]

Fungal IE and PVE respond poorly to antibiotic therapy alone. Early valve replacement followed by prolonged (6 weeks or more) antibiotics is needed in these situations. Valve replacement surgery (discussed later in this chapter) is done in 50% to 60% of cases of IE. Three reasons to perform surgery are for valve dysfunction leading to HF, to prevent embolization, or for uncontrolled infection.[4]

Fever that persists after treatment has been started is managed with aspirin, acetaminophen, fluids, and rest. Complete bed rest is usually not needed unless the temperature stays elevated or there are signs of HF. IE with HF responds poorly to drug therapy and valve replacement, so it can be life threatening.

Safety Alert

Communicating Test Results

- If blood culture results for a patient diagnosed with IE show that the organism is not susceptible to the ordered antibiotic, immediately notify the HCP.
- A National Patient Safety Goal stresses the importance of communicating critical test results to the right HCP in a timely manner.

Nursing Management: Infective Endocarditis

Nursing Assessment

Subjective and objective data to obtain from a patient with IE are

found in Table 36.3. Assess vital signs together with heart sounds to detect a murmur, a change in a preexisting murmur, and extra sounds (e.g., S_3).

Arthralgia (joint pain) and myalgias are common. Assess the patient for joint tenderness, decreased range of motion (ROM), and muscle tenderness. Examine the patient for petechiae, splinter hemorrhages, and Osler's nodes. Complete a general systems assessment to determine any hemodynamic or embolic complications.

Nursing Diagnoses

Nursing diagnoses for the patient with IE include:

- Impaired cardiac output
- Activity intolerance

More information on nursing diagnoses and interventions for the patient with IE is in eNursing Care Plan 36.1 on the website for this chapter.

Planning

The overall goals for the patient with IE include (1) normal or baseline heart function, (2) ability to perform activities of daily living (ADLs) without fatigue, and (3) an understanding of the treatment plan to prevent recurrence.

TABLE 36.3 Nursing AssessmentInfective Endocarditis

Subjective Data

Important Health Information

Past health history: Valvular, congenital, or syphilitic heart disease, including valve repair or replacement. Previous IE, childbirth, staphylococcal or streptococcal infections, hospital-acquired bacteremia
Medications: Immunosuppressive therapy
Surgery or other treatments: Recent obstetric or gynecologic procedures. Invasive procedures, including catheterization, cystoscopy. Recent dental or surgical procedures, GI procedures (e.g., endoscopy)

Functional Health Patterns

Health perception–health management: IV drug use, alcohol use. Malaise
Nutritional-metabolic: Weight gain or loss, anorexia. Chills, diaphoresis
Elimination: Bloody urine
Activity-exercise: Exercise intolerance, generalized weakness, fatigue. Cough, dyspnea on exertion, orthopnea, palpitations
Sleep-rest: Night sweats
Cognitive-perceptual: Chest, back, or abdominal pain. Headache, joint tenderness, muscle tenderness

Objective Data
General

Fever

Integumentary

Osler's nodes on extremities, splinter hemorrhages under nail beds, Janeway's lesions on fingertips, palms, soles of feet, and toes. Petechiae of skin, mucous membranes, or conjunctivae.

Purpura, peripheral edema, finger clubbing

Respiratory

Tachypnea, crackles

Cardiovascular

Dysrhythmia, tachycardia, new murmurs, S_3, S_4. Retinal hemorrhages

Possible Diagnostic Findings

Leukocytosis, anemia, ↑ ESR, ↑ CRP and cardiac biomarkers. Positive blood cultures, hematuria. Echocardiogram showing chamber enlargement, valvular dysfunction, and vegetations. Chest x-ray showing cardiomegaly and pulmonary infiltrates. ECG showing ischemia and conduction defects. Signs of systemic embolization or pulmonary embolism

Nursing Implementation

Health Promotion

Teaching the patient at high risk for IE (Tables 36.1 and 36.2) helps reduce the incidence and recurrence of IE. Tell the patient to avoid people with infections, especially upper respiratory tract infections, and to report cold, flu, and cough symptoms. Stress the importance of avoiding excessive fatigue, planning rest periods, using good oral hygiene, and scheduling regular dental visits.[5]

Tell the patient to inform HCPs scheduling invasive procedures about the history of IE, as prophylactic antibiotic therapy may be needed. Refer the patient with a history of IVDA for drug rehabilitation.

Ambulatory Care

A patient with IE has many problems that need nursing management. IE generally requires treatment with antibiotics for 4 to 6 weeks. After initial treatment in the hospital, the patient may continue treatment at home if hemodynamically stable and adherent. Assess the home setting for adequate support. Patients who receive outpatient IV antibiotics need vigilant home nursing care.

Assessment findings are often nonspecific (Table 36.3). Tell the patient and caregiver about the importance of monitoring body temperature. Persistent temperature elevations may mean that the antibiotic is ineffective. Patients are at risk for life-threatening complications, such as stroke, pulmonary edema, and HF. Teach patients and caregivers to recognize signs and symptoms of these complications (e.g., change in mental status, dyspnea, chest pain, unexplained weight gain).

The patient needs adequate periods of physical and emotional rest. Bed rest may be needed when the patient has fever or complications (e.g., heart damage). Otherwise, the patient may perform moderate activity. To prevent problems related to decreased mobility, have the patient to wear elastic compression stockings, perform ROM exercises, and deep breathe and cough every 2 hours. The patient may have anxiety and fear. You must recognize this and begin strategies to help the patient cope with the illness.

Monitor laboratory data, including blood cultures, to determine antibiotic effectiveness. Assess IV lines for patency and signs of complications (e.g., phlebitis). Give antibiotics as prescribed. Monitor the patient for any adverse drug reactions.

Teach the patient and caregiver the nature of the disease and on how to reduce the risk for reinfection. Explain the relationship of follow-up care, good nutrition and dental care, and prompt treatment of common infections (e.g., colds) to stay healthy. Teach the patient about symptoms to report that may indicate another infection (e.g., fever, fatigue, chills). Finally, explain the importance of prophylactic antibiotic therapy before certain invasive procedures (Table 36.2).

Evaluation

The expected outcomes are that the patient with IE will

- Maintain adequate tissue and organ perfusion
- Maintain normal body temperature
- Report an increase in physical and emotional comfort

Acute Pericarditis

Pericarditis is a condition caused by inflammation of the pericardial sac (pericardium), often with fluid accumulation. The pericardium is composed of the inner serous membrane (visceral pericardium) and the outer fibrous (parietal) layer (Fig. 36.1). The pericardial space between these 2 layers normally holds 10 to 15 mL of serous fluid. The pericardium anchors the heart, provides lubrication to decrease friction between heart contractions, and helps to prevent excess dilation of the heart during diastole.

Etiology and Pathophysiology

Common causes of acute pericarditis are listed in Table 36.4. Most often the cause of acute pericarditis is *idiopathic* (unknown) or viral.[6] The coxsackievirus B is the most commonly identified virus.[7]

There are 3 types of pericarditis: acute, subacute, and chronic. Acute pericarditis develops rapidly, causing the pericardial sac to become inflamed and leak fluid (pericardial effusion). The characteristic pathologic finding in acute pericarditis is inflammation. There is an influx of neutrophils, increased pericardial vascularity, and eventually fibrin deposition on the epicardium (Fig. 36.4). Subacute pericarditis occurs weeks to months after an event. We refer to pericarditis lasting more than 6 months as chronic.[7]

Myocardial infarction (MI) causes 5% to 8% of acute pericarditis cases. Post-MI syndrome (Dressler syndrome) pericarditis can occur 4 to 6 weeks after transmural MI (see Chapter 33). This syndrome is

more common after a large anterior infarct.[6] Viral pericarditis is often seen after respiratory or GI illness.[6]

Clinical Manifestations

Clinical symptoms include progressive, severe, sharp chest pain.[6] The pain is generally worse with deep inspiration and when lying flat. Sitting up and leaning forward relieves the pain. The pain may radiate to the neck, arms, or left shoulder, making it hard to distinguish from angina. One distinction is that the pain from pericarditis can be referred to the trapezius muscle (shoulder, upper back). Dyspnea is related to the patient's breathing in rapid, shallow breaths to avoid chest pain. Fever and anxiety may worsen dyspnea.

TABLE 36.4 Common Causes of Pericarditis

Infectious

- Bacterial: Pneumococci, staphylococci, streptococci, *Neisseria gonorrhoeae, Legionella pneumophila, Mycobacterium tuberculosis,* septicemia from gram-negative organisms
- Fungal: Histoplasma, *Candida* species
- Viral: Coxsackie A and B virus, echovirus, adenovirus, mumps, hepatitis, Epstein-Barr, varicella zoster, human immunodeficiency virus
- Others: Toxoplasmosis, Lyme disease

Noninfectious

- Acute MI
- Cancers: Lung, breast, leukemia, Hodgkin's lymphoma, non-Hodgkin's lymphoma

- Dissecting aortic aneurysm
- Myxedema
- Radiation
- Renal failure
- Trauma: Thoracic surgery, pacemaker insertion, cardiac diagnostic procedures

Hypersensitive or Autoimmune

- Dressler syndrome
- Drug reactions (e.g., procainamide, hydralazine)
- Postpericardiotomy syndrome
- Rheumatic fever
- Rheumatologic diseases: Rheumatoid arthritis, systemic lupus erythematosus, systemic sclerosis (scleroderma), ankylosing spondylitis

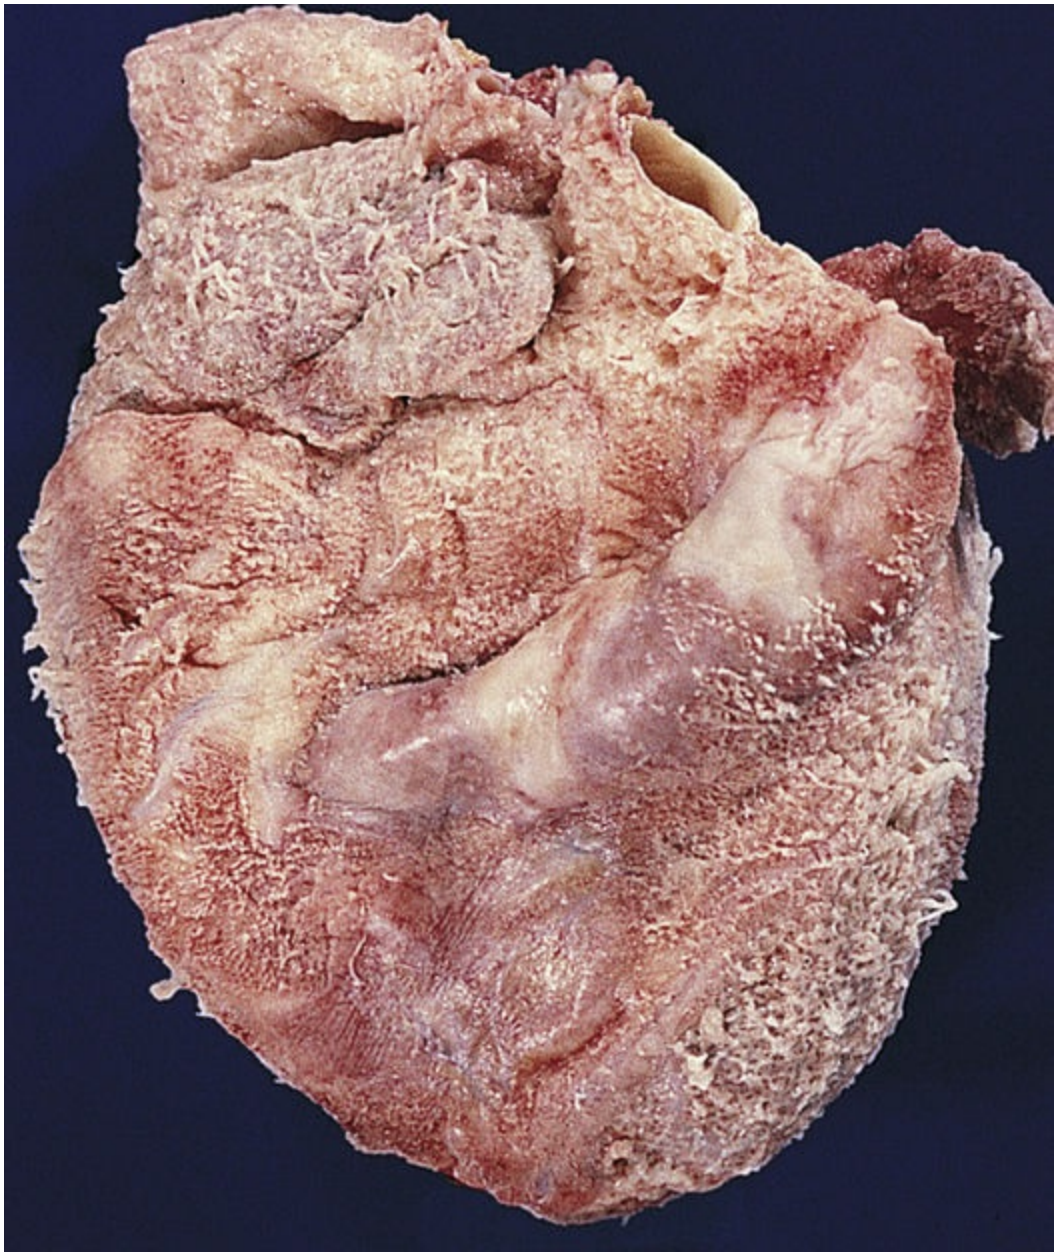

FIG. 36.4 Acute pericarditis. Note shaggy coat of fibers covering surface of heart.
From Damjanov I, Linder J: *Pathology: A color atlas,* St Louis, 2000, Mosby.

The hallmark finding in acute pericarditis is the *pericardial friction rub.* The rub is a scratching, grating, high-pitched sound believed to result from friction between the roughened pericardial and epicardial surfaces. It is best heard with the stethoscope at the lower left sternal border of the chest with the patient leaning forward. Since it is hard to

tell a pericardial friction rub from a pleural friction rub, ask the patient to hold their breath. If you still hear the rub, it is cardiac. Pericardial friction rubs may be hard to identify because they are often intermittent.

Complications

The major complications are pericardial effusion and cardiac tamponade. *Pericardial effusion* is a build-up of fluid in the pericardium. It can occur rapidly (e.g., chest trauma) or slowly (e.g., tuberculosis pericarditis). Large effusions compress nearby structures. Pulmonary tissue compression can cause cough, dyspnea, and tachypnea. Phrenic nerve compression can cause hiccups. Compression of the laryngeal nerve may result in hoarseness. Heart sounds are generally distant and muffled. BP is usually maintained.

TABLE 36.5 Measurement of Pulsus Paradoxus

1. Position the patient in a semirecumbent position.
2. Have patient breathe normally.
3. Using a manually operated BP cuff, measure systolic BP.
4. Inflate BP cuff at least 20 mm Hg above systolic BP.
5. Deflate cuff slowly until you hear sounds throughout the respiratory cycle (inspiration and expiration) and note the pressure.
6. Determine the difference between the measurements taken in steps 4 and 5. This will equal the amount of paradox:

Sounds heard on expiration at	110 mm Hg
Sounds heard throughout cycle at	82 mm Hg
Amount of paradox	28 mm Hg

The difference is normally <10 mm Hg. If the difference is >10 mm Hg, cardiac tamponade may be present.

Cardiac tamponade develops as the pericardial effusion volume

increases and compresses the heart. The speed of fluid accumulation affects the severity of clinical signs. Cardiac tamponade can occur acutely (e.g., rupture of heart, trauma) or subacutely (e.g., from renal failure, cancer).

The patient with cardiac tamponade may report chest pain and is often confused, anxious, and restless. As the compression of the heart increases, there is decreased CO, muffled heart sounds, narrowed pulse pressure, tachypnea, and tachycardia. Neck veins are markedly distended because of increased jugular venous pressure. *Pulsus paradoxus,* if present, is a large decrease in systolic BP during inspiration (Table 36.5). In a patient with a slow onset of a cardiac tamponade, dyspnea may be the only manifestation.

Diagnostic Studies

The ECG is useful in diagnosing acute pericarditis, with changes noted in 90% of cases. The most sensitive ECG changes include diffuse (widespread) ST segment elevations. This reflects the abnormal repolarization from the pericardial inflammation. These changes are different from the ST changes seen in MI. In myocardial ischemia, there are usually localized ST segment changes. In acute pericarditis serial ECGs do not show evolving changes, such as those with MI.

An echocardiogram can determine the presence of a pericardial effusion or cardiac tamponade. Doppler imaging and color M-mode can assess diastolic function and diagnose constrictive pericarditis (discussed later in the chapter). A CT scan and MRI can visualize the pericardium and pericardial space. Chest x-ray findings are generally normal, but a large pericardial effusion may appear as cardiomegaly (Fig. 36.5).

Common laboratory findings include leukocytosis and increased CRP and ESR. Troponin levels may be increased in patients with ST segment elevation and acute pericarditis, which could indicate concurrent heart damage. Fluid obtained during pericardiocentesis or tissue from a pericardial biopsy may be studied to determine the cause of the pericarditis.

Interprofessional Care

Management is aimed at identifying and treating the underlying problem and symptoms (Table 36.6). Antibiotics treat bacterial pericarditis, and nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., salicylates [aspirin], ibuprofen) control the pain and inflammation. Corticosteroids are used for patients with pericarditis from systemic lupus erythematosus, patients already taking corticosteroids for autoimmune conditions, or patients who do not respond to NSAIDs. They are used cautiously because of their many side effects (see Chapter 49). Colchicine, an antiinflammatory drug used for gout, may help patients who have recurrent pericarditis.[6]

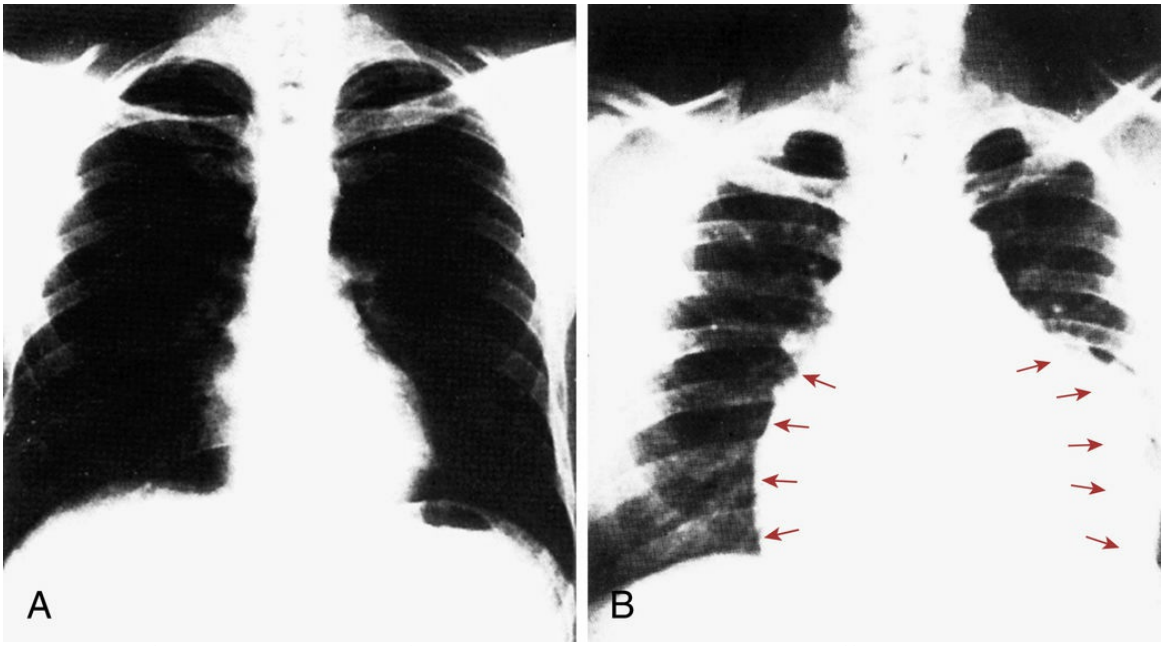

FIG. 36.5 **A,** X-ray of a normal chest. **B,** Pericardial effusion is present, and the cardiac silhouette is enlarged with a globular shape *(arrows).*
From Guzzetta CE, Dossey BM*: Cardiovascular nursing: Holistic practice,* St Louis, 1992, Mosby.

Pericardiocentesis is usually done for pericardial effusion with acute cardiac tamponade, purulent pericarditis, or suspected cancer. Hemodynamic support for the patient before the procedure may

include giving volume expanders and inotropic agents (e.g., dopamine) and stopping any anticoagulants. The procedure is done rapidly and safely using a percutaneous approach guided by echocardiography (Fig. 36.6). A needle is inserted into the pericardial space to remove fluid for analysis and relieve heart pressure. Complications include dysrhythmias, further cardiac tamponade, pneumomediastinum, pneumothorax, myocardial laceration, and coronary artery laceration.

A *pericardial window* is a surgical procedure for diagnosis or drainage of excess fluid. Cutting a "window," or part of the pericardium, allows the fluid to drain continuously into the peritoneum or chest.

TABLE 36.6 Interprofessional CareAcute Pericarditis

Diagnostic Assessment

- History and physical examination (assess for pericardial friction rub, pulsus paradoxus)
- Laboratory: CRP, ESR, white blood cell count
- ECG
- Chest x-ray
- Echocardiogram
- CT scan
- MRI
- Pericardiocentesis, pericardial window
- Pericardial biopsy

Management

- Treatment of underlying disease

- Bed rest
- Drug therapy
    - NSAIDs
    - Corticosteroids
- Pericardiocentesis (for tamponade)
- Pericardial window (for tamponade or ongoing pericardial effusion)

CRP, C-reactive protein; *ESR*, erythrocyte sedimentation rate.

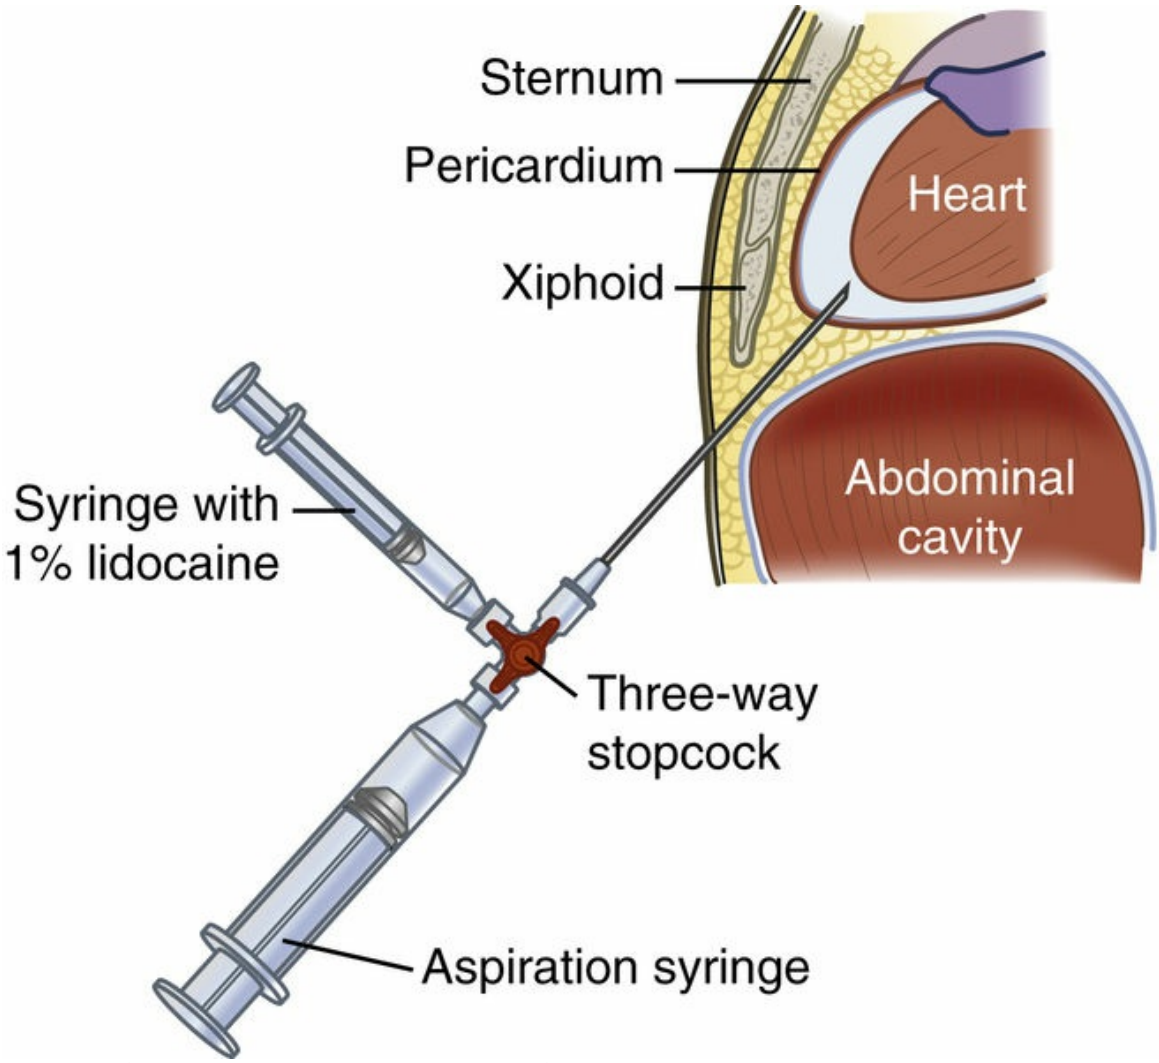

FIG. 36.6 Pericardiocentesis performed under sterile conditions in conjunction with ECG and hemodynamic measurements.

Nursing Management: Acute Pericarditis

Managing the patient's pain and anxiety during acute pericarditis is your key nursing consideration. Assess the pain to distinguish angina (myocardial ischemia) (see Table 33.8) from the pain of pericarditis. Pericarditis pain is usually found in the precordium or left trapezius region and has a sharp quality that increases with inspiration. Pain is often relieved when the patient sits up or leans forward and is worse when lying flat.

Pain relief measures include keeping the patient on bed rest with the head of the bed raised to 45 degrees and providing an overbed table for support. Antiinflammatory drugs can help control the pain. Give these drugs with food or milk. Tell the patient to avoid alcohol because of the risk for GI bleeding. Other drugs, such as a proton pump inhibitor (e.g., pantoprazole, omeprazole), can reduce stomach acid.

Provide simple, complete explanations of procedures and possible causes of the pain to help reduce anxiety. These explanations are particularly important when the patient is undergoing testing and for the patient who has previously had angina or an MI.

The patient with acute pericarditis is at risk for cardiac tamponade and decreased CO. Monitor for manifestations of tamponade and prepare for possible pericardiocentesis.

Check Your Practice

You are assigned to a 58-yr-old male patient who had an MI 3 days ago. He has now developed pericarditis. When you are making rounds, you assess that the patient is slightly confused and has prominent neck veins. His heart rate is 118 beats/min.

- What should you do next?

Chronic Constrictive Pericarditis

Etiology and Pathophysiology

Chronic constrictive pericarditis results from fibrotic thickening and rigidity of the pericardium, usually after an episode of acute pericarditis. It is characterized by fibrin deposition and pericardial effusion. Reabsorption of the effusion slowly follows, with progression to fibrous scarring, thickening of the pericardium from calcium deposits, and eventual destruction of the pericardial space. The fibrotic, thickened, and adherent pericardium encases the heart and prevents adequate atrial and ventricular stretch.

Clinical Manifestations and Diagnostic Studies

Manifestations of chronic constrictive pericarditis occur over time. They mimic HF and cor pulmonale. Decreased CO accounts for many of the manifestations. These include dyspnea on exertion, peripheral edema, ascites, fatigue, anorexia, and weight loss. The most prominent finding on physical examination is jugular venous distention (JVD). Unlike with cardiac tamponade, the presence of pulsus paradoxus (greater than 10 mm Hg) is not common.[6]

ECG changes are often nonspecific in chronic constrictive pericarditis. The heart on the chest x-ray may be normal or enlarged. Echocardiography findings may show a thickened pericardium but without a large pericardial effusion. CT and MRI can measure pericardial thickness and assess diastolic filling patterns.

Interprofessional and Nursing Care

The treatment of choice for symptomatic chronic constrictive pericarditis is a *pericardiectomy.* This involves complete resection of the pericardium through a median sternotomy with the use of cardiopulmonary bypass (see Chapter 33). Some patients show

immediate improvement, but others may take weeks. The prognosis improves when the patient has surgery before becoming clinically unstable.

Myocarditis

Etiology and Pathophysiology

Myocarditis is a focal or diffuse inflammation of the myocardium. Causes include viruses, bacteria, fungi, radiation therapy, and pharmacologic and chemical factors. Coxsackie A and B viruses are the most common causative agents. Autoimmune disorders (e.g., polymyositis) have been linked with the development of myocarditis. It also may be idiopathic.

When the myocardium becomes infected, the causative agent invades the myocytes and causes cellular damage and necrosis. This activates the immune response. Cytokines and O_2 free radicals are released. As the infection progresses, an autoimmune response is activated. This causes further destruction of myocytes. Myocarditis results in heart dysfunction. Dilated cardiomyopathy can occur (discussed later in this chapter).[8]

Clinical Manifestations

The features of myocarditis vary from a benign course without any overt symptoms to progressive HF, dysrhythmias, or sudden cardiac death (SCD).[8] Fever, fatigue, malaise, myalgias, pharyngitis, dyspnea, lymphadenopathy, and nausea and vomiting are early manifestations of the viral illness.

Early cardiac signs appear 7 to 10 days after viral infection because pericarditis often accompanies myocarditis. These include pleuritic chest pain with a pericardial friction rub and effusion. Late cardiac signs relate to the development of HF and include an S_3 heart sound, crackles, JVD, syncope, peripheral edema, and angina.

Diagnostic Studies and Interprofessional Care

The ECG changes with myocarditis are often nonspecific but reflect associated pericardial involvement (e.g., diffuse ST segment changes). Dysrhythmias and conduction problems may be present. Laboratory findings are often inconclusive. They may include mild to moderate leukocytosis and atypical lymphocytes, elevated viral titers, and increased ESR, CRP levels, and levels of cardiac biomarkers, such as troponin. The virus is generally present in tissue and pericardial fluid samples only during the first 8 to 10 days of illness.

Endomyocardial biopsy provides histologic confirmation of myocarditis.[8] A biopsy is most diagnostic during the first 6 weeks of acute illness, when lymphocytic infiltration and myocyte damage are present. Nuclear scans, echocardiography, and MRI are used to assess heart function.

Treatment consists of managing symptoms. Angiotensin-converting enzyme (ACE) inhibitors and β-adrenergic receptor blockers (β-blockers) are used if the heart is enlarged or to treat HF (see Chapter 34). Diuretics reduce fluid volume and preload. If the patient is not hypotensive, IV drugs such as nitroprusside and milrinone reduce afterload and improve CO by decreasing systemic vascular resistance. Digoxin (Lanoxin) improves heart contractility and reduces HR. It is used cautiously in patients with myocarditis because of increased sensitivity to the adverse effects (e.g., dysrhythmias) and the potential toxicity. Anticoagulation reduces the risk for clot formation from blood stasis in patients with a low ejection fraction (EF).

Drug Alert

Digoxin (Lanoxin)

- Use cautiously in patients with myocarditis.
- Myocarditis predisposes to drug-related dysrhythmias and toxicity.

Myocarditis with an autoimmune basis is treated with immunosuppressive agents. These drugs reduce heart inflammation and damage. However, the use of these drugs for the treatment of myocarditis is controversial because they may lead to recurrence.[8] In some instances, antivirals may be used as adjunct therapy to treat myocarditis.

General supportive measures include O_2 therapy, bed rest, and restricted activity. In cases of severe HF, intraaortic balloon pump therapy and ventricular assist devices (VAD) may be needed (see Chapters 34 and 65).

Nursing Management: Myocarditis

Focus your interventions on improving CO and managing the signs and symptoms of HF. Select nursing measures to decrease cardiac workload. These include placing the patient in a semi-Fowler's position, spacing activity and rest periods, and providing a quiet environment. Carefully monitor drugs that increase the heart's contractility and decrease preload, afterload, or both. Evaluate the effectiveness of your interventions on an ongoing basis.

The patient may be anxious about the diagnosis of myocarditis. Assess the level of anxiety, take measures to decrease anxiety, and keep the patient and caregiver informed about the therapeutic plan.

The patient who receives immunosuppressive therapy is at increased risk for infection. Monitor for complications and provide the patient with proper infection control procedures.

Although most patients recover spontaneously, some develop dilated cardiomyopathy (discussed later in this chapter). If severe HF occurs, the patient may need a heart transplant.

Rheumatic Fever and Rheumatic Heart Disease

Rheumatic fever (RF) is an acute inflammatory disease that can

involve all the heart layers. RF occurs most often between the ages of 5 and 15.[9] **Rheumatic heart disease** is a chronic scarring and deformity of the heart valves resulting from RF.

Etiology and Pathophysiology

RF occurs as a complication 2-3 weeks after a group A streptococcal pharyngitis. Signs of RF appear to be from an abnormal immune response to bacterial antigens.[9] RF affects the heart, skin, joints, and CNS. Rheumatic heart disease, caused by RF, primarily affects young adults.

RF has declined in developed countries because of the effective use of antibiotics to treat streptococcal infections. However, it is an important public health problem in developing countries.[9] Risk factors include age, gender, and environmental factors.[10]

Cardiac Lesions and Valve Deformities

About 50% of RF episodes are *rheumatic pancarditis,* involving all layers of the heart (endocardium, myocardium, and pericardium) (Fig. 36.1).[11]

Rheumatic IE is found mainly in the valves, with swelling and erosion of the valve leaflets. Vegetation forms from deposits of fibrin and blood cells in areas of erosion. The lesions initially create thickening of the valve leaflets, fusion of commissures and chordae tendineae, and fibrosis of the papillary muscle. Valve leaflets may become calcified, resulting in stenosis. The less mobile valve leaflets may not close properly, resulting in regurgitation. The mitral and aortic valves are most often affected.

Nodules, called *Aschoff's bodies,* are formed by a reaction to inflammation with swelling and destruction of collagen fibers. As the Aschoff's bodies age, they become more fibrous, and scar tissue forms in the myocardium. Rheumatic pericarditis develops and affects both layers of the pericardium. The layers become thick and covered with a fibrinous exudate. A serosanguineous pericardial effusion may develop. When healing occurs, fibrosis and adhesions develop that

partially or completely destroy the pericardial sac. Damage to the heart begins during the first attack of RF. Recurrent infections cause further structural damage.

Extracardiac Lesions

The systemic lesions of RF involve the skin, joints, and CNS. Painless subcutaneous nodules, arthralgias or arthritis, and chorea may develop.

Clinical Manifestations

Jones criteria are used to diagnose acute RF.[9] The presence of 2 major criteria or 1 major and 2 minor criteria plus evidence of a preceding group A streptococcal infection indicate a high probability of acute RF (Table 36.7).

TABLE 36.7 Revised Jones Criteria for Diagnosing Rheumatic Fever*

Major Criteria

- Carditis: Clinical and/or subclinical
- Arthritis
    - Monoarthritis or polyarthritis
    - Polyarthralgia
- Erythema marginatum
- Subcutaneous nodules
- Sydenham's chorea

Minor Criteria

- Monoarthralgia

- Fever
- Laboratory findings: ↑ ESR and/or ↑ CRP
- ECG findings: Prolonged PR interval after accounting for age variability (unless carditis is a major criterion)

Evidence of Group A Streptococcal Infection

- Laboratory findings
    - ↑ Antistreptolysin-O titer, positive throat culture, or positive rapid antigen test for group A streptococci

* Criteria apply to initial episode of rheumatic fever in moderate- or high-risk populations as defined by an all-age prevalence of rheumatic heart disease of ≥1 per 1000 population per year.

Modified from Gewitz MH, Baltimore RS, Tani LY, et al: Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: A scientific statement from the AHA, *Circulation* 131:1806, 2015.

Major Criteria

Carditis is the most important manifestation of RF. It results in 3 signs: (1) heart murmur or murmurs of mitral or aortic regurgitation, or mitral stenosis; (2) heart enlargement and HF from myocarditis; and (3) pericarditis resulting in muffled heart sounds, chest pain, pericardial friction rub, or signs of effusion.

Monoarthritis or *polyarthritis* is the most common finding in RF, occurring in up to 75% of patients.[9] The inflammatory process affects the synovial membranes of the joints. This causes swelling, heat, redness, tenderness, and limitation of motion. The larger joints, particularly the knees, ankles, elbows, and wrists, are most often affected.

Sydenham's chorea is the major CNS manifestation.[9] It is characterized by involuntary movements, especially of the face and limbs; muscle weakness; and speech and gait problems.

Erythema marginatum lesions are a less common feature of RF. They only occur in less than 10% of RF patients.[10] The bright pink, nonpruritic, maplike macular lesions occur mainly on the trunk and proximal extremities. They intensify with heat (e.g., warm bath). *Subcutaneous nodules* associated with severe carditis are small, hard, painless swellings found over extensor surfaces of joints, particularly the knees, wrists, and elbows.

Minor Criteria

Minor clinical manifestations (Table 36.7) are helpful in diagnosing the disease. The minor criteria confirm the presence of RF when only 1 major criterion is present.

Evidence of Infection

In addition to the major and minor criteria, there must be evidence of a preceding group A streptococcal infection. Table 36.7 lists the various laboratory tests used to confirm evidence of infection.

Complications

Chronic rheumatic carditis results from changes in valve structure months to years after an episode of RF. Rheumatic IE can result in fibrous tissue growth in valve leaflets and chordae tendineae with scarring and contractures. The mitral valve is most often involved. The aortic and tricuspid valves may be affected.

Diagnostic Studies and Interprofessional Care

No single diagnostic test exists for RF. An echocardiogram may show valvular insufficiency and pericardial fluid or thickening.[11] A chest x-ray may show an enlarged heart. The most consistent ECG change is a prolonged PR interval from delayed AV conduction.

Treatment consists of drug therapy and supportive measures (Table 36.8). Antibiotic therapy does not change the course of the acute disease or the development of carditis. It eliminates residual group A streptococci in the tonsils and pharynx and prevents the spread of organisms to close contacts. Salicylates, NSAIDs, and corticosteroids are the antiinflammatory agents most widely used to control the fever and joint manifestations.[10]

TABLE 36.8 Interprofessional CareRheumatic Fever

Diagnostic Assessment

- History and physical examination
- Laboratory studies (Table 36.7)
    - Chest x-ray
    - Echocardiogram
    - ECG

Management

- Bed rest or limited activity
- Drug therapy
    - Antibiotics
    - NSAIDs
    - Salicylates
    - Corticosteroids

Nursing Management: Rheumatic Fever and Rheumatic Heart Disease

Nursing Assessment

Table 36.9 presents the subjective and objective data to obtain from a patient with RF and rheumatic heart disease.

Inspect the patient's skin for subcutaneous nodules and erythema marginatum. Palpate for subcutaneous nodules over all bony surfaces and along extensor tendons of the hands and feet. The nodules range in size from 1 to 4 cm and are hard, painless, and freely movable. Erythema marginatum can occur on the trunk and inner aspects of the upper arm and thigh. Assess for these bright pink maculae in good light because the rash is hard to see, especially in dark-skinned patients.

Nursing Diagnoses

Nursing diagnoses for the patient with RF and rheumatic heart disease include:

- Impaired cardiac output
- Activity intolerance

TABLE 36.9 Nursing AssessmentRheumatic Fever and Rheumatic Heart Disease

Subjective Data

Important Health Information

Past health history: Recent streptococcal infection, history of RF or rheumatic heart disease

Functional Health Patterns

Health perception–health management: Family history of rheumatic fever. Malaise

Nutritional-metabolic: Anorexia, weight loss

Activity-exercise: Palpitations, generalized weakness, fatigue, impaired coordination
Cognitive-perceptual: Chest pain, widespread joint pain and tenderness (especially large joints)

Objective Data

General

Fever

Integumentary

Subcutaneous nodules and erythema marginatum

Cardiovascular

Tachycardia, pericardial friction rub, muffled heart sounds, murmurs, peripheral edema

Neurologic

Chorea (involuntary, purposeless, rapid motions; facial grimaces)

Musculoskeletal

Signs of monoarthritis or polyarthritis, including swelling, heat, redness, limitation of motion (especially of knees, ankles, elbows, shoulders, wrists)

Possible Diagnostic Findings

Cardiomegaly on chest x-ray. Prolonged PR interval on ECG. Valve abnormalities, chamber dilation, and pericardial effusion on echocardiogram. ↑ Antistreptolysin-O titer, positive throat culture, positive rapid antigen test for group A streptococci, ↑ ESR, ↑ CRP, leukocytosis

Planning

The goals for a patient with RF and rheumatic heart disease include (1) normal or baseline heart function, (2) resumption of daily activities without joint pain, and (3) ability to manage the long-term antibiotic therapy.

Nursing Implementation

Health Promotion

Early detection and immediate treatment of group A streptococcal pharyngitis can prevent RF. Treatment with oral penicillin V (Penicillin-VK) or amoxicillin for 10 days is recommended.[9] If the patient is allergic to penicillin, a narrow-spectrum cephalosporin (e.g., cephalexin), clindamycin (Cleocin), or azithromycin (Zithromax) is used.[12] Therapy requires strict adherence to the full course of treatment. Teach people in the community to seek prompt medical care for symptoms of streptococcal pharyngitis.

Acute Care

Give antibiotics as prescribed to treat the streptococcal infection. Teach the patient that completing the full course of antibiotics is vital to successful treatment.

Promote optimal rest to reduce cardiac workload and the body's metabolic needs. Position painful joints for proper alignment and apply heat for comfort. Give salicylates, NSAIDs, and corticosteroids as prescribed for joint pain.

After the acute symptoms subside, the patient without carditis can walk. The patient with carditis with HF may be restricted to bed rest

(see Chapter 34 for care of a patient with HF). Stress the importance of gentle activities during recovery.

Check Your Practice

Your 28-yr-old male patient is recovering from carditis after RF. As you are preparing him for discharge from the hospital, he is pacing the floor and seems quite upset. You ask him to sit down so you can talk. He tells you, "I'm a cardiac cripple. I'll never be able to play ball with my sons or go skiing again. I might as well just go to bed and stay there."

- What are the key elements to include in your teaching plan?

Ambulatory Care

The aim of secondary prevention is to stop the recurrence of RF. Prior history of RF makes the patient more susceptible to a second attack after a streptococcal infection. The best prevention is treatment with prophylactic antibiotics. Patients with RF without carditis need prophylaxis until age 20 and for a minimum of 5 years. Patients with rheumatic carditis and residual heart disease (e.g., persistent valve disease) need lifelong prophylaxis.[12]

Teach the patient with a history of RF about the disease process and the need for ongoing antibiotic prophylaxis. Teach the patient about good nutrition, hygienic practices, and adequate rest. Caution the patient about the possible development of heart valve disease. Tell the patient to seek medical care for symptoms, such as excessive fatigue, dizziness, palpitations, unexplained weight gain, or exertional dyspnea.[12]

Evaluation

The expected outcomes are that the patient with RF and rheumatic heart disease will

- Be able to perform ADLs with minimal fatigue and pain
- Adhere to treatment regimen
- Express confidence in managing disease
- Use measures to prevent complications

Valvular Heart Disease

Two AV valves (mitral and tricuspid) and 2 semilunar valves (aortic and pulmonic) control blood flow through the heart (see Fig. 31.1). Valvular heart disease is defined by the valves affected and the type of dysfunction: stenosis or regurgitation (Fig. 36.7).

The pressure on either side of an open valve is normally equal. However, in a stenotic valve, the valve opening is smaller. The forward flow of blood is impaired. This creates a difference in pressure on the 2 sides of the open valve. The amount of **stenosis** (constriction or narrowing) is seen in the pressure differences (i.e., the higher the difference, the greater the stenosis). When **regurgitation** occurs (referred to as *incompetence* or *insufficiency*), there is incomplete closure of the valve. This results in the backward flow of blood.

Congenital heart conditions are the most common cause of valve disorders in children and adolescents. Aortic stenosis and mitral regurgitation (MR) often occur in older adults who have some form of heart disease. Other causes of valve disease in adults are related to acquired immunodeficiency syndrome and the use of some antiparkinsonian drugs.[12]

Mitral Valve Stenosis

Etiology and Pathophysiology

Worldwide, the most common cause of mitral stenosis is rheumatic heart disease.[13] Rheumatic mitral stenosis is widespread in developing countries. Less common causes are congenital mitral stenosis, rheumatoid arthritis, radiation exposure, and systemic lupus erythematosus. Rheumatic IE causes scarring of the valve leaflets and

the chordae tendineae. Contractures and adhesions develop between the commissures (the junctional areas). The stenotic mitral valve takes on a "fish mouth" shape because of the thickening and shortening of the mitral valve structures. Severe mitral annular calcification is another cause in the aging population.

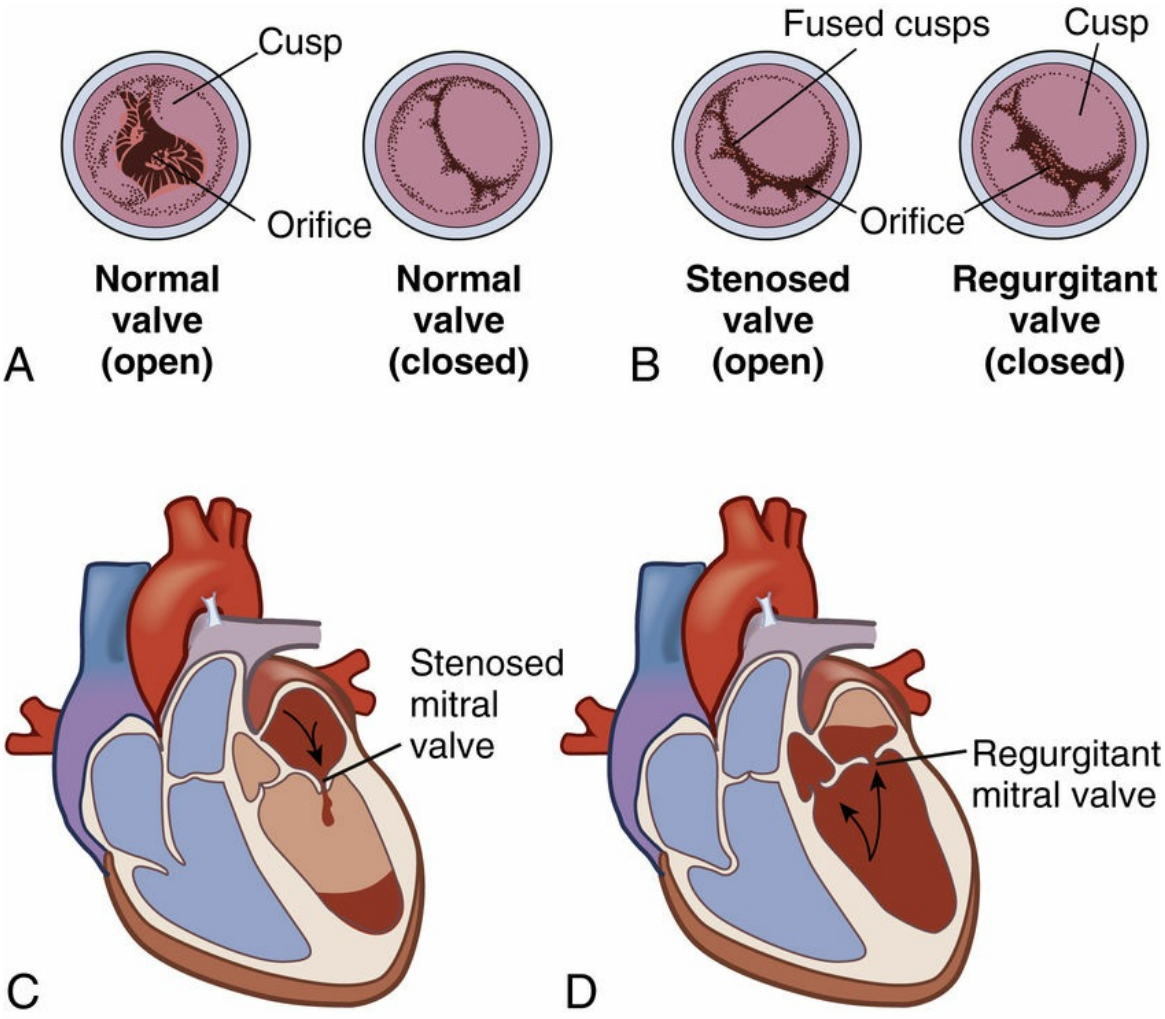

FIG. 36.7 Valvular stenosis and regurgitation. **A,** Normal position of the valve leaflets, or cusps, when the valve is open and closed. **B,** Open position of a stenosed valve *(left)* and closed position of regurgitant valve *(right).* **C,** Hemodynamic effect of mitral stenosis. The stenosed valve is unable to open sufficiently during left atrial systole, inhibiting left ventricular filling. **D,** Hemodynamic effect of mitral regurgitation. The mitral valve does not close completely during left ventricular systole, letting blood reenter the left atrium. At the same time, blood is moving forward through the aortic valve.
From McCance KL, Huether SE: *Pathophysiology: The biologic basis*

for disease in adults and children, ed 6, St Louis, 2010, Mosby.

These deformities block the blood flow and create a pressure difference between the left atrium and left ventricle during diastole. As a result, left atrial pressure and volume increase, causing higher pulmonary vasculature pressure. The overloaded left atrium places the patient at risk for atrial fibrillation. In chronic mitral stenosis, pressure overload occurs in the left atrium, pulmonary bed, and right ventricle.

Clinical Manifestations

The main symptom of mitral stenosis is exertional dyspnea caused by reduced lung compliance (Table 36.10). Heart sounds include a loud first heart sound and a low-pitched, diastolic murmur (best heard at the apex with the stethoscope). Less often, patients may have hoarseness (from atrial enlargement pressing on the laryngeal nerve), hemoptysis (from pulmonary hypertension), and chest pain (from decreased CO and coronary perfusion). Emboli can form in the left atrium from atrial fibrillation and cause a stroke.[13] Fatigue and palpitations from atrial fibrillation may occur.

Mitral Valve Regurgitation

Etiology and Pathophysiology

Mitral valve function depends on intact mitral leaflets, mitral annulus, chordae tendineae, papillary muscles, left atrium, and left ventricle. A defect in any of these structures can cause regurgitation. MR may result from problems with the leaflets or from the surrounding structures. In primary (degenerative) MR, a problem with the leaflets causes the regurgitation. In secondary (functional) MR, myocardial disease causes the regurgitation.[13] Most cases of MR are caused by MI, chronic rheumatic heart disease, mitral valve prolapse, ischemic papillary muscle dysfunction, and IE. MI with left ventricular failure increases the risk for rupture of the chordae tendineae and acute MR.

TABLE 36.10 Manifestations of Valvular Heart Disease

Type	Manifestations
Mitral valve prolapse	Palpitations, dyspnea, chest pain, activity intolerance, syncope, holosystolic murmur
Mitral valve regurgitation	*Acute:* Generally poorly tolerated. New systolic murmur with pulmonary edema. Cardiogenic shock develops rapidly *Chronic:* Weakness, fatigue, exertional dyspnea, palpitations, S_3 gallop, holosystolic murmur
Mitral valve stenosis	Dyspnea on exertion, hemoptysis, fatigue. Atrial fibrillation on ECG. Palpitations. Loud, accentuated S_1. Low-pitched, diastolic murmur
Aortic valve regurgitation	*Acute:* Abrupt onset of profound dyspnea, chest pain, left ventricular failure and cardiogenic shock *Chronic:* Fatigue, exertional dyspnea, orthopnea, PND. Water-hammer pulse, heaving precordial impulse, decreased or absent S_1, S_3, or S_4. Soft high-pitched diastolic murmur, Austin Flint murmur
Aortic valve stenosis	Angina, syncope, dyspnea on exertion, HF, normal or soft S_1, decreased or absent S_2, systolic murmur, prominent S_4
Tricuspid and pulmonic stenosis	*Tricuspid:* Peripheral edema, ascites, hepatomegaly. Diastolic low-pitched murmur with increased intensity during inspiration *Pulmonic:* Fatigue, loud midsystolic murmur

PND, Paroxysmal nocturnal dyspnea.

MR allows blood to flow backward from the left ventricle to the left atrium because of incomplete valve closure during systole. Both the left ventricle and left atrium must work harder to preserve an adequate CO. In acute MR, the sudden increase in pressure and volume transmits back to the pulmonary bed. This results in pulmonary edema and, if not treated, cardiogenic shock. In chronic MR, the added volume results in left atrial enlargement, left ventricular dilation and hypertrophy, and, finally, a decrease in CO.

Clinical Manifestations

The nature of its onset determines the clinical course of MR (Table 36.10). Patients with acute MR have thready peripheral pulses and cool, clammy extremities. A low CO may mask a new systolic murmur. Rapid assessment (e.g., heart catheterization) and intervention (e.g., valve repair or replacement) are critical.

Patients with chronic MR may remain asymptomatic for many years. Early symptoms of left ventricular failure may include weakness, fatigue, palpitations, and dyspnea. These gradually progress to orthopnea, paroxysmal nocturnal dyspnea, and peripheral

edema. Increased left ventricular volume leads to an audible third heart sound (S_3), even with normal left ventricular function. The murmur is a loud holosystolic murmur at the apex radiating to the left axilla. Patients with asymptomatic MR must be monitored carefully.

Treatment for MR depends on the cause of the regurgitation. Primary MR typically requires valve repair or replacement before significant left ventricular failure or pulmonary hypertension develop.[14] Medical management includes standard HF therapy.[13]

Mitral Valve Prolapse

Etiology and Pathophysiology

Mitral valve prolapse (MVP) is an abnormality of the mitral valve leaflets and the papillary muscles or chordae that allows the leaflets to prolapse, or buckle, back into the left atrium during systole (Fig. 36.8). MVP affects 2% to 3% of the general population.[15]

The use of the term *prolapse* can be misleading because it is used even when the valve is working normally. MVP is usually benign, but serious complications can occur, including MR, IE, SCD, HF, and cerebral ischemia.

Genetic Link

Although the cause of MVP is unknown, there is an increased familial incidence. The genetic inheritance is often autosomal dominant (see Chapter 12). MVP in this group results from a connective tissue defect affecting only the valve, or as part of Marfan's syndrome or other hereditary conditions that affect collagen structure.

Clinical Manifestations

MVP has a broad range of severity. Most patients are asymptomatic for their entire lives. About 10% of those with MVP become symptomatic. A characteristic of MVP is a regurgitation murmur that

is louder during systole. MVP does not alter S_1 or S_2 heart sounds. Severe MR is an uncommon but serious complication of MVP.

M-mode and 2-D echocardiography are used to confirm MVP. Dysrhythmias, such as premature ventricular contractions, paroxysmal supraventricular tachycardia, and ventricular tachycardia, may cause palpitations, light-headedness, and syncope. IE may occur in patients with MR associated with MVP.

Patients may have chest pain.[15] The cause of the chest pain may be the result of abnormal tension on the papillary muscles. Chest pain episodes tend to occur in clusters, especially during periods of emotional stress. Dyspnea, palpitations, and syncope sometimes accompany the chest pain and do not respond to antianginal treatment (e.g., nitrates). β-Blockers may control palpitations and chest pain. Encourage the patient to stay hydrated, exercise regularly, and avoid caffeine.

Most patients with MVP have a benign, manageable course. For those who do develop symptomatic MR, no current therapy delays the need for valve surgery.[16] A teaching plan for patients with MVP is outlined in Table 36.11.

Aortic Valve Stenosis

Etiology and Pathophysiology

Congenital **aortic stenosis (AS)** is generally found in childhood, adolescence, or young adulthood. In older adults, AS is a result of RF or degeneration, similar to coronary artery disease. AS is the most frequent degenerative valve disorder, affecting 3% of people over 65 years of age.[17] In rheumatic valve disease, fusion and calcification cause the valve leaflets to stiffen and retract, resulting in stenosis. AS due to rheumatic heart disease accompanies mitral valve disease. Isolated AS is usually nonrheumatic.

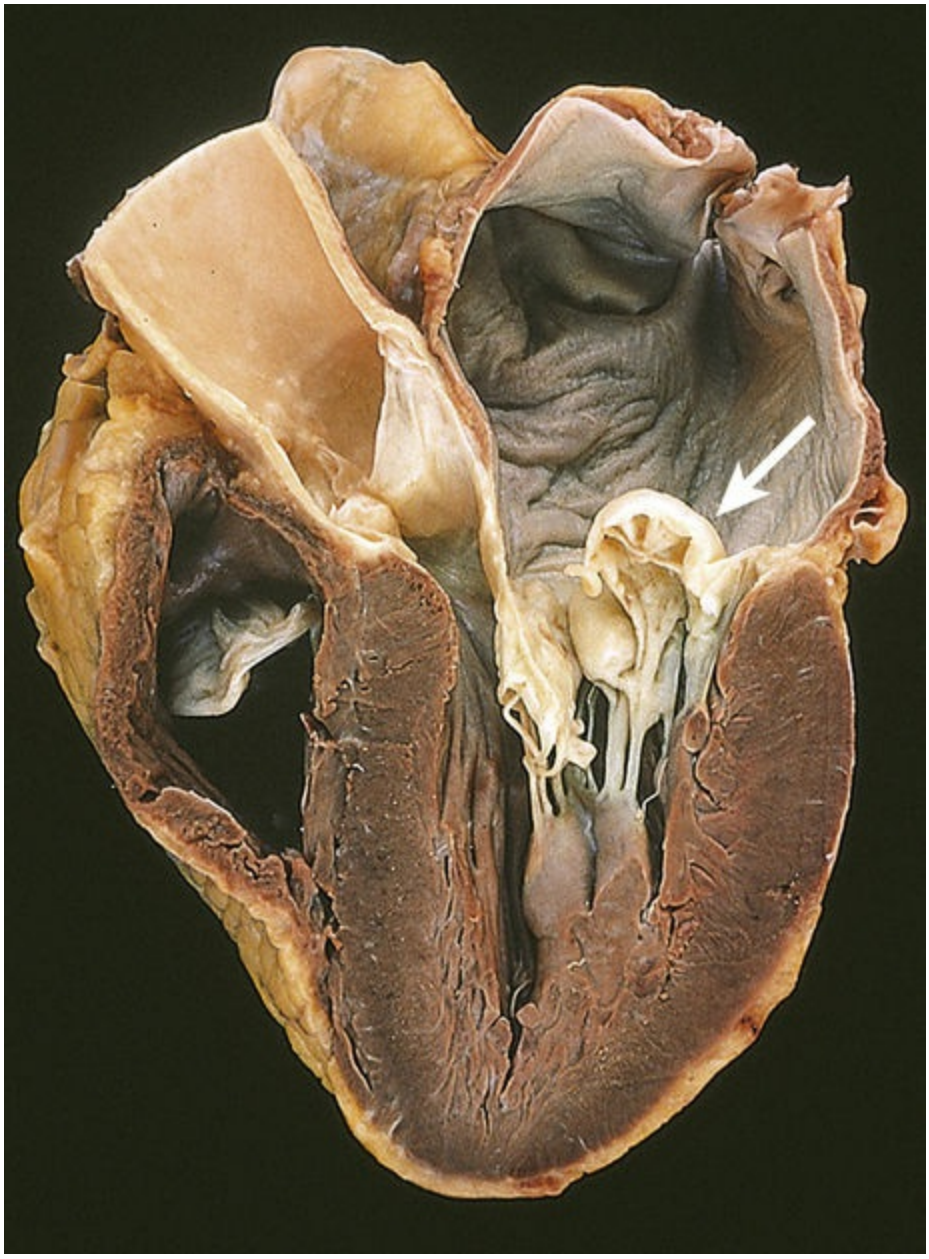

FIG. 36.8 Mitral valve prolapse. In this valvular abnormality, the mitral leaflets have prolapsed back into the left atrium. There is hooding *(arrow).* The left ventricle is on the right.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

TABLE 36.11 Patient & Caregiver TeachingMitral

Valve Prolapse

Include the following information in the teaching plan for a patient with mitral valve prolapse (MVP) and the patient's caregiver:

- Take drugs as prescribed (e.g., β-blockers to control palpitations, chest pain).
- Adopt healthy eating habits.
- Avoid caffeine because it is a stimulant and may worsen symptoms.
- If you use diet pills or other over-the-counter drugs, check for common ingredients that are stimulants (e.g., caffeine, ephedrine), since these can worsen symptoms.
- Begin, or maintain, an exercise program to achieve optimal health.
- Contact the HCP or emergency response system (ERS) if symptoms develop or worsen (e.g., palpitations, fatigue, shortness of breath, anxiety).

AS causes obstruction of blood flow from the left ventricle to the aorta during systole. The result is left ventricular hypertrophy and increased myocardial O_2 consumption because of the increased myocardial mass. As the disease progresses and compensation fails, reduced CO leads to decreased tissue perfusion, pulmonary hypertension, and HF. Left untreated, severe AS has a poor prognosis.[18]

Clinical Manifestations

Manifestations of AS (Table 36.10) develop when the valve orifice becomes about one-third its normal size. They include the classic triad of angina, syncope, and exertional dyspnea, reflecting left ventricular failure.[17] Auscultation often reveals a normal or soft S_1, a decreased or absent S_2, and a crescendo-decrescendo systolic murmur, with radiation to the carotids.

Some patients may be asymptomatic. The prognosis is poorer for patients with symptoms and those whose valve obstruction is not fixed. Nitroglycerin is used cautiously to treat angina, since the drug can significantly reduce BP and worsen chest pain.

Drug Alert

Nitroglycerin

- Use cautiously in patients with AS since significant hypotension may occur.
- The drug can worsen chest pain due to the decrease in preload and drop in BP.

Aortic Valve Regurgitation

Etiology and Pathophysiology

Aortic regurgitation (AR) may be the result of primary disease of the aortic valve leaflets, the aortic root, or both.[19] Trauma, IE, or aortic dissection can cause acute AR, which is a life-threatening emergency. Chronic AR generally results from rheumatic heart disease, a congenital bicuspid aortic valve, syphilis, a connective tissue problem, or a postsurgical cause.[19]

AR causes retrograde (backward) blood flow from the ascending aorta into the left ventricle during diastole. This results in volume overload. The left ventricle initially compensates for chronic AR by dilation and hypertrophy. Myocardial contractility eventually declines, and blood volume in the left atrium and pulmonary bed increases. This leads to pulmonary hypertension and right ventricular failure.

Clinical Manifestations

Patients with acute AR have sudden signs of cardiovascular collapse (Table 36.10). The patient develops severe dyspnea, chest pain, and hypotension indicating left ventricular failure and cardiogenic shock, a life-threatening emergency.

Patients with chronic, severe AR develop a *water-hammer pulse* (strong, quick beat that collapses immediately). Heart sounds may include a soft or absent S_1, S_3, or S_4 and a soft, high-pitched diastolic murmur.

The patient with chronic AR generally is asymptomatic for years.[19] Exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea develop only after considerable heart dysfunction has occurred (Table 36.10). Angina occurs less often than in AS.

Tricuspid and Pulmonic Valve Disease

Etiology and Pathophysiology

Tricuspid regurgitation (TR) can be primary or secondary. Primary TR is less common and is typically due to IE. Secondary TR is caused by right ventricular (RV) dilatation from pulmonary hypertension, cor pulmonale, or pulmonary outflow tract obstruction. The patient does not show JVD, enlarged liver, and peripheral edema until regurgitation is severe. Diagnosis is made by history and physical as well as echocardiogram. The prognosis is poor for severe TR.

Tricuspid stenosis is almost always caused by RF. Signs and symptoms include a fluttering discomfort in the neck, fatigue, and possible right upper quadrant pain.

Pulmonary regurgitation is often asymptomatic. A crescendo-decrescendo murmur is present. Potential causes include pulmonary hypertension, surgical repair of tetralogy of Fallot (TOF), or congenital valve disease. It can cause RV dilation.

Pulmonic stenosis is almost always a congenital part of TOF. It results in right ventricular hypertension and hypertrophy (Table 36.10). It is largely asymptomatic. When symptoms develop, they are similar to those of AS (syncope, dyspnea, angina). Symptoms typically

do not present until adulthood.

Diagnostic Studies: Valvular Heart Disease

Diagnosis of valvular heart disease includes information from the history and physical examination and a variety of tests (Table 36.12). An echocardiogram shows valve structure, function, and heart chamber size. Transesophageal echocardiography and Doppler color-flow imaging help diagnose and monitor valvular heart disease progression. Real-time 3-D echocardiography can help assess mitral valve and congenital heart disease.

TABLE 36.12 Interprofessional CareValvular Heart Disease

Diagnostic Assessment

- History and physical examination
- Chest x-ray
- Complete blood count
- ECG
- Echocardiography (Doppler and transesophageal)
- Heart catheterization

Management

Conservative Therapy

- Prophylactic antibiotic therapy (Table 36.2)
    - Rheumatic fever
    - IE

- Sodium restriction
- Drug therapy to treat or control HF
    - Vasodilators* (e.g., nitrates, ACE inhibitors)
    - Positive inotropes (e.g., digoxin)
    - Diuretics
    - β-Blockers
- Anticoagulation therapy (see Table 37.10)
- Antidysrhythmic drugs (see Table 35.9)
- Percutaneous transluminal balloon valvuloplasty
- Percutaneous valve replacement

Surgical Therapy

- Valve repair
    - Annuloplasty
    - Commissurotomy (valvulotomy)
    - Valvuloplasty
- Valve replacement

---

* Use cautiously in patients with aortic stenosis.

Chest x-ray shows the heart size, altered pulmonary circulation, and valve calcification. An ECG identifies HR, rhythm, and any ischemia or ventricular hypertrophy. Heart catheterization detects pressure changes in the heart chambers, records pressure differences across the valves, and measures the size of valve openings.

Interprofessional Care: Valvular Heart Disease

Conservative Therapy

Overall treatment focuses on preventing exacerbations of HF, acute pulmonary edema, thromboembolism, and recurrent RF and IE (Table 36.12). HF is treated with vasodilators, positive inotropes, β-blockers, diuretics, and a low-sodium diet (see Chapter 34).

Atrial dysrhythmias are common. They are treated with calcium channel blockers, β-blockers, antidysrhythmic drugs, or electrical cardioversion (see Chapter 35). Anticoagulant therapy is used in patients with atrial fibrillation to prevent systemic or pulmonary emboli.

Percutaneous Transluminal Balloon Valvuloplasty

An alternative treatment for some patients with valvular heart disease is *percutaneous transluminal balloon valvuloplasty* (PTBV). During PTBV, the fused commissures are split open. Balloon valvuloplasty treats mitral, tricuspid, pulmonic, and AS. [14]

The PTBV procedure is done in the heart catheterization laboratory. It involves threading a balloon-tipped catheter from the femoral artery or vein to the stenotic valve. The balloon is inflated to separate the valve leaflets. A single- or double-balloon technique may be used. Using a single Inoue balloon with hourglass shape allows sequential inflation. This technique is the most popular because it is easy and has good results with few complications (Fig. 36.9).

Like PTBV, the Sapien Transcatheter Heart Valve (THV) is used for select patients with AS. The THV is inserted through the femoral artery and moved to the heart. It is released and expanded with a balloon in the location of the aortic valve. This procedure is limited to patients who are eligible for surgery but who are at high risk for surgical complications (e.g., those with multiple co-morbidities).

Ethical/Legal Dilemmas

Do Not Resuscitate

Situation

J.L., a 68-yr-old man, is admitted for a second mitral valve surgery and coronary artery bypass graft surgery. He did not adhere to the treatment plan after his original surgery 7 years ago. You are worried about his future adherence with drugs, diet, and exercise. His kidneys are failing, and he is on dialysis, making him a high-risk surgical patient. J.L. and his caregiver want all treatment and refuse to discuss advance directives (ADs) or do-not-resuscitate (DNR) orders.

Ethical/Legal Points for Consideration

- Patient adherence with past treatment plans is not a factor when considering DNR decisions. Many circumstances related to nonadherence are outside the patient's control, such as finances, transportation, availability of help, and declining physical and medical capabilities. Based on their expertise, HCPs have the right to refuse to provide treatment that offers no benefit to the patient.
- ADs do not include a DNR order. If the patient is unable to speak for himself or herself, the HCP can start a DNR order only after conversation with the health care proxy and/or nearest kin. The decision usually depends on evidence of the patient's preferences (substituted judgment standard) or what is thought to be in the best interest of the patient.
- If there is an AD refusing resuscitation, the HCP is required to act accordingly but is not compelled to enact a DNR without clear direction from the patient or proxy.
- If the involved parties disagree about the patient's treatment plan, a referral can be made to an ethics committee, they can seek treatment from another HCP, or they may seek legal intervention by way of a court order.

Discussion Questions

1. How can a lack of understanding or limited financial resources contribute to nonadherence with the plan of care?
2. What type of information should be given to a patient and caregiver in discussions about ADs and DNR orders? Who should provide this information?
3. Who can initiate a referral to an ethics committee?

Surgical Therapy

The decision for valve repair or replacement depends on the patient's symptoms using the New York Heart Association classification system for functional disability (see Table 34.3).[14] Theprocedure used depends on the (1) valves involved, (2) pathology and severity of the disease, and (3) patient's clinical condition.

Valve Repair

Valve repair is preferred over replacement when clinically appropriate. Repair has a lower operative mortality rate than valve replacement. It is often used in mitral or tricuspid valve disease.[14] Although repair avoids the risks of replacement, it may not restore total valve function.

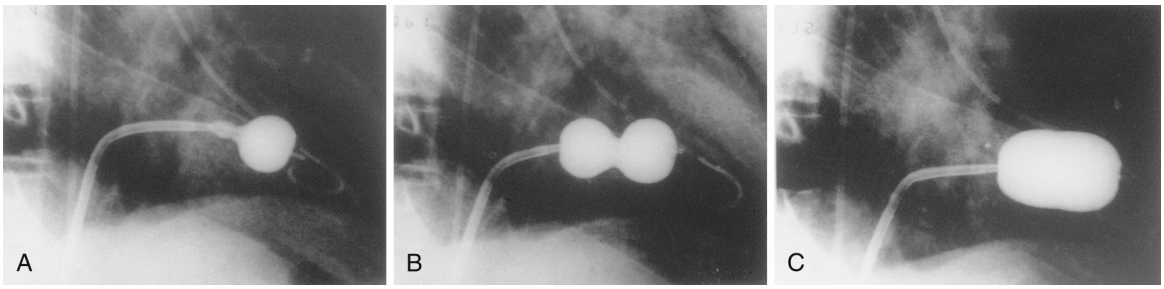

FIG. 36.9 Mitral valvuloplasty performed by the Inoue technique. The catheter is placed in the mitral valve and the distal part of the Inoue balloon inflated **(A).** The balloon is then pulled back in the mitral valve and inflated for 10 to 15 sec under fluoroscopic control **(B)** until the waist of the balloon is no longer visible **(C)** and the balloon falls back

into the left atrium.
From Crawford MH, DiMarco JP, Paulus WJ: *Cardiology,* ed 3, Edinburgh, 2010, Mosby.

Open surgical *valvuloplasty* involves repair of the valve by suturing the torn leaflets, chordae tendineae, or papillary muscles. It is primarily used to treat mitral or tricuspid regurgitation.

Minimally invasive valve surgery involves a mini-sternotomy or parasternal approach. It may include robotic and thoracoscopic surgical systems. Advantages include shorter lengths of stay, fewer blood transfusions, less pain, and lower risk for sternal infection and postoperative atrial fibrillation.

For patients with mitral or tricuspid regurgitation, further valve repair or reconstruction using annuloplasty is an option. *Annuloplasty* involves reconstruction of the annulus, with or without the aid of prosthetic rings.

Valve Replacement

Valve replacement may be needed for mitral, aortic, tricuspid, and pulmonic valve disease. A wide variety of prosthetic valves are available. Desirable valves are nonthrombogenic, are durable, and create minimal stenosis. Valves are either mechanical or biologic (tissue) valves (Fig. 36.10).

Mechanical valves are made from artificial materials. They consist of combinations of metal alloys, pyrolytic carbon, and Dacron. *Biologic valves* are made from bovine, porcine, and human (cadaver) heart tissue. They usually contain some human-made materials. A "decellularizing" process removes the cadaver cells from the valve to lower the risk for tissue rejection. Biologic valves are asymmetric in shape. They produce a more natural pattern of blood flow compared with mechanical valves.

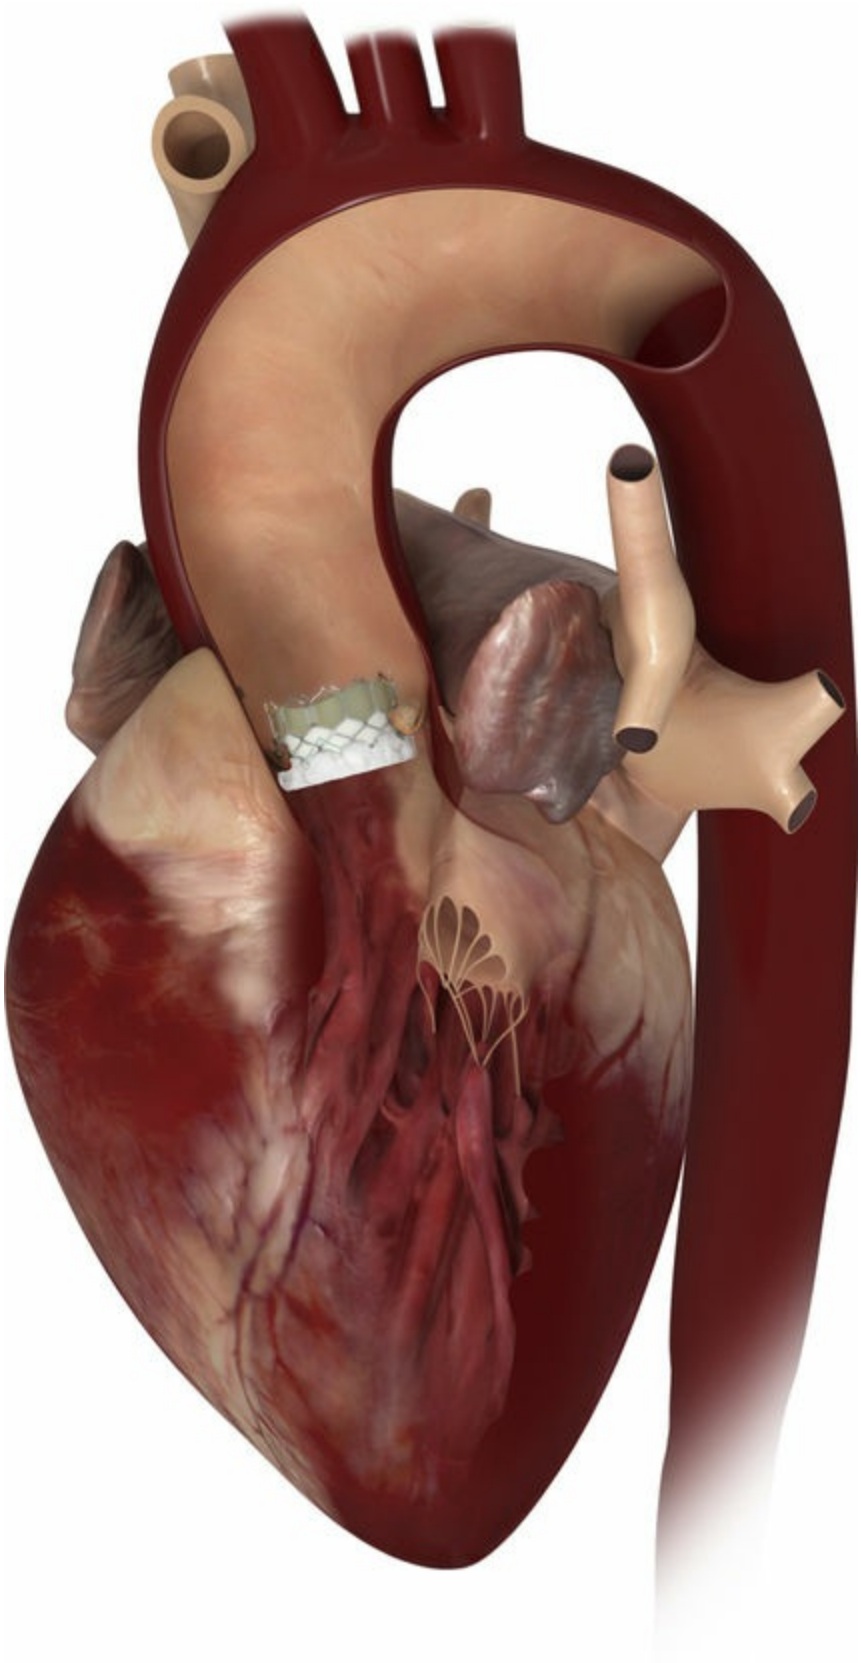

FIG. 36.10 Edwards Sapien 3 Transcatheter Heart Valve.

Courtesy Edwards Lifesciences LLC, Irvine, CA.

Mechanical valves are more durable and last longer than biologic valves. However, they have an increased risk for thromboembolism. Patients need long-term anticoagulation therapy, which increases the risk of bleeding.[13] Anticoagulation therapy is not needed with biologic valves because of their low thrombogenicity. However, they are less durable and tend to cause early calcification, tissue degeneration, and stiffening of the leaflets. Both valve types are subject to leaking and risk of IE.

Transcatheter therapies are another option for treating valvular heart disease. They are used to treat patients at high risk for surgery who have aortic or mitral bioprosthetic valve failure. Transcatheter pulmonary valve replacement is approved for use in pediatric and adult patients with pulmonary valve disease caused by congenital heart disease.

Transcatheter aortic valve replacement (TAVR) is an option for patients with severe, symptomatic AS who are at intermediate risk or higher for surgical aortic valve replacement (SAVR).[20] Symptomatic AS has a poor prognosis if left untreated. The procedure is ideally done using a transfemoral approach. The evaluation for TAVR includes echocardiogram, coronary CT angiogram, heart catheterization, and pulmonary function testing.[21] Imaging can determine valve size and plan the procedure. Currently, there are 2 TAVR valves in the United States. The Edwards Sapien 3 valve is made of bovine pericardial tissue. It is a balloon expandable valve (Fig. 36.10).[22] The CoreValve transcatheter aortic valve is a self-expanding valve made of porcine pericardial tissue (Fig. 36.11, *D*).[23]

Long-term anticoagulation is needed for those patients with biologic valves who have atrial fibrillation. Some patients with biologic valves or annuloplasty with prosthetic rings may need anticoagulation the first few months after surgery until the suture lines are covered by endothelial cells (endothelialized).

The choice of valves depends on many factors. A mechanical valve may be best for a younger patient because it is more durable. If a

patient cannot take an anticoagulant (e.g., women of childbearing age), a biologic valve is considered. Frail patients with co-morbidities should be referred to a qualified heart team for a full evaluation before considering surgery.[20] Encourage patients to discuss short- and long-term consequences of valve choices with their HCPs.[21]

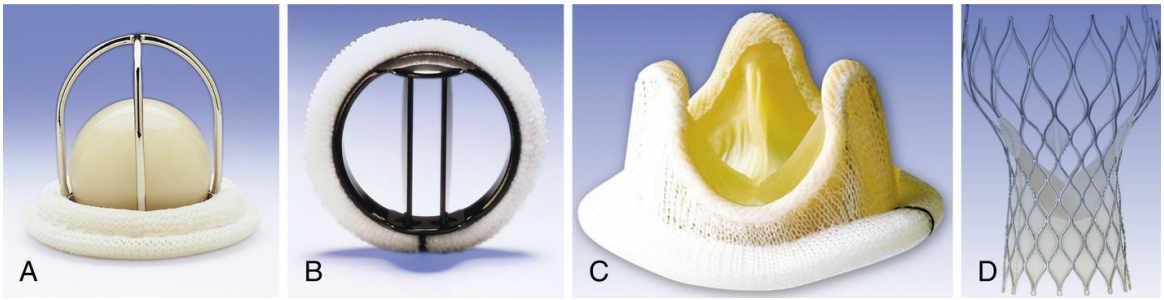

FIG. 36.11 Types of prosthetic heart valves. **A,** Starr-Edwards caged ball valve. **B,** St. Jude bi-leaflet valve. **C,** Carpentier-Edwards porcine valve. **D,** CoreValve transcatheter aortic valve (CV26 Hero), Medtronic 2015.

Informatics in Practice

Heart Surgery Videos

Many patients prefer to watch recorded videos instead of reading educational pamphlets. For a patient facing heart surgery, these formats can be effective tools to teach the patient and caregiver what to expect before and after the procedure.

- Remember that the recorded video is not the teacher.
- Beforehand, discuss what the video presentation will cover.
- Encourage the patient and caregiver to write down questions or note what they do not understand.

- After the patient and caregiver view the material, answer any questions they have. Reinforce important information.

Nursing Management: Valvular Disorders

Nursing Assessment

Table 36.13 presents the subjective and objective data to obtain from a patient with valve disease.

Nursing Diagnoses

Nursing diagnoses for the patient with valvular heart disease include:

- Impaired cardiac output
- Activity intolerance
- Fluid imbalance

More information on nursing diagnoses and interventions is in eNursing Care Plan 36.2, available on the website for this chapter.

Planning

The overall goals for the patient with valve disease include (1) normal heart function, (2) improved activity tolerance, and (3) an understanding of the disease process and health maintenance measures.

Nursing Implementation

Health Promotion

Encouraging early treatment of streptococcal infections and providing prophylactic antibiotics for patients with a history of RF are critical to

prevent acquired rheumatic valve disease. The patient at risk for IE and any patient with certain heart conditions must receive prophylactic antibiotics (Table 36.2). Teach the person with a history of RF, IE, or congenital heart disease the symptoms of valvular heart disease to report.

Acute Care and Ambulatory Care

A patient with progressive valvular heart disease may need outpatient care or hospitalization for management of HF, IE, embolic disease, or dysrhythmias. HF is the most common reason for ongoing medical care.

Design activities considering the patient's limitations. An appropriate exercise plan can increase cardiac tolerance, but activities that cause fatigue and dyspnea should be limited. Tell the patient to avoid strenuous physical exercise because damaged valves may not handle the increased CO demand. Develop your patient's care plan to emphasize conserving energy, setting priorities, and taking planned rest periods. Discourage tobacco use. Consider a referral to a vocational counselor if the patient has a physically or emotionally demanding job.

Perform ongoing cardiac assessments to monitor the effectiveness of drugs. Teach the actions and side effects of drugs to increase adherence. The patient must understand the importance of prophylactic antibiotic therapy to prevent IE (Table 36.2).

When valvular heart disease can no longer be managed medically, surgery is needed (see Chapter 33 for the care of a patient having heart surgery). The patient on anticoagulants (e.g., warfarin) after surgery for valve replacement must have the international normalized ratio (INR) checked regularly to determine proper dosage and adequacy of therapy. INR values of 2.5 to 3.5 are therapeutic for patients with mechanical valves.

A teaching guide related to anticoagulation therapy is found in Table 37.14. Teach the patient to follow up with an HCP regularly and when to seek urgent medical care. Tell the patient to notify the HCP of any signs of infection, HF, or bleeding and any planned invasive or

dental work. Last, encourage patients to wear a Medic Alert device or bracelet and carry the manufacturer's valve information card.

Evaluation

The expected outcomes are that a patient with valvular heart disease will

- Maintain adequate tissue and organ perfusion
- Achieve fluid balance
- Achieve optimal level of activity
- Describe disease process and measures to prevent complications

TABLE 36.13 Nursing AssessmentValvular Heart Disease

Subjective Data

Important Health Information

Past health history: RF, IE; congenital defects, heart attack, chest trauma, cardiomyopathy; syphilis, Marfan's syndrome, streptococcal infections

Functional Health Patterns

Health perception–health management: IV drug use, fatigue
Activity-exercise: Palpitations, generalized weakness, activity intolerance, dizziness, fainting, dyspnea on exertion, cough, hemoptysis, orthopnea
Sleep-rest: Paroxysmal nocturnal dyspnea
Cognitive-perceptual: Angina or atypical chest pain

Objective Data

General

Fever

Integumentary

Diaphoresis, flushing, cyanosis, clubbing, peripheral edema

Respiratory

Crackles, wheezes, hoarseness

Cardiovascular

Abnormal heart sounds, including murmurs, S_3, and S_4. Dysrhythmias, including atrial fibrillation, premature ventricular contractions. Tachycardia. ↑ or ↓ in pulse pressure, hypotension, water-hammer or thready peripheral pulses

Gastrointestinal

Ascites, hepatomegaly, unexplained weight gain

Possible Diagnostic Findings

Cardiomegaly on chest x-ray. ECG abnormalities specific to involved valve. Echocardiogram (valve disorders, chamber dilation), heart catheterization (abnormal valves, chamber pressures, CO, and blood flow, depending on involved valve)

Cardiomyopathy

Cardiomyopathy (CMP) is a group of diseases that directly affect myocardial structure or function. CMP is classified as primary or secondary. *Primary CMP* refers to those conditions in which the cause is idiopathic. The heart muscle is the only part of the heart involved, and other heart structures are unaffected. In *secondary CMP*, the cause of the myocardial disease is known and is due to another disease process. Common causes of secondary CMP are listed in Table 36.14.

Three major types of CMP are dilated, hypertrophic, and restrictive. Each type has its own pathogenesis, clinical presentation, and treatment protocols (Tables 36.15 and 36.16). CMP that leads to cardiomegaly and HF is the main reason for heart transplants.

Takotsubo cardiomyopathy is a transient heart syndrome that mimics acute coronary syndrome. Patients often have chest pain, ST segment elevation on ECG, and elevated cardiac biomarkers consistent with an MI. However, when the patient undergoes heart catheterization, there is no significant coronary artery disease. It is an acute, stress-related syndrome that is more common in postmenopausal women. Most patients recover rapidly without lasting symptoms.[24]

TABLE 36.14 Causes of Cardiomyopathy

Dilated

- Cardiotoxic agents: alcohol, cocaine, doxorubicin
- Coronary artery disease
- Genetic (autosomal dominant)
- Hypertension
- Metabolic problems
- Muscular dystrophy
- Myocarditis
- Pregnancy

- Valve disease

Hypertrophic

- Aortic stenosis
- Genetic (autosomal dominant)
- Hypertension

Restrictive

- Amyloidosis
- Cancer
- Endomyocardial fibrosis
- Post-radiation therapy
- Sarcoidosis
- Ventricular thrombus

TABLE 36.15 Types of Cardiomyopathy

Dilated	Hypertrophic	Restrictive
Cardiac Output		
Decreased	Normal or decreased	Normal or decreased
Cardiomegaly		
Moderate to severe	Mild to moderate	Mild
Contractility		
Decreased	Increased or decreased	Normal or decreased
Dysrhythmias		
Sinus tachycardia, atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias
Major Manifestations		
Fatigue, weakness, palpitations, dyspnea	Exertional dyspnea, fatigue, angina, syncope, palpitations	Dyspnea, fatigue
Outflow Tract Obstruction		
None	Increased	None
Valvular Incompetence		
Atrioventricular (AV) valves, especially mitral	Mitral valve	AV valves

Dilated Cardiomyopathy

Etiology and Pathophysiology

Dilated cardiomyopathy is the most common type of CMP, with a prevalence of 5 to 8 cases per 100,000 people in the United States. It causes HF in 25% to 40% of cases and occurs more often in middle-aged blacks and men. Dilated CMP often follows an infectious myocarditis. Some evidence links dilated CMP with an autoimmune process or genetic causes.[25] Alcohol-related dilated CMP has its own unique presentation and treatment.[21] Other common causes of dilated CMP are listed in Table 36.14.

Dilated CMP appears with diffuse inflammation and rapid degeneration of heart fibers. This results in ventricular dilation, impaired systolic function, atrial enlargement, and blood stasis in the left ventricle. SCD from dysrhythmias is a leading cause of death in idiopathic dilated CMP.[26] Ventricular dilation causes *cardiomegaly* (Fig. 36.12) and contractile dysfunction. In contrast to HF, the walls of the ventricles do not hypertrophy.

Clinical Manifestations

The signs and symptoms of dilated CMP may develop acutely after an infection or slowly over time. Most people eventually develop HF. Symptoms can include decreased exercise capacity, fatigue, dyspnea at rest, paroxysmal nocturnal dyspnea, and orthopnea. As the disease progresses, the patient may have a dry cough, palpitations, abdominal bloating, nausea, vomiting, and anorexia. Signs can include an abnormal S_3 and/or S_4, dysrhythmias, heart murmurs, pulmonary crackles, edema, weak peripheral pulses, pallor, hepatomegaly, and JVD. Decreased blood flow through an enlarged heart promotes stasis and blood clot formation and may lead to systemic embolization.

TABLE 36.16 Interprofessional Care

Cardiomyopathy
Diagnostic Assessment

- History and physical examination
- ECG
- b-Type natriuretic peptide (BNP)
- Chest x-ray
- Echocardiogram
- Nuclear imaging studies
- Heart catheterization
- Endomyocardial biopsy

Management

- Drug therapy
    - Nitrates (except in hypertrophic cardiomyopathy)
    - β-Blockers
    - Antidysrhythmics
    - ACE inhibitors
    - Diuretics
    - Digitalis (except in hypertrophic CMP unless used to treat atrial fibrillation)
    - Anticoagulants (if indicated)
- VAD
- Cardiac resynchronization therapy
- Implantable cardioverter-defibrillator
- Surgical repair
- Heart transplant
- Cardiac rehabilitation
- Palliative and hospice care

Diagnostic Studies

The diagnosis of dilated CMP is based on the patient's history and exclusion of other causes of HF. Doppler echocardiography is usually the basis for diagnosing dilated CMP. Echocardiography can assess EF. EF less than 20% is associated with a 50% mortality rate within 1 year. The chest x-ray may show cardiomegaly with signs of pulmonary venous hypertension and pleural effusion. The ECG may show tachycardia, bradycardia, and dysrhythmias with conduction problems. Laboratory studies may show increased b-type natriuretic peptide (BNP) levels if HF is present.

Heart catheterization confirms or rules out coronary artery disease. An endomyocardial biopsy done at the time of the right-sided heart catheterization will identify any infectious organisms or other causes of disease.

Interprofessional and Nursing Care

Interventions focus on controlling HF by enhancing heart contractility and decreasing preload and afterload. This is similar to the management of chronic HF. Treatment guidelines are based on the specific stage of disease progression (see Table 34.3). Treatment of patients with Class IV (stage D) HF is more palliative than curative.

Several different types of drugs are available to manage HF (see Table 34.7). Nitrates (e.g., nitroglycerin) and diuretics (e.g., furosemide) decrease preload. ACE inhibitors reduce afterload. β-Blockers (e.g., metoprolol [Lopressor]) and aldosterone antagonists (e.g., spironolactone [Aldactone]) control the neurohormonal stimulation that occurs in HF. Dysrhythmias are treated with the appropriate antidysrhythmic (see Chapter 35). Anticoagulation therapy reduces the risk for systemic embolization from clots that form in the heart chambers.

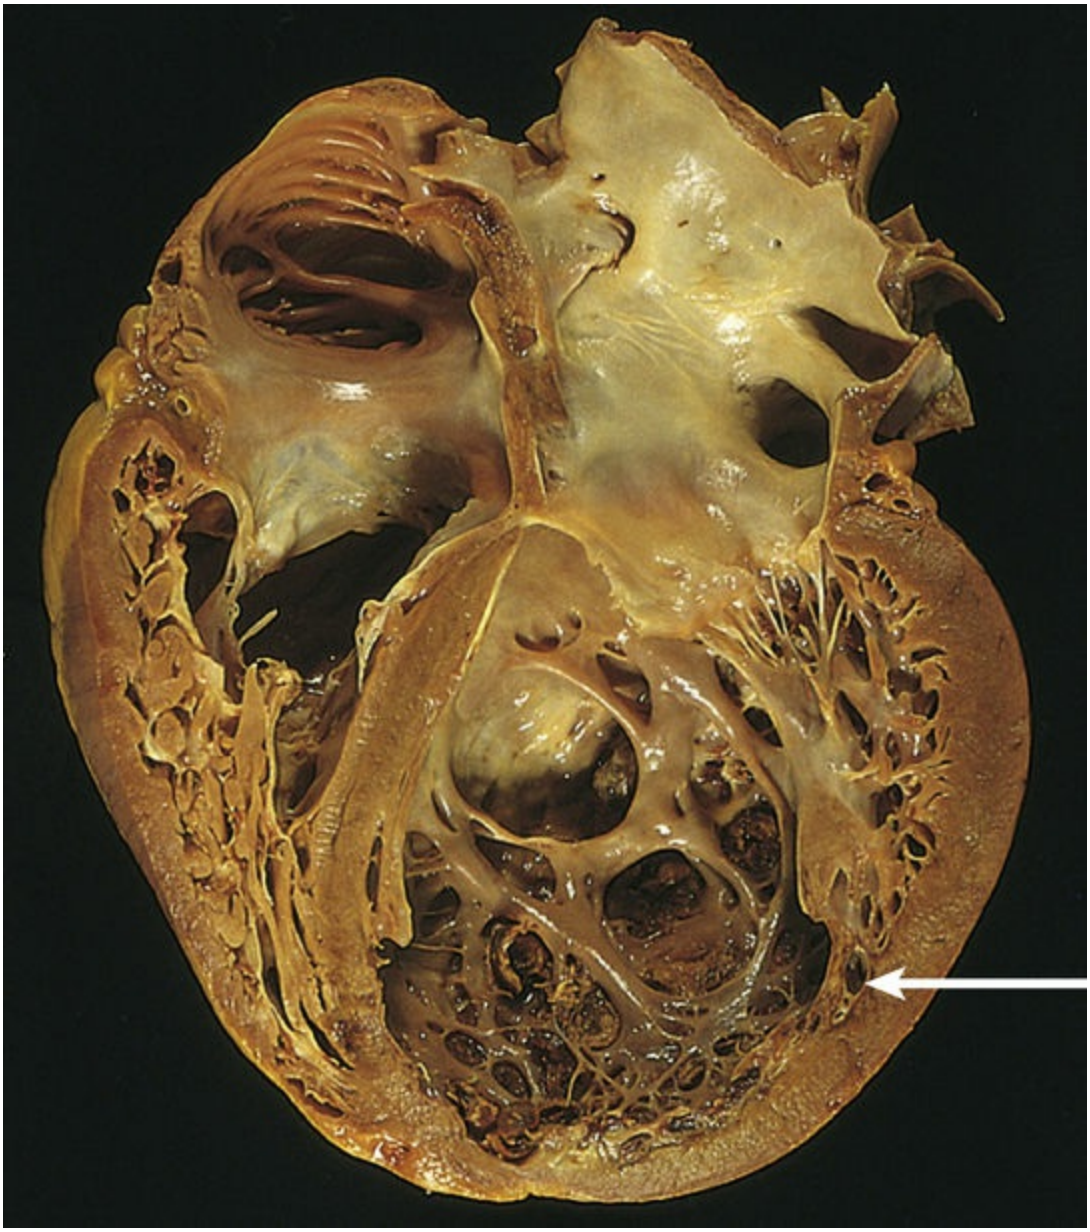

FIG. 36.12 Dilated cardiomyopathy. The dilated left ventricular wall has thinned *(arrow),* and the chamber size and volume are increased. From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Drug and nutritional therapy and cardiac rehabilitation may help (1) lessen symptoms of HF and (2) improve CO and quality of life. A patient with secondary dilated CMP is treated for the underlying disease process. For example, teach the patient with alcohol-related dilated CMP to abstain from alcohol. (See Chapter 10 for more on alcohol use.)

Unfortunately, dilated CMP does not respond well to therapy and patients have multiple episodes of HF. Patients may be hospitalized for infusions of dobutamine or milrinone, followed by aggressive diuresis. Sometimes these treatments are done in an outpatient setting or in the home under nursing supervision. After treatment, many patients see an improvement in symptoms for several weeks. Medical management is based on clinical guidelines for HF.[27] Statins may be helpful (see Table 33.6).

Patients may benefit from nondrug therapies. A VAD allows the heart to rest and recover from acute HF. It may also serve as a bridge to a heart transplant. Other options include cardiac resynchronization therapy and an implantable cardioverter-defibrillator (ICD) (see Chapter 34).

The patient with terminal or end-stage CMP may consider a heart transplant. A permanent, implantable VAD, known as *destination therapy*, is an option for patients with advanced disease who are not candidates for a heart transplant (see Chapter 34). Currently, about 50% of heart transplants are done to treat CMP. Heart transplant recipients have a good prognosis. However, donor hearts are hard to obtain, and many patients with dilated CMP die before receiving a heart.

Patients with dilated CMP are very ill and have a grave prognosis. Your expert nursing care is critical. Observe for signs and symptoms of worsening HF, dysrhythmias, embolus formation, and drug effectiveness. The goals of therapy are to keep the patient at an optimal level of functioning and out of the hospital. Always include caregivers when planning a patient's care. Encourage caregivers to learn cardiopulmonary resuscitation (CPR). Teach them when and how to access emergency care.

Home health and hospice nursing can provide the patient and caregiver with palliative care. This includes strategies to maximize and maintain functional status or end-of-life care to prepare for a peaceful death.

Hypertrophic Cardiomyopathy

Etiology and Pathophysiology

Hypertrophic cardiomyopathy is asymmetric left ventricular hypertrophy without ventricular dilation.[28] In one form of the disease, the septum between the 2 ventricles becomes enlarged and blocks the blood flow from the left ventricle. We call this *hypertrophic obstructive cardiomyopathy* (HOCMP) or *asymmetric septal hypertrophy* (ASH).

Hypertrophic CMP occurs less often than dilated CMP. It is more common in men than in women. It is usually diagnosed in young adults and, most often, in active, athletic persons. Hypertrophic CMP is the most common cause of SCD in otherwise healthy young people. It accounts for 3% of deaths in young competitive athletes.[29] There is a link between genetic mutations and HOCMP. MYH7 and MYBPC3 are the 2 most common genes involved. They are found in about 50% of cases of HOCMP.[29]

Early identification is important (Table 36.14). The 4 main characteristics of hypertrophic CMP are (1) massive ventricular hypertrophy; (2) rapid, forceful contraction of the left ventricle; (3) impaired relaxation (diastole); and (4) obstruction to aortic outflow (not present in all patients). Ventricular hypertrophy is associated with a thickened intraventricular septum and ventricular wall (Fig. 36.13). The result is poor filling of the stiff ventricle. Decreased ventricular filling and obstruction to outflow can result in decreased CO, especially during exertion.

Clinical Manifestations

Patients with hypertrophic CMP may be asymptomatic or may have exertional dyspnea, fatigue, angina, and syncope. The most common symptom is dyspnea caused by an elevated left ventricular diastolic pressure. Fatigue occurs because of the resulting decrease in CO and in exercise-induced flow obstruction. Angina can occur and is often caused by the increased left ventricular mass or compression of the small coronary arteries by the hypertrophic ventricular myocardium.

The patient may have syncope from obstruction to aortic outflow during increased activity. This results in decreased CO and cerebrovascular circulation. Syncope also can be caused by dysrhythmias, such as supraventricular tachycardia, atrial fibrillation, ventricular tachycardia, and ventricular fibrillation (see Chapter 35).

Diagnostic Studies

Clinical findings on examination may be unremarkable. On chest palpation the apical impulse can be exaggerated and displaced to the left. Auscultation may reveal an S_4 and a systolic murmur between the apex and sternal border at the fourth intercostal space. ECG findings usually show ventricular hypertrophy, ST-T wave abnormalities, prominent Q waves in the inferior or precordial leads, and dysrhythmias (see Chapter 35).

The echocardiogram is the main diagnostic tool used to confirm hypertrophic CMP. It may show wall motion abnormalities and diastolic dysfunction. Heart catheterization and nuclear stress testing may help diagnose and guide the treatment of hypertrophic CMP.

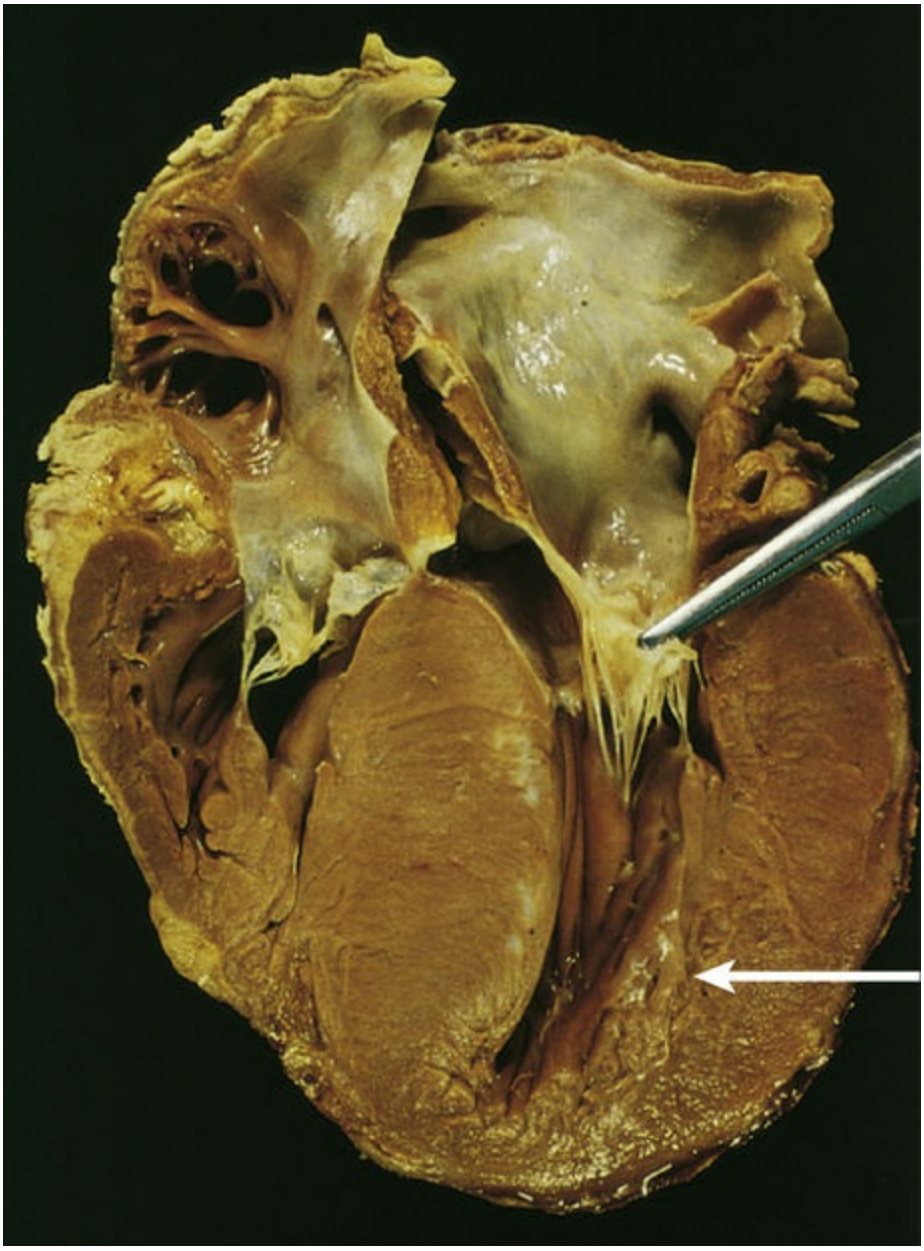

FIG. 36.13 Hypertrophic cardiomyopathy. There is marked left ventricular hypertrophy *(arrow),* with decreased chamber size and volume.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Interprofessional and Nursing Care

Goals of care are to improve ventricular filling by reducing ventricular contractility and relieving left ventricular outflow obstruction. These

can be achieved with β-blocker (e.g., metoprolol) or calcium channel blocker (e.g., verapamil) therapy. Digitalis is considered if needed to treat atrial fibrillation. Amiodarone or sotalol (Betapace) are effective antidysrhythmic drugs. However, their use does not prevent SCD. Patients at risk for SCD need a cardioverter-defibrillator (see Chapter 35).

AV pacing is helpful for patients with hypertrophic CMP and outflow obstruction. When the ventricles are paced from the apex of the right ventricle, septal depolarization occurs first. This allows the septum to move away from the left ventricular wall and reduces the degree of obstruction of the outflow tract.

Some patients with severe symptoms unresponsive to therapy may be candidates for surgical treatment of their hypertrophied septum. A *ventriculomyotomy and myectomy* involves cutting into the thickened septal muscle and removing some of the ventricular muscle. Most patients have an improvement in symptoms and exercise tolerance after surgery.

An alternative nonsurgical procedure to reduce symptoms and the left ventricular outflow obstruction is alcohol-induced *percutaneous transluminal septal myocardial ablation* (PTSMA). This procedure consists of injecting alcohol into the first septal artery branching off the left anterior descending artery to cause ischemia and septal wall infarction. Ablation of the septal wall decreases the obstruction to flow, and the patient's symptoms decrease. The procedure can improve HF symptoms and exercise capacity.[29] Potential complications of PTSMA include conduction problems (e.g., heart block) and MI.

Nursing interventions for hypertrophic CMP focus on relieving symptoms, observing for and preventing complications, and providing emotional support. Focus your teaching on helping patients plan to avoid strenuous activity and dehydration. Any activity that causes an increase in systemic vascular resistance (thus increasing the obstruction to forward flow) is dangerous. Rest and elevation of the feet to improve venous return to the heart can help manage chest pain. Vasodilators, such as nitroglycerin, may worsen the chest pain

by decreasing venous return and further increasing obstruction of blood flow from the heart.

Restrictive Cardiomyopathy

Etiology and Pathophysiology

Restrictive cardiomyopathy is the least common type of CMP. It is a disease of the myocardium that impairs diastolic filling and stretch. Systolic function stays unchanged. Although the specific cause of restrictive CMP is unknown, several pathologic processes may be involved in its development. Myocardial fibrosis, hypertrophy, and infiltration produce stiffness of the ventricular wall with loss of ventricular compliance. Secondary causes of restrictive CMP include amyloidosis, endocardial fibrosis, sarcoidosis, and radiation to the thorax. With restrictive CMP, the ventricles are resistant to filling and demand high diastolic filling pressures to maintain CO.

Clinical Manifestations and Diagnostic Studies

Classic manifestations of restrictive CMP are fatigue, exercise intolerance, and dyspnea. These occur because the heart cannot increase CO by increasing the HR without further compromising ventricular filling. Other symptoms may include angina, orthopnea, syncope, and palpitations. The patient may have signs of HF, including dyspnea, peripheral edema, weight gain, ascites, hepatomegaly, and JVD.

The chest x-ray may be normal, or it may show cardiomegaly from atrial enlargement. Pleural effusions and pulmonary congestion may occur as the patient progresses to HF. The ECG may show mild tachycardia at rest. The most common dysrhythmias are supraventricular (atrial fibrillation) or AV block. Echocardiography may show a left ventricle that is normal size with a thickened wall, slightly dilated right ventricle, and dilated atria. Endomyocardial biopsy, CT scan, and nuclear imaging may help in the diagnosis.

Interprofessional and Nursing Care

There is no specific treatment for restrictive CMP. Interventions are aimed at improving diastolic filling and the underlying disease process. Treatment includes conventional therapy for HF and dysrhythmias. Heart transplant may be an option. Nursing care is similar to the care of a patient with HF. As in the treatment of patients with hypertrophic CMP, teach the patient to avoid situations that impair ventricular filling and increase systemic vascular resistance, such as strenuous activity and dehydration.

Nursing care of a patient with CMP includes individualized teaching based on the patient's manifestations. All patients with CMP are at risk for IE from any procedure that may cause bacteremia. Teach the patient about the need for prophylactic antibiotics (Table 36.2). A guide for patient and caregiver teaching is outlined in Table 36.17.

TABLE 36.17 Patient & Caregiver TeachingCardiomyopathy

Include the following information in the teaching plan for a patient with cardiomyopathy and the patient's caregiver.

1. Take all drugs as prescribed and regularly follow up with HCP.
2. Follow a low-sodium diet (if prescribed) and read all product labels (food and over-the-counter drugs) for sodium content.
3. Drink 6 to 8 glasses of water a day unless fluids are restricted.
4. Achieve and maintain a reasonable weight and avoid large meals.
5. Avoid alcohol, caffeine, diet pills, and over-the-counter cold medicines that may contain stimulants.
6. Balance activity and rest periods.
7. Avoid heavy lifting or vigorous isometric exercises and check with HCP for exercise guidelines.

8. Use stress management techniques: relaxation breathing, guided imagery.
9. Report any signs of HF to HCP, including weight gain, edema, shortness of breath, and increased fatigue.
10. Encourage caregivers to learn CPR because of the potential for cardiac arrest (see Appendix A).
11. Access emergency response system (ERS) according to the HCP's instructions.

Case Study

Valvular Heart Disease

© JennaDub/iStock/Thinkstock.

Patient Profile

R.B., a 50-yr-old white man, is admitted to the hospital for acute decompensated HF due to valvular heart disease.

Subjective Data

- History of IV drug use
- Reports current regular alcohol intake of 1 pint of whiskey per day
- States, “I’m short of breath all the time. I can’t sleep when I lay down.”
- Describes chest pain with minimal exertion
- Recently unemployed
- States, “I’m always tired.”
- States, “The drugs are too expensive. I can’t afford them.”
- Smokes a pack of cigarettes a day for past 35 years

Objective Data
Physical Examination

- Third heart sound (S_3)
- Loud holosystolic murmur of mitral regurgitation
- Missing all teeth from periodontal disease
- Vital signs: temperature 99.0° F (37.2° C); apical-radial pulse equal at 110 beats/min, irregular; respirations 24; BP 104/58

Diagnostic Studies

- ECG shows atrial fibrillation with a rapid ventricular response
- Chest x-ray shows pulmonary congestion and cardiomegaly
- Transesophageal echocardiography shows left atrial and ventricular hypertrophy and mitral and aortic regurgitation. EF 30%

Discussion Questions

1. Identify the cause and course of R.B.'s disease based on his history and current examination.
2. Distinguish between mitral and aortic regurgitation.
3. What medical treatments or surgical procedures will R.B. probably need as his condition worsens?
4. ***Priority Decision:*** Identify the priority nursing interventions for R.B.
5. ***Safety:*** What safety precautions should be initiated for R.B.?
6. ***Collaboration:*** Identify the tasks that you could delegate to unlicensed assistive personnel (UAP).
7. ***Evidence-Based Practice:*** R.B. asks you why he needs to be on "blood thinners" after his valves are replaced. How would you respond?

Answers are available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which signs and symptoms should the nurse expect to find when assessing a patient with infective endocarditis who uses IV cocaine? *(select all that apply)*
   a. Retinal hemorrhages
   b. Splinter hemorrhages
   c. Presence of Osler's nodes
   d. Painless nodules over bony prominences
   e. Erythematous macules on the palms and soles
2. *Priority* nursing management for a patient with

myocarditis includes interventions related to

a. meticulous skin care.

b. antibiotic prophylaxis.

c. tight glycemic control.

d. oxygenation and ventilation.

3. When teaching a patient about the long-term consequences of rheumatic fever, the nurse should discuss the possibility of

a. valvular heart disease.

b. pulmonary hypertension.

c. superior vena cava syndrome.

d. hypertrophy of the right ventricle.

4. Which is a *priority* nursing intervention for a patient during the acute phase of rheumatic fever?

a. Giving IV antibiotics as prescribed

b. Managing pain with opioid analgesics

c. Encouraging fluid intake for hydration

d. Performing frequent active range-of-motion exercises

5. A patient is diagnosed with mitral stenosis and new-onset atrial fibrillation. Which interventions could the nurse delegate to unlicensed assistive personnel (UAP)? *(select all that apply)*

a. Obtain and record daily weight.

b. Determine apical-radial pulse rate.

c. Observe for overt signs of bleeding.

d. Teach the patient how to get a Medic Alert device.

e. Obtain and record vital signs, including pulse oximetry.

6. The nurse is caring for a patient newly admitted with heart failure secondary to dilated cardiomyopathy. Which intervention would be a *priority*?

   a. Encourage caregivers to learn CPR.

   b. Consider a consultation with hospice for palliative care.

   c. Monitor the patient's response to prescribed medications.

   d. Arrange for the patient to enter a cardiac rehabilitation program.

1. a, b, c, e, 2. d, 3.a, 4. a, 5. a, c, e, 6. c

LEARNING OUTCOMES

1. Relate the etiology and pathophysiology of peripheral artery disease (PAD) to the major risk factors.
2. Describe the clinical manifestations and interprofessional and nursing management of the patient with PAD of the lower extremities.
3. Plan appropriate nursing and interprofessional management for the patient with acute arterial ischemic disorders of the lower extremities.
4. Distinguish the pathophysiology, clinical manifestations, and nursing and interprofessional management of the patient with thromboangiitis obliterans (Buerger's disease) and Raynaud's phenomenon.
5. Distinguish the pathophysiology, clinical manifestations, and interprofessional and nursing management of patients with different types of aortic aneurysms.
6. Select appropriate nursing interventions for a patient undergoing an aortic aneurysm repair.
7. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with aortic dissection.
8. Evaluate the risk factors predisposing patients to develop

superficial vein thrombosis or venous thromboembolism (VTE).

9. Distinguish between the clinical characteristics of superficial vein thrombosis and VTE.
10. Outline the interprofessional and nursing management of patients with superficial vein thrombosis and VTE.
11. Prioritize the key aspects of nursing management for the patient receiving anticoagulant therapy.
12. Relate the pathophysiology and clinical manifestations to the interprofessional care of patients with varicose veins, chronic venous insufficiency, and venous leg ulcers.

Conceptual Focus

Clotting
Glucose Regulation
Perfusion
Tissue Integrity

Problems of the vascular system include disorders of the arteries, veins, and lymphatic vessels. These problems can result in decreased perfusion to the peripheral tissues, causing ischemia. Patients often have pain and difficulties with mobility and taking part in activities of daily living. Education is a key part of management. Proper nutrition, smoking cessation, and exercise are important health promotion behaviors. Following measures to promote safety, especially for those on anticoagulant therapy, is critical.

We classify arterial disorders as atherosclerotic, aneurysmal, and nonatherosclerotic vascular diseases. Atherosclerotic vascular disease is divided into coronary, cerebral, peripheral, mesenteric, and renal artery disease.[1] This chapter discusses peripheral artery disease, aortic aneurysm and dissection, and venous diseases.

Peripheral Artery Disease

Peripheral artery disease (PAD) involves thickening of artery walls. This results in a progressive narrowing of the arteries of the upper and lower extremities. PAD prevalence increases with age. It typically becomes symptomatic between ages 50 and 70 years. In people with diabetes, PAD occurs earlier. In the United States, about 8.5 million

people over age 40 have PAD, with higher prevalence in blacks.[2,3]

PAD is strongly related to other types of cardiovascular disease (CVD) and their risk factors. Patients with PAD have a significantly higher risk for mortality (in general), CVD mortality, major coronary events, and stroke.[3] PAD is a marker of advanced systemic atherosclerosis. Patients with PAD are more likely to have coronary artery disease (CAD) and/or cerebral artery disease.

Unfortunately, many people in the United States are unaware of PAD and its risk factors. PAD remains underdiagnosed and undertreated.

Etiology and Pathophysiology

The leading cause of PAD is *atherosclerosis*, a gradual thickening of the *intima* (the innermost layer of the arterial wall) and *media* (middle layer of the arterial wall). This results from cholesterol and lipids deposited within the vessel walls and leads to narrowing of the artery (see Fig. 33.1). Although the exact cause of atherosclerosis is unknown, inflammation and endothelial injury play a major role (see Chapter 33). Atherosclerosis often affects certain segments of the arterial tree. These include the coronary, carotid (see Chapter 57), and lower extremity arteries.

Other risk factors for PAD are similar, but not identical, to those for CAD. Important risk factors for PAD are tobacco use (most important), diabetes, hypertension, high cholesterol, and age over 60.[2] The presence of multiple risk factors dramatically increases the risk for PAD, especially in blacks.[2] Symptoms occur when vessels are 60% to 75% blocked.

Gender Differences

Vascular Disorders

Men

- Thromboangiitis obliterans (Buerger's disease) occurs most often in men younger than 40 yrs of age.
- Abdominal aortic aneurysms (AAAs) and aortic dissections are more common in men.
- Men with AAAs are more likely to undergo endovascular aneurysm repair or open aneurysm repair than women.
- Sexual dysfunction in male patients is common after aortic surgery.

Women

- Women with PAD have poorer physical and social functioning and higher rates of depression than men with PAD.[4]
- Women with PAD have faster functional decline and greater mobility loss than men with PAD.
- Raynaud's phenomenon occurs primarily in women between 15 and 40 yrs of age.
- Risk for venous thromboembolism (VTE) is greater in women over age 35 who use tobacco and oral contraceptives or oral hormone therapy, are pregnant or postpartum, or have a family history of VTE.
- Primary varicose veins are more common and more symptomatic in women than men.
- Risk for varicose veins is greater in multiparous women.
- Women with AAAs are at higher risk for rupture.
- In-hospital mortality is higher in women undergoing revascularization than men, regardless of disease severity or procedure done.
- Women, particularly black and Hispanic women, have more graft thrombosis and amputation after lower extremity bypass surgery than men.

Peripheral Artery Disease of The Lower Extremities

Lower extremity PAD may affect the iliac, femoral, popliteal, tibial, or peroneal arteries, or any combination of these arteries (Fig. 37.1). The femoral popliteal area is the most common site in nondiabetic patients. Patients with diabetes tend to develop PAD in the arteries below the knee. Those with advanced PAD often have multiple arterial occlusions.

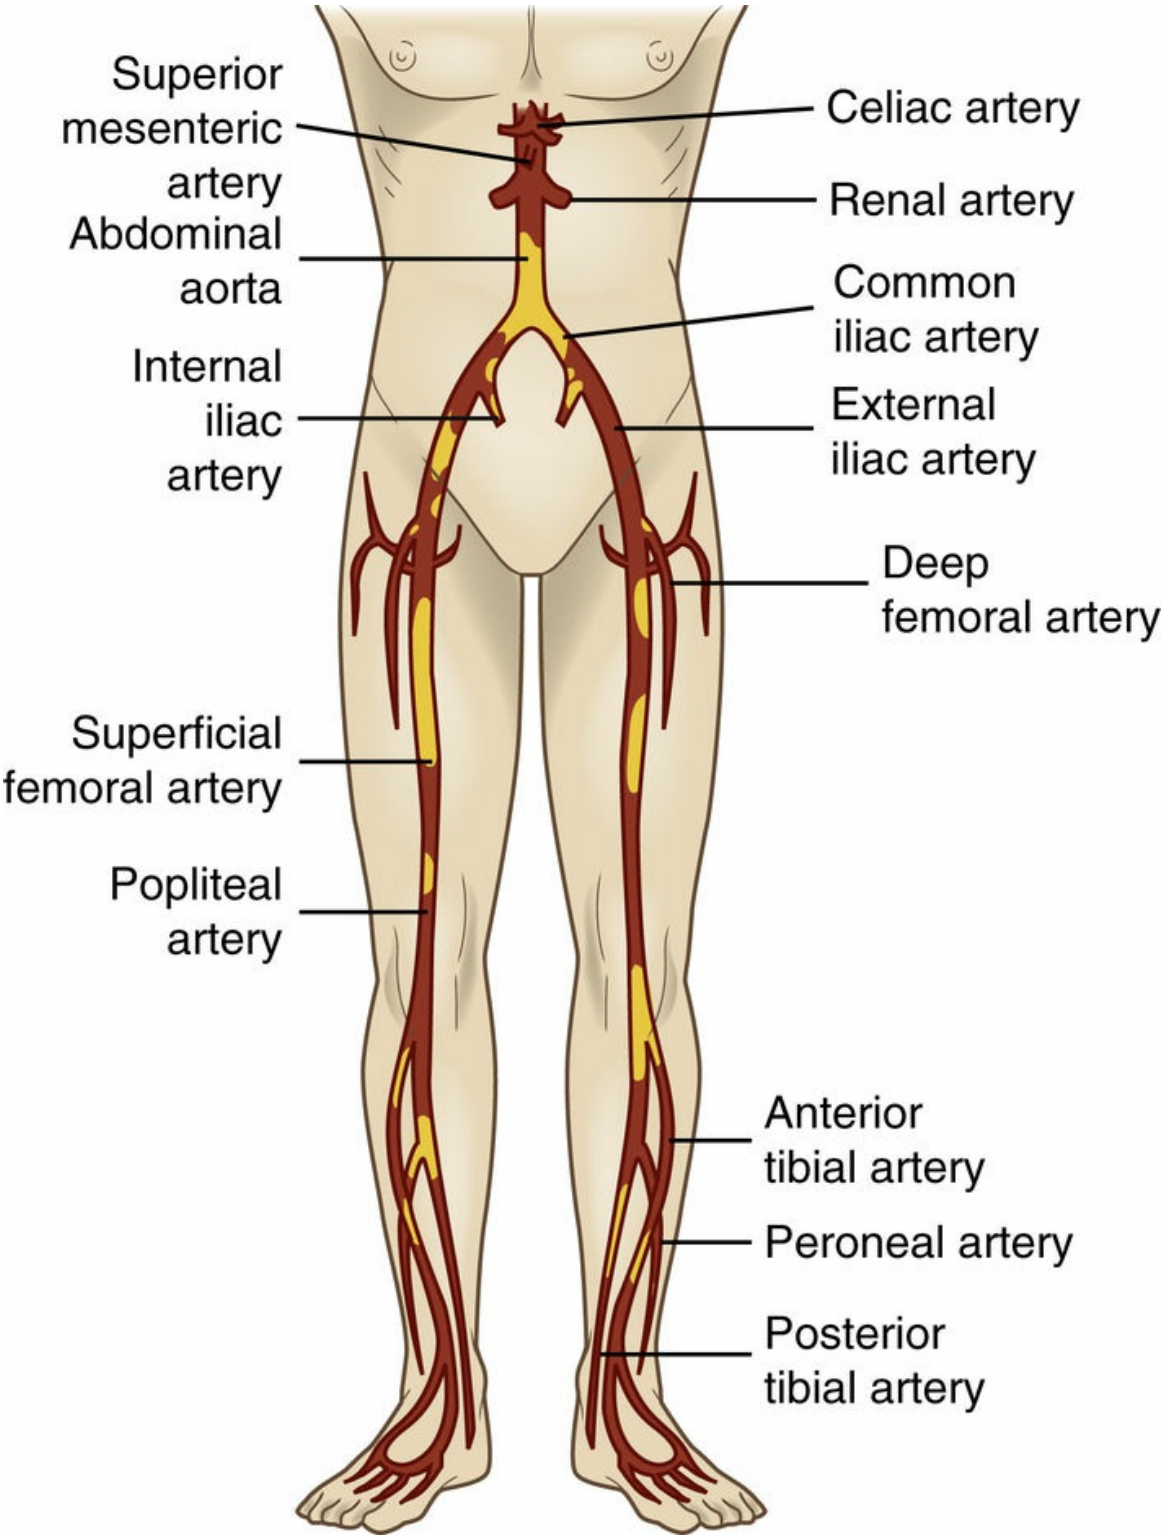

FIG. 37.1 Common anatomic locations of atherosclerotic lesions (shown in *yellow*) of the abdominal aorta and lower extremities.

Clinical Manifestations

The severity of PAD symptoms depends on the site and extent of the blockage and the amount of collateral circulation. The classic symptom of lower extremity PAD is **intermittent claudication**. This ischemic muscle pain is caused by exercise, resolves within 10 minutes or less with rest, and is reproducible. The ischemic pain is due to the buildup of lactic acid from anaerobic metabolism. Once the patient stops exercising, the lactic acid clears, and the pain subsides. PAD of the iliac arteries causes claudication in the buttocks and thighs. Calf pain indicates femoral or popliteal artery involvement.

As many as one third of patients with PAD report classic symptoms. Others have no symptoms or present with atypical leg symptoms (e.g., burning, heaviness, pressure, soreness, tightness, weakness) in atypical locations (e.g., ankle, foot, hamstring, hip, knee, shin). PAD involving the internal iliac arteries may result in erectile dysfunction.

Paresthesia (numbness or tingling) in the toes or feet may result from nerve tissue ischemia. True peripheral neuropathy occurs more often in patients with diabetes (see Chapter 48) and in those with long-standing ischemia. Neuropathy causes severe shooting or burning pain in the extremity. It does not follow particular nerve roots and may be present near ulcerated areas. Gradual, reduced blood flow to neurons causes loss of pressure and deep pain sensations. So, patients may not notice lower extremity injuries.

The limb's appearance gives vital information about reduced blood flow. The skin becomes thin, shiny, and taut. The lower legs lose their hair. Pedal, popliteal, or femoral pulses are decreased or absent. Pallor (blanching of the foot) develops when the leg is elevated *(elevation pallor).* Conversely, *reactive hyperemia* (redness of the foot) develops when the limb is in a dependent position *(dependent rubor)* (Table 37.1).

TABLE 37.1 Comparison of Peripheral Artery and Venous Disease

Characteristic	Peripheral Artery Disease	Venous Disease
Ankle-brachial index	≤0.90	>0.90
Capillary refill	>3 sec	<3 sec
Dermatitis	Rarely occurs	Often occurs
Edema	Absent unless leg constantly in dependent position	Lower leg edema
Hair	Loss of hair on legs, feet, toes	Hair may be present or absent
Nails	Thickened, brittle	Normal or thickened
Pain	Intermittent claudication or rest pain in foot Ulcer may or may not be painful	Dull ache or heaviness in calf or thigh Ulcer often painful
Peripheral pulses	Decreased or absent	Present, may be hard to palpate with edema
Pruritus	Rarely occurs	Often occurs
Skin color	Dependent rubor, elevation pallor	Bronze-brown pigmentation Varicose veins may be visible
Skin temperature	Cool, temperature gradient down the leg	Warm, no temperature gradient
Skin texture	Thin, shiny, taut	Skin thick, hardened, and indurated
Ulcer		
• Location	Tips of toes, foot, or lateral malleolus	Near medial malleolus
• Margin	Rounded, smooth, looks "punched out"	Irregularly shaped
• Drainage	Minimal	Moderate to large amount
• Tissue	Black eschar or pale pink granulation	Yellow slough or dark red, "ruddy" granulation

As PAD progresses and involves multiple arterial segments, continuous pain develops at rest. *Rest pain* most often occurs in the foot or toes. It is worse with limb elevation. Rest pain occurs when blood flow is insufficient to meet basic metabolic requirements of the distal tissues. Rest pain occurs more often at night because cardiac output tends to drop during sleep and the limbs are at the level of the heart. Patients often try to achieve pain relief by gravity, dangling the leg over the side of the bed or sleeping in a chair.

Critical limb ischemia (CLI) is a condition characterized by chronic ischemic rest pain lasting more than 2 weeks, nonhealing arterial leg ulcers, or gangrene of the leg from PAD. Patients with PAD who have diabetes, heart failure (HF), and a history of a stroke are at increased risk for CLI.[3]

Complications

Lower extremity PAD progresses slowly. Prolonged ischemia leads to atrophy of the skin and underlying muscles. Minor trauma to the feet (e.g., stubbing one's toe, blister from shoes) can result in delayed healing, wound infection, and tissue necrosis, especially in the patient

with diabetes. Arterial (ischemic) ulcers most often occur over bony prominences on the toes, feet, and lower legs (Table 37.1). Nonhealing arterial ulcers and gangrene are the most serious complications. If PAD develops over an extended period, collateral circulation may prevent gangrene.

TABLE 37.2 Interprofessional CarePeripheral Artery Disease

Diagnostic Assessment

- Health history and physical examination, including palpation of peripheral pulses
- Doppler ultrasound studies
- Segmental BPs
- ABI (Table 37.3)
- Duplex imaging
- Angiography
- Magnetic resonance angiography

Management

- CVD risk factor modification
    - Tobacco cessation
    - Regular physical exercise
    - Achieve or maintain ideal body weight
    - Follow Dietary Approaches to Stop Hypertension (DASH) diet
    - Tight glucose control with diabetes, including Hb A1C monitoring
    - Tight BP control
    - Treatment of hyperlipidemia and hypertriglyceridemia

(see Table 33.6)
    - Antiplatelet agent (aspirin, clopidogrel [Plavix])
    - ACE inhibitors (see Table 32.6)
- Treatment of claudication symptoms
    - Structured walking or exercise program
    - Cilostazol or pentoxifylline
- Nutritional therapy
- Physical/occupational therapy
- Proper foot care (see Table 48.21)

Surgical Therapy

- Percutaneous transluminal balloon angioplasty with or without stent
- Percutaneous transluminal atherectomy
- Percutaneous transluminal cryoplasty
- Peripheral artery bypass surgery
- Patch graft angioplasty, often in conjunction with bypass surgery
- Endarterectomy (for localized stenosis; rarely done as a stand-alone procedure)
- Thrombolytic therapy or mechanical clot extraction therapy (for acute ischemia only)
- Sympathectomy (for pain management only)
- Amputation

Amputation may be needed if adequate blood flow is not restored or if severe infection occurs. Uncontrolled pain and severe, spreading infection are indicators for amputation in people who are not candidates for revascularization.

Diagnostic Studies

Various tests assess blood flow and the vascular system (Table 37.2). Doppler ultrasound with duplex imaging maps blood flow throughout the entire region of an artery. When palpating a peripheral pulse is hard because of severe PAD, Doppler ultrasound can determine the degree of blood flow. A palpable pulse and a Doppler pulse are not equivalent, and the terms are not interchangeable.

Segmental BPs are obtained using Doppler ultrasound and a sphygmomanometer at the thigh, below the knee, and at ankle level while the patient is supine. A drop in segmental BP of greater than 30 mm Hg suggests PAD. Angiography and magnetic resonance angiography show the location and extent of PAD (see Table 31.7).

The *ankle-brachial index* (ABI) is a PAD screening tool. It is done using a hand-held Doppler. The ABI is calculated by dividing the ankle systolic BPs (SBPs) by the higher of the left and right brachial SBPs. PAD guidelines recommend uniform reporting of ABI results (Table 37.3).[3] Calcified and stiff arteries in older patients and those with diabetes often show a falsely elevated ABI.

TABLE 37.3 Interpreting Ankle-Brachial Index Results

Ankle-Brachial Index (ABI)	Clinical Significance
>1.30	Noncompressible arteries
1.00–1.30	Normal ABI
0.91–0.99	Borderline ABI
≤0.90	Abnormal ABI
Classification of PAD Severity	
0.90–0.71	Mild PAD
0.70–0.41	Moderate PAD
≤0.40	Severe PAD

Interprofessional Care

Table 37.2 outlines the interprofessional care for a patient with PAD.

Risk Factor Modification

The first treatment goal for patients with PAD is to reduce CVD risk factors regardless of the severity of symptoms. Encourage risk factor modification with both drug therapy and lifestyle changes (see Tables 33.2 to 33.5). Hypertension is another well-known risk factor for PAD progression. Encourage reducing dietary sodium and following the Dietary Approaches to Stop Hypertension (DASH) diet. Chapter 32 discusses hypertension.

Tobacco cessation is essential to reduce the risk for CVD events, PAD progression, and death. This is a complex, difficult process with a high incidence of relapse. Suggest comprehensive tobacco cessation strategies (see Tables 10.3 to 10.6).

Diabetes is a major risk factor for PAD and increases the risk for amputation. Patients with diabetes should maintain a glycosylated hemoglobin (A1C) below 7.0% and, optimally, as near as possible to 6.0%.[5] Chapter 48 discusses diabetes.

Support aggressive lipid management for all patients with PAD. Both dietary interventions and drug therapy are needed. Statins (e.g., simvastatin [Zocor]) and a fibric acid derivative (gemfibrozil [Lopid]) may be used (see Table 33.6).

Drug Therapy

Angiotensin-converting enzyme (ACE) inhibitors (e.g., ramipril [Altace]) can reduce PAD symptoms. Antiplatelet agents are critical for reducing the risks for CVD events and death. Oral antiplatelet therapy should include low-dose aspirin therapy. Aspirin-intolerant patients may take clopidogrel (Plavix) daily. Combination antiplatelet therapy with aspirin and clopidogrel may be used by select high-risk patients. Anticoagulants (e.g., warfarin [Coumadin]) are not recommended for prevention of CVD events in patients with PAD.

Drug Alert

Clopidogrel (Plavix) and Omeprazole (Prilosec)

- Antiplatelet effect of clopidogrel is reduced by about half when given with omeprazole.
- This reduced effect increases the risk for myocardial infarction (MI) and stroke.

Two drugs are available to treat intermittent claudication: cilostazol and pentoxifylline. Cilostazol, a phosphodiesterase inhibitor, inhibits platelet aggregation and increases vasodilation. Pentoxifylline, a xanthine derivative, improves the flexibility of RBCs and WBCs and decreases fibrinogen concentration, platelet adhesiveness, and blood viscosity. It is not as effective as cilostazol. Cilostazol is usually stopped within 3 months due to side effects.[3]

Drug Alert

Cilostazol

- Contraindicated in patients with HF.

Exercise Therapy

A supervised exercise program is recommended as part of the initial treatment for all patients with intermittent claudication. Exercise should be done for 30 to 45 min/day, at least 3 times/week, for a minimum of 3 months. Although walking is most commonly prescribed, other modes of exercise (e.g., cycling) improve walking ability and quality of life.[3]

Encouraging taking part in exercise is particularly important for women with PAD. Women have faster functional decline and greater mobility loss than men with PAD. Overall, patients with PAD who have higher levels of daily physical activity have better survival

rates.[3,4]

Nutritional Therapy

Teach patients with PAD to maintain a body mass index (BMI) less than 25 kg/m^2 and a waist circumference less than 40 inches for men and less than 35 inches for women. Even modest, sustained weight loss of 3% to 5% yields important reductions in triglycerides, glucose, A1C, and the risk for developing type 2 diabetes. Greater weight loss has greater benefits.[5] Recommend a diet reduced in calories and salt for obese or overweight persons.[5]

Complementary and Alternative Therapies

Patients taking antiplatelet agents, nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., ibuprofen), and anticoagulants (e.g., warfarin) should consult with their HCP before taking any dietary or herbal supplements because of potential interactions and bleeding risks.[6,7] See the Complementary & Alternative Therapies box on p. 818.

Care of the Leg With Critical Limb Ischemia

Optimal therapy for the patient with CLI is revascularization via bypass surgery using an *autogenous* (native) vein. An alternative is percutaneous transluminal angioplasty (PTA).[3,8] Patients with CLI who are not candidates for surgery or PTA may receive IV prostanoids (e.g., iloprost [Ventavis]). However, the FDA has not approved this drug for CLI treatment.[3,8] Patients with CLI should continue optimal drug therapy (e.g., statin, antiplatelet, ACE inhibitor, β-blocker) to reduce the risk for a CVD event.

Conservative management includes protecting the extremity from trauma, decreasing ischemic pain, preventing and controlling infection, and improving perfusion. Carefully inspect, cleanse, and lubricate feet to prevent skin cracking and infection. Avoid lubrication between the toes and soaking the patient's feet to prevent skin *maceration* (or breakdown). Keep the affected foot clean and dry. Cover any ulcers with a dry, sterile dressing. Deep ulcers are treated

with a variety of wound care products. Healing is unlikely without increasing the blood flow.

Encourage the patient to wear soft, roomy, and protective footwear and avoid extremes of heat and cold. Keep the patient's heels free of pressure. Place a pillow under the calves so that the heels are off the mattress or use a commercially available heel protection device. Giving analgesics and placing the bed in the reverse Trendelenburg position may control pain and increase perfusion to the lower extremities.

Spinal cord stimulation may help manage pain for patients with CLI. Other promising strategies include growth factors and gene and stem cell therapy to stimulate blood vessel growth *(angiogenesis).* Unfortunately, almost half of the patients with CLI will die within 5 years.[8]

Interventional Radiology Catheter-Based Procedures

Interventional radiology catheter-based procedures are alternatives to open surgery for treatment of lower extremity PAD. These procedures take place in a catheterization laboratory rather than in an operating room.

All these procedures are similar to angiography in that they involve the insertion of a specialized catheter into the femoral artery. The PTA procedure uses a catheter that has a balloon at the tip. The end of the catheter is moved to the narrowed (stenotic) area of the artery. The balloon is then inflated, compressing the atherosclerotic intimal lining.[3]

Stents, expandable metallic devices, are placed within the artery after the balloon angioplasty. The stent holds the artery open. Angioplasty balloons and peripheral stents may be coated with a drug (e.g., paclitaxel) to limit the growth of new tissue in the treated area and improve long-term patency rates.[3,9]

Atherectomy is the removal of the obstructing plaque. A directional atherectomy device uses a high-speed cutting disk that cuts long strips of the atheroma. Laser atherectomy uses ultraviolet energy to break up the atheroma. Other types of atherectomy catheters have a

diamond-coated tip that rotates at a high speed (like a dental drill).

Cryoplasty combines PTA and cold therapy. A specialized balloon is filled with liquid nitrous oxide, which changes to gas as it enters the balloon. Expansion of the gas results in cooling to 14° F (−10° C). The cold temperature limits restenosis by reducing smooth muscle cell activity.

Nursing care is the same as for diagnostic angiography (see Tables 31.7 and 31.8). Antiplatelet agents are needed postprocedure to reduce the risk for restenosis. Long-term, low-dose aspirin therapy or clopidogrel is recommended.

Surgical Therapy

Various surgical approaches can be used to improve blood flow beyond a blocked artery. When possible, peripheral artery bypass surgery is done with an autogenous vein to bypass (carry blood around) the lesion (Fig. 37.2). Synthetic grafts are used for long routes, such as an axillary-femoral bypass. When a person's own vein is not available, human umbilical vein or a composite sequential bypass graft (native vein plus synthetic graft) can be used.[3] PTA with stenting also may be done in combination with bypass surgery.

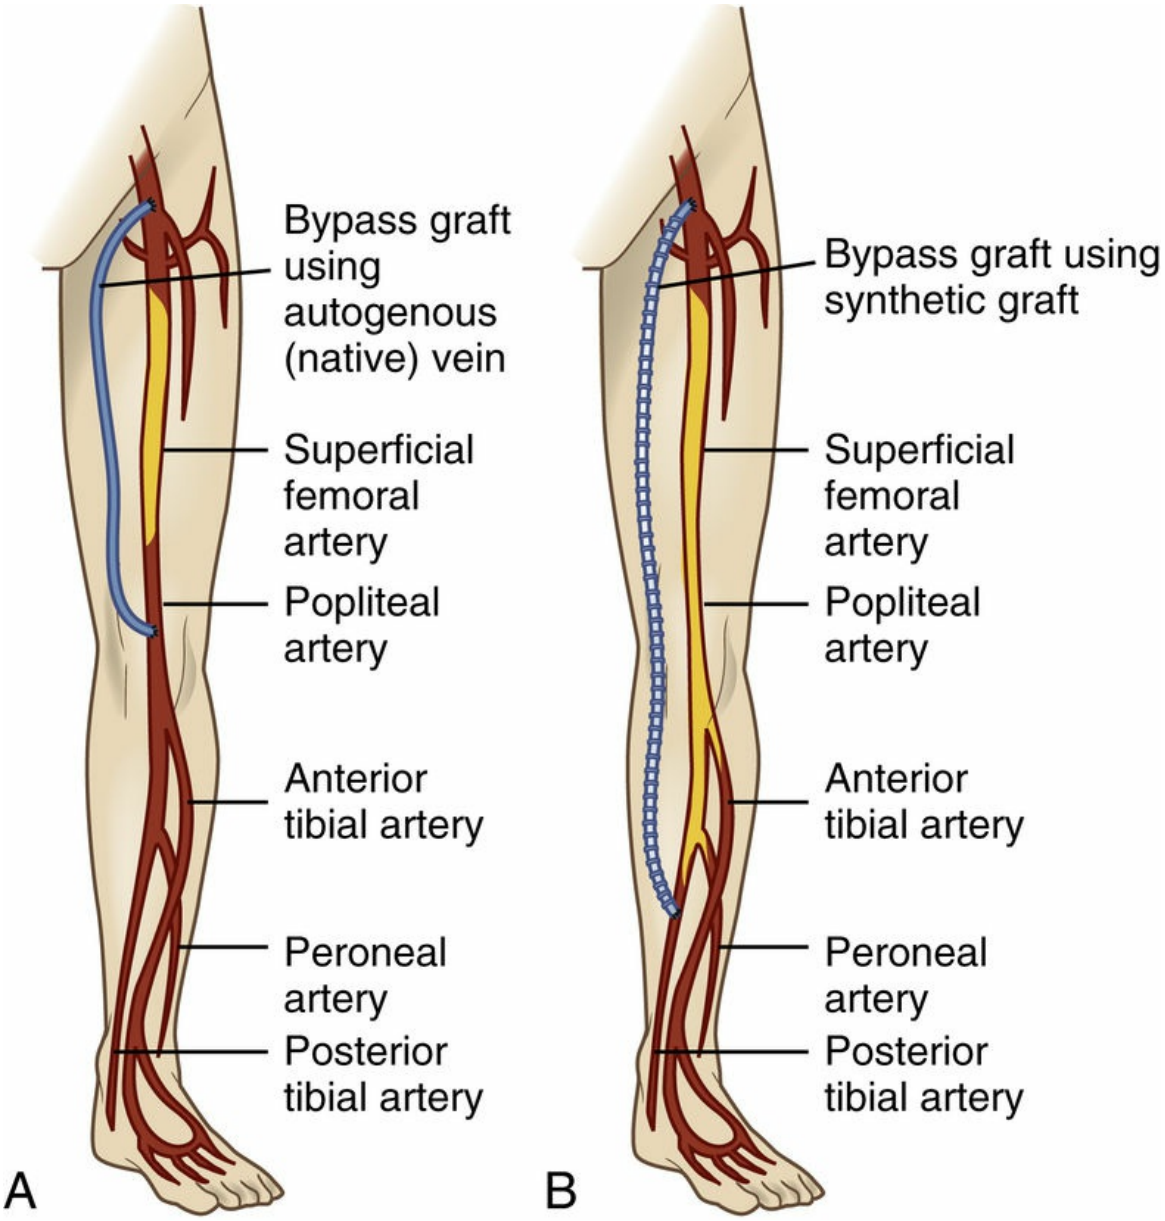

FIG. 37.2 **A,** Femoral-popliteal bypass graft around an occluded superficial femoral artery. **B,** Femoral–posterior tibial bypass graft around occluded superficial femoral, popliteal, and proximal tibial arteries.

Other surgical options include *endarterectomy* (opening the artery and removing the obstructing plaque) and *patch graft angioplasty* (opening the artery, removing plaque, and sewing a patch to the opening to widen the lumen). In-hospital mortality is higher in women undergoing revascularization than men, regardless of disease severity or procedure done.[4]

Amputation may be needed if tissue necrosis is extensive, gangrene or osteomyelitis develops, or all major arteries in the limb are blocked. We make every effort to preserve as much of the limb as possible to improve rehabilitation potential. Amputation is discussed in Chapter 62.

Nursing Management: Lower Extremity Peripheral Artery Disease

Nursing Assessment

Table 37.4 presents subjective and objective data that you should obtain from a patient with PAD.

Nursing Diagnoses

Nursing diagnoses for the patient with PAD may include:

- Ineffective tissue perfusion
- Activity intolerance

Additional information on nursing diagnoses and interventions for the patient with PAD of the lower extremities is presented in eNursing Care Plan 37.1 on the website for this chapter.

Planning

Nursing care focuses on the priority problems of poor tissue perfusion and pain. The overall goals for the patient who has lower extremity PAD include (1) adequate tissue perfusion; (2) relief of pain; (3) increased exercise tolerance; (4) intact, healthy skin on the extremities; and (5) increased knowledge of disease and treatment plan.

Nursing Implementation

Health Promotion

Assess the patient for and provide instructions on how to control CVD risk factors (see Table 33.2). Teach diet modification to reduce cholesterol, saturated fat, and refined sugars (see Tables 33.4 and 33.5). Teach proper foot care and injury prevention. Encourage patients with positive family histories of cardiac, diabetes, or vascular disease to obtain regular follow-up care.

Acute Care

After surgical or radiologic intervention, observe the patient in a recovery area. Check the operative extremity every 15 minutes initially and then hourly for color, temperature, capillary refill, presence of peripheral pulses, and sensation and movement. Immediately notify the HCP of any loss of palpable pulses or change in the Doppler sound over a pulse. Postoperative ABI measurements are not obtained as they place the patient at risk for graft thrombosis. Compare assessment findings with the patient's baseline and with findings in the opposite limb.

PAD patients with a history of chronic ischemic rest pain may have developed a tolerance to opioids. Thus aggressive pain management may be needed after surgery.

After the patient leaves the recovery area, continue to monitor extremity perfusion. Assess for complications, such as bleeding, hematoma, thrombosis, embolization, and compartment syndrome. A dramatic increase in pain, loss of previously palpable pulses, extremity pallor or cyanosis, numbness or tingling, or a cold extremity suggests graft or stent blockage. Report these findings to the HCP at once.

TABLE 37.4 Nursing AssessmentPeripheral Artery Disease

Subjective Data

Important Health Information

Past health history: Tobacco use, diabetes, hypertension, hyperlipidemia, hypertriglyceridemia, hyperuricemia, impaired renal function, obesity. ↑ High-sensitivity C-reactive protein, homocysteine, or lipoprotein (a) [Lp(a)] levels. Positive family history, sedentary lifestyle, stress

Functional Health Patterns

Health perception–health management: Family history of CVD. Tobacco use, including exposure to environmental smoke
Nutritional-metabolic: High sodium, saturated fat, and cholesterol intake. Elevated Hb A1C
Activity-exercise: Exercise intolerance
Cognitive-perceptual: Buttock, thigh, or calf pain that is precipitated by exercise and that subsides with rest (intermittent claudication) or progresses to pain at rest. Burning pain in feet and toes at rest. Numbness, tingling, sensation of cold in legs or feet. Progressive loss of sensation and deep pain in extremities
Sexuality-reproductive: Erectile dysfunction

Objective Data
Integumentary

Loss of hair on legs and feet. Thick toenails. Pallor with elevation. Dependent rubor. Thin, cool, shiny skin with muscle atrophy. Skin breakdown and arterial ulcers, especially over bony areas. Gangrene

Cardiovascular

Decreased or absent peripheral pulses. Feet cool to touch. Capillary refill >3 seconds. Bruits may be present at pulse sites.

Neurologic

Mobility or sensation impairment

Possible Diagnostic Findings

Arterial stenosis evident with duplex imaging, ↓ Doppler pressures, ↓ ABI, angiography shows peripheral atherosclerosis

Do not place the patient in a knee-flexed position except for exercise. Turn the patient and position frequently with pillows to support the incision. On postoperative day 1, assist the patient out of bed several times. Walking even short distances is desirable. A walker may be helpful, especially for frail, older patients. Discourage prolonged sitting with legs lowered, since it may cause pain and edema, increase the risk for venous thrombosis, and place stress on the suture lines. Graduated compression stockings may help control leg edema. If edema develops, position the patient supine, and elevate the leg above heart level.

Check Your Practice

You are caring for a 74-yr-old male patient who is recovering from left femoral-popliteal bypass graft surgery. When you respond to the patient's call bell, the patient reports severe pain in the operative leg. On assessment, you note that the dorsalis pedis and posterior tibial pulses are no longer palpable and the foot is cold to touch.

- What are your next actions?

Surgical site infection (SSI) is a serious complication. Careful postoperative assessment and wound care are important. SSIs are associated with early graft loss, longer hospitalizations, reoperation, and sepsis. If no complications occur, discharge occurs 3 to 5 days after surgery.

Ambulatory Care

Assess for CVD risk factors. Be alert for opportunities to teach patients health promotion strategies. Continued tobacco use dramatically decreases the patency rates of grafts and stents and increases the risk for an MI or stroke.

Long-term antiplatelet therapy with aspirin or clopidogrel is used after surgery. Patients having distal peripheral bypass surgery (i.e., below the knee) using synthetic graft materials receive dual antiplatelet therapy (clopidogrel plus aspirin) for 1 to 3 months, followed by lifelong single antiplatelet therapy.[10]

Encourage supervised exercise training after revascularization. Explain that exercise decreases CVD risk factors, including hypertension, hyperlipidemia, obesity, and glucose levels. Teach foot care to all patients with PAD. Meticulous foot care is especially important in the patient with diabetes and PAD (see Table 48.21). Diabetic neuropathy increases the patient's risk for injury and results in delay in seeking treatment. Tell patients to inspect their legs and feet daily for changes in skin color or texture. Show patients how to check skin temperature and capillary refill and to palpate pulses. Stress reporting any changes in these findings or the development of ulceration or inflammation to the HCP.

Thick or overgrown toenails and calluses are potentially serious and need regular attention by an HCP (e.g., podiatrist). Patients who have poor eyesight, back problems, obesity, or arthritis may need help with foot care. Encourage patients to wear clean, all-cotton or all-wool socks and comfortable shoes with rounded (not pointed) toes and soft insoles. Tell patients to lace shoes loosely and to break in new shoes gradually (Table 37.5).

Evaluation

The expected outcomes are that a patient with PAD of the lower extremities will have

- Adequate peripheral tissue perfusion
- Increased activity tolerance
- Effective pain management
- Knowledge of disease and treatment plan

Acute Arterial Ischemic Disorders

Etiology and Pathophysiology

Acute arterial ischemia is a sudden interruption in the arterial blood supply to a tissue, an organ, or an extremity that, if left untreated, can result in tissue death. It is caused by embolism, thrombosis of an atherosclerotic artery, or trauma. *Embolization* of a thrombus from the heart is the most frequent cause of acute arterial occlusion. Heart conditions in which thrombi can develop include infective endocarditis, mitral valve disease, atrial fibrillation, cardiomyopathies, and prosthetic heart valves. Noncardiac sources of emboli include aneurysms, ulcerated atherosclerotic plaque, recent endovascular procedures, and venous thrombi.

Thrombi that originate in the left side of the heart may dislodge and travel anywhere in the systemic circulation. Most emboli block an artery of the leg where vessels branch (e.g., iliofemoral, popliteal, tibial) or narrow. Sudden local thrombosis may occur at the site of an atherosclerotic plaque. Hypovolemia (e.g., shock), hyperviscosity (e.g., polycythemia), and hypercoagulability (e.g., chemotherapy) predispose a person to thrombotic arterial occlusion.

TABLE 37.5 Patient & Caregiver

TeachingPeripheral Artery Bypass Surgery

Include the following information in the teaching plan for a patient undergoing peripheral artery bypass surgery and the patient's caregiver:

1. Reduce risk factors by stopping the use of all tobacco products, controlling blood glucose levels with diabetes and BP, lowering cholesterol and triglyceride levels, achieving or maintaining ideal body weight, and exercising regularly.
2. Provide teaching about the basic mechanism of action (why prescribed for patient) and side effects of drugs, such as antiplatelets, antihypertensives, lipid-lowering therapy, and pain medication.
3. Eat healthy—it is essential to recovery. Drink plenty of fluids, eat a well-balanced diet (e.g., foods high in protein, vitamins C and A, and zinc; high-fiber foods; fresh fruits and vegetables), eat fewer high-fat foods, and reduce salt intake.
4. Take part in a supervised exercise program or take a daily walk. In the beginning, take several short walks a day and rest between activities. Gradually increase your walking to 30 to 40 min/day, 3 to 5 days/wk.
5. Care for feet and legs. Inspect feet and wash them daily. Wear clean cotton or wool socks and well-fitting shoes. File toenails straight across. Avoid sitting with legs crossed, extreme hot and cold temperatures, and prolonged standing.
6. Follow routine postoperative wound care that includes keeping incision clean and dry; do not disturb Steri-Strips (if present).
7. Monitor for signs and symptoms of impaired healing or infection of the leg incision, and notify HCP if any of the following occur:
    - Prolonged drainage or pus from the incision
    - Increased redness, warmth, pain, or hardness along incision
    - Separation of wound edges
    - Temperature >100° F (37.8° C)
8. Keep all follow-up appointments with HCP.

9. Notify HCP at once of increased leg or foot pain or a change in the color or temperature of leg or foot.

Traumatic injury to an extremity may cause partial or total arterial blockage. Acute arterial occlusion may develop from arterial dissection in the carotid artery or aorta or from a procedure-related arterial injury (e.g., after angiography).

Clinical Manifestations

Manifestations of acute arterial ischemia include the *6 Ps: pain, pallor, pulselessness, paresthesia, paralysis,* and *poikilothermia* (adaptation of the limb to the environmental temperature, most often cool). If you detect these signs, immediately notify the HCP. Without immediate intervention, ischemia may progress to tissue necrosis and gangrene within a few hours.

Paralysis is a late sign of acute arterial ischemia and signals the death of nerves supplying the extremity. Foot drop occurs from nerve damage. Because nerve tissue is extremely sensitive to hypoxia, limb paralysis or ischemic neuropathy may persist even after revascularization.

Interprofessional Care

Early diagnosis and treatment are essential to keep the affected limb viable during acute arterial ischemia. Anticoagulant therapy with IV unfractionated heparin (UH) is started to prevent thrombus growth and inhibit further embolization. In patients undergoing embolectomy, UH should be followed by long-term anticoagulation (see discussion of anticoagulant options later in this chapter).

To restore blood flow, the thrombus is removed as soon as possible. Options consist of surgical thrombectomy (recommended procedure), percutaneous catheter-directed thrombolytic therapy, percutaneous mechanical thrombectomy with or without thrombolytic therapy, or surgical bypass.

Percutaneous catheter-directed thrombolytic therapy using alteplase or urokinase is recommended for acute arterial ischemia of less than 14 days. The HCP inserts a catheter into the femoral artery and moved it to the site of the clot, and the thrombolytic drug is continuously infused. Thrombolytic agents work by directly dissolving the clot over a period of 24 to 48 hours. (Chapter 33 discusses thrombolytic therapy.) Close monitoring is required to make sure the catheter does not move and the patient does not bleed from the site of the catheter insertion.

Surgical revascularization may be used in a patient with trauma (e.g., laceration of the artery) or with significant arterial blockage. Amputation is reserved for patients with ischemic rest pain and tissue loss in whom limb salvage is not possible. If the patient is at risk for further embolization from a persistent source (e.g., chronic atrial fibrillation), long-term anticoagulation is recommended.[6,10]

Thromboangiitis Obliterans

Thromboangiitis obliterans (Buerger's disease) is a nonatherosclerotic, segmental, recurrent inflammatory disorder of the small and medium arteries and veins of the arms and legs. Rarely, cerebral, coronary, mesenteric, pulmonary, and/or renal arteries may be involved. The disease occurs mostly in men younger than 45 years of age with a long history of tobacco and/or marijuana use without other CVD risk factors (e.g., hypertension, hyperlipidemia, diabetes).[11]

In the acute phase of Buerger's disease, an inflammatory thrombus blocks the vessel. Over time, the thrombus becomes more organized and the inflammation in the vessel wall subsides.[11] During the chronic phase, thrombosis and fibrosis in the vessel cause tissue ischemia.

The symptoms of Buerger's disease often are confused with PAD and other autoimmune diseases (e.g., scleroderma). Patients may have intermittent claudication of the feet, hands, or arms. As the disease progresses, rest pain and ischemic ulcerations develop. Other signs and symptoms may include color and temperature changes of the

limbs, paresthesia, superficial vein thrombosis, and cold sensitivity.

There are no laboratory or diagnostic tests specific to Buerger's disease. The diagnosis is based on age of onset; history; symptoms; involvement of distal vessels; presence of ischemic ulcerations; and exclusion of autoimmune disease, diabetes, thrombophilia (inherited tendency to clot), and other sources of emboli, such as atherosclerosis and aneurysm.[11]

The main treatment for Buerger's disease is the complete cessation of tobacco and marijuana use in any form. Use of nicotine replacement products is contraindicated.

Conservative management includes avoiding limb exposure to cold temperatures, a supervised walking program, antibiotics to treat any infected ulcers, and analgesics to manage the ischemic pain. Teach patients to avoid trauma to the extremities.

IV iloprost (Ventavis), a prostaglandin analog that promotes vasodilation, is used to manage rest pain, promote healing of ischemic ulcers, and decrease the need for amputation.[11] Surgical options include lumbar sympathectomy (transection of a nerve, ganglion, and/or plexus of the sympathetic nervous system), implanting a spinal cord stimulator, microsurgical flap and omental transfer, bypass surgery, and stem cell therapy.[11] Sympathectomy and a spinal cord stimulator can improve distal blood flow, reduce pain, and decrease the rate of amputation, but neither alters the inflammatory process. Bypass surgery typically is not an option because of the involvement of smaller, distal vessels. It may be used in select patients with severe ischemia. Stem cells can differentiate into specialized adult cells, with the potential to become any tissue in the human body. Stem cell therapy promotes ulcer healing, new blood vessel formation, and nerve cell regeneration.[11]

Painful ulcerations may require finger or toe amputations. Amputation below the knee may be needed in severe cases. The rate of amputation in those who continue tobacco or marijuana use after diagnosis is much higher than in those who stop.[11]

Raynaud's Phenomenon

Raynaud's phenomenon is an episodic vasospastic disorder of small cutaneous arteries, most often involving the fingers and toes. It occurs more often in women, especially those between 15 and 40 years of age. The pathogenesis of Raynaud's phenomenon is due to abnormalities in the vascular, intravascular, and neuronal mechanisms that cause vasodilation.[12]

Raynaud's phenomenon may occur in isolation (primary Raynaud's phenomenon) or with an underlying disease (e.g., thyroid conditions, scleroderma, systemic lupus erythematosus) (secondary Raynaud's phenomenon). Other contributing factors include the use of vibrating machinery or work in cold environments, exposure to heavy metals (e.g., lead), and high homocysteine levels.

Diagnosis is based on persistent symptoms for at least 2 years. Patients with Raynaud's phenomenon should have routine follow-up to monitor for development of connective tissue or autoimmune diseases.

Raynaud's phenomenon is characterized by vasospasm-induced color changes of fingers, toes, ears, and nose (white, blue, and red). Decreased perfusion results in pallor (white). The digits then appear cyanotic (bluish purple) (Fig. 37.3). These changes are followed by rubor (red), a hyperemic response when blood flow is restored. The patient usually describes coldness and numbness in the vasoconstrictive phase. This is followed by throbbing, aching pain, tingling, and swelling in the hyperemic phase. An episode usually lasts only minutes but may last for several hours. Exposure to cold, emotional upsets, tobacco use, and caffeine often bring on symptoms.

FIG. 37.3 Raynaud's phenomenon.
From James WD, Elston DM, Dirk M: *Andrews' diseases of the skin clinical atlas*, St Louis, 2018, Elsevier.

After frequent, prolonged attacks, the skin may become thickened and the nails brittle. Sometimes, complications include *punctate* (small hole) lesions of the fingertips and superficial gangrenous ulcers.

Patient teaching is the focus of nursing care for Raynaud's phenomenon. Focus your instructions on preventing episodes. Tell patients to avoid temperature extremes and wear loose, warm clothing as protection from the cold, including gloves when handling cold objects. The patient should stop using all tobacco products and avoid caffeine and other drugs that have vasoconstrictive effects (e.g., cocaine, amphetamines, ergotamine, pseudoephedrine). Provide patients with appropriate stress management strategies. Immersing hands in warm water often decreases the vasospasm.

Sustained-release calcium channel blockers (e.g., nifedipine [Procardia]) are the first-line drug therapy. They relax smooth muscles of the arterioles by blocking the influx of calcium into the cells. This reduces the frequency and severity of vasospastic attacks. If symptoms persist, other vasodilators (e.g., phosphodiesterase-5

inhibitors [sildenafil]) or topical nitroglycerin 2% ointment may be used. Calcium channel blockers can be taken with nitroglycerin topical ointment. Phosphodiesterase-5 inhibitors are not used with topical nitroglycerin due to risk for hypotension.[12]

Prompt intervention is needed for patients with digital ulceration or critical ischemia. Treatment options include prostacyclin infusion therapy (e.g., iloprost), antibiotics, analgesics, and surgical debridement of necrotic tissue. Botulinum toxin A and statins may lessen the severity of Raynaud's phenomenon.[12] Sympathectomy is done only in severe cases refractory to medical treatment where digit survival is threatened.

Aortic Aneurysms

The aorta is the largest artery and supplies O_2, nutrients, and blood to all vital organs. One of the most common problems affecting the aorta is an **aneurysm**, which is a permanent, localized outpouching or dilation of the vessel wall. Aneurysms occur in men more often than in women and in whites more often than blacks. The incidence increases with age.[3,13] Aneurysms may occur in more than 1 location.

Etiology and Pathophysiology

Aortic aneurysms may involve the aortic arch and thoracic and/or abdominal aorta. Three fourths of aortic aneurysms occur in the abdominal aorta (Fig. 37.4) and one fourth in the thoracic aorta. Most abdominal aortic aneurysms (AAAs) occur below the renal arteries.

A variety of disorders are associated with aortic aneurysms. The main causes are classified as degenerative, congenital, mechanical (e.g., penetrating or blunt trauma), inflammatory (e.g., aortitis [Takayasu's arteritis]), or infectious (e.g., aortitis [*Chlamydia pneumoniae*, human immunodeficiency virus]).

Risk factors for aortic aneurysms include age, male gender, hypertension, CAD, family history, tobacco use, high cholesterol, lower extremity PAD, carotid artery disease, previous stroke, and

obesity. Tobacco use is the most important modifiable risk factor.[1,13] The larger the aneurysm, the greater is the risk for rupture.

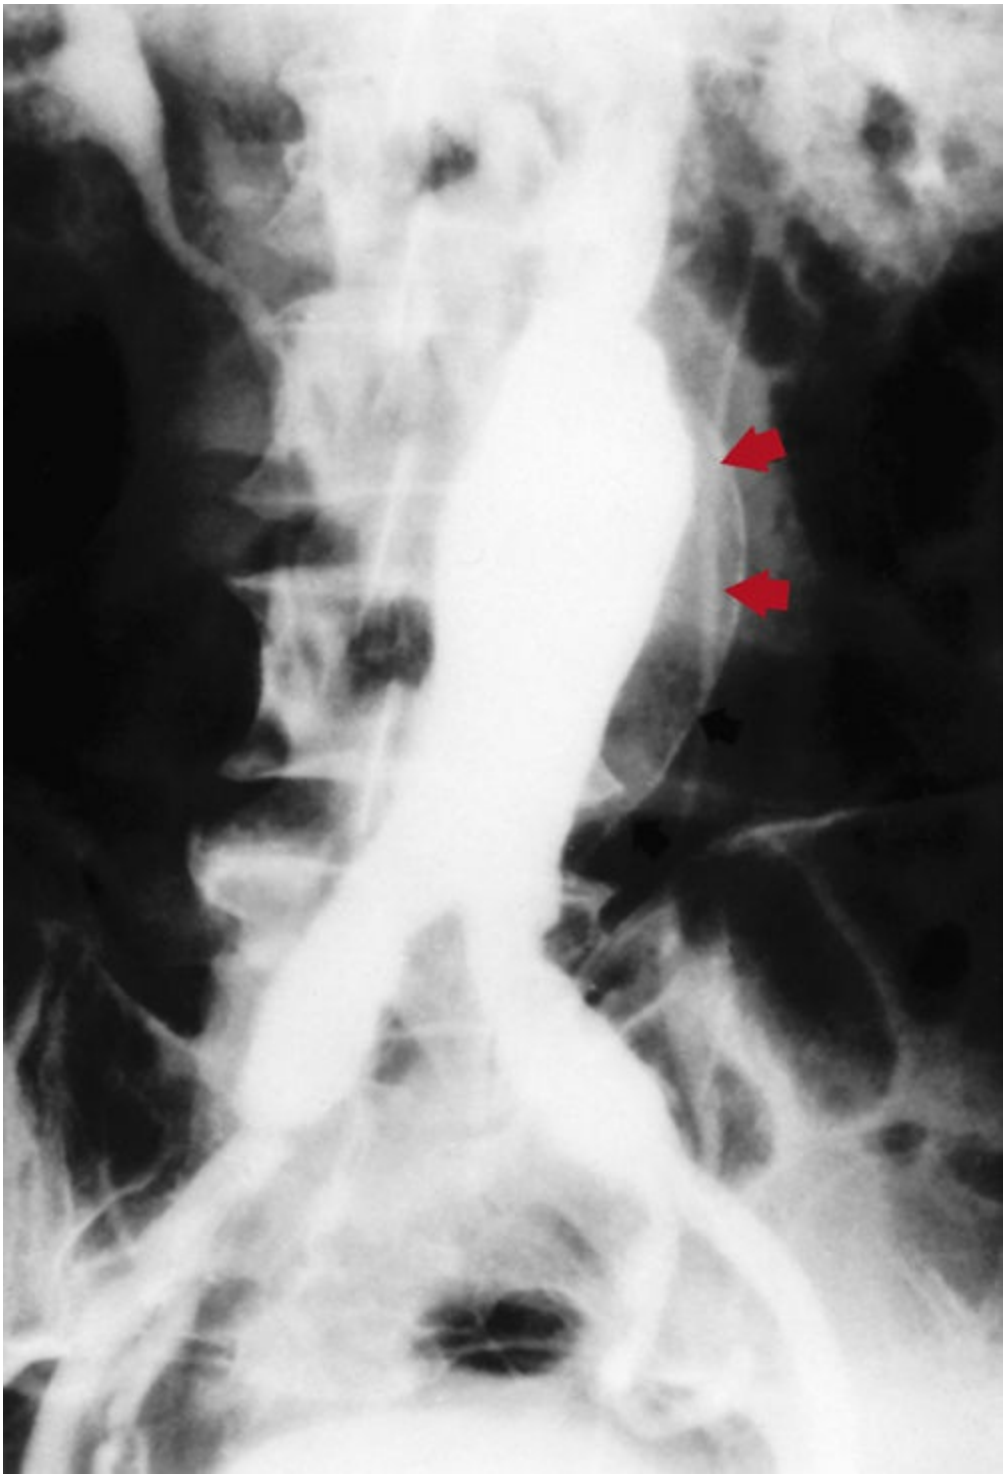

FIG. 37.4 Angiography showing fusiform abdominal aortic aneurysm. Note calcification of the aortic wall *(arrows)* and extension of the aneurysm into the common iliac arteries. Courtesy Jo Menzoian, Boston, MA.

Genetic Link

Both aortic aneurysm and aortic dissection has a strong genetic component. The familial tendency is related to several congenital anomalies. Examples include bicuspid aortic valve, coarctation of the aorta, Turner syndrome, autosomal dominant polycystic kidney disease, specific collagen defects (e.g., Ehlers-Danlos syndrome), and premature breakdown of vascular elastic tissue (e.g., Marfan's syndrome).[1,13]

Classification

Aneurysms are classified as true or false aneurysms (Fig. 37.5, *A* to *C*). A *true aneurysm* is one in which the wall of the artery forms the aneurysm, with at least 1 vessel layer still intact. True aneurysms are subdivided into fusiform and saccular types. A *fusiform aneurysm* is circumferential and relatively uniform in shape. A *saccular aneurysm* is pouchlike with a narrow neck connecting the bulge to 1 side of the arterial wall.

A *false aneurysm*, or *pseudoaneurysm*, is not an aneurysm. It is a disruption of all arterial wall layers with bleeding that is contained by surrounding anatomic structures. False aneurysms may result from trauma, infection, peripheral artery bypass graft surgery (at the site of the graft-to-artery anastomosis), or arterial leakage after removal of cannulae (e.g., femoral artery catheters, intraaortic balloon pump devices).

Clinical Manifestations

Thoracic aortic aneurysms (TAAs) are often asymptomatic. When present, symptoms include deep, diffuse chest pain that may extend

to the interscapular area. Ascending aorta and aortic arch aneurysms can cause (1) angina from decreased blood flow to the coronary arteries; (2) transient ischemic attacks from decreased blood flow to the carotid arteries; and (3) coughing, shortness of breath, hoarseness, and/or difficulty swallowing from pressure on the laryngeal nerve. If the aneurysm presses on the superior vena cava, decreased venous return can result in jugular venous distention and edema of the face and arms.

AAAs are often asymptomatic. They are often found during routine physical examinations or evaluations for an unrelated problem (e.g., abdominal x-ray, CT scan). A pulsatile mass in the periumbilical area slightly to the left of the midline may be present. Bruits may be auscultated over the aneurysm. Physical findings may be hard to detect in obese persons.

FIG. 37.5 **A,** True fusiform abdominal aortic aneurysm. **B,** True saccular aortic aneurysm. **C,** False aneurysm, or pseudoaneurysm. **D,** Aortic dissection.

AAA symptoms may mimic pain associated with abdominal or back disorders. Compression of nearby anatomic structures and nerves may cause symptoms, such as back pain, epigastric discomfort, altered bowel elimination, and intermittent claudication. Sometimes, aneurysms spontaneously embolize plaque, causing "blue toe syndrome" (patchy mottling of the feet and toes in the presence of palpable pedal pulses).

Complications

Aneurysm rupture is the most serious complication. It is more likely to occur in people who smoke tobacco.[13] If rupture occurs into the retroperitoneal space, bleeding may be controlled by surrounding anatomic structures, preventing exsanguination and death. In this case, the patient often has severe back pain. Back or flank ecchymosis *(Grey Turner sign)* may be present.

If rupture occurs into the thoracic or abdominal cavity, patients can die from massive hemorrhage. The patient who reaches the hospital will be in hypovolemic shock with tachycardia, hypotension, pale clammy skin, decreased urine output, altered level of consciousness, and abdominal tenderness. (Shock is discussed in Chapter 66.) In this situation, simultaneous resuscitation and immediate surgical repair are needed. For patients admitted to the hospital with a ruptured AAA, in-hospital mortality is high at 53%.[13]

Diagnostic Studies

Chest x-rays are done to reveal abnormal widening of the thoracic aorta. An abdominal x-ray may show calcification within the aortic wall. An ECG may rule out MI, since thoracic aneurysm or dissection symptoms can mimic angina. Echocardiography assesses the function of the aortic valve. Ultrasound is useful for aneurysm screening and to

monitor aneurysm size. A CT scan or MRI can diagnose and assess the location and severity of aneurysms. Angiography gives helpful information by using contrast imaging to map the entire aortic system. (Chapter 31 and Table 31.7 discuss angiography.)

Interprofessional Care

The main goal of interprofessional care is to prevent the rupture of an aneurysm. Early detection and prompt treatment are essential. Conservative medical therapy of small, asymptomatic AAAs (less than 5.4 cm) is the best practice.[13] This consists of risk factor modification (ceasing tobacco use, decreasing BP, optimizing lipid profile, gradually increasing physical activity).[13] Patients should receive medical management for hypertension, hyperlipidemia, diabetes, and other CVD risk factors. A statin and an ACE inhibitor could prove to be beneficial. Those with small aneurysms, 4.0 to 5.4 cm, should have monitoring of aneurysm size using ultrasound or CT every 6 to 12 months. Ultrasound monitoring every 3 years is done for patients with AAAs smaller than 4.0 cm in diameter.

Surgical repair is recommended in patients with asymptomatic aneurysms 5.5 cm in diameter or larger. Surgical intervention may occur sooner if the patient has a genetic disorder (e.g., Marfan's, Ehlers-Danlos syndrome), the aneurysm expands rapidly, the patient becomes symptomatic, or the risk for rupture is high.[13] A careful review of body systems is needed to identify any co-morbidities as they affect the patient's surgical risk. Correcting existing carotid or coronary artery blockages may be needed before aneurysm repair.

Surgical Therapy

For elective aneurysm repair surgery, the patient should be well hydrated with normal electrolytes, coagulation, and hematocrit. If the aneurysm ruptures, emergent surgery is required.

Open aneurysm repair (OAR) involves a large abdominal incision through which the surgeon (1) cuts into the diseased aortic segment, (2) removes any thrombus or plaque, (3) sutures a synthetic graft to

the aorta proximal and distal to the aneurysm, and (4) sutures the native aortic wall around the graft to act as a protective cover (Fig. 37.6). For iliac artery aneurysms, a bifurcated graft replaces the entire diseased segment. With saccular aneurysms, it may be possible to excise only the bulbous lesion and repair the artery by primary closure (suturing the artery together) or applying an autogenous or synthetic patch graft.

All OARs require aortic cross-clamping proximal and distal to the aneurysm. Most resections are done in 30 to 45 minutes, then the clamps are removed and blood flow is restored. The risk for postoperative complications, such as acute kidney injury, increases in patients who have OAR of AAAs above the level of the renal arteries.

Endovascular Graft Procedure

Minimally invasive endovascular aneurysm repair (EVAR) is an alternative to OAR for select patients. Eligibility criteria include iliofemoral vessels that allow for safe graft insertion and vessels of sufficient length and width to support the graft.[13]

EVAR involves the placement of a sutureless aortic graft into the abdominal aorta inside the aneurysm via the femoral artery. Grafts are made of various materials, such as a Dacron cylinder consisting of several sections, and supported with multiple rings of flexible wire.

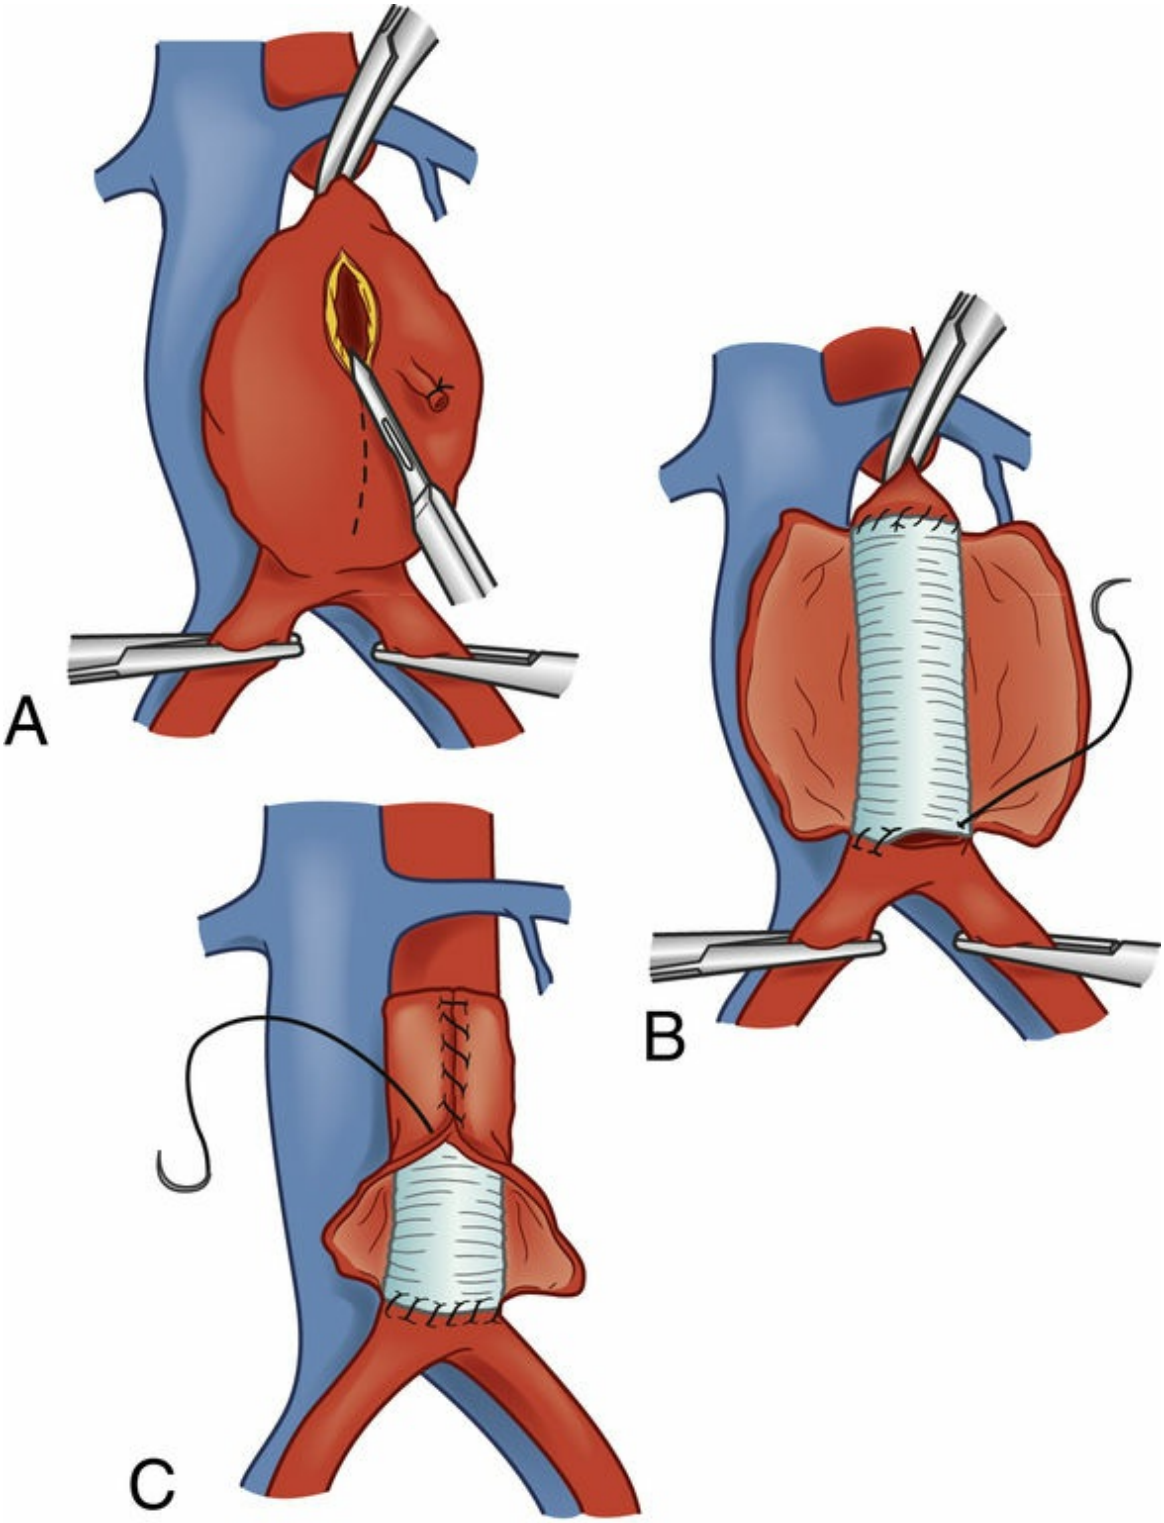

FIG. 37.6 Surgical repair of an abdominal aortic aneurysm. **A,** Incising the aneurysmal sac. **B,** Insertion of synthetic graft. **C,** Suturing native aortic wall over synthetic graft.

The main section of the graft is bifurcated. It is delivered through a femoral artery catheter. The second part of the graft is inserted through the opposite femoral artery. When all graft components are in place, they are deployed against the vessel wall by balloon inflation. The blood then flows through the endovascular graft, preventing further expansion of the aneurysm (Fig. 37.7).

Angiography is done afterward to check for any leaks and to confirm patency of all stent-graft components. The aneurysmal wall shrinks over time because the blood is diverted through the endograft.

Complications

EVAR is less invasive than OAR and requires a shorter hospital stay. EVAR also has fewer complications, such as paraplegia and death.

The most common complication of AAA repair is *endoleak,* the seepage of blood back into the old aneurysm. This may result from an inadequate seal at either graft end, a tear through the graft fabric, or leakage between overlapping graft segments. Repair may require coil embolization (insertion of beads) for hemostasis.

Other complications include aneurysm growth above or below the graft, aneurysm rupture, aortic dissection, bleeding, renal artery occlusion caused by stent migration, graft thrombosis, incisional site hematoma, and incisional infection. Patients undergoing EVAR need periodic imaging for the rest of their lives to monitor for an endoleak, document stability of the aneurysm sac, and determine the need for surgical intervention.

A potentially lethal complication in an emergency repair of a ruptured AAA is the development of *intraabdominal hypertension* (IAH) with associated *abdominal compartment syndrome*. Persistent IAH reduces blood flow to the viscera. Abdominal compartment syndrome refers to the impaired organ perfusion caused by IAH and resulting multisystem organ failure. IAH is confirmed by measuring the patient's intraabdominal pressure indirectly through a catheter and transducer system.

Treatment goals include control of situations that lead to IAH. Interventions include open (surgical) decompression, percutaneous

drainage, and percutaneous drainage combined with a thrombolytic infusion. Conservative measures, such as intubation, ventilation, patient positioning, gastric decompression, cautious fluid resuscitation, pain management, and temporary hemofiltration, are used.

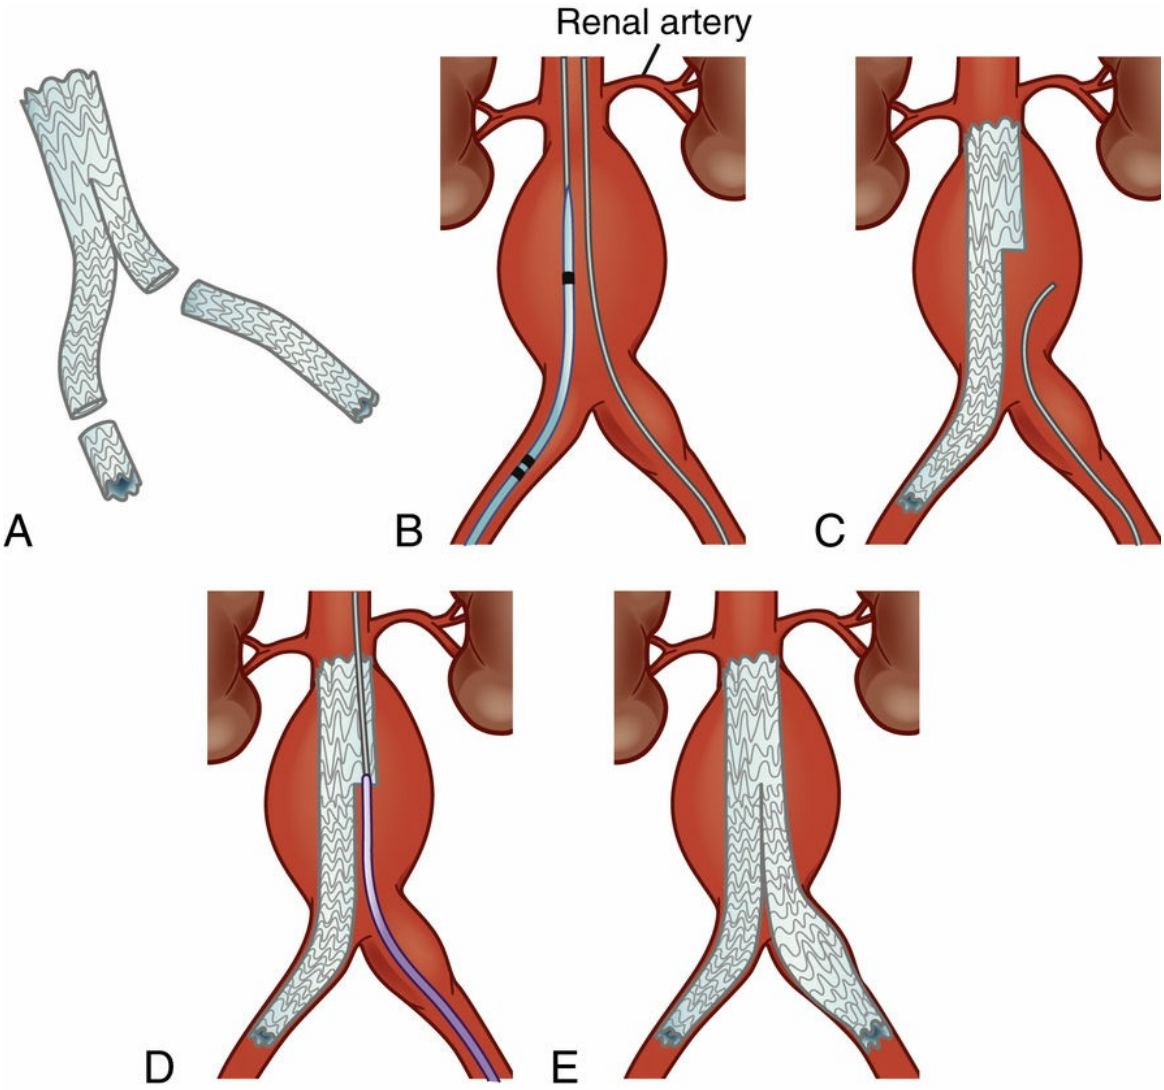

FIG. 37.7 Bifurcated (2-branched) endovascular stent grafting of an aneurysm. **A,** Insertion of a woven polyester graft covered by a tubular metal web (stent). **B,** The stent graft is inserted through a large blood vessel (e.g., femoral artery) using a delivery catheter. The catheter is positioned below the renal arteries in the area of the aneurysm. **C,** The stent graft is slowly released into the blood vessel. When the stent comes in contact with the blood vessel, it expands to a preset size. **D,**

A second stent graft can be inserted in the opposite vessel, if needed.

Nursing Management: Aortic Aneurysms

Nursing Assessment

Begin by performing a thorough history and physical assessment. Because atherosclerosis is a systemic disease, look for signs of coexisting cardiac, pulmonary, cerebral, and lower extremity vascular problems. Monitor the patient for signs of aneurysm rupture. These include diaphoresis; pallor; weakness; tachycardia; hypotension; abdominal, back, groin, or periumbilical pain; changes in level of consciousness; or a pulsating abdominal mass.

Establish baseline data to compare with later assessments. Pay special attention to the character and quality of the patient's peripheral pulses and renal and neurologic status. Before surgery, mark pedal pulse sites (dorsalis pedis, posterior tibial) with a single-use marker and document any skin lesions on the lower extremities.

Planning

The overall goals for a patient undergoing aortic surgery include (1) normal tissue perfusion; (2) intact motor and sensory function; and (3) no complications related to surgical repair, such as thrombosis, infection, or rupture.

Nursing Implementation

Health Promotion

To promote overall health, encourage the patient to reduce CVD risk factors (see Table 33.2), including controlling BP, ceasing tobacco use (see Chapter 10), and maintaining normal body weight and serum

lipid levels. These measures also help ensure continued graft patency after surgical repair. Counsel the patient about taking part in moderate physical activity.

Acute Care

Before surgery, provide emotional support and teaching to the patient and caregiver. Preoperative teaching includes a brief explanation of the disease process, the planned surgical procedure(s), preoperative routines, what to expect right after surgery (e.g., recovery room, tubes, drains), and usual postoperative timelines. Specific routines vary by agency and HCP. In general, aortic surgery patients have a bowel preparation and skin cleansing with an antimicrobial agent the day before surgery, have NPO after midnight the day of surgery, and receive IV antibiotics before the incision is made. Patients with a history of CVD should receive a β-blocker (e.g., metoprolol [Lopressor]). Scheduling a preoperative visit to the ICU may be helpful to the patient and caregiver.

After surgery, patients typically go to an ICU for 24 to 48 hours for close monitoring. When the patient arrives in the ICU, various devices are in place. These include an endotracheal tube for mechanical ventilation, an arterial line, a central venous pressure (CVP) catheter, peripheral IV lines, an indwelling urinary catheter, and a nasogastric (NG) tube. The patient needs continuous ECG and pulse oximetry monitoring. If the thorax is opened during surgery, chest tubes will be in place. The patient may have a lumbar catheter draining cerebrospinal fluid to prevent neurologic deficits. Pain medication is given via subcutaneous infusion into incision site (e.g., On-Q pain pump), epidural catheters, or IV patient-controlled analgesia (PCA).

In addition to the usual goals of care for a postoperative patient (e.g., maintaining adequate respiratory function, fluid and electrolyte balance, and pain control [see Chapter 19]), check for graft patency and renal perfusion. Watch for and intervene to limit or treat cardiac ischemia, dysrhythmias, infections, VTE, and neurologic complications. eNursing Care Plan 37.2 for the patient with an aneurysm repair or other aortic surgery is available on the website for

this chapter.

Graft Patency

An adequate BP is important to maintain graft patency. Prolonged low BP may result in graft thrombosis. Give IV fluids and blood components as ordered to maintain adequate blood flow. Monitor CVP or PA pressures and urine output hourly in the immediate postoperative period to assess the patient's hydration and perfusion status.

Avoid severe hypertension, which may stress the arterial anastomoses, resulting in leakage of blood or rupture at the suture lines. Drug therapy with IV diuretics (e.g., furosemide) or IV antihypertensive agents (e.g., labetalol, metoprolol, hydralazine, sodium nitroprusside [Nipride]) may be indicated.

Cardiovascular Status

Myocardial ischemia or infarction may occur in the perioperative period because of decreased myocardial O_2 supply or increased myocardial O_2 demands. Dysrhythmias may occur because of electrolyte imbalances, hypoxemia, hypothermia, or myocardial ischemia. Nursing interventions include continuous ECG monitoring; frequent electrolyte and arterial blood gas determinations; O_2 administration, IV antidysrhythmic and antihypertensive drugs, and electrolytes as needed; adequate pain control; and resumption of cardiac drugs.

Infection

A prosthetic vascular graft infection is a rare but potentially life-threatening complication. Nursing interventions to prevent infection include giving a broad-spectrum antibiotic as prescribed. Assess temperature regularly, and promptly report elevations. Monitor laboratory results for a high WBC count, which may be the first sign of an infection. Ensure adequate nutrition and assess the surgical incision for signs of infection (e.g., redness, swelling, drainage). Keep

surgical incisions clean and dry and perform wound care as prescribed.

Use good hand-washing and strict aseptic technique in the care of all peripheral, arterial, and CVP catheter insertion sites, since these are ports of entry for bacteria. Meticulous perineal care for the patient with an indwelling urinary catheter and early catheter removal are essential to minimize the risk for urinary tract infection.

Gastrointestinal Status

After OAR, postoperative ileus may develop because of anesthesia and the handling of the bowel during surgery. The intestines may become swollen and bruised, and peristalsis ceases for variable intervals. A retroperitoneal surgical approach decreases the risk for bowel complications.

An NG tube may be present and connected to low, intermittent suction to decompress the stomach, prevent aspiration of stomach contents, and decrease pressure on suture lines. Record the amount and character of the NG output. While the patient is NPO, provide frequent oral care. Ice chips or lozenges can help soothe a dry or irritated throat. Assess for bowel sounds every 4 hours. Note the passing of flatus as it signals returning bowel function. Encourage early ambulation since this will help the return of bowel function. A postoperative ileus rarely lasts beyond the 4th postoperative day.

If the blood supply to the bowel is disrupted during surgery, ischemia or infarction (death) of intestinal tissue may result. Manifestations of this rare, but serious, complication include absent bowel sounds, fever, abdominal distention and pain, diarrhea, and bloody stools. If bowel infarction occurs, immediate reoperation is needed to restore blood flow, with resection of the infarcted bowel.

Neurologic Status

Neurologic complications can occur after aortic surgery. When the ascending aorta and aortic arch are involved, assess the patient's level of consciousness, pupil size and response to light, facial symmetry, tongue position, speech, upper extremity movement, and quality of

hand grasps). When the descending aorta is involved, perform a neurovascular assessment of the lower extremities. Record all assessments and report changes from baseline to the HCP immediately.

Peripheral Perfusion Status

The location of the aneurysm determines what type of peripheral perfusion assessment to do. Check and record all peripheral pulses hourly for several hours and then routinely (based on agency policy). When the ascending aorta and aortic arch are involved, assess the carotid, radial, and temporal artery pulses. For surgery of the descending aorta, assess the femoral, popliteal, posterior tibial, and dorsalis pedis pulses (see Fig. 31.6). You may need a Doppler to assess peripheral pulses. Check skin temperature and color, capillary refill time, and sensation and movement of the extremities.

Sometimes, lower extremity pulses may be absent for a short time after surgery because of vasospasm and hypothermia. A decreased or absent pulse together with a cool, pale, mottled, or painful extremity may indicate embolization or graft occlusion. Report these findings to the HCP at once. Graft occlusion requires reoperation if identified early. It is essential to compare your findings with the preoperative status to determine the cause of a decreased or absent pulse and the proper treatment. In some patients, pulses may have been absent before surgery because of coexistent PAD.

Renal Perfusion Status

The patient will have an indwelling urinary catheter after surgery. In the immediate postoperative period, record hourly urine output. Further evaluate renal function by monitoring daily BUN and serum creatinine levels. CVP pressures give vital information about hydration status. Maintain accurate fluid intake and output and record daily weights until the patient resumes a regular diet.

Decreased renal perfusion can occur from embolization of an aortic thrombus or plaque to 1 or both renal arteries. This causes ischemia of 1 or both kidneys. Hypotension, dehydration, prolonged aortic

clamping during surgery, or blood loss can lead to decreased renal perfusion. Irreversible renal failure may occur after surgery, particularly in high-risk people (e.g., patients with diabetes). (Acute kidney injury is discussed in Chapter 46.)

Ambulatory Care

Teach the patient and caregiver to gradually increase activities once home. Fatigue, poor appetite, and irregular bowel patterns are common. Have the patient avoid heavy lifting for 6 weeks after surgery. Report any redness, swelling, increased pain, drainage from incisions, or fever greater than 100° F (37.8° C) to the HCP.

Teach the patient and caregiver to look for changes in color or warmth of the extremities. Patients and caregivers can learn to palpate peripheral pulses to assess changes in their quality.

Sexual dysfunction in male patients is common after aortic surgery. A referral to a urologist and counseling may be useful if erectile dysfunction occurs.

Evaluation

Expected outcomes are that the patient who undergoes aortic surgery will have:

- Patent arterial graft with adequate distal perfusion
- Adequate urine output
- No signs of infection

Aortic Dissection

Aortic dissection, often misnamed *"dissecting aneurysm,"* is not a type of aneurysm. Rather, dissection results from the creation of a false lumen between the intima (inner lining) and the media (middle layer) of arterial wall (Figs. 37.5, *D,* and 37.8). Aortic dissection is classified based on the location of the dissection and duration of onset. *Type A dissection* affects the ascending aorta and arch, requiring emergency

surgery. *Type B dissection* begins in the descending aorta, allowing for potential conservative management. We also describe dissections as acute (first 14 days), subacute (14 to 90 days), or chronic (greater than 90 days) based on symptom onset.[14,15]

Etiology and Pathophysiology

Nontraumatic aortic dissection is caused by weakened elastic fibers in the arterial wall. Chronic hypertension hastens this process. In aortic dissection, a tear develops in the inner layer of the aorta. Blood surges through this tear into the middle layer of the aorta, causing the inner and middle layers to separate (dissect). If the blood-filled channel ruptures through the outside aortic wall, aortic dissection is often fatal.

As the heart contracts, each pulsation increases the pressure on the damaged area and worsens the dissection. Extension of the dissection may cut off blood supply to the brain, kidneys, spinal cord, and extremities. The false lumen may remain patent, become thrombosed (clotted), rejoin the true lumen by way of a distal tear, or rupture.

Men are at a higher risk for developing aortic dissection than women.[15] Women who develop aortic dissection are older and more likely than men to present with HF, coma, or altered mental status.[15] Hypertension is the most important risk factor for aortic dissection.[15] Other predisposing factors include age, aortic diseases (e.g., aortitis, coarctation, arch hypoplasia), atherosclerosis, blunt trauma, tobacco use, cocaine or methamphetamine use, congenital heart disease (e.g., bicuspid aortic valve), connective tissue disorders (e.g., Marfan's syndrome), family history, history of heart surgery, and pregnancy.[15]

Clinical Manifestations

About 80% of patients with an acute Type A aortic dissection report an abrupt onset of severe anterior chest or back pain. Patients with acute Type B aortic dissection are more likely to report pain in their back, abdomen, or legs. Pain location may overlap between Type A

and B dissections. The pain may be described as “sharp” and “worst ever,” or as “tearing,” “ripping,” or “stabbing.”

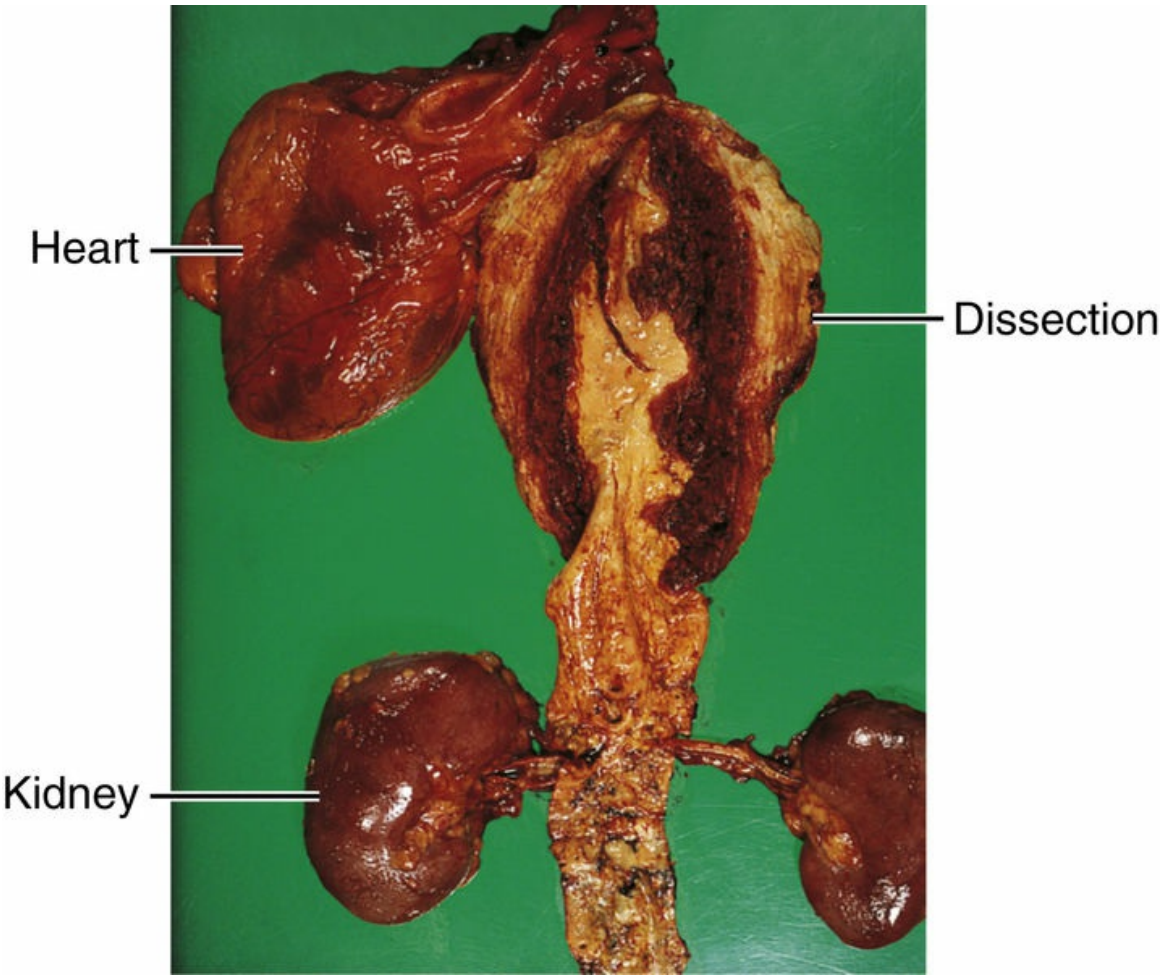

FIG. 37.8 Aortic dissection of the thoracic aorta.
From Damjanov I, Linder J, editors: *Anderson’s pathology,* ed 10, St Louis, 1996, Mosby.

Dissection pain can be distinguished from MI pain, which is more gradual in onset and has increasing intensity. As the dissection progresses, pain may follow the path of the dissection. Older patients are less likely to have an abrupt onset of pain and more likely to have hypotension and vague symptoms. Some patients have a painless aortic dissection, emphasizing the importance of the physical examination.

If the aortic arch is involved, the patient may have neurologic deficits. These include altered level of consciousness, weakened or absent carotid and temporal pulses, and dizziness or syncope. Type A aortic dissection usually disrupts blood flow in the coronary arteries and causes aortic valve insufficiency. When either subclavian artery is involved, the radial, ulnar, and brachial pulse quality and BP readings may be different between the left and right arms. As the dissection progresses down the aorta, the abdominal organs and lower extremities show evidence of decreased tissue perfusion.

Complications

A severe and life-threatening complication of an acute ascending aortic dissection is *cardiac tamponade.* This occurs when blood from the dissection leaks into the pericardial sac. Manifestations of tamponade include hypotension, narrowed pulse pressure, jugular venous distention, muffled heart sounds, and pulsus paradoxus (see Chapter 36).

An aorta weakened by dissection may rupture. Hemorrhage may occur into the mediastinal, pleural, or abdominal cavities. Aortic rupture typically results in exsanguination and death.

Aortic dissection can lead to occlusion of the blood supply to vital organs. Spinal cord ischemia leads to weakness and decreased sensation and rarely to complete lower extremity paralysis. Renal ischemia can lead to renal failure. Abdominal (mesenteric) ischemia can occur and cause abdominal pain, decreased bowel sounds, altered bowel function, and bowel necrosis.

Diagnostic Studies

Diagnostic studies to detect aortic dissection are similar to those for suspected aneurysms (Table 37.6). An ECG can help rule out cardiac ischemia. A chest x-ray may show a widening of the mediastinum and pleural effusion. MRI, 3-D CT scanning, and transesophageal echocardiography (TEE) are equally reliable for the diagnosis of acute aortic dissection. A CT scan or MRI can give more detailed

information on the severity of the dissection and related complications (e.g., pericardial effusions, carotid dissection). TEE is preferred in very unstable patients or those with contraindications to CT or MRI (e.g., those with metal implants, allergies to contrast material).[15]

TABLE 37.6 Interprofessional Care Aortic Dissection

Diagnostic Assessment

- Health history and physical examination
- ECG
- Chest x-ray
- CT scan
- Transesophageal echocardiogram
- MRI

Management

- Bed rest
- Pain relief with opioids
- Blood transfusion (if needed)

Drug Therapy (see Table 32.6)

- IV β-blockers
- IV calcium channel blockers
- ACE inhibitors

Surgical Therapy

- Endovascular aortic dissection repair
- Open surgical repair

Interprofessional Care

Patients with acute aortic dissection are managed in the ICU. The initial goals of therapy for acute aortic dissection without complications are heart rate (HR) and BP control and pain management. HR and BP control reduces aortic wall stress by decreasing SBP and myocardial contractility (Table 37.6). An IV β-blocker (e.g., esmolol [Brevibloc]) is titrated to a target HR under 60 beats/min or SBP between 100 and 110 mm Hg.

A calcium channel blocker (e.g., diltiazem) can be used to lower HR if a β-blocker is contraindicated. Reducing the HR, BP, and myocardial contractility limits extension of the dissection. Morphine decreases sympathetic nervous system stimulation and relieves pain. Supportive treatment for an acute aortic dissection serves as a bridge to surgery.

Conservative Therapy

The patient with an acute or chronic Type B aortic dissection without complications can be treated conservatively. Conservative treatment includes pain relief, HR and BP control, and CVD risk factor modification with close surveillance imaging with CT or MRI.

Endovascular Dissection Repair

Endovascular repair is a treatment option for acute Type B aortic dissections with complications (e.g., hemodynamic instability) and chronic Type B aortic dissection with complications (e.g., peripheral ischemia). Thoracic endovascular aortic repair (TEVAR) is similar to EVAR. Fewer postsurgical complications occur with TEVAR. However, TEVAR does not prevent the risk for renal failure, paraplegia, or stroke.[16] A lumbar spinal drain may be inserted to help decrease or prevent neurologic complications. If a lumbar drain is used, strict aseptic technique is essential to prevent infection.

Surgical Therapy

An acute Type A aortic dissection is a surgical emergency. Mortality rate is 50% within 48 hours of symptom onset. Otherwise, surgery is indicated when conservative therapy is ineffective or when complications (e.g., HF) occur. Open surgical repair is recommended for patients with a chronic dissection who have a connective tissue disorder or an aneurysm greater than 5.5 cm.[13,15]

The aorta is fragile after dissection. Surgery is delayed, when possible, to allow time for edema to decrease and to permit blood clotting in the false lumen. Surgery involves resection of the aortic segment with the intimal tear and replacement with a synthetic graft. Even with prompt surgical intervention, the in-hospital mortality is high.[15,16] Causes of death include aortic rupture, mesenteric ischemia, MI, sepsis, stroke, and multiorgan failure.

Nursing Management: Aortic Dissection

Preoperative nursing care includes keeping the patient in bed in a semi-Fowler's position and maintaining a quiet environment. These measures help to keep the HR and SBP at the lowest possible level that maintains vital organ perfusion (typically HR less than 60 beats/min; SBP between 100 and 120 mm Hg). Give opioids and sedatives as ordered. Manage pain and anxiety because they can cause elevations in the HR and SBP.

Titrating IV antihypertensive agents requires careful supervision, including continuous ECG and arterial BP monitoring. Monitor vital signs frequently, sometimes as often as every 2 to 3 minutes, until target HR and BP are reached. Look for changes in peripheral pulses and signs of increasing pain, restlessness, and anxiety. Postoperative care is similar to that after OAR (see earlier section on nursing management of aortic aneurysms).

In preparation for discharge, focus on patient and caregiver teaching. All patients with a history of aortic dissection require long-

term health care to control HR and BP. Help patients understand that they need to take antihypertensive drugs daily for the rest of their lives. β-Blockers are used to control HR and BP and decrease myocardial contractility. ACE inhibitors (e.g., lisinopril [Zestril]) are given if the patient cannot tolerate β-blockers. It is important that patients understand the drug regimen and side effects (e.g., dizziness, depression, fatigue, erectile dysfunction). Tell the patient to discuss any side effects with the HCP before stopping any medication.

Follow-up with regularly scheduled MRIs or CTs is essential. The most common cause of death in long-term survivors is aortic rupture from redissection or aneurysm formation. Tell patients that if the pain or other symptoms return, they should activate the emergency response system (ERS) for immediate care.

Acute and Chronic Venous Disorders

Phlebitis

Most hospitalized patients have an IV catheter inserted for fluids and/or drugs. *Phlebitis* is an acute inflammation of the walls of small cannulated veins of the hand or arm. Manifestations include pain, tenderness, warmth, erythema, swelling, and a palpable cord. Risk factors are mechanical irritation from the catheter, infusion of irritating drugs, and catheter location. Severe phlebitis is more likely to occur in areas of flexion (e.g., wrist and antecubital area). Avoid IV catheter insertion in this area whenever possible.

Phlebitis is rarely infectious and usually resolves quickly after catheter removal. If edema is present, elevate the extremity to promote reabsorption of fluid. Apply warm, moist heat and give oral NSAIDs (e.g., ibuprofen) or topical NSAIDs (e.g., diclofenac gel) to relieve pain and inflammation.

Venous Thrombosis

Venous thrombosis involves the formation of a *thrombus* (blood clot)

with vein inflammation. It is the most common disorder of the veins. We classify it as either superficial vein thrombosis or deep vein thrombosis. **Superficial vein thrombosis** is the formation of a thrombus in a superficial vein, usually the greater or lesser saphenous vein. **Deep vein thrombosis (DVT)** involves a thrombus in a deep vein, most often the iliac and/or femoral veins. **Venous thromboembolism (VTE)** is the preferred terminology. It represents the spectrum from DVT to pulmonary embolism (PE) (Table 37.7). (Chapter 27 discusses PE.)

Superficial vein thrombosis is serious. Nearly 25% of patients with superficial vein thrombosis have a DVT or PE at the time of diagnosis. Further, these patients are at risk for developing recurrent VTE.

Etiology

The 3 key factors (called **Virchow's triad**) that cause venous thrombosis are (1) venous stasis, (2) damage of the endothelium (inner lining of the vein), and (3) hypercoagulability of the blood (Fig. 37.9). The patient at risk for developing VTE usually has predisposing conditions to these 3 disorders (Table 37.8).

TABLE 37.7 Comparison of Superficial Vein Thrombosis and Venous Thromboembolism

	Superficial Vein Thrombosis	Venous Thromboembolism (VTE)
Usual location	Typically, superficial leg veins (e.g., varicosities). Sometimes superficial arm veins.	Deep veins of arms (e.g., axillary, subclavian), legs (e.g., femoral), pelvis (e.g., iliac), vena cava, and pulmonary system.
Clinical findings	Tenderness, itchiness, redness, warmth, pain, inflammation, and induration along the course of superficial vein. Vein appears as a palpable cord. Edema rarely occurs.	Tenderness to pressure over involved vein, induration of overlying muscle, venous distention. Edema. May have mild to moderate pain, deep reddish color to area caused by venous congestion. Some have no obvious physical changes in the affected extremity.
Sequelae	If untreated, clot may extend to deeper veins and VTE may occur.	Embolization to lungs (PE) may occur and may result in death. Pulmonary hypertension and post-thrombotic syndrome with or without venous leg

		ulceration may develop.

Venous Stasis

Normal venous blood flow depends on the action of muscles in the extremities and the function of venous valves, which allow flow in one direction. *Venous stasis* occurs when the valves are dysfunctional or the muscles of the extremities are inactive. Venous stasis occurs most often in people who are obese or pregnant, have chronic HF or atrial fibrillation, have been traveling on long trips without regular exercise, have a prolonged surgical procedure, or are immobile for long periods (e.g., spinal cord injury, fractured hip, limb paralysis).[17]

Endothelial Damage

Damage to the endothelium of the vein may be caused by direct (e.g., surgery, intravascular catheterization, trauma, burns, prior VTE) or indirect (chemotherapy, diabetes, sepsis) injury. Damaged endothelium stimulates platelet activation and starts the coagulation cascade. This predisposes the patient to thrombus development.

Hypercoagulability of Blood

Blood hypercoagulability occurs in many disorders. These include severe anemias, polycythemia, cancers (e.g., breast, brain, pancreas, GI tract); nephrotic syndrome; high homocysteine levels; and protein C, protein S, and antithrombin deficiency.[17] A patient with sepsis is predisposed to hypercoagulability because of endotoxins released from bacteria. Some drugs (e.g., corticosteroids, estrogens) predispose a patient to thrombus formation.

Women who use tobacco, are of childbearing age and take estrogen-based oral contraceptives, are postmenopausal on oral hormone therapy, are over 35 years old, and have a family history of VTE are at a very high risk for VTE.[17] Women who use oral contraceptives with tobacco double their risk. Smoking causes hypercoagulability by increasing plasma fibrinogen and homocysteine levels and activating the intrinsic coagulation pathway.

Pathophysiology

Localized platelet aggregation and fibrin entrap RBCs, WBCs, and more platelets to form a thrombus. A frequent site of thrombus formation is the valve cusps of veins, where venous stasis occurs. As a thrombus enlarges, increased numbers of blood cells and fibrin collect behind it. This makes a larger clot with a "tail" that eventually blocks the lumen of the vein.

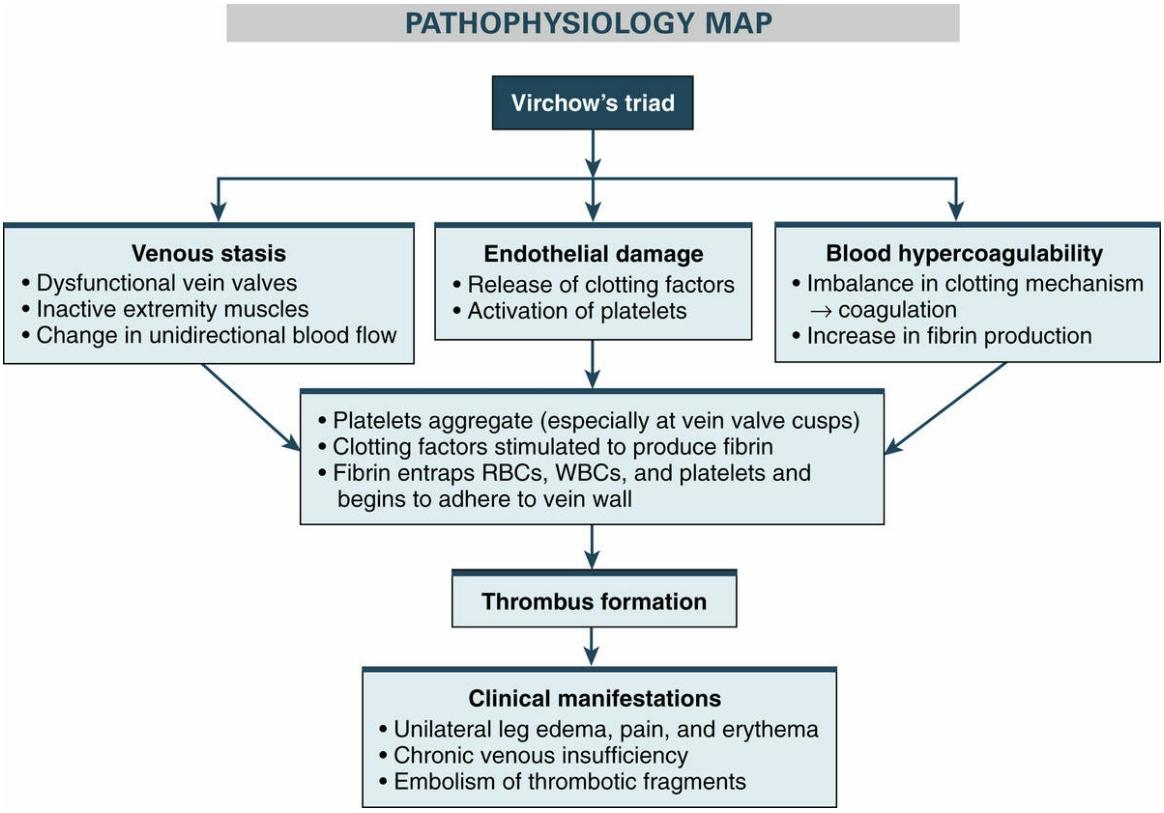

FIG. 37.9 Pathophysiology of venous thromboembolism.

TABLE 37.8 Risk Factors for VTE

Endothelial Damage

- Abdominal and pelvic surgery (e.g., gynecologic, urologic surgery)
- Caustic or hypertonic IV drugs
- Pelvis, hip, or leg fractures
- History of VTE
- Indwelling, peripherally inserted central vein catheter
- IV drug abuse
- Trauma

Venous Stasis

- Advanced age
- Atrial fibrillation
- Bed rest
- Chronic heart failure
- Fractured leg or hip
- Long trips without adequate exercise
- Obesity
- Orthopedic surgery (especially hip or lower extremity)
- Pregnancy and postpartum period
- Prolonged immobility
- Spinal cord injury or limb paralysis
- Stroke
- Varicose veins

Hypercoagulability of Blood

- Antiphospholipid antibody syndrome
- Antithrombin III deficiency
- Cancer (especially breast, brain, hepatic, pancreatic, GI)

- Dehydration or malnutrition
- Elevated (clotting) factor VIII or lipoprotein (a)
- Erythropoiesis-stimulating drugs (e.g., epoetin alfa [Procrit])
- High altitudes
- Hormone therapy
- High homocysteine levels
- Nephrotic syndrome
- Oral contraceptives, especially in women older than 35 years who use tobacco
- Polycythemia vera
- Pregnancy and postpartum period
- Protein C deficiency
- Protein S deficiency
- Sepsis
- Severe anemias
- Tobacco use

If a thrombus only partially blocks the vein, endothelial cells cover the thrombus and stop the thrombotic process. If the thrombus does not become detached, it undergoes lysis or becomes firmly organized and adherent within 5 to 7 days. The organized thrombus may detach and result in an embolus. Turbulence of blood flow is a major factor in embolization. The thrombus can become an embolus that flows through the venous circulation to the heart and lodges in the pulmonary circulation, becoming a PE.

Superficial Vein Thrombosis

Clinical Manifestations

The patient with superficial vein thrombosis may have a palpable, firm, subcutaneous cordlike vein (Table 37.7). The area surrounding the vein may be itchy, painful to the touch, reddened, and warm. A mild temperature elevation and leukocytosis may be present.

Extremity edema may occur. Lower extremity superficial vein thrombosis often involves 1 or more varicose veins.

Risk factors include increased age, pregnancy, obesity, cancer, recent fracture(s), estrogen therapy, recent sclerotherapy (e.g., treatment for varicose veins), recent surgery or long-distance travel, hypercoagulability, and a history of chronic venous insufficiency (CVI), superficial vein thrombosis, or VTE.[18] It can occur in people with endothelial problems (e.g., Buerger's disease).

Interprofessional Care

Ultrasound is used to confirm the diagnosis (clot 5 cm or larger) and to rule out clot extension to a deep vein.[18] If the superficial vein thrombosis affects a very short vein segment (less than 5 cm) and is not near the saphenofemoral junction, anticoagulants may not be needed and oral NSAIDs can ease symptoms. Other interventions include telling the patient to wear graduated compression stockings or bandages, apply warm compresses, elevate the affected limb above the level of the heart, apply topical NSAIDS, and perform mild exercise, such as walking.

Venous Thromboembolism

Clinical Manifestations

The patient with lower extremity VTE may or may not have unilateral leg edema, pain, tenderness with palpation, dilated superficial veins, a sense of fullness in the thigh or the calf, paresthesias, warm skin, erythema, or a systemic temperature greater than 100.4° F (38° C) (Table 37.7). If the inferior vena cava is involved, both legs may be edematous and cyanotic. About 10% of VTEs involve the upper extremity veins and may extend into the internal jugular vein or superior vena cava.[17] If the superior vena cava is involved, similar symptoms may occur in the arms, neck, back, and face. Diagnosis of an initial VTE is based on the assessment combined with D-dimer testing and/or ultrasound.

Complications

The most serious complications of VTE are PE, chronic thromboembolic pulmonary hypertension, post-thrombotic syndrome, and phlegmasia cerulea dolens. **Post-thrombotic syndrome (PTS)** occurs in 8% to 70% of patients. It results from chronic inflammation and chronic venous hypertension. Chronic venous hypertension is caused by vein wall and vein valve damage (from acute inflammation and thrombus reorganization), venous valve reflux, and persistent venous (outflow) obstruction. Symptoms include pain, aching, fatigue, heaviness, sensation of swelling, cramps, pruritus, tingling, paresthesia, bursting pain with exercise, and venous claudication.[19]

Manifestations include persistent edema, spider veins (telangiectasia), venous dilation (ectasia), redness, cyanosis, increased pigmentation, eczema, pain during compression, atrophie blanche (white scar tissue), and *lipodermatosclerosis* (Fig. 37.10). Venous ulceration can occur with severe PTS. Signs of PTS typically begin within a few months to a few years of a VTE. Risk factors include persistent leg symptoms 1 month after VTE, proximal VTE location (e.g., near the iliofemoral junction), extensive VTE, recurrent ipsilateral (same side) VTE, residual thrombus, obesity, older age, poor INR control, daily tobacco use before pregnancy, increased D-dimer levels, elevated inflammatory markers, varicose veins, and asymptomatic VTE.[17-19]

Phlegmasia cerulea dolens (swollen, blue, painful leg) is a rare complication of a severe lower extremity VTE(s). It involve(s) the major leg veins, causing near-total occlusion of venous outflow. Patients typically have sudden, massive swelling; deep pain; and intense cyanosis of the extremity. If untreated, the venous obstruction causes arterial occlusion and gangrene, requiring amputation.

Diagnostic Studies

Table 37.9 presents the diagnostic studies used to determine the site or location and extent of a VTE.

Interprofessional Care

Prevention

All members of the interprofessional team have important roles in VTE prevention. VTE prevention is a core measure of high-quality health care in high-risk hospitalized patients developed by The Joint Commission (TJC) and the National Quality Forum. There are 3 VTE measures. TJC recommends that hospitals have a policy that addresses VTE prevention on admission of all adult patients. In patients at risk for VTE, interventions used are based on bleeding and thrombosis risk, past medical history, current drugs, medical diagnoses, scheduled procedures, and patient preferences.

Early and aggressive mobilization is the easiest and most cost-effective method to decrease VTE risk. Patients on bed rest should change position at least every 2 hours. Unless contraindicated, teach patients to flex and extend their feet, knees, and hips at least every 2 to 4 hours while awake. Patients who can get out of bed need to be in a chair for meals and walk at least 4 to 6 times per day. Tell the patient and caregiver about the importance of these measures. Early and frequent ambulation is sufficient prophylaxis for patients at very low risk for VTE who had minor surgical procedures.[20] Anticoagulation and mechanical prophylaxis are not recommended for acutely ill medical patients at low risk for VTE.

FIG. 37.10 Lipodermatosclerosis. Skin on lower leg becomes scarred, and the leg becomes tapered like an "inverted bottle." Hallmark signs are leathery skin, brown discoloration, changes in pigmentation, and circumferential or near circumferential scarring and shrinking of the extremity.
From Etufugh CN, Phillips TJ: Venous ulcers, *Clin Dermatol* 25[1]:125, 2007.

Graduated compression stockings (e.g., thromboembolic deterrent [TED] hose) are a part of VTE prevention in hospitalized patients. VTE prevention is enhanced if the stockings are used along with anticoagulation. Proper stocking use means any toe hole is under the toes, the heel patch is over the heel, a thigh gusset is on the inner thigh (thigh length only), and there are no wrinkles. The stockings should not be rolled down, cut, or otherwise altered. If the stockings are not fitted and worn correctly, venous return is impeded. This can cause arterial ischemia, edema, skin breakdown, and VTE. Stockings are not recommended if the patient already has a VTE.[20]

Intermittent pneumatic compression devices (IPCs) use inflatable

sleeves or boots to compress the calf and thigh and/or foot and ankle to improve venous return. The sleeves apply external pressure through an electric pump. IPCs may be used with graduated compression stockings. Ensure correct fit of IPCs by accurately measuring the extremities. IPCs will not be effective if they are not applied correctly, if the fit is incorrect, or if the patient does not wear the device continuously while at rest. The IPCS can be removed for bathing, skin assessment, and ambulation. IPCs are not worn when a patient has an active VTE because of the risk for PE.[20]

Drug Therapy

Anticoagulants are used routinely for VTE prevention and treatment. The regimen depends on the patient's VTE risk. The goal of anticoagulant therapy for VTE prevention is to prevent clot formation. The goals for treatment of a confirmed VTE are to prevent new clot development, spread of the clot, and embolization.[20]

The 3 major classes of anticoagulants available are (1) vitamin K antagonists (VKAs), (2) thrombin inhibitors (both indirect and direct), and (3) factor Xa inhibitors (Table 37.10).[21] Anticoagulant therapy does not dissolve the clot. Clot lysis begins naturally through the body's intrinsic fibrinolytic system (see Chapter 29).

TABLE 37.9 Diagnostic StudiesVTE

Study	Description and Abnormal Findings
Blood Laboratory Studies	
ACT, aPTT, INR, bleeding time, Hgb, Hct, platelet count	Altered if patient has underlying blood dyscrasia (e.g., increased Hgb and Hct in patient with polycythemia)
D-dimer	Fragment of fibrin formed from fibrin degradation and clot lysis. High results suggest VTE. *Normal results:* <250 ng/mL (<250 mcg/L)
Fibrin monomer complex	Forms when concentration of thrombin exceeds that of antithrombin. Presence is evidence of thrombus formation and suggests VTE. *Normal results:* <6.1 mg/L
Noninvasive Venous Studies	
Duplex ultrasound	Combination of compression ultrasound with spectral and color flow Doppler. Veins examined for compressibility and intraluminal filling defects to help determine location and extent of thrombus (most widely used test to diagnose VTE).
Venous compression ultrasound	Evaluation of deep femoral, popliteal, and posterior tibial veins *Normal finding:* Veins collapse with application of external pressure. *Abnormal finding:* Veins do not collapse with application of external pressure. Failure to collapse suggests a thrombus.
Invasive Venous Studies	
Computed tomography venography (CTV)	Uses spiral CT to evaluate veins in the pelvis, thighs, and calves after injection of contrast material. May be done simultaneously with CT angiography of pulmonary vessels for patients being evaluated for VTE.
Magnetic resonance venography	Uses MRI with specialized software to evaluate blood flow through veins. Can be done with or without contrast. Highly accurate for pelvic and proximal veins. Less accurate for calf veins. Can distinguish acute and chronic thrombus
Contrast venography (phlebogram)	X-ray determination of location and extent of clot using contrast media to outline filling defects. Identifies the presence of collateral circulation. Once the gold standard, but now rarely done

ACT, Activated clotting time.

TABLE 37.10 Drug TherapyAnticoagulant Therapy

Drug	Route of Administration	Considerations
Vitamin K Antagonists (VKA)		
warfarin (Coumadin)	PO	INR used to monitor therapeutic levels. Give at the same time each day. Variations of certain genes (e.g., *CYP2CP, VKORC1*) may influence response to drug. *Antidote:* Vitamin K. For VKA-related bleeding, treatment with prothrombin complex concentrate (human) (Kcentra), IV vitamin K and/or fresh frozen plasma is recommended.
Thrombin Inhibitors: Indirect		
Low-Molecular-Weight Heparin (LMWH)		
dalteparin (Fragmin) **enoxaparin (Lovenox)**	Subcutaneous	Routine coagulation tests typically not needed. Monitor CBC count at regular intervals. Do not expel air bubble from prefilled syringe. If giving subcutaneously, inject deep into subcutaneous tissue (preferably into the abdominal fatty tissue or above the iliac crest), inserting the entire length of the needle. Hold skinfold during injection but release before removing needle. Do not aspirate. Do not inject IM. Do not rub site after injection. Rotate sites. Reduced dosage needed in patients with renal impairment. Use extreme caution in patients with a history of HIT. *Antidote:* Protamine neutralizes the effects of LMWH.
Unfractionated Heparin (UH)		
heparin sodium	Continuous IV Intermittent IV Subcutaneous	Therapeutic effects measured at regular intervals by the aPTT or ACT. Monitor CBC counts at regular intervals and titrate according to parameters. Follow administration guidelines for LMWH if giving subcutaneously. *Antidote:* Protamine neutralizes the effect of UH.
Factor Xa Inhibitors		
apixaban (Eliquis)	PO	All are approved for VTE prevention and treatment. Routine coagulation tests not needed. Monitor CBC and creatinine at regular intervals. May cause thrombocytopenia. Do not expel air bubble before giving fondaparinux. Follow administration guidelines as described for subcutaneous LMWHs. *Antidote:* Andexanet alfa (Andexxa) reverses the effects of rivaroxaban and apixaban.
betrixaban (Bevyxxa)	PO	
edoxaban (Savaysa)	PO	
fondaparinux (Arixtra)	Subcutaneous	
rivaroxaban (Xarelto)	PO	
Thrombin Inhibitors: Direct		
Hirudin Derivatives		
bivalirudin (Angiomax)	IV	Therapeutic effect measured by ACT or aPTT. Used in patients with HIT when anticoagulation is needed. *Antidote:* None.
desirudin (Iprivask)	Subcutaneous	
Synthetic Thrombin Inhibitors		
argatroban (Acova)	IV	Argatroban therapeutic effect measured by aPTT. No routine coagulation tests needed for dabigatran. Used in patients at risk for or with HIT, for VTE prevention in joint replacement surgery, stroke prevention in nonvalvular atrial fibrillation *Antidote:* Idarucizumab (Praxbind) neutralizes the effect of dabigatran only.
dabigatran (Pradaxa)	PO	

ACT, Activated clotting time; *HIT,* heparin-induced thrombocytopenia.

Vitamin K antagonists

The oral anticoagulant for long-term or extended anticoagulation is warfarin, a VKA. Warfarin inhibits activation of the vitamin K–dependent coagulation factors II, VII, IX, and X and the anticoagulant proteins C and S. (See the list of clotting factors in Table 29.2. Fig. 29.4 shows the clotting pathways.) Warfarin begins to take effect in 48 to

72 hours. It then takes several more days to achieve a maximum effect. Thus an overlap of a parenteral anticoagulant (e.g., UH or low-molecular-weight heparin [LMWH]) and warfarin typically is required for 5 days. The level of anticoagulation is monitored daily using the INR. The INR is a standardized system of reporting prothrombin time (PT) (Table 37.11). The antidote for warfarin-related bleeding is vitamin K, prothrombin complex concentrate (human) (Kcentra), or fresh frozen plasma (FFP).

Take a careful history before starting warfarin. Do not give antiplatelet drug or NSAIDs with warfarin as these increase bleeding risk.[21] Many other drugs, vitamins, minerals, and dietary and herbal supplements interact with warfarin (see the Complementary & Alternative Therapies box). A diet that varies in vitamin K intake (e.g., green leafy vegetables) can make it hard to achieve and maintain a target INR level. Genetic variants in the genes *VKORC1* and cytochrome P450 2C9 *(CYP2C9)* may influence how some people respond to warfarin (see Table 12.5 and Fig. 12.7).

Thrombin inhibitors

There are 2 major classes of *indirect thrombin inhibitors*: UH and LMWHs. UH (e.g., heparin) affects both the intrinsic and common pathways of blood coagulation by way of the plasma antithrombin. Antithrombin inhibits thrombin-mediated conversion of fibrinogen to fibrin by affecting factors II (prothrombin), IX, X, XI, and XII (see Fig. 29.4).

TABLE 37.11 Blood Coagulation Tests

Test and Drugs Monitored	Normal Value	Therapeutic Value
Activated Clotting Time (ACT)	70–120 sec*	>300 sec
• Hirudin derivatives (e.g., bivalirudin [Angiomax]) • Synthetic thrombin inhibitors (e.g., argatroban [Acova]) • Unfractionated heparin (e.g., heparin [Hep-Lock])		
Activated Partial Thromboplastin Time (aPTT)	30–40 sec	46–70 sec
• Hirudin derivatives • Synthetic thrombin inhibitors • Unfractionated heparin		
Anti-Factor Xa		
• Factor Xa inhibitors (e.g., fondaparinux [Arixtra], rivaroxaban [Xarelto]) • Low-molecular-weight heparin (e.g., enoxaparin [Lovenox])	0 units/mL 0 units/mL	0.6–1.0 units/mL 0.2 1.5 units/mL
International Normalized Ratio (INR)	0.75–1.25	2–3
• Vitamin K antagonists (e.g., warfarin [Coumadin])		

* Varies based on type of system and test reagent or activator used.

Complementary & Alternative Therapies

Herbal and Dietary Supplements That May Affect Clotting

Scientific Evidence

Many herbs and dietary supplements may affect blood clotting. These include bilberry, black cohosh, chamomile, chondroitin sulfate, dehydroepiandrosterone (DHEA), feverfew, garlic, ginger, ginkgo biloba, ginseng, goldenseal, grapeseed extract, green tea, horse chestnut seed extract, melatonin, niacin, omega-3 fatty acids, psyllium, red yeast rice extract, saw palmetto, soy, turmeric.

Nursing Implications

- Tell patients that taking these herbs or dietary supplements may increase their risk for bleeding.
- Caution patients with bleeding disorders about using these herbs and dietary supplements. Teach them to consult with their HCP before using these substances.

Heparin can be given subcutaneously for VTE prevention or by continuous IV infusion for VTE treatment. When given IV, heparin requires frequent monitoring of clotting status as measured by

activated partial thromboplastin time (aPTT) (Table 37.11). Protamine sulfate reverses the effect of heparin.

One serious side effect of heparin is *heparin-induced thrombocytopenia* (HIT). HIT is an immune reaction to heparin. It causes a severe, sudden reduction in the platelet count along with a paradoxical increase in venous or arterial thrombosis. HIT is diagnosed by measuring the presence of heparin antibodies in the blood. Treatment includes immediately stopping heparin therapy and, if further anticoagulation is needed, using a non-heparin anticoagulant (e.g., fondaparinux).[21] Another side effect of long-term heparin therapy is osteoporosis.

LMWHs (e.g., enoxaparin [Lovenox]) are derived from UH. They have more predictable dose response, longer half-life, and fewer bleeding complications than UH. LMWHs are less likely to cause HIT and osteoporosis. LMWHs typically do not require ongoing anticoagulant monitoring and dose adjustment. Their antiinflammatory properties may help prevent PTS and venous ulcer development.[21] Protamine neutralizes the effect of LMWH.

Direct thrombin inhibitors are classified as hirudin derivatives or synthetic thrombin inhibitors. Hirudin is made using recombinant deoxyribonucleic acid (DNA) technology. It binds specifically with thrombin and directly inhibits its function without causing plasma protein and platelet interactions. Hirudin derivatives (e.g., bivalirudin [Angiomax]) are given by continuous IV infusion. Bivalirudin is approved for patients with or at risk for HIT having a percutaneous coronary intervention. Anticoagulant activity is monitored using aPTT or activated clotting time (ACT) (Table 37.11). If bleeding occurs, there is no antidote for hirudin derivatives.

Argatroban, a synthetic direct thrombin inhibitor, hinders thrombin. Like bivalirudin, it is an alternative to heparin for the prevention and treatment of HIT and for patients with or at risk for HIT needing percutaneous coronary interventions. The effect of argatroban is not reversible. Its anticoagulant effect is monitored using aPTT or ACT.

Dabigatran (Pradaxa) is an oral direct thrombin inhibitor. It is used

for VTE prevention after elective joint replacement, for stroke prevention in nonvalvular atrial fibrillation, and as a treatment for VTE. Idarucizumab (Praxbind) neutralizes the effect of dabigatran. Dabigatran has 5 major advantages compared to warfarin: rapid onset, no need to monitor anticoagulation, few drug-food interactions, lower risk for major bleeding, and predictable dose response.[21]

Factor Xa inhibitors

Factor Xa inhibitors inhibit factor Xa directly or indirectly, producing rapid anticoagulation. These include fondaparinux (Arixtra), rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). All are used for both VTE prevention and treatment. Fondaparinux is given subcutaneously. It is contraindicated in patients with severe renal disease. Rivaroxaban, apixaban, and edoxaban are oral drugs. Although coagulation monitoring or dose adjustment is not needed, the drug's anticoagulant activity can be measured using anti-Xa assays (Table 37.11). If uncontrollable bleeding occurs, recombinant factor VIIa may be useful. Andexanet Alfa (Andexxa) reverses the effects of rivaroxaban and apixaban.

Anticoagulant therapy for VTE prevention

For VTE prevention in the hospitalized medical patient at risk for thrombosis who is not bleeding, low-dose UH, LMWH, or fondaparinux is used. If the patient is at low VTE risk, drug prophylaxis is not needed. Patients with moderate VTE risk (e.g., general, gynecologic, urologic surgery) should receive either UH or LMWH. Patients with high VTE risk (e.g., trauma) should receive UH or LMWH until discharge. Patients having abdominal or pelvic surgery for cancer or major orthopedic surgery (e.g., total knee or hip replacement) should receive VTE prophylaxis.[20]

Anticoagulant therapy for VTE treatment

Patients with confirmed VTE should receive initial treatment with either LMWH, UH, or an oral factor Xa drug. Oral VKA therapy may be an option. A therapeutic INR is maintained between 2.0 and 3.0 if

VKA therapy is used. Active treatment of VTE should continue for at least 3 months and may continue longer in some patients.[20]

Patients with multiple co-morbidities, complex medical issues, or a very large VTE usually are hospitalized for treatment. Parenteral administration of UH is the typical initial treatment. Depending on the presentation and home situation, patients may be safely and effectively managed as outpatients.

Thrombolytic therapy for VTE treatment

Another treatment option for patients with a thrombus is catheter-directed administration of a thrombolytic drug (e.g., urokinase, tPA). It dissolves the clot(s), reduces the acute symptoms, improves deep venous flow, reduces valvular reflux, and may help to decrease the incidence of PTS. Catheter-directed thrombolysis is an option for select patients who are at a low bleeding risk and present with an acute, extensive, symptomatic, proximal VTE. Systemic anticoagulation is needed before, during, and after catheter-directed thrombolysis. (Chapter 33 discusses thrombolytic therapy.)

Check Your Practice

Your 55-yr-old female patient is admitted with an extensive VTE in her right leg. She is receiving weight-based IV heparin per agency protocol: 18 units/kg/hr. You receive the following critical laboratory result: aPTT 122 seconds.

- Describe your next actions.

Surgical and Interventional Radiology Therapies

A few patients with extensive, acute, proximal VTE who are not candidates for catheter-directed thrombolysis and/or interventional radiology therapies (due to bleeding risk) may have surgery.[3,16] Surgical options include open venous thrombectomy and inferior

vena cava interruption. *Venous thrombectomy* involves the removal of a clot through a vein incision. Anticoagulant therapy is used after venous thrombectomy.

Vena cava interruption devices (e.g., Greenfield, Vena Tech, TrapEase filters) can be placed percutaneously through the right femoral or right internal jugular veins. The filter device is opened, and the spokes penetrate the vessel walls (Fig. 37.11). The filters act as a "sieve-type" device, allowing filtration of clots without interruption of blood flow. Complications after the insertion are rare but include air embolism, improper placement, migration of the filter, and perforation of the vena cava with retroperitoneal bleeding. Over time, clots can clog the filter and completely block the vena cava, requiring filter removal and replacement. A filter device is recommended with acute PE or proximal VTE of the leg in patients with active bleeding or if anticoagulant therapy is contraindicated or ineffective.

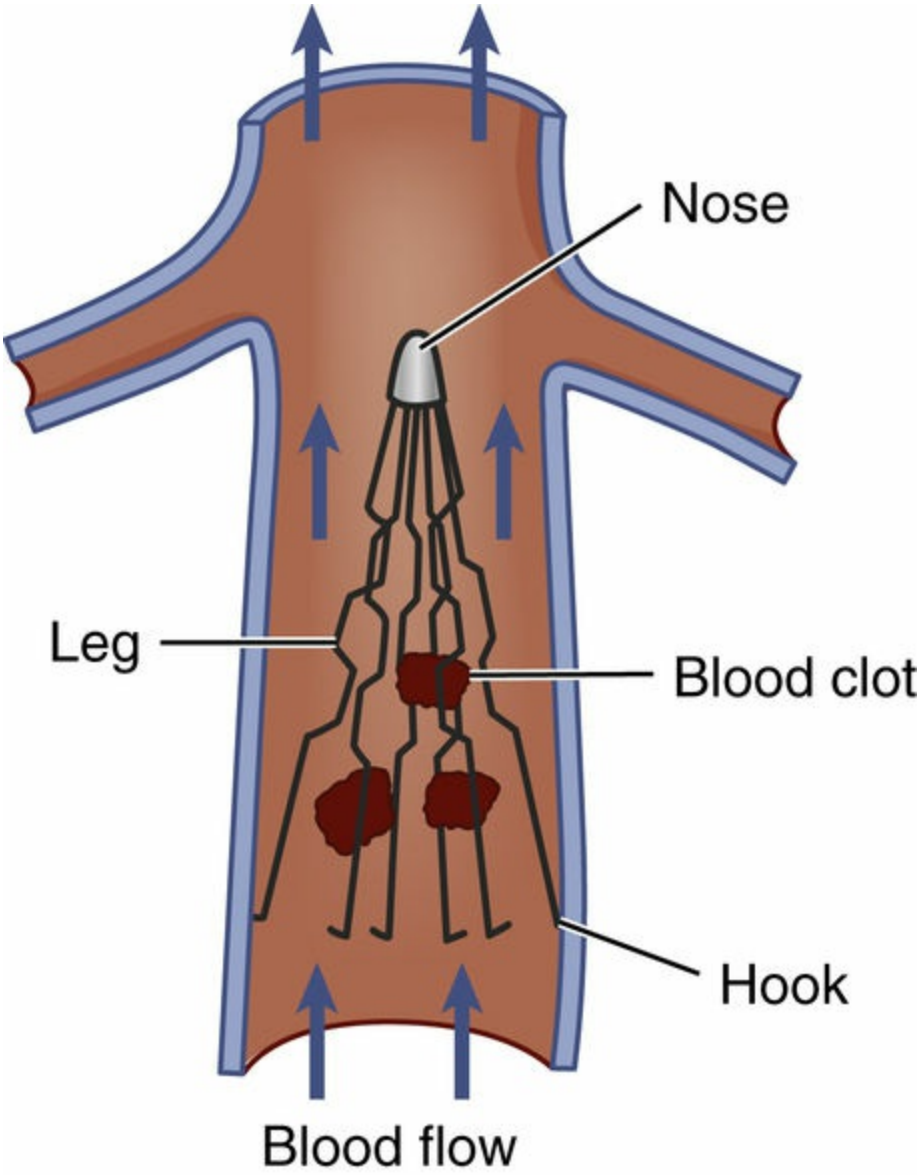

FIG. 37.11 Inferior vena cava interruption technique using Greenfield stainless steel filter to prevent pulmonary embolism. As blood travels up the vena cava, clots are trapped in the filter.

Percutaneous endovascular interventional radiology procedures can be used along with catheter-directed thrombolytic therapy, especially for severely symptomatic patients with iliocaval or iliofemoral obstruction.[17] The interventional radiology procedures are like those used in the treatment of lower extremity PAD. The difference is accessing an occluded vein instead of an artery. Options include mechanical thrombectomy, pharmacomechanical devices, and post-

thrombus extraction, angioplasty, and/or stenting.[17] Anticoagulation therapy is recommended after an iliofemoral interventional radiology procedure. Postprocedure nursing care focuses on (1) maintaining catheter systems (if continuous infusions); (2) monitoring for bleeding, embolization, and impaired perfusion; and (3) VTE prevention teaching.[17]

Nursing Management: Venous Thromboembolism

Nursing Assessment

Table 37.12 presents the subjective and objective data to obtain from a patient with VTE.

TABLE 37.12 Nursing AssessmentVTE

Subjective Data Important Health Information (Table 37.8)
Past health history: Trauma to vein, intravascular catheter (e.g., peripherally inserted central catheter), varicose veins, pregnancy or recent childbirth, bacteremia, obesity, prolonged bed rest, irregular heartbeat (e.g., atrial fibrillation), COPD, HF, cancer, coagulation disorders and hypercoagulable states, systemic lupus erythematosus, MI, spinal cord injury, stroke, prolonged travel, recent bone fracture, dehydration
Medications: Use of estrogens (including oral contraceptives, hormone therapy), tamoxifen, raloxifene (Evista), corticosteroids, excessive amounts of vitamin E, erythropoiesis-stimulating drugs
Surgery or other treatments: Any recent surgery, especially orthopedic, gynecologic, GI, or urologic. Previous surgery

involving veins. Central venous catheter

Functional Health Patterns

Health perception–health management: IV drug abuse, tobacco use, obesity
Activity-exercise: Inactivity
Cognitive-perceptual: Pain in area on palpation or ambulation

Objective Data
General

Fever, anxiety, pain

Integumentary

Increased size of extremity when compared with other side. Taut, shiny, warm skin, erythematous, tender to palpation. No physical changes in the affected extremity in some patients

Cardiovascular

Distention and warmth of superficial veins in affected area. Edema and cyanosis of extremities, neck, back, and face (if superior vena cava involvement)

Possible Diagnostic Findings

Leukocytosis, abnormal coagulation, anemia or ↑ hematocrit and RBC count, ↑ D-dimer level, positive venous compression on duplex ultrasound study; positive CT venogram, magnetic

resonance venogram, or contrast venogram study

Nursing Diagnoses

Nursing diagnoses and collaborative problems for the patient with VTE include:

- Acute pain
- Impaired tissue integrity
- Impaired physical mobility
- Risk for bleeding

Planning

The overall goals for the patient with VTE include (1) pain relief, (2) decreased edema, (3) increased knowledge of disorder and treatment plan, (4) no skin ulceration, (5) no bleeding complications, and (6) no evidence of PE.

Nursing Implementation

Acute Care

Focus your nursing care for the patient with VTE on preventing thrombi and reducing inflammation. Review with the patient any drugs, vitamins, minerals, and dietary and herbal supplements that may interfere with anticoagulant therapy (see the Complementary & Alternative Therapies box on p. 818). Depending on the anticoagulant ordered, monitor INR, aPTT, ACT, anti-factor Xa levels, complete blood count (CBC), creatinine, factor X levels, hemoglobin, hematocrit, platelet levels, and/or liver enzymes.[21] Monitor platelet counts for patients getting UH or LMWH to assess for HIT. Titrate doses of UH, warfarin, and direct thrombin inhibitors based on results of blood studies and agency protocols. Direct thrombin inhibitors may need adjustment for patients with renal or liver disease. Check the results of pertinent tests before starting, giving, or changing anticoagulant

therapy.

Monitor for and reduce the risk for bleeding with anticoagulant therapy (Table 37.13). Bleeding risk is greater in people receiving LMWH or UH with an active gastroduodenal ulcer, prior bleeding history, low platelet count, hepatic or renal failure, rheumatic disease, cancer, or age greater than 85 years.[21] Patients receiving warfarin with an INR of 5.0 or more are at increased risk for bleeding. In case of anticoagulation above target goals, give reversal agents (e.g., protamine, vitamin K) or make dosage adjustments as prescribed.

Drug Alert

Anticoagulant Therapy

- Avoid IM injections.
- Observe closely for any signs of bleeding: hypotension, tachycardia, hematuria, melena, hematemesis, petechiae, bruising, oozing or visible bleeding from trauma site or surgical incision.
- Tell patients to report bleeding: black or bloody stools, bleeding gums, bloody urine or sputum, coffee-ground or bloody vomit, excessive bruising, nosebleeds, excessive menstrual bleeding.
- Assess for mental status changes, especially in the older patient, since this may indicate cerebral bleeding.
- Tell patients to avoid taking aspirin, NSAIDs, fish oil supplements, garlic supplements, ginkgo biloba, and certain antibiotics (e.g., sulfamethoxazole and trimethoprim [Bactrim]).

Early ambulation does not increase the short-term risk of a PE in patients with VTE. In addition, early ambulation after acute VTE results in a more rapid decrease in edema and limb pain, fewer PTS symptoms, and better quality of life. Teach the patient and caregiver the importance of physical activity. Help the patient ambulate several

times a day. For patients with acute VTE with severe edema and limb pain, bed rest with limb elevation may initially be prescribed.

Ambulatory Care

Focus discharge teaching on modifying VTE risk factors, monitoring laboratory values, dietary and drug instructions, and guidelines for follow-up. If appropriate, suggest the patient stop smoking and avoid all nicotine products. Teach the patient to avoid constrictive clothing. Tell women with a history of VTE to stop oral contraceptives or hormone therapy. Teach patients to limit standing or sitting in a motionless, leg-dependent position.

TABLE 37.13 Nursing Management Patients Receiving Anticoagulants

Assessment

- Monitor vital signs as indicated.
- Examine urine and stool for overt and occult signs of blood.
- Inspect skin often, especially under any splinting devices.
- Evaluate platelet count for signs of heparin-induced thrombocytopenia.
- Evaluate appropriate laboratory coagulation tests for target therapeutic levels.
- Evaluate lower extremity for bruising or hematoma development if intermittent pneumatic compression device used.
- Perform assessments frequently for signs and symptoms of bleeding (e.g., hypotension, tachycardia) or clotting.
- Notify the HCP of any abnormalities in assessments, vital signs, or laboratory values.

Injections

- Avoid IM injections.
- Minimize venipunctures.
- Use small-gauge needles for venipunctures unless therapy requires a larger gauge.
- Apply manual pressure for at least 10 minutes (or longer if needed) on venipuncture sites.

Patient Care

- Avoid restrictive clothing.
- Apply moisturizing lotion to skin.
- Use electric razors, not straight razors.
- Perform physical care in a gentle manner.
- Tell patient not to forcefully blow nose.
- Avoid removing or disrupting established clots.
- Humidify O_2 source if supplemental O_2 is ordered.
- Use soft toothbrushes or foam swabs for oral care.
- Reposition the patient carefully at regular intervals.
- Limit tape application. Use paper tape as appropriate.
- Give stool softeners to avoid hard stools and straining.
- Lubricate tubes (e.g., suction catheter) adequately before insertion.
- Use support pads, mattresses, bed cradles, and therapeutic beds as indicated.
- Apply graduated compression stockings or intermittent pneumatic compression devices (if ordered) and with attention to proper size, application, and use.
- Perform risk for fall and skin breakdown assessments per agency policy and implement safety and preventive measures as needed.

When traveling long distances, tell patients to frequently exercise the calf muscles, take short walks, and drink nonalcoholic,

noncaffeinated beverages. For those at high risk for VTE who are planning a long trip, recommend properly fitted, knee-high graduated compression stockings during travel to decrease edema and VTE risk. Aspirin or anticoagulant use is not suggested for long-distance travelers. Teach the patient and caregiver about signs and symptoms of PE, such as sudden onset of dyspnea, tachypnea, and pleuritic chest pain. They should contact ERS if these symptoms occur.

Review drug dosage, actions, and side effects; the need for routine blood tests; and what symptoms need immediate medical attention (Table 37.14). Devices are available for home monitoring of INR. Teach patients taking LMWH or fondaparinux and their caregivers how to give the drug subcutaneously. Active or young patients need to avoid contact sports and activities with high risk for trauma (e.g., skiing). Teach older patients about safety precautions to prevent falls (e.g., avoid use of throw rugs). Tell the patient and caregiver to apply pressure for 10 to 15 minutes if bleeding occurs (e.g., nosebleed).

Nursing Management

Caring for the Patient With Venous Thromboembolism (VTE)

- Assess patients for VTE risk and monitor for VTE in at-risk patients.
- Teach patients who are at risk for VTE about preventive measures, such as increasing mobility, using graduated compression stockings and IPCs, and taking anticoagulant drugs.
- Measure patients for graduated compression stockings and/or IPCs.
- Assess for the use of dietary supplements or herbs that may affect the coagulation status before the start of anticoagulant therapy.
- Give prescribed oral, subcutaneous, and IV anticoagulants.
- Evaluate the effect of anticoagulant drugs by monitoring

appropriate laboratory results and side effects of therapy.

- Assess for complications of VTE, including PE and chronic venous insufficiency.
- Teach the patient and caregiver the manifestations of PE and the need to contact the ERS if these occur.
- Provide discharge teaching about use of graduated compression stockings, anticoagulant drugs, diet, laboratory testing, and subcutaneous anticoagulant therapy (if needed).
- Teach safety precautions to prevent falls or other injuries that might result in bleeding.
- Discuss how to use pressure to stop bleeding and to contact ERS for persistent bleeding.
- Teach the patient about lifestyle measures to prevent VTE, including leg exercises, ambulation, and avoiding nicotine and oral contraceptives.
- Oversee the UAP:
    - Reposition patients who are on bed rest at least every 2 hrs.
    - Remind patients about the need to flex and extend the legs and feet at least every 2 hrs while in bed.
    - Help ambulatory patients to walk at least 4 to 6 times daily.
    - Help patients with putting on graduated compression stockings.
    - Apply IPCs.
- Collaborate with the physical therapist*:*
    - Assess patient's mobility status.
    - Develop exercise/muscle strengthening program as needed.
- Collaborate with the dietitian:
    - Assess patient's diet and nutritional status.
    - Provide diet teaching as needed.

A well-balanced diet is important. Teach patients taking warfarin to follow a consistent diet of foods containing vitamin K and to avoid any supplements containing vitamin K (e.g., vitamins, green tea). Tell the patient to avoid excess amounts of vitamin E and alcohol. Encourage proper hydration to prevent hypercoagulability of the blood, which may occur with dehydration.

The overweight patient needs to limit carbohydrates and total caloric intake and increase physical activity to achieve and maintain desired weight. Exercise may help patients with VTE and PTS.[17,20] Help the patient develop an exercise program with an emphasis on leg strength training and aerobic activity. An exercise program also improves the patient's quality of life.

Graduated compression stockings reduce symptomatic swelling in patients with a proximal VTE.[17,20] Alternatively, IPCs may be used for patients with significant edema and moderate to severe PTS. The long-term use of graduated compression stockings may not prevent PTS development.

TABLE 37.14 Patient & Caregiver TeachingAnticoagulant Therapy

Include the following information in the teaching plan for a patient receiving anticoagulant therapy and the patient's caregiver:

1. Give reasons for and action of anticoagulant drug and how long therapy will last.
2. Take drug at the same time each day (preferably in afternoon or evening).
3. Depending on drug prescribed, obtain blood tests to assess therapeutic effect of the drug and whether change in dosage is needed.
4. Contact ERS immediately for any of the following adverse side effects of drug therapy:
    - Blood in urine or stool; or black, tarry stools

- Vomiting blood, coffee-grounds emesis
- Unusual bleeding from gums, skin, or nose, or heavy menstrual bleeding
- Severe headaches or stomach pain
- Chest pain, shortness of breath, palpitations (heart racing)
- Weakness, dizziness, mental status changes
- Cold, blue, or painful feet

5. Avoid any trauma or injury that may cause bleeding (e.g., vigorous brushing of teeth, contact sports, rollerblading, use of straight razor).
6. Avoid all aspirin-containing drugs and NSAIDs.
7. Limit alcohol intake to small to moderate amounts (12 oz beer, 4 oz wine, 1 oz hard liquor/day).
8. Wear a Medic Alert device saying what anticoagulant drug is being taken.
9. If taking warfarin (Coumadin), avoid frequent or dramatic changes in eating foods high in vitamin K (e.g., broccoli, spinach, kale, greens). Do not take supplemental vitamin K.
10. Consult with HCP before beginning or stopping any drug, vitamin, mineral, or dietary or herbal supplement (see Complementary & Alternative Therapies box on p. 818).
11. Inform all HCPs, including dentist, of anticoagulant therapy.
12. Correct dosing is essential. Provide supervision if patient has confusion or cognitive impairment.

Evaluation

The expected outcomes are that the patient with VTE will have

- Minimal to no pain
- Intact skin
- Increased knowledge of disorder and treatment plan
- No signs of hemorrhage or occult bleeding

Varicose Veins

Varicose veins, or *varicosities,* are dilated (3 mm or larger in diameter), tortuous superficial veins often found in the saphenous vein system. Varicosities may be small and harmless or large and bulging. *Primary varicose veins* (idiopathic) are due to a weakness of the vein walls. They are more common in women. *Secondary varicose veins* result from direct injury, a previous VTE, or excessive vein distention. Secondary varicose veins may occur in the esophagus (esophageal varices), vulva, spermatic cords (varicoceles), and anorectal area (hemorrhoids), and as abnormal arteriovenous (AV) connections.

Congenital varicose veins result from chromosomal defects that cause abnormal development of the venous system.[22] *Reticular veins* are smaller varicose veins that appear flat, less tortuous, and blue-green in color. *Telangiectasias* (often called spider veins), are small visible vessels (generally less than 1 mm in diameter) that appear bluish black, purple, or red.

Etiology and Pathophysiology

Superficial veins in the lower extremities become dilated and tortuous in response to backward (retrograde) blood flow and increased venous pressure. Risk factors include family history of chronic venous disease, weak vein structure, female gender, tobacco use, increasing age, obesity, multiparity, history of VTE, venous obstruction resulting from extrinsic pressure by tumors, thrombophilia, phlebitis, previous leg injury, and occupations that require prolonged standing or sitting.[22,23]

In primary varicose veins, weak vein walls allow the vein valve ring to enlarge, so the leaflets no longer fit together properly (incompetent). Incompetent vein valves allow backward blood flow, particularly when the patient is standing. This results in increased venous pressure and further venous distention. High pressure in the superficial veins also can be caused by vein valve dysfunction in the deep veins or perforator veins (veins that perforate the deep fascia of

muscles to connect the superficial veins to the deep veins).

Clinical Manifestations and Complications

Discomfort from varicose veins varies among people and tends to be worse after episodes of superficial vein thrombosis. Symptoms affect women more often than men.[23] The most common symptoms include a heavy, achy feeling or pain after prolonged standing or sitting, which is relieved by walking or limb elevation. Some patients feel pressure or an itchy, burning, tingling, throbbing, or cramp-like leg sensation. Swelling, restless or tired legs, fatigue, and nocturnal leg cramps may occur.

Superficial venous thrombosis is the most frequent complication of varicose veins. It may occur spontaneously or after trauma, surgical procedures, or pregnancy. Rare complications include rupture of the varicose veins resulting in external bleeding and skin ulcerations.

Diagnostic Studies and Interprofessional Care

Superficial varicose veins often can be diagnosed by careful physical examination. Duplex ultrasound imaging is the gold standard to evaluate venous anatomy, valvular competence, and venous obstruction.[22] Conservative treatment involves rest with limb elevation; graduated compression stockings; leg strengthening exercise, such as walking; and weight loss, if indicated.

Drug Therapy

Venoactive drugs, derived from plant extracts, are powerful antioxidants that work by stimulating release of chemicals within the vein walls to strengthen the circulation and reduce inflammation and edema. Several natural and synthetic venoactive agents have been used to treat varicose veins and advanced chronic venous disease. These include micronized purified flavonoid fraction, rutosides (e.g., horse chestnut seed extract [*Aesculus hippocastanum*]), proanthocyanidins (from grapes and apples), and *Ruscus* (butcher's

broom).[23]

Therapeutic benefits of venoactive drugs include pain relief, edema reduction, and decreased leg cramping and restless legs. These drugs are widely used in Europe. They are not approved by the FDA. However, many are available over the counter as dietary or herbal supplements.

Drug Alert

Horse Chestnut Seed Extract (Aesculus hippocastanum)

- May interact with lithium and antidiabetes, antiplatelet, and anticoagulant drugs.
- Should not be taken by persons with liver or kidney disease or with a latex allergy.

Interventional and Surgical Therapies

Sclerotherapy involves the direct IV injection of a liquid or foam sclerosing substance (e.g., hypertonic saline, polidocanol, glycerin) that chemically ablates (destroys) the treated veins. Sclerotherapy can be used on telangiectasias, perforator veins, reticular veins, varicose veins 5 mm in diameter or smaller, and venous malformations (Fig. 37.12). This procedure is done in an office setting and causes minimal discomfort.

The most common complications of sclerotherapy are residual pigmentation, matting (new telangiectasias develop in the area), thrombophlebitis, and ulcers.[23] After injection, a graduated compression stocking or compression bandage is worn. Patients should not travel long distances during the first week after sclerotherapy to minimize the risk for a VTE.

Other noninvasive options include transcutaneous laser therapy for telangiectasias and high-intensity pulsed-light therapy for reticular

veins. Transcutaneous laser or light therapy is used for patients in whom sclerotherapy is contraindicated or has been ineffective.[23] Vascular lasers work by heating the hemoglobin in the vessels, resulting in vessel sclerosis. Complications of these therapies include pain, blistering, hyperpigmentation, and superficial erosions.

A minimally invasive treatment option for saphenous vein reflux is endovenous ablation using thermal energy from radiofrequency or laser therapy. The HCP inserts a catheter into the vein to heat the vein wall, which then causes the vein to collapse. Complications include bruising, skin burns, hyperpigmentation, infection, paresthesia, superficial or deep vein thrombosis, and pulmonary embolism. Graduated compression stockings or bandages are worn afterwards. Endovenous thermal ablation may be done in combination with surgical ligation or phlebectomy.

FIG. 37.12 **A,** Lateral aspect of varicose veins before treatment. **B,** Lateral aspect of varicose veins 2 years after initial treatment with sclerotherapy.
From Goldman MP, Guex JJ, Weiss RA: *Sclerotherapy: Treatment of varicose and telangiectatic leg veins,* ed 5, Philadelphia, 2011, Mosby.

Surgical intervention is needed for recurrent superficial venous thrombosis or when symptoms cannot be controlled with other therapy. The traditional surgical intervention involves ligation of the entire vein (usually the greater saphenous vein) and removal of its incompetent branches. An alternative but time-consuming technique is *ambulatory phlebectomy*. This involves pulling the varicosity through a "stab" incision followed by excision of the vein. *Transilluminated powered phlebectomy* involves the use of a tissue resector to destroy clusters of varicosities and removes the pieces via aspiration. Complications include bleeding, bruising, and infection.

Nursing Management: Varicose Veins

Prevention is a key factor related to varicose veins. Tell the patient to avoid sitting or standing for long periods, maintain ideal body weight, take precautions against injury to the extremities, avoid wearing constrictive clothing, and walk daily.

After vein ligation surgery, encourage the patient to deep breathe, which promotes venous return. Check the extremities regularly for color, movement, sensation, temperature, edema, and quality of pedal pulses. Some bruising and discoloration are normal. Elevate the legs 15 degrees to limit edema. Apply graduated compression stockings or bandages. Remove them every 8 hours for short periods and then reapply.

Long-term management of varicose veins is directed toward improving circulation and appearance, relieving discomfort, and avoiding complications and ulceration. Varicosities can recur in other veins after surgery. Teach the patient the proper use and care of custom-fitted graduated compression stockings. The patient should apply stockings in bed before rising in the morning.

Emphasize the importance of periodic positioning of the legs above the heart. The overweight patient may need help with weight loss. The patient with a job that requires long periods of standing or sitting needs to frequently flex and extend the hips, legs, and ankles and change positions. Remind patients to consult with their HCP before taking any dietary or herbal supplements to avoid drug interactions.

Chronic Venous Insufficiency and Venous Leg Ulcers

Chronic venous insufficiency (CVI) describes abnormalities of the venous system that result in advanced signs and symptoms, such as edema, skin changes, and/or venous leg ulcers.[22] CVI can lead to *venous leg ulcers* (formerly called *venous stasis ulcers* or *varicose ulcers*). Although CVI and venous leg ulcers are not life-threatening diseases,

they are painful, slow to heal, debilitating, and costly conditions that adversely affect patients' quality of life. They are a common problem in older adults.

Etiology and Pathophysiology

Both long-standing primary varicose veins and PTS can progress to CVI. *Ambulatory venous hypertension* causes serous fluid and RBCs to leak from the capillaries and venules into the tissue. This causes edema and chronic inflammatory changes. Enzymes in the tissue eventually break down RBCs, causing the release of *hemosiderin*, which causes a brownish skin discoloration. Over time, fibrous tissue replaces the skin and subcutaneous tissue around the ankle. This results in thick, hardened, contracted skin. Although the causes of CVI are known, the exact pathophysiology of venous leg ulcers is unknown.

Clinical Manifestations and Complications

In patients with CVI, the skin of the lower leg is leathery, with a characteristic brownish or "brawny" appearance from the hemosiderin deposition. Edema usually has been persistent for a prolonged period. Eczema with itching and scratching is often present (Table 37.1).

Venous ulcers classically occur above the medial malleolus (Fig. 37.13). The ulcer is often quite painful, particularly when edema or infection is present. Pain may be worse when the leg is in a dependent position. If the venous ulcer is untreated, the wound becomes wider and deeper, increasing the risk for infection.

Interprofessional and Nursing Care

Compression is essential for venous ulcer healing and preventing venous ulcer recurrence.[22,23] A variety of options are available for compression therapy. These include custom-fitted graduated compression stockings, elastic tubular support bandages, a Velcro

wrap (CircAid), IPCs, and multilayer (3 or 4) bandage systems (e.g., Profore).[22,23] Evaluate patients individually when choosing a compression method. Before starting compression therapy, assess the arterial status to make sure that PAD is not present. An ABI of 0.4 or less suggests severe PAD, and the patient should not have any type of compression therapy.[3] Show how to correctly apply the compression therapy and have the patient "show back" the skill. Stockings should be worn daily to prevent recurrent leg ulcers. Tell the patient to replace stockings every 4 to 6 months.

Discuss activity guidelines and proper limb positioning. Tell patients with CVI to avoid standing or sitting for long periods, which decreases blood return from the lower extremities. Teach patients to frequently elevate their legs above the level of the heart to reduce edema. Encourage patients to begin a daily walking program once an ulcer heals. Tell the patient and caregiver to avoid trauma to the limbs. Teach proper foot and leg care to avoid more skin trauma.

Moist environment dressings are the basis of wound care. A variety of dressings are available. These include transparent film dressings, hydrocolloids, hydrogels, foams, alginates, gauze, and combination dressings. Dressing decisions should be based on wound characteristics, cost, best evidence, and clinician judgment. Chapter 11 and Table 11.9 discuss dressings.

Evaluate the nutritional status of a patient with a venous ulcer. A balanced diet with adequate protein, calories, and nutrients is essential. Foods high in protein (e.g., meat, beans, cheese, tofu), vitamin A (green leafy vegetables), vitamin C (citrus fruits, tomatoes, cantaloupe), and zinc (meat, seafood) are most important for healing. For patients with diabetes, maintaining normal blood glucose levels aids the healing process.

FIG. 37.13 Venous leg ulcer.
From Mosti G: Compression and venous surgery for venous leg ulcers, *Clin Plast Surg* 39:269, 2012.

Though venous leg ulcers are colonized by bacteria, routine use of antibiotics is not indicated. Signs of infection include change in quantity, color, or odor of the drainage; pus; erythema of the wound edges; change in sensation around the wound; warmth around the wound; increased local pain, edema, or both; dark-colored granulation tissue; induration around the wound; delayed healing; and cellulitis. If signs of infection occur, obtain a wound culture. Culture results guide antibiotic therapy. The usual treatment for infection is wound debridement, wound excision, and systemic antibiotics.

If the ulcer does not heal with conservative therapy, drug therapy should be considered. Pentoxifylline or micronized purified flavonoid fraction (Daflon) is recommended with compression therapy to improve healing.[23] Pentoxifylline minimizes WBC activation and adhesion to capillary endothelium and decreases oxidative stress. Micronized purified flavonoid fraction acts on WBCs to decrease inflammation and edema.[23]

Other treatments are considered for large venous leg ulcers that do not respond to standard therapy after 4 to 6 weeks. These include coverage with a skin replacement or substitute, such as split-thickness

skin grafts or artificial bioengineered skin.[22] (Chapter 24 discusses skin grafting.) Although grafts may aid with healing, they do not replace the need for lifelong compression therapy.

Patients with CVI have dry, flaky, itchy skin. Daily moisturizing decreases itching and prevents skin cracking. Contact dermatitis may result from contact with sensitizing products, such as topical antimicrobial agents (e.g., gentamicin); additives in bandages or dressings (e.g., adhesives); ointments containing lanolin, alcohols, or benzocaine; and over-the-counter creams or lotions with fragrance or preservatives. Assess wounds for signs of infection with each dressing change.

Nursing Management

Caring for the Patient With Chronic Venous Insufficiency

Many patients with CVI and venous ulcers receive outpatient care. The registered nurse (RN) does the initial wound assessment, develops and implements the plan of care, and periodically evaluates the patient and venous ulcer. Routine wound care can be done by LPN/VNs and UAP depending on the state nurse practice act and agency policy.

- Assess the patient for increases in edema, eczema, and venous leg ulcers.
- Assess diet and nutritional status and make referrals as needed.
- Assess for the use of venoactive dietary supplements or herbs that may adversely affect co-morbid conditions and/or prescription drugs.
- Choose best options for compression therapy and wound care.
- Give prescribed analgesics, antibiotics, or other drugs.
- Apply compression therapy.
- Provide wound care for venous leg ulcers.

- Evaluate for the effectiveness of therapies and need for alternative approaches.
- Teach patient and caregiver about the manifestations, complications, and treatment of venous insufficiency.
- Oversee the UAP in providing care:
    - Aid patients in elevating legs to reduce edema and pain.
    - Apply graduated compression stockings.
- Collaborate with the dietitian:
    - Assess diet and nutritional status.
    - Provide diet education as needed.

Case Study

Peripheral Artery Disease

© IPGGutenbergUKLtd/iStock/Thinkstock.

Patient Profile

S.J., a 73-yr-old black man, is admitted to the hospital with rest pain in both legs and a nonhealing ulcer of the big toe on the right foot.

Subjective Data

- History of a myocardial infarction, stroke, hypertension, HF, and type 1 diabetes
- Underwent a left femoral-popliteal bypass 5 yrs ago
- Has a 45-pack-yr history of tobacco use
- Has been using insulin for 30 yrs
- Reports sudden, intense increase in right foot pain for past 2 hrs
- Has slept in recliner with right leg in dependent position for several months to decrease leg pain

Current Medications

- Furosemide (Lasix) 40 mg/day PO
- Isosorbide dinitrate/hydralazine hydrochloride (BiDil) 1 tablet every 8 hr
- Aspart (NovoLog) insulin with meals
- Glargine insulin 50 units/day subcutaneously
- Diltiazem sustained release (Cardizem LA) 240 mg/day PO
- Aspirin 325 mg/day PO
- Fish oil daily (self-prescribed)

Objective Data

Physical Examination

- BP 148/92 mm Hg, irregular apical HR 90/min, respiratory rate 22/min, temperature 97.9° F (36.6° C)
- Alert and oriented, anxious, with no apparent physical or mental

deficits from stroke

- Has 1+ right femoral pulse, popliteal pulse by Doppler only, posterior tibial pulse by Doppler only, and dorsalis pedis pulse absent (not palpable or present by Doppler). Left leg pulses are 1+
- Right leg ABI: 0.20. Left leg ABI: 0.68
- Has a 2-cm necrotic ulcer on tip of right big toe
- Has thickened toenails. Shiny, thin skin on legs. No hair on both lower legs
- Right foot is very cool, pale, and mottled in color with decreased sensation
- No peripheral edema
- Bedside glucose measurement 298 mg/dL (last meal 4 hrs before admission)

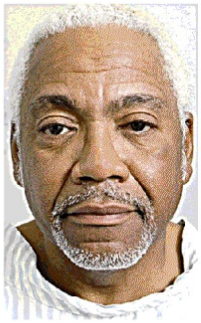
Discussion Questions

1. Assess S.J.'s risk factors for PAD.
2. Distinguish S.J.'s signs and symptoms of chronic PAD and acute arterial ischemia.
3. Identify the possible cause(s) for the sudden, intense increase in right foot pain.
4. How would you interpret S.J.'s ABI findings?
5. What other diagnostic tests can be done to assess the extent of his PAD?
6. Given the physical examination data, what initial drug(s) would you expect the HCP to prescribe?
7. What treatment modalities are possible for S.J.?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
9. ***Priority Decision:*** What are the priority nursing responsibilities in caring for S.J.?
10. ***Collaboration:*** Identify activities that can be delegated to UAP.
11. ***Evidence-Based Practice:*** When teaching S.J., what evidence-

based advice would you give him about the use of dietary supplements, such as fish oil?

12. ***Safety:*** To ensure S.J.'s safety, what nursing interventions are necessary to initiate?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.



Case Study

Managing Care of Multiple Patients

You are working on the cardiovascular stepdown unit and have been assigned to care for the following 6 patients. You have 1 LPN and 1 UAP assigned to help you.

Patients

 © Jupiterimages/Banana-Stock/Thinkstock.	L.P. is a 63-yr-old Asian American man who came to the ED with chest pain, shortness of breath, and palpitations. L.P.'s CK-MB and troponin levels are within normal limits. His ECG showed atrial fibrillation with a rapid ventricular response. He has been on IV diltiazem and IV heparin for 24 hr. Although his heart rate has decreased to 102 beats/min, the atrial fibrillation persists.
 © iStockphoto/Thinkstock.	J.E. is a 70-yr-old Hispanic woman admitted with increasing shortness of breath, fatigue, and weight gain. She has a systolic murmur and bilateral crackles. Her ejection fraction is 20%. She is receiving IV furosemide, oral potassium and enalapril (Vasotec), and a continuous infusion of nesiritide (Natrecor). She has O_2 at 6 L via nasal cannula to keep her O_2 saturation >93%. Normal initial set of cardiac enzymes.
 © iStockphoto/Thinkstock.	D.M. is a 51-yr-old man who was admitted 2 days ago with a suspected inferolateral wall MI. His cardiac-specific troponin I level was high, and the ECG showed marked ST segment elevation in the inferior leads. Cardiac catheterization showed a 90% blockage of his left anterior descending (LAD) artery. Coronary angioplasty was done, and 2 stents inserted. He is now 2 days post-PTCA, has had no recurrence of his chest pain, and is to be discharged today.
 © JennaDub/iStock/Thinkstock.	R.B. is a 50-yr-old man admitted for HF due to valvular heart disease. He has a history of IV drug and alcohol use. He reports chest pain with minimal exertion. He has atrial fibrillation with a rapid ventricular response. His rhythm converted to normal sinus rhythm after receiving IV amiodarone. TEE shows left atrial and ventricular hypertrophy and mitral and aortic regurgitation.

 © iStockphoto/Thinkstock.	J.M. is a 68-yr-old man admitted 3 days ago with a diagnosis of acute decompensated HF. He had a cardiac arrest (pulseless VT) and was successfully defibrillated after 1 shock. He underwent electrophysiology studies and implantation of an implantable cardiodefibrillator (ICD). He now is being treated for HF.
 © IPGGutenbergUKLtd/iStock/Thinkstock.	S.J. is a 73-yr-old black man admitted with rest pain in both legs and a nonhealing ulcer of the big toe on the right foot. He has history of an MI, stroke, hypertension, and type 1 diabetes. He had a left femoral-popliteal bypass 5 years ago. His right foot is cool, pale, and mottled in color with decreased sensation. He has a 1+ right femoral pulse, right popliteal and posterior tibial pulses only obtained by Doppler, and his right dorsalis pedis pulse is absent (not palpable or present by Doppler). His left leg pulses are 1+. His right leg ABI: 0.20; left leg ABI: 0.68.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Second? Provide a rationale for your decision.
2. ***Collaboration:*** Which tasks could you delegate to the LPN? *(select all that apply)*
    a. Monitor L.P.'s heparin infusion.
    b. Report changes in pain or sensation of S.J.'s legs.
    c. Teach D.M. about activity restriction after PTCA.
    d. Administer prescribed medications to R.B. and J.M.
    e. Hook up J.M. to 12-lead ECG and monitor for dysrhythmias.
3. ***Priority Decision and Collaboration:*** As you are assessing L.P., the LPN tells you that S.J. is diaphoretic and reports chest pain.

Which initial action would be *most* appropriate?

a. Ask the LPN to notify S.J.'s HCP.
b. Have the LPN administer prescribed nitroglycerin to S.J.
c. Leave L.P.'s room to perform a focused assessment on S.J.
d. Finish assessing L.P. while the UAP obtains a 12-lead ECG on S.J.

Case Study Progression

S.J. rates his chest pain as a 9/10. His blood pressure is 110/70, heart rate 110, respiratory rate 26, and O_2 saturation 93% on room air. You obtain a 12-lead ECG and administer 0.4 mg SL nitroglycerin with minimal pain relief after 5 minutes. The 12-lead ECG shows new ST elevation in leads II, III, and aVF.

4. Which interventions would you expect the HCP to order for S.J.? *(select all that apply)*
    a. IV nitroglycerin
    b. IV morphine sulfate
    c. Emergent cardiac catheterization
    d. Furosemide 40 mg IV push STAT
    e. Increase the O_2 flow rate to 12 L/min
5. What would you include in teaching about ICDs with J.M. and his family?
    a. Avoid air travel.
    b. Avoid driving for 6 weeks.
    c. Avoid any sexual activity in case the ICD discharges.
    d. Avoid standing near antitheft devices in stores and public buildings.
6. J.E is receiving nesiritide. What information is the priority to monitor?
    a. Blood pressure
    b. Respiratory rate

c. b-Natriuretic peptide (BNP) level
d. Troponin and CK-MB laboratory values

7. ***Priority Decision***: You are preparing to give morning medications. Which patient's medication should be given first?
    a. Oral potassium and enalapril to J.E.
    b. Oral metoprolol, aspirin, and clopidogrel to D.M.
    c. IV furosemide, oral enalapril and metoprolol to R.B.
    d. Subcut Novolog, oral diltiazem and furosemide to S.J.
8. ***Management Decision:*** You ask the UAP to take D.M.'s vital signs before and after having him walk 300 feet. When reviewing the patient's chart, you note record of the patient's walk but not his vital signs. What is your initial action?
    a. Report the incident to the charge nurse for follow-up.
    b. Talk to the UAP about why the vital signs were not recorded.
    c. Walk D.M. yourself again and take his vital signs pre- and post-activity.
    d. Ask the LPN to ambulate D.M. and obtain his vital signs before and after.

Answers and rationales available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A 50-year-old woman who weighs 95 kg has a history of tobacco use, high blood pressure, high sodium intake, and sedentary lifestyle. Which is the *most important* risk factor for peripheral artery disease (PAD) to address in the nursing plan of care?
    a. Salt intake

b. Tobacco use

c. Excess weight

d. Sedentary lifestyle

2. When teaching a patient about rest pain with PAD, what should the nurse explain as the cause of the pain?

a. Vasospasm of cutaneous arteries in the feet.

b. Decrease in blood flow to the nerves of the feet.

c. Increase in retrograde venous perfusion to the lower legs.

d. Constriction in blood flow to leg muscles during exercise.

3. A patient with infective endocarditis develops sudden left leg pain with pallor, paresthesia, and a loss of peripheral pulses. What should be the nurse's *initial* action?

a. Notify the HCP of the change in perfusion.

b. Start anticoagulant therapy with IV heparin.

c. Elevate the leg to improve the venous return.

d. Position the patient in reverse Trendelenburg.

4. Which clinical manifestations can the nurse expect to see in both patients with Buerger's disease and patients with Raynaud's phenomenon? *(select all that apply)*

a. Intermittent low-grade fevers

b. Sensitivity to cold temperatures

c. Gangrenous ulcers on fingertips

d. Color changes of fingers and toes

e. Episodes of superficial vein thrombosis

5. A patient is admitted to the hospital with a diagnosis of

abdominal aortic aneurysm. Which signs and symptoms would suggest that the aneurysm has ruptured?

a. Rapid onset of shortness of breath and hemoptysis

b. Sudden, severe low back pain and bruising along his flank

c. Gradually increasing substernal chest pain and diaphoresis

d. Sudden, patchy blue mottling on feet and toes and rest pain

6. What are the *priority* nursing interventions 8 hours after an abdominal aortic aneurysm repair?

a. Assessing nutritional status and dietary preferences

b. Initiating IV heparin and monitoring anticoagulation

c. Administering IV fluids and watching kidney function

d. Elevating the legs and applying compression stockings

7. What is the *first* priority of interprofessional care for a patient with a suspected acute aortic dissection?

a. Reduce anxiety.

b. Monitor chest pain.

c. Control blood pressure.

d. Increase myocardial contractility.

8. Which patient is at *highest* risk for venous thromboembolism (VTE)?

a. A 62-yr-old man with spider veins who is having arthroscopic knee surgery

b. A 32-yr-old woman who smokes, takes oral contraceptives, and is planning a trip to Europe

c. A 26-yr-old woman who is 3 days postpartum and received maintenance IV fluids for 12 hours during her labor

d. An active 72-yr-old man at home recovering from transurethral resection of the prostate for benign prostatic hyperplasia

9. Which clinical findings should the nurse expect in a person with an acute lower extremity VTE? *(select all that apply)*

a. Pallor and coolness of foot and calf

b. Mild to moderate calf pain and tenderness

c. Grossly decreased or absent pedal pulses

d. Unilateral edema and induration of the thigh

e. Palpable cord along a superficial varicose vein

10. Which treatment should the nurse anticipate for an otherwise healthy person with an initial VTE?

a. IV argatroban as an inpatient

b. IV unfractionated heparin as an inpatient

c. Subcutaneous unfractionated heparin as an outpatient

d. Subcutaneous low-molecular-weight heparin as an outpatient

11. Which instruction is a *key* aspect of teaching for the patient on anticoagulant therapy?

a. Monitor for and report any signs of bleeding.

b. Do not take acetaminophen (Tylenol) for a headache.

c. Decrease your dietary intake of foods containing vitamin K.

d. Arrange to have blood drawn twice a week to check

drug effects.

12. The nurse is planning care and teaching for a patient with venous leg ulcers. What is the *most* important patient action in healing and control of this condition?

a. Following activity guidelines.

b. Using moist environment dressings.

c. Taking horse chestnut seed extract daily.

d. Applying graduated compression stockings.

1. b, 2. b, 3. a, 4. b, c, d, 5. b, 6. c, 7. c, 8. b, 9. b, d, 10. d, 11. a, 12. d

Assessment

Gastrointestinal System

Kara Ann Ventura

LEARNING OUTCOMES

1. Describe the structures and functions of the organs of the gastrointestinal tract.
2. Describe the structures and functions of the liver, gallbladder, biliary tract, and pancreas.
3. Distinguish the processes of ingestion, digestion, absorption, and elimination.
4. Explain the processes of biliary metabolism, bile production, and bile excretion.
5. Link the age-related changes of the gastrointestinal system to the differences in assessment findings.
6. Obtain significant subjective and objective assessment data related to the gastrointestinal system from a patient.
7. Perform a physical assessment of the gastrointestinal system using appropriate techniques.
8. Distinguish normal from abnormal findings of a physical assessment of the gastrointestinal system.
9. Describe the purpose, significance of results, and nursing

responsibilities related to diagnostic studies of the gastrointestinal system.

Conceptual Focus

Elimination
Fluids and Electrolytes
Nutrition

The gastrointestinal (GI) system, also called the *digestive system*, consists of the GI tract and its associated organs and glands. Included in the GI tract are the mouth, esophagus, stomach, small intestine, large intestine, rectum, and anus. The associated organs are the liver, pancreas, and gallbladder (Fig. 38.1). Problems that change physiologic processes or associated organs affect a person's ability to maintain nutritional status and eliminate waste.

Structures and Functions of Gastrointestinal System

The GI tract extends around 30 ft (9 m) from the mouth to the anus. The GI tract is essentially a tube composed of 4 layers. From the inside to the outside, these layers are (1) mucosa lining; (2) submucosa connective tissue, which contains glands, blood vessels, and lymph nodes; (3) muscle; and (4) serosa. The muscular coat has 3 smooth muscle layers: the oblique (inner) layer, circular (middle) layer, and longitudinal (outer) layer.

Parasympathetic and sympathetic branches of the autonomic nervous system (ANS) innervate the GI tract. The parasympathetic (cholinergic) system is mainly excitatory. The sympathetic (adrenergic) system is mainly inhibitory. For example, parasympathetic stimulation increases peristalsis and sympathetic stimulation decreases it. Both sympathetic and parasympathetic afferent fibers relay sensory information.

The GI tract has its own nervous system: the enteric nervous system (ENS) or intrinsic nervous system. The ENS system regulates motility and secretion along the entire GI tract. The ENS is composed of 2 networks: (1) Meissner plexus in the submucosa and (2) Auerbach (myenteric) plexus between the muscle layers. The submucosal plexus

controls secretion and is involved in many sensory functions. The myenteric plexus is the major nerve supply to the GI tract and controls GI movements. Although the ENS receives innervation from the ANS, it functions independently of the brain and spinal cord.

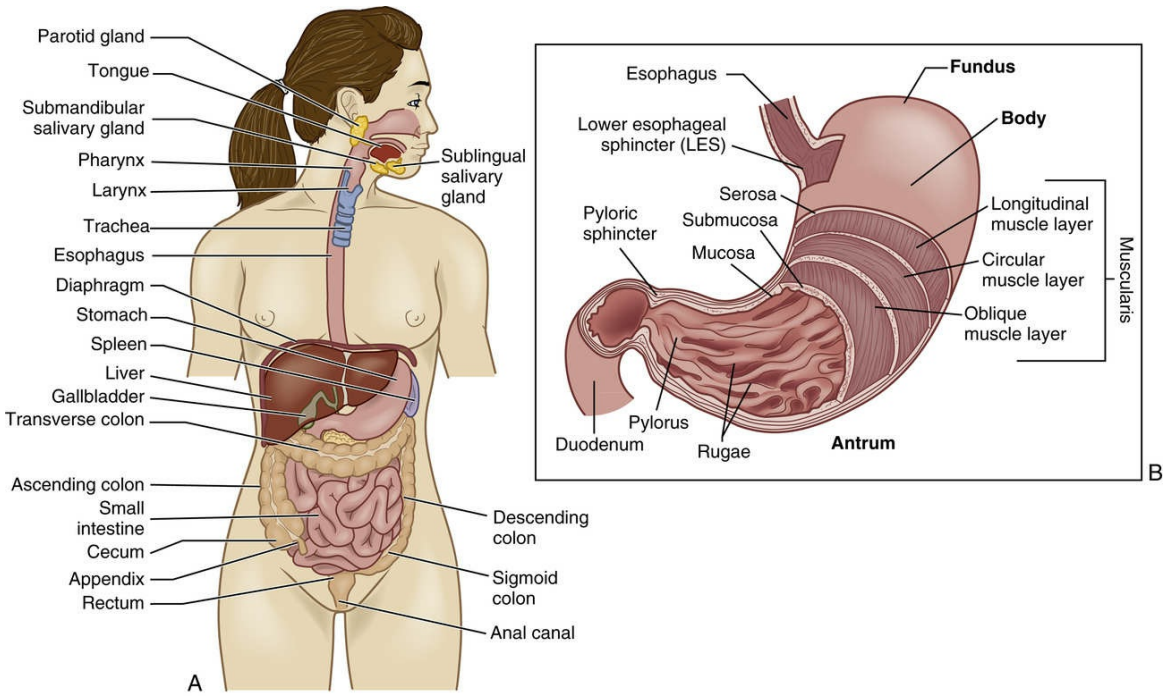

FIG. 38.1 **A,** Location of organs of the gastrointestinal system. **B,** Parts of the stomach.

Circulation in the GI system is unique in that venous blood draining the GI tract organs empties into the portal vein, which then perfuses the liver. This allows the liver to clean the blood of bacteria and toxins from the GI tract. The celiac artery, superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA) supply arterial blood to the GI tract. The stomach and duodenum receive their blood supply from the celiac axis. The distal small intestine to mid large intestine receives its blood supply from branches of the hepatic and SMA. The distal large intestine through the anus receives its blood supply from the IMA. The GI tract and accessory organs receive 25% to 30% of the cardiac output at rest and 35% or more after eating. Because such a large percent of the cardiac output perfuses these organs, the GI tract

is a major source from which to divert blood flow during exercise, stress, or injury.

The peritoneum almost completely covers the abdominal organs. The 2 layers of the peritoneum are the *parietal layer,* which lines the abdominal cavity wall, and the *visceral layer,* which covers the abdominal organs. The peritoneal cavity is the potential space between the parietal and visceral layers. The 2 folds of the peritoneum are the mesentery and omentum. The mesentery attaches the small intestine and part of the large intestine to the posterior abdominal wall. It contains blood and lymph vessels. The omentum hangs like an apron from the stomach to the intestines. It contains fat and lymph nodes.

The main function of the GI system is to supply nutrients to body cells. This is accomplished through the processes of (1) *ingestion* (taking in food), (2) *digestion* (breaking down food), and (3) *absorption* (transferring food products into circulation). *Elimination* is the process of excreting the waste products of digestion.

Ingestion

Ingestion is the intake of food. *Appetite,* the desire to ingest food, influences how much food a person eats. An appetite center is found in the hypothalamus. Several factors, including hypoglycemia, an empty stomach, and a decrease in body temperature, stimulate appetite. The hormone *ghrelin* released from the stomach mucosa plays a role in appetite stimulation. Another hormone, *leptin,* is involved in appetite suppression. (See Chapter 40 for a discussion of ghrelin and leptin.) The sight, smell, and taste of food can stimulate appetite. Stomach distention, illness (especially accompanied by fever), hyperglycemia, nausea and vomiting, and certain drugs (e.g., amphetamines) inhibit appetite.

Deglutition, or swallowing, is the mechanical portion of ingestion. The organs involved in deglutition are the mouth, pharynx, and esophagus.

Mouth

The mouth consists of the lips and oral (buccal) cavity. The lips surround the opening of the mouth and function in speech. The hard and soft palates form the roof of the oral cavity. The oral cavity contains the teeth, used in *mastication* (chewing), and the tongue. The tongue is a solid muscle mass. It aids in chewing and moving food to the back of the throat for swallowing. The taste receptors (taste buds) are on the sides and tip of the tongue. The tongue is also important in speech.

Within the oral cavity are 3 pairs of salivary glands: parotid, submaxillary, and sublingual glands. These glands produce saliva, which consists of water, protein, mucin, inorganic salts, and salivary amylase.

Pharynx

The pharynx is a muscular tube lined with mucous membrane. It has 3 divisions: nasopharynx, oropharynx, and laryngeal pharynx. The mucous membrane is continuous with the nasal cavity, mouth, auditory tubes, and larynx. During ingestion, the oropharynx is the route for food from the mouth to the esophagus. Food or liquid stimulates receptors in the oropharynx, initiating the swallowing reflex. During swallowing, the epiglottis closes over the opening to the larynx and prevents food from entering the respiratory tract. The tonsils and adenoids, composed of lymphoid tissue, help the body prevent infection.

Esophagus

The esophagus is a hollow, muscular tube that receives food from the pharynx and moves it to the stomach. It is 7 to 10 in (18 to 25 cm) long and 0.8 in (2 cm) in diameter. The esophagus is in the thoracic cavity. It is structurally composed of 4 layers: inner mucosa, submucosa, muscularis propria, and outermost adventitia. The upper third of the esophagus is composed of striated skeletal muscle. The distal two thirds are composed of smooth muscle.

Between swallows, the esophagus is collapsed and the *upper esophageal sphincter* (UES) closed. With swallowing, the UES relaxes

and a peristaltic wave moves the bolus into the esophagus. The muscular layers contract *(peristalsis)* and propel the food to the stomach. The *lower esophageal sphincter* (LES) at the distal end of the esophagus controls the opening of the esophagus into the stomach. It stays contracted except during swallowing, belching, or vomiting. The LES is an important barrier that normally prevents reflux of acidic gastric contents into the esophagus.

Digestion and Absorption

Stomach

The stomach's functions are to store food, mix food with gastric secretions, and empty contents in small boluses into the small intestine. The stomach absorbs only small amounts of water, alcohol, electrolytes, and certain drugs.

The stomach is usually J shaped and lies obliquely in the epigastric, umbilical, and left hypochondriac regions of the abdomen (Fig. 38.5 later in the chapter). It always contains gastric fluid and mucus. The 3 main parts of the stomach are the fundus (cardia), body, and antrum (Fig. 38.1). The pylorus is a small portion of the antrum proximal to the pyloric sphincter. The LES and pyloric sphincter guard the entrance to and exit from the stomach.

The stomach wall has 4 layers. The serous (outer) layer of the stomach is continuous with the peritoneum. The muscular layer consists of the longitudinal (outer) layer, circular (middle) layer, and oblique (inner) layer. The mucosal layer forms folds called rugae that have many small glands. In the fundus the glands contain (1) chief cells, which secrete pepsinogen and (2) parietal cells, which secrete hydrochloric (HCl) acid, water, and intrinsic factor. The secretion of HCl acid makes gastric juice acidic. This acidic pH helps protect us against ingested organisms. Intrinsic factor promotes cobalamin (vitamin B_{12}) absorption in the small intestine.

Small Intestine

The primary functions of the small intestine are digestion and

absorption, the uptake of nutrients from the gut lumen to the bloodstream. The small intestine is a coiled tube about 23 ft (7 m) in length and 1 to 1.1 in (2.5 to 2.8 cm) in diameter. It extends from the pylorus to the ileocecal valve. The small intestine is composed of the duodenum, jejunum, and ileum. The ileocecal valve prevents reflux of large intestine contents into the small intestine.

The mucosa of the small intestine is thick, vascular, and glandular. The functional units of the small intestine are *villi.* They are minute, fingerlike projections in the mucous membrane. Villi contain epithelial cells that produce the intestinal digestive enzymes. The epithelial cells on the villi also have *microvilli.* The circular folds in the mucous and submucous layers, along with the villi and microvilli, increase the surface area for digestion and absorption.

The digestive enzymes on the brush border of the microvilli chemically break down nutrients for absorption. Between the bases of the villi lie the crypts of Lieberkühn, which contain the multipotent stem cells. These are the precursors for the other epithelial cell types. Brunner's glands in the submucosa of the duodenum secrete an alkaline fluid containing bicarbonate that neutralizes acidic fluids and protects the mucosa. Intestinal goblet cells secrete mucus that protects the mucosa.

Physiology of Digestion

Digestion is the physical and chemical breakdown of food into absorbable substances. The timely movement of food through the GI tract and the secretion of specific enzymes promote digestion. These enzymes break down foodstuffs to particles of appropriate size for absorption (Table 38.1).

TABLE 38.1 Gastrointestinal Secretions

Daily Amount (mL)	Secretions/Enzymes	Action
Salivary Glands		
1000–1500	Salivary amylase	Initiation of starch digestion
Stomach		
2500	HCl acid	Activation of pepsinogen to pepsin
	Intrinsic factor	Essential for cobalamin absorption in ileum
	Lipase	Fat digestion
	Pepsinogen	Protein digestion
Small Intestine		
3000	Aminopeptidases	Protein digestion
	Amylase	Carbohydrate digestion
	Enterokinase	Activation of trypsinogen to trypsin
	Lactase	Lactose to glucose and galactose
	Lipase	Fat digestion
	Maltase	Maltose to 2 glucose molecules
	Peptidases	Protein digestion
	Sucrase	Sucrose to glucose and fructose
Pancreas		
700	Amylase	Starch to disaccharides
	Chymotrypsin	Protein digestion
	Lipase	Fat digestion
	Trypsinogen	Protein digestion
Liver and Gallbladder		
1000	Bile	Emulsification of fats and aid in absorption of fatty acids and fat-soluble vitamins (A, D, E, K)

The process of digestion begins in the mouth, where food is chewed, mechanically broken down, and mixed with saliva. Saliva helps us swallow by lubricating food. Saliva contains amylase, which breaks down starches to maltose. Chewing and the sight, smell, thought, and taste of food stimulate the release of saliva. A person makes about 1 L of saliva each day. After swallowing, food moves through the esophagus to the stomach. No digestion or absorption occurs in the esophagus.

Both GI secretion and motility are under neural and hormonal control. Food entering the stomach and small intestine triggers the release of hormones into the bloodstream (Tables 38.2 and 38.3). These hormones play important roles in the control of HCl acid secretion, production and release of digestive enzymes, and motility.

In the stomach, muscle action mixes the food with gastric secretions to form *chyme,* which is now ready for absorption. Protein digestion begins with the release of pepsinogen from chief cells. The stomach's acidic environment results in the conversion of pepsinogen to its

active form, pepsin. Pepsin begins the breakdown of proteins. There is minimal digestion of starches and fats. The stomach also serves as a reservoir for food, releasing it slowly into the small intestine. The length of time that food stays in the stomach depends on the composition of the food. The average meal stays in the stomach for 3 to 4 hours.

TABLE 38.2 Phases of Gastric Secretion

Stimulus to Secretion	Secretion
Cephalic (nervous)	
Sight, smell, taste of food (before food enters stomach). Initiated in the CNS and mediated by the vagus nerve.	HCl acid, pepsinogen, mucus
Gastric (hormonal and nervous)	
Food in antrum of stomach, vagal stimulation.	Release of gastrin from antrum into circulation to stimulate gastric secretions and motility
Intestinal (hormonal)	
Presence of chyme in small intestine.	*Acidic chyme* (pH <2): Release of secretin, gastric inhibitory polypeptide, cholecystokinin into circulation to decrease HCl acid secretion *Chyme* (pH >3): Release of gastrin from duodenum to increase acid secretion

In the small intestine, the physical presence and chemical nature of chyme stimulates motility and secretion. Secretions involved in digestion include enzymes from the pancreas, bile from the liver, and enzymes from the small intestine (Table 38.1). Carbohydrates are broken down to monosaccharides, fats to glycerol and fatty acids, and proteins to amino acids. Enzymes on the brush border of the microvilli complete the digestion process. These enzymes break down disaccharides to monosaccharides and peptides to amino acids for absorption.

The absorption of most of the end products of digestion occurs in the small intestine. The movement of the villi enables these end products to come in contact with the absorbing membrane. Monosaccharides, fatty acids, amino acids, water, electrolytes, vitamins, and minerals are absorbed.

Elimination

Large Intestine

The large intestine is a hollow, muscular tube around 5 to 6 ft (1.5 to 1.8 m) long and 2 in (5 cm) in diameter. The 4 parts of the large intestine are shown in Fig. 38.2.

The most important functions of the large intestine are water and electrolyte absorption. The large intestine also forms feces and serves as a reservoir for the fecal mass until defecation occurs. Feces are composed of water (75%), bacteria, unabsorbed minerals, undigested foodstuffs, bile pigments, and desquamated (shed) epithelial cells. The large intestine secretes mucus, which acts as a lubricant and protects the mucosa.

Microorganisms in the colon contribute to digestion by (1) producing vitamin K and some B vitamins and (2) breaking down proteins that are not digested or absorbed in the small intestine into amino acids. Bacteria deaminate the amino acids, resulting in ammonia. Ammonia is carried to the liver, where it is converted to urea. Urea is excreted by the kidneys. Bacteria produce gas that escapes the colon through the anus, a phenomenon called *flatulence* or *flatus*. If an infection or antibiotics alter the normal microbiome, an overgrowth of pathogenic bacteria can occur and cause disease.

The movements of the large intestine are usually slow. However, propulsive (mass movements) peristalsis does occur. Food entering the stomach and duodenum triggers gastrocolic and duodenocolic reflexes, resulting in peristalsis in the colon. These reflexes are more active after the first daily meal and often result in bowel evacuation.

Defecation is a reflex action involving voluntary and involuntary control. Feces in the rectum stimulate sensory nerve endings that produce the desire to defecate. The reflex center for defecation is in the parasympathetic nerve fibers in the sacral part of the spinal cord. These fibers produce contraction of the rectum and relaxation of the internal anal sphincter. When a person feels the desire to defecate, they can voluntarily relax the external anal sphincter. An acceptable environment for defecation is usually needed or the urge to defecate

will be ignored. If defecation is suppressed for long periods, problems can occur, such as constipation or fecal impaction.

TABLE 38.3 Hormones Controlling GI Secretion and Motility

Hormone	Source	Activating Stimuli	Function
Gastrin	Gastric and duodenal mucosa	Stomach distention, partially digested proteins in pylorus	Stimulates gastric acid secretion and motility. Maintains lower esophageal sphincter tone.
Cholecystokinin	Duodenal mucosa	Fatty acids and amino acids in small intestine	Contracts gallbladder and relaxes sphincter of Oddi. Allows increased flow of bile into duodenum. Release of pancreatic digestive enzymes.
Gastric inhibitory peptide	Duodenal mucosa	Fatty acids and lipids in small intestine	Inhibits gastric acid secretion and motility.
Secretin	Duodenal mucosa	Acid entering small intestine	Inhibits gastric motility and acid secretion. Stimulates pancreatic bicarbonate secretion.

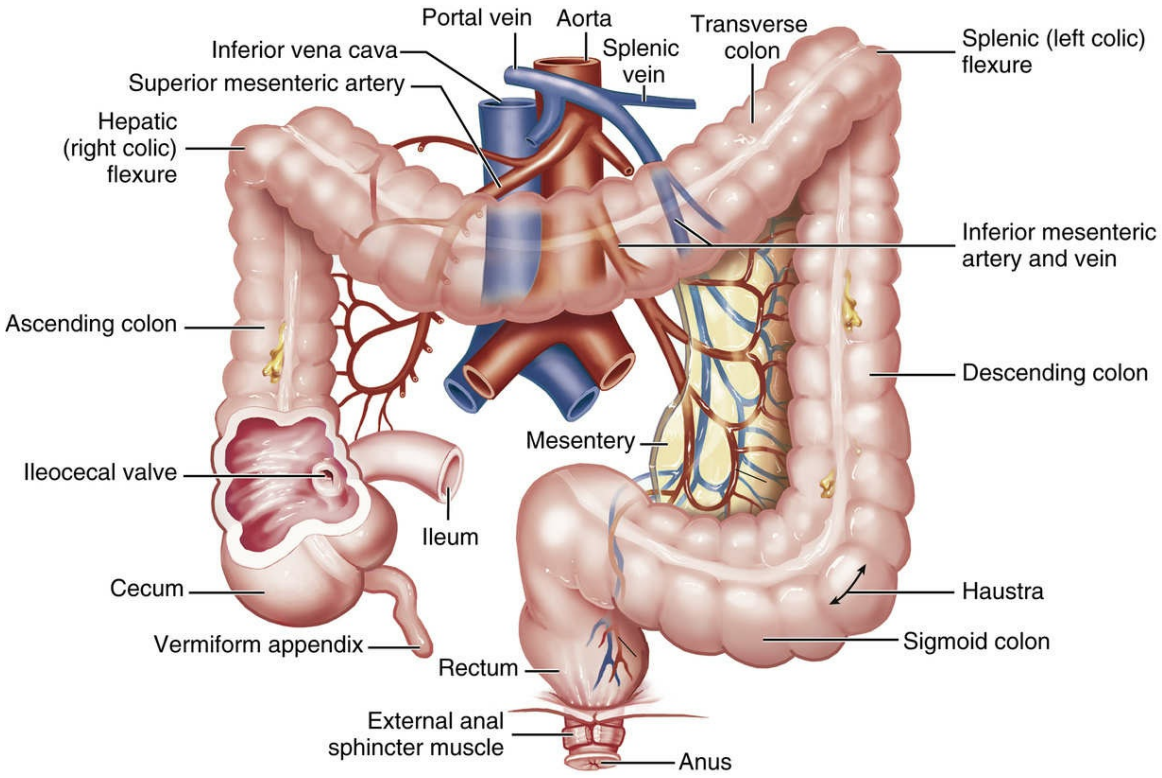

FIG. 38.2 Anatomic locations of the large intestine.

The **Valsalva maneuver**, often referred to as "bearing down," can promote defecation. During this maneuver, the person inspires deeply and holds the breath, closing the airway, while contracting abdominal muscles and bearing down. This increases both intraabdominal and intrathoracic pressures and reduces venous return to the heart. The heart rate temporarily decreases along with a decrease in cardiac output. This results in a transient drop in BP. When the patient relaxes, thoracic pressure falls, resulting in a sudden flow of blood into the heart, increased heart rate, and an immediate rise in BP. The Valsalva maneuver may be contraindicated in the patient with a head injury, eye surgery, heart problems, hemorrhoids, abdominal surgery, or liver cirrhosis with portal hypertension.

Liver, Biliary Tract, and Pancreas

Liver

The liver is the largest internal organ in the body, weighing around 3 lb (1.36 kg). It lies in the right epigastric region (Fig. 38.5 later in the chapter). Most of the liver is enclosed in peritoneum. It has a fibrous capsule that divides it into right and left lobes (Fig. 38.3).

The functional units of the liver are lobules. A lobule consists of rows of hepatic cells *(hepatocytes)* arranged in cords that radiate out from a central vein. Capillaries called *sinusoids* lie between the rows of hepatocytes. Sinusoids are lined with **Kupffer cells**, which carry out phagocytic activity, removing bacteria and toxins from the blood. The hepatic cells secrete bile into tiny canals called *canaliculi.* These merge with other canals to form larger, interlobular bile ducts, which unite into the 2 main left and right hepatic ducts.

The liver has a rich blood supply. The portal circulatory system brings blood to the liver from the stomach, intestines, spleen, and pancreas. About 25% of the blood supply comes from the hepatic artery, a branch of the celiac artery. The other 75% comes from the portal vein. The portal vein carries absorbed products of digestion

directly to the liver. Once in the liver, the portal vein branches and comes in contact with each lobule.

The liver performs many functions and is essential for life. It has metabolic, secretory, vascular, and storage functions (Table 38.4). The hepatic cells constantly make bile. Bile consists of water, cholesterol, bile salts, electrolytes, fatty acids, and bilirubin. It provides the alkaline medium needed for the action of pancreatic lipase. Bile salts are needed for fat emulsification and digestion.

Bilirubin Metabolism

The liver constantly makes **bilirubin**, a pigment derived from the breakdown of hemoglobin (Fig. 38.4). When released into the bloodstream, it binds to albumin. This form of bilirubin is called *unconjugated.* It is insoluble in water and transported to the liver. In the liver, unconjugated bilirubin is conjugated with glucuronic acid and excreted in bile into the intestine. *Conjugated* bilirubin is soluble in water. In the intestines, bacterial action reduces bilirubin to stercobilinogen and urobilinogen. Stercobilinogen accounts for the brown color of stool. A small amount of urobilinogen is reabsorbed into the blood, where it is returned to the liver through the portal circulation. There, it is excreted again in the bile or entered into circulation and excreted by the kidneys.

Biliary Tract

The biliary tract consists of the gallbladder and ducts that connect the liver, gallbladder, and duodenum. The gallbladder is a pear-shaped sac found below the liver. The gallbladder's function is to concentrate and store bile. It holds around 45 mL of bile. The presence of fat in the upper duodenum triggers the release of cholecystokinin, which causes the gallbladder to contract and release bile.

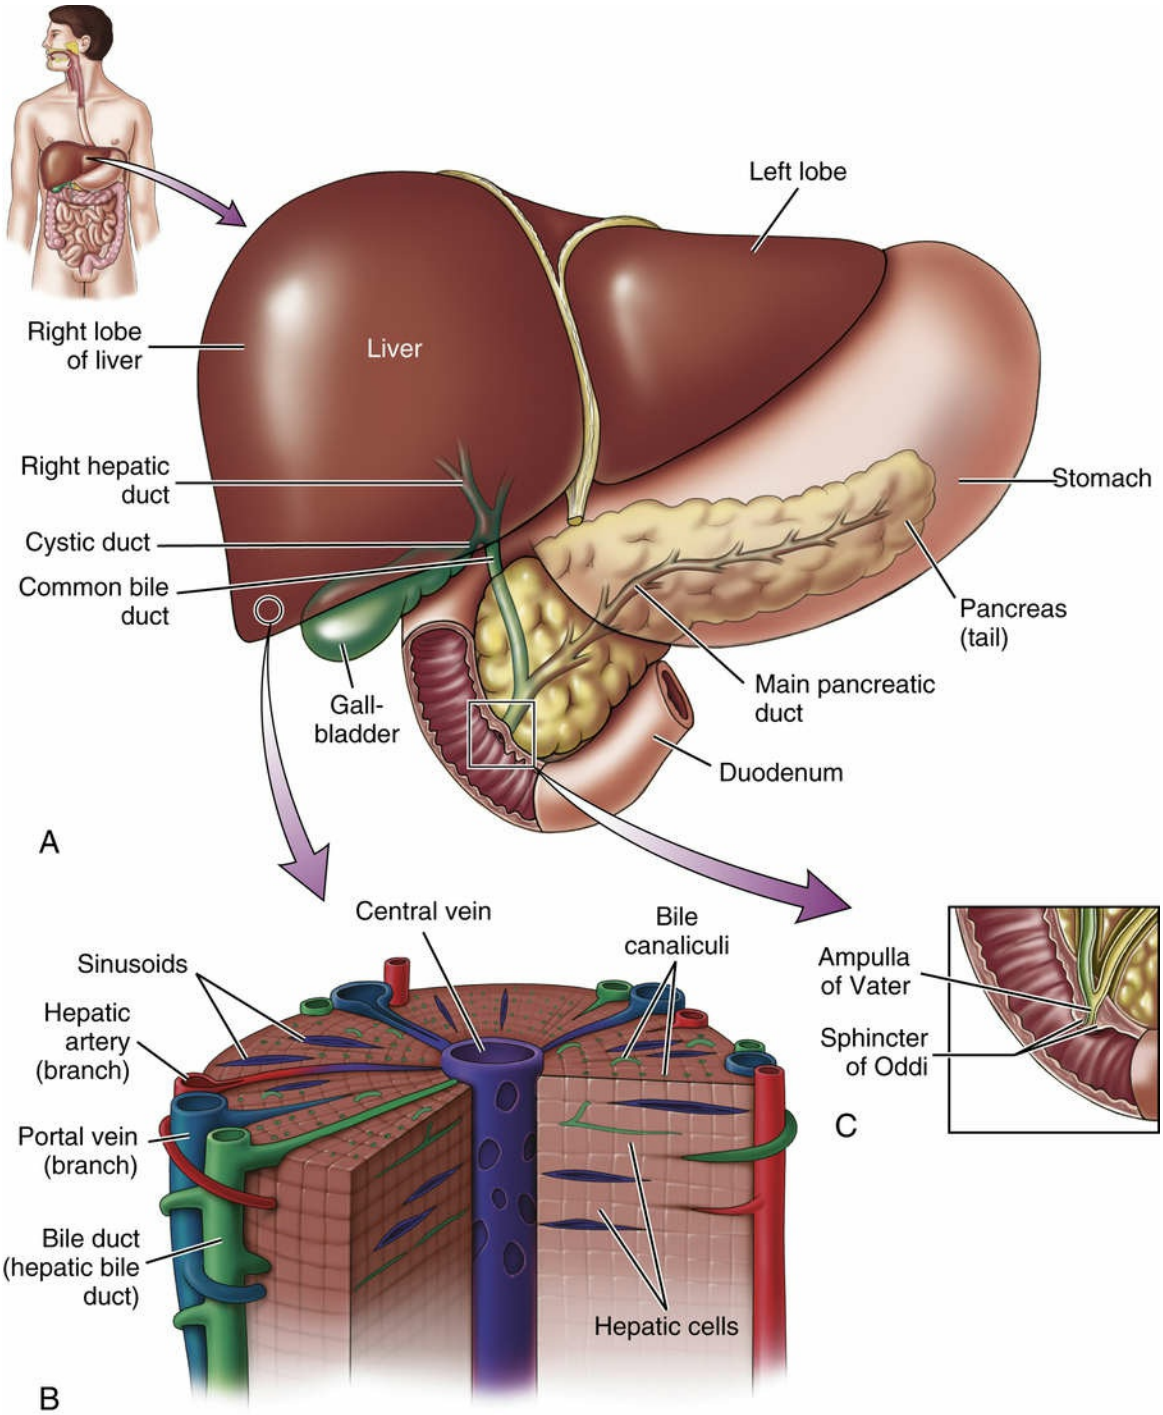

FIG. 38.3 **A,** Gross structure of the liver, gallbladder, pancreas, and duct system. **B,** Liver lobule. **C,** Entrance of the common bile duct into the duodenum.

The hepatic ducts receive bile from the canaliculi in the liver lobules. The left and right hepatic ducts merge with the cystic duct from the gallbladder to form the common bile duct. Bile moves down

the common bile duct to enter the duodenum at the ampulla of Vater (Fig. 38.3). The pancreatic duct also enters the duodenum at this point.

Pancreas

The pancreas is a long, slender gland lying behind the stomach and in front of the first and second lumbar vertebrae. It consists of a head, body, and tail. The peritoneum covers the anterior surface of the pancreas. The pancreas has lobes and lobules. The pancreatic duct extends along the gland and enters the duodenum through the common bile duct at the ampulla of Vater (Fig. 38.3).

The pancreas has both exocrine and endocrine functions. The exocrine function contributes to digestion through the production and release of enzymes (Table 38.1). The endocrine function occurs in the islets of Langerhans, whose β cells secrete insulin and amylin; α cells secrete glucagon; δ cells secrete somatostatin; and F cells secrete pancreatic polypeptide.

Gerontologic Considerations: Effects of Aging on Gastrointestinal System

The process of aging changes the functional ability of the GI system. Diet, alcohol intake, and obesity affect organs of the GI system, making it a challenge to separate the sole effects of aging from lifestyle. Many factors can lead to a decrease in appetite and make eating less pleasurable. Caries and periodontal disease can lead to loss of teeth. Taste buds decline in number and the sense of smell lessens, leading to decreased ability to taste. With less saliva, a very dry mouth *(xerostomia)* is common.[1]

Age-related changes in the esophagus include delayed emptying, resulting from smooth muscle weakness; reduced UES opening; and an incompetent LES. Although GI motility decreases with age, secretion and absorption are less affected. The older adult often has a decrease in intrinsic acid and HCl acid secretion *(hypochlorhydria)*.[1]

TABLE 38.4 Functions of Liver

Function	Description
Metabolic Functions	
Blood clotting	Synthesis of prothrombin (factor I), fibrinogen (factor II) and factors V, VII, IX, and X.
Carbohydrate metabolism	Performs glycogenesis (conversion of glucose to glycogen), glycogenolysis (process of breaking down glycogen to glucose), gluconeogenesis (formation of glucose from amino acids and fatty acids).
Detoxification	Inactivation of drugs and harmful substances and excretion of their breakdown products.
Fat metabolism	Synthesis of lipoproteins, breakdown of triglycerides into fatty acids and glycerol, formation of ketone bodies, synthesis of fatty acids from amino acids and glucose, synthesis and breakdown of cholesterol.
Protein metabolism	Synthesis of nonessential amino acids, synthesis of plasma proteins (except gamma globulin), synthesis of clotting factors. Bacteria in colon deaminate amino acids to form ammonia (NH_3). which is then changed to urea (NH_4).
Secretory Functions	
Bile production	Formation of bile, which contains bile salts, bile pigments (mainly bilirubin), and cholesterol.
Bilirubin	Conjugation and secretion of bilirubin.
Vascular Functions	
Blood filtration	Breakdown of old RBCs, WBCs, bacteria, and other particles. Breakdown of hemoglobin from old RBCs to bilirubin and biliverdin.
Blood reservoir	Serves as temporary storage for blood within general circulation.
Storage Functions	
Storage	Stores glucose in form of glycogen; vitamins, including fat-soluble (A, D, E, K) and water-soluble (B_1, B_2, cobalamin, folic acid); fatty acids; minerals (iron, copper); and amino acids in form of albumin and β-globulins.

Constipation affects 30% to 40% of adults over age 60.[2] Factors that may increase the risk for constipation include slower peristalsis, anorectal dysfunction, inactivity, decreased dietary fiber, inadequate fluid intake, and constipating medications. Neurologic, cognitive, and metabolic problems may play a role. See Chapter 42 for a detailed discussion of constipation.

The liver size decreases after 50 years of age but results of liver function tests stay within normal ranges. Age-related enzyme changes in the liver decrease the liver's ability to metabolize drugs and hormones.[1]

The size of the pancreas is unaffected by aging. It does undergo structural changes, such as fibrosis, fatty acid deposits, and atrophy. Gallbladder diseases increase with age.[3]

Older adults, especially those over 85, are at risk for decreased food intake. The inability to obtain food affects nutritional intake. Economic constraints may reduce the number of fresh fruits and vegetables

consumed and thus the amount of fiber. Immobility limits the ability to prepare meals. Age-related changes in the GI system and differences in assessment findings are outlined in Table 38.5.

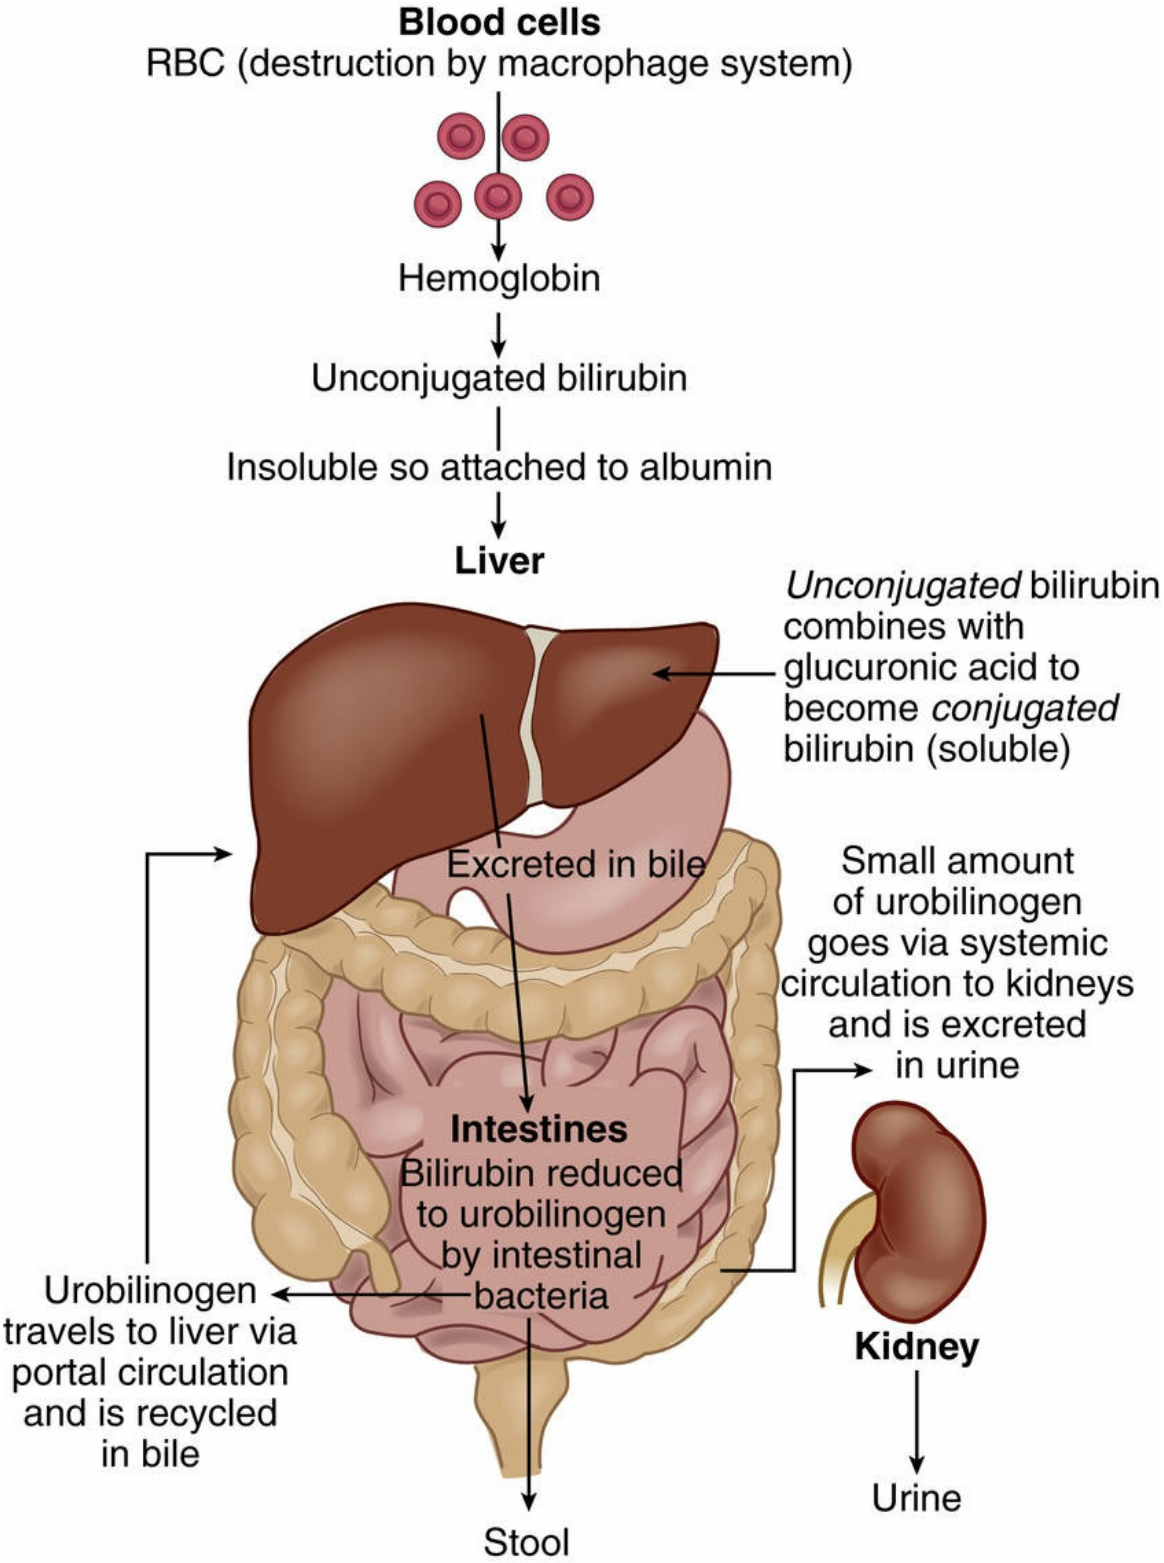

FIG. 38.4 Bilirubin metabolism and conjugation.

Assessment of Gastrointestinal System

Subjective Data

Important Health Information

Past Health History

Obtain information from the patient about the history or presence of the problems related to GI functioning and fully explore any symptoms. Ask about any abdominal pain, nausea, vomiting, abdominal distention, jaundice, heartburn, dyspepsia, changes in appetite, hematemesis, indigestion, bloating, and trouble swallowing. Review the patient's bowel habits. Ask about diarrhea, constipation, melena, rectal bleeding and excessive gas, Document related conditions, such as food intolerance or allergies, lactose intolerance, and anemia. Ask the patient about a history or presence of diseases such as reflux, gastritis, hepatitis, colitis, gallstones, hemorrhoids, peptic ulcer, cancer, diverticuli, or hernias.

Ask the patient about weight history. Explore in detail any unexplained or unplanned weight loss or gain within the past 6 to 12 months. Discuss any history of chronic dieting and repeated weight loss and gain.

Medications

Assess the patient's past and current use of medications. Ask about the reason for taking the medication, its name, the dose and frequency, length of time taken, its effect, and any side effects. It is critical to include information about over-the-counter (OTC) medications, prescription drugs, herbal products, vitamins, probiotics, and nutritional supplements. Many medications cause side effects in the GI system. GI problems can affect drug absorption and effectiveness.

TABLE 38.5 Gerontologic Assessment Differences Gastrointestinal System

Expected Aging Changes	Differences in Assessment Findings
Mouth	
Atrophy of gingival tissue	Poor-fitting dentures
Decreased taste buds, decreased sense of smell	Decreased sense of taste (especially salty and sweet)
Decreased volume of saliva	Dry oral mucosa
Gingival retraction	Loss of teeth, dental implants, dentures, difficulty chewing
Esophagus	
Lower esophageal sphincter pressure decreased, motility decreased	Epigastric distress, dysphagia, potential for hiatal hernia and aspiration
Abdominal Wall	
Decreased number and sensitivity of sensory receptors	Less sensitivity to surface pain
Thinner and less taut	More visible peristalsis, easier palpation of organs
Stomach	
Atrophy of gastric mucosa, decreased blood flow	Food intolerances, signs of anemia as result of cobalamin malabsorption, slower gastric emptying
Small Intestines	
Slightly decreased motility and secretion of most digestive enzymes	Indigestion, slowed intestinal transit, delayed absorption of fat-soluble vitamins
Liver	
Decreased protein synthesis, ability to regenerate decreased	Decreased drug and hormone metabolism
Decreased size and lowered position	Easier palpation because of lower border extending past costal margin
Large Intestine, Anus, Rectum	
Decreased anal sphincter tone and nerve supply to rectal area	Fecal incontinence
Decreased muscular tone, decreased motility	Flatulence, abdominal distention, relaxed perineal musculature
Increased transit time, decreased sensation to defecation	Constipation, fecal impaction
Pancreas	
Pancreatic ducts distended, lipase production decreased, pancreatic reserve impaired	Impaired fat absorption, decreased glucose tolerance

Many chemicals and drugs are potentially hepatotoxic (see *livertox.nih.gov*) and result in significant harm unless monitored closely. For example, chronic high doses of acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) may be hepatotoxic. NSAIDs may predispose a patient to upper GI bleeding, with an increasing risk as the person ages. Other medications, such as antibiotics, may change the normal bacterial composition in the GI tract, resulting in diarrhea. Antacids and laxatives may affect medication absorption. Ask the patient about laxative or antacid use, including the kind and frequency.

Case Study

Patient Introduction

© iStockphoto/Thinkstock.

Patient Profile

L.C. is a 58-yr-old Native American man from a Pueblo tribe in northern New Mexico. L.C.'s wife and family drove 50 miles to take

him to the Indian Health Service hospital. He comes into the emergency department (ED) doubled over with abdominal pain. He is grimacing and holding his abdomen with both arms. You are working as the triage nurse that morning.

Discussion Questions

1. What are the possible causes for L.C.'s acute abdominal pain?
2. Is his condition stable or is it an emergency?
3. What type of assessment should you do: comprehensive, focused, or emergency?
4. What assessment questions will you ask him?
5. How will you individualize the assessment based on his ethnic/cultural background?

You will learn more about L.C. and his condition as you read through this assessment chapter.

(See p. 838 for more information on L.C.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

TABLE 38.6 Gastrointestinal Surgeries

Procedure	Description
Appendectomy	Removal of appendix
Cholecystectomy	Removal of gallbladder
Choledochojejunostomy	Opening between common bile duct and jejunum
Choledocholithotomy	Opening into common bile duct for removal of stones
Colectomy	Removal of colon
Colostomy	Opening into colon
Esophagoenterostomy	Removal of part of esophagus with segment of colon attached to remaining part
Esophagogastrostomy	Removal of esophagus and anastomosis of remaining part to stomach
Gastrectomy	Removal of stomach

Gastrostomy	Opening into stomach
Glossectomy	Removal of tongue
Hemiglossectomy	Removal of half of tongue
Herniorrhaphy	Repair of a hernia
Ileostomy	Opening into ileum
Mandibulectomy	Removal of mandible
Pyloroplasty	Enlargement and repair of pyloric sphincter area
Vagotomy	Resection of branch of vagus nerve

Surgery or Other Treatments

Obtain information about hospitalizations for any problems related to the GI system. Record any abdominal or rectal surgery, including the year, reason for surgery, postoperative course, and blood transfusions. Terms related to common GI surgeries are listed in Table 38.6.

TABLE 38.7 Health History Gastrointestinal System

Health Perception–Health Management

- Describe any measures used to treat GI symptoms such as diarrhea or constipation.
- Do you smoke?* Do you drink alcohol?*
- Are you exposed to any chemicals on a regular basis?* Have you been exposed in the past?*
- Have you recently traveled outside the United States?*

Nutritional-Metabolic

- Describe your usual daily food and fluid intake.

- Do you take any supplemental vitamins or minerals?*
- Have you had any changes in appetite or food tolerance?*
- Has there been any weight change in the past 6 to 12 months?*
- Are you allergic to any foods?*

Elimination

- Describe the frequency and time of day you have bowel movements. What is the consistency of the bowel movement?
- Do you use laxatives or enemas?* If so, how often?
- Have there been any recent changes in your bowel pattern?*
- Do you have any pain with bowel movements or pain relieved by bowel movements?
- Describe any skin problems caused by GI problems.
- Do you need any assistive equipment, such as ostomy equipment, raised toilet seat, commode?

Activity-Exercise

- Do you have limitations in mobility that make it hard for you to obtain and prepare food?*

Sleep-Rest

- Do you have any problem sleeping because of a GI problem?*
- Are you awakened by symptoms such as gas, abdominal pain, diarrhea, or heartburn?*

Cognitive-Perceptual

- Have you had any change in taste or smell that has affected your appetite?*
- Do you have any heat or cold sensitivity that affects eating?*
- Does pain interfere with food preparation, appetite, or chewing?*
- Do pain medications cause constipation, diarrhea, or appetite suppression?*

Self-Perception–Self-Concept

- Describe any changes in your weight that have affected how you feel about yourself.
- Have you had any changes in normal elimination that have affected how you feel about yourself?*
- Have any symptoms of GI disease caused physical changes that are a problem for you?*

Role-Relationship

- Describe the impact of any GI problem on your usual roles and relationships.
- Have any changes in elimination affected your relationships?*
- Do you live alone? Describe how your family or others assist you with your GI problems.

Sexuality-Reproductive

- Describe the effect of your GI problem on your sexual activity.

Coping–Stress Tolerance

- Do you have GI symptoms in response to stressful or emotional situations?*
- Describe how you deal with any GI symptoms that result.

Value-Belief

- Describe any culturally specific health beliefs about food and food preparation that may influence the treatment of your GI problem.

* If yes, describe.

Functional Health Patterns

Key questions to ask a patient with a GI problem are outlined in Table 38.7.

Health Perception–Health Management Pattern

Ask about the patient's health practices related to the GI system, such as maintaining normal body weight, proper dental care, adequate nutrition, and effective elimination habits.

Ask about recent foreign travel with possible exposure to hepatitis or parasitic infestation. Explore any sexual and drug use behaviors that may increase risk for hepatitis exposure. Determine whether the patient has received hepatitis A and B vaccination.

Assess the patient for habits that directly affect GI functioning. The intake of alcohol in large quantities or for long periods has detrimental effects on the stomach mucosa. Chronic alcohol exposure causes fatty infiltration of the liver and can cause damage, leading to cirrhosis and hepatocellular cancer. Obtain a history of cigarette smoking. Nicotine is irritating to the GI tract mucosa. Cigarette smoking is related to GI cancers (especially mouth and esophageal cancers), esophagitis, and ulcers. Smoking delays the healing of ulcers.

Family history is an important part of this health pattern. About one third of cases of colorectal cancer occur in patients with a family history. Because of the relationship between colorectal and breast cancer, ask about a history of either type of cancer in the family.

Genetic Risk Alert

Colorectal Cancer

- Colorectal cancer may run in families if first-degree relatives (parents, siblings) or many other family members (grandparents, aunts, uncles) had colorectal cancer. This is especially true when family members are diagnosed with colorectal cancer before age 50
- Genetic conditions associated with an increased risk for colorectal cancer include:
- Hereditary nonpolyposis colorectal cancer (HNPCC). It is caused by mutations in several different genes.
- Familial adenomatous polyposis (FAP). FAP is characterized by multiple polyps that are noncancerous at first but eventually develop into cancer if not treated. Most cases of FAP are due to mutations of the adenomatous polyposis coli *(APC)* gene.

Inflammatory Bowel Disease (IBD)

- People with IBD have a genetic predisposition or susceptibility to the disease.
- First-degree relatives have a 5- to 20-fold increased risk for developing IBD.

Nutritional-Metabolic Pattern

A thorough nutritional assessment is essential. Take a diet history and

ask about both content and amount or portion size. Food preferences and preparation may vary by culture. Open-ended questions allow the patient to express beliefs and feelings about the diet. For example, you can say, "Please tell me about your food and beverage intake over the past 24 hours." A 24-hour dietary recall can be used to analyze the adequacy of the diet. Help the patient recall the preceding day's food intake, including early morning and nighttime intake, snacks, liquids, and vitamin supplements. You can then evaluate the diet in relation to recommended servings for dietary intake using a guide such as MyPlate *(www.choosemyplate.gov)*. A 1-week recall may provide more information on usual dietary patterns. Compare weekday and weekend dietary intake patterns in relation to both the quality and quantity of food.

Ask the patient about the use of sugar and salt substitutes, caffeine intake, and amount of fluid and fiber intake. Note any changes in appetite, food tolerance, and weight. Anorexia and weight loss may indicate cancer or inflammation. Decreased food intake also can be the consequence of economic problems or depression.

Ask about food allergies and dietary intolerances, including lactose and gluten. Have the patient describe the allergic response and any GI symptoms.

Elimination Pattern

Elicit a detailed account of the patient's bowel elimination pattern. Note the frequency, time of day, and usual stool consistency. Ask about the presence of pain with bowel movements, if bowel movements relieve pain, and any recent changes in bowel patterns. Explore the use of laxatives and enemas, including type, frequency, and results.

Document the amount and type of fluid and fiber intake. These influence the frequency and consistency of stools. Inadequate fiber intake can be associated with constipation. Look for any association between a skin and GI problem. Food allergies can cause skin lesions, pruritus, and edema. Diarrhea can result in redness, irritation, and pain in the perianal area. External drainage systems, such as an

ileostomy or ileal conduit, may cause local skin irritation.

Activity-Exercise Pattern

Activity and exercise affect GI motility. Immobility is a risk factor for constipation. Assess ambulatory status to determine if the patient can secure and prepare food. If the patient is unable to do these tasks, see if a family member or an outside agency is meeting this need. Note any limitation in the ability to feed oneself. Assess for access to a toilet. Identify the use of and access to supplies such as a commode or ostomy supplies.

Sleep-Rest Pattern

GI symptoms can interfere with the quality of sleep. Nausea, vomiting, diarrhea, indigestion, and bloating can produce sleep problems. Ask the patient if GI symptoms affect sleep or rest. For example, a patient with gastroesophageal reflux disease (GERD) may wake with burning epigastric pain.

A patient may have a bedtime ritual that involves a specific food or beverage. Herbal teas may be sleep inducing. Document individual routines and comply with these whenever possible to avoid sleeplessness. Hunger can prevent sleep, and a light, easily digested snack may be helpful.

Cognitive-Perceptual Pattern

Sensory changes can result in problems related to acquiring, preparing, and ingesting food. Changes in taste or smell can affect appetite and eating pleasure. Vertigo can make shopping or standing at a stove difficult and dangerous. Heat or cold sensitivity can make certain foods painful to eat. Problems in expressive communication limit the patient's ability to state personal dietary preferences.

Both acute and chronic pain influence dietary intake. Behaviors associated with pain include avoiding activity, fatigue, and disrupted eating patterns. For patients receiving opioid medications, assess for decreased appetite, constipation, nausea, and sedation.

Self-Perception–Self-Concept Pattern

Many GI and nutritional problems affect the patient's self-perception. Overweight and underweight persons may have problems related to self-esteem and body image. Repeated attempts to achieve a personally acceptable weight can be discouraging and depressing for some people. The way a person recounts a weight history can alert you to potential problems in this area.

The need for external devices to manage elimination, such as a colostomy or an ileostomy, may be challenging for some patients. The patient's willingness to engage in self-care and to discuss this situation provides you with valuable information related to body image and self-esteem.

The altered physical changes often associated with advanced liver disease can be disturbing for the patient. Jaundice and ascites cause significant changes in external appearance. Assess the patient's attitude about these changes.

Role-Relationship Pattern

Problems related to the GI system, such as cirrhosis, hepatitis, ostomies, obesity, and cancer, may affect the patient's ability to maintain usual roles and relationships. A person may need to leave a job or reduce work hours. Changes in body image and self-esteem can affect relationships.

Sexuality-Reproductive Pattern

Changes related to sexuality and reproductive status can result from problems of the GI system. For example, obesity, jaundice, and ascites could decrease the acceptance of a potential sexual partner. An ostomy can affect the patient's confidence related to sexual activity. Your sensitive questioning can identify potential problems.

Anorexia can affect the reproductive status of a female patient. Obesity leads to reduced fertility and increased miscarriage rates in women.

Coping–Stress Tolerance Pattern

Determine what is stressful for the patient and what coping mechanisms the patient uses. Factors outside the GI tract can influence its functioning. Both psychologic and emotional factors, such as stress and anxiety, influence GI functioning in many people. Stress can manifest as anorexia, nausea, epigastric and abdominal pain, or diarrhea. It can worsen some diseases of the GI system, such as peptic ulcer disease, irritable bowel syndrome, and IBD. However, never attribute GI symptoms solely to psychologic factors.

Value-Belief Pattern

Assess the patient's spiritual and cultural beliefs about food and food preparation. Whenever possible, respect these preferences. Determine if any value or belief could interfere with planned interventions. For example, if the patient with anemia is a vegetarian, you will need to consider how to increase dietary intake of iron-rich foods other than meat. Thoughtful assessment and consideration of the patient's beliefs and values usually increase adherence and satisfaction.

Objective Data

Physical Examination

Mouth

Inspection

Inspect the mouth for symmetry, color, and size. Observe for abnormalities such as pallor or cyanosis, cracking, ulcers, or fissures. The dorsum (top) of the tongue should have a thin white coating. The undersurface should be smooth. Observe for any lesions. Using a tongue blade, inspect the buccal mucosa and note the color, any areas of pigmentation, and any lesions. Dark-skinned persons normally have patchy areas of pigmentation. In assessing the teeth and gums, look for caries; loose teeth; abnormal shape and position of teeth; and swelling, bleeding, discoloration, or gingival inflammation. Note any

distinctive breath odor.

Case Study

Subjective Data

© iStockphoto/Thinkstock.

A focused subjective assessment of L.C. revealed the following

information:

- ***Past Medical History:*** Negative history for medical or surgical problems.
- ***Medications:*** None.
- ***Health Perception–Health Management:*** L.C. states he has not been feeling well for the past several weeks. He feels weak and is easily fatigued. Denies exposure to chemicals. No recent travel outside of the United States. Smokes 1 pack of cigarettes per day for 20 yrs. Drinks 3 to 4 bottles of beer per day.
- ***Nutritional-Metabolic:*** L.C. is 5 ft, 9 in tall and weighs 140 lb (BMI: 20.7 kg/m^2). States has been losing weight over the past several months and does not have an appetite. No food allergies.
- ***Elimination:*** States has had alternating episodes of constipation and diarrhea. He noticed some bright red blood in stools. Has not had a bowel movement for 4 days.
- ***Cognitive-Perceptual:*** Rates pain as a 9 on a scale of 0 to 10. States pain comes and goes in waves. Prefers to lie still with knees flexed and drawn into his abdomen.

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. Based on these subjective assessment findings, what should be included in the physical assessment? What would you be looking for?
3. What would be your priority assessment?

You will learn more about physical examination of the gastrointestinal system in the next section.

(See p. 840 for more information on L.C.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Inspect the pharynx by tilting the patient's head back and depressing the tongue with a tongue blade. Observe the tonsils, uvula, soft palate, and anterior and posterior pillars. Tell the patient to say "ah." The uvula and soft palate should rise and remain in the midline.

Palpation

Palpate any suspicious areas in the mouth. Note ulcers, nodules, indurations, and areas of tenderness. The mouth of the older adult needs careful assessment. Pay attention to dentures (e.g., fit, condition), the ability to swallow, and the tongue, and note any lesions. Ask the patient with dentures to remove them during an oral examination to allow for good visualization and palpation of the area.

Abdomen

We use 2 systems to anatomically describe the surface of the abdomen. One system divides the abdomen into 4 quadrants by a perpendicular line from the sternum to the pubic bone and a horizontal line across the abdomen at the umbilicus (Fig. 38.5, *A*, and Table 38.8). The other system divides the abdomen into 9 regions (Fig. 38.5, *B*). Only the epigastric, umbilical, and suprapubic or hypogastric regions are commonly assessed.

For the abdominal examination, good lighting should shine across the abdomen. The patient should be in the supine position and as relaxed as possible. To help relax the abdominal muscles, have the patient slightly flex the knees and raise the head of the bed slightly. The patient should have an empty bladder. Use warm hands when doing the abdominal examination to avoid eliciting muscle guarding. Ask the patient to breathe slowly through the mouth.

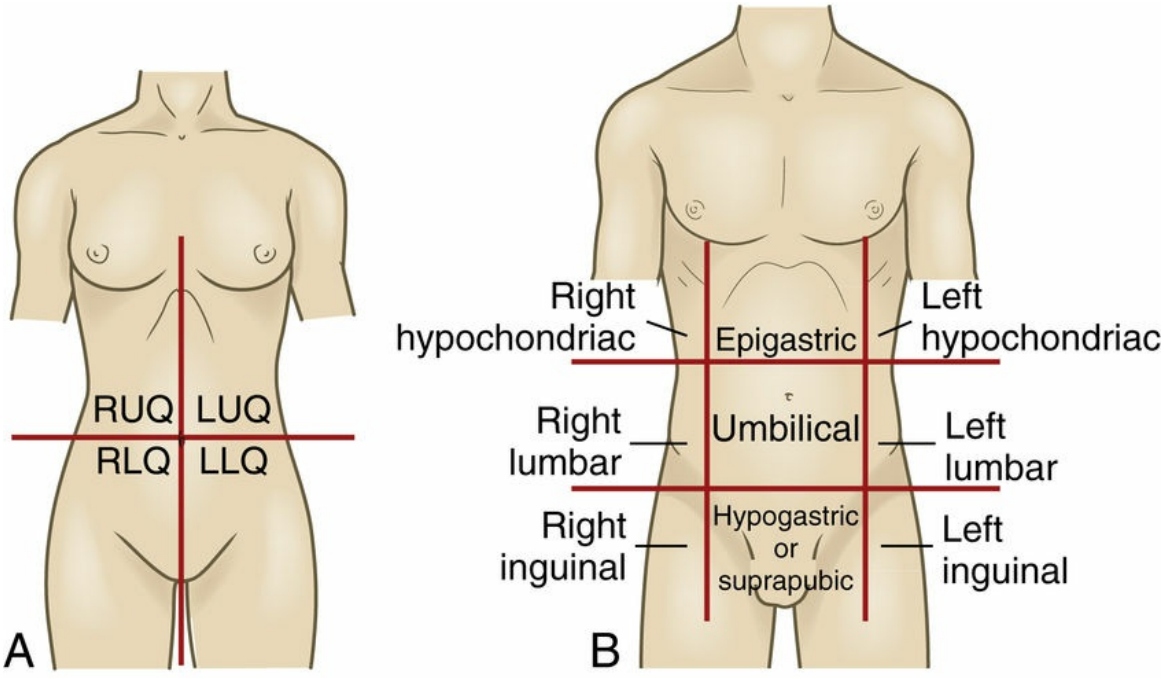

FIG. 38.5 **A,** Abdominal quadrants. **B,** Abdominal regions. *LLQ,* Left lower quadrant; *LUQ,* left upper quadrant; *RLQ,* right lower quadrant; *RUQ,* right upper quadrant.

The standard approach for examining the abdomen is appropriate for an older adult. The abdomen may be thinner and laxer unless the patient is obese.

Inspection

Assess the abdomen for skin changes (color, texture, scars, striae, dilated veins, rashes, lesions), umbilicus (location and contour), symmetry, contour (flat, rounded [convex], concave, protuberant, distended), observable hernias or masses, and movement (pulsations, peristalsis). A normal aortic pulsation may be seen in the epigastric area. Look across the abdomen tangentially (across the abdomen in a line) for peristalsis. Peristalsis is not normally visible in an adult but may be visible in a thin person.

Auscultation

When you examine the abdomen, auscultate before percussion and palpation because these latter procedures may alter the bowel sounds. Use the diaphragm of the stethoscope to auscultate bowel sounds

because they are relatively high pitched. Use the bell of the stethoscope to detect lower pitched sounds. Warm the stethoscope in your hands before auscultating to help prevent abdominal muscle contraction. Listen in the epigastrium and in all 4 quadrants. Start in the right lower quadrant because bowel sounds are normally present there. Listen for bowel sounds for at least 2 minutes. Do not count bowel sounds. Determine if they are normal, hypoactive, or hyperactive.

The frequency and intensity of bowel sounds vary depending on the phase of digestion. Normal sounds are relatively high pitched and gurgling. Stomach growling or loud gurgles *(borborygmi)* indicate hyperperistalsis. The bowel sounds are high pitched (rushes and tinkling) when the intestines are under tension, as in intestinal obstruction. Listen for decreased or absent bowel sounds. A perfectly "silent abdomen" is uncommon.[4] If you are patient and listen for several minutes, you will often find the bowel sounds are not absent but are hypoactive. If you do not hear bowel sounds, note the amount of time you listened in each quadrant without hearing bowel sounds.

Listen for vascular sounds. A *bruit,* best heard with the bell of the stethoscope, is a swishing or buzzing sound and indicates turbulent blood flow. Normally you should not hear aortic bruits.

Percussion

The purpose of percussing the abdomen is to estimate the size of the liver and determine the presence of fluid, distention, and masses. Sound waves vary according to the density of underlying tissues. Air produces a higher pitched, hollow sound termed *tympany.* Fluid or masses produce a short, high-pitched sound with little resonance termed *dullness.* Lightly percuss all 4 quadrants of the abdomen and assess the distribution of tympany and dullness (Fig. 38.6). Tympany is the predominant percussion sound of the abdomen.

TABLE 38.8 Structures Located in Abdominal

Regions

Right Upper Quadrant	Left Upper Quadrant	Right Lower Quadrant	Left Lower Quadrant
• **Liver and gallbladder**	• Left lobe of liver	• Lower pole of right kidney	• Lower pole of left kidney
• **Pylorus**	• Spleen	• Cecum and appendix	• Sigmoid flexure
• **Duodenum**	• Stomach	• Portion of ascending colon	• Part of descending colon
• **Head of pancreas**	• Body of pancreas	• Bladder (if distended)	• Bladder (if distended)
• **Right adrenal gland**	• Left adrenal gland	• Right ovary and fallopian tube	• Left ovary and fallopian tube
• **Portion of right kidney**	• Portion of left kidney	• Uterus (if enlarged)	• Uterus (if enlarged)
• **Hepatic flexure of colon**	• Splenic flexure of colon	• Right spermatic cord	• Left spermatic cord
• **Portion of ascending and transverse colon**	• Portion of transverse and descending colon	• Right ureter	• Left ureter

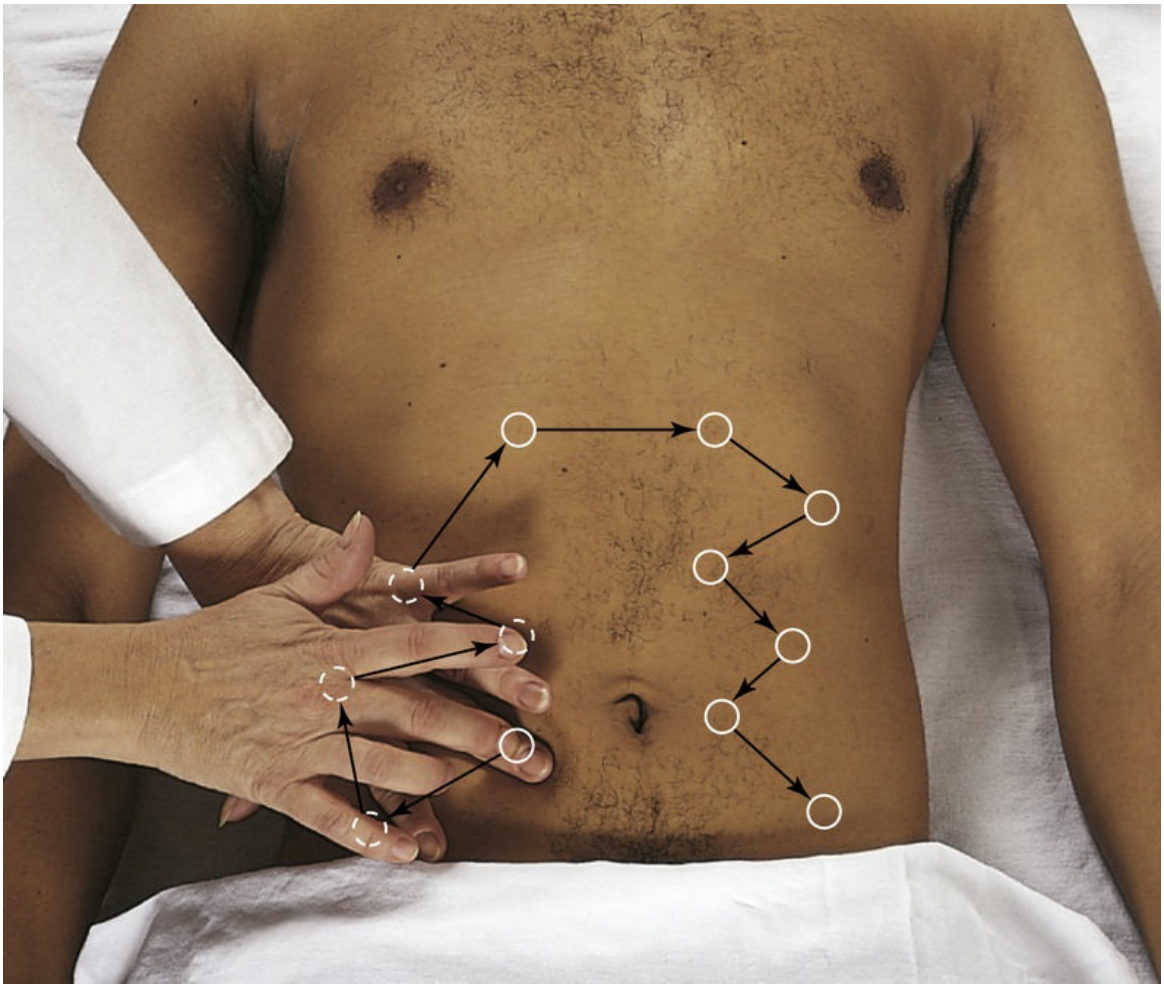

FIG. 38.6 Technique for percussion of the abdomen. Moving clockwise, percuss lightly in all 4 quadrants.
From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.

To percuss the liver, start below the umbilicus in the right midclavicular line and percuss lightly upward until you hear dullness. This is the lower border of the liver. Next, start at the nipple line in the right midclavicular line and percuss downward between ribs to the area of dullness indicating the upper border of the liver. Measure the height or vertical space between the 2 borders to determine the size of the liver. The normal range of liver height in the right midclavicular line is 2.4 to 5 in (6 to 12.7 cm).

Palpation

Use palpation to assess the abdominal organs and detect any tenderness, distention, masses, or fluid. Palpation is important because it may reveal a tumor. Begin with light palpation. Palpate any areas in which the patient reports tenderness last.

Use *light palpation* to detect tenderness or cutaneous hypersensitivity, muscular resistance, masses, and swelling. Help the patient relax for deeper palpation. Keep your fingers together and press gently with the pads of the fingertips, depressing the abdominal wall about 0.4 in (1 cm). Use smooth movements and palpate all quadrants (Fig. 38.7, *A*).

Use *deep palpation* to delineate abdominal organs and masses (Fig. 38.7, *B*). Use the palmar surfaces of your fingers to press more deeply. Again, palpate all quadrants and note the location, size, and shape of masses, as well as the presence of tenderness. During these maneuvers, observe the patient's facial expression because it will provide nonverbal cues of discomfort or pain.

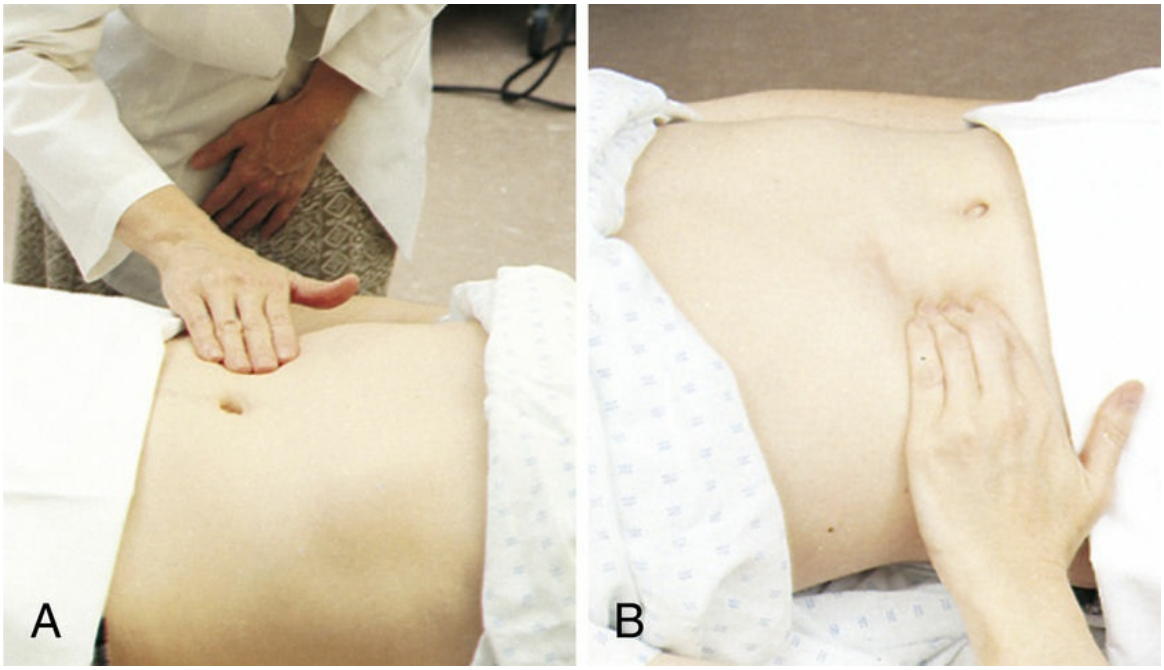

FIG. 38.7 **A,** Technique for light palpation of the abdomen. **B,** Technique for deep palpation.

An alternative method for deep abdominal palpation is the two-hand method. Place 1 hand on top of the other and apply pressure to the bottom hand with the fingers of the top hand. With the fingers of the bottom hand, feel for organs and masses. Practice both methods of palpation to determine which is most effective.

Check a problem area on the abdomen for rebound tenderness by pressing in slowly and firmly over the painful site. Withdraw the palpating fingers quickly. Pain on withdrawal of the fingers indicates peritoneal inflammation. Because assessing for rebound tenderness may produce pain and severe muscle spasm, it should be done at the end of the examination and only by an experienced practitioner.

To palpate the liver, place your left hand behind the patient to support the right eleventh and twelfth ribs (Fig. 38.8). The patient may relax on your hand. Press the left hand forward and place the right hand on the patient's right abdomen lateral to the rectus muscle. The fingertips should be below the lower border of liver dullness and pointed toward the right costal margin. Gently press in and up. The patient should take a deep breath with the abdomen so that the liver drops and is in a better position for palpation. Try to feel the liver

edge as it comes down to the fingertips. During inspiration, the liver edge should feel firm, sharp, and smooth. Describe the surface and contour and any tenderness. If the patient has chronic obstructive pulmonary disease, large lungs, or a low diaphragm, the liver may be palpated 0.4 to 0.8 in (1 to 2 cm) below the right costal margin.

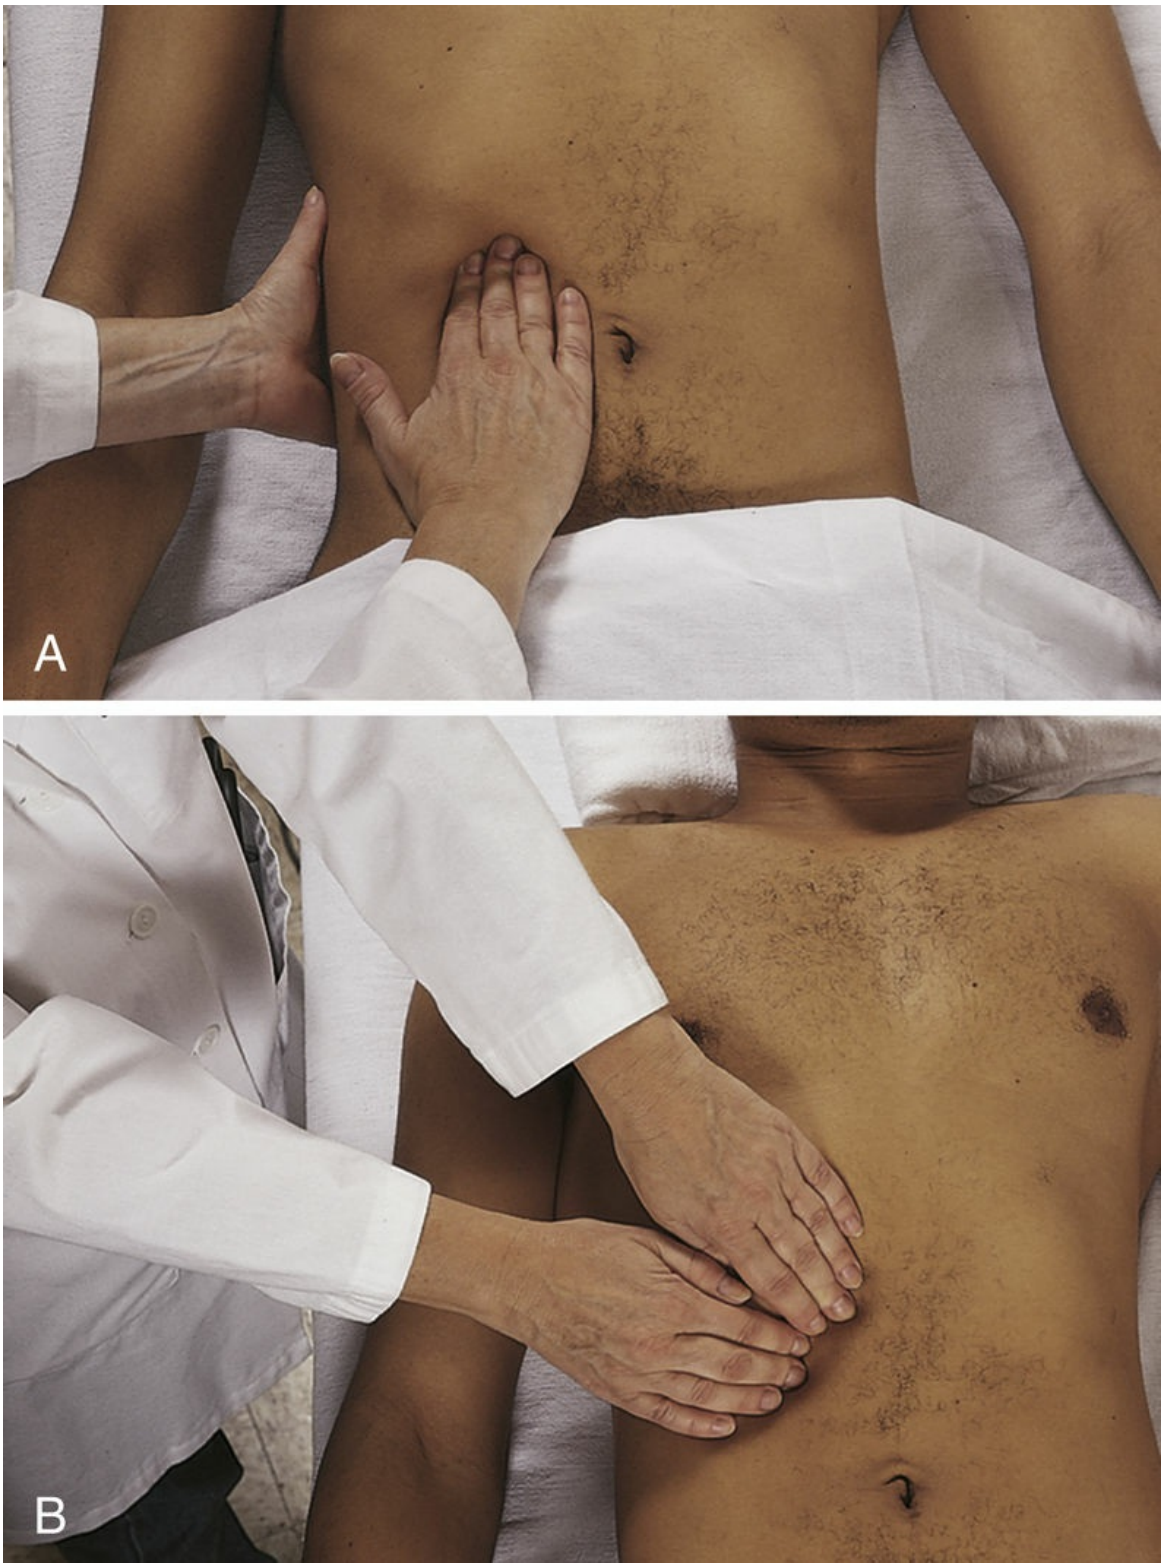

FIG. 38.8 **A,** Technique for liver palpation. **B,** Alternative technique to palpate liver with fingers hooked over the costal region.
From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.

To palpate the spleen, move to the patient's left side. Place your right hand under the patient, and support and press the patient's left lower rib cage forward. Place your left hand below the left costal margin and press it in toward the spleen. Ask the patient to breathe deeply. The fingertips can feel the tip or edge of an enlarged spleen. The spleen is normally not palpable. If it is palpable, do not continue because manual compression of an enlarged spleen may cause it to rupture.

Rectum and Anus

Inspect perianal and anal areas for color, texture, masses, rashes, scars, erythema, fissures, and external hemorrhoids. Palpate any masses or unusual areas with a gloved hand.

For the digital examination of the rectum, place a gloved, lubricated index finger against the anus while having the patient gently bear down (Valsalva maneuver). Then, as the sphincter relaxes, insert the finger. Point the finger toward the umbilicus. Try to get the patient to relax. Insert the finger into the rectum as far as possible and palpate all surfaces. Assess any nodules, tenderness, or irregularities. Use the gloved finger to remove a stool sample and check it for occult blood. However, a single guaiac-based fecal occult blood test has limited sensitivity in detecting colorectal cancer.

Findings of a normal physical assessment of the GI system are given in Table 38.9. Table 38.10 outlines assessment abnormalities. Gerontologic differences in the GI system and differences in assessment findings are described in Table 38.5. A *focused assessment* is used to evaluate the status of previously identified GI problems and to monitor for signs of new problems. A focused assessment of the GI system is shown on this page.

Case Study

Objective Data: Physical Examination

© iStockphoto/Thinkstock.

A focused assessment of L.C. reveals the following: BP 120/74, heart rate 110, respiratory rate 24, temperature 100.4° F (38° C). Abdomen firm and slightly distended. High-pitched bowel sounds in upper quadrants. No bowel sounds auscultated in left lower quadrant. Mild abdominal palpation elicits pain.

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based upon the subjective and objective assessment data

presented so far, what would be 3 priority nursing diagnoses?
3. What diagnostic studies do you think may be ordered for L.C.?

You will learn more about diagnostic studies related to the gastrointestinal system in the next section.

(See p. 847 for more information on L.C.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Focused Assessment

Gastrointestinal System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Loss of appetite	Y	N
Abdominal pain	Y	N
Changes in stools (e.g., color, blood, consistency, frequency, pain)	Y	N
Nausea, vomiting	Y	N
Painful swallowing	Y	N

Objective: Diagnostic

Check the following results for critical values.

Endoscopy: colonoscopy, sigmoidoscopy, esophagogastroduodenoscopy	✓
CT scan	✓
Radiologic series: upper GI, lower GI	✓
Stool for occult blood or ova and parasites	✓
Liver function tests	✓

Objective: Physical Examination

Inspect

Skin for color, scars, petechiae, and other lesions.	✓
Abdominal contour for symmetry and distention	✓
Perianal area for intact skin, hemorrhoids	✓

Auscultate*

Bowel sounds	✓

Palpate

Abdominal quadrants using light touch	✓
Abdominal quadrants using a deep technique	✓

* NOTE: Perform auscultation before palpation.

Diagnostic Studies of Gastrointestinal System

Tables 38.11 and 38.12 present common diagnostic studies of the GI system. Selected diagnostic studies are described in more detail in the following discussion.

For most diagnostic studies, make sure a signed consent form for the procedure has been completed and is in the medical record. The HCP doing the procedure is responsible for explaining the procedure and obtaining written consent. You have a key role in teaching patients about the procedures. When preparing the patient, it is important to ask about any known allergies to drugs, iodine, shellfish,

or contrast media.

TABLE 38.9 Normal Physical Assessment of Gastrointestinal System

Mouth

- Moist and pink lips
- Pink and moist buccal mucosa and gingivae without plaques or lesions
- Teeth in good repair
- Protrusion of tongue in midline without deviation or twitches
- Pink uvula (in midline), soft palate, tonsils, and posterior pharynx
- Swallows smoothly without coughing or gagging

Abdomen

- Flat without masses or scars. No bruises
- Bowel sounds in all quadrants
- No abdominal tenderness; nonpalpable liver and spleen
- Liver 10 cm in right midclavicular line
- Generalized tympany

Anus

- Absence of lesions, fissures, and hemorrhoids
- Good sphincter tone
- Rectal walls smooth and soft

- No masses
- Stool soft, brown, and heme negative

Many GI system diagnostic procedures require (1) measures to cleanse the GI tract and (2) ingestion or injection of a contrast medium or a radiopaque tracer. Often the patient has a series of GI diagnostic tests done. Monitor the patient closely to ensure adequate hydration and nutrition during the testing period.

Some diagnostic studies are especially difficult and uncomfortable for the older adult. Adjustments may be needed during the preparation, especially for those with certain health conditions (e.g., diabetes).[5] Make sure to consider any physical limitations when positioning the older patient during testing. Close monitoring is needed to avoid problems, such as dehydration from prolonged fluid restriction and diarrhea from bowel-cleansing procedures.

Radiologic Studies

Upper Gastrointestinal Series

An upper GI series with small bowel follow-through provides visualization of the oropharyngeal area, esophagus, stomach, and small intestine. The procedure consists of the patient swallowing contrast medium (a thick barium solution or gastrografin) and then assuming different positions on the x-ray table. The movement of the contrast medium is observed with fluoroscopy, and a series of x-rays are taken. An upper GI series is useful in identifying esophageal strictures, polyps, tumors, hiatal hernias, foreign bodies, and ulcers.

Lower Gastrointestinal Series

The purpose of a lower GI series, or a barium enema, is to observe (using fluoroscopy) the colon filling with contrast medium and to observe (by x-ray) the filled colon. The patient receives an enema of contrast medium. This procedure identifies polyps, tumors, and other lesions in the colon. Adding air contrast after the barium provides

better visualization (Fig. 38.9). Because the patient must retain the barium, an older or immobile patient may not tolerate it very well.

TABLE 38.10 Assessment AbnormalitiesGastrointestinal System

Finding	Description	Possible Etiology and Significance
Mouth		
Acute marginal gingivitis	Friable, edematous, painful, bleeding gingivae	Irritation from ill-fitting dentures or orthodontic appliances, calcium deposits on teeth, food impaction
Candidiasis	White, curdlike lesions surrounded by erythematous mucosa	*Candida albicans*
Cheilitis	Inflammation of lips (usually lower) with fissuring, scaling, crusting	Often unknown
Cheilosis	Softening, fissuring, and cracking of lips at angles of mouth	Riboflavin deficiency
Geographic tongue	Scattered red, smooth (loss of papillae) areas on dorsum of tongue	Unknown
Glossitis	Reddened, ulcerated, swollen tongue	Exposure to streptococci, irritation, injury, vitamin B deficiencies, anemia
Herpes simplex	Benign vesicular lesion	Herpesvirus
Leukoplakia	Thickened white patches	Premalignant lesion
Pyorrhea	Recessed gingivae, purulent pockets	Periodontitis
Smooth tongue	Red, slick appearance	Cobalamin deficiency
Ulcer, plaque on lips or in mouth	Sore or lesion	Cancer, viral infections
Esophagus and Stomach		
Dyspepsia	Burning or indigestion	Peptic ulcer disease, gallbladder disease
Dysphagia	Difficulty swallowing, sensation of food sticking in esophagus	Esophageal problems, cancer of esophagus
Eructation	Belching	Gallbladder disease
Hematemesis	Vomiting of blood	Esophageal varices, bleeding peptic ulcer
Nausea and vomiting	Feeling of impending vomiting, expulsion of gastric contents through mouth	GI infections, common manifestation of many GI diseases; stress, fear, and pathologic conditions
Odynophagia	Painful swallowing	Cancer of esophagus, esophagitis
Pyrosis	Heartburn, burning in epigastric or substernal area	Hiatal hernia, esophagitis, incompetent lower esophageal sphincter
Abdomen		
Absence of liver dullness	Tympany on percussion	Air from viscus (e.g., perforated ulcer)
Absent bowel sounds	No bowel sounds on auscultation	Peritonitis, paralytic ileus, obstruction
Ascites	Accumulated fluid within abdominal cavity, eversion of umbilicus (usually)	Peritoneal inflammation, heart failure, metastatic cancer, cirrhosis
Borborygmi	Waves of loud, gurgling sounds	Hyperactive bowel as result of eating
Bruit	Humming or swishing sound heard through stethoscope over vessel	Partial arterial obstruction (narrowing of vessel), turbulent flow (aneurysm)
Distention	Excessive gas accumulation, enlarged abdomen, generalized tympany	Obstruction, paralytic ileus
Hepatomegaly	Enlargement of liver, liver edge >1–2 cm below costal margin	Metastatic cancer, hepatitis, venous congestion
Hernia	Bulge or nodule in abdomen, usually appearing on straining	Inguinal (in inguinal canal), femoral (in femoral canal), umbilical (herniation of umbilicus), or incisional (defect in muscles after surgery)
Hyperresonance	Loud, tinkling rushes	Intestinal obstruction
Masses	Lump on palpation	Tumors, cysts
Nodular liver	Enlarged, hard liver with irregular edge or surface	Cirrhosis, cancer
Rebound tenderness	Sudden pain when fingers withdrawn quickly	Peritoneal inflammation, appendicitis
Splenomegaly	Enlarged spleen	Chronic leukemia, hemolytic states, portal hypertension, some infections
Rectum and Anus		
Fissure	Ulceration in anal canal	Straining, irritation
Hemorrhoids	Thrombosed veins in rectum and anus (internal or external)	Portal hypertension, chronic constipation, prolonged sitting or standing, pregnancy
Mass	Firm, nodular edge	Tumor, cancer
Melena	Abnormal, black, tarry stool containing digested blood	Cancer, bleeding in upper GI tract from ulcers, varices

Finding	Description	Possible Etiology and Significance
Pilonidal cyst	Opening of sinus tract, cyst in midline just above coccyx	Probably congenital
Steatorrhea	Fatty, frothy, foul-smelling stool	Chronic pancreatitis, biliary obstruction, malabsorption problems
Tenesmus	Painful and ineffective straining at stool. Sense of incomplete evacuation	Inflammatory bowel disease, irritable bowel syndrome, diarrhea secondary to GI infection (e.g., food poisoning)

TABLE 38.11 Diagnostic StudiesGastrointestinal System

Study	Description and Purpose	Nursing Responsibility
Endoscopy		
Colonoscopy	Directly visualizes entire colon up to ileocecal valve with flexible fiberoptic scope. Patient's position is changed frequently during procedure to assist with advancement of scope to cecum. Used to diagnose or detect inflammatory bowel disease, polyps, tumors, and diverticulosis and dilate strictures. Procedure allows for biopsy and removal of polyps without laparotomy.	*Before:* Bowel preparation prior varies depending on HCP. Patient should avoid fiber for up to 72 hr prior, then either a clear or full liquid diet 24 hr before. Bowel cleansing should follow a split-dose regimen. The evening before the procedure, the patient should drink a cleansing solution. The second dose should begin 4–6 hr before the procedure. A split-dose regimen started early morning the day of a procedure provides better cleansing for patients scheduled in the afternoon. Encourage the patient to drink all the solution. Stools will be clear or clear yellow liquid when the colon is clean. Bisacodyl tablets or suppositories may be given before the cleansing solution to remove the bulk of the stool. Explain to patient that a flexible scope will be inserted while patient in side-lying position and sedation will be given. *After:* Patient may have abdominal cramps caused by stimulation of peristalsis because the bowel is constantly inflated with air during procedure. Teach patients about pain post-colonoscopy and the characteristics of this pain. Tell patients if pain lasts longer than 24 hr to notify HCP. Check vital signs. Observe for rectal bleeding and manifestations of perforation (e.g., malaise, abdominal distention, tenesmus).

Table Continued

Study	Description and Purpose	Nursing Responsibility
Endoscopic retrograde cholangiopancreatography (ERCP)	Fiberoptic endoscope (using fluoroscopy) is orally inserted into descending duodenum. Then common bile and pancreatic ducts are cannulated. Contrast medium is injected into ducts to allow for direct visualization of structures. Can be used to retrieve a gallstone from distal common bile duct, dilate strictures, biopsy, and diagnose pseudocysts.	*Before:* Explain procedure. Keep patient NPO 8 hr before. Ensure consent form is signed. Give sedation immediately before and during procedure. Give antibiotics if ordered. *After:* Check vital signs. Assess for perforation or infection. Pancreatitis is most common complication. Check for return of gag reflex.
Esophagogastroduodenoscopy (EGD)	Directly visualizes mucosal lining of esophagus, stomach, and duodenum with flexible endoscope. Test may use video imaging to visualize stomach motility. Detects inflammation, ulcerations, tumors, varices, or Mallory-Weiss tears. Biopsies may be taken. Varices can be treated with band ligation or sclerotherapy.	*Before:* Keep patient NPO for 8 hr. Ensure consent form is signed. Give preoperative medication if ordered. Explain to patient that local anesthesia may be sprayed on throat before insertion of scope and that patient will be sedated during procedure. *After:* Keep patient NPO until gag reflex returns. Gently tickle back of throat to determine reflex. Use warm saline gargles for relief of sore throat. Check temperature q15–30min for 1–2 hr (sudden temperature spike is sign of perforation).
Laparoscopy (peritoneoscopy)	Visualize peritoneal cavity and contents with laparoscope. Double-puncture peritoneoscopy permits better visualization of abdominal cavity, especially liver. Done in operating room. Can obtain biopsy specimen.	*Before:* Ensure consent form is signed. Keep patient NPO 8 hr. Give preoperative sedative medication. Ensure bladder and bowels are emptied. *After:* Observe for complications of bleeding and bowel perforation after the procedure.
Sigmoidoscopy	Directly visualizes rectum and sigmoid colon with lighted flexible endoscope. Sometimes a special table is used to tilt patient into knee-chest position. Used to detect tumors, polyps, inflammatory and infectious diseases, fissures, hemorrhoids.	*Before:* Bowel preparation similar to colonoscopy. Explain to patient knee-chest position, need to take deep breaths during insertion of scope, and possible urge to defecate as scope is passed. Encourage patient to relax and let abdomen go limp. *After:* Observe for rectal bleeding after polypectomy or biopsy.
Video capsule endoscopy	Patient swallows a vitamin-sized capsule with camera, which provides endoscopic visualization of GI tract (Fig. 38.11). Camera takes >50,000 images during test, relaying them to monitoring device that patient wears on a belt. Images then downloaded to computer. Used to look at areas of GI tract not accessible by upper and lower endoscopy.	*Before:* Keep patient NPO for 8 hr. May have bowel preparation similar to colonoscopy. After swallowing capsule, clear liquids resumed in 2 hr and food in 4 hr. *After:* 8 hr after swallowing device, patient returns to have monitoring device removed. Tell patient that capsule is disposable and will be present in a bowel movement.
Radiology		
Cholangiography		
• **Magnetic resonance cholangiopancreatography (MRCP)**	Use of MRI technology to obtain images of biliary and pancreatic ducts.	Same as MRI.
• **Percutaneous transhepatic (PTC)**	Under local anesthesia and monitored anesthesia care, a long needle is passed into liver (under fluoroscopy) and into bile duct. Bile is removed, and radiopaque contrast medium directly injected into biliary system. Used to determine filling of hepatic and biliary ducts.	*Before:* Assess patient's medications for contraindications, precautions, or complications with use of contrast medium. Keep patient NPO for 8–12 hr before test. Start prophylactic IV antibiotics 1 hr prior. *After:* Observe patient for signs of hemorrhage, bile leakage, and infection. Observe safety precautions until sedation wears off. Maintain bed rest for 6 hr.
• **Surgical cholangiogram**	Contrast medium is injected into common bile duct during surgery on biliary structures.	*Before:* Explain that anesthetic will be used. Assess patient's medications for contraindications, precautions, or complications with use of contrast medium.
Computed tomography (CT) scan	Noninvasive radiologic examination allows for exposures at different depths. Using oral and IV contrast medium accentuates density differences. Detects biliary tract, liver, and pancreatic disorders.	*Before:* Before contrast medium used, evaluate renal function. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO prior. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Defecography	Uses fluoroscopy or MRI to assess the shape and position of the rectum during defecation. Using a lubricated small plastic tip, fill rectum and anus with barium. Oral barium allows small bowel to be visualized. The person then sits on a toilet-like seat attached to the x-ray table and is asked to push and empty the rectum. Images are taken while person is sitting at rest, straining, squeezing, and during defecation. Detects pelvic floor abnormalities.	*Before:* Keep patient NPO for 2 hr. 2 enemas are given 2 hr before, 15 min apart. Oral barium is given 1 hr before.
Gastric emptying breath test (GEBT)	Noninvasive test that measures CO_2 in a patient's breath. Used to diagnose delayed gastric emptying. Baseline breath test done. Then patient eats a special test meal that includes a scrambled egg mix and *Spirulina platensis*, a protein enriched with carbon-13. It is measured in breath samples collected at multiple time points after the meal.	*Before:* Teach patient to be NPO after midnight and that the test takes 4 hr. *During:* Can be done in any clinical setting. It does not require special training or special precautions related to radiation.
Lower GI or barium enema	Fluoroscopic x-ray examination of colon using contrast medium, which is given rectally (enema) (Fig. 38.9). Double-contrast or air-contrast barium enema is test of choice. Air is infused after the barium flows through transverse colon. Used to detect the presence of tumors, diverticula, and polyps.	*Before:* Give laxatives and enemas until colon is clear of stool evening before procedure. Follow clear liquid diet evening before procedure. Keep patient NPO for 8 hr before test. Teach patient about the barium enema. Explain that cramping and urge to defecate may occur during procedure and patient may be placed in various positions on tilt table. *After:* Give fluids, laxatives, or suppositories to help in expelling barium. Observe stool for passage of contrast medium. Tell patient that stool may be white for up to 72 hr.
Magnetic resonance imaging (MRI)	Noninvasive procedure using radiofrequency waves and a magnetic field. IV contrast medium (gadolinium) may be used. Used to detect hepatobiliary disease, hepatic lesions, and sources of GI bleeding and stage colorectal and other cancers.	*Before:* Check for pregnancy, allergies, and renal function. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during scan.
Nuclear imaging scans (scintigraphy)	Tracer doses of a radioactive isotope are injected IV, and a scanning device picks up radioactive emission, which is recorded on paper. Shows size, shape, and position of organ. Identifies functional disorders and structural defects.	*Before:* Tell patient that the substance used contains only traces of radioactivity and poses little to no danger. Schedule no more than 1 radionuclide test a day. Explain to patient need to lie flat during scanning.
• **Gastric emptying studies**	Assesses ability of stomach to empty solids. Patient eats cooked egg containing ^{99m}Tc and toast with water. Images are obtained at 0, 1, 2, and 4 hr later. Used to study gastric emptying disorders caused by ulcers, ulcer surgery, diabetes, cancer, or functional disorders.	Same as above.
• **Hepatobiliary scintigraphy (HIDA)**	Patient is given IV injection of ^{99m}Tc and positioned under camera to record distribution of tracer dose in liver, biliary tree, gallbladder, and proximal small intestine. Used to identify obstructions of bile ducts (gallstones, tumors), diseases of gallbladder, and bile leaks.	Same as above.
• **Scintigraphy of GI bleeding**	^{99m}Tc–labeled sulfur colloid or ^{99m}Tc labeling of the patient's own RBCs to determine the site of active GI blood loss. Sulfur colloid or patient's RBCs are injected, then images of abdomen taken at intermittent intervals.	Same as above.
Small bowel series	Contrast medium is ingested, and films taken every 30 min until medium reaches terminal ileum.	*Before:* Explain procedure, including the need to drink contrast medium and assume various positions on x-ray table. Keep patient NPO for at least 8 hr. Tell patient to avoid smoking after midnight. *After:* Take measures to prevent contrast medium impaction (fluids, laxatives). Tell patient that stool may be white for up to 72 hr.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Upper gastrointestinal (GI) or barium swallow	Fluoroscopic x-ray study using contrast medium. Used to diagnose structural abnormalities of esophagus, stomach, and duodenum.	Same as for small bowel series.
Ultrasound	Noninvasive procedure using high-frequency ultrasound waves, which are passed into body structures and recorded as they are reflected. Used to show size and configuration of an organ.	
• **Abdominal ultrasound**	A conductive gel is applied to skin, and a transducer is placed on the area. Detects abdominal masses (tumors, cysts), gallstones, biliary and liver disease.	*Before:* Teach patient to be NPO for 8–12 hr. Air or gas can reduce quality of images. Food intake can cause gallbladder contraction, resulting in suboptimal study.
• **Endoscopic ultrasound (EUS)**	Small ultrasound transducer is installed on tip of endoscope. Because EUS transducer gets close to the organ(s) being examined, images obtained are more accurate and detailed than those provided by traditional ultrasound. Detects and stages esophageal, gastric, rectal, biliary, and pancreatic tumors and abnormalities.	Same as esophagogastroduodenoscopy (EGD).
• **Ultrasound elastography (Fibroscan)**	Transient elastography uses an ultrasound transducer to assess level of liver fibrosis. Used to monitor patients with chronic liver disease.	*Before:* Explain the need to lie in dorsal decubitus position with right arm in extreme abduction.
Virtual colonoscopy	Combines CT scanning or MRI with computer virtual reality software. Air is introduced via a tube placed in rectum to enlarge colon to enhance visualization. Images obtained while patient is on back and abdomen. Computer combines images to form 2-D and 3-D pictures that are viewed on monitor. Detects intestine and colon diseases, including polyps, cancer, diverticulosis, and lower GI bleeding.	*Before:* Bowel preparation similar to colonoscopy.

TABLE 38.12 Laboratory StudiesGastrointestinal System

Test	Reference Interval	Description and Purpose
Blood Studies		
Amylase	60–120 U/L (30–220 U/L)	Enzyme secreted by pancreas. Important in diagnosing acute pancreatitis. Level of amylase peaks in 24 hr and then returns to normal in 48–72 hr
Gastrin	25–100 pg/mL when fasting	Hormone secreted by cells of the antrum of the stomach, the duodenum, and the pancreatic islets of Langerhans
Lipase	0–160 U/L	Enzyme secreted by pancreas. Important in diagnosing pancreatitis. Level stays higher longer than serum amylase in acute pancreatitis
Fecal Tests		
Fecal analysis	Note form, consistency, and color. Specimen examined for mucus, blood, pus, parasites, and fat content	Teach patient to keep diet free of red meat for 24–48 hr before occult blood test
Stool culture	Normal intestinal flora	Tests for the presence of bacteria, including *Clostridium difficile*

Virtual Colonoscopy

Virtual colonoscopy combines CT scanning or MRI to produce images of the colon and rectum less invasively. It requires radiation and prior cleansing of the colon but no sedation.

Compared to conventional colonoscopy, virtual colonoscopy provides a better view inside the colon that is narrow from inflammation or a growth.[6] If a polyp is found, it will have to be removed by conventional colonoscopy. Virtual colonoscopy may be less sensitive in obtaining information on the details and color of the mucosa and in detecting small (less than 10 mm) or flat polyps.

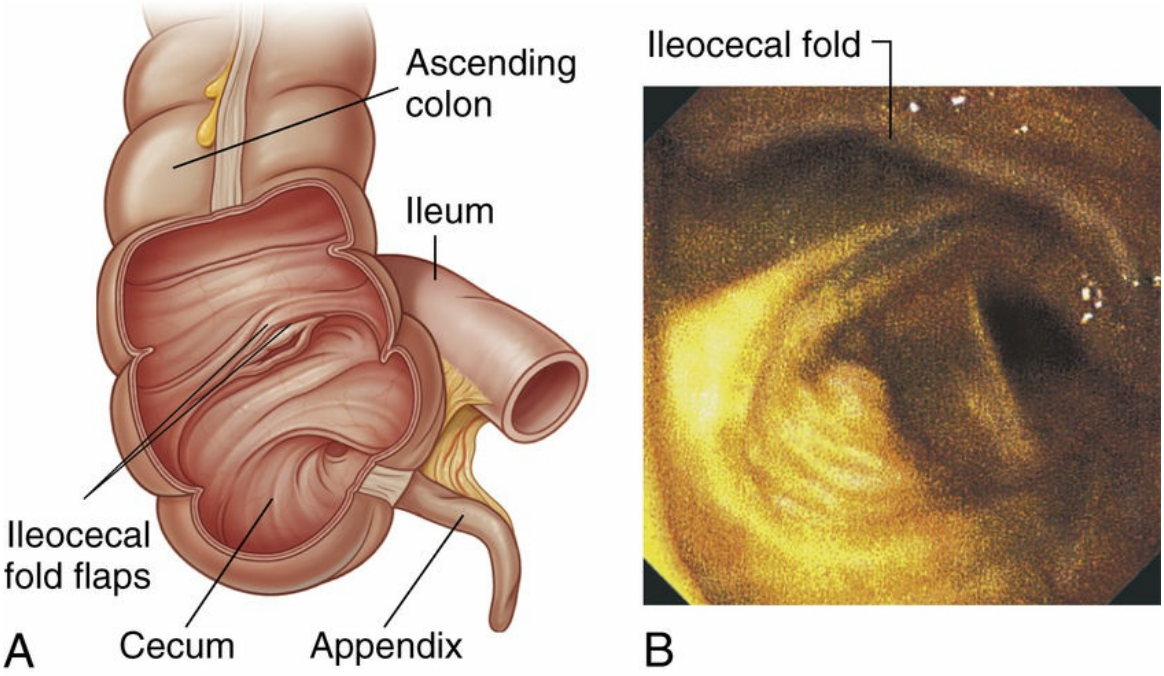

FIG. 38.10 **A,** Illustration showing the ileocecal junction and the ileocecal fold. **B,** Endoscopic image of the ileocecal fold.
From Drake RL, Vogl W, Mitchell AWM: *Gray's anatomy for students,* ed 3, Edinburgh, 2015, Churchill Livingstone.

Endoscopy

Endoscopy refers to the direct visualization of a body structure through an endoscope. An endoscope is a fiberoptic instrument with a light and camera attached, allowing the ability to take video and still pictures (Fig. 38.10). Some endoscopes have a channel through which to pass instruments, such as biopsy forceps and cytology brushes.

Endoscopy can examine the esophagus, stomach, duodenum, and colon. *Endoscopic retrograde cholangiopancreatography* (ERCP) visualizes the pancreatic, hepatic, and common bile ducts. Endoscopy is often combined with diagnostic procedures, including biopsy, cytologic

studies, invasive, and therapeutic procedures. Examples include polypectomy, sclerosis or banding of varices, cauterization of bleeding sites, common bile duct stone removal, and balloon dilation.

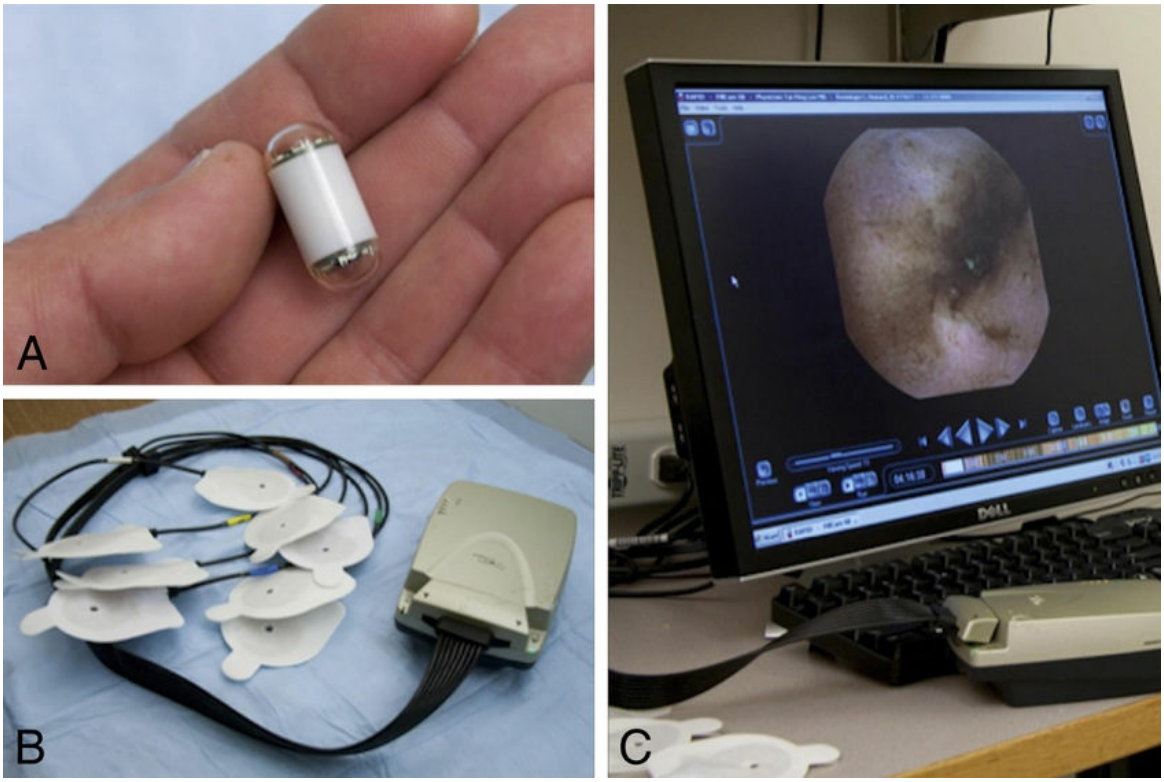

FIG. 38.11 Capsule endoscopy. **A,** The pill-sized video capsule has its own camera and light source. **B,** As it travels through the GI tract, it sends messages through sensing electrodes placed on the chest and abdomen to a data recorder worn on a waist belt. **C,** After the test, the images are viewed on a computer.
From Dye CE, Gaffney RR, Dykes TM, et al: Endoscopic and radiographic evaluation of the small bowel in 2012, *Am J Med* 125:1228e1, 2012.

The major complication of GI endoscopy is perforation through the structure being studied. Many endoscopic procedures require short-acting IV sedation. All endoscopic procedures require informed, written consent. Specific endoscopy procedures are discussed in Table 38.11.

Capsule endoscopy is a noninvasive approach to visualize the GI tract (Fig. 38.11). Colon capsule endoscopy is useful in diagnosing small

bowel disease and monitoring inflammation in patients with IBD. Its sensitivity in detecting small lesions, colonic polyps, and colorectal cancer is under investigation.[7]

Liver Function Studies

Liver function tests (LFTs) are laboratory (blood) studies that reflect hepatic disease. Table 38.13 describes the most common LFTs.

Liver Biopsy

The purpose of a liver biopsy is to obtain hepatic tissue to use to establish a diagnosis of cancer or assess and stage fibrosis. It may be done to follow the progress of liver disease, such as chronic hepatitis.

The 2 types of liver biopsy are open and closed. The *open method* involves making an incision and removing a wedge of tissue. It is done in the operating room with the patient under general anesthesia, often with another surgical procedure. The *closed,* or *needle, biopsy* is a percutaneous procedure. It is often done with ultrasound or CT guidance. The HCP administers a local anesthetic, then inserts a needle between 6th and 7th or 8th and 9th intercostal spaces on the right side to obtain specimen of hepatic tissue. Table 38.14 outlines the nursing management of a patient undergoing a liver biopsy.

TABLE 38.13 Liver Function Tests

Test	Reference Interval	Description and Purpose
Bile Formation and Excretion		
Serum bilirubin		Measures liver's ability to conjugate and excrete bilirubin, distinguishing between unconjugated (indirect) and conjugated (direct) bilirubin in plasma
• **Total**	0.3–1.0 mg/dL (5.1–17 µmol/L)	Measures direct and indirect total bilirubin
• **Direct**	0.1–0.3 mg/dL (1.7–5.1 µmol/L)	Measures conjugated bilirubin. High in obstructive jaundice
• **Indirect**	0.2–0.8 mg/dL (3.4–12 µmol/L)	Measures unconjugated bilirubin. High in hepatocellular and hemolytic conditions
Urinary bilirubin	0 or negative	Measures urinary excretion of conjugated bilirubin
Hemostatic Function		
Prothrombin time (PT)	11–12.5 sec	Determination of prothrombin activity
Vitamin K	0.1–2.2 ng/mL (0.22–4.88 nmol/L)	Essential cofactor for many clotting factors
Lipid Metabolism		
Cholesterol (serum)	200 mg/dL (<5.2 mmol/L), varying with age	Synthesized and excreted by liver. High in biliary obstruction. Low in cirrhosis and malnutrition
Protein Metabolism		
α-Fetoprotein	<10 ng/mL (<10 mcg/L)	Sign of hepatocellular cancer
Ammonia	10–80 mcg/dL (6–47 µmol N/L)	Conversion of ammonia to urea normally occurs in liver. Increase can result in hepatic encephalopathy secondary to liver cirrhosis
Protein (serum)	• Albumin: 3.5–5.0 g/dL (35–50 g/L) • Globulin: 2.3–3.4 g/dL (23–34 g/L) • Total protein: 6.4–8.3 g/dL (64–83 g/L)	Measures serum proteins made by liver
Serum Enzymes		
Alanine aminotransferase (ALT)	4–36 U/L	High in liver damage and inflammation
Alkaline phosphatase (ALP)	30–120 U/L (0.5–2.0 µkat/L)	Originates from bone and liver. Serum levels rise when excretion is impaired because of obstruction in biliary tract
γ-Glutamyl transpeptidase (GGT)	Male and Female > 45: 8–38 U/L Female < 45: 5–27 U/L	Present in biliary tract, not in skeletal or heart muscle. High in hepatitis and alcoholic liver disease. More sensitive for liver dysfunction than ALP
Aspartate aminotransferase (AST)	0–35 U/L (0.0–0.58 µkat/L)	High in liver damage and inflammation

TABLE 38.14 Nursing ManagementCare of the Patient Undergoing Liver Biopsy

Preprocedure

- Perform baseline assessment, including vital signs, pulse oximetry.
- Withhold food and fluids for 8–12 hr before.
- Check patient's coagulation status (prothrombin time, clotting or

bleeding time).

- Give sedative and other drugs, as ordered
- Obtain type and crossmatch.
- Teach patient and caregiver about procedure and postprocedure care. Explain need to hold breath after expiration when needle is inserted.
- Ensure informed consent has been signed.

Postprocedure

- Check vital signs to detect internal bleeding q15min × 2, q30min × 4, q1hr × 4.
- Notify HCP of dyspnea, cyanosis, and restlessness, which may occur with pneumothorax.

- Keep patient lying on right side for minimum of 2 hr to splint puncture site. Then maintain bed rest for 12–14 hr, as ordered.
- Apply a small dressing over the needle insertion site.
- Teach patient and caregiver about discharge care including signs and symptoms to report to HCP (e.g., site complications) and any activity restrictions. Tell patient to avoid straining or coughing, which cause increased intraabdominal pressure.

Case Study

Objective Data: Diagnostic Studies

© iStockphoto/Thinkstock.

The ED physician performs a rectal examination and finds a palpable mass. The following diagnostic tests are ordered:

- CBC
- Electrolytes
- Liver function tests
- Urinalysis
- CT scan of the abdomen
- Colonoscopy

The CBC reveals an Hgb of 6.8 g/dL and Hct of 20%. The WBC count is normal. The electrolytes, liver function tests, and urinalysis are within normal limits. The CT scan reveals pockets of gas and fluid in the ascending colon and 2 medium-sized tumors in the transverse colon.

Discussion Questions

1. Which diagnostic study results are of most concern to you?
2. With this information, what other diagnostic studies would you expect to be ordered for L.C.?
3. What are the interprofessional team's priorities for L.C. at this time?

Case study continued in Chapter 42 on p. 966.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient is admitted to the hospital with a diagnosis of diarrhea with dehydration. The nurse recognizes that increased peristalsis resulting in diarrhea can be related to
   a. sympathetic inhibition.
   b. mixing and propulsion.
   c. sympathetic stimulation.
   d. parasympathetic stimulation.
2. A patient has a high blood level of indirect (unconjugated) bilirubin. One cause of this finding is that
   a. the gallbladder is unable to contract to release stored

bile.

b. bilirubin is not being conjugated and excreted into the bile by the liver.

c. the Kupffer cells in the liver are unable to remove bilirubin from the blood.

d. there is an obstruction in the biliary tract preventing flow of bile into the small intestine.

3. As gastric contents move into the small intestine, the bowel is normally protected from the acidity of gastric contents by the

a. inhibition of secretin release.

b. secretion of mucus by goblet cells.

c. release of pancreatic digestive enzymes.

d. release of gastrin by the duodenal mucosa.

4. A patient is jaundiced, and her stools are clay colored. This is *most* likely related to

a. decreased bile flow into the intestine.

b. increased production of urobilinogen.

c. increased bile and bilirubin in the blood.

d. increased production of cholecystokinin.

5. An 80-yr-old man states that, although he adds a lot of salt to his food, it still does not have much taste. The nurse's response is based on the knowledge that the older adult

a. should not have any changes in taste.

d. has a loss of taste buds, especially for sweet and salt.

c. has some loss of taste but no problems chewing food.

d. loses the sense of taste because the ability to smell is

decreased.

6. When the nurse is assessing the health perception–health maintenance pattern as related to gastrointestinal function, an appropriate question to ask is
   a. "What is your usual bowel elimination pattern?"
   b. "What percentage of your income is spent on food?"
   c. "Have you traveled to a foreign country in the last year?"
   d. "Do you have diarrhea when you are under a lot of stress?"

7. During an examination of the abdomen the nurse should
   a. position the patient in the supine position with the bed flat and knees straight.
   b. listen for bowel sounds in the epigastrium and all four quadrants for 2 minutes.
   c. describe bowel sounds as absent if no sound is heard in a quadrant after 2 minutes.
   d. use the following order of techniques: inspection, palpation, percussion, auscultation.

8. Normal physical assessment findings of the gastrointestinal system are *(select all that apply)*
   a. nonpalpable spleen.
   b. borborygmi in upper right quadrant.
   c. tympany on percussion of the abdomen.
   d. liver edge 2 to 4 cm below the costal margin.
   e. finding of a firm, nodular edge on the rectal examination.

9. In preparing a patient for a colonoscopy, the nurse explains that

a. a signed permit is not needed.

b. sedation will be used during the procedure.

c. one cleansing enema part of the required preparation.

d. light meals should be eaten for 3 days before the procedure.

1. d, 2. b, 3. b, 4. a, 5. b, 6. c, 7. b, 8. a, c, 9. b

Nutritional Problems

Mariann M. Harding

LEARNING OUTCOMES

1. Relate the essential components of a well-balanced diet to their impact on health outcomes.
2. Describe the etiology, clinical manifestations, and interprofessional and nursing management of malnutrition.
3. Describe the components of a nutritional assessment.
4. Explain the indications, complications, and nursing management related to the use of enteral nutrition.
5. Explain the indications, complications, and nursing management related to the use of parenteral nutrition.
6. Compare the etiology, clinical manifestations, and nursing management of eating disorders.

Conceptual Focus

Functional Ability
Health Promotion
Nutrition

This chapter focuses on problems related to nutrition. A review of normal nutrition provides a basis for evaluating nutritional status. We need sufficient energy, protein, and other nutrients to maintain health. Many problems affect nutrition by changing the way we ingest, absorb, digest, and metabolize nutrients. These changes can lead to malnutrition, and health problems which affect functional status and quality of life. This makes it important for nurses to incorporate assessment and interventions aimed at promoting optimal nutrition.

Nutritional Problems

Nutrition is the sum of processes by which one takes in and uses nutrients. We view nutritional status on a continuum from undernutrition to normal nutrition to overnutrition. Any change in nutrient intake or use can cause nutritional problems. Nutritional

problems occur in all ages, cultures, ethnic groups, and socioeconomic classes and across all educational levels.

Many factors influence nutritional status. A person establishes attitudes toward food and eating habits early. Dietary intake often reflects cultural or religious preferences. A person or family's financial status influences the type and amount of nutritious food they can buy.[1]

Normal Nutrition

Nutrition is important for energy, growth, and maintaining and repairing body tissues. Optimal nutrition (in the absence of any underlying disease process) results from eating a balanced diet. The major components of the basic food groups are macronutrients (carbohydrates, fats, proteins), micronutrients (vitamins, minerals, electrolytes), and water. Optimal nutrition and daily physical activity are essential for a healthy lifestyle.

Body type, age, gender, medications, physical activity, and the presence or absence of disease influence a person's daily caloric requirements. Adjustments in caloric intake are necessary depending on changes in health status and daily activity level. There are several ways to estimate caloric need. The Mifflin–St. Jeor equation calculates daily adult energy (calorie) requirements based on resting metabolic rate (Table 39.1).[2] A simpler way to estimate daily calories needed is by kilocalories per kilogram (kcal/kg). An average adult should consume 20 to 25 cal/kg body weight to lose weight, 25 to 30 cal/kg to maintain

TABLE 39.1 Estimating Daily Energy (Calorie) Requirements

Mifflin–St. Jeor Equation

For each gender, use the formula below to calculate energy

expenditure:

Men: 10 × weight (kg) + 6.25 × height (cm) − 5 × age (yr) + 5
Women: 10 × weight (kg) + 6.25 × height (cm) − 5 × age (yr) − 161

To determine total daily calorie needs, the energy expenditure is multiplied by the appropriate activity factor, as follows:

1.200 = sedentary (little or no exercise)
1.375 = lightly active (light exercise/sports 1–3 days/wk)
1.550 = moderately active (moderate exercise/sports 3–5 days/wk)
1.725 = very active (hard exercise/sports 6–7 days a wk)
1.900 = extra active (very hard exercise/sports and physical job)

Example

Man: Weight 180 lb (82 kg); height 5 ft, 10 in (178 cm); age 50, very active
Energy expenditure = 10 (82) + 6.25 (178) − 5 (50) + 5 × 1.725 = 2911
Woman: Weight 150 lb (68 kg); height 5 ft, 6 in (168 cm); age 60; lightly active
Energy expenditure = 10 (68) + 6.25 (168) − 5 (60) −161 × 1.375 = 1745

body weight, and 30 to 35 cal/kg to gain weight.[3] Energy needs may be greater during illness.

Carbohydrates, the body's main source of energy, yield about 4 cal/g. We classify them as either simple or complex, depending on the number of sugars they have. Simple carbohydrates come in 2 forms: monosaccharides (e.g., glucose, fructose), which are found in fruits and honey, and disaccharides (e.g., sucrose, maltose, lactose). They are found in foods such as table sugar, malted cereal, and milk.. Complex carbohydrates (polysaccharides) include starches, such as cereal

grains, potatoes, and legumes.

Carbohydrates are the chief protein-sparing ingredient in a nutritionally sound diet. The Dietary Reference Intake (DRI) recommendations are that 45% to 65% of total calories should come from carbohydrates.[3] A person should take around 14 g of dietary fiber per 1000 calories eaten per day from fruits, vegetables, and whole grains. This equals roughly 28 to 30 g for a typical 2000-calorie diet. We should choose food and beverages with little added sugar or caloric sweeteners.

Fats are a major source of energy for the body. One gram of fat yields 9 calories. Fats are stored in adipose tissue and the abdominal cavity. They act as carriers of essential fatty acids and fat-soluble vitamins. Fats give us a feeling of satiety after eating. Fat intake should be no more than 20% to 35% of total calories.[3]

Fats can be divided into (1) potentially harmful (saturated fat and *trans* fat) and (2) healthier dietary fat (monounsaturated and polyunsaturated fat). One type of polyunsaturated fat, omega-3 fatty acids, may be especially beneficial to your heart. Omega-3 fatty acids (found in some types of fatty fish) appear to decrease the risk for coronary artery disease.[4]

Diets high in excess calories, usually in the form of fats, contribute to the development of obesity. We should consume less than 10% of calories from saturated fatty acids (about 20 g of saturated fat per day in a 2000-calorie diet) and choose foods with no *trans*-fatty acids.

Proteins are an essential part of a well-balanced diet. They are needed for tissue growth, repair, and maintenance; body regulatory functions; and energy production. Ideally, 10% to 35% of daily caloric needs should come from protein.[3] The recommended daily protein intake is 0.8 to 1 g/kg of body weight. For the normal healthy person of average body size, this equals about 45 to 65 g of protein daily. One gram of protein yields 4 calories. Amino acids are the fundamental units of protein structure. We classify the 22 amino acids as essential or nonessential. The body can make nonessential amino acids if an adequate supply of protein is available. The body cannot make the 9 essential amino acids. Their availability depends totally on dietary

sources. We obtain them from both animal and plant sources. *Complete proteins* contain all the essential amino acids. Proteins that lack one or more of the essential amino acids are *incomplete proteins.* Table 39.2 lists foods high in protein.

TABLE 39.2 Nutritional TherapyFoods High in Protein

Complete Proteins

- Eggs
- Fish
- Meats
- Milk and milk products (e.g., cheese)
- Poultry

Incomplete Proteins

- Grains (e.g., corn)
- Legumes (e.g., navy beans, soybeans, peas)
- Nuts (e.g., peanuts)
- Seeds (e.g., sesame seeds, sunflower seeds)

Vitamins are organic compounds needed in small amounts for normal metabolism. Vitamins function primarily in enzyme reactions that facilitate amino acid, fat, and carbohydrate metabolism. A diet consisting of foods from the 5 basic food groups is essential for obtaining the recommended dietary allowances of essential vitamins. Vitamins are divided into 2 categories: *water-soluble* vitamins (vitamin C and the B-complex vitamins) and *fat-soluble* vitamins (vitamins A, D, E, and K). Since the body stores excess fat-soluble vitamins, consuming too much can result in toxicity. There are upper limits for

vitamins A, D, and E.

Promoting Population Health

Health Impact of a Well-Balanced Diet

- Reduces risk for anemia
- Maintains normal body weight and prevents obesity
- Maintains good bone health and reduces risk for osteoporosis
- Lowers the risk for developing high cholesterol and type 2 diabetes
- Decreases the risk for heart disease, hypertension, and certain types of cancers

Mineral salts (e.g., magnesium, iron, calcium) make up about 4% of the total body weight. The body needs minerals to build and repair tissues, regulate body fluids, and assist in various functions. Minerals needed in amounts greater than 100 mg/day are *major minerals*. Minerals present in minute amounts are *trace elements*. Table 39.3 lists the major minerals and trace elements. Some minerals are stored and can be toxic if taken in excess amounts. The amount of minerals needed daily varies from a few micrograms of trace minerals to 1 g or more of the major minerals, such as calcium, phosphorus, and sodium. A well-balanced diet usually meets the daily requirements of minerals. However, deficiency and excess states can occur.

TABLE 39.3 Major Minerals and Trace Elements

Major Minerals

- Calcium

- Chloride
- Magnesium
- Phosphorus
- Potassium
- Sodium
- Sulfur

Trace Elements

- Chromium
- Copper
- Fluoride
- Iodine
- Iron
- Manganese
- Molybdenum
- Selenium
- Zinc

Vegetarian Diet

There are many types of vegetarians and no strict definition of the word "vegetarian." The common element among all vegetarians is the exclusion of red meat from the diet. Many vegetarians are *vegans,* who are pure or total vegetarians and eat only plants, or *lacto-ovo-vegetarians*. They eat plants, dairy products, and eggs.

Without a well-planned diet, vegetarians can have vitamin or protein deficiencies. Plant protein, although a lesser quality than animal protein, fulfills most protein requirements. Combinations of vegetable protein foods (e.g., cornmeal, kidney beans) can increase the nutritional value. Milk made from soybeans or almonds is an excellent protein source and should be calcium fortified. Vegans and lacto-ovo-

vegetarians are also at risk for iron deficiency. Table 39.4 lists examples of foods high in iron.

The primary deficiency for a strict vegan is lack of cobalamin (vitamin B_{12}).[5] We obtain cobalamin from animal protein, special supplements, or foods fortified with the vitamin. Vegans not using cobalamin supplements are susceptible to the development of megaloblastic anemia and the neurologic signs of cobalamin deficiency. Other deficiencies that may be present in a vegan diet include calcium, zinc, and vitamins A and D.

Culturally Competent Care: Nutrition

People have unique cultural heritages that may affect eating customs and nutritional status. Each culture has its own beliefs and behaviors related to food and the role that food plays in the cause and treatment of disease. Culture and religion can influence which foods are considered edible, how they are prepared, when they are eaten, and how and who prepares them. For example, some religions, such as Judaism and Islam, have specific laws about food. Assess the extent to which Jewish or Muslim patients adhere to Kosher or Halal dietary practices to ensure that we serve proper meals. The websites Kosher Quest *(www.kosherquest.org)* and the Islamic Food and Nutrition Council of America *(www.ifanca.org)* provide detailed information.

Assess the patient's diet history and implement needed dietary changes. Avoid cultural stereotyping by not making assumptions or generalizations about diet based on a person's cultural background. Dietary habits differ considerably within and among ethnic groups. Acculturation, the process by which immigrants adopt the lifestyle of a new culture, can affect dietary practices.

It is important to know whether the patient eats "traditional foods" associated with the culture. Assess the impact of eating traditional foods on health. For example, traditional foods eaten by some Asian Americans may be high in fiber and low in fat and cholesterol. The diet may be low in calcium because of limited dairy product intake. "Soul food," identified with some blacks, includes foods such as

collard greens and vegetables prepared with pork; beans; fried meats; grits; and cornbread. This diet may increase the risk for diabetes and heart disease.

TABLE 39.4 Nutritional TherapyFoods High in Iron

These foods provide 25%–39% of the Dietary Reference Intake (DRI) of iron.

Food	Selected Serving Size
Breads, Cereals, and Grain Products	
Farina, regular or quick cooked (enriched)	⅔ cup
Oatmeal, instant, fortified, prepared (enriched)	⅔ cup
Ready-to-eat cereals, fortified (enriched)	1 oz
Meat, Poultry, Fish, and Alternatives	
Beef liver, braised	3 oz
Chicken or turkey liver, braised	½ cup diced
Clams: steamed, boiled, or canned (drained)	3 oz
Oysters: baked, broiled, steamed, or canned (undrained)	3 oz
Pork liver, braised	3 oz
Soybeans, cooked	½ cup

Considering cultural beliefs is important when planning and monitoring acceptance of dietary changes. Culture can influence the perception of body weight and size. Ask the patient or family about how culture affects dietary choices and weight maintenance. For example, in some cultures obesity does not carry the stigma that it does in Western cultures. This may make teaching about weight reduction harder. A Jewish patient who eats only Kosher food may find comfort in knowing that an enteral feeding formula is Kosher. Another example of culturally sensitive planning is adjusting meal plans for the Muslim patient observing Ramadan (the Islamic month of *fasting,* in which Muslims refrain from eating and drinking during daylight hours).

Malnutrition

Malnutrition is a deficit, excess, or imbalance of essential nutrients. It may occur with or without inflammation. Malnutrition affects body composition and functional status. Other terms used to describe malnutrition include *undernutrition* and *overnutrition.*

Undernutrition occurs when nutritional reserves are depleted, and nutrient and energy intake are not sufficient to meet daily needs or added metabolic stress.[6] *Overnutrition* refers to the ingestion of more food than is required for body needs, as in obesity.

Malnutrition is a problem in both developing and developed countries across the care continuum (community, hospital, long-term care). Prevalence rates for malnutrition in the hospital setting range from 30% to 50%.[7] The prevalence of malnutrition in older adults based on the Mini Nutritional Assessment (MNA) ranges from about 3% (community-dwelling older adults) to 30% (rehabilitation settings).[8]

Etiology

Several terms describe the types and causes of adult malnutrition. Older terms still used in some settings include *primary* or *secondary protein-calorie malnutrition* (PCM), *marasmus,* and *kwashiorkor.* Marasmus and kwashiorkor describe forms of malnutrition seen in children in developing countries. You should not use these terms to describe malnutrition in adults.

The following cause-based terms are the preferred ones to use in clinical practice settings, since they indicate the interaction and importance of inflammation on nutritional status (Fig. 39.1).[9]

- *Starvation-related malnutrition,* or primary PCM, occurs when nutritional needs are not met. In primary PCM, there is chronic starvation without inflammation (e.g., anorexia nervosa).
- *Chronic disease–related malnutrition,* or secondary PCM, is

related to conditions that have sustained mild to moderate inflammation. This occurs when dietary intake does not meet tissue needs, although it would under normal conditions. Examples of conditions associated with this type of malnutrition include organ failure, cancer, rheumatoid arthritis, and obesity.

- *Acute disease–related or injury-related malnutrition* is related to acute disease or injury states with marked inflammatory response (e.g., major infection, burns, trauma, surgery).

Contributing Factors

Many factors contribute to the development of malnutrition, including socioeconomic factors, physical illnesses, incomplete diets, and drug-nutrient interactions. Table 39.5 lists conditions that increase the risk for malnutrition.

Socioeconomic Factors

Persons or families with limited financial resources may have *food insecurity* (inadequate access). Food insecurity is a major public health problem. It affects the overall quality of food that is available in both quantity and nutritional value. Those with food insecurity usually choose less expensive "filling" foods, which are more energy dense (high fat) and lack nutritional value. This type of diet increases the risk for nutrient deficiencies.

To help obtain food, people may use "safety net programs." These include food assistance programs; housing and energy subsidies; and in-kind contributions from relatives, friends, food pantries, or charitable organizations. Consult with social workers to help patients gain access to government and local programs, such as Meals on Wheels, that deliver nutritious meals to homebound people.

The "heat or eat" phenomenon is problematic, as those with limited economic resources struggle to pay household utility bills or put food on the table. Older adults on a fixed income have an added burden of deciding on whether to pay for medications or food. You and the

dietitian can help patients in making food choices that meet nutritional requirements while staying within their limited resources.

Physical Illnesses

Malnutrition is a common consequence of illness, surgery, injury, or hospitalization. The hospitalized patient, especially the older adult, is at risk for becoming malnourished. Prolonged illness, major surgery, sepsis, draining wounds, burns, hemorrhage, fractures, and immobilization can all contribute to malnutrition. Undernutrition can worsen a pathologic condition. An existing deficiency state is likely to become more severe during illness.

Anorexia, nausea, vomiting, diarrhea, abdominal distention, and abdominal cramping may accompany gastrointestinal (GI) disease. Any combination of these symptoms interferes with normal food consumption and metabolism. In addition, a patient may restrict intake to a few foods or fluids that may not be nutritious out of fear of worsening an existing GI problem.

Malabsorption syndrome is the impaired absorption of nutrients from the GI tract. Decreases in digestive enzymes or in bowel surface area can quickly lead to a deficiency state. Many drugs have undesirable GI side effects and alter normal digestive and absorptive processes. For example, antibiotics can change the normal flora of the intestines. This decreases the body's ability to make biotin, a B-complex vitamin whose production depends on that gut flora.

Fever accompanies many illnesses, injuries, and infections, with a concomitant increase in the body's basal metabolic rate (BMR) and nitrogen loss. Each degree of temperature increase on the Fahrenheit scale raises the BMR by about 7%. Without an increase in caloric intake, the body uses protein stores to supply calories and protein depletion develops. After the body temperature returns to normal, the rate of protein breakdown and resynthesis may stay increased for several weeks.

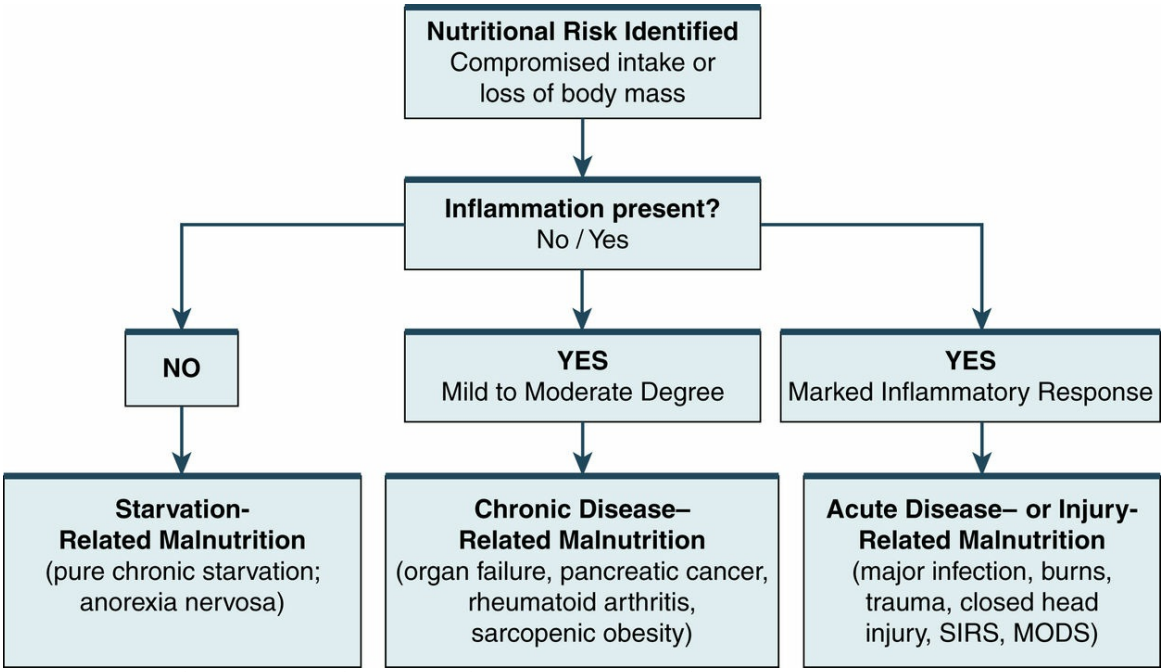

FIG. 39.1 Definitions of malnutrition. *MOD,* Multiple organ dysfunction; *SIRS,* systemic inflammatory response syndrome. From Nix, S: *Williams' basic nutrition and diet therapy,* ed 15, St Louis, 2018, Elsevier.

Consider the nutritional requirements of a patient who is not overtly ill but having diagnostic studies. This patient may be nutritionally fit on entering the hospital but can become malnourished because of the dietary restrictions imposed by multiple diagnostic studies.

Incomplete Diets

Vitamin deficiencies are rare in most developed countries. When vitamin imbalances do occur, they usually involve several vitamins, rather than a single one. This may happen with a person with a pattern of alcohol and drug use, those who are chronically ill, and those who follow poor dietary practices. Persons who had surgery on the GI tract may be at risk for vitamin deficiencies. For example, resection of the terminal ileum poses a risk for deficiencies of fat-soluble vitamins. After a gastrectomy, patients need cobalamin supplements. Because intrinsic factor (normally made in the stomach) is not available to bind with cobalamin, cobalamin cannot be absorbed

in the ileum. Followers of fad diets or poorly planned vegetarian diets are also at risk.

TABLE 39.5 Conditions That Increase the Risk for Malnutrition

- Chronic alcohol use
- Decreased mobility that limits access to food or its preparation
- Dementia
- Depression
- Drugs with antinutrient or catabolic properties (e.g., corticosteroids, antibiotics)
- Excessive dieting to lose weight
- Need for increased nutrients because of hypermetabolism or stress (e.g., infection, trauma, fever)
- No oral intake and/or receiving standard IV solutions for 10 days (adults) or for 5 days (older adults)
- Nutrient losses from malabsorption, dialysis, diarrhea, or wounds
- Swallowing disorders (e.g., head and neck cancer)

Manifestations of vitamin imbalances range from skin conditions to neurologic signs. The recommended dietary allowances for essential vitamins and manifestations of imbalances are outlined in Table 39.6.

Drug-Nutrient Interactions

A *drug-nutrient interaction* occurs when a drug affects the use of nutrients in the body. Many drug and food or beverage interactions may occur. Potential adverse interactions include incompatibilities, altered drug effectiveness, and impaired nutritional status. Many drugs have side effects, such as changes in taste, appetite, and nausea.

Grapefruit juice can increase the absorption of some drugs, enhancing their effect. Drug-nutrient interactions can also occur with the use of herbs and dietary supplements. Monitor and prevent these potential interactions for patients in the hospital and at home.

Pathophysiology of Starvation

Knowing the pathophysiology of the starvation process will help you understand the physiologic changes that occur in malnutrition. Initially, the body selectively uses carbohydrates (glycogen) rather than fat and protein to meet metabolic needs. These carbohydrate stores, found in the liver and muscles, are minimal. They may be totally depleted within 18 hours. During the early phase of starvation, protein is used only in its normal participation in cellular metabolism.

However, once carbohydrate stores are depleted, the body converts skeletal protein to glucose for energy. Alanine and glutamine are the first amino acids used in *gluconeogenesis,* the process by which the liver forms glucose. The resulting plasma glucose allows metabolic processes to continue. When these amino acids are used as energy sources, the person may be in negative nitrogen balance (nitrogen excretion exceeds nitrogen intake).

Within 5 to 9 days, the body uses fat to supply much of the needed energy. In prolonged starvation, fat provides up to 97% of calories, conserving protein. Depletion of fat stores depends on the amount available. Fat stores are generally used up in 4 to 6 weeks. Once fat stores are gone, the body uses visceral and body proteins, including those in internal organs and plasma. They rapidly decrease because they are the only remaining body source of energy available.

TABLE 39.6 Recommended Daily Vitamin Intake and Manifestations of Deficiencies

Vitamin	Dietary Reference Intake	Manifestations of Deficiencies
A (retinol)	*Men:* 900 mcg/retinol equivalents* *Women:* 700 mcg/retinol equivalents	Dry, scaly skin. Increased susceptibility to infection, night blindness, anorexia, eye irritation, keratinization of respiratory and GI mucosa, bladder stones, anemia, retarded growth
D	*Adults ages 19–70:* 600 IU *Adults age >70:* 800 IU	Muscular weakness, excessive sweating, diarrhea and other GI problems, bone pain, active or healed rickets, osteomalacia
E	*Adults:* 15 mg	Neurologic deficits
K	*Men:* 120 mcg *Women:* 90 mcg	Blood coagulation problems
B_1 (thiamine)	*Men:* 1.2 mg *Women:* 1.1 mg	Anorexia, fatigue, nervous irritability, constipation, paresthesias, insomnia
B_6 (pyridoxine)	*Men ages 19–50:* 1.3–1.7 mg *Men age >51:* 1.7 mg *Women ages 19–50:* 1.3–1.5 mg *Women age >51:* 1.5 mg	Seizures, dermatitis, anemia, neuropathy with motor weakness, anorexia
B_{12} (cobalamin)	*Adults:* 2.4 mcg	Megaloblastic anemia, anorexia, glossitis, sore mouth and tongue, pallor, neurologic problems (e.g., depression, dizziness), weight loss, nausea, constipation
C	*Men:* 90 mg *Women:* 75 mg	Bleeding gums, loose teeth, easy bruising, poor wound healing, scurvy, dry, itchy skin
Folate (folic acid)	*Adults:* 400 mcg	Impaired cell division and protein synthesis, megaloblastic anemia, anorexia, fatigue, sore tongue, diarrhea, forgetfulness

* 1 retinol equivalent = 10 international units vitamin A activity from β-carotene or 3.33 international units vitamin A activity from retinol.

If a malnourished patient has surgery, physical trauma, or an infection, the stress response is superimposed on the starvation response. The body uses protein stores for energy to meet the increased metabolic energy expenditure.

As protein depletion continues, liver function becomes impaired and protein synthesis decreases. The decrease in protein synthesis lowers plasma oncotic pressure. A major function of plasma proteins, primarily albumin, is to maintain the osmotic pressure of blood. When the oncotic pressure decreases, body fluids shift from the vascular space into the interstitial compartment. Eventually albumin leaks into the interstitial space along with the fluid. Edema becomes observable. Often edema in the patient's face and legs masks the underlying muscle wasting.

As the total blood volume decreases, the skin appears dry and wrinkled. As fluids shift to the interstitial space, ions also move. Sodium (the main extracellular ion) increases in amount within the cell. Potassium (the main intracellular ion) and magnesium shift to the

extracellular space. The sodium-potassium exchange pump has high-energy needs, using 20% to 50% of all calories ingested. When the diet is extremely deficient in calories and essential proteins, the pump will fail. This leaves sodium inside the cell (along with water), and the cell expands.

The liver is the body organ that loses the most mass during protein deprivation. Fat gradually infiltrates the liver due to decreased synthesis of lipoproteins. Death will rapidly ensue if the person does not receive dietary protein and necessary nutrients.

Impact of Inflammation

Inflammation affects nutrient metabolism and is an important part of nutritional status. During the starvation process, there is a decreased BMR, sparing of skeletal muscle, and decreased protein breakdown. However, in inflammatory states, there are changes in the expression of proinflammatory (e.g., interleukin-6 [IL-6]) and antiinflammatory cytokines (e.g., IL-10). These cytokine changes result in increased protein and skeletal muscle breakdown, increased BMR, increased glucose turnover, decreased negative acute phase protein (albumin, prealbumin) production, and increased positive acute phase protein (e.g., C-reactive protein [CRP]) production.[10]

Clinical Manifestations and Diagnostic Studies

The manifestations of malnutrition range from mild to emaciation and death (Fig. 39.2). The most obvious signs are seen in the skin (dry and scaly skin, brittle nails, rashes, hair loss), mouth (crusting and ulceration, changes in tongue), muscles (decreased mass and weakness), and CNS (mental changes, such as confusion, irritability). The speed at which malnutrition develops depends on the quantity and quality of the protein intake, caloric value, illness, and person's age.

The manifestations result from numerous interactions at the cellular level. As protein intake declines, the muscles (the largest store of protein in the body) become wasted and flabby. This leads to

weakness and fatigability. Decreased protein is available for tissue repair, causing delayed wound healing. The person is more susceptible to infections. Both humoral and cell-mediated immunity are deficient. Leukocytes decrease in the peripheral blood. Impaired phagocytosis occurs because of the lack of energy needed to drive the process. Many malnourished persons are anemic because they lack iron and folic acid (necessary building blocks for red blood cells [RBCs]).

The diagnosis of malnutrition is best determined by body composition, including a thorough history of weight loss, nutrient intake, and measures of functional status. Obtain vital signs, height, and weight. Assess and document the patient's physical state and each body system. Table 39.7 outlines the assessment and findings of the patient with malnutrition.

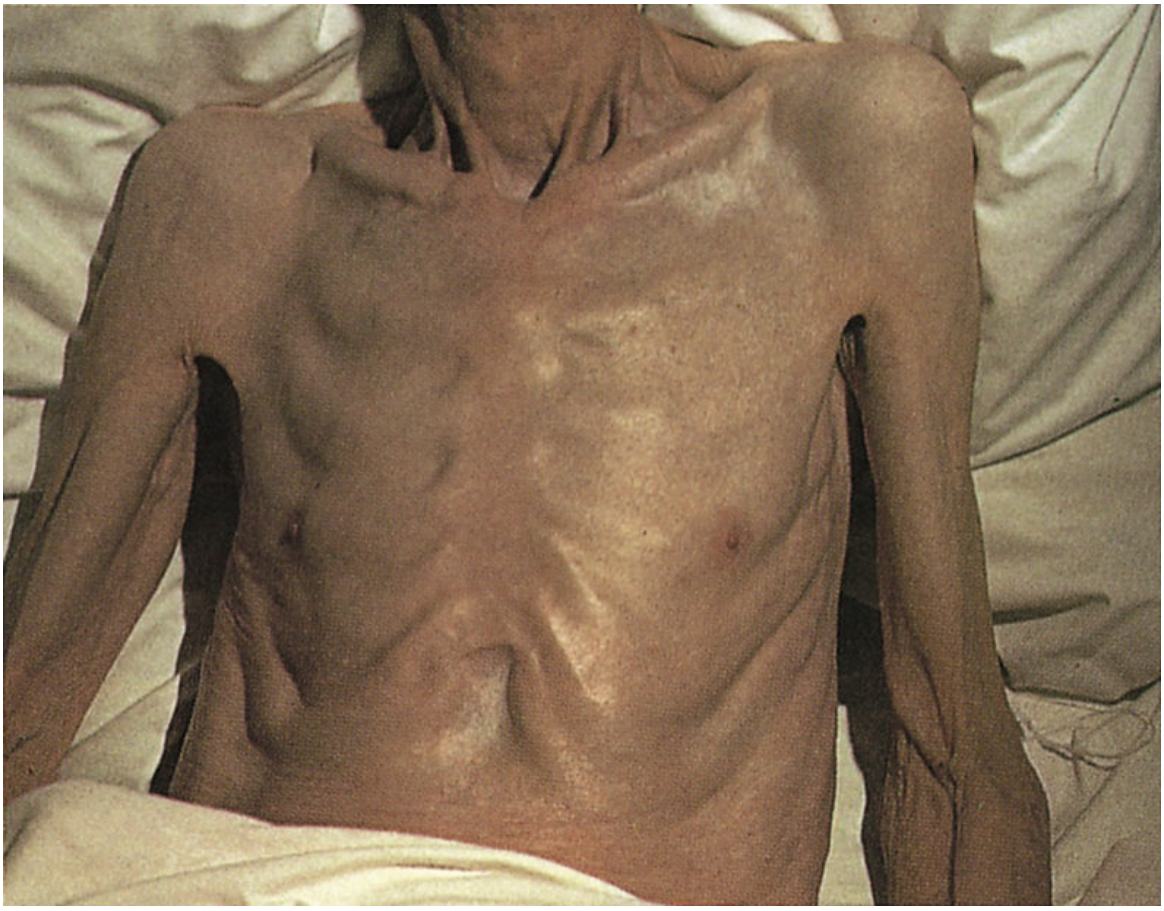

FIG. 39.2 Severe malnutrition results in wasting and extensive loss of adipose tissue.
From Kamal A, Brockelhurst JC: *Color atlas of geriatric medicine,* ed 2, St Louis, 1991, Mosby.

Laboratory Studies

Serum albumin has a half-life of 20 to 22 days. In the absence of marked fluid loss (e.g., from hemorrhage or burns), the serum albumin value lags behind actual protein changes by more than 2 weeks. This makes albumin a poor indicator of acute changes in nutritional status. Prealbumin, a protein made by the liver, has a half-life of 2 days. It is a better indicator of recent or current nutritional status. However, the extent to which visceral proteins, including albumin and prealbumin, are true markers of malnutrition is questionable.

Albumin and prealbumin are *negative acute phase proteins.* This means that during an inflammatory response, the liver decreases synthesis of these proteins. So low or below normal levels of albumin and prealbumin may indicate an inflammatory state rather than accurately depicting nutritional status. One way to determine if low albumin and prealbumin levels are due to malnutrition is to measure CRP, a *positive acute phase protein.* CRP typically increases during inflammation. A high CRP and low albumin or prealbumin suggest that inflammation is driving the change in albumin and prealbumin levels.[11]

Serum electrolyte levels reflect changes taking place between the intracellular and extracellular spaces. The serum potassium level often increases. The RBC count and hemoglobin level indicate the presence and degree of anemia. The total lymphocyte count decreases with malnutrition. Calculate it by multiplying the percent of lymphocytes times the total white blood cell (WBC) count. Liver enzyme levels may increase with malnutrition. Serum levels of both fat-soluble and water-soluble vitamins usually decrease. Low serum levels of fat-soluble vitamins correlate with the presence of *steatorrhea* (fatty stools).

Nursing and Interprofessional Management: Malnutrition

Nursing Assessment

As a nurse, you are responsible for nutritional screening across care settings. Nutritional screening identifies those who are malnourished or at risk for malnutrition. The Joint Commission requires nutritional screening for all patients within 24 hours of admission, with a detailed nutrition assessment if a patient is at risk. Following a standard approach to nutritional screening, using valid and reliable tools, will accurately identify those at risk. Many nutritional screening and assessment tools are available. Hospital-specific screening tools review common admission assessment data, including history of weight loss, intake before admission, use of nutritional support, chewing or swallowing issues, and skin breakdown.

TABLE 39.7 Nursing AssessmentMalnutrition

Subjective Data
Important Health Information

- *Past health history:* Severe burns, major trauma, hemorrhage, draining wounds, bone fractures with prolonged immobility, chronic renal or liver disease, cancer, malabsorption syndromes, GI obstruction, infectious diseases, acute (e.g., trauma, sepsis) or chronic inflammatory condition (e.g., rheumatoid arthritis)
- *Medications:* Corticosteroids, chemotherapy, diet pills, dietary supplements, herbs
- *Surgery or other treatments:* Recent surgery, radiation

Functional Health Patterns

- *Health perception–health management:* Alcohol or drug use. Malaise, apathy
- *Nutritional-metabolic:* Increase or decrease in weight, weight problems. Increase or decrease in appetite, typical dietary intake, food preferences and aversions, food allergies or intolerance. Ill-fitting or absent dentures. Dry mouth, problems chewing or swallowing, bloating, or gas. ↑ Sensitivity to cold, delayed wound healing
- *Elimination:* Constipation, diarrhea, nocturia, decreased urine output
- *Activity-exercise:* Increase or decrease in activity patterns. Weakness, fatigue, decreased endurance
- *Cognitive-perceptual:* Pain in mouth. Paresthesias, loss of position and vibratory sense
- *Role-relationship:* Change in family (e.g., loss of a spouse), financial resources
- *Sexual-reproductive:* Amenorrhea, impotence, decreased libido

Objective Data

General

- Listless, cachectic, underweight for height

Eyes

- Pale or red conjunctivae, gray keratinized epithelium on conjunctiva (Bitot's spots). Dryness and dull appearance of conjunctivae and cornea, soft cornea. Blood vessel growth in cornea. Redness and fissuring of eyelid corners

Integumentary

- Dry, brittle, sparse hair with color changes and lack of luster, alopecia. Dry, scaly lips. Fever blisters, angular crusts and lesions at corners of mouth (cheilosis). Brittle, ridged nails. Decreased tone and elasticity of skin. Cool, rough, dry, scaly skin with brown-gray pigment changes. Reddened, scaly dermatitis, scrotal dermatitis. Slight cyanosis, peripheral edema

Respiratory

- Decreased respiratory rate, ↓ vital capacity, crackles, weak cough

Cardiovascular

- Increased or decreased heart rate, ↓ BP, dysrhythmias

Gastrointestinal

- Swollen, smooth, raw, beefy red tongue (glossitis), hypertrophic or atrophic papillae. Dental cavities, absent or loose teeth, discolored tooth enamel. Spongy, pale, receded gums with a tendency to bleed easily, periodontal disease. Ulcerations, white patches or plaques. Redness, swelling of oral mucosa. Distended, tympanic abdomen. Ascites, hepatomegaly, decreased bowel sounds, steatorrhea

Neurologic

- Decreased or loss of reflexes, tremor; irritability, confusion, syncope, peripheral neuropathy

Musculoskeletal

- Decreased muscle mass with poor tone, “wasted” appearance, bowlegs, knock-knees, beaded ribs, chest deformity, prominent bony structures

Possible Diagnostic Findings

- ↓ Hemoglobin and hematocrit, ↓ mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), or mean corpuscular hemoglobin concentration (MCHC). Altered serum electrolyte levels, especially hyperkalemia. ↓ BUN and creatinine, ↓ serum albumin, transferrin, and prealbumin. ↑ CRP, ↓ lymphocytes, ↑ liver enzymes, ↓ serum vitamin levels

The Malnutrition Universal Screening Tool (Fig. 39.3) and Nutrition Risk Screening are common tools used with adults in acute care. The MNA assesses nutrition status in older adults. In long-term care, the Minimum Data Set (MDS) form is used to obtain nutrition information.[12] In home care settings, the Outcome and Assessment Information Set (OASIS) is used to collect information on diet, oral intake, dental health, swallowing problems, and any need for meal assistance.

If screening identifies a person at nutritional risk, perform a full nutritional assessment. A nutritional assessment is a comprehensive approach that includes medical, nutritional, and medication histories; physical examination; anthropometric measurements; and laboratory data (Table 39.8). Nutritional assessment provides the basis for nutritional intervention.

Obtain a complete diet history from the patient or caregiver. Assessing the foods eaten over the past week reveals a great deal about the patient’s diet habits and knowledge of good nutrition. Often the patient’s nutritional state is not the reason for seeking medical care. However, it may be a contributing factor to the disease and have an impact on management and recovery.

Anthropometric Measurements

Obtain height, weight, and girth measurements. Calculate the body mass index (BMI). We often use waist circumference and hip-to-waist ratio to assess nutritional status (see Chapter 40). Obtaining accurate measures of weight and height are critical. When possible, measure the patient's actual height rather than using the patient's self-report. Alternatives to standing height (stature) measurements include arm demi-span and knee-height measurements. The *arm demi-span* is the distance from a point on the midline at the suprasternal notch to the web between the middle and ring fingers with the arm horizontally outstretched. For persons confined to bed, using a Luft ruler is an alternative to standing height.

When assessing weight, obtain a detailed weight history, noting weight loss. Ask whether the weight loss was intentional or unintentional and the period over which it took place. A loss of more than 5% of usual body weight over 6 months (whether intentional or unintentional) is a critical indicator for further assessment, especially in the older adult.[13] If an involuntary weight loss exceeds 10% of the usual weight, determine the reason. Unintentional weight loss is important to consider in the obese person. Latent malnutrition may be present despite excess body weight. Determine the patient's current weight in relation to ideal body weight.

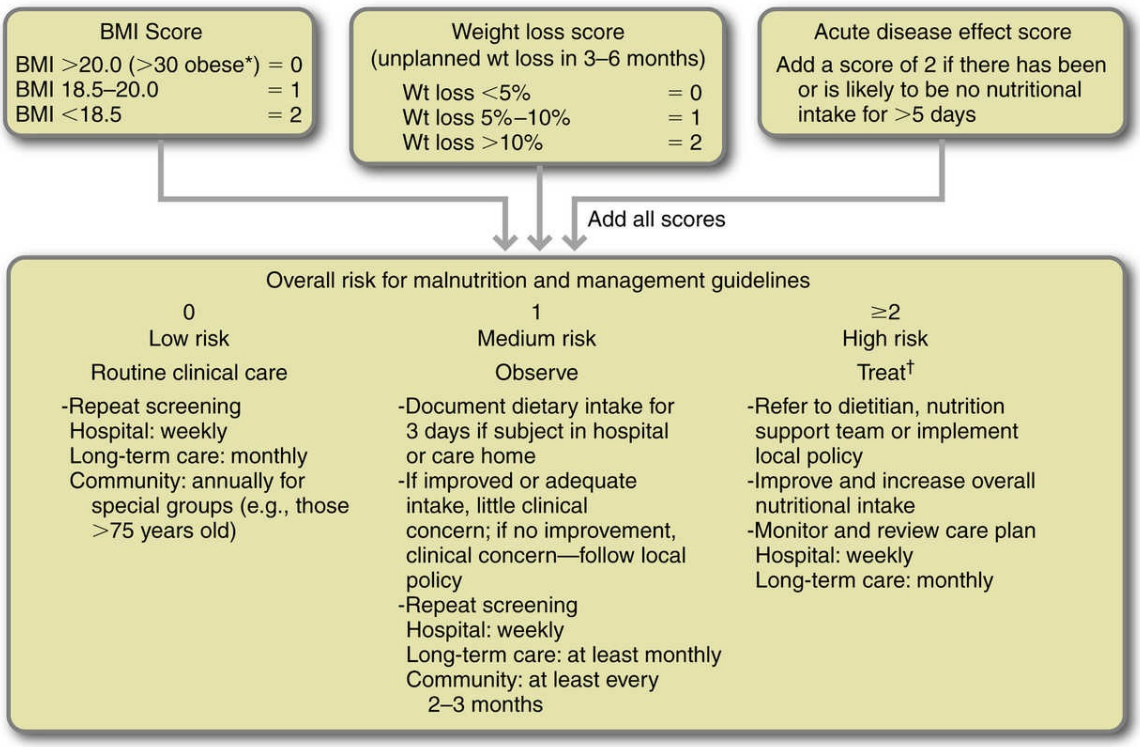

FIG. 39.3 The Malnutrition Universal Screening Tool (MUST) for adults.
Adapted from Mahan LK, Raymond JL: *Krause's food & the nutrition care process,* ed 14, St Louis, 2016, Saunders.

TABLE 39.8 Components of Nutritional Assessment

Anthropometric Measurements

- Height and weight
- Body mass index (BMI)
- Rate of weight change
- Amount of weight loss

Physical Examination

- Physical appearance
- Muscle mass and strength
- Dental and oral health

Health History

- Personal and family history
- Acute or chronic illnesses
- Current medications, herbs, supplements
- Cognitive status, depression

Diet History

- Chewing and swallowing ability
- Changes in appetite or taste
- Food and nutrient intake
- Availability of food

Laboratory Data

- Glucose
- Electrolytes
- Lipid profile
- Blood urea nitrogen (BUN)
- Albumin, prealbumin, C-reactive protein

Functional Status

- Ability to perform basic and instrumental activities of daily living
- Handgrip strength

- Performance tests (e.g., timed walk tests)

Body mass index (BMI) is a measure of weight for height (see Fig. 40.6). A BMI of less than 18.5 kg/m^2 is considered underweight, normal weight is a BMI between 18.5 and 24.9 kg/m^2, and overweight is a BMI between 25 and 29.9 kg/m^2. A BMI of 30 kg/m^2 or greater is obese. BMIs outside the normal weight range are associated with increased morbidity and mortality.

Measure skinfold thickness at various sites (indicators of subcutaneous fat stores) and midarm muscle circumference (indicator of protein stores). The sites most reflective of body fat are those over the biceps and triceps, below the scapula, above the iliac crest, and over the upper thigh. The measures obtained are compared with standards for healthy persons of the same age and gender. Both skinfold thickness and midarm circumference may decrease in malnutrition. Shifts in hydration status influence these measurements. These measurements are most beneficial when done serially and by persons trained in anthropometry.

Functional Measurements

Functional assessment focuses on performance of activities of daily living (ADLs) tools. The tools used most often are the Katz Index and Lawton Scale.[14] Measuring muscle strength can assess physical functional status, an important outcome of nutrition status. Handgrip strength is measured with a hand dynamometer. Timed gait and chair stands are markers of lower extremity strength.

Nursing Diagnoses

Nursing diagnoses for the patient with malnutrition include:

- Impaired nutritional status
- Impaired nutritional intake
- Fluid imbalance

- Risk for impaired tissue integrity

Planning

The overall goals are that the patient with malnutrition will (1) achieve an appropriate weight, (2) consume a specified number of calories per day on an individualized diet, and (3) have no adverse consequences related to malnutrition or nutritional therapies.

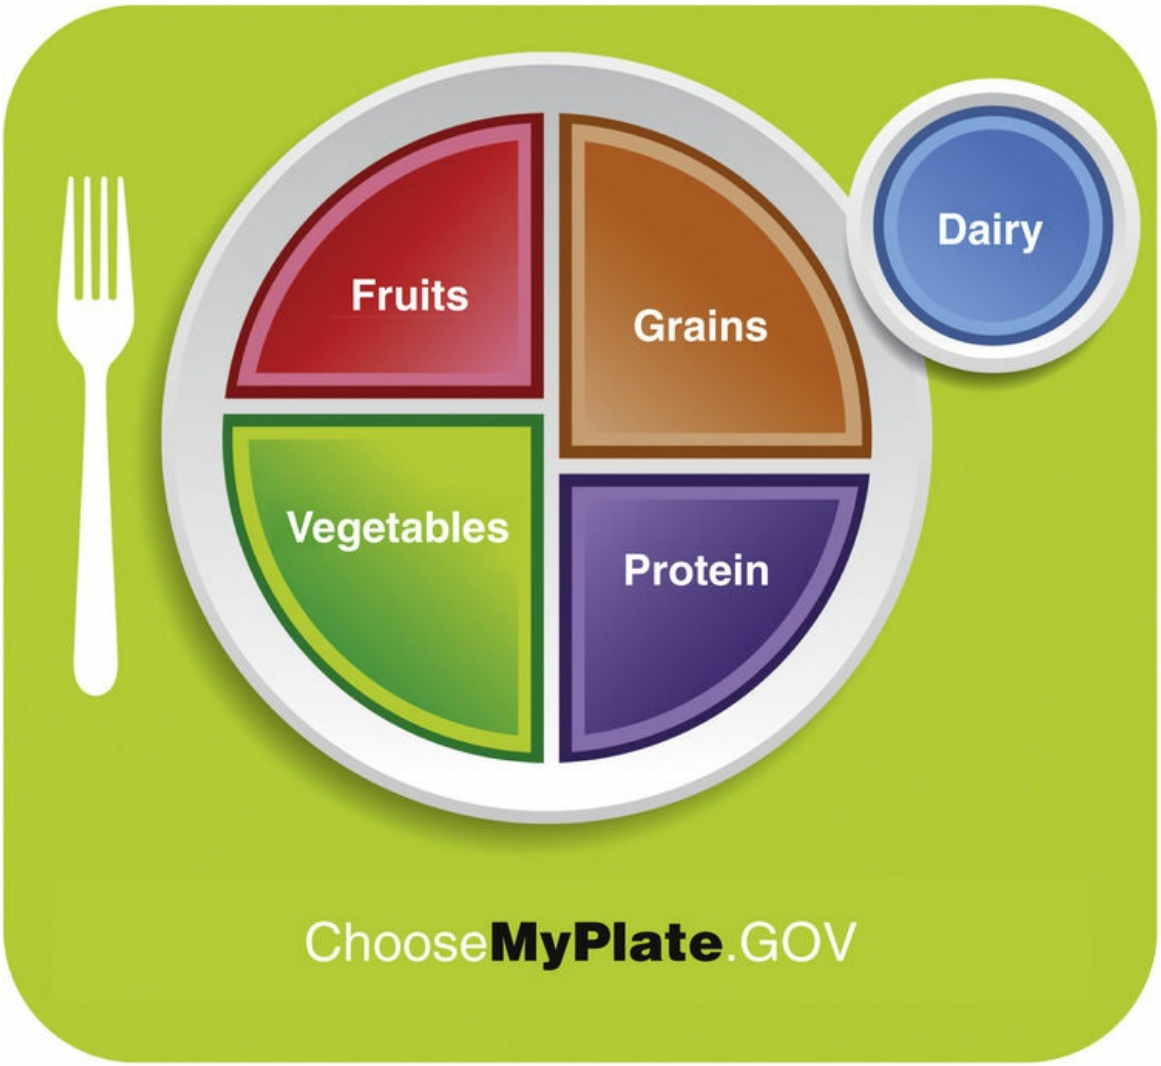

FIG. 39.4 MyPlate is the primary food group symbol that serves as a reminder to make healthy food choices and to build a healthy plate at mealtimes. It is a visual cue that shows the 5 food groups from which to select healthy foods. The plate is divided into 4 slightly different-sized

quadrants, with fruits and vegetables taking up half the space and grains and protein making up the other half. The vegetables and grains portions are the largest portion. Next to the plate is a blue circle for dairy, which could be a glass of milk or a food, such as cheese or yogurt. For more information, see *www.choosemyplate.gov*.
From US Department of Agriculture, Center for Nutrition Policy and Promotion: *Guidance on use of USDA's MyPlate and statements about amounts of food groups contributed by foods on food product labels,* Washington, DC.

Nursing Implementation

Health Promotion

It is part of your role to teach and reinforce healthy eating habits. Use MyPlate, the Dietary Guidelines for Americans, and Nutrition Facts food labels to promote healthy nutrition. The MyPlate approach is a visual guide for sensible meal planning. It helps Americans eat healthfully and make good food choices. MyPlate focuses on the proportions of 5 food groups (grains, protein, fruits, vegetables, and dairy) that you should eat at each meal (Fig. 39.4 and Table 39.9). At the health professionals' link at *www.choosemyplate.gov*, you can download daily food plans, sample menus, and tips for how to be physically active. These materials are valuable to use in patient teaching. MyPlate materials for older adults are available at *https://hnrca.tufts.edu/myplate/*.

There are many resources to help people eat a nutritious diet and maintain a healthy weight. Electronic and print sources are available for determining nutritional information in commonly consumed foods. Many food products have Nutrition Facts labels (Fig. 39.5). Consumer and health professional education materials on Nutrition Facts labels are available on the U.S. Food and Drug Administration (FDA) website *(www.fda.gov/Food/LabelingNutrition/ucm20026097.htm)*.

Help the patient find reliable Internet sources that provide evidence-based food and nutrition recommendations. Interactive web-based programs and mobile device applications are available to track physical activity, calories, nutrients, and foods eaten. Mobile device applications help with making healthy eating choices easier. Some use

built-in barcode scanners to scan foods quickly and give individual food items' nutrition facts. Users can compare items for their nutrition benefit and cost. Other applications give information on portion sizes and adjustments needed to reduce calories, sodium, or fat in the diet based on the user's height, weight, and activity level.

TABLE 39.9 Nutritional TherapyMyPlate Tips for a Healthy Lifestyle

Making food choices for a healthy lifestyle can be as simple as using these 10 tips. Use the ideas in this list to (1) balance your calories, (2) choose foods to eat more often, and (3) cut back on foods to eat less often.

1. Balance calories	• Find out how many calories you need for a day as a first step in managing your weight. Go to *www.choosemyplate.gov* to find your calorie level. • Being physically active also helps you balance calories.
2. Enjoy your food, but eat less	• Take the time to enjoy your food as you eat it. • Eating too fast or when your attention is elsewhere may lead to eating too many calories. • Pay attention to hunger and fullness cues before, during, and after meals. Use them to recognize when to eat and when you have had enough.
3. Avoid oversized portions	• Use a smaller plate, bowl, and glass. • Portion out foods before you eat. • When eating out, choose a smaller size portion, share a dish, or take home part of your meal.
4. Foods to eat more often	• Eat more vegetables, fruits, whole grains, and fat-free or 1% milk and dairy products. • These foods have the nutrients you need for health, including potassium, calcium, vitamin D, and fiber. • Make them the basis for meals and snacks.
5. Make half your plate fruits and vegetables	• Choose red, orange, and dark-green vegetables such as tomatoes, sweet potatoes, and broccoli, along with other vegetables, for your meals. • Add fruit to meals as part of main or side dishes or as dessert.
6. Switch to fat-free or low-fat (1%) milk	• They have the same amount of calcium and other essential nutrients as whole milk. • They have fewer calories and less saturated fat.
7. Make half your grains whole grains	• To eat more whole grains, substitute a whole-grain product for a refined product. • For example, eat whole-wheat bread instead of white bread, or brown rice instead of white rice.
8. Foods to eat less often	• Cut back on foods high in solid fats, added sugars, and salt. • Limit cakes, cookies, ice cream, candies, sweetened drinks, pizza, and fatty meats such as ribs, sausages, bacon, and hot dogs. • Use these foods as occasional treats, not everyday foods.
9. Compare sodium in foods	• Use the Nutrition Facts label (Fig. 39.4) to choose lower sodium versions of foods, such as soup, bread, and frozen meals. • Select foods labeled "low sodium," "reduced sodium," or "no salt added."
10. Drink water instead of sugary drinks	• Cut calories by drinking water or unsweetened beverages. • Soda, energy drinks, and sports drinks are a major source of added sugar and calories in American diets.

Acute Care

Collaborate with the HCP and dietitian to identify patients with

malnutrition and implement appropriate interventions to meet the patient's nutritional needs. Assess nutritional state during your assessment of the patient's other physical problems. Identify risk factors for malnutrition and why they exist. With increased stress, such as surgery, severe trauma, and sepsis, the patient needs more calories and protein. Wound healing requires increased protein synthesis. The patient having major surgery who is malnourished or is at risk for malnutrition needs several weeks of increased protein and calorie intake preoperatively to promote healing postoperatively.

Teach the patient and caregiver the importance of good nutrition and the reason for recording the daily weight, intake, and output. Measure weight and height on admission, then routinely assess the person's weight. Daily weights give an ongoing record of body weight gain or loss. Rapid gains and losses are usually the result of shifts in fluid balance. In conjunction with accurate recording of food and fluid intake, body weight gives a clearer picture of the patient's fluid and nutritional state.

If the patient can take food by mouth, obtain a daily calorie count and diet diary to give an accurate record of food intake. You and the dietitian can help the patient and family in selecting high-calorie and high-protein foods (unless medically contraindicated). Table 39.10 gives examples of high-calorie, high-protein foods. Offering foods preferred by the patient enhances intake. Encourage the family to bring the patient's favorite foods from home.

Make sure the environment is conducive to eating. Provide a quiet environment. Offer oral hygiene and hand hygiene. Help the patient to a comfortable position and place the bedside table at the right height. Clear the bedside table of clutter. Place urinals, bedpans, and emesis basins out of sight. If needed, open cartons and packages. Protect mealtime from unnecessary interruptions by performing nonurgent care before or after mealtime.

TABLE 39.10 Nutritional TherapyHigh-Calorie,

High-Protein Diet

Suggestions for foods for a high-calorie, high-protein diet include:

Breads and Cereals

- Buttermilk biscuits, muffins, banana bread, zucchini bread
- Granola and other cereals with dried fruit
- Hot cereals (oatmeal, cream of wheat) prepared with milk, added fat (butter or margarine), and sugar
- Potatoes prepared with added fat (butter and whole milk)

Vegetables

- Fried vegetables
- Vegetables prepared with added fat (margarine, butter)

Fruits

- Canned fruit in heavy syrup
- Dried fruit

Meat

- Casseroles
- Fried meats
- Meats covered in cream sauces or gravy
- Peanut butter

Milk and Milk Products

- Ice cream

- Milkshakes
- Whipping cream, heavy cream
- Whole milk and milk products (yogurt, ice cream, cheese)
- Whole milk with added nutritional supplements

The undernourished patient usually needs to have between-meal supplements. These may consist of items prepared in the dietary department or commercially prepared products. Eating these items provides extra calories, proteins, fluids, and nutrients. If the patient is unable to consume enough nutrition with a high-calorie, high-protein diet, consider adding oral liquid nutritional supplements.

Some patients may benefit from appetite stimulants, such as megestrol acetate or dronabinol (Marinol), to improve intake. Enteral nutrition (EN) may be an option in the patient who is still unable to take in enough calories (Fig. 39.6). Contraindications for EN include GI obstruction, prolonged ileus, severe diarrhea or vomiting, and enterocutaneous fistula. If EN is not possible, consider starting parenteral nutrition (PN).

Ambulatory Care

Many patients are discharged on a therapeutic diet. Discharge preparation for both the patient and caregiver is essential. Teach them about the cause of the undernourished state and ways to avoid the problem in the future. They need to be aware that undernourishment, whatever the cause, can recur and that adhering to their diet for a few weeks cannot fully restore a normal nutritional state. It may take many months to reach this goal.

Assess their ability to follow the dietary instructions considering past eating habits, religious and ethnic preferences, age, income, resources, and state of health. Emphasize the need for continual follow-up care to achieve and maintain rehabilitation. In your discharge planning, ensure proper follow-up, such as visits by the home health nurse and outpatient dietitian referrals.

Determine the need for nutritious meals and snacks after discharge

from the hospital. If access to a dietitian is limited, you may be the main source of nutritional information. In your assessment, consider the availability and acceptability of community resources that provide meals, such as Meals on Wheels, senior congregate feeding sites, and the Supplemental Nutrition Assistance Program (SNAP). SNAP allows low-income households, regardless of age, to buy more food of a greater variety.

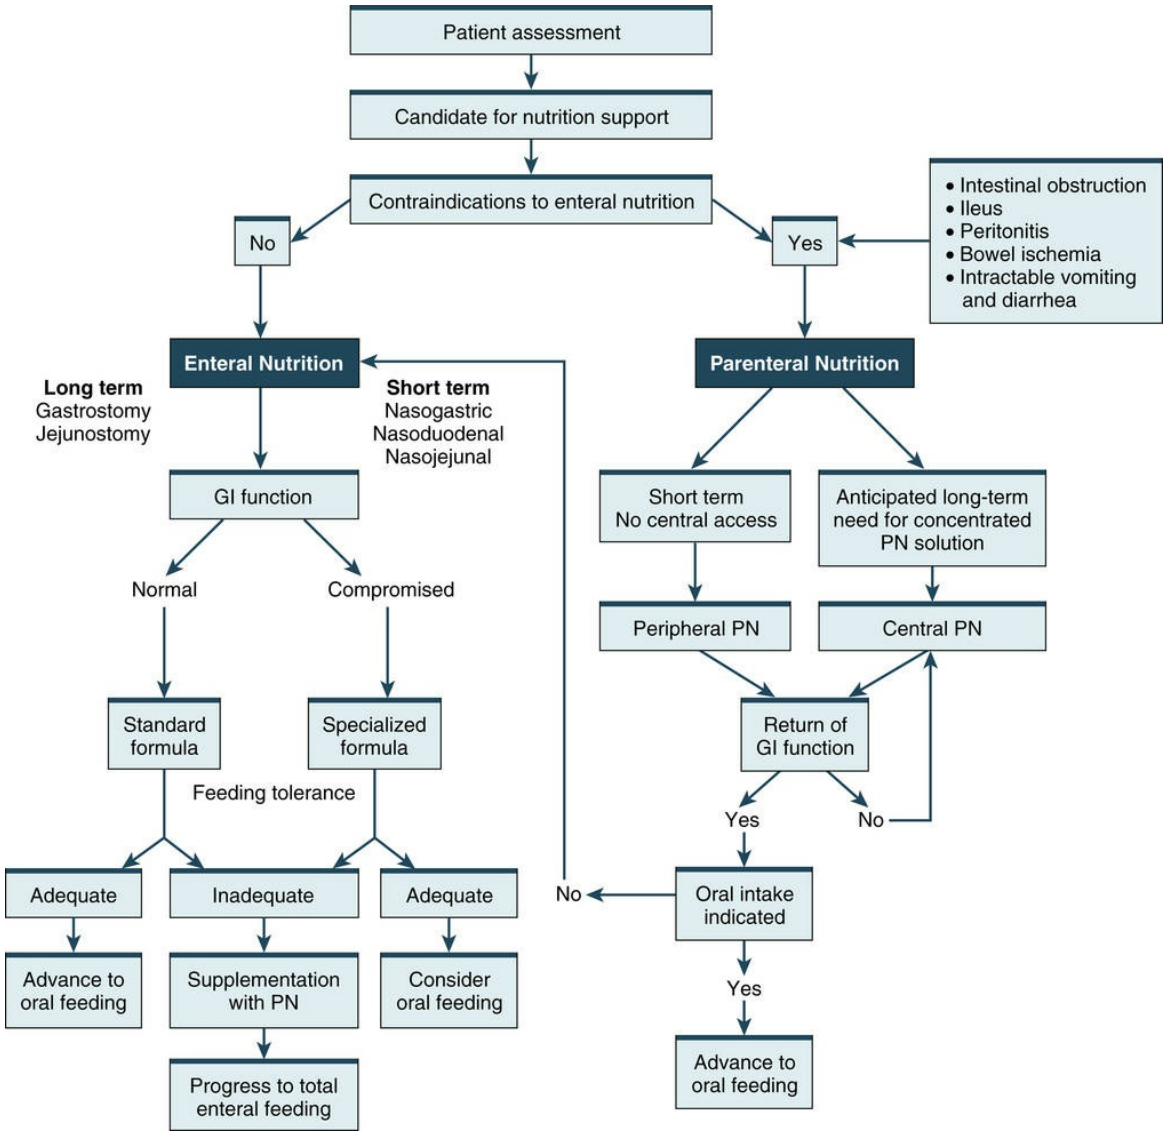

FIG. 39.6 Nutritional support algorithm.
Adapted from Ukleja A, Freeman KL, Gilbert K, ASPEN Board of Directors: Standards for nutrition support: Adult hospitalized patients, *Nutr Clin Pract* 25:403, 2010.

Keeping a diet diary for 3 days at a time is one way to analyze and reinforce healthful eating patterns. These records are also helpful in the follow-up care. Encourage self-assessment of progress by having the patient weigh himself or herself once or twice a week and keep a weight record.

Evaluation

The expected outcomes are that the patient who is malnourished will

- Achieve and maintain optimal body weight
- Consume a well-balanced diet
- Has no adverse outcomes related to malnutrition
- Maintain optimal physical functioning

Gerontologic Considerations: Malnutrition

Nutrition affects quality of life, functional status, and health in older adults. They are particularly vulnerable to malnutrition across care settings. You play a key role in assessing the physiologic, functional, environmental, dietary, psychologic, and social factors related to nutritional risk in older adults. Older hospitalized adults with malnutrition are more likely to have poor wound healing, pressure injuries, infections, decreased muscle strength, postoperative complications, and increased morbidity and mortality risks. They are less able to regain body weight after periods of undernutrition due to illness or surgery.

Older adults may report little or no appetite, problems with eating or swallowing, inadequate servings of nutrients, and fewer than 2 meals per day. Limited incomes may cause them to restrict the number of meals or the dietary quality of meals eaten. Social isolation is a problem in older adults. Those who live alone may lose their desire to cook and report decreased appetite. Functional limitations may affect the ability to feed oneself, buy food, or cook and prepare meals. Some may lack transportation to buy food.

Chronic illnesses associated with aging can affect nutritional status. For example, depression and dysphagia (from a stroke) can affect intake. Poor oral health from gum disease, missing teeth, or dry mouth can impair the ability to chew and swallow food.[15] Medications can cause dry mouth, change the taste of food, or decrease appetite. Older adults with dementia or a stroke present unique nursing challenges regarding eating and feeding. (Dementia is discussed in Chapter 59. Strokes are discussed in Chapter 57.)

Physiologic changes associated with aging include a decrease in lean body mass and redistribution of fat around internal organs, which can decrease caloric requirements. Sarcopenia (loss of lean body mass with aging) affects muscle strength and function. Older adults on bed rest or prolonged inactivity lose more lean body mass than younger adults.[16] Changes in smell and taste (from medications, nutrient deficiencies, taste-bud atrophy) can alter nutritional status.

General nutrient requirements and healthy eating guidelines apply to older adults. Their requirements may vary depending on the degree of malnutrition and physiologic stress. To prevent loss of muscle mass and maintain function, older adults may need to increase their protein intake and ingest a moderate amount of high-quality protein at each meal.[17] Daily vitamin D requirements are higher for older adults (Table 39.6).

Focus your initial care strategies on improving oral intake and providing a stimulating environment for meals. Special strategies, such as use of adaptive devices (e.g., large-handled eating utensils), often are helpful in increasing the patient's dietary intake. Some older adults may need nutritional support therapies until their strength and general health improve. Before starting any nutritional support therapy (e.g., EN, PN) for an older patient unable to give consent, review his or her advance directives about artificial nutrition and hydration.

Malnourished or nutritionally at-risk older adults are vulnerable when discharged from the hospital to the home. Older adults may not be able to shop for or prepare foods during the initial recovery period. Consult with the social worker and dietitian to ensure the older adult has access to food on discharge. Home-delivered meals or groceries or senior congregate feeding programs are an appropriate referral. Community nutritional programs can make mealtime a pleasant, social event. Improving the social setting of a meal often improves dietary intake.

Specialized Nutritional Support

If patients are unable to maintain or achieve adequate nutritional status, nutritional support may be needed. For a decision-making plan related to nutritional support, see Fig. 39.6.

Some agencies have nutritional support teams composed of a physician, nurse, dietitian, and pharmacist. The team's function is to oversee the nutritional support of select inpatients and outpatients. The nutritional support nurse on that team is a key resource for issues about patients' nutrition and nutritional access.

Oral Feeding

Oral supplements are widely used as an adjunct to meals and fluid intake in the patient whose nutritional intake is deficient. They provide advanced nutrition and calories and are relatively inexpensive. These include milkshakes, puddings, or commercially available products (e.g., Carnation Instant Breakfast, Ensure, Boost). Oral liquid supplements have a role in improving the nutritional status of older adults. Do not use supplements as meal substitutes, use them as snacks between meals. In long-term care, using these beverages instead of water for oral medication administration increases caloric intake.

Enteral Nutrition

Enteral nutrition (EN), also known as **tube feeding**, is nutrition (e.g., a nutritionally balanced liquefied food or formula) delivered directly into the GI tract, bypassing the oral cavity. EN is used with the patient who has a functioning GI tract but is unable to take any or enough oral nourishment or when it is unsafe to do so.

Indications for EN include persons with anorexia, orofacial fractures, head and neck cancer, neurologic or psychiatric conditions that prevent oral intake, extensive burns, or critical illness (especially if mechanical ventilation is needed), and those receiving chemotherapy or radiation therapy. EN is easily administered, safer, more physiologically efficient, and less expensive than PN.

There is a wide variety of enteral formulas. Their concentration,

flavor, osmolality, and amounts of protein, sodium, and fat vary. There are special formulas for patients with diabetes and liver, kidney, or lung disease. Most are lactose free. Concentrations range from 1 to 2 cal/mL. Most standard formulas provide between 1 and 1.5 cal/mL. The more calorically dense the formula, the less water it has. The number and size of particles in the formula determines its osmolality. The more hydrolyzed or broken down the nutrients, the greater the osmolality.

A formula with a high sodium content is contraindicated in the patient with cardiovascular problems, such as heart failure. Those with short bowel syndrome or ileocecal resection should not receive one with a high fat content because of impaired fat absorption. Patients receiving EN with a protein content greater than 16% need supplemental fluids through the feeding tube or by mouth (if permitted) to avoid dehydration.

Common delivery options are continuous infusion or intermittent (bolus) feedings by infusion pump, bolus feedings by gravity, and bolus feedings by syringe. Critically ill patients often receive EN by continuous infusion. Bolus feeding may be an option if the patient improves or is receiving EN at home.[17]

We give EN via a tube, catheter, or stoma. The type of access depends on the (1) anticipated length of time EN will be required, (2) degree of risk for aspiration, (3) patient's clinical status, (4) adequacy of digestion and absorption, and (5) patient's anatomy (e.g., extreme obesity).[12] Fig. 39.7 shows the locations of commonly used enteral feeding tubes.

Orogastric, Nasogastric, and Nasointestinal Tubes

Nasally and orally placed tubes (orogastric, nasogastric [NG], nasoduodenal, nasojejunal) are appropriate for short-term feeding (less than 4 weeks). Nasoduodenal and nasojejunal tubes are transpyloric tubes. They are used when pathophysiologic conditions call for feeding the patient below the pyloric sphincter. Placement into the small intestine decreases the chance of regurgitating gastric contents into the esophagus and aspiration.[17] However, the patient

can still aspirate gastric secretions if the stomach is not emptying properly.

Polyurethane or silicone feeding tubes are long, small in diameter, soft, and flexible. This design decreases the risk for mucosal damage from prolonged placement. These tubes are radiopaque, making their position readily identified by x-ray. A stylet is used for tube placement in a comatose patient because the ability to swallow is not essential during insertion. A complication that can result from using a stylet is increased risk for perforation.

While smaller feeding tubes have many advantages over tubes with wider lumens, such as the standard decompression NG tube, there are some disadvantages. Because of the small diameter and length, these tubes clog easily. They are harder to use for checking residual volumes. They are particularly prone to occlusion if you do not thoroughly crush and dissolve oral drugs before administration. Failure to flush the tubing before and after giving drugs or checking residual volume can cause tube occlusion. Vomiting or coughing can dislodge the tubes. They can become knotted or kinked. Problems with a tube may require removal and insertion of a new tube, which adds to cost and patient discomfort.

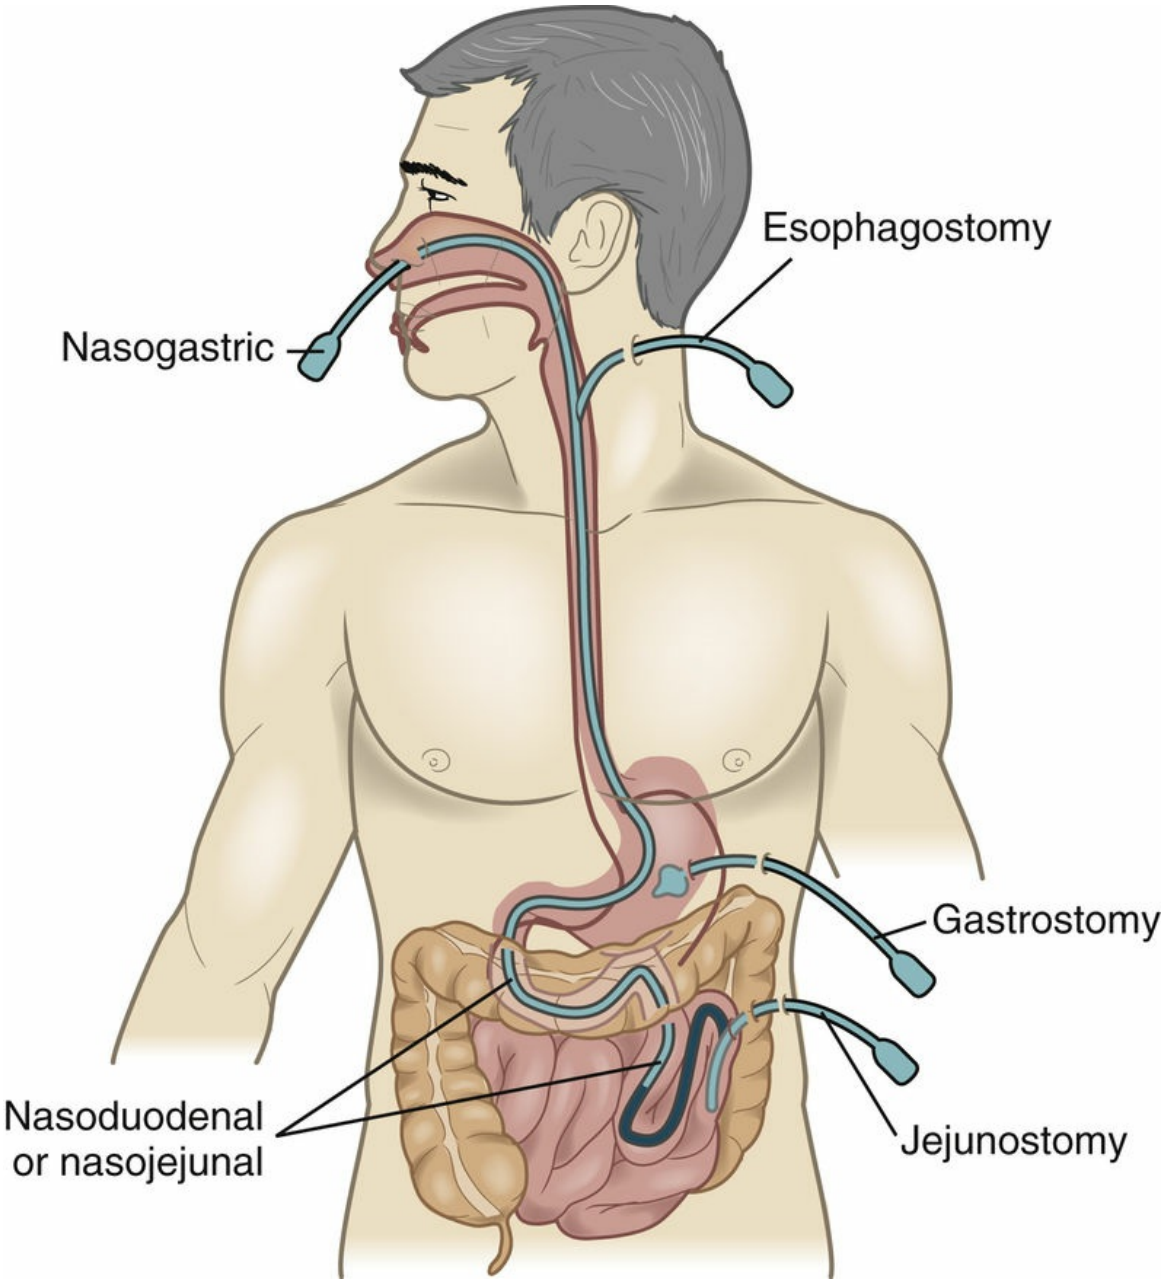

FIG. 39.7 Common enteral feeding tube placement locations.

Gastrostomy and Jejunostomy Tubes

If feedings are needed for an extended time, tubes can be placed in the stomach (gastrostomy) or small bowel (jejunostomy). A gastrostomy tube can be placed surgically, radiologically, or endoscopically (Fig. 39.7). The patient must have an intact, unobstructed GI tract. The esophageal lumen must be wide enough to pass the endoscope for

percutaneous endoscopic gastrostomy (PEG) tube placement (Fig. 39.8). PEG tube and radiologically placed gastrostomy tube procedures have fewer risks than surgical placement. The procedure requires IV sedation and local anesthesia. IV antibiotics are given before the procedure.

For the patient with chronic reflux, feeding through a jejunostomy (J-tube) may be necessary to reduce the risk for aspiration. Jejunostomy tubes are placed either endoscopically or with open or laparoscopic surgery. Combination gastrojejunostomy (G-J) tubes allow for simultaneous gastric decompression and small bowel feeding. When a patient has a G-J tube, it is important to know which port is the gastric and which is the jejunal.

The tube is either premarked or marked at the skin insertion site. Enteral feedings can start within 24 hours after a surgically placed gastrostomy or jejunostomy tube without waiting for flatus or a bowel movement. Most other PEG tube feedings can start within 4 hours of insertion, although agency policies may vary.[17]

EN and Safety

You have a critical role in ensuring that EN is administered safely. Aspiration and dislodged tubes are important safety concerns. Nursing management of enteral feeding is addressed in Table 39.11.

Accidental tube removal can result in delayed feedings and potential discomfort with tube replacement. The management of common problems in patients receiving EN is outlined in Table 39.12. A nursing care plan for the patient receiving EN (eNursing Care Plan 39.1) is available on the website for this chapter.

Specific care and teaching related to feeding tubes and EN are discussed in the following section. Remember that is important to teach the patient and caregiver how to care for the feeding tube and properly administer EN.

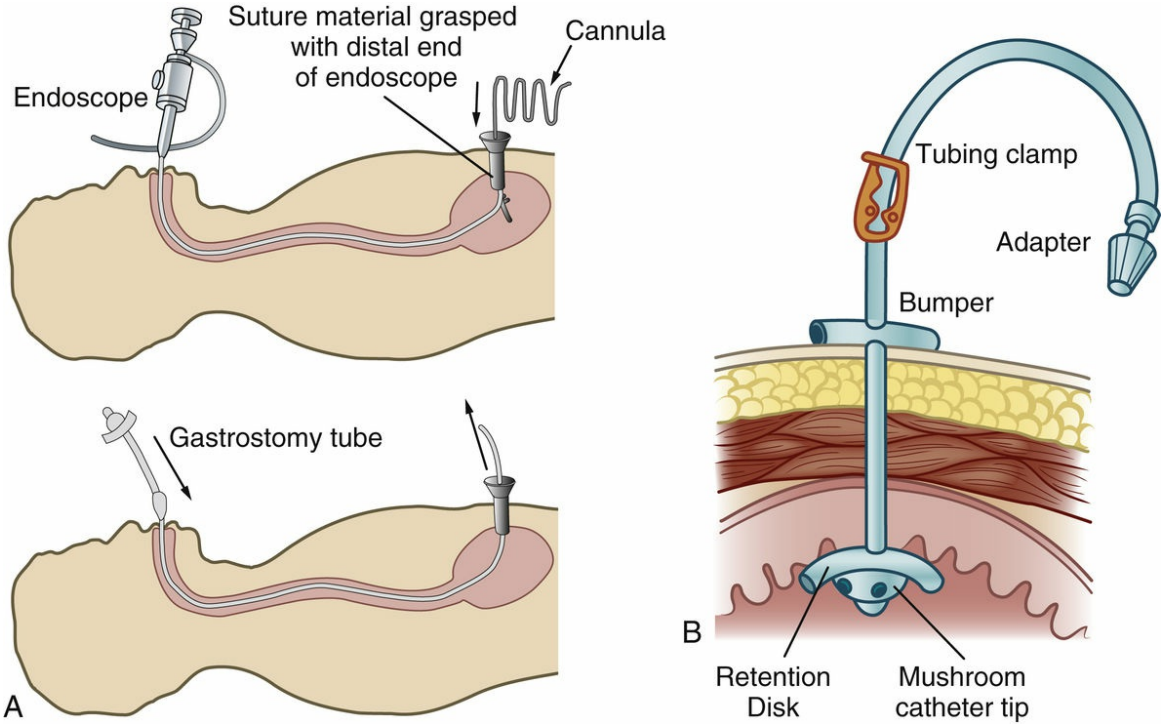

FIG. 39.8 Percutaneous endoscopic gastrostomy. **A,** Gastrostomy tube placement via percutaneous endoscopy. With use of endoscopy, a gastrostomy tube is inserted through the esophagus into the stomach and then pulled through a stab wound made in the abdominal wall. **B,** A retention disk and bumper secure the tube.

TABLE 39.11 Nursing ManagementEN

Maintaining EN Infusions

- Check tube placement before feeding and before each medication administration.
- Assess for bowel sounds before feeding.
- Flush NG or gastrostomy tube as needed.
- Evaluate nutritional status of patient receiving enteral feedings.

Ensuring Patient Safety

- Give medications in the safest form possible.
    - Dilute viscous liquid medications.
    - Use liquid medications only if they are designated safe for enteral use.
    - Do not add medications to enteral feeding formula.
    - If using tablets, only use immediate-release forms.
    - Crush drugs to a fine powder and dissolve in 30–60 mL of purified water.
- Employ measures to decrease aspiration risk.
- Keep head of bed elevated to 30- to 45-degree angle.
- Check for GVR per agency policy.
- Assess regularly for complications related to tubes and enteral feedings (e.g., aspiration, diarrhea, abdominal distention, hyperglycemia, fecal impaction).
- Teach patient and caregiver about home EN and tube care.

Delegate to Licensed Practical/Vocational Nurse (LPN/VN)

- Insert NG tube for stable patient.
- Flush NG and gastrostomy tubes.
- Give bolus or continuous enteral feeding for stable patient.
- Remove NG tube.
- Give medications through NG or gastrostomy tube to stable patient.
- Provide skin care around gastrostomy or jejunostomy tubes.

Oversee Unlicensed Assistive Personnel (UAP)

- Provide oral care to patient with NG, gastrostomy, or jejunostomy tube.
- Weigh patient who is receiving EN.

- Keep the head of bed elevated 30–45 degrees.
- Report patient symptoms (e.g., nausea, diarrhea) that may indicate problems with EN to RN or LPN.
- Alert RN or LPN about infusion pump alarms.
- Empty drainage devices and measure output.

Collaborate With Dietitian

- Evaluate nutritional status of patient receiving EN.
- Select appropriate EN formula.
- Monitor for and manage complications related to EN.
- Teach patient and caregiver about home EN.

Collaborate With Pharmacist

- Select appropriate form of each medication being given enterally.
- Determine if medication must be given separately.

Aspiration Risk

Evaluate all enterally fed patients for risk for aspiration. Before starting feedings, ensure the tube is in the right position. Proper patient positioning decreases the risk for aspiration. To prevent aspiration, always keep the head of bed elevated 30 to 45 degrees.[17] If the patient does not tolerate a backrest elevation, use a reverse Trendelenburg position to elevate the head of the bed, unless contraindicated. If you need to lower the head of the bed for a procedure, quickly returning the patient to at least 30 degrees is critical. Follow agency policy for suspending feeding while the patient is supine. With bolus feedings, the head should remain elevated for 30 to 60 minutes after feeding.

TABLE 39.12 Nursing ManagementEN Problems

Problems and Causes	Management
Constipation	
Decreased fluid intake	• Increase fluid intake if not contraindicated. • Give total fluid intake of 30 mL/kg body weight.
Formula	• Change formula to one with more fiber content. • Give as-needed laxative.
Inactivity	• Encourage ambulation unless contraindicated. • Collaborate with physical therapy to promote activity.
Dehydration	
Diarrhea, vomiting	• Decrease rate or change formula. • Check drugs that patient is receiving, especially antibiotics. • Avoid bacterial contamination of formula and equipment.
Fluid intake	• Increase intake and check amount and number of feedings. • Increase amount of fluid intake if appropriate.
High-protein formula	• Change formula to one with less protein.
Hyperosmotic diuresis	• Check blood glucose levels often. • Change formula to one with less glucose.
Diarrhea	
Contaminated formula	• Refrigerate unused formula and record date opened. • Discard outdated formula. • Discard formula left standing for longer than manufacturer's guidelines. • 8 hrs for ready-to-feed formulas (cans) • 4 hrs for reconstituted formula • 24 hrs for closed-system enteral formulas • Use closed system.
Feeding too fast	• Dilute or decrease rate of feeding. • Change to continuous feedings. • Stop excess water boluses.
Formula	• Change to formula that has more fiber or is less hypertonic. • Change to continuous feedings.
Infection	• Obtain stool culture for fecal leukocyte determination, *C. difficile,* and/or toxin assay.
Medications	• Check for drugs that may cause diarrhea (e.g., sorbitol in liquid medications, antibiotics).
Tube moving distally	• Properly secure tube before beginning feeding. • Check placement before each bolus feeding or at least every 4 hrs if continuous feedings.
Vomiting	
Delayed gastric emptying	• Consult with HCP about use of prokinetic drug. • Follow agency policy to manage GRV.
Improper placement of tube	• Replace tube in proper position. • Check tube position before each bolus feeding and every 4 hrs if continuous feedings.

There is much disagreement about whether to check gastric residual volume (GRV) when giving feedings into the stomach. Some think an increased GRV increases the risk for aspiration. Other research does not support the practice. Follow your agency policy for checking GRV. Common protocols call for checking GRV every 6 to 8 hours in non–critically ill patients and before each bolus feeding.

Other measures to decrease aspiration risk include giving feedings continuously, minimizing the use of sedation, and performing frequent oral suctioning, if needed. Promotility drugs, such as erythromycin or metoclopramide, improve gastric emptying and may reduce aspiration risk.

Tube Position

Obtain x-ray confirmation of newly inserted nasal or orogastric tubes to confirm proper position before starting feedings or medications. Smaller feeding tubes can pass directly into the bronchus on insertion without any obvious respiratory manifestations. Do not rely on the auscultation method to determine between gastric and respiratory or gastric and small bowel placement. Placing a tube under electromagnetic guidance reduces the risk for misplacement associated with blind insertion.[17] Capnography, a direct monitor of breath-to-breath CO_2 level, can determine tube placement in the respiratory tract. However, it still requires x-ray confirmation to verify location before feeding.[17]

Maintain proper placement of the tube after starting feedings. To determine if a tube is still in the proper position, mark the exit site of the tube at the time of the initial x-ray and check the tube external length at regular intervals.[17] Consider applying a nasal bridle in patients who try to pull out a tube or for whom taping the nose is difficult.

A small bowel tube may dislocate upward into the stomach, or the tube's tip can dislocate upward into the esophagus. If you see a significant increase in the external length, use other bedside tests to help determine whether the tube has become dislocated. These measures include assessing aspirate color and pH. Because each of these measures has limitations, confirm placement with more than one test. If you are checking GVR, watch for unexpected changes in volume. An increase in GVR may indicate displacement of a small intestine tube into the stomach.[18]

Site Care

Skin care around gastrostomy and jejunostomy tube sites is important because the action of digestive juices irritates the skin. Assess the skin around the feeding tube daily for signs of redness and maceration. Monitor bumper tension and routinely check for pressure injury.

To keep the skin clean and dry, initially rinse it with sterile water and dry it. Apply a dressing until the site is healed. After that, wash with mild soap and water. A protective ointment (zinc oxide, petroleum gauze) or a skin barrier (Karaya, Stomahesive) may be used on the skin around the tube. If the skin is irritated, consider using other types of drain or tube pouches. Consult a wound, ostomy, and continence nurse (WOCN) if problems occur.

Tube Patency

All enteral feedings require routine flushing. Flush feeding tubes in adults with 30 mL of warm tap water every 4 hours during continuous feedings or before and after each bolus feeding. Use sterile water in immunocompromised and critically ill patients. Always flush tubes between each medication and after all medications are given. Flush clogged tubes with warm water, using a back-and-forth motion. If that does not work, a pancreatic enzyme solution, an enzymatic declogging kit, or mechanical devices for clearing feeding tubes are options.[17]

Misconnection

An *enteral feeding misconnection* is an inadvertent connection between an enteral feeding system and a nonenteral system, such as an IV line, a peritoneal dialysis catheter, or a tracheostomy tube cuff. With an enteral feeding misconnection, nutritional formula intended for the GI tract is given IV or into the respiratory tract. Severe patient injury and death can result from tubing misconnection. Table 39.13 gives tips to decrease the risk for enteral feeding misconnections.

TABLE 39.13 Nursing ManagementDecreasing Enteral Feeding Misconnections

The following are tips to help you decrease your risk for making an enteral feeding misconnection:

1. Teach visitors, LPN/VNs, and UAP to notify the nurse if an enteral feeding line becomes disconnected and not to reconnect any line.
2. Do not change or adapt IV or feeding devices because it may compromise the safety features incorporated into their design.
3. Do not use an IV pump or IV tubing to deliver an enteral feeding.
4. When making a reconnection or connecting any new device or infusion, trace lines back to their origins and ensure connections are secure.
5. When patient arrives on a new unit or setting or during shift handoff, recheck connections and trace all tubes.
6. Route tubes and catheters that have different purposes in unique and standardized directions (e.g., route IV lines toward the patient's head and enteral lines toward the feet).
7. Label or color-code feeding tubes and connectors.
8. When there are multiple access points and/or several bags hanging, place proximal and distal labels on all tubings.
9. Check the patient's vital signs after making any connection.
10. Identify and confirm a solution's label, since a 3-in-1 PN solution can look like an enteral nutrition formulation bag. Label the bags with large, bold statements such as "WARNING! For Enteral Use Only—NOT for IV Use."
11. Make all connections under proper lighting conditions.

Gerontologic Considerations: Enteral Nutrition

EN is used in the older patient to improve nutritional status. Because

of physiologic changes associated with aging, the older adult is more vulnerable to complications associated with EN, especially fluid and electrolyte imbalances. Complications such as diarrhea can leave the patient dehydrated. Decreased thirst perception or impaired cognitive function decreases the patient's ability to seek needed fluids.

With aging, there is an increased risk for glucose intolerance. As a result, the older patient may be more susceptible to hyperglycemia from the high carbohydrate load of some EN formulas. The older adult with compromised cardiovascular function (e.g., heart failure) will have a decreased ability to handle large volumes of formula. If this happens, the patient may need a more concentrated formula (2.0 cal/mL). The older adult has an increased risk for aspiration caused by gastroesophageal reflux disease (GERD), delayed gastric emptying, hiatal hernia, or decreased gag reflex. Physical mobility, fine motor movement, and visual system changes associated with aging may contribute to problems managing EN in the home setting.

Parenteral Nutrition

Parenteral nutrition (PN) is the administration of nutrients directly into the bloodstream. PN is used when the GI tract cannot be used for the ingestion, digestion, and absorption of essential nutrients. Table 39.14 lists common reasons for the use of PN. PN is a relatively safe method of providing complete nutritional support.

TABLE 39.14 Common Indications for PN

- Chronic severe diarrhea and vomiting
- Complicated surgery or trauma
- GI obstruction
- GI tract anomalies and fistulae
- Intractable diarrhea
- Severe anorexia nervosa

- Severe malabsorption
- Short bowel syndrome

Composition

PN is customized to meet the needs of each patient. The composition is reformulated as the patient's condition changes. This requires you to collaborate with the interprofessional team in delivering PN to the patient.

Commercially prepared PN base solutions are available. These base solutions contain dextrose and protein in the form of amino acids. The pharmacy adds prescribed electrolytes (e.g., sodium, potassium, chloride, calcium, magnesium, phosphate), vitamins, and trace elements (e.g., zinc, copper, chromium, selenium, manganese) to meet the patient's needs. A 3-in-1 or total nutrient admixture containing an IV fat emulsion, dextrose, and amino acids is widely used. Premixed PN solutions require mixing the dextrose and amino acid chambers prior to use. Standard electrolytes are available in some premixed solutions. Multivitamins can be added before use.[19]

Calories

Calories in PN mainly come from carbohydrates in the form of dextrose and by fat in the form of fat emulsion. Dextrose 100 to 150 g/day (1 g provides about 3.4 calories, as opposed to oral carbohydrates, which provide 4 calories) has a protein-sparing effect. Providing adequate nonprotein calories in the form of glucose and fat allows the use of amino acids for wound healing and not for energy. However, overfeeding can lead to metabolic complications. To minimize these problems, the recommended energy intake is 25 to 30 cal/kg/day in a nonobese patient.[19]

Fat-emulsion solutions of 10%, 20%, and 30% are available. Fat emulsions supply about 1 cal/mL (10% solution) or 2 cal/mL (20% solution). Fat emulsions primarily contain soybean or safflower triglycerides with egg phospholipids added as an emulsifier. They supply a large number of calories in a small amount of fluid. This is

beneficial when the patient is at risk for fluid overload.

IV fat emulsions should provide up to 20% to 30% of total calories of PN. Most stable patients receive 1 g/kg/day. The maximum daily lipid dose is 2.5 g/kg/day. Critically ill patients may not tolerate this dose and may receive less than 1 g/kg/day. Serum triglyceride levels are done at the beginning of PN and then closely monitored. Give IV fat emulsions administered separately over 12 hours.[19] The infusion rate should not exceed 0.5 mL/kg/hr.

Fat emulsions are contraindicated in the patient with a problem with fat metabolism, such as hyperlipidemia. They are used cautiously in the patient at risk for fat embolism (e.g., fractured femur) and the patient with an allergy to eggs or soybeans.

Protein

Protein is provided at the rate of 1 to 1.5 g/kg/day depending on the patient's needs. In a nutritionally depleted patient who is under the stress of illness or surgery, protein requirements can exceed 150 g/day (2 g/kg/day) to ensure a positive nitrogen balance. Burn and multiple trauma patients may need more than 2 g/kg protein.[20] Protein needs may be lower than 1 g/kg and restricted in those with end-stage renal disease who are not on dialysis.

Electrolytes

The exact amount of electrolytes needed depends on the patient's health problem and on serum electrolyte levels. Assess individual requirements daily at the beginning of therapy and then several times a week as the treatment progresses. The following are ranges for average daily electrolyte requirements for adult patients without renal or liver impairment:

- Sodium: 1 to 2 mEq/kg
- Potassium: 1 to 2 mEq/kg
- Magnesium: 8 to 20 mEq
- Calcium: 10 to 15 mEq

- Phosphate: 20 to 40 mmol

Trace Elements and Vitamins

Zinc, copper, manganese, selenium, and chromium are added according to the patient's condition and needs. Monitor levels of these elements. The daily addition of a multivitamin preparation to the PN generally meets the vitamin requirements. The HCP may order additional amounts.

Methods of Administration

PN is given as central PN or peripheral parenteral nutrition (PPN). Central PN and PPN differ in nutrient content and tonicity, which is measured in milliosmoles (mOsm; the concentration of particles in a fluid).

Central Parenteral Nutrition

Central PN is indicated when long-term support is needed or when the patient has high protein and caloric requirements. We give central PN through a central venous catheter or a peripherally inserted central catheter (PICC) whose tip lies in the superior vena cava (see Chapter 16). Central PN solutions are hypertonic, measuring at least 1600 mOsm/L. The high glucose content ranges from 20% to 50%. Central PN must be infused in a large central vein so that rapid dilution can occur. The use of a peripheral vein for hypertonic, central PN solutions would cause irritation and thrombophlebitis.

Peripheral Parenteral Nutrition

PPN is given through a peripherally inserted catheter or vascular access device into a large vein. PPN is used when (1) nutritional support is needed for only a short time, (2) protein and caloric requirements are not high, (3) the risk for a central catheter is too great, or (4) to supplement inadequate oral intake.

Compared with central PN, PPN has fewer nutrients. While this makes PPN less hypertonic, it still has an osmolality of up to 800

mOsm/L. This increases the risk for phlebitis. Another potential complication is fluid overload. PPN requires large volumes of fluid, which many patients cannot tolerate.

Nursing Management: Parenteral Nutrition

Nursing management of patients receiving PN is outlined in Table 39.15 and eNursing Care Plan 39.2, available on the website for this chapter.

Complications

Complications associated with PN are related to either the catheter or the PN infusion itself (Table 39.16).

Refeeding syndrome can occur any time a malnourished patient starts aggressive nutritional support. It is characterized by fluid retention and electrolyte imbalances (hypophosphatemia, hypokalemia, hypomagnesemia). Hypophosphatemia is the hallmark of refeeding syndrome. It is associated with serious outcomes, including dysrhythmias, respiratory arrest, and neurologic problems (e.g., paresthesias). Conditions that predispose patients to refeeding syndrome include long-standing malnutrition states, such as chronic alcohol use, vomiting and diarrhea, chemotherapy, and major surgery.

TABLE 39.15 Nursing ManagementPN Infusions

Preparation of PN Solutions

- All PN solutions must be prepared by a pharmacist or trained technician using strict aseptic techniques under a laminar flow hood.

- Add nothing to PN solutions after they are prepared in the pharmacy.
- Limit number of people involved in preparing and administering PN to reduce risk for infection.
- PN solutions are ordered daily to adjust to the patient's current needs.
- PN solution label shows the nutrient content, all additives, time mixed, and expiration date and time.
- Solutions are good for 24 hrs and must be refrigerated until 30 min before use.

Maintaining PN Infusions

- Follow proper aseptic techniques to reduce infection risk.
- Use a 0.22-micron filter with parenteral solutions not containing fat emulsion and a 1.2-micron filter with solutions containing fat emulsion.
- Change filters and IV tubing with each new PN container or every 24 hr.
- Label tubing and filter with date and time they are put into use.
- If a multilumen catheter is present, use a dedicated line for PN.
- Do not draw blood from a line dedicated for PN unless absolutely necessary.
- Control the infusion rate. Give PN using an infusion pump.
- Set an alarm to alert for tubing obstruction.
- Periodically check the volume infused because pump malfunctions can change the rate.

Ensuring Patient Safety

- Before starting PN, check label and ingredients in solution to make sure they match what the HCP ordered.

- A second RN should verify infusion pump settings before beginning PN.
- Trace the administration tubing to the point of origin in the body at the start of the infusion and at all handoffs.
- Check the solution for leaks, color changes, particulate matter, clarity, and fat emulsions cracking (separating into layers). If present, promptly return it to the pharmacy for replacement.
- Discontinue a PN solution and replace it with a new solution if bag is not empty at the end of 24 hr. At room temperature, the solution (especially when containing fat emulsion) is a good medium for microorganism growth.
- If fat emulsions are infused separately from the PN solution, the preferred delivery method is a continuous low volume delivered over 12 hr.

Hyperglycemia

- Check glucose blood levels at bedside q4–6hr with glucose-testing meter.
- Maintain a glucose range of 140–180 mg/dL. Give sliding scale doses of insulin to keep the glucose level in normal range.

Hypoglycemia

- If a PN formula bag should empty before the next solution is available, a 10% or 20% dextrose solution (based on the amount of dextrose in the central PN solution) or 5% dextrose solution (based on the amount of dextrose in the peripheral PN solution) can be given to prevent hypoglycemia.

Catheter-Related Infections

- Carefully assess the catheter site for signs of inflammation and infection. Phlebitis can readily occur because of the hypertonic infusion. Catheter-related infection and septicemia can occur:
    - Local manifestations: erythema, tenderness, and exudate at the catheter insertion site
    - Systemic manifestations: fever, chills, nausea, vomiting, and malaise
- Immunosuppressed patients are at high-risk for infection. Note subtle signs in patients receiving chemotherapy, corticosteroids, or antibiotics, which can mask signs of infection.
- To reduce the risk for infection, catheters with antibiotic or antiseptic surfaces may be used.
- Follow agency policy for changing catheter dressings and other central line infection prevention measures (see Chapter 16).
- If you suspect an infection during a dressing change, send a culture specimen of the site and drainage and notify the HCP at once.
- If a catheter-related infection is suspected, blood cultures are drawn. A chest x-ray is taken to detect changes in pulmonary status.

Transitioning to Oral Nutrition

- Encourage oral nourishment and keep a careful record of intake. A general rule is that 60% of caloric needs should be met orally or through EN before discontinuing PN.
- Begin with clear liquids and advance as tolerated to a soft diet.

Assessing Effectiveness

- Monitor initial vital signs q4–8hr.
- Weigh patient daily as a measure of the patient's hydration status.

- Maintain accurate intake and output record.
- Determine the cause of any weight changes (e.g., fluid gained from edema, actual increase or decrease in tissue weight).
- Assess blood levels of glucose, electrolytes, and urea nitrogen.
- CBC and hepatic enzyme studies are obtained a minimum of 3 times per week until stable and then weekly as the patient's condition warrants.

TABLE 39.16 Complications of PN

Metabolic Problems

- Altered renal function
- Essential fatty acid deficiency
- Hyperglycemia, hypoglycemia
- Hyperlipidemia
- Liver dysfunction
- Refeeding syndrome

Catheter-Related Problems

- Air embolus
- Catheter-related sepsis
- Dislodgment
- Hemorrhage
- Occlusion
- Phlebitis
- Pneumothorax, hemothorax, and hydrothorax
- Thrombosis of vein

Home Nutritional Support

Home PN or EN is an accepted mode of nutritional therapy for the person who does not need hospitalization but needs continued nutritional support. Some patients successfully receive home therapy for many months, even years. It is important for you to teach the patient and caregiver about catheter or tube care, proper technique in mixing and handling of the solutions and tubing, and side effects and complications.

Home nutritional therapies are expensive. Specific criteria must be met for expenses to be reimbursed. The discharge planning team must be involved early to help plan for such issues. Home nutritional support may be a burden for the patient and caregivers and affect quality of life. Tell the family about support groups, such as the Oley Foundation *(www.oley.org)*, that provide peer support and advocacy.

Eating Disorders

Eating disorders are psychiatric conditions associated with physiologic alterations and risk for death. The manifestations of eating disorders vary across gender, age, socioeconomic status, and race and ethnicity. Patients with eating disorders may be hospitalized for fluid and electrolyte problems; dysrhythmias; and nutritional, endocrine, and metabolic disorders. Menstrual problems may occur in women of childbearing age. Many of the nutritional problems associated with these disorders require you to implement a nutritional plan of care.

The 3 most common types of eating disorders are anorexia nervosa, bulimia nervosa, and binge-eating disorder. *Binge-eating disorder* is less severe than bulimia nervosa and anorexia nervosa. Those with binge-eating disorder do not have a distorted body image and are often overweight or obese.

Eating disorders also occur in some who are health conscious. For example, men with *bigorexia* or muscle dysmorphia (an extreme concern with becoming more muscular) may use steroids or other drugs to increase muscle mass. They may also use supplements and

protein shakes to increase their body weight and mass.

The *female athlete triad* is a syndrome in which eating disorders, amenorrhea, and osteoporosis are present. The triad occurs in females taking part in sports that emphasize leanness and low body weight.

Anorexia Nervosa

Anorexia nervosa (AN) is characterized by restricting energy intake, difficulties in maintaining an appropriate weight, an intense fear of gaining weight or being fat, and distorted body image.[21] People with AN generally restrict the number of calories and the types of food they eat. Some people exercise compulsively, purge via vomiting and laxatives, and/or binge eat. AN manifests as unwillingness to maintain a healthy weight, refusal to eat, continuous dieting, detailed food rituals, and avoiding social situations.[21] Common assessment findings include signs of malnutrition, extreme thinness, hypothermia, and muscle weakness (Fig. 39.9).

Diagnostic studies often show osteopenia or osteoporosis, iron-deficiency anemia, a high blood urea nitrogen level from marked intravascular volume depletion, and abnormal renal function. A lack of dietary potassium and potassium loss in the urine lead to potassium deficiency. Manifestations of potassium deficiency include muscle weakness, dysrhythmias, and renal failure. Leukopenia; hypoglycemia; and decreased sodium, magnesium, and phosphorus may be present.

Treatment involves a combination of nutritional support and psychiatric care. Nutritional care focuses on reaching and maintaining a healthy weight, normal eating patterns, and perception of hunger and satiety. The patient may be hospitalized if there are medical complications that cannot be managed in an outpatient therapy program. Nutritional repletion is closely supervised to ensure consistent and ongoing weight gains. Refeeding syndrome is a rare but serious complication of refeeding programs. The patient may need EN or PN.

Improved nutrition, however, is not a cure for AN. The underlying

psychiatric issues must be addressed by identifying problematic personal and family interactions, followed by personal and family counseling.

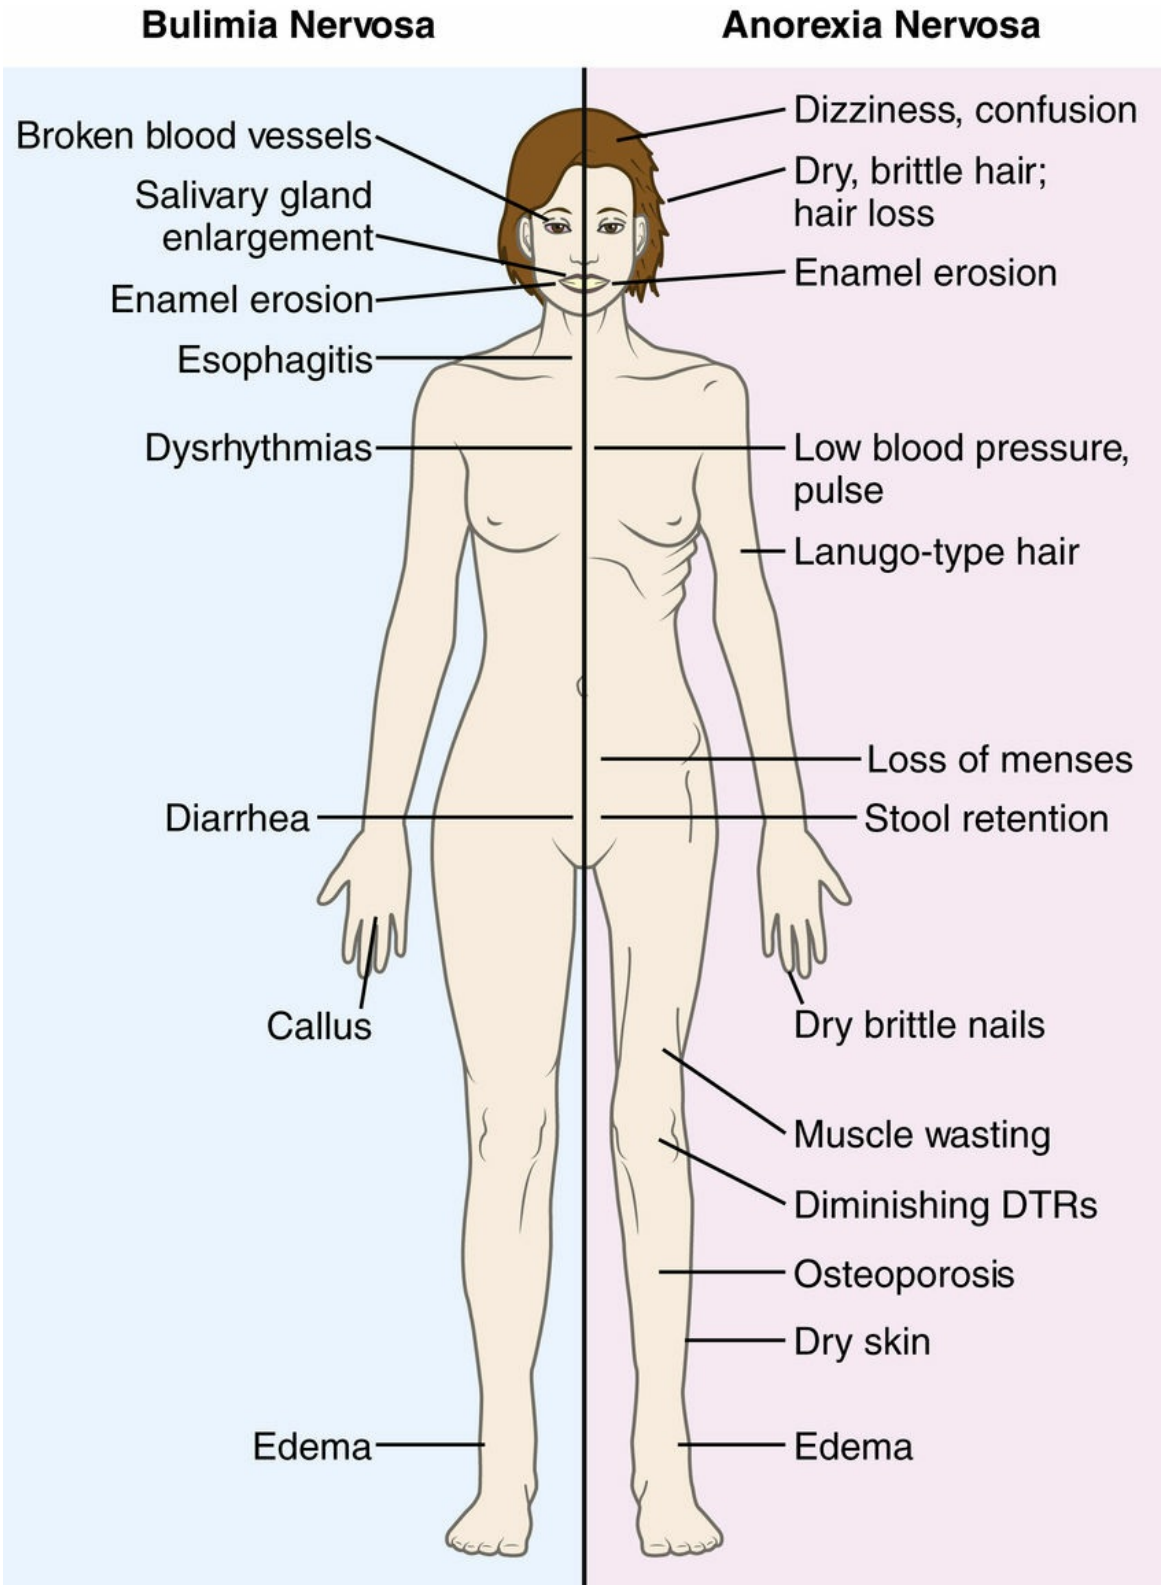

FIG. 39.9 Manifestations of anorexia nervosa and bulimia nervosa. Modified from Mahan LK, Raymond JL: *Krause's food & the nutrition care process,* ed, 14, St Louis, 2016, Saunders.

Bulimia Nervosa

Bulimia nervosa (BN) is a disorder characterized by episodes of binge eating with inappropriate compensatory behaviors to avoid weight gain (vomiting, laxative misuse, overexercise).[21] Like those with AN, the person with BN is concerned with body image and often goes to great lengths to conceal abnormal eating habits.[21] They may have normal weight for height, or their weight may fluctuate with bingeing and purging. There may have signs of frequent vomiting, such as macerated knuckles, swollen salivary glands, broken blood vessels in the eyes, and dental problems (Fig. 39.9). Abnormal laboratory values, including hypokalemia, metabolic alkalosis, and increased serum amylase, may occur from frequent vomiting.

The cause of BN is unclear. It is thought to be similar to that of AN. Some persons with BN report substance use, anxiety, affective disorders, and personality changes. Over time, problems associated with BN become increasingly hard to deal with effectively. A treatment combination of psychologic counseling (i.e., cognitive behavioral therapy) and nutritional counseling is essential.

Fluoxetine (Prozac) is the only FDA-approved antidepressant for treating BN. It may not be appropriate for all patients with BN. Education and emotional support for the patient and family are vital. Support groups, such as the National Association of Anorexia Nervosa and Associated Disorders (ANAD) *(www.anad.org)*, are helpful to those affected by these disorders.

Case Study

Undernutrition

Patient Profile

M.S. is a 70-yr-old white woman who was recently admitted to the inpatient medical unit with a diagnosis of malnutrition.

Subjective Data

- Reports 30-lb weight loss in past 2 mo
- Recently had a thrombotic stroke with hemiparesis and dysphagia
- Has a history of rheumatoid arthritis
- Has had nothing by mouth for the past 24 hr and just started EN via PEG tube
- Lives with her daughter, who is at her bedside

Objective Data
Physical Examination

- Has left-sided weakness
- BP is 150/90 mm Hg
- 5 ft, 4 in tall, weight 100 lb
- PEG tube recently placed

Laboratory Results

- Serum albumin 2.9 g/dL
- Prealbumin 11.0 mg/dL
- C-reactive protein 0.9 mg/L

Discussion Questions

1. What are M.S.'s risk factors for malnutrition?
2. What is her BMI?
3. What are contributing factors to her developing dysphagia and malnutrition?
4. What should you include in a successful weight gain program for M.S.?
5. For which complications of EN could M.S. be at risk?

6. ***Priority Decision:*** What is the priority of the nursing care for M.S.?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Identify any collaborative problems.
8. ***Collaboration:*** Which interventions could be delegated to unlicensed assistive personnel (UAP)?
9. ***Evidence-Based Practice:*** M.S.'s daughter tells you that her mother's abdomen appears bloated and she wonders if she should massage it.
10. ***Collaboration:*** What is the interprofessional team's top priority at this time for M.S.?
11. ***Safety:*** To ensure M.S.'s safety, what nursing interventions are needed considering M.S.'s recent weight loss?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The percentage of daily calories for a healthy person consists of
   a. 50% carbohydrates, 25% protein, 25% fat, and <10% of fat from saturated fatty acids.
   b. 65% carbohydrates, 25% protein, 25% fat, and >10% of fat from saturated fatty acids.
   c. 50% carbohydrates, 40% protein, 10% fat, and <10% of fat from saturated fatty acids.
   d. 40% carbohydrates, 30% protein, 30% fat, and >10% of fat from saturated fatty acids.

2. Place in order the substrates the body uses for energy during starvation, beginning with 1 for the first component and ending with 4 for the last component.
   a. skeletal protein.
   b. glycogen.
   c. visceral protein.
   d. fat stores.

3. A complete nutritional assessment including anthropometric measurements is *most* important for the patient who
   a. has a BMI of 25.5 kg/m^2.
   b. reports episodes of nightly nocturia.
   c. reports a 5-year history of constipation.
   d. reports an unintentional weight loss of 10 lb in 2 months.

4. Which method is *best* to use when confirming initial placement of a blindly inserted small-bore NG feeding tube?
   a. X-ray
   b. Air insertion
   c. Observing patient for coughing
   d. pH measurement of gastric aspirate

5. A patient is receiving peripheral parenteral nutrition. The solution is completed before the new solution arrives on the unit. The nurse gives
   a. 20% intralipids.
   b. 5% dextrose solution.

c. 0.45% normal saline solution.

d. 5% lactated Ringer's solution.

6. A patient with anorexia nervosa shows signs of malnutrition. During initial refeeding, the nurse carefully assesses the patient for *(select all that apply)*

a. hypokalemia.

b. hypoglycemia.

c. hypercalcemia.

d. hypomagnesemia.

e. hypophosphatemia.

1. a, 2. b, a, d, c, 3. d, 4. a, 5. b, 6. a, d, e

Obesity

Mariann M. Harding

LEARNING OUTCOMES

1. Discuss the epidemiology and etiology of obesity.
2. Explain the health risks associated with obesity.
3. Compare the classification systems for determining a person's body size.
4. Discuss nutritional therapy and exercise plans for the obese patient.
5. Distinguish among the bariatric surgical procedures used to treat obesity.
6. Describe the nursing and interprofessional management related to conservative and surgical therapies for obesity.
7. Describe the etiology, clinical manifestations, and nursing and interprofessional management of metabolic syndrome.

Conceptual Focus

Coping
Functional Ability
Nutrition
Self-Management

Obesity

Obesity is an excessively high amount of body fat or adipose tissue (Fig. 40.1). Obesity is a global problem because it is a major risk factor for leading causes of death, including type 2 diabetes, heart disease, and certain cancers. Overweight persons often have a number of other problems, such as problems with mobility and sleeping, that affect health.

The consequences of obesity extend beyond the physical changes. Social stigma can take an emotional toll on a person's psychologic well-being. Many have problems related to altered body image, depression, and low self-esteem and withdraw from social interaction.

Attitudes about obesity can create biases and discrimination against people who are obese. Obesity must be viewed and treated as a chronic disease similar to other chronic diseases, such as diabetes and hypertension.

Epidemiology of Obesity

The obesity problem is a public health crisis. After decades of rising obesity rates among adults, the rate of increase is beginning to slow, but rates are still far too high. Currently, about 40% of adults in the United States are obese. Significant geographic, racial and ethnic, and income disparities exist. Obesity rates are highest in the South (Fig. 40.2) and among blacks, Hispanics, and lower income, less-educated Americans[1] (Fig. 40.3).

Promoting Health Equity

Obesity

- Hispanics (47%) and blacks (46.8%) have the highest rates of obesity.
- Among women, blacks have the highest prevalence of being obese, with 17% having extreme obesity.
- Among men, Hispanics (43.1%) have the highest prevalence of being obese.
- Asian Americans have the lowest prevalence of being obese or extremely obese.

Obesity in adulthood is often a problem that begins in childhood or adolescence. One in 10 children becomes obese as early as age 2 to 5.[1] Reversing the childhood obesity crisis is key to addressing the overall obesity epidemic.

Etiology and Pathophysiology

Obesity is an increase in body weight beyond the body's physical requirements. This results in an abnormal increase and accumulation of fat cells. However, the processes leading to and sustaining the obese state are complex and still undergoing investigation.

In obesity, there is an increase in the number of adipocytes *(hyperplasia)* and an increase in their size *(hypertrophy).* Adipocyte *hypertrophy* is a process by which adipocytes can increase their volume several thousand times to accommodate large increases in lipid storage. When storage of existing fat cells is exceeded, preadipocytes are triggered to become adipocytes. This process occurs primarily in the visceral (intraabdominal) and subcutaneous tissues. The process of *hyperplasia* of adipocytes is greatest from infancy through adolescence.

Most obese persons have *primary obesity,* which is excess calorie intake over energy expenditure for the body's metabolic demands. Others have *secondary obesity,* which can result from various congenital anomalies, chromosomal anomalies, metabolic problems, central nervous system (CNS) lesions and disorders, or drugs (e.g., corticosteroids, antipsychotics).

FIG. 40.1 The obesity epidemic has taken its toll on both adults and children in the United States.
© iStock.com/IPGGutenbergUKLtd.

The cause of obesity involves genetic and biologic factors that are influenced by environmental and psychosocial factors. While each of these factors can and should be considered individually, in reality they are interrelated.

Genetic Link

A genetic predisposition to obesity may be present in as many as 70% of those who are obese.[2] Several genes that are linked to obesity have been found. Genes appear to influence how calories are stored and energy released. "Energy-thrifty" genes, once protective against long periods when food was not available, are now maladaptive in societies in which food availability is no longer an issue. Genes may be responsible for why 2 people living in the same environment can vary considerably in body size.

A strong link exists between a gene known as *FTO* (fat mass and

obesity-associated gene) and body mass index (BMI). Variants of this gene may explain why some people become overweight while others do not. People with a certain allele of the *FTO* gene appear to have an increased appetite, reduced satiety, and higher calorie intake.[2] More research is needed to better understand the role of genes in obesity.

Physiologic Regulatory Mechanisms in Obesity

Research has focused on the physiologic regulatory processes that control eating behavior, energy metabolism, and body fat metabolism. Knowing how appetite is triggered and energy is spent gives important information for understanding obesity and specific targets for the development of drugs.

The hypothalamus, gut, and adipose tissue synthesize hormones and peptides that stimulate or inhibit appetite (Fig. 40.4). The hypothalamus is a major site for regulating appetite. Neuropeptide Y, made in the hypothalamus, is a powerful appetite stimulant. When it is imbalanced, it leads to overeating and obesity. Hormones and peptides made in the gut and adipocyte cells affect the hypothalamus and have a critical role in appetite and energy balance (Table 40.1). When overeating develops at an early age and continues into adulthood, one's ability to sense fullness *(satiety)* is altered.

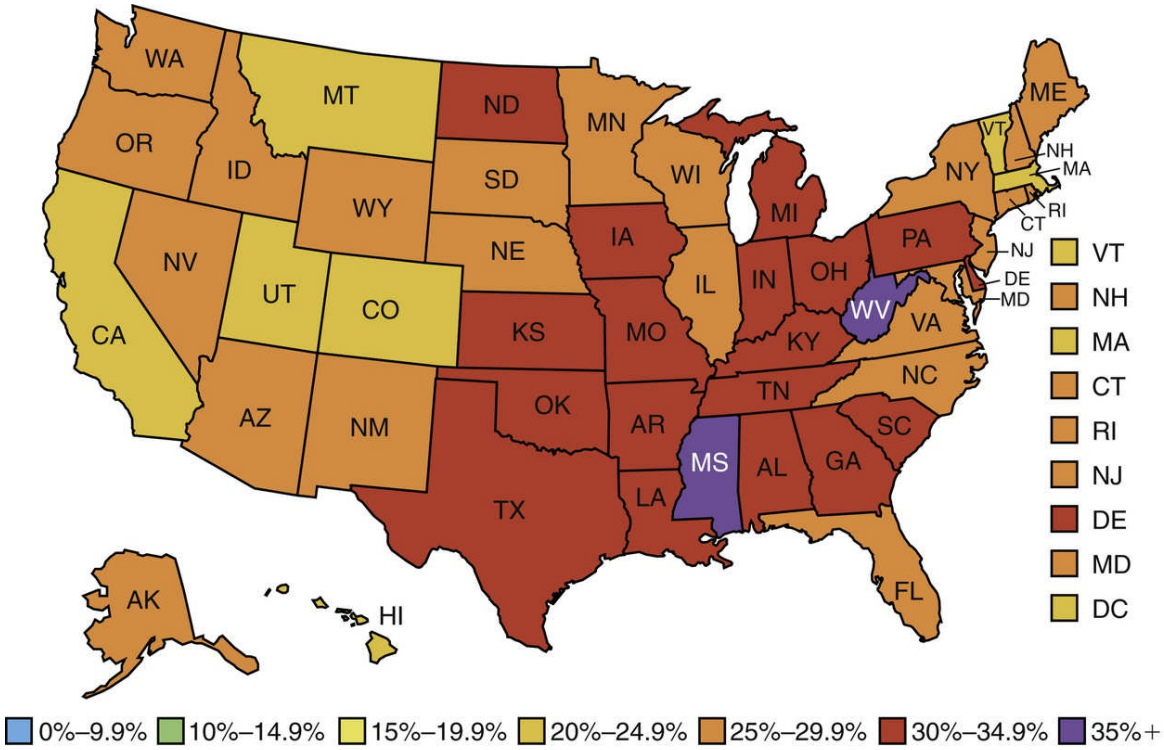

FIG. 40.2 Percent of obese adults (BMI >30 kg/m^2) in the United States. Alabama, Arkansas, Louisiana, Mississippi, and West Virginia have the highest rates of obesity. Colorado has the lowest rate at 22.3%. 20 states have rates at or above 30%, 47 states have rates of at least 25%, and every state is above 20%.
Source: Trust for America's Health, Robert Wood Johnson Foundation. The state of obesity. 2017. Retrieved from *http://stateofobesity.org*.

Leptin, secreted from adipocytes when they fill with fat, acts in the hypothalamus to suppress appetite and increase fat metabolism. A genetic deficiency of leptin causes extreme obesity. However, most obese persons have high leptin levels, suggesting they are leptin resistant. This may be due to a failure to make enough leptin receptors or producing faulty receptors.

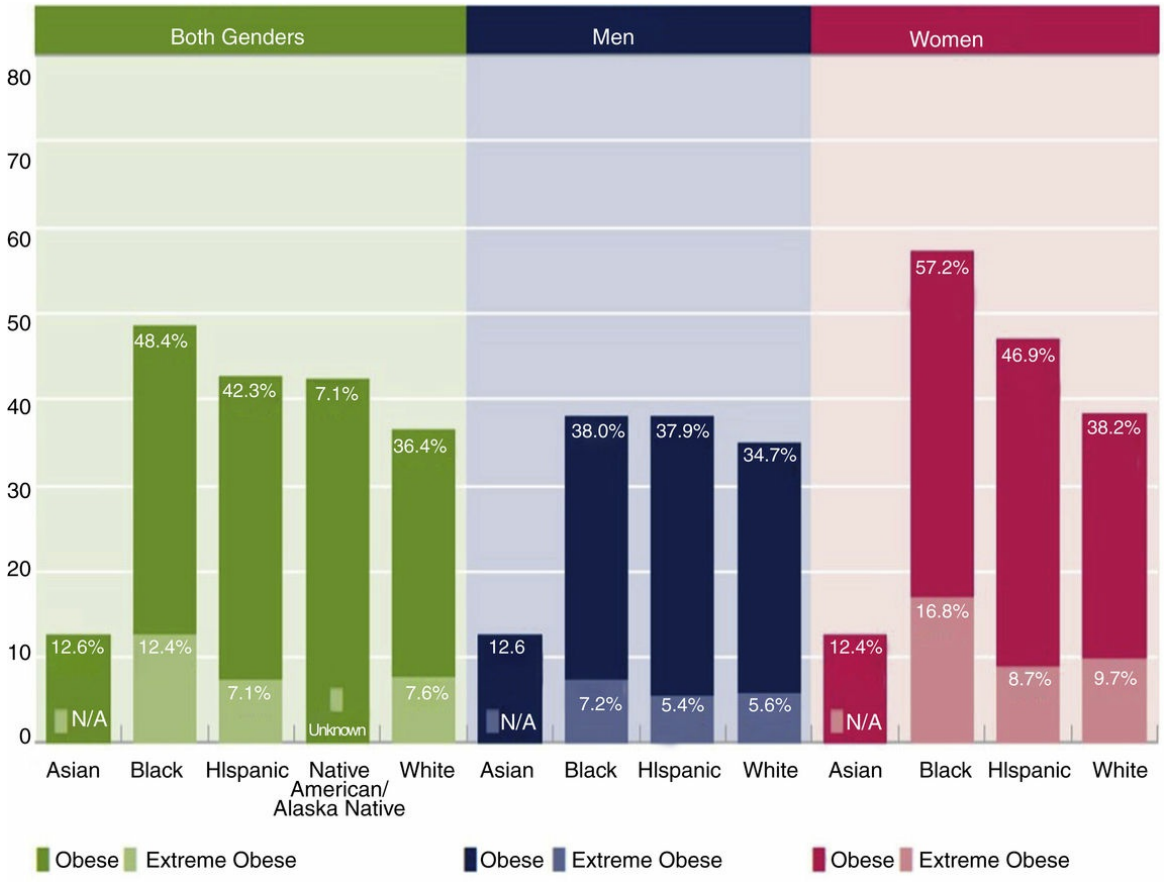

FIG. 40.3 Obesity affects some groups disproportionately. Among U.S. adults, black and Hispanic populations have higher rates of obesity than do white populations.
Source: Trust for America's Health, Robert Wood Johnson Foundation. The state of obesity. 2017. Retrieved from *http://stateofobesity.org*.

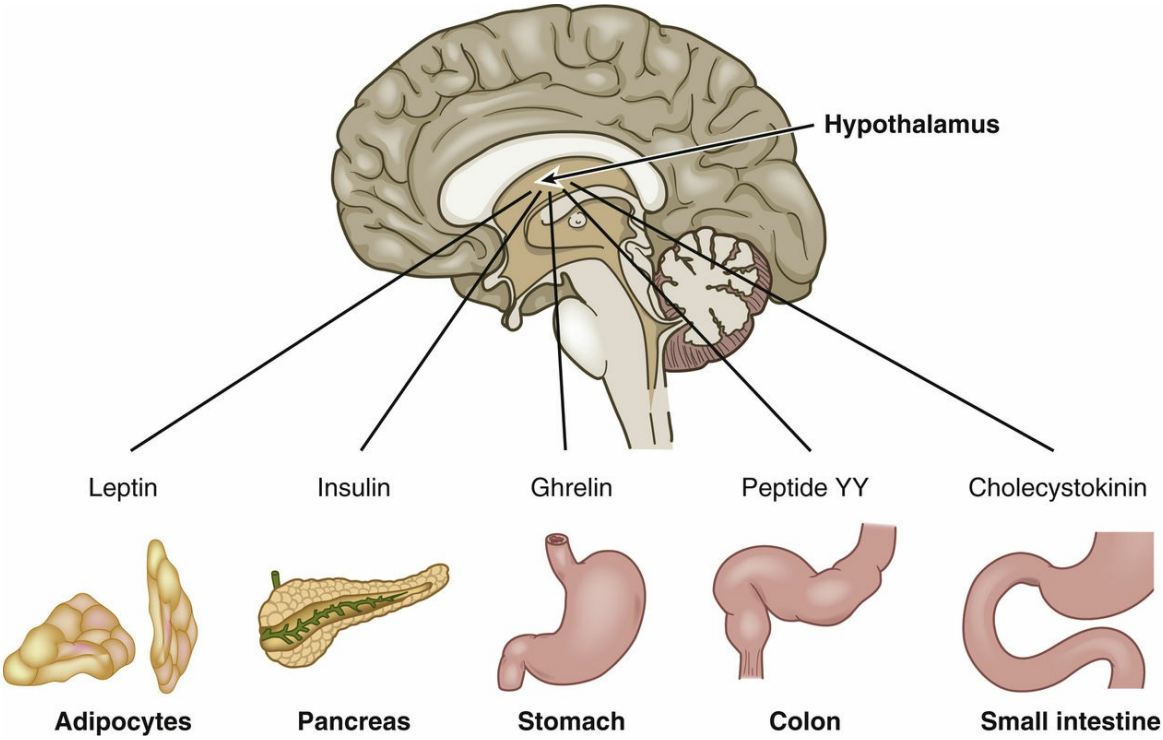

FIG. 40.4 Some of the common hormones and peptides that interact with the hypothalamus to control and influence eating patterns, metabolic activities, and digestion. Obesity disrupts this balance (Table 40.3).

TABLE 40.1 Hormones and Peptides in Obesity

Where Produced	Normal Function	Alteration in Obesity
Anorexins (Suppress Appetite)		
Cholecystokinin		
Small intestine	Inhibits gastric emptying Sends satiety signals to hypothalamus	Unknown role
Glucagon-Like Peptide-1 (GLP-1)		
Small intestine	Stimulates insulin secretion from pancreas Increases satiety (mediated by GLP-1 receptors in brain)	Unknown role
Insulin		
Pancreas	Decreases appetite	Increased insulin secretion, which stimulates ↑ liver synthesis of triglycerides and ↓ HDL production
Leptin		
Adipocytes	Suppresses appetite and hunger Regulates eating behavior	Obesity is associated with high levels Leptin resistance develops so obese people may lose the effect of appetite suppression
Peptide YY		
Colon	Inhibits appetite by slowing GI motility and gastric emptying	Circulating levels are decreased. ↓ Release after eating
Orexins (Stimulate Appetite)		
Ghrelin		
Stomach (primarily)	Stimulates appetite ↑ After food deprivation ↓ In response to food in the stomach	Normal postprandial decline does not occur, which can lead to increased appetite and overeating
Neuropeptide Y		
Hypothalamus	Stimulates appetite	Imbalance causes increased appetite

Ghrelin, a gut hormone, regulates appetite by inhibiting leptin. It acts in the hypothalamus and the brain's pleasure centers to stimulate hunger. In a nonobese person, ghrelin levels are higher when a person is hungry and decrease in response to eating. Ghrelin is thought to play a part in compulsive eating. Low ghrelin levels after gastric bypass surgery helps suppress appetite.[3]

The 2 major consequences of obesity are due to the sheer increase in fat mass and production of adipokines made by fat cells. Adipocytes make at least 100 different proteins. These proteins, secreted as enzymes, adipokines, growth factors, and hormones, contribute to insulin resistance, dyslipidemia, and high blood pressure. Excess visceral fat is associated with more alterations of adipokines. This causes people with abdominal (android) obesity more complications of obesity.[4] An increased release of cytokines from fat cells may disrupt immune factors and predispose the person to certain cancers.

TABLE 40.2 Portion Sizes: 40 Years Ago vs. Today

	40 Yrs Ago	Today
Turkey sandwich	320 cal 	820 cal 
Bagel	333 cal 	590 cal 
Cheeseburger	3-in diameter, 140 cal 	6-in diameter, 350 cal 
Soda	6½ oz, 85 cal 	20 oz, 250 cal 

Environmental Factors

Environmental factors play a key role in obesity. In today's culture, people have greater access to food (particularly prepackaged and fast foods) and soft drinks, which have poor nutritional quality. In addition, eating outside of the home interferes with the ability to control the quality and quantity of food. Portion size of meals has increased dramatically (Table 40.2). Underestimating portion sizes and therefore caloric intake is common. Lack of physical exercise is another factor that contributes to weight gain and obesity. With increases in the use of technology, labor-saving devices, and cars, we expend less energy in our everyday lives. Elimination of physical education programs in schools, along with increased time spent playing video games and watching TV, has contributed to the increase in sedentary habits.

Socioeconomic status is a known risk factor for obesity in a variety of ways.[5] People with low incomes may try to stretch their food dollars by buying less expensive foods that often have poor nutritional quality with a greater caloric content. For example, people with low incomes are more likely to buy pasta, bread, and canned fruit packed with sugar rather than chicken and fresh fruits and vegetables. Low-income residents may live in environments that do not accommodate outdoor activities (e.g., safe playgrounds, walking tracks, tennis, swimming pools).

Psychosocial Factors

People use food for many reasons besides its nutritional value. Associations with food begin in childhood, such as the use of food for comfort or rewards. The social component of eating begins early in life when food is associated with pleasure and fun at such events as birthday parties, Thanksgiving, and religious holidays. "Mindless eating" refers to eating more than one normally would because of outside factors. These factors include the food's presentation and

eating while distracted, such as when studying or watching television. Mindless eating leads to consuming unnecessary calories and an increase in body weight.

Promoting Population Health

Health Impact of Maintaining a Healthy Weight

- Lowers the risk for hypertension and high cholesterol
- Increases chance for longevity and better quality of life
- Reduces the risk for developing type 2 diabetes
- Reduces the risk for heart disease, stroke, and gallbladder disease
- Reduces the risk for breathing problems, including sleep apnea and asthma
- Decreases the risk for developing osteoarthritis, low back pain, and certain types of cancers

Health Risks Associated with Obesity

Hippocrates wrote that "corpulence is not only a disease itself, but the harbinger of others," thus recognizing that obesity has major adverse effects on health. Many problems occur in obese people at higher rates than in people of normal weight (Fig. 40.5).

Mortality rates rise as obesity increases, especially when obesity is associated with visceral fat.[1] In addition to these problems, obese patients have a reduced quality of life. Fortunately, most of these conditions can improve if a person loses weight.

Cardiovascular Problems

Obesity is a significant risk factor for cardiovascular disease (CVD) and stroke in both men and women. Android obesity is the best

predictor of these risks and is linked with increased low-density lipoproteins (LDLs), high triglycerides, and decreased high-density lipoproteins (HDLs).[6] Hypertension can occur because of increased circulating blood volume, abnormal vasoconstriction, increased inflammation (damaging blood vessels), and increased risk for sleep apnea (raises BP). Excess body fat can lead to chronic inflammation throughout the body, especially in blood vessels, thus increasing the risk for heart disease.

Diabetes

Obesity is a major risk factor for the development of type 2 diabetes. Hyperinsulinemia and insulin resistance, common features of type 2 diabetes, are also found in obesity. The term *diabesity* reflects the combined effects of diabetes and obesity.

Excess weight decreases the effectiveness of insulin. When insulin does not work effectively, too much glucose stays in the bloodstream. Thus more insulin is made to compensate. Pancreatic β cells (cells that make insulin) may get overworked and become worn out. Over time, the pancreas is no longer able to keep blood glucose in normal range. Adiponectin, a peptide that increases insulin sensitivity, is decreased in obese people.

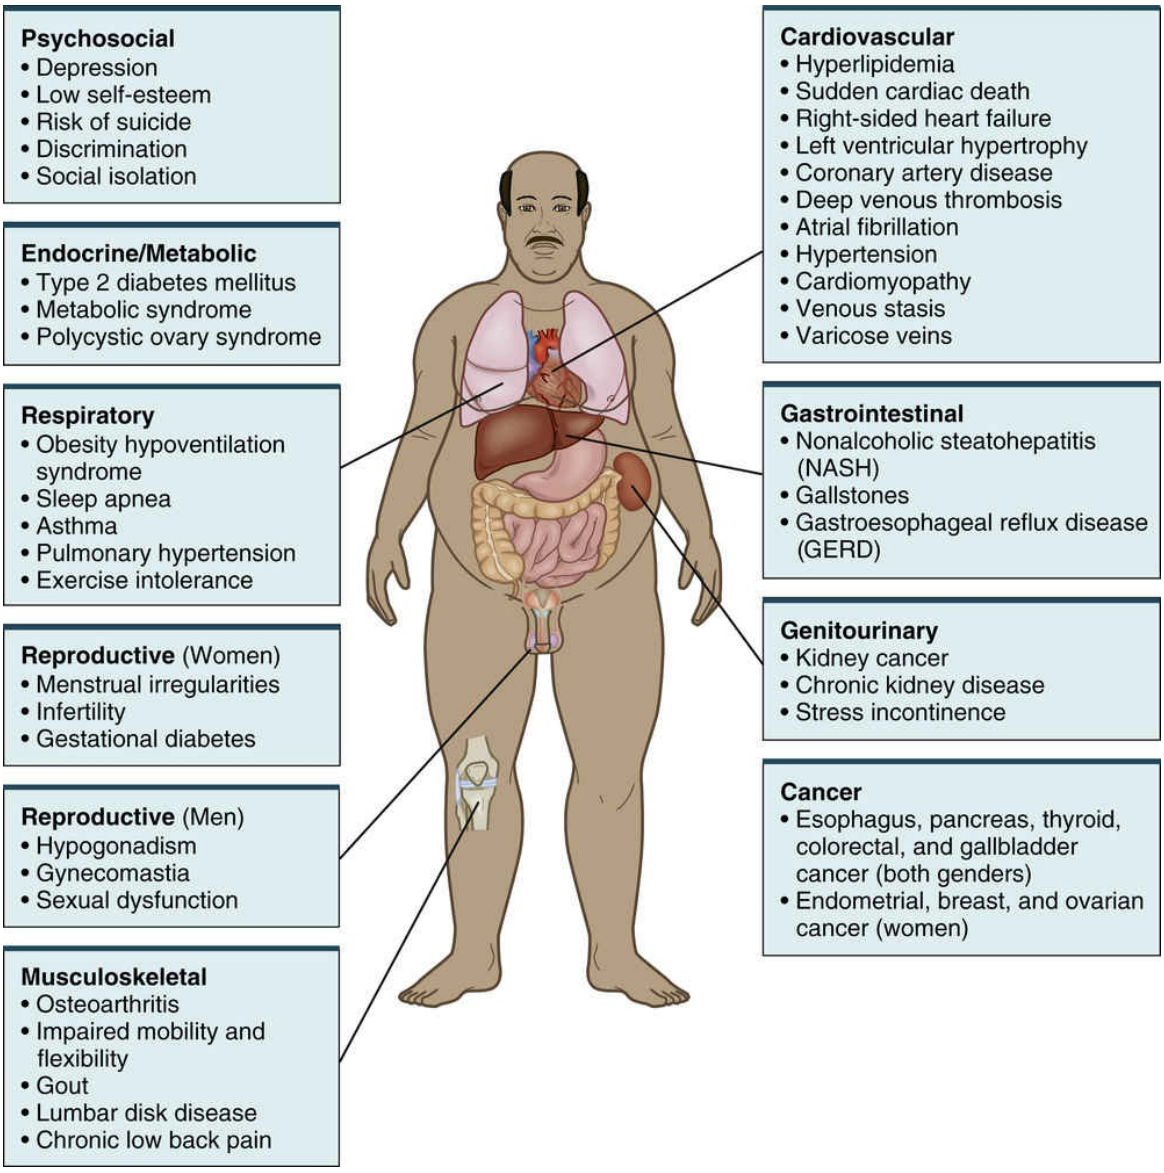

FIG. 40.5 Health risks associated with obesity.

Obesity complicates the management of type 2 diabetes by increasing insulin resistance and glucose intolerance. These factors make drug treatment for diabetes less effective.

Gastrointestinal and Liver Problems

Gastroesophageal reflux disease (GERD) and gallstones are more prevalent in obese people. Gallstones occur due to supersaturation of the bile with cholesterol. Nonalcoholic steatohepatitis (NASH) is a condition in which lipids are deposited in the liver, resulting in a fatty

liver. NASH is associated with increased hepatic glucose production. NASH can eventually progress to cirrhosis and can be fatal. Weight loss can improve NASH.

Respiratory and Sleep Problems

The increased fat mass associated with obesity may lead to sleep apnea and obesity hypoventilation syndrome. The increased distribution of fat around the diaphragm causes reduced chest wall compliance, increased work of breathing, and decreased total lung capacity. Sleep apnea results from increased fat around the neck, leading to snoring and hypoventilation while sleeping. Weight loss can improve lung function.

Poor sleep and sleep deprivation may increase appetite. Sleep deprivation has been associated with obesity. Building up a sleep debt over a matter of days can impair metabolism and disrupt hormone levels. The level of leptin falls in people who are sleep deprived, thus promoting appetite.

Musculoskeletal Problems

Obesity is associated with an increased incidence of osteoarthritis because of the stress put on weight-bearing joints, especially the knees and hips. Increased body fat also triggers inflammatory mediators and contributes to deterioration of cartilage. Hyperuricemia and gout often occur in people who are obese and in those who have metabolic syndrome (discussed later in this chapter).

Cancer

Obesity is one of the most important preventable causes of cancer. The types of cancer most strongly linked to excess body fat are thyroid, liver, kidney, colorectal, breast, endometrial, and gallbladder cancer.[1,7]

The underlying mechanisms linking obesity and cancer remain unclear. Breast and endometrial cancer may be due to the increased

estrogen levels (estrogen is stored in fat cells) associated with obesity in postmenopausal women. Colorectal cancer has been linked to hyperinsulinemia. Esophageal cancer may be related to acid reflux caused by abdominal obesity. Several hormones and factors often present in obese states increase the risk for cancer. For example, insulin, a powerful cellular growth factor, is increased in obesity. The resulting hyperinsulinemia may affect cancer cells. Adipokines from fat cells may stimulate or inhibit cell growth. For example, leptin, which is increased in obese people, promotes cell proliferation.

Metabolic Syndrome

Metabolic syndrome is one of the fastest-growing obesity health concerns. It is discussed later in this chapter on p. 885.

Psychosocial Problems

The consequences of obesity extend beyond the physical changes. Stigmatization of obese people, and in some cases discrimination, occurs in 3 important areas of living: employment, education, and health care. The social stigma associated with obesity has an emotional toll on a person's psychologic well-being. Many obese persons have low self-esteem, withdraw from social interaction, and have major depression.[8]

Nursing and Interprofessional Management: Obesity

Nursing Assessment

The first step in the treatment of obesity is to determine whether any physical conditions are present that may be causing or contributing to obesity. This requires a thorough history and physical examination (Table 40.3). Before you begin, examine your own personal beliefs and any potential biases related to obesity. If you associate obesity with a

lack of willpower and overindulgence, you may convey your attitude to patients. They may experience shame in a setting that claims to be a caring one.

TABLE 40.3 Nursing AssessmentPatients With Obesity

Subjective Data

Important Health Information

Past health history: Time of obesity onset; diseases related to metabolism and obesity, including hypertension, CVD, stroke, cancer, chronic joint pain, respiratory problems, diabetes, cholelithiasis, metabolic syndrome
Medications: Thyroid preparations, diet pills, herbal products
Surgery or other treatments: Prior weight-reduction procedures (bariatric surgery)

Functional Health Patterns

Health perception–health management: Family history of obesity; perception of problem; methods of weight loss tried
Nutritional-metabolic: Amount and frequency of eating; overeating in response to boredom, stress, specific times, or activities; history of weight gain and loss
Elimination: Constipation
Activity-exercise: Typical physical activity; drowsiness, somnolence; dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea
Sleep-rest: Sleep apnea, use of CPAP
Cognitive-perceptual: Feelings of rejection, depression, isolation, guilt, or shame; meaning or value of food; adherence to prescribed reducing diets, degree of long-term commitment to a

weight loss program

Role-relationship: Change in financial status or family relationships; personal, social, and financial resources to support a reducing diet

Sexuality-reproductive: Menstrual irregularity, heavy menstrual flow in women, birth control practices, infertility; effect of obesity on sexual activity and attractiveness to significant other

Objective Data

General

Body mass index ≥30 kg/m^2; waist circumference: woman >35 in (89 cm), man >40 in (102 cm)

Respiratory

Increased work of breathing; wheezing; rapid, shallow breathing

Cardiovascular

Hypertension, tachycardia, dysrhythmias

Musculoskeletal

Decreased joint mobility and flexibility; knee, hip, and low back pain

Reproductive

Gynecomastia and hypogonadism in men

Possible Diagnostic Findings

Elevated serum glucose, cholesterol, triglycerides; chest x-ray showing enlarged heart; ECG showing dysrhythmia; abnormal liver function test results

When assessing a person who is overweight or obese, be sensitive and nonjudgmental in asking specific and leading questions about weight, diet, and exercise (Table 40.4). In doing so, you can often obtain information that the patient may have withheld out of embarrassment or shyness. Patients need to understand the reason for questions asked about weight or dietary habits. You must be ready to respond to their concerns.

Check Your Practice

You are working in the hypertension clinic, and the provider has asked you to do an assessment on a 54-yr-old man for referral to a weight loss program. He is 5 ft, 9 in and weighs 242 lb. His BP has been hard to control with drugs and diet. While you are trying to do an assessment (using the questions in Table 40.4), he interrupts you and asks you if he can leave. He angrily tells you, "I do not want to give up my favorite foods, quit drinking, or exercise. Do you understand that?"

- How would you respond to him?

Assess a patient's willingness to change and potential for change. If people are not ready for change, offer them the opportunity to return for further discussion when they are ready to discuss their weight again and make lifestyle changes.

When obtaining the history, explore genetic and endocrine factors, such as hypothyroidism, hypothalamic tumors, Cushing syndrome, hypogonadism in men, and polycystic ovary syndrome in women. Laboratory tests of liver function and thyroid function, a fasting glucose level, and a lipid panel (triglyceride level, LDL and HDL cholesterol levels) aid in evaluating the cause and effects of obesity. When no organic cause (e.g., hypothyroidism) is associated with obesity, the disorder should be considered a chronic, complex disease.

Assess for any co-morbid diseases associated with obesity (e.g., hypertension, sleep apnea). These obesity-related complications require special treatment.

TABLE 40.4 Assessing Patients With Obesity

When assessing patients with obesity and before selecting a weight loss strategy, ask the following questions:

- What is your history with weight gain and weight loss?
- Are other family members overweight?
- How has your body weight affected your health?
- What do you think contributes to your weight?
- What does food mean to you? How do you use food (e.g., to relieve stress, provide comfort)?
- Describe your motivation for losing weight.
- What have you already tried to lose weight? Was it successful? If not, why not?
- Would you like to manage your weight differently? If so, how?
- What sort of barriers do you think impede your weight loss efforts?
- Are there any major stresses that will make it hard to focus on weight control?
- How much time can you devote to exercise on a daily or weekly basis?

- Describe the support you have from family and/or friends for losing weight.

As part of the initial nursing physical examination, assess each body system with particular attention to the organ system in which the patient has expressed a problem or concern. Measurements used with the obese person may include height (without shoes), weight (obtain in a private location and in a gown, if possible), waist circumference, and BMI. Have the right equipment to take these measurements. Provide special chairs, examination tables, and scales that can accommodate an obese person.

Classifications of Body Weight and Obesity

An important part of your patient assessment is to determine and classify a patient's body weight. Common assessment methods include BMI, waist circumference, waist-to-hip ratio (WHR), and body shape. The most widely used and endorsed measures are BMI and waist circumference. These measures are cost-effective, reliable, and easily used in all practice settings.

Body Mass Index

The most common measure of obesity is the **body mass index (BMI)**. BMI is calculated by dividing a person's weight (in kilograms) by the square of the height in meters (Fig. 40.6). Table 40.5 shows the classification of overweight and obesity by BMI. Persons with a BMI less than 18.5 kg/m^2 are considered underweight. A BMI between 18.5 and 24.9 kg/m^2 reflects a normal body weight. A BMI of 25 to 29.9 kg/m^2 is classified as being **overweight**. Those with values at 30 kg/m^2 or above are considered **obese**. The term **extreme obesity** *(morbid* or *severe obesity)* is used for those with a BMI greater than 40 kg/m^2.

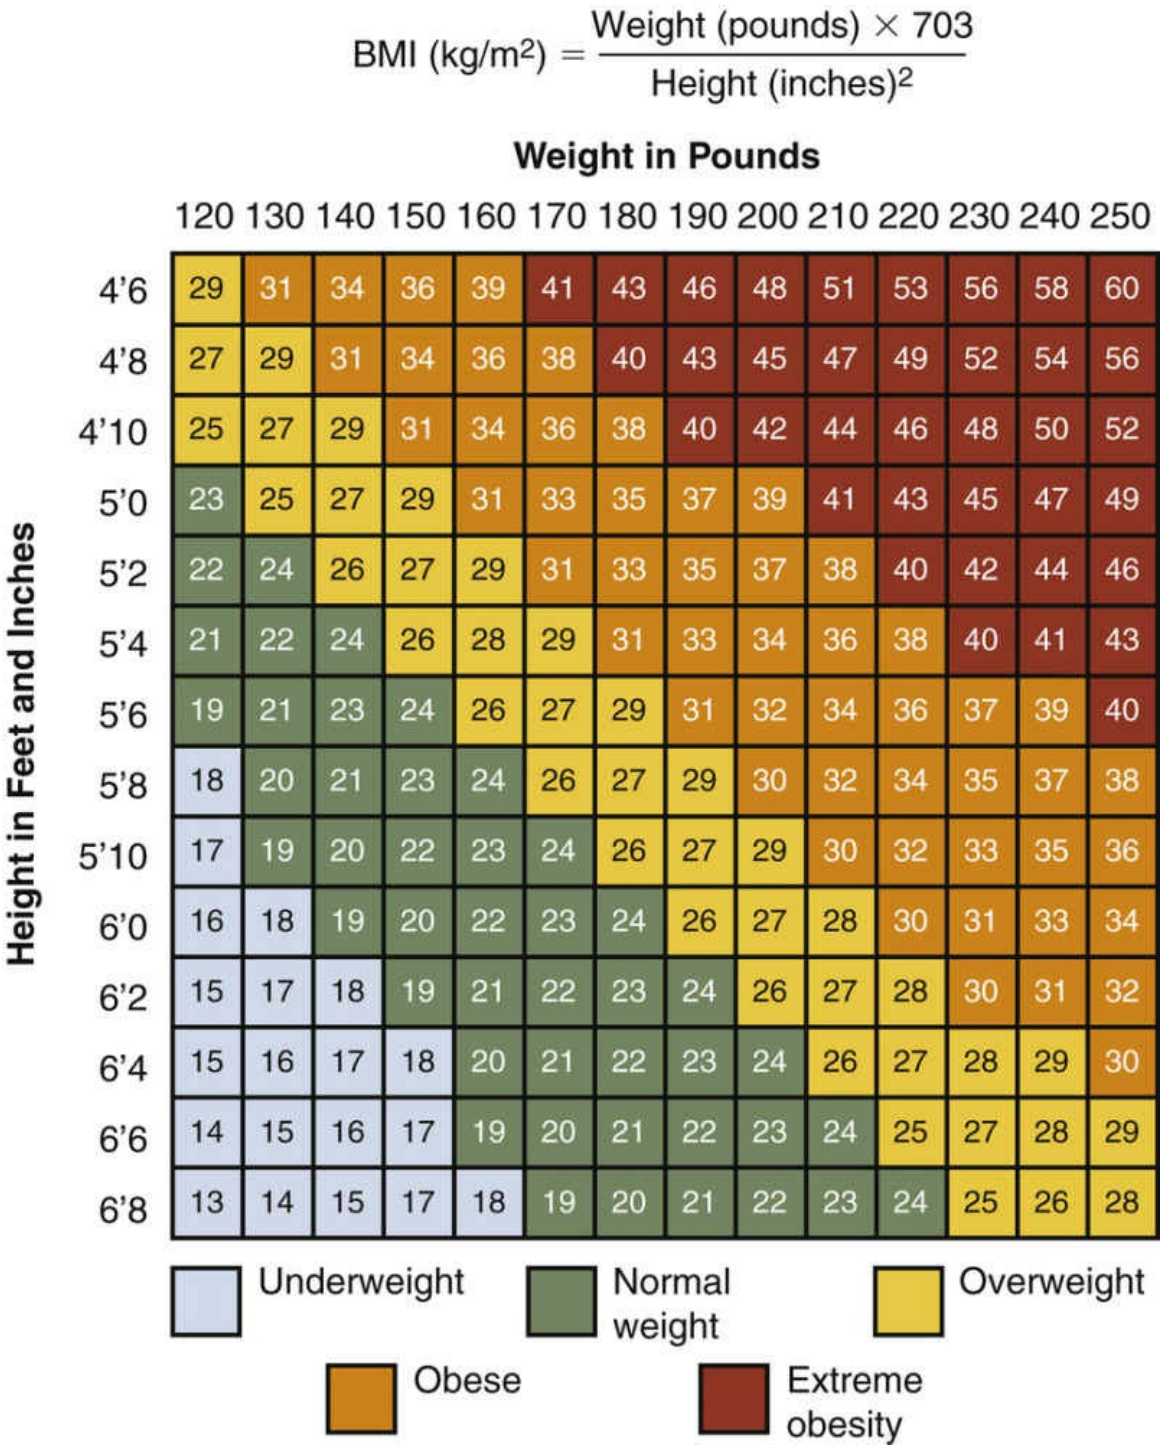

FIG. 40.6 Body mass index (BMI) chart. Healthy weight: BMI 18 to 24.9 kg/m^2; overweight: BMI 25 to 29.9 kg/m^2; obesity: BMI 30 kg/m^2. BMI = weight (kg)/height (m^2).

TABLE 40.5 Classification of Overweight and Obesity

			Disease Risk Relative to Normal Weight and Waist Circumference	
	BMI (kg/m^2)	Obesity Class	Men ≤40 in (102 cm) Women ≤35 in (89 cm)	Men >40 in (102 cm) Women >35 in (89 cm)
Underweight	<18.5	—	—	—
Normal	18.5–24.9	—	—	—
Overweight	25.0–29.9	—	Increased	High
Obesity	30.0–34.9	Class I	High	Very high
	35.0–39.9	Class II	Very high	Very high
Extreme obesity	≥40.0	Class III	Extremely high	Extremely high

Source: National Heart, Lung, and Blood Institute: Classification of overweight and obesity by BMI, waist circumference, and associated disease risks. Retrieved from *www.nhlbi.nih.gov/health/public/heart/obesity/lose_wt/bmi_dis.htm*.

Though BMI provides an overall assessment of fat mass, we must consider BMI in relation to the patient's age, gender, and body build. For example, a body builder may have a BMI associated with obesity, but because of a high muscle mass, the BMI would not be an accurate assessment. In contrast, in those who have lost body mass (e.g., older adults), the BMI would underestimate the degree of obesity. For this reason, other measures must be combined with the BMI for an accurate evaluation of a person's weight.

Waist Circumference

Waist circumference is another way to assess and classify a person's weight. The average waist size has increased by more than 1 inch (from 37.6 inches to 38.8 inches) in the past decade. Health risks increase if the waist circumference is greater than 40 inches in men and greater than 35 inches in women.[9] People who have visceral fat with android obesity have an increased risk for CVD and metabolic syndrome (discussed later in this chapter).

Waist-to-Hip Ratio

The **waist-to-hip ratio (WHR)** is another method used to assess obesity. This ratio describes the distribution of both subcutaneous and visceral adipose tissue. Calculate the WHR by dividing the waist measurement by the hip measurement. A WHR less than 0.8 is best. A WHR greater than 0.8 indicates more truncal fat, which puts a person at a greater risk for health complications.

Body Shape

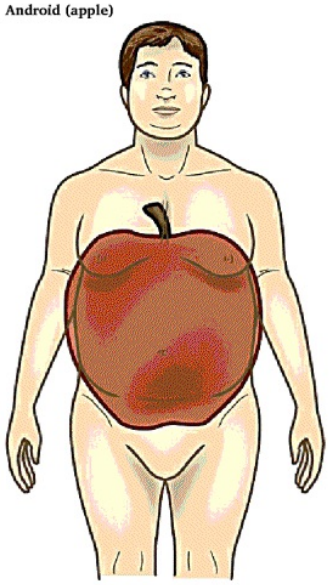
Body shape is another way of identifying those who are at a higher risk for health problems (Table 40.6). People with fat primarily in the abdominal area, an *apple-shaped body,* have *android obesity.* Those with fat distribution in the upper legs, a *pear-shaped body,* have *gynoid obesity.* Genetics has an important role in determining a person's body shape and weight.

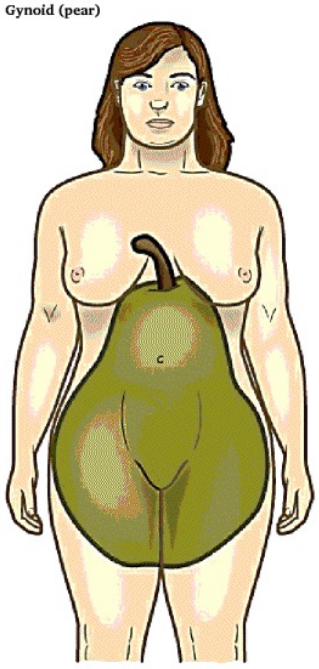
Nursing Diagnoses

Nursing diagnoses for the patient with obesity may include:

- Obesity
- Activity intolerance
- Impaired physical mobility
- Disturbed body image

Planning





The overall goals are that the obese patient will (1) modify eating patterns, (2) take part in a regular physical activity program, (3) achieve and maintain weight loss to a specified level, and (4) minimize or prevent health problems related to obesity.

Nursing Implementation

Obesity is one of the most challenging health problems. For most

patients, successful weight management will be a hard, lifelong project. Obesity treatment begins with patients understanding their weight history and deciding on a plan that is best for them. It is rare to find an obese person who has not tried to lose weight. Some people have met with limited and temporary success, and others have met only with failure.

TABLE 40.6 Relationship Between Body Shape and Health Risks

Body Shape	Characteristics	Health Risks
Android (apple) 	• Fat primarily in abdominal area • Fat also distributed over upper body (neck, arms, shoulders) • Greater risk for obesity-related complications	• Heart disease • Diabetes • Breast cancer • Endometrial cancer • Visceral fat more active, causing ↓ insulin sensitivity • ↑ Triglycerides • ↓ HDL cholesterol • ↑ BP • ↑ Free fatty acid release into blood
Gynoid (pear) 	• Fat mainly in the upper legs • Has a better prognosis but hard to treat	• Osteoporosis • Varicose veins • Cellulite • Subcutaneous fat traps and stores dietary fat • Trapped fatty acids stored as triglycerides

You are in a key position to help obese patients by (1) helping them explore and deal with their negative experiences and (2) teaching other health professionals about stigma and biases experienced by obese patients. Although health care for obese people has greater demands, HCPs often do not address these needs. HCPs are often reluctant to counsel patients about obesity for a variety of reasons,

including (1) time constraints during appointments make it hard, (2) weight management may be viewed as professionally unrewarding, (3) reimbursement for weight management services is hard to obtain, and (4) many HCPs do not feel knowledgeable about giving weight loss advice.

Despite knowing benefits of weight loss, most people find the process tough. Achieving an "ideal" BMI is not necessary and may not be a realistic goal. Modest weight loss of even 3% to 5% of starting weight can have clinical benefits, and greater weight losses produce greater benefits.[10] In general, the average weight loss program (except for bariatric surgery) results in a 10% reduction of body weight. This average should not be considered a failure since it is associated with significant health benefits.[10]

Exploring a person's motivation for weight loss is essential for overall success. Using principles from motivational interviewing (see Chapter 4), you can help patients understand their desire to lose weight and gain confidence in achieving weight loss.

Focusing on the reasons for wanting to lose weight may help patients develop strategies for a weight loss program. Any supervised plan of care must be directed at 2 different processes: (1) successful weight loss, which requires a short-term energy deficit, and (2) successful weight control, which requires long-term behavior changes.

Together with other members of the interprofessional care team, you have a key role in planning for and managing the care of an obese patient. A holistic approach for weight loss must be used that includes nutritional therapy, exercise, behavior modification, and, for some, drugs or surgical intervention (Table 40.7). Combining more than one aspect supports more effective weight loss and weight control efforts. While teaching patients, stress healthy eating habits and adequate physical activity as lifestyle patterns to develop and maintain.

Promoting Population Health

Maintaining a Healthy Weight

- Weigh yourself regularly.
- Consume 5 or more servings of fruits and vegetables daily.
- Choose whole grain foods, such as brown rice and whole wheat bread.
- Avoid highly processed foods made with refined white sugar, flour, and saturated fat.
- Avoid foods that are high in "energy density" or have a lot of calories in a small amount of food.
- Take part in physical activity:
    - 150 minutes of moderate-intensity aerobic activity (i.e., brisk walking) every week
    - Muscle-strengthening activities on 2 or more days a week

Nutritional Therapy

There are no "magic" diets for weight loss. No one diet is superior for weight loss. All diets can work if they reduce caloric intake compared to expenditure and are one to which the patient will adhere.[11] The ability to adhere to a diet and degree of weight loss strongly depends on the patient's motivation. Restricting dietary intake so that it is below energy requirements is a cornerstone for any weight loss or maintenance program. Table 40.8 presents an example of a 1200-calorie diet. It is best to recommend a dietary approach in which calorie restriction includes all food groups. In general, recommend a diet that includes adequate amounts of fruits and vegetables, gives enough bulk to prevent constipation, and meets daily vitamin A and vitamin C requirements. Lean meat, fish, and eggs provide sufficient protein and the B-complex vitamins. Patients will find it easier to incorporate such a change into their lifestyle and not become as bored with their food options.

TABLE 40.7 Interprofessional Care Obesity

Diagnostic Assessment

- History and physical examination
- Family history
- BMI, waist circumference, waist-to-hip ratio
- Assessment of health risks and co-morbidities

Management

- Management of co-morbidities
- Lifestyle interventions
    - Taking part in weight loss program
    - Support groups
    - Behavior modification
    - Nutritional therapy
    - Exercise
    - Behavior modification
    - Support groups
    - Drug therapy (Table 40.9)
    - Surgical therapy (Table 40.10)

A very-low-calorie diet plan that limits calories to a total of 800 or less per day may be prescribed if rapid weight loss is needed.[11] These diets are not sustainable on a long-term basis. They should be provided only by trained professionals in a medical care setting. Persons on very-low-calorie diets need frequent professional monitoring because the severe energy restriction places them at risk for multiple health complications.

Many people try to lose weight by following one of the many fad diets that offer the enticement of quick weight loss with little effort. Often, these quick weight-reduction diets (found in the popular media) advocate eliminating one category of foods (e.g., carbohydrates). Therefore these should be discouraged. Low-

carbohydrate diets do produce a rapid weight loss but reduce the ability to get adequate amounts of fiber, vitamins, and minerals. Restrictive diets are hard to maintain on a long-term basis. The more restrictive the diet, the greater the demand for intense discipline in the face of an intense desire to eat foods not allowed on the diet.

The degree of success of any diet depends in part on the amount of weight to be lost. A moderately obese person will obviously reach a weight goal more easily than a person with extreme obesity. Because men have a higher percent of lean body mass, they are often able to lose weight more quickly than women. Women have a higher percent of body fat, which is metabolically less active than muscle tissue. Postmenopausal women are particularly prone to weight gain, especially increased abdominal fat.

TABLE 40.8 Nutritional Therapy 1200-Calorie–Restricted Weight-Reduction Diet

General Principles

1. Eat regularly. Do not skip meals.
2. Measure foods to determine the correct portion size.
3. Avoid concentrated sweets, such as sugar, candy, honey, pies, cakes, cookies, and regular sodas.
4. Reduce fat intake by baking, broiling, or steaming foods.
5. Maintain a regular exercise program for successful weight loss.

Sample Meal Plan

Meal	Exchanges	Menu Plan
Breakfast	1 meat	1 hard-boiled egg
	2 breads	1 slice toast
		¾ cup dry cereal (unsweetened)
	1 fruit	½ small banana
	1 fat	1 tsp margarine
	1 dairy	1 cup low-fat milk
	Beverage	Coffee
Lunch	2 meats 2 breads Vegetable	Cheese enchiladas (made with 2 oz cheese, 2 corn tortillas, lettuce, chili sauce)
	1 fruit	Fresh grapes (12)
	Beverage	Diet soda
Dinner	2 meats	2 oz baked chicken
	1 bread **1 fat**	Corn on the cob with 1 tsp margarine
	Vegetable	Tossed salad and 1 Tbsp salad dressing
	1 fruit	¾ cup strawberries
	1 milk	1 cup low-fat milk

Setting a realistic and healthy goal, such as losing 1 to 2 lb per week, should be mutually agreed on at the beginning of a weight loss program. Trying to lose too much too fast usually results in a sense of frustration and failure for the patient. You can help patients understand that losing large amounts of weight in a short period causes skin and underlying tissue to lose elasticity and tone. Slower weight loss offers better cosmetic results.

Inevitably, the patient reaches plateau periods during which no weight is lost. These plateaus may last from several days to several weeks. Remind the patient that plateaus are normal occurrences during weight reduction. A weekly check of body weight is a good method of monitoring progress. Daily weighing is not recommended because of fluctuations that result from retained water (including urine) and feces. Teach the patient to record the weight at the same time of the day, wearing the same type of clothing.

Evidence-Based Practice

Obesity Interventions and Faith-Based Organizations

J.W. is a 39-yr-old black woman who is 5 ft, 6 in tall and weighs 196 lb. You work in the clinic that she visits for health care. Your clinic is referring patients who would benefit from losing weight to community and hospital-based weight loss programs. She tells you she has been trying to lose weight by "watching what she eats" and that she is "not sure what else she can do." In further talks with her, you learn she is an active member of her neighborhood church.

Making Clinical Decisions

Best Available Evidence. Obesity is highest among racial and ethnic minority groups in the United States. Many faith-based organizations (FBOs) provide programs that have helped obese persons improve weight-related behaviors (e.g., increase in physical activity and fruit and vegetable intake) and lose weight. Successes in these programs have been more notable for females. Overall, programs that offer comprehensive and intensive behavioral interventions for weight loss are an option for weight management.

Clinician Expertise. You know it is important for J.W. to engage in a weight loss program that will help her to adopt and maintain healthy behaviors. You also know that FBOs can play a major role in providing health promotion programs in the black community.

Patient Preferences and Values. J.W. says she is interested in learning about a weight loss program at her church.

Implications for Nursing Practice

1. Why is it important to discuss with J.W. her motivation for starting a weight loss program at her church?
2. How will you help J.W. to set realistic short- and long-term goals related to weight loss? How may these goals differ?
3. At each clinic visit, how will you support J.W.'s efforts to lose weight?

There is no clear consensus on the number of meals a person on a diet should eat. Some advocate several small meals per day because the body's metabolic rate is temporarily increased right after eating. However, patients eating several small meals a day might consume more calories unless they carefully adhere to portion sizes and total daily calorie allotment.

When a person first starts a weight loss program, food portion sizes must be carefully determined to stay within the dietary guidelines. Portion sizes over the past 40 years have increased considerably (Table 40.2). Food portions can be weighed using a scale, or everyday objects can be used as a visual cue to determine portion sizes. The size of a woman's fist or a baseball is equivalent to a serving of vegetables or fruit. The recommended portion size of meat is 3 oz. This is about the size of a person's palm or a deck of cards. A serving of cheese is about the size of a thumb or 6 dice. The standard size for chopped vegetables is ½ cup, according to MyPlate guidelines (see Table 39.9). A portion size quiz is available at *www.nhlbi.nih.gov/health/educational/wecan/eat-right/portion-distortion.htm*.

Another aspect of the American diet to consider is which foods contribute the most calories—animal sources, fruits, grains, or vegetables. Two thirds or more of a person's diet should be plant-source foods, and the other one third or less should be from animal protein. Being aware of personal consumption habits and striving for the two-thirds to one-third ratio is a simple goal that one can achieve

without weighing and measuring foods at every meal. Once this ratio is part of meal planning, the patient can gradually reduce portions as they gradually increase activity levels to achieve healthy weight loss. A list of healthy or low-calorie foods serves as a good reference and allows the patient to dine out on occasion. Furthermore, the patient who carefully follows the prescribed diet may not need to take vitamin supplements.

Encourage the appropriate fluid intake in the form of water. Alcoholic and sugary beverages should be limited or avoided, since they increase caloric intake and are low in nutritional value.

Exercise

Exercise is an essential part of a weight loss program. Patients should exercise daily, preferably 30 minutes to an hour, with a goal of more than 10,000 steps per day.[11] There is no evidence that increased activity promotes an increase in appetite or leads to dietary excess. In fact, exercise has the opposite effect. The addition of exercise results in more weight loss than dieting alone and has a favorable effect on body fat distribution.

The type of exercise (e.g., high intensity versus low intensity) does not seem to affect overall weight loss. More intensive activity may result in weight loss with a reduced time commitment, making it preferable to some people. Exercise is especially important in supporting weight loss. Higher levels of physical activity, 200 to 300 minutes per week, are recommended to maintain weight loss or minimize weight regain in the long term.[11]

Explore ways to incorporate exercise in daily routines. It may be as simple as parking farther from their place of employment or taking the stairs versus an elevator. Encourage a person to use a pedometer to track progress toward meeting the 10,000 steps a day goal. However, success may be walking one third of the recommended steps with incremental increases over time. Patients can swim and cycle, which both have long-term benefits. Joining a health club can be another way of getting exercise. Stress to patients that engaging in weekend exercise only or in spurts of strenuous activity is not helpful

and can be dangerous.

Behavior Modification

The assumptions behind behavior modification are: (1) obesity is a learned disorder caused by overeating and (2) often the critical difference between an obese person and a person of normal weight is the cues that regulate eating behavior. Therefore most behavior-modification programs deemphasize the diet and focus on how and when to eat. Ideally, behavior intervention should begin with counseling sessions with a trained interventionist. Persons who are in a behavioral therapy program are more successful in maintaining their losses over an extended time than those who do not take part in such training.[12]

Various behavioral techniques for patients engaged in a weight loss program include (1) self-monitoring, (2) stimulus control, and (3) rewards. *Self-monitoring* may involve keeping a record of the type and time food was consumed, what the person was doing, and how the person was feeling when eating. By looking at the cues and events before eating, the person can identify areas in which to make behavior changes to break the chain of events and prevent overeating. These eating behaviors must be changed, or any weight loss will only be temporary.

Stimulus control is aimed at eliminating cues in the environment that trigger eating. For example, if the patient overeats while watching television, limiting eating to a certain area (e.g., kitchen table) can be an effective way to weaken the link between eating and television watching. The more often the person does not eat in front of the television, the less likely television watching will trigger overeating.

Rewards may be incentives for weight loss. Short- and long-term goals are useful benchmarks for earning rewards. It is important that the reward for a specified weight loss not be associated with food, such as dinner out or a favorite treat. Reward items do not need to have a monetary component. For example, time for a hot bath or an hour of pleasure reading would be an enjoyable reward for many people. Praise your patient's successes, even small ones, at every

opportunity. Changing existing behaviors is hard.

Support Groups

People who are on a weight management plan are often encouraged to join a group in which others are also trying to change their eating habits. Many self-help groups offer support and information on dieting tips. For example, Take Off Pounds Sensibly (TOPS) *(www.tops.org)* is the oldest nonprofit organization of this type. Behavior modification is an integral part of the program, along with nutrition education. Weight Watchers International *(www.weightwatchers.com)*, Jenny Craig *(www.jennycraig.com)*, and Nutrisystem *(www.nutrisystem.com)* are probably the most successful commercial weight-loss programs.[13] Weight Watchers offers a food plan that is nutritionally balanced and practical to follow. Group leaders, all of whom have successfully lost weight with Weight Watchers, teach members various behavior-modification techniques.

There are many commercial weight-reduction centers. Most programs are staffed by nurses and dietitians. These weight-reduction centers are cost prohibitive for those with limited financial resources. Most programs offer special prepackaged foods and supplements that a person must buy as part of the weight-reduction plan. The person only consumes these prescribed foods and drinks until an agreed-on amount of weight is lost. The person is encouraged to buy the same type of foods for the maintenance phase of the program, lasting from 6 months to 1 year. Behavior-modification training is part of these programs. People must learn how to adjust their diet once they are no longer using the commercial products. This can be challenging for many. The person may regain weight lost once the restricted food program is completed.[13]

In recent years, many employers have begun weight loss programs at the workplace. The reason for such programs is that better health repays the cost of the programs through improved work performance, decreased absenteeism, less hospitalization, and lower insurance costs. Both employees and employers report benefiting from such programs.

Drug Therapy

Drugs should never be used alone. Rather, drugs should be part of a comprehensive weight loss program that includes reduced-calorie diet, exercise, and behavior modification. They should be reserved for adults with a BMI of 30 kg/m^2 or greater (obese) or adults with a BMI of 27 kg/m^2 or greater (overweight) who have at least 1 weight-related condition, such as hypertension, type 2 diabetes, or dyslipidemia.[10,14] There are currently 5 obesity drugs for long-term management approved by the FDA (Table 40.9).

Appetite-Suppressing Drugs

Sympathomimetic amines suppress appetite by increasing the availability of norepinephrine in the brain, thus stimulating the CNS. Sympathomimetics fall into 2 groups: amphetamines and nonamphetamines. Amphetamines have a much higher abuse potential than nonamphetamines. The FDA does not recommend or approve amphetamines for either short- or long-term weight loss.

We usually do not use nonamphetamines for weight loss because of the potential for abuse. If used, they should be used only short term (for 3 months or less). These drugs include phentermine (Adipex, Lomaira, Suprenza), diethylpropion (Tenuate), and phendimetrazine (Bontril). Adverse effects include palpitations, tachycardia, overstimulation, restlessness, dizziness, insomnia, weakness, and fatigue.

Nursing Interventions Related to Drug Therapy

Drugs will not cure obesity. People must understand that without substantial changes in food intake and increased physical activity, they will gain weight when drug therapy is stopped.

As with any drug treatment, there are side effects (Table 40.9). Careful evaluation for other medical conditions can help determine which drugs, if any, would be advisable for a given patient. Many insurance companies do not cover the cost of weight loss drugs.

Your role related to drug therapy is to teach the patient about

proper administration, side effects, and how the drugs fit into the overall weight loss plan. Changing drug dosages without consultation with the HCP can have detrimental effects. Stress that diet and exercise plans are the cornerstones of permanent weight loss. Finally, discourage patients from buying over-the-counter diet aids unless recommended by an HCP.

Bariatric Surgical Therapy

Bariatric surgery, surgery on the stomach and/or intestines to help a person with extreme obesity lose weight, has become a viable option for treating obesity. Surgery is currently the only treatment that has a successful and lasting impact for sustained weight loss for those with extreme obesity.[15]

Criteria guidelines for bariatric surgery include having a BMI of 40 kg/m^2 or more or a BMI of 35 kg/m^2 or more with other significant co-morbidities (e.g., hypertension, type 2 diabetes, heart failure, sleep apnea).

TABLE 40.9 Drug TherapyObesity

Drug	Mechanism of Action	Nursing Considerations
bupropion/naltrexone (Contrave)	• *bupropion:* antidepressant • *naltrexone:* opioid antagonist	• Common side effects: nausea, constipation, headache, dizziness, insomnia, dry mouth • Suicidal thoughts and behaviors and neuropsychiatric reactions can occur • Can increase BP and heart rate. Should not be used in patients with uncontrolled hypertension • Can cause seizures. Must not be used in patients who have seizure disorder
liraglutide (Saxenda)	• Glucagon-like peptide 1 (GLP-1) agonist • Induces satiety	• Used to treat type 2 diabetes • Injected • Side effects: thyroid tumors, pancreatitis
lorcaserin (Belviq)	• Selective serotonin (5-HT) agonist • Suppresses appetite and creates a sense of satiety	• Side effects: headache, dizziness, fatigue, nausea, dry mouth, constipation
orlistat (Xenical, Alli [low-dose form available over the counter])	• Blocks fat breakdown and absorption in intestine • Inhibits the action of intestinal lipases, resulting in undigested fat excreted in feces	• Associated with stool leakage, flatulence, diarrhea, abdominal bloating, especially if a high-fat diet is consumed • Severe liver injury may occur • May need fat-soluble vitamin supplements
phentermine/topiramate ER (Qsmyia)	• *phentermine*: Sympathomimetic • *topiramate:* Decreases appetite	• Common side effects: dizziness, insomnia, dry mouth • Do not use in patients with glaucoma or hyperthyroidism • Must avoid pregnancy • Can increase heart rate. Should not be used in patients with uncontrolled hypertension or heart disease

Most people who undergo bariatric surgery successfully improve their overall quality of life. In addition to losing weight, outcomes include improved glucose control with improvement or reversal of diabetes, normalization of BP, decreased total cholesterol and triglycerides, decreased GERD, and decreased sleep apnea.[16]

Insurance coverage for bariatric surgery varies. Those who cover surgery often require extensive documentation. This often includes taking part in a supervised weight loss program for around 6 months and a psychologic evaluation.

Although overall mortality is very low, several complications can arise from surgery. Therefore, having surgery is carefully considered. Candidates for surgery must be screened for psychologic, physical, and behavioral conditions that have been associated with poor surgical outcomes. These include untreated depression, binge eating disorders, and drug and alcohol abuse that may interfere with a commitment to lifelong behavioral changes. Other contraindications to surgery include illnesses that are known to reduce life expectancy and are not likely to improve with weight reduction. These include advanced cancer; end-stage kidney, liver, and cardiopulmonary disease; severe coagulopathy; or inability to follow nutritional recommendations.

Bariatric surgeries fall into 1 of 3 broad categories: restrictive, malabsorptive, or a combination of malabsorptive and restrictive (Table 40.10 and Fig. 40.7). In *restrictive procedures,* the stomach is reduced in size (less food eaten). In *malabsorptive procedures,* the small intestine is shortened or bypassed (less food absorbed). Most procedures are done laparoscopically. These patients have fewer wound infections, shorter hospital stays, and a faster recovery period.

Restrictive Surgeries

Restrictive bariatric surgery reduces either the size of the stomach, which causes the patient to feel full more quickly, or the amount allowed to enter the stomach. In these surgeries, digestion is not altered, so the risk for anemia or cobalamin deficiency is low. The most common restrictive surgeries include adjustable gastric banding and sleeve gastrectomy.

Adjustable Gastric Banding

Laparoscopic *adjustable gastric banding* (AGB) involves limiting the stomach size with an inflatable band placed around the fundus of the stomach (Fig. 40.7, *A*). This restrictive procedure can be done using a Lap-Band or Realize Band system. The band is connected to a subcutaneous port that can be inflated or deflated (by fluid injection in the HCP's office) to change the stoma size to meet the patient's needs as weight is lost. The restrictive effect of the band creates a sense of fullness as the upper part of the stomach now accommodates less than the average stomach. The band then causes a delay in stomach emptying, providing patients with further satiety.

The procedure can be either modified or reversed at a later date, if needed. AGB is the preferred option for patients who are surgical risks because it is a less invasive approach. Because it is restrictive only, patients must follow a strict diet to lose weight and not regain weight.

Sleeve Gastrectomy (Gastric Sleeve)

In the sleeve gastrectomy (gastric sleeve), about 75% of the stomach is removed, leaving a sleeve-shaped stomach (Fig. 40.7, *B*). Although the stomach is drastically reduced in size, its function is preserved. Removing most of the stomach results in the elimination of hormones made in the stomach that stimulate hunger, such as ghrelin.

Research is ongoing on a new procedure called *endoscopic sleeve gastroplasty*. It involves using an endoscope rather than making a surgical incision. When the endoscope reaches the stomach, the surgeon places sutures in the stomach, making it smaller and changing its shape.

Gastric Plication

Gastric plication is a minimally invasive weight-loss surgery that reduces the size of the stomach. It is done by folding the stomach wall inward, and then sutures are placed to secure the folded stomach wall. This reduces the stomach volume by as much as 70%. An advantage is reversibility, since there is no gastric resection.

TABLE 40.10 Surgical Therapy for Obesity

Description	Advantages	Disadvantages
Restrictive Surgery		
Adjustable Gastric Banding (AGB) (Lap-Band, Realize Band) (Fig. 40.7, A)		
• **Inflatable band encircles stomach** • **Creation of gastric pouch with about 30 mL (1 oz) capacity** • **Later stretches to 60–90 mL (2–3 oz)** • **Upper gastric pouch connected by very narrow channel to lower section of stomach**	• Food digestion occurs through normal process • Band can be adjusted to ↑ or ↓ restriction • Can be reversed • Absence of dumping syndrome • Lack of malabsorption • Low complication rate	• Some nausea and vomiting initially (eating too much too quickly) • Food intolerance, gastric dysmotility, regurgitation • Problems with adjustment device • Band may slip or erode into stomach wall • Gastric perforation or obstruction may occur, requiring surgery • Weight loss may be more limited than with other types of surgery
Sleeve Gastrectomy (Gastric Sleeve) (Fig. 40.7, B)		
• **About 75% of stomach removed** • **Creation of sleeve-shaped stomach with 60–150 mL (2–5 oz) capacity**	• Function of stomach preserved • No bypass of intestine • Avoids complications of obstruction, anemia, vitamin deficiencies	• Weight loss may be more limited than with other types of surgery • Leakage related to stapling • Irreversible
Gastric Plication		
• **Adapted version of sleeve gastrectomy (gastric sleeve)** • **Sleeve created by suturing rather than removing stomach**	• Minimal surgery compared to sleeve gastrectomy • No rerouting of intestines • Maintains natural nutrient absorption capabilities	• Requires hospital stay of 24–48 hr • Nausea common after procedure • Risks include stomach leakage from sutured areas, blockage of stomach from swelling or fold too tight
Intragastric Balloon		
• **Involves placing a deflated balloon into stomach** • **Balloon then filled with saline and occupies space in stomach**	• Most are placed endoscopically as an outpatient procedure • Does not require invasive surgery	• Can only be left in place for 6 mos • Once device is in stomach, patients may have nausea, vomiting, abdominal pain, indigestion, gastric ulcers
Malabsorptive Surgery		
Biliopancreatic Diversion (BPD) With or Without Duodenal Switch (Fig. 40.7, C)		
• **70% of the stomach removed horizontally** • **Anastomosis between stomach and intestine** • **Decreases the amount of small intestine available for nutrient absorption** • **Duodenal switch cuts the stomach vertically and is shaped like a tube**	• Able to eat larger meals than with gastric bypass or banding procedures • Less food intolerance • Rapid weight loss • Greater long-term weight loss	• Abdominal bloating, diarrhea, foul-smelling gas (steatorrhea) • 3 or 4 loose bowel movements a day • Malabsorption of fat-soluble vitamins • Iron deficiency • Protein-calorie malnutrition • Dumping syndrome • Most complicated of weight loss surgeries
Combination of Restrictive and Malabsorptive Surgery		
Roux-en-Y Gastric Bypass (RYGB) (Fig. 40.7, D)		
• **Surgery on stomach to create a pouch (restrictive)** • **Small gastric pouch connected to jejunum** • **Remaining stomach and first segment of small intestine are bypassed (malabsorptive)**	• Better weight loss results than with restrictive procedures • Lower incidence of malnutrition and diarrhea • Rapid improvement of weight-related co-morbidities • Good long-term results	• Leak at site of anastomosis • Anemia: iron deficiency, cobalamin deficiency, folic acid deficiency • Calcium deficiency • Dumping syndrome • Irreversible
Implanted Gastric Stimulation Device		
Maestro Rechargeable System (Fig. 40.8)		
• **Device implanted into abdomen** • **Works like a pacemaker to deliver electrical impulses to vagus nerve, which tells brain when stomach is full**	• Least invasive of weight loss surgeries • Procedure done on outpatient basis	• Device must be charged 1–2 times/wk • If battery completely drained, device needs to be reprogrammed • Side effects include nausea, vomiting, heartburn, belching, swallowing problems

Intragastric Balloons

Intragastric balloon weight-loss systems use a gastric balloon to occupy space in the stomach. The balloon does not change or alter the

stomach's natural anatomy. It is designed to help patients feel more full, curb the appetite, and reduce food intake. Patients should follow a diet and exercise plan to help with weight loss efforts.

The balloons are less invasive than having gastric bypass surgery. Most are placed endoscopically, while the patient is under mild sedation. The HCP places the balloon into the stomach through the mouth. Once in place, the balloon is filled with saline so that it expands. The balloon can be filled with different amounts of saline (from 400 to 700 mL).

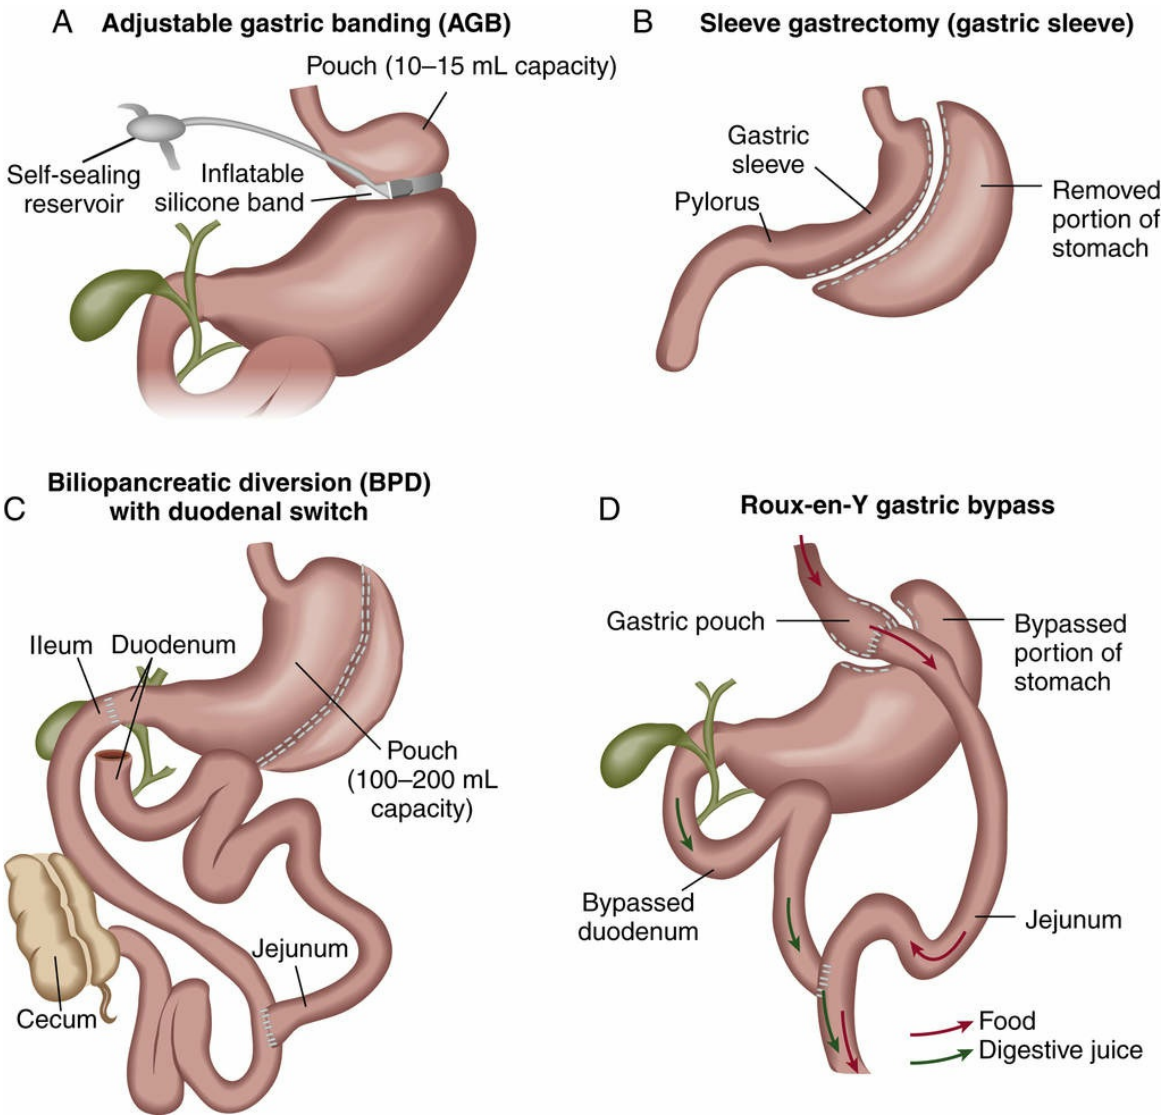

FIG. 40.7 Bariatric surgical procedures. **A,** Adjustable gastric banding (AGB) uses a band to create a gastric pouch. **B,** Sleeve gastrectomy involves creating a sleeve-shaped stomach by removing about 75% of the stomach. **C,** Biliopancreatic diversion (BPD) with duodenal switch procedure creates an anastomosis between the stomach and intestine. **D,** Roux-en-Y gastric bypass procedure involves constructing a gastric pouch whose outlet is a Y-shaped limb of small intestine.

With newer balloons, the patient swallows the balloon in a capsule that is attached to a microcatheter. The balloon is inflated with nitrogen gas through the microcatheter. After inflation, the catheter is detached and removed, leaving the balloon in the stomach.[17] When it is time to remove a balloon, it is first deflated and then removed using another endoscopic procedure.

Balloons should not be used in patients who have had gastrointestinal or bariatric surgery or who have inflammatory bowel disease, large hiatal hernia, delayed gastric emptying, or active *Helicobacter pylori* infection. Patients may have vomiting, nausea, abdominal pain, and feelings of indigestion. Other potential risks are gastric ulcers and balloon deflation.

Combination of Restrictive and Malabsorptive Surgery

Roux-en-Y Gastric Bypass

The Roux-en-Y gastric bypass (RYGB) procedure is a combination of restrictive and malabsorptive surgery. This surgical procedure is the most common bariatric procedure done in the United States. It is considered the gold standard among bariatric procedures. Overall, it has low complication rates, has excellent patient tolerance, and sustains long-term weight loss.

The RYGB involves creating a small gastric pouch and attaching it directly to the small intestine using a Y-shaped limb of the small bowel (Fig. 40.7, *D*). After the procedure, food bypasses 90% of the stomach, the duodenum, and a small segment of jejunum.

A complication of the RYGB is *dumping syndrome,* in which gastric contents empty too rapidly into the small intestine, overwhelming its ability to digest nutrients. Symptoms can include vomiting, nausea, weakness, sweating, faintness, and, on occasion, diarrhea. Patients are discouraged from eating sugary foods after surgery to avoid dumping syndrome. Because sections of the small intestine are bypassed, poor absorption of iron can cause iron-deficiency anemia. Patients need to take a multivitamin with iron and calcium supplements. Chronic anemia caused by cobalamin deficiency may occur. This problem can usually be managed with parenteral or intranasal cobalamin.

Implantable Gastric Stimulation

An implantable gastric stimulation device (e.g., Maestro Rechargeable

System) consists of a pacemaker-like electrical pulse generator, wire leads, and electrodes that are implanted in the abdomen (Fig. 40.8). The Maestro System works by sending intermittent electrical pulses to the vagus nerve, which is involved in regulating stomach emptying and signaling to the brain that the stomach feels empty or full. External controllers allow the patient to charge the device and allow HCPs to adjust the device's settings to provide optimal therapy. Adverse events include nausea, heartburn, problems swallowing, belching, and chest pain.

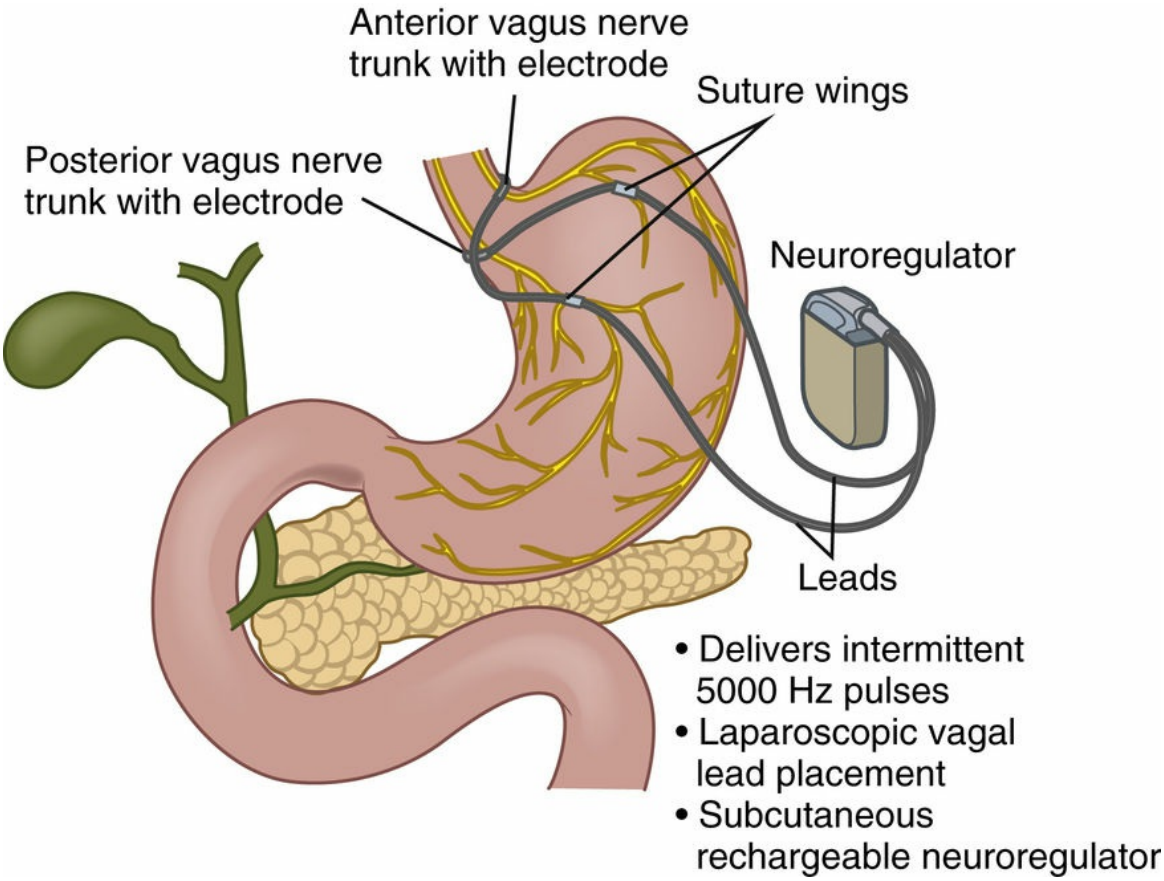

FIG. 40.8 The Maestro Rechargeable System is an electrical stimulator that is surgically implanted into the abdomen. It works by sending intermittent electrical pulses to the vagus nerve, which is involved in regulating stomach emptying and signaling to the brain that the stomach feels empty or full.

Nursing Management: Perioperative Care of The Obese Patient

Nursing Implementation

This section discusses general nursing considerations for the care of the obese patient who is having surgery. Special nursing considerations are described for the patient who is having bariatric surgery (Table 40.11). See Chapters 17 through 19 for more on care of the surgical patient.

Preoperative Care

Special considerations are needed for the obese patient, especially the patient with extreme obesity, who is having surgery. Before surgery, interview the patient to identify past and current health information and any assistive devices currently in use (e.g., continuous positive airway pressure [CPAP] for sleep apnea). Co-morbidities related to obesity increase the risk for complications in the perioperative period. You may need to coordinate care with the patient's specialists.

Have a plan in place before the patients arrive so that they receive optimal care and do not feel like they are a burden to the nursing staff. You must have available appropriate-size hospital gowns, beds that accommodate an increased body size, and necessary patient transfer equipment. A larger BP cuff size is needed to avoid measurement errors. Ensure that an oversized BP cuff is available and placed in the patient's room.

Consider how the patient will be weighed and transported throughout the hospital. A wheelchair with removable arms that is large enough to safely accommodate the patient and pass easily through doorways should be available.

You may need to use alternative assessment techniques to perform assessment of heart, lung, and bowel sounds. For example, because of the large chest wall, breath and heart sounds are often distant. You can use an electronic stethoscope to amplify lung, heart, and bowel sounds.

Teach the patient proper coughing and deep breathing techniques and methods of turning and positioning to prevent pulmonary complications after surgery. If possible, show how to use a spirometer before surgery. Spirometer use helps prevent and treat postoperative lung congestion. Practicing these strategies preoperatively can help the patient perform them correctly postoperatively. If the patient uses CPAP at home for sleep apnea, make arrangements for the use of a machine while the patient is hospitalized.

TABLE 40.11 Nursing ManagementCare of the Patient Undergoing Bariatric Surgery

Preoperative

- Assess for use of assistive devices. Note any physical limitations or mobility issues.
- Perform baseline assessment, including vital signs, pulse oximetry, height, weight, BMI, skin condition, nutrition status, and heart, lung, and bowel sounds.
- Assess baseline laboratory values and diagnostic test results (e.g., pulmonary function tests).
- Teach patient and caregiver about procedure and postoperative care. Review proper coughing and deep breathing techniques, incentive spirometer use, and methods of turning and positioning to prevent pulmonary complications.
- Explain the need for frequent assessment and interventions to prevent VTE.
- Have available proper-sized hospital gowns, beds, BP cuffs, and transfer equipment.

Immediate Postoperative

- Perform assessment and compare to baseline: vital signs, pulse oximetry, and heart and lung sounds.
- Assess abdominal wound for the amount and type of drainage, condition of the incision, and signs of infection.
- Observe for anastomosis leak (tachycardia, fever, tachypnea, chest and abdominal pain).
- Help patient turn, cough and deep breath, and use incentive spirometer at least every 2 hrs.
- Protect the incision against any straining that accompanies turning and coughing.
- Give pain medications as needed.
- Position the patient upright at a minimum of a 45-degree angle.
- Maintain IV and/or oral fluid intake and monitor urine output.
- Institute measures to prevent VTE.
- Nutrition
    - Start with room temperature water and low-sugar clear liquids.
    - Teach the patient to avoid drinking with a straw.
    - Begin with 15 mL every 10–15 minutes, gradually increase to 90 mL every 30 min.
    - Move to a low-fat, full-liquid diet after 48 hrs if tolerating clear liquids.
    - Observe for dehydration (thirst, decreased urine output, headache, dizziness).

Excess adipose tissue may make obtaining venous access difficult. A longer IV catheter is helpful (longer than 1 in) to go through the overlying tissue to the vein. It is important that the cannula is far enough into the vein so it is not dislodged or infiltrated.

Special Considerations for Bariatric Surgery

Ensure that the patient scheduled for bariatric surgery understands the surgical procedure. Your teaching depends on the type of

procedure and surgical approach (Table 40.10). Stress that we will frequently assess vital signs and general assessment to monitor for complications. Tell the patient that they will be assisted with ambulation soon after surgery and encouraged to cough and deep breathe to prevent pulmonary complications.

Postoperative Care

The initial postoperative care focuses on careful assessment and immediate intervention for cardiopulmonary complications, thrombus formation, anastomosis leaks, and electrolyte imbalances. The transfer from surgery may require many staff members. During the transfer, keep the patient's airway stabilized and give attention to managing the patient' pain. Maintain the patient's head at a 45-degree angle to reduce abdominal pressure and increase lung expansion.[18]

The body stores anesthetics in adipose tissue, thus placing patients with excess adipose tissue at risk for resedation. As adipose cells release anesthetics back into the bloodstream, the patient may become sedated after surgery. If this happens, be prepared to perform a head-tilt or jaw-thrust maneuver and keep the patient's oral and nasal airways open.

Diligence in turning and ambulation postoperatively will prevent complications from surgery. The patient will typically begin walking the evening after surgery and then at least 3 or 4 times each day. Assist the patient as needed. The patient may be reluctant to move or may not have the stamina to walk even a short distance. In either situation, you will need help moving an obese patient.

Obesity can cause a patient's breathing to become shallow and rapid. The extra adipose tissue in the chest and abdomen compresses the diaphragmatic, thoracic, and abdominal structures. This compression restricts the chest's ability to expand, preventing the lungs from working as efficiently as they would otherwise. The patient retains more CO_2 with less O_2 delivered to the lungs. This results in hypoxemia, pulmonary hypertension, and polycythemia.

After surgery, the risk for venous thromboembolism (VTE) is increased. Intermittent pneumatic compression devices or

compression stockings with low-dose heparin decrease the risk for VTE. Active and passive range-of-motion exercises are a frequent part of daily care.[18]

Wound infection, dehiscence, and delayed healing are potential problems for all obese patients. Assess the patient's skin for any complications related to wound healing. Keep skinfolds clean and dry to prevent dermatitis and bacterial or fungal infections.

Special Considerations for Bariatric Surgery

Patients have considerable abdominal pain after bariatric surgery (Table 40.11). Give pain medications as needed during the immediate postoperative period (first 24 hours). Be aware that pain could be from an anastomosis leak rather than typical surgical pain. Abdominal wounds require frequent observation for the amount and type of drainage, condition of the incision, and signs of infection. Monitor vital signs to help identify problems, such as infection or anastomosis leak.

Give room temperature water and low-sugar clear liquids as soon as the patient is fully awake and there is no evidence of any anastomosis leaks. Begin with 15-mL increments every 10 to 15 minutes. Gradually increase intake to a goal of 90 mL every 30 minutes by postoperative day 1. Teach the patient to avoid gulping fluids or drinking with a straw to reduce the incidence of air swallowing. The patient who tolerates clear liquids may begin a low-fat, full-liquid diet on postoperative day 3.

Ambulatory and Home Care

Special Considerations for Bariatric Surgery

The patient who has undergone major surgical treatment for obesity has not been successful in the past in following or maintaining a prescribed diet. Now the patient must reduce oral intake because of the anatomic changes from the surgical procedure. The patient must clearly understand the proper diet. A dietitian is usually part of the bariatric team and helps the patient with the transition to the new

diet.

Patients usually are discharged on a full-liquid diet. Within 10 to 14 days after surgery, depending on tolerance, the patient may begin a pureed or soft foods diet with vitamin supplementation. Most patients transition to the usual diet 4 to 6 weeks after surgery.[19]

The usual diet is high in protein and low in carbohydrates, fat, and roughage. It should consist of 6 small feedings daily. Many need a protein supplement once or twice a day for the first few months after surgery to meet their protein needs.[19] Patient should not consume fluids with meals. Fluids and foods high in carbohydrate tend to promote diarrhea and symptoms of dumping syndrome. Calorie-dense foods should be avoided to permit more nutritionally sound food to be consumed. Teach the patient to eat slowly and stop eating when feeling full.

Weight loss is considerable during the first 6 to 12 months. Although behavior modification is not necessarily an intended outcome with these surgical procedures, it becomes an unexpected secondary gain. For example, a person who has had bariatric surgery cannot overeat or binge eat without consequences (e.g., vomiting, abdominal pain). The patient may fail to lose weight if the stomach pouch is too large. An outlet that is much too small may result in the patient losing too much weight. Some patients have been known to overeat when they return home and gain rather than lose weight.

Stress the importance of long-term follow-up care, in part because of potential complications. Teach patients to inform the HCP of any changes in their physical or emotional condition. Nutritional deficiencies are expected after malabsorptive bariatric surgery, including anemia, vitamin deficiencies, and diarrhea. Patients should take multivitamins with folate, calcium, vitamin D, iron, and vitamin B_{12} for life.[20] Peptic ulcer formation, dumping syndrome, and small bowel obstruction may be seen late in the recovery and rehabilitation stage.

Informatics in Practice

Use of Smart Phone for Weight Loss

- Phone apps (e.g., My Fitness Pal) are available to help track calories, weight, exercise, and eating patterns.
- Tracking systems give immediate access to nutritional information for better dietary decision making.
- Some apps can scan the barcode of foods in the grocery store and give nutritional information.
- Calorie tracker apps can be used to monitor daily calorie intake and keep a record of weight loss progress.
- With text messaging, a phone "buddy" can provide support when a person's will power is lacking.
- Share progress with friends and family. Some weight loss apps sync with social media accounts so that a person can share milestones on Twitter and Facebook.

Several potential psychologic problems may arise after surgery. Assess social functioning, self-esteem, sexual life, and activities of daily living in follow-up care. Some patients feel guilty that they had to achieve weight loss by surgical intervention rather than by the "sheer willpower" of reduced dietary intake and exercise. Be ready to provide support and assist the patient in moving away from such negative feelings.

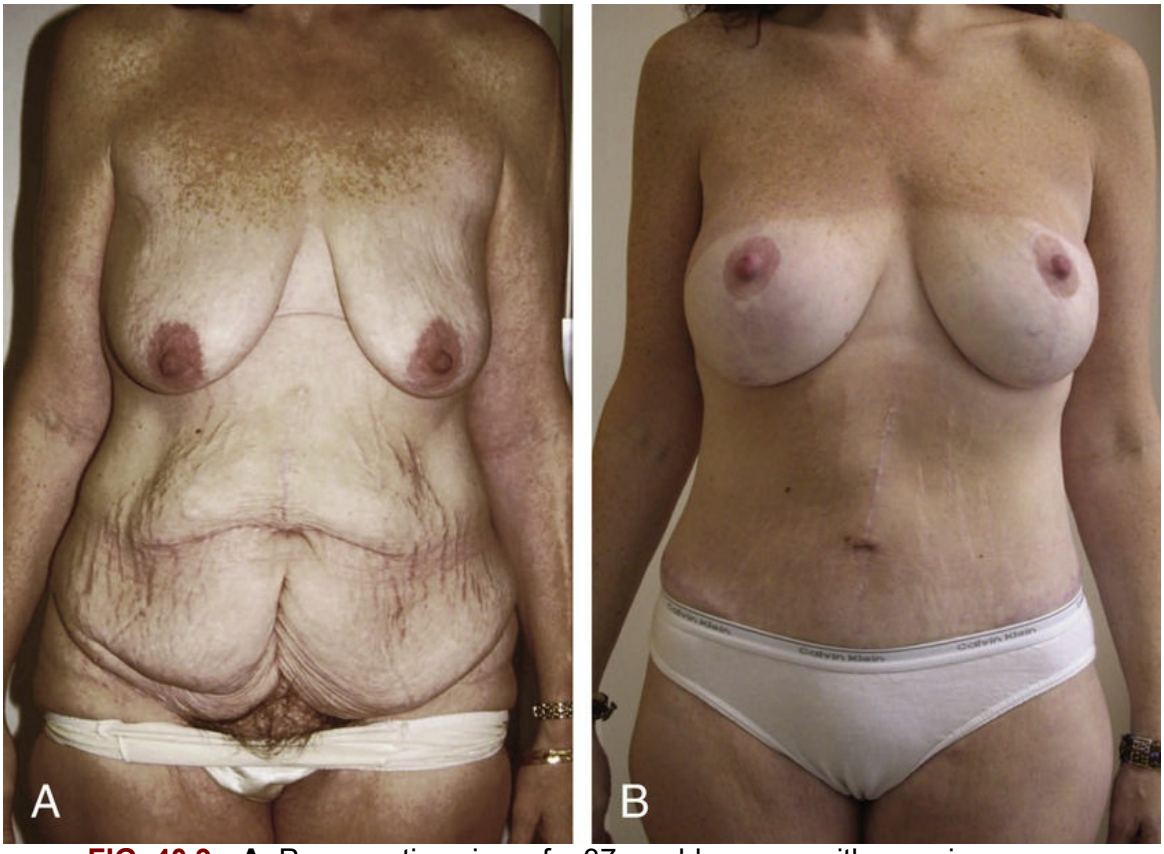

FIG. 40.9 **A,** Preoperative view of a 37-yr-old woman with massive weight loss who had gastric bypass surgery. **B,** Postoperative view 2½ years after abdominoplasty. She underwent breast surgery, thigh lift, back lift with excision of excess skin of the lower back and upper buttocks, and upper arm surgery.
From Shermak MA: Contouring the epigastrium, *Aesthet Surg J* 25:506, 2005.

By 6 to 8 months after surgery, most patients have lost considerable weight and are able to see how much their appearance has changed. Help the patient adjust to a new body image. Massive weight loss may leave the patient with large quantities of flabby skin that can result in problems related to altered body image (Fig. 40.9). Discuss this possible outcome with the patient before surgery and again during the rehabilitation phase. Cosmetic surgery may alleviate this situation. Do not hesitate to encourage counseling for unresolved psychologic issues.

Often one result of bariatric surgery is the return of fertility in women. Pregnancy complications can result from anemia and nutritional deficiencies. Furthermore, depending on the type of

surgery, intestinal obstructions and hernias may occur with pregnancy. Women must carefully consider the risk for pregnancy after bariatric surgery. In general, encourage women to postpone pregnancy for 12 to 18 months after bariatric surgery.

Check Your Practice

You are working in the bariatric surgery outpatient clinic. When you walk into the clinic room where a 36-yr-old woman is waiting for her follow-up visit, you find her distraught and crying. You ask her what is wrong. She responds, "I am a total failure. I have been fat all my life, and I had to have this horrible surgery to help me. Why couldn't I do it on my own?"

- What is an effective way for you to handle this situation?

Evaluation

The expected outcomes are that the obese patient will

- Have long-term weight loss
- Have improvement in obesity-related co-morbidities
- Integrate healthy practices into daily routines
- Monitor for adverse side effects of surgical therapy
- Have an improved self-image

Gerontologic Considerations: Obesity in Older Adults

The prevalence of obesity is increasing in older people. The number of obese older persons has markedly risen because of increases in both the total number of older persons and the percent of the older adults who are obese. Obesity is more common in older women than in older men. A decrease in energy expenditure is an important contributor to

a gradual increase in body fat with age.

Obesity in older adults can worsen age-related declines in physical function and lead to frailty and disability. Obesity is associated with decreased survival. Those who are obese live 6 to 7 years less than people of normal weight.

Obesity worsens many changes associated with aging. Excess body weight places more demands on arthritic joints. The mechanical strain on weight-bearing joints can lead to premature immobility. Excess intraabdominal weight can cause problems with urinary incontinence. Excess weight may contribute to hypoventilation and sleep apnea.

Obesity affects the quality of life for older adults. Weight loss can improve physical functioning and obesity-related health complications. The same therapeutic approaches for obesity discussed earlier also apply to the older adult.

Cosmetic Surgical Therapy

Lipectomy

Lipectomy (adipectomy) is done to remove unsightly flabby folds of adipose tissue (Fig. 40.9). There is no evidence that regeneration of adipose tissue occurs at the surgical sites. However, Stress to the patient that surgical removal does not prevent obesity from recurring, especially if lifetime eating habits stay the same. Although body image and self-esteem may improve with such procedures, these operations are not without complications. Do not underestimate the dangerous effects of anesthesia and the potential for poor wound healing in the obese patient.

Liposuction

Another cosmetic surgical procedure is liposuction, or suction-assisted lipectomy. It is used for cosmetic purposes and not for weight reduction. This surgical intervention helps improve facial appearance or body contours. A good candidate is a person who has achieved

weight reduction and has excess fat under the chin, along the jaw line, in the nasolabial folds, over the abdomen, or around the waist and upper thighs. A long, hollow, stainless steel cannula is inserted through a small incision over the fatty tissue to be suctioned. This surgical procedure is not usually recommended for an older person because the skin is less elastic and will not accommodate the new underlying shape.

Metabolic Syndrome

Metabolic syndrome is a group of metabolic risk factors that increase a person's chance of developing CVD, stroke, and diabetes. About 1 in 3 adults have metabolic syndrome. The syndrome is more prevalent in those 60 years of age and older.[21]

Metabolic syndrome is a cluster of health problems, including obesity, hypertension, abnormal lipid levels, and high blood glucose. Metabolic syndrome is diagnosed if a person has 3 or more of the conditions listed in Table 40.12.

Etiology and Pathophysiology

The main underlying risk factor for metabolic syndrome is insulin resistance related to excess visceral fat (Fig. 40.10). Insulin resistance is the decreased ability of the body's cells to respond to the action of insulin. The pancreas compensates by secreting more insulin, resulting in hyperinsulinemia.

TABLE 40.12 Criteria for Metabolic Syndrome

Any 3 of the 5 measures are needed to diagnose metabolic syndrome:

Measure	Criteria
Waist circumference	≥40 in (102 cm) in men
	≥35 in (89 cm) in women
Triglycerides	>150 mg/dL (1.7 mmol/L)
	OR
	Drug treatment for high triglycerides
HDL cholesterol	<40 mg/dL (0.9 mmol/L) in men
	<50 mg/dL (1.1 mmol/L) in women
	OR
	Drug treatment for high cholesterol
BP	≥130 mm Hg systolic BP
	OR
	≥85 mm Hg diastolic BP
	OR
	Drug treatment for hypertension
Fasting blood glucose	≥100 mg/dL
	OR
	Drug treatment for elevated glucose

Source: National Heart, Lung, and Blood Institute: How is metabolic syndrome diagnosed? Retrieved from *www.nhlbi.nih.gov/health/health-topics/topics/ms/diagnosis*.

Other characteristics include hypertension, increased risk for clotting, and abnormalities in cholesterol levels. The net effect of these conditions is an increased prevalence of coronary artery disease.

Clinical Manifestations and Diagnostic Studies

The signs of metabolic syndrome are impaired fasting blood glucose, hypertension, abnormal cholesterol levels, and obesity. Medical problems develop over time if the condition is not addressed. Patients with this syndrome are at a higher risk for heart disease, stroke, diabetes, renal disease, and polycystic ovary syndrome. Patients who have metabolic syndrome and smoke are at an even higher risk.

Nursing and Interprofessional Management: Metabolic Syndrome

There is no specific management of metabolic syndrome. Interventions focus on reducing the major risk factors of CVD and

type 2 diabetes: reducing LDL cholesterol, stopping smoking, lowering BP, losing weight, and reducing glucose levels. There are no specific medications for metabolic syndrome. Patients receive cholesterol-lowering and antihypertensive drugs as needed. Metformin (Glucophage) can lower glucose levels and enhance the cells' sensitivity to insulin. Obese patients may be candidates for bariatric surgery.

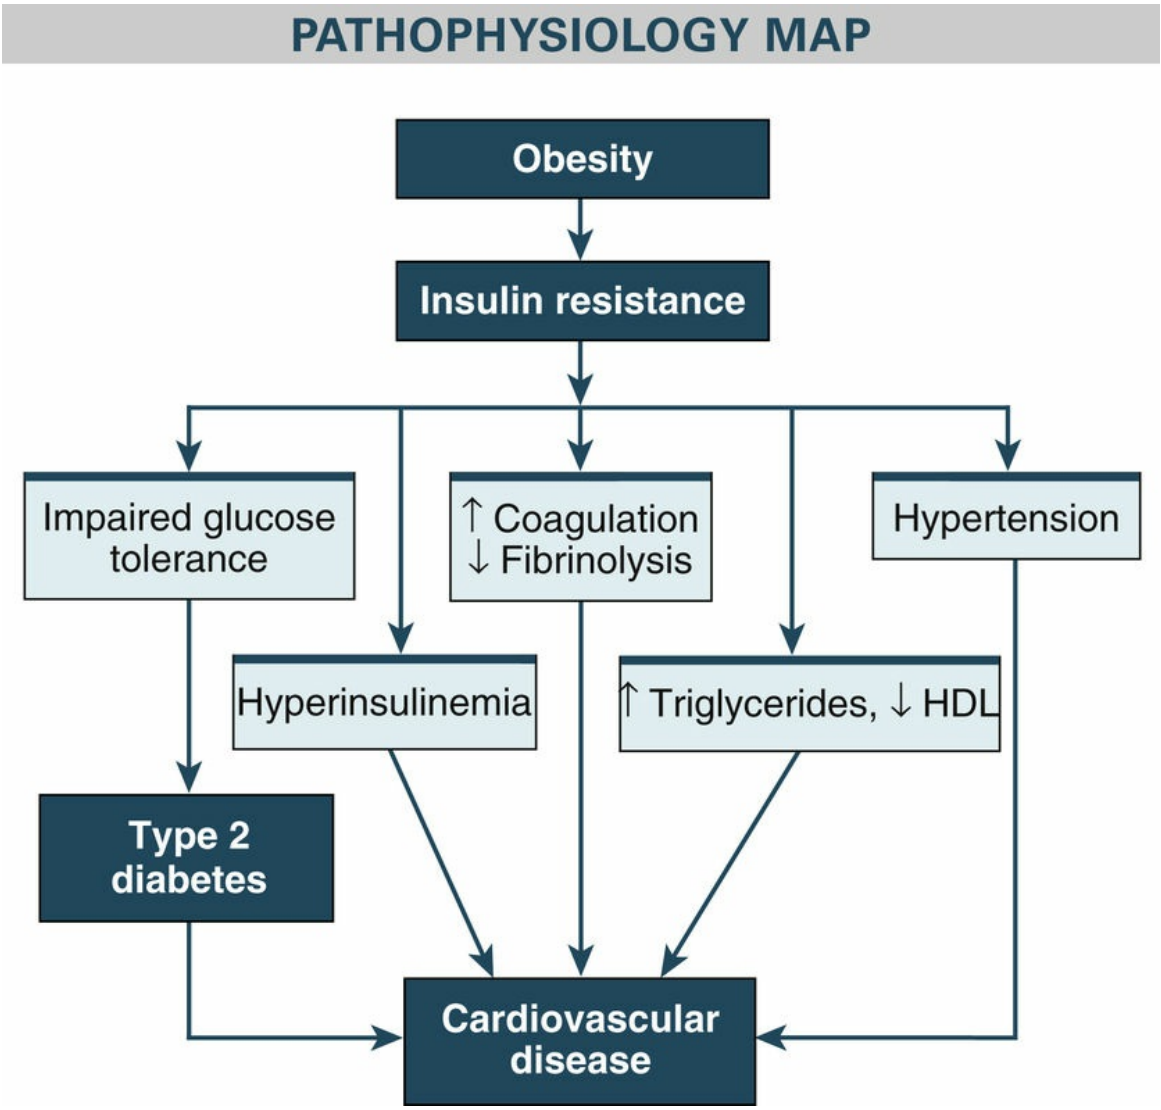

FIG. 40.10 Relationship among insulin resistance, obesity, diabetes, and CVD.

For long-term risk reduction, the person needs to maintain a healthy weight, increase physical activity, and follow healthy diet habits. You can help patients by giving information on healthy diets, exercise, and positive lifestyle changes. The diet, which should be low in saturated fats, should promote weight loss. Weight reduction and maintaining a lower weight are a priority in those with abdominal obesity and metabolic syndrome.

Because sedentary lifestyles contribute to metabolic syndrome, increasing regular physical activity will lower a patient's risk factors. In addition to helping with weight reduction, regular exercise decreases triglyceride levels and increases HDL cholesterol levels in those with metabolic syndrome.

Case Study

Obesity

Patient Profile

S.R. is a 48-yr-old white woman who comes to the clinic reporting hip pain.

Subjective Data

- States that it is “getting hard to get around”

- Reports gradual weight gain of 40 lbs over past 20 yrs
- Lives in a rural community with no sidewalks
- Spends her free time watching television
- Reports a history of type 2 diabetes, shortness of breath, hypertension, and osteoarthritis
- Had knee replacement surgery at age 46 for osteoarthritis
- Tried orlistat (Xenical) but hated the side effects

Objective Data
Physical Examination

- 5 ft, 6 in tall; weighs 230 lb; BMI 37 kg/m^2, waist circumference of 40 in
- Has obese, nontender, soft round, abdomen
- BP 160/100 mm Hg
- Moderate pain with range of motion of both hips

Laboratory Results

- Fasting blood glucose 250 mg/dL (13.9 mmol/L)
- Total cholesterol 205 mg/dL (5.3 mmol/L)
- Triglyceride 298 mg/dL (3.36 mmol/L)
- HDL cholesterol 31 mg/dL (0.8 mmol/L)
- LDL cholesterol 114 mg/dL

Interprofessional Care

- Referral to a community weight loss program
- Consultation with bariatric surgeon
- Diagnosed with bilateral osteoarthritis of the hips

Discussion Questions

1. What are S.R.'s risk factors for obesity?
2. Of the possible complications of obesity, which ones does S.R. have? Why did she develop them?
3. ***Patient-Centered Care:*** How would you help S.R. in designing a successful weight loss and weight management program?
4. ***Collaboration:*** How could a comprehensive community weight loss program be beneficial to S.R.?
5. What are S.R.'s risk factors for metabolic syndrome?
6. Is S.R. a candidate for bariatric surgery? Why or why not?
7. ***Evidence-Based Practice:*** S.R. tells you that she is not sure surgery will work for her. She asks you, "What is the best surgery for me?"

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which statement *best* describes the etiology of obesity?
   a. Obesity primarily results from a genetic predisposition.
   b. Psychosocial factors can override the effects of genetics in causing obesity.
   c. Obesity is the result of complex interactions between genetic and environmental factors.
   d. Genetic factors are more important than environmental factors in the etiology of obesity.
2. Health risks associated with obesity include *(select all that apply)*

a. colorectal cancer.
b. rheumatoid arthritis.
c. polycystic ovary syndrome.
d. nonalcoholic steatohepatitis.
e. systemic lupus erythematosus.

3. The obesity classification that is *most* often associated with cardiovascular health problems is
a. primary obesity.
b. secondary obesity.
c. gynoid fat distribution.
d. android fat distribution.

4. The *best* nutritional therapy plan for a person who is obese
a. is high in animal protein.
b. is fat-free and low in carbohydrates.
c. restricts intake to under 800 calories per day.
d. lowers calories with foods from all the basic groups.

5. This bariatric surgical procedure involves creating a gastric pouch that is reversible, and no malabsorption occurs. Which surgical procedure is this?
a. Vertical gastric banding
b. Biliopancreatic diversion
c. Roux-en-Y gastric bypass
d. Adjustable gastric banding

6. A patient with extreme obesity has undergone Roux-en-Y gastric bypass surgery. In planning postoperative care, the nurse anticipates that the patient

a. may have severe diarrhea early in the postoperative period.

b. will not be allowed to ambulate for 1 to 2 days postoperatively.

c. will require nasogastric suction until the drainage is pale yellow.

d. may have limited amounts of oral liquids during the early postoperative period.

7. Which criteria must be met for a diagnosis of metabolic syndrome? *(select all that apply)*

a. Hypertension

b. High triglycerides

c. Elevated plasma glucose

d. Increased waist circumference

e. Decreased low-density lipoproteins

1. c, 2. a, c, d, 3. d, 4. d, 5. d, 6. d, 7. a, b, c, d

Upper Gastrointestinal Problems

Kara Ann Ventura

LEARNING OUTCOMES

1. Describe the etiology, complications, and interprofessional and nursing management of nausea and vomiting.
2. Relate the etiology, clinical manifestations, and interprofessional and nursing management of common oral inflammations and infections.
3. Describe the etiology, clinical manifestations, complications, and interprofessional and nursing management of oral cancer.
4. Explain the types, pathophysiology, clinical manifestations, complications, and interprofessional and nursing management of gastroesophageal reflux disease and hiatal hernia.
5. Relate the pathophysiology, clinical manifestations, complications, and interprofessional management of esophageal cancer, diverticula, achalasia, and esophageal strictures.
6. Distinguish between acute and chronic gastritis, including the etiology, pathophysiology, and interprofessional and nursing management.
7. Compare and contrast gastric and duodenal ulcers, including the etiology, pathophysiology, clinical manifestations, complications, and interprofessional and nursing management.
8. Describe the clinical manifestations and interprofessional and nursing management of stomach cancer.

9. Explain the common etiologies, clinical manifestations, and interprofessional and nursing management of upper gastrointestinal bleeding.
10. Identify common types of foodborne illnesses and nursing responsibilities related to food poisoning.

Conceptual Focus

Fluids and Electrolytes
Nutrition
Pain
Sleep
Stress
Tissue Integrity

Several upper gastrointestinal (GI) problems and the care of the patient undergoing upper GI surgery are discussed in this chapter. These include nausea and vomiting, oral and gastric cancers, gastroesophageal reflux, ulcerative disease, inflammatory and infectious bowel disorders, GI bleeding, and structural problems. Conceptually, patients with impaired GI function may have malnutrition from impaired nutritional intake. Many are at risk for altered fluid, electrolyte, and acid-base balance. Problems with eating, drinking, or talking may cause pain and impair the ability to communicate. Pain can disrupt sleep and cause fatigue. Difficulty swallowing increases the risk for aspiration.

Nausea and Vomiting

Nausea and vomiting are the most common manifestations of GI disease. Although nausea and vomiting can occur independently, they are closely related and usually treated as one problem. **Nausea** is a feeling of discomfort in the epigastrium with a conscious desire to vomit. **Vomiting** is the forceful ejection of partially digested food and secretions *(emesis)* from the upper GI tract.

Etiology and Pathophysiology

Nausea and vomiting occur in a wide variety of GI disorders and in many conditions unrelated to GI disease. These include pregnancy; infection; central nervous system (CNS) problems (e.g., meningitis, tumor); cardiovascular disease (CVD) (e.g., myocardial infarction, heart failure); metabolic disorders (e.g. psychologic factors (e.g., stress, fear); and when the GI tract becomes overly irritated, excited, or distended. Patients may have nausea and vomiting after surgery with general anesthesia or as a drug side effect (e.g., chemotherapy, opioids). Women are more likely to have nausea and vomiting associated with anesthesia and motion sickness.[1]

A vomiting center in the medulla coordinates the multiple components involved in vomiting. This center receives input from various stimuli. Neural impulses reach the vomiting center via afferent pathways through branches of the autonomic nervous system. Receptors for these afferent fibers are found in the GI tract, kidneys, heart, and uterus. When stimulated, these receptors relay information to the vomiting (emetic) center, which then initiates the vomiting reflex (Fig. 41.1).

Vomiting is a complex act. It requires the coordinated activity of several structures: closure of the glottis, deep inspiration with contraction of the diaphragm in the inspiratory position, closure of the pylorus, relaxation of the stomach and lower esophageal sphincter (LES), and contraction of the abdominal muscles with increasing

intraabdominal pressure. These simultaneous activities force the stomach contents up through the esophagus, into the pharynx, and out the mouth.

The chemoreceptor trigger zone (CTZ), found in the brainstem, responds to chemical stimuli from drugs, toxins, and labyrinthine stimulation (e.g., motion sickness). Once stimulated, the CTZ transmits impulses directly to the vomiting center. This action activates the autonomic nervous system, resulting in both parasympathetic and sympathetic stimulation. Sympathetic activation causes tachycardia, tachypnea, and diaphoresis. Parasympathetic stimulation causes relaxation of the LES, an increase in gastric motility, and a pronounced increase in salivation.

Clinical Manifestations

Nausea is subjective. *Anorexia* (lack of appetite) usually accompanies nausea. When nausea and vomiting occur over a long period, dehydration can develop rapidly. Water and essential electrolytes (e.g., potassium, sodium, chloride, hydrogen) are lost. As vomiting persists, the patient may have severe electrolyte imbalances, extracellular fluid volume loss, decreased plasma volume, and eventually circulatory failure.

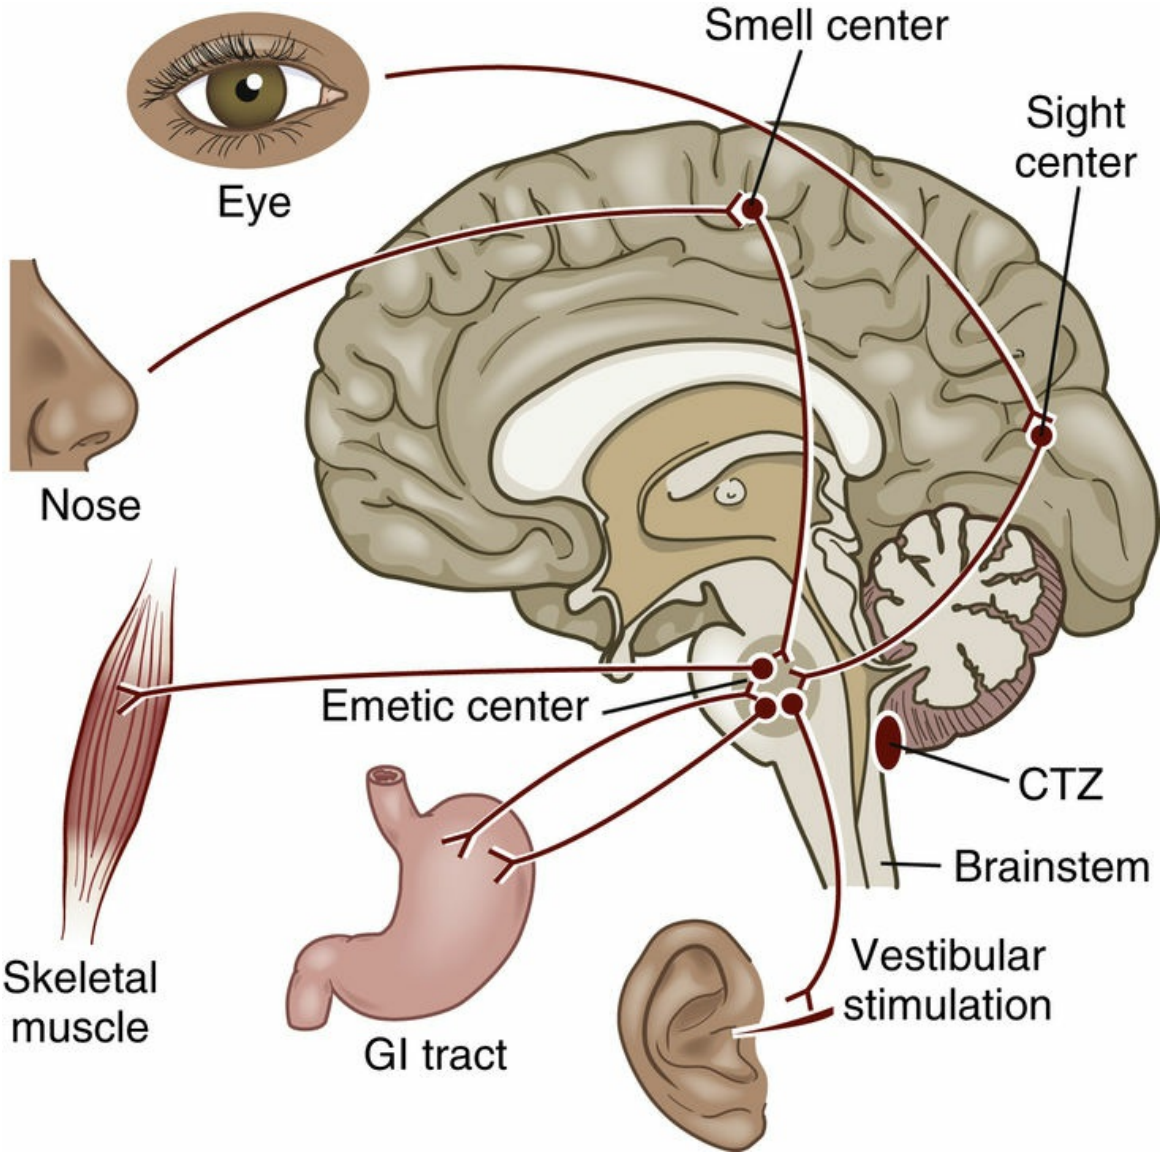

FIG. 41.1 Stimuli involved in the act of vomiting. *CTZ,* Chemoreceptor trigger zone.
Modified from McKenry L, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.

Metabolic alkalosis can result from loss of gastric hydrochloric (HCl) acid. Metabolic acidosis can occur with vomiting of small intestine contents. However, metabolic acidosis is less common than metabolic alkalosis. Weight loss resulting from fluid loss can occur in a short time with severe vomiting.

Interprofessional Care

In managing nausea and vomiting, the goals of care are to determine and treat the underlying cause, recognize and correct any complications, and provide symptomatic relief.

Drug Therapy

The use of drugs to treat nausea and vomiting depends on the cause of the problem (Table 41.1). Many antiemetic drugs act in the CNS via the CTZ to block the neurochemicals that trigger nausea and vomiting. When the cause has not been determined, use drugs with caution. Using antiemetics before knowing the cause can mask the underlying disease process and delay diagnosis and treatment.

Drug Alert

Promethazine Injection

- Do not give into an artery or under the skin because of the risk for severe tissue injury.
- When given IV, it can leak out of the vein and cause severe damage to surrounding tissue.
- Deep muscle injection is the preferred route of injection administration.

5-HT_3 (Serotonin) receptor antagonists are effective in reducing chemotherapy-induced vomiting (CINV), postoperative nausea and vomiting (PONV), and nausea and vomiting related to migraine headache and anxiety. Dexamethasone is given with other antiemetics to manage acute and delayed CINV. Neurokinin-1 receptor antagonists (NK_1RAs) (e.g., aprepitant [Emend], rolapitant [Varubi]), can treat CINV and PONV.[2]

Drug Alert

Metoclopramide (Reglan)

- Chronic use or high doses carry the risk for tardive dyskinesia.
- Tardive dyskinesia is a neurologic condition characterized by involuntary and repetitive movements of the body (e.g., extremity movements, lip smacking).
- Tardive dyskinesia may persist after stopping the drug.

An oral cannabinoid (e.g., dronabinol) may be part of the regimen to manage CINV. Because of the potential for abuse as well as drowsiness and sedation, this is an option only when other therapies are not effective.

Nursing Management: Nausea and Vomiting

Nursing Assessment

Each patient with a history of prolonged and persistent nausea or vomiting needs a thorough nursing assessment. You should have a basic understanding of the common conditions associated with nausea and vomiting and be able to identify the patient who is at high risk. Assess the patient for precipitating factors and describe the contents of the emesis. Table 41.2 presents subjective and objective data to obtain from a patient with nausea and vomiting.

When food is the precipitating cause of nausea and vomiting, help the patient identify the specific food. Determine when it was eaten, prior history with the food, and whether anyone else who ate the food is sick. Emesis containing partially digested food several hours after a meal indicates gastric outlet obstruction or delayed gastric emptying. The presence of fecal odor and bile after prolonged vomiting suggests intestinal obstruction below the level of the pylorus. Bile in the emesis suggests obstruction below the ampulla of Vater.

TABLE 41.1 Drug TherapyNausea and Vomiting

Drug	Mechanism of Action	Side Effects
Anticholinergics		
scopolamine transdermal	Block cholinergic pathways to vomiting center	Xerostomia, somnolence
Antihistamines		
dimenhydrinate (Dramamine) diphenhydramine hydroxyzine meclizine (Antivert)	Block histamine receptors that trigger nausea and vomiting	Dry mouth, hypotension, sedative effects, rashes, constipation
Cannabinoids		
dronabinol (Marinol) nabilone (Cesamet)	Inhibit vomiting control mechanism in the medulla oblongata	Xerostomia, amnesia, ataxia, confusion, coordination problems, dizziness, somnolence
Corticosteroids		
dexamethasone	Not well understood how it prevents nausea and vomiting	Hyperglycemia, insomnia, euphoria
5-HT_3 (Serotonin) Antagonists		
granisetron ondansetron (Zofran) palonosetron (Aloxi)	Block action of serotonin	Constipation, diarrhea, headache, fatigue, malaise, increased liver function tests
Phenothiazines		
chlorpromazine prochlorperazine promethazine	Act in the CNS level of the chemoreceptor trigger zone (CTZ). Block dopamine receptors that trigger nausea and vomiting	Dry mouth, hypotension, sedative effects, rashes, constipation
Prokinetic		
Metoclopramide (Reglan)	Inhibit action of dopamine. ↑ Gastric motility and emptying	CNS side effects ranging from anxiety to hallucinations, extrapyramidal side effects, including tremor and dyskinesias
Substance P/Neurokinin-1 Receptor Antagonists		
aprepitant (Emend) netupitant and palonosetron (Akynzeo) rolapitant (Varubi)	Block interaction of Substance P at NK-1 receptor	Headache, hiccups, fatigue, constipation, diarrhea, anorexia

The color of the emesis helps determine the presence and source of any bleeding. Bright red blood occurs with active bleeding. This could be due to a **Mallory-Weiss tear** (disruption of the mucosal lining near the esophagogastric junction), esophageal varices, gastric or duodenal ulcer, or cancer. Vomitus with a "coffee-grounds" appearance is related to gastric bleeding. The blood changes to dark brown because of its interaction with HCl acid.

It is important to discern among vomiting, regurgitation, and projectile vomiting. *Regurgitation* is an effortless process in which partially digested food slowly comes up from the stomach. Retching or vomiting rarely occurs before it. *Projectile vomiting* is a forceful expulsion of stomach contents without nausea. It often occurs with brain and spinal cord tumors.

The timing of nausea and vomiting can help determine its cause.

Early morning vomiting is common in pregnancy. Emotional stressors may elicit vomiting during or right after eating. Those with *cyclic vomiting syndrome* have recurring episodes of nausea, vomiting, and fatigue that last from a few hours up to 10 days.

Nursing Diagnoses

Nursing diagnoses for the patient with nausea and vomiting may include:

- Nausea
- Fluid imbalance
- Electrolyte imbalance
- Impaired nutritional intake

More information on nursing diagnoses and interventions are in eNursing Care Plan 41.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with nausea and vomiting will (1) have minimal or no nausea and vomiting, (2) have normal electrolyte levels and hydration status, and (3) return to a normal pattern of fluid balance and nutrient intake.

Nursing Implementation

Acute Care

Most people with nausea and vomiting are at home. When nausea and vomiting persist, the patient may need hospitalized to diagnose the underlying problem. Until we confirm a diagnosis, the patient is NPO and given IV fluids. The patient with persistent vomiting, a possible bowel obstruction, or paralytic ileus may need a nasogastric (NG) tube connected to suction to decompress the stomach. Secure the NG tube to prevent its movement in the nose and back of the throat,

because this can stimulate nausea and vomiting.

TABLE 41.2 Nursing AssessmentNausea and Vomiting

Subjective Data

Important Health Information

Past health history: GI disorders, chronic indigestion, food allergies, pregnancy, infection, CNS problems, recent travel, eating disorders, metabolic disorders, cancer, CVD, renal disease
Medications: Antiemetics, digitalis, opioids, ferrous sulfate, aspirin, aminophylline, alcohol, antibiotics, chemotherapy. General anesthesia
Surgery or other treatments: Recent surgery

Functional Health Patterns

Nutritional-metabolic: Amount, frequency, character, and color of vomitus. Dry heaves. Anorexia, weight loss
Activity-exercise: Weakness, fatigue
Cognitive-perceptual: Abdominal tenderness or pain
Coping–stress tolerance: Stress, fear

Objective Data

General

Lethargy, sunken eyeballs

Integumentary

Pallor, dry mucous membranes, poor skin turgor

Gastrointestinal

Amount, frequency, character (e.g., projectile), content (undigested food, blood, bile, feces), and color of vomitus (red, coffee-grounds, green-yellow)

Urinary

Decreased output, concentrated urine

Possible Diagnostic Findings

Altered serum electrolytes (especially hypokalemia), metabolic alkalosis, abnormal upper GI findings on endoscopy or abdominal x-rays

With prolonged vomiting, there is a chance of dehydration and acid-base and electrolyte imbalances. Record intake and output, monitor vital signs, and assess for signs of dehydration. Provide physical and emotional support. Maintain a quiet, odor-free environment. Observe for changes in the patient's physical comfort and mentation. The risk for pulmonary aspiration is a concern when vomiting occurs in older or unconscious patients or in patients with conditions that impair the gag reflex. To prevent aspiration, put the patient who cannot manage self-care in a semi-Fowler's or side-lying position.

Nutritional Therapy

The patient with severe vomiting needs IV fluid therapy with electrolyte and glucose replacement until able to tolerate oral intake. Start oral nutrition beginning with clear liquids once symptoms have

subsided. A patient may be reluctant to resume fluid intake because of fear of symptoms recurring. Water is the initial fluid of choice for oral rehydration. Have the patient sip small amounts of fluid (5 to 15 mL) every 15 to 20 minutes. Other options include carbonated beverages with the carbonation removed at room temperature and warm tea. Extremely hot or cold liquids are often hard to tolerate. Broth and sports drinks (e.g., Gatorade) are high in sodium, so give them with caution. Dry toast, crackers, and plain gelatin may be helpful.

As the patient's condition improves, provide a diet high in carbohydrates and low in fat. Bland foods, such as a baked potato, rice, cooked chicken, and cereal, are ideal. Many patients do not tolerate coffee, spicy foods, highly acidic foods, and those with strong odors. Tell the patient to eat food slowly and in small amounts to prevent overdistending the stomach. Liquids taken between meals rather than with meals reduce overdistention. Consult a dietitian about nutritious foods that the patient can tolerate.

Check Your Practice

You are caring for a newly admitted 76-yr-old man who reports vomiting for the past 3 days. He says, "I cannot keep anything down, not even water."

- What assessment do you need to perform?
- What findings would show he is dehydrated?
- What are your priority nursing interventions?

Ambulatory Care

Teach the patient and caregiver (1) how to manage the unpleasant sensation of nausea, (2) methods to prevent nausea and vomiting, and (3) ways to maintain fluid and nutritional intake. Tell them to keep the immediate environment quiet, free of noxious odors, and well ventilated. Avoiding sudden changes of position and unnecessary

activity are helpful. Encourage the use of relaxation techniques, frequent rest periods, effective pain management strategies, and diversional tactics. Cleansing the face and hands with a cool washcloth and providing mouth care between episodes increase the person's comfort level. When symptoms occur, stop all foods and drugs until the acute phase is over.

If you suspect a medication is the cause, notify the (HCP at once. The HCP can change the dose or prescribe a new drug. Tell the patient that stopping the drug without consulting the HCP may have adverse effects on the person's health. The patient should take an antiemetic drug only if prescribed by the HCP. Taking over-the-counter (OTC) drugs to relieve symptoms may make the problem worse.

Some patients find that acupressure or acupuncture at specific points is effective in reducing PONV.[3] Others use herbs, such as ginger and peppermint oil. Relaxation breathing exercises, changes in body position, or exercise may help some patients.

Complementary & Alternative Therapies

Ginger

Scientific Evidence

- May be effective for nausea and vomiting in pregnancy when used at recommended doses for short periods
- May help CINV if used with antiemetic drugs

Nursing Implications

- Few adverse effects reported with short-term use
- May interact with anticoagulants and increase risk for bleeding
- Use with caution in people with gallbladder disease

Source: www.nccih.nih.gov/health/ginger.

TABLE 41.3 Infections and Inflammation of the Mouth

Infection or Inflammation	Etiology	Manifestations	Treatment
Aphthous stomatitis (canker sore)	• Recurrent and chronic form of infection • Related to systemic disease, trauma, stress, or unknown causes	• Ulcers of mouth and lips, causing extreme pain • Ulcers surrounded by erythematous base	• Corticosteroids (topical or systemic) • Tetracycline oral suspension
Gingivitis	• Neglected oral hygiene, malocclusion, missing or irregular teeth, faulty dentistry • Eating soft rather than fibrous foods	• Inflamed gingivae and interdental papillae • Bleeding during tooth brushing • Development of pus, abscess formation with loosening of teeth (periodontitis)	• Prevention through health teaching, dental care, gingival massage, professional cleaning of teeth • Eat fibrous foods • Conscientious brushing habits with flossing
Herpes simplex (cold sore, fever blister) (see Table 23.6)	• Herpes simplex virus (type 1 or 2) • Predisposing factors of upper respiratory tract infections, excessive exposure to sunlight, food allergies, emotional tension, onset of menstruation	• Lip lesions, mouth lesions, vesicle formation (single or clustered) • Shallow, painful ulcers	• Spirits of camphor, corticosteroid cream, mild antiseptic mouthwash, viscous lidocaine • Remove or control predisposing factors • Antiviral agents (e.g., acyclovir [Zovirax], valacyclovir [Valtrex])
Oral candidiasis (moniliasis or thrush)	• *Candida albicans* (yeastlike fungus) • Debilitation • Prolonged high-dose antibiotic or corticosteroid therapy	• Pearly, bluish white "milk-curd" membranous lesions on mucosa of mouth and larynx • Sore mouth, yeasty halitosis	• Miconazole buccal tablets (Oravig) • Nystatin or amphotericin B as oral suspension or buccal tablets • Good oral hygiene
Parotitis (inflammation of parotid gland, surgical mumps)	• *Staphylococcus* species usually • *Streptococcus* species occasionally • Debilitation and dehydration with poor oral hygiene • Extended NPO status	• Pain in area of gland and ear • Absence of salivation • Purulent exudate from gland, erythema, ulcers	• Antibiotics, mouthwashes, warm compresses • Preventive measures, such as chewing gum, sucking on hard candy (lemon drops) • Adequate fluid intake
Stomatitis (inflammation of mouth)	• Trauma, pathogens, irritants (tobacco, alcohol) • Renal, liver, and hematologic diseases • Side effect of chemotherapy and radiation	• Excess salivation • Halitosis • Sore mouth	• Remove or treat cause • Oral hygiene with soothing solutions, topical medications • Soft, bland diet
Vincent's infection (acute necrotizing ulcerative gingivitis, trench mouth)	• Fusiform bacteria, Vincent spirochetes • Predisposing factors of stress, excessive fatigue, poor oral hygiene • Nutritional deficiencies (B and C vitamins)	• Painful, bleeding gingivae • Eroding necrotic lesions of interdental papillae • Ulcerations that bleed • Increased saliva with metallic taste, fetid mouth odor • Anorexia, fever, general malaise	• Physical and mental rest • Avoid smoking and alcohol • Soft, nutritious diet • Correct oral hygiene habits • Topical applications of antibiotics • Mouth irrigations with chlorhexidine and saline solutions

Evaluation

The expected outcomes are that the patient with nausea and vomiting will

- Be comfortable, with minimal or no nausea and vomiting
- Have electrolyte levels within normal range
- Be able to maintain adequate intake of fluids and nutrients

Gerontologic Considerations: Nausea and Vomiting

The older adult with nausea and vomiting needs careful assessment and monitoring, especially during periods of fluid loss and rehydration therapy. They are more likely to have cardiac or renal problems that places them at greater risk for life-threatening fluid and electrolyte imbalances. Excess fluid and electrolytes replacement may have adverse consequences for a person with heart failure or renal disease. The older adult with a decreased level of consciousness has a high risk for aspirating. Close monitoring of the patient's physical status and level of consciousness during episodes of vomiting is important.

Older adults are particularly susceptible to the CNS side effects of antiemetic drugs. These drugs may cause confusion and increase fall risk. Doses should be reduced and efficacy closely evaluated. Use safety precautions for these patients (e.g., removing rugs that may cause slipping).

Oral Inflammation and Infections

Inflammations and infections of the oral cavity are shown in Table 41.3. They may be due to specific mouth diseases or related to systemic disorders, such as leukemia or vitamin deficiency. The patient who is immunosuppressed (e.g., receiving chemotherapy for cancer) or using corticosteroid inhalant treatment for asthma is at risk for oral infections (e.g., candidiasis). Oral infections may predispose the patient to infections in other body organs. For example, the oral cavity is a potential reservoir for respiratory pathogens. Oral pathogens are associated with diabetes and heart disease.[4]

Managing these problems focuses on identifying the cause, eliminating infection, providing comfort measures, and maintaining nutritional intake. They can severely impair oral ingestion. Regular and good oral and dental hygiene reduces oral infections and inflammation.

Oral Cancer

There are 2 types of oral cancer: *oral cavity cancer*, which starts in the mouth, and *oropharyngeal cancer*, which develops in the part of the throat just behind the mouth (the oropharynx). *Head and neck squamous cell carcinoma* (HNSCC) is a broad term used for cancers of the oral cavity, pharynx, and larynx. Most oral cancer lesions occur on the lower lip. Other common sites are the lateral border and undersurface of the tongue, labial commissure, and buccal mucosa. Annually 51,540 Americans are diagnosed with oral cancer. An estimated 10,030 people die from the disease.[5]

Oral cancer is more common after age 35. The average age at diagnosis is 65 years. It is 2 times more common in men than in women. The 5-year survival rate is 84% for localized cancer and 65% for all stages of oral cavity and pharynx cancer combined.[5] Lip cancer has the most favorable prognosis of any of the oral tumors. The visibility of lip lesions usually leads to an earlier diagnosis.

Promoting Health Equity

Oral, Pharyngeal, and Esophageal Problems

Nausea and Vomiting

- Asian Americans, Middle Easterners, and blacks are more likely to have nausea and vomiting than whites

Cancers of Oral Cavity and Pharynx

- Incidence and mortality rates are higher in black men than in whites
- Death rates from oral cancer are decreasing in whites and

increasing in nonwhites

Esophageal Cancer

- Highest incidence is in non-Hispanic white men
- Lowest incidence occurs in Asian Americans, Pacific Islanders, and Hispanics.

Stomach Cancer

- Asian Americans and Pacific Islanders, Hispanics, and blacks have higher rates of stomach cancer than non-Hispanic whites
- Asian Americans have higher survival rates than other ethnic groups

Etiology and Pathophysiology

Although the exact cause of oral cancer is unknown, there are predisposing factors (Table 41.4). Of those with oral cancer, 75% to 90% report either using tobacco or a history of frequent alcohol use. More than 30% of patients with cancer of the lip have outdoor occupations, showing that prolonged exposure to sunlight is a risk factor. Irritation from the pipe stem resting on the lip is a factor in pipe smokers. Human papillomavirus (HPV) contributes to 25% of oral cancer cases. HPV-associated oropharyngeal cancer is associated with multiple sexual partners, especially multiple oral sex partners.[6]

Clinical Manifestations

The common manifestations are shown in Table 41.4. Patients may report nonspecific symptoms such as chronic sore throat, sore mouth, and voice changes. *Leukoplakia,* called "smoker's patch," is a white patch on the mouth mucosa or tongue. It is a precancerous lesion, although less than 15% actually transform into cancer cells. The patch

becomes *keratinized* (hard and leathery). This is described as hyperkeratosis. Leukoplakia is the result of chronic irritation, especially from smoking. *Erythroplasia* (erythroplakia), a red velvety patch on the mouth or tongue, is another precancerous lesion. More than 50% of cases of erythroplasia progress to squamous cell cancer. About 30% of patients with oral cancer have an asymptomatic neck mass.

Cancer of the lip usually appears as an indurated, painless ulcer on the lip. The first sign of cancer of the tongue is an ulcer or area of thickening. Soreness or pain of the tongue may occur, especially when eating hot or highly seasoned foods. Lesions are most likely to develop in the proximal half of the tongue. Some patients have limited tongue movement. Later symptoms include increased salivation, slurred speech, **dysphagia** (difficulty swallowing), toothache, and earache.

Diagnostic Studies

Diagnostic tests are done to identify oral dysplasia, which is a precursor to oral cancer (Table 41.5). Oral exfoliative cytologic study involves scraping the suspicious lesion and spreading the scraping on a slide for microscopic examination. The toluidine blue test is a screening test for oral cancer. When toluidine blue is applied topically to stain an area, cancer cells preferentially take up the dye. A negative cytologic smear or negative toluidine blue test does not necessarily rule out cancer. Once cancer is diagnosed, CT scan, MRI, and positron emission tomography (PET) are used for staging cancer.

TABLE 41.4 Types and Characteristics of Oral Cancer

Location	Predisposing Factors	Clinical Manifestations	Treatment
Lip	Constant overexposure to sun, ruddy and fair complexion, recurrent herpetic lesions, irritation from pipe stem, syphilis, immunosuppression	Indurated, painless ulcer	Surgical excision, radiation
Oral cavity	Poor oral hygiene, tobacco usage (pipe and cigar smoking, snuff, chewing tobacco), chronic alcohol intake, chronic irritation (jagged tooth, ill-fitting prosthesis, chemical or mechanical irritants), HPV	Leukoplakia, erythroplakia, ulcerations, sore spot, rough area, pain, dysphagia, a lump or thickening in the cheek A sore throat or a feeling that something is stuck Difficulty chewing and speaking (later signs)	Surgery (mandibulectomy, radical neck dissection, resection of buccal mucosa), internal and external radiation
Tongue	Tobacco, alcohol, chronic irritation, syphilis	Ulcer or area of thickening, soreness, or pain Limited tongue movement Increased salivation, slurred speech, dysphagia, toothache, earache (later signs)	Surgery (hemiglossectomy or glossectomy), radiation

Interprofessional Management: Oral Cancer

Management usually consists of surgery, radiation, chemotherapy, or a combination of these. The curative treatments are usually surgery and radiation.

Surgical Therapy

Surgery is the most effective treatment, especially for early-stage disease.[7] The procedure done depends on the location and extent of the tumor. Some patients with small tumors in the mouth and throat are candidates for minimally invasive robotic-assisted surgery. However, many of the operations are radical procedures involving extensive resections. Some examples are partial *mandibulectomy* (removal of the mandible), *hemiglossectomy* (removal of half of the tongue), *glossectomy* (removal of the tongue), resections of the buccal mucosa and floor of the mouth, and radical neck dissection.

Radical neck dissection includes wide excision of the primary lesion with removal of the regional lymph nodes, the deep cervical lymph nodes, and their lymphatic channels. The following structures are removed or transected depending on the extent of the primary lesion: sternocleidomastoid muscle and other closely associated muscles, internal jugular vein, mandible, submaxillary gland, part of the thyroid and parathyroid glands, and spinal accessory nerve. The patient usually has a tracheostomy. Drainage tubes inserted into the

surgical area are connected to suction to remove fluid and blood. Head and neck surgery is described in more detail in Chapter 26.

Nonsurgical Therapy

Radiation therapy may be used alone to treat small cancers or when lesions cannot be removed. Patients usually do not have radiation before surgery because it is hard to remove radiated tissue. The tissue becomes fibrotic and heals slower. Most patients begin radiation about 6 weeks after surgery.

Chemotherapy can shrink lesions before surgery, decrease metastasis, sensitize cancer cells to radiation, or treat distant metastases. Common chemotherapy drugs include fluorouracil, cisplatin, carboplatin, paclitaxel, docetaxel, and hydroxyurea. A common combination is cisplatin and fluorouracil.[8] This combination is more effective than either drug alone. (Chemotherapy is discussed in Chapter 15.)

Palliative treatment is the best management when the prognosis is poor, the cancer is inoperable, or the patient decides against surgery. Palliation aims to treat the symptoms and make the patient more comfortable. If it becomes hard for the patient to swallow, placing a gastrostomy tube will allow for adequate nutritional intake. Give analgesic drugs freely. Frequent suctioning of the oral cavity is needed when swallowing becomes difficult. Other palliative and end-of-life nursing measures are discussed in Chapter 9.

Nutritional Therapy

Many patients are malnourished before surgery. They may need placement of a percutaneous endoscopic gastrostomy (PEG) and enteral nutrition (EN) before radiation treatment or surgery. After radical neck surgery, the patient may be unable to ingest nutrients orally because of mucositis, swelling, location of sutures, or difficulty swallowing. PN is given for the first 24 to 48 hours. After that time, EN is given via NG, gastrostomy, or jejunostomy tube. (See Chapter 39 for information on EN.) Cervical esophagostomy and pharyngostomy are options for some patients.

TABLE 41.5 Interprofessional CareOral Cancer

Diagnostic Assessment

- History and physical examination
- Biopsy
- Oral exfoliative cytology
- Toluidine blue test
- CT, MRI, PET scans

Management

- Surgical therapy
- Surgical excision of the tumor
- Radical neck dissection
- Radiation therapy
- Chemotherapy
- Nutrition therapy

Assess for feeding tolerance and adjust the amount, time, and formula if nausea, vomiting, diarrhea, or distention occurs. Give small amounts of water when the patient can swallow. Observe for choking. Suctioning may be needed to prevent aspiration.

Nursing Management: Oral Cancer

Nursing Assessment

Subjective and objective data to obtain from a patient with oral cancer are outlined in Table 41.6.

Nursing Diagnoses

Nursing diagnoses for the patient with oral cancer may include the following:

- Impaired nutritional intake
- Acute pain
- Anxiety

Planning

The overall goals are that the patient with cancer of the oral cavity will (1) have a patent airway, (2) be able to communicate, (3) have adequate nutritional intake to promote wound healing, and (4) have relief of pain and discomfort.

TABLE 41.6 Nursing AssessmentOral Cancer

Subjective Data Important Health Information
Past health history: Recurrent oral herpetic lesions, HPV infection or vaccination, syphilis, exposure to sunlight *Medications:* Immunosuppressants *Surgery or other treatments:* Removal of prior tumors or lesions

Functional Health Patterns

Health perception–health management: Alcohol and tobacco use, pipe smoking. Poor oral hygiene
Nutritional-metabolic: Reduced oral intake, weight loss, difficulty chewing food, increased salivation, intolerance to certain foods or temperatures of food
Cognitive-perceptual: Mouth or tongue soreness or pain, toothache, earache, neck stiffness, dysphagia, difficulty speaking

Objective Data
Integumentary

Indurated, painless ulcer on lip. Painless neck mass

Gastrointestinal

Areas of thickening or roughness, ulcers, leukoplakia, or erythroplakia on the tongue or oral mucosa. Limited tongue movement. Increased salivation, drooling. Slurred speech. Foul breath odor

Possible Diagnostic Findings

Positive exfoliative smear cytology (microscopic examination of cells removed by scraping), positive biopsy

Nursing Implementation

You play a key role in the early detection and treatment of oral cancer. Identify patients at risk (Table 41.4) and provide information about predisposing factors. Review information about smoking cessation

with the patient who smokes. Warn adolescents and teenagers about the danger of using snuff or chewing tobacco and electronic cigarettes. Smoking cessation is discussed in Chapter 10 and Tables 10.3 to 10.6.

Because early detection of oral cancer is important, teach the patient to report unexplained pain or soreness of the mouth, unusual bleeding, dysphagia, sore throat, voice changes, or swelling or lump in the neck. Refer any person with an ulcerative lesion that does not heal within 2 to 3 weeks to the HCP.

Promoting Population Health

Health Impact of Good Oral Hygiene

- Improves quality of life
- Lowers risk for teeth loss
- Reduces pain and disability
- Aids in early detection of oral and craniofacial cancers
- Decreases cost of care needed from dental professionals
- Decreases risk for periodontal disease, gingivitis, and dental caries

Preoperative care for the patient who will have a radical neck dissection must consider the patient's physical and psychosocial needs. Physical preparation is the same as that for any major surgery, with special emphasis on oral hygiene. Explanations and emotional support should include information on postoperative communication and feeding. Explain the surgical procedure and ensure that the patient understands the information. See Chapter 26 and eNursing Care Plan 26.2 for more information about the nursing management of a patient undergoing a radical neck dissection.

Evaluation

The expected outcomes are that the patient with oral cancer will

- Have no respiratory complications
- Be able to communicate
- Maintain an adequate nutritional intake to promote wound healing
- Have minimal pain and discomfort with eating, drinking, and talking

Esophageal Disorders

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a chronic symptom of mucosal damage caused by reflux of stomach acid into the lower esophagus. GERD is not a disease but a syndrome. GERD is the most common upper GI problem. About 15 million Americans have GERD symptoms (heartburn or regurgitation) each day.[9]

Etiology and Pathophysiology

GERD has no one single cause (Fig. 41.2). GERD results when the reflux of acidic gastric contents into the esophagus overwhelms the esophageal defenses. Gastric HCl acid and pepsin secretions in refluxate cause esophageal irritation and inflammation *(esophagitis).* If it contains intestinal proteolytic enzymes (e.g., trypsin) and bile, this further irritates the esophageal mucosa. The degree of inflammation depends on the amount and composition of the gastric reflux and on the esophagus's mucosal defense mechanisms.

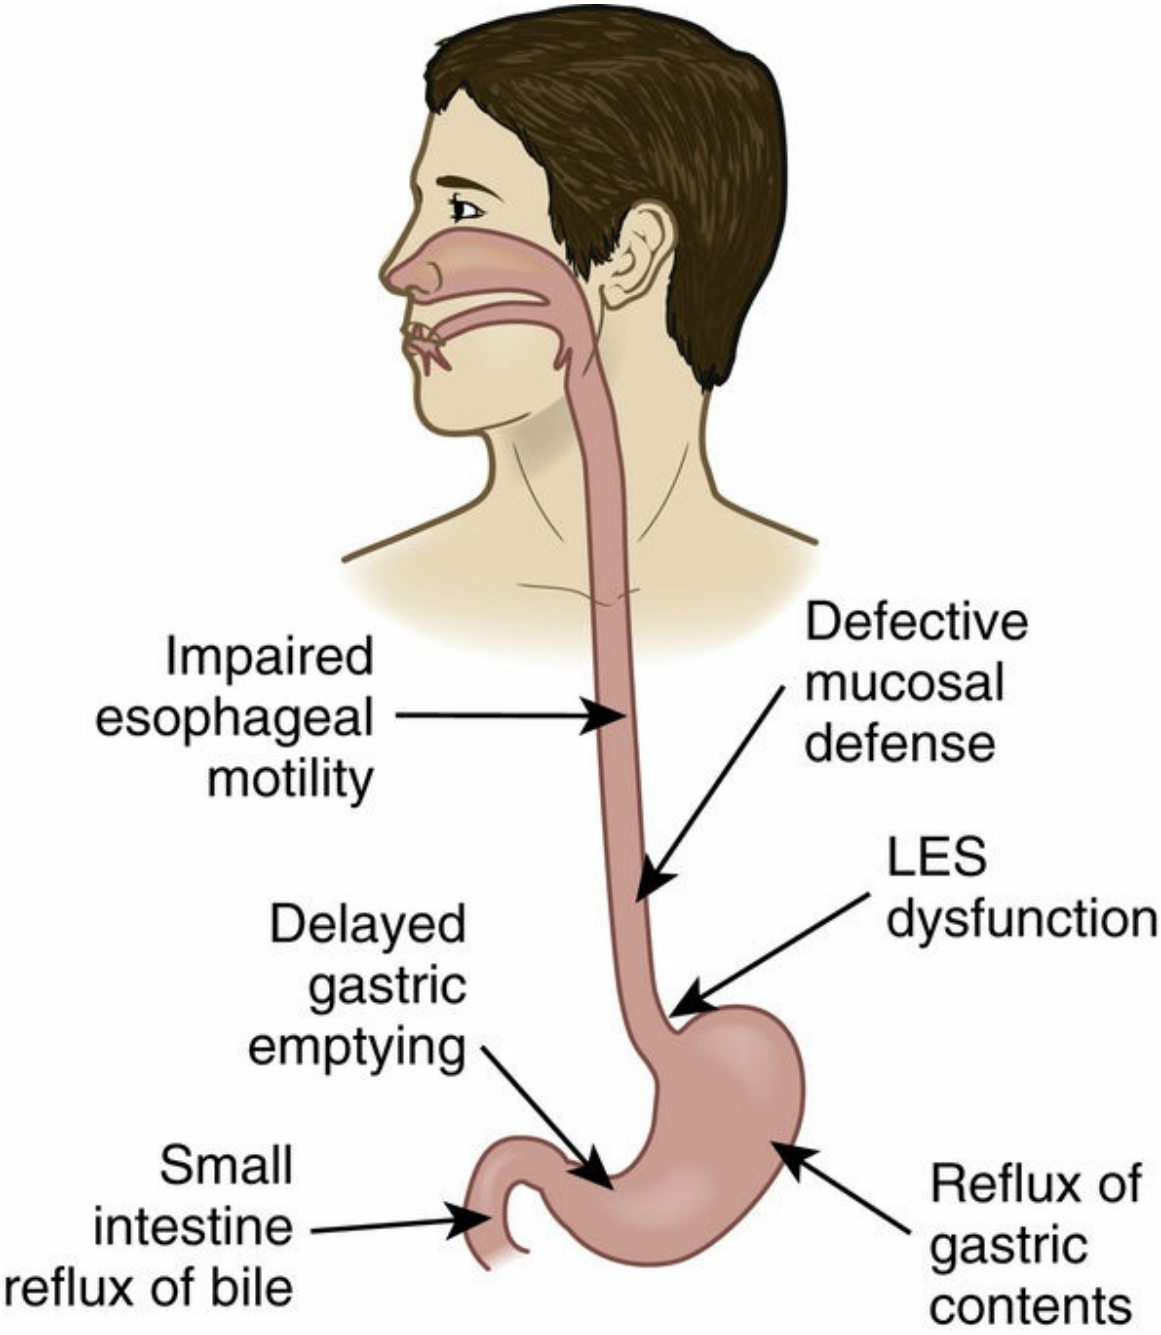

FIG. 41.2 Factors involved in the pathogenesis of GERD.

TABLE 41.7 Factors Affecting Lower Esophageal Sphincter Pressure

Decrease Pressure

- Alcohol
- Chocolate (theobromine)
- Drugs
    - Anticholinergics
    - β-Adrenergic blockers
    - Calcium channel blockers
    - Diazepam (Valium)
    - Morphine sulfate
    - Nitrates
    - Progesterone
    - Theophylline
- Fatty foods
- Nicotine
- Peppermint, spearmint
- Tea, coffee (caffeine)

Increase Pressure

- Bethanechol (Urecholine)
- Metoclopramide (Reglan)

One of the primary factors causing GERD is an incompetent LES. Normally, the LES acts as an antireflux barrier. An incompetent LES lets gastric contents move from the stomach to the esophagus when the patient is supine or has an increase in intraabdominal pressure.

Decreased LES pressure can be due to certain foods and drugs (Table 41.7). Obesity is a risk factor. In an obese person the intraabdominal pressure is increased, which can worsen GERD. Cigarette and cigar smoking can contribute to GERD. Hiatal hernia, discussed in the next section, often causes GERD.

Clinical Manifestations

The symptoms of GERD vary from person to person. Persistent mild symptoms (i.e., more than twice a week) or moderate to severe symptoms once a week is considered GERD.

Heartburn *(pyrosis)* is the most common symptom. Heartburn is a burning, tight sensation felt intermittently beneath the lower sternum and spreading upward to the throat or jaw. It may occur after ingesting food or drugs that decrease the LES pressure or directly irritate the esophageal mucosa. An HCP should evaluate heartburn that occurs more than twice a week, is severe, is associated with dysphagia, or occurs at night and wakes a person from sleep. Older adults who report the recent onset of heartburn should receive medical evaluation.

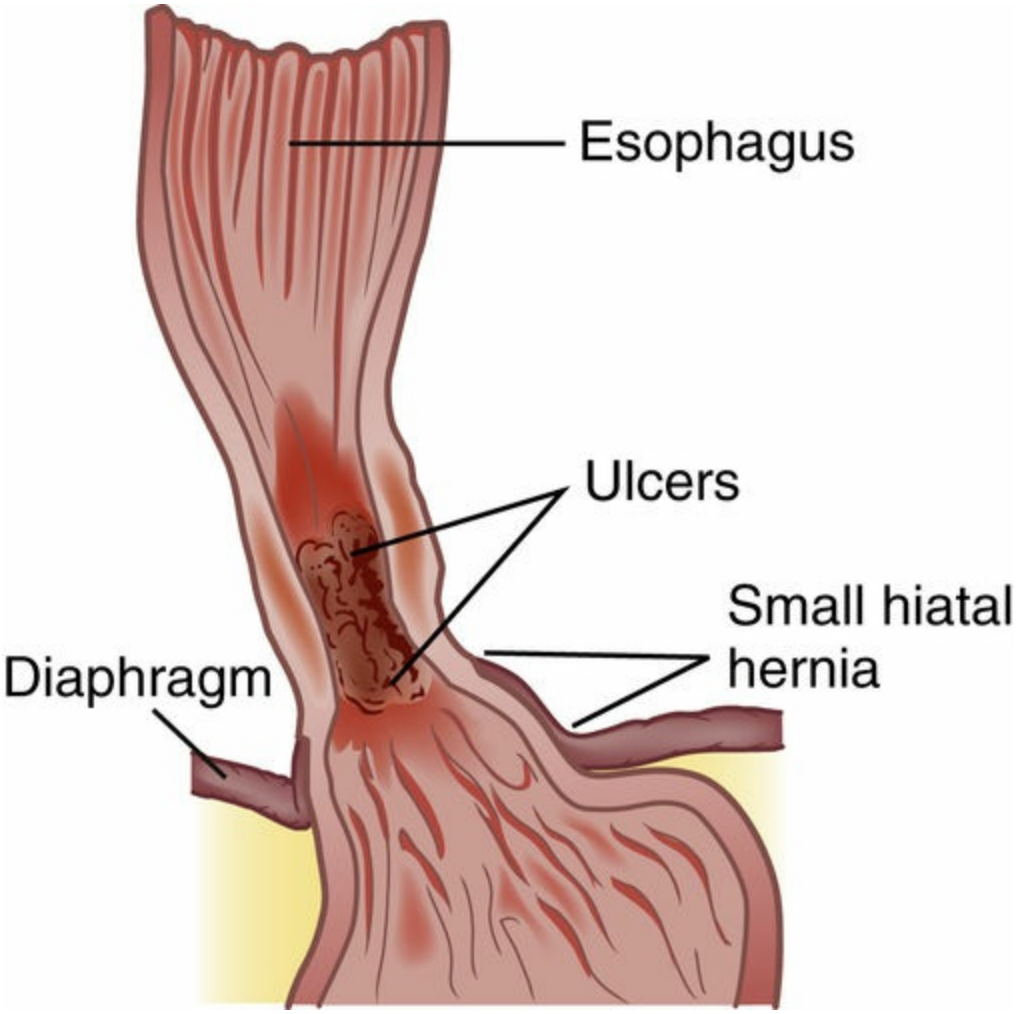

FIG. 41.3 Esophagitis with esophageal ulcerations.

GERD-related chest pain can mimic angina. It is described as burning; squeezing; or radiating to the back, neck, jaw, or arms. Chest pain is more common in older adults with GERD. Unlike angina, GERD-related chest pain is relieved with antacids.

Patients may have dyspepsia or regurgitation. *Dyspepsia* is pain or discomfort centered in the upper abdomen (mainly in or around the midline as opposed to the right or left hypochondrium). Regurgitation is often described as hot, bitter, or sour liquid coming into the throat or mouth.

A person with GERD may report respiratory symptoms, including wheezing, coughing, and dyspnea. Nighttime discomfort and coughing can awaken the person, resulting in disturbed sleep patterns. Otolaryngologic symptoms include hoarseness, sore throat, a

globus sensation (sense of a lump in the throat), hypersalivation, and choking.

Complications

Complications of GERD are due to the direct local effects of gastric acid on the esophageal mucosa. **Esophagitis** (inflammation of the esophagus) is a common complication of GERD. Esophagitis with esophageal ulcerations is shown in Fig. 41.3. Repeated esophagitis may lead to scar tissue formation, stricture, and dysphagia.

Another complication of chronic GERD is **Barrett's esophagus (BE)** (esophageal metaplasia). *Metaplasia* is the reversible change from one type of cell to another type because of an abnormal stimulus. In BE, the flat epithelial cells in the distal esophagus change into columnar epithelial cells. These cell changes are primarily due to GERD. However, some people with no history of GERD develop BE.

About 5% to 20% of people with chronic GERD have BE.[10] Other risk factors include being over age 60, being male, being white, and having central obesity. BE is a precancerous lesion that increases the patient's risk for esophageal cancer. Because of this risk, those with BE undergo surveillance endoscopy or radiofrequency ablation as recommended.

Respiratory complications of GERD include cough, bronchospasm, laryngospasm, and cricopharyngeal spasm. These complications are due to gastric secretions irritating the upper air*way. Asthma, chronic bronchitis, and pneumonia may develop from aspiration into the respiratory system. Dental erosion, especially in the posterior teeth, may result from acid reflux into the mouth.

TABLE 41.8 Interprofessional CareGERD and Hiatal Hernia

Diagnostic Assessment

- History and physical examination
- Upper GI endoscopy with biopsy and cytologic analysis
- Esophagram (barium swallow)
- Motility (manometry) studies
- pH monitoring (laboratory or 24 hr ambulatory)
- Radionuclide studies

Management

Conservative

- Elevate head of bed on 4- to 6-in blocks
- Avoid reflux-inducing foods (fatty foods, chocolate, peppermint)
- Avoid alcohol
- Reduce or avoid acidic pH beverages (colas, red wine, orange juice)

Drug Therapy (Table 41.10)

- PPIs
- H_2 receptor blockers
- Antacids
- Prokinetic drug therapy

Surgical Therapy

- Nissen fundoplication
- Toupet fundoplication

Endoscopic Therapy

- Intraluminal valvuloplasty
- Radiofrequency ablation

Diagnostic Studies

GERD is often diagnosed based on symptoms and the patient's response to behavioral and drug therapies. Diagnostic tests are done when usual therapy is ineffective or when complications are suspected. Diagnostic studies done to determine the cause of the GERD are shown in Table 41.8.

Endoscopy is useful in assessing the LES competence and the degree of inflammation (if present), potential scarring, and strictures. Biopsy and cytologic specimens can distinguish stomach or esophageal cancer from BE. In addition, the degree of dysplasia (low grade versus high grade) is determined. Manometric studies measure pressure in the esophagus and LES and esophageal motility function. Ambulatory esophageal pH monitoring is an option for those with refractory symptoms and no evidence of mucosal inflammation. Radionuclide tests can detect reflux of gastric contents and the rate of esophageal clearance.

Nursing and Interprofessional Management: GERD

Most patients with GERD can successfully manage the condition through lifestyle modifications, drug therapy, and nutrition therapy. These approaches require patient teaching and adherence to therapies. When these therapies are ineffective, surgery is an option (Table 41.8).

Lifestyle Modifications

Teach the patient with GERD to avoid factors that trigger symptoms. The head of the bed is elevated 30 degrees. This can be done using pillows or with 4- to 6-in blocks under the bed. The patient should not be supine for 2 to 3 hours after a meal. A patient and caregiver teaching guide is shown in Table 41.9.

Encourage patients who smoke to stop. If needed, refer the patient to community resources for help in stopping smoking. See Chapter 10 for more information related to smoking cessation. If stress causes symptoms, discuss measures to cope with stress. (See Chapter 6 for stress management techniques.)

TABLE 41.9 Patient & Caregiver TeachingGERD

Include the following instructions when teaching the patient and caregiver about managing GERD:

1. Explain the reason for a low-fat diet.
2. Have the patient to eat small, frequent meals to prevent gastric distention.
3. Explain the reason for avoiding alcohol, smoking (causes an almost immediate, marked decrease in lower esophageal sphincter pressure), and beverages that contain caffeine.

4. Tell the patient to not lie down for 2–3 hr after eating, wear tight clothing around the waist, or bend over (especially after eating).
5. Have the patient avoid eating within 3 hr of bedtime.
6. Have the patient to sleep with head of bed elevated on 4- to 6-in blocks (gravity fosters esophageal emptying).
7. Provide information about drugs, including reason for their use and common side effects.
8. Discuss strategies for weight reduction if appropriate.
9. Encourage patient and caregiver to share concerns about lifestyle changes and living with a chronic problem.

Drug Therapy

Drug therapy for GERD focuses on decreasing the volume and acidity of reflux, improving LES function, increasing esophageal clearance, and protecting the esophageal mucosa (Table 41.10). Proton pump inhibitors (PPIs) and histamine (H_2) receptor blockers are the most common and effective treatments for symptomatic GERD.[11] The goal of HCl acid suppression treatment is to reduce the acidity of the gastric refluxate. Patients who are symptomatic with GERD but do not have esophagitis *(nonerosive GERD)* achieve symptom relief with PPIs and H_2 receptor blockers.

Both PPIs and H_2 receptor blockers are available in prescription or OTC preparations. Teach the patient about side effects. Tell the patient to take medications as prescribed and not to stop without checking with the HCP. Have patients contact the HCP if symptoms persist.

PPIs are more effective in healing esophagitis than H_2 receptor blockers. PPIs also decrease the incidence of esophageal strictures, a complication of chronic GERD. Therapy should start with once-daily dosing, taken before the first meal of the day. Long-term use of PPIs may be associated with decreased bone density, kidney disease, vitamin B_{12} and magnesium deficiency, and increased risk for dementia.[12]

Drug Alert

Proton Pump Inhibitors (PPIs)

- Long-term use or high doses may increase the risk for fractures of hip, wrist, and spine.
- Patients should take the lowest dose for the shortest duration needed to treat their condition.
- Use may increase the risk for *C. difficile* infection in hospitalized patients.[12]

H_2 receptor blockers reduce symptoms and promote esophageal healing in 50% of patients. The onset of action of H_2 receptor blockers is 1 hour. Depending on the specific drug, therapeutic effects last up to 12 hours. We can give famotidine, ranitidine, and cimetidine orally or IV. Nizatidine is only available orally. Some preparations combine an H_2 receptor blocker with an antacid. For example, Pepcid Complete includes famotidine, calcium carbonate, and magnesium hydroxide.

Adjunctive treatments include antacids and prokinetic drugs. Antacids produce quick, short-lived relief of heartburn. Common antacids consist of magnesium hydroxide or aluminum hydroxide as single preparations or in various combinations (Table 41.10). The neutralizing effects of antacids taken on an empty stomach last only 20 to 30 minutes. They are most effective taken 1 to 3 hours after meals and at bedtime. When taken after meals, their effects may last 3 to 4 hours.

Antacids with or without alginic acid (e.g., Gaviscon) may be useful in patients with mild, intermittent heartburn. In patients with moderate to severe or frequent symptoms or patients with esophagitis, antacids are not effective in relieving symptoms or healing lesions. After an acute phase of bleeding, antacids may be given hourly, either orally or through the NG tube. If an NG tube is in place, periodically aspirate the stomach contents and test the pH level.

If pH is less than 5, intermittent suction may be used, or the frequency or dosage of the antacid or antisecretory agent increased.

The type and dosage of antacid given depend on side effects and potential drug interactions. Antacids high in sodium are used cautiously in older adults and patients with CVD, liver, and renal disease. Patients with renal failure should not take magnesium preparations because of the risk for magnesium toxicity. An antacid combination of aluminum and magnesium decreases the side effects of both.

Antacids can interact unfavorably with many drugs. They enhance the effects of some drugs, like benzodiazepines and pseudoephedrine. In many instances, antacids decrease the absorption rates of other drugs, such as thyroid hormones, phenytoin, and tetracycline. Before antacid therapy begins, inform the HCP of any drugs that a patient is taking.

Prokinetics increase LES pressure and improve gastric emptying, which may result in a small improvement in regurgitation and vomiting. Common agents include cisapride, metoclopramide (Reglan), bethanechol, and baclofen. However, many have significant side effects, so their use is limited only to those with known delayed gastric emptying.[13]

Nutritional Therapy

No specific diet is used to treat GERD. Some patients may need to avoid foods that decrease LES pressure, such as chocolate, peppermint, fatty foods, coffee, and tea (Table 41.7), which predispose them to reflux. Certain foods (e.g., tomato-based products, orange juice, cola, red wine) may irritate the esophagus.

Tell the patient to avoid late evening meals, nighttime snacking, and milk, especially at bedtime, since it increases gastric acid secretion. Small, frequent meals and drinking fluids between meals help prevent overdistention of the stomach. Increased saliva production by chewing gum and oral lozenges may help with mild symptoms. Recommend weight reduction if the patient is overweight.

Surgical Therapy

Surgical therapy (*antireflux* surgery) is reserved for patients with complications, such as esophagitis, medication intolerance, stricture, BE, and persistent severe symptoms. The goal of surgical therapy is to reduce reflux by enhancing the integrity of the LES. Most surgical procedures are done laparoscopically. The fundus of the stomach is wrapped around the lower part of the esophagus to reinforce and repair the defective barrier. Nissen and Toupet fundoplications are common laparoscopic antireflux surgeries.

TABLE 41.10 Drug TherapyGERD and Peptic Ulcer Disease (PUD)

Drug	Mechanism of Action	Side Effects
Proton Pump Inhibitors (PPIs)		
dexlansoprazole (Dexilant) **esomeprazole (Nexium)** **lansoprazole (Prevacid)** **omeprazole (Prilosec)** **omeprazole and sodium bicarbonate (Zegerid)** **pantoprazole (Protonix)** **rabeprazole (Aciphex)**	↓ HCl acid secretion by inhibiting the proton pump (H^+-K^+-ATPase) responsible for the secretion of H^+ ↓ Irritation of the esophageal and gastric mucosa	Headache, abdominal pain, nausea, diarrhea, vomiting, flatulence
Histamine (H_2) Receptor Blockers		
cimetidine **famotidine (Pepcid)** **nizatidine (Axid)** **ranitidine (Zantac)**	Block the action of histamine on the H_2 receptors to ↓ HCl acid secretion ↓ Conversion of pepsinogen to pepsin ↓ Irritation of the esophageal and gastric mucosa	Headache, abdominal pain, constipation, diarrhea
Antacids, Acid Neutralizers		
Single Substance **aluminum hydroxide (Amphojel)** **calcium carbonate (Tums)** **sodium bicarbonate (Alka-Seltzer)** **sodium citrate (Bicitra)** ***Aluminum and Magnesium*** **Gelusil, Maalox, Mylanta** **aluminum/magnesium trisilicate (Gaviscon)**	Neutralize HCl acid Taken 1–3 hr after meals and at bedtime	*Aluminum hydroxide:* Constipation, phosphorus depletion with chronic use *Calcium carbonate:* Constipation or diarrhea, hypercalcemia, milk-alkali syndrome, renal calculi *Magnesium preparations:* Diarrhea, hypermagnesemia *Sodium preparations:* Milk-alkali syndrome if used with large amounts of calcium. Use with caution in patients on sodium restrictions
Cholinergic		
bethanechol (Urecholine)	↑ Lower esophageal sphincter pressure, improve esophageal emptying, increase gastric emptying	Lightheadedness, syncope, flushing, diarrhea, stomach cramps, dizziness
Cytoprotective		
sucralfate (Carafate)	Act to form a protective layer and serve as a barrier against acid, bile salts, and enzymes in the stomach	Constipation
Prokinetic		
metoclopramide (Reglan)	Block effect of dopamine ↑ Gastric motility and emptying Reduce reflux	CNS side effects ranging from anxiety to hallucinations Extrapyramidal side effects (tremor and dyskinesias similar to Parkinson's disease)
Prostaglandin (Synthetic)		
misoprostol (Cytotec)	Protect lining of stomach *Cytoprotective:* Increase production of gastric mucus and mucosal secretion of bicarbonate *Antisecretory:* ↓ HCl acid secretion	Abdominal pain, diarrhea, GI bleeding, uterine rupture if pregnant

Laparoscopic fundoplication is often an outpatient procedure. However, patients at risk for complications, including those with prior upper abdominal surgeries or co-morbidities (e.g., cardiac disease, obesity), may be hospitalized after the procedure. A small number of patients have complications, including gastric or esophageal injury, splenic injury, pneumothorax, perforation, bleeding, infection, and pneumonia.

After surgery, reflux symptoms should decrease. However,

recurrence is possible. In the first month after surgery, the patient may report mild dysphagia caused by edema, but it should resolve. Teach the patient to report persistent symptoms, such as heartburn and regurgitation.

A LINX Reflux Management System is an option for patients who have symptoms despite maximum medical management. A LINX system is a ring of small, flexible magnets enclosed in titanium beads and connected by titanium wires. Once implanted laparoscopically into the LES, the ring strengthens the weak LES. Under resting (nonswallowing) conditions, the magnetic attraction between the beads helps keep a weak LES closed to prevent reflux. When the person swallows, the force of pressure associated with the movement of fluids or foods overwhelms the magnetic forces and the fluid or food passes to the stomach. Adverse events with the system include difficulty swallowing, nausea, and pain when swallowing food. Tell patients who have a LINX system not to have an MRI as it could cause serious harm.

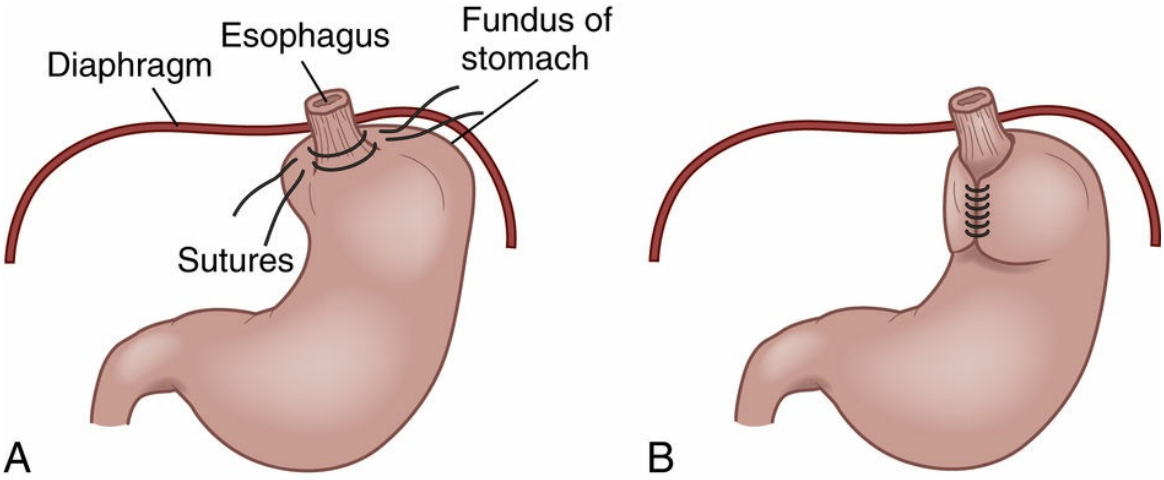

FIG. 41.4 Nissen fundoplication. **A,** Fundus of stomach is wrapped around distal esophagus. **B,** The fundus is then sutured to itself. Modified from Doughty DB, Jackson DB: *Mosby's clinical nursing series: Gastrointestinal disorders,* St Louis, 1993, Mosby.

Endoscopic Therapy

Alternatives to surgical therapy include endoscopic mucosal resection (EMR) and radiofrequency ablation. The heat energy delivered through radiofrequencies creates lesions, which we think thicken the LES. For patients with high-grade dysplasia, EMR can be used as a diagnostic test to obtain biopsy samples. Biopsy results determine whether cancer is present.

Hiatal Hernia

Hiatal hernia is herniation of part of the stomach into the esophagus through an opening, or hiatus, in the diaphragm. We also call it a *diaphragmatic hernia* or *esophageal hernia*. Hiatal hernias are the most common abnormality found on x-ray examination of the upper GI tract. They are common in older adults and occur more often in women.

There are 2 types of hiatal hernias (Fig. 41.4):

1. *Sliding:* The junction of the stomach and esophagus is above the diaphragm, and a part of the stomach slides through the hiatal opening in the diaphragm. This occurs when the patient is supine. The hernia usually goes back into the abdominal cavity when the patient is standing upright. This is the most common type.
2. *Paraesophageal* or *rolling:* The fundus and greater curvature of the stomach roll up through the diaphragm, forming a pocket alongside the esophagus. The esophagogastric junction stays in the normal position. Acute paraesophageal hernia is a medical emergency.

Etiology and Pathophysiology

Many factors contribute to the development of a hiatal hernia. Structural changes (weakening of the muscles in the diaphragm around the esophagogastric opening) occur with aging. Factors that increase intraabdominal pressure may predispose patients to developing a hiatal hernia. These include obesity, pregnancy, ascites, tumors, intense physical exertion, and heavy lifting on a continual basis.

Clinical Manifestations and Complications

Some people with hiatal hernia are asymptomatic. When present, manifestations of hiatal hernia are similar to those described for GERD on pp. 896-897.

Complications that may occur with hiatal hernia include GERD, esophagitis, hemorrhage from erosion, stenosis (narrowing of the esophagus), ulcerations of the herniated part of the stomach, strangulation of the hernia, and regurgitation with tracheal aspiration.

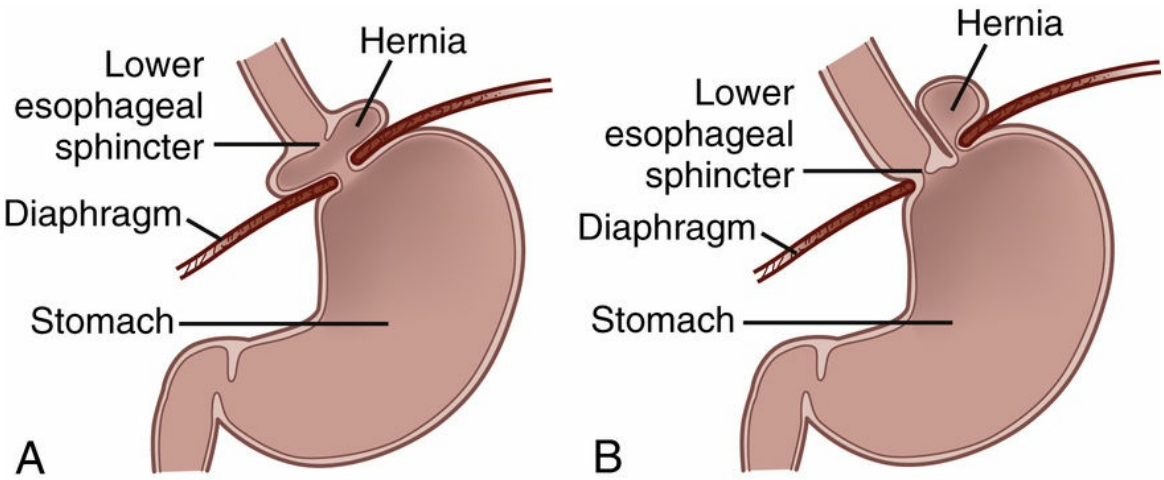

FIG. 41.5 **A,** Sliding hiatal hernia. **B,** Rolling or paraesophageal hernia.

Diagnostic Studies

An esophagram (barium swallow) may show the protrusion of gastric mucosa through the esophageal hiatus. Endoscopic visualization of the lower esophagus gives information on the degree of mucosal inflammation or other abnormalities. Other tests done are the same as those for GERD (Table 41.8).

Nursing and Interprofessional Management: Hiatal Hernia

Conservative therapy of hiatal hernia is similar to that described for GERD (pp. 897-898). Teach the patient to reduce intraabdominal pressure by eliminating constricting garments and avoiding lifting and straining.

Surgical approaches to hiatal hernias can include reduction of the herniated stomach into the abdomen, *herniotomy* (excision of the hernia sac), *herniorrhaphy* (closure of the hiatal defect), fundoplication, and *gastropexy* (attachment of the stomach below the diaphragm to prevent reherniation). The goals are to reduce the hernia, provide an acceptable LES pressure, and prevent movement of the gastroesophageal junction.

Surgery to repair hiatal hernia is often done laparoscopically by either Nissen or Toupet techniques (Fig. 41.5). The approach used (thoracic or abdominal) depends on the patient.

Gerontologic Considerations: GERD and Hiatal Hernia

The incidence of hiatal hernia and GERD increases with age. Hiatal hernia is associated with weakening of the diaphragm, obesity, kyphosis, or other factors (e.g., wearing girdles) that increase intraabdominal pressure. Older patients may take drugs known to decrease LES pressure (e.g., nitrates, calcium channel blockers, antidepressants). Other agents, such as nonsteroidal antiinflammatory drugs (NSAIDs) and potassium, can irritate the esophageal mucosa, causing *medication-induced esophagitis.*

Some older adults with hiatal hernia and GERD are asymptomatic or have less severe symptoms. The first sign may be a serious problem, such as esophageal bleeding from esophagitis or respiratory complications (e.g., aspiration pneumonia) due to aspiration of gastric

contents.

The clinical course and management of GERD and hiatal hernia in the older adult are similar to those for the younger adult. Changes in lifestyle, including smoking cessation and elevating the head of the bed on blocks may be challenging for the older adult.

Laparoscopic procedures reduce the risk associated with surgical repair. An older patient with heart and lung problems may not be a good candidate for surgical intervention.

Esophageal Cancer

Esophageal cancer is not common. However, the rates are increasing. In the United States, around 17,280 new cases are diagnosed and 15,850 deaths occur from esophageal cancer each year.[5] The overall 5-year survival rate is 19%.

Most esophageal cancers are adenocarcinomas. The others are squamous cell tumors. Adenocarcinomas arise from the glands lining the esophagus and resemble cancers of the stomach and small intestine. The incidence of esophageal cancer increases with age. Those between 65 and 75 are at greatest risk. The incidence is higher in men than in women.

Etiology and Pathophysiology

The cause of esophageal cancer is unknown. Key risk factors include BE, smoking, excess alcohol use, and obesity. For example, current smoking or a history of smoking is associated with a twofold higher risk for esophageal cancer. Those with injury to the esophageal mucosa (e.g., from occupational exposure to asbestos and cement dust) are at greater risk. *Achalasia,* a condition marked by delayed emptying of the lower esophagus, is associated with squamous cell cancer.

Most esophageal tumors occur in the middle and lower portions of the esophagus. The tumor usually appears as an ulcerated lesion. It may penetrate the muscular layer and extend outside the wall of the esophagus. Many patients have advanced disease at the time of diagnosis. The cancer spreads via the lymph system, with the liver and lung being common sites of metastasis.

Clinical Manifestations and Complications

By the time the patient has symptoms, the tumor is often advanced. Progressive dysphagia is the most common symptom. It may be

described as a substernal feeling that food is not passing. Initially the dysphagia occurs only with meat, then with soft foods, and eventually with liquids.

Pain develops late. It occurs in the substernal, epigastric, or back areas and usually increases with swallowing. The pain may radiate to the neck, jaw, ears, and shoulders. If the tumor is in the upper third of the esophagus, symptoms, such as sore throat, choking, and hoarseness, may occur. Most patients lose weight. When esophageal stenosis (narrowing) is severe, regurgitation of blood-flecked esophageal contents is common.

Hemorrhage occurs if the cancer erodes through the esophagus and into the aorta. Esophageal perforation with fistula formation into the lung or trachea sometimes develops. The tumor may enlarge enough to cause esophageal obstruction, particularly in the later stages.

TABLE 41.11 Interprofessional CareEsophageal Cancer

Diagnostic Assessment

- History and physical examination
- Endoscopy of esophagus with biopsy
- Endoscopic ultrasonography
- Esophagram (barium swallow)
- Bronchoscopy
- CT, MRI, PET scans

Management

- Surgical therapy
    - Esophagectomy
    - Esophagoenterostomy

        - Esophagogastrostomy
- Endoscopic therapy
        - Dilation
        - Endoscopic mucosal resection
        - Laser therapy
        - Photodynamic therapy
        - Radiofrequency ablation
        - Stent or prosthesis placement
- Radiation therapy
- Chemotherapy

Diagnostic Studies

Endoscopic biopsy is required to diagnose esophageal cancer. Endoscopic ultrasonography (EUS) is important in staging esophageal cancer. Esophagram (barium swallow) may show narrowing of the esophagus at the tumor site (Table 41.11).

Interprofessional Management

The treatment of esophageal cancer depends on the tumor's location and whether invasion or metastasis is present. Esophageal cancer usually has a poor prognosis because it is often diagnosed at an advanced stage. The best results occur with a multimodal approach, including surgery, endoscopic ablation, chemotherapy, and radiation therapy. Depending on the location and cancer spread, only chemotherapy and radiation may be used. Palliative therapy consists of restoring swallowing function and maintaining nutrition and hydration.

Surgical Therapy

The types of surgical procedures done are (1) removal of part or all of the esophagus *(esophagectomy)* with use of a Dacron graft to replace the resected part, (2) resection of a portion of the esophagus and anastomosis of the remaining portion to the stomach

(esophagogastrostomy), and (3) resection of a portion of the esophagus and anastomosis of a segment of colon to the remaining portion *(esophagoenterostomy).* The surgical approaches may be open (thoracic, abdominal incision) or laparoscopic.

Minimally invasive esophagectomy (e.g., laparoscopic vagal nerve–sparing surgery) is being done more often. It has the advantage of using smaller incisions, decreasing intensive care unit (ICU) and hospital stays, and producing fewer pulmonary complications.

Endoscopic Therapy

Endoscopic therapy includes photodynamic therapy, EMR, and radiofrequency ablation. In photodynamic therapy, the patient receives an IV injection of porfimer sodium (Photofrin), a photosensitizer. Although most tissues absorb porfimer, cancer tissue absorbs it to a greater degree. The HCP directs light towards the cancerous area using a fiber passed through an endoscope. The light reacts with porfimer, starting a reaction that destroys the cancer cells. Patients must avoid direct sunlight for up to 6 weeks after the procedure.

EMR is an option for some small, very early stage cancers. It involves the removal of cancer tissue using an endoscope. Radiofrequency ablation uses electric currents to kill cancer cells by heating them.

Dilation, stent placement, or both can relieve obstruction. Dilation increases the lumen of the esophagus. It often relieves dysphagia and allows for improved nutrition. There are various types of dilators. Placement of stents or expandable stents may help when dilation is no longer effective. Stents allow food and liquid to pass through the stenotic area of the esophagus. Self-expandable metal stents are available with features to prevent stent migration and tumor ingrowth. Stents placed before surgery may help improve the patient's nutritional status.

Endoscopic laser therapy may be used in combination with dilation. Laser therapy can be repeated if obstruction recurs as the tumor grows. Sometimes these procedures are combined with radiation

therapy.

Radiation Therapy

Depending on the type and stage of esophageal cancer, the patient may receive chemotherapy with or without radiation therapy. Concurrent therapy is given for palliation of symptoms, especially dysphagia, and to increase survival. Some patients receive radiation therapy before surgery.

Chemotherapy

Many different chemotherapy drugs can be used to treat esophageal cancer. The preferred regimens are carboplatin and paclitaxel, cisplatin with capecitabine (Xeloda), cisplatin and fluorouracil, and oxaliplatin with either fluorouracil or capecitabine. DCF (docetaxel, cisplatin, fluorouracil) is an option for metastatic disease. Other treatments include ECF (epirubicin [Ellence], cisplatin, fluorouracil) and irinotecan (Camptosar).[14] Chemotherapy is discussed in Chapter 15.

Targeted Therapy

Some esophageal cancers have too much HER-2 protein on their cell surfaces, which helps cancer cells to grow. Trastuzumab (Herceptin) is a drug that targets the HER-2 protein and kills the cancer cells. This drug can cause heart damage, so it is not given with other chemotherapy drugs that also cause heart damage, such as epirubicin.[14]

Ramucirumab (Cyramza), an angiogenesis inhibitor, binds to the receptor for *vascular endothelial growth factor* (VEGF), a compound that stimulates blood vessel growth. Thus it prevents VEGF from binding to the receptor and signaling the body to make more blood vessels. This can help slow or stop the growth and spread of cancer. Ramucirumab treats advanced cancers that start at the gastroesophageal junction. Targeted therapies are discussed in Chapter 15.

Nutritional Therapy

After esophageal surgery IV fluids are given. A jejunostomy, gastrostomy, or esophagostomy feeding tube may be placed to feed the patient depending on the type of surgery (e.g., esophagogastrectomy). A swallowing study is often done before allowing the patient to have oral fluids. When starting fluids, give water (30 to 60 mL) hourly and gradually progress to small, frequent, bland meals. Place the patient in an upright position for 2 hours after to prevent regurgitation. With EN, observe the patient for signs of intolerance to the feeding or leakage of the feeding into the mediastinum. Symptoms that indicate leakage are pain, increased temperature, and dyspnea. (EN is discussed in Chapter 39.)

Nursing Management: Esophageal Cancer

Nursing Assessment

Ask the patient about a history of GERD, hiatal hernia, achalasia, BE, and tobacco and alcohol use. Assess the patient for progressive dysphagia and *odynophagia* (burning, squeezing pain while swallowing). Ask about the type of substances (e.g., meats, soft foods, liquids) that cause dysphagia. Assess the patient for pain (substernal, epigastric, or back areas), choking, heartburn, hoarseness, cough, anorexia, weight loss, and regurgitation.

Nursing Diagnoses

Nursing diagnoses for the patient with esophageal cancer include:

- Chronic pain
- Impaired nutritional intake
- Impaired nutritional status
- Risk for aspiration
- Anxiety

Planning

The overall goals are that the patient with esophageal cancer will (1) have relief of symptoms, including pain and dysphagia; (2) achieve optimal nutritional intake; and (3) have a quality of life appropriate to stage of disease and prognosis.

Nursing Implementation

Health Promotion

Counsel the patient with GERD, BE, or hiatal hernia about the

importance of regular follow-up evaluation. Health counseling should focus on smoking cessation and reducing risk factors for GERD (Table 41.7). Maintaining good oral hygiene and dietary habits (e.g., intake of fresh fruits and vegetables) is important. Encourage patients to seek medical attention for any esophageal problems, especially dysphagia.

Acute Care

Preoperative Care

The patient and caregiver usually react with shock, disbelief, and depression when given the diagnosis of esophageal cancer. Provide emotional and physical support, provide information, clarify test results, and maintain a positive attitude with respect to the patient's immediate recovery and long-term survival.

In addition to general preoperative teaching and preparation, pay attention to the patient's nutritional needs. Many are poorly nourished because of the inability to ingest adequate amounts of food and fluids. A high-calorie, high-protein diet is recommended. Some patients need a liquid form of this diet. Others may need IV fluid replacement or parenteral nutrition (PN). Teach the patient and caregiver how to keep an intake and output record and assess for signs of fluid and electrolyte imbalance. Some treatment protocols include preoperative radiation and chemotherapy.

Meticulous oral care is essential. Cleanse the mouth thoroughly, including the tongue, gingivae, and teeth or dentures. It may be necessary to use swabs or a gauze pad and to scrub the mouth, including the tongue. Milk of Magnesia with mineral oil helps remove crust formation.

Teaching should include information about chest tubes (with a planned open thoracic approach), IV lines, NG tubes, pain management, gastrostomy or jejunostomy feeding, turning, coughing, and deep breathing. (General preoperative care is discussed in Chapter 17.)

Postoperative Care

During the immediate postoperative period, the patient usually receives care in the ICU for 1 to 2 days. In addition to usual postoperative complications, dysrhythmias may result from the proximity of the pericardium to the surgical site. Other complications include anastomotic leaks, fistula formation, interstitial pulmonary edema, and acute respiratory distress related to the disruption of the mediastinal lymph nodes.

The patient usually has an NG tube in place for 5 to 7 days. The drainage may be bloody for 8 to 12 hours. The drainage gradually changes to greenish yellow. Assessing the drainage, maintaining the tube, and providing oral and nasal care are key nursing responsibilities. Do not irrigate the NG tube, reposition it, or reinsert it without consulting the HCP.

If the chest cavity is entered, postoperative drainage is achieved with chest tube insertion. Assess the amount and type of drainage. Notify the HCP of excess drainage (e.g., over 400 to 600 mL in 8 hours). Chest surgery and drainage tubes are discussed in Chapter 27.

Because of the location of the surgery and the patient' general condition, implement measures to prevent respiratory complications. Have the patient turn, cough and deep breathe, and use an incentive spirometer every 2 hours. Follow VTE prophylaxis measures and provide effective pain management. Position the patient in a semi-Fowler's or Fowler's position to prevent reflux and aspiration of gastric secretions. When the patient can drink fluids or eat, maintain the upright position for at least 2 hours after eating to assist with gastric emptying.

Ambulatory Care

Many patients need long-term follow-up care after surgery for esophageal cancer. The patient may need chemotherapy and radiation treatment after surgery. Encourage and assist the patient in maintaining adequate nutrition. A permanent feeding gastrostomy may be needed. The patient usually is afraid and anxious about the cancer diagnosis. Know what the HCP has told the patient about the prognosis and provide appropriate counseling.

Referral to a palliative care or home health nurse may be needed. (See Chapter 15 for the care of the cancer patient and Chapter 9 for a discussion of palliative and end-of-life care.)

Evaluation

The expected outcomes are that the patient with esophageal cancer will

- Maintain a patent airway
- Have relief of pain
- Be able to swallow comfortably and consume adequate nutritional intake
- Have a quality of life appropriate to stage of disease and prognosis

Other Esophageal Disorders

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) is characterized by swelling of the esophagus from an infiltration of *eosinophils*. People with EoE often have a personal or family history of other allergic diseases. The most common food triggers are milk, egg, wheat, rye, and beef. Environmental allergens, such as pollens, molds, cat, dog, and dust mite allergens, may be involved in the development of EoE.

Patients may have severe heartburn, difficulty swallowing, food impaction in the esophagus, nausea, vomiting, and weight loss. The diagnosis is based on symptoms and biopsy findings of eosinophils infiltrating esophageal tissue obtained from endoscopy.

Allergy skin testing helps to determine the person's allergens. A trial of avoiding the foods to which the person has positive allergy tests is the first treatment. Other common treatments include the use of PPIs (Table 41.10) and corticosteroids. Corticosteroids are used to treat EoE when avoiding allergic triggers does not relieve symptoms.

Corticosteroids may be used orally (prednisone) or as a topical therapy with inhaled corticosteroids (e.g., fluticasone [Flovent]). The patient takes a puff of fluticasone, and rather than inhaling it, swallows the medication. This directly delivers the drug to the esophagus. The most common side effect is a yeast infection of the throat (esophageal candidiasis).

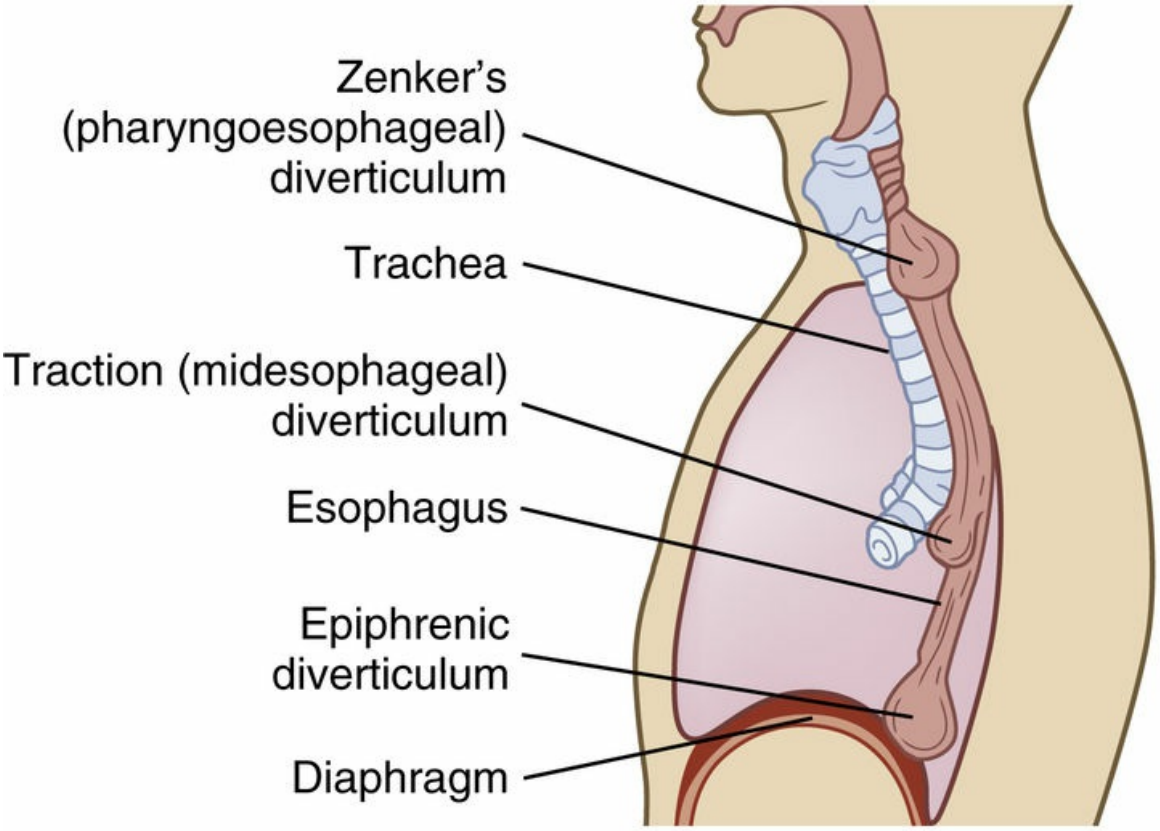

FIG. 41.6 Sites for esophageal diverticula. These hollow outpouchings may occur just above the upper esophageal sphincter (Zenker's), near the midpoint of the esophagus (traction), and just above the lower esophageal sphincter (epiphrenic).
Modified from Price SA, Wilson LM: *Pathophysiology: Clinical concepts of disease processes,* ed 6, St Louis, 2003, Mosby.

Esophageal Diverticula

Esophageal diverticula are saclike outpouchings of 1 or more layers of the esophagus. They occur in 3 main areas: (1) above the upper esophageal sphincter *(Zenker's diverticulum),* which is the most common location; (2) near the esophageal midpoint (traction diverticulum); and (3) above the LES (epiphrenic diverticulum) (Fig. 41.6). Zenker's diverticula occur commonly in people older than 60 years.

Typical symptoms include dysphagia, regurgitation, chronic cough, aspiration, and weight loss. Food becomes trapped in the outpouches. This causes tasting sour food and smelling a foul odor. Complications

include malnutrition, aspiration, and perforation. Endoscopy or barium studies can easily establish a diagnosis.

There is no specific treatment. Some patients find that they can empty the pocket of food that collects by applying pressure at a certain point on the neck. The diet may have to be limited to foods that pass more readily (e.g., blenderized foods). Surgical treatment may be needed if nutrition is disrupted. Endoscopic stapling diverticulotomy or diverticulostomy is associated with decreased complications compared with the open approaches. The most serious surgical complication is esophageal perforation.

Esophageal Structures

The most common cause of *esophageal strictures* (or narrowing) is chronic GERD. The ingestion of strong acids or alkalis, external beam radiation, and surgical anastomosis can also create strictures. Trauma, such as throat lacerations and gunshot wounds, can lead to strictures because of scar formation. Strictures can cause dysphagia and regurgitation, leading to weight loss.

Strictures can be dilated using mechanical *bougies* (dilating instruments) or balloons. Dilation may be done with or without endoscopy, or with fluoroscopy. Surgical excision with anastomosis is sometimes needed. The patient may have a temporary or permanent gastrostomy.

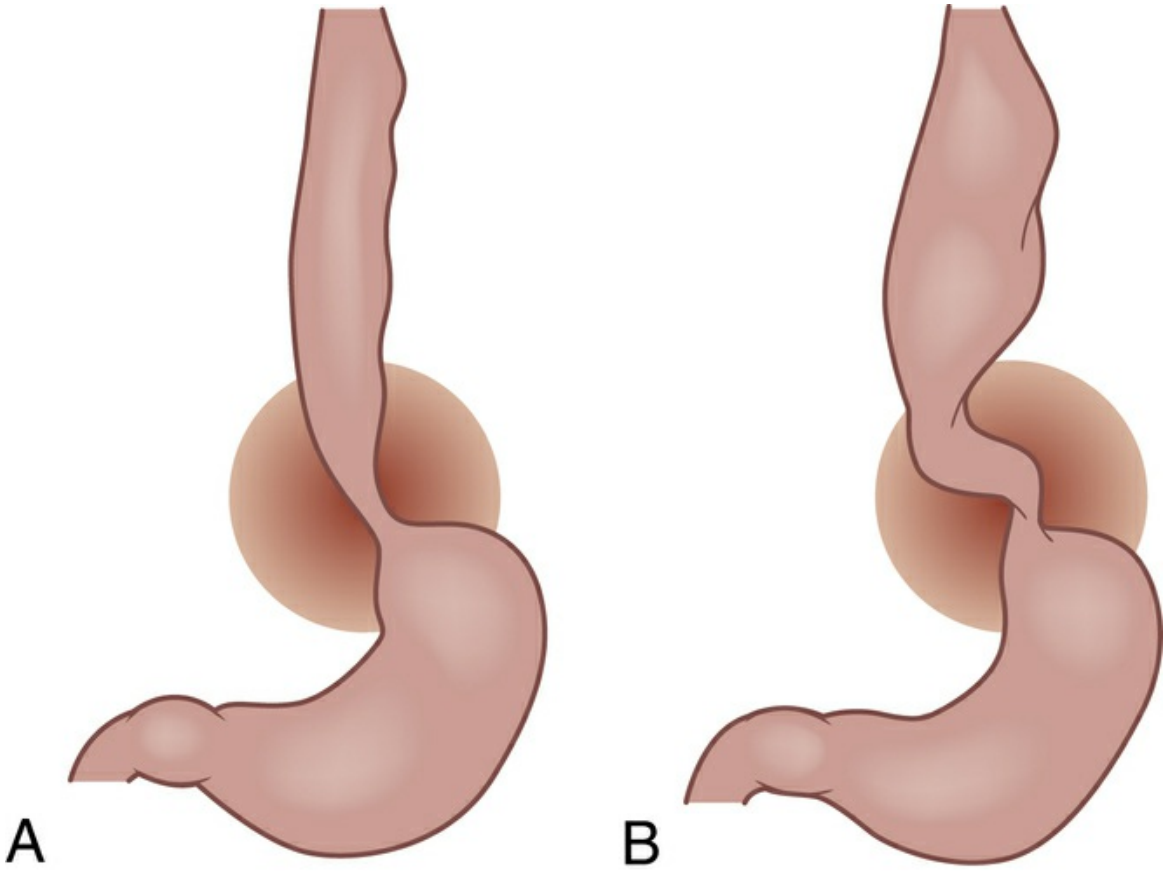

FIG. 41.7 Esophageal achalasia. **A,** Early stage, showing tapering of lower esophagus. **B,** Advanced stage, showing dilated, tortuous esophagus.

Achalasia

In **achalasia**, peristalsis of the lower two thirds (smooth muscle) of the esophagus is absent. Achalasia is a rare, chronic disorder. The exact cause is unknown. With achalasia, the pressure in the LES increases along with incomplete relaxation. Esophageal obstruction at or near the diaphragm occurs. Food and fluid accumulate in the lower esophagus. The result is dilation of the esophagus above the tapered affected segment of the lower esophagus (Fig. 41.7). There is a selective loss of inhibitory neurons, resulting in unopposed contraction of the LES.

The onset of achalasia is usually slow. Dysphagia is the most common symptom and occurs with both liquids and solids. Patients

may report a globus sensation and/or substernal chest pain (similar to angina pain) during or right after a meal. About a third have nighttime regurgitation. *Halitosis* (foul-smelling breath) and the inability to eructate (belch) can occur. Patients may report symptoms of GERD and regurgitation of sour-tasting food and liquids, especially when they are lying down. Weight loss is common.

Diagnosis is made with esophagram (barium swallow), manometric evaluation (high-resolution manometry), and/or endoscopic evaluation. Treatment focuses on symptom management. The goals of treatment are to relieve dysphagia and regurgitation, improve esophageal emptying by disrupting the LES, and prevent the development of megaesophagus (enlargement of the lower esophagus).

Endoscopic pneumatic dilation involves dilating the LES muscle using balloons of progressively larger diameter (3.0, 3.5, and 4.0 cm) (Fig. 41.8). It is an outpatient procedure. If this is ineffective, the next option is a Heller myotomy, done laparoscopically. In this procedure, the HCP cuts through the muscles of the LES, allowing food to pass. Because GERD with esophagitis and stricture is a common complication, the patient often has anti-reflux surgery at the same time. The patient typically returns to usual activities 1 to 2 weeks afterward.

Medical therapy is less effective than invasive procedures. The injection of botulinum toxin endoscopically into the LES gives short-term relief of symptoms and improves esophageal emptying. It works by promoting relaxation of the smooth muscle. This treatment is used for older patients for whom surgery and pneumatic dilation may not be appropriate due to other chronic illnesses.

Nitrates (e.g., isosorbide dinitrate) and calcium channel blockers (e.g., nifedipine [Procardia]) relax the LES and may improve dysphagia. They are taken sublingually 10 to 30 minutes before meals. Side effects (e.g., headache), drug tolerance, and short duration of action limit their use. Symptomatic treatment consists of eating a semisoft diet, eating slowly, drinking fluid with meals, and sleeping with the head elevated.

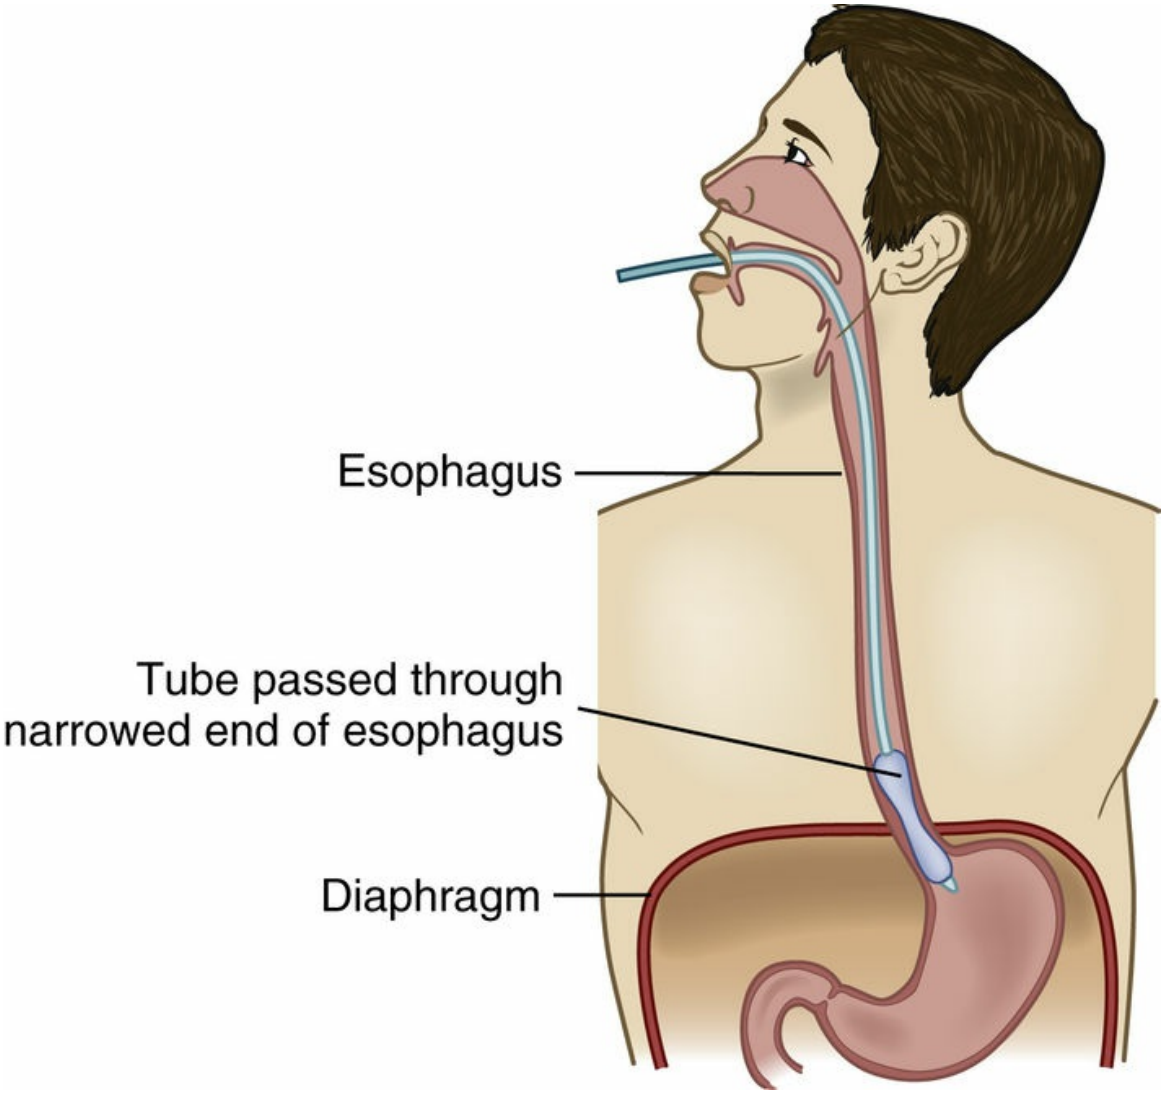

FIG. 41.8 Pneumatic dilation can treat achalasia by maintaining an adequate lumen and decreasing lower esophageal sphincter (LES) tone.
Modified from Price SA, Wilson LM: *Pathophysiology: Clinical concepts of disease processes,* ed 6, St Louis, 2003, Mosby.

Esophageal Varices

Esophageal varices are dilated, tortuous veins occurring in the lower part of the esophagus because of portal hypertension. Esophageal varices are a common complication of liver cirrhosis. They are discussed in Chapter 43.

Disorders of the Stomach and Upper Small Intestine

Peptic Ulcer Disease

Peptic ulcer disease (PUD) is a condition characterized by erosion of the GI mucosa from the digestive action of HCl acid and pepsin. Any part of the GI tract that is in contact with gastric secretions is susceptible to ulcer development. This includes the lower esophagus, stomach, duodenum, and margin of a gastrojejunal anastomosis after surgical procedures. PUD affects about 4.5 million people in the United States each year.[15]

Types

Peptic ulcers are classified as acute or chronic, depending on the degree and duration of mucosal involvement, and gastric or duodenal, according to the location. The *acute ulcer* (Fig. 41.9) is associated with superficial erosion and minimal inflammation. It is of short duration and resolves quickly when the cause is identified and removed. A chronic ulcer (Fig. 41.10) is one of long duration, eroding through the muscular wall with the formation of fibrous tissue. It is present continuously for many months or intermittently throughout the person's lifetime. Chronic ulcers are more common than acute erosions.

Although gastric and duodenal ulcers are both considered PUD, they are different in their incidence and presentation (Table 41.12).

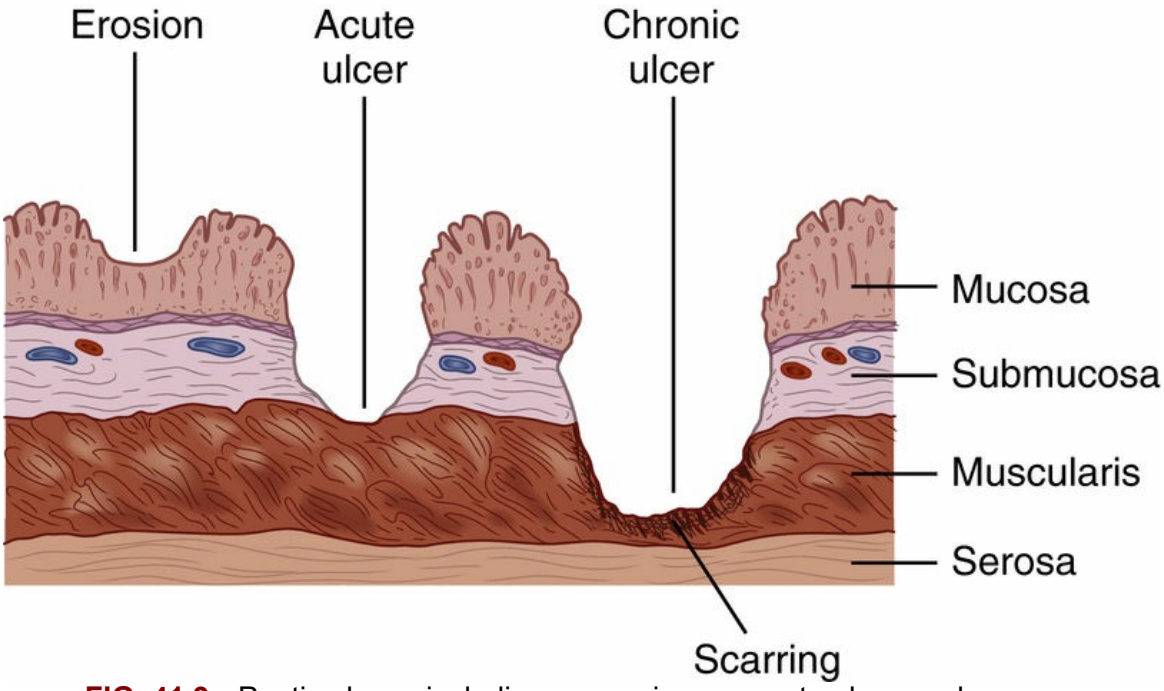

FIG. 41.9 Peptic ulcers, including an erosion, an acute ulcer, and a chronic ulcer. Both the acute ulcer and the chronic ulcer may penetrate the entire wall of the stomach.
Modified from Price SA, Wilson LM: *Pathophysiology: Clinical concepts of disease processes,* ed 6, St Louis, 2003, Mosby.

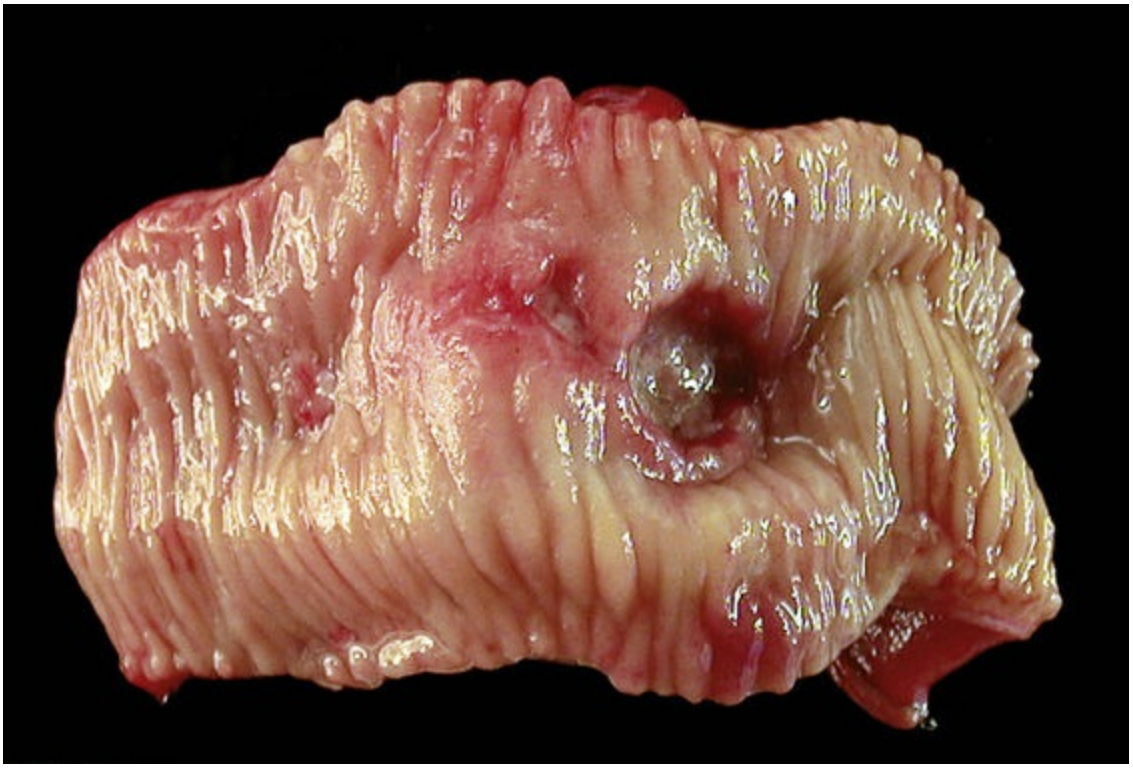

FIG. 41.10 Peptic ulcer of the duodenum.
From Kumar V, Abbas AK, Aster JC, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Etiology and Pathophysiology

Peptic ulcers develop only in an acid environment. However, an excess of HCl acid is not necessary for ulcer development. Pepsinogen, the precursor of pepsin, changes to pepsin in the presence of HCl acid and a pH of 2 to 3. When food or antacids neutralize the stomach acid level or drugs block acid secretion, the pH increases to 3.5 or more. At a pH of 3.5 or more, pepsin has little or no proteolytic activity.

The pathophysiology of ulcer development is outlined in Fig. 41.11. The back diffusion of HCl acid into the gastric mucosa results in cellular destruction and inflammation. Histamine is released from the damaged mucosa. This results in vasodilation, increased capillary permeability, and further secretion of acid and pepsin. Fig. 41.12 shows the interrelationship between the mucosal blood flow and disruption of the gastric mucosal barrier. Several factors damage the

mucosal barrier.

Helicobacter Pylori

The major risk factor for PUD is infection with *Helicobacter pylori.* 80% of gastric and 90% of duodenal ulcers are related to *H. pylori*. In the United States, *H. pylori* affects 20% of persons younger than 30 years and 50% of those older than 60 years. Infection likely occurs during childhood with transmission from family members to the child, possibly through a fecal-oral or oral-oral route. The rate is highest in black and Hispanic people.[15] Although most people with *H. pylori* never develop ulcers, it appears that those infected with *CagA*-positive strains are more likely to have PUD.[16]

In the stomach, the bacteria can survive a long time by colonizing the gastric epithelial cells within the mucosal layer. The bacteria make urease, which metabolizes urea-producing ammonium chloride and other damaging chemicals. Urease activates the immune response with both antibody production and the release of inflammatory cytokines. This leads to increased gastric secretion and causes tissue damage, leading to PUD.

TABLE 41.12 Comparison of Gastric and Duodenal Ulcers

Gastric Ulcers	Duodenal Ulcers
Lesion	
Superficial, smooth margins. Round, oval, or cone shaped	Penetrating (associated with deformity of duodenal bulb from healing of recurrent ulcers)
Location of Lesion	
Predominantly antrum, also in body and fundus of stomach	First 1–2 cm of duodenum
Gastric Secretion	
Normal to decreased	Increased
Incidence	
Greater in women	Greater in men, but increasing in women (especially postmenopausal)
Peak age 50–60 yr	Peak age 35–45 yr
Increased cancer risk	No increase in cancer risk
***H. pylori* infection in 80%**	*H. pylori* infection in 90%
↑ With incompetent pyloric sphincter and bile reflux	Associated with other diseases (e.g., COPD, pancreatic disease, hyperparathyroidism, ZES, chronic renal failure)
Clinical Manifestations	
Burning or gaseous pressure in epigastrium	Burning, cramping, pressure-like pain across midepigastrium and upper abdomen. Back pain with posterior ulcers
Pain 1–2 hr after meals. If penetrating ulcer, aggravation of discomfort with food	Pain 2–5 hr after meals and midmorning, midafternoon, middle of night. Periodic and episodic. Pain relief with antacids and food
Recurrence Rate	
High	High

Medication-Induced Injury

NSAID use is responsible for most non–*H. pylori* peptic ulcers. NSAIDs inhibit prostaglandin synthesis, increase gastric acid secretion, and reduce the integrity of the mucosal barrier. NSAID use in the presence of *H. pylori* further increases the risk for PUD. Patients taking corticosteroids or anticoagulants with NSAIDs have a higher risk for PUD.[15] Corticosteroids affect mucosal cell renewal and decrease its protective effects.

Lifestyle Factors

High alcohol intake is associated with acute mucosal lesions. Alcohol and smoking stimulate acid secretion. Coffee (caffeinated and decaffeinated) is a strong stimulant of gastric acid secretion. Smoking and psychologic distress, including stress and depression, can delay the healing of ulcers once they have developed.

Gastric Ulcers

Gastric ulcers can occur in any part of the stomach. They most often occur in the antrum. Gastric ulcers are less common than duodenal

ulcers. Gastric ulcers are more prevalent in women and those over 50 years of age. Because of the peak incidence of gastric ulcers in older adults, the mortality rate from gastric ulcers is greater than that from duodenal ulcers. Gastric ulcers are more likely than duodenal ulcers to cause an obstruction. *H. pylori,* NSAIDs, and bile reflux are the main risk factors.

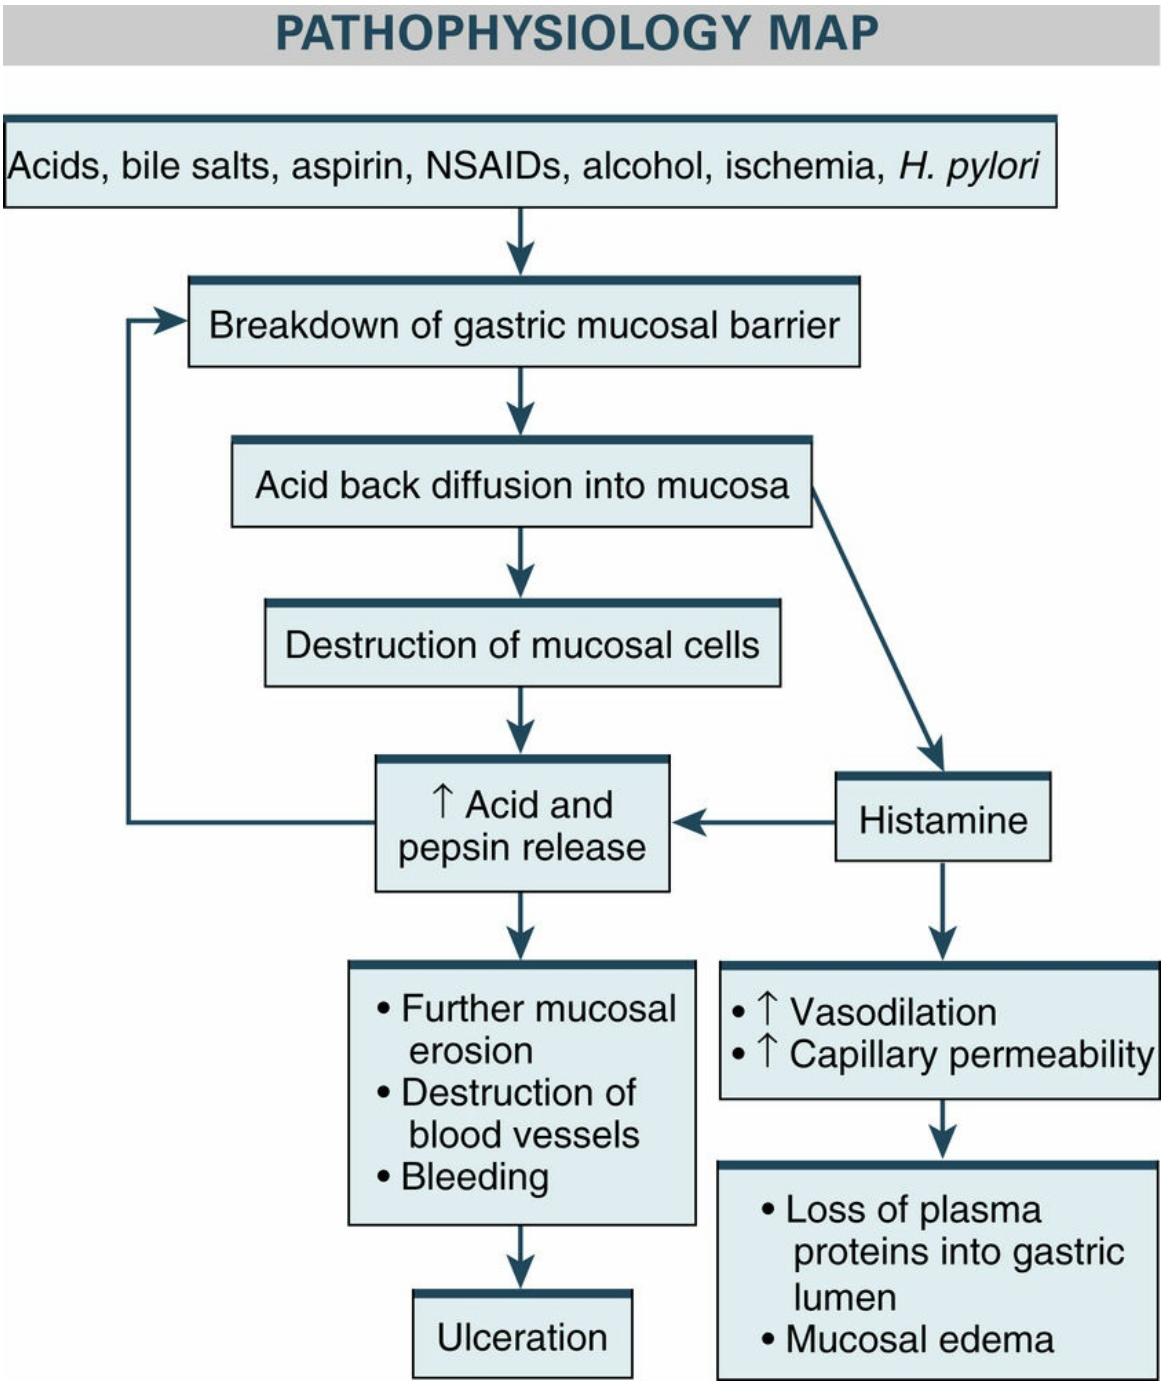

FIG. 41.11 Disruption of gastric mucosa and pathophysiologic consequences of back diffusion of acids.

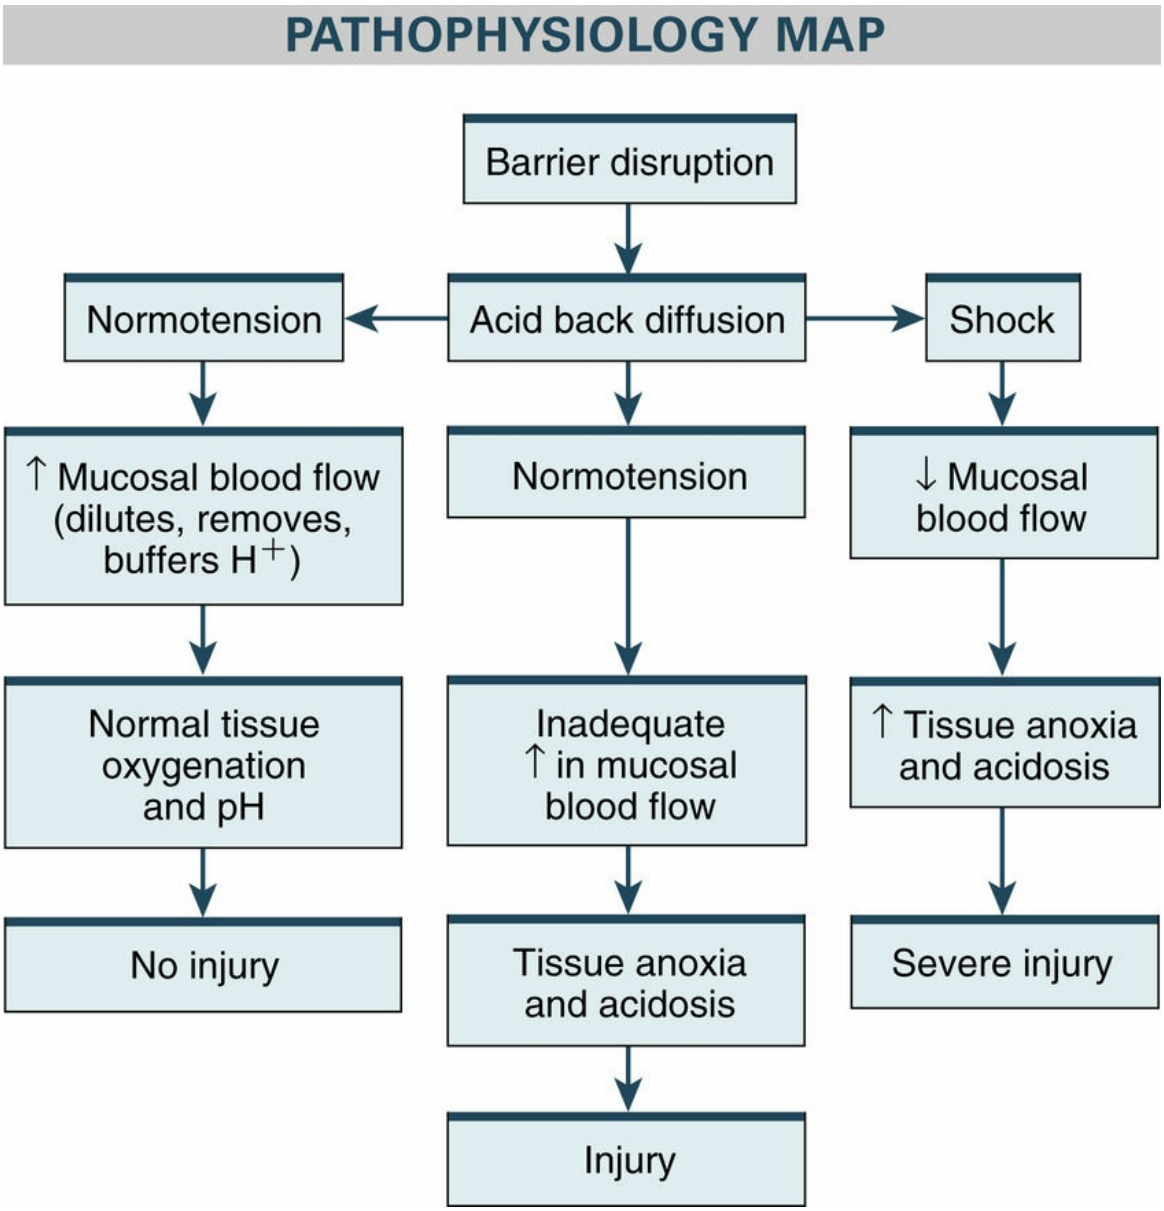

FIG. 41.12 Relationship between mucosal blood flow and disruption of the gastric mucosal barrier.

Duodenal Ulcers

Duodenal ulcers account for about 80% of all peptic ulcers. Duodenal ulcers occur at any age, but the incidence is especially high between 35 and 45 years of age. Although many factors are associated with the development of duodenal ulcers, *H. pylori* is the most common.

The development of duodenal ulcers is often associated with a high HCl acid secretion. Those at high risk include people with chronic

obstructive pulmonary disease (COPD), cirrhosis, pancreatitis, hyperparathyroidism, chronic kidney disease, and *Zollinger-Ellison syndrome* (ZES). ZES is a rare condition characterized by severe peptic ulceration and HCl acid hypersecretion.

Duodenal ulcers tend to occur continuously for a few weeks or months and then disappear for a time, only to recur some months later.

Stress-Related Mucosal Disease (SRMD)

SRMD is described later in this chapter in the section on acute upper GI bleeding on p. 917.

Clinical Manifestations

In gastric ulcers, the discomfort is generally high in the epigastrium and occurs about 1 to 2 hours after meals. The pain is described as "burning" or "gaseous." If the ulcer has eroded through the gastric mucosa, food tends to worsen the pain. For some patients, the earliest symptoms are due to a serious complication, such as perforation.

In duodenal ulcers, symptoms occur when gastric acid comes in contact with the ulcers. With meal ingestion, food is present to help buffer the acid. Symptoms occur generally 2 to 5 hours after a meal. The pain is described as "burning" or "cramplike." It is most often in the midepigastric region beneath the xiphoid process. Duodenal ulcers can also cause back pain.

Some patients have bloating, nausea, vomiting, and early feelings of fullness. Not all patients with ulcers will have pain or discomfort. *Silent* peptic ulcers are more likely to occur in older adults and those taking NSAIDs. The presence or absence of symptoms is not related to the size of the ulcer or the degree of healing.

Diagnostic Studies

Endoscopy is the most accurate procedure to determine the presence and location of an ulcer.[15] It allows for direct viewing of the gastric and duodenal mucosa (Fig. 41.13). During endoscopy, tissue

specimens are taken to determine if *H. pylori* is present and rule out stomach cancer. Endoscopy can also assess the degree of ulcer healing after treatment.

Several noninvasive and invasive tests are available to confirm *H. pylori* infection. The gold standard for diagnosing *H. pylori* infection is a biopsy of the antral mucosa with testing for urease (rapid urease testing). Urea is a by-product of the metabolism of *H. pylori* bacteria. Noninvasive tests include serology, stool, and breath testing. The urea breath and stool antigen tests can identify active infection. Stool tests are not as accurate as the urea breath test. Antibody tests for *H. pylori* can remain positive for years. They are not good for evaluating treatment results.

A barium contrast study may be used to diagnose gastric outlet obstruction or for ulcer detection in those who cannot undergo endoscopy. High fasting serum gastrin levels may show the presence of a possible gastrinoma (ZES). A secretin stimulation test can discern a gastrinoma from other causes of hypergastrinemia.

Laboratory tests, including a CBC, liver enzyme studies, serum amylase, and stool examination, may be done. A CBC may show anemia from ulcer bleeding. Liver enzyme studies help detect any liver problems (e.g., cirrhosis) that may complicate ulcer treatment. Stools are tested for blood. A serum amylase evaluates pancreatic function if we suspect posterior duodenal ulcer penetration of the pancreas.

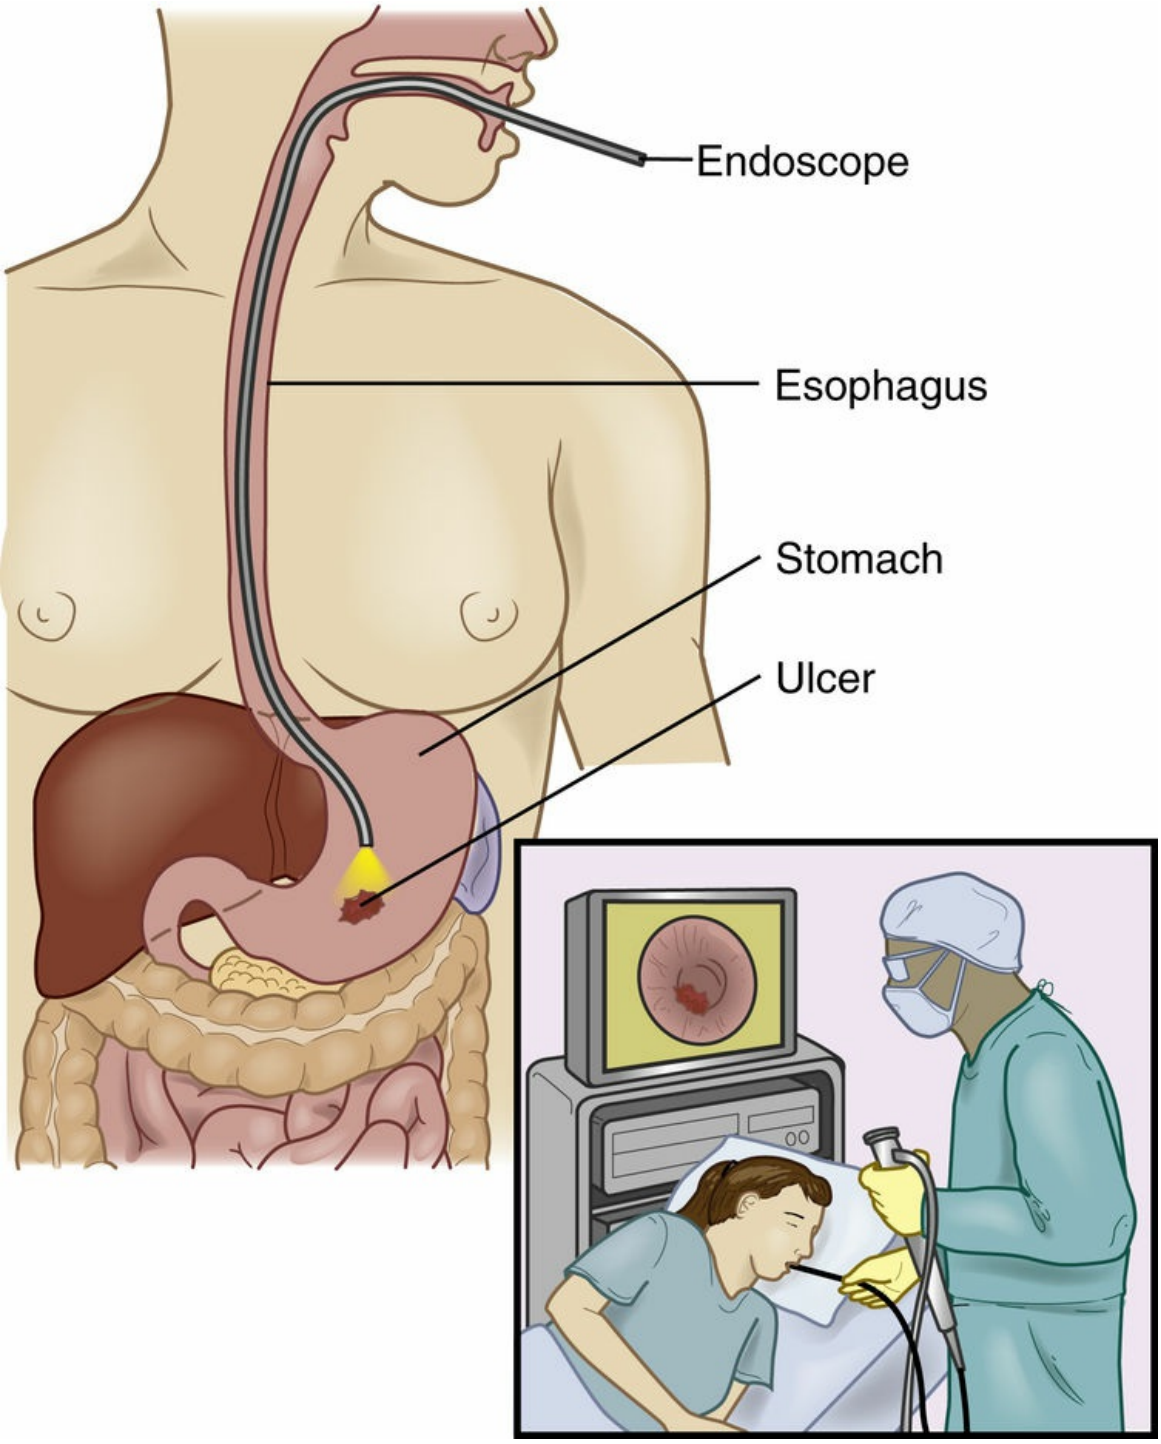

FIG. 41.13 Esophagogastroduodenoscopy (EGD) directly visualizes the mucosal lining of the stomach with a flexible endoscope. Ulcers or tumors can be directly seen and biopsies obtained.

Interprofessional Management

Conservative Care

Treatment begins after diagnostic studies confirm the presence of PUD (Table 41.13). The regimen consists of adequate rest, drug therapy, smoking cessation, dietary modifications (if needed), and long-term follow-up care. The aim of treatment is to decrease gastric acidity and enhance mucosal defense mechanisms.

Patients are generally treated in ambulatory care clinics. Pain disappears after 3 to 6 days, but ulcer healing is much slower. Complete healing may take 3 to 9 weeks, depending on ulcer size, treatment plan, and patient adherence. Endoscopic examination is the most accurate method to monitor ulcer healing. The usual follow-up endoscopic evaluation is done 3 to 6 months after diagnosis and treatment.

Aspirin and nonselective NSAIDs are stopped for 4 to 6 weeks. When aspirin must be continued, co-administration with a PPI, H_2 receptor blocker, or misoprostol may be prescribed. Patients receiving low-dose aspirin (LDA) for CVD and stroke risk who have a history of ulcer disease or complications may need to receive long-term treatment with a PPI. Enteric-coated aspirin decreases localized irritation but does not reduce the overall risk for GI bleeding.

Smoking has an irritating effect on the mucosa and delays mucosal healing. The patient should either stop or severely reduce smoking. (See Chapter 10 for ways to promote smoking cessation.) Adequate rest, both physical and emotional, is important for ulcer healing and may require some changes in the patient's daily routine. Avoiding or restricting alcohol use will enhance healing.

Drug Therapy

Medications are a key part of therapy (Table 41.10). Drug therapy focuses on reducing gastric acid secretion and, if needed, eliminating *H. pylori* infection. Patients with *H. pylori* infection need treatment with antibiotics and a PPI. After the ulcer has healed, many patients can stop PPI therapy. Some may need to continue low-dose maintenance therapy.

Diagnostic Assessment

- History and physical examination
- Upper GI endoscopy with biopsy
- Endoscopic ultrasound
- *H. pylori* testing of breath, urine, blood, tissue
- Complete blood cell count
- Liver enzymes
- Serum amylase
- Stool testing for blood

Management

Conservative Therapy

- Adequate rest
- Smoking and alcohol cessation
- Stress management (see Chapter 6)

Drug Therapy (Tables 41.10 and 41.14)

- Antibiotics for *H. pylori*
- PPIs
- Adjunctive therapy
    - H2-receptor blockers
    - Cytoprotective drugs
    - Antacids

Acute Exacerbation Without Complications

- NPO
- NG suction
- Adequate rest
- IV fluid replacement

Drug Therapy (Tables 41.10 and 41.14)

- Antibiotics for *H. pylori*
- PPIs
- Adjunctive therapy
    - H_2 receptor blockers
    - Cytoprotective drugs
    - Antacids
    - Sedatives

Acute Exacerbation With Complications (Hemorrhage, Perforation, Obstruction)

- NPO
- NG suction
- IV PPI
- Bed rest
- IV fluid replacement (lactated Ringer's solution)
- Blood transfusions
- Stomach lavage (possible)

Surgical Therapy

- Gastric outlet obstruction: Pyloroplasty and vagotomy
- Perforation: Simple closure with omentum graft
- Ulcer removal or reduction
    - Billroth I and II
    - Vagotomy and pyloroplasty

Because ulcers often recur, interrupting or stopping therapy can have harmful results. Strict adherence to the prescribed drug regimen is important. Encourage the patient to adhere to therapy and continue with follow-up care as prescribed. Teach the patient and caregiver about each drug prescribed, why it is ordered, and the expected benefits. Review what to do if pain and discomfort recur or there is blood in vomitus or stools.

TABLE 41.14 Drug TherapyH. pylori *Infection*

Drug Class	Drug	Triple Therapy	Bismuth Quadruple Therapy	Non-Bismuth Quadruple Therapy
Acid suppression	PPI	20–40 mg, 2 times daily	20–40 mg, 2 times daily	20–40 mg, 2 times daily
Standard antibiotics	Amoxicillin	1gram, 2 times daily		1 g, 2 times daily
	Bismuth compound		2 tablets, 2 times daily	
	Clarithromycin	500 mg, 2 times daily		500 mg, 2 times daily
	Metronidazole		500 mg, 3 times daily	500 mg, 2 times daily
	Tetracycline		500 mg, 4 times daily	

Antibiotic Therapy

Eradicating *H. pylori* is the most important part of treating PUD in patients positive for *H. pylori.* Antibiotic therapy is prescribed concurrently with a PPI for 14 days (Table 41.14). If the patient has a penicillin allergy, metronidazole is used instead of amoxicillin in the triple-drug regimen. Bismuth can be given alone or as part of a combination capsule (Pylera) containing bismuth, tetracycline, and metronidazole. Because of the existence of antibiotic-resistant organisms, a growing number of patients do not have *H. pylori*

eradicated with a single round of therapy.

Proton Pump Inhibitors

PPIs are more effective than H_2 receptor blockers in reducing gastric acid secretion and promoting ulcer healing. PPIs are used in combination with antibiotics to treat ulcers caused by *H. pylori*.

Cytoprotective Drug Therapy

Sucralfate is used for short-term ulcer treatment. It provides mucosal protection for the esophagus, stomach, and duodenum. Sucralfate does not have acid-neutralizing capabilities. Since it is most effective at a low pH, give it at least 60 minutes before or after an antacid. Adverse side effects are minimal. It binds with cimetidine, digoxin, warfarin, phenytoin, and tetracycline, reducing their bioavailability.

Adjunct Drugs

H_2 receptor blockers and antacids may be used as adjunct therapy to promote ulcer healing. Antacids increase gastric pH by neutralizing HCl acid. As a result, they reduce the acid content of chyme reaching the duodenum. Some antacids (e.g., aluminum hydroxide) can bind to bile salts, thus decreasing the damaging effects of bile on the gastric mucosa.

Misoprostol is a synthetic prostaglandin analog prescribed to prevent gastric ulcers caused by NSAIDs and LDA. It has protective and some antisecretory effects on gastric mucosa. People who need chronic NSAID therapy, such as those with osteoarthritis, may benefit from its use. However, it can cause diarrhea and abdominal pain. It is teratogenic and must be used with caution in women of childbearing potential.

Tricyclic antidepressants (e.g., imipramine, doxepin) may be prescribed for some patients. They may contribute to overall pain relief through their effects on afferent pain fiber transmission. In addition, they have varying degrees of anticholinergic properties, which result in reduced acid secretion.

Anticholinergic drugs are sometimes used for PUD treatment.

Anticholinergics are associated with several side effects, such as dry mouth, warm skin, flushing, thirst, tachycardia, dilated pupils, blurred vision, and urine retention.

Nutritional Therapy

There is no specific diet used to treat PUD. Patients should eat and drink foods and fluids that do not cause any distressing symptoms. Foods that may cause gastric irritation include pepper, carbonated beverages, broth (meat extract), and hot, spicy foods. Caffeine-containing beverages and foods can increase symptoms in some patients. Teach the patient to avoid alcohol use because it can delay healing.

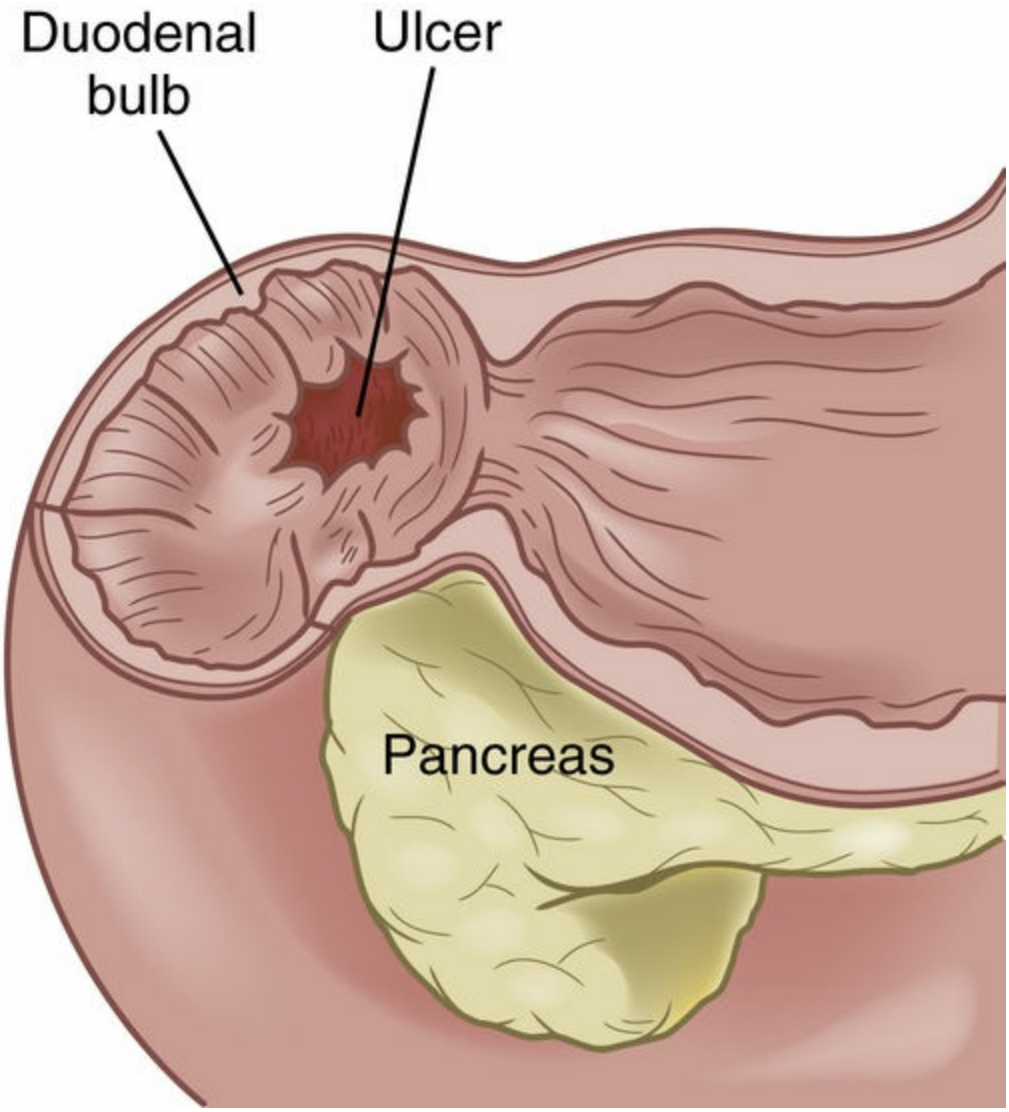

FIG. 41.14 Duodenal ulcer of the posterior wall penetrating the head of the pancreas, resulting in walled-off perforation.

Surgical Therapy

With the use of drug therapy and endoscopic therapy to treat PUD, surgery is used less often. Surgery is done on patients with complications that are unresponsive to medical management or concerns about stomach cancer. Gastric surgeries are described later in this chapter on p. 914.

Complications

The 3 major complications of chronic PUD are hemorrhage, perforation, and gastric outlet obstruction.[16] All these complications are considered emergency situations and may need surgical intervention.

Hemorrhage

Hemorrhage is the most common complication of PUD. Duodenal ulcers cause more upper GI bleeding episodes than gastric ulcers.

Perforation

Perforation is considered the most lethal complication of PUD. Perforation risk is highest with large penetrating duodenal ulcers (Fig. 41.14). However, the mortality rate associated with perforation of gastric ulcers is higher. The patient with gastric ulcers is older and often has concurrent medical problems, which accounts for the higher mortality rate.

With perforation, the ulcer penetrates the serosal surface with spillage of either gastric or duodenal contents into the peritoneal cavity. The contents entering the peritoneal cavity may contain air, saliva, food particles, HCl acid, pepsin, bacteria, bile, and pancreatic fluid and enzymes.

The manifestations of perforation are sudden and dramatic in onset. During the initial phase (0 to 2 hours after perforation), the patient has sudden, severe upper abdominal pain that quickly spreads throughout the abdomen. The pain radiates to the back and shoulders. Food or antacids do not relieve the pain. The abdomen appears rigid and boardlike as the abdominal muscles try to protect from further injury. The patient's respirations become shallow and rapid. The heart rate is elevated, and the pulse is weak. Bowel sounds are usually absent. Nausea and vomiting may occur.

If the condition is untreated, bacterial peritonitis may occur within 6 to 12 hours. The intensity of peritonitis is proportional to the amount and duration of the spillage through the perforation. It is hard to determine from symptoms alone whether a gastric or duodenal ulcer has perforated, because the manifestations of peritonitis are the same

(see Chapter 42).

The immediate focus of managing a patient with a perforation is to stop the spillage of gastric or duodenal contents into the peritoneal cavity and restore blood volume. An NG tube can provide continuous aspiration and gastric decompression to stop spillage through the perforation. For duodenal aspiration, the tube is placed as near to the perforation site as possible to facilitate decompression.

Circulating blood volume is replaced with lactated Ringer's and albumin solutions. These solutions substitute for the fluids lost from the vascular and interstitial space as peritonitis develops. Blood replacement in the form of packed RBCs may be needed. A central venous pressure line and an indwelling urinary catheter may be inserted and monitored hourly. The patient with a history of heart disease needs ECG monitoring or placement of a pulmonary artery catheter for accurate assessment of left ventricular function. Broad-spectrum antibiotic therapy is started immediately to treat bacterial peritonitis.

Small perforations may spontaneously seal themselves and symptoms cease. Spontaneous sealing occurs because of fibrin production in response to the perforation. This can lead to fibrinous fusion of the duodenum or gastric curvature to adjacent tissue (mainly the liver) and strictures that can obstruct the flow of intestinal contents and the passage of stool.

Larger perforations need immediate surgical closure. Whether the patient has an open or laparoscopic repair depends on the location of the ulcer and HCP preference. The procedure involving the least risk to the patient is simple oversewing of the perforation and reinforcement of the area with a graft of omentum. Excess gastric contents are suctioned from the peritoneal cavity during the surgical procedure.

Gastric Outlet Obstruction

Both acute and chronic PUD can cause gastric outlet obstruction. Obstruction in the distal stomach and duodenum is the result of edema, inflammation, pylorospasm, or fibrous scar tissue formation.

With obstruction the patient reports discomfort or pain that is worse toward the end of the day as the stomach fills and dilates. Belching or self-induced vomiting may provide some relief. Vomiting is common and often projectile. The vomitus may contain food particles that were ingested hours or days before. Constipation occurs because of dehydration and decreased diet intake from anorexia. Over time dilation of the stomach and visible swelling in the upper abdomen may occur.

The aim of therapy for obstruction is to decompress the stomach, correct any existing fluid and electrolyte imbalances, and improve the patient's general state of health. An NG tube is used as described previously. With continuous decompression for several days, the ulcer can begin healing and the inflammation and edema will subside. Pain relief results from the decompression.

TABLE 41.15 Nursing AssessmentPeptic Ulcer Disease

Subjective Data

Important Health Information

Past health history: Chronic kidney disease, pancreatic disease, COPD, serious illness or trauma, hyperparathyroidism, cirrhosis of the liver, ZES
Medications: Aspirin, corticosteroids, NSAIDs
Surgery or other treatments: Complicated or prolonged surgery

Functional Health Patterns

Health perception–health management: Chronic alcohol use, smoking, caffeine use. Family history of PUD
Nutritional-metabolic: Weight loss, anorexia, nausea and vomiting, hematemesis, dyspepsia, heartburn, belching

Elimination: Black, tarry stools
Cognitive-perceptual:

- *Duodenal ulcers:* Burning, midepigastric or back pain occurring 2–5 hr after meals and relieved by food; nighttime pain common
- *Gastric ulcers:* High epigastric pain occurring 1–2 hr after meals. Food may precipitate or worsen pain.

Coping–stress tolerance: Acute or chronic stress

Objective Data

General

Anxiety, irritability

Gastrointestinal

Epigastric tenderness

Possible Diagnostic Findings

Anemia. Guaiac-positive stools. Positive blood, urine, breath, or stool tests for *H. pylori.* Abnormal upper GI endoscopic and barium studies

IV fluids and electrolytes are replaced according to the degree of dehydration, vomiting, and electrolyte imbalance shown by laboratory studies. A PPI or H_2 receptor blocker is used if the obstruction is due to an active ulcer. Balloon dilation can open a pyloric obstruction. Surgery may be needed to remove scar tissue.

Nursing Management: Peptic Ulcer Disease

Nursing Assessment

Subjective and objective data to obtain from a patient with PUD are outlined in Table 41.15.

Nursing Diagnoses

Nursing diagnoses related to PUD may include:

- Acute pain
- Lack of knowledge
- Nausea

Additional information on nursing diagnoses and interventions for the patient with PUD are in eNursing Care Plan 41.2 available on the website for this chapter.

Planning

The overall goals are that the patient with PUD will (1) adhere to the prescribed therapeutic regimen, (2) see a reduction in or absence of discomfort, (3) have no signs of GI complications, (4) have complete healing of the peptic ulcer, and (5) make appropriate lifestyle changes to prevent recurrence.

Nursing Implementation

Health Promotion

You play an important role in identifying patients at risk for PUD. Early detection and effective treatment of ulcers are important aspects of reducing morbidity risks associated with PUD. Patients who are

taking ulcerogenic drugs (e.g., NSAIDs, LDA) are at risk for PUD. Encourage patients to take these drugs with food. Teach patients to report symptoms related to gastric irritation, including epigastric pain, to their HCP.

Acute Care

During an acute exacerbation, the patient often reports increased pain, nausea, and vomiting. Some may have bleeding. Initially, many patients try to cope with the symptoms at home before seeking medical care.

During the acute phase, the patient may be NPO for a few days, have an NG tube connected to intermittent suction, and receive IV fluid replacement. Explain to the patient and caregiver the reasons for these therapies so they understand that the advantages far outweigh any temporary discomfort. Regular mouth care relieves the dry mouth. Cleaning and lubricating the nares facilitate breathing and decrease soreness. Analysis of gastric contents may include pH testing and analysis for blood, bile, or other substances. When the stomach is empty of gastric secretions, pain decreases and ulcer healing begins.

The volume of fluid lost, the patient's signs and symptoms, and laboratory test results (hemoglobin, hematocrit, electrolytes) determine the type and amount of IV fluids given. Take vital signs initially and then at least hourly to detect and treat shock. Give IV fluids as ordered and record intake and output.

Physical and emotional rest is helpful to ulcer healing. The patient's environment should be quiet and restful. Give pain medications as ordered. A mild sedative or tranquilizer has beneficial effects when the patient is anxious and apprehensive. Use good judgment before sedating a person who is becoming increasingly restless because the drug could mask the signs of shock from upper GI bleeding.

Hemorrhage

Changes in vital signs and an increase in the amount and redness of aspirate often signal massive upper GI bleeding. With bleeding, the patient's pain often decreases because the blood helps neutralize the

acidic gastric contents. It is important to maintain the patency of the NG tube so that blood clots do not obstruct the tube. If the tube becomes blocked, the patient can develop abdominal distention. Use interventions similar to those described for upper GI bleeding on pp. 918–920.

Perforation

If the patient with an ulcer develops manifestations of a perforation, notify the HCP immediately. Take vital signs promptly and record them every 15 to 30 minutes. Temporarily stop all oral or NG drugs and feedings. If perforation exists, anything taken orally can add to the spillage into the peritoneal cavity and increase discomfort. Give IV fluid as ordered to replace the depleted plasma volume. Giving pain medications provides comfort.

Those with confirmed perforation will start on antibiotic therapy. If the perforation does not seal spontaneously, surgical closure is needed. Since surgery is done as soon as possible, there may not be time to prepare the patient and family.

Gastric Outlet Obstruction

Gastric outlet obstruction can happen at any time. It is most likely to occur in the patient whose ulcer is close to the pylorus. The onset of symptoms is usually gradual. Constant NG aspiration of stomach contents can help relieve symptoms. This allows edema and inflammation to subside and permits normal flow of gastric contents through the pylorus.

Regularly irrigate the NG tube with a normal saline solution per agency policy to assist proper functioning. It may be helpful to reposition the patient from side to side so that the tube tip is not constantly lying against the mucosal surface. Maintain accurate intake and output records, especially of the gastric aspirate.

To check for ongoing obstruction, clamp the NG tube intermittently and measure the gastric residual volume. The frequency and amount of time the tube is clamped are related to the amount of aspirate obtained and the patient's comfort level. A common method is to

clamp the tube overnight (usually 8 to 12 hours) and measure the gastric residual volume in the morning. When the aspirate falls below 200 mL, it is within a normal range and the patient can begin oral intake of clear liquids. Oral fluids begin at 30 mL/hr and then gradually increase in amount. As the amount of gastric residual decreases, solid foods are added, and the tube removed.

If the patient has resumed oral feedings and you note symptoms of obstruction, promptly inform the HCP. Generally, all that is needed to treat the problem is to resume gastric aspiration so that the edema and inflammation resulting from the acute episode resolve. IV fluids with electrolyte replacement keep the patient hydrated during this period. If conservative treatment is not successful, surgery is done after the acute phase has passed.

Ambulatory Care

Patients with PUD have specific needs to prevent recurrence and complications. Teaching should cover aspects of the disease process, drugs, lifestyle changes (alcohol use, smoking), and regular follow-up care. Table 41.16 provides a patient and caregiver teaching guide for PUD.

Knowing the causes of PUD may motivate the patient to become involved in care and improve adherence to therapy. Work with the dietitian to elicit a dietary history and plan ways to incorporate any needed dietary modifications into the patient's home and work setting.

Teach the patient about prescribed drugs, including their actions, side effects, and dangers if omitted for any reason. Make sure the patient knows not to take OTC drugs (e.g., NSAIDs, LDA) unless approved by the HCP. Some H_2 receptor blockers and PPIs are available without a prescription. Tell the patient to check with the HCP before switching from a prescription to an OTC preparation to avoid side effects and incorrect dosing. Obtain information about the patient's psychosocial status. Knowledge of lifestyle, occupation, and coping behaviors can be helpful in planning care. The patient may be reluctant to talk about personal subjects, the stress at home or on the

job, the usual methods of coping, or dependence on drugs or alcohol.

TABLE 41.16 Patient & Caregiver TeachingPeptic Ulcer Disease (PUD)

Include the following instructions when teaching the patient and caregiver about management of PUD:

1. Avoiding foods that cause epigastric distress, such as acidic foods.
2. Avoid cigarettes. Smoking promoting ulcer development and delays ulcer healing.
3. Reduce or eliminate alcohol use.
4. Avoid OTC drugs unless approved by the HCP. Many preparations contain ingredients, such as aspirin, that should not be taken unless approved by the HCP. Check with the HCP about the use of NSAIDs.
5. Do not interchange brands of PPIs, antacids, or H_2 receptor blockers that you can buy OTC without checking with the HCP. This can lead to harmful side effects.
6. Take all medications as prescribed. This includes both antisecretory and antibiotic drugs. Not taking medications as prescribed can cause a relapse.
7. It is important to report any of the following:
    - Increased nausea or vomiting
    - Increased epigastric pain
    - Bloody emesis or tarry stools
8. Stress can be related to signs and symptoms of PUD. Learn and use stress management strategies (see Chapter 6).
9. Share concerns about lifestyle changes and living with a chronic illness.

The patient may not be honest about habitual use of alcohol or cigarettes. Provide information about the negative effects of alcohol

and cigarettes on PUD and ulcer healing. Changes such as smoking cessation and alcohol abstinence are hard for many people. The patient may do better in reducing, rather than totally eliminating, use of these substances. However, the goal is total cessation.

PUD is a chronic, recurring disorder. Teach patients with chronic PUD about potential complications, and what to do until they see the HCP. Emphasize the need for long-term follow-up care. Encourage the patient to seek immediate intervention if symptoms return. Some patients do not adhere to the plan of care and have repeated exacerbations. Patients quickly learn that they often have no discomfort when they omit prescribed drugs, smoke, or drink alcohol. Consequently, they make no or few changes in their lifestyle. After an acute exacerbation, the patient is likely to be more amenable to following the plan of care and open to suggestions for changes in lifestyle.

Evaluation

Expected outcomes are that the patient with PUD will

- Have pain controlled without the use of analgesics
- States an understanding of the treatment plan
- Commit to self-care and management of the disease
- Have no complications (hemorrhage, perforation)

Gerontologic Considerations: Peptic Ulcer Disease

The morbidity and mortality rates associated with PUD in older adults are higher than for younger adults because of concurrent health problems and a decreased ability to withstand hypovolemia. Monitor older adults who use NSAIDs for osteoarthritis for PUD. In older patients, pain may not be the first symptom associated with an ulcer. For some patients the first sign is frank gastric bleeding or a decrease in hematocrit.

The treatment and management of PUD in older adults are similar to those in younger adults. The emphasis is on preventing gastritis and PUD. This includes teaching the patient to take NSAIDs and other gastric-irritating drugs with food, milk, or antacids. Teach the patient to avoid irritating substances, adhere to the PPI therapy as prescribed, and report abdominal pain or discomfort to the HCP.

Stomach Cancer

Stomach (gastric) cancer is an adenocarcinoma of the stomach wall (Fig. 41.15). It accounts for more than 26,240 new cancer cases and 10,800 deaths annually.[5] The rate of stomach (particularly distal) cancer has been steadily declining in the United States. However, cancer in the proximal gastric and gastroesophageal junction is increasing.

Asian Americans, Pacific Islanders, Hispanics, and blacks have higher rates of stomach cancer than non-Hispanic whites. In the United States the incidence is higher in men than in women by a 2:1 ratio. Stomach cancer mostly affects older people. The average age of people at the time of diagnosis is 68.[5]

At the time of diagnosis, only 10% to 20% of patients have disease confined to the stomach. The 5-year survival rate in this group is 71%. However, more than 50% have advanced metastatic disease. The overall 5-year survival rate of all people with stomach cancer is about 31%.[5]

Etiology and Pathophysiology

While many factors are implicated in the development of stomach cancer, no single causative agent has been identified. Stomach cancer probably begins with a nonspecific mucosal injury because of infection *(H. pylori),* autoimmune-related inflammation, repeated exposure to irritants such as bile or NSAIDs, and tobacco use.

Stomach cancer has been associated with diets high in smoked foods, salted fish and meat, and pickled vegetables. Whole grains and fresh fruits and vegetables are associated with reduced rates of stomach cancer. Infection with *H. pylori,* especially at an early age, is a risk factor for stomach cancer. It is possible that *H. pylori* and resulting cell changes can induce a sequence of transitions from dysplasia to cancer. People with lymphoma of the stomach (mucosa-associated lymphoid tissue [MALT]) are at higher risk of stomach cancer.

Other predisposing factors include atrophic gastritis, pernicious anemia, adenomatous polyps, hyperplastic polyps, and *achlorhydria* (absent or low production of gastric HCl). Smoking and obesity both increase the risk for stomach cancer. Although first-degree relatives of patients with stomach cancer are at increased risk, only about 10% of stomach cancers have an inherited component.[17]

Stomach cancer spreads by direct extension and typically infiltrates rapidly to the surrounding tissue and liver. Seeding of tumor cells into the peritoneal cavity occurs late in the course of the disease.

Clinical Manifestations

Stomach cancers often spread to adjacent organs before any distressing symptoms occur. Manifestations include unexplained weight loss, indigestion, abdominal discomfort or pain, and signs and symptoms of anemia. The patient may report *early satiety,* or a sense of being full sooner than usual. Anemia is common. It is caused by chronic blood loss as the lesion erodes through the mucosa or from pernicious anemia (caused by loss of intrinsic factor). The person appears pale and weak. They may report fatigue, weakness, dizziness, and, in extreme cases, shortness of breath. The stool may be positive for occult blood. Supraclavicular lymph nodes that are hard and enlarged suggest metastasis via the thoracic duct. The presence of ascites is a poor prognostic sign.

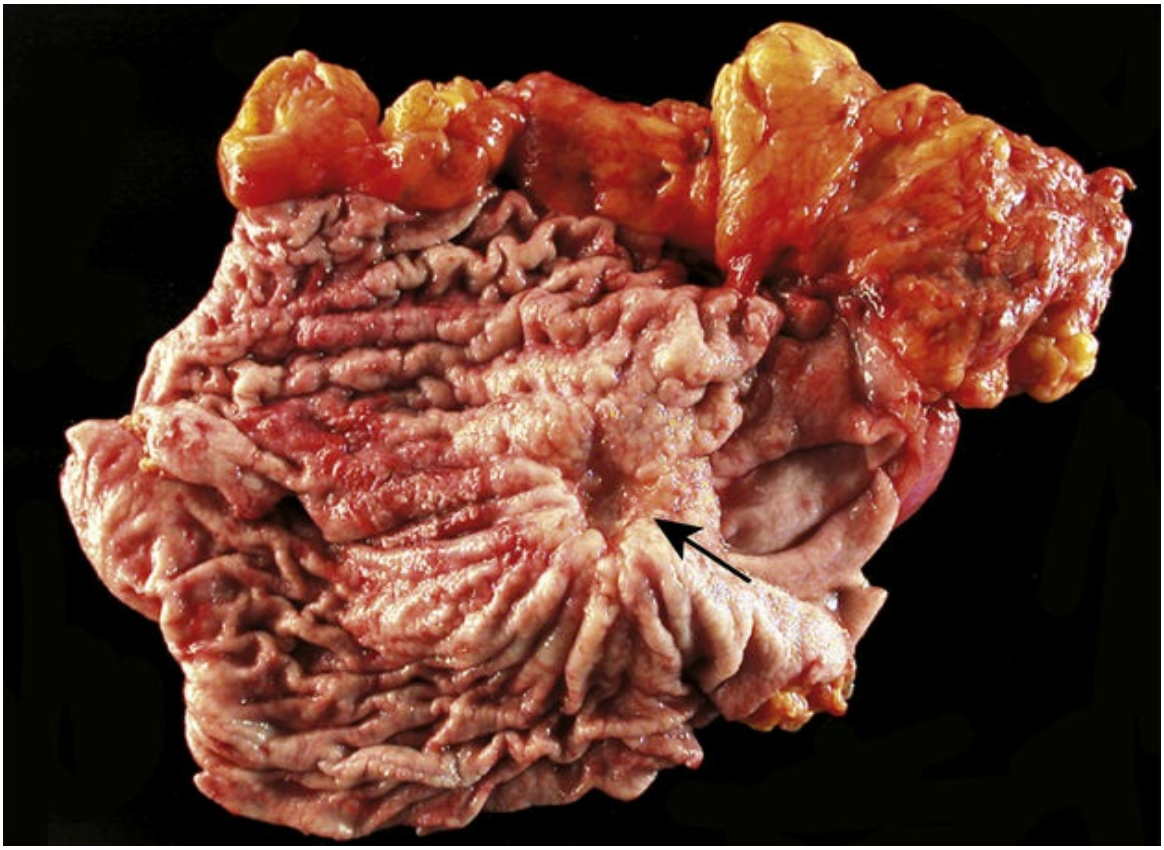

FIG. 41.15 Stomach cancer. Gross photograph showing an ill-defined, excavated central ulcer *(arrow)* surrounded by irregular, heaped-up borders.

TABLE 41.17 Interprofessional CareStomach Cancer

Diagnostic Assessment

- History and physical examination
- Endoscopy and biopsy
- CT, MRI, PET scans
- Upper GI barium study
- Exfoliative cytologic study

- Endoscopic ultrasonography
- CBC
- Liver enzymes
- Urinalysis
- Stool examination
- Serum amylase
- Tumor markers
    - α-Fetoprotein
    - Carbohydrate antigen (CA)-19-9, CA-125, CA 72-4
    - Carcinoembryonic antigen (CEA)

Management

- Surgical therapy
    - Subtotal gastrectomy (Billroth I or II procedure)
    - Total gastrectomy with esophagojejunostomy
    - Chemotherapy
    - Radiation therapy
    - Targeted therapy

Diagnostic Studies

The diagnostic studies for stomach cancer are outlined in Table 41.17. Upper GI endoscopy is the best diagnostic tool. The stomach can be distended with air during the procedure, stretching the mucosal folds. Tissue biopsy and histologic examination are important in diagnosing stomach cancer.

Endoscopic ultrasound, CT, MRI, and PET scanning can be used to stage the disease. Laparoscopy is done to determine peritoneal spread.

Blood studies detect anemia and determine its severity. Increased liver enzymes and serum amylase levels may mean liver and pancreatic involvement. Stool examination provides evidence of occult or gross bleeding. The presence of tumor markers can help

diagnose cancer.

Interprofessional Management

The treatment of choice for stomach cancer is surgical removal of the tumor. Preoperative management focuses on correcting nutritional deficits and treating anemia. Transfusions of packed RBCs correct the anemia. If gastric outlet obstruction occurs, gastric decompression may be needed before surgery.

Surgical Therapy

The surgical aim is to remove as much of the stomach as required to remove the tumor and a margin of normal tissue. The location and extent of the lesion, the patient's physical condition, and the HCP's preference determine the specific surgery used (e.g., open versus laparoscopic).

Lesions in the antrum or pyloric region are generally treated by either a Billroth I or II procedure (Fig. 41.16). When the lesion is in the fundus, a total gastrectomy with esophagojejunostomy is done (Fig. 41.17). When metastasis has occurred to adjacent organs, such as the spleen, ovaries, or bowel, the surgical procedure is extended as needed. If the tumor extends into the transverse colon, partial colon resection is done.

FIG. 41.16 **A,** Billroth I procedure (subtotal gastric resection with gastroduodenostomy anastomosis). **B,** Billroth II procedure (subtotal gastric resection with gastrojejunostomy anastomosis).

Chemotherapy and Radiation Therapy

A number of chemotherapy drugs can be used to treat stomach cancer. These include fluorouracil, capecitabine (Xeloda), carboplatin, cisplatin, docetaxel (Taxotere), epirubicin (Ellence), irinotecan (Camptosar), oxaliplatin (Eloxatin), and paclitaxel. Combination therapies are preferred as the drugs affect different phases of the cell cycle. Examples of combination therapy include ECF (epirubicin, cisplatin, fluorouracil) and docetaxel, irinotecan, oxaliplatin, or cisplatin with fluorouracil or capecitabine.[18] Intraperitoneal administration of chemotherapy agents may also be used to treat metastatic disease. Chemotherapy is discussed in Chapter 15.

Radiation therapy may be used together with chemotherapy to reduce the recurrence or as a palliative measure to decrease tumor mass and provide temporary relief of obstruction.

Targeted Therapy

Trastuzumab (Herceptin) and ramucirumab (Cyramza) are targeted therapies used to treat stomach cancer. About 20% of patients with stomach cancer have too much HER-2 on the surface of the cancer cells. Trastuzumab targets the HER-2 protein and kills the cancer cells. Ramucirumab binds to the receptor for VEGF and prevents VEGF from binding to the receptor, thus preventing the growth and spread of cancer. These drugs are used to treat esophageal cancer and were discussed on p. 902.

Nursing Management: Stomach Cancer

Nursing Assessment

The assessment of a person with stomach cancer is similar to that for PUD (Table 41.15). Important data to obtain from the patient and caregiver include a nutritional assessment, a psychosocial history, the patient's perceptions of the health problem and need for care, and a physical examination.

The nutritional assessment obtains information about appetite and changes in eating patterns over the previous 6 months. Determine the patient's normal weight and any recent weight changes. Unexplained weight loss and anorexia are common. Evaluate the patient's nutritional status. Cachexia may be present if oral intake has been reduced for an extended period. A malnourished patient does not respond well to chemotherapy or radiation therapy and is a poor surgical risk. The patient may report a history of vague abdominal symptoms, including dyspepsia and intestinal gas discomfort or pain. If the patient reports pain, explore where and when it occurs and how it is relieved.

Determine the patient's personal perception of the health problem and method of coping with hospitalization, diagnostic tests, and procedures. A possible diagnosis of cancer and a treatment plan that may include surgery, chemotherapy, or radiation treatment is stressful. If surgery is planned, assess the patient's expectations about surgery (cure or palliation) and how the patient has responded to previous surgical procedures.

Nursing Diagnoses

Nursing diagnoses for the patient with stomach cancer include:

- Impaired nutritional intake

- Impaired nutritional status
- Acute pain
- Anxiety

Planning

The overall goals are that the patient with stomach cancer will (1) have minimal discomfort, (2) achieve optimal nutritional status, and (3) maintain a degree of spiritual and psychologic well-being appropriate to the disease stage.

Nursing Implementation

Health Promotion

Your role in the early detection of stomach cancer focuses on identifying the patient at risk because of specific disorders such as *H. pylori* infection, pernicious anemia, and achlorhydria. Be aware of symptoms associated with stomach cancer and the significant findings on physical examination. Symptoms often occur late and mimic other conditions, such as PUD. Poor appetite, weight loss, fatigue, and persistent stomach distress are symptoms of stomach cancer. Encourage patients with a positive family history of stomach cancer to undergo diagnostic evaluation if anemia, PUD, or vague epigastric distress are present. It is important that you recognize the possibility of stomach cancer in a patient who is treated for PUD and does not get relief with prescribed therapy.

Acute Care

When diagnostic tests confirm cancer, the patient and family generally react with shock, disbelief, and depression. Provide emotional and physical support, provide information, clarify test results, and maintain a positive attitude with respect to the patient's immediate recovery and long-term survival.

Because of changes in appetite and early satiety, the patient may be malnourished. Surgery may be delayed until the patient is more

physically able to withstand it. A positive nutritional state enhances wound healing and the ability to deal with infection and other possible postoperative complications. The patient may better tolerate several small meals a day than 3 regular meals. It may be challenging to persuade the patient to eat when he or she has no appetite and is depressed. Getting the patient's caregiver to help with meals and encourage intake may be beneficial. Diet may be supplemented by commercial liquid supplements and vitamins. If the patient is unable to ingest oral feedings, the HCP may prescribe EN or PN (see Chapter 39).

If needed, packed RBCs and fluid volume restoration may be given during the preoperative period. The preoperative teaching plan and the postoperative care of the patient having stomach cancer surgery is described in the next section on gastric surgery.

Radiation therapy or chemotherapy is used as an adjuvant to surgery or for palliation. Your role is to provide detailed instructions, reassure the patient, and ensure completion of the designated number of treatments. Start by assessing the patient's knowledge of these therapies. Teach the patient about skin care, need for nutrition and fluid intake, and the use of antiemetic drugs. Specific care of the patient receiving chemotherapy and radiation therapy is discussed in Chapter 15.

Ambulatory Care

When chemotherapy or radiation treatment is continuing after discharge, a referral to home health care may be beneficial. The home health nurse can help with recovery, determine the degree of patient adherence, and provide support to the patient and caregiver. Provide the patient with a list of community agencies (e.g., American Cancer Society) that are available before the patient goes home. Encourage the patient to adhere to the prescribed therapies, keep appointments for chemotherapy administration or radiation treatments, and keep the HCP informed of changes in physical condition. Recurrence of cancer is common, and patients need regular follow-up examinations and imaging assessments. Long-term management of the cancer patient is

discussed in Chapter 15.

Evaluation

Expected outcomes are that the patient with stomach cancer will

- Have no or minimal discomfort, pain, or nausea
- Achieve optimal nutritional status
- Maintain a degree of psychologic well-being appropriate to the disease stage

Gastric Surgery

Gastric surgeries are done to treat stomach cancer, as well as polyps, perforation, chronic gastritis, and PUD. Surgeries include partial gastrectomy, gastrectomy, vagotomy, and pyloroplasty. Partial gastrectomy with removal of the distal two thirds of the stomach and anastomosis of the gastric stump to the duodenum is a *gastroduodenostomy* or *Billroth I* operation (Fig. 41.16, *A*). If the gastric stump is anastomosed to the jejunum, the surgery is a *gastrojejunostomy* or *Billroth II* operation (Fig. 41.16, *B*). A total gastrectomy involves resection of the lower esophagus, removal of the entire stomach, and anastomosis of the esophagus to the jejunum.

Vagotomy is the severing of the vagus nerve, either totally *(truncal)* or selectively *(highly selective vagotomy)*. These procedures decrease gastric acid secretion. *Pyloroplasty* consists of surgical enlargement of the pyloric sphincter to facilitate the easy passage of contents from the stomach. It is often done after vagotomy or to enlarge an opening that is constricted from scar tissue.

Postoperative Complications

As with all surgeries, acute postoperative bleeding at the surgical site can occur. Monitoring of patients is similar to that described later under acute upper GI bleeding. The most common long-term postoperative complications from gastric surgery are (1) dumping syndrome, (2) postprandial hypoglycemia, and (3) bile reflux gastritis.

Dumping Syndrome

Dumping syndrome is the direct result of surgical removal of a large part of the stomach and pyloric sphincter. Normally, gastric chyme enters the small intestine in small amounts. After surgery, the stomach no longer has control over the amount of gastric chyme entering the small intestine. Therefore a large bolus of hypertonic fluid enters the intestine and causes fluid to be drawn into the bowel lumen. This

creates a decrease in plasma volume, distention of the bowel lumen, and rapid intestinal transit.

Symptoms begin within 15 to 30 minutes after eating. The patient usually describes feelings of generalized weakness, sweating, palpitations, and dizziness. These symptoms are due to the sudden decrease in plasma volume. The patient may have abdominal cramps, *borborygmi* (audible abdominal sounds made by hyperactive intestinal peristalsis), and the urge to defecate. These manifestations usually last less than 1 hour after eating. A short rest period after each meal reduces the chance of dumping syndrome.

Postprandial Hypoglycemia

Postprandial hypoglycemia is a variant of dumping syndrome. It is the result of uncontrolled gastric emptying of a bolus of fluid high in carbohydrate into the small intestine. The bolus of concentrated carbohydrate results in hyperglycemia and the release of excess amounts of insulin into the circulation. This results in reflex hypoglycemia. Symptoms are similar to those of any hypoglycemic reaction and include sweating, weakness, mental confusion, palpitations, tachycardia, and anxiety. Symptoms generally occur 2 hours after eating.

Bile Reflux Gastritis

Gastric surgery that involves either reconstruction or removal of the pylorus can result in reflux of bile into the stomach. Prolonged contact with bile causes damage to the gastric mucosa, chronic gastritis, and PUD.

The main symptom is continuous epigastric distress that increases after meals. Vomiting relieves the distress, but only temporarily. Although only a small number of patients have bile reflux gastritis, caution the patient to notify the HCP of any continuous epigastric distress after meals. Cholestyramine (Questran), given before or with meals, has been used successfully to treat this problem. Cholestyramine binds with the bile salts that are the source of gastric irritation.

Nursing Management: Gastric Surgery

Preoperative Care

Surgery can involve either laparoscopic or open surgical techniques. The HCP will provide the necessary information about the procedure and expected outcomes, so the patient can make an informed decision. Help the patient and caregiver by answering their questions. Teach them what to expect after surgery, including comfort measures, pain relief, coughing and breathing exercises, use of an NG tube, and IV fluid administration (see Chapter 17 for more on preoperative care).

Postoperative Care

Postoperative care focuses on maintaining fluid and electrolyte balance, preventing respiratory complications, maintaining comfort, and preventing infection. Complications include atelectasis, pneumonia, anastomotic leak, deep vein thrombosis, pulmonary embolus, and bleeding. Morbidly obese patients have a higher risk for many postoperative complications.

After surgery, an NG tube is used for decompression. This decreases pressure on suture lines and allows edema and inflammation resulting from surgical trauma to resolve. Observe the gastric aspirate for color, amount, and odor. Small volumes of bloody drainage from the NG can be expected for the first 2 to 3 hours because bleeding at the anastomotic site is common. Report bright red bleeding that does not decrease after this period or bleeding that becomes excessive (more than 75 mL/hr) immediately to the HCP. The NG aspirate should gradually darken within the first 24 hours after surgery. Normally the color changes to yellow-green within 36 to 48 hours. After total gastrectomy, the NG tube does not drain a large quantity of secretions because removing the stomach has eliminated the reservoir capacity.

Observe the NG tube closely because blood easily clots and clogs the tube. Notify the HCP immediately if the tube stops draining or

appears obstructed with blood. If the tube becomes clogged, the HCP may order periodic gentle irrigations with normal saline solution. It is essential that the NG suction is working and that the tube stays patent so that accumulated gastric secretions do not put a strain on the anastomosis. This can lead to distention of any remaining part of the stomach and result in (1) rupture of the sutures, (2) leakage of gastric contents into the peritoneal cavity, (3) hemorrhage, and (4) abscess formation. If the tube must be replaced or repositioned, call the HCP to perform this task because of the danger of perforating the gastric mucosa or disrupting the suture line.

While the NG tube is connected to suction, maintain IV therapy. Before the NG tube is removed, the patient begins clear liquids to determine the tolerance level. In a partial gastrectomy, the stomach may be aspirated within 1 or 2 hours to assess the amount remaining and its color and consistency. When fluids are well tolerated, the NG tube is removed. Solids are added gradually with the goal of resuming a normal diet.

Closely observe the patient for an anastomotic leak and notify the HCP at once if one is suspected. A leak occurs when there is a breakdown of the suture line in an anastomosis that allows gastric or intestinal contents to enter the abdomen or mediastinum. It requires immediate treatment to prevent sepsis and death. Signs and symptoms include tachycardia, dyspnea, fever, abdominal pain, anxiety, and restlessness.

Since most procedures are done laparoscopically, the risk for respiratory complications is reduced. In an open surgical approach, the incision is relatively high in the epigastrium and respiratory complications may occur. Respiratory assessment includes respiratory rate and rhythm, pulse rate and rhythm, and signs of pneumothorax (e.g., dyspnea, chest pain, cyanosis). Have the patient cough and deep breathe to expand the lungs. Pain may interfere with deep breathing and coughing. Encourage the patient to splint the area with a pillow. Splinting also protects the abdominal suture line from rupturing during deep breathing and coughing. Encourage early ambulation and frequent position changes.

Give pain medications as needed. Be aware that pain could be from an anastomosis leak rather than typical surgical pain. Abdominal wounds need frequent observation for the amount and type of drainage, condition of the incision, and signs of infection. Monitor vital signs to help identify problems such as infection, hemorrhage, or anastomosis leak. Implement measures to control nausea and vomiting. Measure and record the intake and output and obtain daily weights.

Nutritional Therapy

Understanding the patient's surgery and the resulting anatomy is important. Long-term, many patients have malnutrition, metabolic bone disease, anemia, and weight loss. Nutrition interventions help minimize the occurrence of expected complications and maximize nutrient intake (Table 41.18). Start nutrition teaching as soon as the immediate postoperative period has passed. The dietitian usually provides dietary instructions. You must reinforce them. Following dietary measures will decrease symptoms and is essential to long-term adherence.

Postoperative wound healing may be impaired because of poor nutritional intake. Give potassium and vitamin supplements as ordered. For those who were malnourished preoperatively, a small bowel feeding tube may be placed intraoperatively. EN may be started on postoperative day 1 and adjusted depending on how oral intake is tolerated. Some may be discharged with nighttime tube feedings. PN is an option if the patient is not able to tolerate oral nutrition.

Pernicious anemia is a long-term complication of total gastrectomy and may occur after partial gastrectomy. It is due to the loss of intrinsic factor, which is made by the parietal cells. *Intrinsic factor* is essential for the absorption of cobalamin in the terminal ileum. Because it is essential for the growth and maturation of RBCs, the lack of cobalamin results in pernicious anemia and neurologic complications. The patient will require cobalamin replacement therapy (see Chapter 30). Patients should take multivitamins with

folate, calcium, vitamin D, and iron for life.

TABLE 41.18 Nutritional TherapyPostgastrectomy Dumping Syndrome

The amount of time these restrictions should be followed varies. The HCP decides the proper amount of time to remain on this prescribed diet according to the patient's clinical condition and progress.

Purposes

- Slow the rapid passage of food into the intestine
- Control symptoms of dumping syndrome (dizziness, sense of fullness, diarrhea, tachycardia), which sometimes occurs after a partial or total gastrectomy

Diet Principles

- Divide meals into 6 small feedings to avoid overloading the stomach and intestine at mealtimes.
- Do not take fluids with meals but at least 30–45 min before or after meals. This helps prevent distention or a feeling of fullness.
- Avoid concentrated sweets (e.g., honey, sugar, jelly, jam, candies, sweet pastries, and sweetened fruit) because they sometimes cause dizziness, diarrhea, and a sense of fullness.
- Protein consumption is unlimited to promote rebuilding of body tissues. Meat and eggs are specific foods to increase in the diet.
- Milk contains lactose, which may be hard to digest. Introduce milk and milk products slowly several weeks after surgery.
- Avoid carbonated beverages and foods that are gas forming to help prevent gastric distention.
- Low-roughage and raw foods are allowed as tolerated a few weeks after surgery.

- Increase complex carbohydrates (e.g., bread, vegetables, rice, potatoes) and fats to meet energy needs.

Because partial gastrectomy decreases the stomach's reservoir, patients must reduce their meal size accordingly. For the first few weeks after surgery, the patient should consume soft, bland foods with low fiber and high complex carbohydrates and protein content. Teach the patient to eat in small portions and not to drink fluids with meals. Simple sugars, lactose, and fried foods should be avoided. Teach the patient to avoid extreme temperatures in food and to chew food thoroughly.

To avoid hypoglycemic episodes, teach the patient to limit the amount of sugar consumed with each meal and eat small, frequent meals with moderate amounts of protein and fat. The immediate ingestion of sugared fluids or candy relieves hypoglycemic symptoms.

Ambulatory Care

Patients who have had a total gastrectomy and are debilitated may need skilled care after discharge. For those going home, assist the patient and caregiver with symptom management. Make plans for pain relief, including comfort measures and the judicious use of analgesics. Teach wound care (if needed) to the primary caregiver. Dressings, special equipment, or special services may be needed. Collaborate with the dietitian to provide teaching about the diet that will optimize nutrition.

Gastritis

Gastritis, an inflammation of the gastric mucosa, is one of the most common problems affecting the stomach. Gastritis may be acute or chronic and diffuse or localized.

Etiology and Pathophysiology

Gastritis occurs as the result of a breakdown in the normal gastric mucosal barrier. This mucosal barrier normally protects the stomach tissue from the corrosive action of HCl acid and pepsin. When the barrier is broken, HCl acid and pepsin can diffuse back into the mucosa. This back diffusion results in tissue edema, disruption of capillary walls with loss of plasma into the gastric lumen, and possible hemorrhage.

TABLE 41.19 Causes of Gastritis

Drugs

- Aspirin
- Bisphosphonates
- Corticosteroids
- Digitalis
- Iron supplements
- Nonsteroidal antiinflammatory drugs (NSAIDs)

Diet

- Alcohol
- Large amounts of spicy, irritating foods

Microorganisms

- *H. pylori*
- Cytomegalovirus
- *Mycobacterium* species
- *Salmonella* organisms
- *Staphylococcus* organisms
- *Treponema pallidum* (syphilis)

Environmental Factors

- Radiation
- Smoking

Diseases/Disorders

- Burns
- Crohn's disease
- Large hiatal hernia
- Physiologic stress
- Reflux of bile and pancreatic secretions
- Renal failure
- Sepsis
- Shock

Other Factors

- Endoscopy procedures
- Nasogastric tube
- Psychologic stress

Risk Factors

Risk factors and causes of gastritis are listed in Table 41.19. Some risk factors are discussed in this section.

Drug-Related Gastritis

Drugs contribute to the development of acute and chronic gastritis. NSAIDs and corticosteroids inhibit the synthesis of prostaglandins that are protective to the gastric mucosa. This makes the mucosa more susceptible to injury. Factors that increase the risk for NSAID-induced gastritis include being female; being over age 60; having a history of ulcer disease; taking anticoagulants, LDA, or corticosteroids; and having a chronic disorder, such as CVD. Some drugs such as digoxin and alendronate (Fosamax) have direct irritating effects on the gastric mucosa.

Diet

Dietary indiscretions can cause acute gastritis. After an alcoholic drinking binge, acute damage to the gastric mucosa can range from localized injury of superficial epithelial cells to destruction of the mucosa with mucosal congestion, edema, and hemorrhage. Prolonged damage induced by repeated alcohol use results in chronic gastritis. Eating large quantities of spicy, irritating foods can cause acute gastritis.

Helicobacter Pylori

A key cause of chronic gastritis is *H. pylori* infection. *H. pylori* infection causes acute gastritis in most infected persons. Chronic gastritis may develop in some. Prolonged inflammation leads to functional changes in the stomach and may cause stomach cancer. *H. pylori* was discussed earlier in this chapter on p. 905.

Other Risk Factors

Although not as common as *H. pylori,* other bacterial, viral, and fungal infections are associated with chronic gastritis. Gastritis can occur

from reflux of bile salts from the duodenum into the stomach because of anatomic changes after surgical procedures (e.g., gastroduodenostomy, gastrojejunostomy). Prolonged vomiting may cause reflux of bile salts. Intense emotional responses and CNS lesions may cause inflammation of the mucosal lining from hypersecretion of HCl acid.

Autoimmune Gastritis

Autoimmune metaplastic atrophic gastritis (also called *autoimmune atrophic gastritis*) is an inherited condition in which there is an immune response directed against parietal cells. It most often affects women of northern European descent. Patients often have other autoimmune disorders. The loss of parietal cells leads to low chloride levels, inadequate production of intrinsic factor, cobalamin (vitamin B_{12}) malabsorption, and pernicious anemia. It is associated with an increased risk of stomach cancer.

Clinical Manifestations

The symptoms of *acute gastritis* include anorexia, nausea and vomiting, epigastric tenderness, and a feeling of fullness. Hemorrhage is often associated with alcohol use and at times, is the only symptom. Acute gastritis is self-limiting, lasting from a few hours to a few days. Complete healing of the mucosa is expected.

The manifestations of *chronic gastritis* are like those of acute gastritis. Some patients are asymptomatic. However, when parietal cells are lost because of atrophy, the source of intrinsic factor is also lost. *Intrinsic factor* is essential for cobalamin absorption. The lack of cobalamin results in pernicious anemia. Cobalamin deficiency anemia is discussed in Chapter 30.

Diagnostic Studies

Acute gastritis is usually diagnosed based on the patient's symptoms and a history of drug or alcohol use. Occasionally, an endoscopic

examination with biopsy is required to make the diagnosis. Breath, urine, serum, stool, and gastric tissue biopsy tests are done to assess for *H. pylori* infection. A CBC may show anemia from blood loss or lack of intrinsic factor. Stools are tested for occult blood. Serum tests for antibodies to parietal cells and intrinsic factor may be done. A tissue biopsy can rule out gastric cancer.

Nursing and Interprofessional Management: Gastritis

Acute Gastritis

Eliminating the cause and preventing or avoiding it in the future are generally all that is needed to treat acute gastritis. The plan of care is supportive and similar to that described for nausea and vomiting. If vomiting is present, rest, NPO status, and IV fluids may be prescribed. Antiemetics are given (Table 41.1). Monitor for dehydration. It can occur rapidly in acute gastritis with vomiting.

In severe cases of acute gastritis, an NG tube may be used to (1) monitor for bleeding, (2) lavage the precipitating agent from the stomach, or (3) keep the stomach empty and free of noxious stimuli. Clear liquids are resumed when symptoms have subsided. Reintroduce solids gradually.

If the patient is at risk for hemorrhage, frequently check vital signs and test the vomitus for blood. All the management strategies discussed in the section on upper GI bleeding apply to the patient with severe gastritis (see pp. 917–920).

Drug therapy focuses on reducing irritation of the gastric mucosa and providing symptomatic relief. H_2 receptor blockers (e.g., ranitidine, cimetidine) or PPIs (e.g., omeprazole) reduce gastric HCl acid secretion (Table 41.10). Teach the patient about the therapeutic effects of PPIs and H_2 receptor blockers.

Chronic Gastritis

The treatment of chronic gastritis focuses on evaluating and eliminating the specific cause (e.g., cessation of alcohol use, abstinence from drugs, *H. pylori* eradication). Antibiotic combinations are used to eradicate *H. pylori* (Table 41.14). The patient with pernicious anemia needs lifelong cobalamin therapy (see Chapter 30).

TABLE 41.20 Types of Upper GI Bleeding

Type	Manifestations
Obvious bleeding	
• **Hematemesis**	Bloody vomitus appearing as fresh, bright red blood or "coffee-grounds" appearance (dark, grainy digested blood).
• **Melena**	Black, tarry stools (often foul smelling) caused by digestion of blood in the GI tract. Black appearance is from the presence of iron.
Occult bleeding	Small amounts of blood in gastric secretions, vomitus, or stools not apparent by appearance. Detectable by guaiac test

The patient undergoing treatment for chronic gastritis may have to adapt to lifestyle changes and strictly adhere to a drug regimen. Some patients find a nonirritating diet consisting of 6 small feedings a day helpful. Smoking is contraindicated in all forms of gastritis. An interprofessional team approach in which the HCP, nurse, dietitian, and pharmacist provide consistent information and support will increase the patient's success in making these changes.

Upper Gastrointestinal Bleeding

In the United States, 250,000 hospital admissions occur each year for upper GI bleeding.[19] About 60% of these are adults over age 65. Though the mortality rate is still around 2.5%, this rate has decreased over the past few decades due to advances in the prevention and treatment of upper GI bleeding.

Etiology and Pathophysiology

Although the most serious loss of blood from the upper GI tract is characterized by a sudden onset, insidious occult bleeding can be a major problem. The severity of bleeding depends on whether the origin is venous, capillary, or arterial. Types of upper GI bleeding are described in Table 41.20. Bleeding from an arterial source is profuse, and the blood is bright red because it has not been in contact with gastric HCl acid secretion. In contrast, coffee-grounds vomitus means that the blood has been in the stomach for some time. *Melena* (black, tarry stools) occurs with slow bleeding from an upper GI source. The longer the passage of blood through the intestines, the darker the stool color because of the breakdown of hemoglobin and release of iron.

Discovering the cause of the bleeding is not always easy. A variety of areas in the GI tract may be involved. Table 41.21 lists the common causes of upper GI bleeding.

Stomach and Duodenal Origin

Peptic ulcers, due to *H. pylori* infection and the use of NSAIDS, are the most common causes of upper GI bleeding. About 25% of people on chronic NSAIDs (e.g., ibuprofen) develop ulcer disease; of these, 2% to 4% will bleed. Even LDA is associated with a risk for GI bleeding. Many OTC preparations contain aspirin. Obtain a careful medication history whenever upper GI bleeding is suspected.

Stress-related mucosal disease (SRMD), also called *physiologic stress ulcers*, describes mucosal damage in the GI tract ranging from

small single lesions to multiple gastric ulcers and major bleeding. SRMD most often occurs in critically ill patients who have had severe burns, trauma, or major surgery. Patients with coagulopathy, liver disease, or organ failure and those receiving renal replacement therapy are at highest risk for SRMD.[20]

TABLE 41.21 Causes of Upper GI Bleeding

Stomach and Duodenum

- Drug-induced
    - Corticosteroids
    - NSAIDs
    - Salicylates
- Erosive gastritis
- Polyps
- PUD
- Stress-related mucosal disease
- Stomach cancer

Esophagus

- Esophageal varices
- Esophagitis
- Mallory-Weiss tear

Systemic Diseases

- Blood dyscrasias (e.g., leukemia, aplastic anemia)
- Renal failure

Esophageal Origin

Bleeding from the esophagus is likely due to chronic esophagitis, Mallory-Weiss tear, or esophageal varices. Chronic esophagitis can be caused by GERD, smoking, alcohol use, and the ingestion of drugs irritating to the mucosa. Esophageal varices most often occur from cirrhosis of the liver. Esophageal varices are discussed in Chapter 43.

Diagnostic Studies

Endoscopy is the primary tool for diagnosing the source (e.g., esophageal varices, PUD, gastritis) of upper GI bleeding. Angiography is used when endoscopy cannot be done or when bleeding persists after endoscopic therapy. Angiography requires preparation and setup time and may not be appropriate for a high-risk, unstable patient. In this procedure, a catheter is inserted into the femoral artery and advanced to the left gastric or superior mesenteric artery until the site of bleeding is found.

Laboratory studies include CBC, blood urea nitrogen (BUN), serum electrolytes, prothrombin time, partial thromboplastin time, liver enzymes, arterial blood gases (ABGs), and a type and crossmatch for possible blood transfusions. All vomitus and stools are tested for gross and occult blood.

Monitor the patient's laboratory studies to estimate the effectiveness of therapy. The hemoglobin and hematocrit values are not of immediate help in estimating the degree of blood loss, but they provide a baseline for guiding further treatment. The initial hematocrit may be normal and may not reflect the loss until 4 to 6 hours after fluid replacement, since initially the loss of plasma and RBCs is equal.

Assess the patient's BUN level. During a significant hemorrhage, GI tract bacteria break down proteins, resulting in increased BUN levels. An increased BUN level may also show renal hypoperfusion or renal disease.

Interprofessional Management

A massive upper GI hemorrhage is a loss of more than 1500 mL of blood or 25% of intravascular blood volume. Although 80% to 85% of patients with massive hemorrhage spontaneously stop bleeding, the cause must be identified and treatment started at once.

Emergency Assessment and Management

A complete history of events leading to the bleeding episode is deferred until emergency care has been started. To facilitate early intervention, focus your physical examination on identifying signs and symptoms of shock, such as tachycardia, weak pulse, hypotension, cool extremities, prolonged capillary refill, and apprehension. (Shock is discussed in Chapter 66.)

Urine output is one of the best measures of vital organ perfusion. An indwelling urinary catheter is inserted so that hourly output can be accurately assessed. Hemodynamic monitoring provides an accurate and quick assessment of blood flow and pressure in the cardiovascular system (see Chapter 65). A central venous pressure line may be used for fluid volume status assessment. If the patient has a history of valvular heart disease, coronary artery disease, or heart failure, a pulmonary artery catheter may be needed. Give supplemental O_2 to increase blood O_2 saturation.

The patient is at risk for perforation and peritonitis. Do a thorough abdominal examination. Note the presence of a tense, rigid, boardlike abdomen and the presence or absence of bowel sounds.

The type and amount of fluids infused are based on physical and laboratory findings. Generally, an isotonic crystalloid solution (e.g., lactated Ringer's solution) is started. Whole blood, packed RBCs, and fresh frozen plasma may be used for volume replacement in massive hemorrhage. When upper GI bleeding is less profuse, infusion of isotonic saline solution followed by packed RBCs restores the hematocrit more quickly and does not create complications related to fluid volume overload. (The use of blood transfusions and volume expanders is discussed in Chapter 30.)

Endoscopic Therapy

The first-line management of upper GI bleeding is endoscopy. Endoscopy within the first 24 hours of bleeding is important for diagnosis, determining the need for surgical intervention, and providing treatment.

The goal of endoscopic hemostasis is to coagulate or thrombose the bleeding vessel. Several techniques are used, including (1) mechanical therapy with clips or bands, (2) thermal ablation, and (3) injection (e.g., epinephrine, alcohol). Clips and bands directly compress the bleeding vessel. Thermal ablation cauterizes tissue through applying heat to the bleeding site. Common devices include neodymium:yttrium-aluminum-garnet (YAG) laser, monopolar or bipolar electrocoagulation, heater probes, and argon plasma coagulation (APC).[21]

For variceal bleeding, other strategies include variceal ligation, injection sclerotherapy, and balloon tamponade (see Chapter 43).

Surgical Therapy

Surgical intervention is needed when bleeding continues regardless of the therapy provided and when the site of the bleeding has been identified. Surgery may be done if the patient continues to bleed after rapid transfusion of up to 2000 mL of whole blood or is still in shock after 24 hours. The site of the hemorrhage determines the choice of surgery. Mortality rates increase considerably in older patients.

Drug Therapy

During the acute phase of upper GI bleeding, drugs are used to decrease bleeding, decrease HCl acid secretion, and neutralize the HCl acid that is present. Empiric PPI therapy with high-dose IV bolus and subsequent infusion to decrease acid secretion is often started before endoscopy (Table 41.10). Efforts are made to reduce acid secretion because the acidic environment can alter platelet function and interfere with clot stabilization. This may decrease the amount of bleeding and need for endoscopic therapy.

After an acute phase of bleeding, antacids may be given hourly, either orally or through the NG tube. If an NG tube is in place, the

stomach contents should be aspirated and tested periodically for pH level. If pH is less than 5, intermittent suction may be used or the frequency or dosage of the antacid or antisecretory agent increased.

Nursing Management: Upper Gastrointestinal Bleeding

Nursing Assessment

A thorough nursing assessment is an essential first step as you begin care of the patient admitted with upper GI bleeding. The patient may not be able to give specific information about the cause of the bleeding until immediate physical needs are met. Perform an immediate nursing assessment while you are getting the patient ready for initial treatment. The assessment includes the patient's level of consciousness, vital signs, skin color, and capillary refill. Check the abdomen for distention, guarding, and peristalsis. Immediate determination of vital signs indicates whether the patient is in shock from blood loss and provides a baseline BP and pulse for monitoring the progress of treatment. Signs and symptoms of shock include low BP; rapid, weak pulse; increased thirst; cold, clammy skin; and restlessness. Monitor vital signs every 15 to 30 minutes. Inform the HCP of any significant changes.

Once the immediate interventions have begun, the patient or caregiver should answer the following questions: Is there a history of bleeding episodes? Has the patient received blood transfusions? Were there any transfusion reactions? Are there any other illnesses (e.g., liver disease, cirrhosis) or medications that may contribute to bleeding or interfere with treatment? Does the patient have a religious preference that prohibits the use of blood or blood products?

Subjective and objective data to obtain from the patient or caregiver are outlined in Table 41.22.

Nursing Diagnoses

Nursing diagnoses for the patient with upper GI bleeding include:

- Impaired cardiac output

- Fluid imbalance
- Ineffective tissue perfusion
- Anxiety

Planning

The overall goals are that the patient with upper GI bleeding will (1) have no further GI bleeding, (2) have the cause of the bleeding identified and treated, (3) return to a normal hemodynamic state, and (4) have minimal or no symptoms of pain or anxiety.

Nursing Implementation

Health Promotion

Although not all cases of upper GI bleeding can be prevented, you have an important role in identifying patients at high risk. Always consider the patient with a history of chronic gastritis, cirrhosis, or PUD at high risk. The patient who has had an upper GI bleeding episode is more likely to have another bleed. Patients on daily LDA to reduce CVD risk are at risk for upper GI bleeding, especially those over 60 years old with a history of PUD.

Teach the patient who takes regular doses of drugs that cause GI toxicity (peptic ulcer formation, bleeding), such as corticosteroids and NSAIDs, about the risk for GI bleeding. They may need to receive long-term treatment with a PPI, H_2 receptor blocker, or misoprostol. Taking these drugs with meals or snacks lessens their direct irritation.

TABLE 41.22 Nursing AssessmentUpper GI Bleeding

Subjective Data

Important Health Information

Past health history: Precipitating events before bleeding episode, prior bleeding episodes and treatment, PUD, esophageal varices, esophagitis, acute and chronic gastritis, stress-related mucosal disease
Medications: Aspirin, NSAIDs, corticosteroids, anticoagulants

Functional Health Patterns

Health perception–health management: Family history of bleeding, smoking, alcohol use
Nutritional-metabolic: Nausea, vomiting, weight loss, thirst
Elimination: Diarrhea. Black, tarry stools. Decreased urine output. Sweating
Activity-exercise: Weakness, dizziness, fainting
Cognitive-perceptual: Epigastric pain, abdominal cramps
Coping–stress tolerance: Acute or chronic stress

Objective Data
General

Fever

Integumentary

Clammy, cool, pale skin. Pale mucous membranes, nail beds, and conjunctivae. Spider angiomas, jaundice, peripheral edema

Respiratory

Rapid, shallow respirations

Cardiovascular

Tachycardia, weak pulse, orthostatic hypotension, slow capillary refill

Gastrointestinal

Red or coffee-grounds vomitus. Tense, rigid abdomen, ascites. Hypoactive or hyperactive bowel sounds. Black, tarry stools

Urinary

Decreased urine output, concentrated urine

Neurologic

Agitation, restlessness. Decreasing level of consciousness

Possible Diagnostic Findings

↓ Hematocrit and hemoglobin, hematuria. Guaiac-positive stools, emesis, or gastric aspirate. ↓ Levels of clotting factors, ↑ liver enzymes, abnormal endoscopy results

Teach the at-risk patient to avoid known gastric irritants, such as alcohol and smoking, and to take only prescribed medications. OTC drugs can be harmful because they may contain ingredients (e.g., aspirin) that increase the risk for bleeding. Review how to test vomitus or stools for occult blood. Teach them to report positive results promptly to the HCP. Stress the importance of treating an upper respiratory tract infection promptly. Severe coughing or sneezing can increase pressure on the already fragile varices and may

result in massive hemorrhage (see Chapter 43).

Patients with blood dyscrasias (e.g., aplastic anemia) or liver dysfunction or those who are taking chemotherapy drugs are at risk due to a decrease in clotting factors and platelets. Teach patients about their disease process, drugs, and increased risk for GI bleeding.

TABLE 41.23 Emergency ManagementAcute GI Bleeding

Assessment Findings	Interventions
Abdominal and GI Findings • **Abdominal pain** • **Abdominal rigidity** • **Hematemesis** • **Melena** • **Nausea** **Hypovolemic Shock** • **↓ BP** • **↓ Pulse pressure** • **Tachycardia** • **Cool, clammy skin** • **↓ Level of consciousness** • **↓ Urine output (<0.5 mL/kg/hr)** • **Slow capillary refill**	• Initial • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Establish IV access with large-bore catheter and start fluid replacement therapy. Insert a second large-bore catheter if shock present. • Give O_2 via nasal cannula or nonrebreather mask. • Initiate ECG monitoring. • Obtain blood for CBC, clotting studies, and type and crossmatch as appropriate. • Insert NG tube as needed. • Insert indwelling urinary catheter. • Give IV PPI therapy to decrease acid secretion. • Ongoing Monitoring • Monitor vital signs, level of consciousness, O_2 saturation, ECG, bowel sounds, and intake/output. • Assess amount and character of emesis. • Keep patient NPO. • Provide reassurance and emotional support to patient and caregiver.

Acute Care

Emergency management of acute GI bleeding is outlined in Table 41.23. Place IV lines, preferably 2, with a 16- or 18-gauge needle for fluid and blood replacement. Give fluid or blood replacement as ordered. An accurate intake and output record is essential so that the patient's hydration status can be assessed. Measure the urine output hourly. If a central venous pressure line or pulmonary artery catheter in place, record these readings every 1 to 2 hours. Use ECG monitoring to evaluate cardiac function. Close monitoring of vital signs, especially in the patient with CVD, is important because dysrhythmias may occur.

Check Your Practice

You are admitting a 71-yr-old man to the unit from the emergency department. He has a diagnosis of upper GI bleeding. He reports heartburn and pain (6 on a scale of 10) in the upper epigastric region and has just had a 250 mL coffee-grounds emesis.

- What assessment data do you need to obtain?
- What are the priority nursing interventions for this man?

Observe the older adult or the patient with CVD closely for signs of fluid overload. However, volume overload and pulmonary edema are concerns in all patients who are receiving large amounts of IV fluids within a short time. Auscultate breath sounds and closely observe the respiratory effort. Keep the head of the bed elevated to provide comfort and prevent aspiration.

When an NG tube is present, pay special attention to keeping it in proper position and checking the aspirate for blood. Although gastric lavage (room temperature, cool, or iced) is used in some agencies, its effectiveness as a treatment for upper GI bleeding is questionable. When lavage is used, around 50 to 100 mL of fluid is instilled at a time into the stomach. The lavage fluid may be aspirated from the stomach or drained by gravity. When aspiration is the method used, it is important not to aspirate if you feel resistance. The tip of the NG tube may be up against the gastric mucosal lining. When resistance is a factor, use the gravity method.

TABLE 41.24 Bacterial Food Poisoning

Type and Cause	Sources	Manifestations	Treatment and Prevention
Botulism **Toxin from *Clostridium botulinum*; ingested toxin absorbed from gut and blocks acetylcholine at neuromuscular junction**	Improperly canned or preserved food, home-preserved vegetables (most common), preserved fruits and fish, canned commercial products	*Onset:* 12–36 hr *GI:* Nausea, vomiting, abdominal pain, constipation, distention *Central nervous system:* Headache, dizziness, muscular incoordination, weakness, inability to talk or swallow, diplopia, breathing problems, paralysis, delirium, coma	*Treat:* Maintain ventilation, polyvalent antitoxin, guanidine hydrochloric acid (enhances acetylcholine release) *Prevent:* Correct processing of canned foods, boiling of suspected canned foods for 15 min before serving
Clostridial ***Clostridium perfringens***	Meat or poultry dishes cooked at lower temperature (stew, pot pie), rewarmed meat dishes, gravies, improperly canned vegetables	*Onset:* 8–24 hr Diarrhea, nausea, abdominal cramps, vomiting (rare), midepigastric pain	*Treat:* Symptomatic, fluid replacement *Prevent:* Correct preparation of meat dishes. Serving food immediately after cooking or rapid cooling of food
Escherichia coli ***E. coli* O157:H7**	Contaminated beef, pork, milk, cheese, fish, cookie dough	*Onset:* 8 hr to 1 wk (varies by strain) Bloody stools, hemolytic uremic syndrome, abdominal cramping, profuse diarrhea	*Treat:* Symptomatic, fluid and electrolyte replacement *Prevent:* Correct preparation of food
Salmonella ***Salmonella typhimurium* (grows in gut)**	Improperly cooked poultry, pork, beef, lamb, and eggs	*Onset:* 8 hr to several days Nausea and vomiting, diarrhea, abdominal cramps, fever, and chills	*Treat:* Symptomatic, fluid and electrolyte replacement *Prevent:* Correct preparation of food
Staphylococcal **Toxin from *Staphylococcus aureus***	Meat, bakery products, cream fillings, salad dressings, milk Skin and respiratory tract of food handlers	*Onset:* 30 min to 7 hr Vomiting, nausea, abdominal cramping, diarrhea	*Treat:* Symptomatic, fluid and electrolyte replacement, antiemetics *Prevent:* Immediate refrigeration of foods, monitoring food handlers

Approach the patient in a calm manner to help decrease the level of anxiety. Use caution when giving sedatives for restlessness because it is one of the warning signs of shock and may be masked by the drugs.

Assess the stools for blood (black-tarry, bright red). Black, tarry stools are not usually associated with a brisk hemorrhage but are indicative of prolonged bleeding. Determine if menses or bleeding are possible sources of blood in the stools. When vomitus contains blood, but the stool contains no gross or occult blood, the hemorrhage is thought to be of short duration.

When beginning oral nourishment, observe the patient for symptoms of nausea and vomiting and a recurrence of bleeding. Feedings initially consist of clear fluids. They are given hourly until tolerance is determined. Gradually introduce foods if the patient has no signs of discomfort.

When hemorrhage is the result of chronic alcohol use, closely observe the patient for delirium tremens as alcohol withdrawal takes place. Symptoms indicating the onset of delirium tremens are

agitation, uncontrolled shaking, sweating, and hallucinations. (Alcohol withdrawal is discussed in Chapter 10.)

Ambulatory Care

Teach the patient and caregiver how to avoid future bleeding episodes. Ulcer disease, drug or alcohol use, liver and respiratory diseases can all cause upper GI bleeding. Help the patient and caregiver to be aware of the consequences of not adhering to drug therapy.

Emphasize not to take any drugs (especially aspirin, NSAIDs) other than those prescribed by the HCP. Support the patient in smoking and alcohol cessation because they are sources of irritation and interfere with tissue repair. Long-term follow-up care may be needed because of possible recurrence. Teach the patient and caregiver what to do if an acute hemorrhage occurs in the future.

Evaluation

The expected outcomes are that the patient with upper GI bleeding will

- Have no upper GI bleeding
- Maintain normal fluid volume
- Return to a normal hemodynamic state
- Understand potential risk factors and make lifestyle modifications

Foodborne Illness

Foodborne illness (food poisoning) is a nonspecific term that describes acute GI symptoms such as nausea, vomiting, diarrhea, and cramping abdominal pain caused by the intake of contaminated food or liquids.[22] There are more than 250 foodborne illnesses. Each year 1 in 6 Americans, or 48 million, gets a foodborne illness. Of these, 128,000 are hospitalized and around 3000 die.[22]

Bacteria account for most foodborne illnesses. The most common source is raw foods that become contaminated during growing, harvesting, processing, storing, shipping, or final preparation. Bacteria multiply quickly when the temperature of food is between 40 and 140 degrees. So, bacteria can multiply if hot food is not kept hot enough or cold food not cold enough. The most common bacterial food poisonings are described in Table 41.24.

Focus interventions on preventing infection. Teaching includes correct food preparation and cleanliness, adequate cooking, and refrigeration (Table 41.25). For the hospitalized patient, emphasize correcting fluid and electrolyte imbalances from diarrhea and vomiting. With botulism, additional assessment and care related to neurologic symptoms are indicated (see Chapter 60).

TABLE 41.25 Patient & Caregiver TeachingPreventing Food Poisoning

Include these instructions when teaching the patient and caregiver how to prevent food poisoning.

1. Cook all ground beef and hamburger thoroughly.
    - Use a digital instant-read meat thermometer to ensure thorough cooking (ground beef can turn brown before disease-causing bacteria are killed).
    - Cook ground beef until a thermometer inserted into

several parts of the patty, including the thickest part, reads at least 160° F.
- People who cook ground beef without using a thermometer can decrease their risk for illness by not eating ground beef patties that are still pink in the middle.

2. If you are served an undercooked hamburger or other ground beef product in a restaurant, send it back for further cooking. Ask for a new bun and a clean plate.
3. Avoid spreading harmful bacteria. Keep raw meat separate from ready-to-eat foods. Wash hands, counters, and utensils with hot soapy water after they touch raw meat. Never place cooked hamburgers or ground beef on the unwashed plate that held raw patties. Wash meat thermometers in between tests of patties that need more cooking.
4. Drink only pasteurized milk, juice, or cider. Commercial juice with an extended shelf-life that is sold at room temperature (e.g., juice in cardboard boxes, vacuum-sealed juice in glass containers) has been pasteurized. Juice concentrates are heated enough to kill pathogens.
5. Wash fruits and vegetables thoroughly, especially those you will not be cooking.
6. Do not eat raw food products that are supposed to be cooked. Follow package directions for cooking at proper temperatures.
7. People who are immunocompromised should avoid eating alfalfa sprouts until the safety of the sprouts can be ensured.

Escherichia coli O157:H7 Poisoning

Most strains of *Escherichia coli* are harmless and live in the intestines of healthy humans and animals. *E, coli* O157:H7 makes a powerful toxin and can cause severe illness with hemorrhagic colitis and kidney failure. In the very young and older adults, *E. coli* O157:H7 can be life threatening.

E. coli O157:H7 is found primarily in undercooked meats, particularly poultry and hamburger. *E. coli* outbreaks have occurred

with contaminated leafy vegetables, fruits, and nuts. Infection can occur after drinking raw milk, unpasteurized or contaminated fruit juices and after swimming in or drinking sewage-contaminated water. Person-to-person contact in families, nursing homes, and child care centers is an important mode of transmission.

Illness starts 1 to 10 days after swallowing the organism and lasts 5 to 10 days. Manifestations include diarrhea (often bloody), vomiting, and abdominal cramping pain. The diarrhea is variable, ranging from mild to bloody. It may start out as watery but may progress to bloody. Systemic complications, including hemolytic uremia and thrombocytopenic purpura, and even death can occur.

Infection with *E. coli* O157:H7 is diagnosed by detecting the bacteria in the stool. All people who suddenly have diarrhea with blood should have a stool culture for *E. coli* O157:H7.

Treatment involves hydration to maintain blood volume. There is no evidence that antibiotic therapy improves the course of disease. We think that treatment with some antibiotics may precipitate kidney complications. Patients should avoid antidiarrheal agents, such as loperamide (Imodium). Other therapies may include dialysis and plasmapheresis.

A small number of patients, especially young children and older adults, develop hemolytic uremic syndrome (HUS). With HUS, the RBCs are destroyed and the kidneys fail. It is a life-threatening condition usually treated in an ICU. Blood transfusions and kidney dialysis are often needed. The mortality rate is around 5%. About one third of people with HUS have abnormal kidney function for years afterward. A few need long-term dialysis. Other long-term complications of HUS include hypertension, seizures, blindness, and paralysis.

Case Study

Peptic Ulcer Disease

© iStockphoto/Thinkstock.

Patient Profile

F.H., a 40-yr-old male immigrant from Vietnam, has a 1-yr history of epigastric distress. Increasingly, it is not relieved by over-the-counter omeprazole (Prilosec). He is scheduled for an upper endoscopy this morning.

Subjective Data

- Reports increasing substernal pain, especially 2 to 3 hr after

eating
- Currently avoids alcohol and is taking an over-the-counter PPI
- Smoking history of 1 pack of cigarettes per day for 20 yr
- Has had increasing fatigue with exercise
- Reports occasional black bowel movement
- Takes Chinese medicine for frequent back pain

Objective Data
Physical Examination

- Height 5 ft, 5 in tall and weight 140 lb

Diagnostic Studies

- Endoscopy reveals a duodenal ulcer
- Hgb 10.2 g/dL; Hct 30%
- Histology of biopsied tissue reveals *H. pylori* infection

Interprofessional Care

- omeprazole 20 mg twice daily × 10 days
- clarithromycin 500 mg twice daily × 10 days
- amoxicillin 1 gram twice daily × 10 days

Discussion Questions

1. Explain the pathophysiology of peptic ulcer disease.
2. What are the risk factors for duodenal ulcers? Which of these did F.H. have?
3. What is the pathophysiology of *H. pylori*?
4. ***Priority Decision:*** Based on the assessment data provided, what

are the priority nursing diagnoses? Are there any collaborative problems?

5. ***Patient-Centered Care:*** How will you consider F.H.'s cultural preferences in planning care?
6. ***Priority Decision:*** What are the priority nursing interventions for F.H.?
7. What lifestyle interventions would you recommend for F.H.?
8. ***Evidence-Based Decision:*** F.H. asks you if the treatment will work and this will be the end of his problems. How will you respond?
9. ***Collaboration:*** What referrals may be indicated?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. M.J. calls the clinic and tells the nurse that her 85-yr-old mother has been nauseated all day and has vomited twice. Before the nurse hangs up and calls the HCP, she should tell M.J. to
   a. administer antiemetic drugs and assess her mother's skin turgor.
   b. give her mother sips of water and elevate the head of her bed to prevent aspiration.
   c. offer her mother large quantities of Gatorade to decrease the risk for sodium depletion.
   d. give her mother a high-protein liquid supplement to drink to maintain her nutritional needs.
2. The nurse explains to the patient with Vincent's infection that treatment will include
   a. tetanus vaccinations.
   b. viscous lidocaine rinses.
   c. amphotericin B suspension.
   d. topical application of antibiotics.
3. The nurse teaching young adults about behaviors that put them at risk for oral cancer includes
   a. discouraging use of chewing gum.
   b. avoiding use of perfumed lip gloss.
   c. avoiding use of smokeless tobacco.

d. discouraging drinking of carbonated beverages.

4. Which instructions would the nurse include in a teaching plan for a patient with mild gastroesophageal reflux disease (GERD)?
   a. "The best time to take an as-needed antacid is 1 to 3 hours after meals."
   b. "A glass of warm milk at bedtime will decrease your discomfort at night."
   c. "Do not chew gum; the excess saliva will cause you to secrete more acid."
   d. "Limit your intake of foods high in protein because they take longer to digest."

5. A patient who has undergone an esophagectomy for esophageal cancer develops increasing pain, fever, and dyspnea when a full-liquid diet is started postoperatively. The nurse recognizes that these symptoms are *most* indicative of
   a. an intolerance to the feedings.
   b. extension of the tumor into the aorta.
   c. leakage of fluids into the mediastinum.
   d. esophageal perforation with fistula formation into the lung.

6. The pernicious anemia that may accompany gastritis is due to
   a. chronic autoimmune destruction of cobalamin stores in the body.
   b. progressive gastric atrophy from chronic breakage in the mucosal barrier and blood loss.

c. a lack of intrinsic factor normally produced by acid-secreting cells of the gastric mucosa.

d. hyperchlorhydria from an increase in acid-secreting parietal cells and degradation of RBCs.

7. The nurse is teaching the patient and family that peptic ulcers are

a. caused by a stressful lifestyle and other acid-producing factors, such as *H. pylori.*

b. inherited within families and reinforced by bacterial spread of *Staphylococcus aureus* in childhood.

c. promoted by factors that cause oversecretion of acid, such as excess dietary fats, smoking, and alcohol use.

d. promoted by a combination of factors that cause erosion of the gastric mucosa, including certain drugs and *H. pylori.*

8. An optimal teaching plan for an outpatient with stomach cancer receiving radiation therapy should include information about

a. cancer support groups, alopecia, and stomatitis.

b. nutrition supplements, ostomy care, and support groups.

c. prosthetic devices, wound and skin care, and grief counseling.

d. wound and skin care, nutrition, drugs, and community resources.

9. The teaching plan for the patient being discharged after an acute episode of upper GI bleeding includes information about the importance of *(select all that apply)*

a. limiting alcohol intake to 1 serving per day.

b. only taking aspirin with milk or bread products.

c. avoiding taking aspirin and drugs containing aspirin.

d. only taking drugs prescribed by the health care provider.

e. taking all drugs 1 hour before mealtime to prevent further bleeding.

10. Several patients come to the urgent care center with nausea, vomiting, and diarrhea that began 2 hours ago while attending a large family reunion potluck dinner. You ask the patients specifically about foods they ingested containing

a. beef.

b. meat and milk.

c. poultry and eggs.

d. home-preserved vegetables.

1. b, 2. d, 3. c, 4. a, 5. c, 6. c, 7. d, 8. d, 9. c, d, 10. b

Lower Gastrointestinal Problems

Mariann M. Harding

LEARNING OUTCOMES

1. Explain the common etiologies and interprofessional and nursing management of diarrhea, fecal incontinence, and constipation.
2. Describe common causes of acute abdominal pain and nursing management of the patient after a laparotomy.
3. Describe the interprofessional and nursing management of acute appendicitis, peritonitis, and gastroenteritis.
4. Compare and contrast the inflammatory bowel diseases of ulcerative colitis and Crohn's disease, including pathophysiology, clinical manifestations, complications, and interprofessional and nursing management.
5. Distinguish among small and large bowel obstructions, including causes, clinical manifestations, and interprofessional and nursing management.
6. Describe the clinical manifestations and interprofessional and nursing management of colorectal cancer.
7. Select nursing interventions to manage the care of the patient after bowel resection and ostomy surgery.
8. Distinguish between diverticulosis and diverticulitis, including clinical manifestations and interprofessional and nursing management.
9. Compare and contrast the types of hernias, including etiology

and surgical and nursing management.

10. Describe the types of malabsorption syndromes and interprofessional care of celiac disease, lactase deficiency, and short bowel syndrome.
11. Describe the types, clinical manifestations, and interprofessional and nursing management of anorectal conditions.

Conceptual Focus

Acid-Base Balance
Elimination
Fluids and Electrolytes
Inflammation
Nutrition
Pain
Stress

The wide variety of gastrointestinal (GI) problems discussed in this chapter include diarrhea, constipation, and fecal incontinence; inflammatory and infectious bowel problems; bowel trauma; bowel obstructions; colorectal cancer; abdominal and bowel surgery (including ostomy formation); and malabsorption problems. Conceptually, patients often have problems with impaired elimination and nutrition. Many have inflammation and pain and are at risk for altered fluid and electrolyte balance. Promoting optimal bowel habits and nutrition are common goals.

Diarrhea

Diarrhea is the passage of at least 3 loose or liquid stools per day.[1] It may be acute, lasting 14 days or less, or persistent, lasting longer than 14 days. Chronic diarrhea lasts 30 days or longer.

Etiology and Pathophysiology

The primary cause of acute diarrhea is ingesting infectious organisms (Table 42.1). Viruses cause most cases of infectious diarrhea in the United States. While some viral infections can be deadly, most are mild and last less than 24 hours. So, most patients rarely seek treatment.

TABLE 42.1 Causes and Manifestations of Acute Infectious Diarrhea

Type of Organism	Manifestations	Source of Infection/Susceptibility
Bacterial		
Campylobacter jejuni	• Diarrhea, abdominal cramps, and fever. Sometimes nausea and vomiting • Lasts about 7 days	• Undercooked poultry and unpasteurized milk • Most frequent in summer months
Clostridium difficile	• Watery diarrhea, fever, anorexia, nausea, abdominal pain	• Prolonged use of antibiotics followed by exposure to feces-contaminated surfaces • Spores on hands and environmental surfaces are extremely hard to kill
Clostridium perfringens	• Diarrhea, abdominal cramps, nausea, and vomiting • Occurs 6–24 hr after eating contaminated food and lasts about 24 hr	• Associated with meats, gravies, stews, dried or precooked foods • Can cause serious illness in anyone, especially older adults
Enterohemorrhagic *Escherichia coli* (e.g., *E. coli* O157:H7)	• Severe abdominal cramping, bloody diarrhea, and vomiting • Low-grade fever • Usually lasts 5–7 days	• Can cause serious illness, especially in older adults • May progress to life-threatening renal failure • Transmitted in water or food contaminated with infected feces
Enterotoxigenic *E. coli*	• Watery or bloody diarrhea, abdominal cramps • Nausea, vomiting, and fever may be present • Mean duration >60 hr	• Most common cause of traveler's diarrhea • Transmitted in water or food contaminated with infected feces
Salmonella	• Diarrhea, fever, and abdominal cramps • Lasts 4–7 days	• Reservoir is poultry, reptiles, and other animals (especially turtles, lizards, snakes, chicks, and young birds) • Can be transmitted by handling animals • Found in undercooked poultry, meat, and foods prepared with raw eggs
Shigella	• Diarrhea (sometimes bloody), fever, and stomach cramps • Usually lasts 5–7 days • Postinfection arthritis may occur	• Transmitted via fecal-oral route or in food or water contaminated with infected feces • Can contaminate recreational water
Staphylococcus	• Nausea, vomiting, abdominal cramps, and diarrhea • Usually mild • May cause illness in as little as 30 min • Lasts 1–3 days	• 25%–50% of people are carriers in mucous membranes, skin, or hair • Transmitted in food contaminated by food workers who are carriers or through contaminated milk and cheese
Parasitic		
Cryptosporidium	• Watery diarrhea • Lasts about 2 wks • May have abdominal cramps, nausea, vomiting, fever, dehydration, weight loss • May be fatal in those who are immunocompromised (e.g., AIDS)	• Lives in human intestines • Transmitted in stool of infected human or animal • Outer shell allows it to live for long periods outside of body and makes it resistant to chlorine • Common cause of waterborne disease (swimming pools, lakes, drinking water, food contaminated with feces)
Entamoeba histolytica	• Diarrhea, abdominal cramping • Only 10%–20% are ill, and symptoms are usually mild	• Fecally contaminated food, water, or hands • Most common in developing countries • In the United States, high-risk groups include travelers, recent immigrants, and homosexual men
Giardia lamblia	• Abdominal cramps, nausea, diarrhea • May interfere with nutrient absorption	• Highly contagious • Transmitted via fecal-oral route • Found in fresh lakes and rivers. Can be transmitted in swimming pools, water parks, and hot tubs
Viral		
Norovirus (Norwalk-like virus)	• Nausea, vomiting, diarrhea, stomach cramping • Rapid onset. Lasts 1–2 days	• Very contagious • Virus is present in stool and emesis
Rotavirus	• Fever, vomiting, and profuse watery diarrhea • Lasts 3–8 days	• Highly contagious • Transmitted mainly by fecal-oral route

Bacterial infection with *Escherichia coli* O157:H7, a type of enterohemorrhagic *E. coli,* is a common cause of bloody diarrhea in the United States. It is transmitted by undercooked beef or chicken contaminated with the bacteria or in fruits and vegetables exposed to

contaminated manure. Other pathologic *E. coli* strains are endemic in developing countries and often cause traveler's diarrhea. *Giardia lamblia* is the most common intestinal parasite that causes diarrhea in the United States.

Infectious organisms attack the intestines in different ways. Some organisms (e.g., Rotavirus A, Norovirus, *G. lamblia*) change the secretion and/or absorption of enterocytes in the small intestine and do not cause inflammation. Other organisms (e.g., *Clostridium difficile*) impair absorption by destroying cells, causing inflammation in the colon, and producing toxins that cause damage.

Secretory diarrhea is a common result of bacterial or viral infections. It occurs when ingested pathogens survive in the GI tract long enough to absorb into the enterocytes. The resulting chain reaction changes cell permeability and causes the oversecretion of water and sodium and chloride ions into the bowel.

Organisms enter the body in contaminated food (e.g., *Salmonella* in undercooked eggs and chicken) or contaminated drinking water (*G. lamblia* in contaminated lakes or pools). Travelers often get diarrhea, especially if they travel to countries with poorer sanitation than their own. Infection can spread from person to person via the fecal-oral route. For example, adult day care workers can transmit infection from one resident to another if they do not wash their hands after changing soiled diapers or linens.

A person's age, gastric acidity, intestinal microflora, and immune status influence susceptibility to pathogenic organisms. Older adults are most likely to have life-threatening diarrhea. Since stomach acid kills ingested pathogens, taking drugs to decrease stomach acid (e.g., proton pump inhibitors [PPIs]) increases the chance that pathogens will survive.[2]

The healthy human colon contains short-chain fatty acids and bacteria, such as *E. coli.* These organisms aid in fermentation and provide a microbial barrier against pathogenic bacteria. Antibiotics kill the normal flora, making the person more susceptible to pathogenic organisms. For example, patients receiving broad-spectrum antibiotics (e.g., carbapenems, cephalosporins,

piperacillin/tazobactam) are susceptible to pathogenic strains of *C. difficile*.[2] *C. difficile* infection (CDI) causes the most serious antibiotic-associated diarrhea and is a common cause of hospital-acquired GI illness in the United States.

People who are immunocompromised because of disease (e.g., human immunodeficiency virus [HIV]) or immunosuppressive drugs are susceptible to GI tract infection. Immunocompromised patients receiving jejunal enteral nutrition (EN) are especially prone to CDI and other foodborne infections. Jejunostomy and nasointestinal feedings, which bypass the stomach's acid environment, do not contain the poorly digestible fiber that normal colonic bacteria need for survival.

Diarrhea is not always due to infection. Drugs and specific food intolerances can cause diarrhea. Large amounts of undigested carbohydrate in the bowel, lactose intolerance, and certain laxatives (e.g., lactulose, sodium phosphate, magnesium citrate) produce osmotic diarrhea. *Osmotic diarrhea* results from rapid GI transit that prevents fluid and electrolyte absorption. Bile salts and undigested fats lead to excess fluid secretion into the GI tract. Diarrhea from celiac disease and short bowel syndrome result from malabsorption in the small intestine.

Clinical Manifestations

Infections that attack the upper GI tract (e.g., Norovirus, *G. lamblia*) usually produce large-volume, watery stools, cramping, and periumbilical pain (Table 42.1). Patients have either a low-grade or no fever and often have nausea and vomiting before the diarrhea begins. Infections of the colon and distal small bowel (e.g., *Shigella, Salmonella, C. difficile*) cause fever and frequent bloody diarrhea with a small volume.

Leukocytes, blood, and mucus may be present in the stool, depending on the causative agent. Severe diarrhea may cause life-threatening dehydration, electrolyte problems (e.g., hypokalemia), and acid-base imbalances (metabolic acidosis). CDI can progress to

severe colitis and intestinal perforation.

Diagnostic Studies

Stool cultures are usually done only in patients who are very ill; have a fever, bloody diarrhea, or diarrhea lasting longer than 3 days; or were exposed during an outbreak.[1] Those with travelers' diarrhea lasting 14 days or longer should be evaluated for parasitic infections. Stools are examined for blood, mucus, white blood cells (WBCs), and parasites. Cultures reliably identify infectious organisms. Multiple-pathogen stool tests can detect common viral, parasitic, and bacterial organisms from a single stool sample.

TABLE 42.2 Drug TherapyAntidiarrheal Drugs

Drug	Mechanism of Action
bismuth subsalicylate (Pepto-Bismol)	Decreases secretions and has weak antibacterial activity. Used to prevent traveler's diarrhea
calcium polycarbophil (FiberCon)	Bulk-forming agent that absorbs excess fluid from diarrhea to form a gel. Used when intestinal mucosa cannot absorb fluid
diphenoxylate with atropine (Lomotil)	Opioid and anticholinergic. Decreases peristalsis and intestinal motility
loperamide (Imodium, Pepto Diarrhea Control)	Inhibits peristalsis, delays transit, increases absorption of fluid from stools
octreotide acetate (Sandostatin)	Suppresses serotonin secretion, stimulates fluid absorption from GI tract, decreases intestinal motility
paregoric (camphorated tincture of opium)	Opioid. Decreases peristalsis and intestinal motility

Blood cultures should be done in those with signs of sepsis or systemic infection (e.g., high fever) or who are immunocompromised.[1] The WBC count may be high. People with long-standing diarrhea can develop anemia from iron and folate deficiencies. Increased

hematocrit, blood urea nitrogen (BUN), and creatinine levels are signs of fluid deficit.

In patients with chronic diarrhea, measuring stool electrolytes, pH, and osmolality helps determine whether the diarrhea is from decreased fluid absorption or increased fluid secretion. Measuring stool fat and undigested muscle fibers may show fat and protein malabsorption conditions. Some patients with secretory diarrhea have high serum levels of GI hormones, such as vasoactive intestinal polypeptide and gastrin.

Interprofessional Care

Treatment of diarrhea depends on the cause. Acute infectious diarrhea is usually self-limiting. The major concerns are preventing transmission, replacing fluid and electrolytes, and protecting the skin. Most patients tolerate oral fluids. Solutions containing glucose and electrolytes (e.g., Pedialyte) may be enough to replace losses from mild diarrhea. If losses are severe, it will be necessary to give parenteral fluids, electrolytes, vitamins, and nutrition. Teach the patient to avoid foods and drugs that cause diarrhea.

Antidiarrheal agents have limited short-term use. They coat and protect mucous membranes, absorb irritating substances, inhibit intestinal transit, decrease intestinal secretions, or decrease central nervous system stimulation of the GI tract (Table 42.2). Antidiarrheal agents are contraindicated in treating some infectious diarrheas because they potentially prolong exposure to the organism.[1] They are used cautiously in inflammatory bowel disease (IBD) because of the danger of causing *toxic megacolon* (colonic dilation greater than 5 cm).

Antibiotics rarely have a role in treating acute diarrhea. They are given only for certain infections or when the infected person is severely ill or immunosuppressed. The 2 antibiotics recommended for empiric therapy in adults are a fluoroquinolone, such as ciprofloxacin, and azithromycin.[1]

Clostridium difficile infection

CDI is a particularly hazardous health care–associated infection (HAI). The risk for contracting CDI is highest in patients receiving antimicrobial, chemotherapy, gastric acid–suppressing, or immunosuppressive agents. *C. difficile* spores can survive for up to 70 days on objects, including commodes, telephones, bedside tables, and floors. Health care workers who do not adhere to strict infection control precautions can transmit *C. difficile* from patient to patient. Meticulous hand washing with soap and water is extremely important in limiting the spread of *C. difficile*. *Lactobacillus* probiotics may be used to prevent CDI or as an adjunct therapy to help prevent the risk for recurrent CDI.[3]

CDI is treated with either oral vancomycin (125 mg 4 times a day) or fidaxomicin (200 mg twice daily) for 10 days. All nonessential antibiotics, stool softeners, laxatives, and antidiarrheal agents should be stopped. Metronidazole is an option when patients are unable to be treated with vancomycin or fidaxomicin. Patients with severe, complicated CDI with shock, hypotension, ileus, or megacolon should receive vancomycin 500 mg 4 times daily orally with IV metronidazole. Patients with ileus can receive vancomycin via enema.

Recurrent CDI occurs in about 20% of patients. The risk increases with the use of additional antibiotics and CDI recurrences. *Fecal microbiota transplantation* (FMT) is emerging as the most effective treatment for recurrent CDI.[3] FMT reestablishes healthy intestinal flora by infusing fecal bacteria obtained from healthy donor stool into the patient's colon. To perform an FMT, feces obtained from the donor is pureed into a liquid, slurry consistency using saline, water, or pasteurized cow's milk. The donor stool is then placed in the GI tract via an enema, nasoenteral tube, or during colonoscopy. The major concern with FMT is the potential for transmitting infectious agents in the donor stool. Using feces from donors who have intimate physical contact with the recipient and careful screening minimize this risk. Most patients have diarrhea immediately after the procedure.

Nursing Management: Acute Infectious Diarrhea

Nursing Assessment

Begin the nursing assessment with a thorough history and physical examination (Table 42.3). Ask the patient to describe their stool pattern and associated symptoms. Focus on the duration, frequency, character, and consistency of stool and the relationship to other symptoms, such as pain and vomiting. Ask about medical conditions that may cause diarrhea and whether the person is taking drugs, such as antibiotics and laxatives, which are known to cause diarrhea, decrease stomach acidity, or cause immunosuppression. Determine whether the patient has traveled to a foreign country or been at a day care facility recently and if other family members are ill. Ask about food preparation practices, food intolerances (e.g., milk), and changes in diet and appetite.

Assess for fever and signs of dehydration (dry skin, low-grade fever, orthostatic changes in pulse and BP, decreased and concentrated urine). Assess the abdomen for distention, pain, and guarding. Inspect the perineal skin for signs of redness and breakdown from the diarrhea.

TABLE 42.3 Nursing AssessmentDiarrhea

Subjective Data Important Health Information
Past health history: Recent travel, hospitalization, infections, stress. Diverticulitis or malabsorption, metabolic disorders, IBD, IBS
Medications: Laxatives or enemas, magnesium-containing antacids, sorbitol-containing suspensions or elixirs, antibiotics,

methyldopa, digitalis, colchicine; OTC antidiarrheal drugs
Surgery or other treatments: Stomach or bowel surgery, radiation

Functional Health Patterns

Health perception–health management: Chronic laxative use, malaise
Nutritional-metabolic: Ingestion of fatty and spicy foods, food intolerances. Anorexia, nausea, vomiting, weight loss. Thirst
Elimination: Increased stool frequency, volume, and looseness. Change in color and character of stools. Steatorrhea, abdominal bloating. Decreased urine output
Cognitive-perceptual: Abdominal tenderness, abdominal pain and cramping, tenesmus

Objective Data
General

Lethargy, sunken eyeballs, fever, malnutrition

Integumentary

Pallor, dry mucous membranes, poor skin turgor, perianal irritation

Gastrointestinal

Frequent soft to liquid stools that may alternate with constipation, altered stool color. Abdominal distention, hyperactive bowel sounds. Pus, blood, mucus, or fat in stools. Fecal impaction

Urinary

Decreased output, concentrated urine

Possible Diagnostic Findings

Abnormal serum electrolyte levels. Anemia, leukocytosis, eosinophilia, hypoalbuminemia. Positive stool cultures. Ova, parasites, leukocytes, blood, or fat in stool. Abnormal sigmoidoscopy or colonoscopy findings. Abnormal lower GI series

Nursing Diagnoses

Nursing diagnoses for the patient with acute infectious diarrhea include:

- Diarrhea
- Fluid imbalance
- Electrolyte imbalance

For more information on nursing diagnoses and interventions for diarrhea, see eNursing Care Plan 42.1 on the website for this chapter.

Planning

The overall goals are that the patient with diarrhea will have (1) cessation of diarrhea and resumption of normal bowel patterns; (2) normal fluid, electrolyte, and acid-base balance; (3) normal nutritional status; and (4) no perianal/perineal skin breakdown.

Nursing Implementation

Consider all cases of acute diarrhea as infectious until the cause is

known. Strict infection control precautions are needed to prevent the illness from spreading to others. Wash your hands with soap and water before and after contact with each patient and when handling body fluids of any kind. Flush vomitus and stool in the toilet. Teach the patient principles of hygiene, infection control, and the potential dangers of an illness that is infectious to themselves and others. Discuss proper food handling, cooking, and storage with the patient and caregiver (see Tables 41.24 and 41.25).

Viruses and *C. difficile* spores are extremely hard to kill. Alcohol-based hand cleaners and ammonia-based disinfectants are ineffective. Vigorous cleaning with soap and water does not kill everything. Immediately put patients with CDI in isolation. Ensure that visitors and all providers wear gloves and gowns. Give infected patients their own disposable stethoscopes and thermometers. Consider all objects in the room contaminated. Ensure surfaces and equipment are disinfected with a 10% bleach solution or a disinfectant labeled as *C. difficile* sporicidal.

Fecal Incontinence

Etiology and Pathophysiology

Fecal incontinence is the involuntary passage of stool. It occurs when the normal structures that maintain continence are damaged or disrupted. Defecation is a voluntary action when the neuromuscular system is intact (see Chapter 38). Problems with motor function (contraction of sphincters and rectal floor muscles) and/or sensory function (ability to perceive the presence of stool or have the urge to defecate) can result in fecal incontinence. Contributing factors include altered bowel habits, weakness or disruption of the internal or external anal sphincter, damage to the pudendal nerve or other nerves that innervate the anorectum, and damage to the anal tissue (Table 42.4).

For women, obstetric trauma is the most common cause of sphincter disruption. Childbirth, aging, and menopause contribute to the development of fecal incontinence. Anorectal surgery can damage the sphincters and pudendal nerves. Radiation for prostate cancer decreases rectal compliance. Neurologic conditions, including stroke and multiple sclerosis, interfere with defecation.

People with normal functioning defecation can have incontinence if immobility prevents prompt access to a toilet or stool is accidentally discharged with diarrhea. Chronic constipation can lead to *fecal impaction,* a collection of hardened feces in the rectum or sigmoid colon that a person cannot expel. Incontinence occurs as liquid stool seeps around the hardened feces. Fecal impaction is a common problem in older adults with limited mobility. Constipated persons tend to strain during defecation. Straining contributes to incontinence because it weakens the pelvic floor muscles.

Diagnostic Studies and Interprofessional Care

The diagnosis and effective management of fecal incontinence require a thorough health history and physical examination. Ask the patient

about the number of incontinent episodes per week, stool consistency and volume, and the degree that incontinence interferes with work and social activities. A rectal examination can reveal reduced anal canal muscle tone and contraction strength of the external sphincter, as well as detect internal prolapse, rectocele, hemorrhoids, masses, and fecal impaction. Other tests, such as anorectal manometry, anorectal ultrasonography, and anal electromyography, are done when symptoms persist after treating underlying problems or certain problems need further evaluation.[4]

TABLE 42.4 Common Causes of Fecal Incontinence

Anal Sphincter Weakness

- Anorectal infection
- Injury
    - Anorectal surgery for hemorrhoids, fistula, and fissures
    - Childbirth injury
    - Perineal trauma or pelvic fracture
- Internal sphincter thinning

Functional

- Physical or mobility impairments affecting toileting ability (e.g., frail older person who cannot get to the bathroom in time)

Inflammatory

- Inflammatory bowel disease
- Radiation

Neurologic Disease

- Brain tumor
- Congenital abnormalities (e.g., spina bifida, myelomeningocele)
- Dementia
- Diabetes
- Multiple sclerosis
- Neuropathy
- Spinal cord lesions
- Stroke

Pelvic Floor Dysfunction

- Fistula
- Rectal prolapse

Other

- Chronic constipation
- Denervation of pelvic muscles from chronic straining
- Diarrhea
- Fecal impaction

Treatment of incontinence depends on the cause. Maintaining normal stool consistency and a bowel management program are important. This includes regular defecation, a high-fiber diet, and increased intake of caffeine-free fluids. Dietary fiber supplements or bulk-forming laxatives, like psyllium (e.g., Metamucil), increase stool bulk, firm consistency, and promote the sensation of rectal filling. Patients may need to reduce the intake of foods that cause diarrhea and rectal irritation. Common triggers include caffeine, products

containing artificial sweeteners, dairy products, high gas–producing vegetables (e.g., broccoli, cabbage, cauliflower), and vegetables containing insoluble fiber (e.g., lettuce, tomatoes, corn).

Fecal incontinence from fecal impaction usually resolves after manual removal of the hard feces and cleansing enemas. Antidiarrheal agents (e.g., loperamide) are useful in slowing intestinal transit.

Physical therapy and biofeedback training can improve awareness of rectal sensation, coordinate internal and external anal sphincters, and increase the strength of external sphincter contraction. Biofeedback training requires intact sensory and motor nerves and motivation to learn. It is a safe, painless, and effective treatment.[4]

Mild electrical stimulation of the sacral nerves targets communication problems between the brain and nerves that control the pelvic floor muscles and sphincters. Electrical stimulation can improve quality of life. Some patients may achieve complete continence.[4]

For patients who do not respond to conservative measures, treatment with dextranomer/hyaluronic acid gel (Solesta) may be used. In this treatment, the gel is injected into the deep submucosa of the patient's anal canal. It works by building up tissue in the anal area, narrowing the anal canal and allowing muscles to more adequately close. No anesthesia is given. Postinjection pain and bleeding may occur.

Surgery (e.g., sphincter repair procedures) is an option when other conservative treatments fail, the patient has a full-thickness prolapse, or the anal sphincter needs repair. A colostomy is sometimes needed.

Nursing Management: Fecal Incontinence

Nursing Assessment

Fecal incontinence is embarrassing, uncomfortable, and irritating to the skin. Its unpredictable nature makes it hard to maintain school and work activities and hampers social or intimate contact. Be sensitive to the patient's feelings when discussing incontinence.

Ask about bowel patterns before the incontinence developed; current bowel habits; stool consistency, volume, and frequency; and symptoms, including pain during defecation and a feeling of incomplete evacuation *(tenesmus).* The Bristol Stool Scale is helpful to assess stool consistency. Assess whether the patient has a sensation of urgency to evacuate the bowel or sensation of passing flatus and leaking stool. Ask about daily activities (mealtimes and work), diet, and family and social activities and the degree that incontinence interferes with these activities.

Check the perineal area for irritation or breakdown. Patients who have fecal incontinence are at risk for *incontinence-associated dermatitis* (IAD).[4] IAD results from chemical irritants in the feces causing skin damage. Symptoms include redness, skin loss, and rash. The location of IAD is usually the perianal or perineal area, buttocks, or upper thighs. Fungal infection is common and seen as a dark red center surrounded by satellite lesions. Your assessment is important in distinguishing IAD from pressure injury development.

Nursing Implementation

Regardless of the cause of fecal incontinence, bowel training is effective for many patients. Bowel elimination occurs at regular intervals in most people. Knowing the patient's usual bowel pattern can help you plan a bowel program that will achieve optimal stool consistency and establish predictable bowel elimination patterns. For

the hospitalized patient, placement on a bedpan, help to a bedside commode, or walks to the bathroom at a regular time daily help to establish regular defecation. The best time to schedule elimination is within 30 minutes after breakfast.

If these techniques are not effective in reestablishing bowel regularity, administer bisacodyl, a glycerin suppository, or a small phosphate enema 15 to 30 minutes before the usual evacuation time. These preparations stimulate the anorectal reflex. Since stimulation will not occur unless the suppository or enema touches the rectal wall, first check for stool in the rectum and digitally remove it before inserting the laxative. Once a regular pattern is established, stop these drugs. Digital stimulation is another method for stimulating the anorectal reflex. It is often included in bowel programs for people with neurogenic bowels (e.g., from spinal cord injury). Irrigating the rectum and colon (usually with tap water) at regular intervals is another way to achieve continence in patients with neurogenic bowel.

Maintaining perineal skin integrity is a priority, especially in the bedridden patient. Feces can contaminate wounds, damage skin, cause bladder infections, and spread infections such as *C. difficile*. Fecal containment is essential. One way to contain stool is a stool management system (e.g., Flexi-Seal, DigniCare, Actiflo). These systems funnel liquid stool from the rectum into a containment system. Common features include a retention cuff that sits above the anal sphincter and soft tubing that extends from this cuff to a secure hub that allows a person to change the containment canister when it is full. A system can remain in place for weeks. Their use may decrease the risk for CDI, skin damage from exposure to stool, IAD, and pressure injuries. Do not use a rectal tube or urinary catheter as a stool catheter. They can reduce the responsiveness of the rectal sphincter and irritate or ulcerate the rectal mucosa.

Perform frequent skin assessments when using absorbent products. Incontinence pads are an option when the patient is in bed. Briefs should be used only during ambulation or when sitting in a chair. Make sure they are changed promptly after each episode of incontinence.

Use absorbent products in combination with a defined skin care program. This includes prompt cleansing, moisturizing, and skin protection. Cleanse the skin gently, using a skin cleanser rather than soap and water. Options include a cotton cloth moistened with a hydrating skin cleansing foam, incontinence clean-up cloths, or baby wipes. Avoid products that contain alcohol as they can cause drying of the skin and discomfort if skin is irritated. Pat the skin dry or use a blow dryer on a cool setting. Do not rub the skin dry. Apply a moisture barrier and, if needed, a skin barrier cream for more protection. For patients unable to care for themselves at home, you should teach caregivers how to maintain skin integrity.

Fecal incontinence is an overwhelming burden for most patients. Be sensitive to their fears. Teach them ways to reduce incontinence episodes and better cope with them when they do occur. Help patients identify food triggers that may worsen symptoms. Encourage them to avoid those foods and exercise after meals. Tell them to try to use bathrooms when they are available. Patients may be more confident when they use discreet, disposable briefs or pads. Have them wear dark-colored clothing that they can quickly remove for toileting. Ready access to a spare set of clothing and cleansing cloths is important.

Constipation

Constipation is characterized by difficult or infrequent bowel movements, often accompanied by excessive exertion during defecation or a feeling of incomplete evacuation.[5] Constipation is a symptom, not a disease. It can be acute, usually lasting less than 1 week, or chronic, lasting over 3 months.

Etiology and Pathophysiology

Risk factors associated with chronic constipation include a low-fiber diet, decreased physical activity, or ignoring the defecation urge. Ignoring the urge to defecate for a prolonged period can cause the muscles and mucosa of the rectum to become insensitive to the presence of feces. In addition, the prolonged retention of feces results in drying of stool due to water absorption. The harder and drier the feces, the harder it is to expel. Emotions, including anxiety, depression, and stress, affect the GI tract and can contribute to constipation.

Constipation occurs with diseases that slow GI transit and hamper neurologic function, such as diabetes, Parkinson's disease, and multiple sclerosis (Table 42.5). Many drugs, especially opioids, cause constipation (Table 42.6).[5]

Some people think they are constipated if they do not have a daily bowel movement. This can result in chronic laxative use and *cathartic colon syndrome,* a condition in which the colon becomes dilated and atonic (lacking muscle tone). Ultimately, the person cannot defecate without a laxative.

Clinical Manifestations

The clinical presentation varies from a mild discomfort to a more severe event mimicking an "acute abdomen." Stools are absent or hard, dry, and difficult to pass. Abdominal distention, bloating,

increased flatulence, and increased rectal pressure may be present.

TABLE 42.5 Diseases Associated With Constipation

Colonic Disorders

- Cancer
- Diverticular disease
- Inflammatory bowel disease
- Intestinal stenosis
- Intussusception
- Luminal or extraluminal obstructing lesions
- Rectocele
- Prolapse

Systemic Disorders

Collagen Vascular Disease

- Amyloidosis
- Systemic lupus erythematosus
- Systemic sclerosis (scleroderma)

Metabolic/Endocrine

- Chronic renal failure
- Diabetes
- Hypercalcemia/hyperparathyroidism
- Hypokalemia
- Hypothyroidism

- Pheochromocytoma
- Pregnancy

Neurologic Disorders

- Autonomic neuropathy (from diabetes)
- Hirschsprung's megacolon
- Multiple sclerosis
- Neurofibromatosis
- Parkinson's disease
- Spinal cord lesions or injury
- Stroke

TABLE 42.6 Drugs Associated With Constipation

Cardiovascular	• Antihypertensives
	• Furosemide
	• Hypolipidemics (cholestyramine, colestipol, statins)
GI	• Antacids containing aluminum, calcium
	• Antidiarrheals • Proton-pump inhibitors
	• Supplements (e.g., bismuth, calcium, iron)
Central nervous system	• Antidepressants (tricyclics, selective serotonin reuptake inhibitors) • Antiepileptics (carbamazepine, phenytoin, clonazepam)
	• Antipsychotics (butyrophenones, phenothiazines, barbiturates) • Benzodiazepines
Other	• Analgesics (opiates and derivatives)
	• Antitussives (codeine, dextromethorphan)

Hemorrhoids are a common complication of chronic constipation. They result from venous engorgement caused by repeated *Valsalva maneuvers* (straining) and venous compression from hard, impacted stool. The Valsalva maneuver may have serious outcomes for patients with heart failure, cerebral edema, hypertension, and coronary artery

disease. During straining, the patient inspires deeply and holds the breath while contracting abdominal muscles and bearing down. This increases both intraabdominal and intrathoracic pressures and reduces venous return to the heart. The heart rate temporarily decreases along with a decrease in cardiac output. This results in a transient drop in arterial pressure. When the patient relaxes, thoracic pressure falls, resulting in a sudden flow of blood into the heart, increased heart rate, and an immediate rise in arterial pressure. These changes may be fatal for the patient who cannot compensate for the sudden increased blood flow returning to the heart.

Rectal mucosal ulcers and fissures may occur from stool stasis or straining. Diverticulosis is another potential complication of chronic constipation. It is more common in older patients.

In the presence of *obstipation* (absolute constipation with no passage of gas or stool) or fecal impaction secondary to constipation, colonic perforation may occur. Perforation, which is life threatening, causes abdominal pain, nausea, vomiting, fever, and a high WBC count.

Diagnostic Studies and Interprofessional Care

In most patients, the diagnosis of constipation is based on findings from a thorough history and physical examination. The physical should include an abdominal examination, inspection of the perianal and rectal region, and a digital rectal examination. Concerning signs include a sudden, persistent change in bowel habits (>6 weeks) in those over 50 years, rectal bleeding or bloody stools, iron deficiency anemia, weight loss, significant abdominal pain, family or personal history of colorectal cancer (CRC) or inflammatory bowel disease and palpable mass.[5] If any of these are present, tests are needed to rule out serious disease, such as CRC. These may include abdominal x-rays, barium enema, and colonoscopy or sigmoidoscopy.

Increasing dietary fiber, fluid intake, and exercise can prevent many cases of constipation.[6] Laxatives (Table 42.7) and enemas are an option in treating constipation. All promote bowel movements, but each class works differently. Which one a patient receives depends on the

severity and duration of the constipation and the patient's health. Daily bulk-forming laxatives (psyllium) can prevent constipation because they work like dietary fiber and do not cause dependence. In patients with chronic constipation who do not respond to diet and lifestyle modifications, osmotic laxatives are the next recommended treatment. Stimulant laxatives are given to patients who do not respond to osmotic laxatives. Enemas are fast acting and can give immediate treatment of constipation but must be used cautiously. Agents containing sodium phosphate and magnesium can cause electrolyte imbalances in older adults and patients with heart and kidney problems.

Other therapies target specific patient needs. Peripherally acting opioid receptor antagonists (e.g., methylnaltrexone, naldemedine, naloxegol) decrease constipation caused by opioid use. They do not block the analgesic effects of opioids. Biofeedback therapy may help patients who have constipation because of *anismus* (uncoordinated contraction of the anal sphincter during straining).

A patient with severe constipation related to bowel motility or mechanical disorders may need more intense treatment. Diagnostic studies include anorectal manometry, GI tract transit studies, balloon expulsion test, and defecography. A patient with unrelenting constipation may need a colostomy, ileostomy, or continent fecal diversion. These procedures are discussed later in this chapter.[6]

Nutritional Therapy

Diet is a key factor in preventing and treating constipation. Many patients have improved symptoms when they increase their dietary fiber intake. Dietary fiber is found in fruits, vegetables, and grains (Table 42.8). Wheat bran and prunes are especially effective for preventing and treating constipation. Whole wheat and bran are high in insoluble fiber.

Dietary fiber adds to the stool bulk directly by attracting water. Adequate fluid intake (2 L/day) is essential. Large, bulky stools move through the colon much more quickly than small stools. However, the recommended fluid intake may be contraindicated in a patient with

heart disease or renal failure. Tell the patient that increasing fiber intake may initially increase gas production because of fermentation in the colon, but this effect decreases over several days.

TABLE 42.7 Drug TherapyConstipation

Mechanism of Action	Indications	Example	Comments
Bulk Forming			
Absorbs water. Increases bulk, thereby stimulating peristalsis ***Action:*** **Usually within 24 hr**	Acute and chronic constipation, irritable bowel syndrome, diverticulosis	methylcellulose (Citrucel) psyllium (Metamucil, Konsyl, Hydrocil, Fiberall)	Contraindicated in patients with abdominal pain, nausea, and vomiting and those suspected of having appendicitis, biliary tract obstruction, or acute hepatitis. Must be taken with fluids (≥8 oz). Best choice for initial treatment of constipation
Emollients			
Lubricate intestinal tract and soften feces, making hard stools easier to pass. Do not affect peristalsis ***Action:*** **Softeners in 72 hr, lubricants in 8 hr**	Acute and chronic constipation, fecal impaction, anorectal conditions	*Softeners:* docusate (Colace, Surfak) *Lubricants:* mineral oil (Fleet Mineral Oil Enema)	Can block absorption of fat-soluble vitamins, such as vitamin K, which may increase risk for bleeding in patients on anticoagulants
Prosecretory Agents			
Increases intestinal fluid secretion through direct action on epithelial cells, speeding colonic transit ***Action:*** **Usually within 24 hr**	Chronic idiopathic constipation, irritable bowel syndrome with constipation (women only)	linaclotide (Linzess) lubiprostone (Amitiza) plecanatide (Trulance)	Contraindicated in patients with history of mechanical GI obstruction. Can cause nausea and watery diarrhea
Saline and Osmotic Solutions			
Cause retention of fluid in intestinal lumen, reducing stool consistency and increasing volume ***Action:*** **Within 15 min–3 hr**	Chronic constipation, bowel preparation for diagnostic tests and surgery	lactulose magnesium salts (magnesium citrate, Milk of Magnesia) sodium phosphates (Fleet Enema, Phospho-soda) polyethylene glycol (MiraLAX, GoLYTELY)	May cause abdominal distention and diarrhea. Overuse of magnesium or sodium phosphates in older adults or those with renal failure can lead to fluid and electrolyte imbalances; least effective agents in this class
Stimulants			
Increases peristalsis and speeds colonic transit by irritating colon wall and stimulating enteric nerves ***Action:*** **Usually within 12 hr**	Acute constipation, bowel preparation for diagnostic tests and surgery	anthraquinones (cascara sagrada, senna) phenolphthalein: sennosides (Ex-Lax), bisacodyl (Correctol, Dulcolax)	Cause melanosis coli (brown or black pigmentation of colon). Most widely abused laxatives. Should not be used in patients with impaction or obstipation

Evidence-Based Practice

Probiotics and Constipation

L.R. is an 82-yr-old woman with decreased mobility due to a recent

hip fracture. During a check-up visit at the orthopedic clinic, L.R. states she is having discomfort due to constipation. She tells you she is following her discharge instructions, "drinking lots of water," and trying to increase fiber in her diet.

Making Clinical Decisions

Best Available Evidence. Quality of life decreases with increased severity in constipation symptoms. Many patients with constipation have modifiable risk factors related to their lifestyle. These include low-fiber diet, poor hydration, and/or sedentary lifestyle. In adults with constipation, there is an association between the use of probiotics, especially products containing *Bifidobacterium longum* and *Bifidobacterium lactis,* and significant improvements in gut transit time, stool frequency, and stool consistency.

Clinician Expertise. You know that diet, fluid intake, and activity can play a key role in treating and preventing constipation. You recently read about the potential benefit of probiotics in relieving constipation.

Patient Preferences and Values. L.R. asks if you know of anything else she can do as she does not want to take any more drugs.

Implications for Nursing Practice

1. What information would you share with L.R. about probiotics and constipation?
2. What data would you want from L.R. about her diet, activity, medications, and fluid intake?
3. Why is it important for you to know about alternative therapies? What is your role in supporting patients who want alternatives to drug therapy?

Acute Abdominal Pain and Laparotomy

Etiology and Pathophysiology

Acute abdominal pain is pain of recent onset. It may signal a life-threatening problem, so it requires immediate attention. Causes include damage to organs in the abdomen and pelvis, which leads to inflammation, infection, obstruction, bleeding, and perforation (Fig. 42.1). Perforation of the GI tract results in irritation of the *peritoneum* (serous membrane lining the abdominal cavity) and peritonitis. Hypovolemic shock occurs from bleeding or obstruction and peritonitis causing large amounts of fluid to move from the vascular space into the abdomen.

TABLE 42.10 Patient & Caregiver TeachingConstipation

Include the following instructions when teaching the patient and caregiver about management of constipation.

1. Eat Dietary Fiber

Eat 20 to 30 g of fiber per day. Gradually increase the amount of fiber eaten over 1 to 2 wk. Fiber softens hard stool and adds bulk to stool, promoting evacuation. Eat prunes or drink prune juice daily. Prunes stimulate defecation.

- Foods high in fiber: raw vegetables and fruits, beans, breakfast cereals (All Bran, oatmeal)
- Fiber supplements: Metamucil, Citrucel, FiberCon

2. Drink Fluids

Fluid softens hard stools. Drink 2 L per day. Drink water or fruit juices. Avoid caffeinated coffee, tea, and cola. Caffeine stimulates fluid loss through urination.

3. Exercise Regularly

Walk, swim, or bike at least 3 times per wk. Contract and relax abdominal muscles when standing or by doing sit-ups to strengthen muscles and prevent straining. Exercise stimulates bowel motility and moves stool through the colon.

4. Establish a Regular Time to Defecate

First thing in the morning or after the first meal of the day is the best time because people often have the urge to defecate at this time.

5. Do Not Delay Defecation

Respond to the urge to have a bowel movement as soon as possible. Delaying defecation results in hard stools and a decreased "urge" to defecate. Water is absorbed from stool by the intestine over time. The colon becomes less sensitive to the presence of stool in the rectum.

6. Record Your Bowel Elimination Pattern

Develop a habit of recording on your calendar when you have a bowel movement. Regular monitoring of bowel movement will help you identify a problem early.

7. Avoid Laxatives and Enemas

Do not overuse laxatives and enemas, because they cause dependence. People who overuse them become unable to have a bowel movement without them.

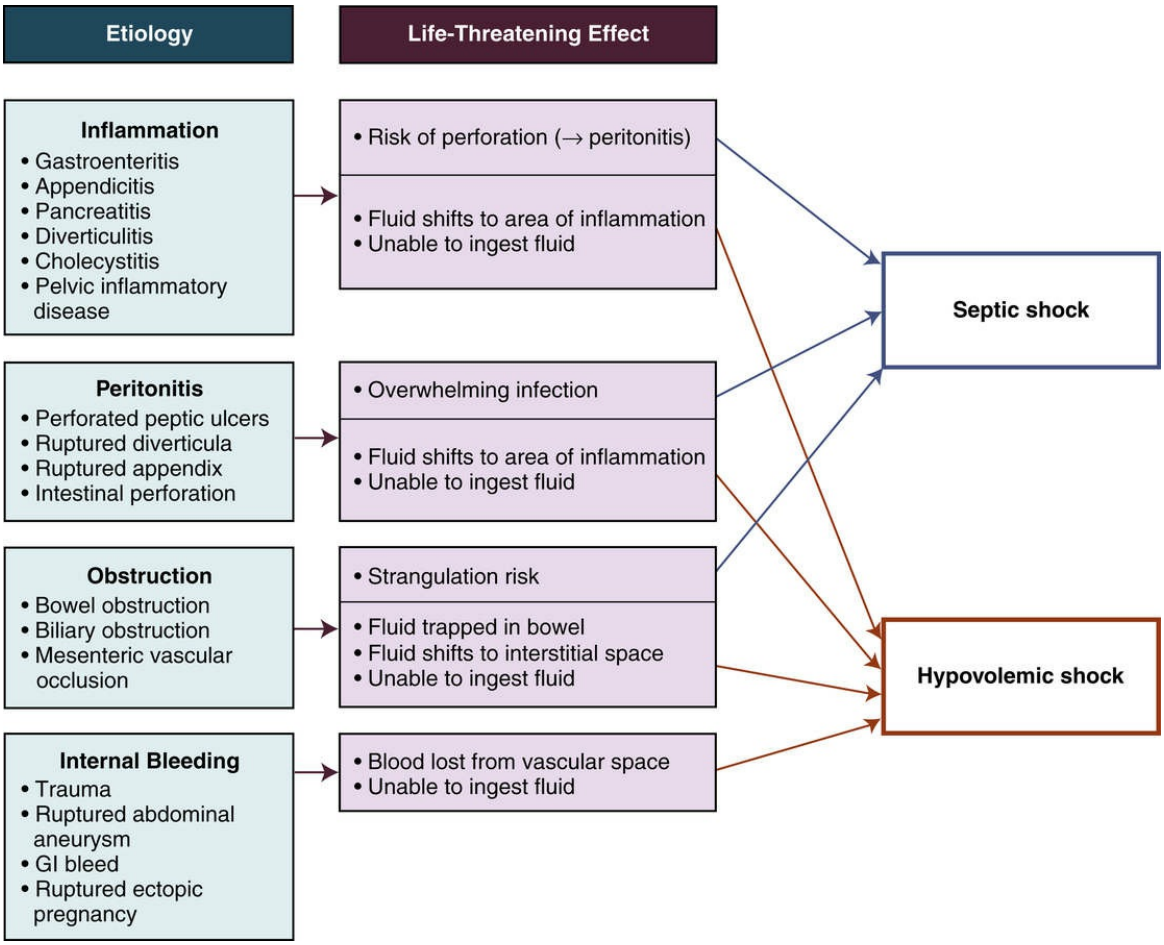

FIG. 42.1 Cause of acute abdominal pain and pathophysiologic sequelae.

Clinical Manifestations

Pain is the most common symptom of an acute abdominal problem. The patient may have nausea, vomiting, diarrhea, constipation, flatulence, fatigue, fever, rebound tenderness, and bloating.

Diagnostic Studies and Interprofessional Care

Diagnosis begins with a complete history and physical examination. Description of the pain (frequency, timing, duration, location), accompanying symptoms, and sequence of symptoms (e.g., pain before or after vomiting) provide vital clues about the origin of the problem. Note the patient's position. The fetal posture is common

with peritoneal irritation (e.g., appendicitis), a supine posture with outstretched legs with visceral pain, and restlessness with a seated posture with bowel obstructions or obstructions from kidney stones and gallstones.

TABLE 42.11 Emergency ManagementAcute Abdominal Pain

Etiology	Assessment Findings	Interventions
Inflammation • **Appendicitis** • **Cholecystitis** • **Diverticulitis** • **Gastritis** • **Inflammatory bowel disease** • **Pancreatitis** • **Pyelonephritis** **Vascular Problems** • **Mesenteric vascular occlusion** • **Ruptured aortic aneurysm** **Gynecologic Problems** • **Pelvic inflammatory disease** • **Ruptured ectopic pregnancy** • **Ruptured ovarian cyst** **Infectious Disease** • ***Escherichia coli* O157:H7** • ***Giardia*** • ***Salmonella*** **Other** • **Obstruction or perforation of abdominal organ** • **GI bleeding or ischemia** • **Myocardial infarction** • **Trauma**	**Abdominal and GI Findings** • Diffuse, localized, dull, burning, or sharp abdominal pain or tenderness • Rebound tenderness • Abdominal distention • Abdominal rigidity • Nausea and vomiting • Diarrhea • Hematemesis • Melena **Hypovolemic Shock** • ↓ BP • ↓ Pulse pressure • Tachycardia • Cool, clammy skin • ↓ Level of consciousness • ↓ Urine output (<0.5 mL/kg/hr)	**Initial** • Ensure patent airway. • Apply O_2 via nasal cannula or nonrebreather mask. • Establish IV access with large-bore catheter and infuse warm normal saline or lactated Ringer's solution. Insert another large-bore catheter if shock present. • Obtain blood for CBC and electrolyte levels. • Obtain blood for amylase level, pregnancy tests, clotting studies, and type and crossmatch as appropriate. • Insert indwelling urinary catheter. • Obtain urinalysis. • Insert NG tube as needed. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, and intake/output. • Assess quality and amount of pain. • Assess amount and character of emesis. • Anticipate surgical intervention. • Keep patient NPO.

Physical examination includes examination of the abdomen, rectum, and pelvis. A complete blood count (CBC), urinalysis, abdominal x-ray, and ECG are done, along with an ultrasound or CT scan. Women of childbearing age may need a pregnancy test to rule out an ectopic pregnancy.

Emergency management of the patient with acute abdominal pain is

shown in Table 42.11. The goal of management is to identify and treat the cause and monitor and treat complications, especially shock. Carefully use pain medications (e.g., morphine) to provide pain relief without interfering with diagnostic accuracy when patients have nontraumatic acute abdominal pain.

An immediate surgical consult may be needed. The HCP may perform a diagnostic laparoscopy to inspect the surface of abdominal organs, obtain biopsy specimens, perform laparoscopic ultrasounds, and remove organs. A laparotomy is done when laparoscopic techniques are inadequate. If the cause of the acute abdomen can be surgically removed (e.g., inflamed appendix) or surgically repaired (e.g., ruptured abdominal aneurysm), surgery is considered definitive therapy.

Nursing Management: Acute Abdominal Pain

Nursing Assessment

For the patient with acute abdominal pain, take vital signs immediately and again at frequent intervals. Increased pulse and decreasing BP indicate impending shock. A fever suggests an inflammatory or infectious process. Intake and output measurement gives essential information about the adequacy of vascular volume. Altered mental status occurs with poor cerebral perfusion. Skin color, skin temperature, and peripheral pulse strength give information about perfusion.

Inspect the abdomen for distention, masses, abnormal pulsation, symmetry, hernias, rashes, scars, and pigmentation changes. Auscultate bowel sounds. Decreased or absent bowel sounds in a quadrant may occur with a bowel obstruction, peritonitis, or paralytic ileus. Perform gentle palpation to help determine the location and level of the patient's pain. Assess for involuntary guarding and rigidity, which occur with peritoneal irritation.

Ask the patient about the onset, location, intensity, duration, frequency, and character of pain. Note whether the pain has spread or moved to new sites (quadrants) and what makes the pain worse or better. Ask if the pain is associated with other symptoms, such as nausea, vomiting, changes in bowel and bladder habits, or vaginal discharge in women. Assessment of vomiting includes the amount, color, consistency, and odor of the emesis. Ask about usual and changes in bowel patterns and habits.

Nursing Diagnoses

Nursing diagnoses for the patient with acute abdominal pain include:

- Acute pain

- Fluid imbalance
- Risk for infection

Planning

The overall goals are that the patient with acute abdominal pain will have (1) relief of abdominal pain, (2) resolution of inflammation, (3) freedom from complications (especially hypovolemic shock), and (4) normal nutritional status.

Nursing Implementation

General care for the patient with acute abdominal pain involves managing fluid and electrolyte imbalances, pain, and anxiety. Assess the quality and intensity of pain at regular intervals. Provide medication and other comfort measures. Maintain a calm environment and give information to help decrease anxiety. A nasogastric (NG) tube with low suction may decrease vomiting and relieve discomfort from gastric distention. Conduct ongoing assessments of vital signs, intake and output, and level of consciousness, which are key indicators of hypovolemic shock.

Acute Care

Preoperative Care

Preoperative care includes the emergency care of the patient described in Table 42.11 and general care of the preoperative patient (see Chapter 17).

Postoperative Care

Postoperative care depends on the type of surgical procedure. See eNursing Care Plan 19.1, a general plan for the postoperative patient, on the website for Chapter 19.

After surgery, some patients will have an NG tube with low suction to empty the stomach and prevent gastric dilation. If the upper GI

tract was entered, drainage from the NG tube may be dark brown to dark red for the first 12 hours. Later it should be light yellowish brown, or it may have a greenish tinge because of bile. If a dark red color continues or you see bright red blood, notify the HCP because of the risk for hemorrhage. "Coffee-grounds" granules in the drainage mean the blood has been changed by acidic gastric secretions.

Nausea and vomiting are common after a laparotomy and result from the surgery, decreased peristalsis, or pain medications. Antiemetics, such as ondansetron (Zofran), promethazine (Phenergan), and aprepitant (Emend), may be ordered. Monitor fluid and electrolyte status along with BP, heart rate, and respirations. See Chapter 41 for further discussion of managing nausea and vomiting.

Swallowed air and reduced peristalsis from decreased mobility, manipulation of the abdominal organs during surgery, and anesthesia can result in abdominal distention and gas pains. Early ambulation helps restore peristalsis, expel flatus, and reduce gas pain. Gradually, as intestinal activity increases, distention and gas pain disappear.

Ambulatory Care

Preparation for discharge begins soon after surgery. Teach the patient and caregiver about any modifications in activity, care of the incision, diet, and drug therapy. Initially the patient starts on clear liquids after surgery and then, if tolerated, progresses to a regular diet.

Early ambulation speeds recovery, but normal activities are resumed gradually, with planned rest periods. Patients generally have restrictions not to lift anything heavier than a few pounds. The patient and caregiver should be aware of any possible complications. Teach them to notify the HCP at once if fever is greater than 101°F (38.6°C), vomiting, pain, weight loss, incisional drainage, or changes in bowel function occur.

Evaluation

The expected outcomes are that the patient with acute abdominal pain will:

- Have resolution of the cause of the acute abdominal pain
- Experience relief of abdominal pain and discomfort
- Be free from complications, especially hypovolemic shock and sepsis
- Have normal fluid, electrolyte, and nutritional status

Abdominal Trauma

Etiology and Pathophysiology

Injuries to the abdominal area usually are a result of blunt trauma or penetrating injuries. Common injuries of the abdomen include lacerated liver, ruptured spleen, mesenteric artery tears, diaphragm rupture, urinary bladder rupture, great vessel tears, renal or pancreas injury, and stomach or intestine rupture.

Blunt trauma often occurs with motor vehicle accidents, direct blows, and falls. It may not be obvious because it does not leave an open wound. Both compression injuries (e.g., direct blow to the abdomen) and shearing injuries (e.g., rapid deceleration in a motor vehicle crash allowing some tissue to move forward while other tissues stay stationary) occur with blunt trauma. *Penetrating injuries* occur when a gunshot or stabbing produces an obvious, open wound into the abdomen.

When solid organs (liver, spleen) are injured, bleeding can be profuse, resulting in hypovolemic shock. When contents from hollow organs (e.g., bladder, stomach, intestines) spill into the peritoneal cavity, the patient is at risk for peritonitis. In addition, abdominal compartment syndrome can develop.

Abdominal compartment syndrome, or abdominal hypertension, is excessively high pressure in the abdomen. Anything that increases the volume in the abdominal cavity (e.g., edematous organs, bleeding) increases abdominal pressure. This high pressure restricts ventilation, potentially leading to respiratory failure. The high pressure decreases cardiac output, venous return, and arterial perfusion of organs. Decreased perfusion to the kidneys can lead to renal failure.

Clinical Manifestations

Careful assessment provides important clues to the type and severity of injury. Intraabdominal injuries are often associated with rib fractures, fractured pelvis, spinal injury, and thoracic injury. If the

patient was in an automobile accident, a contusion or abrasion across the lower abdomen may indicate internal organ trauma due to seat belt use. Seat belts can produce blunt trauma to abdominal organs by pressing the intestine and pancreas into the spinal column.

Classic manifestations of abdominal trauma are (1) guarding and splinting of the abdominal wall (indicating peritonitis); (2) a hard, distended abdomen (occurs with intraabdominal bleeding); (3) decreased or absent bowel sounds; (4) abrasions or bruising over the abdomen; (5) abdominal pain; (6) hematemesis or hematuria; and (7) signs of hypovolemic shock (Table 42.12). Ecchymosis around the umbilicus *(Cullen's sign)* or flanks *(Grey Turner's sign)* may mean retroperitoneal hemorrhage. Loss of bowel sounds occurs with peritonitis. If the diaphragm ruptures, you can hear bowel sounds (if present) in the chest. Auscultation of bruits is indicative of arterial damage.

Diagnostic Studies

Laboratory tests include a baseline CBC and urinalysis. Even when bleeding, the patient will have normal hemoglobin and hematocrit because fluids are lost at the same rate as the red blood cells. Deficiencies are evident after fluid resuscitation begins. Blood in the urine may be a sign of kidney or bladder damage. Other laboratory work includes arterial blood gases, prothrombin time, electrolytes, BUN and creatinine, and type and crossmatch (in anticipation of possible blood transfusions). An abdominal CT scan and focused abdominal ultrasound are the most common diagnostic methods, but the patient must be stable before going for CT.

TABLE 42.12 Emergency ManagementAbdominal Trauma

Etiology	Assessment Findings	Interventions
Blunt • Falls • Motor vehicle collisions • Pedestrian event • Assault with blunt object • Crush injuries • Explosions **Penetrating** • Knife • Gunshot wounds • Impalement • Other missiles	**Hypovolemic Shock** • ↓ Level of consciousness • Tachypnea • Tachycardia • ↓ BP • ↓ Pulse pressure **Surface Findings** • Abrasions or ecchymoses on abdominal wall, flank, or peritoneum • Open wounds: lacerations, eviscerations, puncture wounds, gunshot wounds • Impaled object **Abdominal and GI Findings** • Nausea and vomiting • Hematemesis • Absent or decreased bowel sounds • Hematuria • Abdominal distention • Abdominal rigidity • Abdominal pain with palpation • Rebound tenderness	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Apply appropriate O_2 therapy. • Control external bleeding with direct pressure or sterile pressure dressing. • Establish IV access with 2 large-bore catheters and infuse normal saline or lactated Ringer's solution. • Obtain blood for type and crossmatch and CBC. • Remove clothing. • Stabilize impaled objects with bulky dressing—*do not remove.* • Cover protruding organs or tissue with sterile saline dressing. • Insert indwelling urinary catheter if there is no blood at the meatus, pelvic fracture, or boggy prostate. • Obtain urine for urinalysis. • Insert NG tube if no evidence of facial trauma. • Anticipate diagnostic peritoneal lavage. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, and urine output. • Maintain patient warmth using blankets, warm IV fluids, or warm humidified O_2.

Diagnostic peritoneal lavage can detect blood, bile, intestinal contents, and urine in the peritoneal cavity. It is generally used only for unstable patients to identify blood in the peritoneum.

Interprofessional and Nursing Care

Emergency management of abdominal trauma is outlined in Table 42.12. Volume expanders or blood given if the patient is hypotensive. An NG tube with low suction will decompress the stomach and prevent aspiration. Frequent ongoing assessment is needed to monitor fluid status, detect deterioration in condition, and determine the need for surgery. The decision about whether to do surgery depends on clinical findings, diagnostic test results, and the patient's response to conservative management. Do not remove an impaled object until skilled care is available. Removal may cause further injury and bleeding.

Chronic Abdominal Pain

Chronic abdominal pain may originate from abdominal structures or be referred from a site with the same or a similar nerve supply. The pain is often described as dull, aching, or diffuse. Common causes of chronic abdominal pain include irritable bowel syndrome (IBS), peptic ulcer disease, chronic pancreatitis, hepatitis, pelvic inflammatory disease, adhesions, and vascular insufficiency.

Diagnosing the cause of chronic abdominal pain begins with a thorough history and description of specific pain characteristics, including severity, location, frequency, duration, and onset. The assessment includes factors that increase or decrease the pain, such as eating, defecation, and activities. Endoscopy, CT scan, MRI, laparoscopy, and barium studies may be done. Treatment for chronic abdominal pain depends on the underlying cause.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a disorder characterized by chronic abdominal pain or discomfort and alteration of bowel patterns. Patients may have diarrhea or constipation, alternating periods of both.

IBS has no known organic cause. Psychologic stressors (e.g., depression, anxiety, panic disorders, posttraumatic stress disorder) are associated with the development and exacerbation of IBS. Patients often have a history of GI infections and adverse reactions to food. Dietary intolerances that may contribute to symptoms include gluten and fermentable oligo-, di-, and monosaccharides and polyols (FODMAPs).[7] Examples of oligosaccharides are wheat and rye products, some fruits and vegetables, onions, garlic, legumes, and nuts. The disaccharide lactose is found in milk and milk products. Fructose is a monosaccharide found in honey, apples, pears, and high-fructose corn syrup. Polyols are found in apples, pears, stone fruits, cauliflower, mushrooms, and artificial sweeteners, like sorbitol.[8]

IBS is diagnosed solely on symptoms. The Rome IV criteria for diagnosing IBS require the presence of abdominal pain and/or discomfort at least 1 day per week for 3 months that is associated with 2 or more of the following: related to defecation, change in stool frequency, or change in the stool form.[7] Depending on the stool patterns, IBS is categorized as IBS with constipation (IBS-C), IBS with diarrhea (IBS-D), IBS mixed, and IBS unsubtyped. Other common symptoms include abdominal distention, nausea, flatulence, bloating, urgency, mucus in the stool, and sensation of incomplete evacuation. Non-GI symptoms may include fatigue, headache, and sleep problems.

Gender Differences

Irritable Bowel Syndrome (IBS)

Men

- More likely to have IBS with diarrhea
- Less likely to admit to symptoms or seek help for them

Women

- Overall affects women 2 to 2.5 times more often than men
- More likely to have IBS with constipation
- Report more severe abdominal pain, gas, and bloating
- Have a lower quality of life with higher levels of fatigue and depression

The key to accurate diagnosis is a thorough history and physical examination. Ask patients to describe symptoms, health history (including psychosocial factors, such as stress and anxiety), family history, and drug and diet history. Determine if and how IBS symptoms interfere with school, work, or recreational activities. Diagnostic tests are used to rule out other disorders, such as colorectal cancer, IBD, endometriosis, and malabsorption disorders (lactose intolerance, celiac disease).

No single therapy is effective for all patients with IBS. Treatment may include dealing with psychologic factors, dietary changes, and drugs to regulate stool output and reduce discomfort. Patients may benefit from keeping a diary of symptoms, diet, and episodes of stress to help identify any factors that trigger the IBS symptoms. Cognitive behavior therapy and stress management techniques may help a patient cope. Participating in regular exercise reduces bloating and constipation and reduces stress-related symptoms.

Review with the patient foods that are high in FODMAPs and teach them to follow a low-FODMAP diet.[8] If dairy products tend to cause symptoms, yogurt may be the best option because of the lactobacillus

bacteria it contains. Probiotics can improve symptoms. Tell the patient with flatulence to avoid common gas-producing foods, such as broccoli and cabbage. For those with constipation, encourage an intake of enough dietary fiber to produce soft, painless bowel movements.

Drug therapy focuses on the dominant bowel symptom and pain. The opioid agonist eluxadoline (Viberzi) decreases colonic contractions to reduce diarrhea and pain. It is contraindicated in those without a gallbladder. An option for women with IBS-D is alosetron (Lotronex). Because of serious side effects (e.g., severe constipation, ischemic colitis), it is available only in a restricted access program. Other treatments for IBS-D include loperamide, antidepressants, and antispasmodic medications (hyoscyamine, dicyclomine). Antispasmodics decrease GI motility and smooth muscle spasms, reducing pain and diarrhea.[8]

Drug Alert

Alosetron (Lotronex)

- Taking this drug can cause severe constipation and ischemic colitis (reduced blood flow to intestines).
- Teach the patient to stop the drug and contact the HCP if constipation, rectal bleeding, bloody diarrhea, or abdominal pain occurs.

Women with IBS-C may benefit from lubiprostone (Amitiza). Men or women with IBS-C can take linaclotide (Linzess). It is contraindicated in patients with a history of mechanical obstruction or prior bowel surgery.

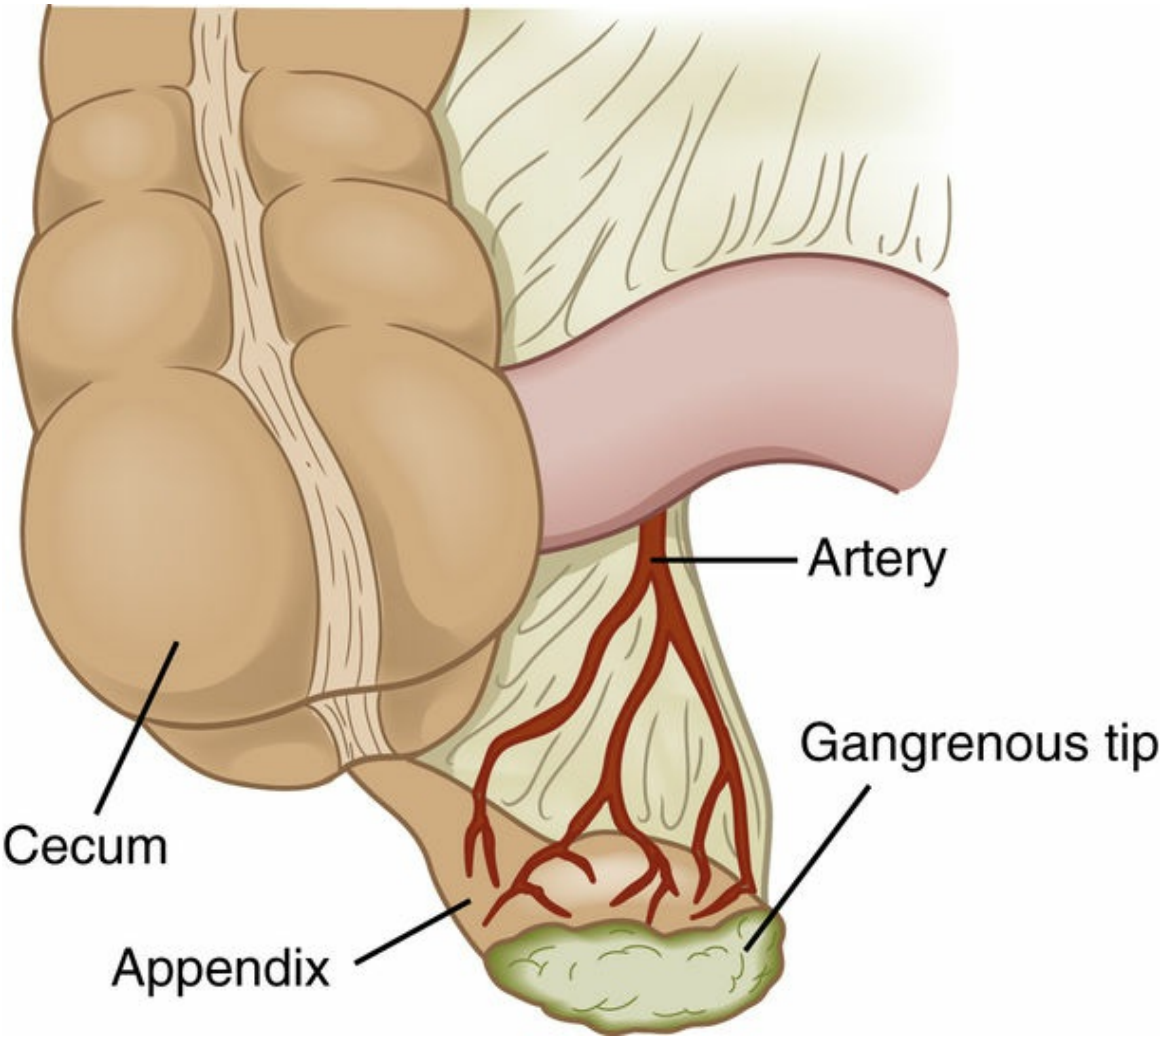

FIG. 42.2 In appendicitis the blood supply of the appendix is impaired by inflammation and bacterial infection, which may result in gangrene.

Inflammatory Disorders

Appendicitis

Appendicitis is inflammation of the appendix, a narrow blind tube that extends from the inferior part of the cecum (Fig. 42.2). It is the most common reason for emergency abdominal surgery.

Etiology and Pathophysiology

About 7% of people will develop appendicitis sometime during their lifetime.[9] It is most common in those 10 to 30 years of age. A common cause of appendicitis is obstruction of the lumen by a fecalith (accumulated feces). Obstruction results in distention; venous engorgement; and the accumulation of mucus and bacteria, which can lead to gangrene, perforation, and peritonitis.

Clinical Manifestations

Diagnosis can be difficult because many patients do not have classic symptoms. Appendicitis typically begins with dull periumbilical pain, followed by anorexia, nausea, and vomiting. The pain is persistent and continuous, eventually shifting to the right lower quadrant and localizing at *McBurney's point* (halfway between the umbilicus and right iliac crest). A low-grade fever may develop. Further assessment reveals localized tenderness, rigidity, rebound tenderness, and muscle guarding. Coughing, sneezing, and deep inhalation worsen pain. The patient usually prefers to lie still, often with the right leg flexed. The older adult may report less severe pain, slight fever, and discomfort in the right iliac fossa.

Diagnostic Studies and Interprofessional Care

Patient examination includes a complete history, physical examination, and a differential WBC count. Most patients have a mildly to moderately high WBC count. A urinalysis is done to rule out

genitourinary conditions that mimic appendicitis. CT scan is the preferred diagnostic procedure. However, ultrasound and MRI are options.

If there is a delay in diagnosis and treatment, the appendix can rupture and the resulting peritonitis can be fatal. The standard treatment of appendicitis is an immediate *appendectomy* (surgical removal of appendix).[9] If the inflammation is localized, surgery should be done as soon as the diagnosis is made. Antibiotics and fluid resuscitation are started before surgery.

If the appendix has ruptured and there is evidence of peritonitis or an abscess, giving parenteral fluids and antibiotic therapy for 6 to 8 hours before the appendectomy helps prevent dehydration and sepsis.

Nursing Management: Appendicitis

Managing the patient who has manifestations of appendicitis focuses on preventing fluid volume deficit, relieving pain, and preventing complications. To ensure the stomach is empty in case surgery is needed, keep the patient NPO until the HCP evaluates the patient. Monitor vital signs and perform ongoing assessment to detect any deterioration in condition. Give IV fluids, analgesics, and antiemetics as ordered. Provide comfort measures.

Postoperative care for the patient who had an appendectomy is similar to the patient after a laparotomy (see p. 935). Patients are usually discharged within 24 hours after an uncomplicated laparoscopic appendectomy. Ambulation begins a few hours after surgery, and the diet is advanced as tolerated. Those who had a perforation usually have a longer length of stay and need IV antibiotic therapy. Most patients resume normal activities 2 to 3 weeks after surgery.

Check Your Practice

A 28-yr-old female patient comes to the emergency department with acute abdominal pain.

- What manifestations would make you suspect appendicitis is the cause of the patient's abdominal pain?

Peritonitis

Etiology and Pathophysiology

Peritonitis results from a localized or generalized inflammatory process of the peritoneum. Causes of peritonitis are listed in Table 42.13. Primary peritonitis occurs when blood-borne organisms enter the peritoneal cavity. For example, the ascites that occurs with cirrhosis of the liver provides an excellent liquid environment for bacteria to flourish. Organisms can enter the peritoneum during peritoneal dialysis.

Secondary peritonitis is much more common. It occurs when abdominal organs perforate or rupture and release their contents (bile, enzymes, and bacteria) into the peritoneal cavity. Common causes include a ruptured appendix, perforated gastric or duodenal ulcer, severely inflamed gallbladder, and trauma from gunshot or knife wounds.

Intestinal contents and bacteria irritate the normally sterile peritoneum and produce an initial chemical peritonitis. Bacterial peritonitis develops a few hours later. The resulting inflammatory response leads to massive fluid shifts (peritoneal edema) and adhesions as the body tries to wall off the infection.

Clinical Manifestations

Abdominal pain is the most common symptom of peritonitis. A universal sign is tenderness over the involved area. Rebound tenderness, muscular rigidity, and spasm are other signs of peritoneal irritation. Patients may lie still and take only shallow breaths because movement worsens the pain. Abdominal distention, fever, tachycardia, tachypnea, nausea, vomiting, and altered bowel habits may be present. These manifestations vary, depending on the severity and acuteness of the underlying condition. Complications include hypovolemic shock, sepsis, intraabdominal abscess formation, paralytic ileus, and acute respiratory distress syndrome. Peritonitis

can be fatal if treatment is delayed.

TABLE 42.13 Causes of Peritonitis

Primary

- Blood-borne organisms
- Cirrhosis with ascites
- Genital tract organisms

Secondary

- Appendicitis with rupture
- Blunt or penetrating trauma to abdominal organs
- Diverticulitis with rupture
- Ischemic bowel disorders
- Pancreatitis
- Perforated intestine
- Perforated peptic ulcer
- Peritoneal dialysis
- Postoperative (breakage of anastomosis)

TABLE 42.14 Interprofessional CarePeritonitis

Diagnostic Assessment

- History and physical examination
- CBC, including WBC differential
- Serum electrolytes

- Abdominal x-ray
- Abdominal paracentesis and culture of fluid
- CT scan or ultrasound
- Peritoneoscopy

Management
Preoperative or Nonoperative

- NPO status
- IV fluid replacement
- NG to low-intermittent suction
- O_2 PRN
- Parenteral nutrition as needed

Drug Therapy

- Antibiotic therapy
- Analgesics (e.g., morphine)
- Antiemetics as needed

Postoperative

- NPO status
- NG to low-intermittent suction
- Semi-Fowler's position
- IV fluids with electrolyte replacement
- PN as needed
- Blood transfusions as needed

Drug Therapy

- Antibiotic therapy
- Sedatives and opioids
- Antiemetics as needed

Diagnostic Studies and Interprofessional Care

A CBC is done to determine elevations in WBC count and hemoconcentration from fluid shifts (Table 42.14). Peritoneal aspiration may be done with the fluid analyzed for blood, bile, pus, bacteria, fungus, and amylase content. An abdominal x-ray may show dilated loops of bowel consistent with paralytic ileus, free air if perforation has occurred, or air and fluid levels if an obstruction is present. Ultrasound and CT scans may be useful in identifying ascites and abscesses. Peritoneoscopy may be helpful in the patient without ascites. It allows for direct examination of the peritoneum and the ability to obtain biopsy specimens for diagnosis.

Patients with milder cases of peritonitis or those who are poor surgical risks receive conservative care. Treatment consists of antibiotics, NG suction, analgesics, and IV fluid administration. Surgery is indicated to locate the cause of the inflammation, drain purulent fluid, and repair any damage (e.g., perforated organs).

Nursing Management: Peritonitis

Nursing Assessment

Assessment of the patient's pain, including the location, is important and may help to determine the cause of peritonitis. Assess for the presence and quality of bowel sounds, increasing abdominal distention, abdominal guarding, nausea, fever, and manifestations of hypovolemic shock.

Nursing Diagnoses

Nursing diagnoses for the patient with peritonitis include:

- Acute pain
- Fluid imbalance
- Impaired gas exchange
- Risk for infection

Planning

The overall goals are that the patient with peritonitis will have (1) resolution of inflammation, (2) relief of abdominal pain, (3) freedom from complications (especially sepsis and hypovolemic shock), and (4) normal nutritional status.

Nursing Implementation

The patient with peritonitis is extremely ill and needs skilled supportive care. Establish IV access so that you can give replacement fluids lost to the peritoneal cavity and have access for antibiotic therapy. Monitor the patient for pain and response to analgesics. You may position the patient with knees flexed to increase comfort. Sedatives may relieve anxiety and promote rest.

Accurate monitoring of intake and output and electrolyte status is

essential to determine replacement therapy. Frequently monitor vital signs. Give antiemetics to decrease nausea and vomiting and prevent further fluid and electrolyte losses. Place the patient on NPO status. The patient may need an NG tube to decrease gastric distention and further leakage of bowel contents into the peritoneum. Give low-flow oxygen therapy as needed.

If the patient had an open surgical procedure, drains are inserted to remove purulent drainage and excess fluid. Postoperative care is similar to that for the patient who had a laparotomy (see p. 935).

Gastroenteritis

Gastroenteritis is an inflammation of the mucosa of the stomach and small intestine. Features of *acute gastroenteritis* are sudden diarrhea accompanied by nausea, vomiting, fever, and abdominal cramping. Viruses are the most common cause of gastroenteritis (Table 42.1).

Norovirus is a leading cause of foodborne outbreaks of acute gastroenteritis. Laboratory testing to identify norovirus is useful when a number of people simultaneously have gastroenteritis and there is a clear avenue for virus transmission, such as a shared location or food.

Most cases of gastroenteritis are self-limiting. Encourage oral fluids containing glucose and electrolytes (e.g., Pedialyte) to prevent and treat dehydration. Older adults and chronically ill patients may be unable to consume enough fluids to make up for fluid loss. If dehydration occurs, IV fluid replacement may be needed. Nursing management of the patient with gastroenteritis is the same as for the patient with acute diarrhea (see p. 927).

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a chronic inflammation of the GI tract characterized by periods of remission interspersed with periods of exacerbation. We classify IBD as either Crohn's disease or ulcerative colitis (UC) based on clinical manifestations (Table 42.15). As the name suggests, **ulcerative colitis** is usually limited to the colon. **Crohn's disease** can involve any segment of the GI tract from the mouth to the anus.

About 1.3 million Americans have IBD. It often begins during the teenage years and early adulthood. IBD has a second peak in the 6th decade. The incidence and frequency of IBD varies depending on geographic location and racial or ethnic background. The highest rates are in the Northern Hemisphere and industrialized nations.[10] The risk for having IBD is greater in urban compared with rural areas and those of white and Ashkenazic Jewish origin than in other racial and ethnic groups.[10] The strongest risk factor is family history. Many people with IBD have a family member with the disorder.

Etiology and Pathophysiology

We do not know the exact cause of IBD. IBD is an autoimmune disease involving an immune reaction to a person's own intestinal tract. We think that it results from an overactive, inappropriate, or sustained immune response to environmental and bacterial triggers, probably in a genetically susceptible person. The resulting inflammation causes widespread tissue destruction.

Environmental factors, such as diet, smoking, and stress, increase susceptibility by changing the environment of the GI microbial flora. We think that dietary factors unique to industrialized countries contribute to the development of IBD. High intake of refined sugar, total fats, polyunsaturated fatty acid (PUFA), and omega-6 fatty acids is associated with an increased risk for IBD. Eating fewer raw fruits, vegetables, omega-3–rich foods, and dietary fiber decrease risk.[11] Use

of nonsteroidal antiinflammatory drugs (NSAIDs), antibiotics, and oral contraceptives are associated with increased risk.[12]

Genetic Link

IBD occurs more often in family members of people with IBD, especially monozygotic twins. To date, we have found over 200 genes associated with IBD. Certain genetic mutations are associated with Crohn's disease, others with UC, and many with both.

The number of gene variations suggests that IBD is a group of diseases that produce similar types of mucosal destruction. The path from genetic mutation to abnormal immune responses varies depending on which gene or genes are affected. Several of the genes are involved in protective functions of the intestines. Others have a role in the immune system, especially in the maturation and function of T cells. Genetic variation may explain differences in patient responses to drug therapies for IBD.

TABLE 42.15 Comparison of Ulcerative Colitis and Crohn's Disease

Characteristic	Ulcerative Colitis	Crohn's Disease
Clinical		
Usual age at onset	Teens to mid-30s. After 60	Teens to mid-30s. After 60
Abdominal pain	Common, severe constant	Common, cramping
Diarrhea	Common	Common
Fever (intermittent)	During acute attacks	Common
Malabsorption and nutritional deficiencies	Minimal incidence	Common
Rectal bleeding	Common	Sometimes
Tenesmus	Common	Rare
Weight loss	Rare	Common, may be severe
Pathologic		
Location	Usually starts in rectum and spreads in a continuous pattern up the colon	Occurs anywhere along GI tract. Most common site is distal ileum
Cobblestoning of mucosa	Rare	Common
Depth of involvement	Mucosa	Entire thickness of bowel wall (transmural)
Distribution	Continuous areas of inflammation	Healthy tissue interspersed with areas of inflammation (skip lesions)
Pseudopolyps	Common	Rare
Small bowel involvement	Minimal	Common
Complications		
Cancer	Increased incidence of colorectal cancer after 10 yrs of disease	Increased incidence of small intestinal cancer Increased incidence of colorectal cancer but less than with ulcerative colitis
C. difficile infection	Increased incidence and severity	Increased incidence and severity
Perforation	Common (because of toxic megacolon)	Common (because inflammation involves entire bowel wall)
Perianal abscess and fistulas	Rare	Common
Strictures	Occasional	Common
Toxic megacolon	More common	Rare

Many of the major genes related to Crohn's disease, including *NOD2, ATG16L1, IL23R,* and *IRGM,* are involved in immune system function. The proteins made from these genes help the immune system sense and respond appropriately to bacteria in the lining of the GI tract. *NOD2* gene changes are associated with a form of Crohn's disease that affects the ileum in persons of northern European descent. Changes in the *NOD2* gene trigger an abnormal immune response that allows bacteria to grow unchecked and invade intestinal cells. This causes chronic inflammation and digestive problems.[13]

IBD is more likely to occur in those with other genetic syndromes, including cystic fibrosis. An increased prevalence occurs in the presence of other inflammatory disorders with genetic susceptibility, such as psoriasis and multiple sclerosis.

Pattern of Inflammation in Ulcerative Colitis vs. Crohn's

Disease

The pattern of inflammation differs between Crohn's disease and UC (Fig. 42.3). Crohn's disease can occur anywhere in the GI tract from the mouth to the anus. It most often involves the distal ileum and proximal colon. Segments of normal bowel can occur between diseased portions, so-called "skip" lesions. The inflammation in Crohn's disease involves all layers of the bowel wall. Typically, ulcerations are deep, longitudinal, and penetrate between islands of inflamed edematous mucosa, causing the classic cobblestone appearance. Strictures at the areas of inflammation can cause bowel obstruction. Since the inflammation goes through the entire wall, microscopic leaks can allow bowel contents to enter the peritoneal cavity and form abscesses or produce peritonitis. In active Crohn's disease, fistulas are common.

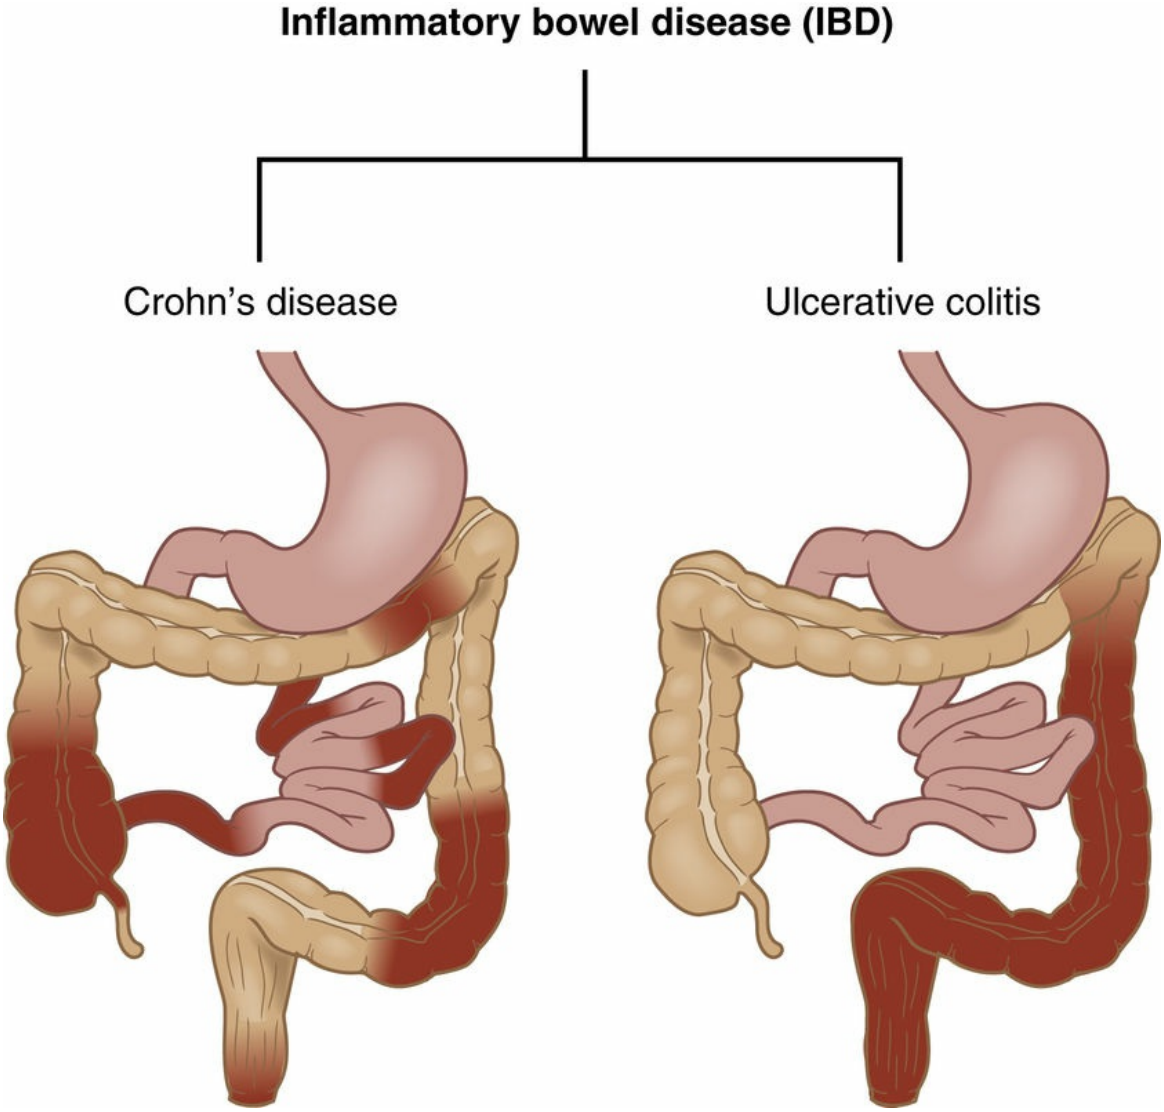

FIG. 42.3 Comparison of distribution patterns of Crohn's disease and ulcerative colitis.

UC usually starts in the rectum and moves in a continual fashion toward the cecum. Although mild inflammation may occur in the terminal ileum, UC is a disease of the colon and rectum. The inflammation and ulcerations occur in the mucosal layer, the innermost layer of the bowel wall. Fistulas and abscesses are rare since inflammation does not extend through all bowel wall layers. Because water and electrolytes are not absorbed through inflamed mucosa, diarrhea with large fluid and electrolyte losses is common. Breakdown of cells results in protein loss through the stool. Areas of inflamed mucosa form *pseudopolyps,* tongue-like projections into the

bowel lumen.

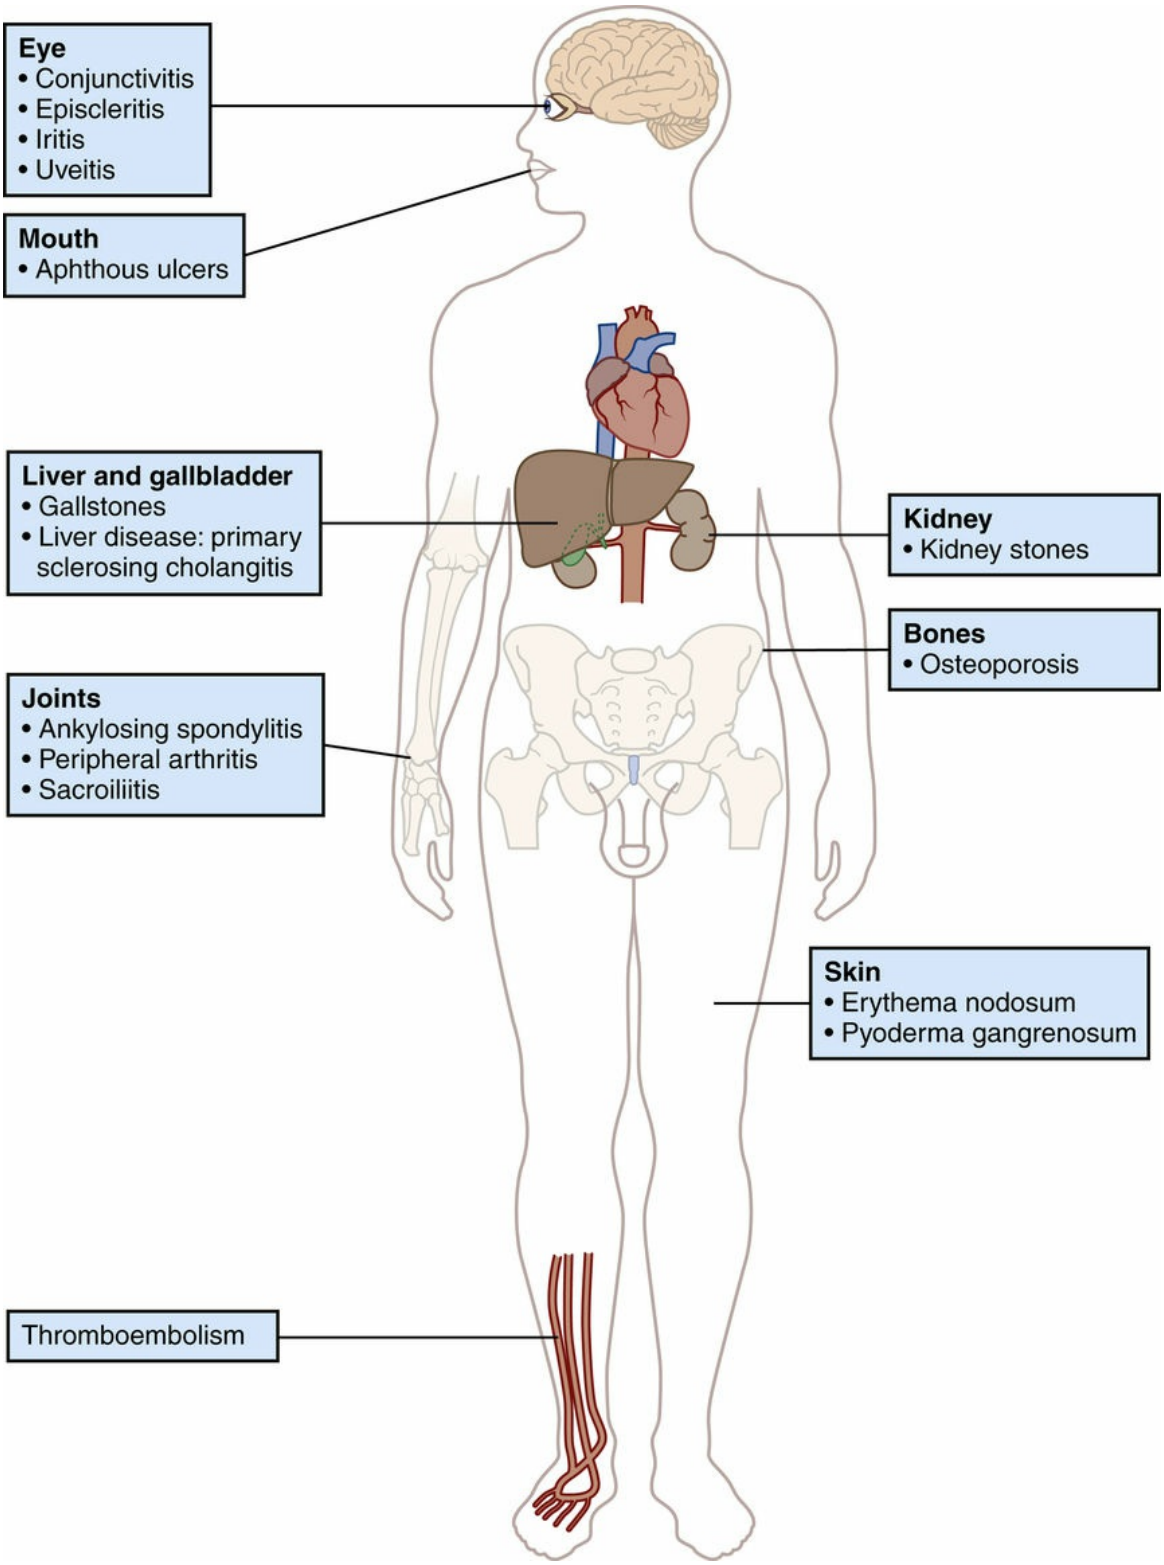

FIG. 42.4 Extraintestinal manifestations of IBD.

Clinical Manifestations

Both forms of IBD are chronic disorders with mild to severe acute exacerbations that occur at unpredictable intervals over many years. Although the manifestations of Crohn's disease and UC are similar (diarrhea, weight loss, abdominal pain, fever, fatigue), there are differences (Table 42.15).

In Crohn's disease, diarrhea and cramping abdominal pain are common symptoms. If the small intestine is involved, weight loss occurs from inflammation of the small intestine causing malabsorption. Rectal bleeding sometimes occurs with Crohn's disease, although not as often as with UC.

In UC, the primary problems are bloody diarrhea and abdominal pain. Pain may vary from the mild lower abdominal cramping associated with diarrhea to severe, constant pain associated with acute perforations. With *mild disease,* diarrhea may consist of no more than 4 semiformed stools daily that contain small amounts of blood. The patient may have no other manifestations. In *moderate disease,* the patient has increased stool output (up to 10 stools/day), increased bleeding, and systemic symptoms (fever, malaise, mild anemia, anorexia). In *severe disease,* diarrhea is bloody, contains mucus, and occurs 10 to 20 times a day. In addition, fever, rapid weight loss greater than 10% of total body weight, anemia, tachycardia, and dehydration are present.

Complications

Patients with IBD have both local (confined to the GI tract) and systemic (extraintestinal) complications (Fig. 42.4). GI tract complications include hemorrhage, strictures, perforation (with possible peritonitis), abscesses, fistulas, CDI, and colonic dilation (toxic megacolon). Toxic megacolon is more common with UC. Patients with toxic megacolon are at risk for perforation and may need an emergency colectomy. Perineal abscess and fistulas occur in up to a third of patients with Crohn's disease. CDI increases in frequency and severity in patients with IBD.

IBD is related to an increased risk for colorectal cancer. Those with Crohn's disease are at increased risk for small intestinal cancer. Cancer screening at regular intervals is important in persons with IBD.

People with IBD may have systemic complications, such as multiple sclerosis and ankylosing spondylitis. Some are related to the inflammatory activity in the bowel. They occur with active inflammation and improve when the IBD improves. Other complications include malabsorption, liver disease (primary sclerosing cholangitis), and osteoporosis. Routine liver function tests are important because primary sclerosing cholangitis can lead to liver failure. Both men and women with IBD are at risk for osteoporosis. They need a bone density scan at baseline and every 2 years.

Diagnostic Studies

The diagnosis of IBD includes ruling out diseases with similar symptoms and figuring out whether the patient has Crohn's disease or UC. The symptoms of early Crohn's disease are like those of IBS. Diagnostic studies provide information about disease severity and complications. A CBC typically shows iron-deficiency anemia from blood loss. A high WBC count may be a sign of toxic megacolon or perforation. Decreased serum sodium, potassium, chloride, bicarbonate, and magnesium levels occur due to fluid and electrolyte losses from diarrhea and vomiting. Hypoalbuminemia is present with severe disease because of poor nutrition or protein loss. Increased erythrocyte sedimentation rate, C-reactive protein, and WBCs reflect inflammation. The stool is examined for blood, pus, and mucus. Stool cultures can determine if infection is present.

Imaging studies, such as double-contrast barium enema, small bowel series (small bowel follow through), transabdominal ultrasound, CT, and MRI, are useful for diagnosing IBD. Colonoscopy allows for examination of the entire large intestine lumen and sometimes the most distal ileum. The HCP can determine the extent of inflammation, ulcerations, pseudopolyps, and strictures and obtain biopsy specimens for a definitive diagnosis. Since a colonoscope can

enter only the distal ileum, capsule endoscopy (see Chapter 38) may be needed to diagnose Crohn's disease in the small intestine.

Interprofessional Care

The goals of treatment of IBD are to (1) rest the bowel, (2) control the inflammation, (3) combat infection, (4) correct malnutrition, (5) provide symptomatic relief, and (6) improve quality of life. There is no cure for IBD. Treatment relies on drugs to treat the inflammation and maintain remission (Table 42.16). Several drugs are available to treat IBD. Since the recurrence rate is high after surgical treatment of Crohn's disease, drugs are the preferred treatment. Hospitalization is needed if the patient does not respond to drug therapy, the disease is severe, or complications are suspected.

Drug Therapy

The goal of drug treatment in IBD is to induce and maintain remission. Five major classes of drugs are used: aminosalicylates, antimicrobials, corticosteroids, immunomodulators, and biologic therapies (Table 42.17). Drug choice depends on the location and severity of inflammation. Patients are treated with either a "step-up" or a "step-down" approach. With the step-up approach, the patient with mild symptoms begins with an aminosalicylate or antimicrobial and adds a more toxic medication (e.g., biologic therapies) when initial therapies do not work. The step-down approach uses immunosuppressant and biologic therapy first.[14]

TABLE 42.16 Interprofessional CareInflammatory Bowel Disease

Diagnostic Assessment

- History and physical examination

- CBC, erythrocyte sedimentation rate
- Serum chemistries
- Testing of stool for occult blood and infection
- Capsule endoscopy
- Radiologic studies with barium contrast
- Sigmoidoscopy and/or colonoscopy with biopsy

Management

- High-calorie, high-vitamin, high-protein, low-residue, lactose-free (if lactase deficiency) diet
- Elemental diet or PN
- Drug therapy (Table 42.17)
    - Aminosalicylates
    - Antimicrobials
    - Biologic therapies
    - Corticosteroids
    - Immunosuppressants
- Physical and emotional rest
- Referral for counseling or support group
- Surgical therapy (Table 42.18)

Drugs containing 5-aminosalicylic acid (5-ASA) remain the mainstay to achieve and maintain remission and prevent flare-ups of IBD. They include sulfasalazine (Azulfidine) and the new generation of sulfa-free drugs (olsalazine, mesalamine). Aminosalicylates can treat both UC and Crohn's disease. They are much more effective for UC.[14]

The exact mechanism of action of 5-ASA is unclear. We think topical application to the intestinal mucosa suppresses proinflammatory cytokines and other inflammatory mediators. People can take aminosalicylates orally or rectally. Oral forms are available with different coatings that affect where the medication is released along

the GI tract. This allows more effective treatment of specific symptoms. Rectal forms include suppositories and enemas. Rectal use offers the advantage of delivering the 5-ASA directly to the affected tissue. This is useful in treating inflammation in the rectum and/or large intestine. The combination of oral and rectal therapy is better than oral or rectal therapy alone.

Corticosteroids can help achieve remission in IBD. They are given for the shortest possible time because of the side effects associated with long-term use. Patients with disease in the left colon, sigmoid, and rectum benefit from suppositories, enemas, and foams because they deliver the corticosteroid directly to the inflamed tissue with minimal systemic effects. Oral prednisone is given to patients with mild to moderate disease who did not respond to either 5-ASA or topical corticosteroids. Those with severe inflammation may need a short course of IV corticosteroids. Corticosteroids must be tapered to very low levels when surgery is planned to prevent postoperative complications (e.g., infection, delayed wound healing, fistula formation).

TABLE 42.17 Drug TherapyInflammatory Bowel Disease

Class	Action	Examples
5-Aminosalicylates (5-ASA)	Decrease inflammation by suppressing proinflammatory cytokines and other inflammatory mediators	*Systemic:* balsalazide (Colazal), mesalamine (Pentasa), olsalazine (Dipentum), sulfasalazine (Azulfidine) *Topical:* 5-ASA enema (Rowasa), mesalamine suppositories
Antimicrobials	Prevent or treat secondary infection	ciprofloxacin (Cipro), clarithromycin (Biaxin), metronidazole (Flagyl)
Biologic therapies	Inhibit the cytokine tumor necrosis factor (TNF)	adalimumab (Humira), certolizumab pegol (Cimzia), golimumab (Simponi), infliximab (Remicade)
	Prevent migration of leukocytes from bloodstream to inflamed tissue	natalizumab (Tysabri), vedolizumab (Entyvio)
Corticosteroids	Decrease inflammation	*Systemic:* corticosteroids (prednisone, budesonide [Uceris]); hydrocortisone or methylprednisolone (IV for severe IBD) *Topical:* hydrocortisone suppository or foam (budesonide, Cortifoam) or enema (Cortenema)
Immunosuppressants	Suppress immune response	azathioprine, cyclosporine, methotrexate, 6-mercaptopurine

Immunosuppressants (6-mercaptopurine, azathioprine) are given for several reasons. They can maintain remission after corticosteroid therapy. Patients who do not respond to aminosalicylates, corticosteroids, or antibiotics; have side effects from corticosteroids; or have fistulas may benefit. These drugs require regular CBC monitoring because they can suppress the bone marrow and lead to inflammation of the pancreas or liver. They have a delayed onset of action and are not useful for acute flare-ups.

Methotrexate is most useful in patients with Crohn's disease who cannot stop corticosteroid use without a flare-up or in whom other drugs have been ineffective. Many patients have flu-like symptoms with use. Some develop bone marrow depression and liver dysfunction. Correct dosing is critical to minimize the risk for toxicity. Careful monitoring of the CBC and liver enzymes is essential. Advise women of childbearing age to avoid pregnancy because use causes birth defects and fetal death.

Biologics reduce IBD-related inflammation by blocking specific proteins that play a role in inflammation. There are 2 main classes: anti–tumor necrosis factor (TNF) agents and integrin receptor antagonists.

The anti-TNF agent infliximab (Remicade) is given IV to induce and maintain remission in patients with Crohn's disease and in patients with draining fistulas who do not respond to conventional drug therapy. The other anti-TNF agents are given subcutaneously.[15] The anti-TNF agents have similar side effects. The most common ones are upper respiratory and urinary tract infections, headaches, nausea, joint pain, and abdominal pain. More serious effects include reactivation of hepatitis and tuberculosis (TB); opportunistic infections; and cancers, especially lymphoma. Patients need to know the risks before starting therapy. They are tested for TB and hepatitis before treatment begins and cannot receive live virus immunizations. Teaching includes how to prevent infection and recognize early signs and symptoms (e.g., fever, cough, malaise, dyspnea).

Integrin receptor antagonists include natalizumab (Tysabri) and vedolizumab (Entyvio). They inhibit leukocyte adhesion by blocking

α_4-integrin, an adhesion molecule. Use is limited to those who have not had an adequate response with other therapies (corticosteroids, immunosuppressants, anti-TNF agents). Both are given by IV infusion. Their use is associated with increased risk for infection, hepatotoxicity, and hypersensitivity reactions. Because of the risk for progressive multifocal leukoencephalopathy, natalizumab is available only through a restricted program.

TABLE 42.18 Indications for Surgical Therapy for IBD

- Drainage of abdominal abscess
- Failure to respond to conservative therapy
- Fistulas
- Inability to decrease corticosteroids
- Intestinal obstruction
- Massive hemorrhage
- Perforation
- Severe anorectal disease
- Suspicion of cancer

The biologic agents do not work for everyone. They are costly and may produce allergic reactions. They are immunogenic, meaning that patients receiving them often make antibodies against them. Immunogenicity leads to acute infusion reactions and delayed hypersensitivity-type reactions. The drugs are most effective when given at regular intervals. Infusion reactions are more likely if a drug is stopped and then restarted.

Surgical Therapy

Ulcerative Colitis

Indications for surgery for UC are outlined in Table 42.18. Surgical procedures used include (1) total proctocolectomy with ileal pouch/anal anastomosis (IPAA) and (2) total proctocolectomy with permanent ileostomy. Since UC affects only the colon, a total proctocolectomy is curative. The most common surgical procedure for UC is a total proctocolectomy with IPAA. For more detail, see the discussion on bowel resection and ostomy surgery later in this chapter on p. 952.

Crohn's Disease

Surgery for Crohn's disease is usually done for complications such as strictures, obstructions, bleeding, and fistula (Table 42.18). Most patients with Crohn's disease eventually need surgery. The most common surgery involves resecting the diseased segments with reanastomosis of the remaining intestine. Unfortunately, the disease often recurs at the anastomosis site. Repeated removal of sections of the small intestine can lead to short bowel syndrome. *Short bowel syndrome (SBS)* occurs when either surgery or disease leaves too little small intestine surface area to maintain normal nutrition and hydration. Lifetime fluid boluses and parenteral nutrition (PN) may be needed. For more detail, see the discussion on short bowel syndrome later in this chapter on p. 962.

The other common surgery for Crohn's disease is a strictureplasty. This opens narrowed areas obstructing the bowel. Since the intestine stays intact, it reduces the risk for developing short-bowel syndrome and its associated complications. Recurrences at the site are uncommon.

Nutritional Therapy

An individualized diet is an important part of treating IBD. Patients with IBD need a balanced, healthy diet with enough calories, protein, and nutrients. Consult a dietitian about dietary recommendations. The goals of diet management are to (1) provide adequate nutrition without worsening symptoms, (2) correct and prevent malnutrition,

(3) replace fluid and electrolyte losses, and (4) prevent weight loss.

Nutritional deficiencies are due to decreased oral intake, blood loss, and, depending on the location of the inflammation, impaired absorption. Patients may reduce food intake to reduce diarrhea. Inflammatory mediators reduce appetite. Blood loss and malabsorption lead to iron-deficiency anemia (see Chapter 30). The patient may need oral iron supplements. Parenteral or IV iron is an option for those who cannot tolerate oral iron or if anemia is severe. Zinc deficiency can result from ostomies or diarrhea. Zinc supplements may be needed.[16]

Disease of the terminal ileum reduces absorption of cobalamin and bile acids. Reduced cobalamin contributes to anemia. Those who develop anemia should receive cobalamin injections. Bile salts are important for fat absorption and contribute to osmotic diarrhea. Cholestyramine, an ion-exchange resin that binds unabsorbed bile salts, helps control diarrhea.

Drug therapy can contribute to nutritional problems. Patients taking sulfasalazine should take 1 mg folate (folic acid) daily.[16] Those receiving corticosteroids are prone to osteoporosis and need calcium supplements. Potassium supplements may be needed with corticosteroids.

During an acute exacerbation, patients with IBD may not be able to tolerate a regular diet. Liquid enteral feedings are preferred over PN because atrophy of the gut and bacterial overgrowth occur when the GI tract is not used. EN is high in calories and nutrients, lactose free, and easily absorbed. They help achieve remission and improve nutritional status. EN is discussed in Chapter 39.

There are no universal food triggers for IBD, but some may find that certain foods cause diarrhea. A food diary helps to identify problem foods to avoid. Patients are typically taught to then avoid or limit foods that cause GI distress or worsen symptoms.

Nursing Management: Inflammatory Bowel Disease

Nursing Assessment

Table 42.19 outlines the subjective and objective data you should obtain from a patient with IBD.

Nursing Diagnoses

Nursing diagnoses for the patient with IBD include:

- Diarrhea
- Impaired nutritional status
- Difficulty coping
- Chronic pain

For more information on nursing diagnoses and interventions for IBD, see eNursing Care Plan 42.2 on the website for this chapter.

TABLE 42.19 Nursing AssessmentInflammatory Bowel Disease

Subjective Data

Important Health Information

Past health history: Infection, autoimmune disorders
Medications: Antidiarrheal drugs

Functional Health Patterns

Health perception–health management: Family history of ulcerative colitis or Crohn's disease. Fatigue, malaise
Nutritional-metabolic: Nausea, vomiting; anorexia. Weight loss
Elimination: Diarrhea. Blood, mucus, or pus in stools
Cognitive-perceptual: Lower abdominal pain (worse before defecation), cramping, tenesmus

Objective Data

General

Intermittent fever, emaciated appearance, fatigue

Integumentary

Pale skin with poor turgor, dry mucous membranes. Skin lesions, anorectal irritation, skin tags, cutaneous fistulas

Gastrointestinal

Abdominal distention, hyperactive bowel sounds, abdominal cramps

Cardiovascular

Tachycardia, hypotension

Possible Diagnostic Findings

Anemia, leukocytosis. Electrolyte imbalance, hypoalbuminemia, vitamin, and trace metal deficiencies. Guaiac-positive stool. Abnormal sigmoidoscopy, colonoscopy, and/or barium enema

findings

Planning

The overall goals are that the patient with IBD will (1) have fewer and less severe acute exacerbations, (2) maintain normal fluid and electrolyte balance, (3) be free from pain or discomfort, (4) adhere to medical regimens, (5) maintain nutritional balance, and (6) have an improved quality of life.

Nursing Implementation

Acute Care

During the acute phase, focus your attention on hemodynamic stability, pain control, fluid and electrolyte balance, and nutritional support. Maintain accurate intake and output records. Monitor the number and appearance of stools. Assess for the presence of blood in stools and emesis. Give IV fluids, electrolytes, analgesics, and antiinflammatory drugs as prescribed. Monitor serum electrolytes, CBC, and vital signs, being alert for changes related to diarrhea and dehydration. If the patient has orthostatic hypotension, teach the patient to change position slowly and use safety precautions.

Help the patient stay clean, dry, and free of odor until the diarrhea is under control. Place a deodorizer in the room. Meticulous perianal skin care using plain water (no harsh soap) with a moisturizing skin barrier cream prevents skin breakdown. Dibucaine, witch hazel, sitz baths, and other soothing compresses or ointments may reduce perianal irritation and pain.

Calculate the adequacy of the daily calorie intake. Obtain a daily weight. Assess the abdomen, including bowel sounds, as needed. Consult with a dietitian about diet modifications and the need for nutritional supplements.

Postoperative care after surgical procedures for IBD is similar to that described later in this chapter in the intestinal and ostomy surgery section (see p. 952) and in the general nursing care plan for

the postoperative patient (see eNursing Care Plan 19.1 on the website for Chapter 19).

Ambulatory Care

IBD is a chronic illness. Assist the patient in accepting the chronicity of IBD and learning ways to cope with its recurrent, unpredictable nature. Teaching includes (1) the importance of rest and diet management, (2) perianal care, (3) drug action and side effects, (4) symptoms of recurrence of disease, (5) when to seek medical care, and (6) ways to reduce stress. Excellent teaching resources, written in easily comprehensible language are available from the Crohn's and Colitis Foundation of America *(www.crohnscolitisfoundation.org).*

It is important to establish rapport and encourage the patient to talk about self-care. Ask patients what you can do to promote their self-care. An explanation of all procedures and treatments helps to build trust, decrease apprehension, and increase self-control. Once you have established a therapeutic relationship, talk with smokers who have Crohn's disease about quitting since smoking is associated with more severe disease.

The patient and caregiver may need your help setting realistic short- and long-term goals. Patients may have severe fatigue, which limits their energy for physical activity. Rest is important. Patients may lose sleep because of frequent episodes of diarrhea and abdominal pain. Nutritional deficiencies and anemia worsen fatigue and leave the patient feeling weak. Teach them to schedule activities around rest periods.

Many patients have intermittent exacerbations and remissions of symptoms. Given the chronicity and uncertainty related to the frequency and severity of flares, the patient may have frustration, depression, and anxiety. Psychotherapy and behavioral therapies may help patients deal with their feelings about the disease and help to manage their symptoms. Because of the relationship between emotions and the GI tract, teach the patient ways to manage stress (see Chapter 6). Suggest the patient seek support through a local or online support group from the Crohn's and Colitis Foundation of America.

Evaluation

The expected outcomes are that the patient with IBD will

- Have a decrease in the number of diarrhea stools
- Maintain body weight within a normal range
- Be free from pain and discomfort
- Use effective coping strategies

Gerontologic Considerations: Inflammatory Bowel Disease

A second peak in occurrence of IBD is in the 6th decade. The cause, natural history, and clinical course of IBD are similar to those seen in younger patients. However, in the older patient, proctitis and left-sided UC are more common. Diagnosis is sometimes difficult in older adults since IBD can be confused with CDI, diverticulitis, or colitis.

The interprofessional care of IBD is also similar; however, challenges exist. Drug therapy and surgery have an increased risk for adverse events, hospitalization, and mortality. Older adults are more prone to adverse events from corticosteroids. Immunosuppressant and biologic therapies have a higher risk for infection and cancer. Anemia and malnutrition are more common.[17] They are more vulnerable to volume depletion from diarrhea. Those with physical limitations may have trouble handling fecal urgency and multiple trips to the bathroom without help.

Intestinal Obstruction

Intestinal obstruction occurs when intestinal contents cannot pass through the GI tract. The obstruction may occur in the small (SBO) or large (LBO) intestine. It can be partial or complete, simple or strangulated. Partial obstructions do not completely occlude the intestinal lumen, allowing for some fluid and gas to pass through. They usually resolve with conservative treatment. A complete obstruction totally occludes the lumen and usually requires surgery. A simple obstruction has an intact blood supply; a strangulated one does not.

Types of Intestinal Obstruction

The causes of intestinal obstruction are either mechanical or nonmechanical.

Mechanical

In *mechanical obstruction,* there is a physical obstruction of the intestinal lumen. Most intestinal obstructions occur in the small intestine. Surgical adhesions are the most common cause of SBO.[18] They can occur within days of surgery or years later (Fig. 42.5). Other causes of SBO are hernia, cancer, strictures from Crohn's disease, and intussusception after bariatric surgery. The most common cause of LBO is colorectal cancer (malignant obstruction) followed by diverticular disease. Other causes include adhesions, ischemia, volvulus, and Crohn's disease.[19]

Nonmechanical

A *nonmechanical obstruction* occurs with reduced or absent peristalsis due to altered neuromuscular transmission of the parasympathetic innervation to the bowel. It may result from a neuromuscular or vascular disorder. **Paralytic ileus** (lack of intestinal peristalsis and

bowel sounds) is the most common form of nonmechanical obstruction. It occurs to some degree after any abdominal surgery. It can be hard to know if a postoperative obstruction is due to paralytic ileus or adhesions. One clue is that bowel sounds usually return before postoperative adhesions develop. Other causes of paralytic ileus include peritonitis, inflammatory responses (e.g., acute pancreatitis, acute appendicitis), electrolyte abnormalities (especially hypokalemia), and thoracic or lumbar spinal fractures.

Pseudo-obstruction is a mechanical obstruction without any cause found on radiologic imaging. It is a GI motility disorder. There are several conditions associated with pseudo-obstruction. These include major surgery, electrolyte imbalance, neurologic conditions, medications, sepsis, cancer, trauma, and burns.[20]

Vascular obstructions are rare. They are the result of an interference with the blood supply to a part of the intestines. The most common causes are emboli and atherosclerosis of the mesenteric arteries. Emboli may originate from thrombi in patients who have chronic atrial fibrillation, diseased heart valves, and prosthetic valves. Venous thrombosis may occur in conditions of low blood flow, such as heart failure and shock.

Etiology and Pathophysiology

About 6 to 8 L of fluid enter the small intestine daily. Most of the fluid is absorbed before it reaches the colon. Around 75% of intestinal gas is swallowed air. When an obstruction occurs, fluid, gas, and intestinal contents accumulate proximal to the obstruction. Distention reduces fluid absorption and initially stimulates intestinal secretions. Distal to the obstruction, the bowel empties, and then collapses. As distention increases in the proximal bowel, intraluminal bowel pressure rises. The increased pressure leads to an increase in capillary permeability and extravasation of fluids and electrolytes into the peritoneal cavity. Eventually the intestinal muscle becomes fatigued, and peristalsis stops. Retention of fluids in the intestine and peritoneal cavity leads to a severe reduction in circulating blood volume. This leads to

hypotension and hypovolemic shock.

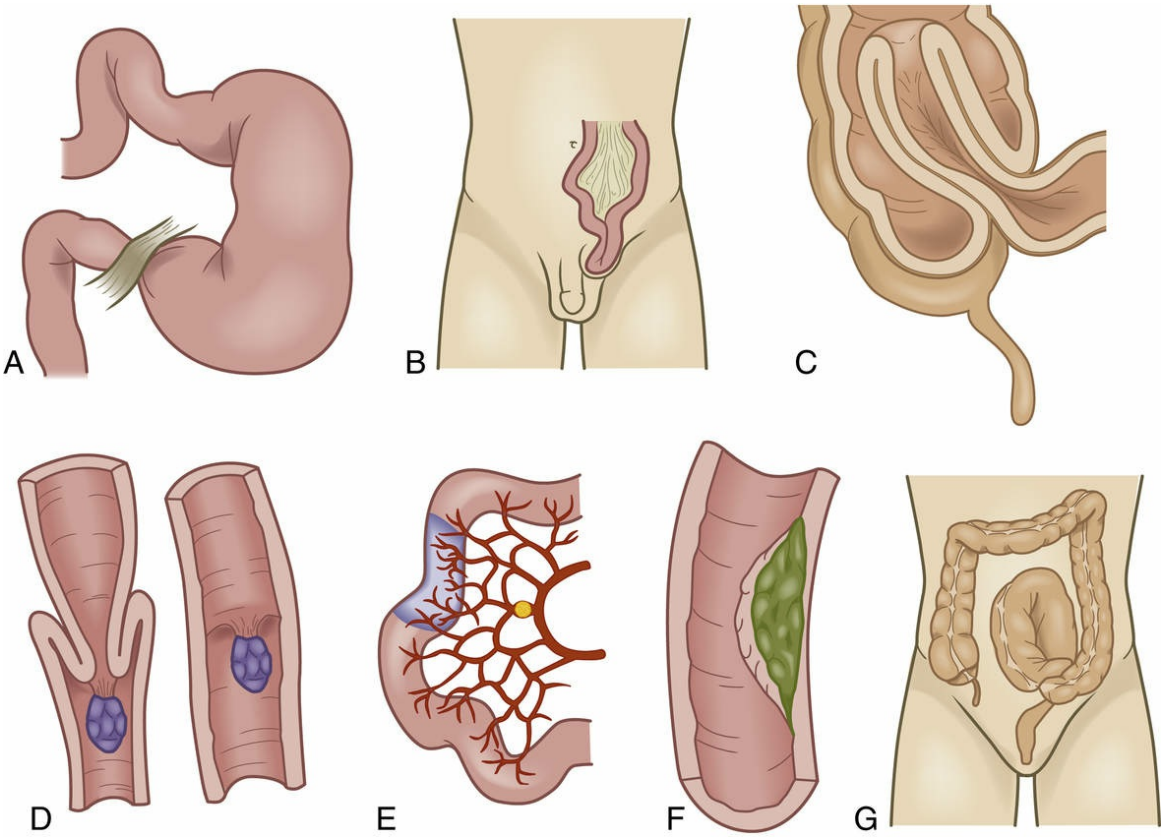

FIG. 42.5 Bowel obstructions. **A,** Adhesions. **B,** Strangulated inguinal hernia. **C,** Ileocecal intussusception. **D,** Intussusception from polyps. **E,** Mesenteric occlusion. **F,** Neoplasm. **G,** Volvulus of the sigmoid colon.

If blood flow is inadequate, bowel tissue becomes ischemic, then necrotic, and the bowel may perforate. In the most dangerous situation the bowel becomes so distended that the blood flow stops, causing edema, cyanosis, and gangrene of a bowel segment. This is called *intestinal strangulation* or *intestinal infarction.* If not quickly corrected, the bowel will become necrotic and rupture, leading to infection, septic shock, and death.

The location of the obstruction determines the extent of fluid, electrolyte, and acid-base imbalances. If the obstruction is high (e.g., upper duodenum), metabolic alkalosis may result from the loss of gastric hydrochloric (HCl) acid through vomiting or NG intubation

and suction. When the obstruction is in the small intestine, dehydration occurs rapidly. Dehydration and electrolyte imbalances do not occur early in large bowel obstruction. If the obstruction is below the proximal colon, solid fecal material accumulates until symptoms of discomfort appear.

Clinical Manifestations

The 4 hallmark clinical manifestations of an obstruction are abdominal pain, nausea and vomiting, distention, and constipation. The order and degree these appear vary by the cause, location, and type of obstruction (Table 42.20). Colicky abdominal pain is usually the first symptom. In SBO, the pain is often of sudden onset. It occurs at 4- to 5-minute intervals for proximal obstructions and less often for distal obstructions. The nature of the vomiting gives a clue to the level of obstruction. In a proximal obstruction, patients rapidly develop nausea and vomiting. It may be projectile and contain bile. Vomiting usually gives temporary relief from abdominal pain in higher obstructions. Vomiting from a more distal small bowel obstruction is more gradual in onset and more fecal and foul smelling. Bowel sounds may be high-pitched above the area of obstruction. Bowel sounds are usually absent with paralytic ileus.

TABLE 42.20 Manifestations of Small and Large Intestinal Obstructions

Manifestation	Small Intestine		Large Intestine
	Proximal	Distal	
Onset	Rapid	Rapid	Gradual
Vomiting	Frequent and copious	Less frequent	Late or absent
Pain	Colicky, cramping, occurs at frequent intervals	Colicky, occurs more intermittently	Persistent, cramping
Bowel movement	Feces for a short time	Gradual constipation	Obstipation
Abdominal distention	Minimal	Increased	Increased

Signs of LBO include abdominal distention, either obstipation or a marked change in bowel function, and lack of flatus. The patient has persistent, cramping abdominal pain. Bowel sounds are usually present and become progressively hypoactive. Vomiting is rare. Strangulation causes severe, constant pain that is rapid in onset.[19]

With both types, abdominal tenderness and rigidity occur. The patient appears acutely ill, with signs of dehydration and sepsis. These include tachycardia, dry mucous membranes, and hypotension. The patient's temperature may rise above 100°F (37.8°C).

Diagnostic Studies

Perform a thorough history and physical examination. Imaging can identify an obstruction and guide decisions about surgery. Abdominal x-rays, CT scan, or contrast enema may be done. Sigmoidoscopy or colonoscopy provides direct visualization of an LBO.

Blood tests include a CBC and blood chemistries. A high WBC count may mean strangulation or perforation. Increased hematocrit values may reflect hemoconcentration. Decreased hemoglobin and hematocrit values may mean bleeding from cancer or strangulation with necrosis. Serum electrolytes, BUN, and creatinine are monitored to assess the degree of dehydration. Metabolic alkalosis can develop from vomiting.

Interprofessional Care

Treatment of a bowel obstruction depends on the cause. If a strangulated obstruction or perforation is present, the patient will need emergency surgery to relieve the obstruction and survive. In some, especially those due to surgical adhesions, an obstruction may resolve without surgery.

Surgery may involve simply resecting the obstructed segment of bowel and anastomosing the remaining healthy bowel back together. Partial or total colectomy, colostomy, or ileostomy may be done when extensive obstruction or necrosis is present. Sometimes, an obstruction can be removed nonsurgically. Colonoscopy offers a means to remove

polyps, dilate strictures, and remove and destroy tumors with a laser.

The initial treatment includes placing the patient on NPO status, providing IV fluid therapy with either normal saline or lactated Ringer's solution, and giving IV antiemetics. If needed, insert an NG tube for decompression and give ordered electrolyte replacement. Obtain blood cultures and start IV antibiotic therapy. Some patients need PN to allow bowel rest and improve nutritional status before surgery.

The treatment goal for a patient with a malignant obstruction is to regain patency and resolve the obstruction. Stents can be placed via endoscopic or fluoroscopic procedures. They are used for palliative purposes or as "a bridge to surgery," allowing a patient to avoid emergency surgery.[19] This gives the interprofessional team time to correct fluid volume problems and treat other problems, thus improving surgical outcomes. Corticosteroids with antiemetic properties that decrease edema and inflammation may be used with stent placement.

Nursing Management: Intestinal Obstruction

Nursing Assessment

Intestinal obstruction is a potentially life-threatening condition. Major concerns are preventing fluid and electrolyte deficiencies and early recognition of deterioration in the patient's condition (e.g., hypovolemic shock, sepsis, bowel strangulation). Nursing assessment begins with a detailed patient history and physical examination. Determine the location, duration, intensity, and frequency of abdominal pain.

Record the onset, frequency, color, odor, and amount of vomitus. Assess bowel function, including the passage of flatus. Auscultate for bowel sounds and document their character and location. Inspect the abdomen for scars, visible masses, and distention. Assess whether abdominal tenderness or rigidity is present. Measure the abdominal girth. Check for signs of peritoneal irritation (e.g., muscle guarding, rebound pain). If the HCP decides to wait to see if the obstruction resolves on its own, assess the patient regularly. Notify the HCP of changes in vital signs, changes in bowel sounds, decreased urine output, increased abdominal distention, and pain.

Maintain a strict intake and output record, including emesis and tube drainage. A urinary catheter allows for hourly monitoring of urine output. Report if the urine output is less than 0.5 mL/kg of body weight per hour. This indicates inadequate vascular volume and the potential for acute kidney injury. Rising serum creatinine and BUN levels are other indicators of acute kidney injury.

Nursing Diagnoses

Nursing diagnoses for the patient with intestinal obstructions include:

- Acute pain

- Fluid imbalance

Planning

The overall goals are that the patient with an intestinal obstruction will have (1) relief of the obstruction and return to normal bowel function, (2) minimal to no discomfort, and (3) normal fluid and electrolyte and acid-base status.

Nursing Implementation

Monitor the patient closely for signs of dehydration and electrolyte imbalances. Give IV fluids as ordered. Assess for signs and symptoms of fluid imbalance. Some patients, especially older adults, may not tolerate rapid fluid replacement. Monitor serum electrolyte levels closely. A patient with a high intestinal obstruction is more likely to have metabolic alkalosis. A patient with a low obstruction is at greater risk for metabolic acidosis. The patient is often restless and constantly changes position to relieve the pain. Provide comfort measures and promote a restful environment. Nursing care of the patient after surgery for an intestinal obstruction is similar to care of the patient after a laparotomy (see p. 935).

With an NG tube in place, oral care is extremely important. Vomiting leaves an unpleasant taste in the patient's mouth, and fecal odor may be present. The patient breathes through the mouth, drying the mouth and lips. Provide frequent oral care and water-soluble lubricant for the lips. Check the nose for signs of irritation from the NG tube. Clean and dry this area daily, apply water-soluble lubricant, and retape the tube. Check the NG tube every 4 hours for patency.

Polyps of Large Intestine

Colonic polyps arise from the mucosal surface of the colon and project into the lumen. They may be *sessile* (flat, broad based, and attached directly to the intestinal wall) or *pedunculated* (attached to the intestinal wall by a thin stalk). Polyps tend to be sessile when small and become pedunculated as they enlarge (Fig. 42.6). They may be found anywhere in the large intestine. As patients age, polyps are increasingly present in the proximal colon. Rectal bleeding and occult blood in the stool are the most common signs, but most patients with polyps are asymptomatic.

Types of Polyps

The most common types of polyps are hyperplastic and adenomatous. *Hyperplastic polyps* are noncancerous. They rarely grow larger than 5 mm and never cause clinical symptoms. Other benign polyps include inflammatory polyps, lipomas, and juvenile polyps.

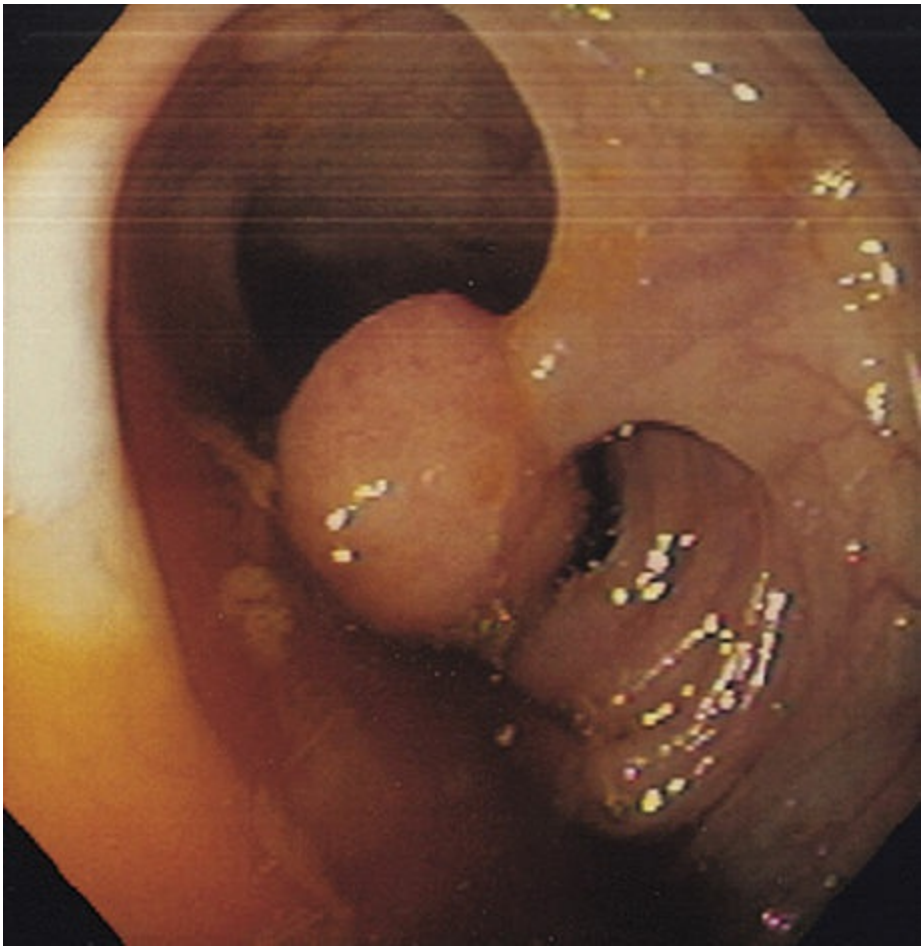

FIG. 42.6 Endoscopic image of pedunculated polyp in descending colon.
Courtesy David Bjorkman, MD, University of Utah School of Medicine, Department of Gastroenterology. In McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.

Adenomatous polyps are neoplastic and closely linked to colorectal adenocarcinoma. There are 3 types: tubular, tubulovillous, and villous. Villous or large adenomatous polyps are more likely to have cancers develop in them. Removing adenomatous polyps decreases the occurrence of colorectal cancer.

Genetic Link

Familial adenomatous polyposis (FAP) is the most common polyposis syndrome (see the Genetics in Clinical Practice box), causing 1% of all CRCs. FAP is a genetic disorder characterized by hundreds or

sometimes thousands of polyps in the colon that appear during adolescence and early adulthood. They eventually become cancerous, usually by age 40. Since CRC is inevitable,

Genetics in Clinical Practice

Familial Adenomatous Polyposis (FAP)

Genetic Basis

- Autosomal dominant FAP
    - Classic form of disease
    - Mutations in adenomatous polyposis coli *(APC)* gene
    - Normally this is a tumor suppressor gene involved in DNA repair
    - Normally this gene makes a protein that keeps polyps from developing in the colon
    - 50% of the offspring of a patient with FAP carry the *FAP* gene
- Autosomal recessive FAP
    - Autosomal recessive disorder
    - Mutations in the *mutY* homolog *(MUTYH)* gene
    - Normally this gene is involved in DNA repair
    - Characterized by fewer polyps, typically <100

Incidence

- Affects 1 in 7000 to 22,000 people
- Equally affects men and women

Genetic Testing

- DNA testing is available

Clinical Implications

- Anyone with a family history of FAP should undergo genetic testing during childhood
- If the FAP gene is present, colorectal screening begins at puberty, and annual colonoscopy begins at age 16
- Persons with a family history of FAP can benefit from genetic counseling

the colon and rectum are removed, usually by age 25, by proctocolectomy with an IPAA or an ileostomy. Patients with classic FAP are at risk for cancers of the thyroid, stomach, small intestine, liver, and brain, so lifetime cancer surveillance is essential.

TABLE 42.21 Risk Factors for Colorectal Cancer

- Alcohol (≥4 drinks/wk)
- Cigarette smoking
- Family history of colorectal cancer (first-degree relative)
- Family or personal history of familial adenomatous polyposis (FAP)
- Family or personal history of hereditary nonpolyposis colorectal cancer (HNPCC) syndrome
- Obesity (body mass index ≥30 kg/m^2)
- Personal history of colorectal cancer, inflammatory bowel disease, or diabetes
- Red meat (≥7 servings/wk)

Diagnostic Studies and Interprofessional Care

Colonoscopy, sigmoidoscopy, barium enema, and virtual colonoscopy (CT or MRI colonography) are used to discover polyps. Colonoscopy is preferred because it allows evaluation of the total colon. All polyps are considered abnormal and should be removed *(polypectomy)*. Polyps can be removed during colonoscopy or sigmoidoscopy. They cannot be removed during barium enema and virtual colonoscopy. After polypectomy, watch the patient for rectal bleeding, fever, severe abdominal pain, and abdominal distention, which may indicate hemorrhage or perforation.

Colorectal Cancer

Of cancers that affect both men and women, colorectal cancer (CRC) is the third leading cause of cancer-related deaths and the third most common cancer in men and women. Annually about 140,250 people in the United States are diagnosed with CRC and 50,600 people die from CRC.[21]

CRC is more common in men than in women. The risk for CRC increases with age, with about 90% of new CRC cases detected in people older than 50. However, while the incidence of CRC in people over 50 years is decreasing, the number of cases in people aged 20 to 49 years is rising and expected to continue to do so.[22] This is thought to be related to diet, physical inactivity, and increasing rates of obesity.

Promoting Health Equity

Colorectal Cancer

- Blacks are most likely to develop colorectal cancer (CRC).
- Blacks are more likely to die of CRC than any other ethnic group.
- Cancer may occur at an earlier age in blacks and Hispanics.
- Hispanics are the least likely to undergo CRC screening.

Etiology and Pathophysiology

Unlike some other cancers, no single risk factor accounts for most cases of CRC (Table 42.21). The risk is highest in those with first-degree relatives with CRC and people with IBD. About 20% of cases of CRC occur in patients with a family history of CRC. Hereditary forms of CRC, including FAP and hereditary nonpolyposis colorectal cancer (HNPCC) syndrome (Lynch syndrome), account for another

10% of cases.

About 30% to 50% of people with CRC have an abnormal *KRAS* gene. The *KRAS* gene, which is primarily involved in regulating cell division, belongs to a class of genes known as *oncogenes.* When mutated, oncogenes have the potential to cause normal cells to become cancerous.

Genetics in Clinical Practice

Hereditary Nonpolyposis Colorectal Cancer (HNPCC) or Lynch Syndrome

Genetic Basis

- Autosomal dominant disorder
- Mutations in *MSH2, MLH1, MSH6,* or *PMS2* genes
- These genes are involved with the repair of mistakes in DNA replication

Incidence

- Affects 1 in 500 to 2000 people

Genetic Testing

- DNA testing is available

Clinical Implications

- Accounts for 3% to 5% of all CRC
- Depending on the genetic mutation, the risk for developing CRC

is from 50% to 80%

- If colon polyps are present, they occur at an earlier age than do polyps in the general population and are more prone to become cancerous
- Have increased risk for stomach, brain, ovary, uterus, skin, urinary tract, small bowel, and bile ducts cancers
- People with HNPCC need to have a colonoscopy every year
- Women with HNPCC should undergo ovarian and endometrial cancer screening

Maintaining a healthy weight, being physically active, limiting alcohol use, not smoking, and eating a diet with large amounts of fruits, vegetables, and grains may decrease the risk for CRC.

CRC usually starts as a polyp on the inner lining of the colon or rectum that grows over a period of 10 to 20 years. Most polyps are adenomas, which arise from the cells that make mucus. As the tumor grows, the cancer invades and penetrates the wall of colon or rectum (Fig. 42.7). Eventually cancer cells gain access to the lymph nodes and vascular system and spread to distant sites. Since venous blood leaving the colon and rectum flows through the portal vein and the inferior rectal vein, the liver is a common site of metastasis. The cancer spreads from the liver to other sites, including the lungs, bones, and brain. CRC can also spread directly into adjacent structures.

Clinical Manifestations

CRC develops slowly, and symptoms do not appear until the disease is advanced. Common manifestations include iron-deficiency anemia, rectal bleeding, abdominal pain, and change in bowel habits.

Physical findings may include:

- *Early disease:* None or nonspecific findings (fatigue, weight loss)
- *More advanced disease:* Abdominal tenderness, palpable abdominal mass, hepatomegaly, ascites

Bleeding can occur with both right- and left-sided CRC. Bleeding on the right side is more common than on the left side. It is often unrecognized, and an early manifestation is often anemia. Hematochezia (fresh blood in the stool) is more often caused by left-sided CRC than right-sided CRC.

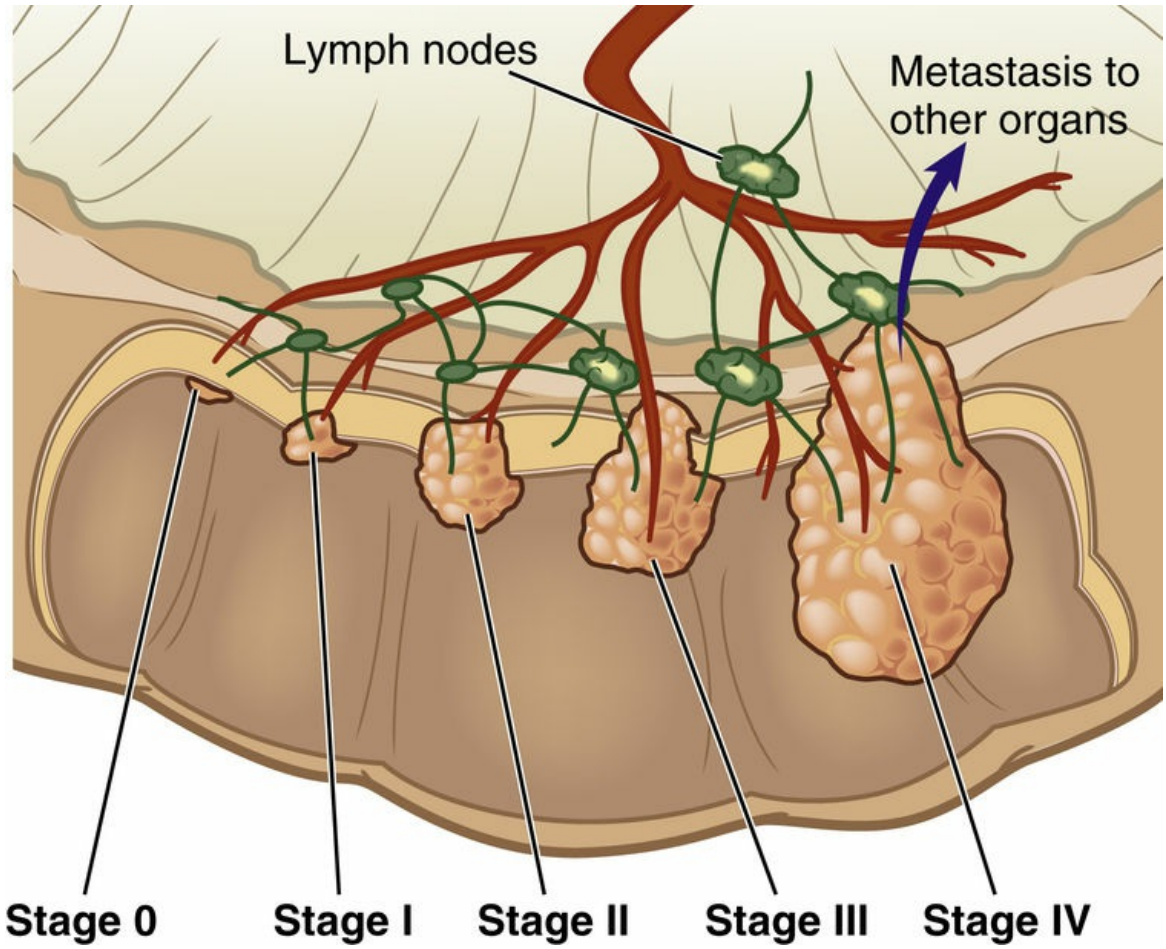

FIG. 42.7 The 5 stages of colorectal cancer. Stage 0 cancer has not grown beyond the mucosal layer. Stage I cancer has grown beyond the mucosa into the submucosa, but no lymph nodes are involved. Stage II cancer has grown beyond the submucosa into the muscle, but there is no lymph node involvement or metastasis. Stage III cancer is any tumor with lymph node involvement but no metastasis. Stage IV cancer is any tumor with lymph node involvement and metastasis.

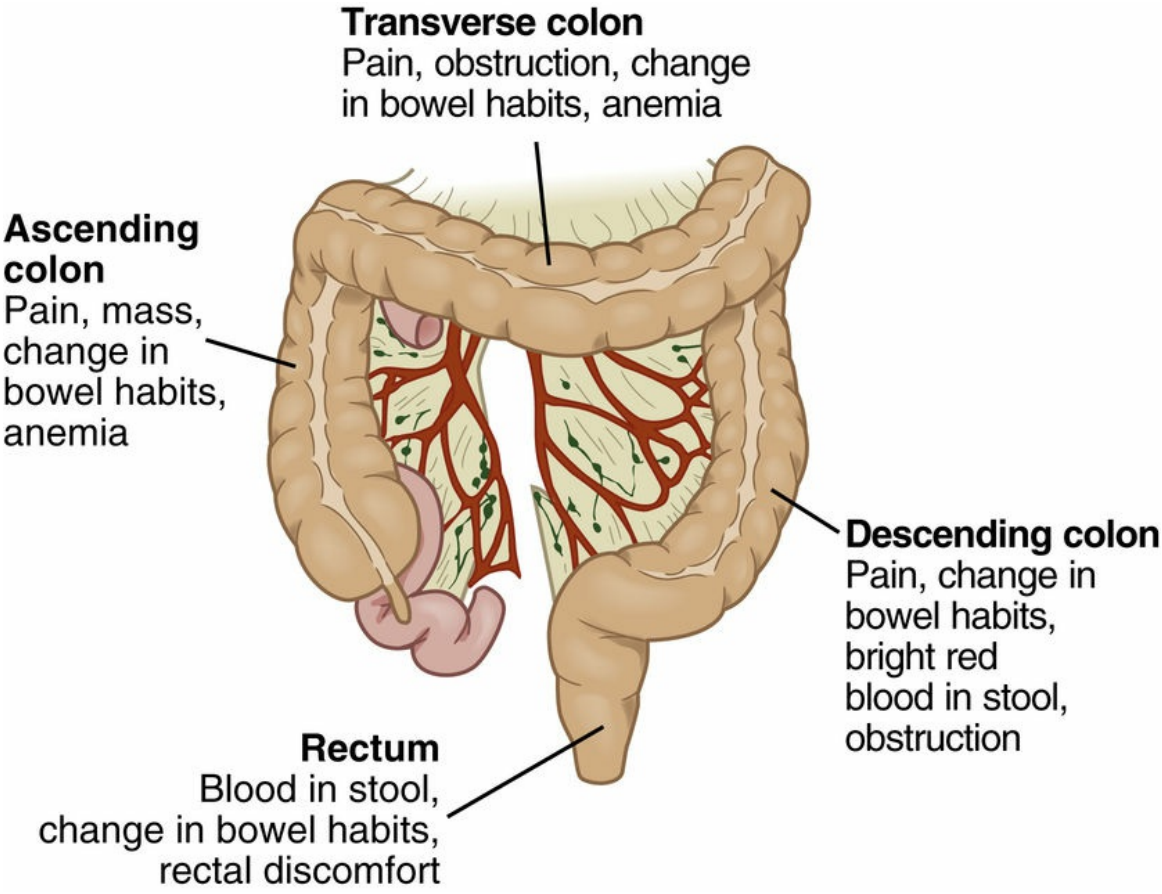

FIG. 42.8 Signs and symptoms of colorectal cancer by location of primary cancer.
Modified from McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.

Right-sided cancers are more likely to cause diarrhea. Left-sided cancers are usually detected later and could present with bowel obstruction (Fig. 42.8). Complications of CRC include obstruction, bleeding, perforation, peritonitis, and fistula formation.

Diagnostic Studies

Obtain a thorough history with close attention to family history (Table 42.22). Since symptoms of CRC do not become evident until the disease is advanced, there is an increased emphasis on screening. Beginning at age 45 and continuing until age 75, men and women at average risk for developing CRC should have screening tests to detect both polyps and cancer based on 1 of these testing schedules:

- Flexible sigmoidoscopy (every 5 years)
- Colonoscopy (every 10 years)

TABLE 42.22 Interprofessional CareColorectal Cancer

Diagnostic Assessment

- History and physical examination
- Digital rectal examination
- Testing of stool for occult blood
- CBC
- Liver function tests
- Barium enema
- Sigmoidoscopy and/or colonoscopy with biopsy
- Abdominal CT scan, ultrasound, or MRI
- Carcinoembryonic antigen (CEA) test

Management

- Surgery
  - Right hemicolectomy
  - Left hemicolectomy
  - Abdominal-perineal resection
  - Laparoscopic colectomy
- Chemotherapy
- Targeted therapy

- Radiation therapy

- Double-contrast barium enema (every 5 years)
- CT colonography (virtual colonoscopy) (every 5 years)
- Tests that primarily find cancer include:
    - High-sensitivity fecal occult blood test (FOBT) (every year), *or*
    - Fecal immunochemical test (FIT) (every year)
    - Stool DNA test (every 3 years)

Colonoscopy is the gold standard for CRC screening. It allows the entire colon to be examined, biopsies obtained, and polyps removed and sent to the laboratory for examination. People at average risk for CRC should undergo colonoscopy every 10 years beginning at age 45.

Persons at risk (Table 42.21) should begin screening earlier and have screening done more often. Those who have a first-degree relative who developed CRC before age 60 or have 2 first-degree relatives with CRC should have a colonoscopy every 5 years beginning at age 40 or 10 years earlier than when the youngest relative developed cancer. Those who have 1 first-degree relative who had CRC after age 60 should have a colonoscopy every 10 years beginning at age 40.[23]

Less favorable, but acceptable, screening methods include stool testing for fecal blood. The FOBT and FIT look for blood in the stool. Stool tests must be done yearly since tumor bleeding occurs at intervals and may easily be missed if a single test is done. Stool DNA tests (PreGen-Plus, Cologuard) can detect DNA mutations that may occur with CRC.

Once tissue biopsies confirm the diagnosis of CRC, the patient needs a CBC to check for anemia and liver function tests. A CT scan or MRI of the abdomen will be done to detect liver metastases, retroperitoneal and pelvic disease, and depth of penetration of tumor into the bowel wall. However, liver function tests may be normal even when metastasis has occurred.

Carcinoembryonic antigen (CEA) is a complex glycoprotein sometimes made by CRC cells. It may be used to monitor for disease

recurrence after surgery or chemotherapy but is not a good screening tool because of the large number of false-positive findings. CEA levels also may be increased in noncolon cancers (e.g., gastric, pancreatic, breast, thyroid cancers) as well as some noncancerous conditions, like IBD, pancreatitis, cirrhosis, and chronic obstructive pulmonary disease.

TABLE 42.23 TNM Classification of Colorectal Cancer

T	Primary Tumor
T_x	Cannot assess primary tumor because of incomplete information.
T_{is}	Carcinoma in situ. Cancer is in earliest stage and has not grown beyond mucosa layer.
T_1	Tumor has grown beyond mucosa into the submucosa.
T_2	Tumor has grown through submucosa into muscularis propria.
T_3	Tumor has grown through the muscularis propria into the pericolorectal tissues.
T_4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure.
N	Lymph Node Involvement
N_x	Cannot assess lymph nodes.
N_0	No regional lymph node involvement is found.
N_1	Cancer is found in 1 to 3 nearby lymph nodes.
N_2	Cancer is found in 4 or more nearby lymph nodes.
M	Metastasis
M_x	Cannot assess presence of metastasis.
M_0	No distant metastasis seen.
M_1	Distant metastasis is present.

TABLE 42.24 Classification System Used to Stage Colorectal Cancer

Stage*	TNM†	5-Yr Survival Rate (%)
0	T_{is} N_0 M_0	>96
I	T_1 N_0 M_0	92
	T_2 N_0 M_0	87
II	T_3 N_0 M_0	70–80
III	Any T, N_{1-2} M_0	53–84
IV	Any T, any N, M_1	12

* Staging system is shown in Fig. 42.7.

† See Table 42.23.

Interprofessional Care

The prognosis and treatment of CRC correlates with pathologic staging of the disease. The most commonly used staging system is the tumor, node, metastasis (TNM) staging (Table 42.23). As with other cancers, prognosis worsens with greater size and depth of tumor, lymph node involvement, and metastasis (Table 42.24).

Surgical Therapy

Goals of surgical therapy include (1) complete resection of the tumor, (2) a thorough exploration of the abdomen to determine if the cancer has spread, (3) removing all lymph nodes that drain the area where the cancer is located, (4) restoring bowel continuity so that normal bowel function will return, and (5) preventing surgical complications.

Some polyps can be removed during colonoscopy, while others require surgery. Polypectomy during colonoscopy can be used to resect CRC in situ. It is considered successful when the resected margin of the polyp is free of cancer, the cancer is well differentiated, and there is no apparent lymphatic or blood vessel involvement.

The decision for surgical treatment depends on the staging and location of the cancer and the ability to restore normal bowel function

and continence. Surgical removal of stage I cancer includes removing the tumor and at least 5 cm of intestine on either side of it, plus nearby lymph nodes. The remaining cancer-free ends are sewn back together (anastomosis). Laparoscopic surgery is sometimes used for stage I tumors, especially those in the left colon. Low-risk stage II tumors are treated with wide resection and reanastomosis. Chemotherapy is used after surgery for high-risk stage II tumors. Stage III tumors are treated with surgery and chemotherapy. Radiation and chemotherapy may be done before surgery to reduce tumor size.

When the tumor is not resectable or metastasis is present, palliative surgery can control hemorrhage or relieve a malignant bowel obstruction. Chemotherapy and radiation can control the spread and provide pain relief. A few patients with limited lung or liver metastases can achieve a cure after primary and metastatic tumor resection and chemotherapy. In rectal cancer, the location and size of the tumor determines the course of treatment. Local excision may be an option. If the tumor is in the distal rectum (1 to 2 cm from the anorectal junction) and the sphincters cannot be preserved, the patient will undergo an *abdominal-perineal resection (APR*). An APR involves removing the entire rectum with the tumor, and the patient will have a permanent colostomy.

If the tumor is in the mid or proximal rectum, it may be possible to preserve the sphincters with a low anterior resection (LAR). A LAR involves removing the rectum and anastomosing the colon to the anal canal. A temporary ileostomy or colostomy may be done to divert stool and allow time for the anastomosis to heal. Another option if the anal sphincters remain is for the HCP to create an alternative reservoir with either a colonic J-pouch or coloplasty. A LAR is increasingly common because of advancements in laparoscopy and stapling techniques.

Chemotherapy and Targeted Therapy

Chemotherapy can be used to shrink the tumor before surgery, as an adjuvant therapy after colon resection, and as palliative treatment for nonresectable cancer. Adjuvant chemotherapy is recommended for

patients with stage III tumors. Current protocols include varying doses of fluorouracil and leucovorin alone or in combination with oxaliplatin (Eloxatin) or irinotecan (Camptosar). The preferred protocol includes oxaliplatin. Oral fluoropyrimidines (e.g., capecitabine [Xeloda]) in combination with oxaliplatin are an alternative to fluorouracil/leucovorin.[24]

Several targeted therapies have a role in treating metastatic CRC. Angiogenesis inhibitors, which inhibit the blood supply to tumors, include aflibercept (Zaltrap), bevacizumab (Avastin), and ramucirumab (Cyramza). Cetuximab (Erbitux) and panitumumab (Vectibix) block the epidermal growth factor receptor. These drugs are often given with a combination chemotherapy regimen (e.g., fluorouracil/leucovorin/oxaliplatin).

Regorafenib (Stivarga) is a multikinase inhibitor that blocks several enzymes that promote cancer growth. It, or Lonsurf, a combination of trifluridine and tipiracil, are given to patients with metastatic CRC who are no longer responding to other therapies. Trifluridine impairs DNA function and angiogenesis. Tipiracil prevents the rapid metabolism of trifluridine, thus increasing its bioavailability.

Radiation Therapy

Some patients may receive radiation therapy as an adjuvant to surgery and chemotherapy or as a palliative measure for those with metastatic cancer. As a palliative measure, the primary goal is to reduce tumor size and provide symptomatic relief. Radiation therapy is described in Chapter 15.

TABLE 42.25 Nursing AssessmentColorectal Cancer

Subjective Data

Important Health Information

Past health history: Previous breast or ovarian cancer, familial polyposis, villous adenoma, adenomatous polyps, IBD
Medications: Medications affecting bowel function (e.g., laxatives, antidiarrheal drugs)

Functional Health Patterns

Health perception–health management: Family history of colorectal, breast, or ovarian cancer; weakness, fatigue
Nutritional-metabolic: High-calorie, high-fat, low-fiber diet. Anorexia, nausea and vomiting, weight loss
Elimination: Change in bowel habits, alternating diarrhea and constipation, defecation urgency. Rectal bleeding, mucoid stools. Black, tarry stools. Increased flatus, decrease in stool caliber. Feelings of incomplete evacuation
Cognitive-perceptual: Abdominal and low back pain, tenesmus

Objective Data
General

Pallor, cachexia, lymphadenopathy (later signs)

Gastrointestinal

Palpable abdominal mass, distention, ascites, and hepatomegaly (liver metastasis)

Possible Diagnostic Findings

Anemia. Guaiac-positive stools, palpable mass on digital rectal examination. Positive sigmoidoscopy, colonoscopy, barium enema, or CT scan. Positive biopsy

Nursing Management: Colorectal Cancer

Nursing Assessment

Table 42.25 outlines the subjective and objective data you should obtain from a patient with CRC.

Nursing Diagnoses

Nursing diagnoses for the patient with CRC include:

- Diarrhea or constipation
- Anxiety
- Difficulty coping

Planning

The overall goals are that the patient with CRC will have (1) normal bowel elimination patterns, (2) quality of life appropriate to the disease progression, (3) relief of pain, and (4) feelings of comfort and well-being.

Nursing Implementation

Health Promotion

Encourage all persons over 45 to have regular CRC screening. Help identify those at high risk who need screening at an earlier age. Discuss with patients how taking part in cancer screening helps decrease mortality rates. Realize that barriers exist, including lack of accurate information and fear of diagnosis.

Endoscopic and radiographic procedures can only reveal polyps when the bowel has been adequately prepared. Provide teaching about bowel cleansing for outpatient diagnostic procedures and give

cleansing preparations to inpatients (see more on diagnostic procedures in Chapter 38).

Acute Care

Nursing care for the patient after a colon resection is discussed in depth in the next section. If enough healthy bowel remained that the HCP could reconnect the bowel ends, normal bowel function is maintained. Routine postoperative care is appropriate. Patients with more extensive surgery (e.g., APR) may have an open wound and drains (e.g., Jackson-Pratt, Hemovac) and a permanent ostomy. Postoperative care includes sterile dressing changes, care of drains, and patient and caregiver teaching about the ostomy. Ostomy care is discussed in the next section on pp. 954–957.

Ambulatory Care

Psychologic support for the patient and caregiver dealing with the diagnosis of cancer is important. Discuss the patient's feelings about the prognosis and future screening. Patients need much emotional support. The special needs of the cancer patient are discussed in Chapter 15. You may need to address issues surrounding palliative care, end-of-life issues, and hospice (see Chapter 9).

Patients with CRC need to know how to manage changes that result from cancer and cancer treatment. Those who had sphincter-sparing surgery may have diarrhea and incontinence of feces and gas. They may need antidiarrheal drugs or bulking agents to control the diarrhea, but overuse can result in constipation. A consult with a dietitian or wound, ostomy, and continence nurse (WOCN) may help patients and caregivers understand how to manage food and fluid options. Ostomy rehabilitation, including teaching and ongoing support, should be available for all ostomy patients. Patients with skin changes from incontinence and/or radiation therapy will need help with managing these conditions.

Evaluation

The expected outcomes for the patient with CRC are that the patient will

- Have minimal changes in bowel elimination patterns
- Achieve optimal nutritional intake
- Experience quality of life appropriate to disease progression
- Have feelings of comfort and well-being

Bowel Resection and Ostomy Surgery

Surgical resection of the bowel may be done to (1) remove cancer; (2) repair a perforation, fistula, or traumatic injury; (3) relieve an obstruction or stricture; and (4) treat an abscess, inflammatory disease, or hemorrhage. For example, if a person has stage III CRC, the HCP will remove the diseased part of the colon along with a certain margin of healthy tissue. It may be a prophylactic procedure for those with complications from IBD. Patients at high risk for CRC, such as those with FAP, and patients with UC may have a total colectomy and an ileostomy.

Depending on the problem being treated, the following surgical procedures may be done:

- *Total proctocolectomy with IPAA:* 2 surgeries, 8 to 12 weeks apart. The first includes colectomy, rectal mucosectomy, ileal pouch (reservoir) construction, ileoanal anastomosis, and temporary ileostomy. A diverting ileostomy is done, and an ileal pouch is created and anastomosed directly to the anus (Fig. 42.9). The second involves closure of the ileostomy to direct stool toward the new pouch.

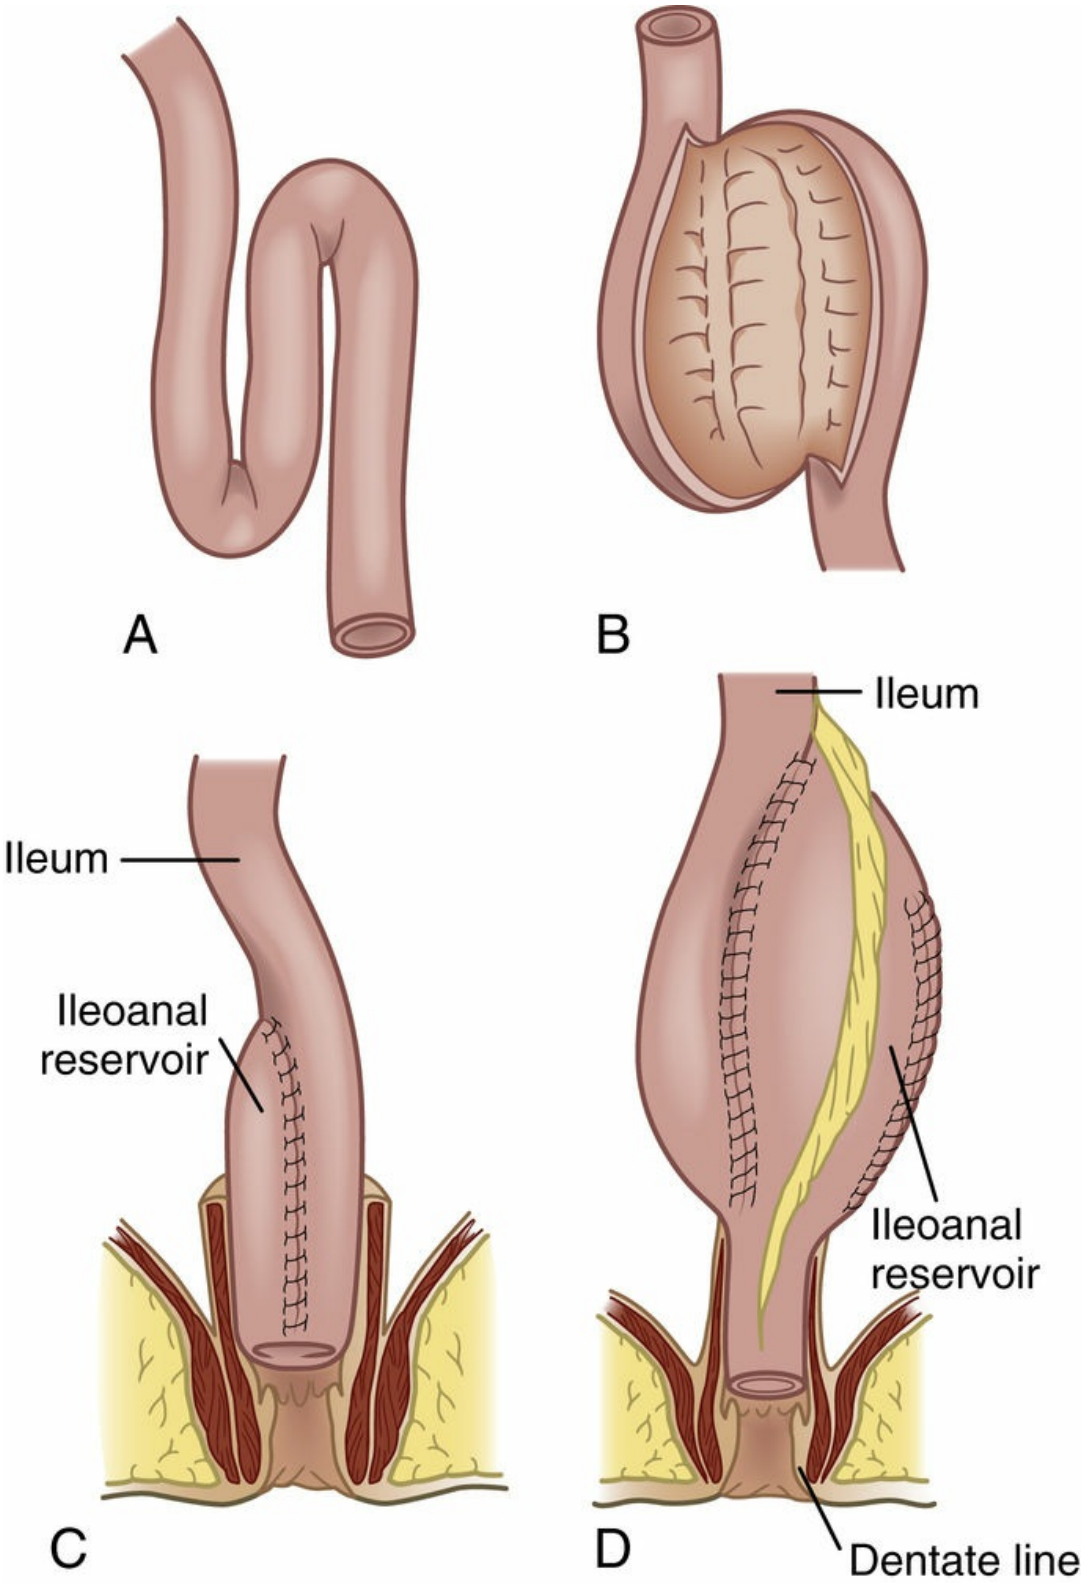

FIG. 42.9 Ileoanal pouch (reservoir). **A,** Formation of a pouch. **B,** Posterior suture lines completed. **C,** J-shaped configuration for ileoanal pouch (J-pouch). **D,** S-shaped configuration for ileoanal pouch (S-pouch).

- *Proctocolectomy with a permanent ileostomy:* Removal of the colon, rectum, and anus with closure of the anal opening. The end of the terminal ileum is brought out through the abdominal wall to form a permanent ileostomy.
- *Right hemicolectomy:* Removal of ascending colon and hepatic flexure with the ileum anastomosed to transverse colon.
- *Left hemicolectomy:* Removal of splenic flexure, descending colon, and sigmoid colon with the transverse colon anastomosed to rectum.
- *Anterior rectosigmoid resection:* Removal of part of descending colon, the sigmoid colon, and upper rectum with the descending colon anastomosed to remaining rectum.
- *Abdominal-perineal resection (APR*): Removal of the entire rectum with creation of a permanent colostomy.
- *Low anterior resection (LAR):* Removal of the rectum and with anastomosis of the colon to the anal canal. A temporary ileostomy or colostomy may be done to divert stool and allow time for the anastomosis to heal. After 8 to 12 weeks, the ostomy can be "taken down," and the ends of the colon surgically reconnected.

Ostomy

An **ostomy** is a surgically created opening on the abdomen that allows the discharge of body waste when the normal elimination route is no longer possible. The outermost part that is visible is a *stoma*. The stoma is the result of the large or small bowel being brought to the outside of the abdomen and sutured in place. When a stoma is created as a fecal diversion, feces will drain through the stoma instead of the anus.

Ostomies are named according to their location and type (Fig. 42.10). An ostomy in the ileum is an ileostomy. An ostomy in the colon is a colostomy. The ostomy is further characterized by its anatomic site (e.g., ascending, transverse, sigmoid). The more distal the ostomy, the more functioning bowel remains and the more likely

that the intestinal contents will resemble the feces that would have been eliminated from an intact colon and rectum. Ileostomy output will be a liquid to thin paste since it did not enter the colon. Patients have no control over ileostomy drainage; it is involuntary. An ileostomy drains frequently, and the patient must wear an ostomy appliance (pouch) to collect the drainage. In contrast, sigmoid colostomy output resembles normal formed stool. Some patients can regulate emptying time with colostomy irrigation and may not need to wear a pouch. See Table 42.26 for a comparison of colostomies and ileostomies.

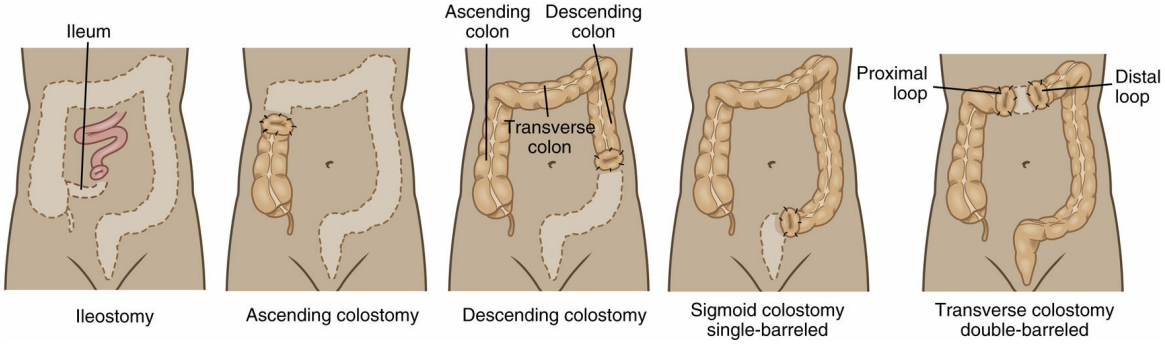

FIG. 42.10 Types of ostomies.

TABLE 42.26 Comparison of Ileostomy and Colostomy

Characteristic	Ileostomy	Colostomy		
		Ascending	Transverse	Sigmoid
Stool consistency	Liquid to semiliquid	Semiliquid	Semiliquid to semiformed	Formed
Fluid requirement	Increased	Increased	Possibly increased	No change
Bowel regulation	No	No	No	Yes, if there is a history of a regular bowel pattern
Pouch and skin barriers	Yes	Yes	Yes	Dependent on regulation
Indications for surgery	Ulcerative colitis, Crohn's disease, diseased or injured colon, familial polyposis, trauma, cancer	Perforating diverticulum in lower colon, trauma, rectovaginal fistula, inoperable tumors of colon, rectum, or pelvis	Same as for ascending	Cancer of the rectum or rectosigmoid area, perforating diverticulum, trauma

Ostomies may be temporary or permanent. For example, the person with a draining fistula may need a temporary ostomy to prevent stool from reaching the diseased area. Cancer involving the rectum requires a permanent ostomy if all bowel distal to the ostomy is removed.

Permanent ostomies may be continent or traditional. *Continent ileostomies* (e.g., Koch pouch, Barnett Continent Ileal Reservoir) use 40 to 45 cm of the terminal ileum to fashion an internal pouch, nipple valve, and abdominal stoma. The pouch replaces the rectum as a reservoir for stool. It can hold around 500 mL of material. Continent ostomies are an option for patients who have had a prior APR with ileostomy for UC or FAP. Patients must be motivated and compliant. They must drain the pouch manually by inserting a catheter through the nipple valve. At first, this is done every 1 to 2 hours. As the pouch enlarges, the frequency decreases to 4 times daily and as needed. They must keep the stool consistency relatively fluid by following a low-residue diet.

The major types of traditional ostomies include end, double-barreled, and loop ostomy.

End Stoma

An end stoma is made by dividing the bowel and bringing out the proximal end as a single stoma, making a colostomy or ileostomy. The distal part of the GI tract is surgically removed or the distal segment is oversewn and left in the abdominal cavity with its mesentery intact. If the distal bowel is removed, the stoma is permanent. When the distal bowel is oversewn and not removed, the procedure is called a *Hartmann's pouch* (Fig. 42.11). With a Hartmann's pouch, the potential exists for the bowel to be reanastomosed and the stoma closed (referred to as a *takedown*).

Loop Stoma

A loop stoma is made by bringing a loop of bowel to the abdominal surface and then opening the anterior wall of the bowel to provide

fecal diversion. This results in 1 stoma with a proximal opening for feces and a distal opening for mucus drainage from the distal colon. An intact posterior wall separates the 2 openings. A plastic rod holds the loop of bowel in place for 7 to 10 days after surgery to prevent it from slipping back into the abdominal cavity (Fig. 42.12). A loop stoma is usually temporary.

Double-Barreled Stoma

To create a double-barreled stoma, the HCP divides the bowel and both the proximal and distal ends are brought through the abdominal wall as 2 separate stomas (Fig. 42.10). The proximal stoma is the functioning stoma. The distal, nonfunctioning stoma is a *mucus fistula.* A double-barreled stoma is usually temporary.

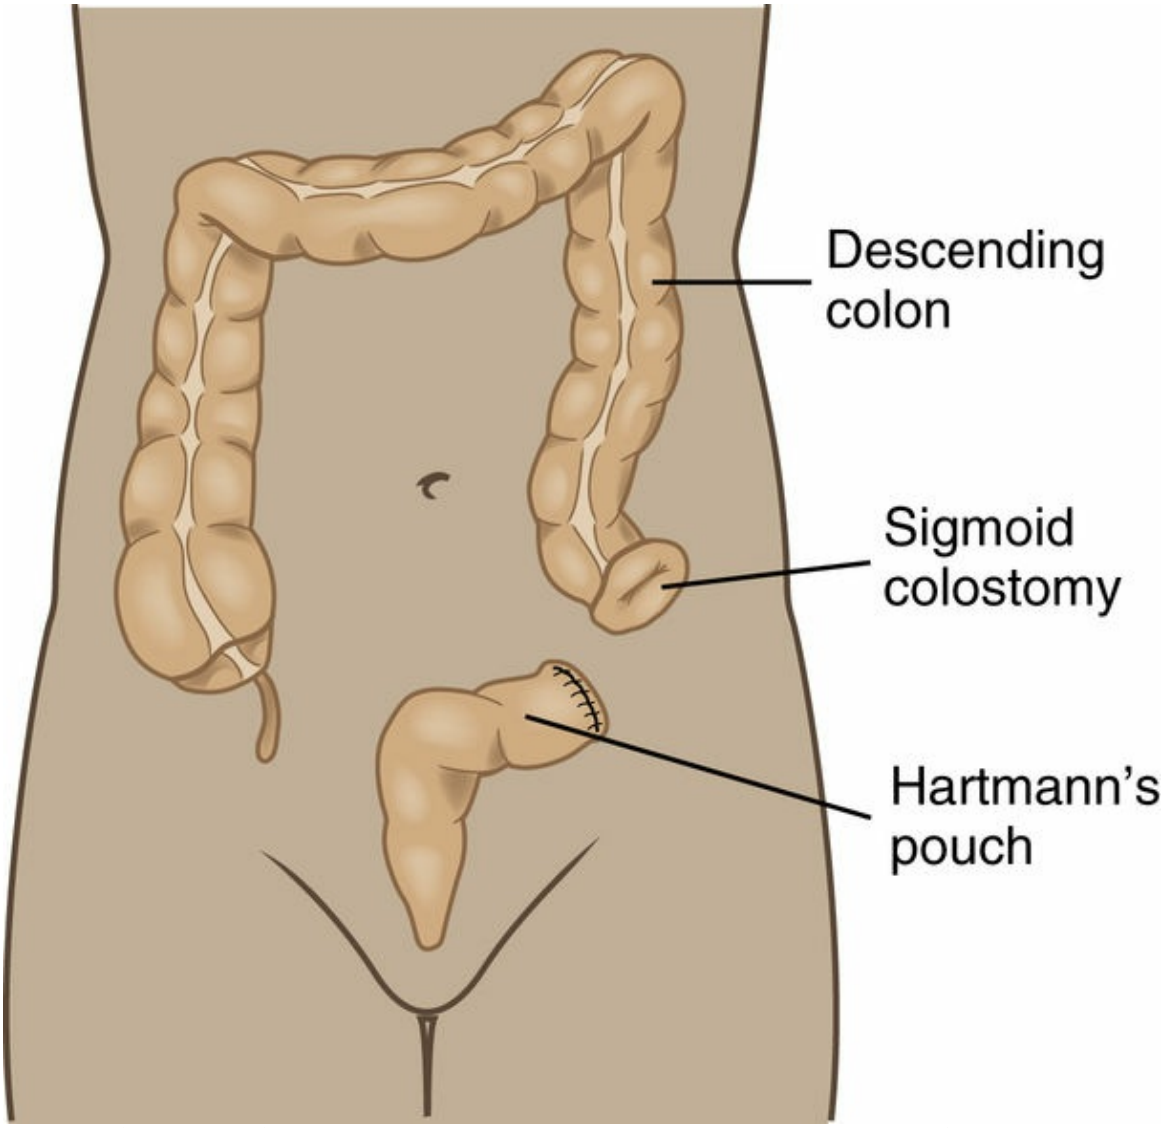

FIG. 42.11 Sigmoid colostomy. Distal bowel is oversewn and left in place to create Hartmann's pouch.

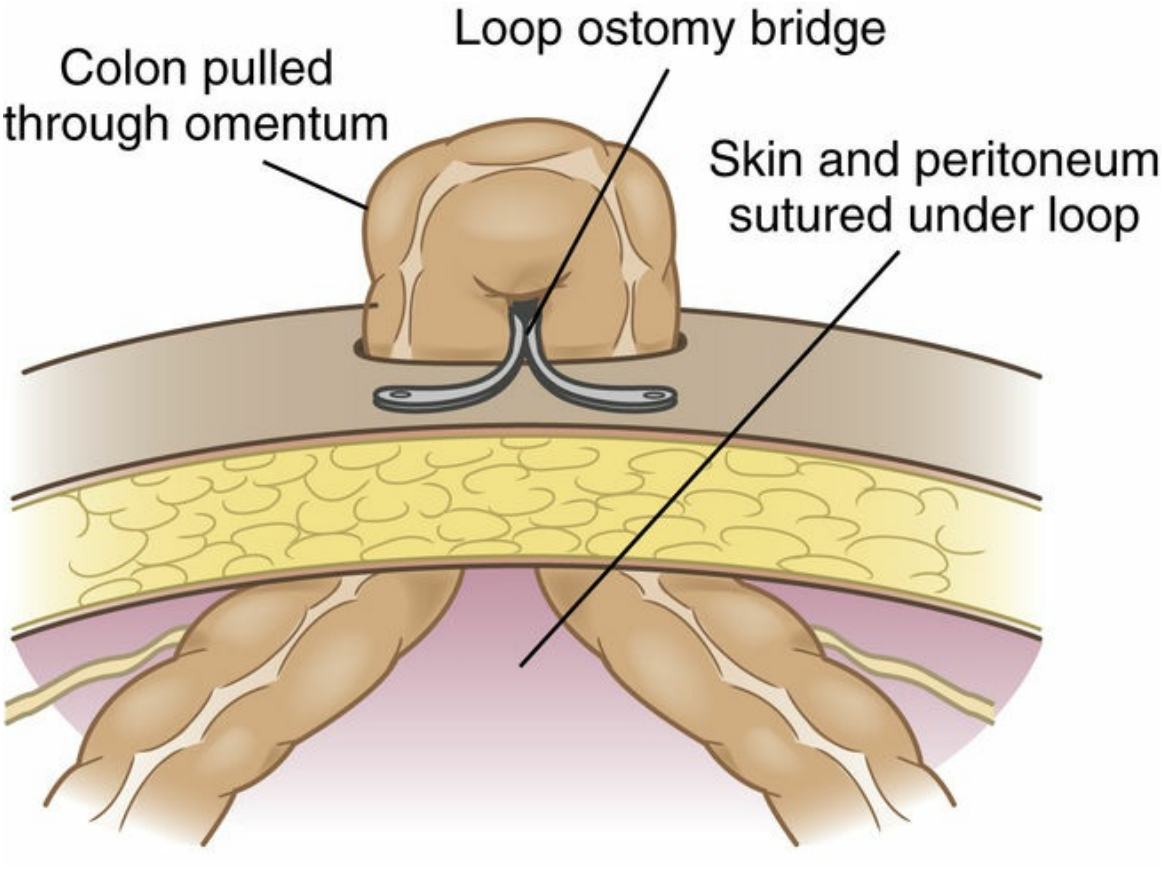

FIG. 42.12 Loop colostomy.

Nursing Management: Bowel Resection and Ostomy Surgery

Preoperative Care

Psychologic preparation and emotional support are particularly important as the person begins to cope with potential changes in body image and elimination. The patient and caregiver should understand the extent of surgery planned. It is normal for the patient and caregiver to have questions concerning the procedures. Provide the patient opportunities to share concerns and questions. This will enhance the patient's feelings of control and ability to cope.

Care that is unique to ostomy surgery includes (1) psychologic preparation for the ostomy, (2) educational preparation, and (3) selecting the best site for the stoma. Ideally, the management of patients facing ostomy surgery begins preoperatively. If available, a WOCN should visit with the patient and caregiver to determine the patient's ability to perform self-care, identify support systems, and determine any modifications that could promote learning during recovery.

A WOCN should choose the site where the ostomy will be and mark the abdomen before surgery. The site should be within the rectus muscle, on a flat surface, and in a place that the patient is able to see. Stomas placed outside the rectus muscle increase the chance of developing a hernia. A flat site makes it much easier to create a good seal and avoid leakage from the bag. Being able to see the stoma makes caring for it easier. Whenever possible, it should be discreetly hidden under clothing and appropriate for normal activities.

TABLE 42.27 Characteristics of Stoma

Characteristic	Description or Cause
Color	
Rose to brick-red	Viable stoma mucosa.
Pale	May indicate anemia.
Blanching, dark red to purple	Indicates inadequate blood supply to the stoma or bowel.
Edema	
Mild to moderate edema	Normal in initial postoperative period. Trauma to the stoma.
Moderate to severe edema	Obstruction of the stoma, allergic reaction to food, gastroenteritis.
Bleeding	
Small amount	Oozing from stoma mucosa when touched is normal because of its high vascularity.
Moderate to large amount	Could indicate lower GI bleeding, coagulation factor deficiency, stomal varices secondary to portal hypertension.

Postoperative Care

If the patient's wound is closed or partially closed, assess the incision for suture integrity and signs and symptoms of wound inflammation and infection. A patient who has an open wound with packing needs meticulous care. Reinforce dressings and change them often during the first several hours postoperatively when drainage is likely to be profuse. Carefully assess all drainage for amount, color, and consistency. The drainage is usually serosanguineous.

Assess the wound regularly and record bleeding, excess drainage, and unusual odor. Monitor for edema, erythema, and drainage around the suture line, as well as fever and a high WBC count. Observe the skin around any drains for signs of inflammation. Keep the area around the drain clean and dry. Complications that can occur include delayed wound healing, hemorrhage, fistulas, and infections.

If an ostomy is present, assess the stoma and place a clear pouching system that protects the skin and contains drainage and odor. The stoma should be rosy pink to red and mildly swollen (Table 42.27). A dusky blue stoma indicates ischemia; a brown-black stoma indicates necrosis. Assess and document stoma color every 4 hours and ensure that there is no excess bleeding. Report any sustained color changes or bleeding to the HCP. Edema will resolve over the first 6 weeks.

The colostomy starts functioning when peristalsis returns. Record the volume, color, and consistency of the drainage. When a colostomy is done on a colon that was not cleaned out before surgery, stool will drain when peristalsis returns. If the bowel was cleansed

preoperatively, it will not begin producing stool until a few days after the patient is eating again. Excessive amounts of gas are common during the first 2 weeks. Because this can be distressing to patients, assure them this is temporary.

In the first 24 to 48 hours after surgery, the amount of drainage from an ileostomy may be negligible. When peristalsis returns, ileostomy output may be as high as 1500 to 1800 mL/24 hr. If the small bowel is shortened by surgery, drainage may be greater. This is because the patient has lost the absorptive functions provided by the colon and the delay provided by the ileocecal valve. Observe the patient for signs and symptoms of fluid and electrolyte imbalance, particularly potassium, sodium, and fluid deficits. Over a period of days to weeks, the proximal small bowel adapts and increases fluid absorption. Then, feces will thicken to a paste-like consistency and the volume decrease to around 500 mL/day. Patients, especially those with Crohn's disease, are at risk for developing a bowel obstruction during the first 30 days postoperatively.

After an IPAA, initially, patients may have 4 to 6 stools or more daily. Adaptation over the next 3 to 6 months will result in fewer bowel movements. The patient can control defecation at the anal sphincter.

After intraoperative manipulation of the anal canal, transient incontinence of mucus may occur. Have the patient start Kegel exercises about 4 weeks after surgery to strengthen the pelvic floor and sphincter muscles (see Table 45.18). Perianal skin care is important to protect the epidermis from mucous drainage and maceration. Teach the patient to gently clean the skin with a mild cleanser, rinse well, and dry thoroughly. A moisture barrier ointment and a perineal pad may be used. Some patients have phantom rectal pain or still feel as if they need to have a bowel movement. This is normal and often subsides over time. Be astute in distinguishing phantom sensations from perineal abscess pain.

Colostomy Care

Two major aspects of nursing care for the patient with an ostomy are

(1) patient and caregiver teaching about ostomy care and (2) emotional support as the patient copes with a radical change in body image. With shorter hospital stays, patient teaching should focus on the critical aspects that patients need to master. Teaching must include (1) basic skills about managing the ostomy (e.g., changing the pouch), (2) diet, and (3) how to get help for problems. Home care and outpatient follow-up may be helpful, especially if there is access to a WOCN. Patient and caregiver teaching is outlined in Table 42.28. Nursing care for the patient with an ostomy is discussed in eNursing Care Plan 42.3 on the website.

An appropriate pouching system is vital to protect the skin and provide dependable stool collection. Most pouching systems have an adhesive skin barrier and a pouch to collect the feces. Most skin barriers are made of pectin-based or karaya mediums with hydrocolloid properties. Adhesion occurs in 2 phases. First, the wafer's backing has adhesive material that forms an immediate bond with the skin. Second, the hydrocolloids interface with the moisture on the skin to form a tighter seal. Caulking strips or "paste" around the stoma may help ensure a secure seal.

If the abdominal stoma site has bends or creases, it is hard to get a good seal and the skin barrier will pull away faster. Since excess weight of collected stool pulls the wafer away from the skin, empty ostomy bags when one-third full.

Use a transparent pouch in the initial postoperative period so that you can easily assess stoma viability and pouch application by the patient. Each time the pouch is changed, assess the skin for irritation. If the peristomal skin is irritated and raw, more products may have to be applied. Do not allow feces to remain on the skin or irritation will quickly develop. If a pouch has failed, it must be changed at once.

TABLE 42.28 Patient & Caregiver TeachingOstomy Self-Care

Include the following points when teaching the patient and/or caregiver

about self-care of an ostomy:

1. Explain what an ostomy is and how it functions.
2. Describe the underlying condition that resulted in the need for an ostomy.
3. Demonstrate and allow the patient and caregiver to practice the following activities:
    - Remove the old skin barrier, cleanse the skin, and correctly apply new skin barriers.
    - Apply, empty, clean, and remove the pouch.
    - Empty the pouch before it is one-third full to prevent leakage.
4. Irrigate the colostomy to regulate bowel elimination (optional).
5. Explain how to contact the wound, ostomy, and continence nurse (WOCN) with questions.
6. Describe how to obtain ostomy supplies.
7. Explain dietary and fluid management.
    - Identify a well-balanced diet and dietary supplements to prevent nutritional deficiencies.
    - Identify foods to avoid to reduce diarrhea or gas (see Table 42.29).
    - Promote fluid intake of least 3000 mL/day to prevent dehydration (unless contraindicated).
    - Increase fluid intake during hot weather, excess perspiration, and diarrhea to replace losses and prevent dehydration.
    - Describe symptoms of fluid and electrolyte imbalance.
    - Explain how to contact the dietitian with questions.
    - Explain how to recognize problems (fluid and electrolyte deficits, fever, diarrhea, skin irritation, stomal problems) and how to contact the HCP and/or WOCN.
8. Describe community resources to assist with emotional and psychologic adjustment to the ostomy.
9. Explain the importance of follow-up care.

10. Describe the ostomy's potential effects on sexual activity, social life, work, and recreation and ways to manage these changes.

Nursing Management

Ostomy Care

Although licensed practical/vocational nurses (LPN/VNs) and unlicensed assistive personnel (UAP) provide much of the ostomy care for patients with established ostomies, patients with new ostomies have complex needs and require frequent assessment, planning, intervention, and evaluation by a registered nurse (RN).

Role of Nursing Personnel

Registered Nurse (RN)

- Assess and document stoma and peristomal skin appearance.
- For patient with a new ostomy, assess patient's psychologic preparation for ostomy care.
- Choose appropriate ostomy pouching system for patient.
- Place ostomy pouching system for a new ostomy.
- Monitor the volume, color, and odor of the ostomy drainage.
- Develop plan of care for skin care around the ostomy.
- Teach ostomy care and skin care to patient and caregiver.
- Irrigate new colostomy, if indicated.
- Teach colostomy irrigation to patient and caregiver.
- Teach patient and caregivers about appropriate dietary choices (Table 42.29).
- Delegate to UAP:
    - Empty ostomy bag and measure liquid contents.
    - Place the ostomy pouching system for an established ostomy.
    - Assist stable patient with colostomy irrigation.

TABLE 42.29 Nutritional TherapyEffects of Food on Stoma Output

Odor Producing	Gas Forming	Diarrhea Causing
Alcohol	Beans	Alcohol
Asparagus	Beer	Beer
Broccoli	Cabbage family	Cabbage family
Cabbage	Carbonated beverages	Coffee
Eggs	Cheeses (strong)	Fruits (raw)
Fish	Onions	Green beans
Garlic	Sprouts	Spicy foods
Onions		Spinach

A colostomy in the ascending and transverse colon has semiliquid stools. Have the patient use a drainable pouch. A drainable pouch may last up to 4 to 7 days. A colostomy in the sigmoid or descending colon has semiformed or formed stools. The patient can use a drainable pouch or choose a disposable, closed end pouch changed every day. Optional charcoal filters can deodorize and automatically release flatus. They are available for both drainable and nondrainable pouches.

Another option is colostomy irrigation. It may be used to stimulate emptying of the colon. Patients who irrigate may not need a regular pouch as they may be able to regulate when the colon empties. Regularity is possible only when the stoma is in the distal colon. The patient may need to wear only a pad or small pouch over the stoma as little or no spillage should occur between irrigations. Irrigation requires manual dexterity and adequate vision. People who irrigate regularly should have ostomy bags available in case they develop diarrhea.

Teach the patient about the importance of fluids and a healthy diet. The effect of food on stoma output is individual. Most patients with colostomies can eat anything they want. However, some choose to avoid certain foods because of possible increased gas, odor, or stoma output (Table 42.29). Teach patients to chew their food very well to reduce the chance of blockage.

The patient can resume activities of daily living within 6 to 8 weeks but should avoid heavy lifting. The patient's physical condition determines when they can resume sports. Swimming with an ostomy pouch intact is not a problem. The patient can bathe and shower with or without the pouching system in place because water does not harm the stoma.

Ileostomy Care

Nursing care for a patient with an ileostomy is similar to that for a patient with a colostomy. Because the stool from an ileostomy is caustic to the skin, a secure pouching system is important. This is easier with stoma protrusion of at least 1 to 1.5 cm. When the stoma is flat, recessed, or in a crease, seepage occurs and results in altered skin integrity. The patient must wear a pouch at all times since regularity is not possible with an ileostomy. An open-ended, drainable pouch is best so drainage can be easily emptied. A drainable pouch usually lasts for 4 to 7 days.

Patients need to increase fluid intake to at least 2 to 3 L/day or more when there are excess fluid losses from heat and sweating. They may need to ingest added sodium. Patients must learn signs and symptoms of fluid and electrolyte imbalance so that they can take appropriate action.

The ileostomy patient is susceptible to obstruction because the lumen is less than 1 inch in diameter. It may narrow further at the point where the bowel passes through the fascia/muscle layer of the abdomen. Foods such as nuts, raisins, popcorn, coconut, mushrooms, olives, stringy vegetables, foods with skins, dried fruits, and meats with casings must be chewed extremely well before swallowing.

Psychologic Adaptation to an Ostomy

The patient's response to a new ostomy is highly individualized. Some have minimal difficulty and view their ostomy positively. It may be curative if their presenting condition was UC or a step toward remission if the diagnosis was CRC. Other patients may have a grief

reaction from the loss of a body part and a change in body image. They may be angry, depressed, or resentful. Anxiety and fear are normal. Concerns about stool leaking, odor, sounds of flatus, pouch reliability, and changes in normal lifestyle are all valid worries. Accurate information, emotional support, and mastering basic skills will help patients learn to live a full life with an ostomy and accept the changes in body appearance.

The patient's emotional state may limit the ability to take part in teaching and ostomy care. Discuss with the patient the psychologic impact of the stoma and its effect on body image and self-esteem. Help the patient identify ways of coping with depression and anxiety resulting from the illness, surgery, or postoperative problems. Support from the caregiver, family, and friends is vital. It reassures the patient of their value despite having the ostomy. Encourage patients to share their concerns and ask questions. Provide information in an easily understood manner and help patients develop confidence and competence in managing the stoma.

New ostomy patients will have questions on a variety of topics ranging from managing gas to intimacy to travel. Give the names and contact information for support groups. The Wound Ostomy Continence Nurses Society *(www.wocn.org)*, local support groups, and United Ostomy Associations of America *(www.ostomy.org)* provide practical information about living with an ostomy. Online support groups are also available. Most hospitals have a visitor's program. These programs give the patient and caregiver an opportunity to talk with a person who has adjusted well to an ostomy and had some of the same feelings and concerns they have.

Sexual Function

Help the patient understand if specific aspects of surgery and treatment have the potential for sexual dysfunction. Pelvic surgery can disrupt nerve and vascular supplies to the genitalia. Pelvic radiation can reduce blood flow to the pelvis by causing scarring in the small blood vessels. Chemotherapy can alter sexual function. The patient's overall physical health influences sexual desire. Generalized

fatigue caused by illness can decrease desire. Understanding this information can help patients plan the timing of sexual activity.

Problems with sexual dysfunction depend on the surgical technique used. Unfortunately, any pelvic surgery that removes the rectum has the potential of damaging the parasympathetic nerve plexus. The HCP should discuss the possibility with the patient.

For men, the main concern may be erection and ejaculation. Erection depends on intact parasympathetic and nonadrenergic noncholinergic nerves as well as adequate blood supply. Sympathetic nerve damage in the presacral area can disrupt the ability to ejaculate. This can occur with the APR procedure. Sexual dysfunction may be temporary and resolve in 3 to 12 months. Nerve-sparing surgical techniques are used when possible to preserve sexual function.

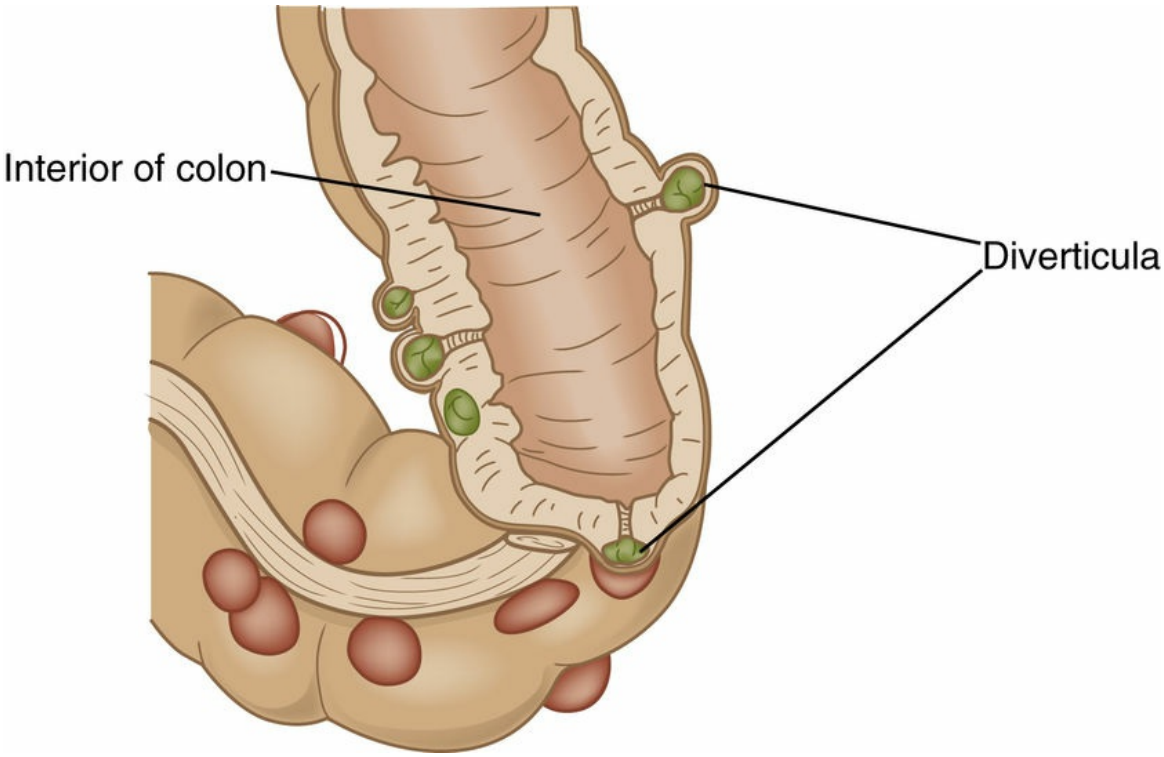

FIG. 42.13 Diverticula are outpouchings of the colon. When they become inflamed, the condition is diverticulitis. The inflammatory process can spread to the surrounding area in the intestine.

For women, nerve damage can result in vaginal dryness and

decreased sensation in the vagina and clitoris, making arousal and achieving orgasm more challenging. Experimenting with positions and using lubrication may help. A woman with an ostomy can still become pregnant.

Sexual function and sexuality concerns affect most patients with an ostomy. The patient with a stoma may fear rejection by a partner or that others will not find them desirable. Discuss sexuality and sexual function. Help the patient realize that it takes time to adjust to the pouch and to body changes before feeling secure with sexual functioning.

Teach the patient to empty the pouch before sexual activities. Some may apply a smaller pouch during sexual activity. Women may consider wearing open panties, a short slip, or similar lingerie. Men may consider wearing a wrap or cummerbund around the midsection to secure the pouch. There are many types of pouch covers that patients can make or purchase.

Diverticulosis and Diverticulitis

Diverticula are saccular dilations or outpouchings of the mucosa that develop in the colon (Fig. 42.13). Diverticulosis is the presence of multiple noninflamed diverticula. **Diverticulitis** is inflammation of 1 or more diverticula, resulting in perforation into the peritoneum. Clinically, diverticular disease covers a spectrum from asymptomatic, uncomplicated diverticulosis to diverticulitis with complications, such as perforation, abscess, fistula, and bleeding. Diverticula are common, especially in older adults, but most people never develop diverticulitis.

Etiology and Pathophysiology

Diverticula may occur anywhere in the GI tract but are most common in the left (descending, sigmoid) colon. They seem to occur at weak points in the intestinal wall, such as where the blood vessels pass through the muscle layer. The cause is thought to include both genetic and environmental factors. We think the main contributing factors are constipation and a lack of dietary fiber. The disease is more prevalent in Western, industrialized populations, where people tend to consume diets low in fiber and high in refined carbohydrates. Diverticula are uncommon in vegetarians. Other risk factors are obesity, inactivity, smoking, excess alcohol use, and NSAID use.

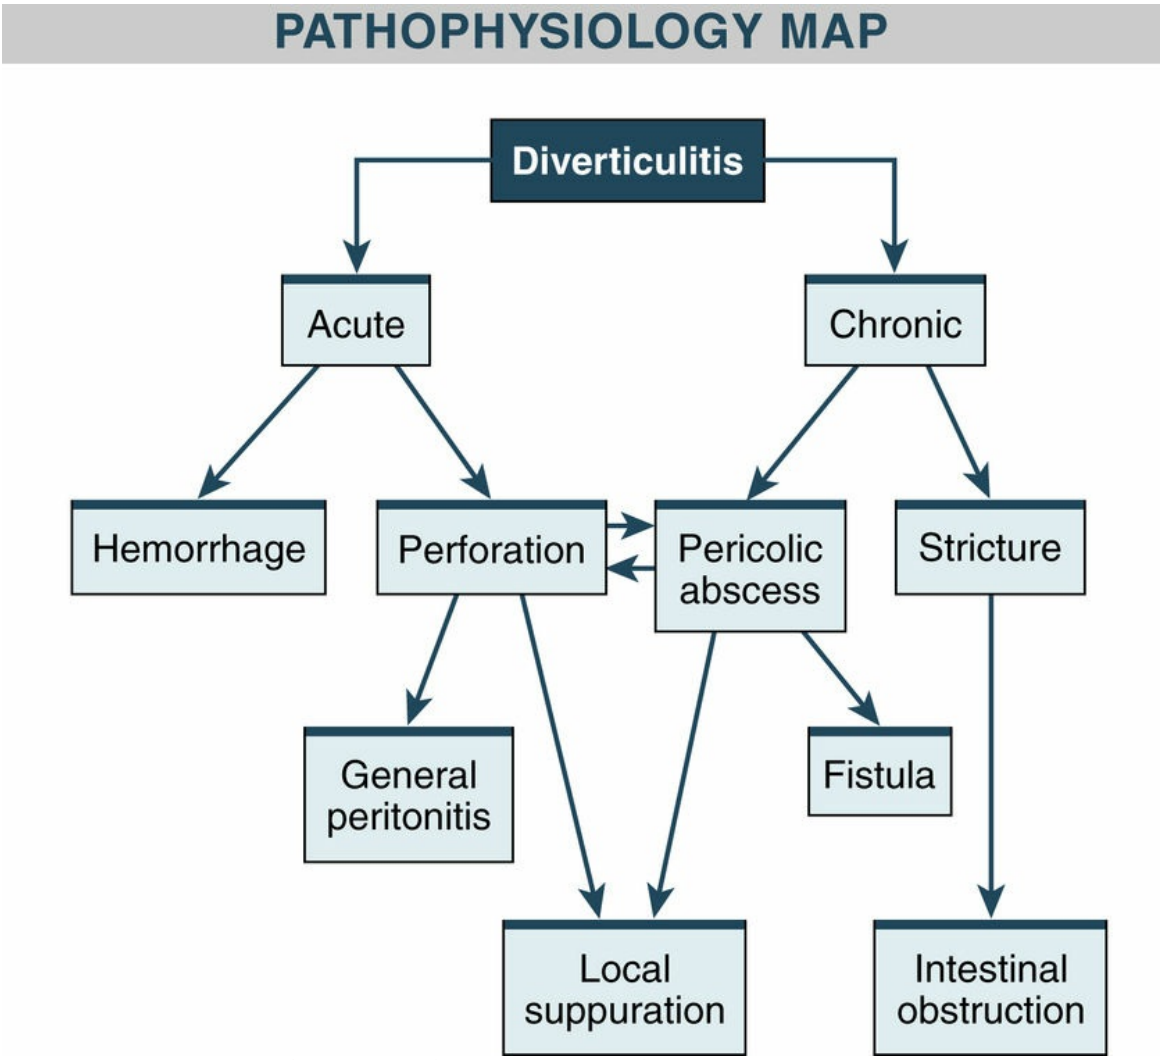

FIG. 42.14 Complications of diverticulitis.

Clinical Manifestations and Complications

Most patients with diverticulosis have no symptoms. Those with symptoms typically have abdominal pain, bloating, flatulence, and changes in bowel habits. In more serious situations, the diverticula bleed or diverticulitis develops. The most common signs and symptoms of diverticulitis are acute pain in the left lower quadrant, distention, decreased or absent bowel sounds, nausea, vomiting, and systemic symptoms of infection (fever, leukocytosis with a shift to the left). Older adults with diverticulitis may be afebrile, with a normal WBC count and little, if any, abdominal tenderness. Diverticulitis can

cause erosion of the bowel wall and perforation into the peritoneum (Fig. 42.14). A localized abscess develops when the body walls off the perforated area. Peritonitis develops if it cannot be contained. Bleeding can be extensive but usually stops spontaneously.

Diagnostic Studies

Diverticular disease can be asymptomatic. It is typically found during routine sigmoidoscopy or colonoscopy. Diagnosis of diverticulitis is based on the history and physical examination (Table 42.30). The preferred diagnostic test is a CT scan with oral contrast. Abdominal and chest x-ray rule out other causes of acute abdominal pain.

Interprofessional and Nursing Care

A high-fiber diet, mainly from fruits and vegetables with a decreased intake of fat and red meat, is the best way to prevent diverticular disease. High levels of physical activity seem to decrease the risk. Currently there is no evidence to support the theory that diverticulitis can be prevented by avoiding nuts and seeds.

In acute diverticulitis, the goal of treatment is to let the colon rest and the inflammation subside. Some patients can be managed at home with a clear liquid diet, bed rest, and analgesics. Hospitalization is needed if symptoms are severe, the patient is unable to tolerate oral fluids, there are systemic manifestations of infection (fever, significant leukocytosis), or the patient has co-morbid conditions (e.g., immunosuppression).

If hospitalized, the patient is kept on NPO status, placed on bed rest, and given IV fluids and antibiotics.[25] Observe for signs of abscess, bleeding, and peritonitis and monitor the WBC count. Give analgesics as needed. Maintain strict intake and output records. If needed, an NG tube with low suction will provide decompression. When the acute attack subsides, give oral fluids first and then progress the diet to semisolids.

Patients with reoccurring diverticulitis or complications, such as an abscess or obstruction, may need surgery. The usual surgical

procedure involves resection of the involved colon with a primary anastomosis. If the HCP is not able to anastomose the colon, the patient will have a temporary diverting colostomy. After the colon heals, the temporary colostomy can be taken down and the ends of the colon reconnected.

Provide the patient with diverticular disease with a full explanation of the condition. Patients who understand the disease process well and adhere to the prescribed regimen are less likely to have an exacerbation. Teach them the importance of following a high-fiber diet (Table 42.8) and encourage a fluid intake of at least 2 L/day. The patient does not have to avoid nuts, seeds, and corn.

A patient with diverticular disease should avoid increased intraabdominal pressure because it may precipitate an attack. Factors that increase intraabdominal pressure are straining at stool, vomiting, bending, heavy lifting, and wearing tight, restrictive clothing. Weight reduction is important for the obese person with diverticular disease.

TABLE 42.30 Interprofessional CareDiverticulosis and Diverticulitis

Diagnostic Assessment

- History and physical examination
- Testing of stool for occult blood
- CBC
- Urinalysis
- Barium enema
- Colonoscopy with biopsy
- Blood culture
- CT scan with oral contrast
- Abdominal and/or chest x-ray

Management
Conservative Therapy

- High-fiber diet
- Dietary fiber supplements
- Stool softeners
- Anticholinergics
- Clear liquid diet
- Weight reduction (if overweight)

Acute Care: Diverticulitis

- Antibiotic therapy
- NPO status
- IV fluids
- Analgesics
- NG suction
- Surgery
- Possible resection of involved colon
- Possible temporary colostomy

Fistulas

A **fistula** is an abnormal tract between 2 hollow organs or a hollow organ and the skin. Fistulas are named by the track that they take from one body part to another. For example, an enterocutaneous fistula is an opening between the small intestine and skin. An enterovaginal fistula is between the small intestine and vagina, allowing stool and gas to drain through the vagina.

A GI fistula occurs between the lumen of the GI tract and another organ. GI fistulas are a serious complication associated with increased morbidity and mortality, extended hospital stays, and increased costs. Most fistulas occur after surgery or are associated with IBD, cancer, or radiation. Fistulas can form with diverticulitis, pancreatitis, and trauma.[26] Fistulas are classified as simple or complex and by the amount of output. A simple fistula has only one short, direct tract. A complex fistula is associated with an abscess, involves multiple organs, and may open into the base of a wound. High-output fistulas drain more than 500 mL/day, moderate-output fistulas drain 200 to 500 mL/day, and low-output fistulas drain less than 200 mL/day.

Fever and abdominal pain are early signs of a fistula. Other manifestations depend on the type of fistula. With an enterocutaneous fistula, there may be pus or intestinal contents draining through the skin opening. Patients with a colocutaneous (colon to skin) fistula may have stool or pus draining through the opening. If a colovesical (colon to urinary tract) fistula is present, manifestations include fecaluria (passing stool with urination), recurrent urinary tract infections, dysuria, and hematuria.

Interprofessional and Nursing Care

A draining fistula can be disheartening for the patient and caregiver and a time-consuming challenge for HCPs. Managing a fistula requires (1) identifying the fistula tract, (2) maintaining fluid and electrolyte balance, (3) controlling infection, (4) protecting the

surrounding skin, (5) managing output, and (6) providing nutritional support. Most fistulas heal spontaneously. Surgery may be needed to treat the complications.

Appropriate fluid and electrolyte replacement can be challenging, especially when the patient has a high-output fistula. Monitor the volume of fistula output as this guides replacement therapies and nutritional support. Assess the character of the drainage, noting the color, consistency, and odor. Monitor laboratory values. Low serum levels of potassium, magnesium, and phosphorus from the loss of GI fluids are common. Give IV fluids and electrolyte replacement as ordered. Keep an accurate intake and output record. Many patients are NPO as this reduces intestinal output. They may receive acid suppression with a proton-pump inhibitor and antimotility agents (e.g., loperamide). Cholestyramine and octreotide decrease GI secretions.[26] Measure vital signs frequently and be alert for signs of dehydration.

Malnutrition is a significant problem, particularly if the patient is NPO or has a small intestinal fistula. Consult a dietitian. High-calorie, high-protein PN or EN is needed to provide enough calories and protein to replace losses and support healing.[26] Many patients need trace element (e.g., copper, zinc, magnesium) and vitamin supplements.

Maintaining skin integrity and optimizing healing is essential. Consult a WOCN if available. Low-output fistulas may

Check Your Practice

A 51-yr-old woman is 4 days postop after a proctocolectomy for ulcerative colitis. You note 2.5 cm of erythema in the center of her incision with heavy, foul-smelling tan drainage pooling on her skin. Suspecting she is developing an enterocutaneous fistula, you notify the HCP and WOCN.

- What will you do to protect her skin?

be managed with a simple absorbent dressing. A high-output enterocutaneous fistula often needs advanced techniques, including specialty pouches; barrier creams, powders, and sealants to protect the skin; and negative pressure wound therapy.

Hernias

A **hernia** is a protrusion of the viscus (e.g., the intestine) through an abnormal opening or a weakened area in the wall of the cavity in which it is normally contained. A hernia may occur in any part of the body, but it usually occurs within the abdominal cavity. *Reducible* hernias easily return into the abdominal cavity. Reducing can be done manually or may occur spontaneously when the person lies supine. *Irreducible,* or *incarcerated,* hernias cannot be placed back into the abdominal cavity. They have abdominal contents trapped in the opening. Strangulation occurs if the blood supply to the contents trapped in an irreducible hernia becomes compromised. The result is an acute intestinal obstruction. Gangrene and necrosis of the hernia contents are possible.

Gender Differences

Hernia

Men

- Inguinal hernias are more common in men.
- Men have a 25% lifetime risk for developing a groin hernia.
- Men undergo 90% of the 850,000 groin hernia repairs done annually in the United States.

Women

- Femoral hernias are more common in women, particularly older women.
- Women have less than a 5% lifetime risk for developing a groin hernia.

Types

An *umbilical hernia* occurs when the rectus muscle is weak (as with obesity) or the umbilical opening does not close after birth (Fig. 42.15, *A*). A *femoral hernia* occurs when there is a protrusion through the femoral ring into the femoral canal. It appears as a bulge below the inguinal ligament. Femoral hernias easily strangulate (Fig. 42.15, *B*).

The *inguinal hernia* is the most common type of hernia and occurs at the point of weakness in the abdominal wall where the spermatic cord (in men) or the round ligament (in women) emerges (Fig. 42.15, *C*).

Ventral or *incisional hernias* are due to weakness of the abdominal wall at the site of a previous incision. They occur most often in those who are obese, have had multiple surgical procedures in the same area, or have had inadequate wound healing because of poor nutrition or infection. Peristomal hernias are ventral hernias.

Clinical Manifestations

Pain is the classic symptom of a hernia. It may worsen with activities that increase intraabdominal pressure, such as lifting, coughing, and straining. A hernia may be readily visible, especially when the person tenses the abdominal muscles. If the hernia becomes strangulated, the patient will have severe pain and symptoms of a bowel obstruction, such as vomiting, cramping abdominal pain, and distention.

Interprofessional and Nursing Care

Diagnosis of a hernia is usually based on history and physical examination findings. Ultrasound, CT, and MRI can help identify a hernia and determine the contents. Laparoscopic surgery is the treatment of choice. The surgical repair of a hernia, known as a *herniorrhaphy,* is usually an outpatient procedure. Reinforcing the weakened area with wire, fascia, or mesh is known as a *hernioplasty*. Emergency surgery is needed for strangulated hernias or inflamed, irreducible hernias. Surgery for strangulated hernias involves resecting the involved area with possible placement of a temporary

colostomy.

After a hernia repair, the patient may have problems voiding. Measure intake and output. Observe for a distended bladder. Scrotal edema is a painful complication after an inguinal hernia repair. A scrotal support with application of an ice bag and elevating the scrotum may help relieve pain and edema. Encourage deep breathing, but not coughing. Teach patients to splint the incision and keep their mouths open when coughing or sneezing is unavoidable. The patient may be restricted from heavy lifting (>10 lb) for 6 to 8 weeks.

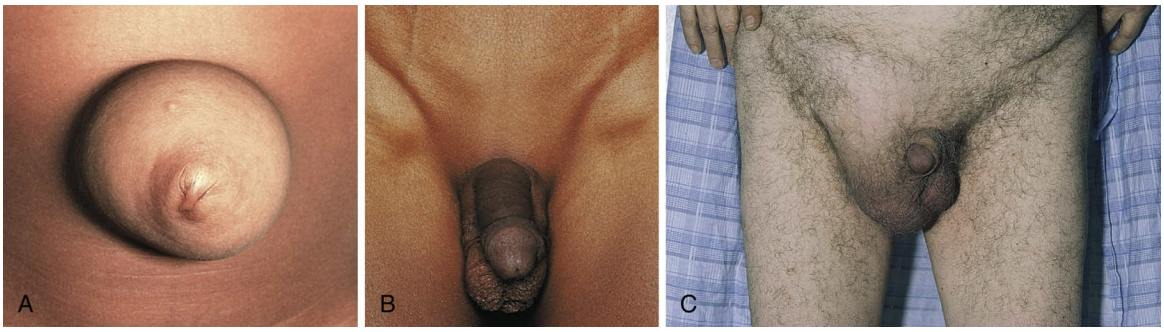

FIG. 42.15 **A,** Umbilical hernia. **B,** Femoral hernias (note swelling below the inguinal ligaments). **C,** Right inguinal hernia. *A* and *B,* From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, Philadelphia, 2012, Saunders. *C,* From Swartz MH: *Textbook of physical diagnosis: History and examination,* ed 6, Philadelphia, 2010, Saunders.

Malabsorption Syndrome

Malabsorption results from impaired absorption of fats, carbohydrates, proteins, minerals, and vitamins. The stomach, small intestine, liver, and pancreas regulate normal digestion and absorption. Digestive enzymes ordinarily break down nutrients so that absorption can take place. Malabsorption may occur if this process is interrupted at any point. Several problems can cause malabsorption (Table 42.31). Lactose intolerance is the most common malabsorption disorder, followed by IBD, celiac disease, tropical sprue, and cystic fibrosis.

The most common signs of malabsorption are weight loss, diarrhea, and **steatorrhea** (bulky, foul-smelling, yellow-gray, greasy stools with putty-like consistency) (Table 42.32). Steatorrhea does not occur with lactose intolerance.

Tests to determine the cause of malabsorption include qualitative examination of stool for fat (e.g., Sudan III stain), a 72-hour stool collection for quantitative measurement of fecal fat, serologic testing for celiac disease, and fecal elastase testing to determine if there is pancreatic insufficiency. Near-infrared reflectance analysis (NIRA) for fecal fat is available at some centers in the United States.

Other diagnostic studies include a CT scan and endoscopy to obtain a small bowel biopsy specimen. A small bowel barium enema can identify abnormal mucosal patterns. Capsule endoscopy is useful in assessing the small intestine for changes in mucosal integrity and inflammation. Tests for carbohydrate malabsorption include the D-xylose test and the lactose tolerance test. Laboratory studies include a CBC, measurement of prothrombin time (to see if vitamin K absorption is adequate), serum vitamin A and carotene levels, serum electrolytes, cholesterol, and calcium. Treatment depends on the cause.

TABLE 42.31 Causes of Malabsorption

Bacterial Proliferation

- Parasitic infection
- Tropical sprue

Biochemical or Enzyme Deficiencies

- Biliary tract obstruction
- Chronic pancreatitis
- Cystic fibrosis
- Lactase deficiency
- Pancreatic insufficiency
- Zollinger-Ellison syndrome

Disturbed Lymphatic and Vascular Circulation

- Heart failure
- Ischemia
- Lymphangiectasia
- Lymphoma

Small Intestinal Mucosal Disruption

- Celiac disease
- Crohn’s disease
- Whipple’s disease

Surface Area Loss

- Billroth II gastrectomy

- Distal ileal resection, disease, or bypass
- Short bowel syndrome

Celiac Disease

Celiac disease is an autoimmune disease that causes damage to the small intestinal mucosa. It is triggered by ingesting gluten, a protein in wheat, barley, and rye.[27] It can occur at any age and has a wide variety of symptoms. *Celiac sprue* and *gluten-sensitive enteropathy* are other names for celiac disease.

Celiac disease is not the same disease as *tropical sprue,* a chronic disorder occurring primarily in tropical areas. Tropical sprue causes progressive disruption of jejunal and ileal tissue, resulting in nutrition problems. It is treated with folic acid and tetracycline.

TABLE 42.32 Manifestations of Malabsorption

Manifestations	Pathophysiology
Cardiovascular	
Hypotension	Dehydration
Peripheral edema	Protein malabsorption, protein loss in diarrhea
Tachycardia	Hypovolemia, anemia
Gastrointestinal	
Diarrhea	Impaired absorption of water, sodium, fatty acids, bile salts, and carbohydrates
Flatulence	Bacterial fermentation of unabsorbed carbohydrates
Glossitis, cheilosis, stomatitis	Deficiency of iron, riboflavin, cobalamin, folic acid, and other vitamins
Steatorrhea	Undigested and unabsorbed fat
Weight loss	Malabsorption of fat, carbohydrates, and protein leading to loss of calories. Marked reduction in caloric intake or increased use of calories
Hematologic	
Anemia	Impaired absorption of iron, cobalamin, and folic acid
Hemorrhagic tendency	Vitamin C deficiency. Vitamin K deficiency inhibiting production of clotting factors II, VII, IX, and X
Integumentary	
Brittle nails	Iron deficiency
Bruising	Vitamin K deficiency
Dermatitis	Fatty acid deficiency, zinc deficiency, niacin, and other vitamin deficiencies
Hair thinning and loss	Protein deficiency
Musculoskeletal	
Bone pain	Osteoporosis from impaired calcium absorption. Osteomalacia secondary to hypocalcemia, hypophosphatemia, inadequate vitamin D
Muscle wasting	Protein malabsorption
Tetany	Hypocalcemia, hypomagnesemia
Weakness, muscle cramps	Anemia, electrolyte depletion (especially potassium)
Neurologic	
Altered mental status	Dehydration
Night blindness	Thiamine deficiency, vitamin A deficiency
Paresthesias	Cobalamin deficiency
Peripheral neuropathy	Cobalamin deficiency

Celiac disease affects about 1 in 100 people worldwide.[28] First-degree relatives of someone with celiac disease have a 4% to 15% chance of developing the disorder. It is associated with other autoimmune diseases, particularly rheumatoid arthritis, type 1 diabetes, and thyroid disease. It is slightly more common in women. Symptoms often begin in childhood.

Etiology and Pathophysiology

Three factors necessary for developing celiac disease are genetic predisposition, gluten ingestion, and an immune-mediated response.

Genetic Link

About 90% to 95% of patients with celiac disease have human leukocyte antigen (HLA) allele HLA-DQ2. The other 5% to 10% have HLA-DQ8. However, not everyone with these genetic markers develops celiac disease, and some people with celiac disease do not have these HLA alleles.

As with other autoimmune diseases, the tissue destruction that occurs with celiac disease is the result of chronic inflammation. Gluten contains specific peptides called *prolamines.* Partial digestion of gluten releases the prolamine peptides, which are absorbed into the intestinal submucosa. In genetically susceptible persons, the peptides bind to HLA-DQ2 and/or HLA-DQ8 and activate an inflammatory response. Inflammation damages the microvilli and brush border of the small intestine, decreasing the amount of surface area available for nutrient absorption. Damage is most severe in the duodenum, probably because it has more exposure to gluten. The inflammation lasts as long as gluten ingestion continues.

Clinical Manifestations

Classic manifestations of celiac disease include foul-smelling diarrhea, abdominal pain, flatulence, abdominal distention, and malnutrition.[27] Some people have no obvious GI symptoms and may instead have atypical signs and symptoms. These include joint pain, osteoporosis, dental enamel hypoplasia, fatigue, peripheral neuropathy, and reproductive problems. An intensely pruritic, vesicular skin lesion, called *dermatitis herpetiformis,* is sometimes present and occurs as a rash on the buttocks, scalp, face, elbows, and knees.

Protein, fat, and carbohydrate absorption is affected. Weight loss, muscle wasting, and other signs of malnutrition may be present. Abnormal serum folate, iron, and cobalamin levels can occur. Iron-deficiency anemia is common. Patients may have lactose intolerance and need to refrain from lactose-containing products until the disease is under control. Inadequate calcium intake and vitamin D absorption can lead to decreased bone density and osteoporosis.

Diagnostic Studies

Early diagnosis and treatment can prevent complications. Screening is recommended for close relatives of patients known to have the disease, young patients with decreased bone density, those with anemia if other causes are ruled out, and certain autoimmune diseases.

Celiac disease is confirmed by a combination of findings from the history and physical examination, serology testing, and histologic analysis of small intestine biopsies.[27] Have the patient complete diagnostic testing before starting a gluten-free diet, since the diet will change the results. Serologic testing for immunoglobulin A (IgA) antitissue transglutaminase and IgA endomysial antibody offer good sensitivity and specificity. Histologic evidence is the gold standard for confirming the diagnosis. Biopsies show flattened mucosa and noticeable losses of villi. Genotyping involves testing for HLA-DQ2 and/or HLA-DQ8 antigens.

Interprofessional and Nursing Care

A gluten-free diet (Table 42.33) is the only effective treatment for celiac disease. Most patients need to stay on a gluten-free diet for the rest of their lives. Periodic nutrition evaluations and laboratory monitoring are done to monitor for anemia and malnutrition. The patient should undergo bone density screening every 2 to 3 years.[28]

Refer all patients for a dietary consultation. You can work with a dietitian to teach the patient how to eat a nutritionally adequate diet while staying within a budget. Teach the patient to avoid wheat, barley, oats, and rye products. Although pure oats do not contain gluten, wheat, rye, and barley can contaminate oat products during the milling process. Teach the patient to read medication and food labels. Some medications and many food additives, preservatives, and stabilizers contain gluten. The patient needs to know where to buy gluten-free products. Good sources are health food stores, many grocery stores, and through Internet sites.

Maintaining a gluten-free diet can be hard, particularly when

traveling or eating in restaurants. Many with celiac disease describe feeling embarrassed or like a burden when having to discuss gluten-free menu options with restaurant staff or when dining in other's homes. Mobile phone users will find apps listing gluten-free menu options at popular restaurants helpful. Many restaurants now indicate which food choices are gluten free. The Celiac Sprue Association website *(www.csaceliacs.info)* and the Celiac Disease Foundation *(www.celiac.org)* provide suggestions for maintaining a gluten-free diet and living with celiac disease.

TABLE 42.33 Nutritional TherapyCeliac Disease

Foods to Eat

- Butter
- Cheese, cottage cheese
- Coffee, tea, and cocoa
- Corn tortillas
- Eggs
- Flax, corn, and rice
- Fresh fruits
- Gluten-free flour breads, crackers, pasta, and cereals
- Meat, fish, poultry (not marinated or breaded)
- Peanut butter
- Potatoes
- Soy products
- Tapioca
- Unflavored milk
- Yogurt

Foods to Avoid

- Baked goods, including muffins, cookies, cakes, pies
- Barley
- Bread, including wheat bread, white bread, “potato” bread
- Flour
- Gluten stabilizers
- Oats
- Pasta, pizza, bagels
- Rye
- Wheat

Lactase Deficiency

Lactase deficiency is a condition in which the lactase enzyme is deficient or absent. Lactase is the enzyme that breaks down lactose into 2 simple sugars: glucose and galactose. Primary lactase insufficiency is often a result of genetic factors. Certain ethnic or racial groups, especially those with Asian or African ancestry, develop low lactase levels in childhood. Less common causes include low lactase levels resulting from premature birth and congenital lactase deficiency, a rare genetic disorder. Lactose malabsorption can occur when conditions leading to bacterial overgrowth promote lactose fermentation in the small bowel or when intestinal mucosal damage interferes with absorption. The latter occurs with IBD and celiac disease.

Symptoms of lactose intolerance include bloating, flatulence, cramping abdominal pain, and diarrhea. Diarrhea results from the excess, undigested lactose in the small intestine attracting water molecules, which prevents them from being properly absorbed. Symptoms generally occur within 30 minutes to several hours after drinking a glass of milk or ingesting a milk product. Lactose intolerance is diagnosed with a lactose tolerance test, a lactose hydrogen breath test, or genetic testing.

Treatment consists of eliminating lactose from the diet by avoiding milk and milk products, and/or replacing lactase with commercially available preparations. A lactose-free diet generally results in prompt resolution of symptoms. Many lactose-intolerant persons are aware of their condition. They likely have been avoiding lactose-containing products and using lactose-free milk products. Lactase enzyme (Lactaid) is available as an over-the-counter (OTC) product. It breaks down the lactose present in ingested milk. A number of milk products treated with lactase enzyme are readily available.

The diet may gradually advance to a low-lactose diet as tolerated. Many lactose-intolerant persons may not have symptoms if they have lactose in small amounts. Cheese has less lactose than milk and ice

cream. Live culture yogurt has less lactose because the bacteria help digest the lactose. Teach the patient to read labels to detect any hidden sources of milk products. Some people tolerate lactose better if taken with meals. Teach the patient that adhering to the diet is important. Since avoiding milk and milk products can lead to calcium deficiency, supplements may be needed to prevent osteoporosis.

Short Bowel Syndrome

Short bowel syndrome (SBS) is a condition in which the small intestine does not have enough surface area to absorb enough nutrients. This leaves the person unable to meet energy, fluid, electrolyte, and nutritional needs to stay healthy on a normal diet. Causes of SBS include diseases that damage the intestinal mucosa, surgical removal of too much small intestine (e.g., with Crohn's disease, cancer), and congenital defects.

SBS is likely to develop in patients with a loss of around 75% of the small intestine. The length and area of the remaining small intestine and the presence of the colon affect the patient's outcome. If the terminal ileum and ileocecal valve are intact, the remaining intestine undergoes adaptive changes that are most pronounced in the ileum. The villi and crypts increase in size, and the absorptive capacity of the remaining intestine increases. When the colon is present, fluid and electrolyte absorption increase. Those with an end jejunostomy often have little to no adaptation.

Clinical Manifestations

SBS results in reduced nutrient, fluid, and electrolyte absorption. This leads to dehydration, weight loss, diarrhea, malnutrition, vitamin deficiencies, and electrolyte imbalances. Other manifestations include abdominal pain, flatulence, and steatorrhea. The patient may develop lactase deficiency and bacterial overgrowth. Those who do not receive appropriate nutrition may have manifestations associated with specific deficiencies. For example, patients may have peripheral neuropathy from vitamin B_{12}, vitamin E, copper, or thiamine deficiencies or fatigue due to anemia from decreased folate or iron.[29]

Interprofessional Care

The treatment goals are that the patient will have fluid and electrolyte

balance, normal nutritional status, and control of diarrhea. The main treatment is nutritional support involving PN, EN, medications, and a tailored diet. In the immediate period after massive bowel resection, patients receive PN to replace fluid, electrolyte, and nutrient losses and to rest the bowel. Those with severe resections will need PN indefinitely. EN and a normal diet are gradually resumed to stimulate the remaining intestine to function better. Some can eventually stop PN.

Refer the patient to a dietitian. The ideal diet is high in protein and complex carbohydrates and low in fat and concentrated sweets. Oral supplements of calcium, zinc, and multivitamins may be needed. Soluble fiber is encouraged if the colon is present. The patient should eat at least 6 small meals per day to increase the time of contact between food and the intestine. Oral intake may be supplemented with elemental nutrient formulas and tube feeding during the night. Patients with severe malabsorption may need PN (see Chapter 39).

Patients often take multiple medications to help control fecal output. PPIs, H_2 blockers, α-adrenergic receptor agonists (e.g., clonidine), or octreotide reduce excess fluid secretion. Opioid antidiarrheal drugs decrease intestinal motility (Table 42.2). For patients who have limited ileal resections, cholestyramine reduces diarrhea resulting from unabsorbed bile acids by increasing their excretion in feces. Bile acids stimulate intestinal fluid secretion and reduce colonic fluid absorption. Antibiotic therapy is used if bacterial overgrowth is contributing to diarrhea.

Three drugs have FDA approval for the treatment of SBS: somatropin, glutamine, and teduglutide (Gattex). Somatropin enhances intestinal adaption and increases the flow of water, electrolytes, and nutrients into the bowel. Glutamine improves intestinal absorption. Teduglutide increases the surface area of the intestine and improves intestinal absorption of fluids and nutrients.

Intestinal transplantation is done at a few specialized transplant centers in the United States. It is considered the only long-term treatment option for patients with intestinal failure who have significant complications from PN or nutrition failure. The leading

cause of intestinal failure is SBS. Transplantation may include the intestine alone, liver and intestine, or multivisceral combinations (stomach, duodenum, jejunum, ileum, colon, and/or pancreas).

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are a rare form of cancer that originates in cells found in the wall of the GI tract. These cells, known as *interstitial cells of Cajal,* help control the movement of food and liquid through the stomach and intestines. About 60% of GISTs are in the stomach; 25% are in the small intestine; and the rest are in the esophagus, colon, or peritoneum.[30] Most GISTs occur in people between the ages of 50 and 70. While the exact cause of GISTs is unknown, genetic mutations likely play a role. A few GISTs occur in people with familial mutations in either the KIT or platelet-derived growth factor receptor a (PDGFRa) or in those with neurofibromatosis type 1.[30]

The manifestations of GISTs depend on the part of the GI tract affected. Early manifestations are often subtle, including early satiety, fatigue, bloating, nausea or vomiting, and a change in bowel habits. Because these manifestations are like those of many other GI problems, early detection of the cancer is difficult. Later manifestations may include GI bleeding and obstruction caused by growth of the tumor. GISTs are often found during imaging for other problems. Diagnosis is based on histologic examination of biopsied tissue. Endoscopic ultrasound, CT, or MRI are used to determine the extent of disease.

Surgery offers the only permanent cure. Often, though, GISTs have metastasized by the time of diagnosis or commonly recur. GISTs are unresponsive to conventional chemotherapy. The discovery of genetic mutations led to the development of tyrosine kinase inhibitor drugs (e.g., imatinib mesylate [Gleevec], sunitinib, regorafenib [Stivarga]) that are effective against certain GISTs.[31]

Anorectal Problems

Hemorrhoids

Hemorrhoids are dilated hemorrhoidal veins. They may be internal (occurring above the internal sphincter) or external (occurring outside the external sphincter) (Figs. 42.16 and 42.17). In affected persons, hemorrhoids appear periodically, depending on the amount of anorectal pressure.

Etiology and Pathophysiology

Hemorrhoids develop because of increased anal pressure and weakening of the connective tissue that supports the hemorrhoidal veins. Weakened supporting tissue allows for downward displacement of the hemorrhoidal veins, causing them to dilate. Blood flow through the veins of the hemorrhoidal plexus is impaired. An intravascular clot in the venule results in a thrombosed external hemorrhoid. Many factors increase the risk for hemorrhoids, including pregnancy, constipation, straining to defecate, diarrhea, heavy lifting, prolonged standing and sitting, obesity, and ascites.[31]

Clinical Manifestations

Hemorrhoids are the most common reason for bleeding with defecation. Internal hemorrhoids most often cause painless bright red bleeding with stools, on the toilet paper, or dripping into the toilet water. If internal hemorrhoids become constricted, the patient will report pain. Internal hemorrhoids can prolapse into the anal canal or externally. Symptoms of prolapse include pressure with defecation and a protruding mass.

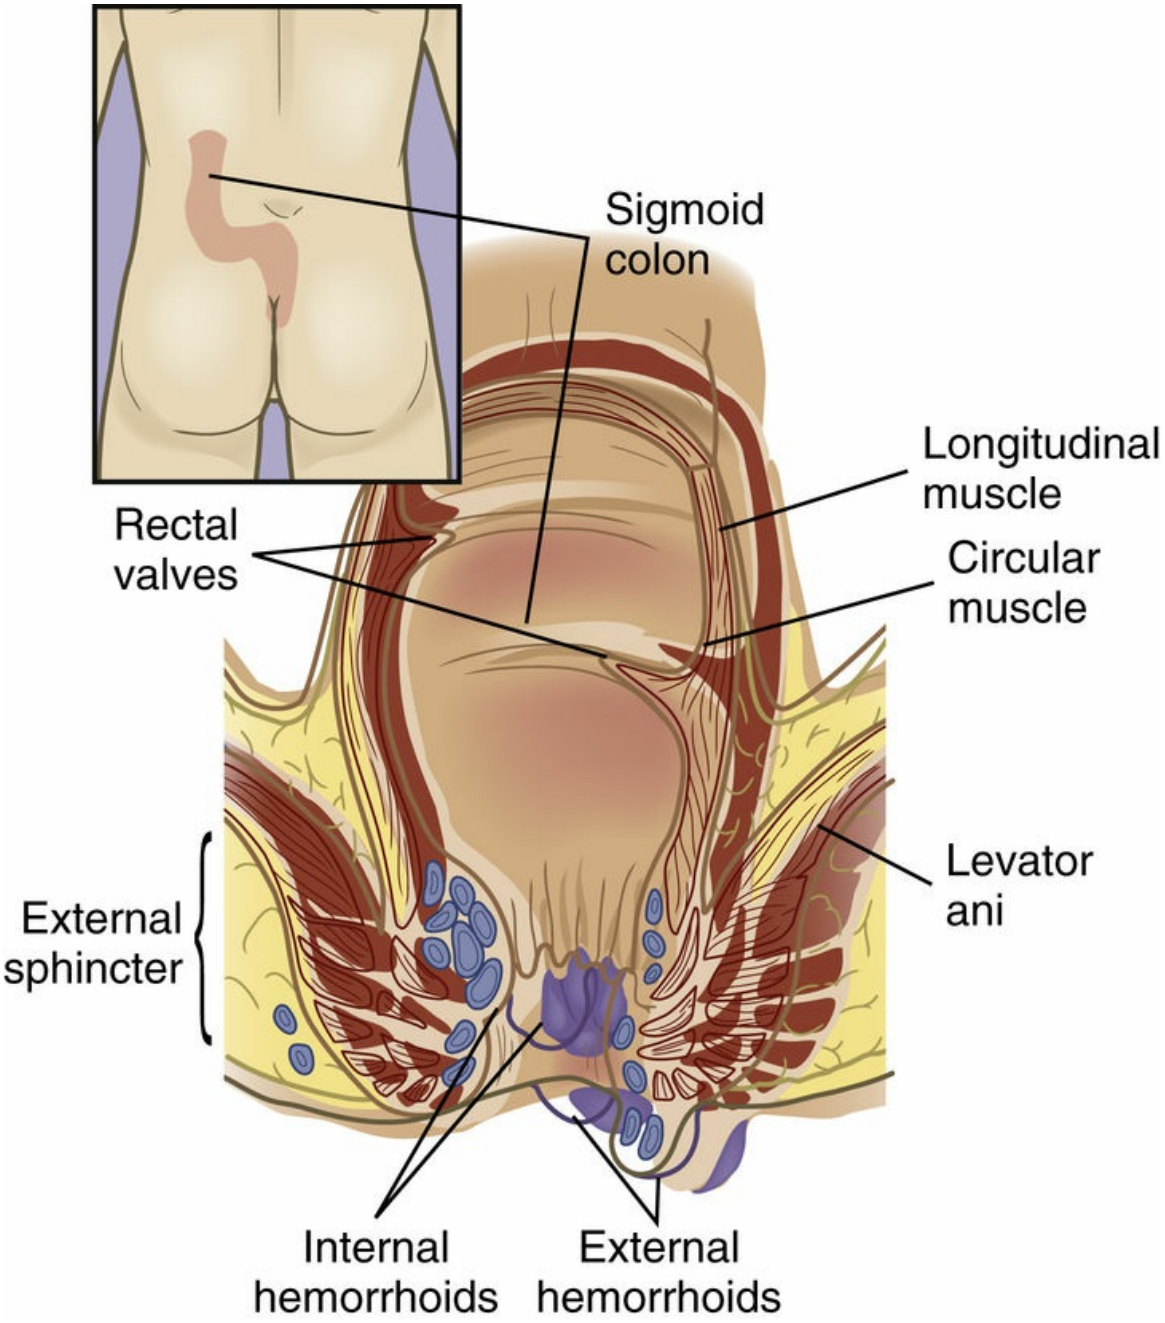

FIG. 42.16 Anatomic structures of the rectum and anus with external and internal hemorrhoids.

FIG. 42.17 Thrombosed external hemorrhoids.
From Townsend CM, Beauchamp RD, Evers BM, et al: *Sabiston textbook of surgery: The biological basis of modern surgical practice,* ed 19, Philadelphia, 2012, Saunders.

External hemorrhoids are reddish blue and seldom bleed. There may be itching, burning, and edema. They usually do not cause pain unless thrombosis (blood clots) is present. Thrombosed hemorrhoids are a bluish-purple tinge and palpable at the anal orifice. They usually cause pain and inflammation. The clot can erode through the overlying stretched skin, causing bleeding with defecation. Constipation or diarrhea can worsen these symptoms.

Diagnostic Studies and Interprofessional Care

It is easy to diagnose external hemorrhoids visual inspection and digital examination. Digital examination, anoscopy, and sigmoidoscopy are used to diagnose internal hemorrhoids.

Therapy is based on the cause and the patient's symptoms. A high-

fiber diet and increased fluid intake prevent constipation and reduce straining, which allows engorgement of the veins to subside. The resulting stool bulk may decrease stool leakage and itching. Ointments, such as dibucaine; creams, suppositories, and impregnated pads that contain antiinflammatory agents (e.g., hydrocortisone); or astringents and anesthetics (e.g., witch hazel, benzocaine), may shrink the mucous membranes and relieve discomfort. Topical corticosteroids use should be limited to 1 week or less to prevent side effects, such as contact dermatitis and mucosal atrophy. Stool softeners can keep the stools soft. Sitz baths help relieve pain.

External hemorrhoids are usually managed by conservative therapy unless they become thrombosed. For internal hemorrhoids, nonsurgical approaches (rubber band ligation, infrared coagulation, sclerotherapy, laser treatment) are options.[31] Rubber band ligation is the most widely used technique. The HCP inserts an anoscope to identify the hemorrhoid and then ligates it with a rubber band. The rubber band around the hemorrhoid constricts circulation. The tissue becomes necrotic, separates, and sloughs off. There is some local discomfort with this procedure, but no anesthetic is needed.

A *hemorrhoidectomy* is the surgical excision of hemorrhoids. Surgery is needed when there is marked prolapse, excessive pain or bleeding, or large or multiple thrombosed hemorrhoids. After removing the hemorrhoids, the tissue is either sutured and the wound heals by primary intention or the area is left open and healing takes place by secondary intention.

Nursing Management: Hemorrhoids

Conservative nursing management includes teaching ways to prevent constipation and to avoid prolonged standing or sitting and proper use of OTC drugs for hemorrhoidal symptoms. Teach the patient to seek medical care for severe symptoms of hemorrhoids (e.g., excessive pain and bleeding, prolapsed hemorrhoids). Sitz baths (15 to 20 minutes, 2 or 3 times each day) may help to reduce discomfort and swelling associated with hemorrhoids.

Nursing care after a hemorrhoidectomy focuses on pain control and promoting wound healing. Be aware that although the procedure is minor, the pain is severe and feared by many. There are several analgesic regimens, using a combination of medications. Most patients receive multimodal analgesia. This may involve an opioid and NSAID in conjunction with topical preparations that provide anesthesia or reduce internal sphincter spasms, such as topical lidocaine, 2% diltiazem, and glyceryl trinitrate.

The patient usually dreads the first bowel movement and often resists the urge to defecate. Give pain medication before the bowel movement to reduce discomfort. Stool softeners (e.g., docusate) and bulking agents are given to help form a soft, bulky stool that is easier to pass. If the patient does not have a bowel movement within 2 or 3 days, an oil-retention enema is given.

Sitz baths are started 1 or 2 days after surgery and continued for 1 to 2 weeks. A warm sitz bath provides comfort and keeps the anal area clean. A sponge ring in the sitz bath helps relieve pressure on the area. Initially, do not leave the patient alone because of the possibility of weakness or fainting. Teach the patient that pressure relief cushions are acceptable to ease discomfort when sitting. Tell the patient not to use a pressure relief ring or “doughnut” because they can reduce blood flow to the area.

The patient may have packing in the rectum to absorb drainage, with a T-binder to hold the dressing in place. Packing is usually removed on the first or second postoperative day. Assess for rectal

bleeding, especially in patients taking clopidogrel or oral anticoagulants. The patient may be embarrassed when the dressing is changed. Provide as much privacy as possible.

Teach the patient care of the anal area, symptoms of complications (especially bleeding), and ways to avoid constipation and straining. Hemorrhoids may recur. Sometimes, anal strictures develop, requiring dilation. Regular checkups are important to prevent any further problems.

Anal Fissure

An *anal fissure* is a skin ulcer or a crack in the lining of the anal wall. Many times, the inciting event is trauma from passing hard stools. Other fissures are related to trauma (anal intercourse, foreign body insertion, such as endoscope), local infection (syphilis, gonorrhea, *Chlamydia,* herpes simplex virus, HIV), or inflammation. An anal fissure is acute when it is of recent onset (less than 6 weeks), and chronic if it has been present for a longer period. Chronic fissures have a characteristic appearance that includes perianal skin tag and fibrotic edges.[32]

Anal tissue ulcerates because of ischemia caused by a combination of high pressure in the internal anal sphincter and poor blood supply to the area. The ischemic tissue may ulcerate spontaneously or when traumatized by factors such as hard stools, which would not normally cause tissue breakdown. Ischemia must be corrected for a fissure to heal.

The hallmark of an anal fissure is severe anal pain. It tends to be worse with defecation and with direct pressure on the site (e.g., sitting). Acute fissures tend to bleed slightly. Patients may report red blood on the toilet paper. Constipation results because of fear of pain associated with bowel movements.

Anal fissures are easy to diagnose with a physical examination. Conservative care with fiber supplements, increased fluid intake, sitz baths, and topical analgesics is successful in most cases, especially if the fissure is acute. Topical preparations, including nitrates and calcium channel blockers, decrease rectal anal pressure and allow the fissure to heal without sphincter damage. Local injections of botulinum toxin can decrease rectal anal pressure. They are most effective when combined with nitrates. Pain is managed by softening stools with a bulk-producing agent (psyllium) or stool softener and warm sitz baths (15 to 20 minutes, 3 times per day).[32]

If conservative treatment fails, a lateral internal sphincterotomy is the recommended surgical procedure. It carries the risk for

postoperative incontinence. Postoperative nursing care is the same as the care for the patient who had a hemorrhoidectomy.

Anorectal Abscess

An *anorectal abscess* is a collection of perianal pus (Fig. 42.18). The abscess results from obstruction of the anal glands, leading to infection and abscess formation. Abscess formation occurs with anal fissures, trauma, or IBD. The most common causative organisms are *E. coli,* staphylococci, and streptococci. Manifestations include local severe pain and swelling, foul-smelling drainage, tenderness, and fever. Sepsis can occur as a complication. Anorectal abscesses are diagnosed by rectal examination.

Anorectal abscesses require surgical drainage. Larger abscesses need packing afterward with impregnated gauze or placement of drains (e.g., Penrose) to promote drainage. The area then heals by granulation. Patients who have diabetes or cellulitis or are immunocompromised (e.g., chemotherapy) may need antibiotic therapy. Nursing care includes warm, moist heat applications and changing packing daily. The patient is usually more comfortable lying on the abdomen or side. A low-fiber diet is given. The patient may leave the hospital with the wound still open. Teach the patient about wound care and the importance of sitz baths, thorough cleaning after urinating or bowel movements, and follow-up visits with the HCP.

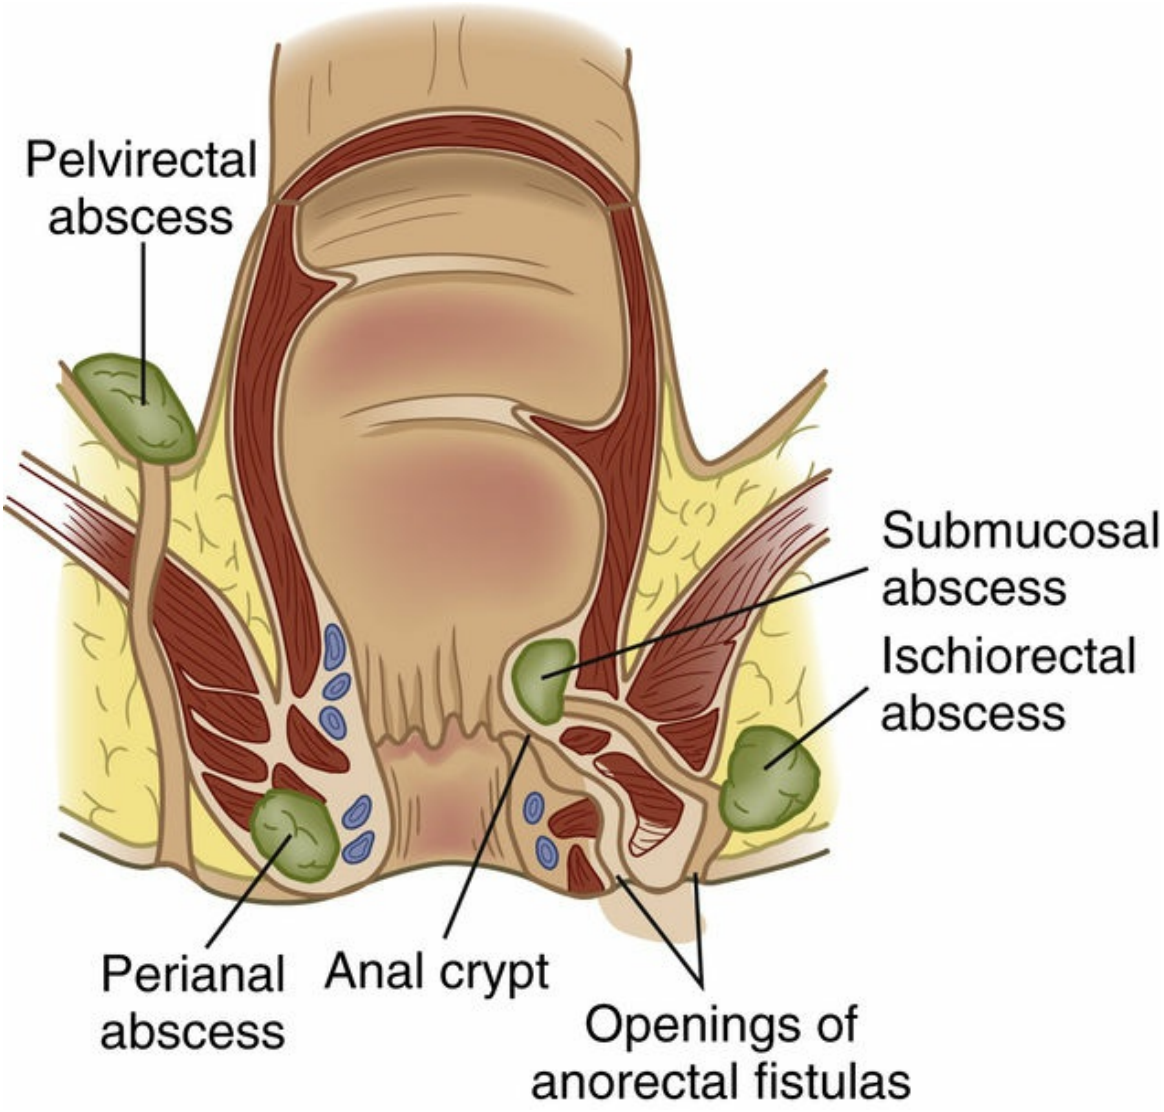

FIG. 42.18 Common sites of anorectal abscesses and fistula formation.

Anal Fistula

An **anal fistula** is an abnormal tunnel leading from the anus or rectum. It may extend to the outside of the skin, vagina, or buttocks and often precedes an abscess. Anal fistulas are a complication of Crohn's disease and may resolve when drug treatment achieves remission of the disease. About 50% of anal fistulas are due to anorectal abscess.

Feces may enter the fistula and cause an infection. There may be persistent, bloody or purulent discharge, or stool leakage from the fistula. The patient may need to wear a pad to avoid staining clothes.

Surgical treatment of an anal fistula depends on the location and nature of the fistula. In a fistulotomy, the HCP opens the fistula and healthy tissue is allowed to granulate in the wound. Care is the same as after a hemorrhoidectomy. Options for complex fistulas include ligation of the intersphincteric fistula tract (LIFT) or the use of rectal flaps, setons, plugs, or fibrin glue injections to seal the fistula.

Anal Cancer

Anal cancer is uncommon in the general population, but the incidence is increasing. In the United States around 8200 people are diagnosed with anal cancer each year.[33] It mainly occurs in older adults, with the average age being in the early 60s. Human papillomavirus (HPV) is associated with about 80% of the cases of anal cancer. Those at high risk for anal cancer include smokers, HIV-positive homosexual men, people who are immunocompromised (e.g., posttransplant immunosuppression), and women with cervical, vaginal, or vulvar cancer.[33]

Rectal bleeding is the most common presenting sign. Other symptoms include rectal pain, fullness, and changes in bowel habits. Some patients have no symptoms, which leads to delayed diagnosis and treatment.

It is especially important to screen high-risk persons using digital rectal examination (DRE) and anal Pap tests. In an anal Pap test, the anal lining is swabbed and the cells examined to identify any cell changes (e.g., dysplasia, neoplasia). High-resolution anoscopy allows for visualization of the mucosa and biopsy. An endoanal *(endorectal) ultrasound* may be done.

Treatment of anal cancer depends on the size and depth of the lesions. Cancer therapy involves surgery or a combination of low-dose radiation and chemotherapy. Chemotherapy regimens include combinations of mitomycin, cisplatin, and fluorouracil.[33] Options for precancerous lesions are surgical removal or treatment with topical imiquimod (Aldara) and fluorouracil. If the tumor involves the rectum and is large enough to require removing the anal sphincters, the anus will be sutured shut and a permanent ostomy created.

Pilonidal Sinus

A *pilonidal sinus* is a small tract under the skin between the buttocks in the sacrococcygeal area. It is thought to be of congenital origin. It may have several openings and is lined with epithelium and hair, hence the name *pilonidal* ("a nest of hair"). The skin is moist, and movement of the buttocks causes the short, wiry hair to penetrate the skin. If the irritated skin becomes infected, it forms a pilonidal cyst or abscess. There are no symptoms with a pilonidal sinus unless there is an infection. Then the patient may have pain and swelling at the base of the spine.

An abscess requires incision and drainage. The wound may be closed or left open to heal by secondary intention. The wound is packed, and sitz baths ordered. Nursing care includes warm, moist heat applications when an abscess is present. The patient is usually more comfortable lying on the abdomen or side. Teach the patient to avoid contaminating the dressing when urinating or defecating and to avoid straining whenever possible.

Case Study

Colorectal Cancer

©iStockphoto/Thinkstock

Patient Profile

L.C., a 58-yr-old Native American man, is from a Pueblo tribe in northern New Mexico. L.C.'s wife and family drove 50 miles to take him to the Indian Health Service hospital because of his deteriorating health (see the case study in Chapter 38 on p. 835).

Subjective Data

See the case study in Chapter 38 on p. 838.

Objective Data

Physical Examination

See the case study in Chapter 38 on p. 840.

Laboratory Tests

- CT scan and colonoscopy show 2 medium-sized tumors in the transverse colon

Interprofessional Care

Surgical Procedure

- Had a transverse hemicolectomy with lymph node biopsies
- Pathology results: Adenocarcinoma, has invaded the muscle wall of colon, 2 of 5 lymph nodes are positive for cancer

Postoperative

- Feels like his life has ended and does not want to leave hospital
- States that there is "no one" to take care of him at his home and he is far away from the hospital

Follow-Up Treatment

Scheduled for outpatient chemotherapy

Discussion Questions

1. What signs and symptoms of colorectal cancer did L.C. have (see the case study in Chapter 38)?
2. What stage of CRC does L.C. probably have? What treatment is recommended for this stage of CRC?
3. How could you provide emotional support to L.C. and his family?
4. ***Patient-Centered Care:*** What is a culturally sensitive way for

you to support L.C. and his family in making decisions about his continued health care?

5. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Priority Decision:*** What are the priority nursing interventions for L.C. at this stage of his illness?
7. ***Collaboration:*** What referrals may be indicated at this time?
8. ***Evidence-Based Practice:*** L.C. is worried that other members of his family may have colon cancer. What can you tell him about the recommendations for colorectal cancer screening?
9. ***Quality Improvement:*** What outcomes would indicate nursing interventions were successful?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Nursing Management: Constipation

Nursing Assessment

Determine the patient's usual defecation patterns and habits. Ask the patient about the onset and duration of symptoms; the shape and consistency of the stool; and any difficulty with evacuation. Is the patient straining during defecation? Is there a feeling of incomplete evacuation or the need to use fingering to expel the feces? Ask about diet, exercise, laxative use, and history that could contribute to problems with defecation. Table 42.9 outlines the subjective and objective data you should obtain from a patient with constipation.

Nursing Implementation

Tailor the nursing management of constipation to your assessment of the patient's symptoms. Teach the patient about the role of diet, adequate fluid intake, and regular exercise in preventing and treating constipation (Table 42.10). Emphasize the importance of a high-fiber diet. Teach the patient to establish a regular time to defecate and not to suppress the urge to defecate. Discourage the use of laxatives and enemas.

Defecation is easiest when the person is sitting on a commode with the knees higher than the hips. The sitting position allows gravity to aid defecation, and flexing the hips straightens the angle between the anal canal and rectum so that stool flows out more easily. Place a footstool in front of the toilet to promote flexion of the hips. It is challenging to defecate while sitting on a bedpan. For a patient in bed, raise the head of the bed as high as the patient can tolerate.

TABLE 42.9 Nursing AssessmentConstipation

Subjective Data

Important Health Information

Past health history: Colorectal disease, neurologic dysfunction, bowel obstruction, environmental changes, cancer, IBD, diabetes
Medications: Aluminum and calcium antacids, antidepressants, hypolipidemics, antipsychotics, diuretics, opioids, iron, PPIs, antidiarrheals

Functional Health Patterns

Health perception–health management: Chronic laxative or enema use. Rigid beliefs about bowel function. Malaise
Nutritional-metabolic: Changes in diet or mealtime. Fiber and fluid intake. Anorexia, nausea
Elimination: Change in usual bowel patterns. Hard, difficult-to-pass stool, decrease in stool frequency and amount. Flatus, abdominal distention. Straining, tenesmus, rectal pressure. Fecal incontinence (if impacted)
Activity-exercise: Daily activity routine. Immobility, sedentary lifestyle
Cognitive-perceptual: Dizziness, headache, anorectal pain. Abdominal pain on defecation
Coping–stress tolerance: Acute or chronic stress

Objective Data
General

Lethargy

Integumentary

Anorectal fissures, hemorrhoids, abscesses

Gastrointestinal

Abdominal distention. Hypoactive or absent bowel sounds. Palpable abdominal mass. Fecal impaction. Small, hard, dry stool. Stool with blood

Possible Diagnostic Findings

Guaiac-positive stools. Abdominal x-ray showing stool in lower colon

The sights, odors, and sounds of defecation embarrass most people. Provide as much privacy as possible and use an odor eliminator. Encourage patients to maintain abdominal muscle tone. Prompt patients to contract abdominal muscles several times a day. Sit-ups and straight-leg raises can help improve abdominal muscle tone.

For the patient whose perceived constipation is related to rigid beliefs about bowel function, start a discussion about these concerns. Give appropriate information on normal bowel function and discuss the adverse consequences of overuse of laxatives and enemas.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The *most* appropriate therapy for a patient with acute diarrhea caused by a viral infection is to
   a. increase fluid intake.
   b. administer an antibiotic.
   c. administer an antimotility drug.
   d. quarantine the patient to prevent spread of the virus.
2. A 35-yr-old female patient is admitted to the emergency department with acute abdominal pain. Which medical diagnoses should you consider as possible causes of her pain? *(select all that apply)*
   a. Gastroenteritis
   b. Ectopic pregnancy
   c. Gastrointestinal bleeding
   d. Irritable bowel syndrome
   e. Inflammatory bowel disease
3. Assessment findings suggestive of peritonitis include *(select all that apply)*
   a. rebound tenderness.
   b. a soft, distended abdomen.
   c. dull, intermittent abdominal pain.
   d. shallow respirations with bradypnea.
   e. observing that the patient is lying still.

3. In planning care for the patient with Crohn's disease, the nurse recognizes that a major difference between ulcerative colitis and Crohn's disease is that Crohn's disease

   a. often results in toxic megacolon.

   b. causes fewer nutritional deficiencies than ulcerative colitis.

   c. often recurs after surgery, while ulcerative colitis is curable with a colectomy.

   d. is manifested by rectal bleeding and anemia more often than is ulcerative colitis.

4. The nurse performs a detailed assessment of the abdomen of a patient with a possible bowel obstruction, knowing that manifestations of an obstruction in the large intestine are *(select all that apply)*

   a. persistent abdominal pain.

   b. marked abdominal distention.

   c. diarrhea that is loose or liquid.

   d. colicky, severe, intermittent pain.

   e. profuse vomiting that relieves abdominal pain.

5. A patient with stage I colorectal cancer is scheduled for surgery. Patient teaching for this patient would include an explanation that

   a. chemotherapy will begin after the patient recovers from the surgery.

   b. both chemotherapy and radiation can be used as palliative treatments.

   c. follow-up colonoscopies will be needed to ensure that

the cancer does not recur.

d. a wound, ostomy, and continence nurse will visit the patient to identify the site for the ostomy.

6. The nurse determines a patient undergoing ileostomy surgery understands the procedure when the patient states

a. "I should only have to change the pouch every 4 to 7 days."

b. "The drainage in the pouch will look like my normal stools."

c. "I may not need to wear a drainage pouch if I irrigate it daily."

d. "Limiting my fluid intake should decrease the amount of output."

7. In contrast to diverticulitis, the patient with diverticulosis

a. has rectal bleeding.

b. often has no symptoms.

c. usually develops peritonitis.

d. has localized cramping pain.

8. A nursing intervention that is *most* appropriate to decrease postoperative edema and pain after an inguinal herniorrhaphy is to

a. apply a truss to the hernia site.

b. allow the patient to stand to void.

c. support the incision during coughing.

d. apply a scrotal support with an ice bag.

9. The nurse determines that the goals of dietary teaching have been met when the patient with celiac disease selects

from the menu

a. scrambled eggs and sausage.

b. buckwheat pancakes with syrup.

c. oatmeal, skim milk, and orange juice.

d. yogurt, strawberries, and rye toast with butter.

10. What should a patient be taught after a hemorrhoidectomy?

a. Take mineral oil before bedtime.

b. Eat a low-fiber diet to rest the colon.

c. Use oil-retention enemas to empty the colon.

d. Take prescribed pain medications before a bowel movement.

1. a, 2. a, b, c, d, e, 3. a, e, 4. c, 5. a, b, 6. c, 7. a, 8. b, 9. d, 10. a, 11. d

Liver, Biliary Tract, and Pancreas Problems

Mary C. Olson

LEARNING OUTCOMES

1. Distinguish among the types of viral hepatitis, including etiology, pathophysiology, clinical manifestations, and complications.
2. Describe the interprofessional and nursing management of the patient with viral hepatitis.
3. Describe the pathophysiology, clinical manifestations, complications, and interprofessional care of the patient with nonalcoholic fatty liver disease.
4. Explain the etiology, pathophysiology, clinical manifestations, complications, and interprofessional and nursing management of the patient with cirrhosis.
5. Describe the clinical manifestations and management of liver cancer.
6. Distinguish between acute and chronic pancreatitis related to pathophysiology, clinical manifestations, complications, interprofessional care, and nursing management.
7. Explain the clinical manifestations and interprofessional and nursing management of the patient with pancreatic cancer.
8. Describe the pathophysiology, clinical manifestations, and interprofessional care of gallbladder disorders.

9. Describe the nursing management of the patient undergoing surgical treatment of cholecystitis and cholelithiasis.

Conceptual Focus

Infection
Inflammation
Nutrition
Pain

Nursing management of patients with a wide range of liver, pancreatic, and gallbladder problems is the focus of this chapter. These organs are closely positioned together anatomically and highly associated in their digestive functions. Liver and pancreatic problems can lead to altered nutrient absorption and use, causing malnutrition and impaired elimination. Inflammation may be present, with the patient having pain, nausea, and vomiting. Nursing care focuses on helping the patient and caregiver manage symptoms and develop ways to cope with the diagnosis and, sometimes, prognosis. Health promotion focuses on reducing risk through immunizations and avoiding substance use.

Disorders of The Liver

Hepatitis

Hepatitis is inflammation of the liver. Hepatitis is most often caused by viruses. It also can be caused by substances (e.g., alcohol, medications, chemicals), autoimmune diseases, and metabolic problems.

Viral Hepatitis

There are several types of viral hepatitis. We designate each type by a letter (A, B, C, D, E). The different types have similar manifestations, but their modes of transmission and disease course vary (Table 43.1). Some can lead to chronic liver disease. Other less common viruses can also cause liver disease. These include cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpesvirus, coxsackievirus, and rubella virus.

TABLE 43.1 Characteristics of Hepatitis Viruses

Incubation Period and Mode of Transmission	Sources of Infection	Infectivity
Hepatitis A Virus (HAV)		
Incubation: 15–50 days (average 28) • Fecal-oral (primarily fecal contamination and oral ingestion)	• Contaminated food, milk, water, shellfish • Crowded conditions (e.g., day care, nursing home) • Persons with subclinical infections, infected food handlers, sexual contact, IV drug users • Poor personal hygiene • Poor sanitation	• Most infectious during 2 wk before onset of symptoms • Infectious until 1–2 wk after the start of symptoms
Hepatitis B Virus (HBV)		
Incubation: 115–180 days (average 56–96) • Percutaneous (parenteral) or mucosal exposure to blood or blood products • Sexual contact • Perinatal transmission	• Contaminated needles, syringes, and blood products • HBV-infected mother (perinatal transmission) • Sexual activity with infected partners. Asymptomatic carriers • Tattoos or body piercing with contaminated needles	• Before and after symptoms appear • Infectious for months • Carriers continue to be infectious for life
Hepatitis C Virus (HCV)		
Incubation: 14–180 days (average 56) • Percutaneous (parenteral) or mucosal exposure to blood or blood products • High-risk sexual contact • Perinatal contact	• Blood and blood products • Needles and syringes • Sexual activity with infected partners, low risk	• 1–2 wk before symptoms appear • Continues during clinical course • 75%–85% go on to develop chronic hepatitis C and remain infectious
Hepatitis D Virus (HDV)		
Incubation: 2–26 wk • HBV must precede HDV • Chronic carriers of HBV always at risk	• Same as HBV • Can cause infection only when HBV is present	• Blood infectious at all stages of HDV infection
Hepatitis E Virus (HEV)		
Incubation: 15–64 days (average 26–42 days) • Fecal-oral route • Outbreaks associated with contaminated water supply in developing countries	• Contaminated water, poor sanitation • Found in Asia, Africa, and Mexico • Not common in United States but is increasing in some areas	• Not known • May be similar to HAV

Hepatitis A Virus

Hepatitis A is a self-limiting infection that can cause a mild flu-like illness and jaundice. In more severe cases, it can cause acute liver failure. Hepatitis A virus (HAV) is a ribonucleic acid (RNA) virus. It is transmitted primarily through the fecal-oral route. It often occurs in small outbreaks caused by fecal contamination of food or drinking water. Poor hygiene, improper handling of food, crowded situations, and poor sanitary conditions are contributing factors.

Transmission occurs between family members, institutionalized persons, and children in day care centers. Foodborne outbreaks are usually due to food contaminated by an infected food handler. People at increased risk for infection include drug users (both injection and noninjection drugs), men who have sex with men (MSM), and persons traveling to developing countries.

The greatest risk for transmission occurs before clinical symptoms appear. The virus is found in feces 1 to 2 weeks before the onset of symptoms and at least 1 week after the onset of illness (Fig. 43.1). This

means it can be carried and transmitted by persons who have undetectable, subclinical infections. It is present only briefly in blood, usually less than 3 weeks. Fecal excretion can occur in infants for months.

Anti-HAV (antibody to HAV) immunoglobulin M (IgM) appears during the acute phase. Detection of hepatitis A IgM indicates acute hepatitis. Hepatitis A IgG without anti-HAV IgM indicates past infection. IgG antibody provides lifelong immunity (Fig. 43.2). HAV vaccination and thorough hand washing are the best measures to prevent outbreaks. In the United States, the incidence of infection has declined since we started vaccinating at-risk persons and children (beginning 12 to 24 months).[1]

FIG. 43.1 Jaundiced patient.
From Butcher GP: *Gastroenterology: An illustrated colour text*, London, 2004, Churchill Livingstone.

Hepatitis B Virus

Hepatitis B virus (HBV) is a blood-borne pathogen that can cause either acute or chronic hepatitis. The incidence of HBV infection has

decreased in areas where the use of the HBV vaccine is widespread.[2]

Asians and Pacific Islanders have an incidence of HBV of up to 8%. Perinatal transmission is the most common mode of transmission in this population and often results in chronic HBV infection.[2]

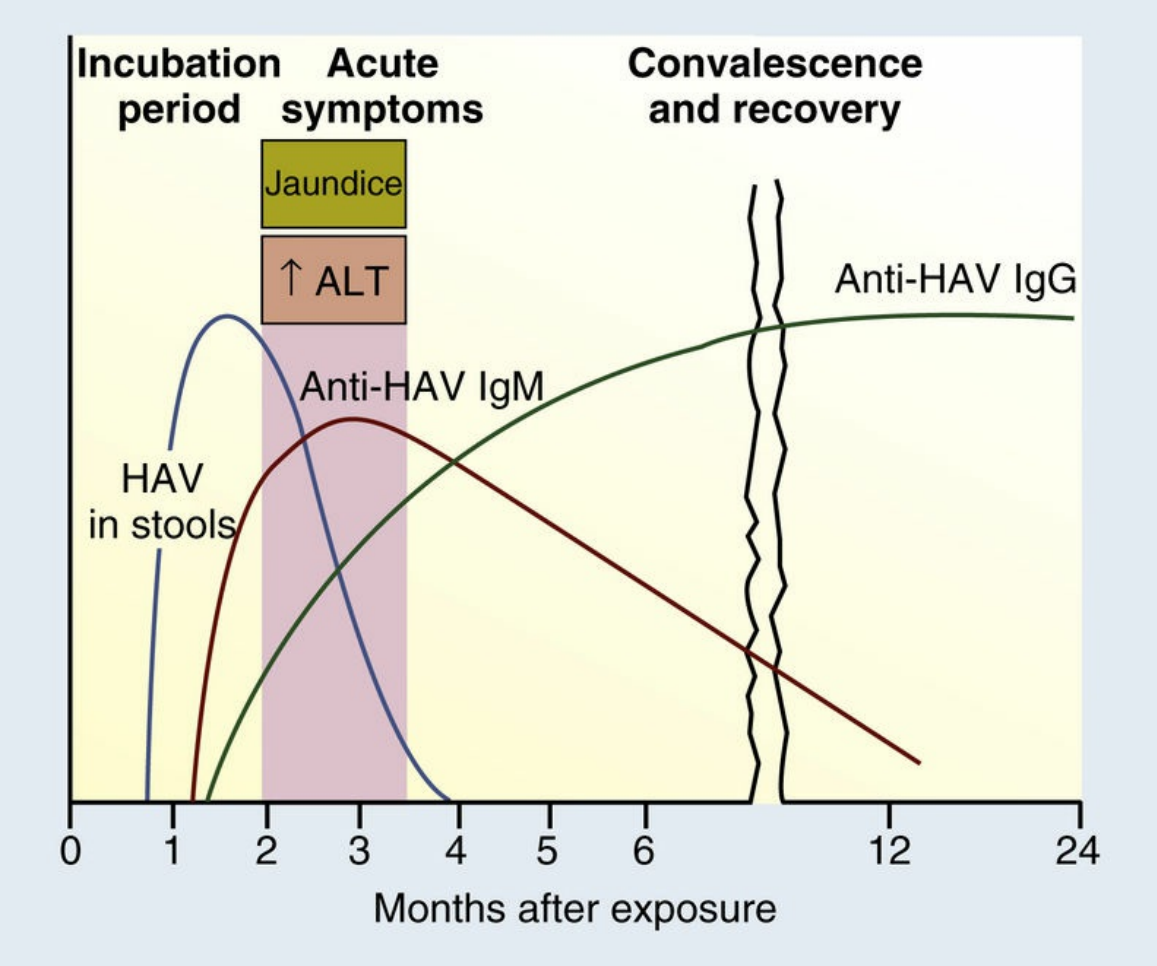

FIG. 43.2 Course of infection with hepatitis A virus *(HAV). ALT,* Alanine aminotransferase.
From McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.

HBV is a deoxyribonucleic acid (DNA) virus. It can be transmitted in several ways: (1) perinatally from mothers infected with HBV to their infants; (2) percutaneously (e.g., IV drug use, accidental needle-stick punctures); or (3) via small cuts on mucosal surfaces and exposure to infectious blood, blood products, or other body fluids

(e.g., semen, vaginal secretions, saliva).

Sexual transmission is a common mode of HBV transmission. MSM (especially those practicing unprotected anal intercourse) are at an increased risk for HBV infection. Most believe that casual encounters, like hugging, kissing, and sharing utensils, do not transmit the disease.

Other at-risk persons include those who live with chronically HBV-infected persons, patients on hemodialysis, health care personnel, public safety workers, IV drug users, recipients of blood products, and Native Alaskans, Pacific Islanders, and Native Americans.

HBV has been detected in almost every body fluid. Infected semen, cervicovaginal secretions, and saliva contain much lower concentrations of HBV than blood, but the virus can be transmitted via these secretions. If gastrointestinal (GI) bleeding occurs, feces can be contaminated with the virus from the blood. There is no evidence of fecal-oral transmission. Organ and tissue transplantation is another potential source of infection. However, in some patients with acute hepatitis B, there is no readily identifiable risk factor.

HBV is a complex structure with 3 distinct antigens: surface antigen (HBsAg), core antigen (HBcAg), and e antigen (HBeAg). Each antigen, along with its corresponding antibody, may appear or disappear in serum depending on the phase of infection and immune response.

In most people who acquire HBV infection as an adult, the infection completely resolves without any long-term complications. In those who develop chronic HBV infections, the liver may range from a normal-appearing liver to severe liver inflammation and scarring (fibrosis). Around 25% of those who become chronically HBV-infected in childhood die from complications of chronic liver disease, including liver cancer.[3]

Screening for HBV usually includes identifying those at high risk for infection and testing the blood for the presence of hepatitis B surface antigen (HBsAg), hepatitis B antibody (anti-HBs), and hepatitis B core antibody (anti-HBc). The presence of anti-HBs in the blood indicates immunity from the HBV vaccine or from past HBV infection (Fig. 43.3). HBsAg in the serum for 6 months or longer after

infection indicates chronic HBV infection.

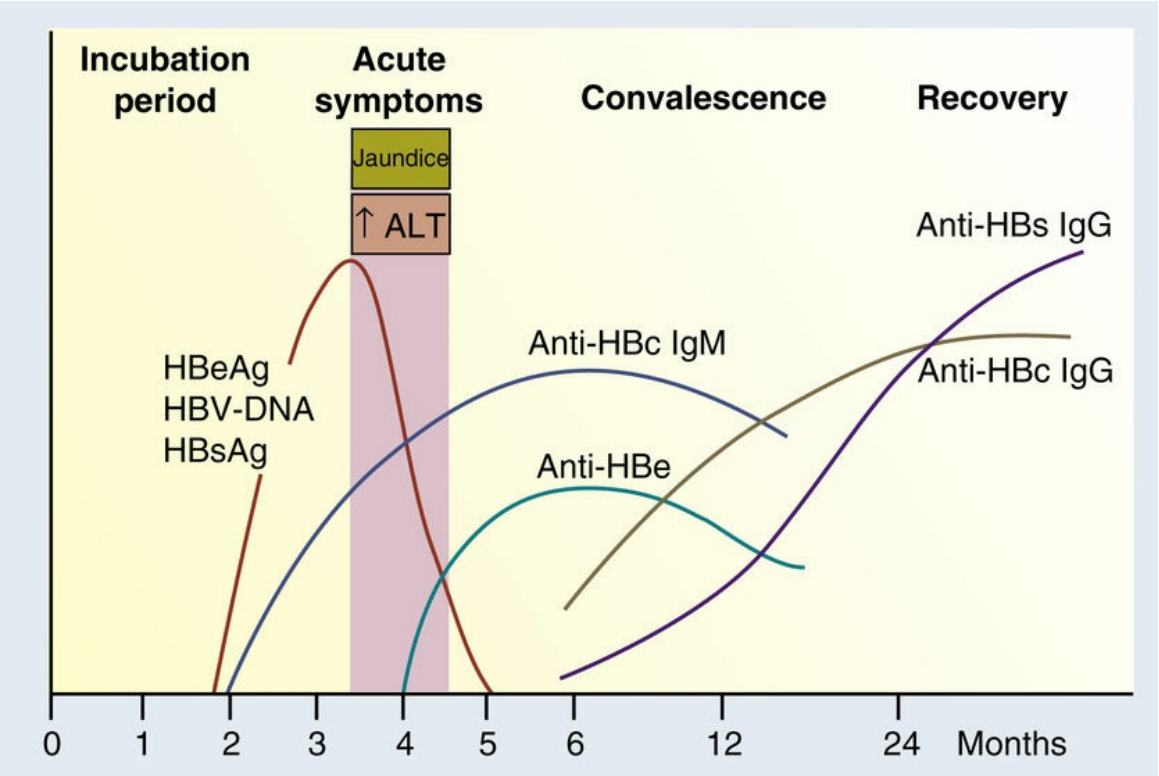

FIG. 43.3 Course of infection with hepatitis B virus *(HBV). Hepatitis C Virus

Hepatitis C virus (HCV) causes a type of hepatitis that can result in both acute illness and chronic infection. Acute hepatitis C, which can be mild in presentation, can be hard to detect unless a diagnosis is made with laboratory testing. The most common causes of acute hepatitis C outbreaks are among injection drug users and MSM with HIV infection.

HCV is an RNA virus that is blood-borne and primarily transmitted percutaneously. The most common mode of HCV transmission is the

sharing of contaminated needles and equipment among injection drug users. High-risk sexual behavior (e.g., unprotected sex, multiple partners), especially among MSM, is associated with increased risk for transmission.

After a needle-stick exposure or sharps exposure to HCV-positive blood, the transmission rate is 0.1%. The risk for perinatal HCV transmission is 4% to 7% per pregnancy. Persons who were given blood or blood products before 1992 (when blood product testing for HCV began) are at higher risk for chronic HCV infection and should be routinely tested.[4] Some patients with HCV infection cannot identify a source of infection.

Most patients usually develop chronic infection. However, because signs and symptoms of HCV infection are generally mild, most people are unaware of their infection. HCV is the most common cause of chronic liver disease and liver failure. About 20% to 30% develop cirrhosis and eventually liver failure and/or liver cancer.[4] Along with chronic HBV, HCV accounts for most cases of liver cancer. HCV hepatitis is the most common reason for liver transplantation in the United States.

Because of the 15- to 20-year delay between infection and the manifestations of liver damage, long-term effects of HCV infection pose important health care challenges.

Persons at risk for HCV infection are also at risk for HBV and HIV infections. About 30% to 40% of HIV-infected patients also have HCV. This high rate of co-infection is primarily related to IV drug use. Co-infection with HIV and HCV places the patient at greater risk for progression to cirrhosis.

People in the United States born between 1945 and 1965 and those at increased risk should be screened for HCV infection. This includes people who engage in high-risk sexual practices, injection drug users, those who may have had blood or blood products prior to 1992, and/or those who have abnormal liver function tests. A positive antibody test for HCV (anti-HCV) is usually enough for a diagnosis.[2] However, a positive viral load is needed to confirm active infection because anti-HCV can also indicate a past infection.

Evidence-Based Practice

Screening and Testing of Hepatitis C

You are caring for S.B., a 32-yr-old man who often visits the community clinic with health concerns. He arrives today saying he feels "tired." He tells you a friend was recently diagnosed with HCV and he wants "a shot" to keep from "getting it." You see on S.B.'s medical record that he injects drugs and has not been tested for HCV.

Making Clinical Decisions

Best Available Evidence. Currently, most HCV-infected persons are undiagnosed and therefore untreated. It is recommended that patients with known risk factors for HCV be tested. Rapid diagnostic tests (RDTs), including oral HCV antibody (Ab) RDTs, have excellent sensitivity and specificity compared to laboratory-based methods for HCV Ab detection.

Clinician Expertise. You know a major risk factor for HCV is injection drug use. You understand early diagnosis of HCV is important for best patient outcomes and prevention of transmission to others.

Patient Preferences and Values. S.B. tells you he is "busy today," but he can come back tomorrow for HCV testing.

Implications for Nursing Practice

1. What information would you provide to S.B. on HCV testing, symptoms, and transmission?
2. Since S.B. is now willing to be tested for HCV, how would you determine barriers to the informed consent process?
3. Should S.B. test positive for HCV, what other information will you provide him?

Hepatitis D Virus

Hepatitis D virus (HDV), also called *delta virus,* is uncommon in the United States. HDV is a defective single-stranded RNA virus that cannot survive on its own. It requires HBV surface Ag to serve as its outer shell. So, only those who are infected with HBV can be infected with HDV. It can be acquired at the same time as HBV or a person with HBV can be infected with HDV later. HDV is transmitted like HBV. It can cause a range of illness, from an asymptomatic chronic carrier state to acute liver failure. There is no vaccine for HDV. However, vaccination against HBV reduces the risk for HDV co-infection.[3]

Hepatitis E Virus

Like hepatitis A, the hepatitis E virus (HEV) is an RNA virus transmitted by the fecal-oral route. The usual mode of transmission is drinking contaminated water. HEV infection occurs primarily in developing countries, with epidemics reported in India, Asia, Mexico, and Africa. Only a few cases of HEV have been reported in the United States. These have been primarily in persons who recently traveled to an HEV-endemic area. It is generally acute and self-resolving, but chronicity in immunosuppressed persons, such as liver transplant recipients, has been reported. Pregnant women may be affected severely, with reported mortality rates of up to 10%. An IgM antibody assay is available to test for acute hepatitis E.[3]

Pathophysiology

Liver

In viral hepatitis, hepatocytes become targets of the virus in one of 2 ways: through direct action of the virus (as in HCV infection) or through a cell-mediated immune response to the virus (as in HBV and HCV infection).[3]

During acute viral hepatitis, large numbers of infected hepatocytes are destroyed. The destruction of hepatocytes leads to a wide range of liver-related dysfunction. Bile production, coagulation, blood glucose, and protein metabolism can be affected. Detoxification and processing of drugs, hormones, and metabolites (e.g., ammonia from protein catabolism) may be disrupted.

After resolution of an acute infection, liver cells can regenerate. If no complications occur, the liver can resume its normal appearance and function. In certain cases, the acute hepatitis can become so severe and irreversible that people develop liver failure or die.

Chronic viral hepatitis can be insidious and silent, causing persistent and continual destruction of infected hepatocytes. Over time scar tissue can develop, which leads to fibrosis and compromised liver function. Fibrosis can lead to cirrhosis and liver failure. Cirrhosis is a generally irreversible condition that can increase one's risk for liver dysfunction, portal hypertension, and primary liver cancer. Cirrhosis is discussed later in this chapter.

Systemic Effects

In the early phases of hepatitis infection, antigen-antibody complexes between the virus and its corresponding antibody may form circulating immune complexes. The circulating immune complexes activate the complement system (see Chapter 11). The manifestations of this activation are rash, angioedema, arthritis, fever, and malaise. *Cryoglobulinemia* (abnormal proteins found in the blood), glomerulonephritis, vasculitis, and involvement of other organs can occur from immune complex activation.

Clinical Manifestations and Complications

The manifestations of the different viral hepatitis infections can be classified into acute hepatitis and chronic hepatitis (Table 43.2).

Acute Hepatitis

Many patients with acute hepatitis have no symptoms and may not even know they have been infected. However, others may have intermittent or ongoing anorexia, lethargy, nausea, vomiting, skin rashes, diarrhea or constipation, malaise, fatigue, myalgias, arthralgias, other flu-like symptoms, and right upper quadrant tenderness (caused by liver inflammation).

Although the acute phase of viral hepatitis varies depending on the type of hepatitis, it usually lasts from 1 to 6 months. During this time, the patient may have a decreased sense of smell and find food repugnant. Smokers may have distaste for cigarettes. Physical examination often reveals hepatomegaly, lymphadenopathy, abdominal tenderness, and sometimes splenomegaly. The acute phase is the period of maximal infectivity.

A patient in the acute phase of hepatitis may be *icteric* (jaundiced) or anicteric. **Jaundice**, a yellowish discoloration of body tissues, results from a change in normal bilirubin metabolism or disruption of the flow of bile into the hepatic or biliary duct systems. The types of jaundice are described in Table 43.3. The urine may appear darker due to excess bilirubin being excreted by the kidneys. If conjugated bilirubin cannot pass into the intestines from the liver because of obstruction or inflammation of the bile ducts, the stools will be clay colored.

Pruritus (intense generalized itching) sometimes accompanies jaundice. It occurs from the accumulation of bile salts beneath the skin. Itching can be intolerable to the patient.

As jaundice fades, the convalescent phase begins. The convalescent phase can last for weeks to months, with an average of 2 to 4 months. During this period, patients typically have malaise and easy fatigability. Hepatomegaly remains for several weeks. Splenomegaly (if present) subsides during this period.

TABLE 43.2 Manifestations of Hepatitis

Acute Hepatitis

- Anorexia
- Clay-colored stools
- Dark urine
- Decreased sense of taste and smell
- Diarrhea or constipation
- Fatigue, lethargy, malaise
- Flu-like symptoms (e.g., headache)
- Hepatomegaly
- Jaundice
- Low-grade fever
- Lymphadenopathy
- Myalgias and/or arthralgias
- Nausea, vomiting
- Pruritus
- Right upper quadrant tenderness
- Splenomegaly
- Weight loss

Chronic Hepatitis

- ALT, AST elevations (may be normal in some people)
- Ascites and lower extremity edema
- Asterixis (“liver flap”)
- Bleeding abnormalities (thrombocytopenia, easy bruising, prolonged clotting time)
- Fatigue, malaise

- Hepatic encephalopathy: confusion, difficulty concentrating, easy agitation
- Hepatomegaly
- Increased bilirubin
- Jaundice
- Myalgias and/or arthralgias
- Palmar erythema
- Spider angiomas

Most patients with acute viral hepatitis recover completely. Almost all cases of acute hepatitis A resolve. However, some patients may have a relapse in the first 2 to 3 months after the infection. The disappearance of jaundice does not mean the patient has totally recovered. Some HBV infections and most HCV infections result in chronic hepatitis.

The overall mortality rate for acute hepatitis is less than 1%. The mortality rate is higher in older adults and those with underlying debilitating illnesses (including chronic liver disease).

Complications that can result from acute hepatitis are acute liver failure, chronic hepatitis, cirrhosis of the liver, portal hypertension, and liver cancer.

Acute Liver Failure

Sometimes, acute liver failure (fulminant hepatic failure) may occur, which is a serious condition with a poor prognosis. Manifestations include encephalopathy, GI bleeding, disseminated intravascular coagulation (DIC), fever with leukocytosis, renal manifestations (oliguria, azotemia), ascites, edema, hypotension, respiratory failure, hypoglycemia, bacterial infections, thrombocytopenia, and coagulopathies. Liver transplantation is usually the cure for these patients. Acute liver failure is discussed in this chapter on p. 989.

Chronic Hepatitis

Manifestations of chronic hepatitis are shown in Table 43.2. Chronic

HBV is more likely to develop in infants born to infected mothers and in those who acquire the infection before age 5 than in those who acquire the virus after age 5.[3]

Problems with the patient's cellular immune response may be important in the development of the chronic HBsAg carrier state and the progression of acute HBV to chronic HBV. More than 50% of immunocompromised adults who are acutely infected with HBV progress to chronic infection.[3]

HCV infection is more likely than HBV to become chronic. As previously mentioned, many patients with chronic HCV infection develop chronic liver disease, cirrhosis, portal hypertension, and liver cancer. Risk factors for progression to cirrhosis include male gender, alcohol use, concomitant fatty liver disease, and excess iron deposition in the liver. In some patients, co-infection with HIV may cause complications or require treatment modification. Manifestations of chronic hepatitis include anemia and coagulation problems (easy bruising, bleeding). Since the liver produces clotting factors, clotting and bleeding times can be impaired or prolonged.

TABLE 43.3 Classification of Jaundice

	Hemolytic Jaundice	Hepatocellular Jaundice	Obstructive Jaundice
Causes	• Blood transfusion reactions, hemolytic anemia, sickle cell crisis	• Cirrhosis, hepatitis, liver cancer	• Cirrhosis, hepatitis, liver cancer • Common bile duct obstruction from stone(s), biliary strictures, pancreatic cancer, sclerosing cholangitis
Description	• Caused by increased breakdown of RBCs, which produces an increased amount of unconjugated bilirubin in blood • Liver is unable to handle increased load	• Results from liver's altered ability to take up bilirubin from blood or to conjugate or excrete it • In hepatocellular disease, damaged hepatocytes leak bilirubin	• Results from decreased or obstructed flow of bile through liver or biliary duct system • Obstruction may occur in intrahepatic or extrahepatic bile ducts • Intrahepatic obstructions are due to swelling or fibrosis of the liver's canaliculi and bile ducts
Diagnostic Findings			
Serum Bilirubin			
Unconjugated (indirect)	↑	↑	↑
Conjugated (direct)	Normal	↑ or ↓ (severe disease)	↑
Urine Bilirubin	Negative	↑	↑
Urobilinogen			
Stool	↑	Normal, ↓	↓
Urine	↑	Normal, ↑	↓

Skin manifestations may include spider angiomas, palmar erythema, and gynecomastia. Some patients have spleen, liver, or cervical lymph node enlargement.

In patients with severe liver damage, *hepatic encephalopathy* is a potentially life-threatening spectrum of neurologic, psychiatric, and motor disturbances. Hepatic encephalopathy results from the liver's inability to remove toxins (especially ammonia) from the blood. Hepatic encephalopathy is discussed later in this chapter on p. 983.)

Ascites, a common manifestation of hepatitis (especially chronic hepatitis), is the accumulation of excess fluid in the peritoneal cavity. Fluid accumulates due to reduced protein levels in the blood, which reduces the plasma oncotic pressure. Ascites is discussed later in this chapter on p. 982.

Diagnostic Studies

The only definitive way to distinguish among the types of viral hepatitis is by testing the patient's blood for the specific antigen or antibody. In some types of viral hepatitis, the blood can be tested for the viral load (viral level). Tests for the different types of viral hepatitis are outlined in Table 43.4. Many liver function tests show

significant abnormalities, as shown in Table 43.5.

Several tests are available to determine the presence of HCV. The screening test for HCV infection is HCV antibody testing. Antibodies can be detected within 4 weeks of infection. If the antibody test is positive, HCV RNA testing is done to assess for chronic infection. A positive result confirms chronic infection. A few patients may have a false-positive HCV antibody result with a negative HCV RNA test. If recent HCV infection is suspected, HCV RNA testing is usually done because it may take several weeks or longer for HCV antibodies to develop.

HCV RNA testing may be used for immunocompromised patients (e.g., patient with HIV). Because of altered or delayed antibody response to HCV, these patients may not have detectable antibody levels even if they are infected with HCV.

Viral genotype testing is done in patients undergoing drug therapy for HBV or HCV infection. HBV has at least 8 different genotypes (A to H). In some centers, HBV genotyping is done before starting treatment. HBV genotype may be useful in predicting disease course and treatment outcomes. HBV core Ab (HBVcAb) IgG indicates that the patient has a history of HBV infection. HBV may reactivate in these patients if they become immunosuppressed.

HCV has 6 genotypes and more than 50 subtypes. In the United States, 75% of HCV infections are caused by HCV genotype 1. For patients who test positive for HCV, genotyping is done before drug therapy is started. The genotype determines the choice and duration of therapy. It is one of the strongest predictors of a patient's response to drug therapy.

A liver biopsy is done in acute hepatitis only if diagnosis is in doubt. In chronic hepatitis, a liver biopsy allows for histologic examination of liver cells and determination of the degree of inflammation, fibrosis, or cirrhosis that may be present. A patient who has a bleeding disorder may not be a candidate for a percutaneous liver biopsy because of the risk for bleeding. In these patients, a transjugular biopsy may be an alternative. This type of biopsy consists of obtaining liver tissue through a rigid cannula introduced into a

hepatic vein, typically using jugular venous access.

Techniques for noninvasive assessment of liver fibrosis are increasingly replacing the need for liver biopsy. One option is the use of ultrasound elastography (e.g., FibroScan), which uses an ultrasound transducer to determine the degree of liver fibrosis.[5] FibroSure (FibroTest) is an example of one of several biomarkers that uses the results of serum tests to assess the extent of hepatic fibrosis.

TABLE 43.4 Diagnostic StudiesViral Hepatitis

Virus	Tests	Significance
A	Anti-HAV immunoglobulin M (IgM)	Acute infection
	Anti-HAV immunoglobulin G (IgG)	Previous infection or immunization Not routinely done in clinical practice
B	HBsAg (hepatitis B surface antigen)	Marker of infectivity Present in acute or chronic infection Positive in chronic carriers
	Anti-HBs (hepatitis B surface antibody)	Indicates previous infection with HBV or immunization
	HBeAg (hepatitis B e antigen)	Indicates high infectivity Used to determine the clinical management of patients with chronic hepatitis B
	Anti-HBe (hepatitis B e antibody)	Indicates previous infection In chronic hepatitis B, indicates a low viral load and low degree of infectivity
	Anti-HBc (antibody to hepatitis B core antigen) IgM	Indicates acute infection Does not appear after vaccination
	Anti-HBc IgG	Indicates previous infection or ongoing infection with hepatitis B Does not appear after vaccination
	HBV DNA quantitation	Indicates active ongoing viral replication Best indicator of viral replication and effectiveness of therapy in patient with chronic hepatitis B
	HBV genotyping	Indicates the genotype of HBV
C	Anti-HCV (antibody to HCV)	Marker for acute or chronic infection with HCV
	HCV RNA quantitation	Indicates active ongoing viral replication
	HCV genotyping	Indicates the genotype of HCV
D	Anti-HDV	Present in past or current infection with HDV
	HDV Ag (hepatitis D antigen)	Present within a few days after infection
E	Anti-HEV IgM and IgG	Present 1 wk–2 mo after illness onset
	HEV RNA quantitation	Indicates active ongoing viral replication

A, Hepatitis A virus (HAV); *B,* hepatitis B virus (HBV); *C,* hepatitis C virus (HCV); *D,* hepatitis D virus (HDV); *E,* hepatitis E virus (HEV).

TABLE 43.5 Diagnostic Findings in Acute

Test	Abnormal Finding	Etiology
Alkaline phosphatase	Moderately ↑	Impaired excretory function of liver
γ-Glutamyl transpeptidase (GGT)	↑	Liver cell injury
Aminotransferases		
• **Aspartate aminotransferase (AST)**	↑ in acute phase Decreases as jaundice disappears	Liver cell injury
• **Alanine aminotransferase (ALT)**	↑ in acute phase Decreases as jaundice disappears	Liver cell injury
Prothrombin time	Prolonged	↓ prothrombin production by liver
Serum proteins		
• **Albumin**	Normal or ↓	Liver cell injury
• **γ-Globulin**	Normal or ↓	Impaired clearance from liver
Total bilirubin (serum)	Increased to about 8–15 mg/dL (137–257 μmol/L)	Liver cell injury
Urinary bilirubin	↑	Conjugated hyperbilirubinemia
Urinary urobilinogen	↑ 2–5 days before jaundice	Decreased urobilinogen reabsorption

Interprofessional Care

There is no specific treatment for acute viral hepatitis. Most patients are managed at home. Emphasis is on providing adequate nutrition and measures to rest the body and help the liver to regenerate and repair (Table 43.6). Rest reduces the metabolic demands on the liver and promotes liver cell regeneration. The degree of rest depends on the severity of symptoms, but usually alternating periods of activity and rest are adequate. Counseling should include the importance of avoiding alcohol and notifying contacts for testing and prophylaxis, if indicated.

In patients with chronic viral hepatitis, care may involve hepatologists, infectious disease specialists, pharmacists, dietitians, and mental health or substance use specialists. The role and extent of involvement of team members is based on the patient's specific needs.

Drug Therapy

Acute Hepatitis

There are no drug therapies for treating acute HAV infection. Treatment of acute HBV may be indicated only in patients with severe

hepatitis and liver failure.

In acute hepatitis C, some patients may choose to be monitored for spontaneous clearance of the infection. For patients who choose treatment, one of the direct-acting antivirals (DAAs) may be used.[6] DAAs are discussed later in the section on chronic hepatitis.

Supportive drug therapy may include antihistamines for generalized itching and antiemetics for nausea. These drugs include promethazine (Phenergan) and ondansetron (Zofran).

TABLE 43.6 Interprofessional CareViral Hepatitis

Diagnostic Assessment

- History and physical examination
- Liver function tests (ALT, AST, alkaline phosphatase, bilirubin, γ-glutamyl transpeptidase [GGT])
- PT time and INR
- Hepatitis testing
    - *Hepatitis A:* Anti-HAV IgM, anti-HAV IgG, or HAV total antibody
    - *Hepatitis B:* HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HBc IgM and IgG, HBV DNA quantitation, HBV genotyping
    - *Hepatitis C:* Anti-HCV, HCV RNA quantitation, HCV genotyping
    - *Hepatitis D:* Anti-HDV, HDV Ag
- FibroScan
- FibroSure (FibroTest)

Management
Acute and Chronic

- Well-balanced diet
- Vitamin supplements
- Rest (degree of strictness varies)
- Avoiding alcohol and drugs detoxified by liver

Chronic HBV and HCV

- Drug therapy (Table 43.7)

HAV, Hepatitis A virus; *HB,* hepatitis B; *HBeAg,* hepatitis B e antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV Ag,* hepatitis D antigen; *HDV,* hepatitis D virus.

Complementary & Alternative Therapies

Milk Thistle (Silymarin)

Scientific Evidence

People have used milk thistle for liver disorders, including hepatitis, cirrhosis, and gallbladder problems.

- Clinical trials of milk thistle for liver diseases have mixed results.
- Silymarin was no better than placebo for chronic hepatitis C in people who had not responded to standard antiviral treatment.
- The 2008 Hepatitis C Antiviral Long-Term Treatment Against Cirrhosis (HALT-C) study found that patients with hepatitis C who used silymarin had fewer and milder symptoms of liver disease and better quality of life but no change in virus activity or liver inflammation.

Nursing Implications

- Well tolerated in recommended doses. Some people report GI side effects
- May lower blood glucose
- May interfere with the liver's cytochrome P450 enzyme system

Chronic Hepatitis B

Drug therapy for chronic HBV focuses on decreasing the hepatitis B viral load and liver enzymes, and in turn, slowing the rate of disease progression. Long-term goals are preventing the development of cirrhosis, portal hypertension, liver failure, and liver cancer. Current drug therapies for chronic HBV do not eradicate the virus but suppress viral replication and prevent complications of infection. First-line therapies now include primarily nucleoside and nucleotide analogs (Table 43.7) and sometimes interferon therapy.[7]

TABLE 43.7 Drug TherapyViral Hepatitis B and C

Drug Class	Examples	Mechanism of Action	Indication
Immune modulator	pegylated interferon (Pegasys, PegIntron)	Has antiviral, antiproliferative, immune-regulating actions	Chronic hepatitis B and C*
Nucleoside and nucleotide analogs	entecavir (Baraclude) lamivudine (Epivir HBV) telbivudine (Tyzeka) tenofovir (Vemlidy, Viread)	Inhibits HBV DNA polymerase enzyme by competing with natural substrates. Prevents viral replication	Chronic hepatitis B
Direct-acting antivirals for hepatitis C			
• **NS3/4A protease inhibitors**	simeprevir (Olysio) glecaprevir† grazoprevir† paritaprevir† voxilaprevir†	Blocks viral protease enzyme. Prevents viral replication in genotype 1 HCV	Chronic hepatitis C
• **NS5A inhibitors**	daclatasvir (Daklinza) elbasvir† ledipasvir† ombitasvir† pibrentasvir† velpatasvir†	Blocks nonstructural protein 5A (NS5A) at early stage in RNA HCV replication	Chronic hepatitis C
• **NS5B polymerase inhibitors**	dasabuvir† sofosbuvir (Sovaldi)	Nucleotide inhibitor and non-nucleoside inhibitor of HCV polymerase. Prevent replication of RNA HCV	Chronic hepatitis C
Combination therapies	elbasvir + grazoprevir (Zepatier) ledipasvir + sofosbuvir (Harvoni) ombitasvir + paritaprevir + ritonvir‡ + dasabuvir (Viekira Pak) Pibrentasvir + glecaprevir (Mavyret) velpatasvir + sofosbuvir (Epclusa) velpatasvir + sofosbuvir + voxilaprevir (Vosevi)	Drugs are combined in single tablet. Drugs may be from the same or different classes.	Chronic hepatitis C

* Use of all oral or noninterferon therapies for chronic hepatitis C is preferred.

† Used only in combination therapy.

‡ CYP3A inhibitor used to enhance the pharmacokinetics of the other agents.

Nucleoside and nucleotide analogs

Nucleoside and nucleotide analogs inhibit viral DNA replication. HBV reproduces by making copies of its viral DNA nucleosides and nucleotides. The nucleoside and nucleotide analog drugs mimic normal building blocks for DNA but are actually faulty viral DNA building blocks. Once they become incorporated into the viral DNA, they halt DNA synthesis.

Nucleoside and nucleotide analogs do not prevent all viral reproduction, but they can substantially lower the amount of virus in the body. These medications include lamivudine (Epivir), adefovir (Hepsera), entecavir (Baraclude), telbivudine (Tyzeka), and tenofovir (Viread). These oral medications are used to treat chronic HBV when there is evidence of significant active viral replication and liver

inflammation.[7]

These drugs also reduce viral load, decrease liver damage, and decrease serum liver enzyme levels. Most patients with HBV need long-term treatment. When these drugs are stopped, many patients' (except those who have seroconverted) HBV DNA and liver enzyme levels return to pretreatment levels.

Severe exacerbations of hepatitis B can develop after ending treatment. If these drugs are stopped for any reason, closely monitor liver function for several months.

Interferon

Interferon is a naturally occurring immune protein made by the body during an infection to recognize and respond to pathogens. It has antiviral, antiproliferative, and immune-modulating effects. (Interferon is discussed in Chapter 13). Pegylated interferon (PEG-Intron, Pegasys) is given by subcutaneous injection.

The many side effects with interferon therapy, including flu-like symptoms (e.g., fever, malaise, fatigue), make adhering to therapy hard for some patients. Currently, the availability of better tolerated and more effective oral treatments limits interferon use. However, it is still among the first-line options recommended by hepatology societies.

Patients receiving interferon should have blood counts and liver function tests every 4 to 6 weeks. Depression is a side effect of interferon. Patients must be screened for depression and other mood disorders before starting interferon treatment and monitored frequently while on therapy.

Chronic Hepatitis C

Treatment of chronic hepatitis C is patient specific and based on the genotype of the HCV, severity of liver disease, and presence of other health problems (e.g., HIV). The goal of drug therapy is eradicating the virus and preventing HCV-related complications. Treatment for HCV primarily includes the use of DAAs (Table 43.7), which block proteins needed for HCV replication.

With DAAs, patients typically complete a 12-week regimen with oral drugs. Almost all (>95%) of those who complete treatment with the DAAs are now able to cure their chronic HCV infection.[6]

Drug Alert

Ribavirin (Rebetol, Ribasphere)

- May cause severe birth defects. During treatment, women taking the drug and women whose male partners are taking the drug must avoid pregnancy.
- Monitor hemoglobin and hematocrit as it may cause anemia.
- Used only for specific populations.

Many patients with HIV also have HCV. Patients who have stable HIV and intact immune systems ($CD4^+$ counts greater than 200/μL) receive HCV treatment with the goal of eradicating HCV and reducing the risk for progression to cirrhosis. HCV treatment may reduce $CD4^+$ counts and increase the patient's risk for anemia and leukopenia.

Patients with advanced fibrosis or cirrhosis can undergo drug therapy if liver decompensation (e.g., ascites, variceal rupture, jaundice, wasting, encephalopathy) is not present.

Nutritional Therapy

No special diet is needed in the treatment of viral hepatitis. Emphasis is placed on a well-balanced diet that the patient can tolerate. During acute viral hepatitis, adequate calories are important because the patient usually loses weight. If fat content is poorly tolerated because of decreased bile production, it should be reduced. Vitamin supplements, particularly B-complex and vitamin K, are often given. If anorexia, nausea, and vomiting are severe, IV solutions of glucose

or supplemental enteral nutrition (EN) therapy may be used. Fluid and electrolyte balance must be maintained.

Nursing Management: Viral Hepatitis

Nursing Assessment

Subjective and objective data that should be obtained from a person with hepatitis are outlined in Table 43.8.

Nursing Diagnoses

Nursing diagnoses for the patient with viral hepatitis may include:

- Impaired nutritional intake
- Activity intolerance
- Risk for bleeding

Additional information on nursing diagnoses and interventions for the patient with hepatitis is presented in eNursing Care Plan 43.1 available on the website for this chapter.

Planning

The overall goals are that the patient with viral hepatitis will (1) have relief of discomfort, (2) be able to resume normal activities, and (3) return to normal liver function without complications.

Nursing Implementation

Health Promotion

Viral hepatitis is a public health problem. Your role is important in the prevention and control of this disease. It is helpful to understand the epidemiology of the different types of viral hepatitis when considering appropriate control measures. Preventive and control measures for hepatitis A, B, and C are outlined in Table 43.9.

A suggested guideline for general practice to prevent you from

contracting viral hepatitis from diagnosed and undiagnosed patients and carriers is for you to wear disposable gloves, goggles, and gowns (sometimes) when fecal or blood contamination is likely in handling (1) soiled bedpans, urinals, and catheters and (2) when the patient's bed linens are soiled by body excreta or secretions.

Hepatitis A

Viral hepatitis outbreaks are usually due to HAV. Preventive measures include personal and environmental hygiene and health education to promote good sanitation. Hand washing is the most important precaution. Teach about careful hand washing after bowel movements and before eating.

Vaccination is the best protection against HAV. All children at 1 year of age should receive the vaccine. Adults at risk should also receive the vaccine. These include people who travel to areas with increased rates of hepatitis A, MSM, injecting and noninjecting drug users, persons with clotting factor disorders (e.g., hemophilia), and persons with chronic liver disease.

TABLE 43.8 Nursing AssessmentHepatitis*

Subjective Data
Important Health Information

Past health history: Hemophilia, cancer, exposure to infected persons, ingestion of contaminated food or water. Exposure to benzene, carbon tetrachloride, or other hepatotoxic agents. Crowded, unsanitary living conditions. Exposure to contaminated needles. Recent travel, organ transplant recipient, exposure to new drug regimens, hemodialysis, transfusion of blood or blood products before 1992. HIV status (if known)

Medications: Use and misuse of acetaminophen, new prescription, over-the-counter, or herbal medications or supplements

Functional Health Patterns

Health perception–health management: IV drug and chronic alcohol use. Malaise, distaste for cigarettes (in smokers), high-risk sexual behaviors
Nutritional-metabolic: Weight loss, anorexia, nausea, vomiting. Feeling of fullness in right upper quadrant
Elimination: Dark urine, light-colored stools, constipation or diarrhea, skin rashes, hives
Activity-exercise: Fatigue, arthralgias, myalgias
Cognitive-perceptual: Right upper quadrant pain and liver tenderness, headache, itching
Role-relationship: Exposure as health care worker, resident in long-term care institution, incarceration, homelessness

Objective Data
General

Low-grade fever, lethargy, lymphadenopathy

Integumentary

Rash or other skin changes, jaundice, icteric sclera, injection sites

Gastrointestinal

Hepatomegaly, splenomegaly

Possible Diagnostic Findings

Elevated liver enzyme levels. ↑ Serum total bilirubin, hypoalbuminemia, anemia, bilirubin in urine and increased

urobilinogen, prolonged PT time, positive tests for hepatitis, including anti-HAV IgM, HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HBc IgM and IgG, HBV DNA quantitation, anti-HCV, HCV RNA quantitation, anti-HDV, HDV Ag. Abnormal liver scan, abnormal results on liver biopsy

HAV, Hepatitis A virus; *HBcAg,* hepatitis B core antigen; *HBeAg,* hepatitis B e antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV Ag*, hepatitis D antigen; *HDV,* hepatitis D virus.

* Tailor history questions to the type of hepatitis.

HAV vaccine is inactivated HAV protein. There are 2 forms of HAV vaccine in the United States: Havrix and Vaqta. Primary immunization consists of 1 dose given IM in the deltoid muscle. A booster is recommended 6 to 12 months after the first dose to ensure adequate antibody titers and long-term protection. Primary immunization provides immunity within 30 days after 1 dose in more than 95% of those vaccinated.

Twinrix, a combined HAV and HBV vaccine, is available for people over 18 years of age. Immunization consists of 3 doses, given on a 0-, 1-, and 6-month schedule, the same schedule as that used for the single HBV vaccine. Twinrix may be given to high-risk persons, including patients with chronic liver disease, users of illicit IV drugs, patients on hemodialysis, MSM, and people with clotting factor disorders who receive therapeutic blood products. The side effects of the vaccine are mild and usually limited to soreness and redness at the injection site.

TABLE 43.9 Preventive Measures for Viral

Hepatitis A

General Measures

- Hand washing
- Proper personal hygiene
- Environmental sanitation
- Control and screening (signs, symptoms) of food handlers
- Serologic screening for those carrying virus
- Active immunization: HAV vaccine

Use of Immune Globulin

- Early administration (1–2 wk after exposure) to those exposed
- Prophylaxis for travelers to areas where hepatitis A is common if not vaccinated with HAV vaccine

Special Considerations for Health Care Personnel

- Wash hands after contact with a patient or removal of gloves
- Use infection control precautions

Hepatitis B and C

Percutaneous Transmission

- Screening of donated blood
- *HBV:* HBsAg
- *HCV:* Anti-HCV
- Use of disposable needles and syringes

Sexual Transmission

- Acute exposure: HBIG administration to sexual partner of HBsAg-positive person
- HBV vaccine series given to uninfected sexual partners
- Condoms used for sexual intercourse

General Measures

- Hand washing
- Avoid sharing toothbrushes and razors
- HBIG administration for one-time exposure (needle stick, contact of mucous membranes with infectious material)
- Active immunization: HBV vaccine

Special Considerations for Health Care Personnel

- Use infection control precautions
- Reduce contact with blood or blood-containing secretions
- Handle the blood of patients as potentially infective
- Dispose of needles properly
- Use needleless IV access devices when available

HAV, Hepatitis A virus; *HBIG,* hepatitis B immune globulin; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus.

Isolation is not needed for HAV infection. For a patient with HAV infection, use infection control precautions. Place the patient who is incontinent of stool or has poor personal hygiene in a private room.

Both hepatitis A vaccine and immune globulin (IG) are used to

prevent HAV infection after exposure to an infected person *(postexposure prophylaxis).* The vaccine is used for preexposure prophylaxis. IG can be given either before or after exposure. IG gives temporary (1 to 2 months) passive immunity and is effective for preventing hepatitis A if given within 2 weeks after exposure. IG is recommended for persons who do not have anti-HAV antibodies and were exposed by close (household, day care center) contact with persons who have HAV or foodborne exposure. Because patients with HAV are most infectious just before the onset of symptoms (the preicteric phase), those exposed through household contact or foodborne outbreaks should receive IG. Although IG may not prevent infection in all persons, it may lessen the illness to a subclinical infection. When hepatitis A occurs in a food handler, IG should be given to all other food handlers at the establishment. Patrons may need to receive IG.

Persons exposed to HAV who have received a dose of HAV vaccine more than 1 month previously or who have a history of laboratory-confirmed HAV infection do not need IG.

Hepatitis B

The best way to reduce HBV infection is to identify those at risk, screen them for HBV, and vaccinate those who are not infected. Teach those at high risk for contracting HBV to reduce risks by following good hygienic practices, including hand washing and using gloves when expecting contact with blood. Patients should not share razors, toothbrushes, and other personal items. Teach patients to use a condom for sexual intercourse. In addition, the partner should be vaccinated.

The HBV vaccine is the best means of prevention. The HBV vaccines (Recombivax HB, Engerix-B) contain HBsAg, which promotes the synthesis of specific antibodies directed against HBV. The vaccine is given in a series of 3 IM injections in the deltoid muscle. The second dose is given within 1 month of the first dose and the third dose within 6 months of the first. The vaccine is more than 95% effective. Minor reactions include transient fever and soreness at the injection

site. The vaccine can be given in pregnancy.

The first dose of hepatitis B vaccine should be given at birth, with the vaccine series completed by age 6 to 18 months. Older children and adolescents who did not receive the hepatitis B vaccine should be vaccinated.[3] It is important to vaccinate adults who are in the at-risk groups and are not immune. Household members of the patient with HBV should be tested and vaccinated if they are HBsAg and antibody negative. Hepatitis vaccination is recommended for patients with chronic kidney disease before they start dialysis. Dialysis patients should routinely have their antibody titer levels checked to determine the need for revaccination.

For postexposure prophylaxis, the HBV vaccine series and hepatitis B immune globulin (HBIG) are given. HBIG has antibodies to HBV and confers temporary passive immunity. HBIG is prepared from plasma of donors with a high titer of anti-HBs. HBIG is recommended for postexposure prophylaxis in cases of needle stick, mucous membrane contact, or sexual exposure and for infants born to mothers who are positive for HBsAg. Ideally HBIG should be given within 24 hours of exposure. Giving antiviral therapy (e.g., tenofovir) to pregnant women in the third trimester with viral levels over 200,000 IU/mL can prevent the small risk for neonatal infection that may occur even with postnatal immunization and vaccination.

The Centers for Disease Control and Prevention (CDC) recommends following standard precautions for the patient with HBV (see Table 14.9). This includes using disposable needles and syringes and disposing of them in puncture-resistant units without recapping, bending, or breaking.

Hepatitis C

No vaccine is currently available for hepatitis C. Therefore it is important to identify those at high risk for contracting HCV and teach them how to reduce their risks. Primary measures to prevent HCV transmission include (1) screening of blood, organ, and tissue donors; (2) using infection control precautions; and (3) modifying high-risk behavior.

In the United States, there are many people who have undiagnosed hepatitis C. Therefore the CDC recommends universal screening for all persons born between 1945 and 1965.[4] The CDC does not recommend IG or antiviral agents (e.g., interferon) for postexposure prophylaxis for HCV infection (e.g., needle-stick exposure from an infected patient). After an acute exposure (e.g., needle stick), the person should have anti-HCV testing done. For the person exposed to HCV, baseline anti-HCV and ALT levels should be measured, with follow-up testing at 4 to 6 months. Testing for HCV RNA may be done after 4 to 10 weeks.[4]

Acute Care

In patients with hepatitis, assess for the presence and degree of jaundice. In light-skinned persons, jaundice is usually seen first in the sclera of the eyes and later in the skin. In dark-skinned persons, jaundice is seen in the hard palate of the mouth and inner canthus of the eyes. The urine may have a dark brown or brownish red color from bilirubin excretion from the kidneys. Comfort measures to relieve itching, headache, and arthralgias are helpful.

Check Your Practice

You are caring for a 32-yr-old man who has acute hepatitis A. He has severe nausea and vomiting. He is admitted to the hospital for IV hydration and monitoring. The patient says, "I'm so weak and I feel like I'm going to vomit all the time. Isn't there something you can do to help me?"

- How would you handle this situation?
- What information and teaching will you give him?

Ensuring that the patient receives adequate nutrition is not always easy. The anorexia and distaste for food may cause nutritional

problems. Assess the patient's tolerance of specific foods and eating pattern. Small, frequent meals may be preferable to 3 large ones and may help prevent nausea. Often a patient with hepatitis finds that anorexia is not as severe in the morning, so it is easier to eat a good breakfast than a large dinner. Include measures to stimulate the appetite, such as mouth care, antiemetics, and attractively served meals in pleasant surroundings, in the care plan. Drinking carbonated beverages and avoiding very hot or cold foods may help ease anorexia. Adequate fluid intake (2500 to 3000 mL/day) is important.

Rest is a critical factor in promoting hepatocyte regeneration. Assess the patient's response to the rest and activity plan. Modify it as needed based on liver function tests and symptoms.

Psychologic and emotional rest is as essential as physical rest. Limited activity may produce anxiety and restlessness in some patients. Diversion activities, such as reading and hobbies, may help a patient cope with the plan of care and ensure adequate rest.

Ambulatory Care

Most patients with viral hepatitis are cared for at home. Assess the patient's knowledge of nutrition and provide any needed dietary teaching. Caution the patient about overexertion and the need to follow the HCP's advice about when to return to work. For patients who have fatigue, tell them to plan activities after periods of rest when energy levels are highest. Teach the patient and caregiver how to prevent transmission to other family members and symptoms to report to the HCP.

Assess the patient for any signs of complications. These include bleeding tendencies with increasing prothrombin (PT) time values, manifestations of encephalopathy, sudden increase in weight and abdominal girth (may indicate fluid retention and/or ascites), bloody or tarry stools, vomiting of blood, or elevated liver enzymes.

Teach the patient to have regular follow-ups for at least 1 year after the diagnosis of hepatitis. Because relapses occur with hepatitis B and C, teach the patient the symptoms of recurrence and the need for follow-up evaluations. All patients with chronic HBV or HCV should

avoid alcohol as it can accelerate disease progression.

Note that patients who are positive for HBsAg (chronic carrier status) or HCV antibody cannot be blood donors.

Evaluation

Expected outcomes are that the patient with hepatitis will

- Maintain food and fluid intake adequate to meet nutritional needs
- Avoid alcohol and other hepatotoxic agents
- Show gradual increase in activity tolerance
- Perform daily activities with scheduled rest periods

Drug- and Chemical-Induced Liver Diseases

Alcohol use is the most frequent cause of both acute and chronic liver disease. It can cause injury and necrosis of liver tissue. Alcohol use can cause a spectrum of manifestations, ranging from mild elevation in liver enzymes to acute alcoholic hepatitis. It may also cause advanced fibrosis and cirrhosis, which usually occurs after decades of excess alcohol use. Patients may have serious liver disease caused by another chronic disease (e.g., chronic HCV infection) in combination with alcoholic liver disease, which can compound the problem.

Acute alcoholic hepatitis is a syndrome of hepatomegaly, jaundice, elevated liver enzymes (AST, ALT, alkaline phosphate), and low-grade fever with possible ascites and prolonged PT time. These manifestations may improve if alcohol intake ceases.

Even at the end-stage of cirrhosis, abstinence can result in significant reversal in some patients. If liver function does not recover after abstaining from alcohol for 6 months or longer, liver transplantation may be considered.

Chemical hepatotoxicity is liver injury caused by exposure to certain compounds (e.g., carbon tetrachloride, gold compounds). Some agents can cause hepatotoxicity, while others may induce cholestasis, necrosis, or liver cancer. Fortunately, because of the decreased use of these agents, the incidence of chemically induced liver toxicity has decreased since the 1980s.

Drug-induced liver injury (DILI) can present similarly to other forms of liver disease. The main cause of DILI is antimicrobial agents, especially amoxicillin-clavulanate. Many drugs (prescription, OTC, diet and herbal supplements) can cause an increase in liver enzymes and, in severe cases, jaundice and acute liver failure. The pattern of injury depends on the drug causing the reaction. The most common cause of acute liver failure is acetaminophen. In patients with chemical hepatotoxicity or DILI, all drugs identified as the cause of

liver injury should be stopped.[3]

Drug Alert

Acetaminophen (Tylenol)

- Safe when taken at recommended levels.
- Its prevalence in a variety of pain relievers, fever reducers, and cough medicines may mean that patients do not realize they are taking several drugs that all contain acetaminophen and overdose may occur.
- Acute liver failure can occur because of overdosing, either intentionally or unintentionally.
- The FDA has asked drug manufacturers to limit the strength of acetaminophen in prescription drug products to 325 mg per tablet, capsule, or other dosage unit, making these products safer.
- Combining the drug with alcoholic beverages increases the risk for liver damage.

Autoimmune, Genetic, and Metabolic Liver Diseases

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic inflammatory disorder of the liver in which the patient's own immune system attacks the liver. The cause of this condition is unknown. Autoimmune hepatitis is characterized by the presence of autoantibodies and high levels of serum immunoglobulins. It often occurs with other autoimmune diseases.

Most patients with autoimmune hepatitis are women. Laboratory tests useful in the diagnosis include antinuclear antibody (ANA), anti–smooth muscle antibody (ASMA), and antimitochondrial antibody (AMA) testing. A liver biopsy is often done to confirm the diagnosis and guide the treatment decision.[8]

Although autoimmune hepatitis can cause acute liver failure, the spectrum of disease is variable. Most patients develop chronic hepatitis. Untreated autoimmune hepatitis can progress to cirrhosis. Prednisone with or without azathioprine (Imuran) is the recommended treatment for active autoimmune hepatitis. Cyclosporine (Gengraf), tacrolimus (Prograf, FK506), budesonide (Entocort), methotrexate, mercaptopurine, and mycophenolate mofetil (CellCept) are options in those who do not respond to prednisone and azathioprine.[8] Mycophenolate is most often used for patients intolerant to azathioprine.

Wilson's Disease

Wilson's disease is an autosomal recessive disorder involving cellular copper transport. A defect in biliary excretion leads to accumulation of copper in the liver, causing progressive liver injury and cirrhosis. About 30 people per million have Wilson's disease. It usually appears between ages 5 and 35.[9]

Once cirrhosis occurs, copper leaks into the plasma, leading to

multiple complications, including neurologic, hematologic, and renal disease. The hallmark of Wilson's disease is corneal Kayser-Fleischer rings. These are brownish red rings seen in the cornea near the limbus on eye examination. Low serum ceruloplasmin levels and markedly elevated copper concentrations from liver biopsy samples are present. Diagnosis is based on clinical findings, including the corneal rings and neurologic symptoms. First-degree relatives of patients with Wilson's disease should be screened for the disease.

The recommended first treatment of symptomatic patients or those with active disease is chelating agents, such as D-penicillamine (Cuprimine) or trientine (Syprine). They promote the excretion of urinary copper. Zinc acetate (Galzin), another therapy, interferes with copper absorption. Once we have reduced the amount of copper in the body, treatment focuses on preventing copper from building up again. Liver transplantation may be an option with severe liver damage.

Hemochromatosis

Hemochromatosis is a condition in which excess iron accumulates in the body. It is primarily caused by a genetic defect *(hereditary hemochromatosis)*. It also can be caused by liver disease and chronic blood transfusions used to treat thalassemia and sickle cell disease. Hemochromatosis is discussed in Chapter 30.

Primary Biliary Cholangitis

Primary biliary cholangitis (PBC), formerly known as primary biliary cirrhosis, is a chronic disease of the small bile ducts of the liver.[3] In PBC, there is a T cell–mediated attack of the small bile duct cells, resulting in loss of bile ducts and cholestasis (blockage of bile flow). Over time, this leads to liver fibrosis and cirrhosis.

Most patients diagnosed with PBC are middle-aged women. The disease is associated with other autoimmune disorders, such as rheumatoid arthritis, Sjögren's syndrome, and scleroderma. High serum alkaline phosphatase levels, AMAs, ANAs, and serum lipid levels occur in patients with PBC.

The goals of treatment are suppressing ongoing liver damage, preventing complications, and symptom management. Drugs for PBC include ursodeoxycholic acid (ursodiol [Actigall]), a bile acid, and obeticholic acid (Ocaliva). It decreases bile in the liver. Management focuses on preventing or minimizing malabsorption, skin disorders, such as itching and xanthomas (cholesterol deposits in the skin), hyperlipidemia, vitamin deficiencies, anemia, and fatigue. Cholestyramine is used to treat itching. Patients are monitored for progression to cirrhosis. Liver transplantation is an option for end-stage liver disease in patients with PBC.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a disease of unknown cause characterized by chronic inflammation, fibrosis, and strictures (narrowing) of the medium and large bile ducts both inside and outside the liver.[3] Most patients with PSC also have ulcerative colitis or, less often, Crohn's disease. Complications of PSC can include cholangitis, cholestasis with jaundice, bile duct cancer, and cirrhosis.

Drug therapy has no proven benefit, although many HCPs use ursodiol. Treatment is directed at reducing the incidence of biliary complications and screening for bile duct and colorectal cancer, which is related to the high incidence of ulcerative colitis. Patients with advanced liver disease may need liver transplantation.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease (NAFLD) refers to a wide spectrum of liver diseases ranging from a fatty liver (steatosis) to **nonalcoholic steatohepatitis (NASH)** to cirrhosis. The term *nonalcoholic* is used because NAFLD and NASH occur in people who do not consume excess amounts of alcohol.

The fundamental characteristic of NAFLD is the accumulation of fatty infiltration in the hepatocytes. In NASH, the fat accumulation is

associated with varying degrees of inflammation and fibrosis of the liver. If NASH is untreated, it can become a serious liver disease leading to cirrhosis, liver cancer, and liver failure.

Currently, NAFLD is increasing because of the growing number of people who are obese. NAFLD occurs in 90% to 95% of severely obese children and adults. NASH occurs in 8% to 20% of obese persons with NAFLD.[3] NAFLD should be considered in patients with risk factors, including obesity, diabetes, hyperlipidemia, and hypertension (also known as *metabolic syndrome*).

Elevated liver function tests (ALT, AST) are often the first sign of NAFLD. Ultrasound and CT scans can be used to diagnose NAFLD. Definitive diagnosis is by a liver biopsy.

There is no currently approved medication for NAFLD.[10] The goal of therapy is weight loss of at least 10% of body weight, if overweight or obese and exercise. Reducing risk factors, including hyperlipidemia, hypertension, and diabetes, is important.

Promoting Health Equity

Liver, Pancreas, and Gallbladder Disorders

Hepatitis

- Hepatitis C has a higher incidence among blacks than whites.
- Hepatitis B has a higher incidence among Asian Americans and Pacific Islanders.
- Deaths caused by hepatitis C are more common in blacks.

Liver and Pancreatic Cancer

- Primary liver cancer has a highest incidence in Hispanics, followed by blacks and whites.
- Pancreatic cancer occurs more often among blacks than whites.

Gallbladder Disease

- Whites and Native Americans have a higher incidence of gallbladder disease than blacks or Asian Americans

Cirrhosis

Cirrhosis is the end stage of liver disease. Cirrhosis is characterized by extensive degeneration and destruction of the liver cells. This results in the replacement of liver tissue by fibrosis (scar tissue) and regenerative nodules that occur from the liver's attempt to repair itself (Fig. 43.4). The development of cirrhosis usually happens after decades of chronic liver disease.

Etiology and Pathophysiology

Any chronic liver disease, including disease from excess alcohol use and NAFLD, can cause cirrhosis. The most common causes of cirrhosis in the United States are chronic hepatitis C infection and alcohol-induced liver disease. In patients with alcohol-induced liver disease, controversy exists as to the degree to which malnutrition adds to the damage caused by the alcohol itself. Some cases of nutrition-related cirrhosis have resulted from extreme dieting, malabsorption, and obesity. Environmental factors and genetic predisposition may lead to the development of cirrhosis, regardless of dietary or alcohol intake.

Around 20% of patients with chronic hepatitis C and 25% of those with chronic hepatitis B develop cirrhosis.[3] Chronic inflammation and cell necrosis from viral hepatitis can result in progressive fibrosis and cirrhosis. Chronic hepatitis combined with alcohol use has a synergistic effect in accelerating liver damage.

Biliary causes of cirrhosis include primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC). Both are described earlier in this chapter.

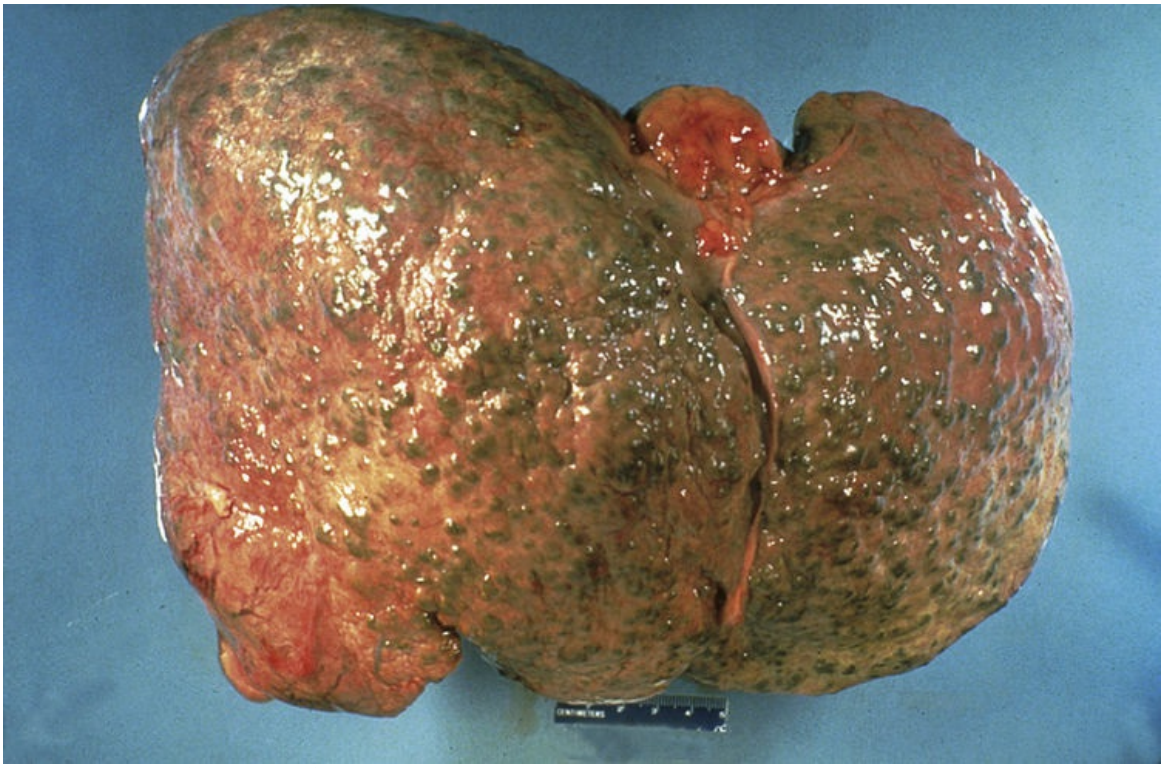

FIG. 43.4 Cirrhosis that developed from alcohol use. The characteristic diffuse nodularity of the surface is due to the combination of regeneration and scarring of the liver.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.

Cardiac cirrhosis includes a spectrum of hepatic problems that result from long-standing, severe, right-sided heart failure. It causes hepatic venous congestion, parenchymal damage, necrosis of liver cells, and fibrosis over time. Treatment is aimed at managing the patient's underlying heart failure.

In cirrhosis, the liver cells try to regenerate, but the regenerative process is disorganized. This results in abnormal blood vessel and bile duct architecture. The overgrowth of new and fibrous connective tissue distorts the liver's normal lobular structure, resulting in lobules of irregular size and shape with impeded blood flow. Eventually, irregular and disorganized liver regeneration, poor cellular nutrition, and hypoxia (from inadequate blood flow and scar tissue) result in decreased liver function.

Clinical Manifestations

Early Manifestations

Patients may be unaware of their liver condition because there are few symptoms in early-stage disease. If a person does have symptoms, these may include fatigue or an enlarged liver. Blood tests may show normal liver function (compensated cirrhosis). The diagnosis of cirrhosis is often made later when a patient presents with symptoms of more advanced liver disease.

Late Manifestations

Late manifestations result from liver failure and portal hypertension (Fig. 43.5). Jaundice, peripheral edema, and ascites develop gradually. Other late manifestations include skin lesions, hematologic problems, endocrine problems, and peripheral neuropathies (Fig. 43.6). In the advanced stages, the liver becomes small and nodular. Liver function is dramatically impaired.

Jaundice

Jaundice results from decreased ability to conjugate and excrete bilirubin into the small intestines (Table 43.3). There is an overgrowth of connective tissue in the liver, which compresses the bile ducts and leads to an obstruction. This results in an increase in the bilirubin in the vascular system, and jaundice occurs. The jaundice may be minimal or severe, depending on the degree of liver damage.

Skin Lesions

Various skin manifestations often occur with cirrhosis. **Spider angiomas** (*telangiectasia* or *spider nevi*) are small, dilated blood vessels with a bright red center point and spiderlike branches. They occur on the nose, cheeks, upper trunk, neck, and shoulders. *Palmar erythema* (a red area that blanches with pressure) occurs on the palms of the hands. Both lesions are due to an increase in circulating estrogen due to the damaged liver's inability to metabolize steroid hormones.

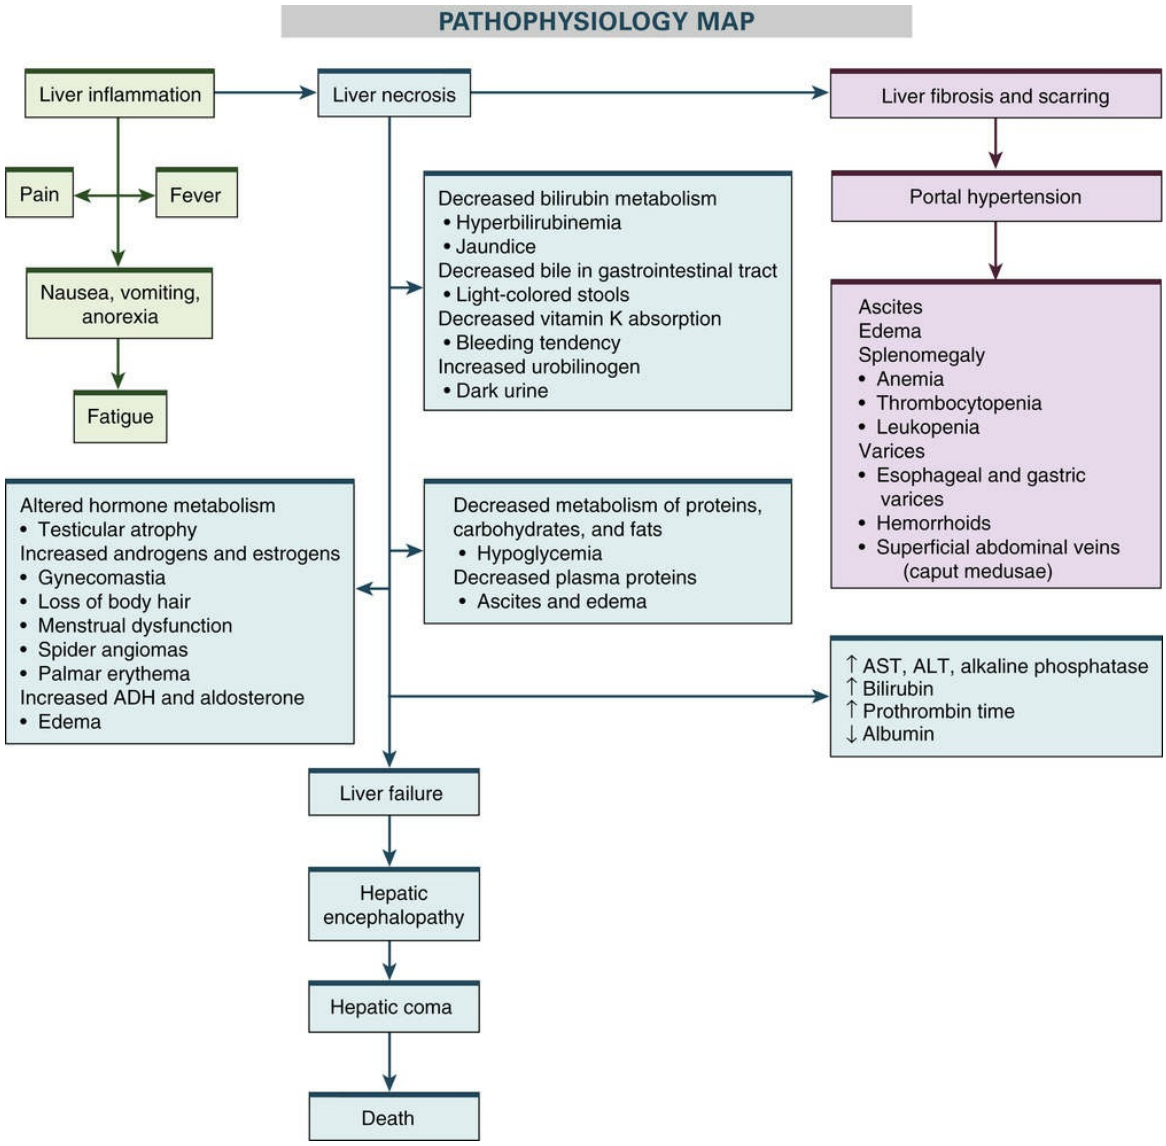

FIG. 43.5 Continuum of liver dysfunction in cirrhosis and resulting manifestations.
Adapted from Huether SE, McCance KL: *Understanding pathophysiology,* ed 5, St Louis, 2012, Mosby.

Hematologic Problems

Hematologic problems include thrombocytopenia, leukopenia, anemia, and coagulation disorders. We think thrombocytopenia, leukopenia, and anemia are caused by the splenomegaly that results from backup of blood from the portal vein into the spleen (portal hypertension). Overactivity of the enlarged spleen results in increased removal of blood cells from circulation. Anemia can result from

inadequate red blood cell (RBC) production and survival, poor diet, poor absorption of folic acid, and bleeding from varices.

The coagulation problems result from the liver's inability to make prothrombin and other factors essential for blood clotting. Manifestations of coagulation problems (bleeding tendencies) include epistaxis, purpura, petechiae, easy bruising, gingival bleeding, and heavy menstrual bleeding.

Endocrine Problems

The liver plays a vital role in the metabolism of hormones, such as estrogen and testosterone. In men with cirrhosis, gynecomastia (benign growth of the glandular tissue of the male breast), loss of axillary and pubic hair, testicular atrophy, and impotence with loss of libido may occur because of increased estrogen levels. Younger women with cirrhosis may develop amenorrhea, and older women may have vaginal bleeding. If the liver does not metabolize aldosterone properly, it can lead to hyperaldosteronism with sodium and water retention and potassium loss.

Peripheral Neuropathy

Peripheral neuropathy is a common finding in alcoholic cirrhosis. It is probably due to a dietary deficiency of thiamine, folic acid, and cobalamin. The neuropathy usually results in sensory and motor symptoms, but sensory symptoms may predominate.

Complications

Major complications of cirrhosis are portal hypertension, esophageal and gastric varices, peripheral edema, abdominal ascites, hepatic encephalopathy (mental status changes, including coma), and hepatorenal syndrome. Patients who are cirrhotic but who have no obvious complications have *compensated cirrhosis.* Those who have 1 or more complications of their liver disease have *decompensated cirrhosis*.

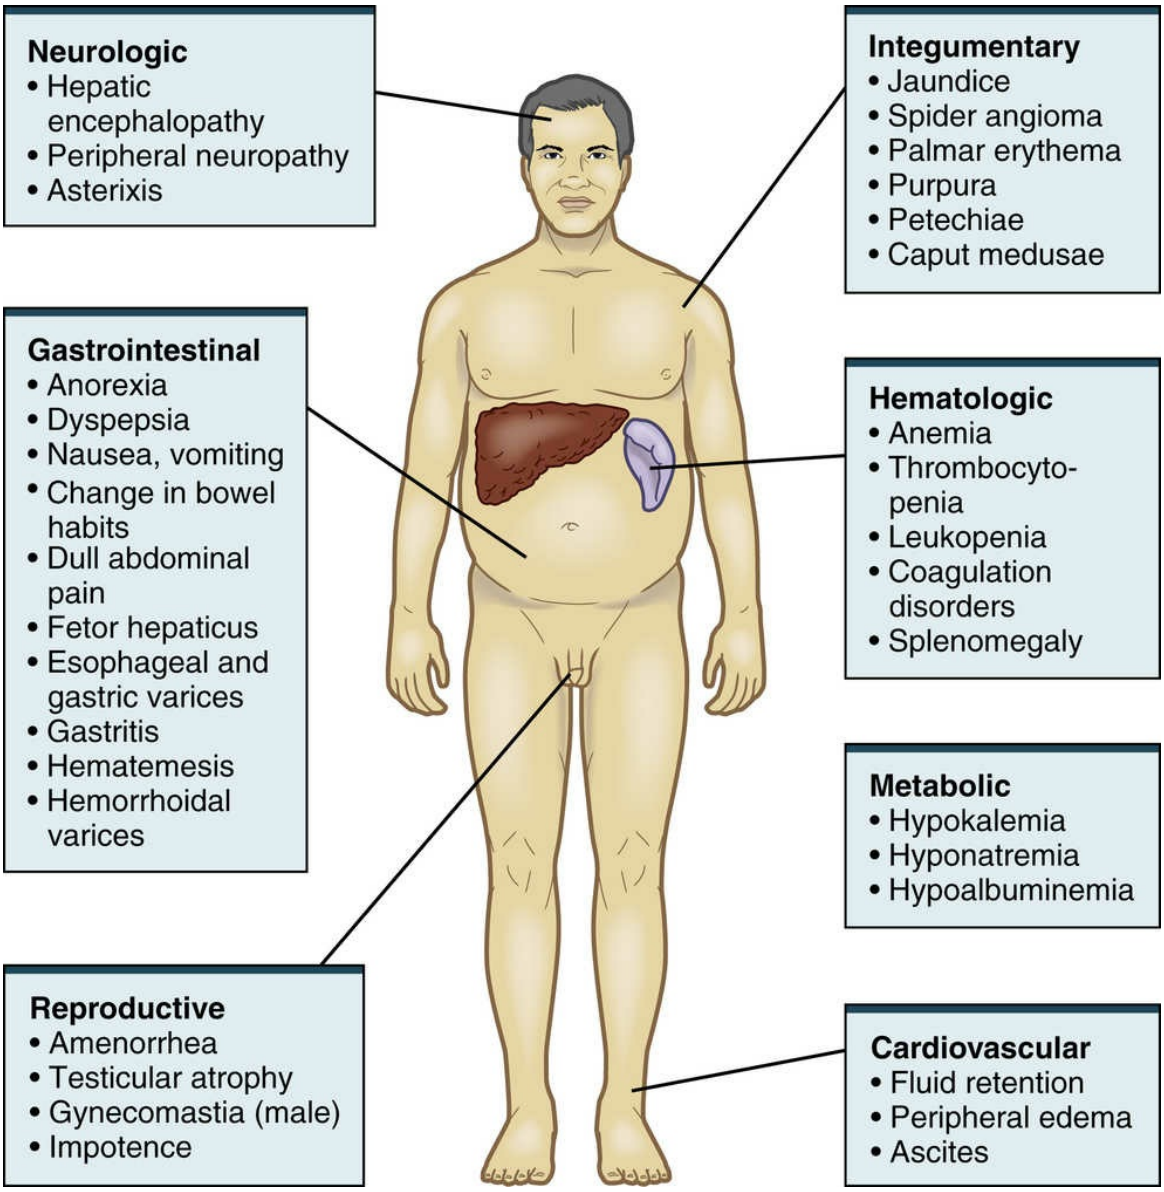

FIG. 43.6 Systemic manifestations of liver cirrhosis.

Portal Hypertension and Esophageal and Gastric Varices

In patients with cirrhosis, the liver undergoes structural changes. These changes lead to obstruction of blood flow in and out of the liver. This results in increased pressure within the liver's circulatory system (portal hypertension). **Portal hypertension** is characterized by increased venous pressure in the portal circulation, splenomegaly, large collateral veins, ascites, and gastric and esophageal varices.

As a way of reducing pressure, the body develops alternate

circulatory pathways, referred to as *collateral circulation.* The collateral channels often form in the lower esophagus, anterior abdominal wall, parietal peritoneum, and rectum. Varicosities (distended veins) develop in areas where the collateral and systemic circulations communicate, resulting in esophageal and gastric varices, *caput medusae* (ring of varices around the umbilicus), and hemorrhoids.

Esophageal varices are a complex of tortuous, enlarged veins at the lower end of the esophagus. **Gastric varices** are found in the upper part of the stomach. These varices are fragile and do not tolerate high pressure, so they can bleed easily. Large varices are more likely to bleed. Esophageal varices can cause variceal hemorrhages with a 5-year mortality of 20%.[11] The patient may present with melena or hematemesis. Ruptured esophageal varices are the most life-threatening complication of cirrhosis and considered a medical emergency.

Peripheral Edema and Ascites

Peripheral edema occurs in the lower extremities and presacral area. Peripheral edema can occur before, concurrently with, or after ascites development. Edema results from decreased colloidal oncotic pressure from impaired liver synthesis of albumin and increased portacaval pressure from portal hypertension.

Ascites is the accumulation of serous fluid in the peritoneal or abdominal cavity. It is a common manifestation of cirrhosis. Several mechanisms lead to ascites. One mechanism of ascites occurs with portal hypertension, which causes proteins to shift from the blood vessels into the lymph space (Fig. 43.7). When the lymphatic system is unable to carry off the excess proteins and water, they leak into the peritoneal cavity. The osmotic pressure of the proteins pulls more fluid into the peritoneal cavity (Table 43.10).

A second mechanism of ascites formation is hypoalbuminemia resulting from the liver's decreased ability to synthesize albumin. The hypoalbuminemia results in decreased colloidal oncotic pressure.

A third mechanism of ascites is hyperaldosteronism, which occurs when the damaged hepatocytes metabolize aldosterone. The increased

aldosterone level causes increased sodium reabsorption by the renal tubules. Sodium retention, combined with an increase in antidiuretic hormone in blood, leads to further water retention and edema. Edema decreases intravascular volume with decreased renal blood flow and glomerular filtration.

Ascites is manifested by abdominal distention with weight gain (Fig. 43.8). If the ascites is severe, the increase in abdominal pressure from the fluid accumulation may cause eversion of the umbilicus. Abdominal striae with distended abdominal wall veins may be present. Patients may have signs of dehydration (e.g., dry tongue and skin, sunken eyeballs, muscle weakness) and a decrease in urine output. Hypokalemia is common. It is due to an excessive loss of potassium caused by hyperaldosteronism. Low potassium levels can also result from diuretic therapy used to treat the ascites.

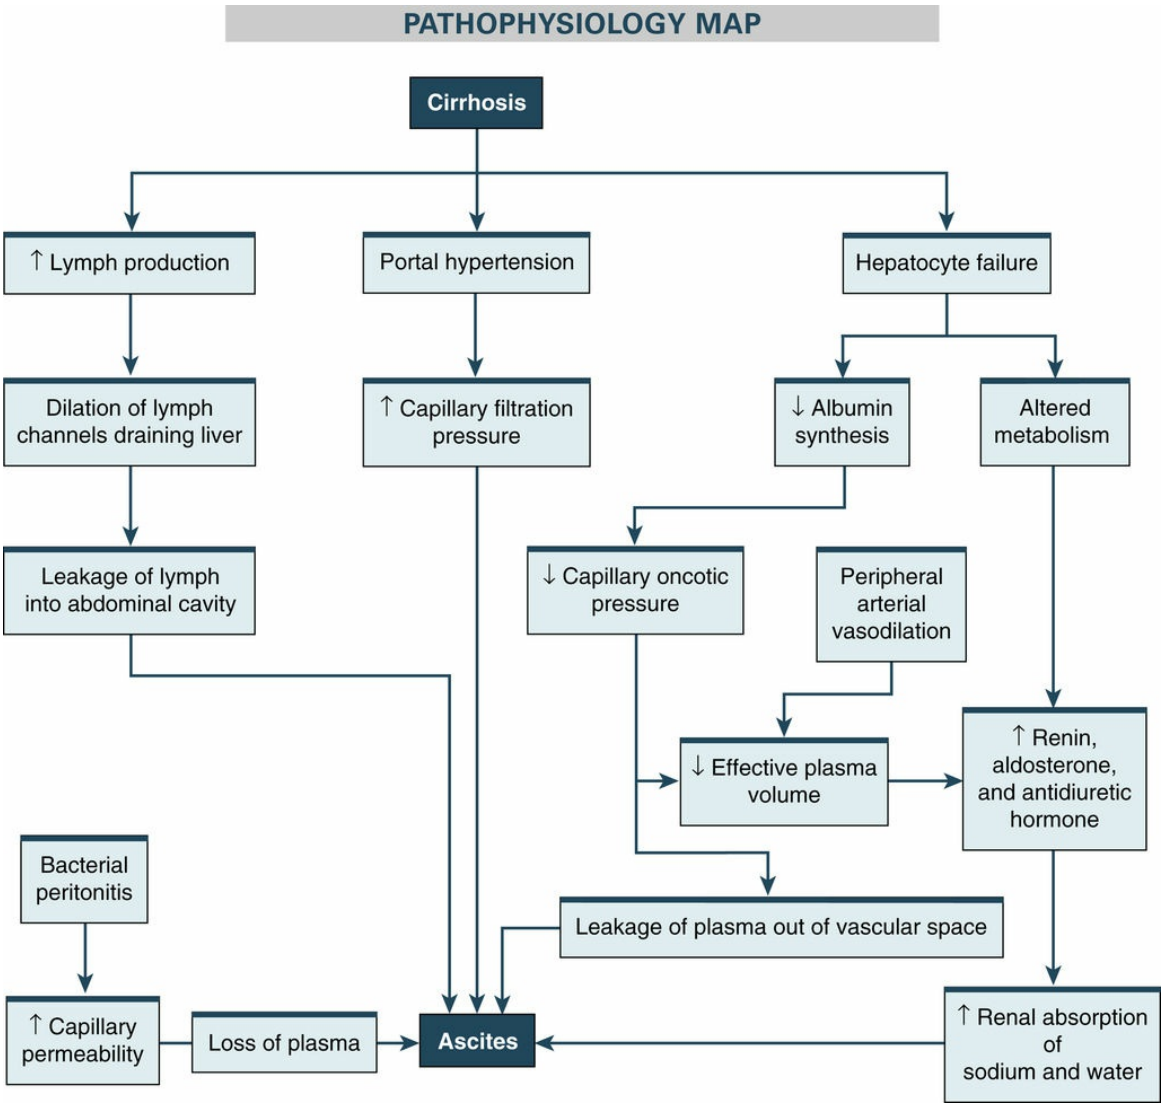

FIG. 43.7 Mechanisms for development of ascites. Adapted from Huether SE, McCance KL: *Understanding pathophysiology,* ed 5, St Louis, 2012, Mosby.

TABLE 43.10 Factors Involved in Ascites

Factor	Mechanism
Decreased serum colloidal oncotic pressure	Impaired liver synthesis of albumin Loss of albumin into peritoneal cavity
Hyperaldosteronism	↑ Aldosterone secretion stimulated by ↓ renal blood flow ↓ Liver catabolism of circulating aldosterone
Impaired water excretion	↑ Antidiuretic hormone stimulated by ↓ renal blood flow
Increased flow of hepatic lymph	Leaking of protein-rich lymph from surface of cirrhotic liver
Portal hypertension	↑ Resistance of blood flow through liver

Because of decreased immune function associated with cirrhosis, patients with ascites are at risk for *spontaneous bacterial peritonitis* (SBP). SBP is a bacterial infection of the ascitic fluid. In SBP, bacteria normally found in the intestines move into the peritoneal space. The bacteria most often responsible for the infection are a gram-negative enteric pathogen, such as *Escherichia coli.* SBP is a common complication of hospitalized patients with cirrhosis and ascites. Worsening vasodilation contributes to the development of SBP.[11]

FIG. 43.8 Gross ascites.

From Butcher GP: *Gastroenterology: An illustrated colour text,* London, 2004, Churchill Livingstone.

Hepatic Encephalopathy

Hepatic encephalopathy is a neuropsychiatric manifestation of liver disease. The pathogenesis is multifactorial. It includes the neurotoxic effects of ammonia, abnormal neurotransmission, astrocyte swelling, and inflammatory cytokines. A major source of ammonia is the bacterial and enzymatic deamination of amino acids in the intestines. The ammonia that results from deamination normally goes to the liver via the portal circulation and is converted to urea. The kidneys then excrete urea. When blood is shunted past the liver via the collateral vessels or the liver is so damaged that it is unable to convert ammonia to urea, the levels of ammonia in the systemic circulation increase. The ammonia crosses the blood-brain barrier and produces neurologic toxic manifestations.

Factors that increase ammonia in the circulation may precipitate hepatic encephalopathy (Table 43.11). Hepatic encephalopathy can occur after placement of a transjugular intrahepatic portosystemic shunt (TIPS). TIPS reduces portal hypertension by diverting blood flow around the liver. (TIPS is discussed on p. 986.)

Manifestations include changes in neurologic and mental responsiveness; impaired consciousness; and inappropriate behavior, ranging from sleep problems to trouble concentrating to deep coma. Changes may occur (1) suddenly from an increase in ammonia in response to bleeding varices or infection or (2) gradually as blood ammonia levels slowly increase. We often use a grading system to classify the stages of hepatic encephalopathy (Table 43.12).

TABLE 43.11 Factors Precipitating Hepatic Encephalopathy

Factor	Mechanism
Cerebral depressants (e.g., opioids)	↓ Metabolism by liver, causing ↑ drug levels and cerebral depression
Constipation	↑ Production of ammonia from bacterial action on feces
Dehydration	Potentiates ammonia toxicity
GI hemorrhage	↑ Ammonia in GI tract
Hypokalemia	Potassium needed by brain to metabolize ammonia
Hypovolemia	↑ Blood ammonia because of hepatic hypoxia Impaired cerebral, hepatic, and renal function because of ↓ blood flow
↑ Metabolism	↑ Workload of liver
Infection	↑ Metabolic rate and cerebral sensitivity to toxins
Metabolic alkalosis	Facilitation of transport of ammonia across blood-brain barrier Increased renal production of ammonia
Paracentesis	Loss of sodium and potassium ions ↓ Blood volume
Uremia (renal failure)	Retention of nitrogenous metabolites

A characteristic manifestation is **asterixis** (flapping tremors). This may take several forms, with the most common involving the arms and hands. When asked to hold the arms and hands stretched out, the patient is unable to hold this position and performs a series of rapid flexion and extension movements of the hands.

Impairments in writing involve difficulty in moving the pen or pencil from left to right and *apraxia* (inability to construct simple figures). Other signs include hyperventilation, hypothermia, tongue fasciculations, and grimacing and grasping reflexes. *Fetor hepaticus* (musty, sweet odor of the patient's breath) occurs in some patients. This odor is from the accumulation of digestive by-products that the liver is unable to degrade.

Hepatorenal Syndrome

Hepatorenal syndrome is a type of renal failure with azotemia, oliguria, and intractable ascites. In this syndrome, the kidneys have no structural abnormality. The cause is complex. The final common pathway is likely to be portal hypertension along with liver decompensation, resulting in splanchnic and systemic vasodilation and decreased arterial blood volume. As a result, renal vasoconstriction occurs, and renal failure follows. Liver transplantation can reverse renal failure. In the patient with cirrhosis, hepatorenal syndrome can follow diuretic therapy, GI hemorrhage, or paracentesis.

Diagnostic Studies

Patients with cirrhosis have abnormalities in most of their liver function tests. Enzyme levels, including alkaline phosphatase, AST, ALT, and γ-glutamyl transpeptidase (GGT), are initially high due to their release from inflamed liver cells. However, in end-stage liver disease, AST and ALT levels may be normal due to the death and loss of hepatocytes. Patients will also have low serum total protein and albumin, increased serum bilirubin (Table 43.3) and globulin levels, and prolonged PT time. Low cholesterol levels reflect the changes in fat metabolism.

Although a liver ultrasound may be able to detect cirrhosis, it is not a reliable diagnostic test for cirrhosis. Ultrasound elastography (Fibroscan) is a noninvasive test used to quantify the degree of liver fibrosis. A liver biopsy, which may be done to identify liver cell changes, is the gold standard for a definitive diagnosis of cirrhosis.

Interprofessional Care

The goal of treatment is to slow the progression of cirrhosis and to prevent and treat any complications. Interprofessional care measures are listed in Table 43.13. Management of specific problems associated with cirrhosis is described next.

Ascites

Management of ascites focuses on sodium restriction, diuretics, and fluid removal.[12] Patients may need to limit sodium intake to 2 g/day. Very low sodium intake can result in reduced nutritional intake and malnutrition. The patient is usually not on restricted fluids unless severe ascites develops. When caring for patients with ascites, accurately monitor fluid and electrolyte balance. An albumin infusion may help maintain intravascular volume and adequate urine output by increasing plasma colloid oncotic pressure.

TABLE 43.12 Grading Scale for Hepatic Encephalopathy

Grade	Level of Consciousness	Intellectual Function	Neurologic Findings
0	Normal to minimal change	Subtle to no change in personality, behavior, memory, concentration	Asterixis absent May have abnormal psychometric test
1	Lack of awareness, sleep disturbance	Short attention span, impaired computational skills, personality change, decrease in short-term memory, mild confusion, depression	Incoordination, asterixis may be absent
2	Lethargy, drowsiness	Disoriented to time, inappropriate behavior, deficits in executive function	Asterixis, abnormal reflexes
3	Somnolent, arousable	Disoriented to time, loss of meaningful conversation, marked confusion, incomprehensible speech	Asterixis, abnormal reflexes
4	Not arousable, comatose	Absent	Decerebrate May be responsive to painful stimuli

TABLE 43.13 Interprofessional CareCirrhosis of the Liver

Diagnostic Assessment

- History and physical examination
- Liver function tests (ALT, AST, alkaline phosphatase, bilirubin, γ-glutamyl transpeptidase [GGT])
- Serum albumin
- Serum electrolytes
- PT time
- Complete blood count
- Liver biopsy (percutaneous needle)
- Liver ultrasound (e.g., FibroScan)
- Upper endoscopy (esophagogastroduodenoscopy)
- CT scan, MRI

Management

Conservative Therapy

- Rest
- B-complex vitamins
- Avoiding alcohol
- Minimizing or avoiding aspirin, acetaminophen, and NSAIDs

Ascites

- Low-sodium diet
- Diuretics
- Paracentesis (if needed)

Esophageal and Gastric Varices

- Endoscopic band ligation or sclerotherapy
- Balloon tamponade
- Transjugular intrahepatic portosystemic shunt (TIPS)

Drug Therapy

- Nonselective β-blocker (e.g., propranolol [Inderal])
- octreotide (Sandostatin)
- vasopressin

Hepatic Encephalopathy
Drug Therapy

- Antibiotics (rifaximin [Xifaxan])
- lactulose

Diuretic therapy is an important part of management. Often a combination of drugs that work at multiple sites of the nephron is more effective than a single agent. Spironolactone (Aldactone) is an effective diuretic, even in patients with severe ascites. Spironolactone is also an antagonist of aldosterone and is potassium sparing. Other potassium-sparing diuretics include amiloride (Midamor) and triamterene (Dyrenium). A high-potency loop diuretic (e.g., furosemide [Lasix]), is often used in combination with a potassium-sparing drug.

Tolvaptan (Samsca), a vasopressin-receptor antagonist, can correct hyponatremia, a common problem in patients with cirrhosis. It causes an increase in water excretion, resulting in an increase in serum sodium concentration.

A **paracentesis** is a sterile procedure in which a catheter is used to withdraw fluid from the abdominal cavity. This procedure can diagnose a medical condition or relieve pain, pressure, or difficulty breathing. In the patient with cirrhosis, this procedure is done for the person with impaired respiration or abdominal discomfort caused by severe ascites who does not respond to diuretic therapy. It is only a temporary measure of palliation because the fluid tends to reaccumulate rapidly.[12]

TIPS (discussed later in this section) is used to treat ascites that does not respond to diuretics. A peritoneovenous shunt is a surgical procedure that provides continuous reinfusion of ascitic fluid into the venous system. It is rarely used due to the high rate of complications.

Esophageal and Gastric Varices

The main therapeutic goal for esophageal and gastric varices is to prevent bleeding and variceal rupture by reducing portal pressure. The patient who has esophageal and/or gastric varices should avoid alcohol, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs).

All patients with cirrhosis should have an upper endoscopy (esophagogastroduodenoscopy [EGD]) to screen for varices. Patients with varices at risk for bleeding are often started on a nonselective β-blocker (nadolol [Corgard] or propranolol [Inderal]) to reduce the risk

of hemorrhage. β-Blockers decrease high portal pressure, which decreases the risk for rupture.

When variceal bleeding occurs, the first step is to stabilize the patient and manage the airway. IV therapy is started and may include giving blood products. Care then moves toward stopping the bleeding, identifying the source, and applying interventions to prevent further bleeding. Management that involves a combination of drug therapy and endoscopic therapy is more successful than either approach alone.

Drug therapy for bleeding varices may include the somatostatin analog octreotide (Sandostatin) or vasopressin. Both produce vasoconstriction of the splanchnic arterial bed, decrease portal blood flow, and decrease portal hypertension. Currently, octreotide is used more often because it has fewer side effects than vasopressin.

At the time of endoscopy, band ligation or sclerotherapy of varices may be used to prevent rebleeding. Endoscopic variceal ligation (EVL, or "banding") is done by placing a small rubber band (elastic O-ring) around the base of the *varix* (enlarged vein). Sclerotherapy involves injecting a sclerosing solution into the swollen veins through a needle placed through the endoscope.

Balloon tamponade is an option when endoscopy does not control acute esophageal or gastric variceal hemorrhage. Balloon tamponade controls the hemorrhage by mechanical compression of the varices. Several types of tubes are available. The Sengstaken-Blakemore tube has 2 balloons, gastric and esophageal, with 3 lumens: 1 for the gastric balloon, 1 for the esophageal balloon, and 1 for gastric aspiration. Two other types of balloons are the Minnesota tube (a modified Sengstaken-Blakemore tube with an esophageal suction port above the esophageal balloon) and the Linton-Nachlas tube.

Safety Alert

Balloon Tamponade

- Label each lumen to avoid confusion.
- Secure the tube to prevent movement of the tube that could result in occlusion of the airway.
- Deflate balloons for 5 minutes every 8 to 12 hr per agency policy to prevent tissue necrosis.

Supportive measures during an acute variceal bleed include giving fresh frozen plasma and packed RBCs, vitamin K, and proton pump inhibitors (PPIs; e.g., pantoprazole). Lactulose and rifaximin (Xifaxan) may be given to prevent hepatic encephalopathy from breakdown of blood and the release of ammonia in the intestine. Antibiotics are given to prevent bacterial infection.

Because of the high incidence of recurrent bleeding with each bleeding episode, continued therapy is necessary. Long-term management of patients who have had an episode of bleeding includes nonselective β-blockers, repeated band ligation of the varices, and portosystemic shunts in patients who develop recurrent bleeding.

Shunting Procedures

Nonsurgical and surgical methods of shunting blood away from the varices are available. Shunting procedures tend to be done more after a second major bleeding episode than during an initial bleeding episode. *Transjugular intrahepatic portosystemic shunt (TIPS)* is a nonsurgical procedure in which a tract (shunt) between the systemic and portal venous systems is created to redirect portal blood flow. A catheter is placed in the jugular vein and then threaded through the superior and inferior vena cava to the hepatic vein. The wall of the hepatic vein is punctured, and the catheter is directed to the portal vein. Stents are positioned along the passageway, overlapping in the liver tissue and extending into both veins.

This procedure reduces portal venous pressure and decompresses the varices, thus controlling bleeding. TIPS does not interfere with a future liver transplantation. Limitations of TIPS include the increased risk for hepatic encephalopathy (toxin-containing blood bypasses the liver) and stenosis of the stent. TIPS is contraindicated in patients with

severe hepatic encephalopathy, liver cancer, severe hepatorenal syndrome, and portal vein thrombosis.

FIG. 43.9 Portosystemic shunts. **A,** Portacaval shunt. The portal vein is anastomosed to the inferior vena cava, diverting blood from the portal vein to the systemic circulation. **B,** Distal splenorenal shunt. The splenic vein is anastomosed to the renal vein. The portal venous flow stays intact while esophageal varices are selectively decompressed. (The short gastric veins are decompressed.) The spleen conducts blood from the high pressure of the esophageal and gastric varices to the low-pressure renal vein.

Various surgical shunting procedures can decrease portal hypertension by diverting some of the portal blood flow while allowing adequate liver perfusion. Currently, the surgical shunts most often used are the portacaval shunt and the distal splenorenal shunt (Fig. 43.9).

Hepatic Encephalopathy

The goal of management of hepatic encephalopathy is to reduce ammonia formation. Lactulose, a drug that traps ammonia in the gut, reduces ammonia formation in the intestines. We can give it orally, as an enema, or through a nasogastric (NG) tube. The drug's laxative effect expels the ammonia from the colon. Antibiotics, such as rifaximin, also may be given, especially in patients who do not respond to lactulose. Regular and frequent bowel movements are necessary to minimize the ammonia buildup, so use measures to prevent constipation.

Control of hepatic encephalopathy also involves treatment of precipitating causes (Table 43.10). This includes lowering dietary protein intake, preventing and controlling GI bleeds, and, in the case of a bleed, removing the blood promptly from the GI tract to decrease the protein accumulation in the gut.

Drug Therapy

There is no specific drug therapy for cirrhosis. However, several drugs are used to treat symptoms and complications of advanced liver disease (Table 43.14).

Nutritional Therapy

The diet for the patient who has cirrhosis without complications is high in calories (3000 cal/day). It is high in carbohydrate content with moderate to low levels of fat. Protein restriction may be needed for some patients right after a severe flare of symptoms (i.e., episodic hepatic encephalopathy). However, protein restriction is rarely needed in patients with cirrhosis and persistent hepatic encephalopathy. For many, malnutrition is a more serious clinical problem than hepatic encephalopathy.[3]

TABLE 43.14 Drug TherapyCirrhosis

Drug	Mechanism of Action
Diuretics	
furosemide (Lasix)	Acts on distal tubule and loop of Henle to ↓ reabsorption of sodium and water
spironolactone (Aldactone)	Blocks actions of aldosterone, potassium sparing
Other Therapy	
lactulose	Acidifies feces in bowel and traps ammonia, causing its elimination in feces
magnesium sulfate	Corrects hypomagnesemia that may occur with liver dysfunction
nadolol (Corgard) **propranolol (Inderal)**	Reduces portal venous pressure and esophageal variceal bleeding
neomycin sulfate **rifaximin (Xifaxan)**	↓ Bacterial flora, thus reducing ammonia formation
octreotide (Sandostatin) **vasopressin**	Hemostasis and control of bleeding in esophageal and gastric varices, constricts splanchnic arterial bed
PPIs (e.g., pantoprazole [Protonix])	↓ Gastric acidity
Vitamin K	Corrects clotting abnormalities from decreased vitamin K levels

A patient with alcoholic cirrhosis often has protein-calorie malnutrition. Oral nutritional supplements containing protein from branched-chain amino acids that are metabolized by the muscles may be needed. These supplements provide protein that the liver can more easily metabolize. Parenteral nutrition or EN are used with severe cases of malnutrition (see Chapter 39).

The patient with ascites and edema is placed on a low-sodium diet. The degree of sodium restriction depends on the patient's condition. Teach the patient and caregiver about the degree of restriction. Table salt is a well-known source of sodium. Other foods high in sodium

include canned soups and vegetables, many frozen foods, salted snacks (e.g., potato chips), nuts, smoked meats and fish, crackers, breads, baking soda, olives, pickles, ketchup, and beer. Teach the patient to read labels for sodium content (see Fig. 34.5). Offer suggestions about how to make the diet more palatable. Seasonings, like garlic, parsley, onion, lemon juice, and spices may make food more appetizing. Collaborate with a dietitian about dietary strategies.

Nursing Management: Cirrhosis

Nursing Assessment

Subjective and objective data that should be obtained from a person with cirrhosis are outlined in Table 43.15.

Nursing Diagnoses

Nursing diagnoses for the patient with cirrhosis may include:

- Impaired nutritional status
- Ineffective tissue perfusion
- Activity intolerance
- Fluid imbalance

Additional information on nursing diagnoses and interventions for the patient with cirrhosis is presented in eNursing Care Plan 43.2 available on the website for this chapter.

Planning

The overall goals are that the patient with cirrhosis will (1) have relief of discomfort, (2) have minimal to no complications (ascites, esophageal varices, hepatic encephalopathy), and (3) return to as normal a lifestyle as possible.

Nursing Implementation

Health Promotion

Common risk factors for cirrhosis include alcohol use, malnutrition, viral hepatitis, biliary obstruction, obesity, and right-sided heart failure. Prevention and early treatment of cirrhosis focus on reducing or eliminating these risk factors. Urge patients to abstain from alcohol.

Encourage those with chronic alcohol use to enroll in support programs that help patients maintain sobriety. (The treatment of alcohol use is discussed in Chapter 10.)

Adequate nutrition, especially for the person who uses alcohol and other people at risk for cirrhosis, is essential to promote normal liver regeneration. Identify and treat acute hepatitis early so that it does not progress to chronic hepatitis and cirrhosis. Bariatric surgery for morbidly obese persons reduces the incidence of NAFLD.

Acute Care

Nursing care for the patient with cirrhosis focuses on conserving the patient's strength while maintaining muscle strength and tone. When the patient needs complete bed rest, implement measures to prevent pneumonia, thromboembolic problems, and pressure injuries. Modify the activity and rest schedule according to signs of improvement (e.g., decreasing jaundice, improvement in liver function studies).

TABLE 43.15 Nursing AssessmentCirrhosis

Subjective Data
Important Health Information

Past health history: Viral, toxic, or idiopathic hepatitis. Alcohol use, metabolic syndrome, chronic biliary obstruction and infection, severe right-sided heart failure

Medications: Adverse reaction to any medication. Use of anticoagulants, aspirin, NSAIDs, acetaminophen

Functional Health Patterns

Health perception–health management: Chronic alcohol use. Weakness, fatigue

Nutritional-metabolic: Anorexia, weight loss, dyspepsia, nausea and vomiting, gingival bleeding. Dry, yellow skin, bruising
Elimination: Dark urine, decreased urine output, light-colored or black stools, flatulence, change in bowel habits.
Cognitive-perceptual: Dull, right upper quadrant or epigastric pain. Numbness, tingling of extremities. Itching
Sexuality-reproductive: Impotence, amenorrhea

Objective Data

General

Fever, cachexia, wasting of extremities

Integumentary

Icteric sclera, jaundice, petechiae, ecchymoses, spider angiomas, palmar erythema, alopecia, loss of axillary and pubic hair, peripheral edema

Respiratory

Shallow, rapid respirations. Epistaxis

Gastrointestinal

Abdominal distention, ascites, distended abdominal wall veins, palpable liver and spleen, foul breath. Hematemesis. Black, tarry stools. Hemorrhoids

Neurologic

Altered mentation, asterixis

Reproductive

Gynecomastia, testicular atrophy, and impotence (men); loss of libido (men and women); amenorrhea or heavy menstrual bleeding (women)

Possible Diagnostic Findings

Anemia, thrombocytopenia; leukopenia. ↓ Serum albumin, potassium. Abnormal liver function studies. ↑ INR, ↓ platelets, ↑ ammonia, ↑ bilirubin levels. Abnormal abdominal ultrasound, CT, or MRI

Anorexia, nausea and vomiting, pressure from ascites, and poor eating habits all interfere with adequate intake of nutrients. Oral hygiene before meals may improve the patient's taste sensation. Make between-meal snacks available so that the patient can eat them at times when food is best tolerated. Offer preferred foods whenever possible. Explain the reason for any dietary restrictions to the patient and caregiver.

Nursing assessment and care should include the patient's physical status. Is jaundice present? Where is it seen—sclera, skin, hard palate? What is the progression of jaundice? If the pruritis accompanies jaundice, use measures to relieve itching. Cholestyramine or hydroxyzine (Atarax) may help. Other measures to relieve itching include baking soda or moisturizing bath oils (Alpha Keri), lotions containing calamine, antihistamines, soft or old linens, and control of the temperature (not too hot and not too cold). Keep the patient's nails short and clean. Teach patients to rub with their knuckles rather than scratch with their nails when they cannot resist scratching.

TABLE 43.16 Nursing ManagementCare of the Patient Undergoing Paracentesis

Preprocedure

- Have the patient void or insert an indwelling catheter.
- Obtain baseline vital signs and pulse oximetry. Weigh patient, inspect and palpate abdomen, and assess abdominal girth. Assess bladder for distention and determine last voiding.
- Assess baseline laboratory values (e.g., CBC, electrolytes, coagulation studies).
- Give any sedation or analgesia, if ordered.
- Teach patient to remain immobile during the procedure.
- Help the patient to a high-Fowler (sitting) position with feet on the floor.

Postprocedure

- Perform assessment and compare to baseline: vital signs, pulse oximetry, abdominal girth, abdominal pain. Note any signs of hypovolemia.
- Have the patient sit on the side of the bed or place in high-Fowler's position.
- Label and send the fluid for laboratory analysis.
- Check the dressing for bleeding and/or leakage of ascitic fluid.
- Give IV fluid and/or albumin as ordered.
- Measure any drainage and describe the collected fluid.
- Reweigh the patient and monitor intake and output.
- Maintain bedrest per agency protocol.

Note the color of urine and stools and assess for improvement or

normalization of color. When jaundice is present, the urine is often dark brown, and the stool is gray or tan.

Edema and ascites require your assessment and intervention. Accurate calculation and recording of intake and output, daily weights, and measurements of extremities and abdominal girth help in the ongoing assessment of the location and extent of the edema. Mark the abdomen with a permanent marker so that you measure the girth at the same location each time.

Immediately before a paracentesis, have the patient void to prevent puncturing of the bladder during the procedure. Other nursing care associated with a paracentesis is outlined in Table 43.16.

Dyspnea is a frequent problem for the patient with severe ascites and can lead to pleural effusions. A semi-Fowler's or Fowler's position allows for maximal respiratory efficiency. Use pillows to support the arms and chest to increase the patient's comfort and ability to breathe.

Meticulous skin care is essential because the edematous tissues are prone to breakdown. Use an alternating-air pressure mattress or other special mattress. A turning schedule (minimum of every 2 hours) must be adhered to rigidly. Support the abdomen with pillows. If the abdomen is taut, cleanse it gently. The patient will tend to avoid moving because of abdominal discomfort and dyspnea. Range-of-motion exercises are helpful. Implement measures such as coughing and deep breathing to prevent respiratory problems. The lower extremities may be elevated. If scrotal edema is present, a scrotal support gives some comfort.

When the patient is taking diuretics, monitor serum sodium, potassium, chloride, and bicarbonate levels. Monitor renal function (blood urea nitrogen [BUN], serum creatinine) routinely and with any change in the diuretic dosage. Observe for signs of fluid and electrolyte imbalance, especially hypokalemia. Dysrhythmias, hypotension, tachycardia, and generalized muscle weakness may occur with hypokalemia. Muscle cramping, weakness, lethargy, and confusion may be present with hyponatremia from water excess.

Observe for and provide nursing care for any hematologic

problems. These include bleeding tendencies, anemia, and increased susceptibility to infection.

Assess the patient's response to altered body image resulting from jaundice, spider angiomas, palmar erythema, ascites, and gynecomastia. The patient may have anxiety and embarrassment about these changes. Explain these phenomena and be a supportive listener. Provide nursing care with concern and encouragement to help the patient maintain his or her self-esteem.

Check Your Practice

You are caring for a 69-yr-old male patient with advanced cirrhosis who just underwent banding for esophageal varices. The UAP tells you that the patient's BP is 80/60 mm Hg and he is hard to arouse.

- What is your concern?
- What would you do?

Bleeding Varices

If the patient has esophageal or gastric varices, observe for any signs of bleeding from the varices, such as hematemesis and melena. If hematemesis occurs, assess the patient for hemorrhage, call the HCP, and be ready to transfer the patient to the endoscopy suite and/or assist with equipment to control the bleeding. Maintain the patient's airway. Patients with bleeding varices are usually admitted to the intensive care unit (ICU).

Balloon tamponade is an option for patients who have bleeding that is unresponsive to band ligation or sclerotherapy. When balloon tamponade is used, explain to the patient and caregiver the use of the tube and how the balloon is inserted. Check the balloons for patency. It is usually the HCP's responsibility to insert the tube by either the nose or mouth. Then the gastric balloon is inflated with 250 mL of air, and the tube is retracted until resistance (lower esophageal sphincter)

is felt. The tube is secured by placing a piece of sponge or foam rubber at the nostrils (nasal cuff). For continued bleeding, the esophageal balloon is then inflated. A sphygmomanometer is used to measure and maintain the desired pressure at 20 to 40 mm Hg. An x-ray verifies the balloon's position.

Nursing care includes monitoring for complications of rupture or erosion of the esophagus, regurgitation and aspiration of gastric contents, and occlusion of the airway by the balloon. If the gastric balloon breaks or is deflated, the esophageal balloon will slip upward, obstructing the airway and causing asphyxiation. If this happens, cut the tube or deflate the esophageal balloon. Keep scissors at the bedside. Minimize regurgitation by oral and pharyngeal suctioning and by keeping the patient in a semi-Fowler's position.

The patient is unable to swallow saliva because the inflated esophageal balloon occludes the esophagus. Encourage the patient to expectorate and provide an emesis basin and tissues. Frequent oral and nasal care offers relief from the taste of blood and irritation from mouth breathing.

Ethical/Legal Dilemmas

Rationing

Situation

T.H., a 43-yr-old female patient with cirrhosis of the liver, is frequently admitted to the hospital. She has been told that her continued alcohol use will inevitably lead to her death. She now has GI bleeding and needs blood transfusions. She has a rare blood type that is hard to match. Should you ask for an ethics consultation?

Ethical/Legal Points for Consideration

- *Rationing,* or the controlled distribution of scarce resources, is a difficult ethical problem. The needs of an individual patient or group of patients are weighed against the needs of many

patients, who may have a greater chance of recovery, and the availability of the necessary resources.

- Health interests can supersede the interests or rights of a person. For example, in anticipation of an anthrax attack, the government could confiscate all relevant antibiotics and restrict their use to treat the disease.
- Two individual rights that must be considered regarding rationing are the (1) constitutional right to privacy and (2) right to consent to or refuse medical procedures and therapy.
- The competent adult is the only person who may consent to or refuse treatment for his or her health care problems.
- If T.H. consents to a blood transfusion, an intervening party may be allowed to refuse that treatment only given substantial intervening circumstances and not as a threat to compel adherent future behavior.
- If involved parties cannot reach an agreement, legal intervention by way of a court order may become necessary.

Discussion Questions

1. Do you think patients with diseases that have a behavioral component, like substance use, deserve aggressive treatment?
2. Would you request an ethics committee consultation in T.H.'s case?

Hepatic Encephalopathy

Nursing care of the patient with hepatic encephalopathy focuses on maintaining a safe environment, sustaining life, and assisting with measures to reduce the formation of ammonia. Patients with hepatic encephalopathy may be confused and at risk for falls or other injuries. Assess the patient's (1) level of responsiveness (e.g., reflexes, pupillary reactions, orientation), (2) sensory and motor abnormalities (e.g., hyperreflexia, asterixis, motor coordination), (3) fluid and electrolyte

imbalances, (4) acid-base imbalances, and (5) response to treatment measures.

Assess the neurologic status, including an exact description of the patient's behavior, at least every 2 hours. Plan your care of the patient based on the severity of the encephalopathy. In patients with altered levels of consciousness or whose airway may become compromised, have emergency equipment readily available. Any GI bleeding may worsen encephalopathy. Institute measures to prevent falls or injuries.

. Control factors known to precipitate encephalopathy as much as possible, including anything that may cause constipation (e.g., dehydration, opioid drugs). Measures to minimize constipation are important to reduce ammonia production. Give drugs, laxatives, and enemas as ordered. Encourage fluids, if not contraindicated. Assess the patient taking lactulose for diarrhea and excessive fluid and electrolyte losses.

Ambulatory Care

The patient with cirrhosis may be faced with a prolonged course and the chance of life-threatening problems and complications. The patient and caregiver need to understand the importance of continual health care and medical supervision. Supportive measures include proper diet, rest, avoiding potentially hepatotoxic OTC drugs, such as acetaminophen in high doses, and abstaining from alcohol. Abstinence from alcohol is important and results in improvement in most patients. However, some patients find abstinence extremely hard and need emotional support. Explore your own attitude toward the patient whose cirrhosis is from chronic alcohol use. Always provide care without being condescending or judgmental. Treat patients with respect and concern for their well-being (see Chapter 10).

TABLE 43.17 Patient & Caregiver TeachingCirrhosis

When teaching the patient and caregiver about management of cirrhosis, do

the following:

1. Explain that cirrhosis is a chronic illness and requires continual health care.
2. Teach the symptoms of complications and when to seek medical attention to enable prompt treatment.
3. Teach the patient to avoid potentially hepatotoxic over-the-counter drugs, because the diseased liver is unable to metabolize them.
4. Encourage abstinence from alcohol because continued use increases the rate of liver disease progression and risk for liver complications.
5. Teach the patient with esophageal or gastric varices to avoid aspirin and NSAIDs to prevent hemorrhage.
6. Teach the patient with portal hypertension and varices that straining at stool, coughing, sneezing, and retching and vomiting may increase the risk for variceal hemorrhage.

Cirrhosis is a chronic disease, and people can live many years with symptoms and complications from cirrhosis. The patient is affected not only physically but also psychologically, socially, and economically. Major lifestyle changes may be needed, especially if chronic alcohol use is the primary cause. Provide information about community support programs, such as Alcoholics Anonymous, for help with chronic alcohol use.

Teach the patient and caregiver about complications and when to seek medical attention (Table 43.17). Include instructions about adequate rest periods, how to detect early signs of complications, skin care, drug therapy side effects, observation for bleeding, and protection from infection.

Referral to a community or home health nurse may help ensure patient adherence to prescribed therapy. Home care for the patient with cirrhosis focuses on helping the patient with activities of daily living while maintaining the highest level of wellness possible.

Evaluation

Expected outcomes are that the patient with cirrhosis will

- Maintain food and fluid intake adequate to meet nutritional needs
- Maintain skin integrity with relief of edema and itching
- Have normal fluid and electrolyte balance
- Acknowledge and get treatment for a substance use problem

Acute Liver Failure

Acute liver failure, or *fulminant hepatic failure,* is a potentially life-threatening clinical syndrome.[3] It is characterized by a rapid onset of severe liver dysfunction in someone with no history of liver disease. It is often accompanied by hepatic encephalopathy.

The most common cause of acute liver failure is drugs, usually acetaminophen. Other drugs that can cause acute liver failure include isoniazid, sulfa-containing drugs, and anticonvulsants. Drugs can cause hepatocyte damage by disrupting essential intracellular processes or causing an accumulation of toxic metabolic products. Other causes can include viral hepatitis, especially HBV. Hepatitis A is a less common cause.

Outcomes depend on the cause. Cerebral edema, cerebellar herniation, and brainstem compression are the most common causes of death. Treatment of cerebral edema is described in Chapter 56. Liver transplantation is associated with a significant survival benefit in patients with a low probability of spontaneous recovery.

Clinical Manifestations and Diagnostic Studies

Manifestations of acute liver failure include jaundice, coagulation abnormalities, and encephalopathy. Changes in cognitive function are often the first clinical sign. Patients are susceptible to a wide variety of complications, including cerebral edema, renal failure, hypoglycemia, metabolic acidosis, sepsis, and multiorgan failure.

Serum bilirubin is high, and the PT time is prolonged. Liver enzyme levels (AST, ALT) are often markedly increased. Other laboratory tests include blood chemistries (especially glucose, since hypoglycemia may be present and need correction), complete blood count (CBC), acetaminophen level, screening for other drugs and toxins, viral hepatitis serology (especially HAV and HBV), serum ceruloplasmin (enzyme synthesized in liver) and α_1-antitrypsin levels, iron levels, ammonia levels, and autoantibodies (ANAs and ASMAs).

CT or MRI can provide information about the liver size and contour, presence of ascites or tumors, and patency of the blood vessels.

Interprofessional and Nursing Care

Since acute liver failure may progress rapidly, with hour-by-hour changes in consciousness, the patient is usually transferred to the ICU once the diagnosis is made. Planning for transfer to a transplant center should begin in patients with grade 1 or 2 encephalopathy because they may worsen rapidly. Early transfer is important because the risks involved with patient transport may increase or even prevent transfer if stage 3 or 4 encephalopathy develops (Table 43.12).

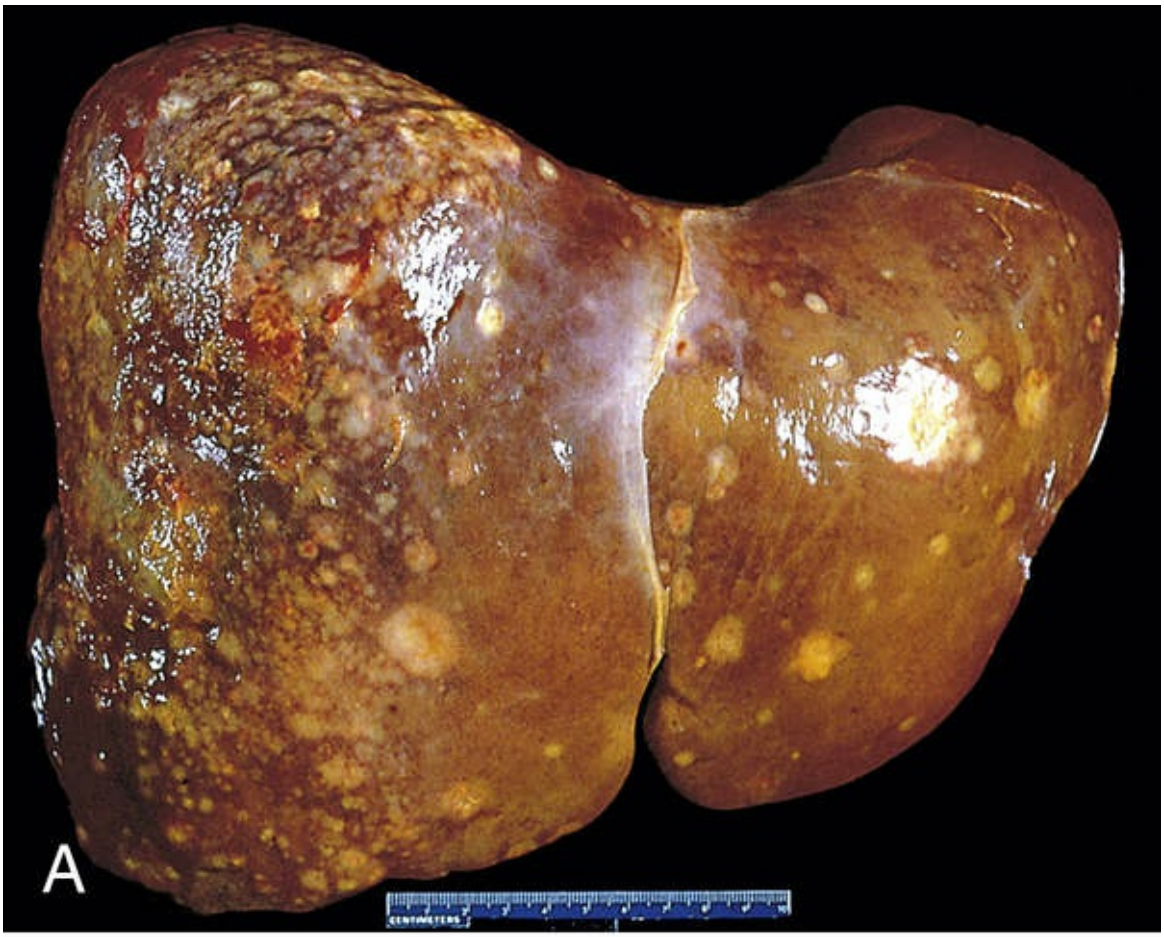
Renal failure is a frequent complication of liver failure. It may be due to dehydration, hepatorenal syndrome, or acute tubular necrosis. The frequency of renal failure may be even greater with acetaminophen overdose or other toxins with which direct renal toxicity occurs. Although few patients die of renal failure alone, it often increases the mortality risk and may worsen the prognosis. Protect renal function by maintaining adequate fluid balance, avoiding nephrotoxic agents (e.g., aminoglycosides, NSAIDs), and promptly identifying and treating infection.

Monitoring and management of hemodynamic and renal function, as well as glucose, electrolytes, and acid-base status, are critical. Conduct frequent neurologic evaluations for signs of increased intracranial pressure. Position the patient with the head elevated at 30 degrees. Avoid excessive patient stimulation. Maneuvers that cause straining or Valsalva-like movements may increase intracranial pressure (ICP). ICP monitoring is discussed in Chapter 56.

Assess the patient regularly for baseline level of consciousness and orientation and report any changes to the HCP. Avoid the use of any sedatives due to their effects on mental status. The effects can be confused with worsening encephalopathy. Only minimal doses of benzodiazepines should be used due to their delayed metabolism by the failing liver. Closely observe the patient to prevent injuries and pad bedrails to avoid injury from possible seizures. Monitor intake

and output for renal function and provide good skin and oral care to avoid breakdown and infection.

Changes in level of consciousness may compromise nutritional intake. Many patients receive vitamin supplementation. Other factors, such as coagulation problems, may influence whether EN is started. An NG tube may be irritating to the nasal and esophageal mucosa and cause bleeding.



Liver Cancer

Primary liver cancer starts in the liver. The most common types of liver cancer are hepatocellular carcinoma (HCC) (75% of cases) and intrahepatic cholangiocarcinoma (bile duct cancer). In 2018 there were about 40,710 cases of HCC and 28,920 HCC deaths in the United States. Worldwide liver cancer is the fifth most common cancer and second most common cause of cancer death.[13]

Liver cancer is the most common cause of death in patients with cirrhosis. Cirrhosis caused by hepatitis C is the most common cause of HCC in the United States, followed by NAFLD. About 2% of patient with cirrhosis develop liver cancer each year.

In primary liver cancer, lesions may be singular or numerous and nodular or diffusely spread over the entire liver. Some tumors infiltrate other organs, such as the gallbladder, or move into the peritoneum or the diaphragm. Primary liver cancer often metastasizes to the lung.

Metastatic cancer in the liver is more common than primary liver cancer (Fig. 43.10). The liver is a common site of metastatic growth because of its high rate of blood flow and extensive capillary network. Cancer cells in other parts of the body are often carried to the liver via the portal circulation.

Clinical Manifestations and Diagnostic Studies

The manifestations of early liver cancer can be absent or subtle. They are often a result of the underlying cirrhosis rather than from the actual liver tumor(s). The patient may present with hepatomegaly, splenomegaly, fatigue, peripheral edema, ascites, and other complications from portal hypertension. In late stages, patients will often have fever/chills, jaundice, anorexia, weight loss, palpable mass, and right upper quadrant pain.

Diagnostic and screening for liver cancer are ultrasound, CT, and MRI. Recent advancements in MRI scanning have allowed for accurate diagnosis of liver cancers without the need for a percutaneous biopsy.[13] Sometimes, a biopsy may be done when the results of diagnostic imaging studies are inconclusive or tissue is needed to guide treatment. Risks of a biopsy include bleeding and potential tumor cell seeding along the needle tract. Therefore a biopsy is generally not done unless a diagnosis cannot be made by CT or MRI and clinical presentation. Serum α-fetoprotein (AFP) levels combined with ultrasound have a high rate of detection of early-stage HCC. (AFP is discussed in Chapter 15.)

Interprofessional and Nursing Care

Prevention of liver cancer focuses on identifying and treating chronic hepatitis B and C viral infections. Treatment of chronic alcohol use may lower the risk for liver cancer. Screening for at-risk patients (e.g., those with cirrhosis) usually involves a combination of serum AFP and CT, MRI, or ultrasound imaging of the liver.

Treatment of liver cancer depends primarily on the stage of cancer:

number, size, and location of tumors; involvement of any blood vessels; patient age and overall health; and extent of underlying liver disease. Surgical liver resection (partial hepatectomy) offers the best chance for a cure. However, only about 15% of people have enough healthy liver tissue for this to be an option. The underlying cirrhosis and portal hypertension often compromise liver function and may cause liver failure after surgery. Furthermore, many patients are diagnosed at an advanced stage of cancer when surgery is not an option. For those patients who have early-stage liver cancer and impaired liver function, liver transplantation offers a good prognosis.

Nonsurgical therapies include percutaneous ablation, chemoembolization, radioembolization, and sorafenib (Nexavar) oral therapy.[13] In ablation, a thin needle is inserted into the core of the tumor. Then various substances can be injected (ethanol, acetic acid) and the temperature of the probe (radiofrequency, microwave, cryotherapy) can be altered to destroy the tumor. This procedure can be done percutaneously, laparoscopically, or through an open incision. It is typically limited by the number, size, and location of liver tumors. It is usually offered to patients with early-stage liver cancer. Although complications are not common, they can include infection, bleeding, dysrhythmias, and skin burn.

In patients with multinodular HCC or intermediate-stage liver cancer, embolization of the tumors is another intervention. There are 2 options typically used: transarterial chemoembolization (TACE) or transarterial radioembolization (TARE). TACE and TARE are minimally invasive procedures done by interventional radiologists. A catheter is placed via the femoral artery or radial artery and advanced to the arterial blood supply of the tumors in the liver. Either a chemotherapy drug (TACE) or radioactive beads (TARE) along with embolizing agents are then injected into the arteries of the tumor(s) region. TACE works by shutting off the blood supply to the tumors and exposing liver tumor cells to the chemotherapy agent. TARE destroys the tumor(s) by slowly releasing radioactive material directly to the site of the tumor. It can take up to 3 months for complete results.

In patients with advanced HCC, sorafenib (Nexavar) is typically the first-line treatment. It is a kinase inhibitor, a type of targeted therapy, that blocks certain proteins (kinases) that play a role in tumor growth and cancer progression (see Table 15.13). This drug has the potential to slow tumor progression and prolong life.

Nursing interventions focus on keeping the patient as comfortable as possible. Since these patients have the same problems as any patient with advanced liver disease, the nursing interventions discussed for cirrhosis of the liver apply to these patients (see p. 987).

Although the prognosis for patients with liver cancer is poor, it is improving with early screening and surveillance programs for those with chronic hepatitis and/or cirrhosis. The cancer often progresses rapidly, with patients having complications from the advancing cancer and declining liver function. Without treatment, death may occur within 6 to 12 months, most often from hepatic encephalopathy or massive blood loss from GI bleeding.

Liver Transplantation

Liver transplantation has become an option for many people with end-stage liver disease or localized HCC. Liver disease related to chronic viral hepatitis is the leading reason for liver transplantation. Other reasons include congenital biliary abnormalities (biliary atresia), inborn errors of metabolism, sclerosing cholangitis, acute liver failure, and chronic end-stage liver disease. In 2018, 11,514 patients were listed for a liver transplant in the United States with 8250 patients undergoing a transplant.[3]

Liver transplant candidates must go through a rigorous transplant evaluation prior to being placed on the transplant list. This is done to confirm the diagnosis of end-stage liver disease and to assess for other co-morbid conditions (e.g., cardiovascular disease, chronic kidney disease) that may affect the patient's surgical outcome. The evaluation includes physical examination, laboratory tests (CBC, liver function tests), cardiac and pulmonary evaluations, endoscopy, CT scan, and psychologic testing. Potential recipients receive counseling about cigarette smoking and alcohol abstinence. Contraindications for liver transplant include severe extrahepatic disease, advanced HCC or other cancer, ongoing drug or chronic alcohol use, and inability to understand or adhere with the rigorous posttransplant care.

Liver transplantation is done using both deceased (cadaver) and live donor livers. The live donor liver transplant was first developed for children whose parents wanted to serve as donors. Today, some liver transplant centers are performing live liver transplant procedures for adults. In this procedure, the living person donates a part of his or her liver to another. However, live liver donation poses potential risks to the donor, including biliary problems, hepatic artery thrombosis, wound infection, postoperative ileus, and pneumothorax.

Because of the limited number of donor livers, when a liver becomes available for transplant it may be divided into 2 parts (split liver transplant) and implanted into 2 recipients. The decision to use a split donor liver is based on the donor's size and health. The recipients

of the split liver generally are smaller than the donor. The success rate associated with split liver transplantation is somewhat lower than that associated with whole organ transplantation.

Postoperative complications of liver transplant include bleeding, infection, and rejection. However, the liver is subject to a less aggressive immunologic attack than other organs, like the kidneys. Transplants and immunosuppressive therapy are discussed in Chapter 13.

Immunosuppressive therapy generally involves a combination of corticosteroids, a calcineurin inhibitor (cyclosporine or tacrolimus), and an antiproliferative agent (e.g., azathioprine). Tacrolimus is superior to cyclosporine in liver transplantation. Standard immunosuppressive regimens often change over the course of the recipient's life. Corticosteroid withdrawal may be done and is relatively safe to do in liver transplant recipients.

About 80% of patients live more than 5 years after liver transplant. Long-term survival depends on the cause of liver failure (e.g., localized HCC, chronic hepatitis B or C, biliary disease). Patients who have liver disease from hepatitis B or C often have reinfection of the transplanted liver. For patients with hepatitis B, treatment after surgery with IV HBIG and a nucleoside or nucleotide analog (used to treat HBV infection) has reduced the rates of reinfection of the transplanted liver. For patients with HCV, treatment with the new direct-acting antivirals (DAAs) that can cure HCV infection has provided the opportunity to use HCV-positive liver grafts. The need for liver transplant may decrease in the HCV population. Research is ongoing to decide if DAAs should be started before or after transplant.

The patient who had a liver transplant needs highly skilled nursing care, either in an ICU or other specialized unit. Postoperative nursing care includes assessing neurologic status; monitoring for signs of hemorrhage; preventing pulmonary complications; electrolyte levels, and urine output; and monitoring for manifestations of infection and rejection. Common respiratory problems are pneumonia, atelectasis, and pleural effusions. To prevent these complications, encourage the

patient to cough, deep breathe, use incentive spirometry, and frequently reposition. Measure the drainage from the Jackson-Pratt drain, NG tube, and T tube and note the color and consistency of the drainage at regular intervals.

The first 2 months after surgery are critical for monitoring for infection. Causes of infection can be viral, fungal, or bacterial. Fever may be the only sign of infection. Adhering to the medication regimen can be hard, especially in the beginning. Emotional support and teaching for the patient and caregiver are essential to the success of the patient with a liver transplant.

Gerontologic Considerations: Liver Disease in the Older Adult

The incidence of liver disease increases with age. The liver's size and metabolic breakdown of drugs decrease, and hepatobiliary function is changed. The liver has a decreased capacity to respond to injury. This especially applies to regeneration after injury. Transplanted livers take longer to regenerate in the older adult compared with the younger adult.

Older adults are particularly vulnerable to drug-induced liver injury. This is due to several factors, including the increased use of multiple prescription and OTC drugs, which can lead to drug interactions and potential drug toxicity. Age-related decreases in liver function result in decreased drug metabolism and a decreased ability to recover from drug-induced injury.

A growing number of older adults have chronic hepatitis C and the resulting cirrhosis. Antibodies to HCV and elevated liver enzymes may be found during a routine health assessment in asymptomatic patients.

Lifetime health behaviors may influence the development of chronic liver disease in the older adult. Chronic alcohol use and obesity can contribute to cirrhosis, fatty liver inflammation (NASH), and liver failure. Because of many older adults' concomitant cardiovascular and lung diseases and possible anticoagulant therapy, variceal bleeding

can cause significant morbidity and mortality and needs immediate medical intervention. In the older adult with liver disease, hepatic encephalopathy is sometimes misdiagnosed as dementia and often overlooked.

Because older adults tend to have more co-morbid conditions, transplantation may have more risks for complications. Therefore older adults may not be good candidates for liver transplants.

Disorders of The Pancreas

Acute Pancreatitis

Acute pancreatitis is an acute inflammation of the pancreas. Spillage of pancreatic enzymes into surrounding pancreatic tissue causes autodigestion and severe pain. The degree of inflammation varies from mild edema to severe hemorrhagic necrosis.

Etiology and Pathophysiology

Many factors can cause injury to the pancreas. In the United States, the most common cause is gallbladder disease (gallstones), which is more common in women. The second most common cause is chronic alcohol use. This is more common in men.

Other less common causes include drug reactions, pancreatic cancer, and hypertriglyceridemia (serum levels over 1000 mg/dL).[14] Biliary sludge and microlithiasis, which is a mix of cholesterol crystals and calcium salts, can be present in patients with acute pancreatitis.

The most common pathogenic mechanism in acute pancreatitis is autodigestion of the pancreas (Fig. 43.11). The causative factors injure pancreatic cells or activate the pancreatic enzymes in the pancreas rather than in the intestine. This may be due to reflux of bile acids into the pancreatic ducts through an open or distended sphincter of Oddi. This reflux may be caused by blockage created by gallstones. Obstruction of pancreatic ducts results in pancreatic ischemia.

The exact mechanism by which chronic alcohol use predisposes a person to pancreatitis is not known. We think that alcohol increases the production of digestive enzymes in the pancreas.

The pathophysiologic involvement of acute pancreatitis is classified as either *mild pancreatitis* (also known as *edematous* or *interstitial pancreatitis*) or *severe pancreatitis* (also called *necrotizing pancreatitis*) (Fig. 43.12). In severe pancreatitis, about half the patients have permanent decreases in pancreatic endocrine and exocrine function. Patients with severe pancreatitis are at high risk for developing

pancreatic necrosis, organ failure, and septic complications, resulting in an overall fatality rate of 5%.[14]

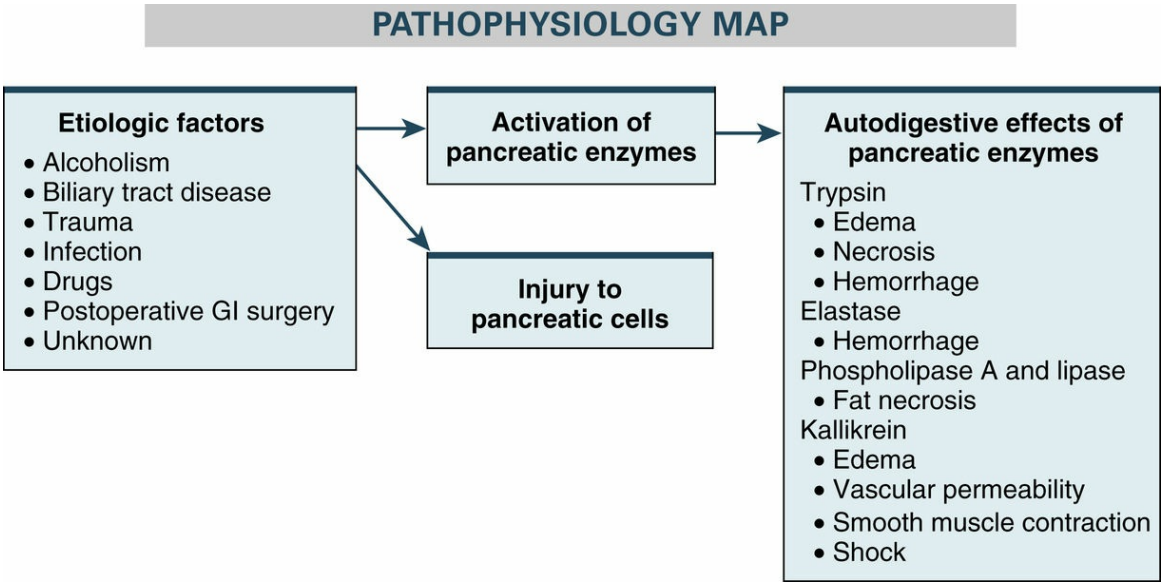

FIG. 43.11 Pathogenic process of acute pancreatitis.

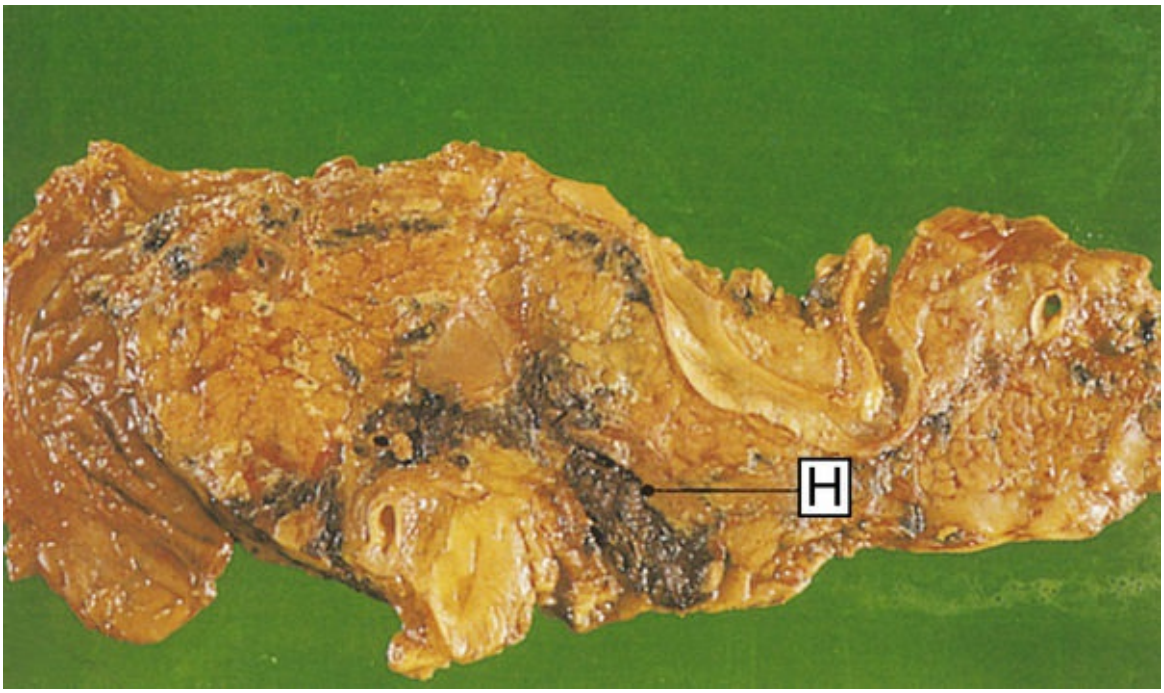

FIG. 43.12 In acute pancreatitis, the pancreas appears edematous and is often hemorrhagic *(H).*
From Stevens A, Lowe J: *Pathology: Illustrated review in colour,* ed 2, London, 2000, Mosby.

Clinical Manifestations

Abdominal pain is the main manifestation of acute pancreatitis. The pain is due to distention of the pancreas, peritoneal irritation, and obstruction of the biliary tract. The pain is usually in the left upper quadrant, but it may be mid-epigastric. It often radiates to the back due to the retroperitoneal location of the pancreas. The pain has a sudden onset. It is described as severe, deep, piercing, and continuous or steady. Eating worsens the pain. It often starts when the patient is recumbent. Pain is not relieved by vomiting and may be accompanied by flushing, cyanosis, and dyspnea. The patient may assume various positions involving flexion of the spine to try to relieve the severe pain.

Other manifestations include nausea and vomiting, low-grade fever, leukocytosis, hypotension, tachycardia, and jaundice. Abdominal tenderness with muscle guarding is common.

Bowel sounds may be decreased or absent. Paralytic ileus may occur and causes marked abdominal distention. The lungs are often involved with crackles present. Intravascular damage from circulating trypsin (a proteolytic enzyme) may cause areas of cyanosis or greenish to yellow-brown discoloration of the abdominal wall. Other areas of ecchymoses are the flanks (*Grey Turner' spots* or *sign,* a bluish flank discoloration) and the periumbilical area (*Cullen's sign,* a bluish periumbilical discoloration). These result from seepage of bloodstained exudate from the pancreas and may occur in severe cases.

Shock may occur from hemorrhage into the pancreas, toxemia from the activated pancreatic enzymes, or hypovolemia due to fluid shift into the retroperitoneal space (massive fluid shifts).

Complications

The severity of acute pancreatitis depends on the extent of pancreatic destruction. Acute pancreatitis can be life threatening. Some patients recover completely, others have recurring attacks, and others develop chronic pancreatitis.

Two significant local complications of acute pancreatitis are pseudocyst and abscess. A *pancreatic pseudocyst* is an accumulation of fluid, pancreatic enzymes, tissue debris, and inflammatory exudates surrounded by a wall next to the pancreas. Manifestations are abdominal pain, palpable epigastric mass, nausea, vomiting, and anorexia. The serum amylase level is often high. CT, MRI, and endoscopic ultrasound (EUS) may detect a pseudocyst. The cysts usually resolve spontaneously within a few weeks but may perforate, causing peritonitis or rupture into the stomach or the duodenum. Treatment options include surgical drainage, percutaneous catheter placement and drainage, and endoscopic drainage.

When a pseudocyst gets infected, a *pancreatic abscess* results from extensive necrosis in the pancreas. It may rupture or perforate into adjacent organs. Manifestations of an abscess include upper abdominal pain, abdominal mass, high fever, and leukocytosis. Pancreatic abscesses need prompt surgical drainage to prevent sepsis.

The main systemic complications of acute pancreatitis are cardiovascular and pulmonary (pleural effusion, atelectasis, pneumonia, and acute respiratory distress syndrome [ARDS]). The pulmonary complications are due to the passage of exudate containing pancreatic enzymes from the peritoneal cavity through transdiaphragmatic lymph channels. Enzyme-induced inflammation of the diaphragm occurs, with the result being atelectasis caused by reduced diaphragm movement. Trypsin can activate prothrombin and plasminogen, increasing the patient's risk for intravascular thrombi, pulmonary emboli, and DIC. Hypotension can occur from fluid shifts and sepsis.

Tetany, which can be caused by hypocalcemia, is a sign of severe disease. It is due in part to the combining of calcium and fatty acids during fat necrosis. We do not understand the exact mechanisms of how or why hypocalcemia occurs. Patients with severe acute

pancreatitis are at risk for abdominal compartment syndrome from intraabdominal hypertension and edema.

Diagnostic Studies

The primary diagnostic tests for acute pancreatitis are serum amylase and lipase (Table 43.18). The serum amylase level is usually high early and stays high for 24 to 72 hours. Serum lipase level, which is high in acute pancreatitis, is an important test because other disorders (e.g., mumps, cerebral trauma, renal transplantation) may increase serum amylase levels. Other serum findings include an increase in liver enzymes, triglycerides, glucose, and bilirubin and a decrease in calcium.

TABLE 43.18 Diagnostic FindingsAcute Pancreatitis

Laboratory Test	Abnormal Finding
Serum amylase	↑
Serum lipase	↑
Urinary amylase	↑
Blood glucose	↑
Serum calcium	↓
Serum triglycerides	↑

TABLE 43.19 Interprofessional CareAcute Pancreatitis

Diagnostic Assessment

- History and physical examination
- Serum amylase and lipase
- Blood glucose
- Serum calcium
- Serum triglycerides
- Flat plate of the abdomen
- Abdominal ultrasound
- Endoscopic ultrasound (EUS)
- MRCP
- ERCP
- Contrast-enhanced CT of pancreas
- Chest x-ray

Management

- NPO with NG tube to suction
- Albumin (if shock present)
- IV calcium gluconate (10%) (if tetany present)
- Lactated Ringer's solution

Drug Therapy

- Pain medication (e.g., morphine)
- PPI (e.g., omeprazole [Prilosec])
- Antibiotics (if necrotizing pancreatitis)

Diagnostic evaluation of acute pancreatitis is directed at determining the cause. An abdominal ultrasound, x-ray, or contrast-enhanced CT scan may identify pancreatic problems. CT scan is the best imaging test for pancreatitis and related complications, such as pseudocysts and abscesses. ERCP is an option (although ERCP can

cause acute pancreatitis), along with EUS, magnetic resonance cholangiopancreatography (MRCP), and angiography. Chest x-rays may show atelectasis and pleural effusions.

Interprofessional Care

Goals of interprofessional care for acute pancreatitis include (1) relief of pain, (2) prevention or alleviation of shock, (3) reduction of pancreatic secretions, (4) correction of fluid and electrolyte imbalances, (5) prevention or treatment of infections, and (6) removal of the precipitating cause, if possible (Table 43.19).

Conservative Therapy

Treatment of acute pancreatitis is focused on supportive care, including aggressive hydration, pain management, management of metabolic complications, and minimization of pancreatic stimulation. Treatment and control of pain are very important. IV opioid analgesics may be given. Pain medications may be combined with an antispasmodic agent. Atropine and other anticholinergic drugs are avoided when paralytic ileus is present because they can decrease GI mobility, making the problem worse. Other drugs that relax smooth muscles (spasmolytics), such as nitroglycerin or papaverine, may be used. Supplemental O_2 is used to maintain O_2 saturation greater than 95%. In patients with severe pancreatitis, serum glucose levels are closely monitored for hyperglycemia.

If shock is present, blood volume replacements are used. Plasma or plasma volume expanders, such as dextran or albumin, may be given. Lactated Ringer's solution or other electrolyte solutions can correct fluid and electrolyte problems. Central venous pressure readings can help determine fluid replacement requirements. Vasoactive drugs, such as dopamine, may be needed to increase systemic vascular resistance in those with hypotension.

Check Your Practice

You are a nurse working in the emergency department. Your patient is a 45-yr-old woman who reports acute abdominal pain in her left upper quadrant. She is diagnosed with acute pancreatitis. She tells you, "I've been waiting in this emergency room for 8 hours and I'm starving. Why can't I get something to eat? My pain is so bad; I think it's becoming worse because you won't give me food."

- How would you respond?
- What information and teaching would you give her?

It is important to reduce or suppress pancreatic enzymes to decrease stimulation of the pancreas and allow it to rest. This is achieved in several ways. First, the patient is NPO. Second, NG suction may be used to reduce vomiting and gastric distention and to prevent gastric acidic contents from entering the duodenum. Certain drugs are given to suppress gastric acid secretion (Table 43.20). With resolution of the pancreatitis, the patient resumes oral intake. For the patient with severe acute pancreatitis who does not resume oral intake, EN support may be started.

The inflamed and necrotic pancreatic tissue is a good medium for bacterial growth. In patients with acute necrotizing pancreatitis, infection is the leading cause of morbidity and mortality. Therefore it is important to prevent infections. Because many of the organisms come from the intestine, enteral feeding reduces the risk for necrotizing pancreatitis. Monitor the patient closely so that antibiotic therapy can be started early if necrosis and infection occur. Endoscopic- or CT-guided percutaneous aspiration with Gram stain and culture may be done.

Surgical Therapy

When the acute pancreatitis is related to gallstones, an urgent ERCP plus endoscopic *sphincterotomy* (severing of the muscle layers of the sphincter of Oddi) may be done. Laparoscopic cholecystectomy may follow ERCP to reduce the potential for recurrence. Surgical intervention may be needed when the diagnosis is uncertain and for

patients who do not respond to conservative therapy.

Those with severe acute pancreatitis may need drainage of necrotic fluid collections. This is done surgically, under CT guidance, or endoscopically. Percutaneous drainage of a pseudocyst can be done, and a drainage tube left in place.

Drug Therapy

Several different drugs are used to prevent and treat problems associated with pancreatitis (Table 43.20). Currently, there are no drugs that cure pancreatitis.

TABLE 43.20 Drug TherapyAcute and Chronic Pancreatitis

Drug	Mechanism of Action
Acute Pancreatitis	
Antacids	Neutralize gastric hydrochloric (HCl) acid secretion ↓ Production and secretion of pancreatic enzymes and bicarbonate
Antispasmodics (e.g., dicyclomine [Bentyl])	↓ Vagal stimulation, motility, pancreatic outflow (↓ volume and concentration of bicarbonate and enzyme secretion) Contraindicated in paralytic ileus
Carbonic anhydrase inhibitor (acetazolamide)	↓ Volume and bicarbonate concentration of pancreatic secretion
Morphine	Pain relief
PPIs (e.g., omeprazole [Prilosec])	↓ HCl acid secretion (HCl acid stimulates pancreatic activity)
Chronic Pancreatitis	
Insulin	Treat diabetes or hyperglycemia, if needed
Pancreatic enzyme products (pancrelipase [Pancrease, Zenpep, Creon, Viokace])	Replacement therapy for pancreatic enzymes

Nutritional Therapy

Initially, the patient with acute pancreatitis is on NPO status to reduce pancreatic secretion. Depending on the severity of the pancreatitis, EN is started. Because of infection risk, parenteral nutrition is reserved for patients who cannot tolerate EN (see Chapter 39). If IV lipids are given, monitor blood triglyceride levels. In cases of moderate to severe pancreatitis, the patient may need enteral feeding via a jejunal feeding

tube.

When food is allowed, small, frequent feedings are given. The diet is high in carbohydrate content because that is the least stimulating to the exocrine part of the pancreas. Suspect intolerance to oral foods when the patient reports pain, has increasing abdominal girth, or has increased serum amylase and lipase levels. Supplemental fat-soluble vitamins may be given.

Nursing Management: Acute Pancreatitis

Nursing Assessment

Subjective and objective data that should be obtained from a person with acute pancreatitis are outlined in Table 43.21.

Nursing Diagnoses

Nursing diagnoses for the patient with acute pancreatitis may include:

- Acute pain
- Fluid imbalance
- Electrolyte imbalance
- Impaired nutritional intake

Additional information on nursing diagnoses and interventions for the patient with acute pancreatitis is presented in eNursing Care Plan 43.3 available on the website for this chapter.

Planning

The overall goals are that the patient with acute pancreatitis will have (1) relief of pain, (2) normal fluid and electrolyte balance, (3) minimal to no complications, and (4) no recurrent attacks.

TABLE 43.21 Nursing AssessmentAcute Pancreatitis

Subjective Data	Important Health Information

Past health history: Biliary tract disease, alcohol use, abdominal trauma, duodenal ulcers, infection, metabolic disorders
Medications: Thiazides, NSAIDs
Surgery or other treatments: Surgical procedures on the pancreas, stomach, duodenum, or biliary tract. Endoscopic retrograde cholangiopancreatography (ERCP)

Functional Health Patterns

Health perception–health management: Chronic alcohol use, fatigue
Nutritional-metabolic: Nausea and vomiting, anorexia
Activity-exercise: Dyspnea
Cognitive-perceptual: Severe midepigastric or left upper quadrant pain that may radiate to the back, worsened by food and alcohol intake, unrelieved by vomiting

Objective Data
General

Restlessness, anxiety, low-grade fever

Integumentary

Flushing, diaphoresis, discoloration of abdomen and flanks, cyanosis, jaundice. Decreased skin turgor, dry mucous membranes

Respiratory

Tachypnea, basilar crackles

Cardiovascular

Tachycardia, hypotension

Gastrointestinal

Abdominal distention, tenderness, and muscle guarding.
Decreased bowel sounds

Possible Diagnostic Findings

↑ Serum amylase and lipase, leukocytosis, hyperglycemia, hypocalcemia, abnormal ultrasound and CT scans of pancreas, abnormal ERCP or MRCP

Nursing Implementation

Health Promotion

The major factors involved in health promotion are (1) assessing the patient for predisposing and etiologic factors and (2) encouraging early treatment of these factors to prevent acute pancreatitis. Encourage the patient to cease alcohol intake, especially if they have had pancreatitis before. Recurrent attacks of pancreatitis may become milder or disappear if alcohol use is stopped. Encourage early diagnosis and treatment of biliary tract disease, such as gallstones.

Acute Care

During the acute phase, it is important to monitor vital signs. Hypotension, fever, and tachypnea may compromise hemodynamic stability. Monitor the response to IV fluids. Closely monitor fluid and electrolyte balance. Frequent vomiting, along with gastric suction, may result in decreased chloride, sodium, and potassium levels.

Respiratory failure may develop in the patient with severe acute

pancreatitis. Assess respiratory function (e.g., lung sounds, O_2 saturation levels). If ARDS develops, the patient may need intubation and mechanical ventilation support.

Safety Alert

Respiratory Distress in Acute Pancreatitis

- Assess for respiratory distress in the patient with severe acute pancreatitis.
- Listen to lung sounds and monitor O_2 saturation on a regular basis.

Because hypocalcemia can occur, observe for symptoms of tetany, including jerking, irritability, and muscular twitching. Numbness or tingling around the lips and in the fingers is an early sign of hypocalcemia. Assess the patient for a positive Chvostek's sign or Trousseau's sign (see Fig. 16.15). Give calcium gluconate (as ordered) to treat symptomatic hypocalcemia. Monitor serum magnesium levels since hypomagnesemia may develop.

Because abdominal pain is a primary symptom of pancreatitis, a major focus of your care is pain relief. Pain and restlessness can increase the metabolic rate and contribute to hemodynamic instability. Opioids may be used for pain relief. Assess and document the duration of pain relief. Comfortable positioning, frequent changes in position, and relief of nausea and vomiting help reduce the restlessness that usually accompanies the pain. Assuming positions that flex the trunk and draw the knees up to the abdomen may decrease pain. A side-lying position with the head elevated 45 degrees decreases tension on the abdomen and may help ease the pain.

For the patient who is on NPO status or has an NG tube, provide frequent oral and nasal care to relieve the dryness of the mouth and nose. Oral care is essential to prevent parotitis. If the patient is taking

anticholinergics to decrease GI secretions, the mouth will be especially dry. If the patient is taking antacids to neutralize gastric acid secretion, they should be sipped slowly or inserted in the NG tube.

Observe for fever and other manifestations of infection in the patient with acute pancreatitis. Respiratory tract infections are common, which causes the patient to take shallow, guarded abdominal breaths. Measures to prevent respiratory tract infections include turning, coughing, deep breathing, and assuming a semi-Fowler's position.

Other important assessments are observation for signs of paralytic ileus, renal failure, and mental changes. Determine the blood glucose level to assess damage to the β cells of the islets of Langerhans in the pancreas.

If patients have surgery to drain necrotic fluid or treat a cyst, they may need special wound care for an anastomotic leak or a fistula. To prevent skin irritation, use skin barriers (e.g., Stomahesive, Karaya Paste), pouching, and drains. In addition to protecting the skin, pouching allows a more accurate determination of fluid and electrolyte losses and increases patient comfort. Sterile pouching systems are available. Consult with a clinical specialist or wound, ostomy, and continence nurse (WOCN).

Ambulatory Care

After acute pancreatitis, the patient may need home care follow-up. Because of loss of physical and muscle strength, physical therapy may be needed. Continued care to prevent infection and detect any complications is important. Counseling about abstinence from alcohol is important to prevent the patient from experiencing future attacks of acute pancreatitis and development of chronic pancreatitis. Because nicotine can stimulate the pancreas, smoking should be avoided.

Teach the patient and caregiver about the treatment plan, including the importance of taking the required medications and following the recommended diet. Dietary teaching should include fat restriction because fats stimulate the secretion of cholecystokinin, which then stimulates the pancreas. Encourage carbohydrates as they are less

stimulating to the pancreas. Teach the patient to avoid crash and binge dieting because they can precipitate attacks.

Teach the patient and caregiver to recognize and report symptoms of infection, diabetes, or steatorrhea (foul-smelling, fatty stools). These changes indicate ongoing destruction of pancreatic tissue and pancreatic insufficiency. The patient may need exogenous enzyme supplementation.

Evaluation

The expected outcomes are that the patient with acute pancreatitis will

- Have adequate pain control
- Maintain adequate fluid and electrolyte balance
- Be knowledgeable about the treatment plan to restore health
- Get help for alcohol use and smoking cessation (if needed)

Chronic Pancreatitis

Chronic pancreatitis is a continuous, prolonged, inflammatory, and fibrosing process of the pancreas. The pancreas is progressively destroyed as it is replaced by fibrotic tissue. Strictures and calcifications may occur in the pancreas.

Etiology and Pathophysiology

Chronic pancreatitis can be due to chronic alcohol use; obstruction caused by gallstones, tumor, pseudocysts, or trauma; and systemic diseases (e.g., systemic lupus erythematosus), autoimmune pancreatitis, and cystic fibrosis. Some patients may not have an identifiable risk factor (idiopathic pancreatitis). Chronic pancreatitis may follow acute pancreatitis, but it may also occur in the absence of any history of an acute condition.

The most common cause of obstructive pancreatitis is inflammation of the sphincter of Oddi associated with gallstones. Cancer of the ampulla of Vater, duodenum, or pancreas can also cause this type of chronic pancreatitis.

The most common cause of nonobstructive pancreatitis (the most common type of chronic pancreatitis) is chronic alcohol use. There is inflammation and sclerosis, mainly in the head of the pancreas and around the pancreatic duct. In some people who drink alcohol, a genetic factor may predispose them to the direct toxic effect of the alcohol on the pancreas.

Clinical Manifestations

As with acute pancreatitis, a major manifestation of chronic pancreatitis is abdominal pain. The patient may have episodes of acute pain, but it usually is chronic (recurrent attacks at intervals of months or years). The attacks may become more frequent until they are almost constant, or they may decrease as pancreatic fibrosis

develops. The pain is found in the same areas as in acute pancreatitis, but is usually described as a heavy, gnawing feeling or sometimes as burning and cramp-like. Food or antacids do not relieve the pain.

Other manifestations include symptoms of pancreatic insufficiency, including malabsorption with weight loss, constipation, mild jaundice with dark urine, steatorrhea, and diabetes. The steatorrhea may become severe, with voluminous, foul-smelling, fatty stools. Some abdominal tenderness may be present.

Chronic pancreatitis is associated with a variety of complications. These include pseudocyst formation, bile duct or duodenal obstruction, pancreatic ascites or pleural effusion, splenic vein thrombosis, pseudoaneurysms, and pancreatic cancer.

Diagnostic Studies

Confirming the diagnosis of chronic pancreatitis can be hard. The diagnosis is based on the patient's signs and symptoms, laboratory studies, and imaging. In chronic pancreatitis, serum amylase and lipase levels may be increased slightly or not at all, depending on the degree of pancreatic fibrosis. Serum bilirubin and alkaline phosphatase levels may be increased. There is usually mild leukocytosis and a high sedimentation rate.

ERCP can visualize the pancreatic and common bile ducts. Imaging studies, such as CT, MRI, MRCP, abdominal ultrasound, and EUS, can show a variety of changes, including calcifications, ductal dilation, pseudocysts, and enlargement of the pancreas.

Stool samples are examined for fecal fat content. Deficiencies of fat-soluble vitamins and cobalamin, glucose intolerance, and diabetes may occur in those with chronic pancreatitis. A secretin stimulation test can assess the degree of pancreatic dysfunction.

Interprofessional and Nursing Care

When the patient with chronic pancreatitis has an acute attack, the therapy is identical to that for acute pancreatitis. At other times, the focus is on prevention of further attacks, relief of pain, and control of

pancreatic exocrine and endocrine insufficiency. It sometimes takes frequent doses of analgesics (morphine, fentanyl patch [Duragesic]) to relieve the pain if dietary measures and enzyme replacement are not effective.

Diet, pancreatic enzyme replacement, and control of diabetes are ways to control the pancreatic insufficiency. Small, bland, frequent meals that are low in fat content are recommended to decrease pancreatic stimulation. Smoking is associated with accelerated progression of chronic pancreatitis. Teach the patient not to consume alcohol and caffeinated beverages. If the patient is dependent on alcohol, refer the patient to other resources as needed (see Chapter 10).

Pancreatic enzyme products, such as pancrelipase (Pancrease, Zenpep, Creon, Viokace), contain amylase, lipase, and trypsin. They are used to replace the deficient pancreatic enzymes. The enzymes are usually enteric coated to prevent their breakdown or inactivation by gastric acid. They are usually taken with meals and snacks. Teach the patient and caregiver to monitor stools for steatorrhea to help determine the effectiveness of the enzymes. Bile salts may be given to help with fat-soluble vitamin (A, D, E, and K) absorption and prevent further fat loss.

If diabetes develops, it is controlled with insulin (most often) or oral hypoglycemic agents. Teach the patient about testing blood glucose levels and drug therapy (see Chapter 48). While acid-neutralizing drugs (e.g., antacids) and acid-inhibiting drugs (e.g., H_2 receptor blockers, PPIs) may be given to control gastric acidity, they have little overall effect on patient outcomes. Antidepressants can reduce any neuropathic pain associated with chronic pancreatitis.

Treatment of chronic pancreatitis sometimes requires endoscopic therapy or surgery. When biliary disease is present or obstruction or pseudocyst develops, surgery may be needed. Surgical procedures can divert bile flow or relieve ductal obstruction. A choledochojejunostomy diverts bile around the ampulla of Vater, where there may be spasm or hypertrophy of the sphincter. In this procedure, the common bile duct is anastomosed into the jejunum.

Another type of surgical diverting procedure is the Roux-en-Y pancreatojejunostomy, in which the pancreatic duct is opened and an anastomosis made with the jejunum. Pancreatic drainage procedures can relieve ductal obstruction and are often done with ERCP. Some patients may have an ERCP with sphincterotomy and/or stent placement at the site of obstruction. These patients need follow-up procedures, such as ERCP, to either exchange or remove the stent.

Pancreatic Cancer

There is a high mortality rate of pancreatic cancer with the incidence almost equal to the mortality rates. The median age at diagnosis is around 71 years of age.[15] Most pancreatic tumors are adenocarcinomas that begin in the epithelium of the ductal system. More than half of the tumors occur in the head of the pancreas. As the tumor grows, the common bile duct becomes obstructed and obstructive jaundice develops. Tumors starting in the body or the tail often remain silent until their growth is advanced. Most cancers have metastasized at the time of diagnosis. The signs and symptoms of pancreatic cancer are similar to those of chronic pancreatitis. The prognosis of a patient with cancer of the pancreas is poor. Most patients die within 5 to 12 months of diagnosis. The 5-year survival rate is only 8%.[15]

Etiology and Pathophysiology

The cause of pancreatic cancer is unknown. Risk factors for pancreatic cancer include chronic pancreatitis, diabetes, age, cigarette smoking, family history of pancreatic cancer, high-fat diet, and exposure to chemicals, such as benzidine. Blacks have a higher incidence of pancreatic cancer than whites. The most established risk factor is cigarette smoking. Smokers are 2 to 3 times more likely to develop pancreatic cancer than nonsmokers. The risk is related to both the duration and number of cigarettes smoked.

Clinical Manifestations

Common manifestations include abdominal pain (dull, aching), anorexia, rapid and progressive weight loss, nausea, and jaundice. The most common manifestations with cancer of the head of the pancreas are pain, jaundice, and weight loss. In general, pain is common and is related to the cancer's location. The pain is often in the

upper abdomen or left hypochondrium and often radiates to the back. It is often related to eating and occurs at night. Extreme, unrelenting pain is related to extension of the cancer into the retroperitoneal tissues and nerve plexuses. Pruritus may accompany obstructive jaundice. Weight loss is due to poor digestion and absorption caused by lack of digestive enzymes from the pancreas.

Diagnostic Studies

Abdominal ultrasound or EUS, spiral CT scan, ERCP, MRI, and MRCP are the most often used diagnostic imaging techniques for pancreatic diseases, including cancer. EUS involves imaging the pancreas with the use of an endoscope positioned in the stomach and duodenum. EUS also allows for fine-needle aspiration of the tumor for pathologic examination. CT scan is often the first study and gives information on metastasis and vascular involvement of the tumor. ERCP allows visualization of the pancreatic duct and biliary system. With ERCP, pancreatic secretions and tissue can be obtained for biopsy and analysis of tumor markers. MRI, PET, PET/CT scans and MRCP may be done to confirm a cancer diagnosis and determine staging. They can also monitor progress and response to therapy.

Tumor markers are used both for diagnosing pancreatic cancer and monitoring the response to treatment. Cancer-associated antigen 19-9 (CA 19-9) is increased in pancreatic cancer. It is the most commonly used tumor marker. However, CA 19-9 also can be increased in gallbladder cancer or in benign conditions, such as acute and chronic pancreatitis, hepatitis, and biliary obstruction.

Interprofessional Care

Surgery is the most effective treatment for pancreatic cancer. Only 15% to 20% of patients have resectable tumors at the time of diagnosis. With the use of neoadjuvant chemotherapy (treatment before surgery), more patients can eventually become surgical candidates. The type of surgery depends on the size and location of the tumor. Pancreatic head tumors require the classic Whipple procedure or

pancreaticoduodenectomy (Fig. 43.13). In the Whipple surgery, the proximal pancreas (proximal pancreatectomy), along with duodenum (duodenectomy), distal segment of the common bile duct and distal part of the stomach (partial gastrectomy) are removed together followed by a surgical anastomosis of the pancreatic duct, common bile duct, and stomach to the jejunum. Pancreatic body and/or tail tumors require a distal pancreatectomy procedure. Sometimes, a total pancreatectomy is done. It causes diabetes and the patient is dependent on exogenous insulin and pancreatic enzyme supplementation for life. If the pancreatic tumor cannot be removed surgically, palliative measures, such as a cholecystojejunostomy, to relieve biliary obstruction and/or endoscopically placed biliary stents, can be done.

Radiation therapy alone has little effect on survival but may be effective for pain relief. External radiation is most common, but implantation of internal radiation seeds into the tumor has been used. The current role of chemotherapy is limited and can have a significant side effect profile. Chemotherapy usually consists of fluorouracil and gemcitabine (Gemzar) either alone or in combination with agents such as capecitabine (Xeloda), paclitaxel (Abraxane), erlotinib (Tarceva), or irinotecan (Onivyde). Erlotinib is a targeted therapy drug (see Chapter 15).

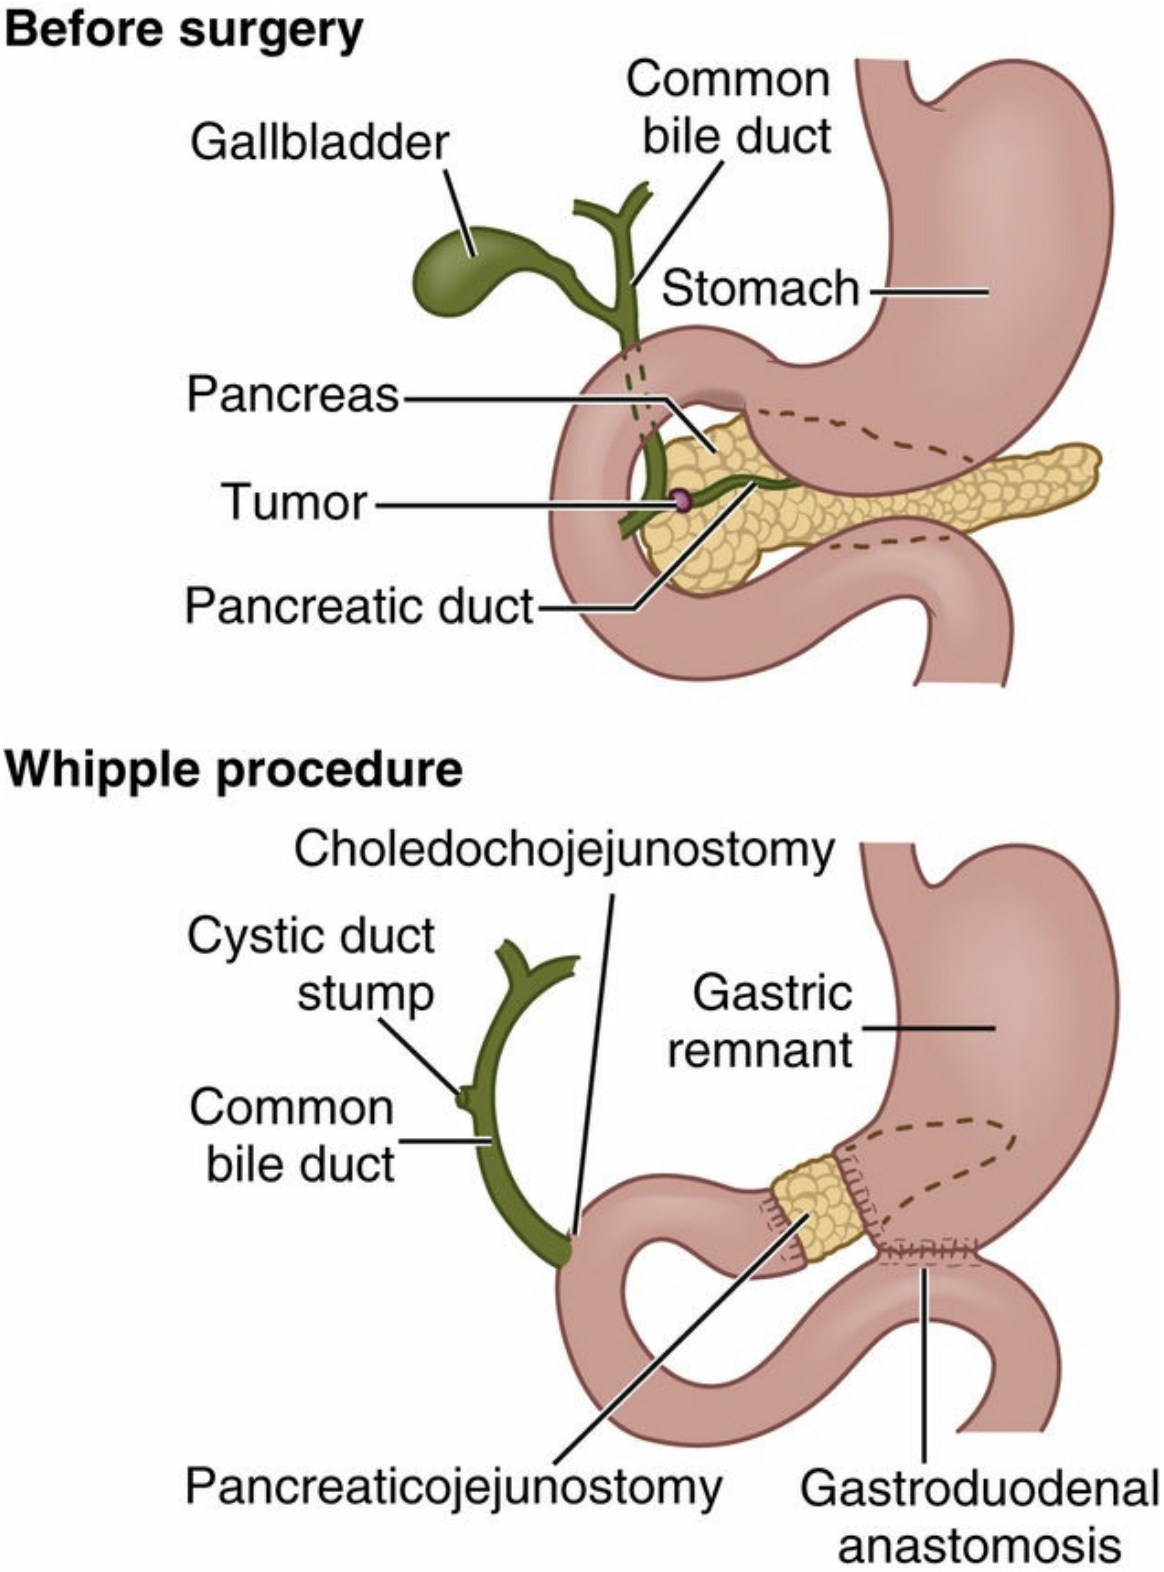

FIG. 43.13 Whipple procedure or radical pancreaticoduodenectomy. This surgical procedure involves resecting the proximal pancreas, adjoining duodenum, distal part of the stomach, and distal part of the common bile duct. An anastomosis of the pancreatic duct, common bile

duct, and stomach to the jejunum is done.
From Butcher GP: *Gastroenterology: An illustrated colour text,* London, 2004, Churchill Livingstone.

Nursing Management: Pancreatic Cancer

Because the patient with pancreatic cancer has many of the same problems as the patient with pancreatitis, nursing care includes many of the same measures (see sections on acute and chronic pancreatitis on pp. 995 and 996). Provide symptomatic and supportive nursing care. This includes giving medications and providing comfort measures to relieve pain. Psychologic support is essential, especially during times of anxiety or depression.

Adequate nutrition is an important part of the nursing care plan. Frequent and supplemental feedings may be needed. Include measures to stimulate the appetite as much as possible and to manage anorexia, nausea, and vomiting. If the patient is undergoing radiation therapy, observe for adverse reactions, such as anorexia, nausea, vomiting, and skin irritation.

The prognosis for a patient with pancreatic cancer is poor. A significant part of the nursing care is helping the patient and caregiver cope with the diagnosis and prognosis. Chapter 9 provides information on palliative and end-of-life care.

Disorders of The Biliary Tract

Cholelithiasis and Cholecystitis

The most common disorder of the biliary system is **cholelithiasis** (stones in the gallbladder) (Fig. 43.14). The gallstones may lodge in the neck of the gallbladder or in the cystic duct. **Cholecystitis** (inflammation of the gallbladder wall) is usually associated with gallstones. They usually occur together, although a person can have gallstones without cholecystitis. Cholecystitis may present acutely or chronically.

Gallbladder disease is a common health problem in the United States. Up to 10% of American adults have cholecystitis caused by gallstones. The actual number is not known because many persons with stones are asymptomatic. *Cholecystectomy* (removal of the gallbladder) is among the most common surgical procedures done in the United States.

Gallstones are more common in women, especially multiparous women and women over 40 years of age. Postmenopausal women on estrogen replacement therapy and younger women on oral contraceptives are at an increased risk for gallbladder disease. Oral contraceptives affect cholesterol production and increase gallbladder cholesterol saturation. Other factors that increase the occurrence of gallbladder disease are a sedentary lifestyle, a familial tendency, and obesity. Obesity causes increased secretion of cholesterol in bile. The incidence of gallbladder disease is especially high in the Native American population.

FIG. 43.14 Cholesterol gallstones in a gallbladder that was removed. From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Gender Differences

Cholelithiasis

Men

- Incidence is lower in men than in women.
- Gender differences in incidence decrease after age 50.

Women

- Pregnancy is the greatest risk factor for increased prevalence in women.
- Obesity increases the risk, especially for women.

Etiology and Pathophysiology

Cholelithiasis

The cause of gallstones is unknown. They develop when the balance that keeps cholesterol, bile salts, and calcium in solution is changed so that these substances precipitate. Conditions that upset this balance include infection and changes in cholesterol metabolism. In patients with gallstones, the bile secreted by the liver is supersaturated with cholesterol (lithogenic bile). The bile in the gallbladder then becomes supersaturated with cholesterol and precipitation of cholesterol occurs in the gallbladder.

Other components of bile that precipitate into stones are bile salts, bilirubin, calcium, and protein. Mixed cholesterol stones, which are mainly cholesterol, are the most common gallstones.

Changes in the composition of bile are significant in gallstone formation. Bile stasis leads to progression of the supersaturation and changes in the chemical composition of the bile (biliary sludge). Immobility, pregnancy, and inflammatory or obstructive lesions in the biliary system decrease bile flow. Hormonal factors during pregnancy may cause delayed emptying of the gallbladder, resulting in bile stasis.

The stones may stay in the gallbladder or migrate to the cystic duct or the common bile duct. They cause pain as they pass through the ducts, and they may lodge in the ducts and cause an obstruction. Small stones are more likely to move into a duct and cause obstruction. Table 43.22 describes the changes and manifestations that occur when the stones obstruct the common bile duct. If the blockage occurs in the cystic duct, the bile can continue to flow into the duodenum directly from the liver. However, when the bile in the gallbladder cannot escape, this stasis of bile may lead to cholecystitis.

Cholecystitis

Cholecystitis is most often associated with obstruction caused by gallstones or biliary sludge. Cholecystitis in the absence of obstruction *(acalculous cholecystitis)* occurs most often in older adults and in patients who are critically ill. Acalculous cholecystitis is also associated with prolonged immobility and fasting, prolonged parenteral nutrition, and diabetes. We think the main cause of this illness is bile stasis. Critically ill patients are more predisposed because of increased bile viscosity due to fever and dehydration and because of prolonged absence of oral feeding resulting in a decrease or absence of cholecystokinin-induced gallbladder contraction. Other risk factors include adhesions, cancer, anesthesia, and opioids.

TABLE 43.22 Manifestations of Obstructed Bile Flow

Manifestation	Etiology
Bleeding tendencies	Lack of or ↓ absorption of vitamin K, resulting in ↓ production of prothrombin
Clay-colored stools	No bilirubin reaching small intestine to be converted to urobilinogen
Dark amber to brown urine, which foams when shaken	↑ Water-soluble (conjugated) bilirubin elimination in urine
Fever and chills	Bacterial reflux from biliary tract to systemic circulation
Intolerance for fatty foods	No bile in small intestine for fat digestion
Jaundice	No bile flow into duodenum, bilirubin accumulates in blood
Pruritus	Deposition of bile salts in skin tissues
Steatorrhea	Undigested fatty components of food are eliminated in stool. Occurs because no bile in small intestine, thus preventing emulsion, digestion, and absorption of fat
Urobilinogen absent in urine	No bilirubin reaching small intestine to be converted to urobilinogen

Once acalculous cholecystitis is present, secondary infection with enteric pathogens, including *E. coli, Enterococcus faecalis, Klebsiella, Pseudomonas,* and *Proteus,* is common. Perforation occurs in severe cases.

Inflammation is the major pathophysiologic condition. It may be confined to the mucous lining or involve the entire wall of the gallbladder. During an acute attack of cholecystitis, the gallbladder is edematous and hyperemic, and it may be distended with bile or pus. The cystic duct is also involved and may become occluded. The wall of the gallbladder becomes scarred after an acute attack. Decreased functioning will occur if large amounts of tissue become fibrotic.

Clinical Manifestations

Gallstones may produce a range of symptoms. The severity depends on whether the stones are stationary or mobile and whether obstruction is present. When a stone is lodged in the ducts or when stones are moving through the ducts, spasms may result in response to the stone. This sometimes causes severe pain, which is termed *biliary colic,* even though the pain is rarely colicky. The pain is more often steady. The pain can be excruciating and accompanied by tachycardia, diaphoresis, and prostration. The severe pain may last up to an hour, and when it subsides, there is residual tenderness in the right upper quadrant. The attacks of pain often occur 3 to 6 hours after a high-fat meal or when the patient lies down.

When total obstruction occurs, symptoms related to bile blockage occur (Table 43.22). If the common bile duct is obstructed, no bilirubin will reach the small intestine to be converted to urobilinogen. Thus the kidneys will excrete bilirubin, causing dark amber to brown urine.

Manifestations of cholecystitis vary from indigestion to moderate to severe pain, fever, chills, and jaundice. Initial symptoms of acute cholecystitis include indigestion and acute pain and tenderness in the right upper quadrant. Pain may be referred to the right shoulder and scapula. The pain may be accompanied by nausea and vomiting, restlessness, and diaphoresis. Inflammation results in leukocytosis and fever. Physical findings include right upper quadrant or

epigastrium tenderness and abdominal rigidity. Chronic cholecystitis may present with a history of fat intolerance, dyspepsia, heartburn, and flatulence.

Complications

Complications of gallstones and cholecystitis include gangrenous cholecystitis, subphrenic abscess, pancreatitis, *cholangitis* (inflammation of biliary ducts), biliary cirrhosis, fistulas, and rupture of the gallbladder, which can cause bile peritonitis. In older adults and those with diabetes, gangrenous cholecystitis and bile peritonitis are the most common complications of cholecystitis. *Choledocholithiasis* (stone in the common bile duct) may occur, producing symptoms of obstruction.

Diagnostic Studies

Ultrasound is often used to diagnose gallstones (see Table 38.11). It is especially useful for patients with jaundice (because it does not depend on renal function) and for patients who are allergic to contrast medium. ERCP allows for visualization of the gallbladder, cystic duct, common hepatic duct, and common bile duct. Bile taken during ERCP is sent for culture to identify possible infecting organisms.

Percutaneous transhepatic cholangiography is the insertion of a needle directly into the gallbladder duct followed by injection of contrast materials. It is generally done after ultrasound shows a bile duct blockage.

Laboratory tests may reveal an increased WBC count because of inflammation. Serum enzymes (e.g., alkaline phosphatase, ALT, and AST), direct and indirect bilirubin levels, and urinary bilirubin levels may be increased if an obstructive process is present (Table 43.3). Serum amylase is increased if there is pancreatic involvement.

Interprofessional Care

Once gallstones become symptomatic, definitive surgical intervention with cholecystectomy is usually needed. However, in some cases,

conservative therapy may be considered.

Conservative Therapy

Cholelithiasis

The treatment of gallstones depends on the stage of disease. Bile acids (cholesterol solvents), such as ursodeoxycholic acid (Ursodiol) and chenodeoxycholic acid (Chenodiol), are used to dissolve stones. However, the gallstones may recur. We usually do not treat gallstones with drugs because of the high use and success of laparoscopic cholecystectomy.

ERCP with endoscopic sphincterotomy (papillotomy) may be used to remove stones (Fig. 43.15). ERCP allows for visualization of the biliary system, dilation (balloon sphincteroplasty), and placement of stents and sphincterotomy. Special catheters with wire baskets or inflatable balloon tip may be used for stone removal.[16] When a stent is placed, it is generally removed or changed after a few months.

Extracorporeal shock-wave lithotripsy (ESWL) is an alternative treatment used when endoscopic approaches cannot remove stones. In ESWL, a lithotripter uses high-energy shock waves to disintegrate gallstones. It usually takes 1 to 2 hours to disintegrate the stones. After they are broken up, the fragments pass through the common bile duct and into the small intestine. Usually ESWL and oral dissolution therapy are used together.

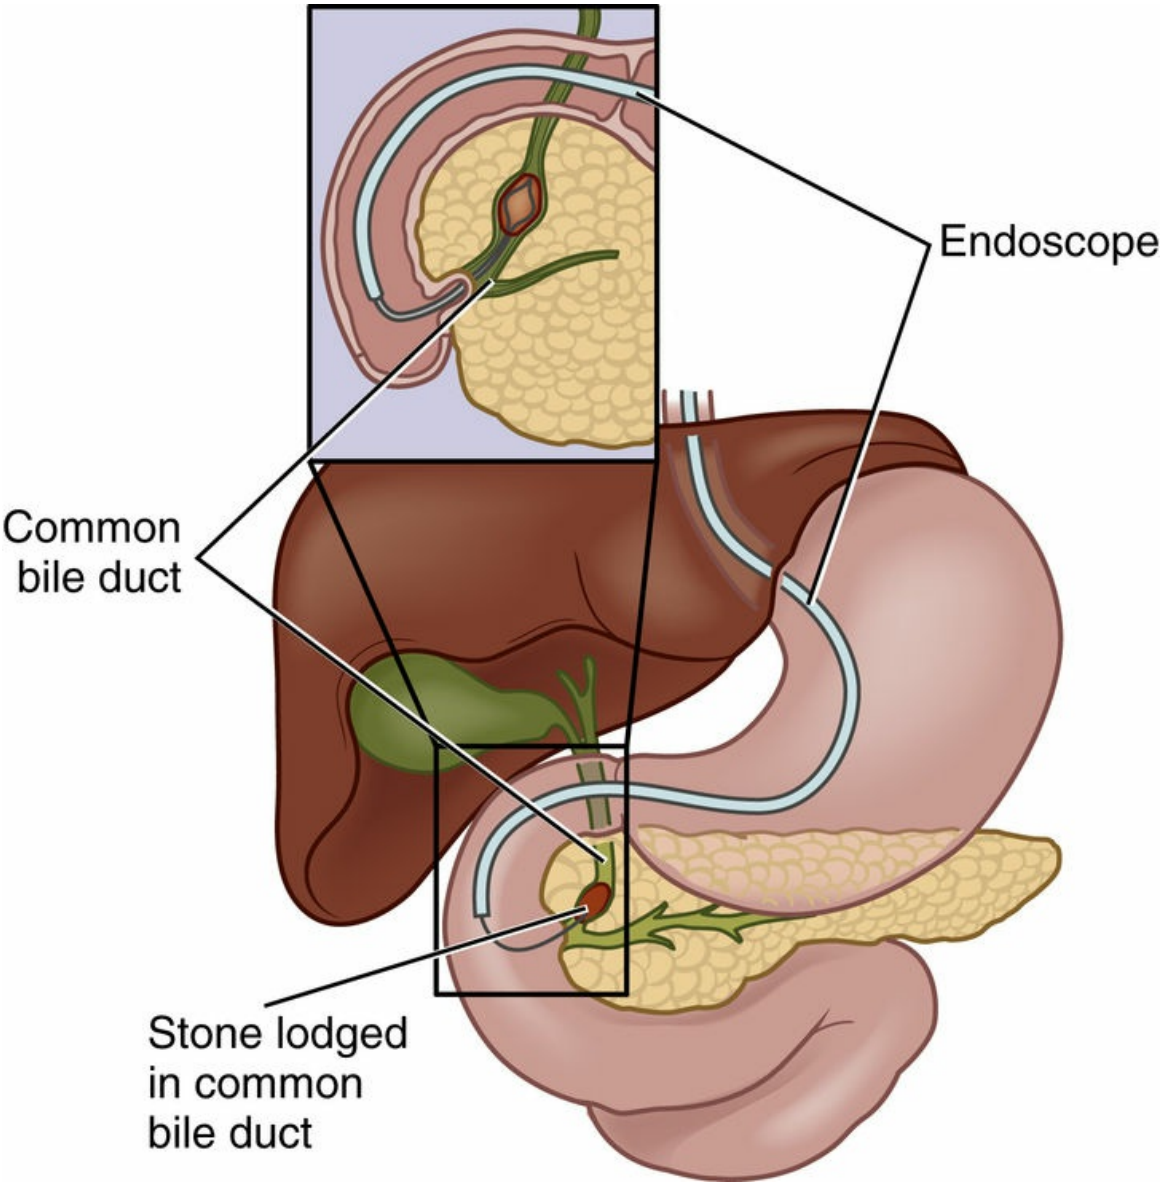

FIG. 43.15 During endoscopic sphincterotomy, an endoscope is advanced through the mouth and stomach until its tip sits in the duodenum opposite the common bile duct. *Inset,* After widening the duct mouth by incising the sphincter muscle, the HCP advances a basket attachment into the duct and snags the stone.

TABLE 43.23 Interprofessional CareCholelithiasis and Acute Cholecystitis

Diagnostic Assessment

- History and physical examination
- Ultrasound
- ERCP
- Percutaneous transhepatic cholangiography
- Liver function tests
- White blood cell count
- Serum bilirubin

Management

Conservative Therapy

- IV fluid
- NPO with NG tube, later progressing to low-fat diet
- Antiemetics
- Analgesics
- Fat-soluble vitamins (A, D, E, and K)
- Anticholinergics (antispasmodics)
- Antibiotics (for secondary infection)
- Transhepatic biliary catheter
- ERCP with sphincterotomy (papillotomy)
- Extracorporeal shock-wave lithotripsy

Dissolution Therapy

- ursodeoxycholic acid (ursodiol [Actigall])

Surgical Therapy

- Laparoscopic cholecystectomy
- Incisional (open) cholecystectomy

Cholecystitis

During an acute episode of cholecystitis, treatment focuses on pain control, control of infection with antibiotics, and maintaining fluid and electrolyte balance (Table 43.23). Treatment is supportive and focused on symptom management. If nausea and vomiting are severe, NG tube insertion and gastric decompression may be used to prevent further gallbladder stimulation. A cholecystostomy may be used to drain purulent material from the obstructed gallbladder. Opioids are given for pain management. Anticholinergics may be used to decrease GI secretions and counteract smooth muscle spasms.

Surgical Therapy

Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones. About 90% of cholecystectomies are done laparoscopically. In this procedure, the gallbladder is removed through 1 to 4 small punctures in the abdomen. The HCP makes a small cut below the umbilicus and inserts a needle into the area. CO_2 gas is passed into the abdomen to expand the area, which allows the HCP to see the organs more clearly and gives more room to work. A laparoscope, which has a camera attached, and grasping forceps are inserted into the abdomen through the punctures. Using closed-circuit monitors to view the abdominal cavity, the HCP retracts and dissects the gallbladder and removes it with grasping forceps. This is a safe and routine procedure with minimal morbidity and quick recovery time.

Most patients have minimal postoperative pain and are discharged the day of surgery or the day after. They can usually resume normal activities and return to work within 1 week. The main complication is injury to the common bile duct. The few contraindications to laparoscopic cholecystectomy include peritonitis, cholangitis, gangrene or perforation of the gallbladder, portal hypertension, and serious bleeding disorders.

Some patients may need an incisional (open) cholecystectomy. This involves removing the gallbladder through a right subcostal incision. A T tube may be inserted into the common bile duct during surgery

when a common bile duct exploration is part of the surgical procedure (Fig. 43.16). This ensures patency of the duct until the edema from the trauma of exploring and probing the duct has subsided. It also allows excess bile to drain while the small intestine is adjusting to receiving a continuous flow of bile.

Transhepatic Biliary Catheter

The transhepatic biliary catheter can be used preoperatively in biliary obstruction and in hepatic dysfunction from obstructive jaundice. It also can be inserted for palliative care when inoperable liver, pancreatic, or bile duct cancer obstructs bile flow. The catheter is used when endoscopic drainage has been unsuccessful. The catheter is inserted percutaneously and allows for decompression of obstructed extrahepatic bile ducts so that bile can flow freely. After placement of the catheter into the obstructed duct internally, the external catheter is connected to a drainage bag. Encourage patients to replace fluids lost in the drainage bag with electrolyte-rich drinks. Cleanse the skin around the catheter insertion site daily with an antiseptic. Observe for bile leakage at the insertion site and any signs or symptoms of sudden abdominal pain, nausea, fever, or chills that may signal an occluded or malfunctioning drain.

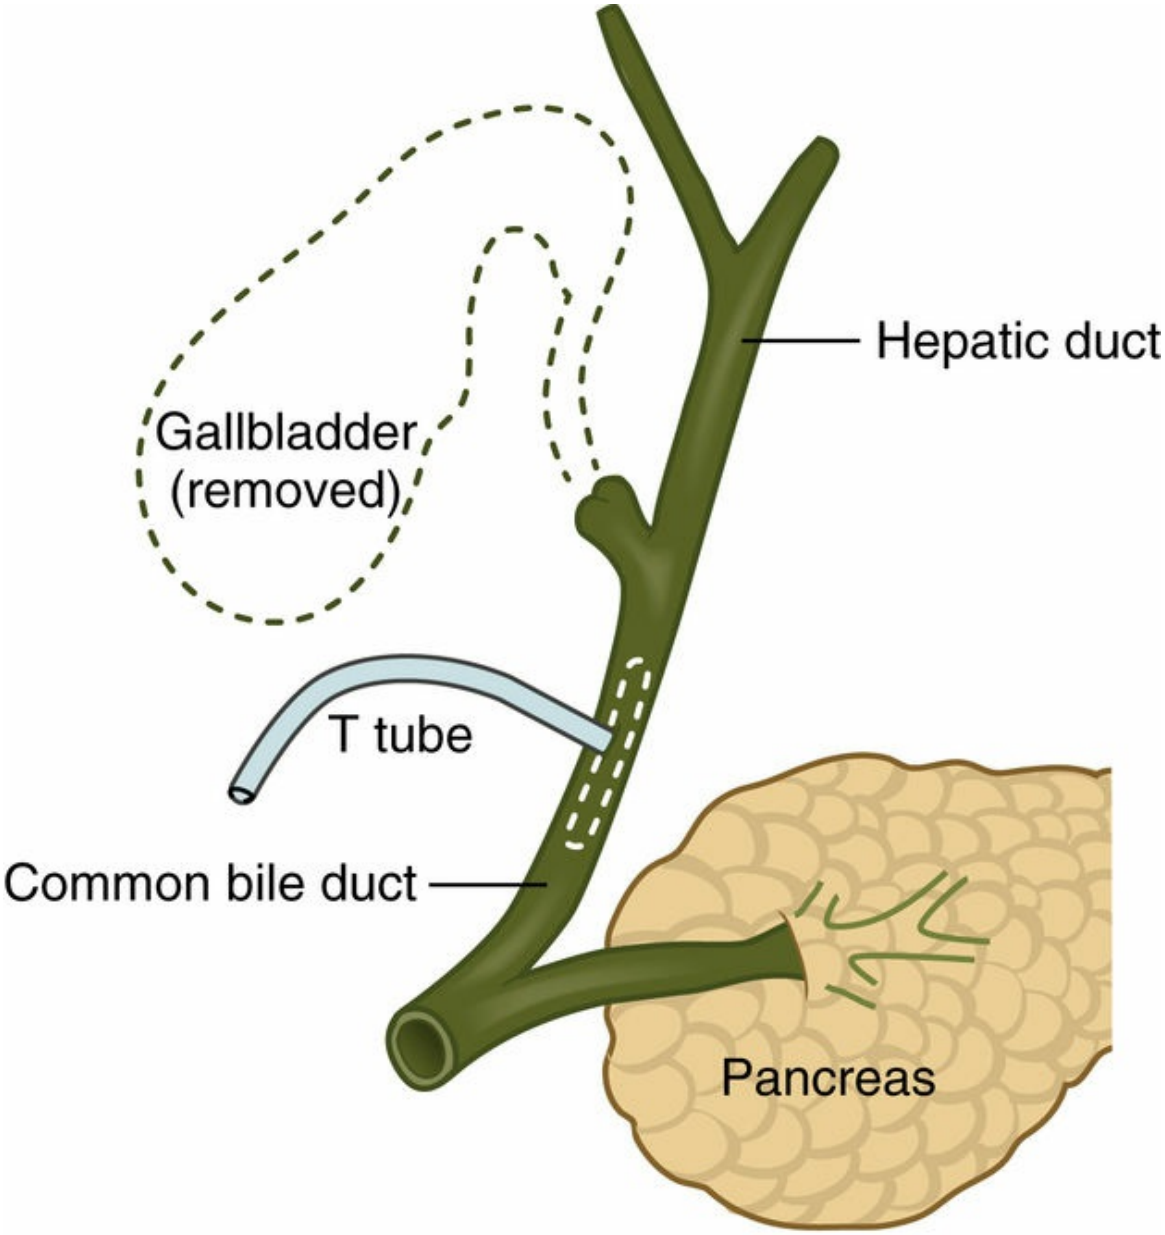

FIG. 43.16 Placement of T tube. *Dotted lines* show parts removed.

Drug Therapy

The most common drugs used in the treatment of gallbladder disease are analgesics, anticholinergics (antispasmodics), fat-soluble vitamins, and bile salts. Morphine may be used initially for pain management. Anticholinergics, such as atropine and other antispasmodics, may be used to relax the smooth muscle and decrease ductal tone.

The patient with chronic gallbladder disease or any biliary tract

obstruction may need fat-soluble vitamin (A, D, E, and K) replacement. Bile salts may be given to help digestion and vitamin absorption.

Cholestyramine may provide relief from pruritus. Cholestyramine is a resin that binds bile salts in the intestine, increasing their excretion in the feces. It comes in powder form that is mixed with milk or juice. Side effects include nausea, vomiting, diarrhea or constipation, and skin reactions. Cholestyramine may bind with other medications, so check drug-to-drug interactions.

Nutritional Therapy

People have fewer gallbladder problems if they eat smaller, more frequent meals with some fat at each meal to promote gallbladder emptying. If obesity is a problem, a reduced-calorie diet is indicated. The diet should be low in saturated fats (e.g., butter, shortening, lard) and high in fiber and calcium. Rapid weight loss should be avoided because it can promote gallstone formation.

After a laparoscopic cholecystectomy, teach the patient to have liquids for the rest of the day and eat light meals for a few days. After an incisional cholecystectomy, the patient will progress from liquids to a regular diet once bowel sounds have returned. The amount of fat in the postoperative diet depends on the patient's tolerance of fat. A low-fat diet may be helpful if the flow of bile is reduced (usually only in the early postoperative period) or if the patient is overweight. Sometimes the patient must restrict fats for 4 to 6 weeks. Otherwise, no special diet is needed other than to eat nutritious meals and avoid excess fat intake.

Nursing Management: Gallbladder Disease

Nursing Assessment

Subjective and objective data that should be obtained from a person with gallbladder disease are outlined in Table 43.24.

Nursing Diagnoses

Nursing diagnoses for the patient with gallbladder disease treated surgically may include:

- Acute pain
- Lack of knowledge

Planning

The overall goals are that the patient with gallbladder disease will have (1) relief of pain and discomfort, (2) no complications postoperatively, and (3) no recurrent attacks of cholecystitis or gallstones.

TABLE 43.24 Nursing AssessmentCholecystitis or Cholelithiasis

Subjective Data

Important Health Information

Past health history: Obesity, multiparity, infection, cancer, extensive fasting, pregnancy

Medications: Estrogen or oral contraceptives

Surgery or other treatments: Abdominal surgery

Functional Health Patterns

Health perception–health management: Positive family history, sedentary lifestyle
Nutritional-metabolic: Weight loss, anorexia, indigestion, fat intolerance, nausea and vomiting, dyspepsia, chills
Elimination: Clay-colored stools, steatorrhea, flatulence. Dark urine
Cognitive-perceptual: Moderate to severe pain in right upper quadrant that may radiate to the back or scapula. Itching

Objective Data
General

Fever, restlessness

Integumentary

Jaundice, icteric sclera, diaphoresis

Respiratory

Tachypnea, splinting during respirations

Cardiovascular

Tachycardia

Gastrointestinal

Palpable gallbladder, abdominal guarding, and distention

Possible Diagnostic Findings

↑ Serum liver enzymes, alkaline phosphatase, and bilirubin. Absence of urobilinogen in urine, ↑ urinary bilirubin, leukocytosis. Abnormal gallbladder ultrasound

Nursing Implementation

Health Promotion

Be aware of predisposing factors for gallbladder disease in general health screening. Teach patients from ethnic groups in which the disease is more common, such as Native Americans, the early manifestations and to see their HCP if these manifestations occur. Patients with chronic cholecystitis may not have acute symptoms and may not seek help until jaundice and biliary obstruction occur. Earlier detection in these patients is important so that they can be managed with a low-fat diet and monitored more closely.

Acute Care

Nursing goals for the patient undergoing conservative therapy include (1) treat pain, (2) relieve nausea and vomiting, (3) provide comfort and emotional support, (4) maintain fluid and electrolyte balance and nutrition, and (5) observe for complications.

The patient with acute cholecystitis or gallstones often has severe pain. Give the drugs ordered to relieve the pain as needed before pain becomes severe. Observe for side effects of the drugs as part of the continued assessment. Nursing comfort measures, such as a clean bed, comfortable positioning, and oral care, are appropriate.

Some patients have more severe nausea and vomiting than others. For these patients, an NG tube and gastric decompression may be ordered. Eliminating intake of food and fluids prevents further stimulation of the gallbladder. Oral hygiene, care of nares, accurate

intake and output measurements, and maintaining suction should be a part of the nursing care plan. For patients with less severe nausea and vomiting, antiemetics are usually adequate. When the patient is vomiting, provide comfort measures, such as frequent mouth rinses. Remove any vomitus at once from the patient's view. If itching occurs with jaundice, use measures to relieve itching. These can include antihistamines or other treatments as previously discussed.

Assess for progression of the symptoms and development of complications. Observe for signs of obstruction of the ducts by stones. These include jaundice; clay-colored stools; dark, foamy urine; steatorrhea; fever; and increased WBC count.

When manifestations of obstruction are present (Table 43.22), bleeding may result from decreased prothrombin production by the liver. Common sites to observe for bleeding are the mucous membranes of the mouth, nose, gingivae, and injection sites. When giving injections, use a small-gauge needle and apply gentle pressure after the injection. Know the patient's PT time and use it as a guide in the assessment process.

Assessment for infections includes monitoring vital signs. A temperature elevation with chills and jaundice may indicate choledocholithiasis.

Your care of the patient after ERCP with papillotomy includes assessment to detect complications, such as pancreatitis, perforation, infection, and bleeding. Monitor the patient's vital signs. Abdominal pain, fever, and increasing amylase and lipase may indicate acute pancreatitis. The patient should be on bed rest for several hours and should be NPO until the gag reflex returns. Teach the patient the need for follow-up if the stent is to be removed or changed.

Postoperative Care

Postoperative nursing care after a laparoscopic cholecystectomy includes monitoring for complications, such as bleeding, making the patient comfortable, and preparing the patient for discharge. Patients may report referred pain to the shoulder because of the CO_2 that the HCP uses to inflate the abdominal cavity during surgery. It may not

be released or absorbed by the body. The CO_2 can irritate the phrenic nerve and diaphragm, causing some difficulty in breathing. Placing the patient in the Sims' position (on left side with right knee flexed) helps move the gas pocket away from the diaphragm. Encourage deep breathing along with movement and ambulation. NSAIDs or codeine can usually relieve pain. The patient is allowed clear liquids and can walk to the bathroom to void. Most patients go home the same day.

Postoperative nursing care for incisional cholecystectomy focuses on adequate ventilation and prevention of respiratory complications. Other nursing care is the same as general postoperative nursing care (see Chapter 19).

If the patient has a T tube (Fig. 43.16), maintain the system and monitor T-tube function and drainage. The T tube is usually connected to a closed gravity drainage system. If the Penrose or Jackson-Pratt drain or the T tube is draining large amounts of bile, it is helpful to use a sterile pouching system to protect the skin. Encourage the patient to replace any lost fluids and electrolytes.

Ambulatory Care

When the patient has conservative therapy, nursing management depends on the patient's symptoms and on whether surgical intervention is planned. Dietary teaching is usually needed. The diet is usually low in fat. The patient may need to take fat-soluble vitamin supplements. If needed, review a weight-reduction diet. Teach the patient signs and symptoms of obstruction (e.g., stool and urine changes, jaundice, itching). Explain the importance of continued health care follow-up.

TABLE 43.25 Patient & Caregiver TeachingPostoperative Laparoscopic Cholecystectomy

Postoperative teaching should include:

1. Remove the bandages on the puncture sites the day after surgery and you can shower.
2. Notify your HCP if any of the following signs and symptoms occurs:
    - Redness, swelling, bile-colored drainage or pus from any incision
    - Severe abdominal pain, nausea, vomiting, fever, chills
3. You can gradually resume normal activities.
4. Return to work within 1 wk of surgery.
5. You can resume your usual diet, but a low-fat diet is usually better tolerated for several weeks after surgery.

The patient who undergoes a laparoscopic cholecystectomy is discharged soon after the surgery, so home care and teaching are important (Table 43.25).

After an incisional cholecystectomy, tell the patient to avoid heavy lifting for 4 to 6 weeks. Usual sexual activities, including intercourse, can be resumed as soon as the patient feels ready, unless otherwise instructed by the HCP.

Sometimes the patient needs to remain on a low-fat diet for 4 to 6 weeks. If so, an individualized dietary teaching plan is needed. A weight-reduction program may be helpful if the patient is overweight. Most patients tolerate a regular diet with no problems but should avoid excess fats.

Evaluation

The overall expected outcomes are that the patient with gallbladder disease will

- Appear comfortable and have pain relief
- State knowledge of activity level and dietary restrictions

Gallbladder Cancer

Gallbladder cancer is the sixth most common GI cancer in the United States.[17] Most gallbladder cancers are adenocarcinomas. They are often found incidentally as the patient is asymptomatic. The majority have advanced disease at the time of diagnosis.

The early symptoms are insidious and similar to those of chronic cholecystitis and gallstones, which makes the diagnosis difficult. Later symptoms are usually those of biliary obstruction.

Diagnosis and staging of gallbladder cancer are done using EUS, abdominal ultrasound, CT, MRI, and/or MRCP. Unfortunately, gallbladder cancer often is not detected until the disease is advanced. When it is found early, surgery can be curative. Several factors influence successful surgical outcomes, including the depth of cancer invasion, extent of liver involvement, venous or lymphatic invasion, and lymph node metastasis. Extended cholecystectomy with lymph node dissection has improved outcomes for those with gallbladder cancer.

When surgery is not an option, endoscopic stenting of the biliary tract can reduce obstructive jaundice. Adjuvant therapies, including radiation therapy and chemotherapy, may be used depending on the disease state. Overall, gallbladder cancer has a poor prognosis.

Nursing management involves palliative care with special attention to nutrition, hydration, skin care, and pain relief. Nursing care measures used for patients with cholecystitis and gallstones and for the patient with cancer (see Chapter 15) are appropriate.

Case Study

Cirrhosis of the Liver

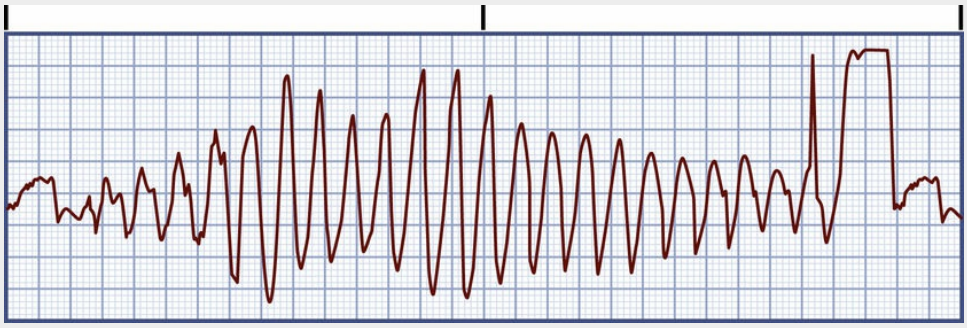
© sbeagle/iStock/Thinkstock.

Patient Profile

M.B., a 58-yr-old male rancher who lives in rural Wyoming, is admitted with a diagnosis of cirrhosis of the liver. He has been vomiting for 2 days and noticed blood in the toilet when he vomited. He lives 40 miles from the nearest hospital. He had one of his ranch hands drive him to the hospital. His medical history includes chronic hepatitis C, depression, and stage II chronic kidney disease.

Subjective Data

- Has been estranged from his 2 children since his divorce 3 years ago



- Has had cirrhosis for 12 yrs
- Acknowledges that he had been drinking heavily for 20 yrs but has been sober for the past 2 yrs
- Reports experiencing anorexia, nausea, and abdominal discomfort

Objective Data
Physical Examination

- Has moderate ascites
- Has jaundice of sclera and skin
- Has 4+ pitting edema of the lower extremities
- Liver and spleen are palpable

Laboratory Values

- Total bilirubin: 15 mg/dL (257 mmol/L)
- AST: 190 U/L (3.2 μkat/L)
- ALT: 210 U/L (3.5 μkat/L)
- Platelets: 45,000/μL
- eGFR: 62 mL/min
- ECG is below:

Discussion Questions

1. What are possible causes of cirrhosis? What type of cirrhosis does M.B. likely have?
2. Describe the pathophysiologic changes that occur in the liver as cirrhosis develops.
3. List M.B.'s clinical manifestations of liver failure. For each manifestation, explain the pathophysiologic basis.
4. Explain the significance of the results of his laboratory values and ECG findings.
5. If M.B. begins to show signs and symptoms of hepatic encephalopathy, what would you monitor? What measures would be used to control or decrease the encephalopathy?
6. What are possible causes of his GI bleeding?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Priority Decision:*** What are the priority nursing interventions for a patient at this stage of his illness?
9. ***Evidence-Based Practice:*** M.B. discusses his prognosis with you. He says, "There is no hope. I might as well keep drinking." How would you respond to his statement?
10. ***Safety:*** Given M.B.'s bleeding history and current laboratory values, identify areas of injury risk and specify actions you will take to ensure patient safety.
11. Develop a conceptual care map for M.B.

Answers and corresponding conceptual care map available at *evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 5 patients. You have 1 LPN and 1 UAP who are assigned to help you.

Patients	
 © iStockphoto/Thinkstock.	L.C. is a 58-yr-old Native American man admitted from the ED with acute abdominal pain. A CT scan and colonoscopy showed 2 medium-sized tumors in the transverse colon. A hemicolectomy was done 4 days ago. The adenocarcinoma had spread to the muscle of the colon wall, and there were 2 positive lymph nodes. He is scheduled to be discharged today.
 © iStockphoto/Thinkstock.	M.S. is a 70-yr-old white woman who was recently admitted to the unit with generalized weakness and malnutrition. She is 5 ft, 4 in tall and weighs 100 lb, with a 30-lb weight loss in past 2 months. Her medical history includes a recent thrombotic stroke with hemiparesis and dysphagia. She has had nothing by mouth for the past 24 hours and just started EN via PEG tube.
 © Christa Brunl/iStock/Thinkstock.	S.R. is a 48-yr-old white woman admitted with hip pain. She has a history of type 2 diabetes, hypertension, and osteoarthritis. She is 5 ft, 6 in tall and weighs 230 lb. Her most recent BP was 160/110 mm Hg. Her morning laboratory results reveal high fasting blood glucose, total cholesterol, LDL cholesterol, and triglycerides. Her HDL cholesterol is low. Her cardiac enzymes and ECG are all within normal limits. She is scheduled to have a cardiac stress test at 10 AM.
 © iStockphoto/Thinkstock.	F.H., a 40-yr-old male immigrant from Vietnam, has a 1-yr history of epigastric distress. He had an upper endoscopy a few weeks ago, which revealed a duodenal ulcer and *H. pylori*. He was started on omeprazole, clarithromycin, and amoxicillin for 10 days. He came to the ED yesterday with severe epigastric pain and melena. His Hgb is 8.2 g/dL and Hct is 26%. He was admitted and put on a pantoprazole (Protonix) continuous infusion and is scheduled for a repeat EGD today.
 © sbeagle/iStock/Thinkstock.	M.B. is a 58-yr-old man admitted with a diagnosis of upper GI bleeding. He has been vomiting for 2 days and noticed blood in the toilet when he vomits. He has had cirrhosis for 12 yr and admits to drinking heavily for 20 yr but has been sober for the past 2 yr. He currently reports anorexia, nausea, and abdominal discomfort. He has moderate ascites, jaundice of sclera and skin, 4+ pitting edema of the lower extremities, and palpable liver and spleen. His bilirubin and liver enzymes are all high. His platelet and RBC counts are low.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Collaboration:*** Which tasks could you delegate to the LPN? *(select all that apply)*
    a. Administer a bolus enteral tube feeding to M.S.
    b. Assess L.C.'s dressing, pain level, and bowel sounds.
    c. Administer a scheduled dose of oral lactulose solution to M.B.
    d. Because she speaks Vietnamese, teach F.H.'s wife about his disease.
    e. Perform bedside glucometer reading and administer oral medications to S.R.
3. ***Priority Decision:*** Which diagnostic finding should you report to the health care provider immediately?
    a. Hemoglobin 7.9 g/dL and hematocrit 25% for F.H.
    b. Serum albumin 2.7 g/dL and prealbumin 11.2 g/dL for M.S.
    c. Cholesterol 250 mg/dL and triglycerides 202 mg/dL for S.R.
    d. Total bilirubin 3.2 mg/dL with positive urine bilirubin for M.B.
4. ***Priority Decision:*** As you are assessing M.B., the LPN informs you that F.H. just vomited a large amount of bright red blood. What initial action would be *most* appropriate?
    a. Have the LPN administer an antiemetic to F.H.
    b. Ask the LPN to notify F.H.'s health care provider.
    c. Leave M.B.'s room to perform a focused assessment on F.H.
    d. Ask the UAP to obtain a unit of packed RBCs from the blood bank.

Case Study Progression

When you enter F.H.'s room, he tells you that his pain actually feels somewhat relieved since he vomited. However, you note that his skin is cool and clammy, his BP is 90/54 mm Hg, and his heart rate is 116

bpm. You notify his HCP.

4. Which interventions would you expect the HCP to order for F.H.? *(select all that apply)*
    a. Stat hemoglobin and hematocrit
    b. Emergent endoscopy with band ligation
    c. Discontinue the pantoprazole (Protonix) infusion
    d. Start a second IV site and administer a 500 mL normal saline bolus
    e. Contact HCP and notify operating room that patient is unstable and needs surgery
5. ***Priority Decision:*** After giving a bolus feeding of enteral nutrition to M.S., it would be *most* important to
    a. assess for gastric residual.
    b. obtain an abdominal x-ray.
    c. keep head of bed elevated 30 to 45 degrees.
    d. record the total amount of fluid administered.
6. Which intervention to treat ascites would you expect the HCP to order for M.B.? *(select all that apply)*
    a. Paracentesis
    b. 2 g sodium diet
    c. Diuretic therapy
    d. 1800 mL/day fluid restriction
    e. Shunt insertion from peritoneum to heart
7. ***Management Decision:*** As you enter the nurse's station, you overhear derogatory comments made by the UAP to the LPN about S.R.'s weight. Which response would be *most* appropriate?
    a. Report the incident to charge nurse for follow-up.
    b. Talk to the UAP to discuss a possible HIPAA violation.
    c. Talk to S.R. about the impact of UAP's bias on the patient's self-image.
    d. Set up an in-service to teach staff members to recognize obesity as a disease process.

Answers and rationales available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with hepatitis A is in the acute phase. The nurse plans care for the patient based on the knowledge that
   a. itching is a common problem with jaundice in this phase.
   b. the patient is most likely to transmit the disease during this phase.
   c. gastrointestinal symptoms are not as severe in hepatitis A as they are in hepatitis B.
   d. extrahepatic manifestations of glomerulonephritis and polyarteritis are common in this phase.
2. A patient with acute hepatitis B is being discharged. The discharge teaching plan should include instructions to
   a. avoid alcohol for the first 3 weeks.
   b. use a condom during sexual intercourse.
   c. have family members get an injection of immunoglobulin.
   d. follow a low-protein, moderate-carbohydrate, moderate-fat diet.
3. A patient has been told that she has elevated liver enzymes caused by nonalcoholic fatty liver disease (NAFLD). The nursing teaching plan should include
   a. having genetic testing done.
   b. recommending a heart-healthy diet.

c. the necessity to reduce weight rapidly.

d. avoiding alcohol until liver enzymes return to normal.

4. The patient with advanced cirrhosis asks why his abdomen is so swollen. The nurse's response is based on the knowledge that

   a. a lack of clotting factors promotes the collection of blood in the abdominal cavity.

   b. portal hypertension and hypoalbuminemia cause a fluid shift into the peritoneal space.

   c. decreased peristalsis in the GI tract contributes to gas formation and distention of the bowel.

   d. bile salts in the blood irritate the peritoneal membranes, causing edema and pocketing of fluid.

5. In planning care for a patient with metastatic liver cancer, the nurse should include interventions that

   a. focus primarily on symptomatic and comfort measures.

   b. reassure the patient that chemotherapy offers a good prognosis.

   c. promote the patient's confidence that surgical excision of the tumor will be successful.

   d. provide information needed for the patient to make decisions about liver transplantation.

6. Nursing management of the patient with acute pancreatitis includes *(select all that apply)*

   a. administering pain medication.

   b. checking for signs of hypocalcemia.

   c. providing a diet low in carbohydrates.

d. giving insulin based on a sliding scale.

e. monitoring for infection, particularly respiratory tract infection.

7. A patient with pancreatic cancer is admitted to the hospital for evaluation of treatment options. The patient asks the nurse to explain the Whipple procedure that the surgeon has described. The explanation includes the information that a Whipple procedure involves

a. creating a bypass around the obstruction caused by the tumor by joining the gallbladder to the jejunum.

b. resection of the entire pancreas and the distal part of the stomach, with anastomosis of the common bile duct and the stomach into the duodenum.

c. removal of part of the pancreas, part of the stomach, the duodenum, and the gallbladder, with joining of the pancreatic duct, the common bile duct, and the stomach into the jejunum.

d. removal of the pancreas, the duodenum, and the spleen, and attachment of the stomach to the jejunum, which requires oral supplementation of pancreatic digestive enzymes and insulin replacement therapy.

8. The nurse caring for a patient with suspected acute cholecystitis would anticipate (*select all that apply*)

a. ordering a low-sodium diet.

b. administration of IV fluids.

c. monitoring of liver function tests.

d. administration of antiemetics for patients with nausea.

e. insertion of an indwelling catheter to monitor urinary

output.

9. Teaching in relation to home management after a laparoscopic cholecystectomy should include
   a. keeping the bandages on the puncture sites for 48 hours.
   b. reporting any bile-colored drainage or pus from any incision.
   c. using over-the-counter antiemetics if nausea and vomiting occur.
   d. emptying and measuring the contents of the bile bag from the T tube every day.

1. a, 2. b, 3. b, 4. b, 5. a, 6. a, b, e, 7. c, 8. b, c, d, 9. b

Assessment

Urinary System

Teresa Turnbull

LEARNING OUTCOMES

1. Identify the anatomic location and functions of the kidneys, ureters, bladder, and urethra.
2. Explain the physiologic events involved in the formation and passage of urine from glomerular filtration to voiding.
3. Obtain significant subjective and objective data related to the urinary system from a patient.
4. Link the age-related changes of the urinary system to the differences in assessment findings.
5. Perform a physical assessment of the urinary system using appropriate techniques.
6. Distinguish normal from abnormal findings of a physical assessment of the urinary system.
7. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the urinary system.
8. Evaluate findings of a urinalysis.

Conceptual Focus

Elimination
Fluids and Electrolytes

Adequate kidney function is essential to health. If a person has complete kidney failure and treatment is not provided, death is inevitable. This chapter discusses the structures and functions, assessment, and diagnostic studies of the urinary system.

Structures and Functions of Urinary System

The *upper urinary system* consists of 2 kidneys and 2 ureters. The *lower*

urinary system consists of a urinary bladder and urethra (Fig. 44.1). Urine is formed in the kidneys, drains through the ureters to be stored in the bladder, and then passes out of the body through the urethra.

Kidneys

The kidneys are the principal organs of the urinary system. The primary functions of the kidneys are to (1) regulate the volume and composition of extracellular fluid (ECF) and (2) excrete waste products from the body. The kidneys also function to control BP, make erythropoietin, activate vitamin D, and regulate acid-base balance.

Macrostructure

The paired kidneys are bean-shaped organs located retroperitoneally (behind the peritoneum) on either side of the vertebral column at about the level of the twelfth thoracic (T12) vertebra to the third lumbar (L3) vertebra. Each kidney weighs 4 to 6 oz (113 to 170 g) and is about 5 in (12.5 cm) long. The right kidney, positioned at the level of the twelfth rib, is lower than the left. An adrenal gland lies on top of each kidney.

Each kidney is surrounded by a considerable amount of fat and connective tissue that cushions, supports, and helps the kidney maintain its position. A thin, smooth layer of fibrous membrane called the *capsule* covers the surface of each kidney. The capsule protects the kidney and serves as a shock absorber if this area is traumatized from a sudden force or strike. The *hilus* on the medial side of the kidney serves as the entry site for the renal artery and nerves and as the exit site for the renal vein and ureter.

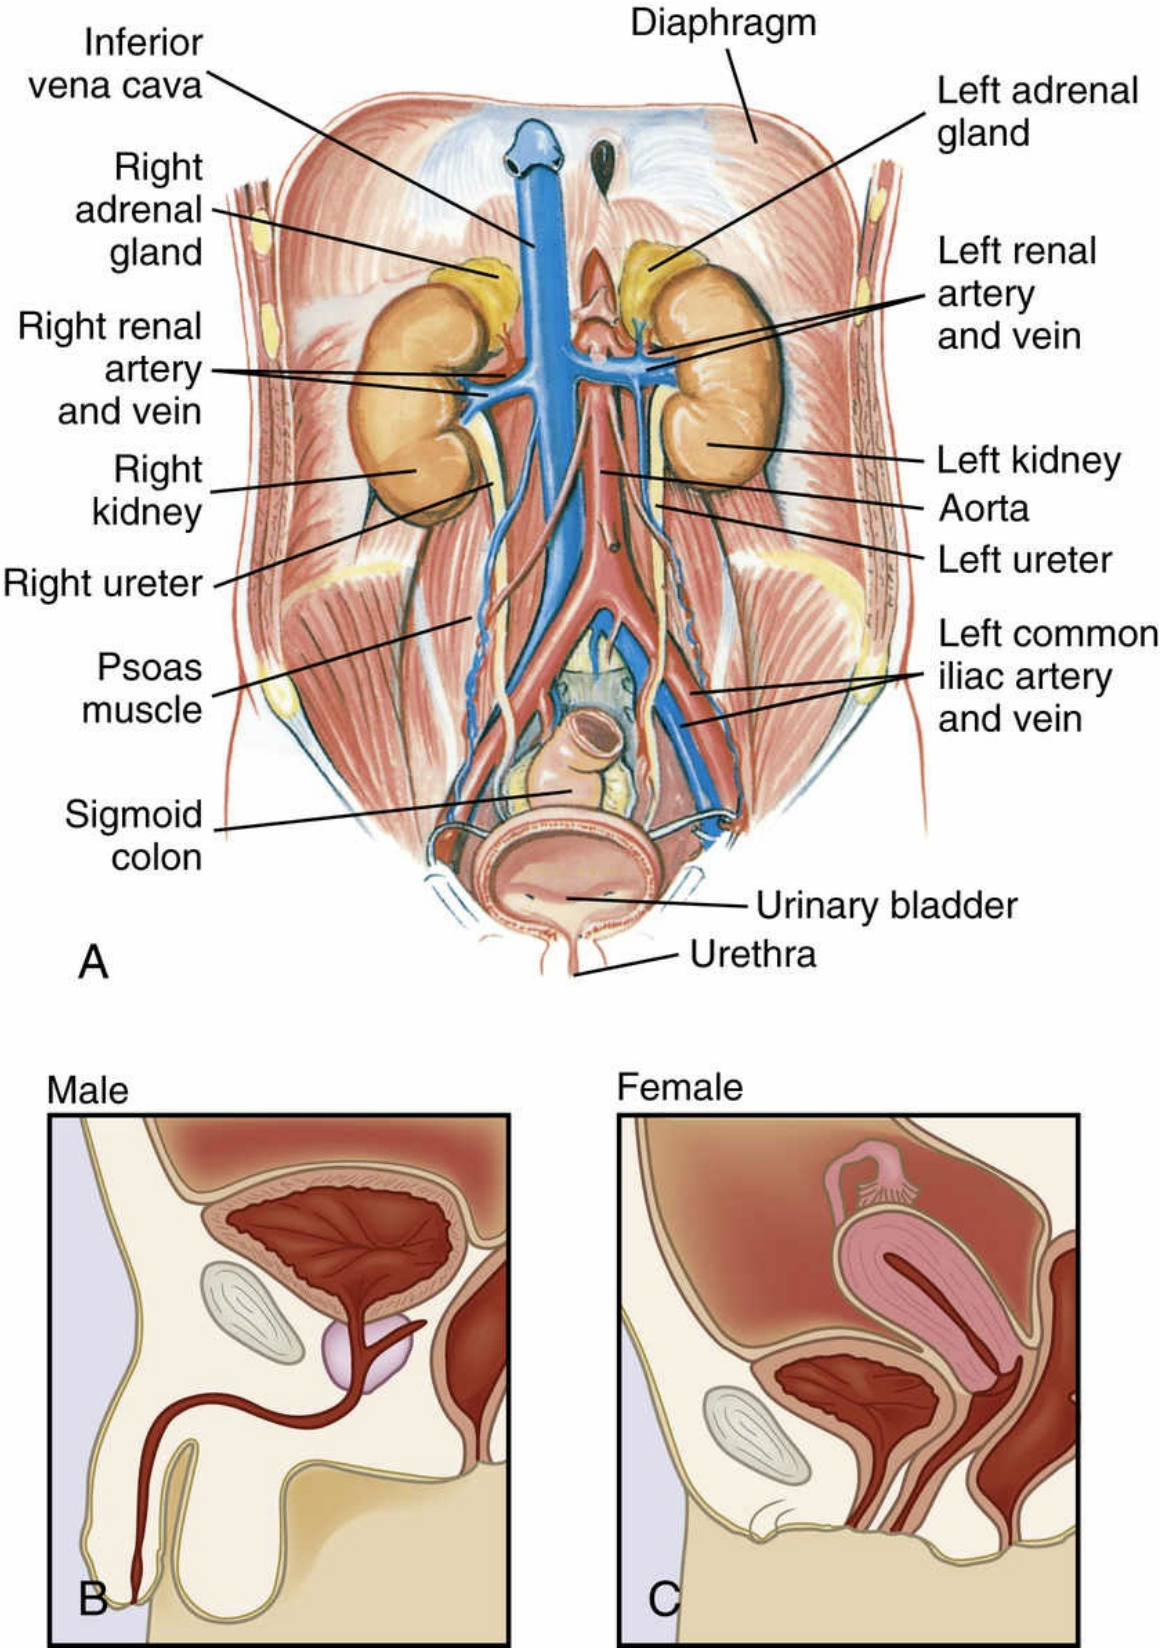

FIG. 44.1 Organs of the urinary system. **A,** Upper urinary tract in relation to other anatomic structures. **B,** Male urethra in relation to

other pelvic structures. **C,** Female urethra.

The *parenchyma* is the actual tissue of the kidney (Fig. 44.2). The outer layer of the parenchyma is the *cortex,* and the inner layer is the *medulla.* The medulla consists of a number of pyramids. The apices (tops) of these pyramids are the *papillae,* through which urine passes to enter the calyces. The minor calyces widen and merge to form major calyces, which form a funnel-shaped sac called the *renal pelvis.* The minor and major calyces transport urine to the renal pelvis, from there it drains through the ureter to the bladder. The renal pelvis can store a small volume of urine (3 to 5 mL).

Microstructure

The **nephron** is the functional unit of the kidney. Each kidney has around 1 million nephrons. Each nephron is composed of the glomerulus, Bowman's capsule, and a tubular system. The tubular system consists of the proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting tubules (Fig. 44.3). The glomerulus, Bowman's capsule, proximal tubule, and distal tubule are in the cortex of the kidney. The loop of Henle and collecting tubules are in the medulla. Several collecting tubules join to form a single collecting duct. The collecting ducts eventually merge into a pyramid that empties via the papilla into a minor calyx.

Blood Supply

Blood flow to the kidneys, around 1200 mL/min, accounts for 20% to 25% of the cardiac output. Blood reaches the kidneys via the renal artery, which arises from the aorta and enters the kidney through the hilus. The renal artery divides into secondary branches and then into still smaller branches, each of which forms an afferent arteriole. The afferent arteriole divides into a capillary network, the **glomerulus**, which is a collection of up to 50 capillaries (Fig. 44.3). The capillaries of the glomerulus unite in the efferent arteriole. This efferent arteriole splits to form a capillary network, the peritubular capillaries, which surround the tubular system. All peritubular capillaries drain into the

venous system. The renal vein empties into the inferior vena cava.

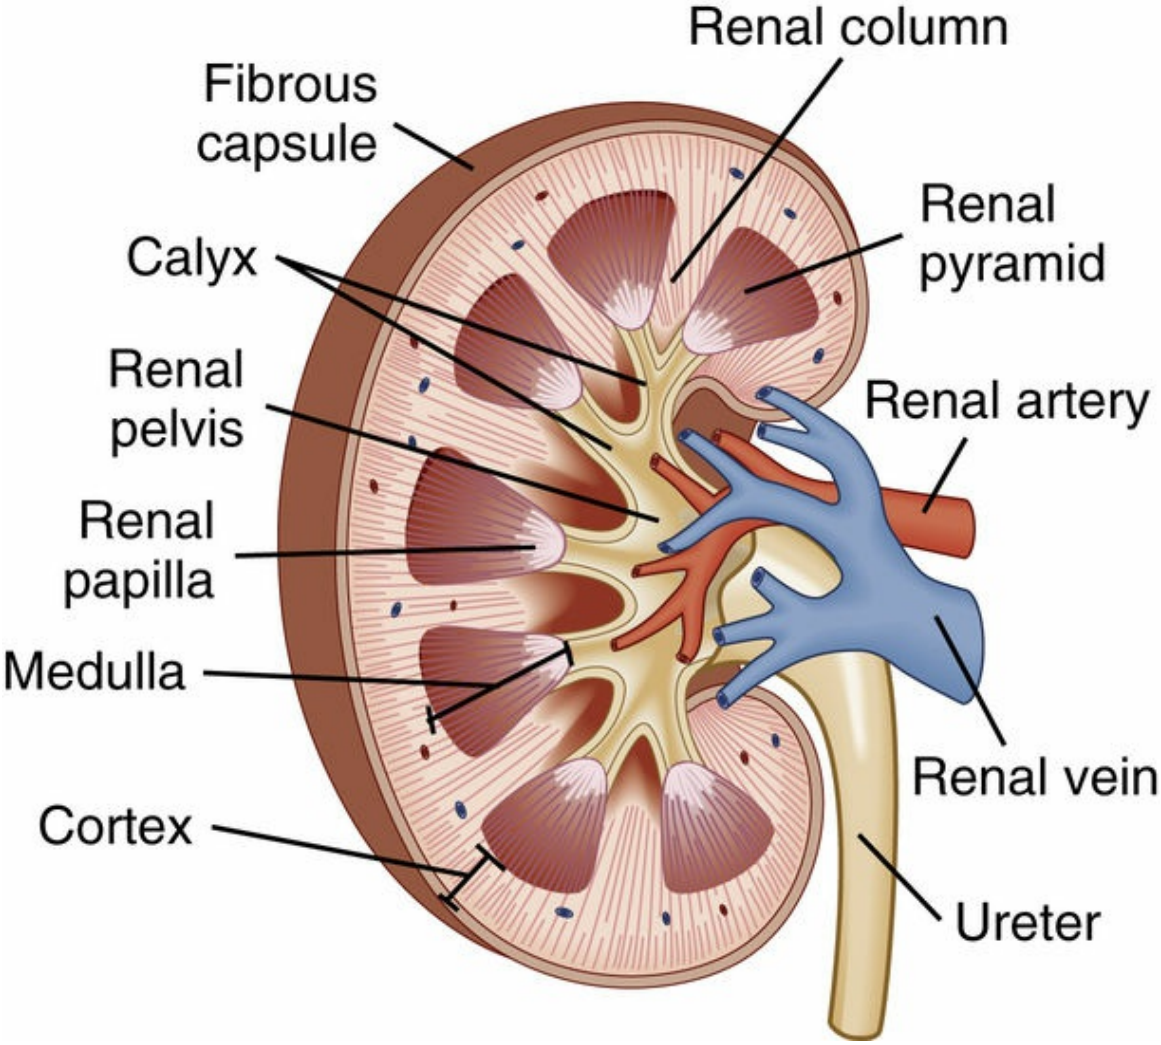

FIG. 44.2 Longitudinal section of the kidney.

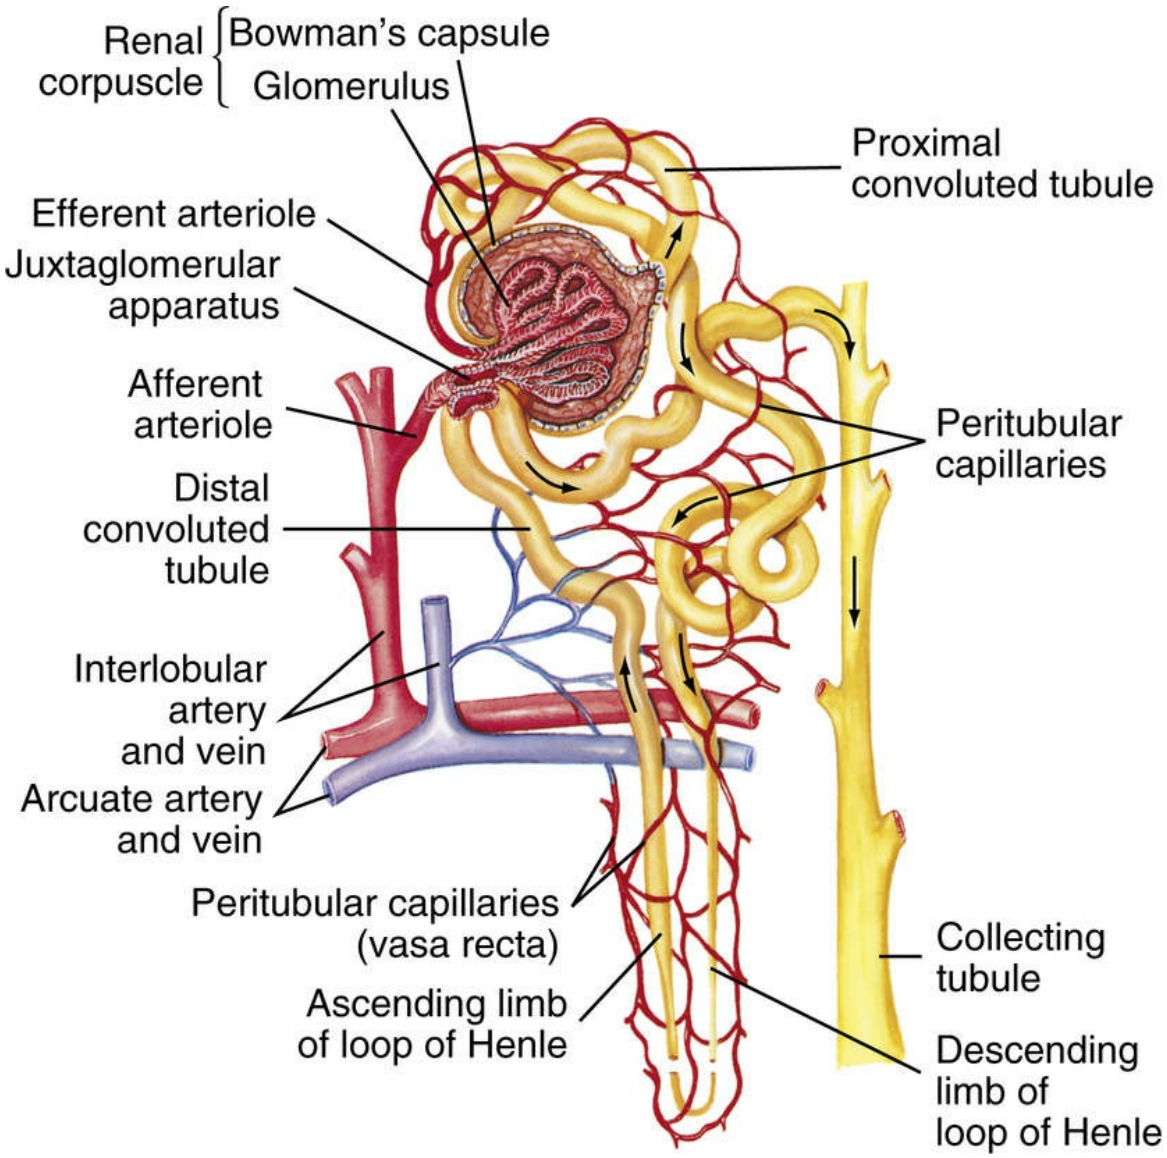

FIG. 44.3 The nephron is the basic functional unit of the kidney. This illustration of a single nephron unit shows the surrounding blood vessels.
Modified from Thibodeau GA, Patton KT: *The human body in health and disease,* ed 4, St Louis, 2005, Mosby.

Physiology of Urine Formation

Urine formation is the outcome of a complex, multistep process of filtration, reabsorption, secretion, and excretion of water, electrolytes, and metabolic waste products. Although urine formation is the result of this process, the primary functions of the kidneys are to filter the

blood and maintain the body's internal homeostasis.

Glomerular Function

Urine formation begins at the glomerulus, where blood is filtered. The glomerulus is a semipermeable membrane that allows filtration (Fig. 44.3). The hydrostatic pressure of the blood within the glomerular capillaries causes a portion of blood to be filtered across the semipermeable membrane into Bowman's capsule. There, the filtered portion of the blood (glomerular filtrate) begins to pass down to the tubule. Filtration is more rapid in the glomerulus than in ordinary tissue capillaries because the glomerular membrane is porous. The glomerular filtrate is similar in composition to blood except that it lacks blood cells, platelets, and large plasma proteins. Under normal conditions, capillary pores are too small to allow the loss of these large blood components. However, in many kidney diseases, capillary permeability increases, which allows plasma proteins and blood cells to pass into the urine.

The amount of blood filtered each minute by the glomeruli is expressed as the **glomerular filtration rate (GFR)**. The normal GFR is about 125 mL/min. The peritubular capillary network reabsorbs most of the glomerular filtrate before it reaches the end of the collecting duct. Therefore only 1 mL/min (on average) is excreted as urine.

Tubular Function

The tubules and collecting ducts are responsible for the reabsorption of essential materials and excretion of nonessential ones (Table 44.1). They carry out these functions by reabsorption and secretion. *Reabsorption* is the passage of a substance from the lumen of the tubules through the tubule cells and into the capillaries. This process involves both active and passive transport mechanisms. Tubular *secretion* is the passage of a substance from the capillaries through the tubular cells into the lumen of the tubule. Reabsorption and secretion cause many changes in the composition of the glomerular filtrate as it moves through the entire length of the tubule.

In the proximal convoluted tubule, about 80% of the electrolytes are

reabsorbed. Normally, this includes all glucose, amino acids, and small proteins. As reabsorption continues in the loop of Henle, water is conserved, which is important for concentrating the filtrate. The descending loop is permeable to water and moderately permeable to sodium, urea, and other solutes. In the ascending limb, chloride ions (Cl^-) are actively reabsorbed, followed by passive reabsorption of sodium ions (Na^+). About 25% of the filtered sodium is reabsorbed in the ascending limb.

Two important functions of the distal convoluted tubules are final regulation of water balance and acid-base balance. Antidiuretic hormone (ADH) is needed for water reabsorption in the kidney and is important in water balance. ADH makes the distal convoluted tubules and collecting ducts permeable to water. This allows water to be reabsorbed into the peritubular capillaries and eventually returned to the circulation.

TABLE 44.1 Functions of Nephron Segments

Segment	Function
Glomerulus	Selective filtration
Proximal tubule	Reabsorption of 80% of electrolytes and water, glucose, amino acids, HCO_3^- Secretion of H^+ and creatinine
Loop of Henle	Concentration of filtrate Reabsorption of Na^+ and Cl^- in ascending limb and water in descending loop
Distal tubule	Reabsorption of water (regulated by ADH) and HCO_3^- Regulation of Ca^{2+} and PO_4^{2-} by parathyroid hormone Regulation of Na^+ and K^+ by aldosterone Secretion of K^+, H^+, ammonia
Collecting duct	Reabsorption of water (requires ADH)

Osmoreceptors in the anterior hypothalamus detect decreases in plasma osmolality. These osmoreceptors send neural input to *superoptic nuclei cells* in the hypothalamus. These superoptic nuclei cells have neuronal axons that end in the posterior pituitary gland and act to inhibit secretion of ADH. In the absence of ADH, the tubules are essentially impermeable to water. Thus any water in the tubules

leaves the body as urine.

Aldosterone (released from the adrenal cortex) acts on the distal tubule to cause reabsorption of Na^+ and water. In exchange for Na^+, potassium ions (K^+) are excreted. The secretion of aldosterone is influenced by both circulating blood volume and plasma concentrations of Na^+ and K^+.

Acid-base regulation involves reabsorbing and conserving most of the bicarbonate (HCO_3^-) and secreting excess hydrogen ions (H^+). The distal tubule has different ways to keep the pH of ECF within a range of 7.35 to 7.45 (see Chapter 16).

Myocyte cells in the right atrium secrete a hormone, atrial natriuretic peptide (ANP), in response to atrial distention from an increase in plasma volume. ANP acts on the kidneys to increase sodium excretion. At the same time, ANP inhibits renin, ADH, and the action of angiotensin II on the adrenal glands, thereby suppressing aldosterone secretion. These combined effects of ANP result in the production of a large volume of dilute urine. ANP also causes relaxation of the afferent arteriole, thus increasing the GFR.

The renal tubules are also involved in calcium balance. The parathyroid gland releases parathyroid hormone (PTH) in response to low serum calcium levels. PTH maintains serum calcium levels by causing increased tubular reabsorption of calcium ions (Ca^{2+}) and decreased tubular reabsorption of phosphate ions (PO_4^{2-}). In kidney disease the effects of PTH may have a major effect on bone metabolism.

Vitamin D is a hormone that we obtain in the diet or synthesize by the action of ultraviolet radiation on cholesterol in the skin. These forms of vitamin D are inactive and go through 2 more steps to become metabolically active. The first step occurs in the liver; the second step occurs in the kidneys. Active vitamin D is essential for the absorption of calcium from the gastrointestinal (GI) tract. The patient with kidney failure (also called *renal failure*) will have a deficiency of the active metabolite of vitamin D and problems with calcium and phosphate balance (see Chapter 47).

In summary, the basic function of nephrons is to cleanse blood plasma of unnecessary substances. After the glomerulus has filtered the blood, the tubules select the unwanted from the wanted portions of tubular fluid. Essential constituents are returned to the blood, and dispensable substances pass into urine.

Other Functions of Kidneys

The kidneys participate in red blood cell (RBC) production and BP regulation. Erythropoietin is a hormone made in the kidneys and secreted in response to hypoxia and decreased renal blood flow. Erythropoietin stimulates RBC production in the bone marrow. A deficiency of erythropoietin occurs in kidney failure, leading to anemia.

Renin is important in the regulation of BP. Renin is made and secreted by the kidney's juxtaglomerular cells (Fig. 44.4). Renin is released into the bloodstream in response to decreased renal perfusion, decreased arterial BP, decreased ECF, decreased serum Na^+ concentration, and increased urinary Na^+ concentration. The plasma protein angiotensinogen (from the liver) is activated to angiotensin I by renin. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). ACE is found on the inner surface of all blood vessels, with especially high levels in the vessels of the lungs. Angiotensin II stimulates the release of aldosterone from the adrenal cortex. This causes Na^+ and water retention, leading to increased ECF volume. Angiotensin II also causes increased peripheral vasoconstriction. An elevated BP inhibits renin release. Excessive renin production caused by impaired renal perfusion may be a contributing factor in causing hypertension (see Chapter 32).

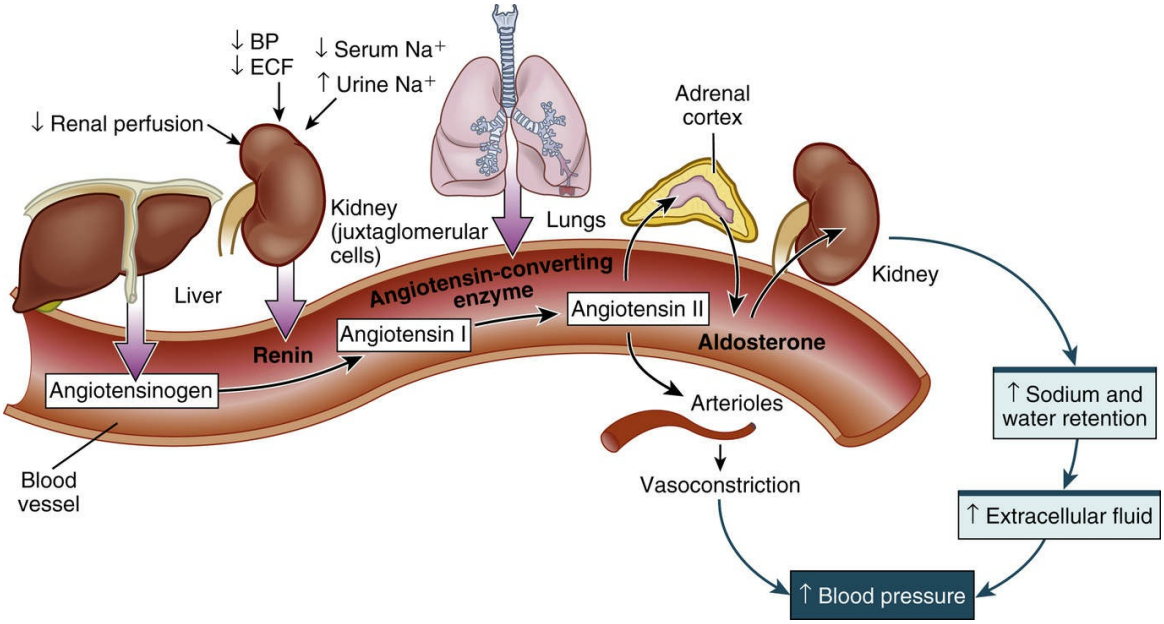

FIG. 44.4 Renin-angiotensin-aldosterone system.
Modified from Herlihy B, Maebius N: *The human body in health and disease*, ed 4, Philadelphia, 2011, Saunders.

Most body tissues synthesize prostaglandins (PGs) from the precursor arachidonic acid in response to appropriate stimuli. (See Chapter 11 and Fig. 11.2 for a more detailed discussion of PGs.) In the kidney, PG synthesis (mainly PGE_2 and PGI_2) occurs primarily in the medulla. These PGs have a vasodilating action, thus increasing renal blood flow and promoting Na^+ excretion. They counteract the vasoconstrictive effect of substances such as angiotensin and norepinephrine. Renal PGs may have a systemic effect in lowering BP by decreasing systemic vascular resistance. The significance of renal PGs is related to the kidneys' role in causing hypertension. In renal failure with a loss of functioning tissue, these renal vasodilator factors are also lost, which may contribute to hypertension (see Chapter 46).

Ureters

The ureters are tubes that carry urine from the renal pelvis to the bladder (Fig. 44.1). Each ureter is about 10 to 12 inches (25 to 30.5 cm) long and 0.08 to 0.3 inches (0.2 to 0.8 cm) in diameter. Arranged in a meshlike outer layer, circular and longitudinal smooth muscle fibers

contract to promote the peristaltic, 1-way flow of urine through the ureters. Distention, neurologic and endocrine influences, and drugs can affect these muscle contractions.

The narrow area where each ureter joins the renal pelvis is the *ureteropelvic junction* (UPJ). Subsequently, the ureters insert into either side of the bladder base at the *ureterovesical junctions* (UVJs). Because the ureteral lumens are narrowest at these junctions, the UPJ and UVJ are often sites of obstruction. The narrow ureteral lumens can be easily obstructed internally (e.g., urinary stones) or externally (e.g., tumors, adhesions, inflammation). Sympathetic and parasympathetic nerves, along with the vascular supply, surround the mucosal lining of the ureters. Stimulation of these nerves during passage of a stone may cause acute, severe pain, termed *renal colic.*

Because the renal pelvis holds only 3 to 5 mL of urine, kidney damage can result from a backflow of more than that amount of urine. The UVJ relies on the ureter's angle of bladder insertion and muscle fiber attachments with the bladder to prevent the backflow *(reflux)* of urine, which predisposes a person to an ascending infection. The distal ureter enters the bladder laterally at its base, courses along obliquely through the bladder wall for about 1.5 cm and intermingles with muscle fibers of the bladder base. Circular and longitudinal bladder muscle fibers adjacent to the imbedded ureter help secure it. When bladder pressure rises (e.g., during voiding or coughing), muscle fibers that the ureter shares with the bladder base contract first, promoting ureteral lumen closure. Next, the bladder contracts against its base, ensuring UVJ closure and prevention of urine reflux through the junction.

Bladder

The urinary bladder is located behind the symphysis pubis and anterior to the vagina and rectum (Fig. 44.5). Its primary functions are to serve as a reservoir for urine and to eliminate waste products from the body. Like the stomach, the bladder is a stretchable, saclike organ that contracts when it is empty.

The *trigone* is the triangular area formed by the 2 ureteral openings

and bladder neck at the base of the bladder. The trigone is attached to the pelvis by many ligaments and does not change its shape during bladder filling or emptying. The bladder muscle *(detrusor)* is composed of layers of intertwined smooth muscle fibers. These fibers are capable of considerable distention during bladder filling and contraction during emptying. It is attached to the abdominal wall by an umbilical ligament, the *urachus.* Because of this attachment, as the bladder fills it rises toward the umbilicus. The dome and the anterior and lateral aspects of the bladder expand and contract.

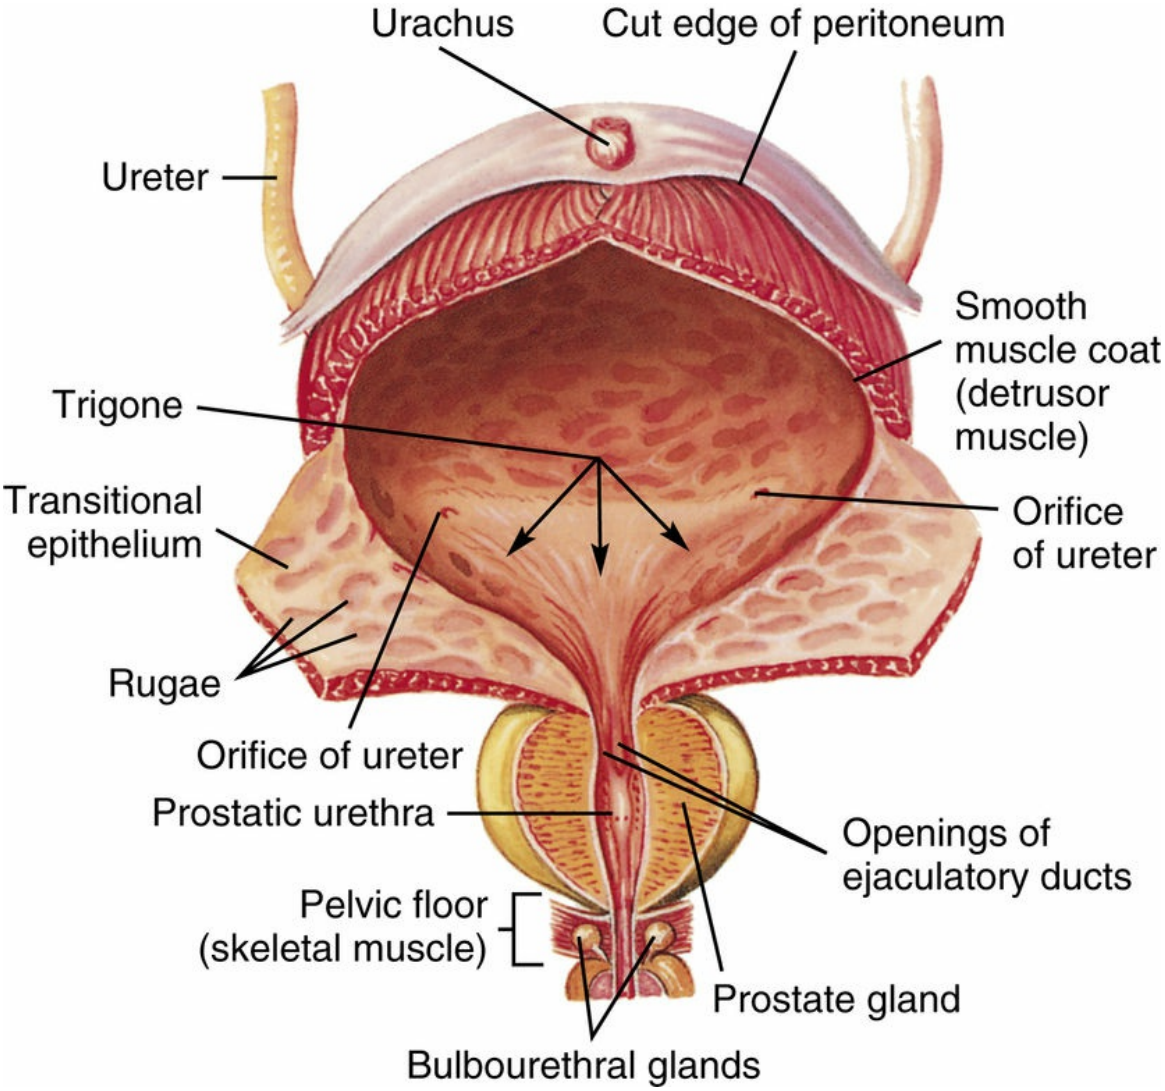

FIG. 44.5 Male urinary bladder.
Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed

Normal adult urine output is around 1500 mL/day, which varies with food and fluid intake. The volume of urine at night is less than half of that formed during the day because of hormonal influences (e.g., ADH). This diurnal pattern of urination is normal. Typically, a person will urinate 5 or 6 times during the day and occasionally at night.

On average, 200 to 250 mL of urine in the bladder cause moderate distention and the urge to urinate. When the quantity of urine reaches 400 to 600 mL, the person feels uncomfortable. Bladder capacity varies with the person, but generally ranges from 600 to 1000 mL. Evacuation of urine is termed *urination, micturition,* or *voiding.*

The bladder has the same mucosal lining as that of the renal pelvises, ureters, and bladder neck. The bladder is lined by transitional cell epithelium referred to as the *urothelium*. Unique to the urinary tract, the urothelium is resistant to absorption of urine. This means that after waste products (made by the kidneys) have left the kidneys, they cannot be reabsorbed in the urinary system. Microscopically, urothelium is only several cells deep. However, as urine enters the bladder, these cells can stretch to accommodate filling. As the bladder empties, the urothelium resumes its multicellular layer formation.

Transitional cell cancers in one section of the urinary tract can easily metastasize to other urinary tract areas given that the mucosal lining throughout the urinary tract is the same. Cancer cells may move down from upper urinary tract cancers and embed in the bladder, or large bladder tumors can invade the ureter. Cancer recurrence within the bladder is common.

Urethra

The urethra is a small tube that incorporates the smooth muscle of the bladder neck and extends to the striated muscle of the external meatus. The urethra's primary functions are to (1) control voiding and (2) serve as a conduit for urine from the bladder to the outside of the

body during voiding.

The female urethra is 1 to 2 in (2.5 to 5 cm) long and lies behind the symphysis pubis but anterior to the vagina (Fig. 44.1, *C*). The male urethra, which is about 8 to 10 in (20 to 25 cm) long, starts at the bladder neck and extends the length of the penis (Fig. 44.1, *B*).

Urethrovesical Unit

Together, the bladder, urethra, and pelvic floor muscles form the *urethrovesical unit*. Voluntary control of this unit is defined as *continence.* Stimulating and inhibiting impulses are sent from the brain through the thoracolumbar (T11 to L2) and sacral (S2 to S4) areas of the spinal cord to control voiding. Bladder distention stimulates stretch receptors within the bladder wall. Impulses are transmitted to the sacral spinal cord and then to the brain, causing a desire to urinate.

If you cannot void at a given time, inhibitor impulses in the brain are stimulated and transmitted back through the thoracolumbar and sacral nerves innervating the bladder. In a coordinated fashion, the detrusor muscle accommodates to the pressure (does not contract) while the sphincter and pelvic floor muscles tighten (contract) to resist bladder pressure.

If you can void, cerebral inhibition is voluntarily suppressed. Impulses are transmitted via the spinal cord for the bladder neck, sphincter, and pelvic floor muscles to relax and for the bladder to contract. The sphincter closes, and the detrusor muscle relaxes when the bladder is empty.

Any disease or trauma that affects the function of the brain, spinal cord, or nerves that directly innervate the bladder, bladder neck, external sphincter, or pelvic floor can affect bladder function. These conditions include diabetes, multiple sclerosis, paraplegia, and tetraplegia (quadriplegia). Drugs affecting nerve transmission can affect bladder function.

Gerontologic Considerations: Effects of

Aging on Urinary System

Anatomic changes in the aging kidney include a 20% to 30% decrease in size and weight between ages 30 and 90 years. By the seventh decade of life, 50% of glomeruli have lost their function.[1] Atherosclerosis accelerates the decrease of renal size with age.

Physiologic changes in the aging kidney include decreased renal blood flow, due in part to atherosclerosis, resulting in a decreased GFR. Changes in hormone levels (including ADH, aldosterone, ANP) result in decreased urinary concentrating ability and changes in the excretion of water, sodium, potassium, and acid. Despite these changes, older adults maintain homeostasis unless they encounter diseases or other physiologic stressors. After abrupt changes in blood volume, acid load, or other insults, the kidney may not be able to function effectively because much of its renal reserve has been lost.[1]

Physiologic changes occur in the aging urethra and bladder. The female urethra, bladder, vagina, and pelvic floor undergo a loss of elasticity and muscle support. Consequently, older women are more prone to bladder infections and incontinence. The prostate surrounds the proximal urethra. As men age, the prostate enlarges and may affect urinary patterns, causing hesitancy, retention, slow stream, and bladder infections.

Constipation, often experienced by older adults, can affect urination. Partial urethral obstruction may occur because of the rectum's close proximity to the urethra. Age-related changes in the urinary system and differences in assessment findings are outlined in Table 44.2.

TABLE 44.2 Gerontologic Assessment DifferencesUrinary System

Gerontologic Changes	Differences in Assessment Findings
Kidney	
• ↓ Amount of renal tissue	• Less palpable
• ↓ Number of nephrons and renal blood vessels. Thickened basement membrane of Bowman's capsule and glomeruli	• ↓ Creatinine clearance, ↑ BUN level, ↑ serum creatinine
• ↓ Function of loop of Henle and tubules	• Changes in drug excretion, nocturia, loss of normal diurnal excretory pattern because of ↓ ability to concentrate urine; less concentrated urine
Ureter, Bladder, and Urethra	
• ↓ Elasticity and muscle tone	• Palpable bladder after urination because of retention
• Weakening of urinary sphincter	• Stress incontinence (especially during Valsalva maneuver), dribbling of urine after urination
• ↓ Bladder capacity and sensory receptors	• Frequency, urgency, nocturia, overflow incontinence
• Estrogen deficiency leading to thin, dry vaginal tissue	• Stress or overactive bladder, dysuria
• ↑ Prevalence of unstable bladder contractions	• Overactive bladder
• Prostatic enlargement	• Hesitancy, frequency, urgency, nocturia, straining to urinate, retention, dribbling

Assessment of Urinary System

Subjective Data

Important Health Information

Past Health History

Ask the patient about the presence or history of kidney disease or other urologic problems. Note specific urinary problems, such as cancer, infections, benign prostatic hyperplasia (BPH), and stones. Ask about other health problems that may affect kidney function, including hypertension, diabetes, gout, connective tissue disorders (e.g., systemic lupus erythematosus), hepatitis, human immunodeficiency virus (HIV) infection, neurologic conditions (e.g., stroke, back injury), and trauma.[2]

Medications

An assessment of the patient's current and past use of medications is important. Include over-the-counter drugs, prescription drugs, and herbal therapies. Drugs affect the urinary tract in several ways. Many drugs can be nephrotoxic (Table 44.3). Certain drugs may alter the quantity and character of urine output (e.g., diuretics). Several drugs change the color of urine. Phenazopyridine (Pyridium) turns urine

orange. Nitrofurantoin (Macrodantin) turns urine dark yellow to brown. Anticoagulants may cause hematuria. Many antidepressants, calcium channel blockers, antihistamines, and drugs used for neurologic and musculoskeletal disorders affect the ability of the bladder or sphincter to contract or relax normally.

Surgery or Other Treatments

Ask the patient about hospitalizations related to renal or urologic diseases and all urinary problems during past pregnancies. Inquire about the duration, severity, and patient's perception of any problem and its treatment. Document

TABLE 44.3 Potentially Nephrotoxic Agents

Antibiotics	Other Drugs	Other Agents
• **amikacin**	• captopril	• Gold
• **amphotericin B**	• cimetidine	• Heavy metals
• **bacitracin**	• cisplatin	
• **cephalosporins**	• cocaine	
• **gentamicin**	• cyclosporine	
• **neomycin**	• ethylene glycol	
• **polymyxin B**	• heroin	
• **streptomycin**	• lithium	
• **sulfonamides**	• methotrexate	
• **tobramycin**	• nitrosoureas (e.g., carmustine)	
• **vancomycin**	• nonsteroidal antiinflammatory drugs (e.g., ibuprofen, indomethacin)	
	• phenacetin	
	• quinine	
	• rifampin	
	• salicylates (large quantities)	

Case Study

Patient Introduction

© iStockphoto/Thinkstock.

A.K. is a 28-yr-old black man who comes to the emergency department (ED) in acute distress with severe abdominal pain. The pain began about 6 hours ago after he finished a 10-mile run as part of his training for a marathon. He says that the pain has steadily

increased and he is nauseous. His urine is a dark, smoky color.

Discussion Questions

1. What are the possible causes of A.K.'s abdominal pain, nausea, and urine color?
2. What type of assessment would be most appropriate for A.K.: comprehensive, focused, or emergency? On what basis did you make that decision?
3. What assessment questions will you ask him?

You will learn more about A.K. and his condition as you read through this assessment chapter.

(See p. 1015 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

past surgeries, especially pelvic surgeries, and urinary tract instrumentation (e.g., catheterization). Ask the patient about any radiation or chemotherapy treatment for cancer.

Functional Health Patterns

Key questions to ask a patient with problems related to the renal system are listed in Table 44.4.

Health Perception–Health Management Pattern

Ask about the patient's general health. Abnormal kidney function may be suspected if the patient reports changes in weight or appetite, excess thirst, fluid retention, headache, pruritus, blurred vision, or "feeling tired all the time." An older adult may report malaise and nonlocalized abdominal discomfort as the only symptoms of a urinary tract infection (UTI). In older adults with a UTI, family members may report the patient is disoriented, has fallen, or has increased confusion.

Obtain a smoking history. Cigarette smoking is a major risk factor for bladder and kidney cancer. Smokers who also work with cancer-

causing chemicals have an especially high risk for bladder cancer.

TABLE 44.4 Health HistoryUrinary System

Health Perception–Health Management

- How is your energy level compared with 1 yr ago?
- Do you notice any visual changes?*
- Have you ever smoked? If yes, how many packs per day?
- Tell me about the types of jobs you have had.

Nutritional-Metabolic

- How is your appetite?
- Has your weight changed over the past year?*
- Do you take vitamins, herbs, or any other supplements?*
- How much and what kinds of fluids do you drink daily?
- How many dairy products and how much meat do you eat?
- Do you drink coffee? Colas? Tea?
- Do you spice your food heavily?*

Elimination

- Are you able to sit through a 2-hr meeting or ride in a car for 2 hr without urinating?
- Do you awaken at night with the desire to urinate? If so, how many times does this occur during an average night?
- Do you ever notice blood in your urine?* If so, at what point in the urination does it occur?
- Have you noticed any change in the color or smell of your urine?*

- Do you ever pass urine when you do not intend to? When?
- Do you use special devices or supplies for urine elimination or control?*
- How often do you move your bowels?
- Do you ever have constipation or diarrhea?*
- Do you ever have problems controlling your bowels?*

Activity-Exercise

- Have you noticed any changes in your ability to perform your usual daily activities?*
- Do certain activities worsen your urinary problem?*
- Has your urinary problem caused you to alter or stop any activity or exercise?*
- Do you need help moving or getting to the bathroom?*

Sleep-Rest

- Do you awaken at night from an urge to urinate?* How does this disturb your sleep?
- Do you awaken at night from pain or other problems and urinate as a matter of routine before returning to sleep?*
- Do you have daytime sleepiness and fatigue because of nighttime urination?*

Cognitive-Perceptual

- Do you ever have pain when you urinate?* If so, where is the pain?

Self-Perception–Self-Concept

- How does your urinary problem make you feel about yourself?
- Do you perceive your body differently since you have developed a urinary problem?

Role-Relationship

- Does your urinary problem interfere with your relationships with family or friends?*
- Has your urinary problem caused a change in your job status or affected your ability to carry out job-related responsibilities?*

Sexuality-Reproductive

- Has your urinary problem caused any change in your sexual pleasure or performance?*
- Do hygiene concerns interfere with sexual activities?

Coping–Stress Tolerance

- Do you feel able to manage the problems associated with your urinary problem? If not, explain.
- What strategies are you using to cope with your urinary problem?

Values-Beliefs

- Has your present illness affected your belief system?*
- Are your treatment decisions related to your urinary problem in

conflict with your value system?*

* If yes, describe.

Exposure to certain chemicals can affect the urinary system. Aromatic amines and some organic chemicals increase the risk for bladder cancer. Phenol and ethylene glycol are examples of nephrotoxic chemicals. Obtain an occupational history. Machinists, painters, hairdressers, printers, and truck drivers have an increased incidence of bladder cancer.[3]

Information about places where a patient has lived is important. Persons living in the Southeast part of the United States have the highest incidence of urinary stones. This may be caused by the higher mineral content of the soil and water.[4] A person living in Middle Eastern countries or Africa can acquire certain parasites that can cause cystitis or bladder cancer.

Genetic Risk Alert

- Polycystic kidney disease and congenital urinary tract abnormalities (e.g., Alport syndrome [congenital nephritis]) are genetic disorders.
- A family history of certain renal or urologic problems increases the chance of similar problems occurring in the patient.
- For any disease reported in the health history, ask if other family members also have/had the same or similar diseases.

Nutritional-Metabolic Pattern

The usual quantity and types of fluid a patient drinks are important in relation to urinary tract disease. Dehydration may contribute to UTIs,

stone formation, and kidney failure. Large intake of specific foods, such as dairy products or foods high in proteins, may lead to stone formation. Asparagus may cause the urine to smell musty. Red urine caused by beet ingestion may be mistaken for bloody urine. Caffeine, alcohol, carbonated beverages, some artificial sweeteners, or spicy foods often worsen urinary inflammatory diseases. Green tea and some herbal teas cause diuresis. An unexplained weight gain may be the result of fluid retention from a kidney problem. Anorexia, nausea, and vomiting can dramatically affect fluid status and require careful monitoring.

Elimination Pattern

Questions about urine elimination patterns are the cornerstone of the health history in the patient with a lower urinary tract disorder. Begin with asking how the patient manages urine elimination. Ask about daytime (diurnal) voiding frequency and the frequency of nocturia. Pelvic organ prolapses, particularly advanced anterior vaginal prolapse, may cause suprapubic pressure, frequency, urgency, and incontinence from urinary retention. Ask about other bothersome lower urinary tract symptoms, including urgency, incontinence, or urinary retention. Table 44.5 lists some common manifestations of urinary tract disorders.

TABLE 44.5 Manifestations of Urinary System Disorders

Specific Manifestations Related to Urinary System					
General Manifestations	**Edema**	**Pain**	**Patterns of Urination**	**Urine Output**	**Urine Composition**
• **Anorexia** • **Blurred vision** • **Change in weight** • **Chills** • **Cognitive changes** • **Excessive thirst** • **Fatigue** • **Headaches** • **High BP** • **Nausea and vomiting**	• Ankle • Ascites • Facial (periorbital) • Generalized edema • Sacral	• Dysuria • Flank or costovertebral angle • Groin • Suprapubic	• Change in stream • Dribbling • Dysuria • Frequency • Hesitancy of stream • Incontinence • Nocturia • Retention • Stress incontinence • Urgency	• Anuria • Oliguria • Polyuria	• Color (red, brown, yellowish green) • Concentrated • Dilute • Hematuria • Pyuria

Changes in the color and appearance of urine are often significant and need evaluated. If blood is visible in the urine, determine if it occurs at the beginning of, throughout, or at the end of urination. This is harder for the female patient.

Assess bowel function. Problems with fecal incontinence may signal neurologic causes for bladder problems because of shared nerve pathways. Constipation and fecal impaction can partially obstruct the urethra, causing inadequate bladder emptying, overflow incontinence, and infection.

Determine the patient's method of managing a urinary problem. A patient may already be using a catheter or collection device. Sometimes a patient must assume a specific position to urinate or perform maneuvers, such as pressing on the lower abdomen (Credé's method) or straining (Valsalva maneuver), to empty the bladder.

Activity-Exercise Pattern

Assess the patient's level of activity. A sedentary person is more likely to have stasis of urine than an active person and thus be predisposed to infection and stones. Demineralization of bones in a person with limited physical activity can cause increased urine calcium precipitation.

An active person may find that increasing activity worsens the urinary problem. The patient who has had prostate surgery or who has weakened pelvic floor muscles may leak urine when trying certain activities, such as running. Some men develop chronic inflammatory prostatitis or epididymitis after heavy lifting or long-distance driving.

Sleep-Rest Pattern

Nocturia is a common and a particularly bothersome symptom that often leads to sleep deprivation, daytime sleepiness, and fatigue. It occurs in multiple problems affecting the lower urinary tract, including urinary incontinence, urinary retention, and interstitial cystitis. Nocturia may be related to polyuria from kidney disease,

poorly controlled diabetes, alcohol use, excess fluid intake, liver disease, heart failure, or obstructive sleep apnea.

When assessing nocturia, determine whether the need to urinate causes the person to arise from sleep or whether pain or other symptoms interrupt sleep. Ask if the person urinates as a matter of habit before returning to bed. Up to 1 episode of nocturia is considered normal in younger adults, and up to 2 episodes are acceptable in adults ages 65 years or older. If an older adult has more than 2 episodes during the night, assess the amount and timing of fluid intake. This information will help determine whether further investigation is needed.

Cognitive-Perceptual Pattern

Assess the level of mobility, visual acuity, and dexterity. These are important factors to evaluate in a patient with urologic problems, especially when urine retention or incontinence is a problem. Determine if the patient is alert, understands instructions, and can recall instructions when needed.

If urinary incontinence is present, ask how the patient is managing the problem. Recognize that incontinence is often distressing and embarrassing. Discuss the problem with the patient with sensitivity in a nonjudgmental manner.

A frequent symptom of renal and urologic problems is pain, including dysuria, groin pain, costovertebral pain, and suprapubic pain. Assess pain and document the location, character, and duration. The absence of pain when other urinary symptoms exist is significant. Many urinary tract cancers are painless in the early stages.

Self-Perception–Self-Concept Pattern

Problems associated with the urinary system, such as incontinence, urinary diversion procedures, and chronic fatigue (may occur with anemia), can result in loss of self-esteem and a negative body image.

Role-Relationship Pattern

Urinary problems can affect many aspects of a person's life, including the ability to work and relationships with others. These factors have important implications for future treatment and management of the patient's condition.

Urinary system problems may be serious enough to cause problems in job-related and social situations. Chronic dialysis therapy often makes regular employment or management of home and family responsibilities difficult. Concurrent poor health and negative body image can seriously affect existing roles.

Sexuality-Reproductive Pattern

Assess the effect of renal problems on the patient's sexual satisfaction. Problems related to personal hygiene and fatigue can negatively affect sexual relationships. Although urinary incontinence is not directly associated with sexual dysfunction, it often has a devastating effect on self-esteem and social and intimate relationships. Counseling both the patient and partner may be needed.

Objective Data

Physical Examination

Inspection

Assess for changes in the following:

- *Skin:* Pallor, yellow-gray cast, excoriations, changes in turgor, bruises, texture (e.g., rough, dry skin) (see Table 22.9 for assessment of dark-skinned persons)
- *Mouth:* Stomatitis, ammonia breath odor
- *Face and extremities:* Generalized edema, peripheral edema
- *Abdomen:* Abdominal contour for midline mass in lower abdomen (may indicate bladder distention and urinary retention) or unilateral mass (sometimes seen in adults, indicating kidney enlargement from large tumor or polycystic kidney)

Case Study—cont'd

Subjective Data

© iStockphoto/Thinkstock.

A focused subjective assessment of A.K. revealed the following information:

Past Medical History: History of 1 isolated incidence of gout 6 years ago. He stopped drinking alcohol with no further occurrence.
Appendectomy 12 years ago.

Medications: None.
Health Perception–Health Management: A.K. states that he is usually healthy. He does not smoke or drink alcohol. He has never had this type of pain before. Describes the pain as being sharp and colicky (coming in waves). Rates the pain as 9 on a scale of 0 to 10.
Nutritional-Metabolic: A.K. is currently on a high-protein diet as he trains for the marathon. He eats a lot of chicken, beef, and seafood. He drinks milk-based protein shakes and water after exercising but admits that he does not think he drinks enough to replace fluid loss from perspiration. He drinks coffee for energy but denies eating chocolate or other sweets. He avoids sodas.
Elimination: Denies any history of problems with urination, constipation, or diarrhea. This is the first time he has ever noticed a change of color in his urine.
Activity-Exercise: Prides himself on his ability to exercise and run without difficulty.
Sleep-Rest: Does not awaken at night to urinate.
Cognitive-Perceptual: Denies pain on urination.
Self-Perception–Self-Concept: Believes he can monitor himself and maintain a healthy lifestyle.
Coping–Stress Tolerance: Worried that this pain may interfere with his marathon training.

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. What would be your priority assessment of A.K.?
3. What should be included in the physical assessment? What would you be looking for?

You will learn more about the physical examination of the urinary system in the next section.

(See p. 1016 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

- *Weight:* Weight gain from edema. Weight loss and muscle wasting in kidney failure
- *General state of health:* Fatigue, lethargy, and decreased alertness

Palpation

The kidneys are posterior organs protected by the abdominal organs, ribs, and heavy back muscles. A landmark useful in locating the kidneys is the **costovertebral angle (CVA)** formed by the rib cage and the vertebral column. The normal-sized left kidney is rarely palpable because the spleen lies directly on top of it. Occasionally the lower

pole of the right kidney is palpable.

To palpate the right kidney, place your left (anterior) hand behind and support the patient's right side between the rib cage and the iliac crest (Fig. 44.6). Elevate the right flank with the left hand. Use your right hand to palpate deeply for the right kidney. The lower pole of the right kidney may be felt as a smooth, rounded mass that descends on inspiration. If the kidney is palpable, note its size, contour, and tenderness. Kidney enlargement is suggestive of cancer or other serious renal pathologic conditions.

The urinary bladder is normally not palpable unless it is distended with urine. If the bladder is full, it may be felt as a smooth, round, firm organ and is sensitive to palpation.

FIG. 44.6 Palpating the right kidney.
From Brundage DJ: *Renal disorders,* St Louis, 1992, Mosby.

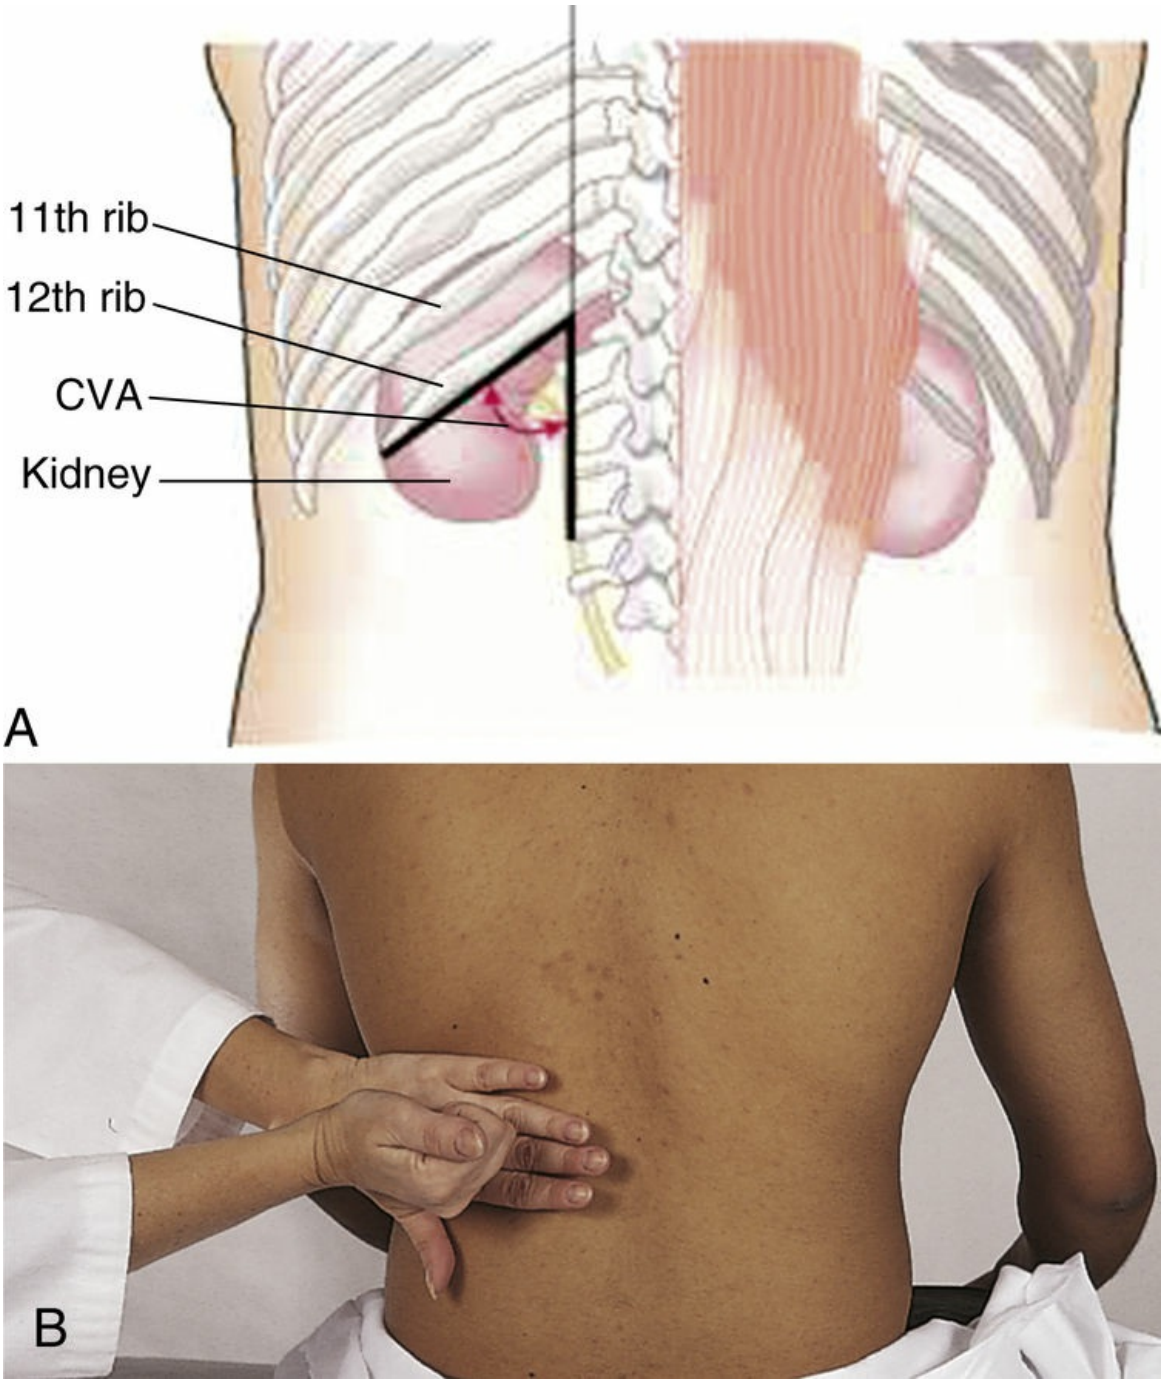

FIG. 44.7 **A,** Costovertebral angle. **B,** Indirect fist percussion of the costovertebral angle *(CVA).* To assess the kidney, place one hand over the twelfth rib at the CVA on the back. Thump that hand with the ulnar edge of the other fist.
From Jarvis C: *Physical examination and health assessment,* ed 7, St Louis, 2016, Saunders.

Percussion

Tenderness in the flank area may be detected by fist percussion *(kidney punch).* This technique is performed by striking the fist of one hand against the dorsal surface of the other hand, which is placed flat along the posterior CVA margin (Fig. 44.7). Normally this type of percussion should not elicit pain. If CVA tenderness and pain are present, it may indicate a kidney infection or polycystic kidney disease.[5]

A bladder does not percuss until it contains at least 150 mL of urine. If the bladder is full, dullness is heard above the symphysis pubis. A distended bladder may be percussed as high as the umbilicus.

Auscultation

Use the diaphragm of the stethoscope to auscultate bowel sounds, since the bowels can affect the urinary system.

Focused Assessment

Urinary System

Use this checklist to ensure that the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Painful urination	Y	N
Changes in color of urine (blood, cloudy)	Y	N
Change in characteristics of urination (decreased, excessive)	Y	N
Problems with frequent nighttime urination (nocturia)	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

Blood urea nitrogen	✓

Serum creatinine	✓
Urinalysis	✓
Urine culture and sensitivity	✓

Objective: Physical Examination

Inspect

Abdomen	✓
Urinary meatus for inflammation or discharge	✓

Palpate

Abdomen for bladder distention, masses, or tenderness	✓

Percuss

Costovertebral angle for tenderness	✓

TABLE 44.6 Normal Physical Assessment of Urinary System

- No costovertebral angle tenderness
- Nonpalpable kidney and bladder
- No palpable masses

Table 44.6 shows how to record the normal physical assessment findings of the urinary system. Table 44.7 describes assessment abnormalities of the urinary system. Assessment findings may vary in the older adult. Table 44.2 presents the age-related changes in the urinary system and differences in assessment findings. Use a *focused*

assessment to evaluate the status of previously identified urinary system problems and to monitor for signs of new problems. A focused assessment of the urinary system is outlined in the box on this page.

Case Study—cont'd

Objective Data: Physical Examination

© iStockphoto/Thinkstock.

A focused assessment of A.K. reveals the following:

A.K. is lying with his knees bent and drawn to his abdominal area. He appears restless and keeps moving from back to side to reduce his discomfort. Vital signs are as follows: BP 156/70, apical pulse 108,

respiratory rate 24, temperature 37.4° C, O_2 saturation 96% on room air. Awake, alert, and oriented × 3. Lungs are clear to auscultation. Apical pulse is regular. Abdomen nondistended with + bowel sounds in all 4 quadrants. No rebound tenderness. Positive left costovertebral tenderness. Voiding small amounts of dark, smoky urine.

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based on the results of the subjective and physical assessment findings, what diagnostic studies do you think may be ordered for A.K.?

You will learn more about diagnostic studies related to the urinary system in the next section.

(See p. 1022 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

TABLE 44.7 Assessment AbnormalitiesUrinary System

Finding	Description	Possible Etiology and Significance
Anuria	Technically no urination (24-hr urine output <100 mL)	Acute kidney injury, end-stage renal disease, bilateral ureteral obstruction
Burning on urination	Stinging pain in urethral area	Urethral irritation, UTI, urethral calculus
Dysuria	Painful or difficult urination	UTI, interstitial cystitis, urethral calculus, and wide variety of pathologic conditions
Enuresis	Involuntary nocturnal urination	Lower urinary tract disorder
Frequency	↑ Incidence of urination	Acutely inflamed bladder, retention with overflow, excess fluid intake, intake of bladder irritants, urethral calculus
Hematuria	Blood in the urine	Cancer of genitourinary tract, blood dyscrasias, kidney disease, UTI, stones in kidney or ureter, anticoagulants

Hesitancy	Delay or difficulty in initiating urination	Partial urethral obstruction, benign prostatic hyperplasia
Incontinence	Inability to voluntarily control discharge of urine	Neurogenic bladder, bladder infection, injury to external sphincter
Nocturia	Frequent urination at night	Kidney disease with impaired concentrating ability, bladder obstruction, heart failure, diabetes, post renal transplant, excess evening and nighttime fluid intake
Oliguria	↓ Amount of urine in a time period (24-hr urine output of 100–400 mL)	Severe dehydration, shock, transfusion reaction, kidney disease, end-stage renal disease
Pain	Suprapubic pain (related to bladder), urethral pain (irritation of bladder neck), flank pain, CVA tenderness	Infection, urinary retention, foreign body in urinary tract, urethritis, pyelonephritis, renal colic, stones
Pneumaturia	Passage of urine containing gas	Fistula connections between bowel and bladder, gas-forming UTI
Polyuria	Large volume of urine in a time period	Diabetes, diabetes insipidus, chronic kidney disease, diuretics, excess fluid intake, obstructive sleep apnea
Retention	Inability to urinate even though bladder contains excess amount of urine	Finding after pelvic surgery, childbirth, catheter removal, anesthesia; urethral stricture or obstruction; neurogenic bladder
Stress incontinence	Involuntary urination with ↑ pressure (sneezing or coughing)	Weakness of sphincter control, lack of estrogen, urinary retention

Diagnostic Studies of Urinary System

Many diagnostic studies are used to assess problems of the urinary system. Tables 44.8, 44.9, 44.10, and 44.11 describe the most common studies. Select studies are described in more detail here.

Many radiologic studies require the use of a bowel preparation the evening before the study to clear the lower GI tract of feces and flatus. Because the kidneys lie in a retroperitoneal location, colon contents can obstruct visualization of the urinary tract. If the bowel preparation does not adequately clear the lower GI tract, the study may be unsuccessful and need rescheduled. Common bowel preparations include enemas, magnesium citrate, and bisacodyl (Dulcolax) tablets or suppositories. Patients with kidney failure should not receive some bowel preparations, such as magnesium citrate and Fleet enema, because the kidneys cannot excrete the magnesium (see Chapter 46).

Iodine-based contrast media used in some diagnostic studies may cause contrast-induced kidney injury (CIN) and allergic reactions. Keeping the patient hydrated is important. Some patients may need IV fluids started hours before the procedure.[6] N-acetylcysteine, a renal vasodilator and antioxidant, is sometimes given to reduce the incidence of CIN. It can be given by oral or IV route.

When a patient has multiple diagnostic studies, it is important to maintain hydration.[6] The patient is at risk for dehydration when they have had nothing by mouth for consecutive days, extended time in the radiology department, and bowel preparations. Severe dehydration, especially in debilitated or older patients and patients with diabetes, may lead to acute kidney injury. Ensure that the patient is properly hydrated and given adequate nourishment between studies. Check with the HCP about insulin dosage for patients with diabetes who are NPO.

TABLE 44.8 Urinalysis

General examination of urine to establish baseline information or provide data to establish a tentative diagnosis and determine whether further studies are needed.

Before: Wash perineal area before collecting specimen.
During: Try to obtain first urinated morning specimen.
After: Ensure specimen is examined within 1 hr of urinating.

Test	Normal	Abnormal Finding	Possible Etiology and Significance
Bilirubin	None	Present	Liver disorders. May appear before jaundice is visible (see Chapter 43)
Casts	None Occasional hyaline	Present	Molds of the renal tubules that may contain protein, WBCs, RBCs, or bacteria. Noncellular casts (hyaline in appearance) occasionally found in normal urine
Color	Amber yellow	Dark, smoky color	Hematuria
		Yellow-brown to olive green	Excess bilirubin
		Orange-red or orange-brown	phenazopyridine (Pyridium)
		Cloudiness of freshly voided urine	UTI
		Colorless urine	Excess fluid intake, kidney disease, or diabetes insipidus
Culture for organisms	No organisms in bladder $<10^4$ organisms/mL result of normal urethral flora	Bacteria counts $>10^5$/mL	UTI; most common organisms are *E. coli*, enterococci, *Klebsiella*, *Proteus*, and streptococci
Glucose	None	Glycosuria	Diabetes, low renal threshold for glucose reabsorption (if blood glucose level is normal). Pituitary disorders
Ketones	None	Present	Altered carbohydrate and fat metabolism in diabetes and starvation; dehydration, vomiting, severe diarrhea
Odor	Aromatic	Ammonia-like odor	Urine allowed to stand
		Unpleasant odor	UTI
Osmolality	50–1200 mOsm/kg (50–1200 mmol/kg)	<50 mOsm/kg >1200 mOsm/kg	Tubular dysfunction. Kidney lost ability to concentrate or dilute urine
pH	4.6–8.0 (average, 6.0)	>8.0	UTI. Urine allowed to stand at room temperature (bacteria decompose urea to ammonia)
Protein	Random protein (dipstick): 0–trace	Persistent proteinuria	Characteristic of acute and chronic kidney disease, especially involving glomeruli. Heart failure.
	24-hr protein (quantitative): 50–80 mg/day		In absence of disease: high-protein diet, strenuous exercise, dehydration, fever, emotional stress, contamination by vaginal secretions
RBCs	0–4/hpf	<4.0	Respiratory or metabolic acidosis
		>4/hpf	Stones, cystitis, cancer, glomerulonephritis, tuberculosis, kidney biopsy, UTI, trauma
Specific gravity	1.005–1.030 Maximum concentrating ability of kidney in morning urine (1.025–1.030)	Low	Dilute urine, excess diuresis, diabetes insipidus
		High	Dehydration, albuminuria, glycosuria
		Fixed at about 1.010	Renal inability to concentrate urine; end-stage renal disease
WBCs	0–5/hpf	>5/hpf	UTI or inflammation

hpf, High-powered field.

TABLE 44.9 Diagnostic StudiesUrine

Study	Description and Purpose	Nursing Responsibility
Composite urine collection	Measures specific components, such as electrolytes, glucose, protein, 17-ketosteroids, catecholamines, creatinine, and minerals. Composite urine specimens are collected over a period ranging from 2–24 hr.	*During:* Have patient urinate and discard this first urine specimen. Note this time as the start of the test. Save all urine from subsequent urinations in a container for designated period. At end of period, ask patient to urinate, and this urine is added to container. Remind patient to save all urine during study period. Specimens may need refrigerated or preservatives added to container used for collecting urine.
Concentration test	Evaluates renal concentration ability. Measured by specific gravity readings. *Reference interval:* 1.005–1.030.	*Before:* Have patient fast after given time in evening (in usual procedure). *During:* Collect 3 urine specimens at hourly intervals in morning.
Creatinine clearance	Creatinine is a waste product of protein breakdown (primarily body muscle mass). Clearance of creatinine by kidney approximates the GFR. Calculated as follows: Reference interval: *Male:* 107–139 mL/min/1.73 m^2 *Female:* 87–107 mL/min/1.73 m^2 (corrected for body surface area).	*During:* Collect 24-hr urine specimen. Discard first urination when test is started. Save urine from all subsequent urinations for 24 hr. Have patient urinate at end of 24 hr and add specimen to collection. Ensure that serum creatinine is measured during 24-hr period.
Protein determination		
• **Dipstick (Albustix, Combistix)**	Detects protein (primarily albumin) in urine. *Reference interval:* 0 to trace.	*During:* Dip end of stick in urine and read result by comparison with color chart on label as directed. Grading is from 0 to 4+. Interpret with caution. Positive result may not indicate significant proteinuria. Some drugs may give false-positive readings.
• **Quantitative protein test**	A 24-hr collection gives a more accurate indication of amount of protein in urine. Persistent proteinuria usually indicates glomerular kidney disease. *Reference interval:* 50–80 mg/day (mainly albumin).	*During:* Perform 24-hr urine collection as above.
Residual urine	Determines amount of urine left in bladder after urinating. Finding may be abnormal in problems with bladder innervation, sphincter impairment, benign prostatic hyperplasia, or urethral strictures. *Reference interval:* ≤ 50 mL urine (increases with age).	*During:* Immediately after patient urinates, catheterize patient or use bladder ultrasound equipment. If a large amount of residual urine is obtained, HCP may want catheter left in bladder.
Urine culture ("clean catch," "midstream")	Confirms suspected UTI and identifies causative organisms. *Normally,* bladder is sterile, but urethra contains bacteria and a few WBCs. *Reference interval:* If properly collected, stored, and handled: $<10^3$ organisms/mL usually indicates no infection. 10^3–10^5/mL is usually not diagnostic. Test may need repeated. $>10^5$/mL indicates infection.	*During:* Use sterile container for collection of urine. Touch only outside of container. *For women:* Wipe the periurethral area from front to back, dry the area thoroughly with sterile swab, separate labia with one hand. *For men:* Retract foreskin (if present), cleanse glans around urethra, replace foreskin after cleaning. After cleaning, have patient start voiding, and collect the specimen 1 to 2 seconds after voiding starts. The initial voided urine flushes out most contaminants in the urethra and perineal area. Catheterization may be needed if patient is unable to cooperate with procedure.
Urine cytologic study	Identifies abnormal cellular structures that occur with bladder cancer. Used to follow the progress of bladder cancer after treatment.	*During:* Obtain specimens by voiding, catheterization, or bladder irrigation. Do not use morning's first voided specimen because epithelial cells may change in appearance in urine held in bladder overnight. *After:* Specimen should be fresh or brought to laboratory within the hour. An alcohol-based fixative is then added to preserve the cellular structure.

Urine Studies

Urinalysis

Urinalysis is one of the first studies done to evaluate disorders of the urinary tract (Table 44.8). Results from the urinalysis may show abnormalities, suggest the need for further studies, or show progression in a previously diagnosed disorder.

Although a specimen may be collected at any time of the day for a routine urinalysis, it is best to obtain the first specimen urinated in the morning. This concentrated specimen is more likely to contain abnormal constituents if they are present in the urine. The specimen should be examined within 1 hour of urinating. Otherwise, bacteria multiply rapidly, RBCs hemolyze, *casts* (molds of renal tubules) disintegrate, and the urine becomes alkaline because of urea-splitting bacteria. If it is not possible to send the specimen to the laboratory immediately, refrigerate it. However, for the best results, coordinate specimen collection with routine laboratory hours.

Creatinine Clearance

A common test used to analyze urinary system disorders is creatinine clearance. **Creatinine** is a waste product made by muscle breakdown. Urinary excretion of creatinine is a measure of the amount of active muscle tissue in the body, not of body weight. Therefore people with larger muscle mass have higher values. Because almost all creatinine in the blood is normally excreted by the kidneys, creatinine clearance is the most accurate indicator of renal function. The result of a creatinine clearance test closely approximates that of the GFR. A blood specimen to measure serum creatinine should be obtained during the period of urine collection.

TABLE 44.10 Blood StudiesUrinary System

Test	Reference Interval	Significance
Bicarbonate	22–26 mEq/L (22–26 mmol/L).	Most patients in renal failure have metabolic acidosis and low serum HCO_3^- levels.
Blood urea nitrogen (BUN)	10–20 mg/dL (3.6–7.1 mmol/L)	Used to detect renal problems. Concentration of urea in blood is regulated by rate at which kidney excretes urea. Nonrenal factors may increase BUN (e.g., rapid cell destruction from infections, fever, GI bleeding, trauma, athletic activity, excessive muscle breakdown).
BUN/creatinine ratio	12:1–20:1	Increased ratio may be due to conditions that decrease blood flow to kidneys (e.g., heart failure, dehydration, GI bleeding) or increased dietary protein. A decreased ratio may occur with liver disease (from decreased urea formation) and malnutrition.
Calcium (total)	9.0–10.5 mg/dL (2.25–2.62 mmol/L)	Main mineral in bone and aids in muscle contraction, neurotransmission, and clotting. In kidney disease, decreased reabsorption of Ca^{2+} leads to renal osteodystrophy.
Creatinine	*Male*: 0.6–1.2 mg/dL (53–106 µmol/L) *Female:* 0.5–1.1 mg/dL (44.97 µmol/L)	More reliable than BUN as a determinant of renal function. Creatinine is a product of muscle and protein metabolism. It is released at a constant rate.
Phosphorus	3.0–4.5 mg/dL (0.97–1.45 mmol/L).	Phosphorus balance is inversely related to Ca^{2+} balance. In kidney disease, phosphorus levels are high because the kidney is the primary excretory organ.
Potassium	3.5–5.0 mEq/L (3.5–5.0 mmol/L)	Kidneys excrete majority of body's potassium. In kidney disease, K^+ determinations are critical because K^+ is one of the first electrolytes to become abnormal. High K^+ levels >6 mEq/L can lead to muscle weakness and cardiac dysrhythmias.
Sodium	136–145 mEq/L (136–145 mmol/L)	Main extracellular electrolyte determining blood volume. Values usually stay within normal range until late stages of renal failure.
Uric acid	*Male:* 4.0–8.5 mg/dL (0.24–0.51 mmol/L) *Female:* 2.7–7.3 mg/dL (0.16–0.43 mmol/L)	Used as screening test for disorders of purine metabolism. Can indicate kidney disease. Values depend on renal function, rate of purine metabolism, and dietary intake of food rich in purines.

TABLE 44.11 Diagnostic StudiesUrinary System

Study	Description and Purpose	Nursing Responsibility
Endoscopy		
Cystoscopy	Inspects interior of bladder with a tubular lighted scope (cystoscope) (Fig. 44.10). Can be used to insert ureteral catheters, remove stones, obtain biopsy specimens of bladder lesions, and treat bleeding lesions. Lithotomy position is used. Procedure may be done using local or general anesthesia, depending on patient's needs and condition. Complications include urinary retention, urinary tract hemorrhage, bladder infection, and perforation of bladder.	*Before:* Give IV fluids if general anesthesia is to be used. Ensure consent form is signed. Explain procedure to patient. Give preoperative medication. *After:* Explain that burning on urination, pink-tinged urine, and urinary frequency are expected effects. Observe for bright red bleeding, which is not normal. Help with ambulation because orthostatic hypotension may occur. Offer warm sitz baths, heat, mild analgesics to relieve discomfort.
Radiologic Procedures		
Computed tomography (CT) scan (CT urogram)	Visualizes kidneys, ureters, and bladder. Can detect tumors, abscesses, suprarenal masses (e.g., adrenal tumors), and obstructions. Done with or without contrast media. Contrast is iodine based.	*Before:* Before contrast medium used, evaluate renal function. Assess if patient is allergic to shellfish, since the contrast is iodine based. Patient may need to be NPO 4 hr prior to study. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
Cystogram	Visualizes bladder and evaluates vesicoureteral reflux. Evaluates patients with neurogenic bladder and recurrent UTIs. Can delineate abnormalities of bladder (e.g., diverticula, stones, tumors). Contrast media is instilled into bladder via cystoscope or catheter.	*Before:* Explain procedure to patient. *During:* If done via cystoscope, follow nursing care related to cystoscopy.
Intravenous pyelogram (IVP)	Visualizes urinary tract after IV injection of contrast media. Evaluates size and shape of kidneys, ureters, and bladder. Cysts, tumors, and ureteral obstructions distort normal appearance of these structures. Patient with decreased renal function should not have IVP because contrast media can be nephrotoxic.	*Before:* Cathartic or enema given night before. Assess patient for iodine sensitivity to avoid anaphylactic reaction. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. *After:* Force fluids to avoid renal problems with contrast.
Kidneys, ureters, bladder (KUB)	X-ray examination of abdomen and pelvis. Delineates size, shape, and position of kidneys, ureter, and bladder. Can see radiopaque stones and foreign bodies.	*Before:* No special preparation needed.
Loopogram	Detects obstructions, anastomotic leaks, stones, and reflux when patient has a urinary pouch or ileal conduit. Because urinary diversions are created with bowel, there is risk for absorption of contrast media.	*Before:* Explain procedure to patient. *During:* Monitor patient for reactions to the contrast media.
Magnetic resonance angiography	Visualizes renal vasculature. Gadolinium-enhanced studies allow visualization of renal artery.	Same as renal arteriogram. Does not require femoral artery puncture
Magnetic resonance imaging (MRI)	Visualizes kidneys. Not proven useful for detecting urinary stones or calcified tumors.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Remove metallic foil patches. Contraindicated for persons with implanted metallic devices or other metal fragments unless noted to be MRI safe. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during scan.
Nephrostogram (Antegrade pyelogram)	Evaluates upper urinary tract when patient has allergy to contrast media, decreased renal function, or abnormalities that prevent passage of a ureteral catheter. Contrast media may be injected percutaneously into renal pelvis or via a nephrostomy tube that is already in place when determining tube function or ureteral integrity after trauma or surgery.	*Before:* Explain procedure and prepare patient as for IVP. *During and after:* Watch for signs of complications (e.g., hematuria, infection, hematoma).
Renal arteriogram (angiogram)	Visualizes renal blood vessels. Can aid in diagnosing renal artery stenosis (Fig. 44.8), extra or missing renal blood vessels, and renovascular hypertension. Can aid in distinguishing between a renal cyst and renal tumor. Included in workup of a potential renal transplant donor. A catheter is inserted into the femoral artery and passed up the aorta to the level of renal arteries (Fig. 44.9). Contrast media is injected to outline renal blood supply.	*Before:* Cathartic or enema may be used the night before. Before injection of contrast material, assess for iodine sensitivity. Tell patient a transient warm feeling may be felt along the course of blood vessel when contrast media is injected. *After:* Place a pressure dressing over femoral artery injection site. Observe site for bleeding and inflammation. Have patient maintain bed rest with affected leg straight. Take peripheral pulses in the involved leg every 30–60 min to detect occlusion of blood flow (from thrombus or emboli).

Study	Description and Purpose	Nursing Responsibility
Renal biopsy	Obtains renal tissue for examination to determine type of kidney disease or to follow progress of kidney disease. Usually done as a skin (percutaneous) biopsy through needle insertion into lower lobe of kidney under CT or ultrasound guidance. Absolute contraindications are bleeding disorders, single kidney, and uncontrolled hypertension. Relative contraindications include suspected renal infection, hydronephrosis, and possible vascular lesions.	*Before:* Type and crossmatch patient for blood. Ensure consent form is signed. Assess coagulation status through patient history, medication history, CBC, hematocrit, prothrombin time, and bleeding and clotting time. Patient should not be taking aspirin or warfarin. *After:* Apply pressure dressing and keep patient on affected side for 30–60 min. Bed rest for 24 hr. Vital signs every 5–10 min, first hour. Assess for flank pain, hypotension, decreasing hematocrit, fever, chills, urinary frequency, dysuria, and gross or microscopic hematuria. Inspect biopsy site for bleeding. Teach patient to avoid lifting heavy objects for 5–7 days and to not take anticoagulant drugs until allowed by HCP.
Renal scan	Evaluates anatomic structures, perfusion, and function of kidneys. IV radioactive isotopes are injected. Radiation detector probes are placed over kidney and scintillation counter monitors radioactive material in kidney. Radioisotope distribution in kidney is scanned and mapped. Shows location, size, and shape of kidney and assesses blood flow, glomerular filtration, tubular function, and urinary excretion. Abscesses, cysts, and tumors may appear as cold spots because of nonfunctioning tissue. Monitors function of a transplanted kidney.	*Before:* No diet or activity restriction. Tell patient that there should not be any pain or discomfort during test.
Renal ultrasound	Detects renal or perirenal masses (tumors, cysts) and obstructions. Small external ultrasound probe is placed on patient's skin. Conductive gel is applied to skin. Noninvasive procedure involves passing sound waves into body structures and recording images as they are reflected. Computer interprets tissue density based on sound waves and displays it in picture form. Can be used safely in patients with renal failure.	*Before:* Explain procedure to patient. No bowel preparation needed. *During:* Because radiation exposure is avoided, repeated images can be obtained over a brief period.
Retrograde pyelogram	X-ray of urinary tract taken after injection of contrast material into kidneys. May be done if an IVP does not visualize the urinary tract or has decreased renal function. A cystoscope is inserted, and ureteral catheters are inserted through it into renal pelvis. Contrast media is injected through catheters.	*Before:* Prepare patient as for IVP. Tell patient that there may be pain from distention of pelvis and discomfort from cystoscope. Anesthesia may be given for procedure. *After:* Complications similar to those for cystoscopy.
Urethrogram	Similar to a cystogram. Contrast media is injected retrograde into urethra to identify strictures, diverticula, or other urethral pathologic conditions. When urethral trauma is suspected, a urethrogram is done before catheterization.	*Before:* Explain procedure to patient.
Voiding cystourethrogram (VCUG)	Voiding study of bladder opening (bladder neck) and urethra. Bladder is filled with contrast media. Fluoroscopic films are taken to visualize bladder and urethra. After urination, another film is taken to assess for residual urine. Can detect abnormalities of lower urinary tract, urethral stenosis, bladder neck obstruction, vesicoureteral reflux, and prostatic enlargement.	*Before:* Explain procedure to patient.
Urodynamic Studies		
Cystometrogram	Evaluates bladder's capacity to contract and expel urine. Involves insertion of catheter and instillation of water or saline solution into bladder. Measurements of pressure exerted against bladder wall are recorded. If abdominal pressure is measured, a second tube is inserted into rectum or vagina. This tube is attached to a small fluid-filled balloon to allow pressure recording.	*Before:* Explain procedure to patient. *During:* Ask patient about sensations of bladder filling, usually including the first desire (urge) to urinate, a strong desire to urinate, and perception of bladder fullness. *After:* Observe patient for manifestations of UTI after procedure.
Radionuclide cystography (RNC)	Detects and grades vesicoureteral reflux. Like VCUG with a small dose of radioisotope tracer instilled into the bladder via urethral catheter. More sensitive than VCUG, and radiation dose is 1/1000 that of the VCUG.	*Before:* Explain procedure to patient as in VCUG.
Sphincter electromyography (EMG)	Recording of electrical activity created when nervous system stimulates muscle tissue. By placing needles, percutaneous wires, or patches near the urethra, pelvic floor muscle activity can be assessed. During the cystometrogram, sphincter EMG is used to identify volurstary pelvic floor muscle contractions and response of these muscles to bladder filling, coughing, and other provocative maneuvers.	*Before:* Explain procedure to patient.

Study	Description and Purpose	Nursing Responsibility
Urine flow study (uroflow)	Measures urine volume in a single voiding expelled in a period. Used to (1) assess the degree of outflow obstruction caused by such conditions as benign prostatic hyperplasia, (2) assess bladder or sphincter dysfunction effects on voiding, and (3) evaluate effects of treatment for lower urinary tract problems. Graphic displays can illustrate straining and intermittent flow patterns or other abnormal voiding disorders. *Normal maximum flow rate:* Men: 20–25 mL/sec; women: 25–30 mL/sec. Volume voided and patient's age can affect the flow rate.	*Before:* Explain procedure to patient. *During:* Ask the patient to start the test with a comfortably full bladder, urinate into a designated container, and try to empty completely. *After:* Measure residual urine volume immediately after a urinary flow study because this will help identify degree of chronic urinary retention that is often associated with abnormal flow patterns.
Videourodynamics	Combination of cystometrogram, sphincter EMG, and/or urinary flow study with anatomic imaging of the lower urinary tract, typically via fluoroscopy. Used in selected cases to identify an obstructive lesion and characterize anatomic changes in bladder and lower urinary tract	*Before:* Explain procedure to patient.
Voiding pressure flow study	Combines a urinary flow rate, cystometric pressures (intravesical, abdominal, and detrusor pressures), and sphincter EMG for detailed evaluation of micturition. It is completed by assisting the patient to a specialized toilet to urinate while the various pressure tubes and EMG apparatus remain in place.	*Before:* Explain procedure to patient.
Whitaker study	Measures the pressure differential between renal pelvis and bladder. Ureteral obstruction can be assessed. Percutaneous access to renal pelvis obtained by placing a catheter in renal pelvis. A catheter is placed in bladder. Fluid is perfused through the percutaneous tube or needle at a rate of 10 mL/min. Pressure data are then collected. Pressure measurements are combined with fluoroscopic imaging to find the level of obstruction.	*Before:* Explain procedure to patient.

Creatinine levels stay remarkably constant for each person because they are not significantly affected by protein ingestion, muscular exercise, water intake, or rate of urine production. Normal creatinine clearance values range from 87 to 139 mL/min (Table 44.10). After age 40, the creatinine clearance rate decreases at a rate of about 1 mL/min/yr.

Urodynamic Studies

Urodynamic studies measure urinary tract function. Urodynamic tests study the storage of urine within the bladder and the flow of urine through the urinary tract to the outside of the body. A combination of techniques may be used for a detailed assessment of urinary function (Table 44.11).

Case Study—cont'd

Objective Data: Diagnostic Studies

© iStockphoto/Thinkstock.

The HCP orders the following initial diagnostic studies for A.K.:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)

- Urinalysis, culture if indicated
- Renal ultrasound

A.K.'s CBC and metabolic panel results are within normal limits. His urinalysis shows moderate hematuria and the renal ultrasound shows several stones in the left ureter. There is no hydronephrosis at present. The HCP prescribes IV opioids for pain management and admits A.K. to a medical unit for further observation.

Discussion Questions

1. Which diagnostic study results are abnormal?
2. Which diagnostic study results are of most concern to you?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge To NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A renal stone in the pelvis of the kidney will change kidney function by interfering with the
   a. structural support of the kidney.
   b. regulation of the concentration of urine.
   c. entry and exit of blood vessels at the kidney.
   d. collection and drainage of urine from the kidney.
2. A patient with kidney disease has oliguria and a creatinine clearance of 40 mL/min. These findings most directly reflect abnormal function of
   a. tubular secretion.
   b. glomerular filtration.

c. capillary permeability.

d. concentration of filtrate.

3. The nurse identifies a risk for urinary stones in a patient who relates a health history that includes

a. hyperaldosteronism.

b. serotonin deficiency.

c. adrenal insufficiency.

d. hyperparathyroidism.

4. Diminished ability to concentrate urine, associated with aging of the urinary system, is attributed to

a. a decrease in bladder sensory receptors.

b. a decrease in the number of functioning nephrons.

c. decreased function of the loop of Henle and tubules.

d. thickening of the basement membrane of Bowman's capsule.

5. During physical assessment of the urinary system, the nurse

a. performs fist percussion to detect tenderness in the flank area.

b. expects a dull percussion sound when 100 mL of urine is present in the bladder.

c. percusses above the symphysis pubis to determine the level of urine in the bladder.

d. palpates the lower pole of the right kidney as a smooth mass that descends on expiration.

6. Normal findings expected by the nurse on physical assessment of the urinary system include *(select all that*

apply)

a. nonpalpable bladder.

b. nonpalpable left kidney.

c. auscultation of renal artery bruit.

d. no CVA tenderness elicited by a kidney punch.

e. full bladder percusses as dullness above the symphysis pubis.

7. A diagnostic study that evaluates renal blood flow, glomerular filtration, tubular function, and excretion is a(n)

a. IVP.

b. VCUG.

c. renal scan.

d. loopogram.

8. On reading the urinalysis results of a dehydrated patient, the nurse would expect to find

a. a pH of 8.4.

b. RBCs of 4/hpf.

c. color: yellow, cloudy.

d. specific gravity of 1.035.

1. d, 2. b, 3. d, 4. c, 5. a, 6. a, b, d, e, 7. c, 8. d

Renal and Urologic Problems

Cynthia Ann Smith

CONCEPTUAL FOCUS

Elimination

Fluids and Electrolytes

Infection

Pain

LEARNING OUTCOMES

1. Discuss the pathophysiology, clinical manifestations, and interprofessional and nursing management of urinary tract infections, cystitis, urethritis, and pyelonephritis.
2. Distinguish the etiology, clinical manifestations, and nursing and interprofessional management of acute poststreptococcal glomerulonephritis, Goodpasture syndrome, and chronic glomerulonephritis.
3. Describe the common causes, clinical manifestations, and interprofessional and nursing management of nephrotic syndrome.
4. Compare and contrast the etiology, clinical manifestations, and interprofessional and nursing management of various types of urinary calculi.
5. Distinguish the common causes and management of renal trauma, renal vascular problems, and hereditary kidney diseases.

6. Describe the clinical manifestations and nursing and interprofessional management of kidney and bladder cancers.
7. Describe the common causes and management of urinary incontinence and urinary retention.
8. Distinguish among urethral, ureteral, suprapubic, and nephrostomy catheters regarding indications for use and nursing responsibilities.
9. Explain the nursing management of the patient undergoing nephrectomy or urinary diversion surgery.

A wide range of renal and urologic disorders contribute to impaired elimination. The diverse causes of these disorders are grouped by common problems, such as infectious, immunologic, obstructive, traumatic, cancerous, and neurologic mechanisms. This chapter discusses disorders of the upper urinary tract (kidneys and ureter) and lower urinary tract (bladder and urethra). Many patients are at risk fluid, electrolyte, and acid-base imbalances because of the kidneys' vital role in homeostasis. The person may have discomfort and incontinence and problems with disrupted sleep or skin integrity.

Infectious and Inflammatory Disorders of Urinary System

Urinary Tract Infection

Urinary tract infections (UTIs) are infections that affect the urinary tract. They are the second most common bacterial disease and the most common bacterial infection in women.[1] *Escherichia coli* is the most common pathogen causing a UTI. It causes 70% to 95% of cases without urinary tract structural abnormalities or stones (Table 45.1). It is seen primarily in women.[2] *Candida albicans* is the second most common pathogen, causing UTIs associated with indwelling catheter use or asymptomatic colonization.

TABLE 45.1 Common Causes of Urinary Tract Infections

- *Candida albicans*
- *Enterobacter*
- *Enterococcus*
- *Escherichia coli*
- *Klebsiella*
- *Proteus*
- *Pseudomonas*
- *Serratia*
- *Staphylococcus*
- Streptococci

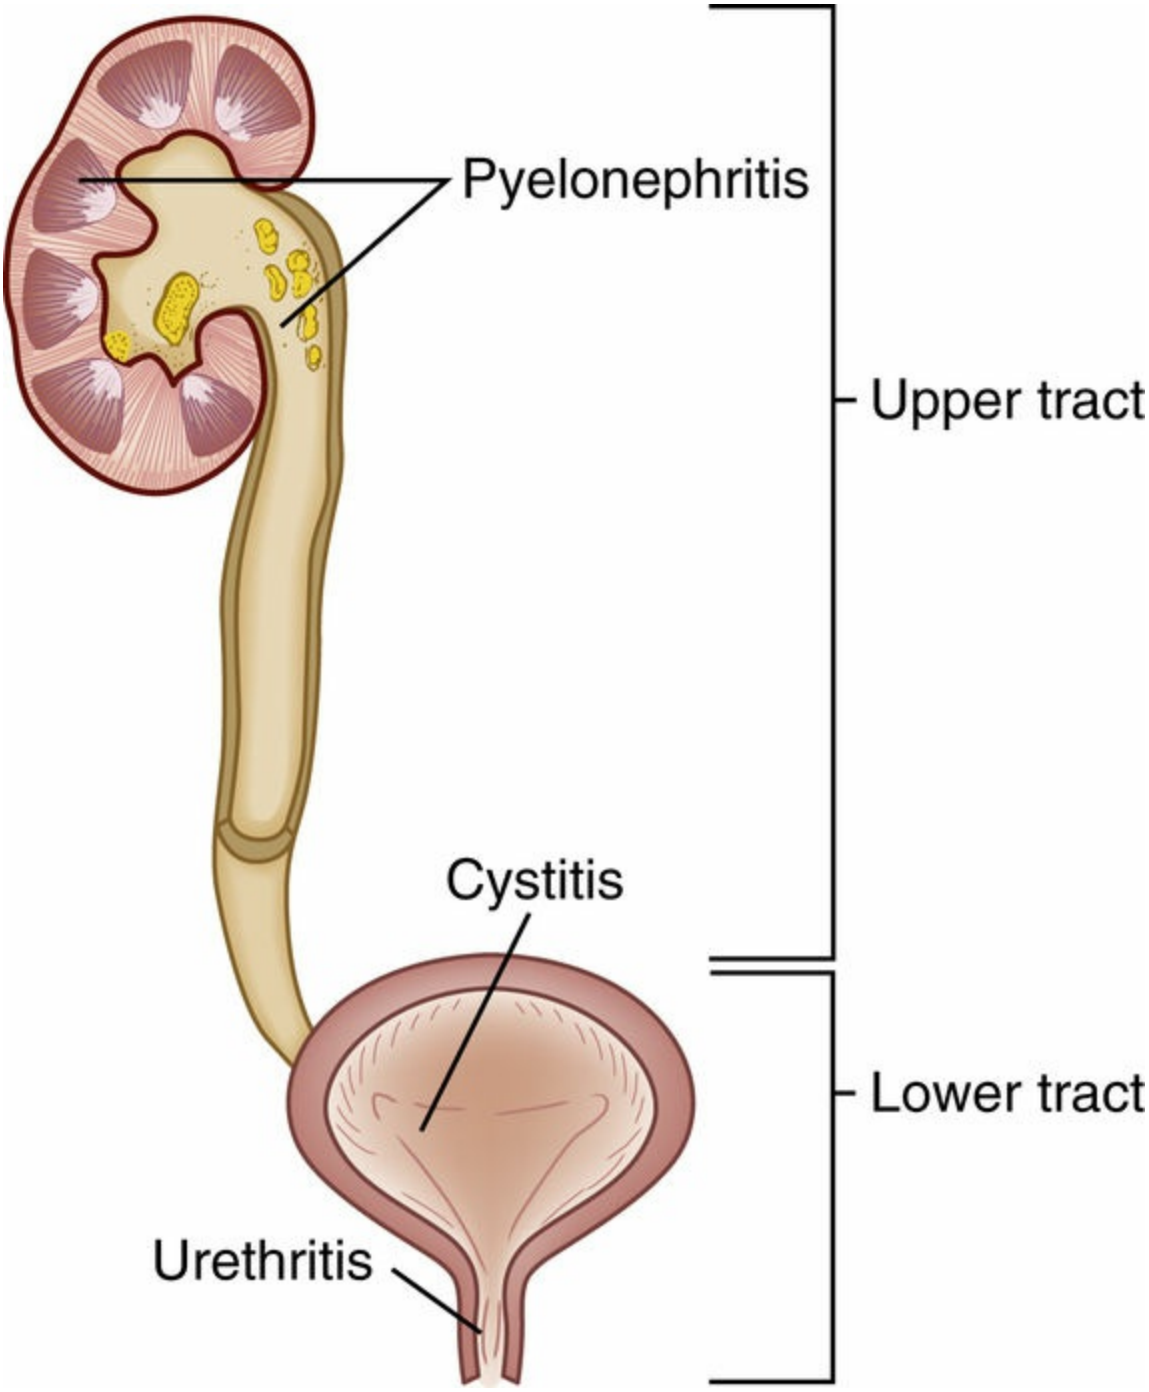

FIG 45.1 Sites of infectious processes in the upper and lower urinary tracts.

Bacterial counts of 10^5 colony-forming units per milliliter (CFU/mL) or higher typically indicate a clinically significant UTI. However, counts as low as 10^2 to 10^3 CFU/mL in a person with signs and symptoms are indicative of UTI.

Although fungal and parasitic infections may cause UTIs, this is uncommon. UTIs from these causes sometimes occur in patients who are immunosuppressed, have diabetes, have kidney problems, or received multiple courses of antibiotic therapy. These types of UTIs may occur in persons who live in or have traveled to certain developing countries.

Classification of Urinary Tract Infection

A UTI can be broadly classified as an upper or lower UTI according to its location within the urinary system (Fig. 45.1). We use specific terms to delineate the location of a UTI. For example, **pyelonephritis** implies inflammation (usually caused by infection) of the renal parenchyma and collecting system. **Cystitis** is an inflammation of the bladder, while **urethritis** is an inflammation of the urethra. **Urosepsis** is a UTI that has spread systemically. It is a life-threatening condition requiring emergency treatment.

Classifying a UTI as complicated or uncomplicated is also useful. *Uncomplicated UTIs* occur in an otherwise normal urinary tract and usually only involve the bladder. *Complicated UTIs* occur in a person with a structural or functional problem in the urinary tract. Examples include obstruction, stones, catheters, abnormal genitourinary (GU) tract, acute kidney injury (AKI), chronic kidney disease (CKD), renal transplant, diabetes, or neurologic diseases. They can also occur when a person has developed antibiotic resistance, is immunocompromised, has pregnancy-induced changes, or has recurrent infection. The person with a complicated infection is at risk for pyelonephritis, urosepsis, and renal damage.

TABLE 45.2 Risk Factors for Urinary Tract Infections

Anatomic Factors

- Congenital defects leading to obstruction or urinary stasis
- Fistula exposing urinary stream to skin, vagina, or fecal stream
- Obesity
- Shorter female urethra and colonization from normal vaginal flora

Factors Compromising Immune Response

- Aging
- Diabetes
- HIV infection

Factors Increasing Urinary Stasis

- Extrinsic obstruction (tumor, fibrosis compressing urinary tract)
- Intrinsic obstruction (stone, tumor of urinary tract, urethral stricture, BPH)
- Renal impairment
- Urinary retention (e.g., neurogenic bladder)

Foreign Bodies

- Catheters (indwelling, external condom catheter, ureteral stent, nephrostomy tube, intermittent catheterization)
- Urinary tract instrumentation (cystoscopy)
- Urinary tract stones

Functional Disorders

- Constipation
- Voiding dysfunction with detrusor sphincter muscle

incoordination

Other Factors

- Habitual delay of urination ("nurse's bladder," "teacher's bladder")
- Pregnancy
- Menopause
- Multiple sex partners (women)
- Poor personal hygiene
- Use of spermicidal agents, contraceptive diaphragm (women), bubble baths, feminine sprays

Etiology and Pathophysiology

The urinary tract above the urethra is normally sterile. Several mechanical and physiologic defense mechanisms aid in maintaining sterility and preventing UTIs. These defenses include normal voiding with complete emptying of the bladder, ureterovesical junction competence, and ureteral peristaltic activity that propels urine toward the bladder. Antibacterial characteristics of urine are maintained by an acidic pH (less than 6.0), high urea concentration, and abundant glycoproteins that interfere with the growth of bacteria. A change in any of these defense mechanisms increases the risk for a UTI (Table 45.2).

The organisms that usually cause UTIs originate in the perineum and are introduced via the ascending route from the urethra. Most infections are caused by gram-negative bacilli normally found in the gastrointestinal (GI) tract. However, gram-positive organisms, such as streptococci, enterococci, and *Staphylococcus saprophyticus,* can also cause UTIs.

A common factor contributing to ascending infection is urologic instrumentation (e.g., catheterization, cystoscopic examinations). Instrumentation allows bacteria that are normally present at the

opening of the urethra to enter the urethra or bladder. Sexual intercourse promotes "milking" of bacteria from the vagina and perineum and may cause minor urethral trauma that predisposes women to UTIs.

TABLE 45.3 Lower Urinary Tract Symptoms (LUTS)

Symptoms	Description
Emptying Symptoms	
Dysuria	• Painful or difficult urination
Hesitancy	• Difficulty starting urine stream • Delay between initiation of urination (because of urethral sphincter relaxation) and beginning of flow of urine • Diminished urinary stream
Intermittency	• Interruption of urinary stream while voiding
Postvoid dribbling	• Urine loss after completion of voiding
Urinary retention or incomplete emptying	• Inability to empty urine from bladder • Caused by atonic bladder or obstruction of urethra • Can be acute or chronic
Storage Symptoms	
Incontinence	• Involuntary or accidental urine loss or leakage
Nocturia	• Awakened by urge to void 2 or more times during sleep • May be diurnal or nocturnal depending on sleep schedule
Nocturnal enuresis	• Adults: loss of urine during sleep
Urgency	• Sudden, strong, or intense desire to void immediately • Often accompanied by frequency
Urinary frequency	• More than 8 times in 24-hr period • Often <200 mL each voiding

UTIs can result from hematogenous transmission, in which blood-borne bacteria invade the kidneys, ureters, or bladder from elsewhere in the body. For a kidney infection to occur in this manner, there must be prior injury to the urinary tract, such as obstruction of the ureter, damage caused by stones, or renal scars.

UTIs are the most common health care–associated infection (HAI). They are primarily associated with use of an indwelling catheter. *Catheter-associated urinary tract infections (CAUTIs)* are often caused by *E. coli* and, less often, *Pseudomonas* organisms. CAUTIs are often underrecognized and undertreated, leading to extended hospital

stays, increased health care costs, and patient morbidity and mortality.[3]

Clinical Manifestations

Manifestations of UTIs range from painful urination in uncomplicated urethritis or cystitis to severe systemic illness associated with abdominal or back pain, fever, sepsis.

Lower urinary tract symptoms (LUTS) occur in patients who have UTIs of the upper urinary tract, as well as those confined to the lower tract. Symptoms are related to either bladder storage or bladder emptying (Table 45.3). These include dysuria, frequency (voiding more than every 2 hours), urgency, and suprapubic discomfort or pressure. The urine may contain grossly visible blood (hematuria) or sediment, giving it a cloudy appearance. Infection of the upper urinary tract (involving the renal parenchyma, pelvis, and ureters) typically causes fever, chills, and flank pain. A UTI confined to the lower urinary tract does not usually have systemic manifestations. People with significant bacteriuria may have no symptoms or may have nonspecific symptoms, such as fatigue or anorexia.

Remember that the characteristic manifestations of a UTI are often absent in older adults. Older adults tend to have nonlocalized abdominal discomfort rather than dysuria and suprapubic pain. They may have cognitive impairment or generalized clinical deterioration. Because older adults are less likely to have a fever with a UTI, temperature is an unreliable indicator of a UTI.[4]

Multiple problems may produce LUTS similar to the symptoms of a UTI. For example, patients with bladder tumors or those receiving intravesical chemotherapy or pelvic radiation usually have urinary frequency, urgency, and dysuria. Interstitial cystitis/painful bladder syndrome (discussed on p. 1031) produces urinary symptoms that are similar to and sometimes confused with a UTI.

A small number of healthy persons have some bacteria colonizing the bladder. This condition is called *asymptomatic bacteriuria.* It does not justify screening or treatment except in pregnant women and those undergoing urologic procedures.

Diagnostic Studies

In a patient suspected of having a UTI, first obtain a dipstick urinalysis to identify the presence of nitrites (indicating bacteriuria), white blood cells (WBCs), and leukocyte esterase (an enzyme present in WBCs, indicating pyuria). Microscopic urinalysis can confirm these findings. After confirmation of bacteriuria and pyuria, a urine culture may be done. A urine culture is needed in persistent bacteriuria, recurring UTIs (more than 2 or 3 episodes per year), or complicated, CAUTI, or HAI UTIs. Urine also may be cultured when the infection is unresponsive to empiric therapy or the diagnosis is questionable.

A voided midstream technique *(clean-catch urine sample)* is preferred for obtaining a urine culture in most circumstances (see Table 44.9). When an adequate clean-catch specimen cannot be obtained, catheterization may be needed. A specimen obtained by catheterization provides more accurate results than a clean-catch specimen.

A urine culture with *sensitivity testing* can determine the bacteria's susceptibility to a variety of antibiotic drugs. The results allow the HCP to choose an antibiotic known to be capable of destroying the bacteria causing a UTI in a specific patient.

Some patients need imaging studies of the urinary tract. An ultrasound or CT scan may be done when obstruction of the urinary system is suspected or UTIs recur.

Interprofessional Care

The interprofessional care and drug therapy of UTIs are outlined in Table 45.4. Once a UTI has been diagnosed, appropriate antimicrobial therapy is started. An antibiotic may be chosen based on the HCP's best judgment *(empiric therapy)* or the results of sensitivity testing.

Uncomplicated UTIs are treated with a short-term course of antibiotics, typically for 3 days. In contrast, complicated UTIs need a longer period of treatment, lasting 7 to 14 days or more.[4,5] Many residents of long-term care facilities, especially women, have chronic asymptomatic bacteriuria. However, we usually only treat symptomatic UTIs.

First-choice drugs to treat uncomplicated or initial UTIs are trimethoprim/sulfamethoxazole (TMP/SMX), nitrofurantoin, cephalexin, and fosfomycin.[5] TMP/SMX has the advantages of being inexpensive and taken twice daily. A disadvantage is *E. coli* resistance to TMP/SMX, β-lactams, and ciprofloxacin, which is an increasing problem in the United States. Nitrofurantoin can be given 3 or 4 times daily, but a twice-daily formulation is available.

TABLE 45.4 Interprofessional Care

Urinary Tract Infection

Diagnostic Assessment

- History and physical examination
- Urinalysis (midstream, "clean-catch" voided specimen)
- Urine for culture and sensitivity (if indicated)
- Imaging studies of urinary tract (if indicated): CT scan , ultrasound, cystoscopy

Management

Uncomplicated UTI

- Patient teaching
- Adequate fluid intake (6 8-oz glasses/day)

Drug Therapy

- Antibiotics
    - fluconazole (in patients with fungal UTI)
    - fosfomycin (Monurol)
    - nitrofurantoin (Macrodantin, Macrobid)

- TMP/SMX (Bactrim, Bactrim DS)
- trimethoprim alone (in patients with sulfa allergy)
- phenazopyridine (Pyridium)

Recurrent UTI

- Repeat urinalysis
- Urine culture and sensitivity testing
- Adequate fluid intake (6 8-oz glasses/day)
- Repeat patient teaching
- Imaging studies of urinary tract (if indicated): see above

Drug Therapy

- Antibiotic: nitrofurantoin, TMP/SMX
- Sensitivity-guided antibiotic therapy: ampicillin, amoxicillin, first-generation cephalosporin, fluoroquinolones
- 3- to 6-month trial of suppressive or prophylactic antibiotic regimen
- Postcoital antibiotic prophylaxis: cephalexin, nitrofurantoin, TMP/SMX

Other antibiotics used in the treatment of uncomplicated UTI include ampicillin, amoxicillin, and cephalosporins. Fluoroquinolones (e.g., levofloxacin, ciprofloxacin) should be used to treat only complicated UTIs. In patients with UTIs from fungi, fluconazole (Diflucan) is the preferred therapy.

Drug Alert

Nitrofurantoin (Macrodantin)

- Avoid use if the patient's creatinine clearance < 30 mL/min.
- Notify HCP at once if fever, chills, cough, chest pain, dyspnea, rash, or numbness or tingling of fingers or toes develops.

A urinary analgesic, such as oral phenazopyridine, may relieve discomfort caused by severe dysuria. Phenazopyridine is an azo dye excreted in urine, where it exerts a topical analgesic effect on the urinary tract mucosa. It is taken up to 2 concurrent days. Teach patients that this drug causes the urine to turn orange or red.

Patients who have repeated UTIs may receive prophylactic or suppressive antibiotics. A low dose of TMP/SMX, nitrofurantoin, or another antibiotic taken daily may prevent recurring UTIs. A single dose may be taken after an event likely to provoke a UTI, such as sexual intercourse. Although suppressive therapy is often effective on a short-term basis, this strategy is limited because of the risk for antibiotic resistance, which leads to breakthrough infections with increasingly virulent pathogens.

TABLE 45.5 Nursing AssessmentUrinary Tract Infection

Subjective Data

Important Health Information

Past health history: Previous UTI. Urinary stones, reflux, strictures, or retention. Neurogenic bladder, pregnancy, benign prostatic hyperplasia, bladder cancer, sexually transmitted infection.
Medications: Antibiotics, anticholinergics, antispasmodics
Surgery or other treatments: Recent urologic instrumentation (catheterization, cystoscopy)

Functional Health Patterns

Cognitive-perceptual: Suprapubic or low back pain, bladder spasms, dysuria, burning on urination
Elimination: Urinary frequency, urgency, hesitancy, dysuria, nocturia
Health perception–health management: Urinary hygiene practices. Lassitude, malaise
Nutritional-metabolic: Nausea, vomiting, anorexia. Chills and fever
Sexuality-reproductive: Multiple sex partners, use of spermicidal agents or contraceptive diaphragm (women)

Objective Data

General

Fever, chills, dysuria
Atypical presentation in older adults: afebrile, absence of dysuria, loss of appetite, altered mental status

Urinary

Hematuria. Cloudy, foul-smelling urine

Possible Diagnostic Findings

Leukocytosis. Urinalysis positive for bacteria, pyuria, RBCs, WBCs, and nitrites. Positive urine culture. Ultrasound, CT scan, MRI, Voiding cystourethrogram (VCUG), and cystoscopy showing urinary tract abnormalities

Nursing Management: Urinary Tract Infection

Nursing Assessment

Subjective and objective data that should be obtained from a patient with a UTI are shown in Table 45.5.

Nursing Diagnoses

Nursing diagnoses for the patient with a UTI may include:

- Impaired urinary system function
- Acute pain
- Lack of knowledge

More information on nursing diagnoses and interventions for the patient with a UTI is presented in eNursing Care Plan 45.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with a UTI will have (1) relief from bothersome symptoms, (2) no upper urinary tract involvement, and (3) no recurrence.

Nursing Implementation

Health Promotion

It is important to recognize people who are at risk for a UTI. These include debilitated persons, older adults, patients who are immunocompromised (e.g., cancer, diabetes), and patients treated with immunosuppressive drugs or corticosteroids. Health promotion activities can help decrease the frequency of UTIs and provide for

early detection of infection. These activities include teaching preventive measures, including (1) emptying the bladder regularly and completely, (2) evacuating the bowel regularly, (3) wiping the perineal area from front to back after voiding and defecation, and (4) drinking an adequate amount of liquid each day.

To estimate the amount of fluid intake a person should have in 24 hours, take the person's weight in pounds, and divide that number in half. The result is the number of ounces of fluid a person should have per day. Thus a 150-lb person would need 75 oz/day. The person will obtain about 20% of this fluid from food, which leaves 60 oz (1775 mL) by drinking, or just over 7 8-oz glasses of fluid.

Routine and thorough perineal hygiene is important for all hospitalized patients, especially after using a bedpan, after a bowel movement, or if fecal incontinence is present. Answer call lights quickly and offer the bedpan or urinal to bedridden patients at frequent intervals. These measures can prevent incontinence and decrease the number of incontinence episodes.

Prevention of CAUTI

All patients undergoing catheterization of the urinary tract are at risk for developing CAUTI. You play a key role in preventing CAUTI. Avoiding unnecessary catheterization and early removal of indwelling catheters are the most effective means for reducing CAUTI. Always follow aseptic technique during these procedures. Wash your hands before and after contact with each patient. Wear gloves for care of urinary catheters. The American Nurses Association offers an evidence-based clinical tool for decreasing CAUTI.[6] Special measures for the care of urethral catheters are discussed later in this chapter on p. 1052.

Acute Care

Acute care for a patient with a UTI includes ensuring adequate fluid intake unless contraindicated. Maintaining adequate fluid intake may be hard because of the patient feeling that fluid intake will make the pain and urinary frequency associated with a UTI worse. Tell patients

that fluids will increase frequency of urination but will also dilute the urine, making the bladder less irritable. Fluids will help flush out bacteria before they have a chance to colonize in the bladder. Caffeine, alcohol, citrus juices, chocolate, and highly spiced foods or beverages should be avoided because they are potential bladder irritants.

Application of local heat to the suprapubic area or lower back may relieve the discomfort associated with a UTI. Have the patient apply a heating pad (turned to its lowest setting) against the back or suprapubic area. A warm shower or sitting in a tub of warm water filled above the waist can also give temporary relief.

Teach the patient about the prescribed drug therapy, including side effects. Emphasize the importance of taking the full course of antibiotics. Often patients stop antibiotic therapy once symptoms disappear. This can lead to inadequate treatment, recurrence of infection, and/or bacterial resistance to antibiotics.

Sometimes a second drug or a reduced dosage of drug is given after the first course to suppress bacterial growth in patients susceptible to recurrent UTI. Teach the patient to monitor for signs of improvement (e.g., cloudy urine becomes clear) as well as a decrease in or cessation of symptoms. Tell patients to promptly report any of the following to their HCP: (1) persistence of bothersome LUTS beyond the antibiotic treatment course, (2) onset of flank pain, or (3) fever.

TABLE 45.6 Patient & Caregiver TeachingUrinary Tract Infection

When teaching a patient and caregiver measures to prevent a recurrence of a urinary tract infection (UTI), include:

1. Take all antibiotics as prescribed. Symptoms may improve after 1–2 days of therapy, but organisms may still be present.
2. Practice appropriate hygiene, including:
    - Carefully clean the perineal region by separating the labia in females, or in males pulling back the foreskin

if present when cleansing.
- Wipe from front to back after urinating.
- Cleanse with warm soapy water after each bowel movement.

3. Empty the bladder before and after sexual intercourse.
4. Void regularly, about every 3–4 hours during the day.
5. Maintain adequate fluid intake.
6. Avoid vaginal douches and harsh soaps, bubble baths, powders, and sprays in the perineal area.
7. Report to the HCP symptoms or signs of recurrent UTI (e.g., fever, cloudy urine, pain on urination, urgency, frequency).

Ambulatory Care

Home care for the patient with a UTI should emphasize the importance of adhering to the drug regimen. Your responsibility is to teach the patient and caregiver about the need for ongoing care (Table 45.6). This includes: (1) taking antimicrobial drugs as ordered, (2) maintaining adequate daily fluid intake, (3) voiding regularly (every 3 to 4 hours), (4) voiding before and after intercourse, and (5) temporarily stopping the use of a diaphragm.

If treatment is complete and the symptoms are still present, teach the patient to get follow-up care. Recurrent symptoms because of bacterial persistence or inadequate treatment typically occur within 1 to 2 weeks after completion of therapy. If the patient has followed the treatment plan, a relapse indicates the need for further evaluation.

Evaluation

The expected outcomes are that the patient with a UTI will

- Have normal urinary elimination patterns
- Report relief of bothersome urinary tract symptoms
- State knowledge of the treatment plan

Acute Pyelonephritis

Etiology and Pathophysiology

Pyelonephritis is an inflammation of the renal parenchyma (Fig. 45.2) and collecting system, including the renal pelvis. The most common cause is bacterial infection. Fungi, protozoa, or viruses can also infect the kidney.[7]

Urosepsis is a systemic infection arising from a urologic source. Its prompt diagnosis and effective treatment are critical because it can lead to septic shock and death unless promptly treated. Septic shock is discussed in Chapter 65.

Pyelonephritis usually begins with colonization and infection of the lower urinary tract via the ascending urethral route. Bacteria normally found in the intestinal tract, including *E. coli* or *Proteus, Klebsiella,* or *Enterobacter* species, often cause pyelonephritis. A preexisting factor can be present, like *vesicoureteral reflux* (retrograde [backward] movement of urine from lower to upper urinary tract) or dysfunction of the lower urinary tract (e.g., obstruction from benign prostatic hyperplasia [BPH], stricture, urinary stone). For residents of long-term care facilities, CAUTI is a common cause of pyelonephritis and urosepsis.

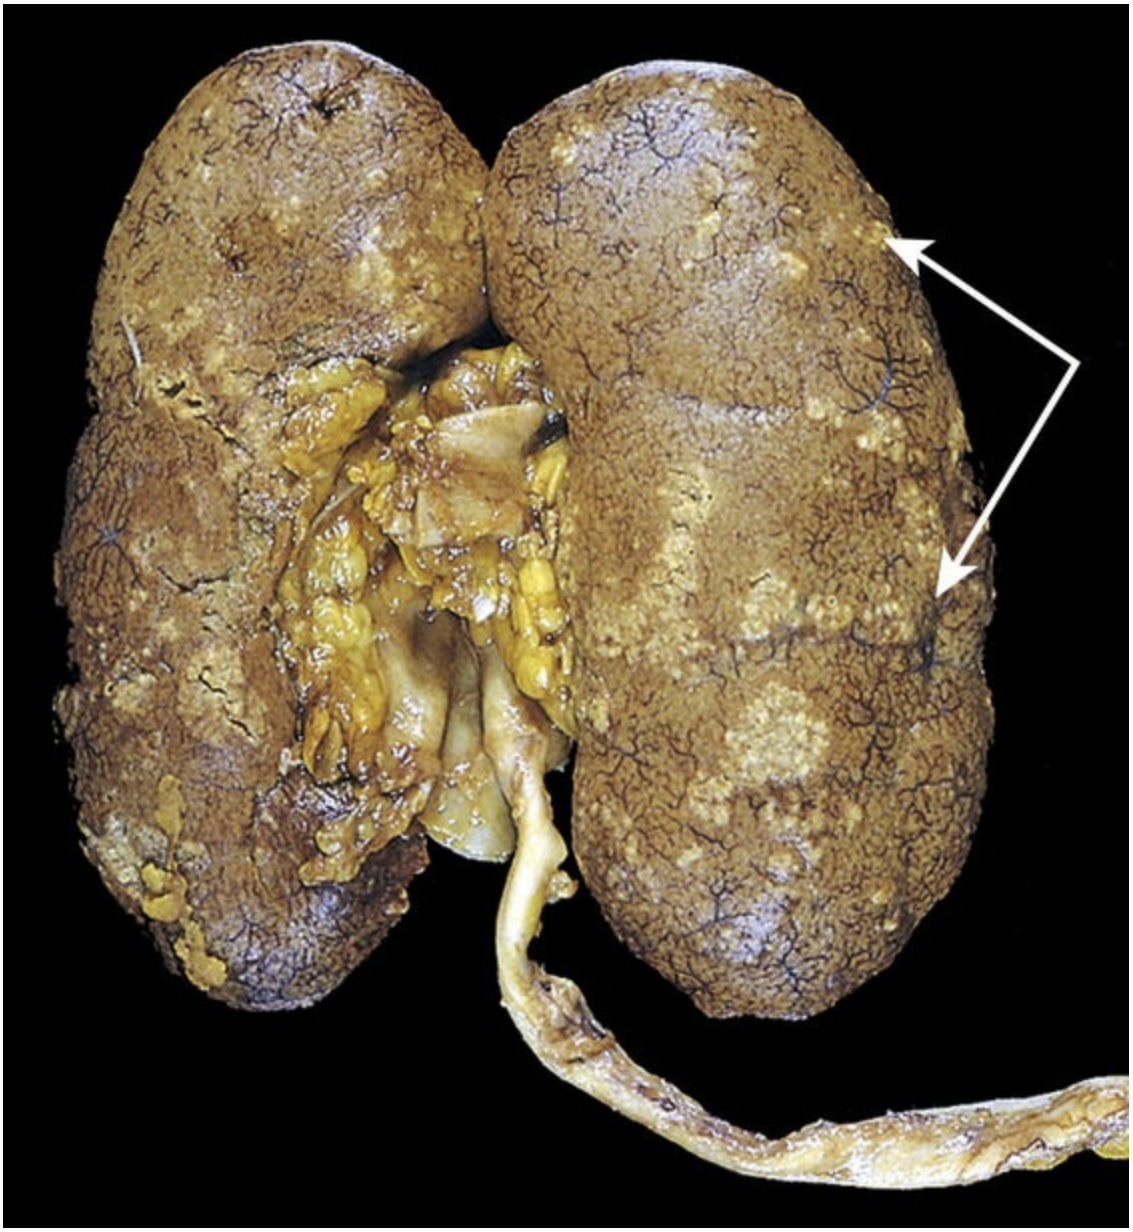

FIG 45.2 Acute pyelonephritis. Cortical surface shows grayish-white areas of inflammation and abscess formation *(arrows).*
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Acute pyelonephritis often starts in the renal medulla and spreads to the adjacent cortex. Pregnancy-induced physiologic changes in the urinary system are one of the most important risk factors for acute pyelonephritis. Recurring episodes of pyelonephritis, especially in the presence of obstructive abnormalities, can lead to *chronic pyelonephritis* (discussed later).

Clinical Manifestations and Diagnostic Studies

The classic manifestations of acute pyelonephritis include (1) fever/chills, (2) nausea/vomiting (3) malaise, and (4) flank pain. They may include the LUTS, such as dysuria, urgency, and frequency. *Costovertebral angle tenderness* to percussion (costovertebral angle [CVA] pain) is typically present on the affected side. In some cases of pyelonephritis, renal scarring and decreased kidney function can occur, which can be potentially life-threatening.

Urinalysis results may show pyuria, bacteriuria, and varying degrees of hematuria. White blood cell (WBC) casts found in the urine may indicate involvement of the renal parenchyma. Urine cultures with sensitivities are done when pyelonephritis is suspected. Blood cultures may be done on hospitalized patients with more severe illness.

Ultrasounds may be done to identify anatomic abnormalities, hydronephrosis, renal abscesses, or an obstructing stone. CT scans are the preferred imaging studies. They can assess for signs of infection in the kidney and complications of pyelonephritis, such as impaired renal function, scarring, chronic pyelonephritis, or abscesses.

Interprofessional Care

The diagnostic tests and interprofessional care of acute pyelonephritis are outlined in Table 45.7. Patients with severe infections or complicating factors, such as nausea and vomiting with dehydration, need hospitalized.

The patient with mild symptoms may be treated as an outpatient with antibiotics for 7 to 14 days (Table 45.7). Parenteral antibiotics are often given initially in the hospital to rapidly establish high serum and urinary drug levels.[7] When initial treatment resolves acute symptoms and the patient can tolerate oral fluids and drugs, the person may be discharged on a regimen of oral antibiotics for an additional 14 to 21 days. Symptoms and signs typically improve or resolve within 48 to 72 hours after starting therapy.

TABLE 45.7 Interprofessional CareAcute Pyelonephritis

Diagnostic Assessment

- History and physical examination
- Urinalysis
- Urine for culture and sensitivity
- Imaging studies: ultrasound (initially), CT scan, cystoscopy, voiding cystourethrogram (VCUG)
- CBC count with WBC differential
- Blood culture (if bacteremia is suspected)
- Percussion for flank (CVA) pain

Management
Mild Symptoms

- Outpatient management or short hospitalization
- Adequate fluid intake
- NSAIDs or antipyretic drugs
- Follow-up urine culture and imaging studies

Drug Therapy

- Empirically selected broad-spectrum antibiotics: ampicillin, fluoroquinolones (ciprofloxacin, levofloxacin), or TMP/SMX if infection expected to be susceptible
- Short course of IV antibiotics, such as aztreonam, ceftriaxone, ciprofloxacin, or levofloxacin, may be indicated
- Switch to sensitivity-guided therapy when results of urine and

blood culture are available

Severe Symptoms

- Hospitalization
- Adequate fluid intake (parenteral initially; switch to oral fluids as nausea, vomiting, and dehydration subside)
- NSAIDs or antipyretic drugs to reverse fever and relieve discomfort
- Follow-up urine culture and imaging studies

Drug Therapy

- Parenteral antibiotics
    - Empirically selected broad-spectrum antibiotics: aminoglycosides without or with ampicillin, extended spectrum cephalosporins, extended-spectrum penicillin-carbapenem
    - Switch to sensitivity-guided antibiotic therapy when results of urine and blood culture are available
- Oral antibiotics when patient tolerates oral intake

Relapses may be treated with a 6-week course of antibiotics. Antibiotic prophylaxis also may be used for recurrent infections. The effectiveness of therapy is based on the presence or absence of bacterial growth on urine culture.

Urosepsis is characterized by bacteriuria and bacteremia (bacteria in blood). Close observation and vital sign monitoring are essential. Prompt recognition and treatment of septic shock may prevent irreversible damage or death.

Nursing Management: Acute Pyelonephritis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with pyelonephritis are similar to those for the patient with a UTI (Table 45.5).

Nursing Diagnoses

Nursing diagnoses for the patient with pyelonephritis include those for the patient with a UTI (see p. 1027).

Planning

The overall goals are that the patient with pyelonephritis will have (1) normal renal function, (2) normal body temperature, (3) no complications, (4) relief of pain, and (5) no recurrence of symptoms.

Nursing Implementation

Health promotion and maintenance measures are similar to those for cystitis (see p. 1031). Early treatment for cystitis can prevent ascending infections. Because patients with structural abnormalities of the urinary tract are at high risk for infection, stress the need for regular medical care.

Nursing interventions vary depending on the severity of symptoms. These include teaching the patient about the disease process with emphasis on (1) continuing medications as prescribed, (2) having a follow-up urine culture, and (3) recognizing signs of recurrence or relapse (Table 45.6). In addition to antibiotic therapy, encourage the patient to drink at least 8 glasses of fluid every day, even after the infection has been treated. Rest will increase patient comfort.

The patient who has frequent relapses or reinfections may receive long-term, low-dose antibiotics. Making certain the patient understands the reason for therapy is important to increase adherence.

Evaluation

The expected outcomes for the patient with pyelonephritis are the same as for UTI (see p. 1028).

Chronic Pyelonephritis

In *chronic pyelonephritis* the kidneys become inflamed, develop fibrosis (scarring) leading to loss of renal function, and can atrophy (shrink). Chronic pyelonephritis is usually the result of significant anatomic abnormalities, such as vesicoureteral reflux or recurring infections involving the upper urinary tract. However, it may occur in the absence of an existing infection, recent infection, or history of UTIs.

Radiologic imaging studies can confirm the diagnosis of chronic pyelonephritis and possible contributing factors. A renal biopsy can show the loss of functioning nephrons, infiltration of the parenchyma with inflammatory cells, and fibrosis.

The level of renal function in chronic pyelonephritis depends on whether 1 or both kidneys are affected, the extent of scarring, and the presence of coexisting infection. Chronic pyelonephritis can progress to end-stage renal disease (ESRD). Monitoring and treating infection and correcting any underlying contributing factors are important. Nursing and interprofessional management of the patient with CKD is discussed in Chapter 46.

Urethritis

Urethritis is inflammation of the urethra. Causes of urethritis include a bacterial or viral infection, *Trichomonas* or monilial infection (especially in women), chlamydial infection, and gonorrhea (especially in men).

In men, the causes of urethritis are usually sexually transmitted. Purulent discharge can indicate a gonococcal urethritis. A clear discharge typically signifies a nongonococcal urethritis. (Sexually transmitted infections are discussed in Chapter 52.) Urethritis produces bothersome LUTS, including dysuria, urgency, and frequency, similar to those seen with cystitis.

In women, urethritis is hard to diagnose. It often produces bothersome LUTS, but urethral discharge may not be present.

Treatment of urethritis is based on identifying and treating the cause and providing symptomatic relief. Drugs used for bacterial infections include TMP/SMX, doxycycline (Vibramycin), ceftriaxone, and nitrofurantoin. Metronidazole (Flagyl) and tinidazole (Monistat) are options for treating *Trichomonas* infection. Drugs, such as nystatin, clotrimazole, or fluconazole, may be used for monilial infections. In chlamydial infections, doxycycline or azithromycin may be used. For treatment of gonococcal urethritis, the preferred first-line treatment is azithromycin 1 g orally with 250 mg intramuscular ceftriaxone. Women with negative urine cultures and no pyuria usually do not respond to antibiotics.

Warm sitz baths may temporarily relieve bothersome symptoms. Teach the patient to (1) avoid using vaginal deodorant sprays, (2) properly cleanse the perineal area after bowel movements and voiding, and (3) avoid sexual intercourse for at least 7 days. Teach patients with sexually transmitted urethritis to refer their sex partners for evaluation and testing if they had sexual contact in the 60 days before the onset of the patient's symptoms or diagnosis.

Urethral Diverticula

Urethral diverticula are localized outpouchings of the urethra. Typically, they result from enlargement of obstructed periurethral glands. In women, who have a higher incidence than men, the diverticula protrude into the anterior vaginal wall. The rare cases reported in males usually are associated with congenital lower urinary tract anomalies or surgical trauma.

The periurethral glands are found along the entire length of the urethra, with the majority draining into the distal third of the urethra. Skene's glands are the largest of these glands. Causes of urethral diverticula include urethral trauma, vaginal delivery, urethral instrumentation, urethral dilation, and frequent infections of the periurethral glands.

Symptoms include dysuria, postvoid dribbling, frequency (voiding more often than every 2 hours), urgency, suprapubic discomfort or pressure, dyspareunia, and a feeling of incomplete bladder emptying. Urinary incontinence is often present. However, many women have no symptoms.

The urine may contain gross blood (hematuria) or sediment, which gives it a cloudy appearance. An anterior vaginal wall mass may be felt on physical examination. When palpated, the mass is often quite tender and expresses purulent discharge through the urethra.

Radiographic studies, such as ultrasound and MRI, are helpful in determining the size of the diverticulum in relation to the urethral lumen. A voiding cystourethrography (VCUG) may be done but has a lower sensitivity than that of ultrasound and MRI. A urethroscopy may be of benefit.

Surgical options include transvaginal diverticulectomy, marsupialization (creation of a permanent opening) of the diverticular sac into the vagina *(Spence procedure),* and urethroscopic surgical excision. Stress urinary incontinence, infection, bleeding, and urethral-vaginal fistula are potential complications of the surgery.

Interstitial Cystitis/Painful Bladder Syndrome

Interstitial cystitis (IC) is a chronic, painful inflammatory disease of the bladder characterized by symptoms of urgency, frequency, and pain in the bladder and/or pelvis. IC is often called bladder pain syndrome or painful bladder syndrome (PBS). The term *IC/PBS* refers to cases of urinary pain that cannot be attributed to other causes, such as UTI or urinary stones. IC/PBS is more common in women, affecting about 3 to 8 million women and 1 to 4 million men each year.[8]

The cause of IC/PBS is unknown. It is likely multifactorial. Possible causes include neurogenic hypersensitivity of the lower urinary tract, changes in mast cells in the muscle and/or mucosal layers of the bladder, infection with an unusual organism (e.g., slow-growing virus), or production of a toxic substance in the urine.

Clinical Manifestations and Diagnostic Studies

The 2 primary manifestations of IC/PBS are pain and bothersome LUTS (e.g., frequency, urgency). People with severe cases may void as often as 60 times in a day, including nighttime urination. The pain is usually in the suprapubic area, but may involve the vagina, labia, or entire perineal region, including the rectum and anus. The pain varies from mild to severe. The pain can be worsened by bladder filling, postponed urination, physical exertion, pressure against the suprapubic area, certain foods, or emotional distress. Voiding temporarily relieves pain. Bothersome LUTS are similar to a UTI. The condition is often misdiagnosed as a recurring or chronic UTI or, in men, chronic prostatitis.

The patient may have periods of remission and exacerbation. Women often report pain that occurs before menstruation. Sexual intercourse or emotional stress worsen pain. Some patients have symptoms that disappear altogether after a period of weeks to

months. Others have persistent symptoms over months to years.

IC/PBS is a diagnosis of exclusion. A careful history and physical examination are necessary to rule out other disorders that produce similar symptoms, such as cancer, UTI, or endometriosis. Urine cultures do not find any bacteria or other organisms in the urine. Cystoscopic examination may reveal a small bladder capacity, Hunner lesions (distinct inflammatory areas on the bladder wall), and glomerulations (superficial ulcerations with pinpoint bleeding), but these findings are not always present.

Interprofessional Care

Because the cause of IC/PBS is unknown, no single treatment consistently reverses or relieves symptoms. Various therapies have been effective, including nutritional and drug therapy. People with IC/PBS do not respond to antibiotic therapy. They rarely need surgical therapy.

Eliminating foods and beverages that are likely to irritate the bladder may provide some relief from symptoms. Typical bladder irritants include caffeine; alcohol; citrus products; carbonated drinks; chocolate; foods containing vinegar, curries, or hot peppers; and foods or beverages likely to lower urinary pH, including fruits such as cranberries. An over-the-counter (OTC) dietary supplement called *calcium glycerophosphate* (Prelief) alkalinizes the urine and may provide relief from the irritating effects of certain foods. Recipes and menus for a well-balanced diet that is specifically designed to avoid bladder-irritating foods and beverages are available at the website for the Interstitial Cystitis Association *(www.ichelp.org)*.

Because stress can worsen or cause flare-ups of IC/PBS symptoms, stress management techniques such as relaxation breathing and imagery (see Chapter 6) may be helpful. Using lubrication or changing positions may decrease pain associated with sexual intercourse.

The tricyclic antidepressants, amitriptyline (preferred) and nortriptyline, may reduce burning and urinary frequency. Pentosan (Elmiron) is the only oral agent approved for the treatment of patients with symptoms of IC. It enhances the protective effects of the

glycosaminoglycan layer of the bladder and relieves pain by reducing the irritative effects of urine on the bladder wall. These drugs provide relief over time (weeks to months) but do not give the immediate relief that may be needed for an acute exacerbation of symptoms. A short course of opioid analgesics may be used for immediate relief. Antihistamine therapy, such as hydroxyzine, may be of use.

Pelvic physical therapy and bladder hypodistention therapy may be useful. Dimethyl sulfoxide (DMSO) can be directly instilled into the bladder through a small catheter. This drug desensitizes pain receptors in the bladder wall. Heparin, lidocaine, or sodium bicarbonate can be instilled into the bladder to relieve acute IC/PBS symptoms. Like pentosan, we think they enhance the protective properties of the glycosaminoglycan layer of the bladder. Intradetrusor botulism toxin and use of cyclosporine A have been found to be of some help.

While uncommon, surgery can be considered to improve severe, debilitating pain. Sacral neuromodulation or fulguration (using high-frequency energy to destroy a lesion) and resection of Hunner lesions are options. Urinary diversion, such as an ileal conduit, without or with removal of the bladder, is an option when other measures fail. Unfortunately, some patients have reported pain within the urinary diversion, which means that some factor in the urine may contribute to IC/PBS in certain cases.

Nursing Management: Interstitial Cystitis/Painful Bladder Syndrome

Assess the characteristics of the pain associated with IC/PBS. Ask the patient about specific dietary or lifestyle factors that relieve pain or make it worse. Teach the patient to keep a bladder log or voiding diary over a period of at least 3 days to determine voiding frequency and patterns of nocturia. Keeping a pain record at the same time may be useful.

A UTI may occur during IC/PBS management because of diagnostic instrumentation and frequent bladder instillations. A UTI is likely to cause an acute exacerbation of bothersome LUTS and urinary frequency, as well as dysuria (not typically associated with IC/PBS), odorous urine, and hematuria.

Review with the patient good nutrition, particularly in light of the broad dietary restrictions often necessary to control IC-related pain. Advise the patient to take a multivitamin containing no more than the recommended dietary allowance for essential vitamins and to avoid high-potency vitamins, because they may irritate the bladder. The patient should avoid clothing that creates suprapubic pressure, including pants with tight belts or restrictive waistlines. Educational materials about diet, coping with the need for frequent urination, and coping with the emotional burden of IC/PBS are available from the Interstitial Cystitis Association *(www.ichelp.org)*. Reassurance that IC/PBS is a real condition experienced by others and that it can be treated may relieve the anxiety, anger, guilt, and frustration related to having chronic pain and voiding dysfunction in the absence of a clear-cut diagnosis and treatment strategy.

Genitourinary Tuberculosis

Genitourinary tuberculosis (GUTB) is the second most common type of extrapulmonary tuberculosis. Between 2% and 20% of patients with pulmonary TB will develop GUTB. Onset can occur 1 to 46 years after the primary lung infection.[9,10] When the kidney is first infected with bacilli, the patient is often asymptomatic. Sometimes the patient will have fatigue and develops a low-grade fever. As the lesions ulcerate, infection descends to the bladder and other GU organs. The patient has cystitis, frequent urination, burning on voiding, and epididymitis (in men). Hematuria, pyuria, and symptoms of a UTI are the first manifestations in most patients with GUTB.

A diagnosis of GUTB is based on finding *Mycobacterium tuberculosis* bacilli in the urine. Radiographic tests include plain radiographs, CT scan, IV pyelography, and VCUG. These studies help determine the extent and severity of the disease. Tuberculin skin test results are positive in most patients, but this finding only means that the person has had previous inhalation of mycobacteria rather than active disease.

Long-term complications of GUTB depend on the duration of the disease. Scarring of the renal parenchyma, calcifications, hydronephrosis, and the development of ureteral strictures occur. The earlier treatment is started, the less likely renal failure will develop. The patient may need long-term urologic follow-up. Nursing and interprofessional management of the patient with TB is discussed in Chapter 27.

Immunologic Disorders of Kidney

Glomerulonephritis

Glomerulonephritis (inflammation of the glomeruli) affects both kidneys equally and is the third leading cause of ESRD in the United States. Although the glomerulus is the primary site of inflammation, tubular and interstitial changes as well as vascular scarring and hardening *(glomerulosclerosis)* within the kidney can occur.[11]

A variety of conditions are associated with glomerulonephritis. These range from kidney infections, drugs toxic to the kidneys, problems with the immune system, and systemic diseases (Table 45.8). Glomerulonephritis can be acute or chronic. With *acute glomerulonephritis,* symptoms come on suddenly and may be temporary or reversible. An example of this is acute poststreptococcal glomerulonephritis (discussed in the next section). *Chronic glomerulonephritis* is slowly progressive glomerulonephritis that can lead to irreversible renal failure (discussed later in this chapter).

TABLE 45.8 Causes and Risk Factors for Glomerulonephritis (GN)

Cause or Risk Factor	Description
Conditions Causing Scarring of Glomeruli	
Diabetic nephropathy	• Primary cause of end-stage renal disease in the United States (see Chapter 46) • Microvascular changes of diffuse glomerulosclerosis involving thickening of the glomerular basement membrane
Focal segmental glomerulosclerosis	• Characterized by scattered scarring of glomeruli • May result from another disease or occur for unknown reasons
Hypertension	• Nephrosclerosis is a complication of hypertension • GN can cause hypertension
Immune Diseases	
Goodpasture syndrome	• Autoimmune disorder that causes lung and kidney disease • Causes bleeding into lungs and GN
Immunoglobulin A (IgA) nephropathy	• Results from deposits of IgA in the glomeruli • Characterized by recurrent episodes of hematuria
Scleroderma	• Disease of unknown cause characterized by widespread changes in connective tissue and vascular lesions in many organs (see Chapter 64) • In the kidney, vascular lesions are associated with fibrosis • Severity of renal involvement varies
Systemic lupus erythematosus (SLE)	• Autoimmune disorder characterized by the involvement of several tissues and organs, particularly joints, skin, and kidneys (see Chapter 64) • GN often occurs in SLE and has a poor prognosis
Infections	
Infective endocarditis	• Bacteria can cause an infection of 1 or more of the heart valves (see Chapter 36) • People at risk include those with a heart defect, such as a damaged or artificial heart valve • Bacterial endocarditis is associated with GN, but the exact cause is not known
Poststreptococcal glomerulonephritis	• GN may develop 1–2 wk after a streptococcal throat infection or, rarely, a skin infection (impetigo) • Antibodies (Ab) to strep antigen (Ag) develop and the Ag-Ab deposit in the glomeruli, causing inflammation
Viral infections	• Viral infections can trigger GN • Common viruses include HIV, hepatitis B, and hepatitis C viruses
Vasculitis	
Polyarteritis	• Autoimmune disease that affects small and medium blood vessels • Can affect any organ but common in heart, kidneys, and intestines
Wegener's granulomatosis	• Form of vasculitis affecting small and medium blood vessels • Most often affects kidneys, lungs, and upper respiratory tract
Other Causes	
Amyloidosis	• Caused by infiltration of tissues with amyloid (hyaline substance) • Hyaline bodies consist largely of protein • Kidney involvement is common • Proteinuria is often the first clinical manifestation
Illegal drug use	• People who use these drugs are at increased risk for GN

GN, Glomerulonephritis.

Diagnostic studies and a comprehensive history, including any recent infection, such as a sore throat or upper respiratory tract infection, or a diagnosis of diabetes, aid in identifying the type of glomerulonephritis present.

Acute Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (APSGN) is a common type of acute glomerulonephritis. It is most common in children, young adults, and adults older than 60 years. APSGN develops about 1 to 2

weeks after an infection of the tonsils, pharynx, or skin (e.g., streptococcal sore throat, impetigo) by nephrotoxic strains of group A β-hemolytic streptococci.[12] The person makes antibodies to the streptococcal antigen. Although the exact mechanism is not known, tissue injury occurs as the antigen-antibody complexes are deposited in the glomeruli, complement is activated (see Chapter 11), and inflammation results.

Manifestations include generalized body edema, hypertension, oliguria, hematuria, and varying degrees of proteinuria. Fluid retention occurs because of decreased glomerular filtration. At first, edema appears in low-pressure tissues, such as those around the eyes *(periorbital edema)*. Later it progresses to involve the total body, with ascites or peripheral edema in the legs. Smoky urine indicates bleeding in the upper urinary tract. The degree of proteinuria varies with the severity of the glomerulonephropathy. Hypertension primarily results from increased extracellular fluid volume. The patient may have abdominal or flank pain. Sometimes the patient may be asymptomatic, and the problem is found on routine urinalysis.

The diagnosis of APSGN is based on a complete history and physical examination. An immune response to the streptococci is often shown by assessment of antistreptolysin-O (ASO) titers. The finding of decreased complement components (especially C3 and CH50) indicates an immune-mediated response. A renal biopsy may be done to confirm the disease.

Dipstick urinalysis and urine sediment microscopy can reveal significant numbers of erythrocytes. Erythrocyte casts are highly suggestive of APSGN. Proteinuria may range from mild to severe. Blood tests include blood urea nitrogen (BUN) and serum creatinine to assess the extent of renal impairment.

Nursing and Interprofessional Management: Acute Poststreptococcal Glomerulonephritis

More than 95% of patients with APSGN recover completely or improve rapidly with conservative management. Accurate recognition and assessment are critical since chronic glomerulonephritis can develop if the patient is not treated appropriately.

Management focuses on symptomatic relief. Rest is recommended until the signs of glomerular inflammation (proteinuria, hematuria) and hypertension subside. Restricting sodium and fluid intake and diuretics can reduce edema. Severe hypertension is treated with antihypertensive drugs. Dietary protein intake may be restricted if there is evidence of an increase in nitrogenous wastes (e.g., increased BUN). The dietary protein restriction varies with the degree of proteinuria. Low-protein, low-sodium, fluid-restricted diets are discussed in Chapter 46.

Antibiotics should be given only if the streptococcal infection is still present. Corticosteroids and cytotoxic drugs are not of value in treating APSGN.

One of the most important ways to prevent APSGN is to encourage early diagnosis and treatment of sore throats and skin lesions. If a culture is positive for streptococci, treatment with the appropriate antibiotic therapy is essential. Encourage the patient to take the full course of antibiotics to ensure that the bacteria have been eradicated. Good personal hygiene is a key factor in preventing the spread of cutaneous streptococcal infections.

In most cases, recovery from the acute glomerulonephritis is complete. However, if progressive involvement occurs and chronic glomerulonephritis develops, ESRD can result.

Chronic Glomerulonephritis

Chronic glomerulonephritis is a syndrome of permanent and progressive renal fibrosis. It can progress to ESRD. Most types of glomerulonephritis and nephrotic syndrome can eventually lead to chronic glomerulonephritis. Some people who develop chronic glomerulonephritis have no history of kidney disease. The cause of a patient's chronic glomerulonephritis may not be found. Although not common, an inherited disorder (e.g., Alport syndrome [see p. 1043]) may be the cause.

With chronic glomerulonephritis, symptoms develop slowly over time. Patients are often unaware that progressive kidney impairment is occurring. They do not realize that they have severe kidney impairment until a diagnostic evaluation is done. Chronic glomerulonephritis is often discovered coincidentally with the finding of an abnormality on a urinalysis, high BP, or increased serum creatinine.

The syndrome is characterized by proteinuria, hematuria, and the slow development of uremia (see Chapter 46) because of decreasing renal function. Chronic glomerulonephritis progresses insidiously toward ESRD over a course of several years.

Manifestations include varying degrees of hematuria (ranging from microscopic to gross), proteinuria, and urinary excretion of various formed elements, including red blood cells (RBCs), WBCs, and casts. Increased BUN and serum creatinine levels are common. Ultrasound and CT scan are the preferred diagnostic measures. However, a renal biopsy may be done to determine the exact cause of the glomerulonephritis.

The patient's history provides vital information related to glomerulonephritis. Assess exposure to drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]), microbial infections, and viral infections (e.g., hepatitis). Evaluate the patient for more generalized conditions involving immune disorders, such as systemic lupus erythematosus (SLE). The patient may not recall any history of renal problems.

Treatment depends on the cause of the chronic glomerulonephritis and includes supportive and symptomatic care. Management of CKD

is discussed in Chapter 46.

Goodpasture Syndrome

Goodpasture syndrome is an autoimmune disease characterized by antibodies that attack the glomerular and alveolar basement membranes. Damage to the kidneys and lungs results when binding of the antibody causes an inflammatory reaction mediated by complement activation (see Chapter 11).

Goodpasture syndrome is a rare disease that occurs primarily in older children and adults, especially those in their 30s to 60s. The manifestations can include flu-like and pulmonary symptoms, such as cough, mild shortness of breath, hemoptysis, crackles, and pulmonary insufficiency. Renal involvement includes hematuria, weakness, pallor, and anemia. It can proceed quickly to renal failure. Pulmonary hemorrhage usually occurs and may precede glomerular abnormalities by weeks or months.

Current management includes corticosteroids, immunosuppressive drugs (e.g., cyclophosphamide, azathioprine [Imuran]), plasmapheresis (see Chapter 13), rituximab, and dialysis. Plasmapheresis removes the circulating anti–glomerular basement membrane (GBM) antibodies, and immunosuppressive therapy inhibits further antibody production. Renal transplantation can be tried after the circulating anti-GBM antibody titer decreases. Although the disease may recur in the transplanted kidney, this is not a contraindication to transplantation.

Encourage smoking cessation. The patient receives nursing care appropriate for a critically ill patient who has AKI (see Chapter 46) and respiratory distress (see Chapter 67). Death is often from hemorrhage in the lungs and respiratory failure.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a type of glomerular disease with glomerular crescent formations. In contrast to chronic glomerulonephritis, which develops slowly and progresses over many

years, RPGN is characterized by rapid, progressive loss of renal function over days to weeks.

RPGN can occur in a variety of situations: (1) as a complication of inflammatory or infectious disease (e.g., APSGN, Goodpasture syndrome), (2) as a complication of a systemic disease (e.g., SLE), (3) or as an idiopathic disease.

Manifestations include hypertension, edema, proteinuria, hematuria, and RBC casts. Treatment is directed toward correction of fluid overload, hypertension, uremia, and inflammatory injury to the kidney. Treatment includes corticosteroids, cyclophosphamide, and plasmapheresis. Dialysis therapy and transplantation are used as maintenance therapy for the patient with RPGN who has progressed to ESRD. After kidney transplantation, RPGN may recur.

Nephrotic Syndrome

Nephrotic syndrome results when the glomerulus is excessively permeable to plasma protein, causing proteinuria that leads to low plasma albumin and tissue edema.

Etiology and Clinical Manifestations

Common causes of nephrotic syndrome are listed in Table 45.9. About one third of patients with nephrotic syndrome have a systemic disease, such as diabetes or SLE.[13]

The characteristic manifestations of nephrotic syndrome include peripheral edema, massive proteinuria, hypertension, hyperlipidemia, hypoalbuminemia, and foamy urine. The increased glomerular membrane permeability found in nephrotic syndrome is responsible for the massive excretion of protein in the urine. This results in decreased total serum protein and subsequent edema formation. Ascites and *anasarca* (massive generalized edema) develop if there is severe hypoalbuminemia.

TABLE 45.9 Causes of Nephrotic Syndrome

Primary Glomerular Disease

- Acute glomerulonephritis
- Membranous glomerulopathy
- Primary nephrotic syndrome
- Rapidly progressive glomerulonephritis

Extrarenal Causes

Allergens (Minimal Change Disease)

- Bee sting
- Pollen

Cancers

- Hodgkin's lymphoma
- Leukemias
- Solid tumors of lungs, colon, stomach, breast

Drugs

- captopril
- heroin
- NSAIDs
- penicillamine

Infections

- Bacterial (streptococcal, syphilis)
- Protozoal (malaria)
- Viral (hepatitis, HIV, mononucleosis)

Multisystem Disease

- Amyloidosis
- Diabetes
- SLE

The diminished plasma oncotic pressure from the decreased serum proteins stimulates hepatic lipoprotein synthesis, which results in hyperlipidemia. At first, cholesterol and low-density lipoproteins are

high. Later, triglyceride levels increase. Fat bodies (fatty casts), often appear in the urine, causing foamy urine.

Immune responses are altered in nephrotic syndrome. As a result, infection is a primary cause of morbidity and mortality. Calcium and skeletal abnormalities may occur, including hypocalcemia, blunted calcium response to parathyroid hormone, hyperparathyroidism, and osteomalacia.

Hypercoagulability is a serious issue for those with nephrotic syndrome. Hypercoagulability increases the risk for arterial and venous thromboembolism, including pulmonary embolism and deep vein or renal thrombus.

Interprofessional and Nursing Care

Specific treatment of nephrotic syndrome depends on the cause. The goals are to cure or control the primary disease and relieve the symptoms. Corticosteroids and cyclophosphamide may be used in the treatment of nephrotic syndrome. Prednisone has been effective to varying degrees for some causes of nephrotic syndrome (e.g., membranous glomerulonephritis, lupus nephritis). Managing diabetes is an important consideration for nephrotic syndrome related to diabetes.

Angiotensin-converting enzyme inhibitor or angiotensin receptor blocker drugs are used to try to reduce urine protein losses. Diuretics (typically loop diuretics) can improve edema.

The treatment of hyperlipidemia includes lipid-lowering agents (see Table 33.6). Anticoagulant therapy may be needed if thrombosis is present.

The patient is placed on a low-sodium (less than 2.3 g/day), moderate-protein (1 to 2 g/kg/day) diet. If urine protein losses are high (more than 10 g/day), more protein may be recommended. Patients with nephrotic syndrome are usually anorexic and have the potential to become malnourished from the excess loss of protein in the urine. Serve small, frequent meals in a pleasant setting to encourage better dietary intake.

A major nursing intervention for a patient with nephrotic syndrome

focuses on the management of edema. Assess the edema by (1) weighing the patient daily, (2) accurately recording intake and output, and (3) measuring abdominal girth or extremity size. Compare this information daily to assess the effectiveness of treatment. Clean the edematous skin carefully. Avoid trauma to the skin. Monitor the effectiveness of diuretic therapy.

Because the patient with nephrotic syndrome is susceptible to infection, teach the patient to avoid exposure to persons with known infections. Support for the patient, especially in helping cope with an altered body image, is essential because of the embarrassment and shame often associated with the edematous appearance.

Obstructive Uropathies

Urinary obstruction refers to any anatomic or functional condition that blocks or impedes the flow of urine (Fig. 45.3). It may be congenital or acquired. Damaging effects from urinary tract obstruction affect the system above the level of the obstruction. The severity of these effects depends on the location, duration of obstruction, amount of pressure or dilation, and presence of urinary stasis or infection. Infection increases the risk for irreversible damage.[14]

When obstruction occurs at the level of the bladder neck or prostate, significant bladder changes can occur. Detrusor muscle fibers *hypertrophy* (increase in size) to contract harder to push urine out a narrower pathway. Over a long period, the detrusor loses its ability to compensate for this resistance, eventually leading to a large residual urine volume in the bladder.

When *bladder outlet obstruction* is present, pressure increases during bladder filling or storage and can be transmitted to the ureter. This pressure leads to *reflux* (backflow, or backward movement, of urine), *hydroureter* (ureteral dilation and distention), vesicoureteral reflux (backflow of urine from the lower to upper urinary tract), and **hydronephrosis** (dilation or enlargement of the renal pelvises and calyces) (Fig. 45.4). Chronic pyelonephritis and renal atrophy may develop. If only 1 kidney is obstructed, the other kidney may try to compensate by enlarging.

Partial obstruction may occur in the ureter or at the ureteropelvic junction (UPJ) (where the renal pelvis narrows into the ureter). If the pressure stays low or moderate, the kidney may continue to dilate with no noticeable loss of function. Urinary stasis and reflux increase the risk for pyelonephritis. If only 1 kidney is involved, and the other kidney is functioning, the patient may be asymptomatic.

If both kidneys or only 1 functioning kidney is involved (e.g., if the patient has only 1 kidney), changes in renal function (e.g., increased BUN and serum creatinine levels) occur. Progressive obstruction can lead to renal failure. Treatment requires finding and relieving the

blockage. This can include insertion of a tube (e.g., urethral or ureteral), surgical correction of the primary problem, or diversion of the urinary stream above the level of blockage.

Urinary Tract Calculi

In their lifetime, 13% of men and 7% of women in the United States will have **nephrolithiasis,** or kidney stone disease. The term **calculus** refers to the stone, and *lithiasis* refers to stone formation.

Most patients are middle-aged adults. The risk for developing kidney stones increases with age.[15]Stone formation is more frequent in whites than in blacks, Hispanics, and Asians. The incidence is higher in persons with a family history of stone formation. Stones recur in up to 50% of patients. In the United States, the incidence of stone disease is highest in the Southeast, followed by the Southwest and Midwest. Stone formation occurs more often in the summer months, supporting the possible contributing factors of a hot climate and dehydration.

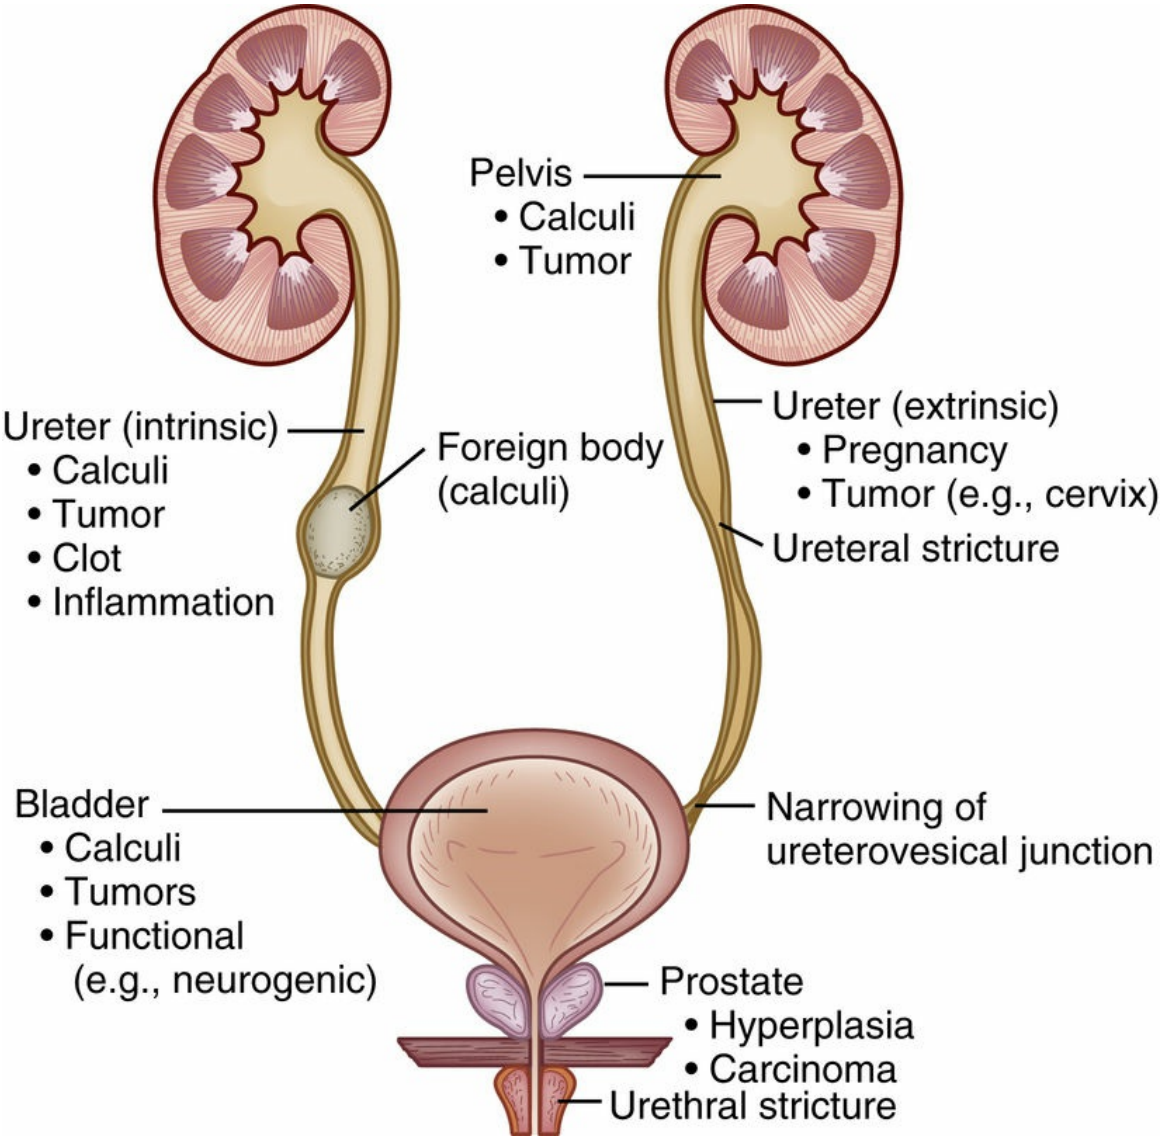

FIG 45.3 Sites and causes of upper and lower urinary tract obstruction.

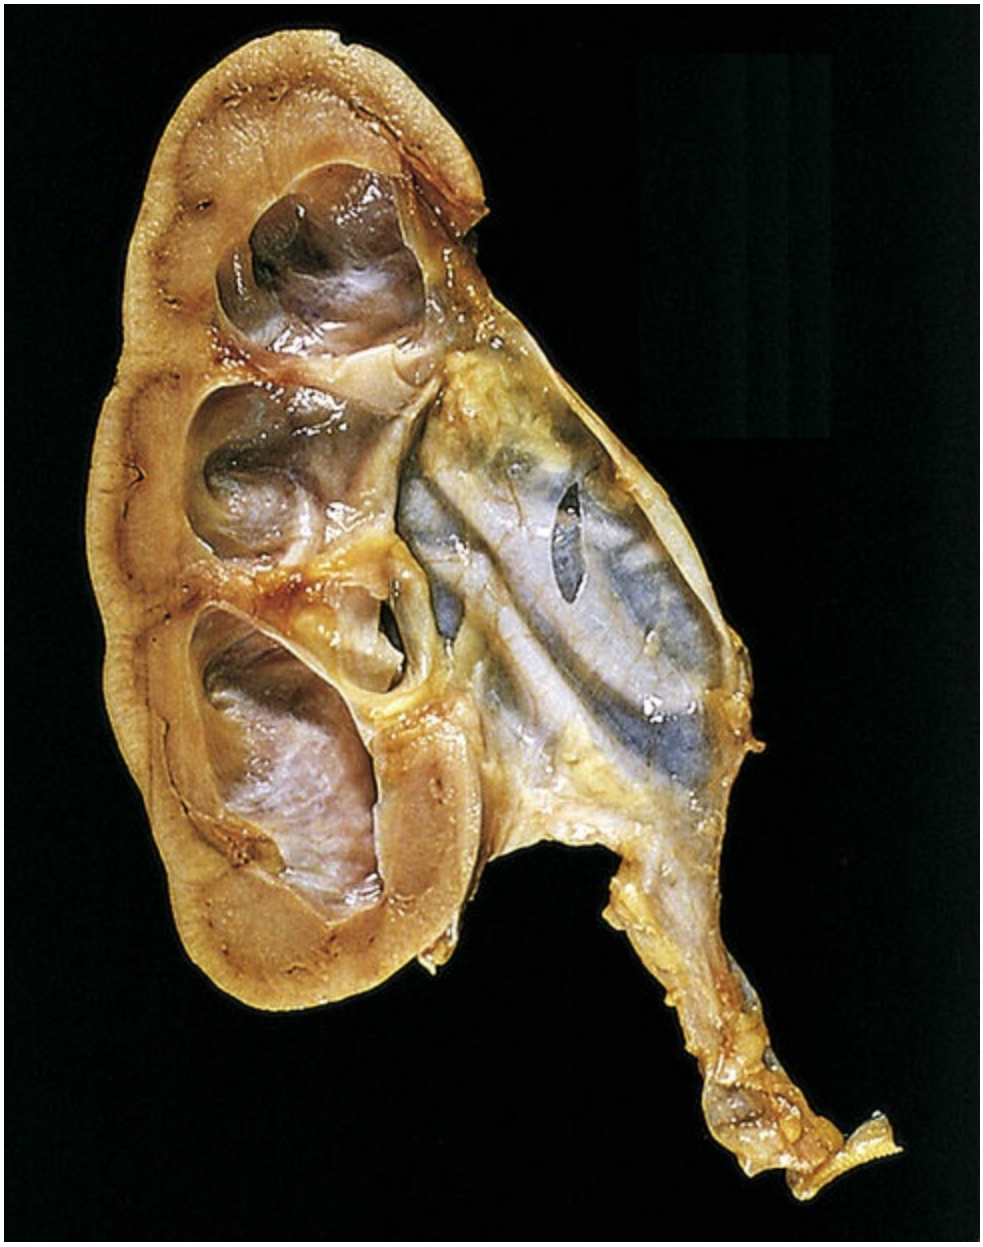

FIG 45.4 Hydronephrosis of the kidney. Note the marked dilation of the pelvis and calyces and thinning of the renal parenchyma. From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Gender Differences

Urinary Tract Stones

Men

- Most likely to have urinary stones, except for struvite stones

Women

- More likely to have struvite stones associated with UTI

TABLE 45.10 Risk Factors for Urinary Tract Stones

Climate

- Warm climates that cause increased fluid loss, low urine volume, and increased solute concentration in urine

Diet

- Excess amounts of tea or fruit juices that increase urinary oxalate level
- Large intake of dietary proteins that increases uric acid excretion
- Large intake of salt, low calcium intake
- Low fluid intake that increases urinary concentration

Genetic Factors

- Family history of stone formation, cystinuria, gout, or renal acidosis

Lifestyle

- Immobility
- Obesity
- Sedentary occupation

Metabolic

- Abnormalities that result in increased urine levels of calcium, oxalate, uric acid, or citric acid

Etiology and Pathophysiology

Many factors are involved in the incidence and type of stone formation, including climatic, dietary, genetic, metabolic, and lifestyle influences (Table 45.10). No single theory accounts for stone formation in all cases. Crystals, when in a supersaturated concentration, can precipitate and unite to form a stone. Keeping urine dilute and free flowing reduces the risk for recurrent stone formation in many people.

We think kidney stones form when certain crystal-forming substances are not diluted by the kidney and/or there is reduced ability of the kidneys to keep the crystals from sticking together. Urinary pH, solute load, and inhibitors in the urine affect the formation of stones. The higher the pH (alkaline), the less soluble are calcium and phosphate. The lower the pH (acidic), the less soluble are uric acid and cystine. When a substance is not very soluble in fluid, it is more likely to precipitate out of solution.

Other key factors in stone formation include obstruction with associated urinary stasis and UTI with urea-splitting bacteria (e.g., *Proteus, Klebsiella, Pseudomonas,* and some species of staphylococci). These bacteria cause the urine to become alkaline and contribute to the formation of struvite stones. Infected stones, trapped in the kidney (Fig. 45.5), may assume a staghorn configuration as the stone branches to occupy a larger part of the collecting system. These stones can lead to a renal infection, hydronephrosis, and loss of kidney function.

Genetic factors may contribute to urine stone formation. Cystinuria,

an autosomal recessive disorder, causes a markedly increased excretion of cystine.

Promoting Health Equity

Urologic Disorders

- Urinary tract stones are more common among whites than blacks.
- Uric acid stones are more common in Jewish men.
- Bladder cancer has a higher incidence among white men than black men.
- Urinary incontinence is underreported because culturally it is seen as a social hygiene problem causing patient embarrassment.

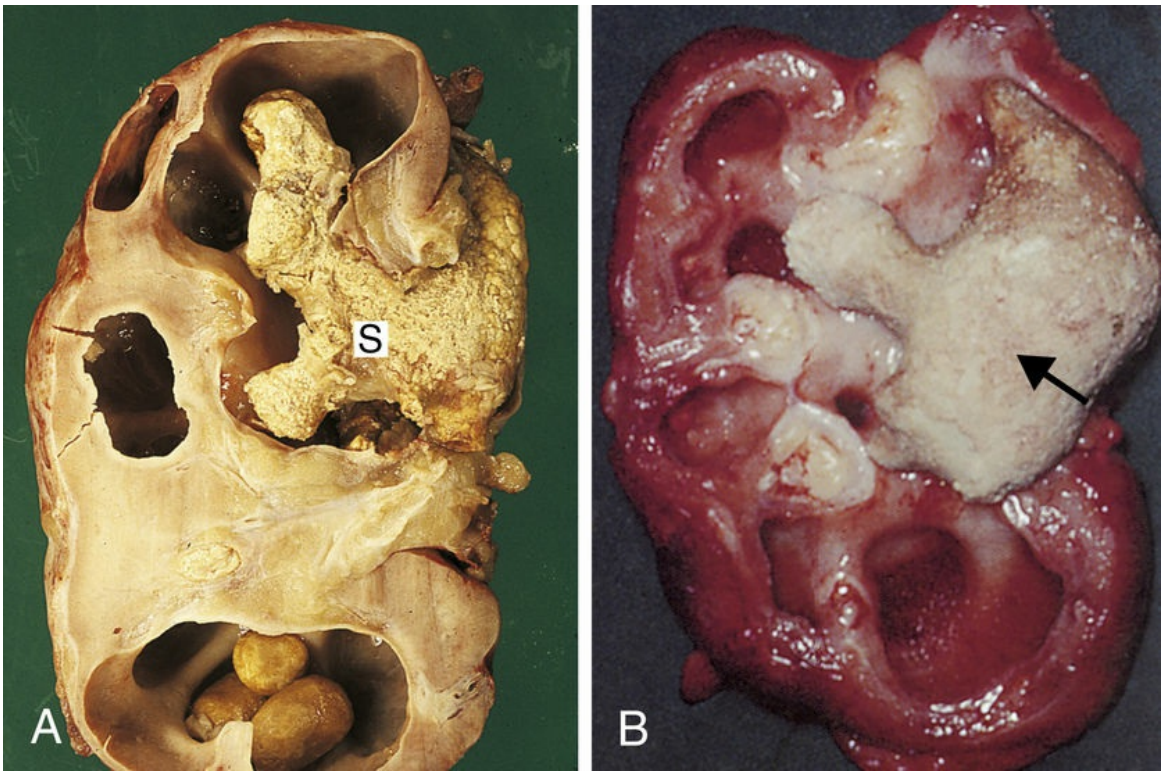

FIG 45.5 **A,** Renal staghorn stone. The renal pelvis is filled with a large stone that is shaped to its contours, resembling the horns of a stag *(S).* **B,** Imbedded staghorn stone *(arrow)* in hydronephrotic,

infected, nonfunctioning kidney.
A, From Stevens A, Lowe JS, Scott I: *Core pathology: Illustrated review in color,* ed 3, London, 2009, Mosby Ltd. *B,* From Bullock N, Doble A, Turner W, et al: *Urology: An illustrated colour text*, London, 2008, Churchill Livingstone.

Types of Urinary Stones

The 5 major categories of stones are (1) calcium oxalate, (2) calcium phosphate, (3) cystine, (4) struvite (magnesium ammonium phosphate), and (5) uric acid (Table 45.11). Calcium stones can exist as calcium oxalate, calcium phosphate, or a mixture of both. Although calcium stones are the most common, stone composition may be mixed. Stones can be found in various locations in the urinary tract (Figs. 45.3 and 45.5).

Clinical Manifestations

The first symptom of a kidney stone is usually severe pain that begins suddenly. Typically, a person feels a sharp, severe pain in the flank area, back, or lower abdomen. People describe the pain as the most excruciating that a person can endure. We call this pain *renal colic*. It results from the stretching, dilation, and spasm of the ureter in response to the obstructing stone. Nausea and vomiting may occur due to the severe pain.

Urinary stones cause manifestations when they obstruct urinary flow. Common sites of obstruction are at the UPJ and ureterovesical junction (UVJ). The type of pain is determined by the location of the stone. If the obstruction is in a calyx or at the UPJ, the patient may have dull costovertebral flank pain or renal colic. Pain resulting from the passage of a stone down the ureter is intense and colicky. If the stone is nonobstructing, pain may be absent.

Patients with renal colic have a hard time being still. They go from walking to sitting to lying down, and then they repeat the process. Some people refer to this as the "kidney stone dance."

The patient may be in mild shock with cool, moist skin. As a stone

nears the UVJ, pain moves around toward the abdomen and down toward the lower quadrant. Men may have testicular pain, while women may have labial pain. Both men and women can have groin pain. The patient may have manifestations of a UTI with dysuria, fever, and chills.

Diagnostic Studies

Stones are easily diagnosed with either a noncontrast helical (spiral) CT scan or ultrasound. A complete urinalysis helps confirm the diagnosis of a urinary stone by assessing for hematuria and crystalluria. Measuring urine pH is useful in the diagnosis of struvite stones (tendency to alkaline or high pH) and uric acid or cystine stones (tendency to acidic or low pH).

TABLE 45.11 Types of Urinary Tract Stones

Characteristics	Predisposing Factors	Treatment
Calcium Oxalate		
Small, can easily get trapped in ureter. More frequent in men than in women. ***Incidence:*** **35%–40%**	Idiopathic hypercalciuria, hyperoxaluria, independent of urinary pH, family history	Increase hydration. Reduce dietary oxalate, animal protein, and sodium (see Table 45.12). Encourage increased intake of calcium, fruits, and vegetables. Give thiazide diuretics. Give potassium citrate to maintain alkaline urine. Avoid vitamin C and calcium supplements.
Calcium Phosphate		
Mixed stones (typically), with struvite or oxalate stones. ***Incidence:*** **8%–10%**	Alkaline urine, primary hyperparathyroidism	Increase hydration. Treat underlying causes and other stones. Reduce dietary sodium and animal protein intake. Increase dietary calcium intake. Avoid vitamin C supplements.
Cystine		
Genetic autosomal recessive defect. Defective absorption of cystine in GI tract and kidney, excess concentrations causing stone formation. ***Incidence:*** **1%–2%**	Acidic urine	Increase hydration. Give α-penicillamine, captopril or tiopronin to prevent cystine crystallization. Give potassium citrate to keep urine alkaline.
Struvite (Magnesium Ammonium Phosphate)		
3–4 times more common in women. Always associated with urinary tract infections. Large staghorn type (usually) (Fig. 45.5). ***Incidence:*** **10%–15%**	Urinary tract infections (usually *Proteus*)	Give antimicrobial agents, acetohydroxamic acid. May need surgery to remove stone. Take measures to acidify urine.
Uric Acid		
Predominant in men, high incidence in Jewish men. ***Incidence:*** **5%–8%**	Gout, acidic urine, inherited condition	Reduce urinary concentration of uric acid. Alkalinize urine with potassium citrate. Give allopurinol. Reduce dietary purines (see Table 45.12).

Retrieval and analysis of the stone(s) is important in the diagnosis of the underlying problem contributing to stone formation. The patient's serum calcium, phosphorus, sodium, potassium, bicarbonate, uric acid, BUN, and creatinine levels are measured. Patients who have recurrent stone formation should have a 24-hour urinary measurement of calcium, phosphorus, magnesium, sodium, oxalate, citrate, cysteine, sulfate, potassium, uric acid, and total urine volume.

Interprofessional Care

Evaluation and management of a patient with renal stones consist of 2 concurrent approaches. The first approach is directed toward managing the acute attack by treating the pain, infection, and/or obstruction. Give opioids to relieve renal colic pain. NSAIDs can be considered if there is no contraindication based upon the renal function. Most stones are 4 mm or less in size and pass spontaneously. However, it may take weeks for a stone to pass.

α-Adrenergic blockers, such as tamsulosin (Flomax) or terazosin, which relax the smooth muscle in the ureter, can help stone passage. These drugs also relax the muscle tissue in the prostate in men with BPH.

The second approach is directed toward evaluating the cause of the stone formation and preventing further stone development. Obtain information from the patient, including a family history of stone formation; geographic residence; nutritional assessment, including fluid intake and the intake of vitamins A, C, and D; activity pattern (active or sedentary); history of prolonged illness with immobilization or dehydration; and any history of disease or surgery involving the GI or genitourinary tract. Include any prior episodes of stone formation, prescribed and OTC medications, and use of dietary supplements.

Therapy for active stone formers requires a comprehensive management approach, with the primary emphasis on teaching. Adequate hydration, dietary sodium restrictions, dietary changes, and drugs are used to minimize urinary stone formation (Table 45.11). Depending on the specific problem underlying the stone formation,

various drugs are prescribed. These drugs prevent stone formation in several ways. These include altering urine pH, preventing excessive urinary excretion of a substance, or correcting a primary disease (e.g., hyperparathyroidism).

Treatment of struvite stones requires control of infection. This may be difficult if the stone is still in place. In addition to antibiotics, acetohydroxamic acid may be used to treat kidney infections that result in the continual formation of struvite stones. Acetohydroxamic acid inhibits the chemical action caused by the persistent bacteria and can slow struvite stone formation. Stones may have to be removed surgically if the infection cannot be controlled.[16]

Endourology, lithotripsy, or open surgical stone removal may be used in the following situations: (1) stones too large for spontaneous passage (usually greater than 7 mm); (2) stones associated with bacteriuria or symptomatic infection; (3) stones causing impaired renal function; (4) stones causing persistent pain, nausea, or paralytic ileus; (5) inability of patient to be treated medically; and (6) patient with only 1 kidney.[16]

Endourologic Procedures

If the stone is in the bladder, a cystoscopy is done to remove small stones. For large stones (Fig. 45.6), a *cystolitholapaxy* is done. In this procedure, large stones are broken up with an instrument called a *lithotrite* (stone crusher), using mechanical crushing or laser energy. The bladder is then irrigated, and the crushed stones washed out. A *cystoscopic lithotripsy* uses ultrasonic waves to break up stones. Complications associated with these procedures include hemorrhage, retained stone fragments, and infection.

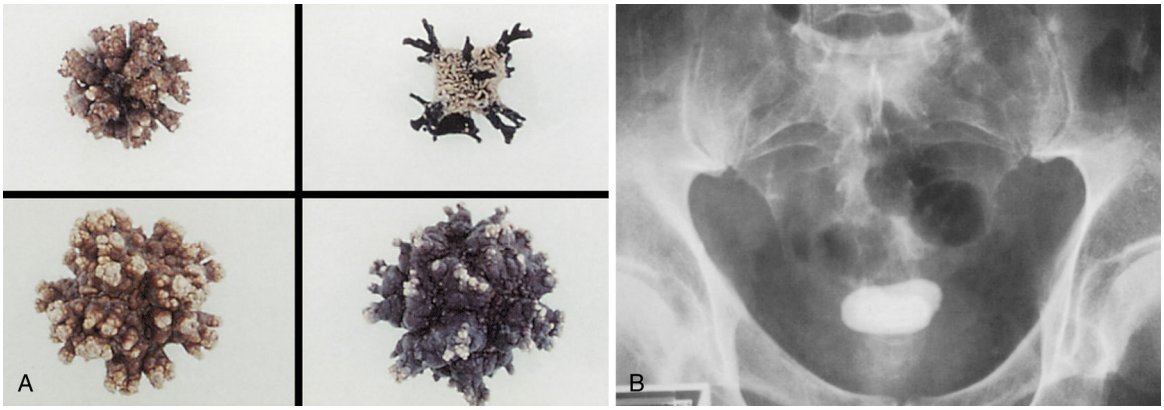

FIG 45.6 **A,** Calcium oxalate stones. **B,** Plain abdominal x-ray showing large bladder stone.
From Bullock N, Doble A, Turner W, et al: *Urology: An illustrated colour text,* London, 2008, Churchill Livingstone.

Flexible *ureteroscopes* can be used to remove stones from the renal pelvis and upper urinary tract. Ultrasonic, laser, or electrohydraulic lithotripsy may be used in conjunction with ureteroscopy to break up the stone.

In *percutaneous nephrolithotomy,* a nephroscope is inserted into the kidney pelvis through a track (using a sheath) in the skin. The track is created in the patient's back. The kidney stones can be fragmented using ultrasound, electrohydraulic, or laser lithotripsy. The stone fragments are removed, and the pelvis is irrigated. A percutaneous nephrostomy tube can be left in place to make sure that the ureter is not obstructed. Complications include bleeding, injury to adjacent structures, and infection.

Lithotripsy

Lithotripsy is a procedure used to eliminate stones from the urinary tract. Lithotripsy techniques include (1) laser lithotripsy, (2) extracorporeal shock-wave lithotripsy (ESWL), (3) percutaneous ultrasonic lithotripsy, and (4) electrohydraulic lithotripsy. *Laser lithotripsy* is used to shatter ureteral and large bladder stones (bladder stones are described earlier). To access ureteral stones, a ureteroscope is used to get close to the stone. A small fiber is inserted up the scope so that the tip (which emits the laser energy) can come in contact with the stone. A holmium laser in direct contact with the stone is

commonly used. The intense energy breaks the stone into small pieces, which can be extracted or flushed out. Because of the type of laser energy, no other tissue is affected. This minimally invasive treatment usually requires general anesthesia.

In *extracorporeal shock-wave lithotripsy (ESWL),* a noninvasive procedure, the patient is anesthetized (spinal or general) to ensure they maintain the same position during the procedure. The HCP uses fluoroscopy or ultrasound to focus the lithotripter over the affected kidney. Then, a high-voltage spark generator produces high-energy acoustic shock waves that shatter the stone without damaging the surrounding tissues. The small pieces of stone are then excreted in the urine. A complication of ESWL is steinstrasse, in which the ureter is blocked by those smaller pieces.

In *percutaneous ultrasonic lithotripsy* an ultrasonic probe is placed in the renal pelvis via a percutaneous nephroscope inserted through a small flank incision. The HCP positions the probe against the stone. The probe produces ultrasonic waves, which break the stone into sand-like particles. The patient receives general or spinal anesthesia.

In *electrohydraulic lithotripsy* the probe is positioned directly on a stone, but it breaks the stone into small fragments that are removed by forceps or suction. A continuous saline irrigation flushes out the stone particles, and all the outflow drainage is strained so that the particles can be analyzed. Stones can also be removed by basket extraction.

Complications of lithotripsy are rare but include hemorrhage, infection, and obstruction. Hematuria is common after lithotripsy procedures. The first few times that the patient voids, the urine is bright red. As the bleeding subsides, the urine becomes dark red or a smoky color. Antibiotics are usually given after the procedure to reduce the risk for infection.

Afterward, the patient usually has moderate to severe colicky pain. A self-retaining ureteral stent is often placed after the procedure to help the passage of sand (shattered stone) and prevent sand buildup within the ureter, which may lead to obstruction. The stent is typically removed within 2 weeks after lithotripsy. If a stone is large or positioned in the mid or distal ureter, other treatment, such as

surgery, may be needed. Encourage fluids to help dilute the urine and reduce the pain from passing stone fragments.

Surgical Therapy

A small group of patients need open surgical procedures. The primary indications for surgery include pain, infection, and obstruction. The type of open surgery done depends on the location of the stone. A *nephrolithotomy* is an incision into the kidney to remove a stone. A *pyelolithotomy* is an incision into the renal pelvis for stone removal. If the stone is in the ureter, a *ureterolithotomy* is done. A *cystotomy* may be indicated for bladder stones. For open surgery on the kidney or ureter, a flank incision directly below the diaphragm and across the side is usually preferred. The most common complications after surgical procedures for stone removal are related to hemorrhage.

Nutritional Therapy

To manage an obstructing stone, the patient should drink adequate fluids to avoid dehydration. Forcing excess fluids is not advised because it does not promote spontaneous passage of stones in the urine. Forcing fluids may increase the pain or precipitate the development of renal colic.

Evidence-Based Practice

Preventing Recurrent Kidney Stones

You are caring for K.D. a 41-yr-old man who is being discharged home after successful kidney stone retrieval. This was his first kidney stone and he says it was "very painful." He asks you, "Can anything be done to prevent another stone?" You see on the chart that the stone was composed of calcium oxalate and that he has gout.

Making Clinical Decisions

Best Available Evidence. Increased fluid intake (about 3 L/day) to produce 2.5 L/day of urine decreases the risk for recurrent calcium stones in patients with a prior stone. Dietary calcium intake should be 1000 to 1200 mg/day. Addition of drugs (e.g., thiazide diuretics, potassium citrate, allopurinol) for persons with recurrent calcium stones can further reduce risk. Nutritional counseling (e.g., registered dietician) for these patients is recommended.

Clinician Expertise. You know risk factors for kidney stone formation include low fluid intake and having conditions such as gout, obesity, diabetes, and/or primary hyperparathyroidism. You understand preventive measures may decrease the chance of recurrent kidney stones after the first incidence.

Patient Preferences and Values. K.D. states it may be hard to increase his fluid intake and he wants to know if a drug is available instead.

Implications for Nursing Practice

1. Why is it important for K.D. to understand the link between increased fluid intake and stone recurrence?
2. How would you help him identify ways to increase his fluid intake?
3. How would you respond to K.D.'s request for a drug to prevent recurrence?

Reference for Evidence

Dion M, Ankawi G, Chew B, et al. CUA guideline on the evaluation and management of the kidney stone patient—2016 Update. *Can Urol Assoc J*. 2016;10:E347.

After an episode of urolithiasis, encourage a high fluid intake

(around 3 L/day) to produce a urine output of at least 2.5 L/day. High urine output prevents supersaturation of minerals (i.e., dilutes the concentration of urine) and promotes excretion of minerals within the urine, thus preventing stone formation. Increasing fluid intake is particularly important for patients at risk for dehydration, including those who (1) are active in sports, (2) live in a dry climate, (3) perform physical exercise, (4) have a family history of stone formation, or (5) work outside or in an occupation that requires a great deal of physical activity. Water is the preferred fluid. Limit consumption of colas, coffee, and tea because high intake of these beverages tends to increase the risk for recurring urinary stones.

A low-sodium diet is recommended, since high-sodium intake increases calcium excretion in the urine. Foods high in calcium, oxalate, and purines are shown in Table 45.12.

Strictures

A ureteral or urethral **stricture** is a narrowing of the lumen of the ureter or urethra.

Ureteral Strictures

Ureteral strictures can affect the entire length of the ureter, from the UPJ to UVJ. While these can be congenital, they are usually from adhesions or scar formation after surgery or radiation. They may be due to extrinsic factors, such as large tumors in the peritoneal cavity. Depending on its severity, ureteral obstruction can threaten the function of the kidney.

Manifestations include mild to moderate colic, flank pain and CVA tenderness. This pain may be moderate to severe in intensity, especially if the patient drinks a large volume of fluids, such as alcohol, over a brief period. Infection is unusual unless a stone or foreign object, such as a stent or nephrostomy tube, is present.

The discomfort and obstruction of a ureteral stricture may be temporarily bypassed by placing a stent using endoscopy or by diverting urinary flow via a nephrostomy tube inserted into the renal pelvis of the affected kidney. Definitive correction requires dilation with a balloon or catheter. If the stricture is severe or recurs after initial balloon or catheter dilation, it is surgically incised using an endoscopic procedure *(endoureterotomy).* In select patients, an open surgical approach may be needed to excise the stenotic area and reanastomose the ureter to the contralateral ureter *(ureteroureterostomy)* or to the renal pelvis. Alternatively, distal ureteral strictures may be treated by a *ureteroneocystostomy* (reimplantation of the ureter into the bladder wall).

Urethral Strictures

A *urethral stricture* is the result of fibrosis or inflammation of the

urethral lumen. Causes of urethral strictures include trauma, urethritis (particularly after gonococcal infection), surgical intervention or repeated catheterizations (iatrogenic), or a congenital defect of the urethra. Once the process of inflammation and fibrosis begins, the lumen of the urethra narrows and its compliance (ability to close or open in response to bladder filling or voiding) is compromised. Meatal stenosis, a narrowing of the urethral opening, is common.

Manifestations associated with a urethral stricture include a diminished force of the urinary stream, straining to void, sprayed stream, postvoid dribbling, or a split urine stream. The patient may report feelings of incomplete bladder emptying with urinary frequency and nocturia. Moderate to severe obstruction of the bladder outlet may lead to acute urinary retention. The patient may have a history of urethritis, difficulty with insertion of a urinary catheter, or trauma involving the penis or the perineum. However, many patients are unable to recall any such events, thus leading to a diagnosis of an idiopathic stricture. A history of UTI is common, particularly if the stricture involves the distal urethra. Retrograde urethrography (RUG), ultrasound urethrography, cystourethrogram, and VCUG are used to identify stricture length, location, and caliber.

Initial management focuses on dilation. A metal instrument (urethral sound) may be placed, or a series of progressively larger stents (filiforms and followers) can be placed into the urethra to expand its lumen in a stepwise fashion. Although this process is initially successful, stenosis often recurs. Recurrences may be managed by teaching the patient to repeatedly dilate the urethra by self-catheterization using a soft (coudé-tip, red rubber) catheter every few days. Alternatively, an endoscopic or open surgical procedure *(urethroplasty)* may be a more definitive therapy for an obstructive urethral stricture. Shorter strictures may be treated by resecting the fibrotic area followed by reanastomosis of the urethra. Longer strictures may require the use of a skin flap as a substitute urethral segment.

Renal Trauma

Renal trauma can be blunt or penetrating. *Blunt trauma* is the most common cause. Injury to the kidney should be considered in sports injuries, motor vehicle accidents, and falls. Renal trauma is especially likely when the patient injures the abdomen, flank, or back. Around 10% of patients with abdominal trauma also have renal trauma. *Penetrating injuries* may result from violent encounters (e.g., gunshot, stabbing incidents).

The severity of renal trauma depends on the extent of the injury. Obtain a history of trauma to the area of the kidneys. Gross or microscopic hematuria may be present. Diagnostic studies include urinalysis, ultrasound, CT, or MRI evaluation. Renal arteriography also may be done. Both the injured kidney and the uninvolved kidney should be evaluated. Treatments range from bed rest, fluids, and analgesia to exploratory surgery and repair or nephrectomy.[17]

Nursing interventions depend on the type of trauma and the extent of any associated injuries. Interventions related to renal trauma include (1) assess the cardiovascular status and monitor for shock, especially in a penetrating injury; (2) ensure adequate fluid intake and monitor intake and output; (3) provide for pain relief and comfort measures; and (4) assess for hematuria and myoglobinuria.

Renal Vascular Problems

Vascular problems involving the kidney include (1) nephrosclerosis, (2) renal artery stenosis, and (3) renal vein thrombosis.

Nephrosclerosis

Nephrosclerosis is sclerosis of the small arteries and arterioles of the kidney. The decreased blood flow results in ischemia, interstitial fibrosis, and necrosis of parts of the kidney. *Benign nephrosclerosis,* which usually occurs in adults older than 60 years of age, is caused by vascular changes from hypertension and atherosclerosis. Atherosclerotic vascular changes account for most of the loss of renal function associated with aging. The degree of nephrosclerosis is related to the severity of hypertension. In the early stages, the patient with benign nephrosclerosis may have normal renal function, with the only detectable abnormality being hypertension.

Accelerated nephrosclerosis (malignant nephrosclerosis) is associated with a significantly high BP, which can be as high as 300/150 mm/Hg, with small focal hemorrhages developing in the kidneys. It begins suddenly and is a medical emergency. It is characterized by systolic BP ≥180 and/or diastolic BP ≥120 mm/Hg with evidence of new or ongoing organ damage. Renal insufficiency progresses rapidly.

The availability and use of antihypertensive drugs have improved the prognosis for patients with benign and malignant nephrosclerosis. Treatment for benign nephrosclerosis is the same as that for essential hypertension (see Chapter 32). Malignant nephrosclerosis is treated with aggressive antihypertensive therapy. The prognosis for a patient with untreated or refractive malignant hypertension is poor. These conditions can lead to death.

Renal Artery Stenosis

Renal artery stenosis is a partial occlusion of 1 or both renal arteries and their major branches. It can be due to atherosclerotic narrowing or fibromuscular hyperplasia. Renal artery stenosis can be a cause of secondary hypertension.

When hypertension develops suddenly, renal artery stenosis should be considered, especially in patients under 30 or over 50 years of age and in those with no family history of hypertension. This contrasts with the age distribution for developing primary hypertension, which is 30 to 50 years of age.

Diagnostic tests used to assess for renal artery stenosis include a renal duplex Doppler ultrasonography, CT or MRI angiography, and renal arteriogram (the gold standard).

The goals of therapy are to control BP and restore perfusion to the kidney. Percutaneous transluminal renal angioplasty, with or without stenting, is the procedure of choice, especially in older patients who are poor surgical risks.

Surgical revascularization of the kidney is needed when decreased blood flow causes renal ischemia or when renovascular hypertension is present. Revascularization of the kidney may result in the patient's BP becoming normotensive. The surgical procedure usually involves anastomosis between the kidney and another major artery, usually the splenic artery or aorta. In certain cases of unilateral renal involvement, unilateral nephrectomy may be indicated.

Renal Vein Thrombosis

Renal vein thrombosis may occur unilaterally or bilaterally. Causes include trauma, extrinsic compression (e.g., tumor, aortic aneurysm), renal cell cancer, pregnancy, contraceptive use, and nephrotic syndrome.

The patient has flank pain, hematuria, fever, or nephrotic syndrome. Anticoagulation (e.g., heparin, warfarin [Coumadin]) is important to treat the high incidence of pulmonary emboli. Corticosteroids may be used for the patient with nephrotic syndrome. Surgical thrombectomy may be done instead of or along with anticoagulation.

Hereditary Kidney Diseases

Hereditary kidney diseases involve developmental abnormalities of the renal parenchyma. Most inherited structural abnormalities are cystic. However, cysts may develop because of obstructive uropathies, metabolic problems, or neurologic diseases. Cysts may be evaluated to rule out tumors.

Polycystic Kidney Disease

Polycystic kidney disease (PKD) is one of the most common life-threatening genetic diseases in the world. It affects 600,000 people in the United States. PKD is the fourth leading cause of ESRD, affecting 5% of those with ESRD. A nongenetic PKD (acquired cystic kidney disease [ACKD]) is seen in those with severe kidney scarring and damage who typically require dialysis. After 5 years on dialysis, 90% of patients will have ACKD.[18]

Genetic Link

PKD has 2 hereditary forms: one manifests in childhood and one in adulthood. The childhood form of PKD is a rare autosomal recessive disorder that is often rapidly progressive (see the Genetics in Clinical Practice box). The adult form of PKD is an autosomal dominant disorder and accounts for 90% of all PKD cases (see Figs. 12.4 and 12.5). If 1 parent has the disease, there is a 50% chance that the disease will pass to the child.

Genetics in Clinical Practice

Polycystic Kidney Disease (PKD)

	Adult	Child
Genetic basis	Autosomal dominant	Autosomal recessive
Incidence	1 in 400–1000	1 in 25,000
Gene location	• *PKD1* gene on chromosome 16 and *PKD2* gene on chromosome 4 • Genes code for polycystins (proteins that promote normal kidney development and function) • Mutations in genes lead to formation of thousands of cysts that disrupt the normal function of kidneys and other organs	• Polycystic kidney and hepatic disease *(PKHD1)* gene on chromosome 6 • Gene codes for fibrocystin • Mutations in gene leads to cyst formation
Genetic testing	DNA testing available	DNA testing available
Age of onset	Ages 30–40, but symptoms can start earlier	Infancy or childhood
Clinical implications	• Multisystem involvement • Systemic hypertension occurs in 60%–80% of patients • Increased risk for cerebral aneurysms • Families at risk should be screened	• Up to 30%–50% of affected newborns die shortly after birth • If infant survives the newborn period, chances of survival are good • One third need dialysis or transplantation by age 10 yr

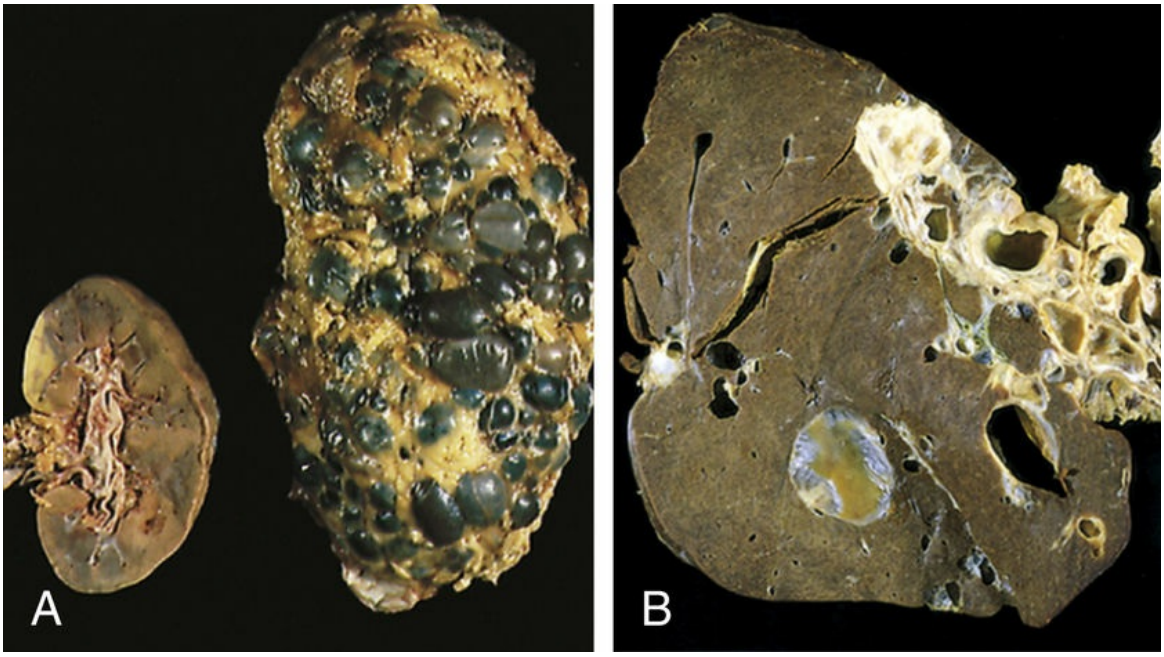

FIG 45.7 **A,** Comparison of polycystic kidney with normal kidney. **B,** Cysts in the liver.
A, From Brundage DJ: *Renal disorders,* St Louis, 1992, Mosby. *B,* From Kumar V, Abbas AK, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.

Adult PKD involves both kidneys and occurs in both men and women. The cortex and medulla are filled with large, thin-walled cysts that are several millimeters to several centimeters in diameter (Fig. 45.7). The cysts enlarge and destroy surrounding tissue by compression. The cysts are filled with fluid and may contain blood or

pus. PKD kidneys appear enlarged and look like they are filled with golf balls.

Adult PKD can be symptomless for many years. Signs and symptoms usually develop between 30 and 40 years of age.[18] Symptoms appear when the renal cysts begin to enlarge. Often the first manifestations are hypertension, hematuria (from rupture of cysts), or a feeling of pain or heaviness in the back, side, or abdomen. However, the first manifestation can be a UTI or urinary stones.

Chronic pain is the most common problem in persons with PKD. The pain can be constant and severe. Bilateral, enlarged kidneys are often palpable on physical examination. Many people have no symptoms, which can delay diagnosis.

PKD can affect the liver (liver cysts [Fig. 45.7]), heart (abnormal heart valves), blood vessels (aneurysms), and intestines (diverticulosis). The most serious complication is a cerebral aneurysm, which can rupture.

Diagnosis is based on manifestations, family history, ultrasound (best screening measure), or CT scan (provides more precise images). The disease usually progresses from loss of kidney function to ESRD by age 60 in 50% of patients.[18]

Interprofessional and Nursing Care

There is no cure for PKD at present. A major aim of treatment is to prevent or treat infections of the urinary tract. Nephrectomy may be done if pain, bleeding, or infection becomes a chronic, serious problem. Dialysis and kidney transplant may be needed to treat ESRD (see Chapter 46).

When the patient begins to have progressive renal failure, the interventions depend on the remaining renal function. Nursing measures are those used for management of ESRD. They include diet modification, fluid restriction, drugs (e.g., antihypertensives), and help for the patient and family in coping with the chronic disease process and financial concerns.

The patient who has adult PKD often has children by the time the

disease is diagnosed. The patient needs appropriate counseling about plans for having more children. Genetic counseling should be provided for the children. More resources can be found at the PKD Foundation website (*www.pkdcure.org*).

Check Your Practice

You are doing a rotation in the dialysis unit. You have been doing vital sign checks on a 45-yr-old man who receives dialysis 3 times/wk. When you ask him why he is on dialysis, he tells you that he has polycystic kidney disease. After further discussion, he tells you that he has 1 son who is now 23 years old, but they are estranged. He does not want to tell him about his medical problems or why he is on dialysis.

- How would you respond to this patient?

Medullary Cystic Disease

Medullary cystic disease is a hereditary disorder that occurs in older adults. Most cysts occur in the medulla. The kidneys are asymmetric in shape and are significantly scarred. Defects in the kidneys' concentrating ability result in polyuria. Other manifestations include hypertension, progressive renal failure, severe anemia, and metabolic acidosis. Genetic counseling may be helpful in family planning. Treatment measures are those related to ESRD (see Chapter 46). A similar disease, familial juvenile nephronophilisis, is found in young children. It can also affect the nervous system and eyes.

Alport Syndrome

Alport syndrome, also known as *chronic hereditary nephritis,* is an inherited disease that primarily affects the glomeruli. The basic defect is a mutation in a gene for collagen that results in altered synthesis of the glomerular basement membrane.[19]

There are 3 genetic types of Alport syndrome: sex-linked, autosomal recessive type, and autosomal dominant type. In sex-linked, the most common type, the earliest manifestation is hematuria. These patients have progressive hearing loss and deformities of the lens of the eye. The other types of Alport syndrome cause hematuria but not deafness or lens deformities.

Males are affected earlier and more severely than females. The disease is often diagnosed in the first decade of life. Alport syndrome causes progressive kidney damage, leading to ESRD. Children with the autosomal recessive type usually develop ESRD by their teens or young adult years. People with autosomal dominant Alport syndrome usually live well into middle age before ESRD develops.

As there is no specific treatment currently available, treatment measures are supportive. Corticosteroids and cytotoxic drugs are not effective. Kidney transplantation is usually successful in people with Alport syndrome and is considered the best treatment. The disease does not recur after kidney transplantation.

Urinary Tract Tumors

Kidney Cancer

Tumors that arise from the cortex, pelvis, or calyces may be benign or cancerous. *Kidney cancer* is more common. In the United States, about 65,340 new cases of kidney cancer are diagnosed each year, and about 14,970 people die from kidney cancer.[20]

Most cases of kidney cancer are renal cell carcinomas (adenocarcinoma) (Fig. 45.8). It occurs twice as often in men as in women. The average age at diagnosis is 64 years. It is uncommon in those under 45 years old. Smoking and obesity are significant risk factors. An increased incidence is found in first-degree relatives of people who have or had renal cell cancer. Other risk factors include ACKD, hypertension, and exposure to asbestos, cadmium, and gasoline.

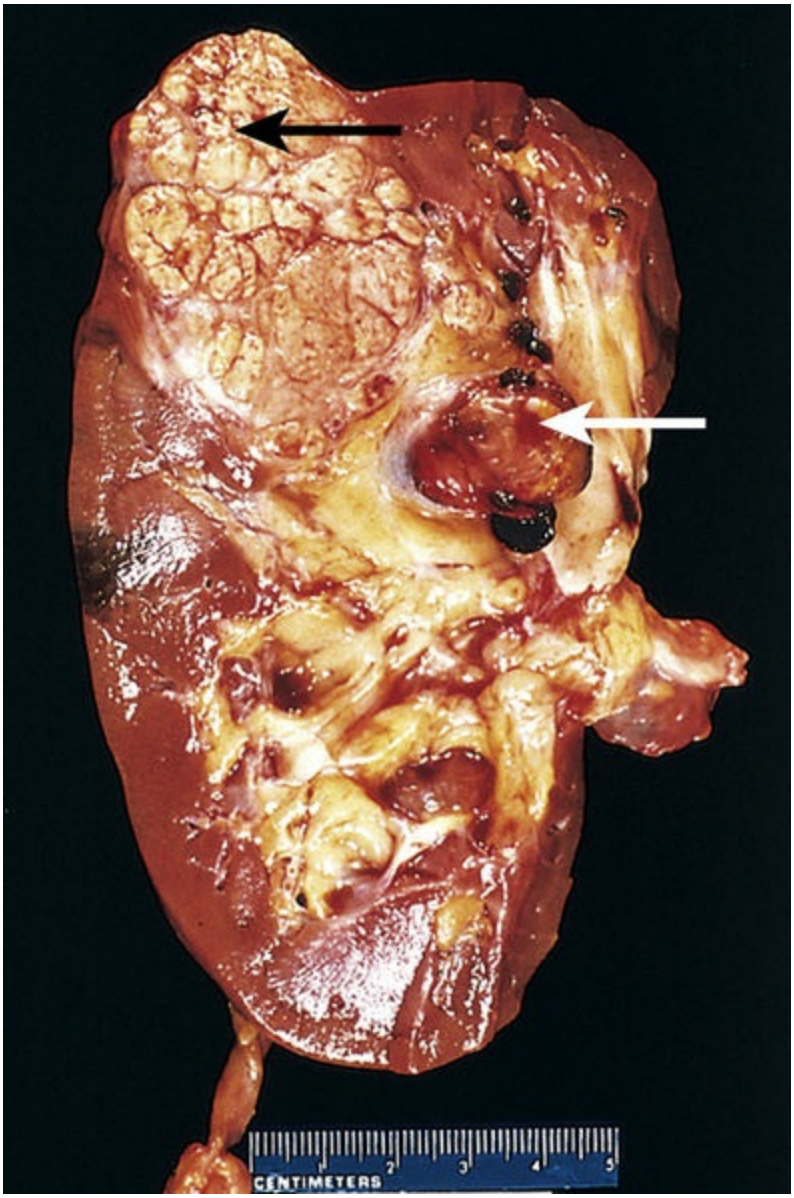

FIG 45.8 Cross section of kidney with renal cell cancer. The cancer *(black arrow)* is on the pole of the kidney. Note that the renal vein is involved and thrombosed *(white arrow).*
From Kumar V, Abbas AK, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.

Clinical Manifestations and Diagnostic Studies

Early-stage kidney cancer usually has no symptoms, so many patients go undiagnosed until the disease has significantly progressed. Many kidney cancers are diagnosed as incidental findings on imaging

studies used to evaluate symptoms for unrelated conditions.

Kidney tumors can cause symptoms by compressing, stretching, or invading structures near or within the kidney. The most common presenting symptoms are hematuria and flank pain. Other manifestations include weight loss, fever, hypertension, hypercalcemia, and a palpable mass in the flank or abdomen. A varicocele may be present.

About 33% of patients have metastasis at the time of diagnosis. Local extension of kidney cancer into the renal vein and vena cava is common (Fig. 45.8). The most common sites of metastases include lungs, liver, and long bones.

CT scan is often used in the diagnosis and can detect small kidney tumors. Ultrasound examinations have improved the ability to determine between a solid mass tumor and a cyst. This is significant because most masses detected on imaging are cysts. Angiography, biopsy, and MRI are used in the diagnosis of renal tumors. Radionuclide isotope scanning can detect metastases.

Interprofessional and Nursing Care

Preventive measures, including quitting smoking, maintaining a healthy weight, controlling BP, and reducing exposure to toxins, can help reduce the incidence of kidney cancer. Patients in high-risk groups should be aware of their increased risk for kidney cancer. Teach them about early manifestations (e.g., hematuria, hypertension). A cure for kidney cancer may be possible when it is detected early and treated.

Interprofessional care of the patient with kidney cancer is outlined in Table 45.14. Staging of kidney cancer provides a basis for determining treatment options. The following is a simple description of staging of kidney cancer:

Stage I: The tumor can be up to 7 cm in diameter and is confined to the kidney.

Stage II: The tumor is larger than a stage I tumor and is still

confined to the kidney.

Stage III: The tumor extends beyond the kidney to the surrounding tissue and may have spread to a nearby lymph node.

TABLE 45.14 Interprofessional CareRenal Cancer

Diagnostic Assessment

- History and physical examination
- Urinalysis
- Ultrasound
- Abdominal CT scan
- MRI
- Renal biopsy
- Renal scan
- Angiography

Management

- Surgical therapy
  - Partial nephrectomy
  - Radical nephrectomy
- Ablation
- Cryoablation
  - Radiofrequency ablation
- Radiation therapy
- Chemotherapy
- Immunotherapy
- Targeted therapy

Stage IV: Cancer spreads outside the kidney to multiple lymph nodes or to distant parts of the body, such as bones, brain, liver, or lung.

The treatment of choice for some kidney cancers is a partial nephrectomy (for smaller tumors), simple total nephrectomy, or a radical nephrectomy (for larger tumors). Radical nephrectomy

involves removal of the kidney, adrenal gland, surrounding fascia, part of the ureter, and draining lymph nodes. Nephrectomy can be performed by a conventional (open) approach or laparoscopically (see discussion of nephrectomy on p. 1053). Other treatment options include cryoablation (freezing technique) and radiofrequency ablation (destroying tumor by using radiofrequency heat). These procedures can be used when surgery is not an option (e.g., patient has co-morbid conditions) and for small renal tumors.

Kidney cancer is relatively resistant to most chemotherapy drugs. While kidney cancer can be resistant to radiation therapy, it may be useful in certain situations, such as metastasis to bone or lungs.

Immunotherapy, including α-interferon and interleukin-2 (IL-2), is another treatment option in metastatic disease. (The use of α-interferon and IL-2 is discussed in Chapter 15.) Another type of drug used as immunotherapy is nivolumab (Opdivo). This drug targets PD-1, a protein on T cells that normally helps keep these cells from attacking other cells in the body. By blocking PD-1, this drug boosts the immune response against cancer cells. This can shrink some tumors or slow their growth.

Targeted therapy is another treatment option for metastatic kidney cancer. Kinase inhibitors, a class of targeted therapies, block certain proteins (kinases) that play a role in tumor growth and cancer progression. Kinase inhibitors include sunitinib (Sutent), sorafenib (Nexavar), cabozantinib (Cabometyx), and axitinib (Inlyta). Bevacizumab (Avastin), sunitinib (Sutent), and pazopanib (Votrient) inhibit the formation of new blood vessel growth to the tumor. Temsirolimus (Torisel) and everolimus (Afinitor) inhibit a specific protein known as the mechanistic target of rapamycin (mTOR).[21] These drugs are discussed in Table 15.13. The mechanisms of action are shown in Fig. 15.16.

The diagnosis of kidney cancer is devastating. Often the disease may already be metastasized by the time a person is diagnosed. The nursing care of the patient with cancer is discussed in Chapter 15.

Bladder Cancer

Bladder cancer is the most common cancer of the urinary system.[22] About 81,190 new cases of bladder cancer are diagnosed annually, and about 17,240 deaths related to bladder cancer are reported every year. Cancer of the bladder is most common in older adults; 90% of cases occur in those over the age of 55. Bladder cancer is far more common in men than in women and in whites than in blacks or Hispanics.[23]

The most frequent cancerous tumor of the urinary tract is transitional cell cancer of the bladder. Most bladder tumors are papillomatous growths within the bladder (Fig. 45.9).

About half of bladder cancers are related to cigarette smoking. Other risk factors include exposure to dyes used in the rubber and other industries. Others at risk include women treated with radiation for cervical cancer; patients who received cyclophosphamide, docetaxel, or gemcitabine; and those who have indwelling catheters for long periods.[22] People with chronic, recurrent urinary tract stones, often in the bladder, and chronic lower UTIs have an increased risk for squamous cell cancer of the bladder.

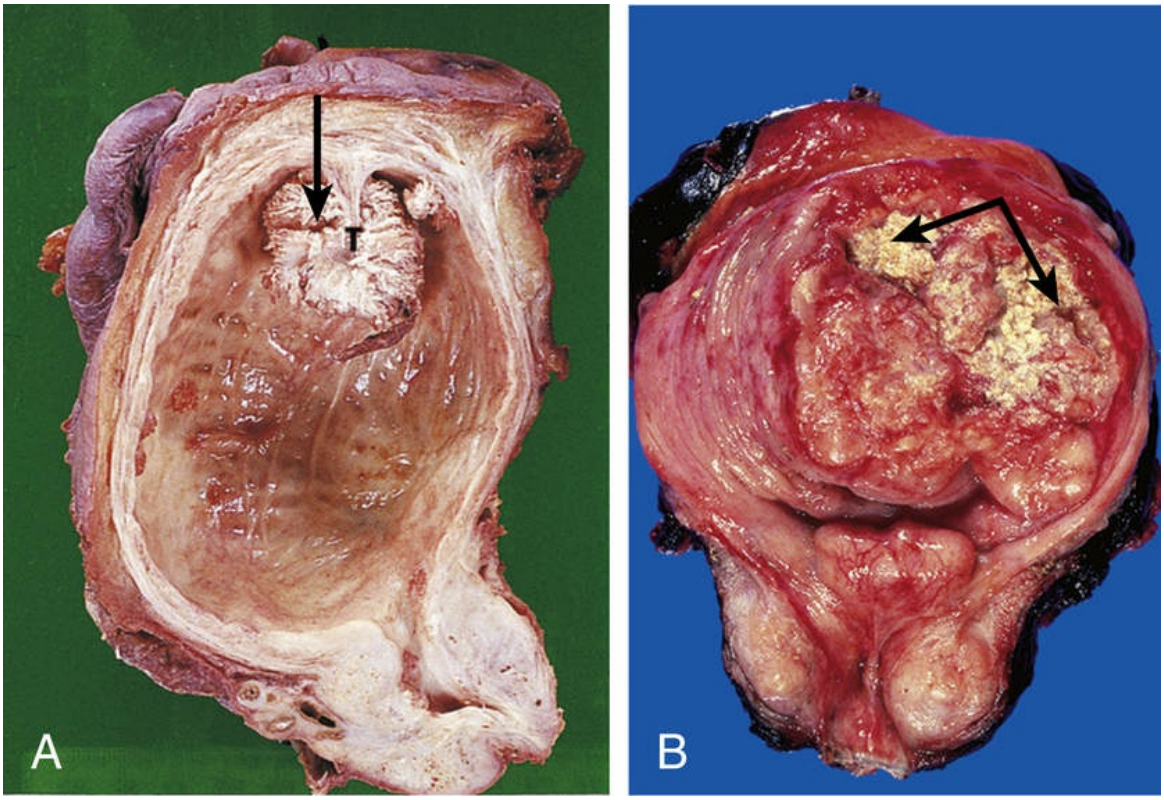

FIG 45.9 **A,** Papillary transitional cell cancer *(T)* seen arising from the dome of the bladder as a cauliflower-like lesion *(arrow).* **B,** Opened bladder showing advanced stage bladder cancer. Yellow areas are ulcerations and necrosis *(arrows).*
A, From Stevens A, Lowe J: *Pathology: Illustrated review in colour,* ed 2, London, 2000, Mosby. *B,* From Kumar V, Abbas AK, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.

Clinical Manifestations and Diagnostic Studies

Microscopic or gross, painless hematuria (chronic or intermittent) is the most common manifestation of bladder cancer. Bladder irritability with dysuria, frequency, and urgency may occur.

When cancer is suspected, obtain urine specimens to identify any cancer or atypical cells. Exfoliated cells from the bladder's epithelial surface can be detected in voided specimens. Other urine tests assess for specific factors associated with bladder cancer, such as bladder tumor antigens. Bladder cancers can be detected using CT, ultrasound, or MRI. The presence of cancer is confirmed by

cystoscopy and biopsy.[24]

Nursing and Interprofessional Management: Bladder Cancer

Most bladder cancers are diagnosed at an early stage when the cancer is treatable. Before treatment is started, bladder cancers are graded based on the cell type and staged based on the extent and invasiveness of the cancer. We use a grading system to classify the cancerous potential of tumor cells, using a scale from well differentiated (closely resembling the normal tissue) to undifferentiated (poorly differentiated) (see p. 239 in Chapter 15).

The clinical staging of bladder cancer is determined by the depth of invasion of the bladder wall and surrounding tissue. The following is a simple description of staging of bladder cancer:

Stage I: Cancer is in the inner lining of the bladder but has not invaded the bladder muscle wall.
Stage II: Cancer has invaded the bladder wall but is still confined to the bladder.
Stage III: Cancer has spread through the bladder wall to surrounding tissue. It may have spread to the prostate in men or the uterus or vagina in women.
Stage IV: Cancer has spread to the lymph nodes and other organs, such as lungs, bones, or liver.

TABLE 45.15 Interprofessional CareBladder Cancer

Diagnostic Assessment

- History and physical examination
- Urinalysis

- Urine cytology studies
- Cystoscopy with biopsy
- Ultrasound
- CT scan

Management

- Surgical therapy
    - Transurethral resection with fulguration
    - Laser photocoagulation
    - Open loop resection with fulguration
    - Cystectomy (segmental, partial, or radical)
- Radiation therapy
- Intravesical immunotherapy
    - Bacille Calmette-Guérin (BCG)
    - α-interferon (Intron A)
- Intravesical chemotherapy
    - doxorubicin
    - epirubicin
    - gemcitabine
    - mitomycin
    - thiotepa
    - valrubicin (Valstar)
- Systemic chemotherapy and immunotherapy

Interprofessional care of bladder cancer includes surgery, radiation, chemotherapy, and intravesical therapy (Table 45.15).

Surgical Therapy

Surgical therapies include a variety of procedures. *Transurethral resection of the bladder tumor* (TURBT) is used for superficial lesions of the bladder's inner lining. The HCP uses a wire loop inserted through

the cystoscope to remove the tumor and tissue, which are sent for pathologic evaluation. The base can be treated by fulguration, which burns the base of the tumor, or by use of a high-energy laser to kill the cancer cells. This procedure is also used to control bleeding in the patient who is a poor operative risk or who has advanced tumors. The primary disadvantages of this approach are reoccurrence of the bladder cancer at another site and potential for scarring and/or limited ability to hold urine with repeated TURBT procedures.[25]

A *segmental cystectomy (partial cystectomy)* is used to treat larger tumors or those that involve only 1 area of the bladder. The part of the bladder wall containing the tumor is removed along with a margin of normal tissue.

When the tumor is invasive or involves the trigone (the area where the ureters insert into the bladder) and the patient is free from metastasis beyond the pelvic area, a radical cystectomy is the treatment of choice. A *radical cystectomy* involves removal of the bladder, prostate, and seminal vesicles in men and the bladder, uterus, cervix, urethra, anterior vagina, and ovaries in women. After a radical cystectomy, a new way must be created for urine to leave the body. This surgical technique is called a *urinary diversion* (discussed later in this chapter).[25]

Postoperative instructions for any of these procedures include drinking a large volume of fluid for the first week after the procedure. Teach the patient to monitor the color and consistency of the urine. The urine is pink for the first several days after the procedure, but it should not be bright red or contain blood clots. For 7 to 10 days after tumor resection, the patient may see dark red or rust-colored flecks in the urine. These may be from the healing tumor resection site.

Give opioid analgesics and stool softeners for a brief period after the procedure. Help the patient and family cope with fears about cancer, surgery, and sexuality. Emphasize the importance of regular follow-up care. Follow-up cystoscopies are needed on a regular basis after surgery for bladder cancer.

Radiation Therapy, Chemotherapy, and

Immunotherapy

Radiation therapy can be used in combination with cystectomy or as the primary therapy when the cancer is inoperable or the patient refuses surgery. Chemotherapy drugs and immunotherapy can be used to treat bladder cancer.

Intravesical Therapy

Chemotherapy with local instillation of immunotherapy or chemotherapy can be delivered directly into the bladder by a urethral catheter.[24] *Intravesical therapy* is usually started at weekly intervals for 6 to 12 weeks. The drug is instilled directly into the patient's bladder and retained for about 2 hours. The patient's bladder must be empty before instillation. Change the patient's position every 15 minutes during the instillation for maximum contact in all areas of the bladder. Maintenance therapy after the initial induction regimen may be beneficial.

Bacille Calmette-Guérin (BCG), a weakened strain of *Mycobacterium bovis,* is the treatment of choice for carcinoma in situ. BCG stimulates the immune system rather than acting directly on cancer cells in the bladder. When BCG fails, α-interferon, in addition to BCG, may be used. Other treatments that can be used when BCG fails include mitomycin, epirubicin, gemcitabine, valrubicin, and thiopeta (an alkylating agent).[24]

Most patients have irritative voiding symptoms and hemorrhagic cystitis after intravesical therapy. Thiotepa can significantly reduce WBC and platelet counts in some people when absorbed into the circulation from the bladder wall. BCG may cause flu-like symptoms, increased urinary frequency, hematuria, or systemic infection. Other side effects of chemotherapy (e.g., nausea, vomiting, hair loss) do not occur with intravesical chemotherapy.

Encourage patients to increase their daily fluid intake and to quit smoking. Assess the patient for secondary UTI and stress the need for routine urologic follow-up. The patient may have fears or concerns about sexual activity or bladder function that must be addressed.

Because of the high rate of disease recurrence and progression in bladder cancer, follow-up studies are important.

Bladder Dysfunction

Urinary Incontinence

Urinary incontinence (UI) is an involuntary leakage of urine. Although incontinence is more prevalent among older adults, it is not a natural consequence of aging. UI has traditionally been viewed as a social or hygienic problem. It has a major effect on quality of life and contributes to serious health problems, especially in older adults.

Gender Differences

Urinary Incontinence

Men

- A common manifestation of BPH and prostate cancer in men
- More likely to have overflow incontinence caused by urinary retention

Women

- Prevalence of UI is higher in women than men
- More likely to have stress and urge incontinence than men

Etiology and Pathophysiology

UI occurs when bladder pressure exceeds urethral closure pressure. Anything that interferes with bladder or urethral sphincter control can result in UI. Using the acronym *DRIP,* the causes can include *D:* delirium, dehydration, depression; *R:* restricted mobility, rectal impaction; *I:* infection, inflammation, impaction; and *P:* polyuria,

polypharmacy. Patients may have more than 1 type of incontinence (Table 45.16). The combination of stress and urge incontinence is referred to as mixed incontinence.

Diagnostic Studies

The basic evaluation for UI includes a focused history, physical assessment, and bladder log or voiding record whenever possible. Obtain information related to the onset of UI, factors that provoke urinary leakage, and associated conditions. Pay special attention to factors known to produce transient UI, particularly when the onset of urine loss is sudden. Whenever possible, ask the patient to keep a bladder log or voiding diary documenting the timing of urinations, episodes of urinary leakage, and frequency of nocturia for a period of 1 to 7 days (minimum of 3 days if possible). This record can be kept by nursing staff if the person is in an inpatient or long-term care facility.

Begin the physical examination with an assessment of general health and functional issues associated with urination, including mobility, dexterity, and cognitive function. A pelvic examination includes careful inspection of the perineal skin for signs of erosion or rashes related to UI and existence of pelvic organ prolapse. Assess local innervation and pelvic floor muscle strength, including a digital examination of the pelvic floor muscle to determine weakness or tension.

A urinalysis can identify factors contributing to transient UI (e.g., UTI, diabetes). Measure postvoid residual (PVR) urine in the patient undergoing evaluation for UI. The PVR volume is obtained by asking the patient to void, followed by catheterization or use of a bladder ultrasound (preferably within 10 to 20 minutes).

Urodynamic testing is needed in select cases of UI. Imaging studies of the upper urinary tract (e.g., ultrasound) are done when UI is associated with UTIs or evidence of upper urinary tract involvement.

Interprofessional Care

Many cases of UI can be cured or significantly improved. Transient,

reversible factors are first corrected, followed by management of the type of UI (Table 45.16). In general, less invasive treatments are tried before more invasive methods (e.g., surgery). Nevertheless, the choice of the initial treatment is patient specific, based on patient preference, the type and severity of UI, and associated anatomic defects.

Several behavioral therapies may be used to improve UI (Table 45.17). Pelvic floor muscle training (Kegel exercises) is used to manage stress, urge, or mixed UI (Table 45.18).[26] Biofeedback can help the patient identify, isolate, contract, and relax the pelvic muscles (see the Complementary & Alternative Therapies box).

Complementary & Alternative Therapies

Biofeedback

Scientific Evidence

Biofeedback is helpful in treating a variety of medical conditions: urinary incontinence, asthma, Raynaud's disease, irritable bowel syndrome, hot flashes, headaches, hypertension, seizure disorders, and nausea and vomiting associated with chemotherapy.

Nursing Implications

- Feedback from monitoring equipment can teach patients to control certain involuntary body responses, such as urinary incontinence.
- Although biofeedback is considered safe, patients should consult a qualified professional before using biofeedback.

Drug Therapy

Drug therapy varies according to the UI type (Table 45.19). In stress UI, drugs have a limited role in the management. Bladder sphincter tone and urethral resistance can be increased with α-adrenergic agonists, but they have limited benefit. In urge and reflex UI, drugs

play a key role.

Anticholinergic drugs (muscarinic receptor blockers) block the action of acetylcholine at muscarinic receptors. They relax the bladder muscle and inhibit overactive detrusor contractions (Table 45.19). Side effects include dry mouth and eyes, constipation, blurred vision, and sleepiness.

Botox (onabotulinumtoxin A) can be used to treat UI from detrusor overactivity. Botox is injected into the bladder, resulting in relaxation of the bladder, an increase in its storage capacity, and a decrease in UI.

Drug Alert

Antimuscarinic Agents

- Overdosage can result in severe anticholinergic effects.
- These effects include GI cramping, diaphoresis, eye pain, blurred vision, and urinary urgency.

Surgical Therapy

Surgical techniques vary depending on the type of UI. Surgical correction of stress UI is aimed at making the urinary structures more receptive to intraabdominal pressure and augmenting the urethral resistance of the internal sphincter. It may involve repositioning the urethra and/or creating a backboard of support to stabilize the urethra and bladder neck and make them more receptive to changes in intraabdominal pressure. Another technique for stress UI augments the urethral resistance of the intrinsic sphincter with a sling or periurethral injectable.

Retropubic colposuspension and pubovaginal sling placement appear to be most effective. Typically, both procedures are done through low transverse incisions. Complications specific to the retropubic suspensions include postoperative voiding dysfunction, urgency, and vaginal prolapse.

Placement of a suburethral sling, using the person's own fascia, cadaveric fascia, or a synthetic material, can correct stress UI in women. Complications include vascular and bowel injury, urinary retention, mesh or sling erosion, infection, urgency, and bladder perforation. Suburethral slings have success rates comparable to those of colposuspension or slings and are associated with shorter recovery periods. An artificial urethral sphincter can be used in men with intrinsic sphincter deficiency and severe stress UI.

TABLE 45.16 Types of Urinary Incontinence

Description	Causes	Treatment
Functional Incontinence		
• **Loss of urine resulting from cognitive, functional, or environmental factors**	• Older adults often have problems that affect balance and mobility (e.g., severe arthritis) • Cognitive problems (e.g., dementia)	• Modifying the environment or care plan to facilitate regular, easy access to toilet and promote patient safety • Includes better lighting, ambulatory assistance equipment, clothing alterations, timed voiding, different toileting equipment
Incontinence After Trauma or Surgery		
• **In women, vesicovaginal or urethrovaginal fistula may occur** • **In men, change in continence involves proximal urethral sphincter (bladder neck and prostatic urethra) and distal urethral sphincter (external striated muscle)**	• Fistulas may occur during pregnancy, after delivery of baby, after hysterectomy or invasive cancer of cervix, or after radiation therapy • Incontinence is a postoperative complication of transurethral, perineal, or retropubic prostatectomy	• External condom catheter • Penile clamp • Placement of artificial implantable sphincter • Surgery to correct fistula • Urinary diversion surgery to bypass urethra and bladder
Overflow Incontinence		
• **Occurs when pressure of urine in overfull bladder overcomes sphincter control** • **Leakage of small amounts of urine is frequent throughout day and night** • **Urination may occur frequently in small amounts** • **Bladder stays distended and is usually palpable**	• Caused by bladder or urethral outlet obstruction (bladder neck obstruction, urethral stricture, pelvic organ prolapse) or by underactive detrusor muscle caused by myogenic or neurogenic factors (e.g., herniated disc, diabetic neuropathy) • May occur after anesthesia and surgery (e.g., hemorrhoidectomy, herniorrhaphy, cystoscopy) • Neurogenic bladder (flaccid type).	• Urinary catheterization to decompress bladder • Use Credé or Valsalva maneuver • α-Adrenergic blockers (Table 45.19) • 5α-Reductase inhibitors (Table 45.19) to decrease outlet resistance • Bethanechol (Urecholine) to enhance bladder contractions • Intermittent catheterization • Intravaginal device, such as a pessary, to support prolapse • Surgery to correct underlying problem
Reflex Incontinence		
• **Condition occurs when no warning or stress precedes periodic involuntary urination** • **Urination is frequent, moderate in volume, and occurs equally during day and night**	• Spinal cord lesion above S2 interferes with central nervous system inhibition • Disorder results in detrusor hyperreflexia and interferes with pathways coordinating detrusor contraction and sphincter relaxation	• Treat underlying cause • Bladder decompression to prevent ureteral reflux and hydronephrosis • Intermittent self-catheterization • Baclofen or diazepam to relax external sphincter • Prophylactic antibiotics • Surgical sphincterotomy
Stress Incontinence		
• **Sudden increase in intraabdominal pressure causes involuntary passage of urine** • **Can occur during coughing, laughing, sneezing, or physical activities, such as heavy lifting, exercising** • **Leakage usually is in small amounts and may not be daily**	• Most common in women with relaxed pelvic floor musculature (from delivery, use of instrumentation during vaginal delivery, or multiple pregnancies) • Structures of female urethra atrophy when estrogen decreases • Prostate surgery for BPH or prostate cancer	• Pelvic floor muscle exercises (e.g., Kegel exercises), weight loss if obese, cessation of smoking, topical estrogen products, external condom catheters or penile incontinence clamp in men, surgery • Urethral inserts, patches, or bladder neck support devices (e.g., incontinence pessary) to correct underlying problem
Urge Incontinence		

• **Often referred to as overactive bladder**
• **Occurs randomly when involuntary urination is preceded by urinary urgency**
• **Leakage is periodic but frequent and usually in large amounts**
• **Nocturnal frequency and incontinence are common**
	• Caused by uncontrolled contraction or overactive detrusor muscle
	• Bladder escapes central inhibition and contracts reflexively
	• Conditions include:
	  • Nervous system disorders (e.g., stroke, Alzheimer's disease, brain tumor, Parkinson's disease)
	  • Bladder disorders (e.g., carcinoma in situ, radiation effects, interstitial cystitis)
	  • Interference with spinal inhibitory pathways (e.g., cancer in spinal cord, spondylosis)
	  • Bladder outlet obstruction or conditions of unknown cause
		• Treat underlying cause
		• Biobehavioral interventions (bladder retraining with urge suppression, decrease in dietary irritants, bowel regularity, pelvic floor muscle exercises)
		• Anticholinergic drugs (Table 45.19)
		• Calcium channel blockers (Table 45.19)
		• mirabegron (Myrbetriq)
		• Vaginal estrogen creams
		• Containment devices (e.g., external condom catheters)
		• Absorbent products

TABLE 45.17 Interventions for Urinary Incontinence

Intervention	Description
Lifestyle Modifications	Self-management to reduce or eliminate risk factors, including: • Smoking cessation • Weight reduction • Good bowel regimen • Reduction of bladder irritants (e.g., caffeine, aspartame artificial sweetener, citrus juices) • Fluid modifications for those with urge incontinence
Scheduled Voiding Regimens	
Bladder retraining and urge-suppression strategies	Scheduled toileting with progressive voiding intervals. Includes teaching of urge-control using relaxation and distraction techniques, self-monitoring, reinforcement techniques, and other strategies, such as conscious contraction of pelvic floor muscles.
Habit retraining	Scheduled toileting with adjustments of voiding intervals (longer or shorter) based on the person's voiding pattern.
Prompted voiding	Scheduled toileting that requires prompts to void from a caregiver (typically every 3 hr). Used in conjunction with operant conditioning techniques to reward people for maintaining continence and appropriate toileting.
Timed voiding	Toileting on a fixed schedule (typically every 2–3 hr during waking hours).
Pelvic Floor Muscle Rehabilitation	
Biofeedback	See Complementary & Alternative Therapies box on p. 1046.
Electrical stimulation	Application of low-voltage electric current to sacral and pudendal afferent fibers through vaginal, anal, or surface electrodes. Used to inhibit bladder overactivity and improve awareness, contractility, and efficiency of pelvic muscle contraction.
Pelvic floor muscle (Kegel) exercises or training	Table 45.18.
Vaginal weight training	Active retention of vaginal weights (devices designed and shaped to exercise and strengthen pelvic floor muscles) at least twice a day. Typically used in combination with pelvic floor muscle exercises.
Anti-Incontinence Devices	
Incontinence clamps (penile compression devices)	Mechanical fixed compression applied to the penis to prevent any flow or leakage via the urethra. Must be released to void.
Intraurethral occlusive device (urethral plug)	Single-use device that is worn in the urethra to provide mechanical obstruction to prevent urine leakage. Removed for voiding.
Intraurethral valve pump	Replaceable urinary prosthesis for use in women who have impaired detrusor contractility (cannot contract muscles to push urine out of the bladder). Draws urine out to empty bladder and blocks urine flow when continence is desired.
Intravaginal support devices (pessaries and bladder neck support prostheses)	Devices support bladder neck, relieve minor pelvic organ prolapse, and change pressure transmission to the urethra.
Containment Devices	
Absorbent products	Variety of reusable and disposable pads and undergarment systems.
External collection devices	External catheter (condom) systems (e.g., penile sheaths) direct urine into a drainage bag. Most often used by men.

A bulking agent can be injected underneath the mucosa of the urethra to correct stress UI in women or men. Bulking agents include glutaraldehyde cross-linked bovine collagen (GAX collagen), autologous fat, carbon beads, carbon hydroxyapatite, and polydimethylsiloxane injections. Although treatment with bulking agents avoids the risk associated with open surgery, reinjection is typically needed after several years.

In artificial sphincter surgery, the bladder sphincter that no longer

works is replaced with an artificial one. A silicone inflatable ring is placed around the urethra (internally), and the patient inflates it to stop the flow and deflates it when the need to empty occurs. The patient must be able to work the pump that is placed internally. This procedure is usually used only as a last resort in a patient who is cognitively aware and able to use the artificial sphincter.[27]

Nursing Management: Urinary Incontinence

It is important to recognize both the physical and emotional problems associated with UI. Maintain and enhance the patient's dignity, privacy, and feelings of self-worth. This involves a 2-step approach with (1) containment devices to manage existing urinary leakage and (2) a definitive plan to reduce or resolve the factors leading to UI.

Check Your Practice

You are doing BP and glucose screening at the community senior center. While you are checking the BP on a 78-yr-old woman, she starts to sob quietly. You tell her that her BP is 134/84 and gently place your hand on her arm. You ask her what is wrong. She tells you, "I have to pee all the time. I soak the bed and my husband won't sleep with me anymore. I am washing sheets and my clothes all the time. Our whole house smells like urine."

- How would you respond to her?

TABLE 45.18 Patient TeachingPelvic Floor Muscle (Kegel) Exercises

Include the following instructions when teaching the patient to perform Kegel exercises:

What Is the Pelvic Floor Muscle?

- Your pelvic floor muscle provides support for your bladder and rectum and, in women, the vagina and uterus.

- If it weakens or is damaged, it cannot support these organs and their position can change.
- This causes problems with the normal bladder and rectal function.
- If you have a weak pelvic floor muscle, you may want to do special exercises to make the muscle stronger, prevent unwanted urine leakage, and lessen urinary urgency.

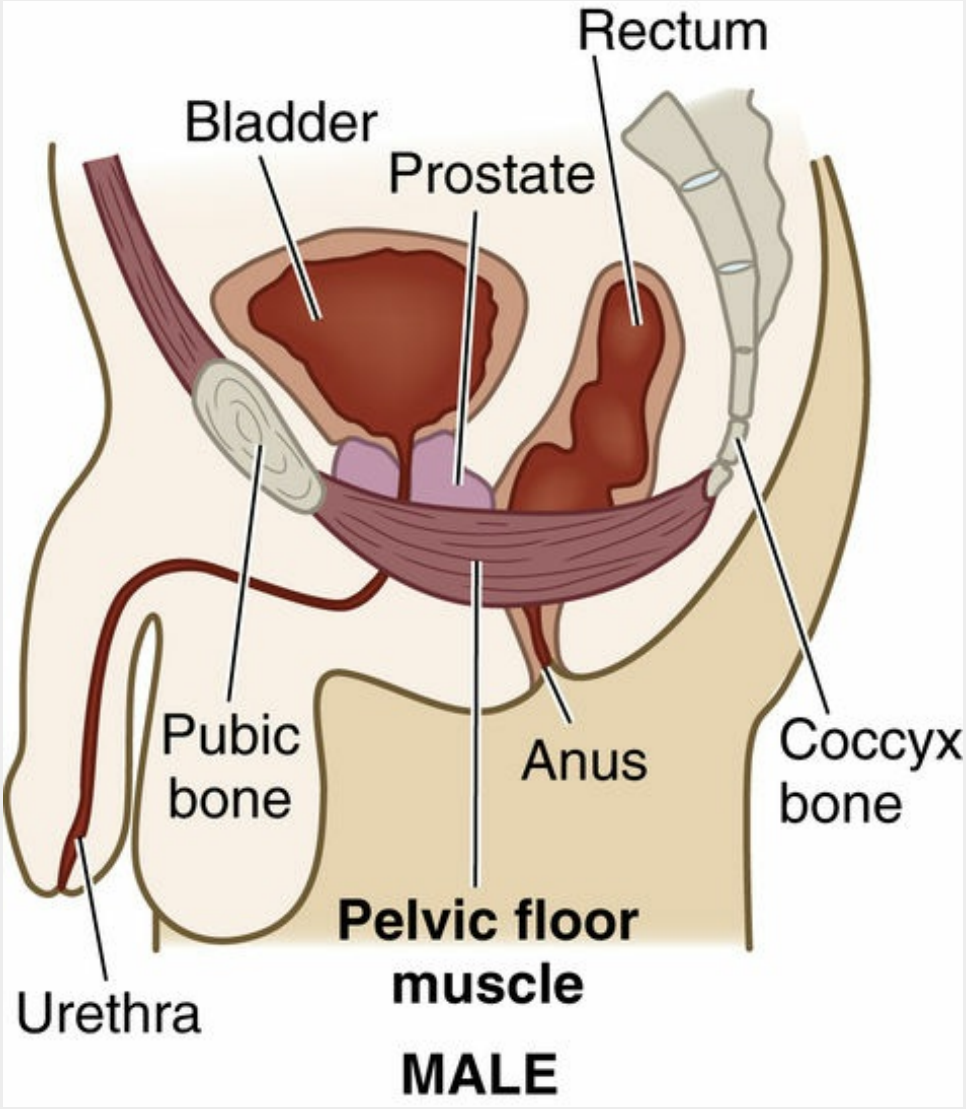
Finding the Pelvic Floor Muscle

- Without tensing the muscles of your leg, buttocks, or abdomen, imagine that you are trying to control the passing of gas or pinching off a stool.
- Or imagine you are in an elevator full of people and you feel the urge to pass gas. What do you do?
- You tighten or pull in the ring of muscle around your rectum—your pelvic floor muscle.
- You should feel a lifting sensation in the area around the vagina or a pulling in of your rectum.

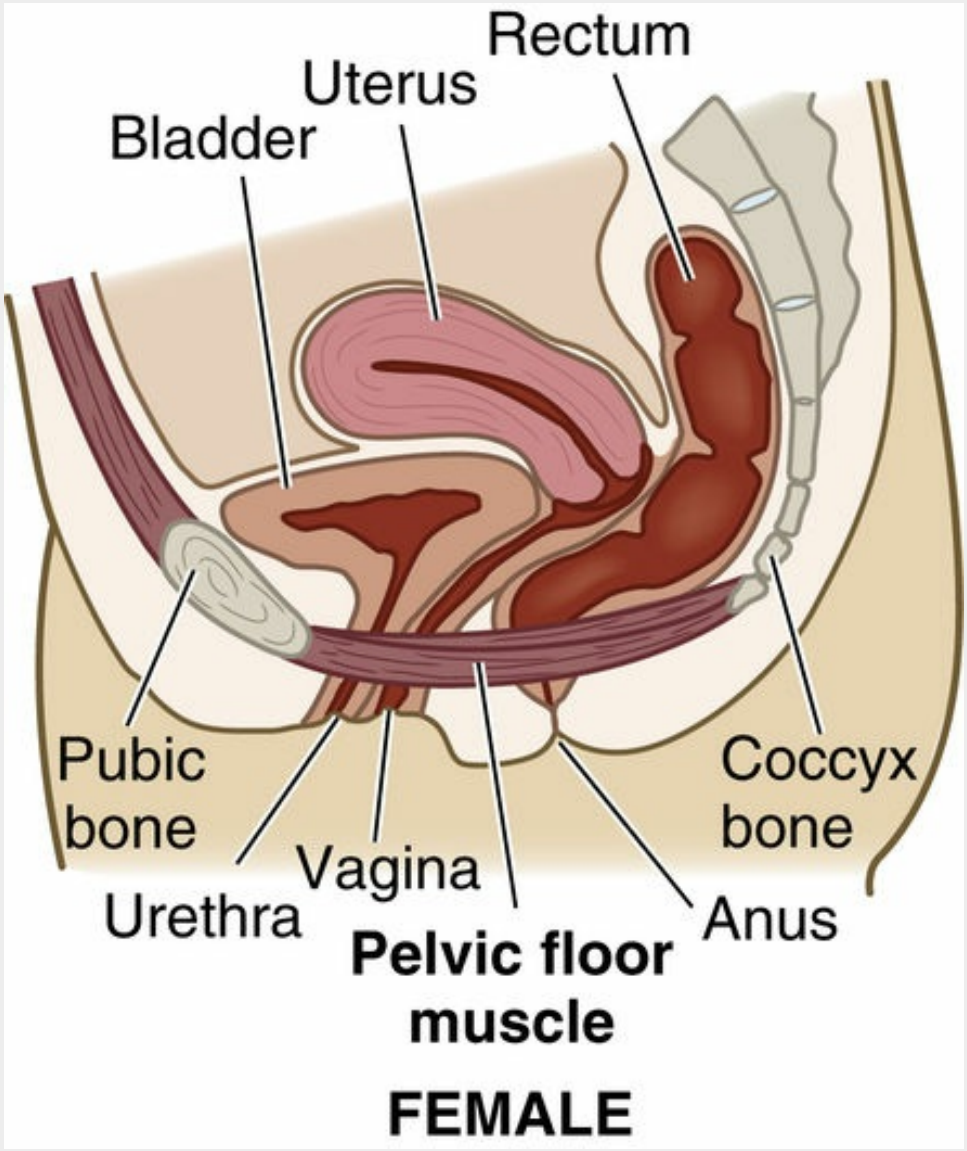
How to Do the Exercises

There are 2 different kinds of exercises—short squeezes and long squeezes.

1. To do the *short squeezes,* tighten your pelvic floor muscle quickly, squeeze hard for 2 seconds, and then relax the muscle. Also, when you have strong urinary urges, try to tighten your pelvic floor muscle quickly and hard several times in a row until the urge passes.
2. To do the *long squeezes,* tighten the muscle for 5–10 seconds before you relax.



Do both of these exercises 40–50 times each day.



When to Do These Exercises

- You can do these exercises anytime and anywhere.
- You can do these exercises in any position but sitting or lying down may be the easiest.

How Long Does It Take Before I Notice a Change?

After 4–6 weeks of doing these exercises, you should start to see less urine leakage and urinary urgency.

Courtesy Diane Newman.

Management options are reviewed in Tables 45.17 and 45.18. They include lifestyle interventions such as teaching the patient about consuming an adequate volume of fluids and reducing or eliminating bladder irritants, particularly caffeine and alcohol, from the diet. Have the patient maintain a regular, flexible schedule of urination, usually

every 2 to 3 hours while awake. Advise patients to quit smoking because this habit increases the risk for stress UI. Teach patients about the relationships among constipation, UI, and urinary retention. Aggressive management of constipation is recommended. Begin with ensuring adequate fluid intake, increasing dietary fiber, lightly exercising, and judiciously using stool softeners. The management of constipation is discussed in Chapter 42.

Behavioral treatments include scheduled voiding regimens (timed voiding, habit training, prompted voiding), bladder retraining, and pelvic floor muscle training. Assess how the patient contains urine and offer alternative devices when indicated. Many women use feminine hygiene pads. Many men and women may use household products, such as rags, paper towels, or folded toilet tissue. Unfortunately, none of these products is designed to wick urine away from the skin, prevent soiling of clothing, and reduce or eliminate odor.

Provide information on products specifically designed to contain urine. For example, patients with mild to moderate UI often benefit from incontinent pads containing superabsorbent material, designed to absorb many times its weight in water. Patients with higher volume urine loss or those with both urinary and fecal incontinence may need disposable or reusable incontinence protective underwear, briefs, or pad/pant systems.

In inpatient or long-term care facilities, nursing management of UI includes maximizing toilet access. This may take the form of offering the urinal or bedpan or helping the patient to the bathroom every 2 to 3 hours or at scheduled times. Ensure that toilets are accessible to patients and provide privacy to allow effective urine elimination.

Nursing Management

Caring for the Patient With Incontinence

All members of the interprofessional care team are responsible for decreasing the risk for incontinence and preventing complications,

such as skin breakdown, in patients who have UI. The RN plays a key role in delivering interventions to prevent and manage UI.

- Assess for risk factors for incontinence or urinary retention.
- Determine type of incontinence that patient is experiencing.
- Develop plan of care to decrease incontinence.
- Teach patient ways to decrease incontinence, such as pelvic floor muscle (Kegel) exercises.
- Assist patient in choosing appropriate products to contain urine.
- Delegate to the LPN/VN:
    - Use bladder scanner to estimate the postvoid residual volume (PVR).
    - Catheterize patient and measure PVR.
    - Give medications to decrease incontinence or urinary retention.
- Oversee UAP:
    - Help incontinent patient to commode or bedpan at regular intervals.
    - Clean patient and provide skin care.
    - Notify RN about new-onset incontinence in a previously continent patient.

Urinary Retention

Urinary retention is the inability to empty the bladder when a person voids or the accumulation of urine in the bladder because of an inability to void. In some cases, it is associated with urinary leakage or postvoid dribbling, called *overflow UI. Acute urinary retention* is the total inability to pass urine via micturition. It is a medical emergency. *Chronic urinary retention* is an incomplete bladder emptying despite urination. The PVR volumes in patients with chronic urinary retention vary widely. Normal PVR is between 50 and 75 mL. Findings over 100 mL indicate the need to repeat the measurement. An abnormal PVR in the older patient of more than 200 mL obtained on 2 separate occasions needs further evaluation. Even smaller volumes may justify further evaluation when the patient has recurring UTIs or LUTS suggestive of UTI.

Etiology and Pathophysiology

Urinary retention is caused by 2 different dysfunctions of the urinary system: bladder outlet obstruction and deficient detrusor (bladder muscle) contraction strength. *Bladder outlet obstruction* leads to urinary retention when the blockage is so severe that the bladder can no longer evacuate its contents despite a detrusor contraction. A common cause of obstruction in men is an enlarged prostate.

Deficient detrusor contraction strength leads to urinary retention when the muscle is no longer able to contract with enough force or for enough time to completely empty the bladder. Common causes are neurologic diseases affecting sacral segments 2, 3, and 4; long-standing diabetes; overdistention; chronic alcoholism; and drugs (e.g., anticholinergic drugs).

Diagnostic Studies

The diagnostic studies for urinary retention are the same as the ones

for UI (see p. 1046).

Interprofessional Care

Behavioral therapies that were described for UI may be used in the management of urinary retention. Scheduled toileting and double voiding may be effective in chronic urinary retention with moderate PVR volumes. *Double voiding* is an attempt to maximize bladder evacuation. The patient is asked to void, sit on the toilet for 3 to 4 minutes, and void again before exiting the bathroom.

TABLE 45.19 Drug TherapyVoiding Dysfunction

Class and Mechanism of Action	Drug
α-Adrenergic Agonists	
Increase urethral resistance	pseudoephedrine
α-Adrenergic Blockers	
Reduce urethral sphincter resistance to urinary outflow	alfuzosin (Uroxatral) doxazosin (Cardura) tamsulosin (Flomax) terazosin
5α-Reductase Inhibitors	
Suppress androgen resulting in epithelial atrophy and decrease in prostate size	dutasteride (Avodart) finasteride (Proscar)
β_3-Adrenergic Agonist	
Improves bladder's storage capacity by relaxing bladder muscle during filling	mirabegron (Myrbetriq)
Anticholinergics (Muscarinic Receptor Blockers)	
Reduce overactive bladder contractions in urge urinary incontinence **Relax bladder muscle during filling and improves the storage capacity of bladder**	darifenacin (Enablex) fesoterodine (Toviaz) flavoxate (Urispas) oxybutynin (Ditropan XL, Oxytrol Transdermal System) solifenacin (VESIcare) tolterodine (Detrol, Detrol LA) trospium chloride
Calcium Channel Blockers	
Reduce smooth muscle contraction strength **May reduce burning pain of interstitial cystitis**	diltiazem (Cardizem) nifedipine verapamil (Calan)
Hormone Therapy	
Local application reduces urethral irritation and increases host defenses against UTI	estrogen cream (Premarin) estrogen vaginal ring (Estring)
Tricyclic Antidepressants	
Reduce sensory urgency and burning pain of interstitial cystitis **Reduce overactive bladder contractions**	amitriptyline imipramine (Tofranil)

For acute or chronic urinary retention, catheterization may be needed. Intermittent catheterization allows the patient to remain free of an indwelling catheter with its associated risk of CAUTI and urethral irritation. In some situations, an indwelling catheter is preferred (e.g., if the patient is unwilling or unable to perform intermittent catheterization). An indwelling catheter is also used when urethral obstruction makes intermittent catheterization uncomfortable or infeasible.

Drug Therapy

Several drugs may be given to promote bladder evacuation. For the patient with obstruction at the level of the bladder neck, an α-adrenergic blocker may be prescribed. These drugs relax the smooth muscle of the bladder neck and prostatic urethra and may decrease urethral resistance. Examples of α-adrenergic blockers are listed in Table 45.19. They are indicated in patients with BPH or bladder neck or detrusor sphincter dyssynergia (muscle incoordination).

Surgical Therapy

Surgical interventions are used to manage urinary retention caused by obstruction. Transurethral or open surgical techniques are used to treat benign or cancerous prostatic enlargement, bladder neck contracture, urethral strictures, or dyssynergia of the bladder neck. Pelvic reconstruction using an abdominal or transvaginal approach can correct bladder outlet obstruction in women with severe pelvic organ prolapse.

While surgery has had a minimal role in the management of urinary retention caused by deficient detrusor contraction strength, a few new procedures may be of benefit. Sacral neuromodulation involves a stimulator device and placement of a lead wire into the S3 foramen. Placement of an intraurethral valve pump, which empties the patient's bladder on command, may be an option.

Nursing Management: Urinary Retention

Acute urinary retention is a medical emergency that requires prompt recognition and bladder drainage. Insert a catheter as ordered. Use a catheter with a retention balloon in anticipation of the need for an indwelling catheter.

Teach the patient with acute urinary retention and the patient predisposed to these episodes ways to minimize risk. Teach the patient to drink small amounts throughout the day and avoid the intake of large volumes of fluid over a brief period. Tell the patient (if chilled) to warm up before trying to void. They should avoid excess alcohol intake because it leads to polyuria and a diminished awareness of the need to void until the bladder is distended.

Have the patient who is unable to void drink a cup of coffee or brewed caffeinated tea to create or maximize urinary urgency. Tell patients that sitting in a tub of warm water or taking a warm shower may help them void. If these measures do not lead to successful urination, have the patient seek immediate care.

Patients with chronic urinary retention may be managed by behavioral methods, indwelling or intermittent catheterization, surgery, or drugs. Scheduled toileting and double voiding are the primary behavioral interventions used for chronic retention. Scheduled toileting can reduce, rather than expand, bladder capacity. In this case, have the patient void every 3 to 4 hours regardless of the desire to void. This is particularly useful in the patient with chronic overdistention, diabetes, or chronic alcoholism with a large bladder capacity and diminished or delayed sensations of bladder filling and urgency.

Catheterization

Indications for and Complications Of Catheterization

Indications for short-term urinary catheterization are listed in Table 45.20. Unacceptable reasons for catheterization include (1) routine acquisition of a urine specimen for laboratory analysis and (2) convenience of the nursing staff or the patient's family. The risk for CAUTI is too high to allow catheterization of a patient for the convenience of hospital personnel or family members.

TABLE 45.20 Indications for Urinary Catheterization

Indwelling Catheter

- Relieve urinary retention caused by lower urinary tract obstruction, paralysis, or inability to void
- Bladder decompression preoperatively and operatively for lower abdominal or pelvic surgery
- Facilitate surgical repair of urethra and surrounding structures
- Splinting of ureters or urethra to promote healing after surgery or other trauma in area
- Accurate measurement of urine output
- Contamination of stage III or IV pressure injuries with urine that has impeded healing, despite appropriate personal care for the incontinence
- Terminal illness or severe impairment, which makes positioning or clothing changes uncomfortable, or which is associated with intractable pain

Intermittent (Straight, in and out) Catheter

- Relieve urinary retention caused by lower urinary tract obstruction, paralysis, or inability to void
- Study of anatomic structures of urinary system
- Urodynamic testing
- Collect sterile urine sample in certain situations
- Instill medications into bladder
- Measure residual urine after voiding (postvoid residual [PVR]) if portable ultrasound not available

Complications that are seen with long-term use (more than 30 days) of indwelling catheters include CAUTI, bladder spasms, periurethral abscess, chronic pyelonephritis, urosepsis, urethral trauma or erosion, fistula or stricture formation, and stones. Catheterization for sterile urine specimens may be needed if the patient has a history of complicated UTI. A catheter should be the last resort to provide the patient with a dry environment to prevent skin breakdown and protect dressings or skin lesions.

Urinary catheterization is often used in the management of the hospitalized patient. However, it is not without serious complications. As previously discussed on p. 1028, CAUTIs are the most common HAI. Scrupulous aseptic technique is mandatory when a urinary catheter is inserted. After insertion, maintenance and protection of the closed drainage system are major nursing responsibilities. Do not routinely irrigate the catheter; this should be done only if ordered.

While the patient has a catheter in place, maintain catheter, manage fluid intake, provide for the patient's comfort and safety, and prevent infection. Address the psychologic implications of urinary drainage. Patient concerns can include embarrassment related to exposure of the body, an altered body image, and fear that care of the catheter will result in increased dependency.

Catheter Construction

Catheter materials include Teflon-coated latex, silicone elastomer, plastic, and hydrogel-coated silicone or latex. Catheters coated with silver or antimicrobial agents may prevent CAUTIs.

Catheters vary in construction materials, tip shape (Fig. 45.10), and size of the lumen. A coudé-tip catheter is often used in men. Catheters are sized according to the French scale. Each French unit (F) equals 0.33 mm of diameter. The diameter listed is the internal diameter of the catheter. The size used varies with the patient's size and the purpose of catheterization. In women, urethral catheter sizes 14F to 16F are the most common. In men, sizes 14F to 18F are used. Balloon sizes are either 5 or 30 mL. The primary problem resulting from too large a catheter is tissue erosion from excessive pressure on the meatus or urethra.

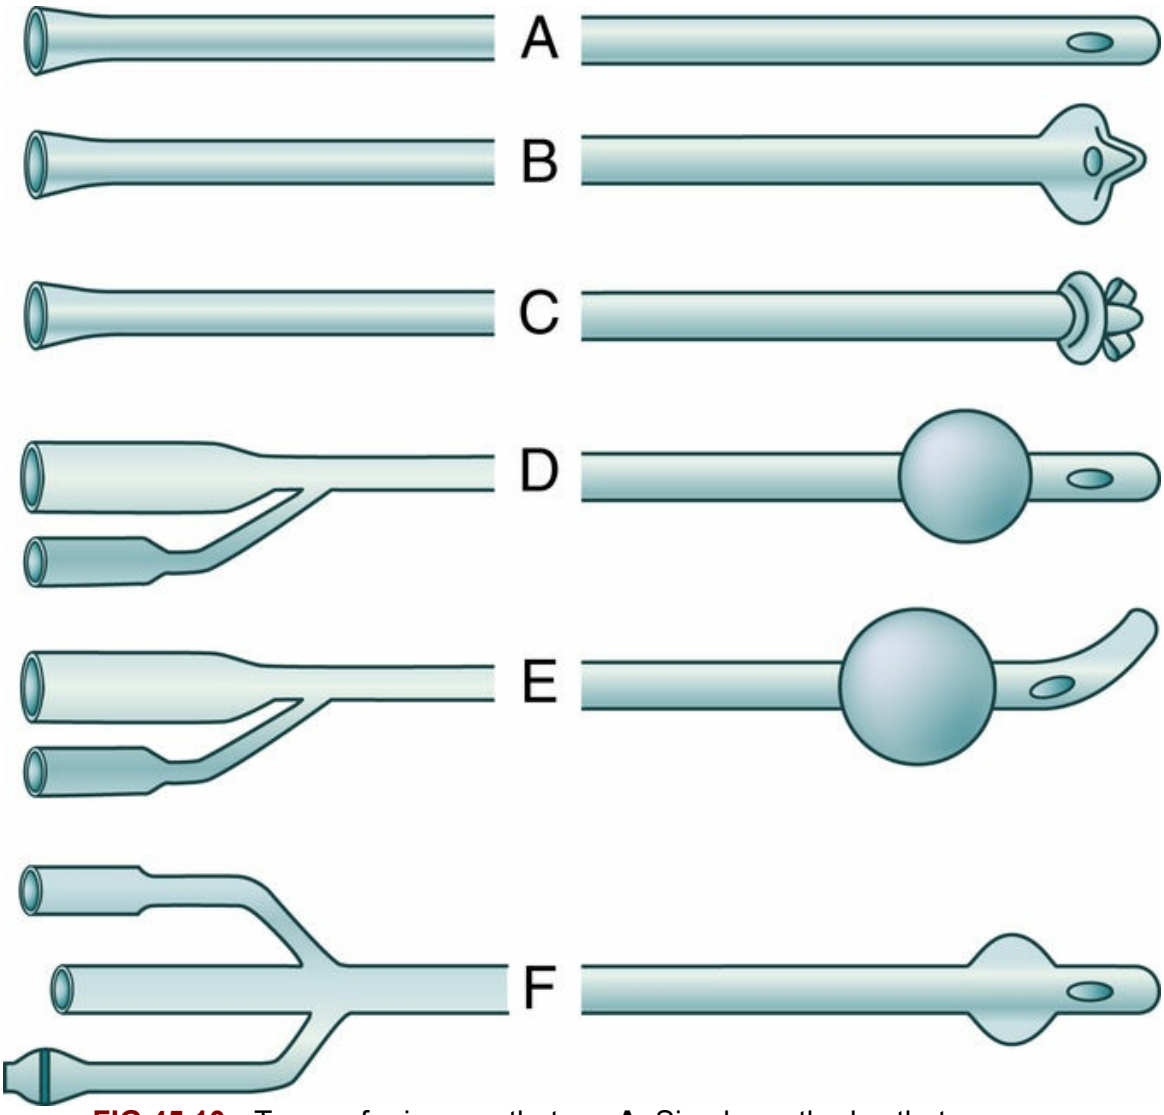


FIG 45.10 Types of urinary catheters. **A,** Simple urethral catheter. **B,** Mushroom-tip de Pezzer catheter (can be for suprapubic catheterization). **C,** Wing-tip Malecot catheter (wings hold catheter in place for temporary drainage). **D,** Indwelling urethral catheter with inflated balloon. **E,** Indwelling Tiemann catheter with coudé-tip (slightly curved tip allows for passage past obstruction). **F,** 3-way indwelling catheter (third lumen can be used for irrigation).

Types of Catheters

Four routes are used for urinary tract catheterization: urethral, ureteral, suprapubic, and via a nephrostomy tube.

Urethral Catheterization

Urethral catheterization, the most common route of catheterization, involves the insertion of a catheter through the external meatus into the urethra, past the internal sphincter, and into the bladder.

Ureteral Catheters

The *ureteral catheter* is placed through the ureters into the renal pelvis. The catheter is inserted either (1) by being threaded up the urethra and bladder to the ureters under cystoscopic observation or (2) by surgical insertion through the abdominal wall into the ureters. The ureteral catheter is used after surgery to splint the ureters and to prevent them from being obstructed by edema. Record the urine volume from the ureteral catheter separately from that of other urinary catheters.

The patient is often kept on bed rest while a ureteral catheter is in place until the HCP orders ambulation. The self-retaining ureteral catheter is often inserted after a lithotripsy procedure or when ureteral obstruction from adjacent tumors or fibrosis threatens renal function. A double-J ureteral catheter is often used and allows the patient to ambulate. One end coils up in the kidney pelvis, while the other coils in the bladder.

Check the placement of the ureteral catheter frequently and avoid tension on the catheter. The catheter drains urine from the renal pelvis, which has a capacity of 3 to 5 mL. If the volume of urine in the renal pelvis increases, tissue damage to the pelvis will result from pressure. Do not clamp the ureteral catheter. If the HCP orders irrigation of the ureteral catheter, use strict aseptic technique. If the

output is decreased, notify the HCP immediately.

Nursing Management

Care of the Patient With a Urethral Catheter

The following measures can be used to manage patients with a urethral catheter and prevent a CAUTI.

- Determine need for catheterization, but HCP must order.
- Choose appropriate type and size of catheter.
- Insert catheter in patient with urethral trauma, pain, or obstruction.
- Develop plan of care to decrease risk for infection in patient with indwelling catheter.
- Teach catheter care to the patient, particularly one who is ambulatory.
- Use a sterile, closed drainage system in short-term catheterization.
- Do not disconnect the distal urinary catheter and proximal drainage tube except for catheter irrigation (if ordered and indicated).
- Use sterile technique whenever the collecting system is open. If frequent irrigations are necessary in short-term catheterization to maintain catheter patency, a triple-lumen catheter may be preferable, permitting continuous irrigations within a closed system.
- A routine catheter change is not needed if the patient is catheterized for less than 2 weeks. For long-term use of an indwelling catheter, replace the catheter based on patient assessment and not on a routine changing schedule.
- If ordered, aspirate small volumes of urine for culture from the catheter sampling port using a sterile syringe and needle. Prepare

the puncture site with an antiseptic solution.

- With long-term use of a catheter, a leg bag may be used. If the collection bag is reused, wash it in soap and water and rinse thoroughly. When it is not reused immediately, fill it with ½ cup of vinegar and drain. Vinegar is effective against *Pseudomonas* and other organisms and eliminates odors.
- Remove the catheter as early as possible. Intermittent catheterization and external catheters are alternatives that are associated with fewer cases of bacteriuria and CAUTI.
- Ensure that UAP:
    - Maintain unobstructed downhill flow of urine.
    - Empty the collecting bag regularly and accurately record the urine output.
    - Provide perineal care (once or twice a day and when needed), cleaning the meatus-catheter junction with soap and water.
    - Do not use lotion or powder near the catheter.
    - Anchor catheter using a securement device. Anchor catheter to upper thigh in women and lower abdomen in men to prevent catheter movement and urethral tension.

Check the drainage often (at least every 1 or 2 hours). It is normal for some urine to drain around the ureteral catheter into the bladder. Accurately record the urine output from the ureteral and urethral catheters. Sometimes a ureteral catheter may be used as a stent and is not expected to drain. It is important to check with the HCP as to the type of catheter and what to expect.

Suprapubic Catheters

Suprapubic catheterization is the simplest and oldest method of urinary diversion. The 2 methods of insertion of a suprapubic catheter into the bladder are (1) through a small incision in the abdominal wall and (2) using a trocar. A suprapubic catheter is placed while the patient is under general anesthesia for another surgical procedure or at the

bedside with a local anesthetic. The catheter may be sutured into place. Tape the catheter to prevent dislodgment. The care of the tube and catheter is similar to that of the urethral catheter. A pectin-base skin barrier (e.g., Stomahesive) is effective in protecting the skin around the insertion site from breakdown.

The suprapubic catheter is used in temporary situations, such as bladder, prostate, and urethral surgery. It is also used on a long-term basis in some patients.

A suprapubic catheter is prone to poor drainage because of mechanical obstruction of the catheter tip by the bladder wall, sediment, and clots. To ensure patency of the tube (1) prevent tube kinking by coiling the excess tubing and maintaining gravity drainage, (2) have the patient turn from side to side, and (3) milk the tube. If these measures are not effective, obtain an order from the HCP to irrigate the catheter using sterile technique.

If the patient has bladder spasms that are hard to control, urinary leakage may result. Oxybutynin or other oral antispasmodics or belladonna and opium (B&O) suppositories may be prescribed to decrease bladder spasms.

Nephrostomy Tubes

The *nephrostomy tube* (catheter) is inserted on a temporary basis to preserve renal function when a ureter is completely obstructed. The tube is inserted through a small flank incision directly into the pelvis of the kidney and attached to connecting tubing for closed drainage. The principle is the same as with the ureteral catheter—that is, the catheter should never be kinked, compressed, or clamped. If the patient has excessive pain in the area or if there is excess drainage around the tube, check the catheter for patency. If irrigation is ordered, use strict aseptic technique. Gently instill no more than 5 mL of sterile saline solution at one time to prevent overdistention of the kidney pelvis and renal damage. Infection and secondary stone formation are complications associated with the insertion of a nephrostomy tube.

Intermittent Catheterization

An alternative approach to a long-term indwelling catheter is *intermittent catheterization,* often referred to as "straight" catheterization or "in-and-out" catheterization. The main goal of intermittent catheterization is to prevent urinary retention, stasis, and compromised blood supply to the bladder caused by prolonged pressure.[28]

It is being used more often in conditions such as neurogenic bladder (e.g., spinal cord injuries, chronic neurologic diseases) and bladder outlet obstruction in men. This type of catheterization is used in the oliguric and anuric phases of AKI to reduce the chance of infection from an indwelling catheter. Intermittent catheterization is also used postoperatively after a surgical procedure to treat UI.

The technique consists of inserting a urethral catheter into the bladder every 3 to 5 hours. Some patients perform intermittent catheterization only once or twice a day to measure residual urine and to ensure an empty bladder.

The techniques and protocols for intermittent catheterization vary. Catheters can be sterile (single use) or clean (multiple use). Catheters can be coated (prelubricated) or uncoated. Research on intermittent catheterization shows no convincing evidence that any specific technique (sterile or clean), catheter type (coated or uncoated), method (single-use or multiple-use), person (self or other), or strategy is better than any other for all clinical settings.[28]

The design of single-use, self-lubricating, silicone-coated (closed-sterile) systems is useful for patients who have recurrent UTIs or need to catheterize while at work or during travel. Teach patients to wash and rinse the catheter and their hands with soap and water before and after catheterization. Lubricant is necessary for men and may make catheterization more comfortable for women. The patient, caregiver, or HCP may insert the catheter.

Sterile technique is used for catheterization in the hospital or long-term care facility. For home care, a clean technique that includes good hand washing with soap and water is used. Teach the patient to observe for signs of UTI so that treatment can be started early. Some

patients are placed on prophylactic antibiotics. Urethral damage from intermittent catheterization in men is similar to problems seen with indwelling catheterization. Complications include urethritis, urethral sphincter damage (especially if there is a forceful catheterization against a closed sphincter), urethral stricture, and creation of a false passage.

Surgery of the Urinary Tract

Renal and Ureteral Surgery

The most common indications for nephrectomy are a renal tumor, polycystic kidneys that are bleeding or severely infected, massive traumatic injury to the kidney, and the elective removal of a kidney from a donor to be transplanted. Surgery involving the ureters and kidneys is most often done to remove stones that become obstructive, correct congenital anomalies, and divert urine when necessary.

Surgical Procedure

Nephrectomy can be performed by a conventional (open) approach or laparoscopically. In the open approach, an incision of about 6 to 10 inches is made through several layers of muscle. The incision can be made in the flank or abdominal area.

Laparoscopic Nephrectomy

Laparoscopic nephrectomy can be done to remove a diseased kidney or obtain a kidney from a living donor for transplant into a person with ESRD. With a laparoscopic nephrectomy, there are 3 to 5 puncture sites. One incision is to view the kidney, and another to dissect it. The laparoscope has a miniature camera so that the surgeons can watch what they are doing on a video monitor. Once dissected, the kidney is maneuvered into a nylon or polyurethane impermeable sack and then safely removed from the patient. Compared with conventional nephrectomy, the laparoscopic approach is less painful, involves a shorter hospital stay, and has a much faster recovery.

Preoperative Management

The basic needs of the patient undergoing renal and ureteral surgery are similar to those of any patient who has surgery (see Chapters 17 through 19). It is important preoperatively to ensure adequate fluid intake and a normal electrolyte balance. Tell the patient that if there is

a flank incision, surgery will require a hyperextended, side-lying position. This position often causes the patient to have muscle aches after surgery. If a nephrectomy is planned, it is important that the patient have 1 working kidney to maintain normal renal function.

Postoperative Management

Specific postoperative needs of a patient are related to urine output, respiratory status, and abdominal distention.

Urine Output

In the immediate postoperative period, measure and record the urine output at least every 1 or 2 hours. Measure drainage from the various catheters and record it separately. Do not clamp or irrigate the catheter or tube without a specific order. The total urine output should be at least 0.5 mL/kg/hr. It is important to assess for urine drainage on the dressing and to estimate this amount. Observe and monitor the color and consistency of urine. Urine with increased amounts of mucus, blood, or sediment may occlude the drainage tubing or catheter.

Weigh the patient daily using the same scale and have the patient wear similar clothing and dressings each time. A significant change in daily weight can indicate retention of fluids, which places the patient at cardiovascular risk for developing heart failure. Fluid retention can increase the work required of the remaining kidney to perform its functions.

Respiratory Status

A nephrectomy can be performed through a flank incision just below the diaphragm. Postoperatively, it is important to ensure adequate ventilation. The patient is often reluctant to turn, cough, and breathe deeply because of the incisional pain. Give adequate pain medication to ensure the patient's comfort and ability to perform coughing and deep-breathing exercises. Have the patient use an incentive spirometer every 2 hours while awake. Early and frequent ambulation

helps maintain respiratory function.

Abdominal Distention

Abdominal distention is present to some degree in most patients who have had surgery on their kidneys or ureters. It is often due to paralytic ileus caused by manipulation and compression of the bowel during surgery. Oral intake is restricted until bowel sounds are present (usually 24 to 48 hours after surgery). IV fluids are given until the patient can take oral fluids. Progression to a regular diet follows.

Urinary Diversion

Urinary diversion may be performed with or without cystectomy. Urinary diversion procedures are done when urinary flow is blocked. Common causes include bladder cancer, neurogenic bladder, congenital anomalies, strictures, trauma to the bladder, and chronic bladder inflammation. Numerous urinary diversion techniques and bladder substitutes are possible, including an incontinent urinary diversion, a continent urinary diversion catheterized by the patient, or an orthotopic neobladder bladder so that the patient voids urethrally.[29] Types of surgical procedures for urinary diversion are described in Table 45.21 and Fig. 45.11.

TABLE 45.21 Urinary Diversion Surgery

Description	Advantages	Disadvantages	Special Considerations
Cutaneous Ureterostomy			
Ureters are excised from bladder and brought through abdominal wall, and stoma is created. Ureteral stomas may be created from both ureters, or ureters may be brought together, and one stoma created.	No need for major surgery.	External appliance necessary because of continuous urine drainage. Possibility of stricture or stenosis of small stoma.	Periodic catheterizations may be needed to dilate stomas to maintain patency.
Ileal Conduit			
Ureters are implanted into part of ileum or colon that has been resected from intestinal tract. **Abdominal stoma is created.**	Relatively good urine flow with few physiologic alterations.	External appliance necessary to continually collect urine.	Surgical procedure is complex. Postoperative complications may be increased. Reabsorption of urea by ileum occurs. Meticulous attention is necessary to care for stoma and collecting device.
Nephrostomy			
Catheter is inserted into pelvis of kidney. Procedure may be done to 1 or both kidneys and may be temporary or permanent. It is most often done in advanced disease as palliative procedure.	No need for major surgery.	High risk for renal infection. Predisposition to stone formation from catheter.	Nephrostomy tube may have to be changed every month. Never clamp the catheter.

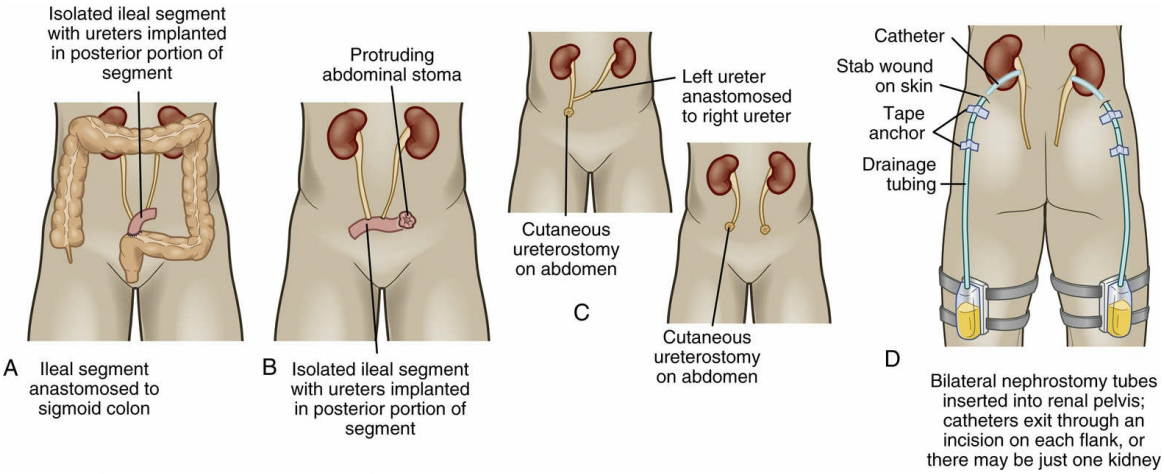

FIG 45.11 Methods of urinary diversion. **A,** Ureteroileosigmoidostomy. **B,** Ileal loop (ileal conduit). **C,** Ureterostomy (transcutaneous ureterostomy and bilateral cutaneous ureterostomies). **D,** Nephrostomy.

FIG 45.12 Urinary stoma. Symmetric, no skin breakdown, protrudes about 1.5 cm. Mucosa is healthy red. This configuration is flat when the

patient is upright or supine.
Courtesy Lynda Brubacher, Virginia Mason Hospital, Seattle, WA.

Incontinent Urinary Diversion

Incontinent urinary diversion is diversion to the skin, requiring an appliance. The simplest form is the cutaneous ureterostomy. However, complications including scarring and strictures of the ureter, have led to the more frequent use of ileal or colonic conduits. The most common incontinent urinary diversion procedure is the **ileal conduit** (ileal loop). In this procedure a 6- to 8-in (15- to 20-cm) segment of the ileum is converted into a conduit for urinary drainage. The colon (colon conduit) can be used instead of the ileum. The ureters are anastomosed into one end of the conduit, and the other end of the bowel is brought out through the abdominal wall to form a stoma (Fig. 45.12). Although the bowel segment is still supported by the mesentery, it is completely isolated from the intestinal tract. The bowel is anastomosed and continues to function normally.

Because there is no valve and no voluntary control over the stoma, drops of urine flow from the stoma every few seconds, requiring a permanent external collecting device. The visible stoma and need for external collection devices are disadvantages of this procedure. The lifelong need to care for and deal with the stoma and collection devices may be difficult. These problems have led to the increasing use of continent diversions and neobladder bladder substitutes.

Continent Urinary Diversions

A *continent urinary diversion* is an intraabdominal urinary reservoir that can be catheterized. Continent diversions are internal pouches created similarly to the ileal conduit. Reservoirs are constructed from the ileum, ileocecal segment, or ascending colon. Large segments of bowel are altered to prevent peristaltic action. A surgically created valve and the large, low-pressure reservoir helps prevent involuntarily leakage. The patient with a continent reservoir needs to

self-catheterize every 4 to 6 hours but does not need to wear external attachments. Patients may wear a small bandage on the stoma to collect any mucous drainage or excess drainage. Examples of continent diversions are the Kock (Fig. 45.13), Mainz, Indiana, and Florida pouches. The main difference among the various diversions is the segment of bowel used. For example, the Indiana pouch uses part of the ilium and right colon as a reservoir. It has become a popular form of continent urinary diversion.

Orthotopic Bladder Reconstruction

Orthotopic bladder reconstruction, or orthotopic neobladder, is the construction of a new bladder in the bladder's normal anatomic position, with discharge of urine through the urethra. The neobladder is surgically shaped from various segments of the intestines to make a low-pressure reservoir. An isolated segment of the distal ileum is often preferred. The ureters and urethra are sutured into the neobladder. Various procedures include the hemi-Kock pouch, Studer pouch, and W-shaped ileoneobladder.

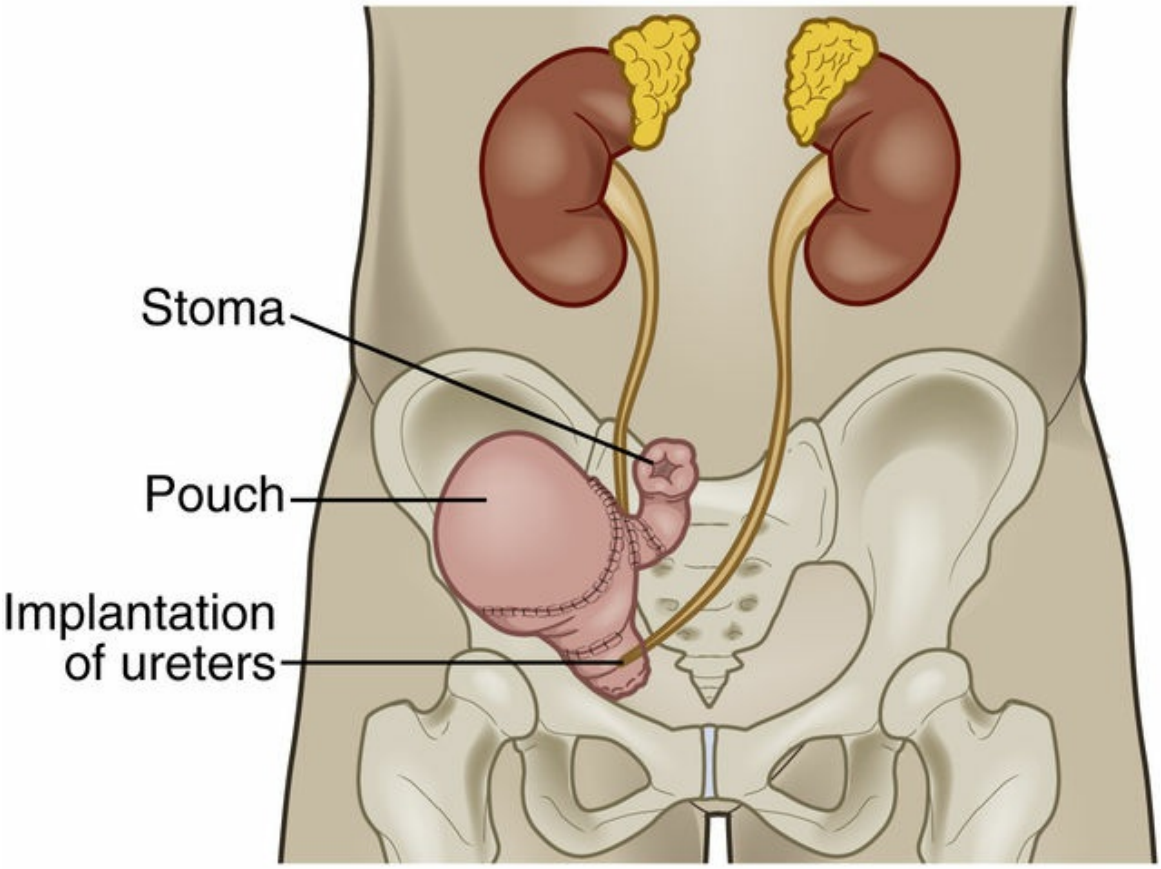

FIG 45.13 Creation of a Kock pouch with implantation of ureters into one intussuscepted part of the pouch and creation of a stoma with the other intussuscepted part.

Orthotopic bladder reconstruction has become a more viable option for both men and women if cancer does not involve the bladder neck or urethra. Ideal patients have normal renal and liver function, longer than 1- to 2-year life expectancy, adequate motor skills, and no history of inflammatory bowel disease or colon cancer. Obese patients and those with inflammatory bowel disease are not good candidates. The advantage of orthotopic bladder substitution is that it allows for natural micturition. Incontinence is a possible problem with this technique, and intermittent catheterization may be needed.

Nursing Management: Urinary Diversion

Preoperative Management

Teaching is important for the patient awaiting cystectomy and urinary diversion surgery. Assess the patient's ability and readiness to learn before starting a teaching program. The patient's anxiety and fear may be decreased by providing more information. However, anxiety and fear may also interfere with learning. Involve the patient's caregiver and family in the teaching process.

Discuss the psychosocial aspects of living with a stoma (including clothing, changes in body image and sexuality, exercise, and odor). This may allay some fears. The patient with an orthotopic neobladder may have problems with incontinence. Discuss patients' concerns about sexual activities and let them know that counseling is available. A wound, ostomy, and continence nurse (WOCN) should be involved in the preoperative phase of the patient's care. A visit from an ostomate can be helpful. Additional interventions are discussed in eNursing Care Plan 45.3 for the patient with an ileal conduit (on the website for this chapter).

Postoperative Management

Plan nursing interventions during the postoperative period to prevent surgical complications, such as atelectasis (see Chapter 19). After pelvic surgery, there is an increased incidence of thrombophlebitis and UTI. Removal of part of the bowel increase the risk of paralytic ileus and small bowel obstruction. The patient is kept NPO, and a nasogastric tube may be needed for a few days.

Prevent injury to the stoma and maintain urine output. Tell the patient that mucus in the urine is a normal occurrence. The mucus is secreted by the mucosa of the intestine (which was used to create the ileal conduit) in response to the irritating effect of urine. Encourage a

high fluid intake to “flush” the ileal conduit or continent diversion.

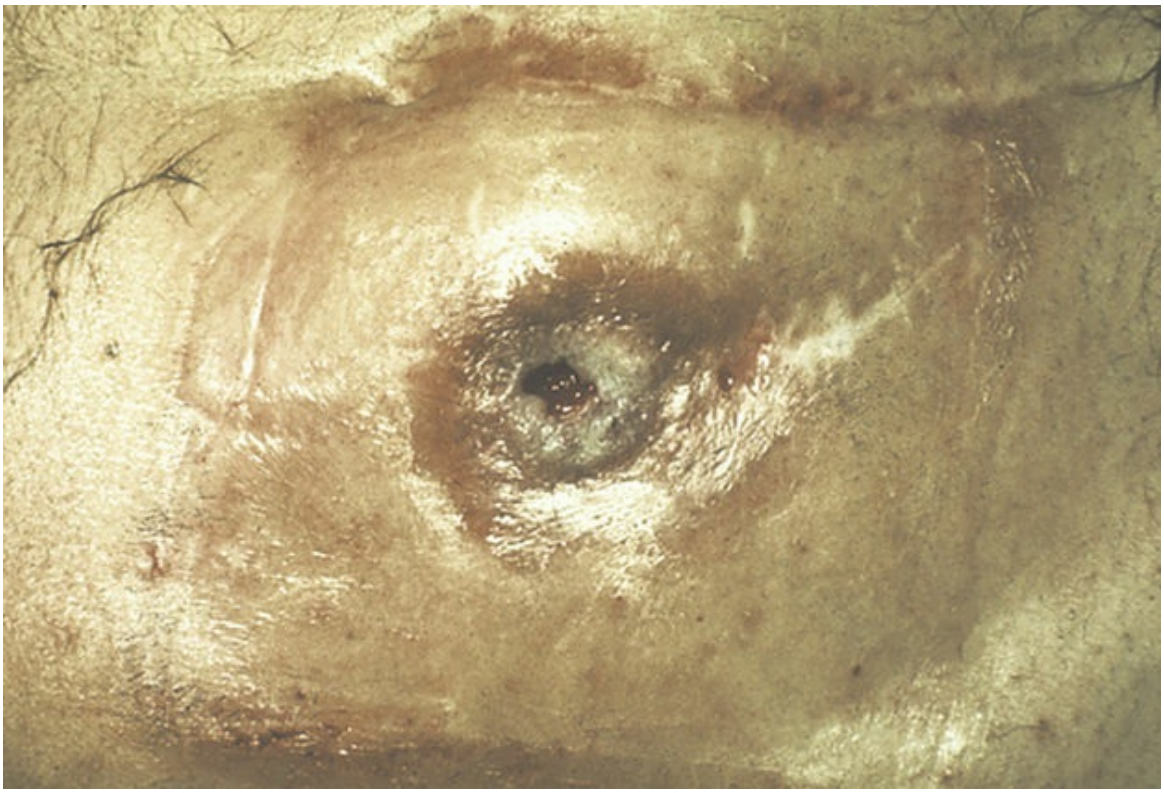

FIG 45.14 Ammonia salt encrustation from alkaline urine.
Courtesy Lynda Brubacher, Virginia Mason Hospital, Seattle, WA.

When an ileal conduit is created, provide meticulous care for the skin around the stoma. Alkaline encrustations with dermatitis may occur when alkaline urine comes in contact with exposed skin (Fig. 45.14). The urine is kept acidic to prevent alkaline encrustations. Other common peristomal skin problems include yeast infections, product allergies, and shearing-effect excoriations. Changing appliances (pouches) is described in Table 45.22. A properly fitting appliance is essential to prevent skin problems. The appliance should be about 0.1 in (0.2 cm) larger than the stoma. It is normal for the stoma to shrink within the first few weeks after surgery.

Teach the patient with a continent diversion (e.g., Indiana pouch) to catheterize at first every few hours. Over time this can be extended to every 4 to 6 hours. Irrigation of the pouch with normal saline or sterile

water is often needed.

Patients with a neobladder may have postoperative urinary retention and need catheterization. It may take up to 6 months for them to regain bladder control. Patients empty their neobladders by relaxing their outlet sphincter muscles and bearing down with their abdominal muscles. Since there is no longer neurologic feedback between the reservoir and the brain, the patient should not expect a normal desire to void. To avoid bladder overdistention, patients should void at least every 2 to 4 hours, sit during voiding, and practice pelvic floor muscle relaxation to aid voiding. Follow-up x-ray studies include a "pouchogram" 3 to 4 weeks after surgery to assess for healing.

Acceptance of the surgery and changes in body image is needed to ensure the patient's best adjustment to a urinary diversion. Patient concerns include fear that the stoma will be offensive to others and will interfere with sexual, personal, professional, and recreational activities. Advise the patient that few activities will be restricted because of the urinary diversion. Meeting and sharing feelings with similar patients can help.

Discharge teaching after an ileal conduit includes teaching the patient about symptoms of obstruction or infection and care of the ostomy. The patient with an ileal conduit is fitted for a permanent appliance 7 to 10 days after surgery. It may have to be refitted later, depending on the degree of stoma healing and shrinkage.

Appliances are made of a variety of products, including natural and synthetic rubbers, plastics, and metals. Most appliances have a faceplate that adheres to the skin, a collecting pouch, and an opening to drain the pouch. The faceplate may be secured to the skin with glues, adhesives, or adherent synthetic wafers. Some appliances do not need adhesives because their design relies on pressure to keep the pouch in place. If improperly fitted or applied, the faceplate may cause skin problems (Fig. 45.15). Tell the patient and caregiver about where to buy supplies, emergency telephone numbers, location of ostomy clubs, and follow-up visits with a WOCN. Follow-up with an HCP is imperative to monitor the patient's recovery, detect any

complications, and assess renal function.

TABLE 45.22 Patient & Caregiver TeachingIleal Conduit Appliances

Include the following instructions when teaching a patient or a caregiver how to change an ileal conduit appliance:

Temporary Appliance

1. Cut hole in pouch to fit over stoma (pouch 0.1 in [0.2 cm] larger than stoma).
2. Remove old pouch.
3. Clean area gently and remove old adhesive.
4. Wash area with warm water.
5. Place wick (rolled-up 4 × 4–in pad) over stoma to keep area dry during rest of procedure.
6. Dry skin around stoma.
7. Apply tincture of benzoin or other skin protectant around stoma to area where pouch will be placed.
8. Apply pouch by first smoothing its edges toward side and lower part of body.
9. Remove wick and complete application of bag.
10. If patient is usually in bed, apply bag so that it lies toward side of body.
11. If patient is ambulatory, apply bag so that it lies vertically.
12. Connect drainage tubing to pouch.
13. Keep drainage pouch on same side of bed as stoma.

Permanent Appliance*

1. Keep appliance in place for 2–14 days.
2. Change appliance when fluid intake has been restricted for several hours.

3. Sit or stand in front of mirror.
4. Moisten edge of faceplate with adhesive solvent and gently remove.
5. Clean skin with adhesive solvent.
6. Wash skin with warm water (may be done while showering).
7. Dry skin and inspect.
8. Place wick (rolled-up 4 × 4–inch pad) over stoma to keep skin free of urine.
9. Apply skin cement to faceplate and skin.
10. Place appliance over stoma.
11. Wash removed appliance with soap and lukewarm water; soak in distilled vinegar; rinse with lukewarm water and air dry.

---

* Many disposable appliances with self-adhesive backing are used as permanent appliances.

Case Study

Painful Bladder and Frequent Urination

© marilook/iStock/Thinkstock.

Patient Profile

L.T., a 38-yr-old woman, comes to the HCP's office today for the eighth time in the past year for a history of pelvic pain with urinary frequency during the day, nocturia, and urgency to void. All previous urine cultures have been negative for bacteria. A recent evaluation by her gynecologist was negative for endometriosis.

Subjective Data

- Has a history of suprapubic and vaginal pain, urinary frequency and urgency
- Reports bladder pain that increases with bladder filling
- States this is her third attack of suprapubic pain and painful urination in 2 months
- Constant pain and discomfort has been physically and emotionally exhausting
- Is worried that she has cancer, and no one cares
- Has had 4 pregnancies with uneventful vaginal deliveries
- Normal menstrual cycles
- Her husband and she rarely have sexual intercourse because she has pain with intercourse
- Has a bowel movement every day. Denies constipation and/or diarrhea
- Recalls having many UTIs as a child

Objective Data
Physical Examination

- Lungs are clear. BP 132/86. Heart rate 86/min. Respiratory rate 18/min. Abdomen soft, tender in suprapubic region.

Diagnostic Studies

- Urinalysis obtained today: normal
- Previous urine cytology ordered to rule out cancer: normal
- Recent referral to urologist for cystoscopy which was done a few weeks ago

Interprofessional Care

- Cystoscopy results indicated glomerulations and Hunner lesions
- Urologist diagnosed interstitial cystitis
- Urologist prescribed pentosan (Elmiron), which she has not started yet
- Follow-up in 4 weeks with the urologist

Discussion Questions

1. After taking the patient's history, would you consider a UTI as a cause of her symptoms? Why or why not?
2. What additional testing and patient information would be helpful?
3. What is the significance of the cystoscopy findings?
4. What is the reason for the use of pentosan (Elmiron)?
5. ***Priority Decision:*** What are the priority nursing diagnoses for L.T.?
6. ***Patient-Centered Care:*** How can you help L.T. deal with her diagnosis and treatment plan?
7. Collaboration: Why is it important to get a dietitian involved in L.T.'s care?
8. ***Evidence-Based Practice:*** L.T. asks you how she can control her interstitial cystitis. How would you respond?

Nursing Management: Urinary Tract Calculi

Nursing Assessment

Subjective and objective data that should be obtained from a patient with urinary tract stones are outlined in Table 45.13.

Nursing Diagnoses

Nursing diagnoses for the patient with urinary tract stones include:

- Impaired urinary system function
- Acute pain
- Lack of knowledge

TABLE 45.12 Nutritional TherapyUrinary Tract Stones

Depending on the type of stone, modifying the diet can be helpful in preventing reoccurrence.

Calcium

High: Milk, cheese, ice cream, yogurt, sauces containing milk; all beans (except green beans), lentils; fish with fine bones (e.g., sardines, kippers, herring, salmon); dried fruits, nuts; Ovaltine, chocolate, cocoa

Oxalate

High: Dark roughage, spinach, rhubarb, asparagus, cabbage,

tomatoes, beets, nuts, celery, parsley, runner beans; chocolate, cocoa, instant coffee, Ovaltine, tea; Worcestershire sauce

Purine

High: Sardines, herring, mussels, liver, kidney, goose, venison, meat soups, sweetbreads
Moderate: Chicken, salmon, crab, veal, mutton, bacon, pork, beef, ham

TABLE 45.13 Nursing AssessmentUrinary Tract Stones

Subjective Data

Important Health Information

Past health history: Recent or chronic UTI. Immobilization. Previous urinary tract stones, obstruction, or kidney disease with urinary stasis. Gout, BPH, hyperparathyroidism, chronic diarrhea
Medications: Prior use of medication for prevention of stones or treatment of UTI, allopurinol, analgesics, loop diuretics, thiazide diuretics
Surgery or other treatments: External urinary diversion, long-term indwelling urinary catheter

Functional Health Patterns

Health perception–health management: Family history of urinary tract stones, sedentary lifestyle
Nutritional-metabolic: Nausea, vomiting. Dietary intake of purines, calcium ingestion, salt excess, oxalates, phosphates and use of

OTC supplements. Low fluid intake. Chills

Elimination: Decreased urine output, urinary urgency, frequency, feeling of bladder fullness

Cognitive-perceptual: Acute, severe, colicky pain in flank, back, abdomen, groin, or genitalia. Burning on urination, dysuria. Anxiety

Objective Data

General

Guarding, back pain, fever, dehydration

Integumentary

Warm, flushed skin or pallor with cool, moist skin (mild shock)

Gastrointestinal

Abdominal distention, absence of bowel sounds

Urinary

Oliguria, hematuria, tenderness on palpation of renal areas, passage of stone or stones

Possible Diagnostic Findings

↑ BUN and serum creatinine levels. Urinalysis showing RBCs, WBCs, pyuria, crystals, casts, minerals, bacteria. ↑ Uric acid, calcium, phosphorus, oxalate, or cystine values on 24-hr urine sample. Stones or anatomic changes on KUB x-ray, CT scan or

renal/bladder US. Direct visualization of obstruction on cystoureteroscopy

More information on nursing diagnoses and interventions for the patient with urinary tract stones is presented in eNursing Care Plan 45.2 (on the website for this chapter).

Planning

The overall goals are that the patient with urinary tract stones will have (1) relief of pain, (2) no urinary tract obstruction, and (3) knowledge of ways to prevent recurrence of stones.

Nursing Implementation

Most people who have had urinary stones can lower their risk for recurrence by changing their lifestyle and dietary habits. Adequate fluid intake is important to produce a urine output of around 2.5 L/day. Consult with the HCP about specific recommendations for fluid intake in a given person. The moderately active, ambulatory person should drink about 3 L/day. Fluid intake must be higher in the active person who works outdoors or who regularly engages in athletic activities.

Preventive measures for a person who is on bed rest or is immobile for a prolonged time include maintaining an adequate fluid intake, turning the patient every few hours, and helping the patient sit or stand, if possible, to maximize urinary flow.

Other preventive measures focus on reducing metabolic or secondary risk factors. For example, dietary restriction of purines may be helpful for the patient at risk for developing uric acid stones. Teach the patient the dosage, scheduling, and potential side effects of drugs used to reduce the risk for stone formation (Table 45.11). Some patients may be taught to self-monitor urinary pH or urine output.

Pain management and patient comfort are primary nursing responsibilities when managing a patient who has an obstructing

stone and renal colic. To ensure that any spontaneously passed stones are retrieved, strain all urine voided by the patient using a gauze or a urine strainer. Encourage ambulation to promote movement of the stone from the upper to the lower urinary tract. To ensure safety, tell the patient who has acute renal colic to ask for help when ambulating, particularly if opioid analgesics are being given.

Evaluation

The expected outcomes are that the patient with urinary tract stones will

- Maintain free flow of urine with minimal hematuria
- Report satisfactory pain relief
- State understanding of disease process and ways to prevent recurrence

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse teaches the female patient who has frequent UTIs that she should
   a. take tub baths with bubble bath.
   b. void before and after sexual intercourse.
   c. take prophylactic sulfonamides for the rest of her life.
   d. restrict fluid intake to prevent the need for frequent voiding.
2. One of the nurse's *most* important roles in relation to acute poststreptococcal glomerulonephritis (APSGN) is to
   a. promote early diagnosis and treatment of sore throats and skin lesions.
   b. encourage patients to obtain antibiotic therapy for upper respiratory tract infections.
   c. teach patients with APSGN that long-term prophylactic antibiotic therapy is needed to prevent recurrence.
   d. monitor patients for respiratory symptoms that indicate the disease is affecting the alveolar basement membrane.
3. The edema that occurs in nephrotic syndrome is due to
   a. increased hydrostatic pressure caused by sodium retention.
   b. decreased aldosterone secretion from adrenal insufficiency.
   c. increased fluid retention caused by decreased

glomerular filtration.

d. decreased colloidal osmotic pressure caused by loss of serum albumin.

4. A patient is admitted to the hospital with severe renal colic. The nurse's *first priority* in management of the patient is to

a. administer opioids as prescribed.

b. obtain supplies for straining all urine.

c. encourage fluid intake of 3 to 4 L/day.

d. keep the patient NPO in preparation for surgery.

5. The nurse recommends genetic counseling for the children of a patient with

a. nephrotic syndrome.

b. chronic pyelonephritis.

c. malignant nephrosclerosis.

d. adult-onset polycystic kidney disease.

6. The nurse identifies a risk factor for kidney and bladder cancer in a patient who relates a history of

a. aspirin use.

b. tobacco use.

c. chronic alcohol use.

d. use of artificial sweeteners.

7. In planning nursing interventions to increase bladder control in the patient with urinary incontinence, the nurse includes *(select all that apply)*

a. teaching the patient to use Kegel exercises.

b. clamping and releasing a catheter to increase bladder

tone.

c. teaching the patient biofeedback mechanisms to train pelvic floor muscles.

d. counseling the patient concerning choice of incontinence containment device.

e. developing a fluid modification plan, focusing on decreasing intake before bedtime.

8. A patient with a ureterolithotomy returns from surgery with a nephrostomy tube in place. Postoperative nursing care of the patient includes

a. clamping the tube for 10 minutes every hour to decrease spasms.

b. encouraging fluids of at least 2 to 3 L/day after nausea has subsided.

c. notifying the provider if nephrostomy tube drainage is more than 30 mL/hr.

d. irrigating the nephrostomy tube with 10 mL of normal saline solution as needed.

9. A patient has had a cystectomy and ileal conduit diversion. Four days after surgery, you note mucous shreds in the drainage bag. The nurse should

a. notify the provider.

b. notify the charge nurse.

c. irrigate the drainage tube.

d. document it as a normal observation.

1. b, 2. a, 3. d, 4. a, 5. d, 6. b, 7. a, c, 8. b, 9. d

Acute Kidney Injury and Chronic Kidney Disease

Hazel Dennison

LEARNING OUTCOMES

1. Outline criteria used to classify acute kidney injury using the acronym RIFLE (*R*isk, *I*njury, *F*ailure, *L*oss, *E*nd-stage renal disease).
2. Relate the clinical course of acute kidney injury.
3. Explain the interprofessional and nursing management of a patient with acute kidney injury.
4. Define chronic kidney disease and delineate its 5 stages based on the glomerular filtration rate.
5. Identify risk factors that contribute to the development of chronic kidney disease.
6. Describe the significance of cardiovascular disease in people with chronic kidney disease.
7. Explain the conservative interprofessional care and related nursing management of the patient with chronic kidney disease.
8. Distinguish among renal replacement therapy options for persons with end-stage renal disease.
9. Compare and contrast nursing interventions for patients on peritoneal dialysis and hemodialysis.
10. Discuss the role of nurses in the management of patients who

receive a kidney transplant.

Conceptual Focus

Acid-Base Balance
Adherence
Coping
Elimination
Fluids and Electrolytes
Nutrition

Kidney failure, also called *renal failure,* is the partial or complete impairment of kidney function. It results in an inability to excrete metabolic waste products and water. Kidney failure contributes to problems with all body systems. All patients have problems with fluid, electrolyte, and acid-base imbalance. Adhering to dietary therapies and the treatment plan can be challenging. The patient must deal with changes in lifestyle, occupation, family relationships, and self-image that can lead to withdrawal and depression. The patient grieves the loss of kidney function and independence.

Kidney failure is classified as acute or chronic (Table 46.1). Acute kidney injury (AKI) has a rapid onset. Chronic kidney disease (CKD) is gradual with a progressive decline in kidney function.

Acute Kidney Injury

Acute kidney injury (AKI) is the term used to encompass the entire scope of the syndrome, ranging from a slight deterioration in kidney function to severe impairment. AKI is characterized by a rapid loss of kidney function. This loss is accompanied by a rise in serum creatinine and/or a reduction in urine output. AKI can develop over hours or days with progressive elevations of blood urea nitrogen (BUN), creatinine, and potassium with or without a reduction in urine output. The severity of dysfunction can range from a small increase in serum creatinine or reduction in urine output to the development of **azotemia**, an accumulation of nitrogenous waste products (urea

nitrogen, creatinine) in the blood.

Although AKI is potentially reversible, it has a high mortality rate.[1] AKI usually affects people with other life-threatening conditions (Table 46.2).[2] AKI often follows severe, prolonged hypotension, hypovolemia, or exposure to a nephrotoxic agent. Hospitalized patients develop AKI at a high rate (1 in 5) and have a high mortality rate. When AKI develops in patients in intensive care units (ICUs), the mortality rate can be as high as 70% to 80%.[3,4]

Etiology and Pathophysiology

The causes of AKI are multiple and complex. We categorize them as prerenal, intrarenal (or intrinsic), and postrenal causes (Table 46.2 and Fig. 46.1).

Table 46.1 Comparison of Acute Kidney Injury and Chronic Kidney Disease

	Acute Kidney Injury	Chronic Kidney Disease
Onset	Sudden	Gradual, often over many years
Most common cause	Acute tubular necrosis	Diabetic nephropathy
Diagnostic criteria	Acute reduction in urine output *AND/OR* Elevation in serum creatinine	GFR <60 mL/min/1.73 m^2 for >3 mo *AND/OR* Kidney damage >3 mo
Reversibility	Potentially	Progressive and irreversible
Primary cause of death	Infection	CVD

Prerenal

Prerenal causes of AKI are factors that reduce systemic circulation, causing a reduction in renal blood flow. The decrease in blood flow leads to decreased glomerular perfusion and filtration of the kidneys.

It is important to distinguish prerenal oliguria from the oliguria of intrarenal AKI. In prerenal oliguria there is no damage to the kidney tissue (parenchyma). The oliguria is caused by a decrease in

circulating blood volume (e.g., severe dehydration, heart failure [HF], decreased cardiac output). Prerenal oliguria is readily reversible with appropriate treatment.[5] With a decrease in circulating blood volume, autoregulatory mechanisms that increase angiotensin II, aldosterone, norepinephrine, and antidiuretic hormone try to preserve blood flow to essential organs. Prerenal azotemia results in a reduction in sodium excretion (less than 20 mEq/L), increased sodium and water retention, and decreased urine output.

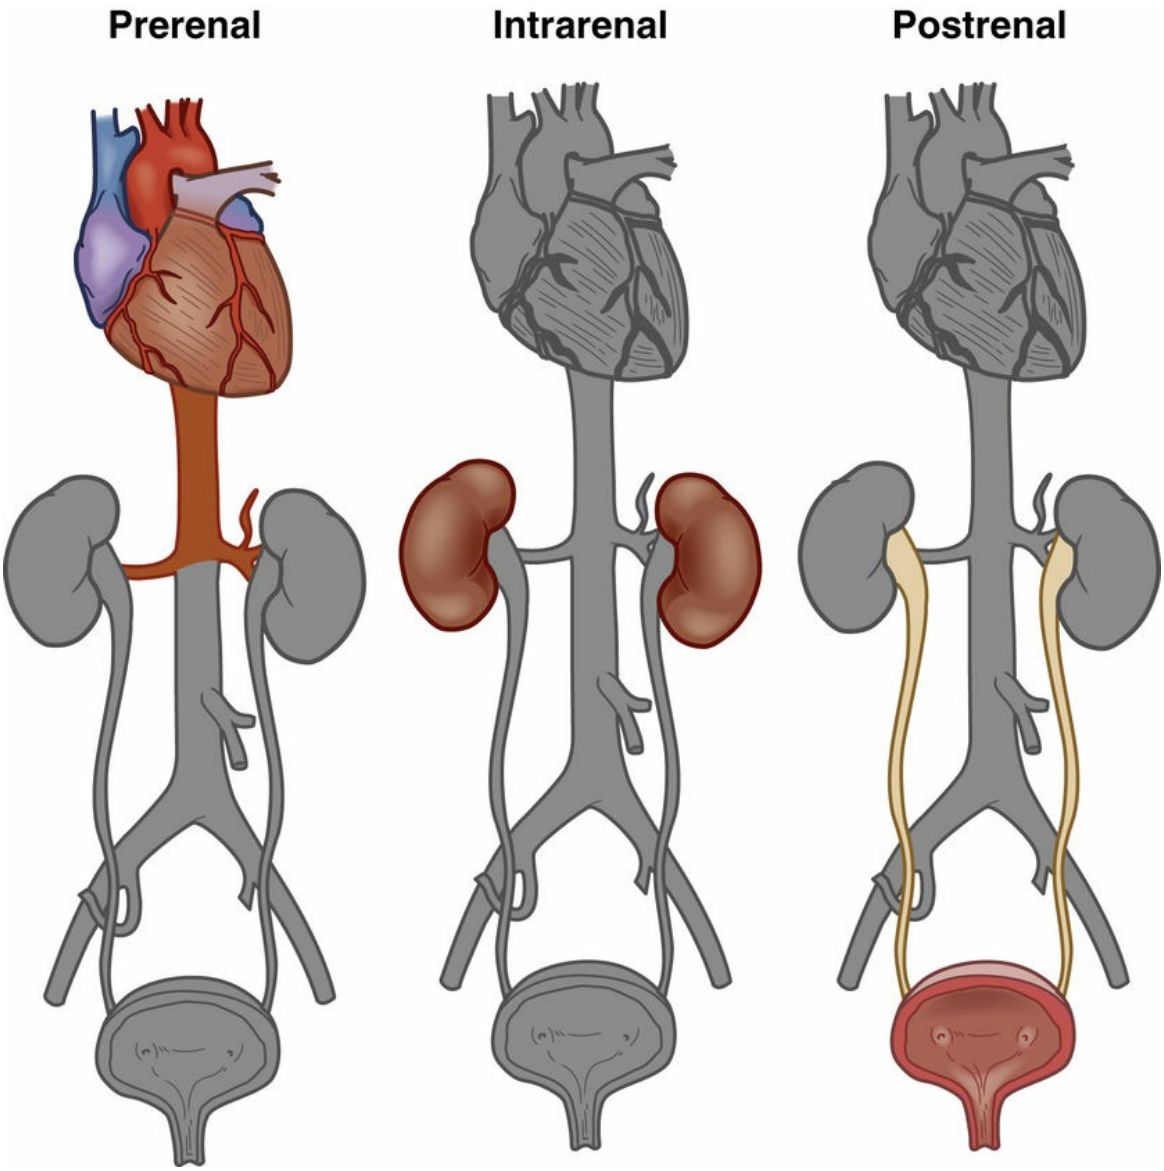

FIG. 46.1 Prerenal, intrarenal, and postrenal causes of AKI.

TABLE 46.2 Common Causes of Acute Kidney Injury

Prerenal	Intrarenal	Postrenal
Decreased Cardiac Output	**Interstitial Nephritis**	• BPH
• **Cardiogenic shock**	• Allergies: antibiotics (sulfonamides, rifampin), NSAIDs, ACE inhibitors	• Bladder cancer
• **Dysrhythmias**	• Infections: bacterial (acute pyelonephritis), viral (Epstein-Barr), fungal (candidiasis)	• Calculi formation
• **HF**	**Nephrotoxic Injury**	• Neuromuscular disorders
• **MI**	• Chemical exposure: ethylene glycol, lead, arsenic, carbon tetrachloride	• Prostate cancer
Decreased Peripheral Vascular Resistance	• Contrast media	• Spinal cord disease
• **Anaphylaxis**	• Drugs: aminoglycosides (gentamicin, amikacin), amphotericin B	• Strictures
• **Neurologic injury**	• Hemolytic blood transfusion reaction	• Trauma (back, pelvis, perineum)
• **Septic shock**	• Severe crush injury	
Decreased Renovascular Blood Flow	**Other Causes**	
• **Bilateral renal vein thrombosis**	• Acute glomerulonephritis	
• **Embolism**	• Malignant hypertension	
• **Hepatorenal syndrome**	• Prolonged prerenal ischemia	
• **Renal artery thrombosis**	• Thrombotic disorders	
Hypovolemia	• Toxemia of pregnancy	
• **Burns**	• Systemic lupus erythematosus	
• **Dehydration**		
• **Excessive diuresis**		
• **GI losses (diarrhea, vomiting)**		
• **Hemorrhage**		
• **Hypoalbuminemia**		

Prerenal conditions contribute to intrarenal AKI. If decreased perfusion persists for an extended time, the kidneys lose their ability to compensate and damage to kidney parenchyma occurs (intrarenal damage).

Intrarenal

Intrarenal causes of AKI (Table 46.2) include conditions that cause direct damage to the kidney tissue, resulting in impaired nephron function. The damage from intrarenal causes usually results from prolonged ischemia, nephrotoxins (e.g., aminoglycoside antibiotics, contrast media), hemoglobin released from hemolyzed red blood cells (RBCs), or myoglobin released from necrotic muscle cells.

Nephrotoxins can cause obstruction of intrarenal structures by crystallizing or causing damage to the epithelial cells of the tubules.

Hemoglobin and myoglobin can block the tubules and cause renal vasoconstriction. Kidney diseases, such as acute glomerulonephritis and systemic lupus erythematosus (SLE), may also cause AKI.

Acute tubular necrosis (ATN) is the most common intrarenal cause of AKI in hospitalized patients. It is primarily the result of ischemia, nephrotoxins, or sepsis. Ischemic and nephrotoxic ATN is responsible for 90% of intrarenal AKI cases.[6,7] Severe kidney ischemia causes a disruption in the basement membrane and patchy destruction of the tubular epithelium. Nephrotoxic agents cause necrosis of tubular epithelial cells, which slough off and plug the tubules. Other risks associated with developing ATN while in the hospital include major surgery, shock, blood transfusion reaction, muscle injury from trauma, and prolonged hypotension. ATN is potentially reversible if the basement membrane is not destroyed and the tubular epithelium regenerates.

Postrenal

Postrenal causes of AKI involve mechanical obstruction in the outflow of urine. With the flow of urine obstructed, urine refluxes into the renal pelvis, impairing kidney function. The most common postrenal causes are benign prostatic hyperplasia (BPH), prostate cancer, stones, trauma, and extrarenal tumors. Bilateral ureteral obstruction leads to *hydronephrosis* (kidney dilation), increase in hydrostatic pressure, and tubular blockage, resulting in a progressive decline in kidney function. If bilateral obstruction is relieved within 48 hours of onset, complete recovery is likely. Prolonged obstruction can lead to tubular atrophy and irreversible kidney fibrosis. Postrenal causes of AKI account for less than 10% of AKI cases.[8]

Clinical Manifestations

Prerenal and postrenal AKI that has not caused intrarenal damage usually resolves quickly with treatment. When parenchymal damage occurs due to either prerenal or postrenal causes, or when parenchymal damage occurs directly as with intrarenal causes, AKI

has a prolonged course. Clinically, AKI may progress through phases: oliguric, diuretic, and recovery. When a patient does not recover from AKI, CKD may develop.

The RIFLE classification describes the stages of AKI (Table 46.3). *R*isk, the first stage of AKI, is followed by *I*njury, which is the second stage. Then AKI increases in severity to the last, or third, stage, *F*ailure. The 2 outcome variables are *L*oss and *E*nd-stage renal disease.[9,10]

Oliguric Phase

The most common manifestations of AKI are discussed in this section.

Urinary Changes

The most common initial manifestation of AKI is **oliguria**, a reduction in urine output to less than 400 mL/day. Oliguria usually occurs within 1 to 7 days of the injury to the kidneys. If the cause is ischemia, oliguria often occurs within 24 hours. When nephrotoxic drugs are involved, the onset may be delayed for as long as 1 week. This phase lasts on average 10 to 14 days but can last months in some cases. The longer the oliguric phase lasts, the poorer the prognosis for complete recovery of kidney function.[1]

TABLE 46.3 RIFLE Classification for Staging Acute Kidney Injury

Stage	GFR Criteria	Urine Output Criteria	Clinical Example
Risk	Serum creatinine increased × 1.5 *OR* GFR decreased by 25%	Urine output <0.5 mL/kg/hr for 6 hr	• 68-yr-old black woman with type 2 diabetes, hypertension, CAD, CKD • Scheduled to undergo emergency coronary artery bypass graft • Serum creatinine is 1.8 mg/dL (increased), weight 60 kg • Calculated GFR is 35 mL/min/1.73 m^2 • Has stage 3b CKD
Injury	Serum creatinine increased × 2 *OR* GFR decreased by 50%	Urine output <0.5 mL/kg/hr for 12 hr	• During surgery, she is hypotensive for a sustained period • Diagnosed with acute tubular necrosis • After surgery: serum creatinine is 3.6 mg/dL, urine output reduced to 28 mL/hr
Failure	Serum creatinine increased × 3 *OR* GFR decreased by 75% *OR* Serum creatinine >4 mg/dL with acute rise ≥0.5 mg/dL	Urine output <0.3 mL/kg/hr for 24 hr (oliguria) *OR* Anuria for 12 hr	• 72 hours after surgery, develops ventilator-associated pneumonia and sepsis while in ICU • Serum creatinine rises to 5.2 mg/dL, urine output drops to 10 mL/hr • BP remains low despite dopamine therapy
Loss	Persistent acute kidney failure. Complete loss of kidney function >4 wk	—	• Starts on continuous venovenous hemodialysis • After 3 wk of therapy she has a cardiopulmonary arrest and does not survive
End-stage renal disease	• Complete loss of kidney function >3 mo	—	—

Nonoliguric AKI has a urine output greater than 400 mL/day. About 50% of patients will be nonoliguric, making the initial diagnosis more difficult.[7]

While changes in urine output generally do not correspond to changes in glomerular filtration rate (GFR), they can be helpful in distinguishing the cause of AKI. For example, **anuria** (no urine output) is usually seen with urinary tract obstruction. Oliguria is often seen with prerenal causes. Nonoliguric AKI occurs with acute interstitial nephritis and ATN.[8]

A urinalysis may show casts, RBCs, and white blood cells (WBCs). Casts form from mucoprotein impressions of the necrotic renal tubular epithelial cells, which slough into the tubules. The specific gravity may be fixed at around 1.010, with urine osmolality at about 300 mOsm/kg (300 mmol/kg). This is the same specific gravity and osmolality of plasma, thus reflecting tubular damage with a loss of concentrating ability by the kidney. Proteinuria may be present if AKI is related to glomerular membrane dysfunction.

Fluid Volume

Hypovolemia (volume depletion) has the potential to worsen all forms

of AKI. Fluid replacement is often enough to treat many forms of AKI, especially prerenal causes. When urine output decreases, fluid retention occurs. The severity of the manifestations depends on the extent of the fluid overload. In the case of reduced urine output (anuria and oliguria), the neck veins may become distended with a bounding pulse. Edema and hypertension may develop. Fluid overload can eventually lead to HF, pulmonary edema, and pericardial and pleural effusions.

Metabolic Acidosis

In the normal kidney, excess hydrogen ions are excreted to maintain a physiologic balance of the blood pH. Impaired kidneys cannot excrete hydrogen ions or the acid products of metabolism. Serum bicarbonate (HCO_3^-) production decreases from defective reabsorption and regeneration of HCO_3^- ions. Serum HCO_3^- is depleted through buffering of acidic hydrogen ions and metabolic end products. The patient with severe acidosis may develop Kussmaul respirations (rapid, deep respirations) to try to compensate by increasing CO_2 exhalation.

Sodium Balance

Damaged tubules cannot conserve sodium. Urinary sodium excretion may increase, resulting in normal or below-normal levels of serum sodium. Excess sodium intake is avoided because it can lead to volume expansion, hypertension, and HF. Uncontrolled hyponatremia or water excess can lead to cerebral edema.

Potassium Excess

The kidneys normally excrete 80% to 90% of the body's potassium. In AKI the serum potassium level increases because the kidney's normal ability to excrete potassium is impaired. The risk for hyperkalemia increases if AKI is caused by massive tissue trauma because the damaged cells release potassium into the extracellular fluid (ECF). Bleeding and blood transfusions may cause cellular destruction,

releasing more potassium into the ECF. Metabolic acidosis worsens hyperkalemia as hydrogen ions enter the cells, and potassium is driven out of the cells into the ECF.

While patients with hyperkalemia are often asymptomatic, some may have weakness with severe hyperkalemia. Because cardiac muscle is intolerant of acute increases in potassium, emergency treatment of hyperkalemia is needed.

Acute or rapid development of hyperkalemia may result in signs that are apparent on electrocardiogram (ECG). These changes include peaked T waves, widening of the QRS complex, and ST segment depression. Progressive changes in the ECG related to increasing potassium levels are shown in Fig. 16.14.

Hematologic Disorders

Several hematologic disorders occur in patients with AKI. Hospital-acquired AKI often occurs in patients who have multiorgan failure. Leukocytosis is often present. The most common cause of death in AKI is infection. The most common sites of infection are the urinary and respiratory systems.

Waste Product Accumulation

The kidneys are the primary excretory organs for urea (an end product of protein metabolism) and creatinine (an end product of endogenous muscle metabolism). BUN and serum creatinine levels are increased in kidney disease. An increased BUN level also can be caused by dehydration; corticosteroids; or catabolism resulting from infections, fever, severe injury, or GI bleeding. The best serum indicator of AKI is creatinine because it is not affected by other factors.

Neurologic Disorders

Neurologic changes can occur as the nitrogenous waste products accumulate in the brain and other nervous tissue. The manifestations can be as mild as fatigue and difficulty concentrating and escalate to seizures, stupor, and coma.

Diuretic Phase

During the diuretic phase of AKI, daily urine output is usually around 1 to 3 L but may reach 5 L or more. The nephrons are still not fully functional even as urine output increases. The high urine volume is caused by osmotic diuresis from the high urea concentration in the glomerular filtrate and the inability of the tubules to concentrate the urine. In this phase, the kidneys have recovered their ability to excrete wastes but not to concentrate the urine. Hypovolemia and hypotension can occur from massive fluid losses.

Patients who develop an oliguric phase will have greater diuresis as kidney function returns. Large losses of fluid and electrolytes require patient monitoring for hyponatremia, hypokalemia, and dehydration. The diuretic phase may last 1 to 3 weeks. Near the end of this phase, the patient's acid-base, electrolyte, and waste product (BUN, creatinine) values stabilize.

Recovery Phase

The recovery phase begins when the GFR increases, allowing the BUN and serum creatinine levels to decrease. Major improvements occur in the first 1 to 2 weeks of this phase. Kidney function may take up to 12 months to stabilize. The patient's overall health, severity of kidney injury, and number and type of complications influence the outcome of AKI. Some patients do not recover and progress to end-stage renal disease (ESRD). The older adult is less likely to have a complete recovery of kidney function. Patients who recover may achieve clinically normal kidney function but remain in an early stage of CKD.

Diagnostic Studies

A thorough history is essential for diagnosing the cause of AKI. Consider prerenal causes when there is a history of dehydration, hypotension, or blood loss. Suspect intrarenal causes if the patient has been exposed to potentially nephrotoxic drugs or contrast media used in a radiologic study. A history of changes in the urinary stream, stones, BPH, or bladder or prostate cancer suggests postrenal causes.

Although changes in urine output and serum creatinine occur relatively late in the course of AKI, they are known diagnostic indicators. An increase in serum creatinine may not be evident until there is a loss of more than 50% of kidney function. The rate of increase in serum creatinine is important as a diagnostic indicator in determining the severity of injury.

Urinalysis is an important diagnostic test. Urine sediment containing abundant cells, casts, or proteins suggests intrarenal disorders. The urine osmolality, sodium content, and specific gravity help in distinguishing the causes of AKI. Urine sediment may be normal in both prerenal and postrenal AKI. In intrarenal problems, hematuria, pyuria, and crystals may be seen. Other testing may be needed (Table 46.4). A kidney ultrasound is often the first test done. It provides imaging without exposure to potentially nephrotoxic contrast agents. It is useful for evaluating for kidney disease and obstruction of the urinary collection system. A renal scan can assess abnormalities in kidney blood flow, tubular function, and the collecting system. A CT scan can identify lesions, masses, obstructions, and vascular anomalies. A renal biopsy is the best method for confirming intrarenal causes of AKI.

Having an MRI or magnetic resonance angiography (MRA) study with the contrast media gadolinium is not advised in patients with kidney failure. Giving gadolinium can be potentially fatal.

In patients with normal kidney function, contrast media poses minimal risk. In patients with kidney disease, *contrast-induced nephropathy* (CIN) can occur when contrast media for diagnostic studies causes nephrotoxic injury. In patients with diabetes receiving metformin, the drug should be held for 48 hours prior to and after the use of contrast media to decrease the risk for lactic acidosis. The best way to avoid CIN is to avoid exposure to contrast media by using other diagnostic tests, such as ultrasound. If contrast media must be given to a high-risk patient, the patient needs to have optimal hydration and the lowest possible dose of the contrast agent. Nursing interventions to ensure adequate fluid intake and hydration can decrease the risks associated with contrast media. Other treatment

options to prevent CIN are controversial, such as giving HCO_3^- or sodium chloride solutions or prophylactic *N*-acetylcysteine.

TABLE 46.4 Interprofessional CareAcute Kidney Injury

Diagnostic Assessment

- History and physical examination
- Identify precipitating cause
- Serum creatinine and BUN levels
- Serum electrolytes
- Urinalysis
- Renal ultrasound
- Renal scan
- CT scan

Management

- Treat precipitating cause
- Fluid restriction (600 mL plus previous 24-hr fluid loss)
- Nutritional therapy
    - Adequate protein intake (0.6–2 g/kg/day) depending on degree of catabolism
    - Enteral nutrition
    - Parenteral nutrition
    - Dietary restrictions (potassium, phosphate, sodium)
- Measures to lower potassium (if high) (Table 46.5)
- Calcium supplements or phosphate-binding agents

- Dialysis (if necessary)
- Continuous RRT (if necessary)

Interprofessional Care

Because AKI is potentially reversible, the primary goals of treatment are to eliminate the cause, manage the signs and symptoms, and prevent complications while the kidneys recover (Table 46.4). The first step is to determine if there is adequate intravascular volume and cardiac output to ensure adequate perfusion of the kidneys. Diuretic therapy may be given and usually includes loop diuretics (e.g., furosemide [Lasix], bumetanide [Bumex]) or an osmotic diuretic (e.g., mannitol). If AKI is already established, forcing fluids and diuretics will not be effective and may be harmful. Closely monitor fluid intake during the oliguric phase of AKI.

The general rule for calculating the fluid restriction is to add all losses for the previous 24 hours (e.g., urine, diarrhea, emesis, blood) plus 600 mL for insensible losses (e.g., respiration, diaphoresis). For example, if a patient excreted 300 mL of urine on Tuesday with no other losses, the fluid allocation on Wednesday would be 900 mL.

Hyperkalemia is one of the most serious complications in AKI because it can cause life-threatening dysrhythmias. Therapies used to treat high potassium levels are listed in Table 46.5. Both insulin and sodium bicarbonate are temporary measures for treating hyperkalemia by promoting a transient shift of potassium into the cells. Potassium will eventually diffuse back into the bloodstream. Calcium gluconate raises the threshold at which dysrhythmias occur, temporarily stabilizing the myocardium. Only sodium polystyrene sulfonate (Kayexalate), patiromer (Veltassa), and dialysis remove potassium from the body.

TABLE 46.5 Therapies for High Potassium Levels

Calcium Gluconate IV

- Generally used in advanced cardiac toxicity (evidence of hyperkalemic ECG changes)
- Raises the threshold for excitation, resulting in dysrhythmias

Dietary Restriction

- Potassium intake is limited to 40 mEq/day
- Primarily used to prevent recurrent elevation, not for acute elevation

Hemodialysis

- Most effective therapy to remove potassium
- Works within a short time

Patiromer (Veltassa)

- Oral suspension that binds potassium in GI tract
- Used to treat patients with CKD
- Do not use as an emergency drug for life-threatening hyperkalemia
- Has a delayed onset of action
- Do not give to a patient with a paralytic ileus as bowel necrosis can occur

Regular Insulin IV

- Potassium moves into cells when insulin is given
- IV glucose given concurrently to prevent hypoglycemia
- When effects of insulin decrease, potassium shifts back out of

cells

Sodium Bicarbonate

- Can correct acidosis and cause a shift of potassium into cells

Sodium Polystyrene Sulfonate (Kayexalate)

- Given by mouth or retention enema
- When resin is in the bowel, potassium is exchanged for sodium
- Produces osmotic diarrhea, allowing for evacuation of potassium-rich stool

- Removes 1 mEq of potassium per 1 g of drug
- Do not give to a patient with a paralytic ileus as bowel necrosis can occur

Conservative therapy may be all that is necessary until kidney function improves. If conservative therapy is not effective in treating AKI, then *renal replacement therapy* (RRT) is used. Controversy exists about the timing of RRT in AKI.[11] The most common indications for RRT in AKI are (1) volume overload, resulting in compromised cardiac and/or pulmonary status; (2) high serum potassium level; (3) metabolic acidosis (serum HCO_3^- level less than 15 mEq/L [15 mmol/L]); (4) BUN level greater than 120 mg/dL (43 mmol/L); (5) significant change in mental status; and (6) pericarditis, pericardial effusion, or cardiac tamponade. Although laboratory values provide rough parameters, the best guideline is the clinical status of the patient.

Of the several RRT therapy options available, there is no consensus about the best approach.[10] Even though peritoneal dialysis (PD) is a viable option for RRT, it is not often used. Intermittent hemodialysis (HD) and continuous renal replacement therapy (CRRT) have both

been used effectively.

CRRT is provided continuously over 24 hours through cannulation of a vein or catheter placement. CRRT has much slower blood flow rates compared with intermittent HD. HD is the method of choice when changes are needed emergently. It is technically more complicated because it requires specialized staff and equipment and vascular access. The patient needs anticoagulation therapy to prevent blood clotting when the blood makes contact with the extracorporeal dialysis circuit. Rapid fluid shifts during HD may cause hypotension. (RRT and CRRT are discussed later in this chapter on pp. 1076–1080.)

Nutritional Therapy

The goal of nutritional management in AKI is to provide adequate calories to prevent catabolism despite restrictions that prevent electrolyte and fluid problems and azotemia. Nutritional intake must maintain adequate caloric intake (providing 30 to 35 kcal/kg and 0.8 to 1.0 g of protein per kilogram of desired body weight) to prevent the breakdown of body protein.

Adequate energy should primarily be from carbohydrate and fat sources to prevent ketosis from endogenous fat breakdown and gluconeogenesis from muscle protein breakdown. Essential amino acids may be supplemented. Potassium and sodium are regulated per plasma levels. Sodium is restricted as needed to prevent edema, hypertension, and HF. Dietary fat intake is increased so that the patient receives at least 30% to 40% of total calories from fat. Fat emulsion IV infusions given as a nutritional supplement provide a good source of nonprotein calories. If a patient cannot maintain adequate oral intake, enteral nutrition is the preferred route for nutritional support (see Chapter 39). When the gastrointestinal (GI) tract is not functional, parenteral nutrition (PN) is necessary to provide adequate nutrition. The patient treated with PN may need daily HD or CRRT to remove the excess fluid. Concentrated PN formulas are available to minimize fluid volume.

Nursing Management: Acute Kidney Injury

Nursing Assessment

A number of assessments are essential for developing an interprofessional plan of care.[12] Daily weights, strict intake and output, and vital signs are key. Daily monitoring of a patient's urine output has prognostic implications and is crucial for determining therapy and daily fluid volume replacement. Examine the urine for color, specific gravity, glucose, protein, blood, and sediment. Assess the patient's general appearance, including skin color, edema, neck vein distention, and bruises. If a patient is receiving dialysis, observe the access site for inflammation and exudate. Evaluate the patient's mental status and level of consciousness. Assess the oral mucosa for dryness and inflammation. Auscultate the lungs for crackles and wheezes or decreased breath sounds. Monitor the heart for an S_3 gallop, murmurs, or a pericardial friction rub. Assess ECG readings for dysrhythmias. Review all laboratory values and diagnostic test results.

Nursing Diagnoses

Nursing diagnoses for the patient with AKI include:

- Electrolyte imbalance
- Fluid imbalance
- Risk for infection
- Anxiety

Planning

The overall goals are that the patient with AKI will (1) completely recover without any loss of kidney function, (2) maintain normal fluid and electrolyte balance, (3) have decreased anxiety, and (4) adhere to

and understand the need for careful follow-up care.

Nursing Implementation

Health Promotion

Prevention and early recognition of AKI are the most important aspects of care. Prevention is directed primarily toward identifying and monitoring high-risk populations, controlling exposure to nephrotoxic drugs and industrial chemicals, and preventing prolonged episodes of hypotension and hypovolemia. In the hospital, factors that increase the risk for developing AKI are preexisting CKD, older age, massive trauma, major surgical procedures, extensive burns, HF, sepsis, and obstetric complications.

Carefully monitor the patient's weight, intake and output, and fluid and electrolyte balance. Assess and record extrarenal losses of fluid from vomiting, diarrhea, hemorrhage, and increased insensible losses. Prompt replacement of significant fluid losses helps prevent ischemic tubular damage associated with trauma, burns, and extensive surgery. Intake and output records and the patient's weight are valuable indicators of fluid volume status. Aggressive diuretic therapy for the patient with fluid overload from any cause can lead to a reduction in renal blood flow.

Monitor kidney function in persons who are taking drugs that are potentially nephrotoxic (see Table 44.3). Nephrotoxic drugs should be used sparingly in the high-risk patient. When these drugs must be used, they should be given in the smallest effective doses for the shortest possible periods. Caution the patient about abuse of over-the-counter (OTC) analgesics (especially nonsteroidal antiinflammatory drugs [NSAIDs]), as these may worsen kidney function in the patient with mild CKD.

Angiotensin-converting enzyme (ACE) inhibitors can decrease perfusion pressure and cause hyperkalemia. If other measures, such as diet modification and diuretics, cannot control the hyperkalemia, ACE inhibitors may have to be reduced or stopped. However, ACE inhibitors are often used to prevent proteinuria and progression of

kidney disease, especially in patients with diabetes.[13]

Acute Care

The patient with AKI is critically ill and may have co-morbid diseases or conditions (e.g., diabetes, cardiovascular disease [CVD]) in addition to kidney injury. Focus on the patient holistically since they will have many physical and emotional needs. Usually the changes caused by AKI arise suddenly. The patient needs help in understanding that kidney disease may affect the entire body's functions.

You have a key role in managing fluid and electrolyte balance during the oliguric and diuretic phases. Observe and record accurate intake and output. Take daily weights with the same scale at the same time each day to detect excessive gains or losses of body fluid (1 kg is equivalent to 1000 mL of fluid). Assess for signs and symptoms of hypervolemia (in the oliguric phase) or hypovolemia (in the diuretic phase), potassium and sodium problems, and other electrolyte imbalances that may occur in AKI (see Chapter 16).

Because infection is the leading cause of death in AKI, meticulous aseptic technique is critical. Protect the patient from those with infectious diseases. Be alert for local manifestations of infection (e.g., swelling, redness, pain) as well as systemic manifestations (e.g., fever, malaise, leukocytosis).

If a patient with renal failure has an infection, it is important to recognize that the temperature may not always be high. Patients with AKI have a blunted febrile response to an infection (e.g., pneumonia). If antibiotics are used to treat an infection, the type, frequency, and dosage must be carefully considered because the kidneys are the primary route of excretion for many antibiotics. Dosages may be decreased depending on the patient's level of kidney function if the drug is eliminated by the kidneys. Nephrotoxic drugs (see Table 44.3) should be used judiciously.

Perform skin care and take measures to prevent pressure injuries as mobility may be impaired. Mouth care is important to prevent stomatitis, which develops when ammonia (made by bacterial breakdown of urea) in saliva irritates the mucous membranes.

Informatics in Practice

Computer Monitoring of Antibiotic Safety

- Many patients receiving antibiotic therapy are at risk for kidney failure.
- Set the computer to alert you about elevated creatinine levels and, if possible, send you a text message.
- By notifying the HCP early, medications can be stopped or doses decreased and the patient's kidney function preserved.

Ambulatory Care

Recovery from AKI is highly variable and depends on whether other body systems fail, the patient's general condition and age, the length of the oliguric phase, and the severity of nephron damage. Protein and potassium intake are dictated by kidney function. Regular evaluation of kidney function is necessary. Teach the patient the signs and symptoms of recurrent kidney disease. Emphasize measures to prevent the recurrence of AKI.

The long-term convalescence of 3 to 12 months may cause psychosocial and financial hardships for the patient, caregiver, and family. Make appropriate referrals for counseling. If the kidneys do not recover, the patient will need to transition to life on chronic dialysis or possible transplantation.

Evaluation

The expected outcomes are that the patient with AKI will

- Regain and maintain normal fluid and electrolyte balance
- Adhere to the treatment regimen
- Have no complications
- Have a complete recovery

Gerontologic Considerations: Acute Kidney Injury

The GFR declines with age. In older adults, impaired function of other organ systems from CVD or diabetes can increase the risk for developing AKI. The aging kidney is less able to compensate for changes in fluid volume, solute load, and cardiac output.

Although the causes of AKI in older adults are similar to younger adults, they are at an increased risk for AKI. Dehydration is a predisposing factor and tends to occur more often in older adults. Dehydration can occur from polypharmacy (diuretics, laxatives, drugs that suppress appetite or consciousness), acute febrile illnesses, and immobility.

Other common causes of AKI in the older adult include hypotension, diuretic therapy, aminoglycoside therapy, obstructive disorders (e.g., BPH), surgery, infection, and contrast media. Mortality rates are similar for older and younger patients. Patients over 65 years of age are less likely to recover from AKI. Despite this, age is not a barrier to offering RRT.[11]

Chronic Kidney Disease

Chronic kidney disease (CKD) involves progressive, irreversible loss of kidney function. More than 26 million American adults, or 1 out of every 9, have CKD. CKD is much more common than AKI (Table 46.1). We partially attribute the increasing prevalence of CKD to increased risk factors, including an aging population, increased rates of obesity, and increased incidence of diabetes and hypertension.

Because the kidneys are highly adaptive, kidney disease is often not recognized until there has been considerable loss of nephrons. Patients with CKD are often asymptomatic, resulting in CKD being underdiagnosed and untreated. It is thought that about 70% of people with CKD are unaware that they have the disease.[14]

CKD has many different causes. The leading ones are diabetes (about 50%) and hypertension (about 25%) (Table 46.6). Less common

causes include glomerulonephritis, cystic diseases, and urologic diseases.[15] Kidney diseases are discussed in Chapter 45.

Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines defines CKD as either the presence of kidney damage or a decreased GFR less than 60 mL/min/1.73 m^2 for longer than 3 months. The stages of CKD are shown in Table 46.7. The last stage of kidney disease, **end-stage renal disease (ESRD)**, occurs when the GFR is less than 15 mL/min. At this point, RRT (dialysis or transplantation) is required to maintain life.

TABLE 46.6 Risk Factors for Chronic Kidney Disease

Risk Factors	Prevention and Management
Age >60 yr	Prevent insult or injury to kidneys
Cardiovascular disease	Institute aggressive risk factor reduction
Diabetes	Achieve optimal glycemic control
Ethnic minority (e.g., black, Native American)	Teach about ↑ risk and assist with appropriate screening (BP measurement, urinalysis)
Exposure to nephrotoxic drugs	Limit exposure and give sodium bicarbonate as treatment
Family history of CKD	Teach about ↑ risk and assist with appropriate screening
Hypertension	Maintain BP in normal range with ACE inhibitors or ARBs

TABLE 46.7 Stages of Chronic Kidney Disease

Description	GFR (mL/min/1.73 m^2)	Clinical Action Plan
Stage 1		
Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment CVD risk reduction Slow progression
Stage 2		
Kidney damage with mild ↓ GFR	60–89	Estimation of progression
Stage 3a		
Moderate ↓ GFR	45–59	Evaluation and treatment of complications
Stage 3b		
Moderate ↓ GFR	30–44	More aggressive treatment of complications
Stage 4		
Severe ↓ GFR	15–29	Preparation for renal replacement therapy (dialysis, kidney transplant)
Stage 5		
Kidney failure	<15 (or dialysis)	Renal replacement therapy (if uremia present and patient desires treatment)

Source: Alseiari M, Meyer KB, Wong JB: Evidence underlying KDIGO (Kidney Disease: Improving Global Outcomes) guideline recommendations: A systematic review, *Am J Kidney Dis* 67:417, 2016.

Over half a million Americans are receiving treatment (dialysis, transplant) for ESRD. Despite all the technologic advances in life-sustaining treatment with dialysis, patients with ESRD have a high mortality rate. As the stage of kidney disease progresses, the mortality rate increases. Mortality rates are as high as 19% to 24% for patients with ESRD on dialysis.[14,16]

The prognosis and course of CKD are highly variable depending on the cause, patient's condition and age, and adequacy of health care follow-up. Some people live normal, active lives with kidney disease, while others may rapidly progress to ESRD (stage 5).

Since 1972, the United States has covered most of the costs of providing dialysis through Medicare benefits. Under Title XVIII of the Social Security Act, ESRD was recognized as a disability. Medicare pays for 80% of eligible charges. The state, private insurance, or patient covers the rest.[16]

Promoting Health Equity

Chronic Kidney Disease

- Has a high incidence in minority populations, especially blacks and Native Americans
- Hypertension and diabetes are more common in blacks and Native Americans

Blacks

- The risk for CKD as a complication of hypertension is significantly higher in blacks
- Have the highest rate of CKD, nearly 4 times that of whites

Native Americans

- Have a rate of CKD twice that of whites
- Rate of CKD is 6 times higher among Native Americans with diabetes than among other ethnic groups with diabetes

Hispanics

- Rate of CKD in Hispanics is 1.5 times higher than in non-Hispanic whites

Clinical Manifestations

As kidney function deteriorates, all body systems become affected. The manifestations result from retained urea, creatinine, phenols, hormones, electrolytes, and water. **Uremia** is a syndrome in which kidney function declines to the point that symptoms may develop in multiple body systems (Fig. 46.2). It often occurs when the GFR is 15 mL/min or less. The manifestations of uremia vary among patients depending on the cause of the kidney disease, co-morbid conditions, age, and degree of adherence to the prescribed medical regimen. Many patients are tolerant of the changes caused by declining kidney

function because they occur gradually.

Urinary System

In the early stages of CKD, patients usually do not report any change in urine output. Since diabetes is the primary cause of CKD, polyuria may be present, but not necessarily from kidney disease. As CKD progresses, patients have increasing difficulty with fluid retention and need diuretic therapy. After a period on dialysis, patients may develop anuria.

Metabolic Disturbances

Waste Product Accumulation

As the GFR decreases, the BUN and serum creatinine levels increase. The BUN increase is not only from kidney disease but also protein intake, fever, corticosteroids, and catabolism. For this reason, serum creatinine clearance determinations (calculated GFR) are considered more accurate indicators of kidney function than BUN or creatinine (Table 46.8). Significant increases in BUN contribute to nausea, vomiting, lethargy, fatigue, impaired thought processes, and headaches.

Altered Carbohydrate Metabolism

Impaired glucose metabolism, resulting from cellular insensitivity to the normal action of insulin, causes defective carbohydrate metabolism. Mild to moderate hyperglycemia and hyperinsulinemia may occur.

Insulin and glucose metabolism may improve (but not to normal values) after starting dialysis. Patients with diabetes who needed insulin before starting dialysis may need less insulin therapy when they start dialysis and their kidney disease progresses. Patients with diabetes who develop uremia may need less insulin than before the onset of CKD. Insulin, which depends on the kidneys for excretion, stays in the circulation longer. Insulin dosing must be individualized,

and glucose levels monitored carefully.

Check Your Practice

You are working in a community-based dialysis unit. One of your patients is a 56-yr-old woman who has been on HD for 3 weeks. You are reviewing her medications with her and she is surprised that her dose of glargine insulin has been decreased. She tells you, "I have been a diabetic for 30 years, and this is the first time ever that my dose of insulin has been decreased."

- How would you respond?

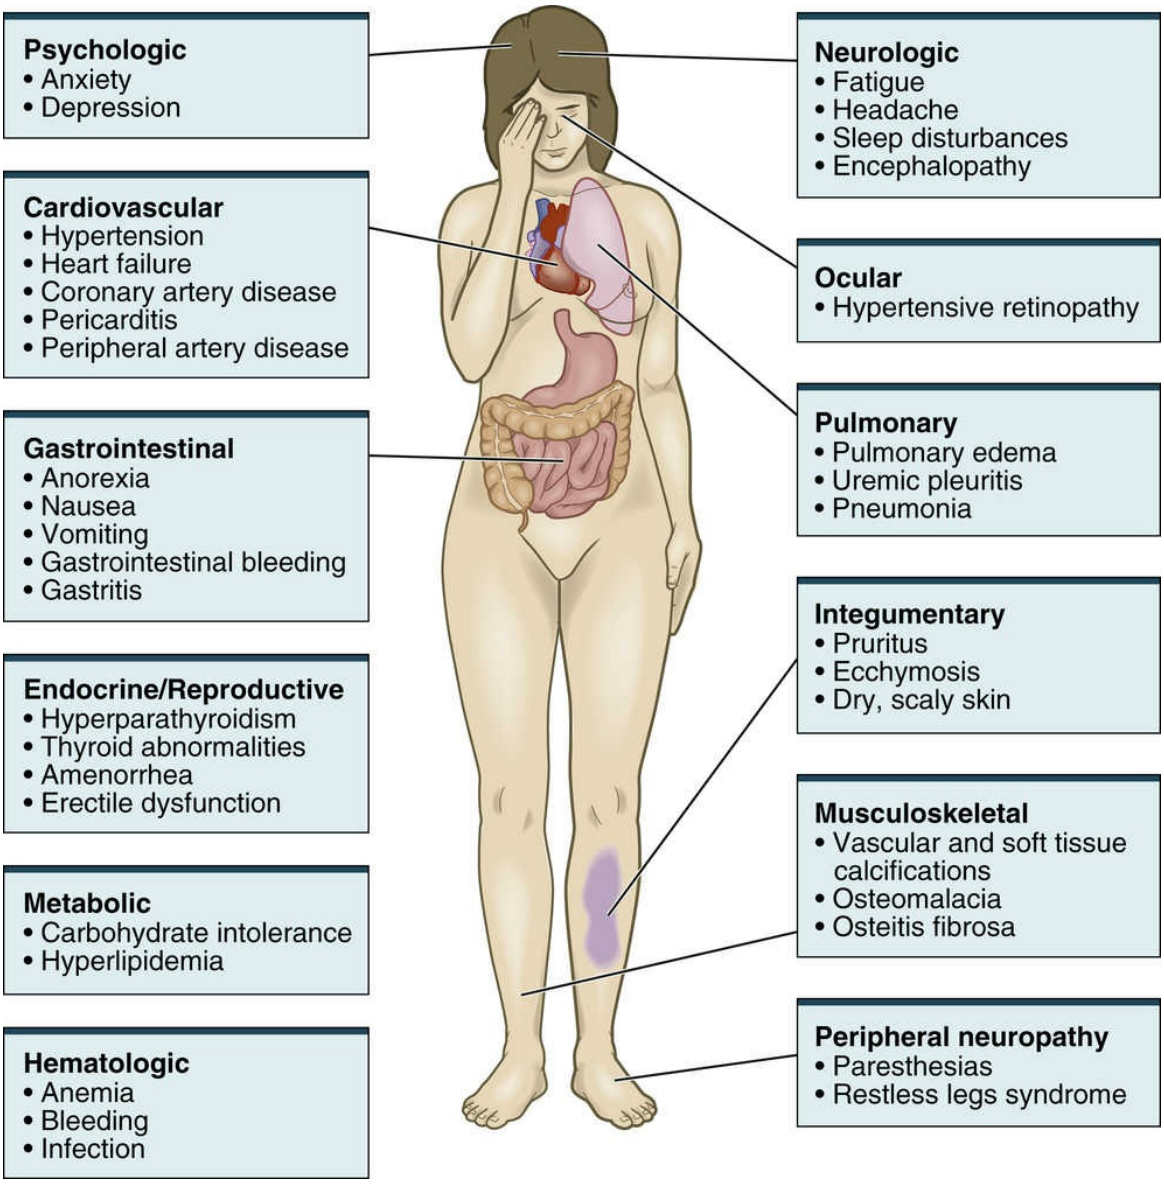

FIG. 46.2 Possible manifestations of CKD.

TABLE 46.8 Indicators of Kidney Function

This example shows why serum creatinine alone is a poor indicator of kidney function. Calculation of GFR is considered the best index to estimate kidney function as shown by the following example.

Estimation of GFR	Type of Patient	
	76-Yr-Old Black Woman (Weight 56 kg)	28-Yr-Old Black Man (Weight 74 kg)
Serum creatinine	1.4 mg/dL	1.4 mg/dL
GFR, estimated by the Cockcroft-Gault formula*	30.2 mL/min	82.2 mL/min
GFR, estimated by MDRD equation†	47 mL/min/1.73 m^2	64 mL/min/1.73 m^2

Cr, Creatinine; *GFR*, glomerular filtration rate; *MDRD*, modification of diet in renal disease.

* Cockcroft-Gault GFR = (140 − Age) × (Weight in kilograms) × (0.85 if female)/(72 × Cr).

† GFR as estimated by MDRD equation calculator can be accessed at www.mdrd.com .

Elevated Triglycerides

Hyperinsulinemia stimulates hepatic production of triglycerides. Many patients with uremia develop dyslipidemia, with increased very-low-density lipoproteins (VLDLs), increased low-density lipoproteins (LDLs), and decreased high-density lipoproteins (HDLs). The altered lipid metabolism is related to decreased levels of the enzyme lipoprotein lipase, which is important in the breakdown of lipoproteins. Most patients with CKD die from CVD.[17]

Electrolyte and Acid-Base Imbalances

Potassium

Hyperkalemia is a serious electrolyte disorder associated with CKD. Fatal dysrhythmias can occur when the serum potassium level reaches 7 to 8 mEq/L (7 to 8 mmol/L). Hyperkalemia results from the decreased excretion of potassium by the kidneys, the breakdown of cellular protein, bleeding, and metabolic acidosis. Potassium may come from foods, dietary supplements, drugs, and IV infusions.

Sodium

Sodium may be high, normal, or low in kidney disease. Because of impaired sodium excretion, sodium is retained with water. If large quantities of water are retained, dilutional hyponatremia occurs. Sodium retention can contribute to edema, hypertension, and HF. Sodium intake is patient specific but is generally restricted to 2 g/day.

Calcium and Phosphate

Calcium and phosphate changes are discussed in the section on the musculoskeletal system on pp. 1068–1069.

Magnesium

Magnesium is primarily excreted by the kidneys. Hypermagnesemia is generally not a problem unless the patient is ingesting magnesium (e.g., Milk of Magnesia, magnesium citrate, antacids containing magnesium). Manifestations can include absent reflexes, decreased mental status, dysrhythmias, hypotension, and respiratory failure.

Metabolic Acidosis

Metabolic acidosis results from the kidneys' impaired ability to excrete excess acid and from defective reabsorption and regeneration of HCO_3^-. The average adult makes 80 to 90 mEq of acid per day. This acid is normally buffered by HCO_3^-. In kidney disease, plasma HCO_3^-, which is an indirect measure of acidosis, usually falls to a new steady state at around 16 to 20 mEq/L (16 to 20 mmol/L). The decreased plasma HCO_3^- reflects its use in buffering metabolic acids. The HCO_3^- level generally does not progress below this level because hydrogen ion production is usually balanced by buffering from demineralization of the bone (the phosphate buffering system).

Hematologic System

Anemia

A normocytic, normochromic anemia is associated with CKD. Anemia in CKD is due to decreased production of the hormone erythropoietin by the kidneys. Erythropoietin normally stimulates precursor cells in the bone marrow to make RBCs (erythropoiesis). Other factors contributing to anemia are nutritional deficiencies, decreased RBC life span, increased hemolysis of RBCs, frequent blood samplings, and GI bleeding. For patients receiving maintenance HD, blood loss in the

dialyzer can contribute to the anemic state. Increased parathyroid hormone (PTH) (made to compensate for low serum calcium levels) can inhibit erythropoiesis, shorten survival of RBCs, and cause bone marrow fibrosis, which can result in decreased numbers of hematopoietic cells.

We need sufficient iron stores for erythropoiesis. Many patients with kidney disease are iron deficient and need iron supplementation. Oral iron supplements may not be effective for the person with CKD. GI side effects can cause adherence difficulties. Medications, such as proton pump inhibitors or phosphate binders, decrease absorption. Patients on dialysis may need IV iron to restore iron levels. Folic acid, essential for RBC maturation, is dialyzable because it is water soluble. Many patients receive supplemental folic acid (1 mg/day).[18]

Bleeding Tendencies

The most common cause of bleeding in uremia is a qualitative defect in platelet function. This dysfunction is caused by impaired platelet aggregation and impaired release of platelet factor III. Changes in the coagulation system occur due to increased concentrations of both factor VIII and fibrinogen. The altered platelet function, hemorrhagic tendencies, and GI bleeding susceptibility can usually be corrected with regular HD or PD.

Infection

Patients with advanced CKD have an increased susceptibility to infection. This is due to changes in WBC function and altered immune response and function. Both cellular and humoral immune responses are suppressed. Other factors contributing to the increased risk for infection include hyperglycemia and external trauma (e.g., catheters, needle insertions into vascular access sites).

Cardiovascular System

The most common cause of death in patients with CKD is CVD. Leading causes of death are myocardial infarction (MI), ischemic heart

disease, peripheral arterial disease, HF, cardiomyopathy, and stroke.[17] CVD and CKD are so closely linked that if patients develop cardiac events (e.g., MI, HF), kidney function is evaluated. Traditional CVD risk factors, such as hypertension and increased lipids, are common in CKD patients.

CVD may be related to vascular calcification and arterial stiffness. Calcium deposits in the vascular medial layer are associated with stiffening of the blood vessels. The mechanisms involved are multifactorial. They include (1) vascular smooth muscle cells changing into chondrocytes or osteoblast-like cells, (2) high total body amount of calcium and phosphate resulting from abnormal bone metabolism, (3) impaired renal excretion, and (4) drug therapies to treat the bone disease (e.g., calcium-phosphate binders).[19]

Hypertension, which is prevalent in patients with CKD, is both a cause and a consequence of CKD. Hypertension is worsened by sodium retention and increased ECF volume.[20] In some people, increased renin production contributes to hypertension. Hypertension and diabetes are contributing risk factors for vascular complications.[19] Long-standing hypertension, ECF volume overload, and anemia contribute to development of left ventricular hypertrophy that may eventually lead to cardiomyopathy and HF. Hypertension can cause retinopathy, encephalopathy, and nephropathy. Because of the many effects of hypertension, BP control is one of the most important therapeutic goals in the management of CKD.[20]

Patients with CKD are susceptible to dysrhythmias from hyperkalemia and decreased coronary artery perfusion. Uremic pericarditis can develop and sometimes progresses to pericardial effusion and cardiac tamponade. Pericarditis typically presents with a friction rub, chest pain, and low-grade fever.

Respiratory System

With severe acidosis, the respiratory system may try to compensate with Kussmaul breathing, which results in increased CO_2 removal by exhalation (see Chapter 16). Dyspnea may occur because of fluid

overload, pulmonary edema, uremic pleuritis (pleurisy), pleural effusions, and respiratory infections (e.g., pneumonia).

Gastrointestinal System

Stomatitis with exudates and ulcerations, a metallic taste in the mouth, and *uremic fetor* (a urinous odor of the breath) often occur in CKD. Anorexia, nausea, and vomiting may develop if CKD progresses to ESRD and is not treated with dialysis. Weight loss and malnutrition may occur. Diabetic *gastroparesis* (delayed gastric emptying) can compound the effects of malnutrition for patients with diabetes. GI bleeding is a risk because of mucosal irritation and the platelet defect.

Constipation may be due to ingesting iron salts or calcium-containing phosphate binders. Limitations on fluid intake and physical inactivity can increase the risk for constipation.

Neurologic System

Neurologic changes are expected as kidney disease progresses. They are the result of increased nitrogenous waste products, electrolyte imbalances, metabolic acidosis, and atrophy and demyelination of nerve fibers.

The central nervous system (CNS) becomes depressed, resulting in lethargy, apathy, decreased ability to concentrate, fatigue, irritability, and altered mental ability. Seizures and coma may result from a rapidly increasing BUN and hypertensive encephalopathy.

Peripheral neuropathy initially manifests as a slowing of nerve conduction to the extremities. The patient may describe paresthesias in the feet and legs as a burning sensation. Eventually, motor involvement may lead to bilateral foot drop, muscular weakness and atrophy, and loss of deep tendon reflexes. Muscle twitching, jerking, *asterixis* (hand-flapping tremor), and nocturnal leg cramps may occur. In patients with diabetic neuropathy, uremic neuropathy can compound symptoms.[21] Those with advanced stage 5 CKD may develop restless legs syndrome (see Chapter 58).

Dialysis should improve general CNS manifestations and may slow or halt the progression of neuropathies. Motor neuropathy may not be

reversible. The treatment for neurologic problems is dialysis or transplantation. Altered mental status, a late manifestation of CKD stage 5, rarely occurs unless the patient has chosen not to have RRT.

Musculoskeletal System

CKD mineral and bone disorder (CKD-MBD) develops as a systemic disorder of mineral and bone metabolism caused by progressive deterioration in kidney function (Fig. 46.3). Activated vitamin D is necessary to optimize absorption of calcium from the GI tract. As kidney function deteriorates, less vitamin D is converted to its active form, resulting in decreased serum levels. Low levels of active vitamin D result in decreased serum calcium levels.[19]

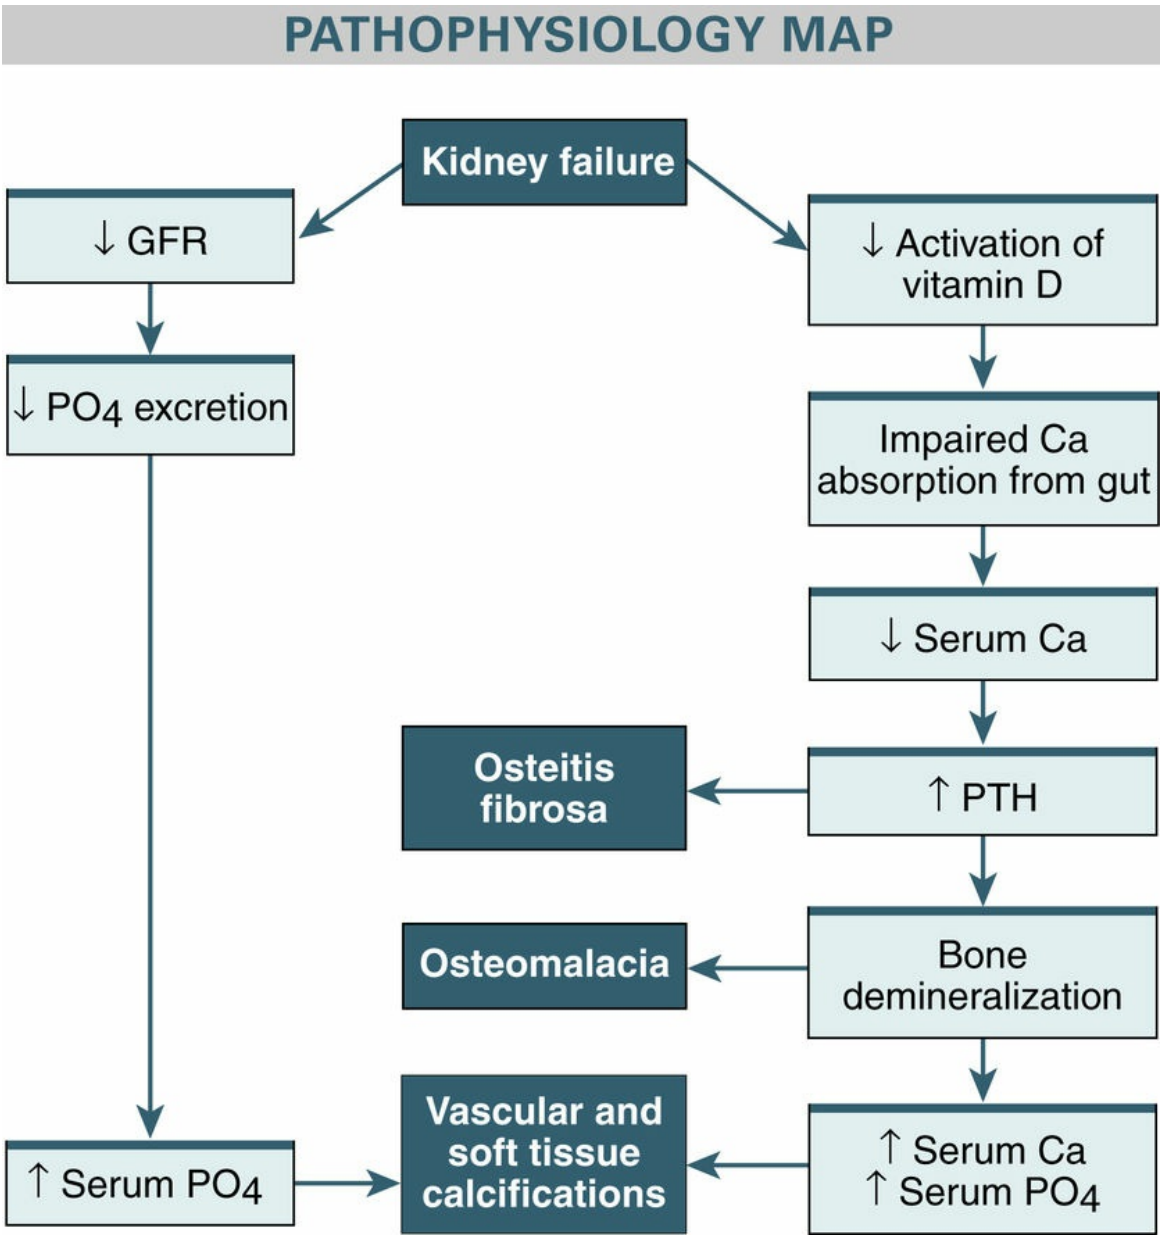

FIG. 46.3 Mechanisms of CKD-MBD. *GFR*, Glomerular filtration rate; *PTH,* parathyroid hormone.

Serum calcium levels are regulated primarily by PTH. When hypocalcemia occurs, the parathyroid gland secretes PTH, which stimulates bone demineralization, releasing calcium from the bones. Phosphate is also released, leading to high serum phosphate levels. Hyperphosphatemia results from decreased phosphate excretion by the kidneys. It decreases serum calcium levels and further reduces the kidneys' ability to activate vitamin D.

Low serum calcium, increased phosphate, and decreased vitamin D contribute to the stimulation of the parathyroid gland and excretion of PTH. PTH acts on the bone to increase remodeling and increase serum calcium levels. The accelerated rate of bone remodeling causes a weakened bone matrix and places the patient at a higher risk for fractures.

Normally plasma calcium is found ionized or free (physiologically active form) or bound to protein. Low ionized calcium levels can lead to tetany (see Chapter 16). However, in CKD, it is unusual for hypocalcemia to be symptomatic. In the acidotic state associated with CKD, more calcium is in the ionized form than is bound to protein.

CKD-MBD is a common complication of CKD and results in skeletal complications, vascular and soft tissue (extraskeletal) complications. Skeletal complications include (1) *osteomalacia* (results from demineralization from slow bone turnover and defective mineralization of newly formed bone) and (2) *osteitis fibrosa* (decalcification of the bone and replacement of bone tissue with fibrous tissue).

Soft tissue complications result from vascular calcifications. Vascular calcifications are a significant contributing factor to CVD. Irritation from calcium deposits in the eye can cause "uremic red eye." Intracardiac calcifications can disrupt the conduction system and cause cardiac arrest.

Integumentary System

A small number of patients develop refractory pruritus that can have a devastating impact on their well-being and quality of life. Pruritus has multiple causes, including dry skin, calcium-phosphate deposition in the skin, and sensory neuropathy. It is more common in patients receiving dialysis than in the earlier stages of CKD. The itching may be so intense that it can lead to bleeding or infection from scratching. Uremic frost is an extremely rare condition in which urea crystallizes on the skin. This is usually seen only when BUN levels are extremely high (e.g., over 200 mg/dL).

Reproductive System

Both men and women can have infertility and a decreased libido. Women usually have low levels of estrogen, progesterone, and luteinizing hormone, causing anovulation and menstrual changes (usually amenorrhea). Menses and ovulation may return after starting dialysis. Men have loss of testicular consistency, decreased testosterone levels, and low sperm counts.

Sexual dysfunction may be caused by anemia, which causes fatigue and decreased libido. Peripheral neuropathy can cause impotence in men and anorgasmia in women. Other factors that may cause changes in sexual function are psychologic problems (e.g., anxiety, depression), physical stress, and medication side effects. Sexual function may improve with maintenance dialysis and become normal with successful transplantation.

Patients who become pregnant while receiving dialysis have been able to carry a fetus to term, but there is significant risk to the mother and infant. Pregnancy in patients with a kidney transplant is more common, but there is still considerable risk to both the mother and fetus.

Psychologic Changes

Personality and behavioral changes, emotional lability, withdrawal, and depression often occur in patients with CKD. Fatigue and lethargy contribute to the feeling of illness. The changes in body image caused by edema, integumentary changes, and access devices (e.g., fistulas, catheters) may lead to anxiety and depression. Decreased ability to concentrate and slowed mental activity can give the appearance of dullness and disinterest in the environment. The patient must deal with significant changes in lifestyle, occupation, family responsibilities, and financial status. Long-term survival depends on medications, dietary restrictions, dialysis, and possibly transplantation. The patient grieves the loss of kidney function and independence.

Diagnostic Studies

Persistent proteinuria is usually the first sign of kidney damage. Screening for CKD involves a dipstick evaluation of protein in the urine or evaluation for albuminuria, which is not detected with routine urinalysis. The urine of patients with diabetes must be examined for albuminuria if no protein is present on routine urinalysis. A person with persistent proteinuria (1+ protein on standard dipstick testing 2 or more times over a 3-month period) should have further assessment of risk factors and a diagnostic workup with blood and urine tests to evaluate for CKD.

A urinalysis can detect RBCs, WBCs, protein, casts, and glucose. A renal ultrasound is usually done to detect any obstructions and determine the size of the kidneys. Other diagnostic studies (Table 46.9) help establish the diagnosis and cause of CKD. A kidney biopsy may be necessary to provide a definitive diagnosis.

Serum creatinine alone poorly reflects kidney function. GFR is the preferred measure to determine kidney function. Several GFR calculators are available. The equations used most often to estimate GFR are the Cockcroft-Gault formula and Modification of Diet in Renal Disease (MDRD) Study equation (Table 46.8). MDRD is the preferred method.[22]

TABLE 46.9 Interprofessional CareChronic Kidney Disease

Diagnostic Assessment

- History and physical examination
- Identification of reversible kidney disease
- Renal ultrasound, renal scan, CT scan
- Renal biopsy
- BUN, serum creatinine, and creatinine clearance levels

- Serum electrolytes
- Lipid profile
- Urinalysis
- Protein-to-creatinine ratio in first morning voided specimen
- Hematocrit and hemoglobin levels

Management

- Correction of extracellular fluid volume overload or deficit
- RRT (dialysis, kidney transplant)
- Nutritional therapy (Tables 46.10 and 16.6)
- Measures to lower potassium (Table 46.5)

Drug Therapy

- Calcium supplementation, phosphate binders, or both
- Antihypertensive therapy
- ACE inhibitors or ARBs
- Erythropoietin therapy
- Lipid-lowering drugs
- Adjustment of drug dosages to degree of renal function

Interprofessional Care

The overall goals of CKD therapy are to preserve existing kidney function, reduce the risks for CVD, prevent complications, and provide for the patient's comfort. Early recognition, diagnosis, and treatment can prevent the progression of kidney disease. It is important that patients with CKD receive appropriate referral to a nephrologist early in the course of the disease. Every effort is made to detect and treat potentially reversible causes of kidney failure (e.g., HF, dehydration, infections, nephrotoxins, urinary tract obstruction,

glomerulonephritis, renal artery stenosis).

Patients with CKD have a high incidence of CVD. More patients die from CVD than live to need dialysis. When a patient has CKD, therapy is aimed at treating CVD in addition to slowing the progression of kidney disease (Table 46.9).

A focus on stages 1 through 4 (Table 46.7) before the need for dialysis (stage 5) includes the control of hypertension, hyperparathyroidism, CKD-MBD, anemia, and dyslipidemia. The next section focuses primarily on the drug and nutritional aspects of care.

Drug Therapy

Hyperkalemia

Multiple strategies are used to manage hyperkalemia (Table 46.5). These include restricting high-potassium foods and drugs. Acute hyperkalemia may need treatment with IV glucose and insulin or IV 10% calcium gluconate.

Sodium polystyrene sulfonate, a cation-exchange resin, is often given to lower potassium levels in stage 4 CKD. Sodium polystyrene sulfonate has an osmotic laxative action and ensures evacuation of the potassium from the bowel. Tell the patient to expect some diarrhea. Never give sodium polystyrene sulfonate to a patient with a hypoactive bowel (paralytic ileus) because fluid shifts could lead to bowel necrosis. Since sodium polystyrene sulfonate exchanges sodium ions for potassium ions, observe the patient for sodium and water retention. If changes appear in the ECG, such as peaked T waves and widened QRS complexes, dialysis may be needed to remove excess potassium.

Patiromer (Veltassa) is an oral suspension that binds potassium in the GI tract. It is used to treat hyperkalemia in persons with CKD. It should not be used in emergency situations to treat hyperkalemia because of its delayed onset of action. Because this drug can bind other oral medications, it needs to be taken at least 6 hours before or 6 hours after other oral medications.

Hypertension

For some, the progression of CKD can be delayed by controlling hypertension.[20] Treatment of hypertension includes (1) weight loss (if indicated), (2) therapeutic lifestyle changes (e.g., exercise, avoidance of alcohol, smoking cessation), (3) diet recommendations (DASH Diet), and (4) antihypertensive drugs. Most patients need 2 or more drugs to reach target BP. The treatment of hypertension is discussed in Chapter 32.

Prescribed medications depend on whether the patient with CKD has diabetes. ACE inhibitors and ARBs are given to patients with diabetes and those with nondiabetic proteinuria. They decrease proteinuria and may delay the progression of CKD. They must be used with caution as they can further decrease the GFR and increase serum potassium levels.

Measure the BP with the patient in the supine, sitting, and standing positions to monitor the effect of antihypertensive drugs. Teach the patient and caregiver how to monitor the BP at home and what readings require immediate intervention.

CKD-MBD

It is hard to determine what type of bone disease a patient may have by just looking at the serum levels of calcium, phosphorus, PTH, and alkaline phosphatase. The gold standard for diagnosis is a bone biopsy.

Interventions for CKD-MBD include limiting dietary phosphorus, giving phosphate binders, supplementing vitamin D, and controlling hyperparathyroidism.[19] Phosphate intake is not usually restricted until the patient needs RRT. At that time, phosphate is usually limited to about 1 g/day, but dietary control alone is usually inadequate.

Phosphate binders include calcium-based binders, calcium acetate, and calcium carbonate. They bind phosphate in the bowel and then excrete it in the stool. Giving calcium may increase the calcium load and place the patient at increased risk for vascular calcifications. So, when calcium levels are increased or there is evidence of existing vascular or soft tissue calcifications, non–calcium-based phosphate

binders may be used. These include lanthanum carbonate (Fosrenol); sevelamer carbonate (Renvela;, and iron-based, calcium-free phosphate binders, such as sucroferric oxyhydroxide (Velphoro) and ferric citrate (Auryxia).

To be most effective, give phosphate binders with each meal. Constipation is a frequent side effect of phosphate binders. Stool softeners may be needed.

Because bone disease (osteomalacia) is associated with excess aluminum, aluminum preparations should be used with caution in patients with kidney disease. Do not use magnesium-containing antacids (e.g., Maalox, Mylanta) because magnesium depends on the kidneys for excretion.

Hypocalcemia is a problem in the later stages of CKD due to the inability of the GI tract to absorb calcium in the absence of active vitamin D. If hypocalcemia persists even if the serum phosphate levels are normal, supplemental calcium and vitamin D should be given. Assess vitamin D levels to determine the need for supplementation. If the levels are low (serum values less than 30 ng/mL), vitamin D is given in the form of cholecalciferol.

Treatment of secondary hyperparathyroidism in ESRD patients requires the activated form of vitamin D because the kidneys cannot activate vitamin D. Active vitamin D is available as oral or IV calcitriol (Rocaltrol), IV paricalcitol (Zemplar), or oral or IV doxercalciferol (Hectorol). Their use can reduce the high PTH levels. Cinacalcet (Sensipar), a calcimimetic agent, is used to control secondary hyperparathyroidism. Calcimimetics mimic calcium and increase the sensitivity of the calcium receptors in the parathyroid glands. As a result, the parathyroid glands detect calcium at lower serum levels and decrease PTH secretion.

If parathyroid disease becomes severe, a subtotal or total parathyroidectomy may be done to decrease the synthesis and secretion of PTH. In most cases, a total parathyroidectomy is done and parathyroid tissue transplanted into the forearm. The transplanted cells make PTH as needed. If PTH production becomes excessive, some cells can be removed from the forearm.

Hypercalcemia may occur with calcium and vitamin D supplementation. If hypercalcemia occurs, vitamin D may be withheld, and calcium-based phosphate binders replaced with non–calcium-based phosphate binders.

Anemia

Anemia in CKD is caused by a decreased production of erythropoietin by the kidneys. Exogenous erythropoietin (EPO) is used to treat anemia. It is available as epoetin alfa (Epogen, Procrit), which can be given IV or subcutaneously, usually 2 or 3 times per week. Darbepoetin alfa (Aranesp) is longer acting and can be given weekly or biweekly.

Hemoglobin and hematocrit levels may take 2 to 3 weeks to increase. Higher hemoglobin levels (more than 12 g/dL) and higher doses of EPO are associated with a higher rate of thromboembolic events and increased risk for death from serious CV events (MI, HF, stroke). The recommendation is to use the lowest possible dose of EPO to treat anemia.

Treatment of CKD-related anemia is patient specific with the goal being to reduce the need for blood transfusions. There is no target hemoglobin or widely accepted EPO dosing strategy. Teach people who are prescribed EPO about the risks and benefits and allow them to decide about their treatment plan.

EPO can increase BP and is contraindicated in uncontrolled hypertension. The underlying mechanism is related to the hemodynamic changes (e.g., increased whole blood viscosity) that occurs as the anemia is corrected.

EPO therapy may lead to iron deficiency from the increased demand for iron to support erythropoiesis. Iron supplementation is recommended if the plasma ferritin concentrations fall below 100 ng/mL. Most CKD patients receive iron supplementation.

Although iron can be given by mouth or IV, the enteral route is limited due to GI side effects, which decrease patient adherence. Oral iron should not be taken at the same time as phosphate binders because calcium binds the iron, preventing its absorption. Tell the

patient that iron may make the stool dark in color. Most patients receiving HD are prescribed IV iron sucrose (Venofer) or sodium ferric gluconate complex (Ferrlecit). Supplemental folic acid (1 mg/day) is usually given because it is needed for RBC formation and is removed by dialysis.

Blood transfusions are avoided unless the patient has an acute blood loss or has symptomatic anemia (i.e., dyspnea, excess fatigue, tachycardia, palpitations, chest pain). Transfusions increase the development of antibodies, thus making it harder to find a compatible donor for kidney transplantation. Multiple blood transfusions may lead to iron overload because each unit of blood has about 250 mg of iron.

Dyslipidemia

Dyslipidemia, a risk factor for CVD, is a common problem in CKD. Statins (HMG-CoA reductase inhibitors), such as atorvastatin (Lipitor), are used to lower LDL cholesterol levels (see Table 33.6). Statins should be used in patients with CKD, especially those with diabetes, not yet on dialysis. [23]

Fibrates (fibric acid derivatives), such as gemfibrozil (Lopid), are used to lower triglyceride levels (see Table 33.6) and can increase HDLs. Specific drugs used in these classes depend on the individual patient response and HCP recommendation.

Complications of Drug Therapy

The kidneys partially or totally excrete many drugs. CKD causes decreased elimination that leads to an accumulation of drugs and the potential for drug toxicity. Drug doses and frequency of administration are adjusted based on the severity of the kidney disease. Increased sensitivity may result as drug levels increase in the blood and tissues. Drugs of particular concern include digoxin, diabetic agents (metformin, glyburide), antibiotics (e.g., vancomycin, gentamicin), and opioid drugs.

Nutritional Therapy

Protein Restriction

The current diet for the person with CKD is designed to maintain good nutrition (Table 46.10). Calorie-protein malnutrition is a potential and serious problem that results from altered metabolism, anemia, proteinuria, anorexia, and nausea. Other factors leading to malnutrition include depression and complex diets that restrict protein, phosphorus, potassium, and sodium. Frequent monitoring of laboratory parameters, especially serum albumin, prealbumin, and ferritin, and anthropometric measurements are necessary to evaluate nutritional status. All patients with CKD should be referred to a dietitian for nutritional teaching.

For the patient undergoing dialysis, protein is not routinely restricted. For CKD stages 1 through 4, many HCPs encourage a diet with normal protein intake. Teach patients to avoid high-protein diets and supplements because they may overburden the diseased kidneys.[24]

Dietary protein guidelines for PD differ from those for HD because of protein loss through the peritoneal membrane. During PD, protein intake must be high enough to compensate for the losses so that the nitrogen balance is maintained. The recommended protein intake is at least 1.2 g/kg of ideal body weight (IBW) per day. This can be increased depending on the patient's needs.

For patients with malnutrition or inadequate caloric or protein intake, commercially prepared products that are high in protein but low in sodium and potassium are available (e.g., Nepro, Amin-Aid). As an alternative, liquid or powder breakfast drinks may be bought at the grocery store.

Fluid Restriction

Water and any other fluids are not routinely restricted in patients with CKD stages 1 to 5 who are not receiving HD. To reduce fluid retention, diuretics are often used. Patients on HD have a more restricted fluid intake than patients receiving PD. For those receiving HD, as their urine output decreases, fluids are restricted. Recommended fluid intake depends on the daily urine output.

Generally, 600 mL (from insensible loss) plus an amount equal to the previous day's urine output is allowed for a patient receiving HD.

TABLE 46.10 Nutritional TherapyChronic Kidney Disease

	Pre-ESRD	Hemodialysis	Peritoneal Dialysis
Calcium	About 1000–1500 mg/day	Patient specific	Patient specific
Calories	30–35 kcal/kg/day	30–35 kcal/kg/day	25–35 kcal/kg/day (includes calories from dialysate glucose absorption)
Fluid allowance	As desired or depends on urine output	Urine output plus 600–1000 mL	Unrestricted if weight and BP controlled and residual renal function
Iron	Supplement recommended if receiving erythropoietin	Supplement recommended if receiving erythropoietin	Supplement recommended if receiving erythropoietin
Phosphate	Patient specific or 1.0–1.8 g/day	Patient specific or about 0.6–1.2 g/day	Patient specific or about 0.6–1.2 g/day
Potassium	Based on laboratory values	Patient specific or about 2–4 g/day	Usually not restricted
Protein	Patient specific or 0.6–1.0 g/kg/day (low protein)	1.2 g/kg/day	1.2–1.3 g/kg/day
Sodium	Patient specific or 1–3 g/day	Patient specific or 2–3 g/day	Patient specific or 2–4 g/day

Foods that are liquid at room temperature (e.g., gelatin, ice) are counted as fluid intake. Space fluid allotment throughout the day so that the patient does not become thirsty. Teach patients to limit fluid intake so that weight gains are no more than 1 to 3 kg between dialyses *(interdialytic weight gain).*

Sodium and Potassium Restriction

Teach patients with CKD to restrict sodium. Sodium-restricted diets may vary from 2 to 4 g/day. Teach the patient to avoid high-sodium foods, such as cured meats, pickled foods, canned soups and stews, frankfurters, cold cuts, soy sauce, and salad dressings (see Table 34.8). Potassium restriction depends on the kidneys' ability to excrete potassium. Salt substitutes should be avoided in potassium-restricted diets because they contain potassium chloride.

Dietary restrictions for potassium range from about 2000 to 3000 mg (39 mg = 1 mEq). Teach patients receiving HD which foods are high in

potassium and to avoid them (see Table 16.6). Patients using PD do not usually need potassium restrictions. They may need oral potassium supplementation because of the loss of potassium with dialysis exchanges.

Phosphate Restriction

As kidney function deteriorates, phosphate elimination by the kidneys is decreased and the patient begins to develop hyperphosphatemia. By the time a patient reaches ESRD, phosphate is limited to around 1 g/day. Foods that are high in phosphate include meat and dairy products (e.g., milk, ice cream, cheese, yogurt, pudding). Many foods that are high in phosphate are also high in protein. Since patients on dialysis are encouraged to eat a diet containing protein, phosphate binders are essential to control the phosphate level.

Nursing Management: Chronic Kidney Disease

Nursing Assessment

Obtain a complete history of any existing kidney disease or family history of kidney disease. Some kidney disorders, including Alport syndrome and polycystic kidney disease, have a genetic component. Other disorders that can lead to CKD are diabetes, hypertension, and SLE.

Because many drugs are potentially nephrotoxic, ask the patient about both current and past use of prescription and OTC drugs and herbal preparations. Decongestants and antihistamines that contain pseudoephedrine and phenylephrine cause vasoconstriction and lead to an increase in BP. Magnesium and aluminum from antacids can accumulate in the body because they cannot be excreted. Some antacids have high levels of salt, contributing to hypertension.

NSAIDs (aspirin, ibuprofen, naproxen) can contribute to the development of AKI and progression of CKD, especially when taken

in higher doses than recommended. If taken as prescribed, these analgesics are usually considered safe.

Assess the patient's dietary habits and discuss any problems with intake. Measure the patient's height and weight and evaluate any recent weight changes.

The chronicity of kidney disease and the long-term treatment affect virtually every area of a person's life, including family relationships, social and work activities, self-image, and emotional state. Assess the patient's support systems. The choice of treatment modality may be related to support systems available.

Nursing Diagnoses

Nursing diagnoses for patients with CKD include:

- Fluid imbalance
- Electrolyte imbalance
- Impaired nutritional status
- Difficulty coping

More information on nursing diagnoses and interventions for the patient with CKD is presented in eNursing Care Plan 46.1, available on the website for this chapter.

Planning

The overall goals are that a patient with CKD will (1) show knowledge of and ability to adhere to the therapeutic plan, (2) take part in decision making for the plan of care and future treatment modality, (3) have effective coping strategies, and (4) continue with activities of daily living within physiologic limitations.

Nursing Implementation

Health Promotion

Identify those at risk for CKD. At-risk persons include those diagnosed with diabetes or hypertension and people with a history (or a family history) of kidney disease or repeated urinary tract infections (UTIs). They should have regular checkups that include a routine urinalysis and calculation of the estimated GFR.

People with diabetes need to have their urine checked for albuminuria if routine urinalysis is negative for protein. Teach patients with diabetes to report any changes in urine appearance (color, odor), frequency, or volume to the HCP. If a patient needs a potentially nephrotoxic drug, it is important to monitor kidney function with serum creatinine, BUN, and GFR. Those at risk must take measures to prevent or delay the progression of CKD. Most important are measures to reduce the risk or progression of CVD. These include glycemic control for patients with diabetes (see Chapter 48), BP control (see Chapter 32), and lifestyle modifications, including smoking cessation.

TABLE 46.11 Patient & Caregiver TeachingChronic Kidney Disease

Include the following information in the teaching plan for the patient and caregiver:

1. Dietary (sodium, potassium, phosphate) and fluid restrictions.
2. Common problems patient will encounter in modifying diet and fluid intake.
3. Signs and symptoms of electrolyte imbalance, especially high potassium.
4. Alternative ways of reducing thirst, such as sucking on ice cubes, lemon, or hard candy.
5. Reasons for prescribed drugs and common side effects.
   Examples:
   - Phosphate binders (including calcium supplements used as phosphate barriers) should be taken with

meals.
- Take calcium supplements prescribed to treat hypocalcemia on an empty stomach, but not at the same time as iron supplements.
- Iron supplements should be taken between meals.

6. The importance of reporting any of the following: weight gain >4 lb (2 kg), increasing BP, shortness of breath, edema, increasing fatigue or weakness, or confusion or lethargy
7. Need for support and encouragement. Share concerns about lifestyle changes, living with a chronic illness, and decisions about type of dialysis or transplantation.

Promoting Population Health

Prevention and Detection of Chronic Kidney Disease

- Early detection and treatment are the primary methods for reducing CKD.
- Ensure proper diagnosis and treatment of diabetes as it is the leading cause of CKD.
- Monitor BP to detect elevations so that treatment can be started early.
- Treat hypertension appropriately and aggressively as it is the second leading cause of CKD.

Acute Care

Most of the care of the patient with CKD occurs on an outpatient basis. In-hospital care is needed for management of complications and for kidney transplantation (if applicable).

Ambulatory Care

Encourage patients to take part in their care. Teach the patient and caregiver about the diet, drugs, and follow-up medical care (Table 46.11). The patient needs to understand the drugs and common side effects. Because patients with CKD take many medications, a pillbox organizer or a list of the drugs and the times of administration may be helpful. Tell the patient to avoid OTC medications, such as NSAIDs and aluminum- and magnesium-based laxatives and antacids. Teach the patient to take daily BP readings and watch for signs and symptoms of fluid overload, hyperkalemia, and other electrolyte imbalances.

The dietitian should meet with the patient and caregiver on a regular basis for diet planning. A diet history and consideration of cultural variations help with diet planning and adherence. The rate of progression of CKD is dependent on the type of kidney disease and presence of other co-morbid conditions.

The patient can complete an evaluation for a kidney transplant prior to the need to start dialysis. Patients may receive a transplant before ever having to start dialysis. Even though transplantation offers the best therapeutic management for many ESRD patients, the critical shortage of donor organs limits this option for many patients.

Most patients need either PD or HD. Most patients use HD. Explain to the patient and caregiver what is involved in PD or HD and home HD modalities, transplantation, and palliative care. Offer information about all treatment options so that the patient can be involved in the decision-making process, giving a sense of control over life-altering decisions. Tell the patient that even while on dialysis, transplant is still an option. Let the patient know that if a transplanted organ fails, the patient can return to dialysis.

It is important to respect the patient's choice to not receive treatment. Patients themselves often start the conversation about palliative care. Focus the discussion on moving from the curative approach to promotion of comfort care and consideration of hospice care. Listen to the patient and caregiver, allowing them to do most of the talking and pay special attention to their hopes and fears. (Palliative and end-of-life care is discussed in Chapter 9.)

Evaluation

The expected outcomes are that the patient with CKD will maintain

- Fluid and electrolyte levels within normal ranges
- An acceptable weight with no more than a 10% weight loss

Dialysis

Dialysis is the movement of fluid and molecules across a semipermeable membrane from one compartment to another. Clinically, dialysis is a technique in which substances move from the blood through a semipermeable membrane and into a dialysis solution *(dialysate).* It corrects fluid and electrolyte imbalances and removes waste products in kidney failure. It also can be used to treat drug overdoses.

The 2 methods of dialysis available are **peritoneal dialysis (PD)** and **hemodialysis (HD)** (Table 46.12). In PD the peritoneal membrane acts as the semipermeable membrane. In HD an artificial membrane (usually made of cellulose-based or synthetic materials) is used as the semipermeable membrane and is in contact with the patient's blood.

Dialysis is begun when the patient's uremia can no longer be adequately treated with conservative medical management. Generally, this is when the GFR is less than 15 mL/min/1.73 m^2. This criterion can vary widely in different clinical situations. The nephrologist determines when to start dialysis based on the patient's clinical status. Certain uremic complications, including encephalopathy, neuropathies, uncontrolled hyperkalemia, pericarditis, and accelerated hypertension, indicate a need for immediate dialysis.

Most patients with ESRD are treated with dialysis because (1) there is a lack of donated organs, (2) some patients are physically or mentally unsuitable for transplantation, or (3) some patients do not want transplants. An increasing number of people, including older adults and those with complex medical problems, are receiving

maintenance dialysis. A patient's age is not a factor in determining candidacy for dialysis.

TABLE 46.12 Comparison of Peritoneal Dialysis and Hemodialysis

Advantages	Disadvantages
Peritoneal Dialysis (PD)	
• Immediate initiation in almost any hospital • Less complicated than hemodialysis • Portable system with CAPD • Fewer dietary restrictions • Rather short training time • Usable in patient with vascular access problems • Less cardiovascular stress • Home dialysis possible • Preferable for patient with diabetes	• Bacterial or chemical peritonitis • Protein loss into dialysate • Exit site and tunnel infections • Self-image problems with catheter placement • Hyperglycemia • Surgery for catheter placement • Contraindicated in patient with multiple abdominal surgeries, trauma, unrepaired hernia • Requires completion of education program • Catheter can migrate • Best instituted with willing partner
Hemodialysis (HD)	
• Rapid fluid removal • Rapid removal of urea and creatinine • Effective potassium removal • Less protein loss • Lowering of serum triglycerides • Home dialysis possible • Temporary access can be placed at bedside	• Vascular access problems • Dietary and fluid restrictions • Heparinization may be necessary • Extensive equipment necessary • Hypotension during dialysis • Added blood loss that contributes to anemia • Specially trained personnel necessary • Surgery for permanent access placement • Self-image problems with permanent access

General Principles of Dialysis

Solutes and water move across the semipermeable membrane from the blood to the dialysate or from the dialysate to the blood per concentration gradients. The principles of diffusion, osmosis, and ultrafiltration are involved in dialysis (Fig. 46.4). *Diffusion* is the movement of solutes from an area of greater concentration to an area of lesser concentration. In kidney failure, urea, creatinine, uric acid, and electrolytes (potassium, phosphate) move from the blood to the dialysate with the net effect of lowering their concentration in the blood. RBCs, WBCs, and plasma proteins are too large to diffuse through the pores of the membrane. Small-molecular-weight substances can pass from the dialysate into a patient's blood, so the

purity of the water used for dialysis is monitored and controlled.

Osmosis is the movement of fluid from an area of lesser concentration to an area of greater concentration of solutes. Glucose is added to the dialysate and creates an osmotic gradient across the membrane, pulling excess fluid from the blood.

Ultrafiltration (water and fluid removal) results when there is an osmotic gradient or pressure gradient across the membrane. In PD, excess fluid is removed by increasing the osmolality of the dialysate (osmotic gradient) with the addition of glucose. In HD, the gradient is created by increasing pressure in the blood compartment (positive pressure) or decreasing pressure in the dialysate compartment (negative pressure). ECF moves into the dialysate because of the pressure gradient. The excess fluid is removed by creating a pressure differential between the blood and the dialysate solution with a combination of positive pressure in the blood compartment and negative pressure in the dialysate compartment.

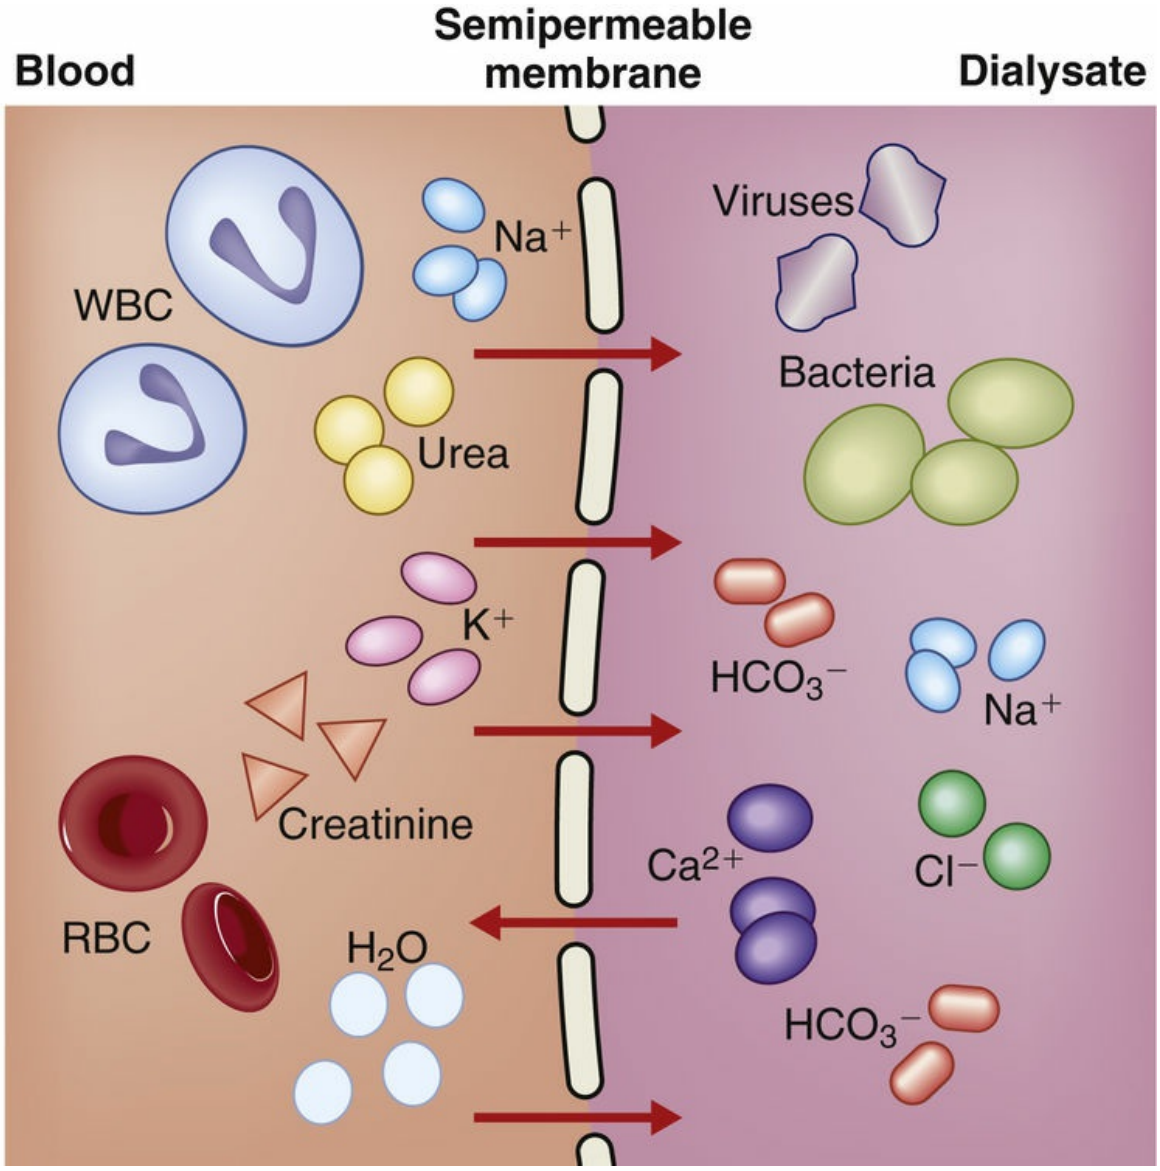

FIG. 46.4 Osmosis and diffusion across a semipermeable membrane.

Peritoneal Dialysis

Although PD was first used in 1923, it did not come into widespread use for chronic treatment until the 1970s with the development of soft, pliable peritoneal solution bags and the introduction of the concept of continuous PD. In the United States, about 12% of patients receiving dialysis treatments are on PD.

Catheter Placement

Peritoneal access is obtained by inserting a catheter through the anterior abdominal wall (Fig. 46.5). The catheter is about 24 in (60 cm) long and has 1 or 2 Dacron cuffs. The cuffs act as anchors and prevent the migration of microorganisms into the peritoneum. Within a few weeks, fibrous tissue grows into the Dacron cuff, holding the catheter in place and preventing bacterial penetration into the peritoneal cavity. The tip of the catheter rests in the peritoneal cavity. It has many perforations spaced along the distal end of the tubing, allowing fluid movement through the catheter.

The technique for catheter placement varies. It is usually placed surgically so that the catheter can be seen directly, minimizing potential complications. Patient preparation for catheter insertion includes emptying the bladder and bowel, weighing the patient, and obtaining a signed consent form. After placement, PD may be started at once with low-volume exchanges or delayed for 2 weeks pending healing and sealing of the exit site. Once the catheter incision site is healed, the patient may shower and then pat the catheter and exit site dry.[25] Daily catheter care varies. Some patients just wash with soap and water and go without a dressing (Fig. 46.6). Others need daily dressing changes. Showering is preferred to bathing.

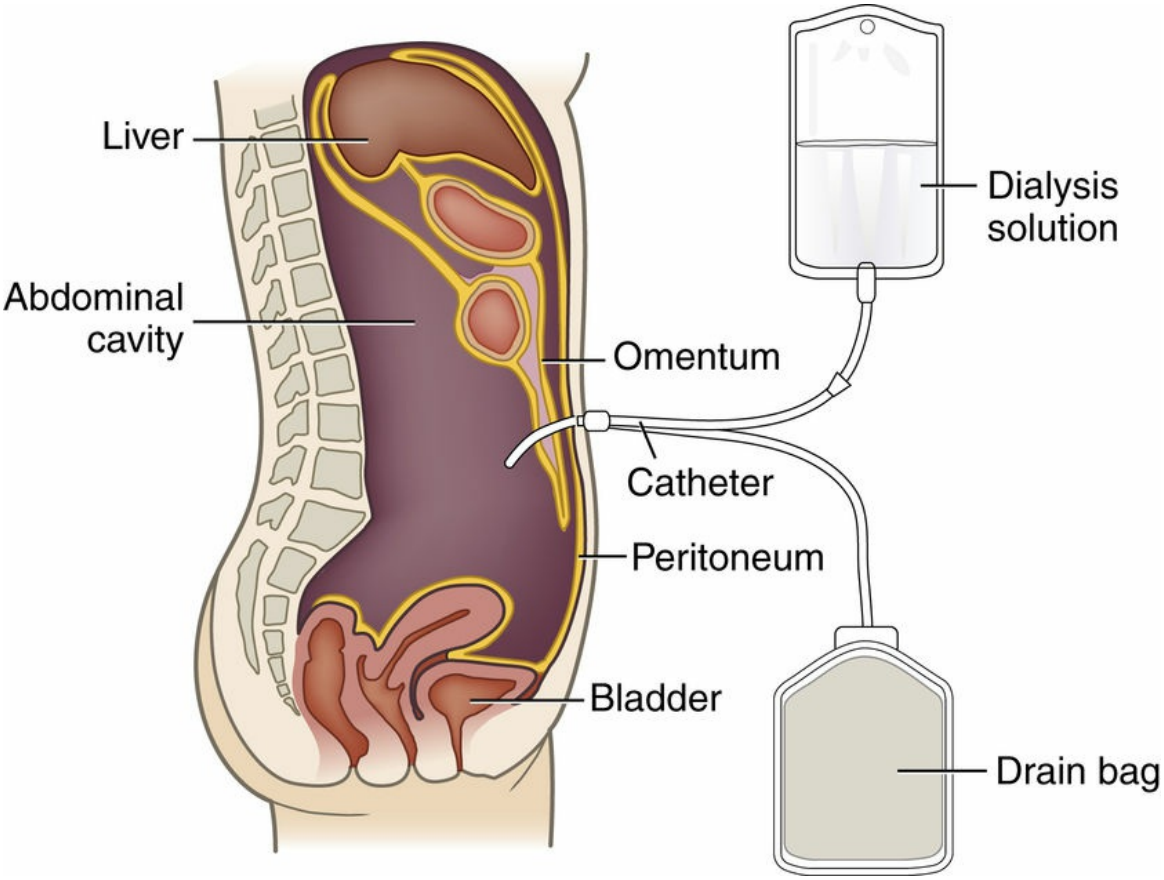

FIG. 46.5 Peritoneal dialysis showing peritoneal catheter inserted into peritoneal cavity.

FIG. 46.6 Peritoneal catheter exit site.
Courtesy Mary Jo Holechek, Baltimore, MD.

In PD it is critical to maintain aseptic technique to avoid peritonitis. Several tubing connections and devices are commercially available to help maintain an aseptic system. Teach all patients to examine their catheter site for signs of infection.

Dialysis Solutions and Cycles

PD is done by putting dialysis solution into the peritoneal space. The 3 phases of the PD cycle are inflow (fill), dwell (equilibration), and drain. Together, the 3 phases are an *exchange.* For manual PD, a period of about 30 to 50 minutes is needed to complete an exchange. During *inflow,* a prescribed amount of solution, usually 2 L, is infused through an established catheter over about 10 minutes. The flow rate may be decreased if the patient has pain. After the solution has been infused, the inflow clamp is closed.

The next part of the cycle is the *dwell* phase, or equilibration, during which diffusion and osmosis occur between the patient's blood and

peritoneal cavity. The duration of the dwell time is usually between 4 and 6 hours. *Drain* time takes 15 to 30 minutes. It may be facilitated by gently massaging the abdomen or changing position. The cycle starts again with the infusion of another 2 L of solution.

PD solutions vary. The choice of the exchange volume is primarily determined by the size of the peritoneal cavity. An average-size person typically uses a 2-L exchange. A larger person may need a 3-L exchange volume. Smaller exchange volumes are used for patients with a smaller body, pulmonary compromise (the added pressure of the large volume may cause respiratory problems), or inguinal hernias.

FIG. 46.7 Automated PD that can be used while the patient is sleeping.

Ultrafiltration (fluid removal) during PD depends on osmotic forces. Dextrose is the most commonly used osmotic agent in PD solutions. It

is relatively safe and inexpensive. It is associated with high rates of peritoneal glucose absorption, leading to problems with hypertriglyceridemia, hyperglycemia, and long-term peritoneal membrane dysfunction.

Alternatives to dextrose PD solution include icodextrin and amino acid solutions. Icodextrin is a commercially available iso-osmolar preparation. It induces ultrafiltration by its oncotic effect. Amino acid PD solutions are available and used mainly for patients who need nutritional supplementation.

Peritoneal Dialysis Systems

Automated Peritoneal Dialysis

Automated peritoneal dialysis (APD) is the most popular form of PD because it allows patients to do dialysis while they sleep. An automated device called a *cycler* delivers the dialysate for APD (Fig. 46.7). The size of a cycler is similar to a DVD player. The automated cycler times and controls the fill, dwell, and drain phases. The machine cycles 4 or more exchanges per night with 1 to 2 hours per exchange. Alarms and monitors are built into the system to make it safe for the patient to sleep while dialyzing. The patient disconnects from the machine in the morning and usually leaves fluid in the abdomen during the day.

It is hard to achieve the required solute and fluid clearance solely with nighttime APD. One or 2 daytime manual exchanges may be prescribed to ensure adequate dialysis.

Continuous Ambulatory Peritoneal Dialysis

Continuous ambulatory peritoneal dialysis (CAPD) is done every few hours during the day. The patient may perform an exchange of 2 L of peritoneal dialysate 4 times daily, with dwell times averaging 4 hours. A common schedule includes exchanges at 7 AM, 12 noon, 5 PM, and 10 PM.

In CAPD, the person instills 2 to 3 L of dialysate from a plastic bag into the peritoneal cavity through a disposable administration line.

The bag and line are then disconnected. After the equilibration period, the line is reconnected to the catheter, the dialysate (effluent) is drained from the peritoneal cavity, and a new 2- to 3-L bag of dialysate solution is infused.

Complications of Peritoneal Dialysis

Exit Site Infection

Infection of the peritoneal catheter exit site is most often caused by *Staphylococcus aureus* or *Staphylococcus epidermidis* (from skin flora). Manifestations include redness at the site, tenderness, and drainage. Superficial exit site infections caused by these organisms generally resolve with antibiotic therapy. If not treated immediately, subcutaneous tunnel infections may progress and may cause peritonitis, necessitating catheter removal.

Peritonitis

Peritonitis results from contact contamination or an exit site or tunnel infection. Most often it occurs because of improper technique when connections for exchanges are contaminated. Peritonitis is usually caused by *S. aureus* or *S. epidermidis.* It rarely results from bacteria in the intestine crossing into the peritoneal cavity.

The main manifestations are abdominal pain, rebound tenderness, and cloudy peritoneal effluent with a WBC count greater than 100 cells/μL (more than 50% neutrophils) or bacteria in the peritoneal effluent shown by Gram stain or culture. GI manifestations may include diarrhea, vomiting, abdominal distention, and hyperactive bowel sounds. Fever may or may not be present. To determine if the peritoneal effluent is cloudy, drain the effluent and place the drained bag on reading material, such as a newspaper. If you cannot read the print through the effluent, it is cloudy.

Cultures, Gram stain, and a WBC differential of the peritoneal effluent are used to confirm the diagnosis of peritonitis. Antibiotics can be given orally, IV, or intraperitoneally. In most cases, the patient is treated on an outpatient basis.

The formation of adhesions in the peritoneum can result from repeated infections and interferes with the peritoneal membrane's ability to act as a dialyzing surface. Repeated infections may require the removal of the peritoneal catheter and a temporary or permanent change of modality to HD.

Hernias

Increased intraabdominal pressure from the dialysate volume can cause hernias to develop in predisposed persons, such as multiparous women and older men. After hernia repair, PD often can be resumed after several days using small dialysate volumes and keeping the patient supine.

Lower Back Problems

Increased intraabdominal pressure can cause or worsen lower back pain. The lumbosacral curvature is increased by intraperitoneal infusion of dialysate. Orthopedic binders and a regular exercise program for strengthening the back muscles are helpful for some patients.

Bleeding

After peritoneal catheter placement, it is common for the PD effluent drained after the first few exchanges to be pink or slightly bloody from trauma associated with catheter insertion. Bloody effluent over several days or the new appearance of blood in the effluent can indicate active intraperitoneal bleeding. If this occurs, check the BP and hematocrit. Blood may be present in the effluent of women who are menstruating or ovulating. This requires no intervention.

Pulmonary Complications

Atelectasis, pneumonia, and bronchitis may occur from repeated upward displacement of the diaphragm, resulting in decreased lung expansion. Longer dwell times increase the risk for pulmonary problems. Frequent repositioning and deep-breathing exercises can

help. When the patient is lying in bed, elevate the head of the bed to prevent these problems.

Protein Loss

The peritoneal membrane is permeable to plasma proteins, amino acids, and polypeptides. These substances are lost in the dialysate fluid. The amount of loss is usually about 0.5 g/L of dialysate drainage, but it can be as high as 10 to 20 g/day. This loss may increase to as much as 40 g/day during episodes of peritonitis as the peritoneal membrane becomes more permeable. Unresolved peritonitis is associated with excessive protein loss that can result in malnutrition. PD may need to stop temporarily or sometimes permanently.

Effectiveness of Chronic Peritoneal Dialysis

Mortality rates are similar between in-center HD patients and PD patients for the first few years. After about 2 years, mortality rates for patients receiving PD increase, especially for the older person with diabetes and patients with a prior history of CVD.[25]

The primary advantage of PD is its simplicity and that it is a home-based program, increasing patient participation in their care. Learning the self-management skills needed to do PD usually involves a 3- to 7-day training program. There is no need for special water systems. Equipment setup is relatively simple.

Hemodialysis

Vascular Access Sites

HD requires a very rapid blood flow and access to a large blood vessel. Obtaining vascular access is one of the hardest problems associated with HD. Enough time is needed for evaluation and consideration of the best arteriovenous (AV) access for HD. The types of vascular access include AV fistulas (AVFs), AV grafts (AVGs), and

temporary vascular access.[26]

Arteriovenous Fistulas and Grafts

A subcutaneous **arteriovenous fistula (AVF)** is usually created in the forearm or upper arm with an anastomosis between an artery and a vein (usually cephalic or basilic) (Figs. 46.8, *A*, and 46.9). The fistula allows arterial blood to flow through the vein.

The vein becomes "arterialized," increasing in size and developing thicker walls. The arterial blood flow is essential to provide the rapid blood flow needed for HD. As the fistula matures, it is more amenable to repeated venipunctures. Maturation may take 6 weeks to months. AVF should be placed at least 3 months before starting HD. A fistula is the preferred access for HD.[26]

Normally, a *thrill* (buzzing sensation) can be felt by palpating the fistula, and a *bruit* (rushing sound) can be heard with a stethoscope. The thrill and bruit are created by arterial blood moving at a high velocity through the vein.

Check Your Practice

You are rotating to the inpatient dialysis unit today. It is your first time working with HD patients. You are helping a hemodialysis tech "hook-up" a 56-yr-old man to HD. He has been on HD for 5 years due to polycystic kidney disease. You take his vital signs, palpate his AV fistula, and then use your stethoscope to auscultate the AV fistula. You are concerned because you feel a super-strong pulse and hear a very loud "whoosh" sound. The patient turns to you and just smirks, "I bet you have never had a thrill like that."

- You are very flustered and not sure how to respond. What should you say to him?

AVFs are harder to create in patients with a history of severe

peripheral vascular disease (e.g., people with diabetes), those with prolonged IV drug use, and obese women. These persons may need a synthetic graft.

Arteriovenous grafts (AVGs) are made of synthetic materials (polytetrafluoroethylene [PTFE, Teflon]) and form a "bridge" between the arterial and venous blood supplies. Grafts are placed under the skin and are surgically anastomosed between an artery (usually brachial) and a vein (usually antecubital) (Fig. 46.8, *B*). An interval of 2 to 4 weeks is usually needed to allow the graft to heal, but it may be used earlier. Because grafts are made of artificial materials, they are more likely than AVFs to become infected and tend to form clots. When AVG infections occur, they may need surgical removal, since it is hard to completely resolve the infection from the synthetic material.

FIG. 46.8 Vascular access for hemodialysis. **A,** AVF. **B,** AVG. **C,** HeRO Graft.

A common problem in patients on HD is central venous stenosis (CVS) or occlusion. CVS is serious and has a greater impact than peripheral venous stenosis because the central veins are the final pathway for blood flow to the heart. As CVS progresses, vascular access for HD is often lost.

HeRO (Hemodialysis Reliable Outflow) *Graft* is a special bridge access used in patients when other access options are exhausted. It consists of 2 pieces: a reinforced tube to bypass blockages in veins and a dialysis graft anastomosed to an artery to be accessed for HD (Fig. 46.8, *C*). The HeRO Graft is placed under the skin, like both a fistula and standard graft. The HeRO Graft bypasses the venous system and provides blood flow directly from a target artery to the heart. It may be harder to auscultate the bruit or feel the thrill in this type of access because of the absence of a venous anastomosis.

Surgical creation of AV access for HD has several risks. These include distal ischemia *(steal syndrome)* and pain because too much arterial blood is being shunted or "stolen" from the distal extremity. Manifestations of steal syndrome are pain distal to the access site, numbness or tingling of fingers that may worsen during dialysis, and poor capillary refill. Aneurysms can develop in the AV access and can rupture if left untreated.

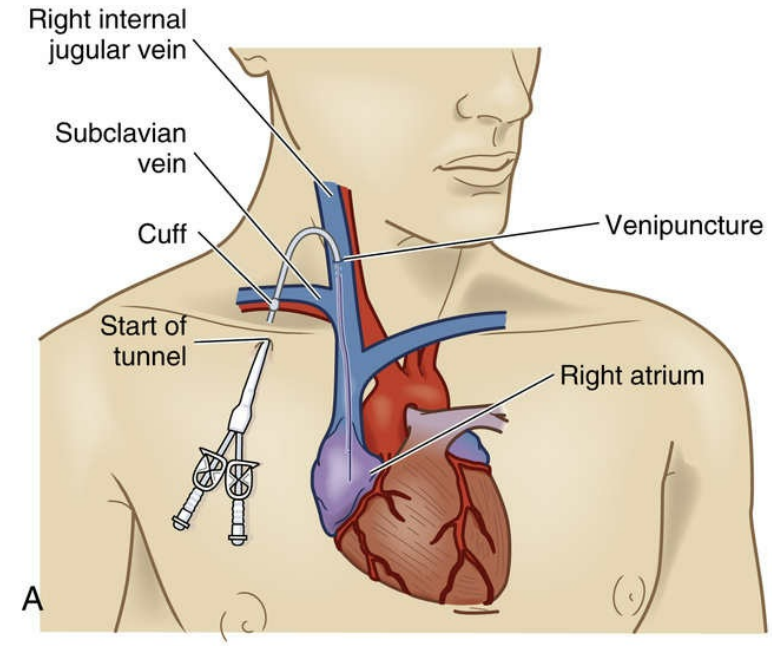
Safety Alert



AV Fistulas and Grafts

- Never perform BP measurements, IV line insertion, or venipuncture in an extremity with AV access.

- These special precautions are taken to prevent infection and clotting of the vascular access.
- When a patient is hospitalized, place signs in patient's room and label the arm with a band that says, "No BP, blood draws, or IV in this arm."

Temporary Vascular Access

When immediate vascular access is needed, catheterization of the internal jugular or femoral vein is done. A flexible catheter inserted at the bedside into 1 of these large veins gives access to the circulation without surgery (Fig. 46.10). The catheters usually have a double external lumen with an internal septum separating the 2 internal segments. One lumen is used for blood removal and the other for blood return (Fig. 46.11, *A* and *B*). Temporary catheters have high rates of infection, dislodgment, and malfunction. A patient should not be discharged from the hospital with a temporary catheter in place.

B and *C,* Courtesy Dr. Stephen Van Voorst, MD.

Long-term cuffed HD catheters are often used for temporary vascular access. These catheters give temporary access while the patient is waiting for fistula placement or as long-term access when other forms of access have failed. They exit on the upper chest wall and are tunneled subcutaneously to the internal or external jugular vein (Fig. 46.11, *C*). The catheter tip rests in the right atrium. It has 1 or 2 subcutaneous Dacron cuffs that prevent infection from tracking along the catheter and anchor the catheter, eliminating the need for sutures.

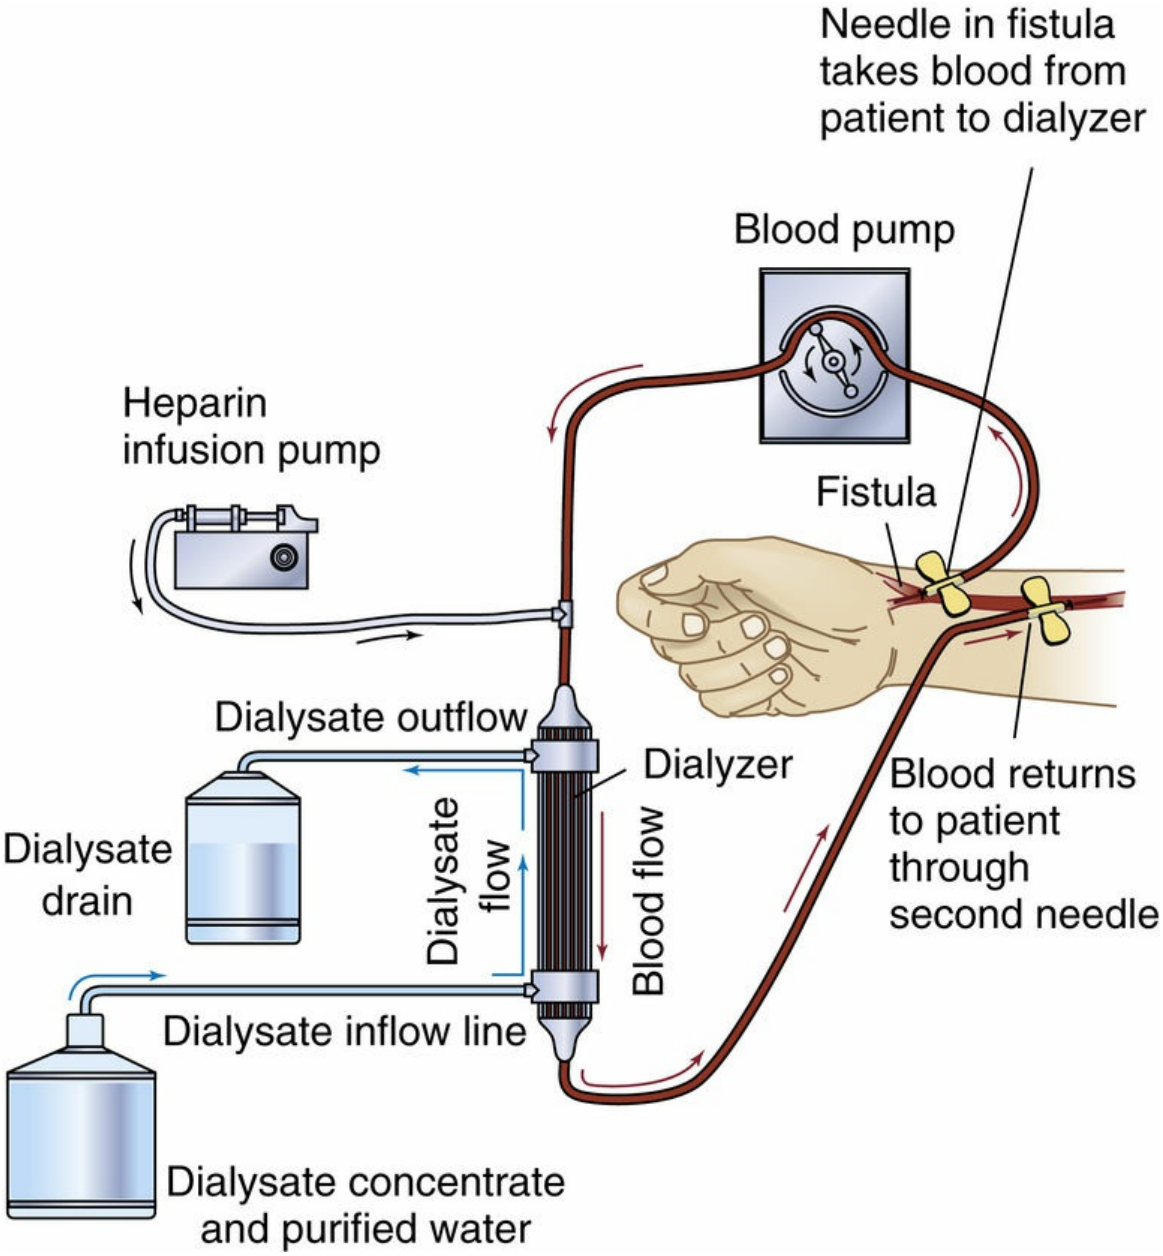

FIG. 46.12 Parts of a hemodialysis system. Blood is removed via a needle inserted in a fistula or via catheter lumen. It is propelled to the dialyzer by a blood pump. Heparin is infused either as a predialysis bolus or through a heparin pump continuously to prevent clotting. Dialysate is pumped in and flows in the opposite direction of the blood. The dialyzed blood is returned to the patient through a second needle or catheter lumen. Old dialysate and ultrafiltrate are drained and discarded.

Dialyzers

The HD dialyzer is a plastic cartridge that has thousands of parallel hollow tubes or fibers. The fibers are semipermeable membranes made of cellulose-based or other synthetic materials. The blood is pumped into the top of the cartridge and dispersed into all the fibers. Dialysis fluid *(dialysate)* is pumped into the bottom of the cartridge and bathes the outside of the fibers. Ultrafiltration, diffusion, and osmosis occur across the pores of this semipermeable membrane. When the dialyzed blood reaches the end of the thousands of semipermeable fibers, it converges into a single tube that returns it to the patient. Dialyzers differ in surface area, membrane composition and thickness, clearance of waste products, and removal of fluid.

Procedure for Hemodialysis

The needles used for HD are large bore, usually 14 to 16 gauge. They are inserted into the fistula or graft to obtain vascular access. One needle is placed to pull blood from the circulation to the HD machine, and the other needle is used to return the dialyzed blood to the patient. The needles are attached via tubing to dialysis lines. If a patient has a catheter, the 2 blood lines are attached to the 2 catheter lumens. The needle closer to the fistula (red catheter lumen) pulls blood from the patient to the dialyzer using a blood pump. Blood is returned from the dialyzer to the patient through the second needle (blue catheter lumen).[27]

When blood comes in contact with a foreign material, such as the dialyzer, it tends to clot. Heparin is added to the blood to prevent clotting.

In addition to the dialyzer, a dialysate delivery and monitoring system is used (Fig. 46.12). This system pumps the dialysate through the dialyzer, countercurrent to the blood flow. To end the treatment, a saline solution is used to return the blood in the extracorporeal circuit back to the patient through the vascular access. The needles are removed from the patient, and firm pressure is applied to the venipuncture sites until the bleeding stops.

FIG. 46.13 Home hemodialysis is growing in popularity, and machines are more compact.
From NxStage Medical, Inc, Lawrence, MA.

Before beginning treatment, assess fluid status (weight, BP, peripheral edema, lung and heart sounds), condition of vascular access, and temperature. The difference between the last postdialysis weight and the present predialysis weight determines the ultrafiltration or the amount of weight (from fluid) to be removed. While the patient is on dialysis, take vital signs at least every 30 to 60 minutes because rapid BP changes may occur.

Settings and Schedules for Hemodialysis

Most HD patients are treated in a community-based center and dialyze for 3 to 4 hours 3 days per week. Most people sleep, read, talk,

or watch television during HD.

Other schedule options for HD are short daily HD and long nocturnal HD. The patient receiving long nocturnal HD has the advantage of sleeping while dialyzing. Each nocturnal treatment lasts 6 to 8 hours, and the patient dialyzes up to 6 times per week.

In addition to in-center HD, home HD is available (Fig. 46.13). The use of home HD often depends on a patient's family support. One of the main advantages of home HD is that it allows greater freedom in choosing dialysis times. In short daily HD, the patient dialyzes for 2½ to 3 hours per session 5 to 6 days per week. Short daily HD is usually done at home.

Patients who choose daily dialysis or nocturnal dialysis may have fewer uremic symptoms, tend to need fewer medications, and have fewer dialysis-related side effects (e.g., hypotension, cramps). In addition, they have more autonomy. Although daily home HD offers the potential of significant health benefits, only about 2% of HD patients dialyze at home.

Complications of Hemodialysis

Hypotension

Hypotension that occurs during HD primarily results from rapid removal of vascular volume (hypovolemia), decreased cardiac output, and decreased systemic vascular resistance. The drop in BP may cause light-headedness, nausea, vomiting, seizures, vision changes, and chest pain from cardiac ischemia. The usual treatment for hypotension includes decreasing the volume of fluid removed and infusing 0.9% saline solution.

Muscle Cramps

We do not completely understand the cause of muscle cramps in HD. Factors associated with developing muscle cramps include hypotension, hypovolemia, high ultrafiltration rate, and low-sodium dialysis solution. Treatment includes reducing the ultrafiltration rate and giving fluids (saline, glucose, mannitol). Hypertonic saline is not

recommended since the sodium load can be problematic. Hypertonic glucose is preferred.

Loss of Blood

Blood loss may result from blood not being completely rinsed from the dialyzer, accidental separation of blood tubing, dialysis membrane rupture, or bleeding after removing the needles at the end of HD. If a patient has received too much heparin or has clotting problems, postdialysis bleeding can occur. It is essential to rinse back all blood, avoid excess anticoagulation, and hold firm but nonocclusive pressure on access sites until the risk for bleeding has passed.

Hepatitis

Hepatitis B used to have an unusually high prevalence in dialysis patients, but the incidence today is low. Lower transfusion requirements, screening, and recommendations for vaccinations have lowered the incidence. Outbreaks of hepatitis B still occur, likely from breaks in infection control practices. To prevent transmission, all patients and personnel in dialysis units receive hepatitis B vaccine.

Currently, hepatitis C virus (HCV) causes most cases of hepatitis in dialysis patients. (Hepatitis is discussed in more detail in Chapter 43.) About 10% of patients undergoing dialysis in the United States are positive for anti-HCV, which indicates a previous infection. Infection control precautions are mandated in caring for the patient with hepatitis C to protect the patient and staff (see Chapter 14). Currently no vaccine is available for hepatitis C.

Effectiveness of Hemodialysis

HD is still an imperfect therapy for management of ESRD. It cannot fully replace the normal biologic functions of the kidneys. It can ease many of the symptoms of CKD and, if started early, can prevent certain complications. It does not alter the accelerated rate of CVD and the related high mortality rate.

The yearly death rate of patients receiving maintenance HD is

around 19% to 24%. CVD (stroke, MI) causes most deaths. Infectious complications are the second leading cause of death.[27]

Adaptation to maintenance HD varies considerably. At first, many patients feel positive about the dialysis because it makes them feel better and keeps them alive, but there is often great ambivalence about whether it is worthwhile. Dependence on a machine is a reality. In response to their illness, dialysis patients may be nonadherent or depressed and show suicidal tendencies. The primary nursing goals are to (1) help the patient to maintain a healthy self-image and (2) return the patient to the highest level of function possible, including returning to work.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy (CRRT) is a method for treating AKI. It provides a means by which uremic toxins and fluids are removed while acid-base status and electrolytes are adjusted slowly and continuously in a hemodynamically unstable patient. The principle of CRRT is to dialyze patients in a more physiologic way (over 24 hours), just like the kidneys. CRRT is contraindicated if a patient has life-threatening manifestations of uremia (hyperkalemia, pericarditis) that need rapid treatment. CRRT can be used in conjunction with HD.

Several types of CRRT are available (Table 46.13). CRRT often uses the venovenous approaches of continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

Vascular access for CRRT is achieved by using a double-lumen catheter (as used in HD [Fig. 46.10]) placed in the jugular or femoral vein. A blood pump propels the blood through the circuit. A highly permeable, hollow-fiber hemofilter removes plasma water and nonprotein solutes, which are collectively termed *ultrafiltrate.* The ultrafiltration rate (UFR) may range from 0 to 500 mL/hr. Under the

influence of hydrostatic pressure and osmotic pressure, water and nonprotein solutes pass out of the filter into the extracapillary space and drain through the ultrafiltrate port into a collection device (drainage bag) (Fig. 46.14). The remaining fluid continues through the filter and returns to the patient via the return port of the double-lumen catheter.

TABLE 46.13 Continuous Renal Replacement Therapies

Therapy	Abbreviation	Purpose
Continuous venovenous hemofiltration	CVVH	Removes fluid and solutes Requires replacement fluid
Slow continuous ultrafiltration	SCUF	Simplified version of CVVH Removes fluid No fluid replacement required
Continuous venovenous hemodialysis	CVVHD	Removes fluids and solutes Requires dialysate and replacement fluid
Continuous venovenous hemodiafiltration	CVVHDF	Removes fluids and solutes Requires dialysate and replacement fluid

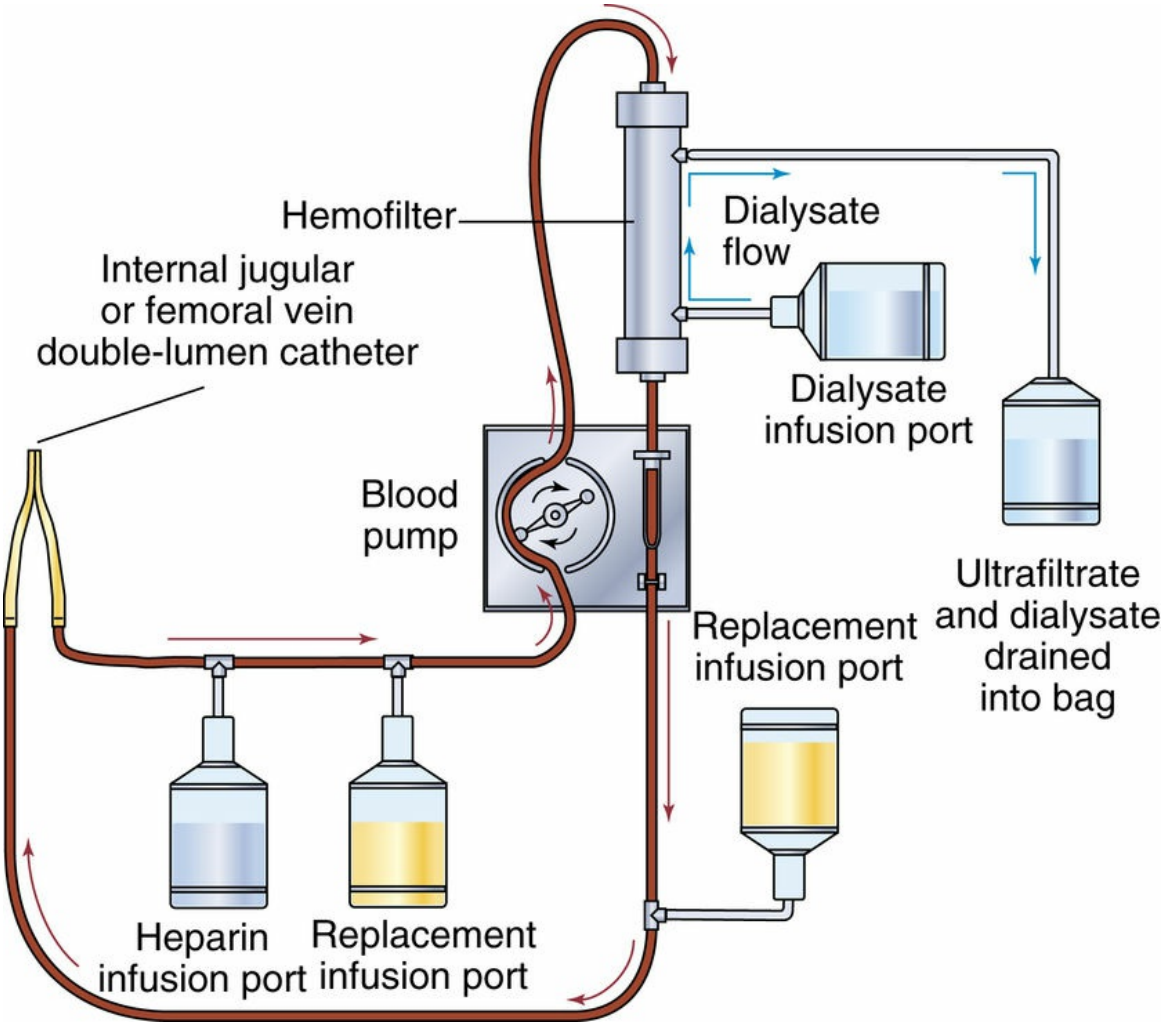

FIG. 46.14 Basic schematic of continuous venovenous therapies. A blood pump is required to pump blood through the circuit. Replacement ports are used for instilling replacement fluids and can be given prefilter or postfilter. Dialysate port is used for infusing dialysis solution. Regardless of modality, ultrafiltrate is drained via the ultrafiltration drain port.

As ultrafiltrate drains out of the hemofilter, fluid and electrolyte replacements can be infused through a port found before or after the filter as the blood returns to the patient. Replacement fluid is designed to replace volume and solutes, such as sodium, chloride, HCO_3^-, and glucose. The infusion rate of replacement fluid is determined by the degree of fluid and electrolyte imbalance. Replacement fluid infused into the infusion port before the hemofilter allows for greater clearance of urea and can decrease filter clotting. An infusion port after the filter dilutes intravascular fluid and decreases the

concentration of unwanted solutes, such as BUN, creatinine, and potassium. Anticoagulants are given to prevent blood clotting. They may be infused as a bolus at the initiation of CRRT or through an infusion port before the hemofilter.

The type of CRRT can be customized to the patient's needs. Some types involve the introduction of replacement fluids. CVVHD and CVVHDF use dialysate. Dialysis fluid is attached to the distal end of the hemofilter, and the fluid is pumped countercurrent to the blood flow (Fig. 46.14). As in hemodialysis, diffusion of solutes and ultrafiltration via hydrostatic pressure and osmosis occur. This is an ideal treatment for a patient who needs both fluid and solute control but cannot tolerate the rapid fluid shifts associated with HD.

Several features of CRRT differ from HD:

- The blood pump in CRRT runs at a slower (150 mL/min average) rate. This may improve hemodynamic stability.
- Continuous rather than intermittent. Fluid volume can be removed over days (24 hours to more than 2 weeks) versus hours (3 to 4 hours).
- Solute removal can occur by *convection* (no dialysate required) in addition to osmosis and diffusion.
- Causes less hemodynamic instability (e.g., hypotension)
- Does not need constant monitoring by a specialized HD nurse but does require a trained ICU nurse
- Does not require complicated HD equipment

CRRT can be continued as long as 30 to 40 days. The hemofilter should be changed every 24 to 48 hours because of loss of filtration efficiency or potential for clotting. The ultrafiltrate should be clear yellow. Specimens may be obtained for serum chemistries. If the ultrafiltrate becomes bloody or blood tinged, suspect a rupture in the filter membrane. Stop treatment to prevent blood loss.

Specific nursing interventions include obtaining weights and monitoring and documenting laboratory values daily to ensure adequate fluid and electrolyte balance. Assess hourly intake and

output, vital signs, and hemodynamic status. Although reductions in central venous pressure and pulmonary artery pressure are expected, there should be little change in mean arterial pressure or cardiac output. Assess and maintain the patency of the CRRT system. Care for the patient's vascular access site to prevent infection. Once the patient's AKI is resolved or there is a decision to withdraw treatment, CRRT is stopped and the needle(s) removed.

Wearable Artificial Kidney

The wearable artificial kidney (WAK) has recently been developed and is approved for use to improve the quality of life of an ESRD patient. The WAK is a miniaturized dialysis machine that can be worn on the body. The carrier resembles a tool belt. The device connects to a patient via a catheter. Like conventional dialysis machines, it is designed to filter the blood of ESRD patients. Unlike current portable or stationary dialysis machines, it can run continuously on batteries. The present version weighs about 10 lb, but future modifications could make it lighter and more streamlined.[28]

Kidney Transplantation

Major advances have been made in kidney transplantation since the first live donor kidney transplant was done in 1954 between identical twins. These advances include organ procurement and preservation, surgical techniques, tissue typing and matching, immunosuppressant therapy, and prevention and treatment of graft rejection. A general discussion of organ transplantation is in Chapter 13.

Even though kidney transplantation is the best treatment option available to patients with ESRD, fewer than 4% ever receive a transplant. This is due to the large disparity between the supply and demand for kidneys. Every year thousands are waiting for kidney transplants (more than 100,000 are currently on the list), yet only about 17,000 transplants take place every year. Most die while waiting. Transplants from a deceased (cadaveric) donor usually

require a prolonged waiting period, with differences in waiting time depending on age, gender, and race. Average wait times in the United States for a deceased kidney usually range from 2 to 5 years.[29-31]

Kidney transplantation is very successful, with 1-year graft survival rates over 90% for deceased donor transplants and 95% for live donor transplants.[30] An advantage of kidney transplantation when compared with dialysis is that it reverses many of the pathophysiologic changes associated with renal disease. It eliminates the dependence on dialysis and the accompanying dietary and lifestyle restrictions. Transplantation is less expensive than dialysis after the first year.

Recipient Selection

Appropriate recipient selection is important for a successful outcome. Candidacy is determined by a variety of medical and psychosocial factors that vary among transplant centers. Some transplant programs exclude patients who are morbidly obese or who continue to smoke despite smoking cessation interventions. A careful evaluation is done to identify and minimize potential complications after transplantation. Certain patients, particularly those with CVD and diabetes, are considered high risk. They must be carefully evaluated and then monitored closely after transplantation.

For a small number of patients who are approaching ESRD, a *preemptive transplant* (before dialysis is required) is possible if they have a living donor. This approach is best for patients with diabetes, who have a much higher mortality rate on dialysis than nondiabetics.

Contraindications to transplantation include advanced cancer, refractory or untreated heart disease, chronic respiratory failure, extensive vascular disease, chronic infection, and unresolved psychosocial disorders (e.g., nonadherence to medical regimens, alcohol use, drug use). Being HIV-positive or having hepatitis B or C infection is not a contraindication to transplantation.

Surgical procedures may be done before transplantation based on the results of the recipient evaluation. Coronary artery bypass or

coronary angioplasty may be needed for advanced coronary artery disease. Cholecystectomy may be necessary for patients with a history of gallstones, biliary obstruction, or cholecystitis. On rare occasions, bilateral nephrectomies are done for patients with refractory hypertension, recurrent UTIs, or grossly enlarged kidneys from polycystic kidney disease. In general, the recipient's own kidneys are not removed before receiving a kidney transplant.

Histocompatibility Studies

Histocompatibility studies, including human leukocyte antigen (HLA) testing and crossmatching, are discussed in Chapter 13 on p. 205.

Donor Sources

Kidneys for transplantation are obtained from compatible blood-type deceased donors, blood relatives, emotionally related (close and distant) living donors (e.g., spouses, distant cousins,), and altruistic living donors who are known (friends) or unknown to the recipient. Living donation accounts for around 27% of all kidney transplants in the United States. Most transplant centers regard them as the preferred donation modality. [31]

Ethical/Legal Dilemmas

Allocation of Resources

Situation

T.H., a transplant nurse coordinator, is considering her feelings about 2 patients who are being evaluated for placement on the deceased kidney transplant waiting list. One patient is a 40-yr-old black schoolteacher. She is married and has 2 children. The other patient is a 22-yr-old unemployed white man. He misses 3 or 4 dialysis treatments per month and does not take his antihypertensive drugs

consistently.

Ethical/Legal Points for Consideration

- Ethical principles that are important in the allocation of human organs include utility and justice.
- Allocation policies based on utility require we use standardized outcome measures to give a rough estimate about which allocation would produce the greatest good. Factors considered include patient survival, quality of life, availability of alternative treatments, and age.
- We must give equal respect and concern to each patient. Allocation based on social characteristics (e.g., race, socioeconomic class, gender) conflict with the principle of justice and violate constitutional law.
- Constitutional laws prohibit discrimination based on race, gender, religion, and ethnic background. It is highly unlikely that these standard prohibitions will change. It is possible that definitions of unhealthy behavior, such as substance use, alcohol use, smoking, and obesity, may be used to screen out candidates.
- Nurses are concerned about social justice because of their health advocacy role. Today the situation is immensely more complex because of the cost and availability of care.

Discussion Questions

1. What does the American Nurses Association Code of Ethics say about how you as a nurse should view patients?
2. What are your thoughts about which patient should receive the next available kidney transplant?
3. Can you assign value to the lives of various patients? Who is worth more?

Live Donors

Live donors undergo an extensive evaluation to ensure that they are in good health and have no history of disease that would place them at risk for developing kidney disease or operative complications. Crossmatches are done at the time of the evaluation and about a week before the transplant to ensure that no antibodies to the donor are present or that the antibody titer is below the allowed level. Advantages of a live donor kidney include (1) better patient and graft survival rates regardless of histocompatibility match, (2) immediate organ availability, (3) immediate function due to minimal *cold time* (kidney out of body and not getting blood supply), and (4) the opportunity to have the recipient in the best possible medical condition because the surgery is elective.

The potential donor sees a nephrologist for a complete history and physical examination and laboratory and diagnostic studies. Laboratory studies include a 24-hour urine study for creatinine clearance and total protein, complete blood count, and chemistry and electrolyte profiles. Hepatitis B and C, HIV, and cytomegalovirus (CMV) testing is done to assess for transmitted diseases. An ECG and chest x-ray are done. A renal ultrasound and renal arteriogram or 3-dimensional CT scan is done to ensure that the blood vessels supplying each kidney are adequate and that no anomalies exist and to determine which kidney will be used in the transplant.

A transplant psychologist or social worker determines if the person is emotionally stable and able to deal with the issues related to organ donation. All donors must be informed about the risks and benefits of donation, the potential short- and long-term complications, and what to expect during the hospitalization and recovery phases. Kidney donation is considered safe without any long-term health consequences. Although the recipient's insurance covers the costs of the evaluation and surgery, no compensation is available for lost wages during the posthospitalization recovery period. This period can last 6 weeks or longer.

When there is ABO incompatibility between a donor and recipient, paired donor exchange is a viable alternative. *Paired organ donation,* in which one donor/recipient pair who are incompatible or poorly

matched with each other find another donor/recipient pair with whom they can exchange kidneys. Thus a spouse (person A) who wants to donate a kidney to his wife (person B) but is incompatible is paired with another donor/recipient pair involving a son with ESRD (person C) and his mother (person D). In this example, person A would donate his kidney to person C, and person D would donate her kidney to person B. Paired organ donation is the practice of matching biologically incompatible donor/recipient pairs to permit transplantation of both candidates with a well-matched organ.

Another option for ABO incompatibility or a positive crossmatch between the donor and recipient is to use plasmapheresis to remove antibodies from the recipient. This allows transplant candidates to receive kidneys from live donors with blood types that we have traditionally considered incompatible. After the transplant, the patient undergoes more plasmapheresis treatments.

Deceased Donors

Deceased (cadaver) kidney donors are relatively healthy persons who have an irreversible brain injury and are declared brain dead. The most common causes of injury are cerebral trauma from motor vehicle accidents or gunshot wounds, intracerebral or subarachnoid hemorrhage, and anoxic brain damage caused by cardiac arrest. The brain-dead donor must have effective CV function and be supported on a ventilator to preserve the organs.

Even if the donor carried a signed donor card, permission from the donor's legal next of kin is still requested after brain death has been declared. That is why it is important for you to talk with your family about your wishes before losing the capacity to convey your desires.

In deceased kidney donation, the kidneys are removed and preserved. They can be preserved for up to 72 hours. Most transplant surgeons prefer to transplant kidneys before the cold time (time outside of the body when being transported from the deceased donor to the recipient) reaches 24 hours. Prolonged cold time increases the chance that the kidney will not function immediately, and ATN may develop.

The United Network for Organ Sharing (UNOS) distributes deceased donor kidneys using an objective computerized point system. A new kidney allocation system (KAS) started in early 2015 after several years of refinement. All donor kidneys receive a kidney donor profile index (KDPI). The KDPI includes 10 donor factors that evaluate the risk for a kidney transplant failure. The KDPI can help predict how long a kidney may function. Each kidney transplant candidate gets an individual Estimated Post-Transplant Survival (EPTS) score. This score ranges from 0 to 100 percent. The score is related to how long a candidate will need a functioning kidney transplant when compared with other candidates. For example, a person with an EPTS score of 20% is likely to need a kidney longer than 80% of other candidates. The EPTS score is based on age, length of time on dialysis, previous transplants, and having diabetes.[32]

When a donor becomes available, the donor's key information is compared with the data of all patients awaiting transplantation locally and nationwide. When a kidney arrives at the recipient's transplant center, a final crossmatch is done. It must be negative for the deceased donor transplantation to proceed.

The only exception is if a patient needs an emergency transplant or if a donor and recipient match on all 6 HLA antigens (zero antigen mismatch). The patient meeting either of these criteria goes to the top of the list. Emergency transplants receive priority because the patient is facing imminent death if not transplanted. If a zero antigen mismatch patient is found nationally, since statistically these grafts have better survival rates, one of the donor kidneys must be sent to that recipient's transplant center regardless of location.

Surgical Procedure

Live Donor

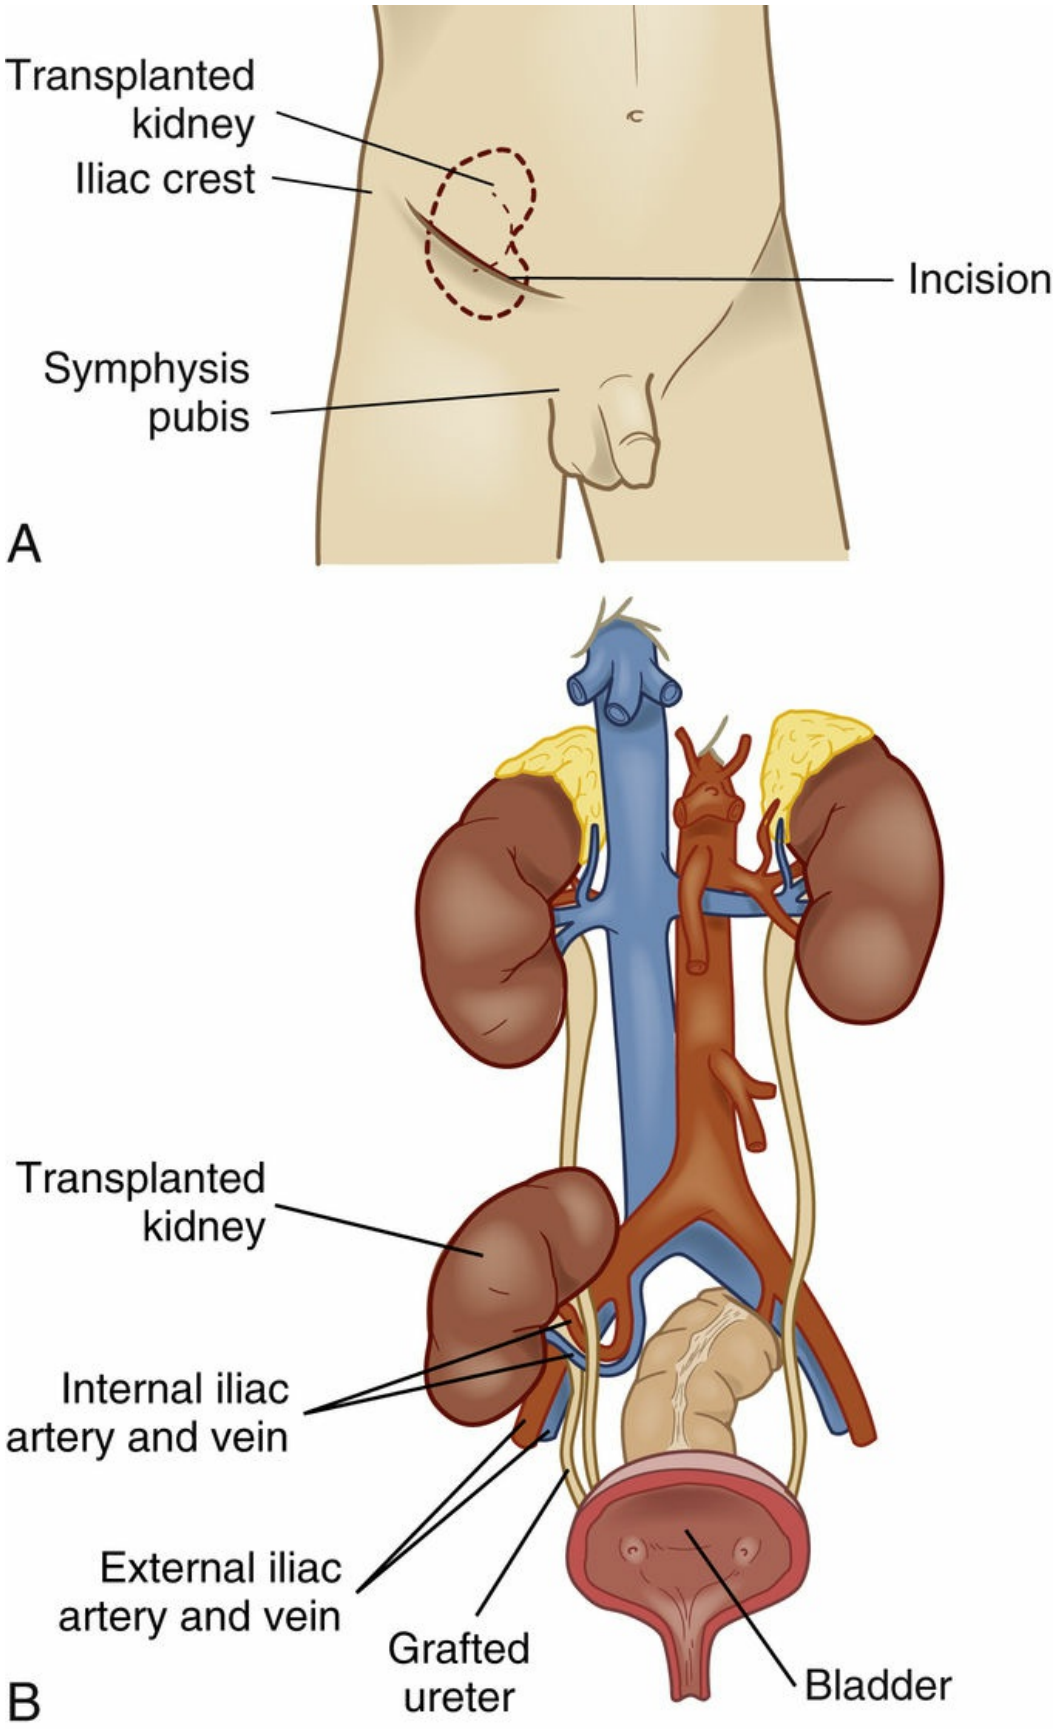
A transplant surgeon performs the live donor nephrectomy. The donor's surgery begins 1 to 2 hours before the recipient's surgery. The recipient is surgically prepared for the kidney transplant in a nearby operating room.

Laparoscopic donor nephrectomy is the most common technique for removing a kidney in a living donor. (Laparoscopic nephrectomy is discussed in Chapter 45.) After the kidney is removed, it is flushed with a chilled, sterile electrolyte solution and prepared for immediate transplant into the recipient. The use of a laparoscopic donor nephrectomy procedure is minimally invasive, with fewer risks and shorter recovery time than an open procedure. The laparoscopic approach significantly decreases hospital stay, pain, operative blood loss, debilitation, and length of time off work. For these reasons, the number of people willing to donate a kidney has increased significantly.

For an *open (conventional) nephrectomy*, the donor is placed in the lateral decubitus position on the operating table so that the flank is exposed laterally. An incision is made at the level of the eleventh rib. The rib may have to be removed to give adequate visualization of the kidney.

Kidney Transplant Recipient

The transplanted kidney is usually placed extraperitoneally in the iliac fossa. The right iliac fossa is preferred to facilitate anastomoses of the blood vessels and ureter and minimize the occurrence of paralytic ileus. A urinary catheter is placed into the bladder, and an antibiotic solution is instilled to distend the bladder and decrease the risk for infection. A crescent-shaped incision is made extending from the iliac crest to the symphysis pubis (Fig. 46.15).



Transplanted kidney

Transplanted kidney
Internal iliac artery and vein
External iliac artery and vein
Grafted ureter
Bladder
B

FIG. 46.15 **A,** Surgical incision for a renal transplant. **B,** Surgical placement of transplanted kidney.

Rapid revascularization is critical to prevent ischemic injury to the kidney. The donor artery is anastomosed to the recipient's internal iliac (hypogastric) or external iliac artery. The donor vein is anastomosed to the recipient's external iliac vein. When the anastomoses are complete, the clamps are released, and blood flow to the kidney is reestablished. The kidney should become firm and pink. Urine may begin to flow from the ureter at once. The donor ureter is then tunneled through the bladder submucosa before entering the bladder cavity and being sutured in place. This approach is called *ureteroneocystostomy*. This allows the bladder wall to compress the ureter as it contracts for micturition, thereby preventing reflux of urine up the ureter into the transplanted kidney. Transplant surgery takes about 3 to 4 hours.

Nursing Management: Kidney Transplant Recipient

Preoperative Care

Nursing care of the patient in the preoperative phase includes emotional and physical preparation for surgery. Because the patient and caregiver may have been waiting years for the kidney transplant, a review of the operative procedure and what can be expected in the immediate postoperative recovery period is necessary. Stress that there is a chance the kidney may not function at once, and dialysis may be needed for days to weeks. Review the need for immunosuppressive drugs and measures to prevent infection.

To ensure the patient is in the best physical condition for surgery, an ECG, chest x-ray, and laboratory studies are done. Dialysis may be needed before surgery for fluid overload or hyperkalemia. Because dialysis may be needed after transplantation, the patency of the vascular access must be maintained. Label the vascular access

extremity “dialysis access, no procedures” to prevent use of that extremity for BP measurement, blood drawing, or IV infusions. A patient on PD must empty the peritoneal cavity of all dialysate solution before going to surgery and have the PD catheter capped.

Postoperative Care

Live Donor

Postoperative care for the donor is similar to that after open (conventional) or laparoscopic nephrectomy (see Chapter 45). Closely monitor renal function to assess for impairment and the hematocrit to assess for bleeding. Donors usually have more pain than the recipient. Donors who had an open surgical approach may have more pain than those after a laparoscopic approach.

Donors who had an open approach are usually discharged from the hospital in 4 or 5 days and return to work in 6 to 8 weeks. With a laparoscopic approach, donors are discharged from the hospital in 2 to 4 days and return to work in 4 to 6 weeks. The surgeon sees the donor 1 to 2 weeks after discharge.

Nurses caring for the living donor must acknowledge the precious gift that this person has given. The donor has taken physical, emotional, and financial risks to help the recipient. It is vital that the donor is not forgotten after surgery. The donor will need support if the donated organ does not work at once or for some reason fails.

Kidney Transplant Recipient

The priority during the postoperative period is maintaining fluid and electrolyte balance. Kidney transplant recipients require close monitoring and spend the first 12 to 24 hours in the ICU. Large volumes of urine may be made soon after the blood supply to the transplanted kidney is reestablished. This diuresis is due to the (1) new kidney’s ability to filter BUN, which acts as an osmotic diuretic; (2) abundance of fluids given during the surgery; and (3) initial renal tubular dysfunction, which inhibits the kidney from concentrating urine normally. Urine output during this phase may be as high as 1

L/hr and gradually decreases as the BUN and serum creatinine levels return toward normal. Urine output is replaced with fluids milliliter for milliliter hourly for the first 12 to 24 hours.

Central venous pressure readings are essential for monitoring fluid status. Dehydration must be avoided to prevent renal hypoperfusion and renal tubular damage. Electrolyte monitoring to assess for hyponatremia and hypokalemia often associated with rapid diuresis is critical. Treatment with potassium supplements or infusion of 0.9% normal saline may be needed. IV sodium bicarbonate may be given if the patient develops metabolic acidosis from a delay in the return of kidney function.

ATN in the transplanted kidney can occur because of prolonged cold times causing ischemic damage or the use of marginal cadaveric donors (those who are medically suboptimal). While the patient is in ATN, dialysis is needed to maintain fluid and electrolyte balance. Some patients have high-output ATN with the ability to excrete fluid but not metabolic wastes or electrolytes. Other patients have oliguric or anuric ATN. These patients are at risk for fluid overload in the immediate postoperative period and must be assessed closely for the need for dialysis. ATN can last from days to weeks, with gradually improving kidney function. Most patients with ATN are discharged from the hospital on dialysis. This is extremely discouraging for the patient, who needs reassurance that renal function usually improves. Dialysis is discontinued when urine output increases and serum creatinine and BUN begin to normalize.

A sudden decrease in urine output in the early postoperative period is a cause for concern. It may be due to dehydration, rejection, a urine leak, or obstruction. A common cause of early obstruction is a blood clot in the urinary catheter. Catheter patency must be maintained since the catheter stays in the bladder for 3 to 5 days to allow the ureter-bladder anastomosis to heal. If you suspect blood clots, gentle catheter irrigation (if ordered) can reestablish patency.

With a hospital length of stay averaging 4 to 5 days, identify and address discharge planning and teaching needs early. Patient teaching ensures a smooth transition from the hospital to home. Include how to

recognize signs of rejection, infection, and any complications of surgery. Frequent blood tests and clinic visits help to detect rejection early.

Immunosuppressive Therapy

The goal of immunosuppression is to adequately suppress the immune response to prevent rejection of the transplanted kidney while maintaining sufficient immunity to prevent overwhelming infection. Immunosuppressive therapy is discussed in Chapter 13.

Complications of Transplantation

Complications of PD, HD, and kidney transplantation are compared in Table 46.14.

Rejection

Rejection is one of the major problems after kidney transplantation. Rejection can be hyperacute, acute, or chronic. The types of rejection are discussed in Chapter 13 on p. 206. Patients with chronic rejection may be placed on the transplant list to be retransplanted before dialysis is required.

Infection

Infection is a significant cause of morbidity and mortality after transplantation.[32] The transplant recipient is at risk for infection because of suppression of the body's normal defense mechanisms by surgery, immunosuppressive drugs, and the effects of ESRD. Underlying systemic illness, such as diabetes or SLE, malnutrition, and older age, can further compound the negative effects on the immune response. The signs and symptoms of infection can be subtle. You must be astute in your assessment of kidney transplant recipients because prompt diagnosis and treatment of infection improves patient outcomes.

TABLE 46.14 Complications of Dialysis and Transplantation

Peritoneal Dialysis (PD)	Hemodialysis (HD)	Transplantation

• Abdominal pain
• Carbohydrate abnormalities
• Catheter outflow
• CVD
• Encapsulating sclerosing peritonitis
• Exit site infection
• Hernias
• Lipid abnormalities
• Lower back pain
• Peritonitis
• Protein loss
• Pulmonary problems
  • Atelectasis
  • Pneumonia
  • Bronchitis
	• CVD
	• Disequilibrium syndrome
	• Exsanguination
	• Hepatitis
	• Hypotension
	• Infection, including sepsis
	• Muscle cramp
		• Cancers
		• Corticosteroid-related complications
		• CVD
		• Recurrence of kidney disease
		• Susceptibility to infection
		• Transplant rejection
		  • Hyperacute
		  • Acute
		  • Chronic

The common infections seen in the first month after transplantation are like those of any postoperative patient. These include pneumonia, wound infections, UTIs, and IV line and drain infections. Fungal and viral infections are common due to the patient's immunosuppressed state. Fungal infections include *Candida, Cryptococcus,* and *Aspergillus* organisms and *Pneumocystis jiroveci.* Fungal infections are hard to treat, require prolonged treatment periods, and often involve the administration of nephrotoxic drugs. Transplant recipients usually receive prophylactic antifungal drugs to prevent these infections, such as clotrimazole, fluconazole (Diflucan), and trimethoprim/sulfamethoxazole (Bactrim).

Viral infections, including CMV, Epstein-Barr virus, herpes simplex virus (HSV), varicella-zoster virus, and polyomavirus (e.g., BK virus), can be primary infections or reactivations of existing disease. Primary infections occur as new infections after transplantation from an exogenous source such as the donated organ or a blood transfusion. Reactivation occurs when a virus exists in a patient and becomes reactivated after transplantation because of immunosuppression.

CMV is one of the most common viral infections. If a recipient has

never had CMV and receives an organ from a donor with a history of CMV, antiviral prophylaxis will be needed (e.g., ganciclovir, valganciclovir [Valcyte]). To prevent HSV infections, oral acyclovir (Zovirax) is given for several months after the transplant.

Cardiovascular Disease

CVD is the leading cause of death after renal transplantation.[32] Transplant recipients have an increased incidence of atherosclerotic vascular disease. Hypertension, dyslipidemia, diabetes, smoking, rejection, infections, and increased homocysteine levels (many of which existed prior to the transplant) can all contribute to CVD. Immunosuppressants can worsen hypertension and dyslipidemia.

Teach the patient to control risk factors, such as high cholesterol, triglycerides, and blood glucose and weight gain. Adherence to the prescribed antihypertensive regimen is essential to prevent CV events and damage to the new kidney.

Cancers

The overall incidence of cancer in kidney transplant recipients is greater than in the general population, primarily because of immunosuppressive therapy. Not only do immunosuppressants suppress the immune system to prevent rejection, they also suppress the ability to fight infection and the production of abnormal cells, including cancer cells.

The most common types of cancer after transplant are (1) skin cancers—basal and squamous cell cancers and melanoma—and (2) *posttransplant lymphoproliferative disorder (PTLD).* Most PTLDs are of B-cell origin, associated with Epstein-Barr virus (EBV), and cause aggressive lymphomas (Hodgkin's and non-Hodgkin's lymphoma). Most cases of PTLD occur within the first year of transplant.

Patients are also at risk for cancers of the colorectum, breast, cervix, liver, stomach, oropharynx, anus, vulva, and penis. Regular screening for cancer is an important part of the transplant recipient's preventive care. Teach the patient to avoid sun exposure by using protective clothing and sunscreens to minimize the incidence of skin cancers.

Recurrence of Original Kidney Disease

Recurrence of the original disease that destroyed the native kidneys occurs in some kidney transplant recipients. It is most common with certain types of glomerulonephritis, immunoglobulin A (IgA) nephropathy, diabetic nephropathy, and focal segmental sclerosis. Disease recurrence can result in the loss of a functioning kidney transplant. Patients must be advised before transplantation if they have a disease known to recur.

Corticosteroid-Related Complications

Aseptic necrosis of the hips, knees, and other joints can result from chronic corticosteroid therapy and renal osteodystrophy. Other significant problems related to corticosteroids include peptic ulcer disease, diabetes, cataracts, dyslipidemia, infections, and cancers. The use of tacrolimus and other immunosuppressants has allowed corticosteroid doses to be much lower than they were in the past.

Many transplant programs have started corticosteroid-free drug regimens because of the problems of long-term corticosteroid use. Other centers withdraw patients from corticosteroids after transplantation. For patients who stay on corticosteroids, vigilant monitoring for side effects and prompt treatment is essential. Corticosteroid therapy as immunosuppression is discussed in Chapter 13 on p. 207.

Gerontologic Considerations: Chronic Kidney Disease

The incidence of CKD in the United States is increasing most rapidly in older adults. The most common diseases leading to renal disease in older adults are hypertension and diabetes.[33]

The care of older patients is particularly challenging, not only because of the normal physiologic changes of aging but also because of the disabilities, chronic diseases, and co-morbid conditions that occur with aging. Physiologic changes include decreased

cardiopulmonary function, bone loss, immunodeficiency, altered protein synthesis, impaired cognition, and altered drug metabolism. Malnutrition is common in these patients for a variety of reasons, including lack of mobility, social isolation, physical disability, and impaired cognitive function.

When conservative therapy for CKD is no longer effective, the older patient needs to consider the best treatment modality based on physical and emotional health, personal preferences, and availability of support. Quality-of-life measures show no justification for excluding the older adult from dialysis programs. Rationing dialysis based on age alone is not a reasonable decision for health care professionals to make. Older adults have successfully used dialysis, especially PD. Many choose treatment with in-center HD due to a lack of help in the home and reluctance to manage the technology of home HD or PD. Establishing vascular access for HD may be difficult because of atherosclerotic changes.

Although transplantation is an option, older adults must be carefully screened to ensure that the benefits of transplantation outweigh the risks.[34] Although a living donor is preferable, this may not be an option for many older patients.

The most common cause of death in older ESRD patients is CVD (MI, stroke), followed by withdrawal from dialysis. If a competent patient decides to withdraw from dialysis, it is essential to support the patient and family. Ethical issues (see the Ethical/Legal Dilemmas box) to consider in this situation include patient competency, benefit versus burden of treatment, and futility of treatment. Withdrawal from treatment is not a failure if the patient is well informed and comfortable with the decision.

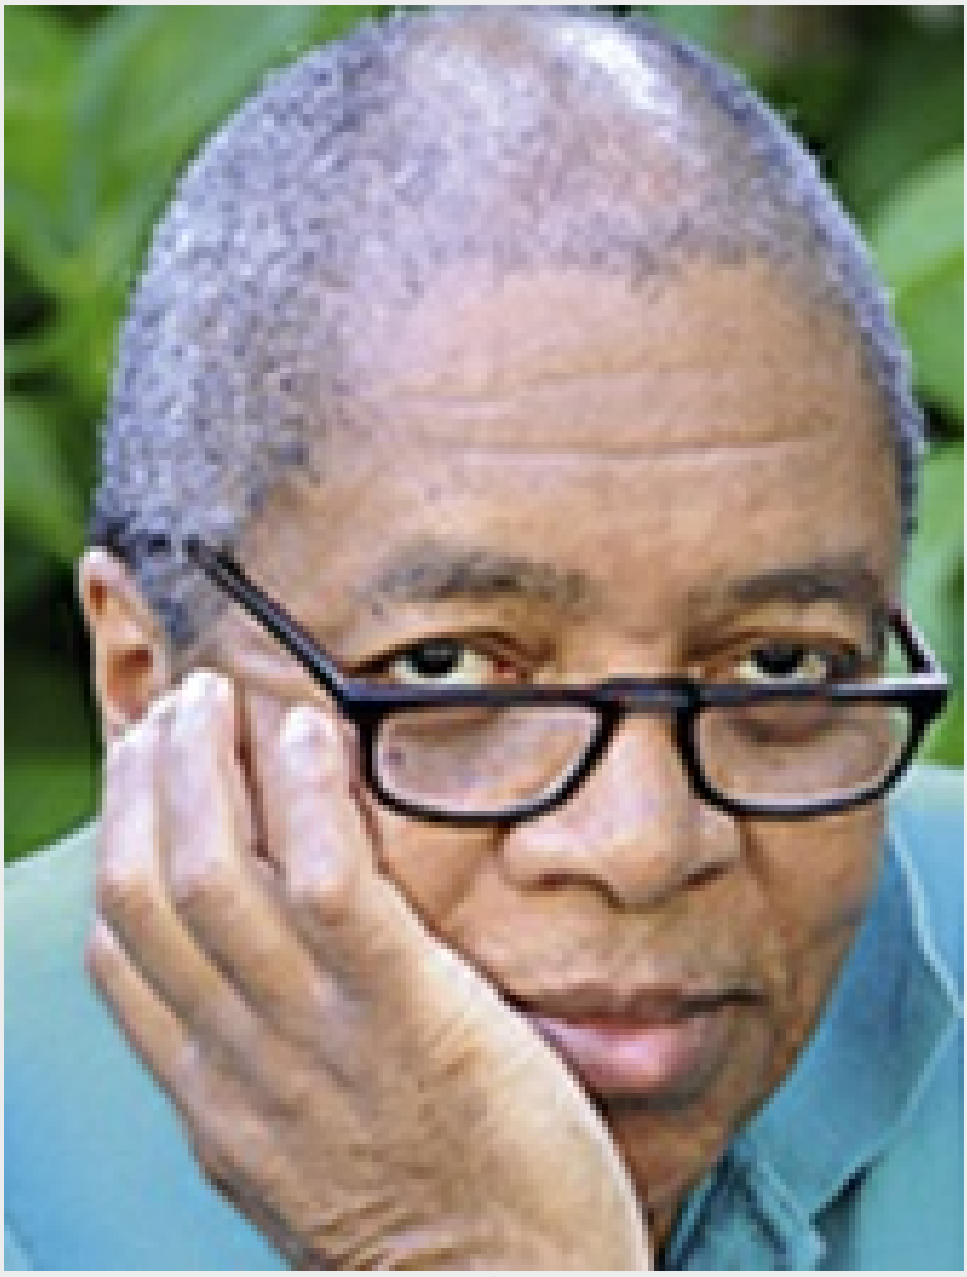
Ethical/Legal Dilemmas

Withdrawing Treatment

Situation

L.R., a 70-yr-old patient with diabetes and ESRD, has been on dialysis for 10 years. He tells you that he wants to stop his dialysis. His quality of life has diminished during the past 2 years since his wife died. He is not a transplant candidate.

Ethical/Legal Points for Consideration



- Informed consent includes the legal right to refuse treatment. However, the right to refuse may be more difficult if (1) it is contrary to the wishes of family and friends, (2) the treatment still appears to have effectiveness, and (3) the treatment has been in place for some time.
- Quality-of-life decisions often outweigh the benefit against the burden of treatment. When a treatment becomes too burdensome, the patient, if competent, may request to withdraw the treatment.
- It must be determined whether some other treatable problem, such as depression, may be clouding the patient's judgment.
- Although there is no ethical or legal difference between withdrawing treatment and withholding treatment, withdrawing treatment feels different because it requires an action.
- Some health care professionals become conflicted when asked to withdraw treatment, since they may think they are contributing to the patient's premature death.
- If a decision is made to withdraw treatment, the interprofessional care team, patient, and family should develop a follow-up plan that includes palliative care and hospice support.

Discussion Questions

1. How should you respond to L.R.'s request?
2. What is the American Nurses Association's position on withdrawing or withholding treatment that no longer benefits the patient or causes suffering?

Case Study

Chronic Kidney Disease

© iStockphoto/Thinkstock.

Patient Profile

M.B. is a 56-yr-old black college professor. He is seen by his primary care provider for a routine physical examination. He has not seen an HCP in a little over a year. He reports generalized malaise, frequent urination, and "increasing thirst." His medical history is significant for borderline hypertension and dyslipidemia. He smokes 1 pack of cigarettes per day. His efforts to quit have been unsuccessful.

Subjective Data

- Family history: father died of an MI at age 62, brother had coronary artery bypass graft (CABG) at age 50, mother died from complications of diabetes
- Becomes "winded" when walking from his car to his office at the university
- Wakes up at night to urinate and has more frequent urination
- Increasing thirst

Objective Data

Laboratory Data

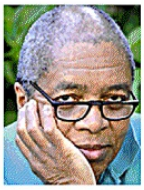
- Calculated creatinine clearance using the MDRD equation: 42 mL/min/1.73 m^2
- Serum creatinine 2.5 mg/dL
- BUN 35 mg/dL
- Serum glucose 264 mg/dL
- Hgb 13 g/dL
- Serum cholesterol 236 mg/dL

Physical Examination

- Weight 220 lb, height 5 ft, 11 in

- BP 168/104 mm Hg

Discussion Questions



1. What do you think caused M.B.'s kidney disease?
2. What stage of chronic kidney disease does he have?
3. Identify the abnormal diagnostic study results and why each would occur.
4. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
5. What are the most important treatment measures that the interprofessional team can provide for M.B.?
6. ***Patient-Centered Care:*** What are the nursing interventions that would help promote M.B.'s self-management of his disease process?
7. ***Collaboration:*** How can the interprofessional team work together with M.B. to decide on the best form of renal replacement therapy?
8. ***Evidence-Based Practice:*** M.B. tells you that he has not been taking his BP medications regularly. When he asks you how important they are, what will you tell him?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 4 patients. You are also assigned to receive the next new admission to the clinical unit. You have 1 UAP on your team to help you.

Patients	
 © iStockphoto/Thinkstock.	A.K., a 28-yr-old black man, was admitted for observation after a renal ultrasound found several stones in the left ureter. A.K. came to the ED with sharp, colicky left flank pain for which the HCP prescribed IV opioids. His last pain medication was given 2 hours ago. His current pain level is 4 on a scale of 1 to 10. He is voiding dark, smoky-colored urine. His vital signs are within normal limits. He has positive costovertebral tenderness.
 © iStockphoto/Thinkstock.	S.U., a 29-yr-old Hispanic woman with type 1 diabetes, was admitted with acute pyelonephritis following a recent UTI. She has bilateral flank pain and has abdominal tenderness to palpation. Her temperature is 101.5°F (38.6°C). Her urinalysis shows pyuria and hematuria. The WBC is high at 14,800/μL. Blood culture results are pending. IV antibiotics have been started. Most recent blood glucose is 215 mg/dL.
 © iStockphoto/Thinkstock.	M.B., a 56-yr-old black college professor, was admitted with uncontrolled hypertension. He was recently diagnosed with CKD. He smokes at least 1 pack of cigarettes per day and is having some nicotine withdrawal symptoms. His BP on admission was 224/102 mm Hg. He is receiving IV metoprolol (Lopressor) 5 mg q4hr prn for SBP >180 mm Hg. His most recent BP 3 hr ago was 174/86 mm Hg. Laboratory results show a BUN of 66 mg/dL and serum creatinine of 3.2 mg/dL.
 © iStockphoto/Thinkstock.	D.M., an 82-yr-old woman, was admitted to the ED with severe dehydration, heart failure, and acute kidney injury. Her daughter found her unconscious and lying on the floor. She is confused. Her serum potassium is 6.3 mEq/L. Her urine output for the past 8 hours was 90 mL.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Second? Provide a rationale for your decision.
2. ***Collaboration:*** Which tasks could you delegate to the UAP (select all that apply)?
    a. Obtain vital signs on M.B.
    b. Strain A.K.'s voided urine.
    c. Report D.M.'s potassium level to the HCP.
    d. Measure D.M.'s urine output and report the results to the RN.

e. Assess S.U. for manifestations of sepsis and diabetic ketoacidosis.

3. ***Priority Decision:*** As you are assessing D.M., the UAP tells you that M.B.'s BP is 190/96. He is asymptomatic. Additionally, the charge nurse tells you that you will be receiving a patient with heart failure from the ED within the next 20 minutes. Which action would be *most* appropriate?
    a. Ask the charge nurse to assign the new admission to someone else.
    b. Have the UAP admit the new patient while you administer M.B.'s IV metoprolol.
    c. Call the ED and have them hold the new admission until after you have assessed all your patients.
    d. Ask the charge nurse to give M.B.'s IV metoprolol while you complete your assessment of D.M. and S.U.

Case Study Progression

As you complete your assessment of D.M., you note her apical pulse is irregular. She has 1+ pitting edema in her lower extremities. Her BP is 160/90 mm Hg, heart rate 108 beats/min, and respiratory rate 28/min. Auscultation of her lungs reveals crackles in the bases and O_2 saturation is 92% on room air. You notify her HCP.

4. Which interventions would you expect the HCP to order for D.M.? *(select all that apply)*
    a. Administer IV Kayexalate.
    b. Obtain arterial blood gas levels.
    c. Administer 40 mg of furosemide IV push.
    d. Prepare her for hemodialysis and notify her family.
    e. Obtain a 12-lead ECG and start continuous ECG monitoring.
5. ***Priority Decision:*** Which concern has the *highest* priority when planning care for A.K.?
    a. Acute pain
    b. Infection risk

c. Risk for injury
d. Difficulty coping

6. ***Priority Decision:*** You begin S.U.'s scheduled infusion of IV ceftriaxone. Which parameters are the *most* important to monitor while she is receiving this drug?
    a. PT and INR
    b. BUN and creatinine
    c. CBC with differential
    d. Liver function studies
7. Which statement would be *most* appropriate when teaching S.U. about her kidney infection?
    a. "The damage to your kidneys will likely require dialysis."
    b. "You will need to be in the hospital for a 2-week course of IV antibiotics."
    c. "It is very important that you maintain adequate hydration to flush your kidneys."
    d. "You will not need further antibiotics once you are discharged from the hospital."
8. ***Collaboration:*** As the UAP prepares the room for the patient being admitted from the ED, you overhear her telling a co-worker that she does all your work for you. What is your *best* initial action?
    a. Report the incident to the charge nurse for follow-up.
    b. Ask the UAP to discuss her concerns with you in private.
    c. Tell the UAP how much you appreciate and value her input on your team.
    d. Immediately clarify the situation by telling the UAP all the tasks you are completing.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. RIFLE defines the first 3 stages of AKI based on changes in
   a. blood pressure and urine osmolality.
   b. fractional excretion of urinary sodium.
   c. estimation of GFR with the MDRD equation.
   d. serum creatinine or urine output from baseline.
2. During the oliguric phase of AKI, the nurse monitors the patient for *(select all that apply)*
   a. hypotension.
   b. ECG changes.
   c. hypernatremia.
   d. pulmonary edema.
   e. urine with high specific gravity.
3. If a patient is in the diuretic phase of AKI, the nurse must monitor for which serum electrolyte imbalances?
   a. Hyperkalemia and hyponatremia
   b. Hyperkalemia and hypernatremia
   c. Hypokalemia and hyponatremia
   d. Hypokalemia and hypernatremia
4. A patient is admitted to the hospital with chronic kidney disease. The nurse understands that this condition is characterized by
   a. progressive irreversible destruction of the kidneys.
   b. a rapid decrease in urine output with an elevated BUN.
   c. an increasing creatinine clearance with a decrease in urine output.

d. prostration, somnolence, and confusion with coma and imminent death.

5. Nurses can screen patients at risk for developing chronic kidney disease. Those considered to be at increased risk include *(select all that apply)*
   a. older black patients.
   b. patients more than 60 years old.
   c. those with a history of pancreatitis.
   d. those with a history of hypertension.
   e. those with a history of type 2 diabetes.
6. Patients with chronic kidney disease have an increased incidence of cardiovascular disease related to *(select all that apply)*
   a. hypertension.
   b. vascular calcifications.
   c. a genetic predisposition.
   d. hyperinsulinemia causing dyslipidemia.
   e. increased high-density lipoprotein levels.
7. Nutritional support and management are essential across the entire continuum of chronic kidney disease. Which statements are true related to nutritional therapy? *(select all that apply)*
   a. Sodium and salt may be restricted in someone with advanced CKD.
   b. Fluid is not usually restricted for patients receiving peritoneal dialysis.
   c. Decreased fluid intake and a low-potassium diet are part

of the diet for a patient receiving hemodialysis.

d. Decreased fluid intake and a low-potassium diet are part of the diet for a patient receiving peritoneal dialysis.

e. Decreased fluid intake and a diet in protein-rich foods are part of a diet for a patient receiving hemodialysis.

8. An ESRD patient receiving hemodialysis is considering asking a relative to donate a kidney for transplantation. In helping the patient decide about treatment, the nurse informs the patient that

a. successful transplantation usually provides better quality of life than that offered by dialysis.

b. if rejection of the transplanted kidney occurs, no further treatment for the renal failure is available.

c. hemodialysis replaces the normal functions of the kidneys, and patients do not have to live with the continual fear of rejection.

d. the immunosuppressive therapy after transplantation makes the person ineligible to receive other treatments if the kidney fails.

9. To assess the patency of a newly placed arteriovenous graft for dialysis, the nurse should *(select all that apply)*

a. monitor the BP in the affected arm.

b. irrigate the graft daily with low-dose heparin.

c. palpate the area of the graft to feel a normal thrill.

d. listen with a stethoscope over the graft to detect a bruit.

e. assess the pulses and neurovascular status distal to the graft.

10. A kidney transplant recipient has had fever, chills, and

dysuria over the past 2 days. What is the *first* action that the nurse should take?

a. Assess temperature and initiate workup to rule out infection.

b. Reassure the patient that this is common after transplantation.

c. Provide warm covers to the patient and give 1 gram oral acetaminophen.

d. Notify the nephrologist that the patient has manifestations of acute rejection.

1. d, 2. b, d, 3. c, 4. a, 5. a, b, d, e, 6. a, b, d, 7. a, b, c, 8. a, 9. c, d, e, 10. a

Assessment

Endocrine System

Julia A. Hitch

LEARNING OUTCOMES

1. Describe the common characteristics and functions of hormones.
2. Identify the locations of the endocrine glands.
3. Describe the functions of hormones secreted by the pituitary, thyroid, parathyroid, and adrenal glands and the pancreas.
4. Describe the locations and roles of hormone receptors.
5. Obtain significant subjective and objective assessment data related to the endocrine system from a patient.
6. Perform a physical assessment of the endocrine system using the appropriate techniques.
7. Link age-related changes in the endocrine system to differences in assessment findings.
8. Distinguish normal from common abnormal findings of a physical assessment of the endocrine system.
9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the endocrine system.

Conceptual Focus

Homeostasis
Hormonal Regulation
Reproduction
Stress

Structures and Functions of Endocrine System

Glands

Endocrine glands include the hypothalamus, pituitary, thyroid, parathyroids, adrenals, pancreas, ovaries, testes, and pineal gland (Fig. 47.1). These glands make and release special chemical messengers called *hormones.* The endocrine system has 5 general functions: (1) a role in reproductive and central nervous system (CNS) development in the fetus, (2) stimulating growth and development during childhood and adolescence, (3) sexual reproduction, (4) maintaining homeostasis, and (5) responding to emergency demands.[1]

Hormones

Hormones are chemical substances made by endocrine glands that control and regulate the activity of certain target cells or organs. Many are made in one part of the body and control and regulate the activity of certain cells or organs in another part of the body. The thyroid gland makes the hormone thyroxine, which affects many body tissues when released directly into the circulation. Other hormones act locally on cells where they are released and never enter the bloodstream. We call this local effect *paracrine action.* The action of sex steroids on the ovary is an example of paracrine action.

Most hormones have common characteristics, including (1) secretion in small amounts at variable but predictable rates, (2) regulation by feedback systems, and (3) ability to bind to specific target cell receptors. Table 47.1 reviews the major hormones, the glands or tissues that make the hormones, their target organs or tissues, and their functions.

Testes
(male)

FIG. 47.1 Location of the major endocrine glands. The parathyroid glands lie on the posterior surface of the thyroid gland. Modified from Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St Louis, 2013, Mosby.

There is a strong connection between the endocrine system and nervous system. *Catecholamines* (e.g., epinephrine), secreted by the adrenal gland, travel through the bloodstream and affect multiple organ systems. These same substances, when secreted by nerve cells in the brain and peripheral nervous system, act as neurotransmitters, sending important impulses across nerve synapses.[1]

Organs can act as endocrine glands by secreting hormones. For example, the kidneys secrete erythropoietin, a substance that stimulates red blood cell production. The heart secretes atrial natriuretic peptide (ANP). The gastrointestinal (GI) tract secretes many peptide hormones (e.g., gastrin), that aid in digestion. These hormones are discussed in their respective assessment chapters.

Hormone Receptors

Hormones exert their effects by recognizing their target tissues and attaching to receptor sites in a "lock-and-key" type of mechanism. This means a hormone will act only on cells that have a receptor specific for that hormone (Fig. 47.2).

Lipid-Soluble and Water-Soluble Hormones

We classify hormones by their chemical structure as either lipid soluble or water soluble. The differences in solubility become important in understanding how the hormone interacts with the target cell (Fig. 47.3). Lipid-soluble hormones (steroids, thyroid) are bound to plasma proteins as they travel to target cells. They cross the cell membrane by simple diffusion. Water-soluble hormones (insulin, growth hormone, prolactin) circulate freely in the blood and act directly on target tissues.

Regulation of Hormonal Secretion

Specific mechanisms control endocrine activity by either stimulating

or inhibiting hormone synthesis and secretion. These include positive and negative feedback, nervous system control, and physiologic rhythms.

Simple Feedback

Negative feedback relies on the blood level of a hormone or other chemical compound regulated by the hormone (e.g., glucose). It is the most common type of endocrine feedback system. It results in the gland increasing or decreasing the release of a hormone. Negative feedback functions like a thermostat. Cold air in a room activates the thermostat to release heat. Warm air signals the thermostat to turn off the heater. An example of negative feedback is calcium and parathyroid hormone (PTH) regulation. Low blood levels of calcium stimulate the parathyroid gland to release PTH. PTH acts on the bone, intestine, and kidneys to increase blood calcium levels. The increased blood calcium level then inhibits further PTH release (Fig. 47.4).

With **positive feedback**, increasing hormone levels cause another gland to release a hormone that then stimulates further release of the first hormone. Something must stop the release of the first hormone (e.g., follicle death) or its release will continue. The ovarian hormone estradiol works by this type of feedback. Increased levels of estradiol made by the follicle during the menstrual cycle result in the production and release of follicle-stimulating hormone (FSH) by the anterior pituitary. FSH causes further increases in estradiol until the death of the follicle. This results in a drop of FSH serum levels.

Nervous System Control

Nervous system activity directly affects some endocrine glands. Pain, fear, sexual excitement, and other stressors can stimulate the nervous system to control hormone secretion. For example, when the CNS senses or perceives stress, the sympathetic nervous system (SNS) secretes catecholamines (e.g., epinephrine), which maximize heart and lung function and vision to deal with the stress more effectively. Chronic exposure to some stressors can cause persistent increases in heart rate and BP and changes in the endocrine system. This puts

patients at risk for chronic disease, such as hypertension and heart disease. Stress-related effects are discussed in Chapter 6.

Rhythms

A common physiologic rhythm is the **circadian rhythm**. It is a 24-hour rhythm that is driven by sleep-wake or dark-light 24-hour (diurnal) cycles. Hormone levels and the responsiveness of target tissues fluctuate predictably during these cycles. Cortisol, made by the adrenal cortex, rises early in the day, declines toward evening, and rises again toward the end of sleep to peak by morning (Fig. 47.5). Growth hormone, thyroid-stimulating hormone, and prolactin levels peak during sleep. Reproductive cycles are often longer than 24 hours *(ultradian)*. An example is the menstrual cycle. These rhythms are important to consider when interpreting laboratory results for hormone levels.

Hypothalamus

Although many refer to the pituitary gland as the "master gland" of the endocrine system, most of its functions rely on its interrelationship with the hypothalamus, which lies next to the pituitary gland. The hypothalamus releases substances that either stimulate or inhibit the production and release of hormones from the pituitary gland (Table 47.2). Examples of these hormones include corticotropin-releasing hormone and thyrotropin-releasing hormone. Somatostatin inhibits growth hormone release.

Table 47.1 Endocrine Glands and Hormones

Hormones	Target Tissue	Functions
Anterior Pituitary (Adenohypophysis)		
Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Fosters growth of adrenal cortex Stimulates corticosteroid secretion
Gonadotropic hormones **• Follicle-stimulating hormone (FSH)** **• Luteinizing hormone (LH)**	Reproductive organs	Stimulate sex hormone secretion, reproductive organ growth, reproductive processes
Growth hormone (GH), or somatotropin	All body cells	Promotes protein anabolism (growth, tissue repair) and lipid mobilization and catabolism
Melanocyte-stimulating hormone (MSH)	Melanocytes in skin	↑ Melanin production in melanocytes to make skin darker
Prolactin	Ovary and mammary glands in women Testes in men	Stimulates milk production in lactating women. ↑ Response of follicles to LH and FSH Stimulates testicular function in men
Thyroid-stimulating hormone (TSH), or thyrotropin	Thyroid gland	Stimulates synthesis and release of thyroid hormones, growth and function of thyroid gland
Posterior Pituitary (Neurohypophysis)		
Antidiuretic hormone (ADH)	Renal tubules, vascular smooth muscle	Promotes reabsorption of water from the renal tubules, vasoconstriction
Oxytocin	Uterus, mammary glands	Stimulates milk secretion, uterine contractility
Thyroid		
Calcitonin	Bone tissue	Regulates calcium and phosphorus serum levels. ↓ Serum Ca^{2+} levels
Thyroxine (T_4)	All body tissues	Precursor to T_3
Triiodothyronine (T_3)	All body tissues	Regulates metabolic rate of all cells and processes of cell growth and tissue differentiation
Parathyroids		
Parathyroid hormone (PTH) or parathormone	Bone, intestine, kidneys	Regulates calcium and phosphorus serum levels. Promotes bone demineralization and ↑ intestinal absorption of Ca^{2+}. ↑ Serum Ca^{2+} levels
Adrenal Medulla		
Epinephrine (adrenaline)	Catecholamine	↑ In response to stress. Enhances and prolongs effects of sympathetic nervous system
Norepinephrine (noradrenaline)	Catecholamine	↑ In response to stress. Enhances and prolongs effects of sympathetic nervous system
Adrenal Cortex		
Androgens (e.g., dehydroepiandrosterone [DHEA] , androsterone) and estradiol	Reproductive organs	Promote growth spurt in adolescence, secondary sex characteristics, and libido in both sexes
Corticosteroids (e.g., cortisol, hydrocortisone)	All body tissues	Promote metabolism. ↑ In response to stress. Antiinflammatory
Mineralocorticoids (e.g., aldosterone)	Kidney	Regulate sodium and potassium balance and thus water balance
Pancreas (Islets of Langerhans)		
Amylin (from β cells)	Liver, stomach	↓ Gastric motility, glucagon secretion, and endogenous glucose release from liver. ↑ Satiety
Glucagon (from α cells)	General	Stimulates glycogenolysis and gluconeogenesis
Insulin (from β cells)	General	Promotes glucose transport from the blood into the cell
Pancreatic polypeptide	General	Influences regulation of pancreatic exocrine function and metabolism of absorbed nutrients
Somatostatin	Pancreas	Inhibits insulin and glucagon secretion
Gonads		
Women: Ovaries		
Estrogen	Reproductive system, breasts	Stimulates development of secondary sex characteristics, preparation of uterus for fertilization and fetal development. Stimulates bone growth
Progesterone	Reproductive system	Maintains lining of uterus needed for successful pregnancy
Men: Testes		
Testosterone	Reproductive system	Stimulates development of secondary sex characteristics, spermatogenesis

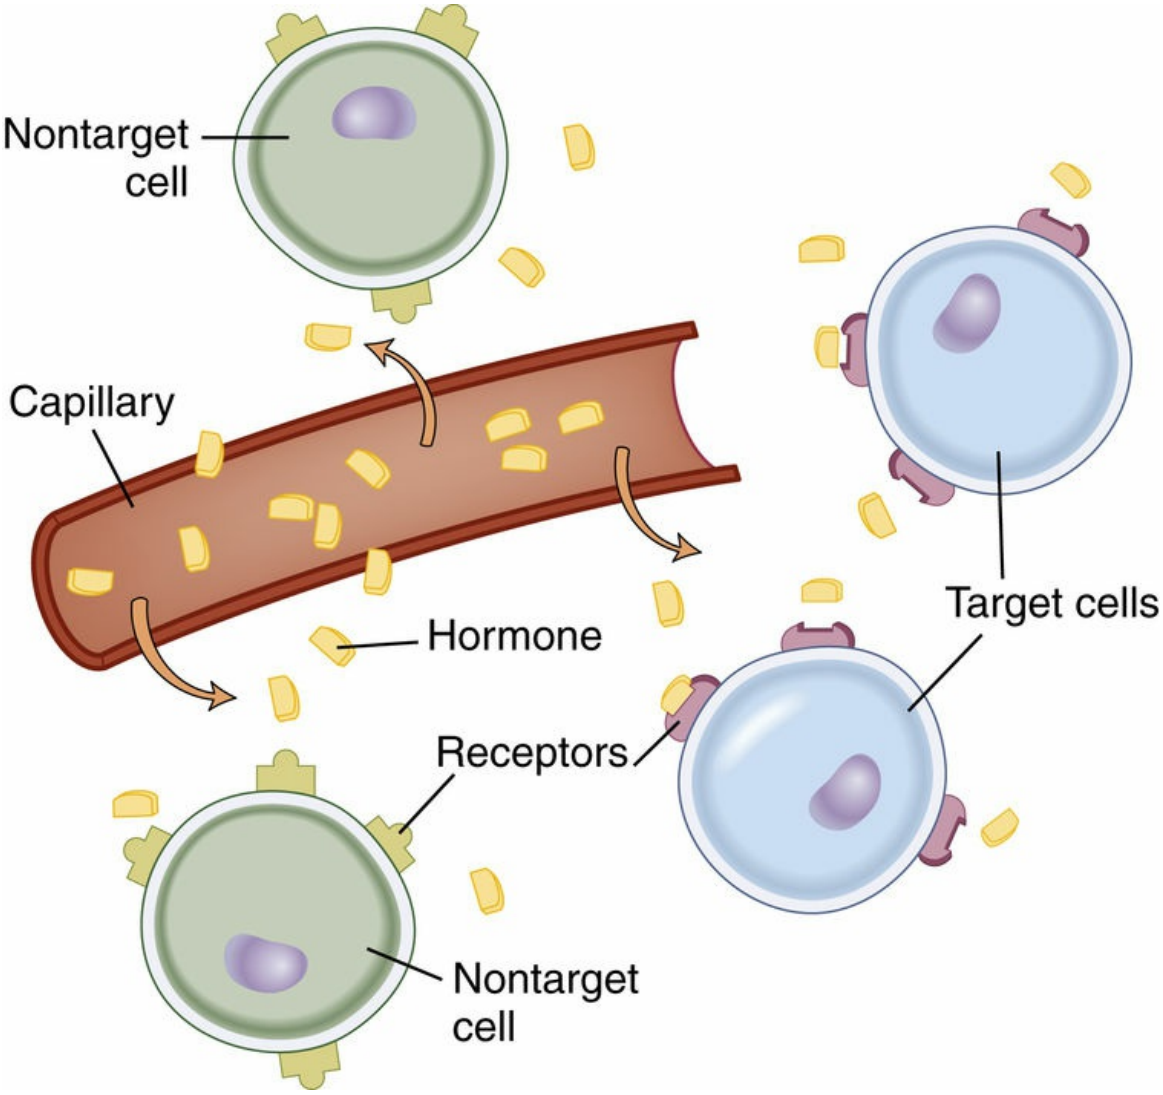

FIG. 47.2 The target cell concept. Hormones act only on cells that have receptors specific to that hormone, since the shape of the receptor determines which hormone can react with it. This is an example of the lock-and-key model of biochemical reactions.

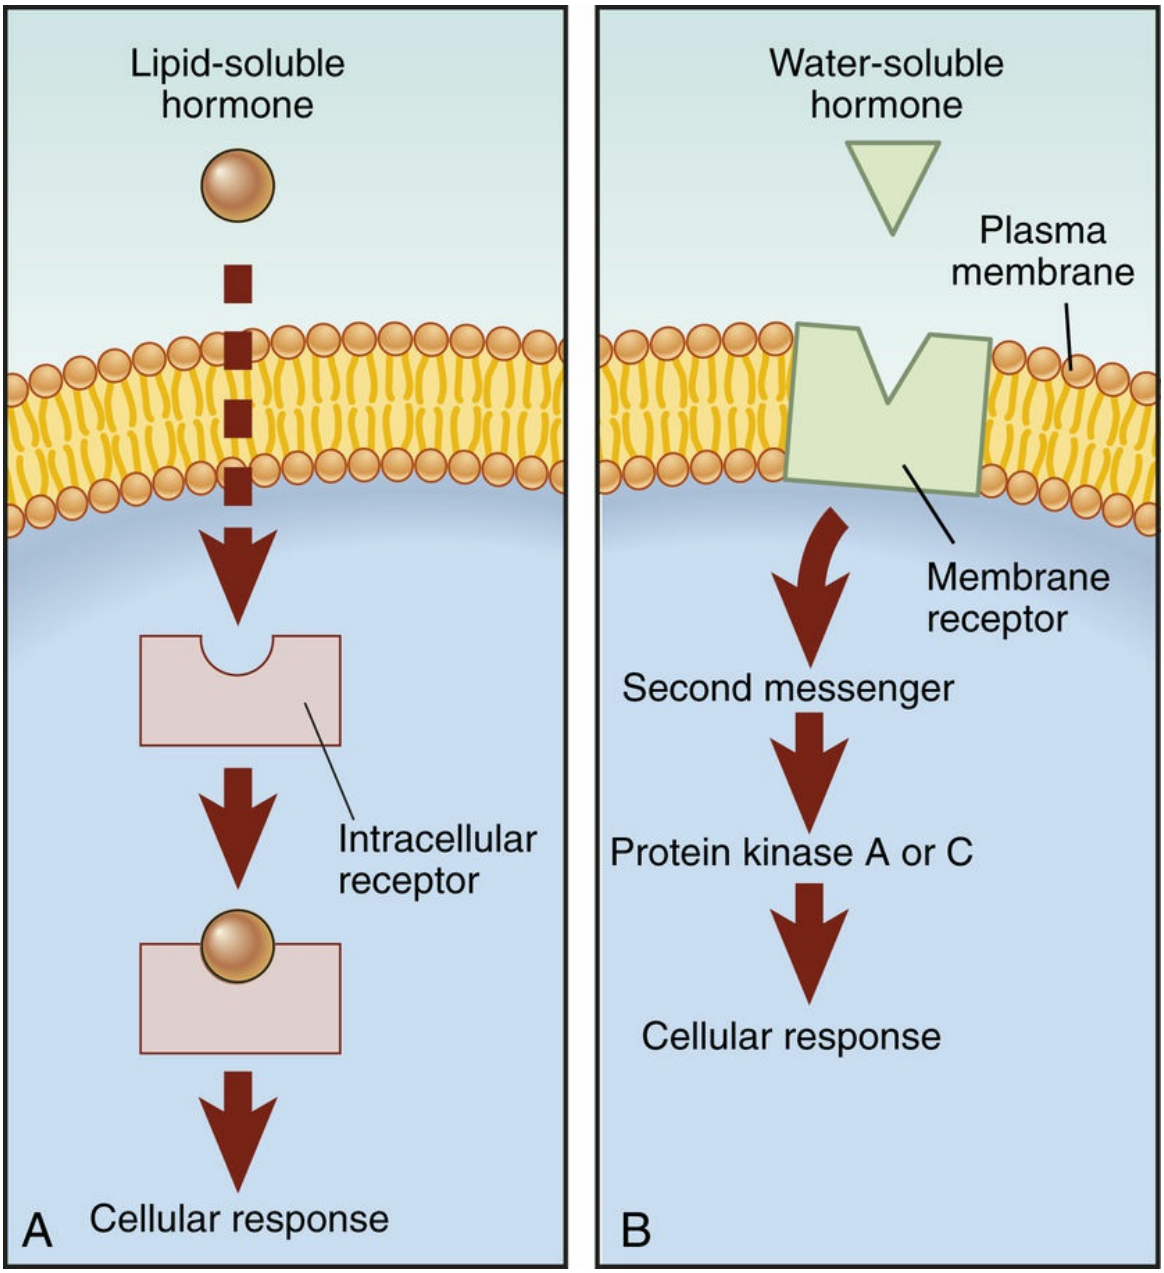

FIG. 47.3 **A,** Lipid-soluble hormones (e.g., steroid hormones) penetrate the cell membrane and interact with intracellular receptors. **B,** Water-soluble hormones (e.g., protein hormones) bind to receptors in the cell membrane. The hormone-receptor interaction stimulates various cell responses.
Modified from McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children*, ed 6, St Louis, 2010, Mosby.

Neurons in the hypothalamus receive input from the CNS, including the brainstem, limbic system, and cerebral cortex. These neurons create a circuit that helps coordinate the endocrine system

and autonomic nervous system (ANS). The hypothalamus also coordinates the expression of complex behavioral responses, such as anger, fear, and pleasure.

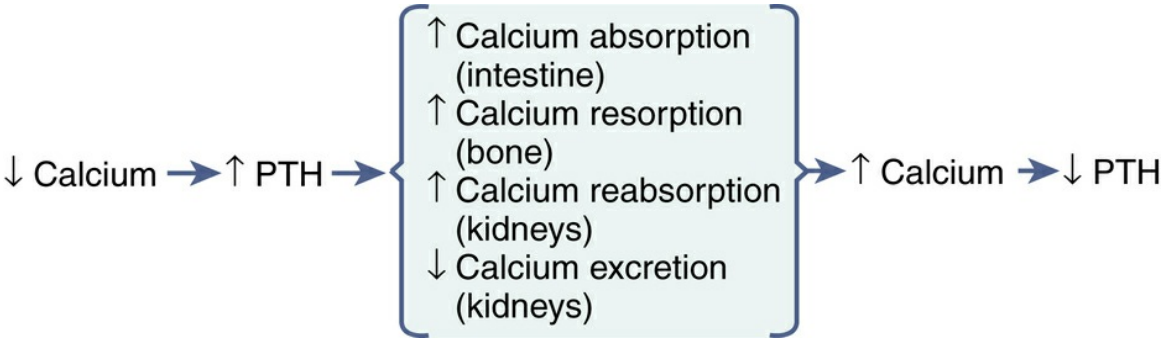

FIG. 47.4 Feedback mechanism between PTH and calcium.

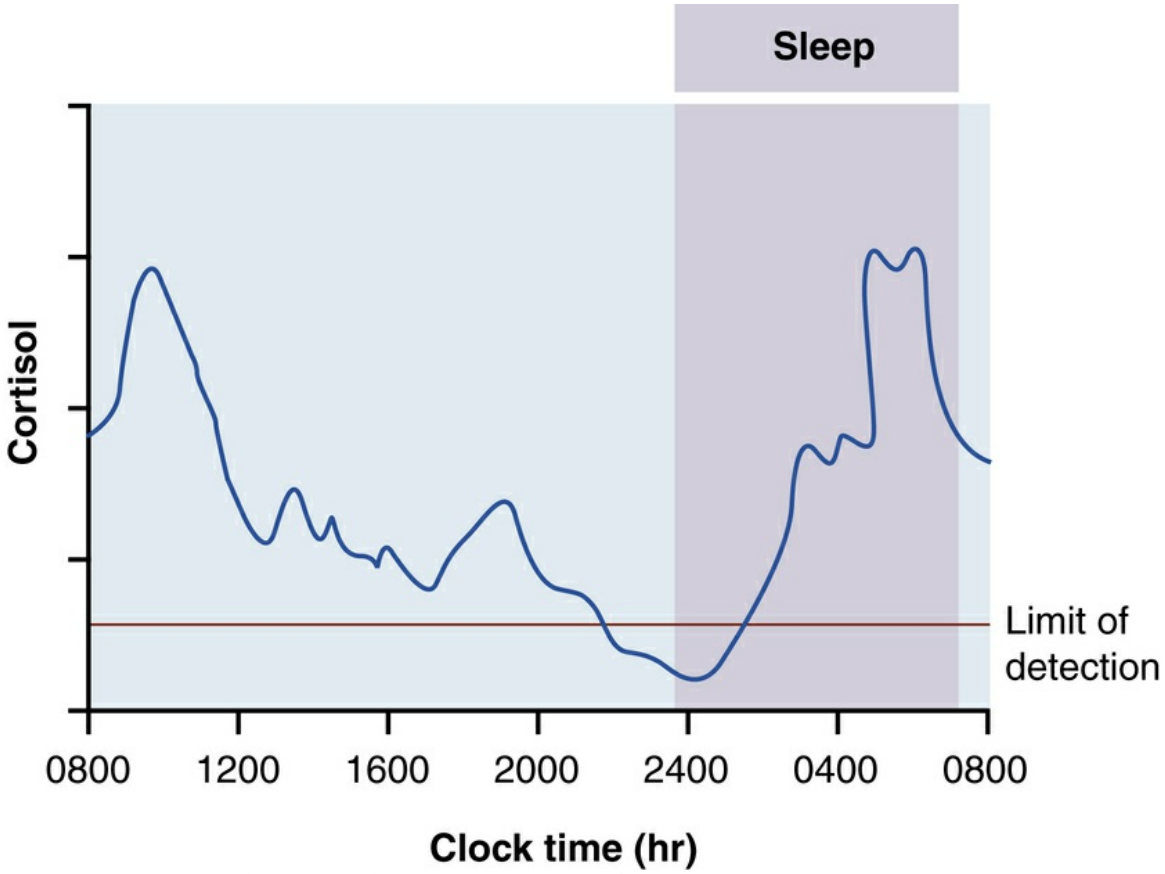

FIG. 47.5 Circadian rhythm of cortisol secretion.

TABLE 47.2 Hormones of the Hypothalamus

The following hormones from the hypothalamus target the anterior pituitary:

Releasing Hormones

- Corticotropin-releasing hormone (CRH)
- Thyrotropin-releasing hormone (TRH)
- Growth hormone–releasing hormone (GHRH)
- Gonadotropin-releasing hormone (GnRH)
- Prolactin-releasing factor (PRF)

Inhibiting Hormones

- Somatostatin (inhibits growth hormone release)
- Prolactin-inhibiting factor (PIF)

Pituitary

The pituitary gland *(hypophysis)* is in the sella turcica under the hypothalamus at the base of the brain above the sphenoid bone (Fig. 47.1). The infundibular *(hypophyseal)* stalk connects the pituitary and hypothalamus. This stalk relays information between the hypothalamus and pituitary, creating a strong neuroendocrine connection. The pituitary consists of 2 major parts, the anterior lobe *(adenohypophysis)* and posterior lobe *(neurohypophysis).* A smaller intermediate lobe makes melanocyte-stimulating hormone (MSH).

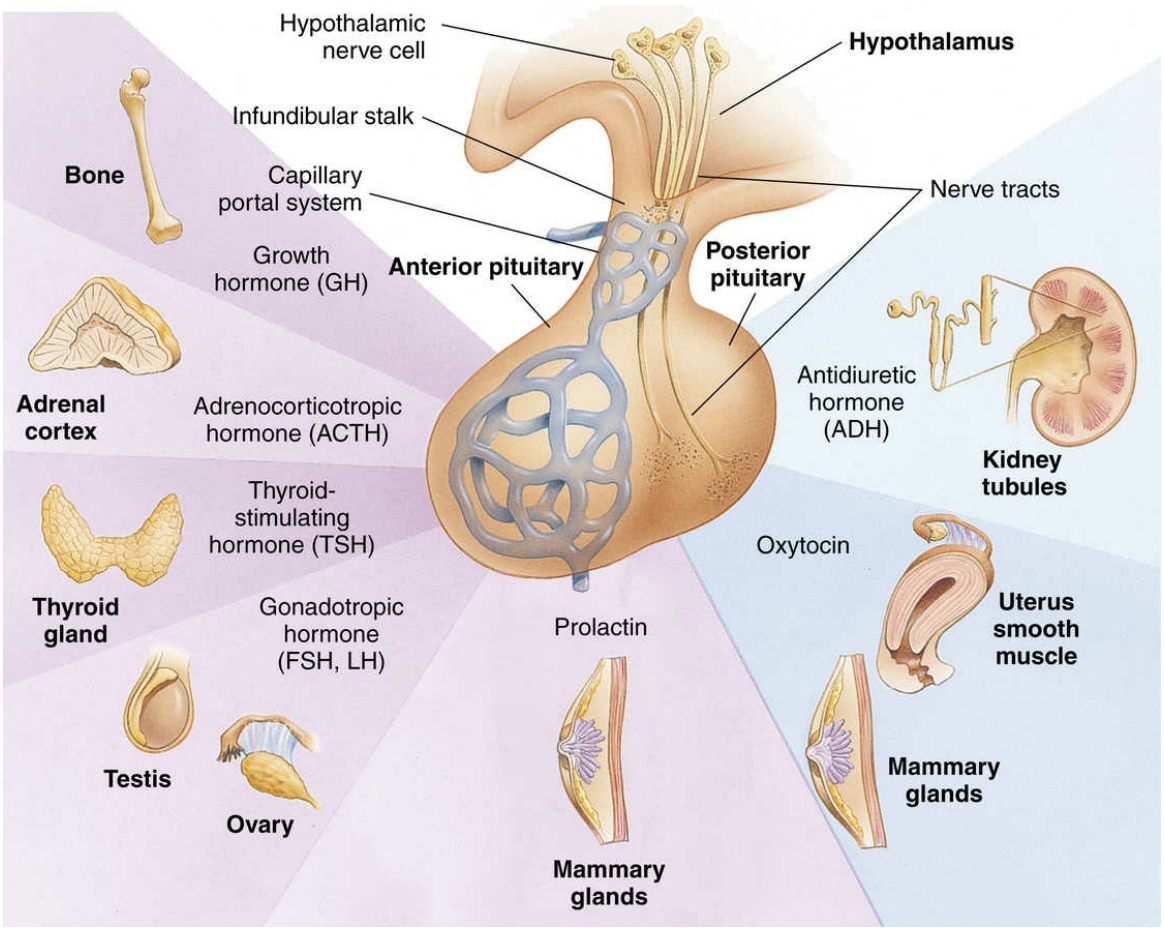

FIG. 47.6 Relationship between the hypothalamus, pituitary, and target organs. The hypothalamus communicates with the anterior pituitary via a capillary system and with the posterior pituitary via nerve tracts. The anterior and posterior pituitary hormones are shown with their target tissues.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Anterior Pituitary

The anterior lobe of the pituitary accounts for 80% of the gland by weight. The hypothalamus regulates the anterior lobe through releasing and inhibiting hormones. These hypothalamic hormones reach the anterior pituitary through a network of capillaries known as the *hypothalamus-hypophyseal portal system.* These releasing and inhibiting hormones in turn affect the secretion of 6 hormones from the anterior pituitary (Fig. 47.6).

We refer to several hormones secreted by the anterior pituitary as

tropic hormones. Tropic hormones control the secretion of hormones by other glands. Thyroid-stimulating hormone (TSH) stimulates the thyroid gland to secrete thyroid hormones. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to secrete corticosteroids. FSH stimulates secretion of estrogen and the development of ova in women and sperm in men. Luteinizing hormone (LH) stimulates ovulation in women and secretion of sex hormones in both men and women.

Growth hormone (GH) affects the growth and development of all body tissues. It has many biologic actions, including a role in protein, fat, and carbohydrate metabolism. *Prolactin,* or lactogenic hormone, stimulates the breast development needed for lactation after childbirth.

Posterior Pituitary

The posterior pituitary is composed of nerve tissue and is essentially an extension of the hypothalamus. Communication between the hypothalamus and posterior pituitary occurs through nerve tracts. The hormones secreted by the posterior pituitary, **antidiuretic hormone (ADH)** and oxytocin, are made in the hypothalamus. These hormones travel down the nerve tracts from the hypothalamus to the posterior pituitary and are stored there until stimuli trigger their release (Fig. 47.6).

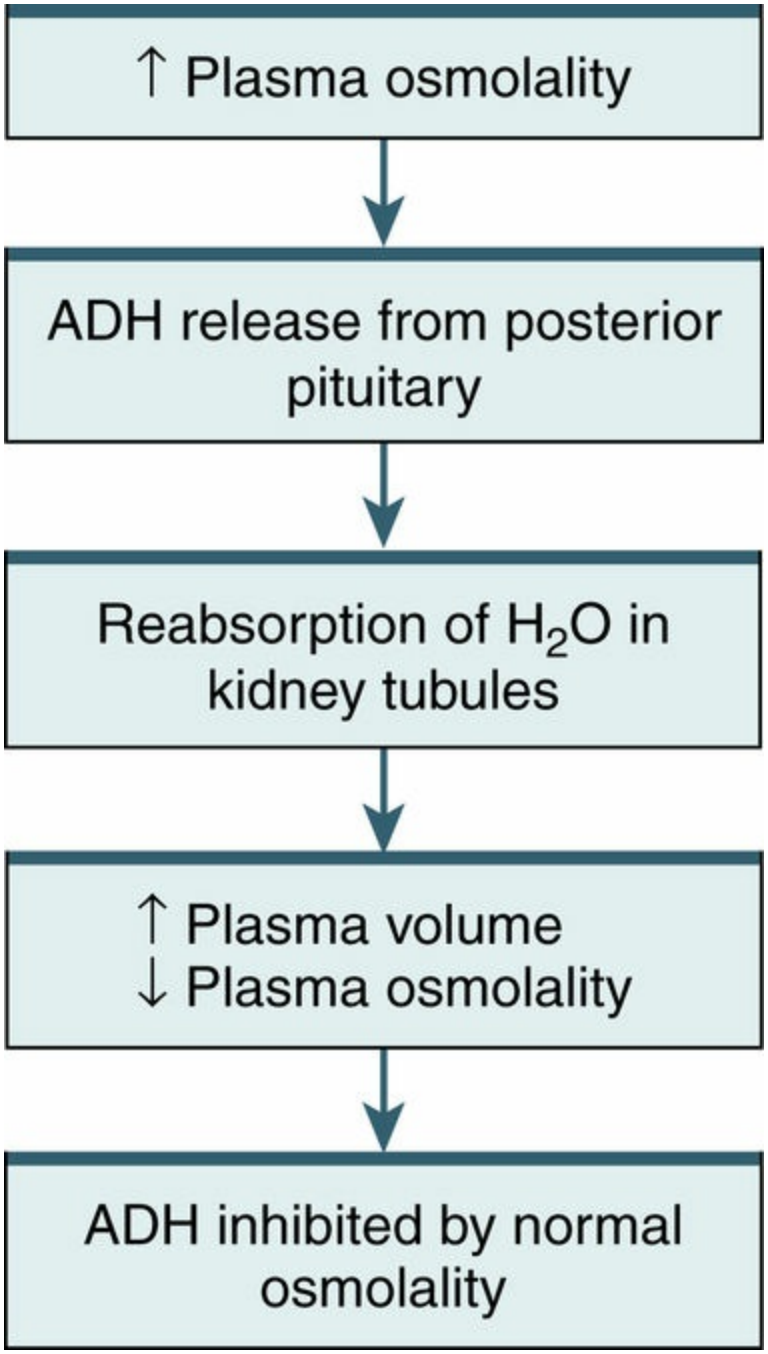

FIG. 47.7 Relationship of plasma osmolality to ADH release and action.

The major physiologic role of ADH (also called *arginine vasopressin*) is to regulate fluid volume. It causes the renal tubules to reabsorb water, making the urine more concentrated. A rise in plasma osmolality or hypovolemia causes specialized neurons in the hypothalamus, known as *osmoreceptors,* to stimulate ADH release from

the posterior pituitary (Fig. 47.7). When ADH release is inhibited, renal tubules do not reabsorb water, resulting in a more dilute urine. Volume receptors in large veins, heart atria, and carotid arteries that sense pressure changes (from hypovolemia) also contribute to ADH control. ADH is also a potent vasoconstrictor.

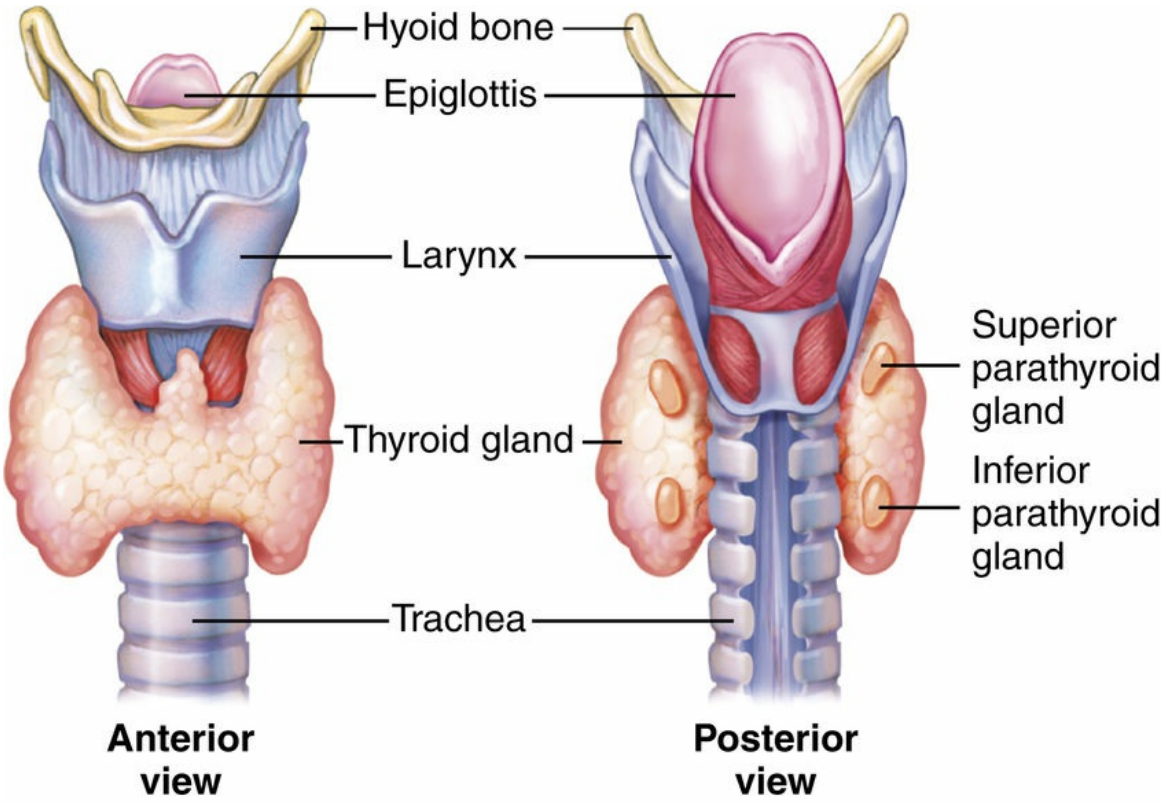

FIG. 47.8 Thyroid and parathyroid glands. Note the surrounding structures.
From Thibodeau GA, Patton KT: *The human body in health and disease,* ed 4, St Louis, 2005, Mosby.

Pineal Gland

The pineal gland is in the brain. It is composed of photoreceptive cells. Its primary function is the secretion of the hormone *melatonin.* Melatonin secretion increases in response to exposure to the dark and decreases in response to light exposure. The gland helps to regulate

circadian rhythms and the reproductive system at the onset of puberty.

Thyroid Gland

The thyroid gland is in the anterior part of the neck in front of the trachea. It consists of 2 encapsulated lateral lobes connected by a narrow isthmus (Fig. 47.8). The thyroid gland is highly vascular. Its size is related to TSH secretion by the anterior pituitary. The 3 hormones made and secreted by the thyroid gland are thyroxine (T_4), triiodothyronine (T_3), and calcitonin.

Thyroxine and Triiodothyronine

Thyroxine (T_4) accounts for 90% of thyroid hormone made by the thyroid gland. However, **triiodothyronine (T_3)** is much more potent and has greater metabolic effects. The thyroid gland directly secretes about 20% of circulating T_3. The rest comes from the conversion of T_4 after its release into the bloodstream. Iodine is required for the synthesis of both T_3 and T_4. Both hormones affect metabolic rate, caloric requirements, O_2 consumption, carbohydrate and lipid metabolism, growth and development, brain function, and other nervous system activities. More than 99% of thyroid hormones are bound to plasma proteins, especially thyroxine-binding globulin made by the liver. Only the unbound "free" hormones are biologically active.

TSH from the anterior pituitary gland stimulates thyroid hormone production and release. When circulating levels of thyroid hormone are low, the hypothalamus releases thyrotropin-releasing hormone (TRH). TRH causes the anterior pituitary to release TSH. High circulating thyroid hormone levels inhibit the secretion of both TRH from the hypothalamus and TSH from the anterior pituitary gland.

Calcitonin

Calcitonin is made by C cells (parafollicular cells) of the thyroid gland

in response to high circulating calcium levels. Calcitonin lowers serum calcium levels by (1) inhibiting the transfer of calcium from the bone to blood, (2) increasing calcium storage in bone, and (3) increasing renal excretion of calcium and phosphorus. Calcitonin and PTH regulate calcium balance.

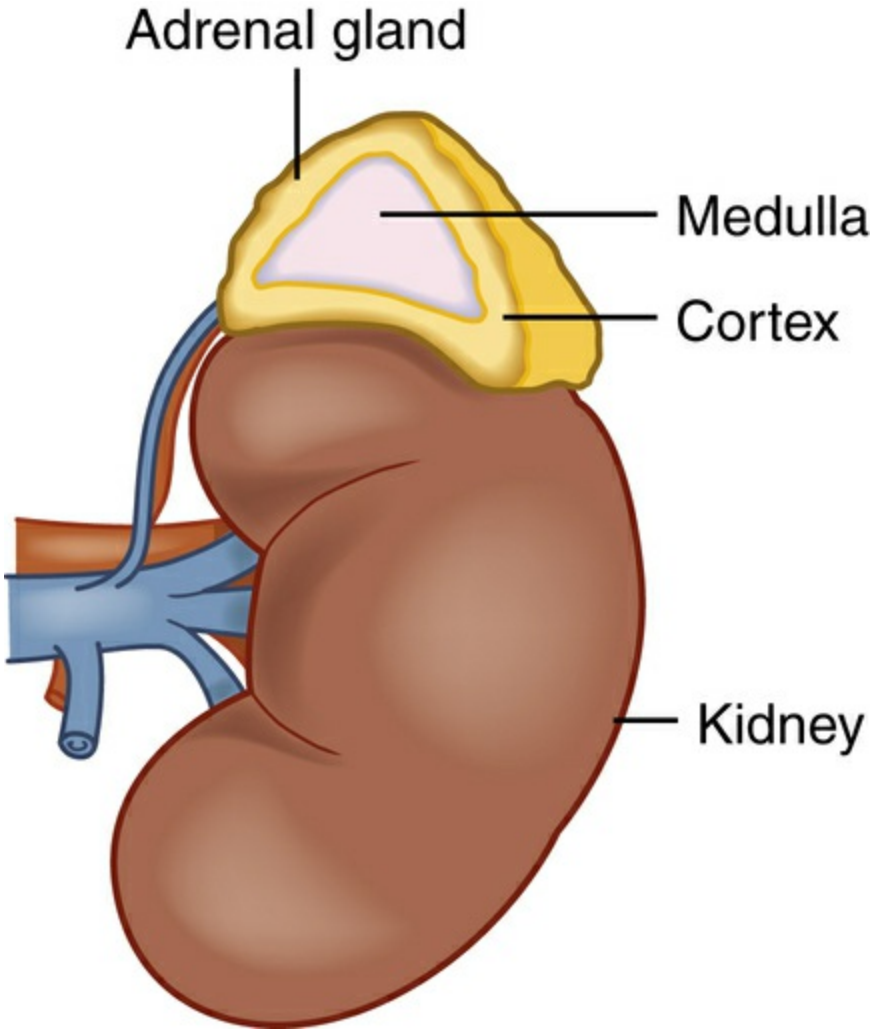

FIG. 47.9 The adrenal gland is composed of the adrenal cortex and the adrenal medulla.

Parathyroid Glands

There are usually 2 pairs of parathyroid glands lying behind each

thyroid lobe (Fig. 47.8). Although there are usually 4 glands, their number may range from 2 to 6.

Parathyroid Hormone

The parathyroid glands secrete parathyroid hormone (PTH), also called *parathormone.* Its major role is to regulate serum calcium levels. PTH increases serum calcium levels by acting on bone, the kidneys, and indirectly on the GI tract. PTH stimulates the transfer of calcium from the bone into the blood. In the kidney, PTH promotes calcium reabsorption (moving calcium from the renal tubules back into the bloodstream) and phosphate excretion. PTH stimulates the renal conversion of vitamin D to its most active form (1,25-dihydroxyvitamin D_3). This form of vitamin D promotes calcium and phosphorus absorption in the GI tract. PTH secretion is regulated by a negative feedback system. When serum calcium or magnesium levels are low, PTH secretion increases. When serum calcium or active vitamin D levels are high, PTH secretion falls.

Adrenal Glands

The adrenal glands are small, paired, highly vascular glands located on the upper part of each kidney. Each gland consists of 2 parts: medulla and cortex (Fig. 47.9). Each part has distinct functions and act independently from the other.

Adrenal Medulla

The adrenal medulla is the inner part of the adrenal gland. It consists of sympathetic postganglionic neurons. The medulla secretes the **catecholamines** *epinephrine* (adrenaline), *norepinephrine* (noradrenaline), and *dopamine*. We consider catecholamines neurotransmitters when they are secreted by neurons and hormones when they are secreted by the adrenal medulla. They are an essential part of the SNS's "fight or flight" response.

Adrenal Cortex

The adrenal cortex is the outer part of the adrenal gland. It secretes several steroid hormones, including *glucocorticoids, mineralocorticoids,* and *androgens.* Cholesterol is the precursor for steroid hormone synthesis. Glucocorticoids (e.g., cortisol) are named for their effects on glucose metabolism. They inhibit the inflammatory response and are considered antiinflammatory. Mineralocorticoids (e.g., aldosterone) are essential for maintaining fluid and electrolyte balance. The term **corticosteroid** refers to both glucocorticoids and mineralocorticoids.

Cortisol

Cortisol, the most abundant and potent glucocorticoid, is necessary to maintain life and protect the body from stress. It is secreted in a diurnal pattern (Fig. 47.5). A negative feedback mechanism controls cortisol secretion. The release of corticotropin-releasing hormone (CRH) from the hypothalamus stimulates the secretion of ACTH by the anterior pituitary.

A major function of cortisol is regulating blood glucose concentration by stimulating hepatic glucose formation *(gluconeogenesis).* Cortisol inhibits peripheral glucose use in the fasting state, inhibits protein synthesis, and stimulates the mobilization of glycerol and free fatty acids. It helps maintain vascular integrity and fluid volume through its action on mineralocorticoid receptors. Cortisol decreases the inflammatory response by stabilizing the membranes of cellular lysosomes and preventing increased capillary permeability. Stress, burns, infection, fever, acute anxiety, and hypoglycemia increase cortisol levels.

Aldosterone

Aldosterone is a potent mineralocorticoid that maintains extracellular fluid volume. It acts on the renal tubule to promote renal reabsorption of sodium and excretion of potassium and hydrogen ions. Hyponatremia, hyperkalemia, and angiotensin II stimulate aldosterone synthesis and secretion. ANP and hypokalemia inhibit aldosterone synthesis and release.

Adrenal Androgens

The adrenal cortex secretes small amounts of androgens. They are converted to sex steroids in peripheral tissues: testosterone in men and estrogen in women. The most common adrenal androgens are dehydroepiandrosterone (DHEA) and androstenedione. Because they are precursors to other sex steroids, their actions are like those of testosterone and estrogen. In postmenopausal women, the major source of estrogen is the peripheral conversion of adrenal androgens to estrogen.

Pancreas

The pancreas is a long, tapered, lobular, soft gland located behind the stomach and anterior to the first and second lumbar vertebrae. The pancreas has both exocrine and endocrine functions. The hormone-secreting part of the pancreas is the *islets of Langerhans.* The islets account for less than 2% of the gland. They consist of 4 types of hormone-secreting cells: α, β, delta, and F cells. The α cells make and secrete the hormone glucagon. The β cells make and secrete insulin and amylin. Delta cells make and secrete somatostatin. F (or PP) cells secrete pancreatic polypeptide.

Glucagon

Pancreatic α cells release *glucagon* in response to low blood glucose levels, protein ingestion, and exercise. Glucagon increases blood glucose, providing fuel for energy by stimulating glycogenolysis (breakdown of glycogen into glucose), gluconeogenesis (formation of glucose from noncarbohydrate molecules), and ketogenesis. Glucagon and insulin function in a reciprocal manner to maintain normal blood glucose levels.

Insulin

Insulin is the main regulator of metabolism and storage of ingested carbohydrates, fats, and proteins. Insulin facilitates glucose transport into cells, transport of amino acids across muscle membranes, and the

synthesis of amino acids into protein in the peripheral tissues. However, the brain, nerves, lens of the eye, hepatocytes, erythrocytes, and cells in the intestinal mucosa and kidney tubules are not dependent on insulin for glucose uptake. After a meal, insulin is responsible for how we use and store nutrients *(anabolism).* An increased blood glucose level is the major stimulus for insulin synthesis and secretion. Low blood glucose levels, glucagon, somatostatin, hypokalemia, and catecholamines usually inhibit insulin secretion.

TABLE 47.3 Gerontologic Assessment DifferencesEndocrine System

Changes	Clinical Significance
Thyroid	
Atrophy of thyroid gland **↓ secretion of T_3, T_4, TSH** **↑ Nodules**	↑ Incidence of hypothyroidism with aging Most older adults maintain adequate thyroid function Thyroid hormone replacement dose lower in older adults
Parathyroid	
↑ Secretion of PTH **↑ Basal level of PTH**	↑ Calcium resorption from bone Hypercalcemia, hypercalciuria (may reflect defective renal mechanism)
Adrenal Cortex	
Adrenal cortex becomes more fibrotic and slightly smaller **↓ Metabolism of cortisol** **↓ Plasma levels of adrenal androgens and aldosterone**	↓ Metabolic clearance rate for glucocorticoids
Adrenal Medulla	
↑ Secretion and basal level of norepinephrine	↓ Responsiveness to β-adrenergic agonists and receptor blockers
↓ β-Adrenergic receptor response to norepinephrine	May partly explain ↑ incidence of hypertension with aging
Pancreas	
↑ Fibrosis and fatty deposits in pancreas **↑ Glucose intolerance with ↓ sensitivity to insulin**	May partly contribute to ↑ incidence of diabetes with advanced aging
Gonads	
***Women:* ↓ Estrogen secretion**	Have menopausal symptoms ↑ Risk for arteriosclerosis and osteoporosis
***Men:* ↓ Testosterone secretion**	Men may or may not have symptoms

Gerontologic Considerations: Effects of Aging on Endocrine System

Normal aging has many effects on the endocrine system (Table 47.3).

These include (1) decreased hormone production and secretion, (2) altered hormone metabolism and biologic activity, (3) decreased responsiveness of target tissues to hormones, and (4) changes in circadian rhythms.

Assessing the effects of aging on the endocrine system may be difficult because the subtle changes of aging may mimic manifestations of endocrine disorders. Endocrine problems may manifest differently in an older adult than in a younger person. Older adults may have multiple co-morbidities and take medications that change the body's usual response to endocrine function. Symptoms of endocrine problems, such as fatigue, constipation, or mental impairment, may be attributed to aging, resulting in delayed treatment.

Assessment of Endocrine System

Endocrine problems generally result from too much or too little of a specific hormone. The onset of symptoms is often gradual. Subtle or vague symptoms are often attributed to other physiologic or psychologic causes. Patients may present with fluid and electrolyte imbalances, altered tissue perfusion, inadequate coping mechanisms, changes in heart rhythm, or changes in skin integrity that can be interpreted as many other conditions. Alternatively, patients may present with acute symptoms that are life threatening and demand immediate intervention.

Case Study

Patient Introduction

© iStockphoto/Thinkstock.

L.M. is a 35-yr-old Hispanic woman who comes to the clinic saying she is "just not feeling well." Her husband, H.M., is with her. L.M. states that she has gained a lot of weight despite trying to watch her diet and just seems to be getting more and more tired. H.M. voices concerns about the changes in his wife's energy level.

Discussion Questions

1. What are the possible causes of L.M.'s weight gain, fatigue, and irritability?

2. What would be your priority assessment of L.M.?
3. What questions would you ask L.M.?

You will learn more about L.M. and her condition as you read through this assessment chapter.

(See p. 1098 for more information on L.M.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Subjective Data

Information obtained from the patient can provide important clues as to the functioning of the endocrine system. You will need to obtain a thorough history from the patient and/or a caregiver if the patient's mental acuity is compromised.

Important Health Information

Past Health History

Patients with endocrine disorders often present with nonspecific complaints. The chief complaint may relate to not just one but a group of symptoms. The most common presenting problems include fatigue, weakness, menstrual irregularities, and weight changes. It is important to determine if the onset of symptoms has been gradual or sudden and what the patient has done about them.

Because some of the more general signs of problems are the easiest to overlook, you must evaluate any reported or observed changes in weight, appetite, skin, libido, mental acuity, emotional stability, or energy levels.

Medications

Ask about the use of all medications (both prescription and over-the-counter), herbs, and dietary supplements. Ask about the reason for taking the drug, the dosage, and the length of time the drug has been taken. In particular, ask about the use of hormone replacements. Knowing that the patient is currently taking hormone replacements,

such as insulin, thyroid hormone, or corticosteroids (e.g., prednisone), should alert you to potential adverse drug events. For example, corticosteroids may increase blood glucose levels and cause bone loss with long-term use. Thyroid preparations may cause tachycardia or dysrhythmias. Drug-to-drug interactions and adverse effects of nonhormonal medications can contribute to endocrine problems.

Surgery or Other Treatments

Ask about past medical, surgical, and obstetric history, including number of pregnancies and live births. Assess growth patterns and stages of physical and emotional development. For example, knowing about radiation therapy to the head and neck is important when you suspect thyroid or pituitary problems.

Functional Health Patterns

Key questions to ask the patient with an endocrine problem are outlined in Table 47.4.

Health Perception–Health Management Pattern

Heredity plays a key role in the development of endocrine problems. Ask about first-degree relatives with diabetes, thyroid disease, or endocrine gland cancers, since these conditions have a familial tendency. A genetic assessment of family members may be needed.

Genetic Risk Alert

Pituitary

- Nephrogenic diabetes insipidus can be inherited as a sex-linked or autosomal disorder.

Thyroid

- Genetics has a role in many cases of hypothyroid and hyperthyroid disorders.
- Hashimoto's thyroiditis, the most common cause of hypothyroidism, and Graves' disease, a cause of hyperthyroidism, are autoimmune disorders. Both likely result from a combination of genetic and environmental factors.[2]

Multiple Endocrine Neoplasia

- Multiple endocrine neoplasia (MEN) involves tumors in 2 or more different endocrine glands.
- There are several types of MEN. Mutations of *MEN1, RET,* and *CDKN1B* genes determine the type.
- The features of MEN are relatively consistent within a family.
- A common tumor associated with MEN type 2 is medullary thyroid cancer.[2]

Diabetes

- Genetics has a strong role in the development of type 1 and type 2 diabetes.

Nutritional-Metabolic Pattern

Changes in appetite and weight can indicate an endocrine problem. Ask about a history of weight distribution and changes. Weight loss with increased appetite may occur with hyperthyroidism or diabetes. Weight gain may occur with hypothyroidism or hypocortisolism. Obese persons are more likely to develop type 2 diabetes.

Ask if there have been problems with nausea, vomiting, or diarrhea. An enlarged thyroid gland can cause difficulty swallowing or a change in neck size. Increased SNS activity, including nervousness, palpitations, sweating, and tremors, may occur with thyroid problems

or a rare tumor of the adrenal medulla *(pheochromocytoma).* Heat or cold intolerance occur with hyperthyroidism or hypothyroidism, respectively.

Ask about changes in the patient's skin, especially on the face, neck, hands, or body creases. Changes in skin texture and skin that seems thicker or drier may suggest an endocrine problem. A patient with hypothyroidism or excess GH may have skin that feels coarse or leathery. Ask if the patient has noticed any change in the distribution of hair anywhere on the body.

TABLE 47.4 Health HistoryEndocrine System

Health Perception–Health Management

- What is your usual day like?
- Have you noticed any changes in your ability to perform your usual activities compared with last year? 5 years ago?*

Nutritional-Metabolic

- What are your weight and height?
- How much do you want to weigh?
- Have there been any changes in your appetite or weight?*
- Have you noticed any changes in the distribution of the hair anywhere on your body? *
- Have you noticed any changes in the color of your skin, especially on your face, neck, hands, or body creases? *
- Has the texture of your skin changed? For example, does it seem thicker and drier than it used to?*
- Have you noticed any difficulty swallowing, throat pain, or hoarseness? Is the top button on your shirt or blouse hard to

button?*

- Do you feel more nervous than you used to? Do you notice your heart pounding or that you sweat when you do not think you should be sweating?
- Do you have difficulty holding things because of shakiness of your hands?*
- Do you feel that most rooms are too hot or too cold? Do you often have to put on a sweater, or feel as though you need to open windows when others in the room seem comfortable?*
- Do you have, or have you had any wounds that were slow to heal?*

Elimination

- Do you have to get up at night to urinate? If so, how many times? Do you keep water by your bed at night?
- Have you ever had a kidney stone?*
- Describe your usual bowel pattern. Have you noted any bowel changes?*
- Do you use anything, such as laxatives, to help you move your bowels?*

Activity-Exercise

- What is your usual activity pattern during a typical day?
- Do you have a planned exercise program? If yes, what is it and have you had to make any changes in this routine lately? If so, why, and what kinds of changes?
- Do you have fatigue with or without activity?*
- Have you had any trouble with breathing?*

Sleep-Rest

- How many hours do you sleep at night? Do you feel rested on awakening?
- Are you ever awakened by sweating during the night?*
- Do you have nightmares?*

Cognitive-Perceptual

- How is your memory? Have you noticed any changes?*
- Have you had any blurring or double vision?*
- When was your last eye examination?

Self-Perception–Self-Concept

- Have you noticed any changes in your physical appearance or size?*
- Are you concerned about your weight?*
- Do you feel you are able to do what you think you can do? If not, why not?
- Does your health problem affect how you feel about yourself?*

Role-Relationship

- Do you have a support system or partner? Are you married? Do you have any children? Do you think you are able to take care of your family and home? If not, why not?
- Where do you work? What kind of work do you do? Are you able to do what is expected of you and what you expect of yourself?
- Are you retired? What type of work did you do before you

retired? How do you spend your time now that you have retired?

Sexuality-Reproductive

Women

- When did you start to menstruate? Was this earlier or later than other women in your family?
- When was your last menstrual period? Do you have scant, heavy, or irregular menstrual flows?
- How many children have you had? How much did they weigh at birth? Were you told you had diabetes during any pregnancy?*
- Are you menopausal? If so, for how long?
- Are you trying to get pregnant but cannot?*
- Are you postmenopausal? If so, do you have any bleeding from your uterus?

Men

- Have you noticed any changes in your ability to get and maintain an erection?*
- Are you trying to have children but cannot?*

Coping–Stress Tolerance

- What kind of stressors do you have?
- How do you deal with stress or problems?
- What is your support system? To whom do you turn when you have a problem?

Value-Belief

- Do you think medicine should still be taken even though you feel okay?
- Do any of your prescribed therapies cause any conflict in your value-belief system?*

* If yes, describe.

Elimination Pattern

Because maintaining fluid balance is a major role of the endocrine system, questions related to fluid intake and elimination patterns may uncover endocrine problems. For example, increased thirst and urination can indicate diabetes (pancreas disorder) or diabetes insipidus (pituitary disorder). Ask about the frequency and consistency of bowel movements. Diarrhea can occur with hyperthyroidism or thyroid cancer. Constipation occurs with hypothyroidism, hypoparathyroidism, and hypopituitarism.

Activity-Exercise Pattern

Determine if there are any acute or gradual changes in energy level or persistent fatigue. A patient with chronic fatigue secondary to hypothyroidism, hypocortisolism, or diabetes may report changes in activity level.

Sleep-Rest Pattern

Ask the patient how many hours they typically sleep, and if they feel rested on awakening. Sleep problems can result from nocturia, nightmares, anxiety, depression, or insomnia that occur with diabetes or thyroid problems.

Cognitive-Perceptual Pattern

Memory deficits may occur with hypothyroidism and changes in sodium levels. Inappropriate secretion of antidiuretic hormone

(SIADH) or pituitary tumors can cause hyponatremia. These issues can occur gradually. Gathering information from patient and family about memory, cognitive abilities, and balance can increase the chances of an earlier diagnosis.

Self-Perception–Self-Concept Pattern

Many endocrine disorders may affect a patient's self-esteem because of associated changes in physical appearance. For example, weight gain associated with hypothyroidism or exophthalmos and goiter associated with hyperthyroidism can cause problems related to body image.

Role-Relationship Pattern

Questions related to roles and relationships can highlight depression, chronic fatigue, and sleep problems. With chronic fatigue, depression, and anxiety, patients and their families will have stressed relationships. Questions related to home life and the patients' ability to fulfill their role in the family will aid in identifying problems.

Sexuality-Reproductive Pattern

The endocrine system regulates GH, prolactin, LH, FSH, testosterone, and estrogen. Therefore, menstrual problems, hirsutism, infertility, decreased libido, and growth disorders can be a result of endocrine disorders. Some women develop hypothyroidism during or after menopause. Other patients begin to develop type 2 diabetes during middle age when sex hormones are changing. Document the presence of abnormal secondary sex characteristics, such as facial hair *(hirsutism)* in women. Obtain a detailed history of menstruation and pregnancy. Menstrual problems can occur with disorders of the ovaries and pituitary, thyroid, and adrenal glands. A history of large-birth-weight babies or gestational diabetes increases the risk for developing type 2 diabetes later in life. Male sexual problems may include impotence, infertility, or the lack of development of secondary sexual characteristics. Retrograde ejaculation can occur in diabetes.

Coping–Stress Tolerance Pattern

Because stress worsens some endocrine conditions, ask patients about their stress level and usual coping patterns. Patients with adrenal insufficiency have difficulty dealing with stress. These patients are at risk for developing hypotension and fluid and electrolyte imbalance.

Value-Belief Pattern

Determining a patient's ability to make lifestyle changes is an important nursing function. Identify the patient's value-belief patterns so that you can help to determine appropriate treatment plans. This is especially important in a condition such as diabetes, which may require major lifestyle changes. Other disorders, such as hypothyroidism or hypocortisolism, may be managed with medications but need lifelong monitoring.

Case Study—cont'd

Subjective Data

© iStockphoto/Thinkstock.

A focused subjective assessment of L.M. revealed the following information:

- ***Past Medical History:*** Denies any medical or surgical history. Has not seen an HCP for 8 yr.
- ***Medications:*** None.
- ***Health Perception–Health Management:*** L.M. works as a receptionist for a local law firm and says it is all she can do to make it through the work day. She often wakes up with a

headache and goes to bed with the same headache, describing it as a dull, throbbing ache between her eyes. She does not have the energy she had 5 yr ago or even 6 mo ago. She used to enjoy gardening and going out with friends but now can barely manage work and coming home.

- ***Nutritional-Metabolic:*** L.M. reports a steady weight gain over the past 6 mo, mainly in her abdominal area. She feels as if she looks pregnant but knows that is not possible. Her appetite has decreased, but she is not able to lose any weight. She says she feels "bloated." She reports growth of facial hair and notices she is bruising easily. L.M. denies difficulty with swallowing, hoarseness, palpitations, or tremors.
- ***Elimination:*** Denies any changes or problems with urination or bowel movements.
- ***Activity-Exercise:*** L.M. states that she has no ambition to exercise. She is just too tired at the end of the workday and has no energy on the weekends either. She reports leg cramps with walking.
- ***Sleep-Rest:*** Sleeps 10+ hr at night but does not feel rested on awakening.
- ***Cognitive-Perceptual:*** L.M. is worried she is going crazy. She finds herself easily angered and irritable, often snapping at co-workers and her husband. She says this is not her usual self. At first, she thought it was because she was dealing with a constant, dull headache. Lately, she has noticed that her vision is blurry and that is making work and life more stressful. She says her headache hurts between her eyes. She rates the pain as a 4 on a scale of 0 to 10 and states that ibuprofen does not ease the pain. The pain is typically worse on arising in the morning. It slowly decreases during the day.
- ***Self-Perception–Self-Concept:*** L.M. hates the way she looks. She says when she looks in the mirror, she cannot believe what she sees. She feels as if she has aged 10 yr over the past 6 mo and has gained weight in her face, neck, and trunk. She is concerned that

her scalp hair is thinning, and she is growing a beard. She tells you she feels "old and ugly"!

- ***Coping–Stress Tolerance:*** L.M. states that she is finding it harder to cope with the stresses of her job, her relationship with her husband, and life in general. She believes her emotions are very "raw and labile," so different from the easy-going, smiling person she had once prided herself in being.

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. Based on the subjective assessment findings, what should you include in the physical assessment? What would you be looking for?

You will learn more about the physical examination of the endocrine system in the next section.

(See p. 1099 for more information on L.M.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Except the thyroid and testes, most endocrine glands are inaccessible to direct examination. Assessment can be accomplished using objective data from the physical examination and diagnostic tests. It is essential to understand the actions of hormones in order to assess the function of a gland by monitoring the target tissue.

Physical Examination

Use the following general examination when evaluating endocrine function.[3] Specific clinical findings for the various endocrine problems are discussed in Chapters 48 and 49. Endocrine disorders may cause changes in mental and emotional status. Throughout the examination,

assess the patient's orientation, alertness, memory, cognitive abilities, affect, personality, and appropriateness of their behavior.

Take a full set of vital signs at the beginning of the examination. Variations in temperature, heart rate, and BP can occur with a variety of endocrine-related problems. Obtain height and weight. Calculate body mass index (BMI) to assess nutritional status.

Integument

Assess the color and texture of the skin, hair, and nails. Note the overall skin color as well as pigmentation and bruising. Decreased skin pigmentation can occur in hypopituitarism, hypothyroidism, and hypoparathyroidism. Hyperpigmentation, or "bronzing" of the skin, especially on knuckles, elbows, knees, genitalia, and palmar creases, is a classic finding in a form of adrenal insufficiency known as *Addison's disease*. Palpate the skin for texture and moisture. Examine hair distribution on the head, face, trunk, and extremities. Assess the hair's appearance and texture. Hair loss, excess hair growth, or dull, brittle hair may suggest endocrine problems. Assess for delayed wound healing.

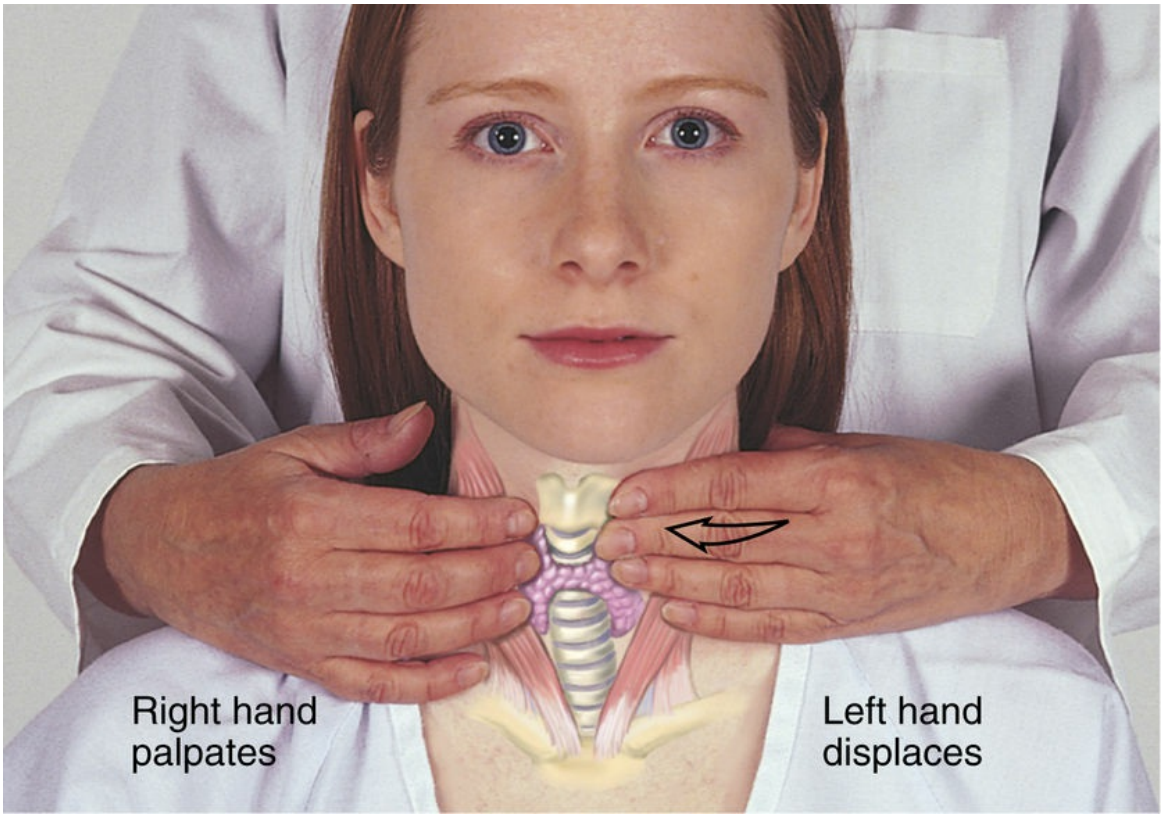

FIG. 47.10 Posterior palpation of the thyroid gland.
From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.

Head

Inspect the size and contour of the head. Facial features should be symmetric. Hyperreflexia and facial muscle contraction upon percussion of the facial nerve *(Chvostek's sign)* may occur in hypoparathyroidism. Inspect the eyes for position, symmetry, and shape. Large and protruding eyes (exophthalmos) are associated with hyperthyroidism. Assess visual acuity using a Snellen eye chart. Visual field loss may occur with a pituitary tumor. In the mouth, inspect the buccal mucosa, condition of teeth, and tongue size. Note hair distribution on the scalp and face. Hearing loss is common in acromegaly from excess GH.[4]

Neck

The thyroid gland is not usually visible during inspection. A feature

that distinguishes the thyroid from other masses in the neck is its upward movement on swallowing. Inspect the neck while the patient swallows a sip of water. The neck should appear symmetric without lumps or bulging.

Palpate the thyroid for its size, shape, symmetry, and tenderness and for any nodules. *Goiter,* an enlarged thyroid gland, can occur with hyperthyroidism or hypothyroidism. Be careful not to press too hard or massage an enlarged thyroid gland. This can cause a sudden release of thyroid hormone into an already overloaded system. An experienced clinician should perform palpation in patients with a known diagnosis of hyperthyroidism.

Perform palpation using a posterior or anterior approach. For *anterior palpation,* stand in front of the patient, with the patient's neck flexed. Place your thumb horizontally with the upper edge along the lower border of the cricoid cartilage. Then move your thumb over the isthmus as the patient swallows water. Place your fingers laterally to the anterior border of the sternocleidomastoid muscle and palpate each lateral lobe before and while the patient swallows water.

For *posterior palpation,* stand behind the patient (Fig. 47.10). With the thumbs of both hands resting on the nape of the patient's neck, use your index and middle fingers of both hands to feel for the thyroid isthmus and for the anterior surfaces of the lateral lobes. To relax the neck muscles, ask the patient to flex the neck slightly forward and to the right. Displace the thyroid cartilage to the right with your left hand and fingers. Palpate with your right hand after placing the thumb deep and behind the sternocleidomastoid muscle with the index and middle fingers in front of it. Ask the patient to swallow water and feel for the thyroid to move up. In a normal person, the thyroid is often not palpable. If palpable, it usually feels smooth with a firm consistency. It is not tender with gentle pressure.[5] If nodules, enlargement, asymmetry, or hardness (abnormal findings) are present, refer the patient for further evaluation. Auscultate the lateral lobes of an enlarged thyroid gland with the stethoscope bell to hear a *bruit,* a soft swishing sound that can occur with a goiter or hyperthyroidism.

Thorax

Inspect the thorax for shape and characteristics of the skin. Note the presence of breast gynecomastia in men. Auscultate lung sounds and heart sounds. Note any adventitious lung sounds (wheezing, decreased sounds) or extra heart sounds. Signs of fluid overload or heart failure may be present in patients with SIADH or hypothyroidism.

Abdomen

Inspect the contour of the abdomen and note the symmetry and color. Cushing syndrome (hypercortisolism) causes the skin to be fragile, resulting in purple-blue striae across the abdomen. Note general obesity or truncal obesity. Auscultate bowel sounds.

Extremities

Assess the size, shape, symmetry, and general proportion of hands and feet. Patients with acromegaly from pituitary tumors may have large hands and feet. Inspect the skin for changes in pigmentation, lesions, and edema. Assess muscle strength and deep tendon reflexes. In the upper extremities, assess for tremors by placing a piece of paper on the outstretched fingers, palm down. Muscular spasms of the hand elicited on application of an occlusive BP cuff for 3 minutes *(Trousseau's sign)* may occur in hypoparathyroidism.

Genitalia

Inspect the genital hair distribution pattern, since it may be changed with hormone problems.

Assessment abnormalities related to the endocrine system are outlined in Table 47.5. A focused assessment of the endocrine system is shown on p. 1101.

Case Study—cont'd

Objective Data: Physical Examination

A focused assessment of L.M. reveals the following:

© iStockphoto/Thinkstock.

L.M. is sitting on the edge of the examination table. She appears somewhat anxious. Her BP is 190/80, heart rate 84, respiratory rate 20, temp 98.6° F (37° C). Her weight is 160 lb, and she is 5 ft, 4 in tall. L.M.'s face is reddened and puffy. She appears to have a lump on the

back of her neck and shoulders. There is some acne on her face, along with some hair growth on her upper lip and chin area. Her abdomen is protruding, but her arms and legs are thin. She has +1 edema in her ankles bilaterally. There are several bruises on her upper and lower extremities, as well as purple stretch marks on her abdomen.

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based upon the subjective and objective assessment data presented so far, what are 3 priority nursing diagnoses?
3. What diagnostic studies would you expect to be ordered?

You will learn more about diagnostic studies related to the endocrine system in the next section.

(See p. 1106 for more information on L.M.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

TABLE 47.5 Assessment AbnormalitiesEndocrine System

Finding	Description	Possible Etiology and Significance
Cardiovascular		
Chest pain	Angina caused by increased metabolic demands, effusions	Hyperthyroidism, hypothyroidism
Dysrhythmias	Tachycardia, atrial fibrillation	Hypothyroidism, hyperthyroidism, hypoparathyroidism, hyperparathyroidism, pheochromocytoma
Fluid overload or signs of heart failure	Crackles in the lungs, peripheral edema, shortness of breath	SIADH, hypothyroidism, myxedema
Hypertension	High BP caused by ↑ metabolic demands and catecholamines	Hyperthyroidism, pheochromocytoma, Cushing syndrome
Gastrointestinal		
Constipation	Passage of infrequent hard stools	Hypothyroidism, hyperparathyroidism
Head and Neck		
Exophthalmos	Eyeball protrusion from orbits	Occurs in hyperthyroidism because of fluid accumulation in eye and retroorbital tissue
Goiter	Generalized enlargement of thyroid gland	Hyperthyroidism, hypothyroidism, iodine deficiency
Moon face	Periorbital edema and facial fullness	Cushing syndrome because of ↑ cortisol secretion
Myxedema	Puffiness, periorbital edema, masklike affect	Hydrophilic mucopolysaccharides infiltrating dermis in patients with hypothyroidism
Thyroid nodule(s)	Localized enlargement of thyroid gland	May be benign or malignant
Visual changes	↓ Visual acuity and/or ↓ peripheral vision	Pituitary gland enlargement or tumor leading to pressure on optic nerve
Integument		
Bruises easily	Multiple bruises over various parts of body	Cushing syndrome
Changes in hair distribution	Hair loss	Hypothyroidism, hyperthyroidism, ↓ pituitary secretion
	↓ Axillary and pubic hair	Cortisol deficiency
	Hirsutism (excess facial hair on women)	Cushing syndrome, prolactinoma (a pituitary tumor)
Changes in skin texture	Thick, cold, dry skin	Hypothyroidism
	Thick, leathery, oily skin	GH excess (acromegaly)
	Warm, smooth, moist skin	Hyperthyroidism
Depigmentation (vitiligo)	Patchy areas of light skin	May be a marker of autoimmune endocrine disorders
Edema	Generalized edema	Mucopolysaccharide accumulation in tissue in hypothyroidism
Hyperpigmentation	Darkening of the skin, especially in skinfolds and creases	Increased secretion of MSH from Addison's disease, acanthosis nigricans
Skin ulceration	Areas of ulcerated skin, most often found on legs and feet	Peripheral neuropathy and peripheral vascular disease, which are contributory factors in the development of diabetic foot ulcers
Striae	Purplish red marks below the skin surface. Usually seen on abdomen, breasts, and buttocks	Cushing syndrome
Musculoskeletal		
Changes in muscular strength or muscle mass	Generalized weakness and/or fatigue	Common with many endocrine problems, including pituitary, thyroid, parathyroid, and adrenal problems Diabetes, diabetes insipidus
	↓ Muscle mass	Specifically seen in GH deficiency and Cushing syndrome from protein wasting
Enlargement of bones and cartilage	Coarsening of facial features. ↑ In size of hands and feet over a period of several years	Gradual enlargement and thickening of bony tissue occurring with GH excess in adults as seen in acromegaly secondary to pituitary dysfunction
Neurologic		
↑ Deep tendon reflexes	Hyperreflexia	Hyperthyroidism, hypoparathyroidism
Lethargy	State of mental sluggishness or somnolence	Hypothyroidism
Seizure	Sudden involuntary contraction of muscles	Consequence of a pituitary tumor Hypervolemia and hyponatremia with SIADH Complications of diabetes, severe hypothyroidism
Tetany	Intermittent involuntary muscle spasms usually involving the extremities	Severe hypocalcemia that can occur with hypoparathyroidism
Nutrition		
Changes in weight	Weight loss	Hyperthyroidism caused by ↑ in metabolism, type 1 diabetes, diabetic ketoacidosis
	Weight gain	Hypothyroidism, Cushing syndrome, type 2 diabetes

Table Continued

Finding	Description	Possible Etiology and Significance
Glucose levels altered	↑ Serum glucose	Diabetes, Cushing syndrome, GH excess
Reproductive		
Changes in reproductive function	Menstrual irregularities, ↓ libido, ↓ fertility, impotence	Pituitary hypofunction, GH excess, thyroid problems, adrenocortical problems
Other		
↓ Urine output	↓ Water reabsorption from kidney tubules	SIADH
Polydipsia	Excessive thirst	Extreme water losses in diabetes (with severe hyperglycemia), diabetes insipidus, dehydration
Polyuria	Excess urine output	Diabetes (from hyperglycemia) or diabetes insipidus (associated with ↓ ADH)
Thermoregulation	Cold insensitivity	Hypothyroidism caused by a slowing of metabolic processes
	Heat intolerance	Hyperthyroidism caused by excessive metabolism

Focused Assessment

Endocrine System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Excessive or increased thirst	Y	N
Excess or decreased urination	Y	N
Excessive hunger	Y	N
Heat or cold intolerance	Y	N
Excessive sweating	Y	N
Recent weight gain or loss	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

Potassium	✓
Glucose	✓
Sodium	✓
Glycosylated hemoglobin (A1C)	✓
Thyroid studies: TSH, T_3, T_4	✓
Serum osmolality	✓

Objective: Physical Examination Inspect/Measure

Body temperature	✓
Height and weight	✓
Alertness and emotional state	✓
Skin for changes in color and texture	✓

Hair for changes in color, texture, and distribution	✓

Auscultate

Heart rate, BP	✓

Palpate

Extremities for edema	✓
Skin for texture and temperature	✓
Neck for thyroid size, shape	✓

Diagnostic Studies of Endocrine System

Diagnostic studies of the endocrine system are shown in Tables 47.6 and 47.7. Pertinent findings from the history and physical examination guide the selection of diagnostic studies. Imaging studies can identify pituitary tumors, thyroid nodules, or adrenal tumors. Laboratory studies may include direct measurement of the hormone level or an indirect measure of gland function by evaluating blood or urine components affected by the hormone, such as glucose or electrolytes. We can also measure the releasing or stimulating hormone. For example, we can evaluate thyroid function by measuring TSH.

We can assess hormones with constant basal levels, such as T_4, with a single measurement. Note the time of the sample collection on the laboratory slip. Information about night shift work is important for hormones with circadian or sleep-related secretion (e.g., cortisol). Evaluating other hormones may require multiple blood samplings, such as in suppression tests (e.g., dexamethasone) and stimulation tests (e.g., glucose tolerance). In these situations, it is often necessary

to obtain IV access to give the testing medication and fluids and draw multiple blood samples.

Pituitary gland problems can manifest in a wide variety of ways because of the number of hormones produced. Many diagnostic studies evaluate these hormones either directly or indirectly.

Several tests are available to evaluate thyroid function. The most sensitive and accurate laboratory test is the measurement of TSH. Thus it is often the first diagnostic test done to evaluate thyroid function.[6] Follow-up tests ordered when the TSH level is abnormal include total T_4, free T_4, and total T_3. Free T_4 is the unbound thyroxine and more accurately reflects thyroid function than total T_4.

The only hormone secreted by the parathyroid glands is PTH. Because PTH regulates serum calcium and phosphate levels, these levels reflect abnormalities in PTH secretion. For this reason, diagnostic tests for the parathyroid gland typically include PTH, serum calcium, and serum phosphate levels.

Tests associated with the adrenal cortex function focus on measuring blood plasma and urine levels of the 3 types of hormones secreted: glucocorticoids, mineralocorticoids, and androgens. Urine studies often require a 24-hour urine collection to eliminate the impact of short-term fluctuations in plasma hormone levels.

The tests used to evaluate glucose metabolism are important in the diagnosis and management of diabetes. See Chapter 48 for information about diagnostic studies for diabetes.

TABLE 47.6 Serology and Urine StudiesEndocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Adrenal Studies			
Blood Studies			
Adrenal steroid precursors • **Androstenediones (AD)** • **Dehydroepiandrosterone DHEA)** • **Dehydroepiandrosterone sulfate (DHEA S)** • **11-Deoxycortisol**	AD • *Female:* 0.05–2.05 ng/mL • *Male:* 0.04–1.06 ng/mL DHEA • *Female:* 0.14–7.88 ng/mL • *Male:* 0.11–6.73 ng/mL DHEA S • *Female:* 7–488 mcg/dL • *Male:* 7–371 mcg/dL 11-Deoxycortisol • *Adults:* 10–79 ng/dL	Assesses for congenital adrenal hyperplasia, sex hormones abnormalities, adrenal or gonadal tumors.	*Before:* Tanner stage I–V of physical development needed for accurate assessment. Determine date of last menstrual period (LMP) for females. Test should be done 1 wk before or after menstrual cycle. *After:* Note date of LMP on laboratory slip.
Adrenocorticotropic hormone (ACTH, corticotropin)	• *Female:* 6–58 pg/mL • *Male:* 7–69 pg/mL	Measures amount of ACTH made by the anterior pituitary gland. Levels determine if there is an overproduction or underproduction of cortisol, and whether cause is an adrenal gland or pituitary gland abnormality.	*Before:* Patient should be NPO after midnight. Do morning blood draw between 6 and 8 AM. *During:* Use prechilled blood tube and place on ice.
ACTH stimulation test with cosyntropin (Cortisol stimulation test)	*Rapid test:* Cortisol levels increase more than 7 mcg/dL higher than baseline *24-Hour test:* Cortisol levels >40 mcg/dL *3-Day test:* Cortisol levels greater than 40 mcg/dL	Used to evaluate cause of adrenal insufficiency. If cortisol levels increase after cosyntropin injection, the cause of adrenal insufficiency is the pituitary gland. If there is no or little rise in cortisol levels, the cause of adrenal insufficiency is the adrenal gland.	*Before:* Obtain baseline cortisol level at beginning of cosyntropin infusion. *During:* Inject bolus of IV cosyntropin with a plastic syringe. Draw cortisol samples 30 and 60 min after bolus. Monitor site and rate of IV infusion. Ensure sample collection at appropriate times.
Aldosterone	*Supine:* 3–10 ng/dL (0.08–0.30 nmol/L) *Upright:* • *Female:* 5–30 ng/dL (0.14–0.08 nmol/L) • *Male:* 6–22 ng/dL (0.17–0.61 nmol/L)	Used to identify hyperaldosteronism. Helps distinguish primary aldosteronism from adrenal disease versus secondary aldosteronism from extraadrenal disease.	*Before:* Usually morning blood sample is preferred. Tell patient that the required position (supine/sitting/standing) must be maintained for 2 hr before specimen is drawn.
Cortisol (hydrocortisone, serum cortisol)	• *8 AM:* 5–23 mcg/dL (138–635 nmol/L) • *4 PM:* 3–13 mcg/dL (83–359 nmol/L)	Measures serum cortisol level to evaluate adrenal activity. Cortisol levels are normally highest in the morning, slowly drop during the day, and are lowest around midnight.	*Before:* Sample should be drawn in morning. Note if patient works night shift. Mark time of blood draw on laboratory slip. Stress and excessive physical activity produce elevated results.
Dexamethasone suppression (DST, prolonged/rapid DST, cortisol suppression test, ACTH suppression test)	Prolonged method: • *Low dose:* >50% reduction of plasma cortisol and 17-hydroxycorticosteroid (17-OCHS) • *High dose:* >50% reduction of plasma cortisol and 17-OCHS Rapid (overnight) method: • Plasma cortisol levels suppressed to <2 mcg/dL	Helps to identify and determine cause of adrenal hyperactivity (e.g., Cushing syndrome).	*Before:* Patient should fast for 8–10 hr prior. Do not test acutely ill patients or those under stress. Stress-stimulated ACTH may override suppression. Screen patient for drugs, such as estrogen and corticosteroids, that may give false-positive results. *Overnight method:* Dexamethasone 1 mg (low dose) or 4 mg (high dose) is given at 11 PM to suppress secretion of corticotropin-releasing hormone. Plasma cortisol sample is drawn at 8 AM.
Metanephrine, plasma free (fractionated metanephrines)	*Normetanephrine:* <0.5 nmol/L or 18–111 pg/mL by HPLC *Metanephrine:* <0.9 nmol/L or 12–60 pg/mL by HPLC	Used to identify pheochromocytoma of the adrenal or extraadrenal glands.	*Before:* Ask about recent history of vigorous exercise, high stress levels, or starvation (may artificially ↑ levels). Assess for drugs (e.g., caffeine, alcohol, levodopa, nitroglycerin, acetaminophen, and those containing epinephrine or norepinephrine) that can alter results.
Urine Studies			

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Cortisol (hydrocortisone, urine cortisol, free cortisol)	24-Hour specimen: <100 mcg/24 hr (<276 nmol/day)	Measures urine cortisol level to evaluate adrenal activity.	*Before*: Explain 24-hr urine collection and need to avoid stressful situations and excessive physical exercise. Assess for drug use (e.g., reserpine, diuretics, phenothiazines, insulin, amphetamines) that may alter results.

Table Continued

Study	Reference Interval	Purpose and Description	Nursing Responsibility
17-Hydroxycorticosteroids (17-OCHS)	24-Hour specimen: *Adults:* • *Male:* 3–10 mg/24 hr (8.3–27.6 µmol/day) • *Female:* 2–8 mg/24 hr (5.2–22.1 µmol/day)	Measures 17-OCHS, a cortisol metabolite, to evaluate adrenocortical function. Older adults may have slightly lower values.	*Before*: Explain 24-hr urine collection and need to avoid stressful situations and excessive physical exercise. Assess for drug use (e.g., erythromycin, spironolactone) that may alter results.
17-Ketosteroids (17-KS)	24-Hour specimen: • *Male:* 6–20 mg/24 hr (20–70 µmol/day) • *Female:* 6–17 mg/24 hr (20–60 µmol/day)	Evaluates adrenocortical and gonadal functions by measuring urinary androgen metabolites. Older adults may have slightly lower values.	*Before:* Explain 24-hr urine collection.
Vanillylmandelic acid (VMA)	24-Hour specimen: <6.8 mg/24 hr (<35 µmol/24 hr)	Measures the excretion of catecholamine metabolite. Used to identify catecholamine-producing tumors, such as pheochromocytoma.	*Before*: Explain 24-hr urine collection. Must follow VMA-restricted diet 2–3 days before and during the urine collection. *During*: Keep 24-hr urine collection at pH <3.0 with HCl acid as preservative. Keep on ice.
Pancreatic Studies			
Blood Studies			
C-Peptide (connecting peptide insulin, insulin C-peptide, proinsulin C-peptide)	*Fasting*: 0.78–1.89 ng/mL (0.26–0.62 nmol/L) *1 hour after glucose load:* 5–12 ng/mL	Measures amount of C-peptide, which is released with insulin. Distinguishes between type 1 (low levels) and type 2 diabetes (normal or high levels).	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Glucagon	50–100 pg/mL (50–100 ng/L)	Assesses for glucagonoma (α islet cell tumor). Evaluates pancreatic function, especially in people with diabetes who have low blood glucose (hypoglycemia).	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Glucose (blood sugar, fasting blood glucose [FBG])	*Fasting* (defined as no caloric intake for at least 8 hr): 74–106 mg/dL (4.1–5.9 mmol/L) *Casual* (defined as any time of day): ≤200 mg/dL (<11.1 mmol/L)	Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8-12 hr prior. Water intake is allowed. Assess for the many drugs that may influence results.
Glucose, postprandial (2-hour postprandial glucose [2-hr PPG])	*0–50 yr*: <140 mg/dL (<7.8 mmol/L) *50–60 yr*: <150 md/dL *60 yr and older*: <160 mg/dL	Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8–12 hr, then eat a meal of at least 75 g of carbohydrate. Patient must fast after eating this meal until blood is drawn. No exercise during test.
Glucose tolerance test (GTT, oral glucose tolerance [OGTT])	*Nonpregnancy:* *Fasting:* <110 mg/dL (<6.1 mmol/L *1 hr*: <180 mg/dL (<11.1 mmol/L) *2 hr:* <140 mg/dL (<7.8 mmol/L)	Assesses glucose levels in people with symptoms of (hypoglycemia). Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8–12 hr prior. Many drugs may influence results, including caffeine and smoking. Ensure that patient's diet 3 days before test includes 150–300 g of carbohydrate with intake of at least 1500 cal/day.
Glycosylated hemoglobin (GHb, GHB, glycohemoglobin, hemoglobin A1C [Hb A1C], diabetic control index, glycated protein)	*Nondiabetic adult/child*: 4%–5.6% *Prediabetes:* 5.7%–6.4% *Good diabetic control:* <7%[7]	Measures the average blood glucose for the past 90 days. Used to diagnose and screen diabetes treatment plans.	*Before:* Tell patient that fasting is not necessary and that blood sample will be drawn.

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Insulin assay	6–26 µU/mL (43–186 pmol/L)	Assesses insulin levels in people with symptoms of hypoglycemia. Assesses for insulinomas and carbohydrate and lipid absorption abnormalities.	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Urine Studies			
Glucose (urine sugar)	*Random specimen:* negative *24-hour specimen:* 50–300 mg/day (0.3–1.7 mmol/day)	Measures amount of glucose in the urine. Assesses diabetes management.	*Before:* Use freshly voided urine. Many drugs alter glucose readings. Follow directions exactly to avoid errors.
Ketones	None or negative	Measures amount of ketones in the urine. Assesses for diabetic ketoacidosis, a life-threatening condition seen most often in people with type 1 diabetes.	*Before:* Use freshly voided urine specimen. Test is often done with glucose test. Follow directions exactly. Certain drugs can produce false-positive or false-negative results.

Table Continued

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Parathyroid Studies			
Blood Studies			
Calcium (total)	9.0–10.5 mg/dL (2.25–2.62 mmol/L)	Assesses the function of the parathyroid gland and calcium absorption.	*Before:* Patient must fast 8–12 hr prior. Assess for drug use (e.g., albuterol, heparin, diuretics) that may alter results. *After:* Keep sample on ice.
Calcium (ionized)	4.5–5.6 mg/dL (1.05–1.3 mmol/L)	Free form of total calcium. Unchanged by inconsistent serum albumin levels that occur in certain populations, such as critically ill patients.	As above.
Parathyroid hormone (PTH, parathormone)	*Intact (whole):* 10–65 pg/mL (10–65 ng/L) *N terminal:* 8–24 pg/mL *C terminal:* 50–330 pg/mL	Used to determine the cause of changes in calcium levels caused by parathyroid or nonparathyroid problems. Monitored in patients with chronic kidney disease, especially those on dialysis.	*Before:* Patient should fast 8–12 hr prior. Obtain sample in the morning. *During:* Obtain serum calcium level at same time. *After:* Mark time of blood draw on laboratory slip.
Phosphate (PO_4), phosphorus (P)	3.0–4.5 mg/dL (0.97–1.45 mmol/L)	Measures amount of inorganic phosphate in the blood. Assesses for disorders related to calcium and phosphorus disorders.	*Before:* Patient must fast 8–12 hr prior. If possible, hold IV fluids containing glucose for 8 hr prior.
Pituitary Studies			
Blood Studies			
Antidiuretic hormone (ADH, vasopressin, Arginine vasopressin [AVP])	1–5 pg/mL	Assesses for diabetes insipidus (DI) or SIADH.	*Before:* Patient must fast 8–12 hr prior.
Gonadotropins • **Follicle-stimulating hormone (FSH) assay** • **Luteinizing hormone (LH assay, Lutropin)**	*FSH (Adult)* • *Male:* 1.42–15.4 IU/L • *Female:* *Follicular phase:* 1.37–9.9 IU/L *Ovulatory phase:* 6.17–17.2 IU/L *Luteal phase:* 1.09–9.2 IU/L *Postmenopause:* 19.3–100.6 IU/L *LH (Adult)* • *Male:* 1.24–7.8 IU/L • *Female:* *Follicular phase:* 1.68–15 IU/L *Ovulatory phase:* 21.9–56.6 IU/L *Luteal phase:* 0.61–16.3 IU/L *Postmenopause:* 14.2–52.3 IU/L	Assesses for pituitary, puberty or infertility conditions and menopause.	*Before:* Tell patient that fasting is not necessary and that blood sample will be drawn. *During:* Note on the laboratory slip time of LMP or whether woman is menopausal.
Growth hormone (GH, human growth hormone [HGH], somatotropin hormone [SH])	• *Men:* <5 ng/mL • *Women:* <10 ng/mL	Evaluates GH secretion and pituitary gland function.	*Before:* Patient must fast 8–12 hours prior. Emotional and physical stress may alter results. Indicate patient fasting status and recent activity level on the laboratory slip.

Study	Reference Interval	Purpose and Description	Nursing Responsibility
GH stimulation (GH provocation, insulin tolerance test [ITT], arginine test)	GH levels >10 mg/mL	Aids in identifying GH deficiency and conditions caused from decreased pituitary hormone production.	*Before*: Patient must fast 10-12 hours prior. Water is allowed on morning of test. Establish IV access for medication administration and blood sampling. *During*: Continually assess for hypoglycemia and hypotension. Keep 50% dextrose and 5% dextrose IV solution at the bedside in case severe hypoglycemia occurs.
Insulin-like growth factor (IGF-1, somatomedin C, insulin-like growth factor binding proteins [IGF BP])	42–110 ng/mL	Evaluates GH and pituitary gland function. Provides a more accurate reflection of mean plasma concentration of GH because it is not subject to circadian rhythm and fluctuations.	*Before:* Patient must fast 8–12 hr prior.

Table Continued

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Urine Studies			
Water deprivation (ADH stimulation)	*Neurogenic DI:* >9% rise in urine osmolality *Nephrogenic DI:* <9% rise in urine osmolality *Psychogenic polydipsia:* <9% rise in urine osmolality	Distinguishes among neurogenic, nephrogenic, or psychogenic DI.	*Before*: Obtain baseline weight and urine and plasma osmolality. Should be done only if serum sodium is normal and urine osmolality is <300 mOsm/kg. *During*: Patient may need to fast. Severe dehydration may occur. Assess urine hourly for volume and specific gravity. Send hourly urine samples to laboratory for osmolality determination. Send blood samples for sodium and osmolality every 2 hr. Stop test and rehydrate if patient's weight drops >2 kg at any time. *After*: Rehydrate with oral fluids. Check orthostatic BP and pulse to ensure adequate fluid volume.
Thyroid Studies			
Blood Studies			
Antithyroglobulin antibody (thyroid autoantibody, thyroid antithyroglobulin antibody, thyroglobulin antibody, thyroid peroxidase antibody [TPO])	<116 IU/mL	Measures thyroid antibody levels. Aids in diagnosing autoimmune thyroid disease and separates it from other forms of thyroiditis. One or more antibody tests may be ordered depending on symptoms.	*Before:* Explain blood draw procedure to the patient.
Thyroglobulin (Tg, thyrogen-stimulated thyroglobulin)	• *Male:* 0.5–53 ng/mL • *Female:* 0.5–43.0 ng/mL	Identifies functioning thyroid tissue and thyroid cancer cells. Used primarily as a tumor marker for patients being treated for thyroid cancer.	As above.
Thyroid-stimulating hormone (TSH, thyrotropin)	2–10 μU/mL	Most sensitive diagnostic test for evaluating thyroid function. Helps in distinguishing primary (thyroid), secondary (pituitary), and tertiary (hypothalamus) hypothyroidism.	As above.
Thyroxine-binding globulin (TBG, thyroid-binding globulin)	*10–19 yr:* • *Male:* 1.4–2.6 mg/dL • *Female:* 1.4–3.0 mg/dL *20 yr:* 1.7–3.6 mg/dL *Oral contraceptives:* 1.5–5.5 mg/dL	Measures TBG, the main thyroid hormone protein carrier. Used to assess thyroid function when T_4 and T_3 levels are abnormal.	As above.
Thyroxine, total and Free (T_4, thyroxine screen, FT_4)	*Free T_4: 0.8–2.8 ng/dL (10–36 pmol/L)* *Total T_4:* • *Male:* 4–12 mcg/dL (51–154 nmol/L) • *Female:* 5–12 mcg/dL (64–154 nmol/L) • >60 yr: 5–11 mcg/dL (64–142 nmol/L)	Used to evaluate thyroid function and monitor thyroid replacement or suppressive therapy. Free T_4 levels not affected by protein levels like total T_4 is, so it is thought to be more precise marker of thyroid function.	As above.
Triiodothyronine (total T_3 radioimmunoassay [T_3 by RIA], free T_3)	*16–20 yr:* 80–210 ng/dL *20–50 yr:* 70–205 ng/dL (1.2–3.4 nmol/L) *>50 yr:* 40–180 ng/dL (0.6–2.8 nmol/L)	Evaluates thyroid function. Free T_3 measures the active component of total T_3. Used to diagnose hyperthyroidism if TSH is abnormal and T_4 levels are normal. May be used to monitor drug therapy.	As above.
T_3 uptake (thyroid hormone–binding ratio [THBR], T_3 resin uptake)	24%–39%	Use in conjunction with T_4 to assess thyroid function. Indirectly measures binding capacity of thyroid-binding globulin	As above.

TABLE 47.7 Radiologic StudiesEndocrine System

Study	Description and Purpose	Nursing Responsibility
Adrenal arteriography (angiography; adrenal)	Assesses for arterial obstructive conditions and/or tumors of the adrenal glands.	*Before:* Assess for allergies, especially to contrast dye. Have patient fast 6–12 hr prior. Give sedative and other drugs, as ordered. *During:* Patient will feel flushed when dye is injected. *After:* Check pressure dressing site after procedure. Monitor BP, pulse, and circulation distal to injection site. Place compression device over site. Maintain IV and/or oral fluid intake.
Computed tomography (CT)	*Abdominal:* Used to detect adrenal hyperplasia and tumors or pancreatic abnormalities, such as pancreatitis, tumors, or cysts. *Brain:* Used to detect a pituitary tumor and its size. *Neck:* Can locate thyroid nodules and assess for thyroid cancer.	*Before:* Before contrast medium used, evaluate renal function. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 hr prior to study. If the patient is taking metformin, hold it the day of the test to prevent hypoglycemia or acidosis. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
Magnetic resonance cholangiopancreatography (MRCP)	Assesses for the source of pancreatitis and can detect pancreatobiliary tumors.	*Before:* Patient may need to be fasting. Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function. *During:* Patient must lie completely still during scan.
Magnetic resonance imaging (MRI)	*Abdominal:* Can distinguish benign tumors from adrenal cancers. *Brain:* Study of choice for radiologic evaluation of the pituitary gland and hypothalamus. Used to identify tumors in these glands.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during scan.
Parathyroid scan (parathyroid scintigraphy)	Used to find the parathyroid glands. Radioactive isotopes are taken up by cells in parathyroid glands. Obtains image of the glands and any abnormally active areas.	*Before:* Check for iodine allergy. Some foods and medications are restricted a few weeks before the scan.
Radioactive iodine (RAIU) uptake	Direct measure of thyroid activity and evaluates function of thyroid nodules. For 2–4 hours: 3%–19%. *For 24 hr:* 11%–30%	*Before:* Radioactive iodine given orally or IV. Check for allergies. *During:* Uptake by the thyroid gland is measured with a scanner at several time intervals, such as 2–4 hr and at 24 hr. *After:* Encourage patient to increase fluid intake as radionuclide takes 6–24 hr to be eliminated from body.
Thyroid scan	Used to evaluate nodules of thyroid. Benign nodules appear as warm spots because they take up radionuclide. Cancer tumors appear as cold spots because they tend not to take up radionuclide.	*Before:* Radioactive isotopes are given orally or IV. Check for allergies. *After:* Encourage patient to increase fluid intake as radionuclide takes 6–24 hr to be eliminated from body.
Thyroid ultrasound	Evaluates thyroid nodules to determine size and characteristics (cystic or solid tumors). Used to observe management and surveillance of nodules and unaffected portions of the gland.	*Before:* Explain that gel and a transducer will be used over the neck. The test lasts 15 min. No fasting or sedation required.

Case Study—cont'd

Objective Data: Diagnostic Studies

© iStockphoto/Thinkstock.

The HCP orders the following initial diagnostic studies to be drawn in the morning after an 8-hr fast:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Fasting blood glucose (FBG)
- TSH, free T_4
- Plasma cortisol levels
- Plasma ACTH levels

CBC results reveal a WBC of 12,200/μL and a decreased lymphocyte count at 800 cells/μL. The rest of the CBC is within normal limits (WNL). The FBG is 130 mg/dL. The plasma cortisol and ACTH levels are high. Thyroid studies are WNL.

Discussion Questions

1. Which diagnostic study results are of most concern to you?
2. Do you expect the HCP to order any other diagnostic studies for L.M.?
3. What are the interprofessional team's priorities for L.M. at this time?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A characteristic common to all hormones is that they
   a. circulate in the blood bound to plasma proteins.
   b. influence cellular activity of specific target tissues.
   c. accelerate the metabolic processes of all body cells.
   d. enter a cell and change the cell's metabolism or gene expression.
2. A patient is receiving radiation therapy for cancer of the kidney. The nurse monitors the patient for signs and symptoms of damage to the
   a. pancreas.
   b. thyroid gland.
   c. adrenal glands.

d. posterior pituitary gland.

3. A patient has a serum sodium level of 152 mEq/L (152 mmol/L). The normal hormonal response to this situation is
   a. release of ADH.
   b. release of ACTH.
   c. secretion of aldosterone.
   d. secretion of corticotropin-releasing hormone.
4. All cells in the body are believed to have intracellular receptors for
   a. insulin.
   b. glucagon.
   c. growth hormone.
   d. thyroid hormone.
5. When obtaining subjective data from a patient during assessment of the endocrine system, the nurse asks specifically about
   a. energy level.
   b. intake of vitamin C.
   c. employment history.
   d. frequency of sexual intercourse.
6. An appropriate technique to use during physical assessment of the thyroid gland is
   a. asking the patient to hyperextend the neck during palpation.
   b. percussing the neck for dullness to define the size of the thyroid.

c. having the patient swallow water during inspection and palpation of the gland.

d. using deep palpation to determine the extent of a visibly enlarged thyroid gland.

7. Endocrine disorders often go unrecognized in the older adult because

a. symptoms are often attributed to aging.

b. older adults rarely have identifiable symptoms.

c. endocrine disorders are relatively rare in the older adult.

d. older adults usually have subclinical endocrine disorders that minimize symptoms.

8. Abnormal findings during an endocrine assessment include *(select all that apply)*

a. excess facial hair on a woman.

b. blood pressure of 100/70 mm Hg.

c. soft, formed stool every other day.

d. 3-lb weight gain over last 6 months.

e. hyperpigmented coloration in lower legs.

9. A patient has a total serum calcium level of 3 mg/dL (1.5 mEq/L). If this finding reflects hypoparathyroidism, the nurse would expect further diagnostic testing to reveal

a. decreased serum PTH.

b. increased serum ACTH.

c. increased serum glucose.

d. decreased serum cortisol levels.

1. b, 2. c, 3. a, 4. d, 5. a, 6. c, 7. a, 8. a, e, 9. a

LEARNING OUTCOMES

1. Describe the pathophysiology and clinical manifestations of diabetes mellitus.
2. Distinguish between type 1 and type 2 diabetes mellitus.
3. Describe the interprofessional care of a patient with diabetes.
4. Describe the role of nutrition and exercise in managing diabetes mellitus.
5. Discuss the nursing management of a patient with newly diagnosed diabetes mellitus.
6. Describe the nursing management of a patient with diabetes mellitus in the ambulatory and home care settings.
7. Relate the pathophysiology of acute and chronic complications of diabetes mellitus to the clinical manifestations.
8. Explain the interprofessional care and nursing management of a patient with acute and chronic complications of diabetes mellitus.

Sensory Perception

This chapter discusses the pathophysiology, manifestations, complications, and management of diabetes. The long-term complications associated with diabetes can make it a devastating

disease. Diabetes is the leading cause of adult blindness, end-stage renal disease, and nontraumatic lower limb amputations. It is a major contributing factor to heart disease and stroke. Managing diabetes requires daily decisions about food intake, blood glucose monitoring, medication, and exercise. You play a vital role in promoting the patient's self-management of diabetes through providing comprehensive patient and caregiver education.

Diabetes Mellitus

Diabetes mellitus (DM), most often referred to as diabetes, is a chronic multisystem disease characterized by hyperglycemia from abnormal insulin production, impaired insulin use, or both. Diabetes is a serious health problem throughout the world. Its prevalence is rapidly increasing. Currently in the United States, an estimated 29.1 million people, or 9.3% of the population, have diabetes. 86 million more people have prediabetes.[1] About 8.1 million people with diabetes have not been diagnosed and are unaware that they have the disease. Diabetes is the seventh leading cause of death in the United States.[2] Adults with diabetes have heart disease death rates and risk for strokes that are 2 to 4 times higher than adults without diabetes. In addition, more than half of adults with diabetes have hypertension and high cholesterol levels.[2]

Etiology and Pathophysiology

Current theories link the causes of diabetes, singly or in combination, to genetic, autoimmune, and environmental factors (e.g., virus, obesity). Regardless of its cause, diabetes is primarily a disorder of glucose metabolism related to absent or insufficient insulin supply and/or poor use of the available insulin.

The American Diabetes Association (ADA) recognizes 4 different classes of diabetes. The 2 most common are type 1 and type 2 diabetes (Table 48.1). The 2 other classes are gestational diabetes and other specific types of diabetes with various causes.

Normal Glucose and Insulin Metabolism

Insulin is a hormone made by the β cells in the islets of Langerhans of the pancreas. Under normal conditions, insulin is continuously released into the bloodstream in small amounts, with increased release when food is ingested (Fig. 48.1). Insulin lowers blood glucose and facilitates a stable, normal glucose range of about 74 to 106 mg/dL

(4.1 to 5.9 mmol/L). The amount of insulin secreted daily by an adult is about 40 to 50 U, or 0.6 U/kg of body weight.

TABLE 48.1 Comparison of Type 1 and Type 2 Diabetes

Factor	Type 1 Diabetes	Type 2 Diabetes
Age at onset	More common in young people but can occur at any age	More common in adults but can occur at any age Incidence increasing in children
Type of onset	Signs and symptoms usually abrupt, but disease process may be present for several years	Gradual, may go undiagnosed for years
Prevalence	Accounts for 5%–10% of all types of diabetes	Accounts for 90%–95% of all types of diabetes
Endogenous insulin	Absent	Initially increased in response to insulin resistance. Secretion decreases over time
Environmental factors	Virus, toxins	Obesity, lack of exercise
Islet cell antibodies	Often present at onset	Absent
Primary defect	Absent or minimal insulin production	Insulin resistance, decreased insulin production over time, and changes in adipokines production
Symptoms	Polydipsia, polyuria, polyphagia, fatigue, weight loss without trying	Often none. Fatigue, recurrent infections. May also have polyuria, polydipsia, and polyphagia
Ketosis	Present at onset or during insulin deficiency	Not present except during infection or stress
Insulin therapy	Required for all	Required for some. Disease is progressive and insulin treatment may need to be added to treatment plan
Nutrition status	Thin, normal, or obese	Often overweight or obese. May be normal
Nutrition therapy	Essential	Essential
Vascular and neurologic complications	Frequent	Frequent

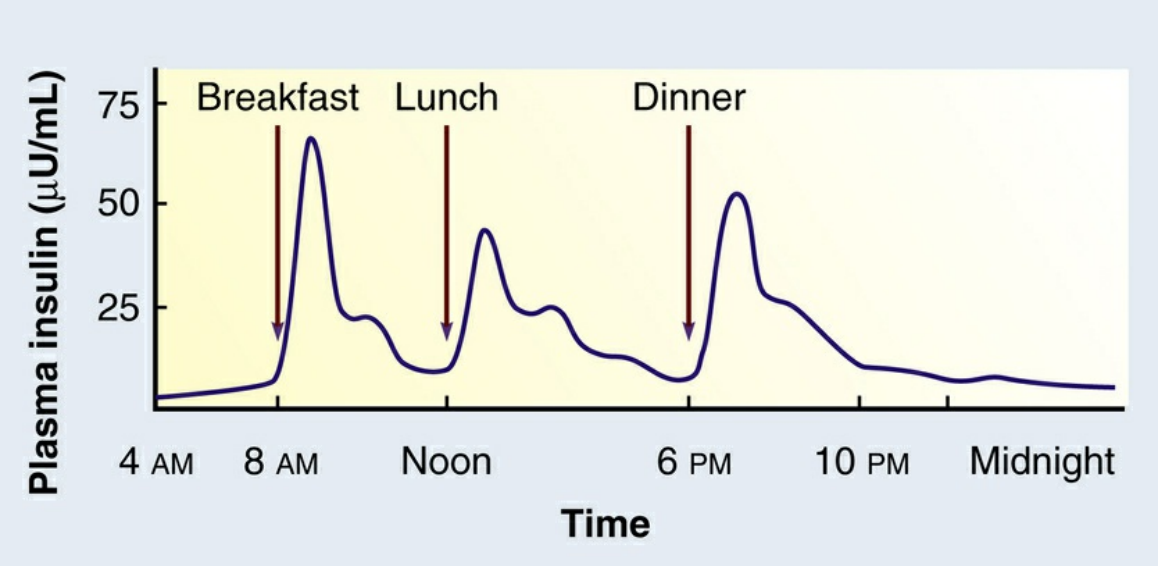

FIG. 48.1 Normal endogenous insulin secretion. After meals, insulin concentrations rise rapidly in blood and peak at about 1 hour. Then insulin concentrations promptly decline toward preprandial values as carbohydrate absorption from the GI tract declines. After carbohydrate absorption from the GI tract is complete and during the night, insulin concentrations are low and fairly constant, with a slight increase at dawn.

Insulin promotes glucose transport from the bloodstream across the cell membrane to the cytoplasm of the cell (Fig. 48.2). Cells break down glucose to make energy. Liver and muscle cells store excess glucose as glycogen. The rise in plasma insulin after a meal inhibits gluconeogenesis, enhances fat deposition of adipose tissue, and increases protein synthesis. For this reason, insulin is an *anabolic,* or storage, hormone. The fall in insulin level during normal overnight fasting promotes the release of stored glucose from the liver, protein from muscle, and fat from adipose tissue.

Skeletal muscle and adipose tissue have specific receptors for insulin and are considered insulin-dependent tissues. Insulin is required to "unlock" these receptor sites, allowing the transport of glucose into the cells to be used for energy. Other tissues (e.g., brain, liver, blood cells) do not directly depend on insulin for glucose transport but require an adequate glucose supply for normal function. Although liver cells are not considered insulin-dependent tissue, insulin receptor sites on the liver facilitate uptake of glucose and its conversion to glycogen.

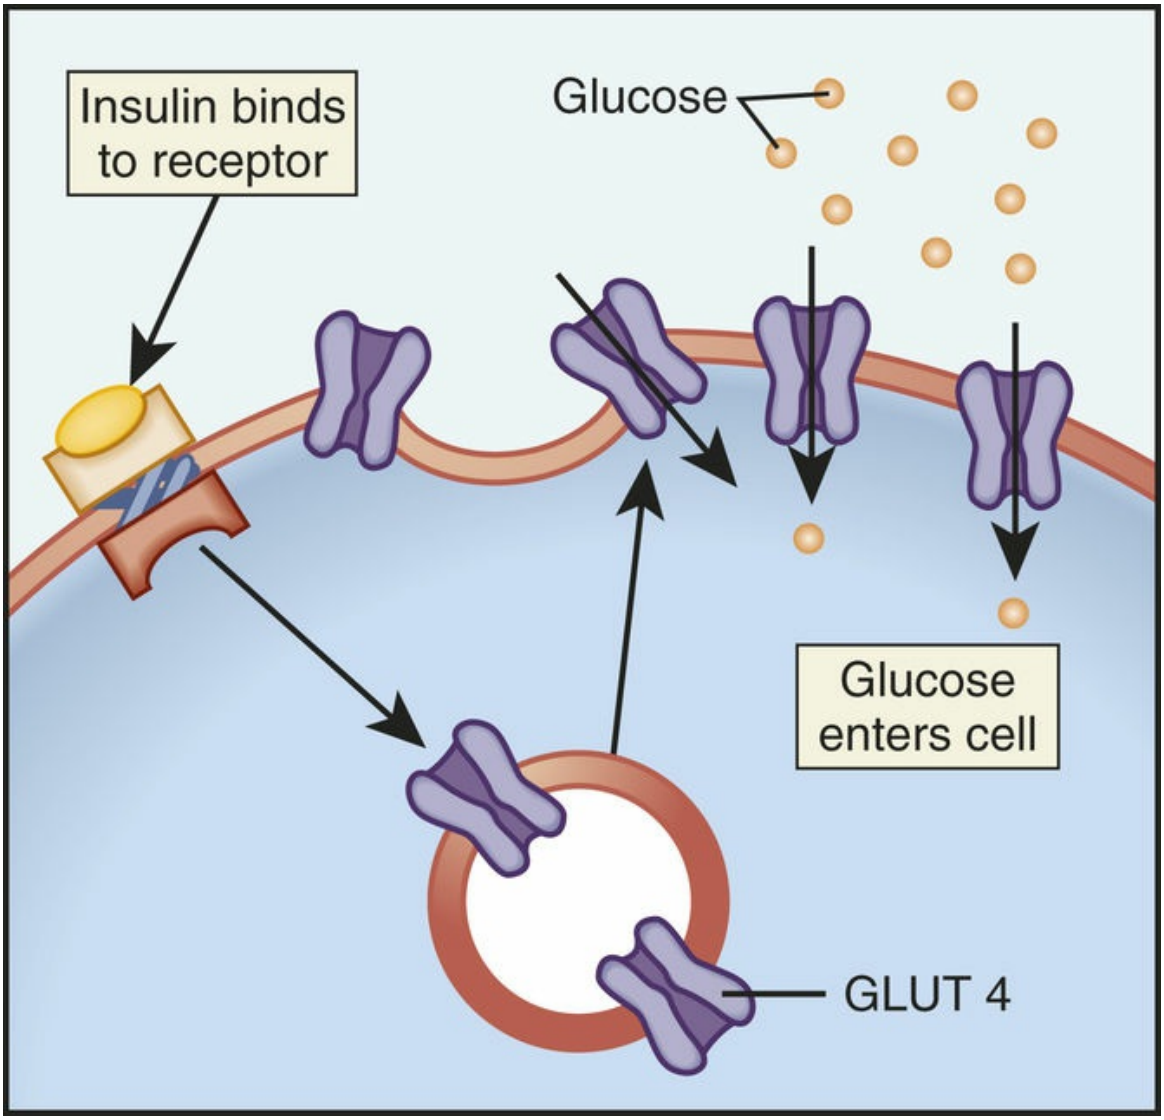

FIG. 48.2 Normal glucose metabolism. Insulin binds to receptors along the cell walls of muscle, adipose, and liver cells. Glucose transport proteins (GLUT 4s) then attach to the cell wall and allow glucose to enter the cell, where it is either stored or used to make energy.

Other hormones (glucagon, epinephrine, growth hormone [GH], cortisol) work against the effects of insulin. They are *counterregulatory hormones.* These hormones increase blood glucose levels by (1) stimulating glucose production and release by the liver and (2) decreasing the movement of glucose into the cells. The counterregulatory hormones and insulin work together to maintain blood glucose levels within the normal range by regulating the release of glucose for energy during food intake and periods of fasting.

Insulin is synthesized from its precursor, proinsulin. Enzymes split proinsulin to form insulin and C-peptide, and the 2 substances are released in equal amounts. Therefore measuring C-peptide in serum and urine is a useful clinical indicator of pancreatic β-cell function and insulin levels.

Genetics in Clinical Practice

Type 1 and Type 2 Diabetes and Maturity-Onset Diabetes of the Young (MODY)

Type 1 Diabetes	Type 2 Diabetes	MODY
Genetic Basis		
• Increased susceptibility (40%–50%) when a person has specific human leukocyte antigens (HLA-DR3, HLA-DR4) • Polygenic (>40 genes influence susceptibility)	• Polygenic (>25 genes influence susceptibility)	• Autosomal dominant • Monogenic (single gene) • Caused by mutations in any of 6 MODY genes (types 1–6) • Gene mutations lead to β-cell dysfunction
Risk to Offspring		
• Risk to offspring of mothers with diabetes is 1%–4% • Risk to offspring of fathers with diabetes is 5%–6% • When 1 identical twin has type 1 diabetes, the other gets the disease about 30%–40% of the time	• Risk to offspring is 8%–14% • When 1 identical twin has type 2 diabetes, the other gets it about 60%–75% of the time	• If 1 parent has MODY, a child has a 50% chance of developing disease • If 1 parent has MODY, a child has a 50% chance of being a carrier
Clinical Implications		
• Result of complex interaction of genetic, autoimmune, and environmental factors	• Result of complex genetic interactions and other metabolic factors • Metabolic factors are modified by environmental factors, such as body weight and exercise.	• Accounts for 1%–5% of people with diabetes • Young age of onset (often before age 25) • Not associated with obesity or hypertension • Treatment depends on the genetic mutation that caused MODY

Type 1 Diabetes

Type 1 diabetes, formerly known as *juvenile-onset diabetes* or *insulin-dependent diabetes mellitus (IDDM),* accounts for about 5% to 10% of all people with diabetes. Type 1 diabetes generally affects people under 40 years of age, although it can occur at any age.[3]

Etiology and Pathophysiology

Type 1 diabetes is an autoimmune disorder in which the body develops antibodies against insulin and/or the pancreatic β cells that make insulin. This eventually results in not enough insulin for a person to survive. A genetic predisposition and exposure to a virus are factors that may contribute to the development of immune-related type 1 diabetes.

Genetic Link

Predisposition to type 1 diabetes is related to human leukocyte antigens (HLAs) (see Chapter 13). In theory, when a person with certain HLA types is exposed to a viral infection, the β cells of the pancreas are destroyed, either directly or through an autoimmune process. The HLA types associated with an increased risk for type 1 diabetes include HLA-DR3 and HLA-DR4.

Idiopathic diabetes is a form of type 1 diabetes that is strongly inherited and not related to autoimmunity. It only occurs in a small number of people with type 1 diabetes, most often of Hispanic, African, or Asian ancestry.[3] *Latent autoimmune diabetes in adults* (LADA), a slowly progressing autoimmune form of type 1 diabetes. It occurs in adults and is often mistaken for type 2 diabetes.

Onset of Disease

In type 1 diabetes, the islet cell autoantibodies responsible for β-cell destruction are present for months to years before the onset of symptoms. Manifestations develop when the person's pancreas can no longer make enough insulin to maintain normal glucose. Once this occurs, the onset of symptoms is usually rapid. Patients often are initially seen with impending or actual ketoacidosis. The patient usually has a history of recent and sudden weight loss and the classic symptoms of *polydipsia* (excessive thirst), *polyuria* (frequent urination), and *polyphagia* (excessive hunger).

The person with type 1 diabetes requires insulin from an outside source *(exogenous insulin)* to sustain life. Without insulin, the patient will develop diabetes-related ketoacidosis (DKA), a life-threatening

condition resulting in metabolic acidosis. Newly diagnosed patients may have a remission, or "honeymoon period," for 3 to 12 months after starting treatment. During this time, the patient needs little injected insulin because β-cell insulin production is still sufficient for healthy blood glucose levels. Eventually, as more β cells are destroyed and blood glucose levels increase, the honeymoon period ends and the patient will require insulin on a permanent basis.

Type 2 Diabetes

Type 2 diabetes, formerly known as *adult-onset diabetes* or *non–insulin-dependent diabetes mellitus (NIDDM),* accounts for about 90% to 95% of people with diabetes.[2] Many risk factors contribute to the development of type 2 diabetes. These include being overweight or obese, being older, and having a family history of type 2 diabetes. Although the disease is seen less often in children, the incidence is increasing due to the increasing prevalence of childhood obesity. Type 2 diabetes is more prevalent in some ethnic populations. Blacks, Asian Americans, Hispanics, Native Hawaiians or other Pacific Islanders, and Native Americans have a higher rate of type 2 diabetes than whites.[2]

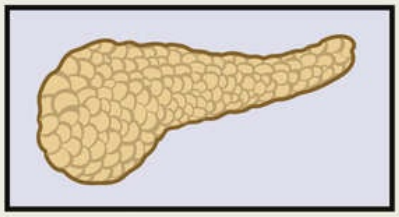
Promoting Health Equity

Diabetes

- Native Americans and Alaska Natives have highest prevalence for both men (14.9%) and women (15.3%).
- Pima Indians in Arizona have the highest rate of diabetes in the world (50% of adults).
- Native American and Alaska Native women are twice as likely to die from diabetes as white women.
- Rates are higher among blacks (12.7%) and Hispanics (12.1%) than among whites (7.4%) and Asians (8.0%).

- Blacks are twice as likely as whites to die from diabetes.

Etiology and Pathophysiology

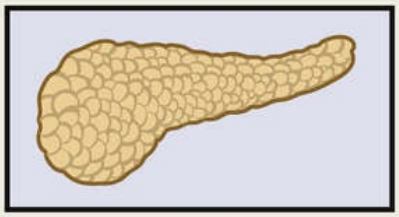


Type 2 diabetes is characterized by a combination of inadequate insulin secretion and insulin resistance. The pancreas usually makes some *endogenous* (self-made) insulin. However, the body either does not make enough insulin or does not use it effectively, or both. The presence of endogenous insulin is a major distinction between type 1 and type 2 diabetes. In type 1 diabetes, there is an absence of endogenous insulin.

Genetic Link

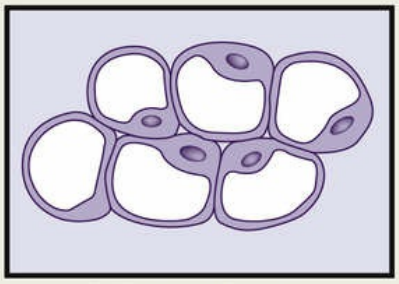
Although we do not fully understand the genetics of type 2 diabetes, it is likely multiple genes are involved. We have found genetic mutations that lead to insulin resistance and a higher risk for obesity in many people with type 2 diabetes. Persons with a first-degree relative with the disease are 10 times more likely to develop type 2 diabetes.

Metabolic abnormalities have a role in the development of type 2 diabetes (Fig. 48.3). The first factor is **insulin resistance**, a condition in which body tissues do not respond to the action of insulin because insulin receptors are unresponsive, are insufficient in number, or both. Most insulin receptors are located on skeletal muscle, fat, and liver cells. When insulin is not properly used, the entry of glucose into the cell is impeded, resulting in hyperglycemia. In the early stages of insulin resistance, the pancreas responds to high blood glucose by producing greater amounts of insulin (if β cell function is normal). This creates a temporary state of hyperinsulinemia that coexists with hyperglycemia.



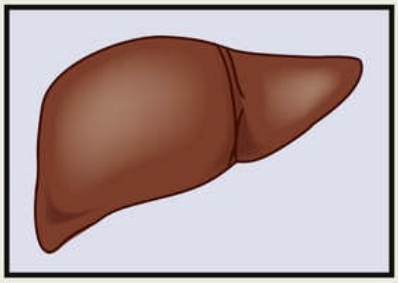
Type 1 Diabetes Mellitus

Pancreas



- Autoimmune destruction of β cells
- Autoantibodies present for months to years before clinical symptoms
- Insufficient production of insulin

Type 2 Diabetes Mellitus



Pancreas

- Defective β cell secretion of insulin
- Insulin resistance stimulates ↑ insulin secretion
- Eventual exhaustion of β cells in many people
- ↑ Glucagon secretion

Adipose tissue

- ↓ Adiponectin and ↑ leptin
- Results in altered glucose and fat metabolism

Liver

- Excess glucose production
- Inappropriate regulation of glucose production

Muscle

- Defective insulin receptors
- Insulin resistance
- Decreased uptake of glucose by cells resulting in hyperglycemia

FIG. 48.3 Altered mechanisms in type 1 and type 2 diabetes.

A second factor in the development of type 2 diabetes is a marked decrease in the ability of the pancreas to make insulin, as the β cells become fatigued from the compensatory overproduction of insulin or when β-cell mass is lost. The underlying basis for the failure of β cells to adapt is unknown. It may be linked to the adverse effects of chronic hyperglycemia or high circulating free fatty acids. In addition, the α cells of the pancreas increase production of glucagon.

This leads to a third factor, which is inappropriate glucose production by the liver. Instead of properly regulating the release of glucose in response to blood levels, the liver does so in a haphazard way that does not correspond to the body's needs at the time.

A fourth factor is altered production of hormones and cytokines by adipose tissue *(adipokines)*. Adipokines secreted by adipose tissue appear to play a role in glucose and fat metabolism and are likely to contribute to the development of type 2 diabetes.[4] We think adipokines cause chronic inflammation, a factor involved in insulin resistance, type 2 diabetes, and cardiovascular disease (CVD). The 2 main adipokines thought to affect insulin sensitivity are adiponectin and leptin. Finally, the brain, kidneys, and gut have roles in the development of type 2 diabetes. We are continuously learning more about metabolic factors in the development of type 2 diabetes.[4]

People with *metabolic syndrome* have an increased risk for developing type 2 diabetes. Metabolic syndrome has 5 components: increased glucose levels, abdominal obesity, high BP, high levels of triglycerides, and decreased levels of high-density lipoproteins (HDLs) (see Table 40.12). A person with 3 of the 5 components is considered to have metabolic syndrome.[5] Overweight persons with metabolic syndrome can reduce their risk for diabetes through a program of weight loss and regular physical activity. See Chapter 40 for more about metabolic syndrome.

Onset of Disease

The disease onset in type 2 diabetes is usually gradual. The person

may go for many years with undetected hyperglycemia and few, if any, symptoms. Many people are diagnosed on routine laboratory testing or when they undergo treatment for other conditions, and elevated glucose or glycosylated hemoglobin (A1C) levels are found. The signs and symptoms of hyperglycemia develop when about 50% to 80% of β cells are no longer secreting insulin. At the time of diagnosis, the average person has had type 2 diabetes for 6½ years.

Prediabetes

Persons diagnosed with prediabetes are at increased risk for developing type 2 diabetes. **Prediabetes** is defined as **impaired glucose tolerance (IGT)**, **impaired fasting glucose (IFG)**, or both. It is an intermediate stage between normal glucose homeostasis and diabetes, in which the blood glucose levels are elevated but not high enough to meet the diagnostic criteria for diabetes.[6] A diagnosis of IGT is made if the 2-hour oral glucose tolerance test (OGTT) values are 140 to 199 mg/dL (7.8 to 11.0 mmol/L). IFG is diagnosed when fasting blood glucose levels are 100 to 125 mg/dL (5.56 to 6.9 mmol/L).

Persons with prediabetes usually do not have symptoms. However, long-term damage to the body, especially the heart and blood vessels, may already be occurring. It is important for patients to undergo screening and to understand risk factors for diabetes. People with prediabetes can take action to prevent or delay the development of type 2 diabetes. Encourage those with prediabetes to have their blood glucose and A1C checked regularly and monitor for symptoms of diabetes, such as fatigue, frequent infections, or slow-healing wounds. Maintaining a healthy weight, exercising regularly, and making healthy food choices reduce the risk for developing overt type 2 diabetes in people with prediabetes.

Gestational Diabetes

Gestational diabetes develops during pregnancy and occurs in about 2% to 10% of pregnancies in the United States.[7] Women with gestational diabetes have a higher risk for cesarean delivery, and their babies have increased risk for perinatal death, birth injury, and neonatal

complications. Women who are at high risk for gestational diabetes are screened at the first prenatal visit. Those at high risk include women who are obese, are of advanced maternal age, or have a family history of diabetes. Women with an average risk for gestational diabetes are screened using an OGTT at 24 to 28 weeks of gestation. Most women with gestational diabetes have normal glucose levels within 6 weeks postpartum. Women with a history of gestational diabetes have up to a 63% chance of developing type 2 diabetes within 16 years.[7] Gestational diabetes and managing the pregnant patient with diabetes are specialized areas not covered in detail in this chapter. Consult an obstetric text for more information.

Other Specific Types of Diabetes

Diabetes occurs in some people because of another medical condition or treatment of a medical condition that causes abnormal blood glucose levels. Conditions that may cause diabetes can result from injury to, interference with, or destruction of the β-cell function in the pancreas. These include Cushing syndrome, hyperthyroidism, recurrent pancreatitis, cystic fibrosis, hemochromatosis, and parenteral nutrition. Common drugs that can induce diabetes include corticosteroids (prednisone), thiazides, phenytoin (Dilantin), and atypical antipsychotics (e.g., clozapine [Clozaril]). Diabetes caused by medical conditions or drugs can resolve when the underlying condition is treated or the drug is discontinued.

Clinical Manifestations

Type 1 Diabetes

Because the onset of type 1 diabetes is rapid, the first manifestations are usually acute. The classic symptoms are *polyuria, polydipsia,* and *polyphagia.* The osmotic effect of excess glucose in the bloodstream causes polydipsia and polyuria. Polyphagia is a result of cellular malnourishment when insulin deficiency prevents cells from using glucose for energy. Weight loss may occur because the body cannot get glucose and instead breaks down fat and protein to try to make

energy. Weakness and fatigue may result because body cells lack needed energy from glucose. Ketoacidosis, a complication most common in those with untreated type 1 diabetes, is associated with additional manifestations. It is discussed later in this chapter.

Type 2 Diabetes

The manifestations of type 2 diabetes are often nonspecific. It is possible a person with type 2 diabetes will have classic symptoms associated with type 1 diabetes, including polyuria, polydipsia, and polyphagia. Some of the more common manifestations associated with type 2 diabetes are fatigue, recurrent infections, recurrent vaginal yeast or candida infections, prolonged wound healing, and vision problems.

Diagnostic Studies

The diagnosis of diabetes is made using 1 of the following 4 methods:

1. A1C of 6.5% or higher
2. Fasting plasma glucose (FPG) level of 126 mg/dL (7.0 mmol/L) or greater. *Fasting* is defined as no caloric intake for at least 8 hours
3. A 2-hour plasma glucose level of 200 mg/dL (11.1 mmol/L) or greater during an OGTT, using a glucose load of 75 g
4. In a patient with classic symptoms of hyperglycemia (polyuria, polydipsia, unexplained weight loss) or hyperglycemic crisis, a random plasma glucose level of 200 mg/dL (11.1 mmol/L) or greater

If a patient is seen with a hyperglycemic crisis or clear symptoms of hyperglycemia (polyuria, polydipsia, polyphagia) with a random plasma glucose level of 200 mg/dL or greater, repeat testing is not needed. Otherwise, criteria 1 through 3 require confirmation by repeat testing to rule out laboratory error. It is preferable for the repeat test to be the same test used initially. For example, if a random elevated

blood glucose is used for the initial measurement, that same measure should be used to confirm a diagnosis.

The accuracy of laboratory results depends on adequate patient preparation and attention to the many factors that may influence the results. For example, factors that can falsely elevate values include recent severe restrictions of dietary carbohydrate, acute illness, drugs (e.g., contraceptives, corticosteroids), and restricted activity, such as bed rest. A patient with impaired gastrointestinal (GI) absorption or who has recently taken acetaminophen may have false-negative results.

A1C measures the amount of glycosylated hemoglobin (Hgb) as a percentage of total Hgb. For example, A1C of 6.5% means that 6.5% of the total Hgb has glucose attached to it. The amount of glycosylated Hgb depends on the blood glucose level. When blood glucose levels are elevated over time, the amount of glucose attached to Hgb increases. This glucose stays attached to the red blood cell (RBC) for the life of the cell (about 120 days). Therefore, A1C provides a measurement of blood glucose levels over the previous 2 to 3 months, with increases in the Hb A1C reflecting elevated blood glucose levels. The A1C has several advantages over the FPG, including greater convenience, since fasting is not needed. Diseases affecting RBCs (e.g., iron deficiency anemia, sickle cell anemia) can influence the A1C and should be considered when interpreting results.

A1C results can be converted to the same units (mg/dL or mmol/L) that patients use in blood glucose measurements. An *estimated average glucose* (eAG) can be determined from the A1C. The eAG = 28.7 × A1C − 46.7. For example, an A1C of 8.0% is equivalent to a glucose level of 183 mg/dL.

Teach patients with diabetes and prediabetes to have their A1C monitored regularly to determine how well the current treatment plan is working and make changes in the plan if glycemic goals are not achieved. The ADA identifies an A1C goal for patients with diabetes of less than 7.0%. The American College of Endocrinology recommends an A1C of less than 6.5%. When the A1C is maintained at near-normal levels, the risk for developing microvascular and

macrovascular complications is greatly reduced. For people with prediabetes, monitoring the A1C can detect overt diabetes and provide feedback on efforts to prevent diabetes.

Fructosamine is another way to assess glucose levels. It is formed by a chemical reaction of glucose with plasma protein. It reflects glycemia in the previous 1 to 3 weeks. Fructosamine levels may show a change in blood glucose levels before A1C does. It is used for people with hemoglobinopathies, or for short-term measurement of glucose levels, for instance, after a change in medication or during pregnancy.

Islet cell autoantibody testing is primarily done to help distinguish between autoimmune type 1 diabetes and diabetes from other causes. Autoantibodies can develop to 1 or several autoantigens, including GAD65, IA-2, or insulin.

Interprofessional Care

The goals of diabetes management are to reduce symptoms, promote well-being, prevent acute complications related to hyperglycemia and hypoglycemia, and prevent or delay the onset and progression of long-term complications. These goals are most likely to be met when the patient maintains blood glucose levels as near to normal as possible. Patient teaching, which enables the patient to become the most active participant in their own care, is essential to achieve glycemic goals. Nutrition therapy, drug therapy, exercise, and self-monitoring of blood glucose are the tools used in managing diabetes (Table 48.2).

The 3 major types of glucose-lowering agents (GLAs) used in the treatment of diabetes are insulin, oral agents (OAs), and noninsulin injectable agents. All persons with type 1 diabetes require insulin. For some people with type 2 diabetes, a healthy eating plan, regular physical activity, and maintaining a healthy body weight are enough to attain optimal blood glucose levels. Eventually, most people will need medication management because type 2 diabetes is a progressive disease.

Drug Therapy: Insulin

Exogenous (injected) insulin is needed when a patient has inadequate insulin to meet specific metabolic needs. People with type 1 diabetes require exogenous insulin to survive. They often use multiple daily injections of insulin (often 4 or more) or continuous insulin infusion via an insulin pump to adequately manage blood glucose levels. People with type 2 diabetes may need exogenous insulin during periods of severe stress, such as illness or surgery. Since type 2 diabetes is a progressive disease, over time, the combination of nutrition therapy, exercise, OAs, and noninsulin injectable agents may no longer adequately manage blood glucose levels. At that point, exogenous insulin is added as part of the management plan. People with type 2 diabetes may also need up to 4 injections per day to adequately maintain their blood glucose levels. Insulin pumps also can be used for patients with type 2 diabetes.

TABLE 48.2 Interprofessional CareDiabetes

Diagnostic Assessment

- History and physical examination
- Blood tests, including fasting blood glucose, postprandial blood glucose, A1C, fructosamine, lipid profile, BUN and serum creatinine, electrolytes, islet cell autoantibodies
- Urine for complete urinalysis, albuminuria, and acetone (if indicated)
- BP
- ECG (if indicated)
- Funduscopic examination (dilated eye examination)
- Dental examination
- Neurologic examination, including monofilament test for sensation to lower extremities

- Ankle-brachial index (ABI) (if indicated) (see Table 37.3)
- Foot (podiatric) examination
- Monitoring of weight

Management

- Patient and caregiver teaching and follow-up programs
- Nutrition therapy (Table 48.8)
- Exercise therapy (Tables 48.9 and 48.10)
- Self-monitoring of blood glucose (SMBG) (Table 48.11)

Drug Therapy

- Insulin (Fig. 48.3 and Tables 48.3 and 48.4)
- OAs and noninsulin injectable agents (Table 48.7)
- Enteric-coated aspirin (81–162 mg/day)
- ACE inhibitors (see Table 32.6)
- Angiotensin II receptor blockers (ARBs) (see Table 32.6)
- Antihyperlipidemic drugs (see Table 33.6)

Types of Insulin

Today, people use only genetically engineered human insulin made in laboratories. The insulin is derived from common bacteria (e.g., *Escherichia coli*) or yeast cells using recombinant deoxyribonucleic acid (DNA) technology. In the past, insulin was extracted from beef and pork pancreases. These forms of insulin are no longer available.

Insulins differ by their onset, peak action, and duration (Fig. 48.4). They are categorized as rapid-acting, short-acting, intermediate-acting, and long-acting insulin (Table 48.3).

Insulin Plans

Examples of insulin plans are shown in Table 48.4. The insulin approach that most closely mimics endogenous insulin production is the **basal-bolus plan** (often called *intensive or physiologic insulin therapy*). It consists of multiple daily insulin injections (or an insulin pump) together with frequent self-monitoring of blood glucose (or a continuous glucose monitoring system). Injections include rapid- or short-acting (bolus) insulin before meals and intermediate- or long-acting (basal) background insulin once or twice a day. The goal is to achieve a glucose level as close to normal as possible, as much of the time as possible. This is referred to as "time in range."

Other, less intense plans can promote healthy blood glucose levels for some people. Ideally, the patient and the HCP will work together to choose a plan. Selection criteria are based on the desired and feasible blood glucose levels and the patient's lifestyle, food choices, and activity patterns. If a less intense plan is not giving the person optimal results, the HCP may encourage a more intense approach.

Mealtime Insulin (Bolus)

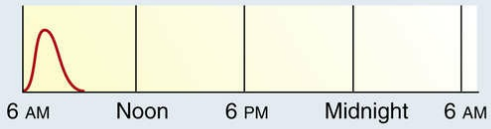
To manage postprandial blood glucose levels, the timing of rapid- and short-acting insulin in relation to meals is crucial. Rapid-acting synthetic insulin analogs, which include aspart (NovoLog), glulisine (Apidra), and lispro (Humalog), have an onset of action of about 15 minutes. They should be injected within 15 minutes of mealtime. The rapid-acting analogs most closely mimic natural insulin secretion in response to a meal.

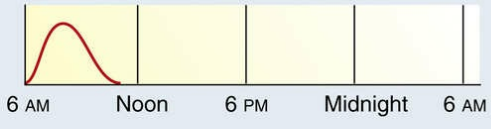
Short-acting regular insulin has an onset of action of 30 to 60 minutes. It is injected 30 to 45 minutes before a meal to ensure that the insulin is working at the same time as meal absorption. Because timing an injection 30 to 45 minutes before a meal is hard for some people to do with their lifestyles, the flexibility that rapid-acting insulins offer is preferred by those taking insulin with their meals.[8] Short-acting insulin is more likely to cause hypoglycemia because of a longer duration of action.

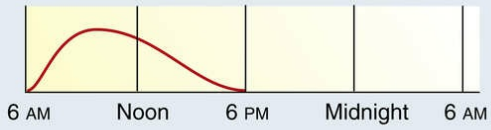
Long- or Intermediate-Acting (Basal) Background Insulin

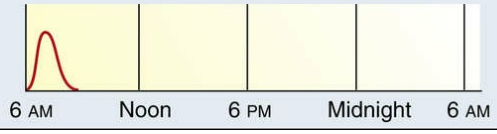
In addition to mealtime insulin, people with type 1 diabetes use a long- or intermediate-acting basal (background) insulin to maintain blood glucose levels in between meals and overnight. Without 24-hour background insulin, people with type 1 diabetes are more prone to developing DKA. Many people with type 2 diabetes who use OAs will need basal insulin to adequately manage blood glucose levels.

The long-acting insulins include degludec (Tresiba), detemir (Levemir), and glargine (Lantus, Toujeo, Basaglar).This type of insulin is released steadily and continuously. For most people, it does not have a peak of action. The action time for long-acting insulin varies (Fig. 48.4). Although they can be given once daily, detemir is often given twice daily. Because they lack peak action time, the risk for hypoglycemia from this type of insulin is greatly reduced. Glargine and detemir must not be diluted or mixed with any other insulin or solution in the same syringe. If OAs and long-acting insulin are not adequate to achieve glycemic goals, mealtime insulin may be added.









INSULIN PREPARATION	ONSET, PEAK, DURATION	EXAMPLE
Rapid acting lispro (Humalog) aspart (NovoLog) glulisine (Apidra)	*Onset:* 10–30 min *Peak:* 30 min–3 hr *Duration:* 3–5 hr	
Short acting Regular (Humulin R, Novolin R)	*Onset:* 30 min–1 hr *Peak:* 2–5 hr *Duration:* 5–8 hr	
Intermediate acting NPH (Humulin N, Novolin N)	*Onset:* 1.5–4 hr *Peak:* 4–12 hr *Duration:* 12–18 hr	
Long acting glargine (Lantus) detemir (Levemir) degludec (Tresiba)	*Onset:* 0.8–4 hr *Peak:* Less defined or no pronounced peak *Duration:* 16–24 hr	
Inhaled insulin Afrezza	*Onset:* 12–15 min *Peak:* 60 min *Duration:* 2.5–3 hr	

FIG. 48.4 Commercially available insulin preparations showing onset, peak, and duration of action. Individual patient responses to each type of insulin are different and affected by many different factors.

TABLE 48.3 Drug TherapyTypes of Insulin

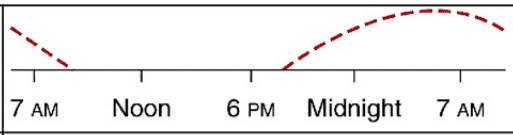
Classification	Examples
Rapid-acting insulin	aspart (NovoLog) glulisine (Apidra) lispro (Humalog)
Short-acting insulin	regular (Humulin R, Novolin R)
Intermediate-acting insulin	NPH (Humulin N, Novolin N)
Long-acting insulin	degludec (Tresiba) detemir (Levemir) glargine (Basaglar, Lantus, Toujeo) insulin glargine (Basaglar)
Combination therapy (premixed)	aspart protamine/aspart 70/30* (NovoLog Mix 70/30) degludec/aspart 70/30 (Ryzodeg) lispro protamine/lispro 75/25* (Humalog Mix 75/25) lispro protamine/lispro 50/50* (Humalog Mix 50/50) NPH/regular 70/30* (Humulin 70/30, Novolin 70/30) NPH/regular 50/50* (Humulin 50/50)
More concentrated insulin	Humulin R U-500 Toujeo U-300 (insulin glargine)
Inhaled insulin	Afrezza

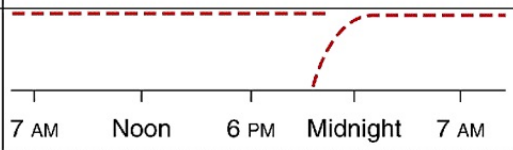
* These numbers refer to percentages of each type of insulin.

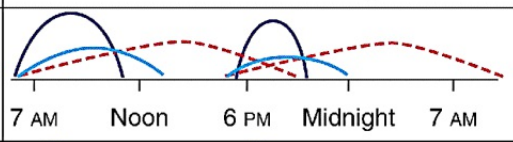
Intermediate-acting insulin (NPH) can be used as a basal insulin. It has a duration of 12 to 18 hours. The disadvantage of NPH is that it has a peak ranging from 4 to 12 hours, which can result in hypoglycemia. NPH can be mixed with short- and rapid-acting insulins. It should never be given IV.

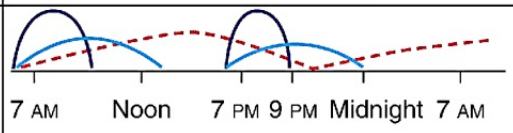
Check Your Practice

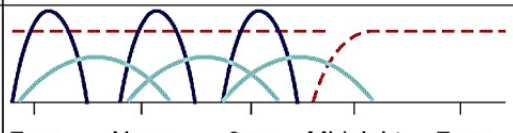
You are preparing your patient's order for NPH insulin. When you look at the vial, you notice that it is cloudy. You are thinking that you should throw away the vial because has become contaminated.

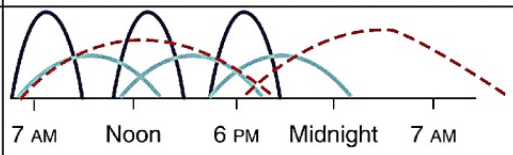












- Before you take this action, what should you do?

All insulins are clear solutions except NPH, lispro protamine, and aspart protamine. They are cloudy because they contain a protein called protamine, which makes them work longer. These insulins must be gently agitated before administration.

Combination Insulin Therapy

For those who want to use only 1 or 2 injections per day, a short- or rapid-acting insulin is mixed with intermediate-acting insulin in the same syringe. This allows the patient to have both mealtime and basal coverage without having to give 2 separate injections. Although this may be more appealing to the patient, most patients achieve optimal blood glucose levels with basal-bolus therapy. Patients may mix the 2 types of insulin themselves or use a commercially premixed formula or pen (Table 48.3). Premixed formulas offer convenience to patients, who do not have to draw up and mix insulin from 2 different vials. This is especially helpful to those who lack the visual, manual, or cognitive skills to mix insulin themselves. However, the convenience of these formulas limits the potential for optimal blood glucose levels because there is less opportunity for flexible dosing based on need.

TABLE 48.4 Drug TherapyInsulin Regimens

Regimen	Type of Insulin and Frequency	Action Profile	Comments
Once a day Single dose	Intermediate (NPH) *At bedtime*		1 injection should provide nighttime coverage.
	OR		
	Long-acting (degludec [Tresiba], detemir [Levemir], glargine [Lantus]) *In am or at bedtime*		1 injection may last up to 24 hr with fewer defined peaks and less chance for hypoglycemia. Does not cover postprandial blood glucose levels.
Twice a day Split-mixed dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast and at dinner*		2 injections provide coverage for 24 hr. Patient must eat at certain times to avoid hypoglycemia.
Three times a day Combination of mixed and single dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast* + Regular or rapid *Before dinner* + NPH *At bedtime*		3 injections provide coverage for 24 hr, especially during early AM hours. Decreased potential for 2–3 AM hypoglycemia
Basal-bolus Multiple dose	Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + Long-acting (degludec, detemir, or glargine) *Once or twice a day*		More flexibility is allowed at mealtimes and for amount of food intake. Good postprandial coverage. Preprandial blood glucose checks and following an individualized plan is necessary. Patients with type 1 diabetes require basal insulin to cover 24 hr. Most physiologic approach, except for pump
	OR		
	Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + **NPH *Twice a day***		

Rapid-acting (lispro, aspart, glulisine) insulin.

Short-acting (regular) insulin.

Intermediate-acting (NPH) or long-acting (glargine, detemir, degludec) insulin.

Storage of Insulin

As a protein, insulin has special storage considerations. Extreme temperatures alter the insulin molecule and can make it less effective.

Insulin vials and pens in use may be left at room temperature for up to 4 weeks unless the room temperature is higher than 86° F (30° C) or below freezing (less than 32° F [0° C]). Teach patients to avoid prolonged exposure to direct sunlight. A patient who is traveling in hot climates may store insulin in a thermos or cooler to keep it cool (not frozen). Store unopened insulin vials and pens in the refrigerator.

Patients who are traveling or caregivers of patients who are sight impaired or who lack the manual dexterity to fill their own syringes may prefill insulin syringes. Prefilled syringes with 2 different insulins are stable for up to 1 week when stored in the refrigerator. Syringes with only 1 type of insulin are stable up to 30 days.

Teach patients to store syringes in a vertical position with the needle pointed up to avoid clumping of suspended insulin in the needle. Before injection, gently roll prefilled syringes between the palms 10 to 20 times to warm the insulin and resuspend the particles. Some insulin combinations cannot be prefilled and stored because the mixture can alter the onset, action, and/or peak times of either insulin. Consult a reference as needed when mixing and prefilling different types of insulin.

Administration of Insulin

Routine doses of insulin are given by subcutaneous injection. Regular insulin can be given IV when immediate onset of action is desired. Insulin is not taken orally because it is inactivated by gastric fluids. Teach patients to avoid injecting insulin IM because rapid and unpredictable absorption could result in hypoglycemia.

Insulin Injection

The steps in giving a subcutaneous insulin injection are outlined in Table 48.5. Teach this technique to new insulin users and review it periodically with long-term users. Never assume that because the patient already uses insulin, they know and practice the correct insulin injection technique. The patient may not have understood prior instructions, or changes in eyesight may result in inaccurate preparation.[9] The patient may not see air bubbles in the syringe or

may improperly read the scale on the syringe. The patient receiving mixed insulins in the same syringe needs to learn the proper technique for combining them if commercially prepared premixed insulins are not used.

TABLE 48.5 Patient & Caregiver TeachingPreparing an Insulin Injection

Include the following instructions when teaching the patient and caregiver about insulin therapy:

1. Wash hands thoroughly.
2. Always inspect insulin bottle before using it. Make sure that it is the proper type and concentration, expiration date has not passed, and top of bottle is in perfect condition. Insulin solutions (except for NPH, lispro protamine, aspart protamine) should look clear and colorless. Discard if it appears discolored or if you see particles in the solution.
3. For intermediate-acting insulins (which are normally cloudy), gently roll the insulin bottle between the palms of hands to mix the insulin. Clear insulins do not need to be agitated.
4. Choose proper injection site (Fig. 48.5).
5. Ensure that the site is clean and dry.
6. Push the needle straight into the skin (90-degree angle). If you are very thin, muscular, or using an 8- or 12-mm needle, you may need to pinch the skin and/or use a 45-degree angle.
7. Push the plunger all the way down, leave needle in place for 5 sec to ensure that all insulin has been injected, and then remove needle.
8. Destroy and dispose of single-use syringe safely.

The speed with which peak serum concentrations are reached varies with the injection site. The fastest subcutaneous absorption is from the abdomen, followed by the arm, thigh, and buttock. Although the

abdomen is often the preferred injection site, other sites work well (Fig. 48.5). Caution the patient about injecting into a site that is to be exercised. For example, injecting into the thigh and then going jogging could increase body heat and circulation. This could increase the rate of insulin absorption and speed the onset of action, resulting in hypoglycemia.

Teach patients to rotate the injection within and between sites. This allows for better insulin absorption. It may be helpful to think of the abdomen as a checkerboard, with each ½-in square representing an injection site. Injections are rotated systematically across the board, with each injection site at least ½ to 1 inch away from the previous injection site. It can be helpful to inject fast-acting insulin into faster-absorbing sites and slow-acting insulin into slower absorbing sites.

Most commercial insulin is available as U100. This means that 1 mL contains 100 U of insulin. U100 insulin must be used with a U100-marked syringe. Disposable plastic insulin syringes are available in a variety of sizes, including 1.0, 0.5, and 0.3 mL. The 0.5-mL size may be used for doses of 50 U or less. The 0.3-mL syringe can be used for doses of 30 U or less. The 0.5- and 0.3-mL syringes are in 1-unit increments. This provides more accurate delivery when the dose is an odd number. The 1.0-mL syringe is necessary for patients who inject more than 50 U of insulin. The 1.0-mL syringe is in 2-unit increments. When patients change from a 0.3- or a 0.5-mL to a 1.0-mL syringe, tell them of the dose increment difference.

Insulin syringe needles come in 3 lengths: 6 mm (½ in), 8 mm (5⁄16 in), and 12.7 mm (½ in).[10] Needle gauges vary among syringes. The needle gauges available are 28, 29, 30, and 31. The higher the gauge number, the smaller the diameter, thus resulting in a more comfortable injection. Only the person using the syringe should recap the needle; never recap a needle used for a patient. To prepare the site, routine hygiene, such as washing with soap and rinsing with water, is adequate. This applies primarily to patient self-injection technique. When injection occurs in a health care agency, policy usually mandates site preparation with alcohol to prevent health care–associated infection (HAI).

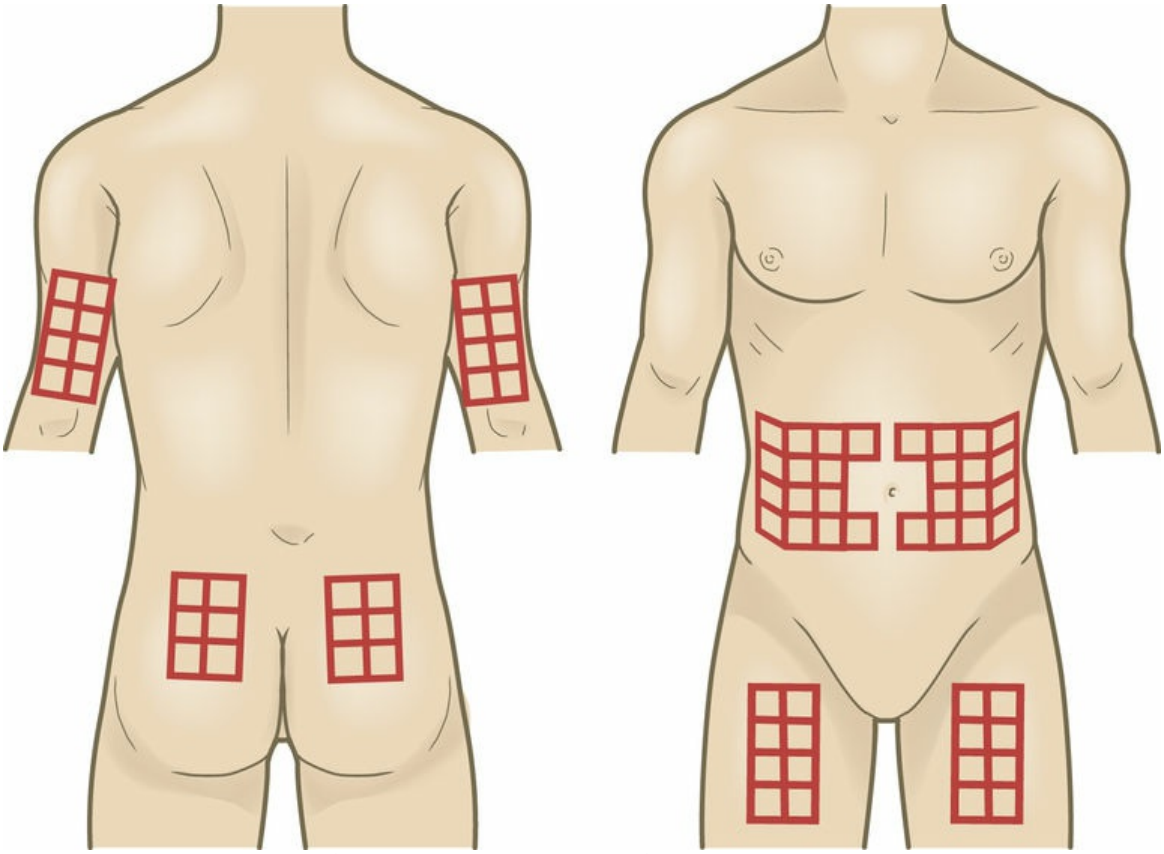


FIG. 48.5 Injection sites for insulin.

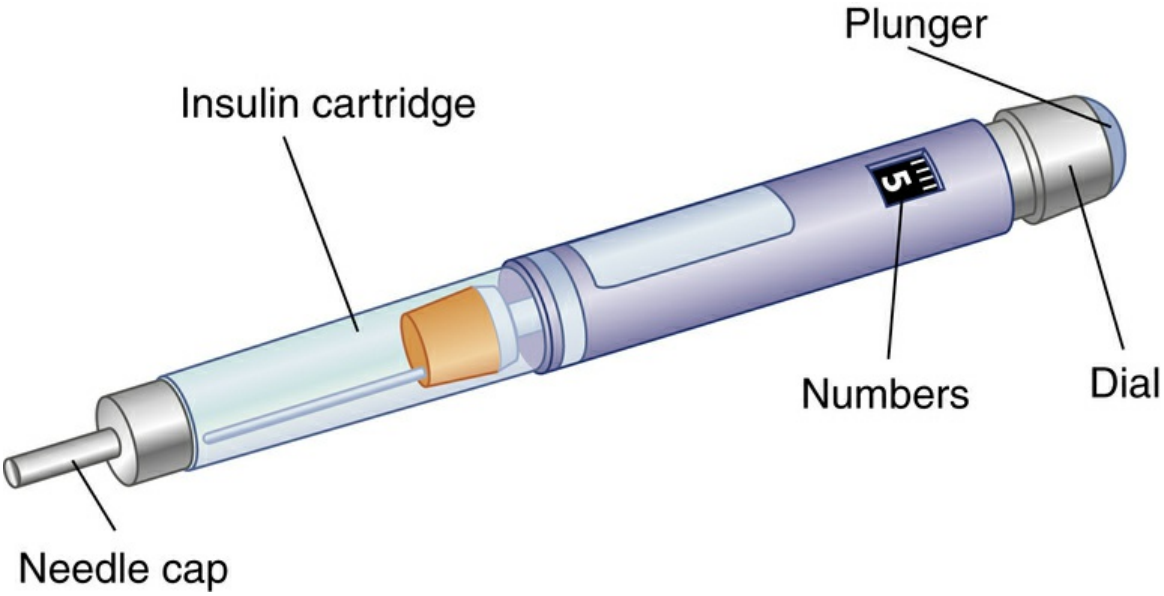

FIG. 48.6 Parts of insulin pen.

Insulin injections are typically given at a 90-degree angle. For extremely thin or muscular patients in the hospital, perform injections at a 45-degree angle. At home, patients inject at a 90-degree angle using the shortest needle desired. Pinching up of the skin to avoid IM injection is no longer done because of the use of short needles.

An insulin pen is a compact portable device loaded with an insulin cartridge that serves the same function as a needle and syringe (Fig. 48.6). Pen needles are available in lengths of 4 mm (5⁄32 in), 5 mm (3⁄16 in), 8 mm (5⁄16 in), and 12.7 mm (½ in) and in 3 gauges: 29, 31, and 32. Insulin pens offer convenience and flexibility. They are portable and compact, are more discreet than using a vial and syringe, and provide consistent and accurate dosing. For patients with poor vision, the pen is a better option, since they can hear the clicks of the pen as the dose is selected. Insulin pens come packaged with printed instructions, including pictures of the steps to take when using the pen. These instructions are helpful when teaching new users and reviewing technique with current users of a pen.

Insulin Pump

An *insulin pump* delivers a continuous subcutaneous insulin infusion through a small device worn on the belt, in a pocket, or under clothing. Insulin pumps use rapid-acting insulin. It is loaded into a reservoir or cartridge and connected via plastic tubing to a catheter inserted into the subcutaneous tissue. Insulet Corporation has an insulin pump that is a tubing-free system (Fig. 48.7). All insulin pumps are programmed to deliver a continuous infusion of rapid-acting insulin 24 hours a day, known as the *basal rate.* Basal insulin can be temporarily increased or decreased based on carbohydrate intake, activity changes, or illness. Pump users need different basal rates at different times of the day.

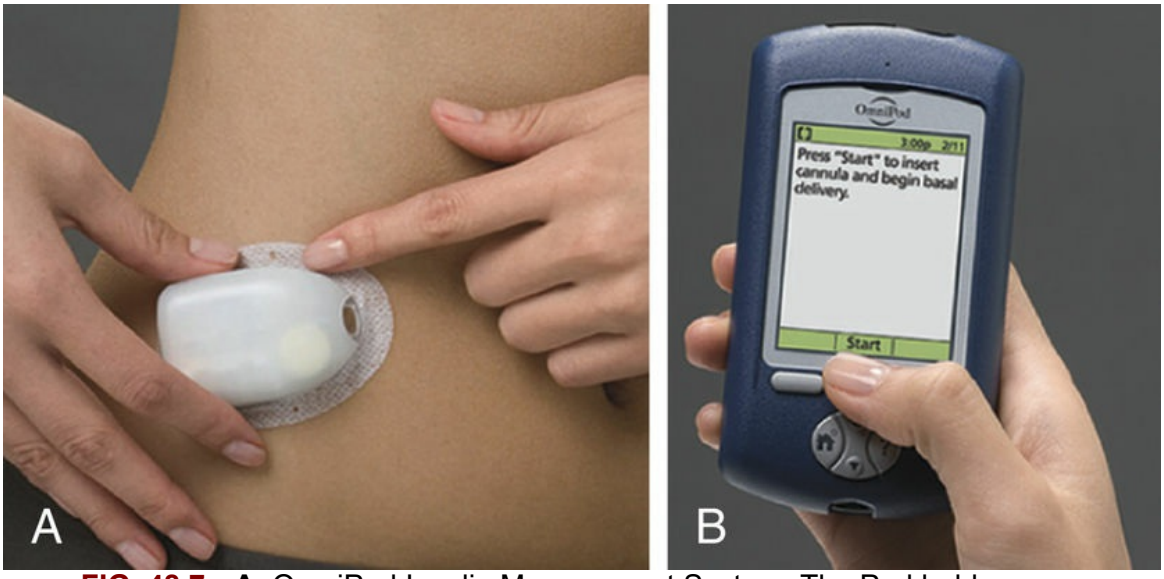

FIG. 48.7 **A,** OmniPod Insulin Management System. The Pod holds and delivers insulin. **B,** The Personal Diabetes Manager (PDM) wirelessly programs insulin delivery via the Pod. The PDM has a built-in glucose meter.
Courtesy of Insulet Corporation.

At mealtime, the user programs the pump to deliver a bolus infusion of insulin appropriate to the amount of carbohydrate ingested and an additional amount, if needed, to bring down or "correct" high preprandial blood glucose. The infusion set is changed every 2 to 3 days and placed in a new site to avoid infection and promote good insulin absorption. Insulin pump users check their blood glucose level at least 4 times per day and/or use a continuous glucose monitoring system. Monitoring 8 times or more per day is common.

A major advantage of the insulin pump is the potential for keeping blood glucose levels in a tighter range with a goal of eliminating both high and low glucose. With careful programming and constant monitoring, this is possible because insulin delivery is similar to the normal physiologic pattern. Pumps offer users more flexibility with meal and activity patterns. Potential challenges of insulin pump therapy include infection at the insertion site, an increased risk for DKA if the insulin infusion is disrupted, the cost of the pump and supplies, and being attached to a device.[11]

Problems With Insulin Therapy

Problems associated with insulin therapy include hypoglycemia, allergic reactions, lipodystrophy, hypertrophy, and the Somogyi effect. Hypoglycemia is discussed in detail later in this chapter. Guidelines for assessing patients treated with insulin and other GLAs are outlined in Table 48.6.

Allergic Reactions

Local inflammatory reactions to insulin may occur, such as itching, erythema, and burning around the injection site. Local reactions may be self-limiting within 1 to 3 months or may improve with a low dose of antihistamine. A true insulin allergy, which is rare, is manifested by a systemic response with urticaria and possibly anaphylactic shock. Preservative in the insulin and the latex or rubber stoppers on the vials have been implicated in allergic reactions.

Lipodystrophy and Hypertrophy

Lipodystrophy (loss of subcutaneous fatty tissue) may occur if the same injection sites are used frequently. The use of human insulin has significantly reduced the risk for lipodystrophy. *Atrophy*, which is uncommon, is the wasting of subcutaneous tissue and presents as indentations in injection sites. *Hypertrophy* happens more often and is a thickening of the subcutaneous tissue. It eventually regresses if the patient does not use the site for at least 6 months. Injecting into a hypertrophied site may result in erratic insulin absorption.

TABLE 48.6 Assessing the Patient Treated With Glucose-Lowering Agents

Category	Assessment
For Patient With Newly Diagnosed Diabetes or for Reevaluation of Medication Plan	
Affective	• What emotions and attitudes are patient and caregiver displaying concerning diagnosis of diabetes and insulin or OA treatment?
Cognitive	• Is patient or caregiver able to understand why insulin or OAs are being used as part of diabetes management? • Is patient or caregiver able to understand concepts of asepsis, combining insulins, and side effects of medications? • Is patient able to remember to take >1 dose/day? • Does patient take medications at right times in relation to meals?
Psychomotor	• Is patient or caregiver physically able to prepare and give accurate doses of the drugs?
For Patient Follow-up	
Effectiveness of therapy	• Is patient having symptoms of hyperglycemia? • Does blood glucose record show blood glucose levels in or out of the target range? • Is A1C in a healthy range and consistent with glucose records?
Self-management behaviors	• If patient is having hyperglycemia or hypoglycemia, how are those episodes managed? • Has patient determined reason for hyperglycemia or hypoglycemia? • How much insulin or OA is patient taking and at what time of day? Is patient adjusting insulin dose? Under what circumstances and by how much? • Has the exercise pattern changed? • Is patient making healthy food choices? Are meals taken at times corresponding to peak insulin action?
Side effects of therapy	• Is atrophy or hypertrophy present at injection sites? • Has patient had hypoglycemia? If so, how often? What time of day? What were the symptoms of hypoglycemia? • Are there reports of nightmares, night sweats, or early morning headaches? • Has patient had a skin rash or GI upset since taking OAs? • Has patient gained or lost weight?

Somogyi Effect and Dawn Phenomenon

Hyperglycemia in the morning may be due to the **Somogyi effect**. A high dose of insulin causes a decline in blood glucose levels during the night. As a result, counterregulatory hormones (e.g., glucagon, epinephrine, GH, cortisol) are released. They stimulate lipolysis, gluconeogenesis, and glycogenolysis, which in turn cause rebound hyperglycemia. The danger of this effect is that when blood glucose levels are measured in the morning, hyperglycemia is apparent and the patient (or the HCP) may increase the insulin dose.

If a patient has morning hyperglycemia, checking blood glucose levels between 2:00 and 4:00 AM for hypoglycemia will help determine if the cause is the Somogyi effect. The patient may report headaches on awakening and recall having night sweats or nightmares.

The **dawn phenomenon** is also characterized by hyperglycemia that is present on awakening. Two counterregulatory hormones (GH and cortisol), which are excreted in increased amounts in the early morning hours, may be the cause of this phenomenon. The dawn phenomenon affects many people with diabetes and tends to be most severe when GH is at its peak in adolescence and young adulthood.

Careful assessment is needed to diagnose the Somogyi effect or

dawn phenomenon because the treatment for each differs. The treatment for Somogyi effect is a bedtime snack, reducing the dose of insulin, or both. The treatment for dawn phenomenon is an increase in insulin or an adjustment in administration time. Your assessment must include insulin dose, injection sites, and variability in the time of meals or insulin administration. Ask the patient to measure and document bedtime, nighttime (between 2:00 and 4:00 AM), and morning fasting blood glucose levels on several occasions. If the predawn levels are less than 60 mg/dL (3.3 mmol/L) and signs and symptoms of hypoglycemia are present, the insulin dosage should be reduced. If the 2:00 to 4:00 AM blood glucose is high, the insulin dosage should be increased. Counsel the patient on appropriate bedtime snacks.

Inhaled Insulin

Afrezza is a rapid-acting inhaled insulin. It is given at the beginning of each meal or within 20 minutes after starting a meal. Afrezza must be used in combination with long-acting insulin in patients with type 1 diabetes. It should not be used to treat diabetic ketoacidosis. Patients with chronic lung disease, such as asthma or COPD, or who smoke, should not use Afrezza because bronchospasm can occur. Other common adverse reactions are hypoglycemia, cough, and throat pain or irritation.

Drug Therapy: Oral and Noninsulin Injectable Agents

OAs and noninsulin injectable agents work to improve the mechanisms by which the body makes and uses insulin and glucose. These drugs primarily work on 3 defects of type 2 diabetes: (1) insulin resistance, (2) decreased insulin production, and (3) increased hepatic glucose production (Fig. 48.8). These drugs may be used in combination with agents from other classes or with insulin to achieve blood glucose goals. OAs and noninsulin injectable agents are listed in Table 48.7.

Biguanides

The most widely used OA is metformin. It is the only drug in the biguanide class available in the United States. Metformin is the most effective first-line treatment for type 2 diabetes.[8] Forms of metformin include Glucophage (immediate release), Glucophage XR (extended release), Fortamet (extended release), and Riomet (liquid). The primary action of metformin is to reduce glucose production by the liver. It enhances insulin sensitivity at the tissue level and improves glucose transport into the cells. It also has beneficial effects on plasma lipids.

Because it may cause moderate weight loss, metformin may be useful for people with type 2 diabetes and prediabetes who are overweight or obese. It is also used to prevent type 2 diabetes in those with prediabetes who are younger than age 60 and have risk factors, such as hypertension or a history of gestational diabetes.

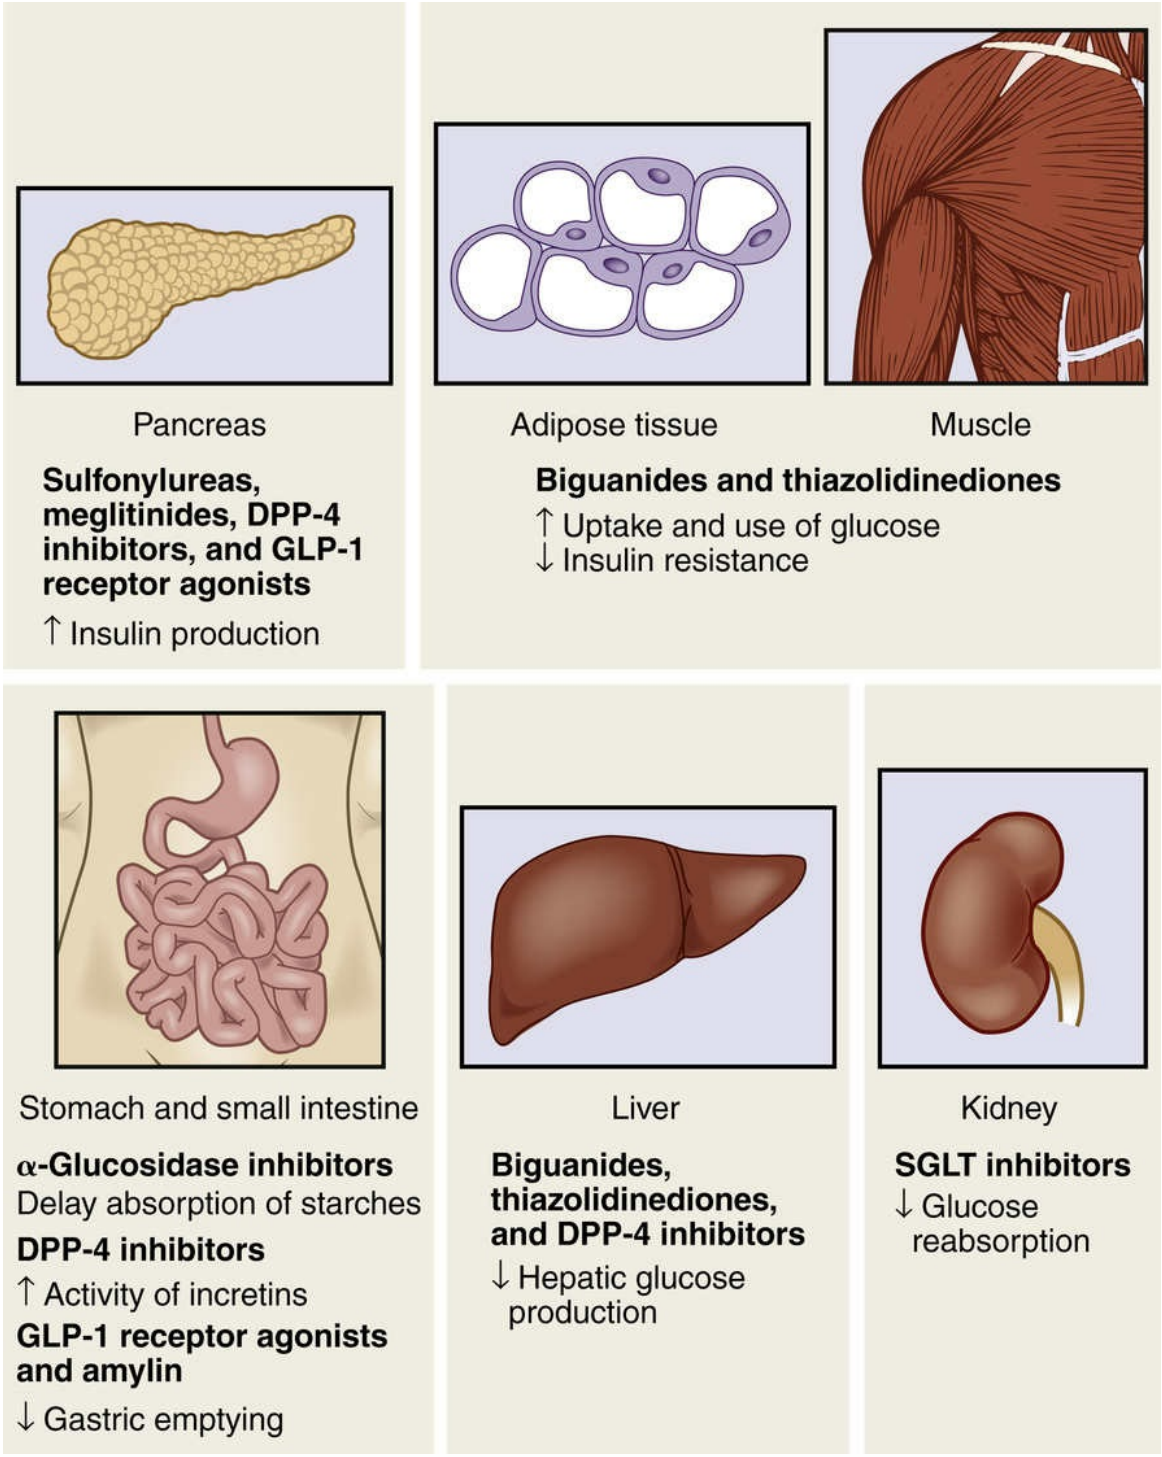

FIG. 48.8 Sites and mechanisms of action of type 2 diabetes drugs. *DDP-4,* Dipeptidyl peptidase; *GLP-1,* glucagon-like peptide-1; *SGLT,* sodium-glucose co-transporter.

TABLE 48.7 Drug TherapyOral Agents and Noninsulin Injectable Agents

Type	Mechanism of Action	Side Effects
Oral Agents		
α-Glucosidase Inhibitors		
acarbose (Precose) **miglitol (Glyset)**	Delays absorption of complex carbohydrates (starches) from GI tract	Gas, abdominal pain, diarrhea
Biguanides		
metformin (Fortamet Glucophage, Glucophage XR, Glumetza, Riomet)	↓ Rate of hepatic glucose production. ↑ Insulin sensitivity. Improves glucose uptake by tissues, especially muscles	Diarrhea, lactic acidosis. Must be held 1–2 days before IV contrast media given and for 48 hr after
Dipeptidyl Peptidase-4 (DPP-4) Inhibitors		
alogliptin (Nesina) **linagliptin (Tradjenta)** **saxagliptin (Onglyza)** **sitagliptin (Januvia)**	Enhances activity of incretins. Stimulates release of insulin from pancreatic β-cells. ↓ Hepatic glucose production	Pancreatitis, allergic reactions
Dopamine Receptor Agonists		
bromocriptine (Cycloset)	Activates dopamine receptors in central nervous system. Unknown how it improves glucose levels	Orthostatic hypotension
Meglitinides		
nateglinide (Starlix) **repaglinide (Prandin)**	Stimulates a rapid and short-lived release of insulin from the pancreas	Weight gain, hypoglycemia
Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors		
canagliflozin (Invokana) **dapagliflozin (Farxiga)** **empagliflozin (Jardiance)** **ertugliflozin (Steglatro)**	↓ Renal glucose reabsorption and ↑ urinary glucose excretion	↑ Risk for genital infections and UTIs. Hypoglycemia
Sulfonylureas		
glimepiride (Amaryl) **glipizide (Glucotrol, Glucotrol XL)** **glyburide (DiaBeta, Glynase)**	Stimulates release of insulin from pancreatic islets. ↓ Glycogenolysis and gluconeogenesis. Enhances cellular sensitivity to insulin	Weight gain, hypoglycemia
Thiazolidinediones		
pioglitazone (Actos) **rosiglitazone (Avandia)**	↑ Glucose uptake in muscle. ↓ Endogenous glucose production	Weight gain, edema *pioglitazone:* May ↑ risk for bladder cancer and worsen HF. *rosiglitazone:* May ↑ risk for cardiovascular events (e.g., MI, stroke)
Combination Oral Therapy		
Actoplus Met, Actoplus Met XR	Same as for metformin and pioglitazone	See side effects for individual drugs
Duetact	Same as for pioglitazone and glimepiride	
Glucovance	Same as for metformin and glyburide	
Glyxambi	Same as for empagliflozin and linagliptin	
Janumet, Janumet XR	Same as for metformin and sitagliptin	
Jentadueto	Same as for linagliptin and metformin	
Kazano	Same as for alogliptin and metformin	
Kombiglyze	Same as for saxagliptin and metformin	
Oseni	Same as for alogliptin and pioglitazone	
PrandiMet	Same as for metformin and repaglinide	
Segluromet	Same as for metformin and ertugliflozin	
Steglujan	Same as for sitagliptin and ertugliflozin	
Synjardy	Same as metformin and empagliflozin	
Xigduo	Same as for dapagliflozin and metformin	
Noninsulin Injectable Agents		
Amylin Analogs		
pramlintide (Symlin)	Slows gastric emptying, decreases glucagon secretion and endogenous glucose output from liver. ↑ Satiety	Hypoglycemia, nausea, vomiting, ↓ appetite, headache
Glucagon-Like Peptide-1 (GLP-1) Receptor Agonists		

Type	Mechanism of Action	Side Effects
albiglutide (Tanzeum) dulaglutide (Trulicity) exenatide (Byetta) exenatide extended-release (Bydureon) liraglutide (Victoza) lixisenatide (Adlyxin) semaglutide (Ozempic)	Stimulates release of insulin, ↓ glucagon secretion, and slow gastric emptying. ↑ Satiety	Nausea, vomiting, hypoglycemia, diarrhea, headache

Patients who are undergoing surgery or radiologic procedures that involve the use of a contrast medium need to temporarily discontinue metformin before surgery or the procedure. This reduces the risk of contrast-induced kidney injury (CIN) (see Chapter 44). They should not resume the metformin until 48 hours afterward, once their serum creatinine has been checked and is normal.

Drug Alert

Metformin

- Do not use in patients with kidney disease, liver disease, or heart failure. Lactic acidosis is a rare complication of metformin accumulation.
- IV contrast media that contain iodine pose a risk for CIN, which could worsen metformin-induced lactic acidosis.
- To reduce risk for CIN, discontinue metformin 2 days before the procedure.
- May be resumed 48 hours after the procedure, assuming kidney function is normal.
- Do not use in people who drink excess amounts of alcohol.
- Take with food to minimize GI side effects.

Sulfonylureas

Sulfonylureas include glimepiride (Amaryl), glipizide (Glucotrol,

Glucotrol XL), and glyburide (DiaBeta, Glynase). The primary action of sulfonylureas is to increase insulin production by the pancreas. Therefore hypoglycemia is the major side effect.

Meglitinides

Like sulfonylureas, nateglinide (Starlix) and repaglinide (Prandin) increase insulin production by the pancreas. However, because they are more rapidly absorbed and eliminated than sulfonylureas, they are less likely to cause hypoglycemia. When taken just before meals, pancreatic insulin production increases during and after the meal, mimicking the normal response to eating. Teach patients to take meglitinides any time from 30 minutes before each meal right up to the time of the meal. These drugs should not be taken if a meal is skipped.

α-Glucosidase Inhibitors

These drugs, also known as "starch blockers," work by slowing down carbohydrate absorption in the small intestine. Acarbose (Precose) and miglitol (Glyset) are the available drugs in this class. Taken with the first bite of each main meal, they are most effective in lowering postprandial blood glucose. Their effectiveness is measured by checking 2-hour postprandial glucose levels.

Thiazolidinediones

Thiazolidinediones, sometimes called "insulin sensitizers," include pioglitazone (Actos) and rosiglitazone (Avandia). They are most effective for people who have insulin resistance. These agents improve insulin sensitivity, transport, and use at target tissues. Because they do not increase insulin production, they do not cause hypoglycemia when used alone. However, these drugs are rarely used today because of their adverse effects. Rosiglitazone is associated with adverse cardiovascular events (e.g., myocardial infarction [MI]) and can be obtained only through restricted access programs. Pioglitazone can worsen heart failure (HF) and is associated with an increased risk for

bladder cancer.

Dipeptidyl Peptidase-4 (DPP-4) Inhibitors

Normally, the intestines release incretin hormones throughout the day. When glucose levels are normal or elevated, incretins increase insulin synthesis and release from the pancreas and decrease hepatic glucose production. Levels increase in response to a meal. The 2 main incretin hormones are gastric inhibitory peptide [GIP] and glucagon-like peptide-1 [GLP-1]). They are quickly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4).

DPP-4 inhibitors (also known as *gliptins*) come in pill form. They include alogliptin (Nesina), linagliptin (Tradjenta), saxagliptin (Onglyza), and sitagliptin (Januvia). DPP-4 inhibitors block the action of DPP-4, which inactivates incretin hormones. The result is an increase in insulin release, decrease in glucagon secretion, and decrease in hepatic glucose production. Since the DPP-4 inhibitors are glucose dependent, they lower the potential for hypoglycemia. The main benefit of these drugs over other medications with similar effects is the absence of weight gain as a side effect.

Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors

Normally, sodium glucose transporters reabsorb glucose from the kidneys back into the blood stream. Sodium-glucose co-transporter 2 (SGLT2) inhibitors work by blocking the reabsorption of glucose by the kidney, increasing urinary glucose excretion. Drugs in this class include canagliflozin (Invokana), dapagliflozin (Farxiga), and empagliflozin (Jardiance).

Dopamine Receptor Agonist

Bromocriptine (Cycloset) is a dopamine receptor agonist that improves glucose levels. The mechanism of action is unknown. We think patients with type 2 diabetes have low levels of dopamine activity in the morning. These low dopamine levels may interfere with the body's ability to control blood glucose. Bromocriptine increases

dopamine receptor activity. It can be used alone or as an add-on to another type 2 diabetes treatment.

Combination Oral Therapy

Many combination drugs are currently available (Table 48.7). These drugs combine 2 different classes of medications to treat diabetes. One advantage of combination therapy is that the patient takes fewer pills, thus improving medication taking.

Glucagon-Like Peptide-1 Receptor Agonists

Albiglutide (Tanzeum), dulaglutide (Trulicity), exenatide (Byetta), exenatide extended-release (Bydureon), liraglutide (Victoza), and lixisenatide (Adlyxin) simulate GLP-1 (an incretin hormone), which is decreased in people with type 2 diabetes. These drugs increase insulin synthesis and release from the pancreas, inhibit glucagon secretion, slow gastric emptying, and reduce food intake by increasing satiety.

These drugs may be used as monotherapy or adjunct therapy for patients with type 2 diabetes who have not achieved optimal glucose levels on OAs. These drugs are given using a subcutaneous injection in a prefilled pen. Byetta is given twice daily. Liraglutide is given once daily. Albiglutide, dulaglutide, and Bydureon are given once every 7 days. The delayed gastric emptying that occurs with these drugs may affect the absorption of oral medications. Advise patients to take fast-acting oral medications at least 1 hour before injecting a GLP-1 agonist drug.

Drug Alert

Exenatide (Byetta)

- Acute pancreatitis and kidney problems have been associated with its use.

Drug Alert

Liraglutide (Victoza) and Dulaglutide (Trulicity)

- Do not use in patients with a personal or family history of medullary thyroid cancer.
- Acute pancreatitis has been associated with its use.

Amylin Analogs

Pramlintide (Symlin) is the only available amylin analog. Amylin, a hormone secreted by the β cells of the pancreas in response to food intake, slows gastric emptying, reduces glucagon secretion, and increases satiety. Pramlintide is used in addition to mealtime insulin in patients with type 1 or type 2 diabetes who have elevated blood glucose levels on insulin therapy. It is only used concurrently with insulin and is not a replacement for insulin. Pramlintide is given before meals subcutaneously into the thigh or abdomen. It cannot be injected into the arm because absorption from this site is too variable. The drug cannot be mixed in the same syringe with insulin.

The concurrent use of pramlintide and insulin increases the risk for severe hypoglycemia during the 3 hours after injection, especially in patients with type 1 diabetes. Teach patients to eat a meal with at least 250 calories and keep a form of fast-acting glucose on hand in case hypoglycemia develops. When pramlintide is used, the bolus dose of insulin should be reduced.

Drug Alert

Pramlintide (Symlin)

- Can cause severe hypoglycemia when used with insulin.

Other Drugs Affecting Blood Glucose Levels

Both the patient and the HCP must be aware of drug interactions that can potentiate hypoglycemia and hyperglycemia effects. For example, β-adrenergic blockers can mask symptoms of hypoglycemia and prolong the hypoglycemic effects of insulin. Thiazide and loop diuretics can worsen hyperglycemia by inducing potassium loss, although low-dose thiazide therapy is usually considered safe.

Nutrition Therapy

Individualized nutrition therapy, consisting of counseling, education, and ongoing monitoring, is a cornerstone of care for people with diabetes and prediabetes.[12] Changing eating habits can be challenging for many people. Achieving nutrition goals requires a coordinated team effort that considers the person's behavioral, cognitive, socioeconomic, cultural, and religious backgrounds and preferences. Because of these complexities, it is recommended that a dietitian with expertise in diabetes management work with the person who has diabetes. The dietitian starts with a nutrition assessment and develops an individualized food plan. Other team members may include nurses, certified diabetes educators (CDEs), clinical nurse specialists, social workers, and other HCPs.

Guidelines from the ADA state that, within the context of an overall healthy eating plan, a person with diabetes can eat the same foods as a person who does not have diabetes. This means that the same principles of healthy nutrition that apply to the general population also apply to the person with diabetes. Table 48.8 describes nutrition guidelines for patients with diabetes. According to the ADA, the overall goal of nutrition therapy is to help people with diabetes make healthy food choices that will lead to achieving and/or maintaining safe and healthy blood glucose levels. Additional specific goals include:

- Maintain blood glucose levels as close to normal as safely possible to prevent or reduce the risk for complications of

diabetes.

- Achieve lipid profiles and BP levels that reduce the risk for CVD.
- Prevent or slow the rate of development of chronic complications of diabetes by modifying nutrient intake and lifestyle.
- Address individual nutrition needs while considering personal and cultural preferences and respecting the person's willingness or ability to change eating and dietary habits.
- Maintain the pleasure of eating by encouraging a variety of healthy food choices.

TABLE 48.8 Nutrition TherapyDiabetes

Component	Recommendations
Total carbohydrate	• Include carbohydrate from fruits, vegetables, grains, legumes, and low-fat milk • Monitor by carbohydrate counting, exchange lists, or use of appropriate proportions • Fiber intake at 25–30 g/day • Nonnutritive sweeteners are safe when consumed within FDA daily intake levels
Protein	• Individualize goals • High-protein diets are not recommended for weight loss
Fat	• Individualize goals • Minimize *trans* fat • Dietary cholesterol <200 mg/day • ≥2 servings of fish per week to provide polyunsaturated fatty acids
Alcohol	• Limit to moderate amount (maximum 1 drink per day for women, 2 drinks per day for men) • Consume alcohol with food to reduce risk for nocturnal hypoglycemia in those using insulin or drugs that promote insulin secretion • Moderate alcohol consumption has no acute effect on glucose and insulin concentrations • Carbohydrates taken with the alcohol (mixed drink) may raise blood glucose

Type 1 Diabetes

People with type 1 diabetes base their meal planning on usual food intake and preferences balanced with insulin and exercise patterns. The patient coordinates insulin dosing with eating habits and activity pattern in mind. Day-to-day consistency in timing and amount of food eaten makes it much easier to manage blood glucose levels, especially

for those using conventional, fixed insulin regimens. Patients using rapid-acting insulin can adjust the dose before each meal based on the current blood glucose level and the carbohydrate content of the meal. Intensified insulin therapy, such as multiple daily injections or the use of an insulin pump, allows considerable flexibility in food selection and can be adjusted for changes from usual eating and exercise habits. This does not diminish or replace the need for healthy food choices and a well-balanced diet.

Type 2 Diabetes

Nutrition therapy in type 2 diabetes emphasizes achieving glucose, lipid, and BP goals. Modest weight loss has been associated with improved insulin sensitivity. Therefore weight loss is recommended for all persons with diabetes who are overweight or obese.[13]

There is no one proven strategy or method. A nutritionally adequate meal plan with appropriate serving sizes, a reduction of saturated and *trans* fats, and low carbohydrates can decrease calorie consumption. Spacing meals is another strategy that spreads nutrient intake throughout the day. A weight loss of 5% to 7% of body weight often improves blood glucose levels, even if desirable body weight is not achieved. Weight loss is best achieved by a moderate decrease in calories and an increase in caloric expenditure. Regularly exercising and adopting new behaviors and attitudes can promote long-term lifestyle changes. Monitoring blood glucose levels, A1C, lipids, and BP gives feedback on how well the goals of nutrition therapy are being met.

Food Composition

A healthy balance of nutrients is essential to maintain blood glucose levels and overall health. Energy from food intake can be balanced with the patient's energy output. Teach patients to plan their individual meal plan with their lifestyle and health goals in mind. The following are general recommendations for nutrient balance.

Carbohydrate

Carbohydrates include sugars, starches, and fiber. They are an important source of energy, fiber, vitamins, and minerals and needed by all people, including those with diabetes. Foods containing carbohydrate from whole grains, fruits, vegetables, and low-fat dairy are part of a healthy meal plan. The ADA recommends individualizing carbohydrate intake as there is no ideal amount for all people with diabetes.

All persons benefit from including dietary fiber as part of a healthy meal plan. The current recommendation for the general population is 25 to 30 g/day.[13]

Nutritive and nonnutritive sweeteners may be included in a healthy meal plan in moderation. Nonnutritive sweeteners include the sugar substitutes saccharine, aspartame, sucralose, stevia, neotame, and acesulfame-K.

Fat

Dietary fat provides energy, transports fat-soluble vitamins, and provides essential fatty acids. The ADA recommends individualizing saturated fat intake. Less than 200 mg/day of cholesterol and limited *trans* fats are recommended as part of a healthy meal plan. Decreasing fat and cholesterol intake helps reduce the risk for CVD. Healthy fats are those that come from plants, such as olives, nuts, and avocados.

Protein

The amount of daily protein in the diet for people with diabetes and normal renal function is the same as for the general population. The ADA recommends individualizing protein intake. Teach patients to choose lean protein whenever possible.

Alcohol

Alcohol inhibits gluconeogenesis (breakdown of glycogen to glucose) by the liver. This can cause severe hypoglycemia in patients on insulin or OAs that increase insulin secretion. Create a trusting environment in which patients feel comfortable being honest about their alcohol

use because its use can make blood glucose harder to manage.

Moderate alcohol consumption can be safely incorporated into the meal plan if the person is monitoring blood glucose levels and not at risk for other alcohol-related problems. Moderate consumption is defined as 1 drink per day for women and 2 drinks per day for men. A patient can reduce the risk for alcohol-induced hypoglycemia by eating carbohydrates when drinking alcohol. On the other hand, mixed drinks often contain sweetened mixers and can increase blood glucose levels. To decrease the carbohydrate content, recommend using sugar-free mixes and drinking dry, light wines.

Patient Teaching Related to Nutrition Therapy

Most often, the dietitian initially teaches the principles of nutrition management. Whenever possible, work with dietitians as part of an interprofessional diabetes care team. Some patients who have limited insurance coverage or live in remote areas do not have access to a dietitian. In these cases, you may need to assume responsibility for teaching basic nutrition principles to patients with diabetes.

Carbohydrate counting is a meal planning technique used to keep track of the amount of carbohydrate eaten with each meal and per day. Teach patients to keep carbohydrate intake within a healthy range. The amount of total carbohydrate per day depends on blood glucose levels, age, weight, activity level, patient preference, and prescribed medications. A serving size of carbohydrate is 15 g. A typical adult usually starts with 45 to 60 g of carbohydrate per meal. For some patients, insulin doses are tailored to the amount of carbohydrate foods that a patient will consume at the meal, with a set number of units of insulin given per gram of carbohydrate (e.g., 1 U/15 g carbohydrate, 2 U/25 g carbohydrate). Teach the patient about the foods that contain carbohydrate, how to read food labels, and appropriate serving sizes.

Diabetes exchange lists are another method for meal planning. Instead of counting carbohydrate, the person is given a meal plan with specific numbers of helpings from a list of exchanges for each meal and snack. The exchanges are starches, fruits, milk, meats, vegetables,

fats, and free foods. The patient chooses foods from the various exchanges based on the prescribed meal plan. This method may be easier for some patients than carbohydrate counting. It also encourages a well-balanced meal plan. Another advantage is that this approach helps the patient limit portion sizes and overall food intake, an important part of weight management.

MyPlate was developed by the U.S. Department of Agriculture (USDA) to represent national nutrition guidelines for people with or without diabetes. This simple method helps the patient see the amount of vegetables, starch, and meat that fills a 9-in plate. The recommendation is that each meal has half of the plate filled with nonstarchy vegetables, one fourth filled with a starch, and one fourth filled with a protein *(www.diabetes.org/food-and-fitness/food/planning-meals/create-your-plate)*. An 8-oz glass of nonfat milk and a small piece of fresh fruit complete the meal.[12]

Whenever possible, include family members and caregivers in nutrition education and counseling, especially the person who cooks for the household. However, the responsibility for maintaining a healthy eating plan still belongs to the person with diabetes. Reliance on another person to make health decisions interferes with the patient's ability to develop self-care skills, which are essential in managing diabetes. Foster independence, even in patients with visual or cognitive impairment. It is important to discuss traditional foods with the patient. Individualize food choices considering the patient's preferences and culturally appropriate foods.

Exercise

Regular, consistent exercise is an essential part of diabetes and prediabetes management.[14] The ADA recommends that people with diabetes engage in at least 150 min/wk (30 minutes, 5 days/week) of a moderate-intensity aerobic physical activity (Table 48.9). The ADA encourages people with type 2 diabetes to perform resistance training 3 times a week unless contraindicated.[15]

TABLE 48.9 Activities That Affect Caloric Expenditure

Light Activity (100–200 kcal/hr)	Moderate Activity (200–350 kcal/hr)	Vigorous Activity (400–900 kcal/hr)
• Fishing	• Active housework	• Aerobic exercise
• Light housework	• Bicycling (light)	• Bicycling (vigorous)
• Secretarial work	• Bowling	• Hard labor
• Teaching	• Dancing	• Ice skating
• Walking casually	• Gardening	• Outdoor sports
	• Golf	• Running
	• Roller skating	• Soccer
	• Walking briskly	• Tennis
		• Wood chopping

Exercise decreases insulin resistance and can have a direct effect on lowering blood glucose levels. It contributes to weight loss, which further decreases insulin resistance. The therapeutic benefits of regular physical activity may result in a decreased need for diabetes medications to reach target blood glucose goals in people with type 2 diabetes. Regular exercise may also help reduce triglyceride and low-density lipoprotein (LDL) cholesterol levels, increase HDL, reduce BP, and improve circulation.

Encourage patients to be active every day and to seek medical clearance before starting a new or more intensive exercise program. Patients start slowly with gradual progression toward the desired goal. Patients who use insulin, sulfonylureas, or meglitinides are at increased risk for hypoglycemia when they increase physical activity, especially if they exercise at the time of peak drug action or eat too little to maintain adequate blood glucose levels. This can also occur if a normally sedentary patient with diabetes has an unusually active day.

The glucose-lowering effects of exercise can last up to 48 hours after the activity, so it is possible for hypoglycemia to occur long after the activity. Patients who use drugs that can cause hypoglycemia should exercise about 1 hour after a meal or have a 10- to 15-g carbohydrate snack and check their blood glucose before exercising. It is preferable

not to increase caloric intake for exercise. If needed, they can eat small carbohydrate snacks every 30 minutes during exercise to prevent hypoglycemia. Patients using drugs that place them at risk for hypoglycemia should always carry a fast-acting source of carbohydrate, such as glucose tablets or hard candies, when exercising. If they have frequent lows from exercise, the medication dose may need to be lowered. Table 48.10 describes exercise guidelines for patients with diabetes.

TABLE 48.10 Patient & Caregiver TeachingExercise for Patients With Diabetes

Include the following information in the exercise teaching plan for the patient and caregiver:

1. Exercise does not have to be vigorous to be effective. The blood glucose-reducing effects of exercise can be reached with activity such as brisk walking.
2. Choose exercises that are enjoyable to foster regularity.
3. Use properly fitting footwear to avoid rubbing or injury.
4. The exercise session includes a warm-up period and a cool-down period. Start the exercise program gradually and increase slowly.
5. Exercise is best done after meals, when the blood glucose level is rising.
6. Exercise plans are patient specific and monitored by the HCP.
7. Monitor blood glucose levels before, during, and after exercise to determine the effect exercise has on blood glucose levels at specific times of the day.
8. Before exercise, if blood glucose ≤100 mg/dL, eat a 15-g carbohydrate snack. After 15 to 30 min, recheck blood glucose levels. Delay exercise if <100 mg/dL.
9. Before exercise, if blood glucose ≥250 mg/dL in a person with type 1 diabetes and ketones are present, delay vigorous activity

until ketones are gone. Drink fluids.
10. Exercise-induced hypoglycemia may occur several hours after the completion of exercise.
11. Planned or spontaneous exercise can still occur when taking a glucose-lowering medication.
12. It is important to compensate for extensive planned and spontaneous activity by monitoring blood glucose levels and making adjustments in the insulin dose (if taken) and food intake.

The body can perceive strenuous activity as a stress, causing a release of counterregulatory hormones and a temporary elevation of blood glucose. In a person with type 1 diabetes who has hyperglycemia and ketones, exercise can worsen these conditions. Teach these patients to delay activity if the blood glucose level is over 250 mg/dL and ketones are present in the urine. If hyperglycemia is present without ketosis, it is not necessary to postpone exercise.[12]

Monitoring Blood Glucose

Self-monitoring of blood glucose (SMBG) is a critical part of diabetes management. By providing a current blood glucose reading, SMBG lets the patient make decisions about food intake, activity patterns, and medication dosages. It produces accurate records of daily glucose fluctuations and trends and alerts the patient to acute episodes of hyperglycemia and hypoglycemia. SMBG provides patients with a tool for achieving and maintaining specific glycemic goals. It is recommended for all patients who use insulin to manage their diabetes. Other patients with diabetes use SMBG to help achieve and maintain glycemic goals and monitor for acute fluctuations in blood glucose related to drugs, food, and exercise.

The frequency of SMBG depends on several factors. These include the patient's glycemic goals, type of diabetes, medication regimen, patient's ability to check blood glucose independently, access to supplies and equipment, and patient's willingness and ability to do

so. The recommendation for patients who use multiple insulin injections or insulin pumps is to monitor their blood glucose 4 to 8 times each day. Patients using less frequent insulin injections, noninsulin therapy, or nutrition management will monitor as often as needed to achieve their glycemic goals.[9]

Patients who perform SMBG use portable blood glucose monitors. A wide variety of blood glucose monitors are available (Fig. 48.9). Disposable lancets are used to get a small drop of capillary blood (usually from a finger stick) that is placed in a reagent strip. After a specified time, the monitor displays a digital reading of the capillary blood glucose value. The technology of SMBG is rapidly changing. Newer, more convenient systems are introduced on an ongoing basis.

Some systems allow the user to collect blood from alternative sites, such as the forearm or palm. Alternative site use is not recommended with rapidly changing blood glucose readings, during pregnancy, or when symptoms of low blood glucose are present. The data from some glucose monitors can be uploaded to a computer and reviewed by HCPs, allowing for more frequent and efficient adjustment of the plan of care if needed.

Continuous glucose monitoring (CGM) systems are another route for monitoring glucose. More people with type 1 diabetes are using CGMs. These systems are slowly being used by people with type 2 diabetes as well. Insurance coverage and cost are the most common limiting factors. Some insulin pumps have CGM integrated as part of the system. Flash glucose monitoring is another option. It allows users to wave a reader over a subcutaneous sensor and get glucose readings at any time (Fig. 48.10).

Using a sensor inserted subcutaneously, the systems display glucose values that are updated every 1 to 5 minutes. CGM assesses interstitial glucose, which lags behind blood glucose by 5 to 10 minutes.[16] The patient inserts the sensor using an automatic insertion device. Data are sent from the sensor to a transmitter, which displays the glucose value on either an insulin pump or a pager-like receiver. The CGM can be used with or without an insulin pump. Newer CGMs can "share" data with a smart phone.

CGMs help the patient and HCP identify trends and patterns in glucose levels. The goal is to increase "time in range" (70 to 180 mg/dL) and have fewer highs and lows. They are useful for managing insulin therapy or when continuous blood glucose readings are clinically important. The patient is alerted to episodes of hypoglycemia and hyperglycemia, thus allowing corrective action to be quickly taken. Some systems need finger-stick measurements using a blood glucose monitor to calibrate the sensor and to make treatment decisions. In 2016 the FDA approved making insulin dosing decisions based on a CGM reading, without first checking a finger-stick blood glucose value.

Blood glucose meters available today are reliable when used consistently and correctly. It is not necessary to compare meter readings to laboratory readings. If the A1C result does not correspond to the blood glucose readings on the home meter, it is a good idea to troubleshoot any problems with the meter, strips, or hand washing technique.

FIG. 48.10 Glucometers that connect to a smartphone allow the patient to measure blood glucose, log the measurements in an app, and share the results with health care providers.

Because errors in monitoring technique can cause errors in management strategies, comprehensive patient teaching is essential. Initial instruction should be followed with regular reassessment. Review the instructions that come with each product. If a product has a control solution, teach patients to use and interpret control solutions. Control solution should be used when first using a blood glucose meter or when there is a reason to believe that the readings are not correct. Table 48.11 lists the steps to include when teaching the patient how to perform SMBG.

People with type 1 diabetes often check their blood glucose before meals. This is because many patients use insulin pumps or multiple daily injections and base the insulin dose on the carbohydrates in a meal or make adjustments if the preprandial value is above or below target. Checking blood glucose 2 hours after the first bite of food helps a person determine if the bolus insulin dose was adequate for that meal.

Teach patients to monitor blood glucose whenever hypoglycemia is suspected and then take immediate action. During times of illness, check blood glucose levels at 4-hour intervals to determine the effects of the illness on glucose levels. Teach the patient to monitor blood glucose before and after exercise to determine the effects of exercise on blood glucose levels. This is especially important in the patient with type 1 diabetes.

A patient who is visually impaired, cognitively impaired, or limited in manual dexterity needs careful evaluation of the degree to which SMBG can be done independently. Nurses preparing patients for discharge from the hospital and nurses working in home health and outpatient settings may need to identify caregivers who can assume this responsibility. Adaptive devices are available to help patients with certain limitations. These include talking meters and other equipment for the visually impaired.

Bariatric Surgery

Bariatric surgery may be an option for patients with type 2 diabetes, especially if the diabetes or associated co-morbidities are hard to

manage with lifestyle and drug therapy. Patients with type 2 diabetes who have undergone bariatric surgery need lifelong lifestyle support and monitoring. Bariatric surgery is discussed in Chapter 40.

TABLE 48.11 Patient & Caregiver TeachingSelf-Monitoring of Blood Glucose (SMBG)

Include the following instructions when teaching the patient and caregiver about SMBG:

1. Wash and dry hands completely. It is not necessary to clean the site with alcohol, and it may interfere with test results.
2. If it is hard to get an adequate drop of blood for testing, warm the hands in warm water or let the arms hang dependently for a few minutes before making the finger puncture.
3. A lancing device is usually used. Place the lancet in the device, following the instructions that come with it. If the puncture is made on the finger, use the side of the finger pad rather than near the center. Fewer nerve endings are along the side of the finger pad. If using an alternative site (e.g., forearm), special equipment may be needed. Refer to manufacturer's instructions for alternative site use, except during hypoglycemia episodes.
4. Set lancing device to make a puncture just deep enough to get a sufficiently large drop of blood. Unnecessarily deep punctures may cause pain and bruising. Current meters need very small amounts of blood.
5. Follow instructions on monitor for checking the blood glucose level.
6. Record results. Compare with personal blood glucose goals.

Pancreas Transplantation

Pancreas transplantation is an option for select patients with type 1
