diabetes. Usually it is done for patients who have end-stage renal disease (ESRD) and have had or plan to have a kidney transplant. Kidney and pancreas transplants are often done together, or a pancreas may be transplanted after a kidney transplant. If renal failure is not present, the ADA recommends that pancreas transplantation be considered only for patients who exhibit these 3 criteria: (1) a history of frequent, acute, and severe metabolic complications (e.g., hypoglycemia, hyperglycemia, ketoacidosis) requiring medical attention; (2) clinical and emotional problems with the use of exogenous insulin therapy that are so severe as to be incapacitating; and (3) consistent failure of insulin-based management to prevent acute complications.

Successful pancreas transplantation can improve quality of life, primarily by eliminating the need for exogenous insulin and frequent blood glucose measurements. Transplantation can eliminate acute complications experienced by patients with type 1 diabetes (e.g., hypoglycemia, hyperglycemia). However, transplantation is only partially successful in reversing the long-term renal and neurologic complications of diabetes. The patient will need lifelong immunosuppression to prevent rejection of the organ. Complications can result from immunosuppressive therapy. Immunosuppressive therapy is discussed in Chapter 13.

Pancreatic islet cell transplantation is another potential treatment measure. During this procedure, the islets are harvested from the pancreas of a deceased organ donor. Most recipients need the use of 2 or more pancreases. The islets are infused via a catheter through the upper abdomen into the portal vein of the liver. With only the islets transplanted, pain and recovery time are less than with whole pancreas transplants. Currently, this procedure is experimental in the United States. Research is continuing to investigate the best ways to implant the islet cells and prevent their rejection.

Culturally Competent Care: Diabetes

Because culture can have a strong influence on dietary preferences and meal preparation practices, culturally competent care has special

relevance for the patient with diabetes. For example, certain ethnic and cultural groups, such as Hispanics, Native Americans, blacks, and Asians and Pacific Islanders have a high incidence of diabetes. The increased prevalence can be attributed to genetic predisposition, environmental factors, and dietary choices.

Explore the influences of culture on food choices and meal planning with the patient as part of the health history. When teaching about nutrition, consider the patient's cultural food preferences. Nutrition resources specifically designed for members of different cultural groups are available from the ADA.

Nursing Management: Diabetes

Nursing Assessment

Table 48.12 provides initial subjective and objective data to gather from a person with diabetes. After the initial assessment, perform periodic patient assessments on a regular basis.

TABLE 48.12 Nursing AssessmentDiabetes

Subjective Data
Important Health Information

Past health history: Mumps, rubella, coxsackievirus, or other viral infections. Recent trauma, infection, or stress. Pregnancy, gave birth to infant >9 lb. Chronic pancreatitis, Cushing syndrome, acromegaly, family history of type 1 or type 2 diabetes
Medications: Use of insulin or OAs, corticosteroids, diuretics, phenytoin (Dilantin)
Surgery or other treatments: Any recent surgery

Functional Health Patterns

Health perception–health management: Positive family history, malaise
Nutrition-metabolic: Obesity, weight loss (type 1), weight gain (type 2). Thirst, hunger, nausea and vomiting. Poor healing (especially involving the feet), eating habits
Elimination: Constipation or diarrhea, frequent urination, frequent bladder infections, nocturia, urinary incontinence
Activity-exercise: Muscle weakness, fatigue
Cognitive-perceptual: Abdominal pain, headache, blurred vision,

numbness or tingling of extremities, pruritus
Sexuality-reproductive: ED, frequent vaginal infections, vaginal dryness or pain, ↓ libido
Adaptation: Depression, irritability, apathy
Value-belief: Health beliefs, commitment to lifestyle changes involving food, medication, and activity patterns

Objective Data

Eyes

Soft, sunken eyeballs.* History of vitreal hemorrhages, cataracts

Integumentary

Dry, warm, inelastic skin. Pigmented lesions (on legs), ulcers (especially on feet), loss of hair on toes, acanthosis nigricans

Respiratory

Rapid, deep respirations (Kussmaul respirations)*

Cardiovascular

Hypotension.* Weak, rapid pulse*

Gastrointestinal

Dry mouth, vomiting.* Fruity breath*

Neurologic

Altered reflexes, restlessness, confusion, stupor, coma*

Musculoskeletal

Muscle wasting*

Possible Findings

Serum electrolyte abnormalities. Fasting blood glucose level ≥126 mg/dL. OGTT >200 mg/dL, random glucose ≥200 mg/dL. Leukocytosis. ↑ BUN, creatinine, triglycerides, cholesterol, LDL, VLDL. ↓ HDL. A1C >6.0% (A1C >7.0% in those with diagnosed diabetes), glycosuria, ketonuria, albuminuria. Acidosis

---

* Indicates manifestations of diabetes-related ketoacidosis (DKA).

Nursing Diagnoses

Nursing diagnoses related to diabetes may include:

- Lack of knowledge
- Hyperglycemia
- Hypoglycemia
- Risk for injury
- Impaired peripheral neurovascular function

Additional information on nursing diagnoses and interventions for the patient with diabetes is presented in eNursing Care Plan 48.1 available on the website.

Planning

The overall goals are for the patient with diabetes to (1) engage in self-care behaviors to actively manage diabetes, (2) have few or no hyperglycemia or hypoglycemia emergencies, (3) maintain blood glucose levels at normal or near-normal levels, (4) reduce the risk for chronic complications from diabetes, and (5) adjust lifestyle to accommodate the diabetes plan with minimum stress. The goal is for the patient with diabetes to safely and effectively fit diabetes into life, rather than living life around diabetes.

Nursing Implementation

Health Promotion

Your role in health promotion is to identify, monitor, and teach the patient at risk for diabetes. Obesity is the main risk factor for type 2 diabetes. The ADA recommends routine screening for type 2 diabetes for all adults who are overweight or obese (BMI 25 kg/m^2 or greater) or have 1 or more risk factors. For people who do not have risk factors for diabetes, begin screening at age 45. Table 48.13 provides criteria to screen for prediabetes and diabetes. If results are normal, repeat screening at 3-year intervals.[3]

Many other factors put a person at an increased risk for diabetes. These include age, ethnicity (being Native American, Hispanic, black, Asian, Pacific Islander), having a baby that weighed more than 9 lb at birth, history of gestational diabetes, and a family history of diabetes. A diabetes risk test is available at *www.diabetes.org/risk-test.jsp*. The diabetes risk test determines if the person is at risk for prediabetes or diabetes based on the number of risk factors present.

TABLE 48.13 Screening for Diabetes in Asymptomatic, Undiagnosed Persons

Who to Screen

1. Consider screening all adults who are overweight (BMI >25 kg/m^2) and have additional risk factors:
    - First-degree relative with diabetes
    - Physically inactive
    - Members of a high-risk ethnic population (e.g., black, Hispanic, Native American, Asian American,* Pacific Islander)
    - Women who delivered a baby weighing >9 lb or were diagnosed with gestational diabetes
    - Hypertensive (≥140/90 mm Hg) or on therapy for hypertension
    - HDL cholesterol level ≤35 mg/dL (0.90 mmol/L) and/or a triglyceride level ≥250 mg/dL (2.82 mmol/L)
    - Women with polycystic ovary syndrome
    - A1C ≥5.7%, IGT, or IFG on previous screening
    - Other conditions associated with insulin resistance (e.g., acanthosis nigricans)
2. In the absence of the above criteria, screening for diabetes should begin at age 45 yr.
3. If results are normal, repeat screening at least every 3 years, with more frequent screening depending on initial results and risk status.

What Measurements Are Used

To screen for diabetes or to assess risk of future diabetes, A1C, FPG, or 2-hour OGTT is appropriate.

---

* Consider screening Asian Americans with a BMI of 23 kg/m^2 or higher.

Source: American Diabetes Association: Standards of medical care in diabetes, *Diabetes Care* 41:S15, 2018.

Primary prevention is a cost-effective approach. Current recommendations for primary prevention include lifestyle modifications for at-risk people. A modest weight loss of 5% to 7% of body weight and 150 minutes of physical activity a week lowered the risk for developing type 2 diabetes by 34% to 58%.[17]

Promoting Population Health

Preventing Diabetes

- Increase level of exercise by aiming for 150 minutes of moderate activity each week.
- Maintain a healthy weight through a nutritionally balanced diet.
- If overweight, lose weight and take part in a regular exercise program.
- Follow a diet low in fat, total calories, and processed foods and high in whole grains, fruits, and vegetables.
- If overweight and over age 45, get screened for diabetes yearly.
- Avoid cigarette smoking or tobacco products.
- Limit consumption of alcohol to moderate levels.
- Follow the prescribed treatment plan for hypertension.

Acute Care

Acute situations involving the patient with diabetes include hypoglycemia, DKA, and hyperosmolar hyperglycemic syndrome (HHS). Nursing management for these situations is discussed in more detail later in this chapter. Other areas of acute care relate to management during acute illness and surgery.

Acute Illness and Surgery

Both emotional and physical stress can increase the blood glucose level and result in hyperglycemia. Because stress is unavoidable,

certain situations may require more intense treatment, such as extra insulin and more frequent blood glucose monitoring, to maintain glycemic goals and avoid hyperglycemia.

Acute illness, injury, and surgery may evoke a counterregulatory hormone response, resulting in hyperglycemia. Even common illnesses, such as a viral upper respiratory tract infection or the flu, can cause this response. Encourage patients with diabetes to check blood glucose at least every 4 hours during times of illness. Teach acutely ill patients with type 1 diabetes and a blood glucose greater than 240 mg/dL (13.3 mmol/L) to check urine for ketones every 3 to 4 hours.

Teach patients to contact the HCP when glucose levels are over 300 mg/dL twice in a row or urine ketone levels are moderate to high. A patient with type 1 diabetes may need an increase in insulin to prevent DKA. Elevated blood glucose levels can lead to poor healing and infection. Insulin therapy may be needed for a patient with type 2 diabetes to prevent or treat hyperglycemia symptoms and avoid an acute hyperglycemia emergency. In critically ill patients, insulin therapy may be started if the blood glucose is persistently greater than 180 mg/dL. These patients have a higher targeted blood glucose goal, which is usually 140 to 180 mg/dL. Food intake is important during times of stress and illness, when the body needs extra energy. If patients can eat normally, they can continue with their regular meal plan while increasing the intake of noncaloric fluids, such as water, sugar-free gelatin, and other decaffeinated beverages, and continue taking OAs, noninsulin injectable agents, and insulin as prescribed. When illness causes patients to eat less than normal, they can continue to take OAs, noninsulin injectable agents, and/or insulin as prescribed while supplementing food intake with carbohydrate-containing fluids. Examples include low-sodium soups, juices, and regular, sugar-sweetened decaffeinated soft drinks. It is important to tell the patient to contact an HCP if they are unable to keep down food or fluid.

During the intraoperative period, adjustments in the diabetes plan can be made to ensure safe and healthy blood glucose levels. The patient is given IV fluids and insulin (if needed) just before, during,

and after surgery when there is no oral intake. Explain to the patient with type 2 diabetes who has been on OAs that this is a temporary measure, not a sign of worsening diabetes.

When caring for an unconscious surgical patient receiving insulin, be alert for signs of hypoglycemia, such as sweating, tachycardia, and tremors. Frequent monitoring of blood glucose can prevent episodes of severe hypoglycemia.

Ambulatory Care

Successful diabetes management involves ongoing interaction among the patient, caregiver, and interprofessional team. It is important that a CDE be involved in the care of the patient and family. Because diabetes is a complex chronic condition, a great deal of patient contact takes place in outpatient and home settings. The major goal of patient care in these settings is to enable the patient (with the help of a caregiver as needed) to reach an optimal level of independence in self-care activities. Unfortunately, many patients face challenges in reaching these goals. Diabetes increases the risk for other chronic conditions that can affect self-care activities. These include visual impairment, lower extremity problems that affect mobility, and other functional limitations related to a stroke.

An important nursing function is to assess the ability of patients and caregivers in performing activities such as SMBG and insulin injection. Assistive devices for self-administration of insulin include syringe magnifiers, vial stabilizers, and dosing aids for the visually impaired. In some cases, referrals are made to help the patient achieve the self-care goal. These may include an occupational therapist, a social worker, a home care nurse, a home health aide, or a dietitian.

A diagnosis of diabetes affects the patient in many profound ways. Self-management of the disease is demanding. Patients with diabetes continually face lifestyle choices that affect the foods they eat, their activities, and demands on their time and energy. The requirements of scheduled meals, SMBG, medication, and insulin management may interfere with the patient's other responsibilities. Any change in the daily routine can be hard. In addition, they face the challenge of

preventing or dealing with the devastating complications of diabetes.

Careful assessment of what it means to the patient to have diabetes is a good starting point for teaching. The goals of teaching are mutually determined by the patient and you, based on individual needs and therapeutic requirements. Identify the patient's support system, and include them in planning, teaching, and counseling. When family members and other persons close to the patient are included, they can support the patient's self-care behaviors. They can also provide care if self-care is not possible. Encourage the family and caregivers to provide emotional support and encouragement as the patient deals with the reality of living with a chronic disease.

Insulin Therapy

Nursing responsibilities for the patient receiving insulin include proper administration, assessment of the patient's response to insulin therapy, and teaching the patient about administration, storage, and side effects of insulin (Table 48.5). Table 48.6 lists guidelines for assessing a patient using GLAs, including insulin and OAs.

Evidence-Based Practice

Interactive Self-Management and Diabetes

A.Y. is a 62-yr-old woman with a history of poorly controlled type 2 diabetes. She knows the importance of keeping blood glucose levels close to normal to prevent long-term complications. A.Y. tells you she wants to be more involved in her care. You see she is motivated and wants to learn how to better manage her diabetes.

Making Clinical Decisions

Best Available Evidence. The delivery of education and skills related to diabetes self-management includes a variety of formats. These include the use of electronic messages transmitted by phone or the Web and behavioral change

techniques, such as goal-setting, problem-solving, and action planning. Evidence supports multiple benefits from using interactive self-management interventions. These include improved glycemic control as measured by A1C levels, increased knowledge and self-efficacy, and reduced diabetes-related distress.

Clinician Expertise. You know interactive self-management strategies are effective in helping patients improve glycemic control. You are aware that several options, such as text messaging and Web-based programs, can be useful for delivering information to and from patients with diabetes who manage their own care.

Patient Preferences and Values. A.Y. shows a strong interest in taking more control of her diabetes and wishes to receive information on physical activity, blood glucose monitoring, and diet.

Implications for Nursing Practice

1. What options for interactive self-management of her diabetes will you offer A.Y.?
2. As you empower A.Y. to initially manage her care, why is it important for you to assess A.Y.'s knowledge and skills?
3. What parameters will you use to assess if she is able to manage her own care?

Reference for Evidence

Cheng L, Sit J.W.H, Choi K.-C, et al. Effectiveness of interactive self-management interventions in individuals with poorly controlled type 2 diabetes: a meta-analysis of randomized controlled trials. *Worldviews Evid Based Nurs*. 2017;14:65.

Assessment of the patient who is a new user of insulin includes

evaluating their ability to safely manage this therapy. This includes the ability to understand the interaction of insulin, food, and activity and to recognize and treat the symptoms of hypoglycemia appropriately. If the patient does not have the cognitive skills to do these things, identify and teach another responsible person. The patient or caregiver must have the cognitive and manual skills needed to prepare and inject insulin. Otherwise, additional resources will be needed to assist the patient. For patients with cognitive, physical, and other barriers, consider referral to a CDE. A CDE has the specialized knowledge and skills to promote self-care behaviors for these patients.

Many patients are fearful when they first begin using insulin. Some find it hard to self-inject because they are afraid of needles or the pain associated with an injection. Others may think that they do not need insulin or that they will be hypoglycemic after an injection. Explore the patient's underlying fears before beginning the teaching. Assessing the patient's beliefs and concerns about starting insulin will guide the teaching, counseling, and plan of care. Having open discussion with patients, providing educational materials and programs, and working with a CDE are all beneficial for patients starting insulin.

Follow-up assessment of the patient who has been using insulin therapy includes inspecting injection sites for signs of lipodystrophy and other reactions, reviewing insulin preparation and injection technique, taking a history of the occurrence of hypoglycemia, and assessing how the patient managed hypoglycemia. A review of the patient's recorded blood glucose readings is vital in assessing how the patient is doing and making any needed adjustments.

Oral and Noninsulin Injectable Agents

Your responsibilities for the patient taking OAs and noninsulin injectable agents are similar to those for the patient taking insulin. Proper administration, assessment of the patient's use of and response to these drugs, and teaching the patient and family are all essential nursing actions.

Your assessment is valuable in determining the most appropriate

drug for a patient. Factors such as the patient's mental status, eating habits, home environment, learning ability, resources, attitude toward diabetes, and medication history all play a significant role in determining the most appropriate drug. For example, frail older adults who live alone are at high risk for severe hypoglycemia because low blood glucose is often undetected or untreated. This is especially true if the patient has cognitive impairment. In these cases, an OA that does not cause hypoglycemia, or a shorter-acting OA, would be most appropriate.

Patient teaching is essential. Some patients may assume that their diabetes is not a serious condition if they are only taking a pill to treat it. Teach the patient that OAs will help manage blood glucose and help prevent serious long- and short-term complications of diabetes. Discuss how OAs and noninsulin injectable agents are used in addition to food choices and activity as therapy for diabetes and the importance of following their meal and activity plans. Teach patients not to take extra pills if they have overeaten. If the patient uses sulfonylureas and metformin, teach the patient about the prevention, recognition, and management of hypoglycemia.

Personal Hygiene

The potential for infection requires diligent skin and dental hygiene practices. Because of the susceptibility to periodontal disease, encourage daily brushing and flossing and regular dental visits. When having dental work done, have the patient tell the dentist they have diabetes.

Routine care includes regular bathing, with an emphasis on foot care. Advise patients to inspect their feet daily, avoid going barefoot, and wear shoes that are supportive and comfortable. If cuts, scrapes, or burns occur, treat them promptly and monitor them carefully. Wash the area and apply a nonabrasive or nonirritating antiseptic ointment. Cover the area with a dry, sterile pad. Teach patients to notify the HCP at once if the injury does not begin to heal within 24 hours or if signs of infection develop.

Medical Identification and Travel

Teach the patient to always carry medical identification indicating that they have diabetes. Police, paramedics, and many private citizens are aware of the need to look for this identification when working with sick or unconscious persons. An identification card (Fig. 48.11) can supply valuable information, such as the name of the HCP; the type of diabetes; and the type and dosage of insulin, noninsulin injectable agents, or OAs.

Travel for a patient with diabetes requires planning. Being sedentary for long periods may raise the person's glucose level. Encourage the patient to get up and walk at least every 2 hours to lower the risk for deep vein thrombosis and prevent elevation of glucose levels. Teach the patient to have a full set of diabetes care supplies in the carry-on luggage when traveling by plane, train, or bus. This includes blood glucose monitoring equipment, insulin, noninsulin injectable agents, OAs, and syringes or insulin pens and pen needles.

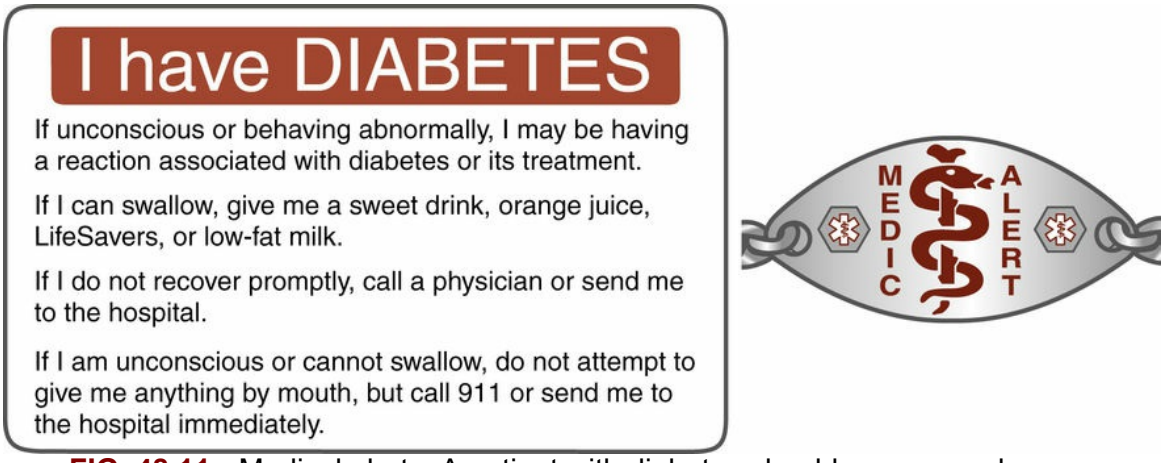

FIG. 48.11 Medical alerts. A patient with diabetes should carry a card and wear a bracelet or necklace that indicates diabetes. If the patient with diabetes is unconscious, these measures will ensure prompt and appropriate attention.

Nursing Management

Caring for the Patient With Diabetes

You will need to collaborate with many health care team members to deliver, delegate, and coordinate care based on the patient's status.

- Assess for risk factors for prediabetes and type 1 and type 2 diabetes.
- Teach the patient and caregiver about diabetes management, including SMBG, insulin, noninsulin injectables, OAs, nutrition, physical activity, and managing hypoglycemia.
- Develop a plan to avoid hypoglycemia or hyperglycemia in a patient with DM who is acutely ill or having surgery.
- Assess for acute complications and implement appropriate actions for hypoglycemia, DKA, and HHS.
- In patients having acute complications, perform or directly supervise actions, including IV fluid and insulin administration.
- Assess for chronic complications, including CVD, retinopathy, nephropathy, neuropathy, and foot complications.
- Teach the patient and caregiver about prevention and management of chronic complications related to diabetes.
- Oversee LPN/VNs, and in some states and settings UAP, administer insulin, noninsulin injectable agents, and OAs to stable patients.

Collaborate With Other Team Members

Dietitian

- Obtain a diet history from the patient.
- Work with patient and caregiver to create an individualized meal plan.
- Provide instructions for meal plan as needed.

Physical Therapist

- Assess patient's current level of fitness.
- Develop an exercise plan with the patient.

Occupational Therapist

- Teach with patient with vision impairment how to use devices to draw up and measure insulin.
- Provide teaching on how to use a talking blood glucose monitor or use any blood glucose monitor one handed.
- Develop protective techniques for activities that involve exposure to heat, cold, and sharp objects.

Social Worker

- Aid the patient in finding resources to meet medical and financial needs.
- Help with coping with diabetes, including managing problems within the family or workplace.

Best practices for traveling with diabetes supplies and equipment change frequently. Encourage patients to check TSA guidelines before traveling at *www.diabetes.org/living-with-diabetes/know-your-rights/discrimination/public-accommodations/air-travel-and-diabetes/*. Notify screeners if an insulin pump is used so that they can inspect it while it is on the body, rather than removing it.

For patients who use insulin or OAs that can cause hypoglycemia, keep snack items and a quick-acting carbohydrate source for treating hypoglycemia in the carry-on luggage. Keep extra insulin available in case a bottle breaks or is lost. For longer trips, carry a full day's supply of food in case of canceled flights, delayed meals, or closed

restaurants. If the patient is planning a trip out of the country, it is wise to have a letter from the HCP explaining that the patient has diabetes and requires all the materials, especially syringes, for ongoing health care.

When travel involves time changes, such as traveling coast to coast or across the International Date Line, the patient can contact the HCP to plan an appropriate insulin schedule. During travel, most patients find it helpful to keep watches set to the time of the city of origin until they reach their destination. The key to travel when taking insulin is to know the type of insulin being taken, its onset of action, the anticipated peak time, and mealtimes.

Patient and Caregiver Teaching

The goals of diabetes self-management education are to match the level of self-management to the patient's individual ability so that they can become the most active participant possible. Patients who actively manage their diabetes care have better outcomes than those who do not. For this reason, an educational approach that facilitates informed decision making by the patient is advocated. We call this the *empowerment approach* to education.

The empowerment approach includes eliminating messages that are judgmental and negative and replacing them with empowering, person-centered, and strengths-based language. An example includes referring to a patient as a person with diabetes versus calling them a diabetic. This places the emphasis on the person versus the disease. Other examples of words that may be perceived as negative or judgmental include compliant, uncontrolled, and poorly controlled."[18] Research has shown that people with diabetes feel the impact of negative language and would trust their HCPs more if they used empowering language and made them feel like a partner in their care.

Complementary & Alternative Therapies

Herbs and Supplements That May Affect Blood Glucose

Scientific Evidence

Herbs and supplements that may lower blood glucose include aloe, ginger, cinnamon, St. John's wort, garlic, and ginseng. However, many studies have been small and not well designed. Further research is needed.

Nursing Implications

- Teach patients to use herbs and supplements with caution since they may affect blood glucose.
- Encourage patients with diabetes to talk with their HCP before using herbs or nutritional supplements.
- Teach patients who use herbs to regularly monitor their blood glucose levels.

Source: Gupta RC, Chang D, Nammi S, et al: Interactions between antidiabetic drugs and herbs: an overview of mechanisms of action and clinical implications, *Diabetol Metab Syndr* 9:59, 2017.

Informatics in Practice

Patient Teaching Using Smart Phone Apps

- Teaching is a critical part of nursing care for patients with diabetes. Put some fun into patient teaching by using smart phone applications.
- Apps offer convenient, quick access to up-to-date information.
- Introduce patients to a variety of smart phone apps for healthy living and managing diabetes.
- Sample apps include Glooko, Health2Sync, Glucosio, MyNetDiaryPRO, Diabetes Tracker, mySugr, and BeatO.

Source: Based on a list provided by Healthline. Retrieved from *www.healthline.com/health/diabetes/top-iphone-android-apps*.

Unfortunately, patients can encounter a variety of physical, psychologic, and emotional barriers when it comes to effectively managing their diabetes. These barriers may include feelings of inadequacy about one's own abilities, unwillingness to make behavioral changes, ineffective coping strategies, and cognitive deficits. If the patient is not able to manage the disease, a family member may be able to assume part of this role. If the patient or caregiver cannot make decisions related to diabetes management, consider a referral to a CDE, social worker, or other resources within the community. These resources can help the patient and family in outlining a feasible treatment program that meets their capabilities.

An assessment of the patient's knowledge of diabetes and lifestyle preferences is useful in planning a teaching program. Tables 48.14 and 48.15 present guidelines to use for patient and caregiver teaching. Assess the patient's knowledge base frequently so that gaps in knowledge or incorrect or inaccurate ideas can be corrected.

The ADA offers resources for patients in the form of pamphlets, booklets, books, and a monthly magazine called *Diabetes Forecast.* Affiliates of the ADA are found in all states. Most can be reached by dialing 1-800-DIABETES (800-342-2383). The ADA publishes materials and sponsors conferences for health care professionals concerned with diabetes education, research, and management of patients. The ADA website *(www.diabetes.org)* has extensive information for the public and health care professionals. The ADA also recognizes education programs that meet the national standards of diabetes education and can provide a list of these programs. Most drug companies manufacturing diabetes-related products have free educational materials for patients and HCPs. It is critical that you stay current in your diabetes knowledge so that you can effectively teach and support patients with diabetes.

Evaluation

The expected outcomes are that the patient with diabetes will

- State key elements of the treatment plan
- Describe self-care measures that may prevent or slow progression of chronic complications
- Maintain a balance of nutrition, activity, and insulin availability that results in stable, safe, and healthy blood glucose levels
- Have no injury from decreased sensation in the feet
- Implement measures to increase peripheral circulation

Acute Complications of Diabetes

The acute complications of diabetes arise from events associated with hyperglycemia and hypoglycemia. Hyperglycemia (high blood glucose) occurs when there is not enough insulin working. Hypoglycemia (low blood glucose) occurs when there is too much insulin working. Many signs and symptoms of hyperglycemia and hypoglycemia overlap. It is important for the HCP to distinguish between them because hypoglycemia worsens rapidly and is a serious threat if action is not immediately taken. Table 48.16 compares the manifestations, causes, management, and prevention of hyperglycemia and hypoglycemia.

TABLE 48.14 Patient & Caregiver TeachingManagement of Diabetes

Include the following instructions when teaching the patient and caregiver how to manage diabetes:

Component	What to Teach
Disease process	• Introduce the pancreas and the islets of Langerhans. • Describe how insulin is made and what affects its production. • Discuss the relationship of insulin and glucose. • Explain the difference between type 1 and type 2 diabetes.
Physical activity	• Discuss the effect of regular exercise on managing blood glucose and improving cardiovascular function and general health.
Menu planning	• Stress the importance of a well-balanced diet as part of a diabetes management plan. • Explain the impact of carbohydrates on blood glucose levels.
Medication	• Ensure that the patient understands the proper use of prescribed medication (e.g., insulin [Table 48.5], OAs, noninsulin injectables). • Account for a patient's physical or other limitations or inabilities for self-medication. If necessary, involve the family or caregiver in proper use of medication. • Discuss all side effects and safety issues about medication.
Monitoring blood glucose	• Teach correct blood glucose monitoring. • Include when to check blood glucose levels, how to record them, and how to adjust insulin levels, if necessary.
Risk reduction	• Ensure that the patient understands and appropriately responds to the signs and symptoms of hypoglycemia and hyperglycemia (Table 48.16). • Stress the importance of proper foot care (Table 48.21), regular eye examinations, and consistent glucose monitoring. • Teach the patient about the effect that stress can have on blood glucose.
Psychosocial	• Help the patient identify resources that are available to help with the adjustment and answer questions about living with a chronic condition such as diabetes.

Diabetic Ketoacidosis

Etiology and Pathophysiology

Diabetes-related ketoacidosis (DKA) is caused by a profound deficiency of insulin. It is characterized by hyperglycemia, ketosis, acidosis, and dehydration. It is most likely to occur in people with type 1 diabetes. DKA may be seen in people with type 2 diabetes in conditions of severe illness or stress in which the pancreas cannot meet the extra demand for insulin. Precipitating factors include illness; infection; inadequate insulin dosage; undiagnosed type 1 diabetes; lack of education, understanding, or resources; and neglect.

TABLE 48.15 Patient & Caregiver TeachingInstructions for Patients With Diabetes

Include the following essential instructions for diabetes management for the patient and caregiver:

Blood Glucose

- Monitor your blood glucose at home and record results in a log.
- Take your insulin, OA, and/or noninsulin injectable agent as prescribed.
- Take insulin consistently, especially when you are sick.
- Keep an adequate supply of insulin on hand at all times.
- Obtain A1C blood test every 3–6 mo as an indicator of your long-term blood glucose levels.
- Be aware of symptoms of hypoglycemia and hyperglycemia.
- Always carry a form of rapid-acting glucose so that you can treat hypoglycemia quickly.
- Teach family members how and when to use glucagon if patient becomes unresponsive because of hypoglycemia.

Exercise

- Learn how exercise and food affect your blood glucose levels.
- Remember that exercise will usually lower your blood glucose level.
- Begin an exercise program after approval from HCP.

Food

- Work with a dietitian to create a patient specific meal plan.
- Make healthy food choices and eat regular meals at regular times.
- Choose foods low in saturated and *trans* fat. Know your cholesterol level.
- Limit the amount of alcohol you drink.
- Be aware that excess amounts of alcohol may lead to unpredictable low blood glucose events.
- Avoid fad diets.
- Limit regular soda and fruit juice.

Other Guidelines

- Obtain an annual eye examination by an ophthalmologist.
- Obtain annual urine monitoring for protein.
- Examine your feet at home.
- Wear comfortable, well-fitting shoes to help prevent foot injury. Break in new shoes gradually.
- Always carry identification that says you have diabetes.
- Have other medical problems treated, especially high BP and high cholesterol.
- Have a yearly influenza vaccination.
- Quit or never start smoking cigarettes or using nicotine products.

- Avoid applying heat or cold directly to your feet.
- Avoid going barefoot.
- Keep skin moisturized by applying cream to surfaces of feet, but not between toes.

When the circulating supply of insulin is insufficient, glucose cannot be properly used for energy. The body compensates by breaking down fat stores as a secondary source of fuel (Fig. 48.12). Ketones are acidic by-products of fat metabolism that can cause serious problems when they become excessive in the blood. Ketosis alters the pH balance, causing metabolic acidosis to develop. Ketonuria is a process that occurs when ketone bodies are excreted in the urine. During this process, electrolytes that are cations are also excreted with the anionic ketones to try to maintain electrical neutrality.

Insulin deficiency impairs protein synthesis and causes excessive protein degradation. This results in nitrogen losses from the tissues. Insulin deficiency stimulates the production of glucose from amino acids (from proteins) in the liver and leads to further hyperglycemia. Because of the insulin deficiency, the additional glucose cannot be used and the blood glucose level rises further, adding to the osmotic diuresis.

TABLE 48.16 Comparison of Hyperglycemia and Hypoglycemia

Hyperglycemia	Hypoglycemia
Manifestations	
• **Elevated blood glucose** • **Increase in urination** • **Increase in appetite followed by lack of appetite** • **Weakness, fatigue** • **Blurred vision** • **Headache** • **Glycosuria** • **Nausea and vomiting** • **Abdominal cramps** • **Progression to DKA or HHS** • **Mood swings**	• Blood glucose <70 mg/dL (3.9 mmol/L) • Cold, clammy skin • Numbness of fingers, toes, mouth • Tachycardia • Emotional changes • Headache • Nervousness, tremors • Faintness, dizziness • Unsteady gait, slurred speech • Hunger • Changes in vision • Seizures, coma
Causes	
• **Illness, infection** • **Corticosteroids** • **Too much food** • **Too little or no diabetes medication** • **Inactivity** • **Emotional, physical stress** • **Poor absorption of insulin**	• Alcohol intake without food • Too little food—delayed, omitted, inadequate intake • Too much diabetes medication • Too much exercise without adequate food intake • Diabetes medication or food taken at wrong time • Loss of weight without change in medication • Use of β-adrenergic blockers interfering with recognition of symptoms
Clinical Course	
• **More gradual onset** • **Definition of elevated glucose varies by person, based on personal glucose targets**	• More rapid onset • Pattern of manifestations changes over time
Treatment	
• **Get medical care** • **Continue diabetes medication as prescribed** • **Check blood glucose frequently and check urine for ketones; record results** • **Drink fluids at least on an hourly basis** • **Contact HCP about ketonuria**	• Follow the Rule of 15 (see pp. 1134–1135). • See Table 48.19 for emergency treatment of hypoglycemia.
Preventive Measures	
• **Take prescribed dose of medication at proper time** • **Accurately give insulin, noninsulin injectables, OA** • **Make healthy food choices** • **Follow sick-day rules when ill** • **Check blood glucose routinely** • **Wear or carry diabetes identification**	• Take prescribed dose of medication at proper time • Accurately give insulin, noninsulin injectables, OA • Coordinate eating with medications • Eat adequate food intake needed for calories for exercise • Be able to recognize symptoms and treat them immediately • Carry simple carbohydrates • Teach family and caregiver about symptoms and treatment • Check blood glucose routinely • Wear or carry diabetes identification

PATHOPHYSIOLOGY MAP

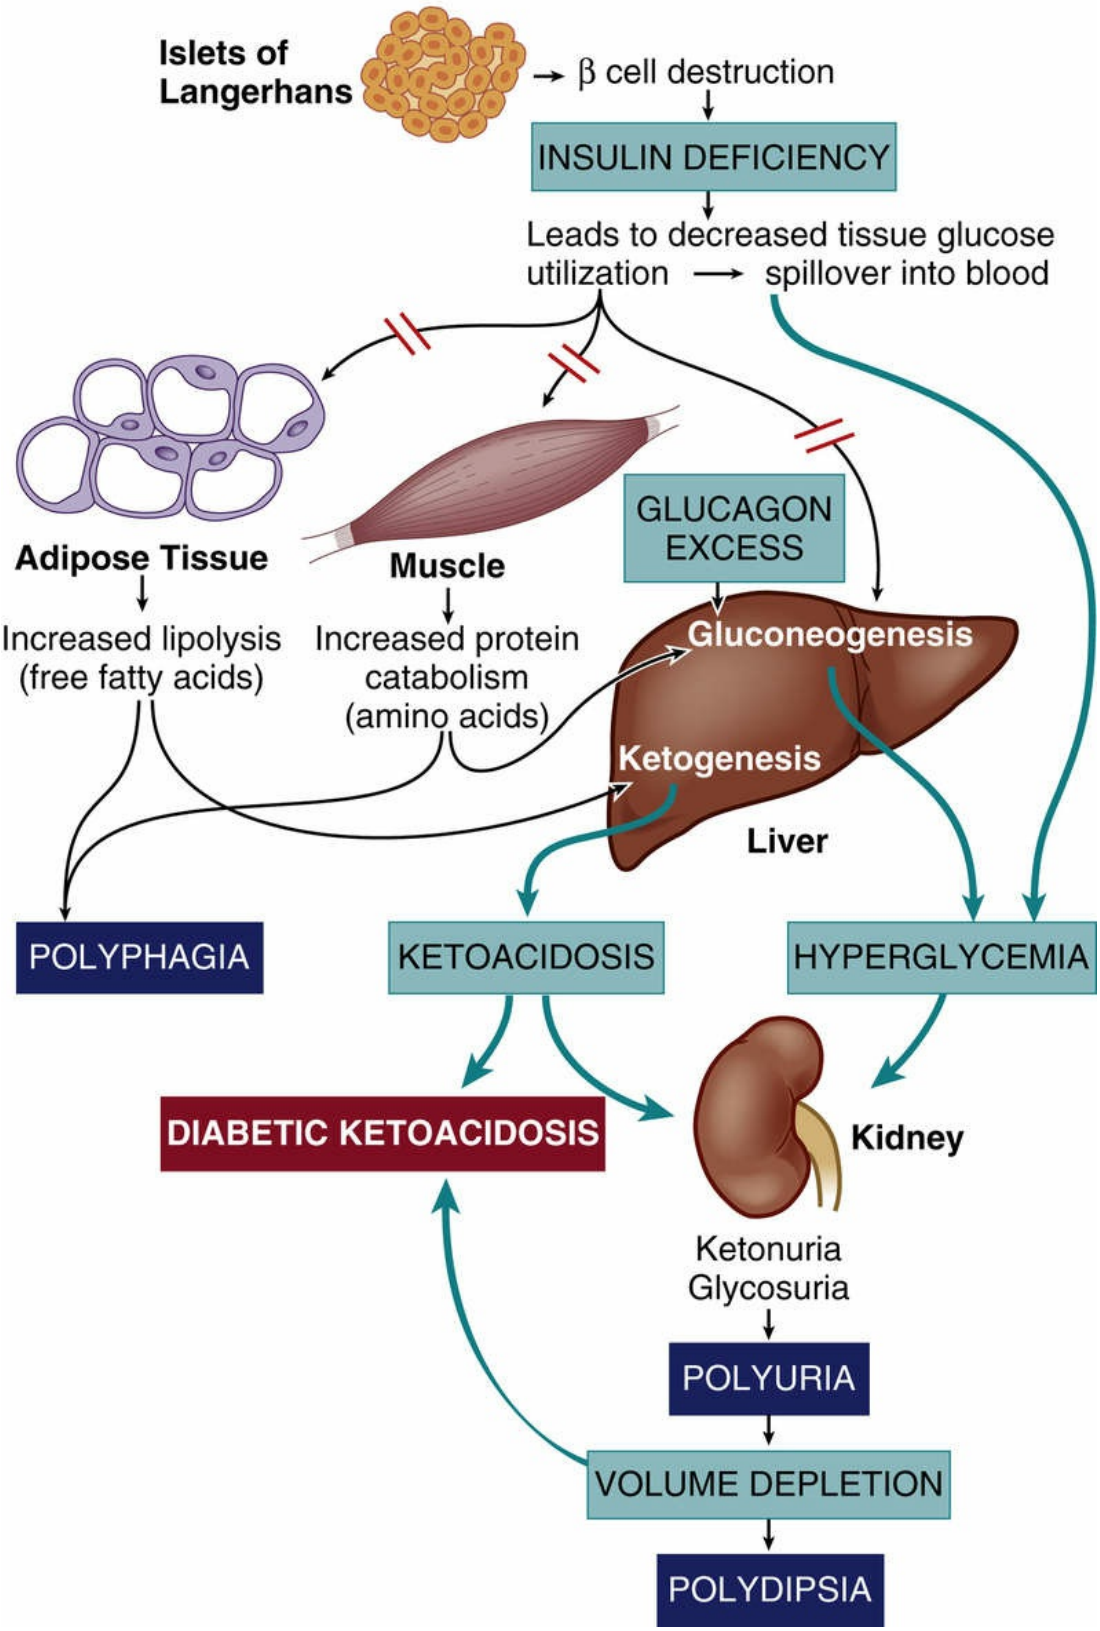

FIG. 48.12 Metabolic events leading to diabetic ketoacidosis. Modified from Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.

If not treated, the patient will develop severe depletion of sodium, potassium, chloride, magnesium, and phosphate. Vomiting caused by the acidosis results in more fluid and electrolyte losses. Eventually, hypovolemia, followed by shock, will ensue. Renal failure, which may eventually occur from hypovolemic shock, causes the retention of ketones and glucose, and the acidosis progresses. Untreated, the patient becomes comatose from dehydration, electrolyte imbalance, and acidosis. If the condition is not treated, death is inevitable.

Clinical Manifestations

Dehydration occurs in DKA with manifestations of dry mucous membranes, tachycardia, and orthostatic hypotension. Early symptoms may include lethargy and weakness. As the patient becomes severely dehydrated, the skin becomes dry and loose, and the eyes become soft and sunken. Abdominal pain may be present and accompanied by anorexia, nausea, and vomiting. Acetone is noted on the breath as a sweet, fruity odor.

Kussmaul respirations (rapid, deep breathing associated with dyspnea) are the body's attempt to reverse metabolic acidosis through the exhalation of excess CO_2. (See Chapter 16 for a discussion of respiratory compensation of metabolic acidosis.) Laboratory findings include a blood glucose level of 250 mg/dL (13.9 mmol/L) or greater, arterial blood pH less than 7.30, and serum bicarbonate level less than 16 mEq/L (16 mmol/L). Moderate to large ketones are present in the urine or serum.

Interprofessional Care

Before we had SMBG, patients with DKA needed hospitalization for treatment. Today, hospitalization may not be needed. If fluid and electrolyte imbalances are not severe and blood glucose levels can be safely monitored at home, DKA can be managed on an outpatient

basis (Table 48.17). Other factors to consider when deciding where the patient is managed include the presence of fever, nausea, vomiting, and diarrhea; altered mental status; the cause of the ketoacidosis; and availability of frequent communication with the HCP (every few hours). Patients with DKA who have an illness such as pneumonia or a urinary tract infection (UTI) usually need admitted to the hospital.

TABLE 48.17 Interprofessional CareDiabetes-Related Ketoacidosis (DKA) and Hyperosmolar Hyperglycemia Syndrome (HHS)

Diagnostic Assessment

- History and physical examination
- Blood studies, including blood glucose, CBC, pH, ketones, electrolytes, BUN, arterial or venous blood gases
- Urinalysis, including specific gravity, glucose, acetone

Management

- Administration of IV fluids
- IV administration of short-acting insulin
- Electrolyte replacement
- Assessment of mental status
- Recording of intake and output
- Central venous pressure monitoring (if indicated)
- Assessment of blood glucose levels
- Assessment of blood and urine for ketones
- ECG monitoring
- Assessment of cardiovascular and respiratory status

DKA is a serious condition that proceeds rapidly and must be treated promptly. Refer to Table 48.18 for the emergency management of a patient with DKA. Because fluid imbalance is potentially life threatening, the first goal of therapy is to establish IV access and begin fluid and electrolyte replacement. Typically, the initial fluid therapy involves an IV infusion of 0.45% or 0.9% NaCl at a rate to raise BP and restore urine output to 30 to 60 mL/hr. When blood glucose levels approach 250 mg/dL (13.9 mmol/L), 5% to 10% dextrose is added to prevent hypoglycemia and a sudden drop in glucose that can be associated with cerebral edema. Overzealous rehydration, especially with hypotonic IV solutions, can cause cerebral edema.

The aim of fluid and electrolyte therapy is to replace extracellular and intracellular water and to correct deficits of sodium, chloride, bicarbonate, potassium, phosphate, and magnesium. Monitor patients with renal or cardiac compromise for fluid overload. Obtain a serum potassium level before starting insulin. If the patient is hypokalemic, giving insulin will further decrease potassium levels, making early potassium replacement essential. Although initial serum potassium may be normal or high, levels can rapidly decrease once therapy starts as insulin drives potassium into the cells, leading to life-threatening hypokalemia.

IV insulin therapy is given to correct hyperglycemia and hyperketonemia. It is important to prevent rapid drops in serum glucose to avoid cerebral edema. A blood glucose reduction of 36 to 54 mg/dL/hr (2 to 3 mmol/L/hr) will avoid complications. Insulin allows water and potassium to enter the cell along with glucose and can lead to a depletion of vascular volume and hypokalemia, so monitor the patient's fluid balance and potassium levels.

Check Your Practice

A 22-yr-old female patient admitted with DKA has a blood glucose level of 554 mg/dL. You are trying to regulate her IV rate. You know that giving IV fluids too rapidly and quickly lowering of serum

glucose can lead to cerebral edema. You also know that incorrect fluid replacement, especially with hypotonic fluids, can cause a sudden fall in serum sodium that can cause cerebral edema.

- What are the best clinical indicators of successful treatment of DKA?
- What is your role as a nurse in caring for this patient?

TABLE 48.18 Emergency ManagementDiabetes-Related Ketoacidosis

Etiology	Assessment Findings	Interventions
• **Undiagnosed diabetes** • **Inadequate treatment of existing diabetes** • **Insulin not taken as prescribed** • **Illness, infection** • **Change in eating, insulin, or exercise plan** • **Malfunction of insulin pump/nondelivery of insulin**	• Abdominal pain • Breath odor of ketones (fruity) • Dry mouth • Eyes appearing sunken • Fever • Flushed, dry skin • Glucosuria and ketonuria • Increasing restlessness, confusion, lethargy • Labored breathing (Kussmaul respirations) • Nausea and vomiting • Rapid, weak pulse • Serum glucose >250 mg/dL (13.9 mmol/L) • Thirst • Urinary frequency	Initial • Ensure patent airway. • Give O_2 via nasal cannula or nonrebreather mask. • Establish IV access with large-bore catheter. • Begin fluid resuscitation with 0.9% NaCl solution 1 L/hr until BP stabilized and urine output 30-60 mL/hr. • Begin continuous regular insulin drip 0.1 U/kg/hr. • Identify history of diabetes, time of last food, and time and amount of last insulin injection. Ongoing Monitoring • Monitor vital signs, level of consciousness, ECG, O_2 saturation, and urine output. • Assess breath sounds for fluid overload. • Monitor serum glucose and serum potassium. • Give potassium to correct hypokalemia. • Give sodium bicarbonate if severe acidosis (pH <7.0). • Add dextrose to IV fluid for blood glucose <250 mg/dL.

Hyperosmolar Hyperglycemia Syndrome

Hyperosmolar hyperglycemia syndrome (HHS) is a life-threatening syndrome that can occur in the patient with diabetes who is able to make enough insulin to prevent DKA, but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion (Fig. 48.13). HHS is less common than DKA (Table 48.17). It often occurs in patients over 60 years of age with type 2 diabetes.

Common causes of HHS are UTIs, pneumonia, sepsis, any acute illness, and newly diagnosed type 2 diabetes. HHS is often related to impaired thirst sensation and/or a functional inability to replace fluids. There is usually a history of inadequate fluid intake, increasing mental depression or cognitive impairment, and polyuria.

PATHOPHYSIOLOGY MAP

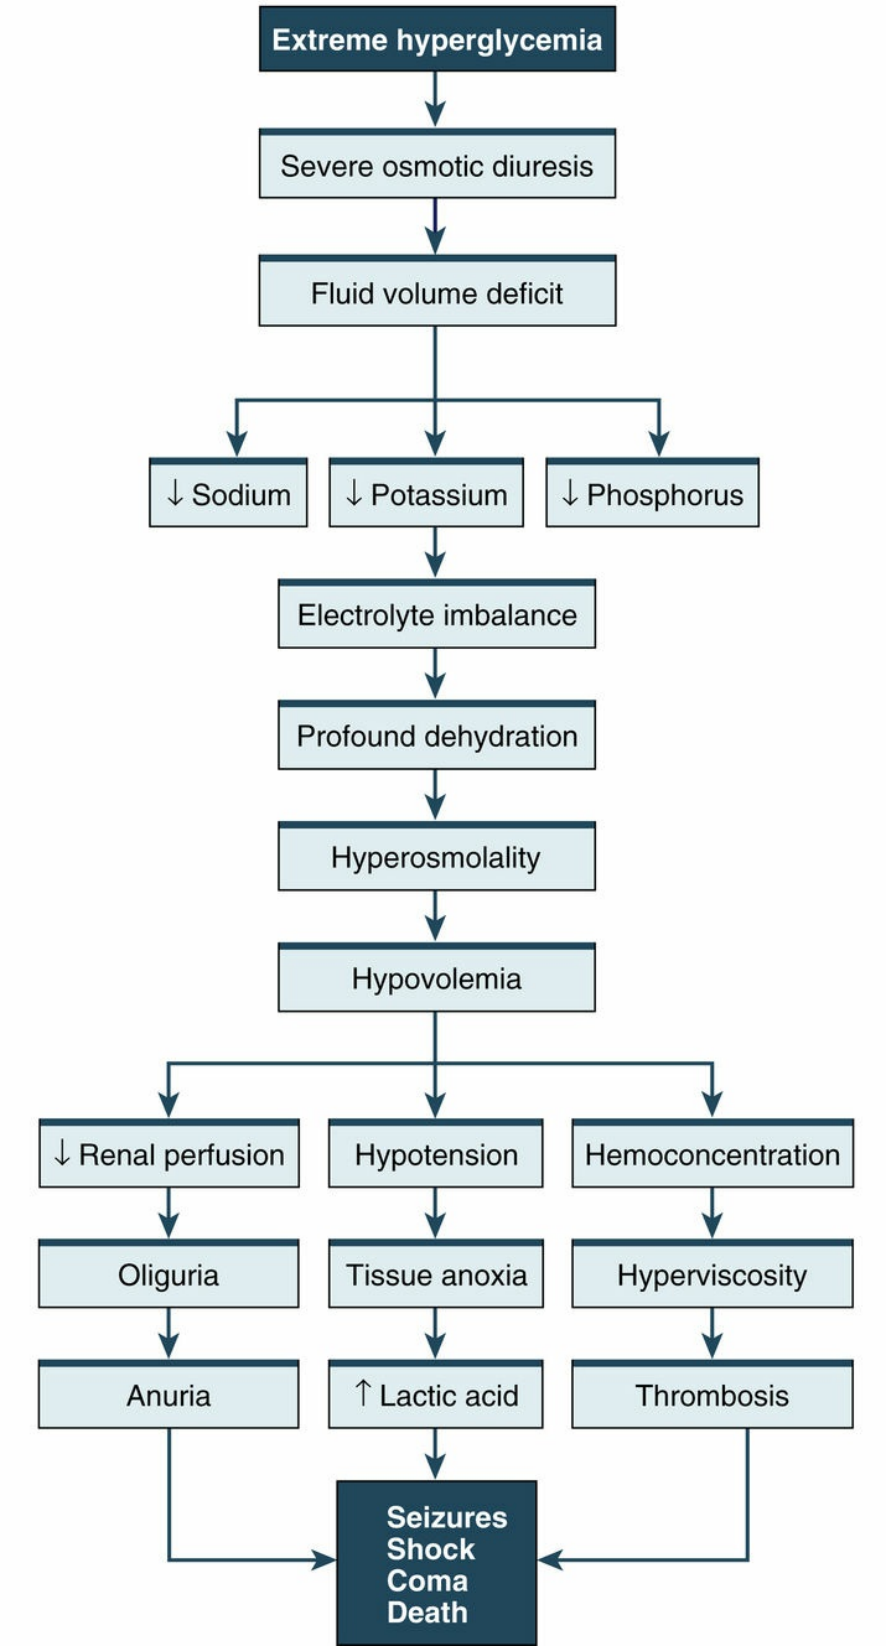

FIG. 48.13 Pathophysiology of hyperosmolar hyperglycemic syndrome.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

The main difference between HHS and DKA is that the patient with HHS usually has enough circulating insulin so that ketoacidosis does not occur. Because HHS has fewer symptoms in the earlier stages, blood glucose levels can climb quite high before the problem is recognized. The higher blood glucose levels increase serum osmolality and cause more severe neurologic manifestations, such as somnolence, coma, seizures, hemiparesis, and aphasia. Since these manifestations resemble a stroke, immediate determination of the glucose level is critical for correct diagnosis and treatment.

Laboratory values in HHS include a blood glucose level greater than 600 mg/dL (33.33 mmol/L) and a marked increase in serum osmolality. Ketone bodies are absent or minimal in both blood and urine.

Interprofessional Care

HHS is a medical emergency. It has a high mortality rate. The management of HHS is similar to DKA. It includes immediate IV administration of insulin and either 0.9% or 0.45% NaCl. HHS usually requires large volumes of fluid replacement. This should be done slowly and carefully. Patients with HHS are often older and may have cardiac or renal compromise, requiring hemodynamic monitoring to avoid fluid overload during fluid replacement. When blood glucose levels fall to about 250 mg/dL (13.9 mmol/L), IV fluids containing dextrose are given to prevent hypoglycemia.

Electrolytes are monitored and replaced as needed. Hypokalemia is not as significant in HHS as it is in DKA, although fluid losses may result in milder potassium deficits that require replacement. Assess vital signs, intake and output, laboratory values, and cardiac monitoring to check the efficacy of fluid and electrolyte replacement. This includes monitoring serum osmolality and frequently assessing cardiac, renal, and mental status. Once the patient is stabilized, begin

attempts to detect and correct the underlying cause.

Nursing Management: Diabetes-Related Ketoacidosis and Hyperosmolar Hyperglycemia Syndrome

Closely monitor the hospitalized patient with appropriate blood and urine tests. You are responsible for monitoring blood glucose and urine for output and ketones and using laboratory data to determine appropriate patient care.

Monitor the administration of (1) IV fluids to correct dehydration, (2) insulin therapy to reduce blood glucose and serum ketone levels, and (3) electrolytes given to correct electrolyte imbalance. Assess renal status and cardiopulmonary status related to hydration and electrolyte levels. Monitor the level of consciousness.

Assess for signs of potassium imbalance resulting from low levels of insulin and osmotic diuresis (see Chapter 16). When insulin treatment is started, serum potassium levels may decrease rapidly as potassium moves into the cells once insulin is available. This movement of potassium into and out of extracellular fluid influences cardiac functioning. Cardiac monitoring is useful in detecting characteristic changes of potassium excess or deficit that are observable on ECG tracings (see Fig. 16.14). Assess vital signs often to identify fever, hypovolemic shock, tachycardia, and Kussmaul respirations.

Hypoglycemia

Hypoglycemia, or low blood glucose, occurs when there is too much insulin in proportion to available glucose in the blood. This causes the blood glucose level to drop to less than 70 mg/dL (3.9 mmol/L). When glucose drops below 70 mg/dL, counterregulatory hormones are released and the autonomic nervous system is activated. Suppression of insulin secretion and production of glucagon and epinephrine provide a defense against hypoglycemia. Epinephrine release causes manifestations that include shakiness, palpitations, nervousness, diaphoresis, anxiety, hunger, and pallor. Because the brain needs a constant supply of glucose in sufficient quantities to function properly, hypoglycemia can affect mental functioning. These "neuroglycopenia" manifestations are difficulty speaking, visual changes, stupor, confusion, and coma. Manifestations of hypoglycemia can mimic alcohol intoxication. Untreated hypoglycemia can progress to loss of consciousness, seizures, coma, and death.

Hypoglycemia unawareness is a condition in which a person does not have the warning signs and symptoms of hypoglycemia until the glucose level reaches a critical point. Then the person may become incoherent and combative or lose consciousness. This is often a result of diabetes-related autonomic neuropathy that interferes with the secretion of counterregulatory hormones that cause these symptoms. Patients at risk for hypoglycemia unawareness include those who have had repeated episodes of hypoglycemia, older adults, and patients who use β-adrenergic blockers. Using intensive treatment to lower blood glucose levels in patients who have or are at risk for hypoglycemia unawareness may not be an appropriate goal. These patients usually keep blood glucose levels somewhat higher than those who can detect and manage the onset of hypoglycemia.

Causes of hypoglycemia are often related to a mismatch in the timing of food intake and the peak action of insulin or OAs that increase endogenous insulin secretion. The balance between blood

glucose and insulin can be disrupted by giving too much insulin or medication, ingesting too little food, delaying the time of eating, and performing unusual or unexpected exercise. Hypoglycemia can occur at any time, but most often occurs when the OA or insulin is at its peak of action or when the patient's daily routine is disrupted without adequate adjustments in diet, drugs, and activity. Although hypoglycemia is most common with insulin therapy, it can occur with noninsulin injectable agents and OAs and may persist for an extended time because of the longer duration of action of these drugs.

Symptoms of hypoglycemia may occur when a very high blood glucose level falls too rapidly (e.g., a blood glucose level of 300 mg/dL [16.7 mmol/L] falling quickly to 150 mg/dL [10 mmol/L]). Although the blood glucose level is above normal by definition and measurement, the sudden metabolic shift can cause hypoglycemia symptoms. Aggressively managing blood glucose levels, lowering high blood glucose levels for the first time, or lowering blood glucose with insulin after a long period of hyperglycemia can cause this situation.

Nursing and Interprofessional Management: Hypoglycemia

Hypoglycemia can usually be quickly reversed with effective treatment. At the first sign of hypoglycemia, check the blood glucose, if possible. If it is less than 70 mg/dL (3.9 mmol/L), immediately begin treatment for hypoglycemia. If the blood glucose is greater than 70 mg/dL, investigate other possible causes of the signs and symptoms. If the patient has manifestations of hypoglycemia and monitoring equipment is not available or the patient has a history of fluctuating blood glucose levels, assume hypoglycemia, and start treatment.

Follow the "Rule of 15" to treat hypoglycemia (Table 48.19). A blood glucose value less than 70 mg/dL is treated by ingesting 15 g of a simple (fast-acting) carbohydrate, such as 4 to 6 oz of fruit juice or a regular soft drink. Commercial products, such as gels or tablets containing specific amounts of glucose, are convenient for carrying in a purse or pocket to be used in such situations. Recheck the blood glucose 15 minutes later. If the value is still less than 70 mg/dL, ingest 15 g more of carbohydrate and recheck the blood glucose in 15 minutes. If no significant improvement occurs after 2 or 3 doses of 15 g of simple carbohydrate, contact the HCP. After an acute episode of hypoglycemia, the patient may need a snack with carbohydrate and protein if the next meal is more than an hour away or if they are being active.

TABLE 48.19 Emergency ManagementHypoglycemia

Etiology	Assessment Findings	Interventions
• **Too little food—delayed, omitted, inadequate intake** • **Too much diabetes medication** • **Too much exercise without adequate food intake** • **Diabetes medication or food taken at wrong time** • **Alcohol use without food intake**	• Blood glucose <70 mg/dL (3.9 mmol/L) • Cold, clammy skin • Numbness of fingers, toes, mouth • Tachycardia • Emotional changes • Headache • Nervousness, tremors • Faintness, dizziness • Unsteady gait, slurred speech • Hunger • Changes in vision • Seizures, coma	Initial • Check blood glucose. • Determine cause of hypoglycemia (after correction of condition). Management *Conscious Patient* • Have patient eat or drink 15 g of quick-acting carbohydrate (4–6 oz of regular soda, 5–8 LifeSavers, 1 Tbsp syrup or honey, 4 tsp jelly, 4–6 oz orange juice, commercial dextrose products [per label instructions]). • Wait 15 min. Check blood glucose again. • If blood glucose is still <70 mg/dL, have patient repeat treatment of 15 g of carbohydrate. • Once the glucose level is stable, give patient additional food of carbohydrate plus protein or fat (e.g., crackers with peanut butter or cheese) if the next meal is more than 1 hr away or patient is engaged in physical activity. • Immediately notify HCP or emergency service (if patient outside hospital) if symptoms do not subside after 2 or 3 doses of quick-acting carbohydrate. *Worsening Symptoms or Unconscious Patient* • Subcutaneous or IM injection of 1 mg glucagon or IV administration of 20–50 mL of 50% glucose. • Turn the patient on the side to prevent aspiration.

Avoid treatment with carbohydrates that contain fat, such as candy bars, cookies, whole milk, and ice cream. The fat in those foods will slow the absorption of the glucose and delay the response to treatment. Do not overtreat with large quantities of quick-acting carbohydrates because a rapid fluctuation to hyperglycemia can occur.

In an acute care setting, patients with hypoglycemia may be given 20 to 50 mL of 50% dextrose IV. If the patient is not alert enough to swallow and no IV access is available, another option is to give 1 mg of glucagon by IM or subcutaneous injection. An IM injection in a site such as the deltoid muscle will result in a quicker response. Glucagon stimulates a strong hepatic response to convert glycogen to glucose and makes glucose rapidly available. Nausea is a common reaction after glucagon injection. To prevent aspiration if vomiting occurs, turn the patient on the side until they are alert. Patients with minimal glycogen stores will not respond to glucagon. This includes patients with alcohol-related hepatic disease, starvation, and adrenal insufficiency. Teach family members and others likely to be present if severe hypoglycemia occurs when and how to inject glucagon.

Once the acute hypoglycemia is reversed, explore with the patient the reasons why the situation developed. This assessment may indicate the need for further patient teaching to avoid future episodes

of hypoglycemia.

Chronic Complications Associated with Diabetes

Angiopathy

Chronic complications associated with diabetes are primarily those of end-organ disease from damage to blood vessels *(angiopathy)* from chronic hyperglycemia (Fig. 48.14). Angiopathy is a leading cause of diabetes-related deaths, with about 68% of deaths caused by CVD and 16% caused by strokes for those ages 65 or older.[19] These chronic blood vessel dysfunctions are divided into 2 categories: macrovascular complications and microvascular complications.

Several theories exist as to how and why chronic hyperglycemia damages cells and tissues. Possible causes include (1) the accumulation of damaging by-products of glucose metabolism, such as sorbitol, which is associated with damage to nerve cells; (2) the formation of abnormal glucose molecules in the basement membrane of small blood vessels, such as those that circulate to the eyes and kidneys; and (3) a derangement in RBC function that leads to a decrease in oxygenation to the tissues.

The Diabetes Control and Complications Trial (DCCT), a landmark study in diabetes management, showed the risk for microvascular complications could be significantly reduced in patients with type 1 diabetes by keeping blood glucose levels as near to normal as possible for as much of the time as possible *(tight or intensive therapy).*[20] Those who maintained tight glucose levels reduced their risk for developing retinopathy and nephropathy, common microvascular complications. Based on these findings, the ADA issued recommendations for diabetes management that included treatment goals to maintain blood glucose levels as near to normal as possible. Specific targets for individual patients must consider the risk for severe or undetected hypoglycemia as a side effect of intensive management.

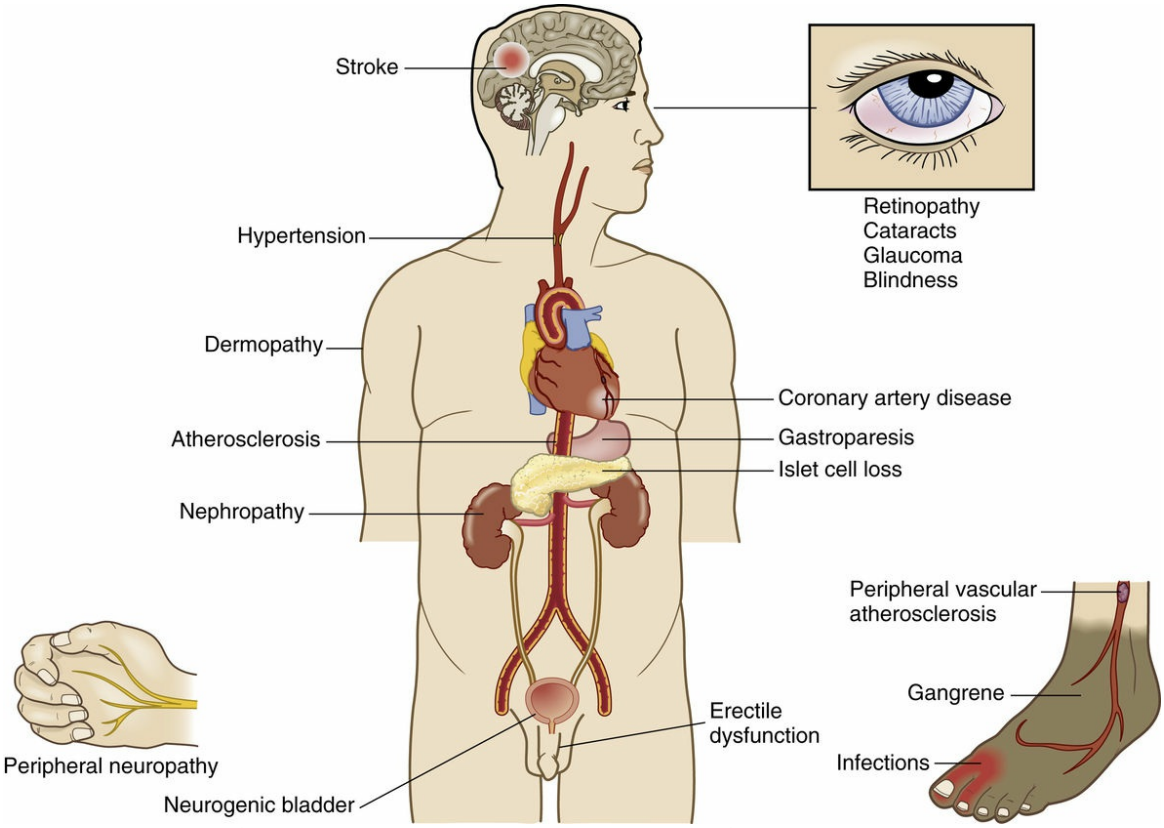

FIG. 48.14 Long-term complications of diabetes.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

The United Kingdom Prospective Diabetes Study (UKPDS) showed that intensive treatment of type 2 diabetes significantly lowered the risk for developing diabetes-related eye, kidney, and neurologic problems. The findings included a 25% reduction of microvascular disease and a 16% reduction in the risk for MI in those who maintained long-term blood glucose levels.[21]

Because of the devastating effects of long-term complications, patients with diabetes need scheduled and ongoing monitoring for the detection and prevention of chronic complications. The ADA recommendations for ongoing evaluation are shown in Table 48.20. It is essential that patients understand the importance of regular follow-up visits.

Macrovascular Complications

Macrovascular complications are diseases of the large and medium-size

blood vessels that occur with greater frequency and with an earlier onset in people with diabetes. Macrovascular diseases include cerebrovascular, cardiovascular, and peripheral vascular disease. Women with diabetes have a 4 to 6 times increased risk for CVD. Men with diabetes have a 2 to 3 times increased risk for CVD compared with those without diabetes.[2]

TABLE 48.20 Monitoring for Long-Term Complications Related to Diabetes

Complication	Type of Examination	Frequency
Retinopathy	• Funduscopic: dilated eye examination • Fundus photography	• Annually
Nephropathy	• Urine for albuminuria • Serum creatinine	• Annually
Neuropathy (foot and lower extremities)	• Visual examination of foot	• Daily by patient • Every visit to HCP
	• **Comprehensive foot:** • **Visual examination** • **Sensory examination with monofilament and tuning fork** • **Palpation (pulses, temperature, callus formation)**	• Annually*
Cardiovascular disease	• Risk factor assessment: hypertension, dyslipidemia, smoking, family history of premature coronary artery disease, and presence of albuminuria or	• Every visit • At least annually
	• **Exercise stress testing (may include stress ECG, stress echocardiogram, stress nuclear imaging)**	• As needed, based on risk factors

* If patients have a history of foot ulcers, loss of sensation in their feet, or other foot abnormalities, the recommendation is to have a foot examination at every visit.

Source: American Diabetes Association: Standards of medical care in diabetes, *Diabetes Care* 41:S86, 2018.

Patients with diabetes can decrease several risk factors associated with macrovascular complications, such as obesity, smoking, hypertension, high fat intake, and sedentary lifestyle. The ADA recognizes that diabetes alone is a CVD risk factor. The ADA recommends yearly screening for CVD risk factors in people with diabetes.[22]

Insulin resistance is important in the development of CVD and implicated in the pathogenesis of essential hypertension and

dyslipidemia. We do not completely understand the role of insulin resistance in the pathogenesis of CVD. It seems to combine with dyslipidemia in contributing to greater risk for CVD in patients with diabetes.

Optimizing BP control in patients with diabetes is significant in preventing CVD and renal disease. Treating hypertension in those with diabetes results in a decrease in macrovascular and microvascular complications. Hypertension in people with diabetes causes an increase in mortality greater than for those with hypertension without diabetes. The ADA recommends BP screening at every visit for people with diabetes. They recommend lifestyle counseling for BP greater than 130/80 mm Hg and treatment to achieve a target BP of less than 140/90 mm Hg for most patients with diabetes.[22] Hypertension is discussed in Chapter 32, and coronary artery disease is discussed in Chapter 33.)

Patients with diabetes have an increase in lipid abnormalities that contribute to their increased risk for CVD. The ADA recommends screening all adults for dyslipidemia at the time diabetes is diagnosed and starting statin therapy as needed. Dosing is based on the presence of age and other CVD risk factors. The ADA advocates treating hyperlipidemia with lifestyle interventions, including nutrition therapy, exercise, weight loss, and smoking cessation.

Smoking, which is detrimental to health in general, is especially dangerous for people with diabetes. It significantly increases their risk for blood vessel and CVD, stroke, and lower extremity amputation.

Microvascular Complications

Microvascular complications result from thickening of the vessel membranes in the capillaries and arterioles (small vessels) in response to conditions of chronic hyperglycemia. Although microangiopathy can be found throughout the body, the areas most noticeably affected are the eyes (retinopathy), kidneys (nephropathy), and nerves (neuropathy). Microvascular changes are present in some patients with type 2 diabetes at the time of diagnosis.

Retinopathy

Etiology and Pathophysiology

Diabetes-related retinopathy refers to the process of microvascular damage to the retina because of chronic hyperglycemia, nephropathy, and hypertension in patients with diabetes. Diabetes-related retinopathy is the leading cause of new cases of adult blindness.[2]

We classify retinopathy as nonproliferative or proliferative. In *nonproliferative retinopathy,* the most common form, partial occlusion of the small blood vessels in the retina causes microaneurysms to develop in the capillary walls. The walls of these microaneurysms are so weak that capillary fluid leaks out, causing retinal edema and eventually hard exudates or intraretinal hemorrhages. This may cause mild to severe vision loss, depending on which parts of the retina are affected. If the center of the retina (macula) is affected, vision loss can be severe.

Proliferative retinopathy, the most severe form, involves the retina and vitreous. When retinal capillaries become occluded, the body compensates by forming new blood vessels to supply the retina with blood, a pathologic process known as *neovascularization.* These new vessels are extremely fragile and hemorrhage easily, producing vitreous contraction. Eventually light is prevented from reaching the retina as the vessels break and bleed into the vitreous cavity. The patient sees black or red spots or lines. If these new blood vessels pull the retina while the vitreous contracts, causing a tear, partial or complete retinal detachment will occur. If the macula is involved, vision is lost. Without treatment, more than half of patients with proliferative diabetic retinopathy will be blind.

Persons with diabetes are prone to other visual problems. Glaucoma occurs because of the occlusion of the outflow channels from neovascularization. This type of glaucoma is hard to treat and often results in blindness. Cataracts develop at an earlier age and progress more rapidly in people with diabetes.

Interprofessional Care

The earliest and most treatable stages of diabetes-related retinopathy often cause no changes in the vision. Therefore teach patients with type 2 diabetes to have a dilated eye examination by an ophthalmologist or a specially trained optometrist at the time of diagnosis and annually thereafter for early detection and treatment. Those with type 1 diabetes need to have a dilated eye examination within 5 years after the onset of diabetes and then annually.

The best approach to managing diabetes-related eye disease is to prevent it by maintaining healthy blood glucose levels and managing hypertension. Laser photocoagulation therapy can reduce the risk for vision loss in patients with proliferative retinopathy or macular edema and, sometimes, nonproliferative retinopathy. Laser photocoagulation destroys the ischemic areas of the retina that make growth factors that encourage neovascularization. A patient who develops vitreous hemorrhage and retinal detachment of the macula may need to undergo vitrectomy. *Vitrectomy* is the aspiration of blood, membrane, and fibers from the inside of the eye through a small incision just behind the cornea. (Photocoagulation and vitrectomy are discussed in Chapter 20.)

A fluocinolone acetonide intravitreal implant (Iluvien) is used to treat retinopathy. It is an injectable microinsert that provides sustained treatment through continuous delivery of corticosteroid fluocinolone acetonide for 36 months. Iluvien is injected in the back of the patient's eye with an applicator that uses a 25-gauge needle, which allows for a self-sealing wound.

Vascular endothelial growth factor (VEGF) plays a key role in the development of diabetes-related retinopathy. We are currently studying drugs injected into the eye that block the action of VEGF and reduce inflammation for their effectiveness in treating retinopathy.[23]

Nephropathy

Diabetes-related nephropathy is a microvascular complication associated with damage to the small blood vessels that supply the glomeruli of the kidney. It is the leading cause of ESRD in the United States and seen in 20% to 40% of people with diabetes. Risk factors include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Keeping blood glucose levels in a healthy range is critical in the prevention and delay of diabetes-related nephropathy.[21]

Patients are screened for nephropathy annually with a random spot urine collection to assess for albuminuria and measure the albumin-to-creatinine ratio. Serum creatinine is measured to give an estimate of the glomerular filtration rate and the degree of kidney function.

Patients with diabetes who have albuminuria receive either ACE inhibitor drugs (e.g., lisinopril [Prinivil, Zestril]) or angiotensin II receptor blockers (e.g., losartan [Cozaar]). Both classifications of these drugs are used to treat hypertension and delay the progression of nephropathy in patients with diabetes. Hypertension significantly accelerates the progression of nephropathy. Therefore aggressive BP management is indicated for all patients with diabetes. See Chapter 32 for a discussion of hypertension and Chapter 46 for a discussion of renal failure.

Neuropathy

Diabetes-related neuropathy is nerve damage that occurs because of the metabolic imbalances associated with diabetes. About 60% to 70% of patients with diabetes have some degree of neuropathy.[2] The most common type affecting persons with diabetes is sensory neuropathy. This can lead to the loss of protective sensation in the lower extremities. Coupled with other factors, it significantly increases the risk for complications that result in a lower limb amputation. More than 60% of nontraumatic amputations in the United States occur in people with diabetes.[2] Screening for neuropathy begins at the time of diagnosis in patients with type 2 diabetes and 5 years after diagnosis in patients with type 1 diabetes.[3]

Etiology and Pathophysiology

We do not completely understand the pathophysiologic processes of diabetes-related neuropathy. Theories include metabolic, vascular, and autoimmune factors. The prevailing theory is that persistent hyperglycemia leads to an accumulation of sorbitol and fructose in the nerves that causes damage. How they cause damage is unknown. The result is reduced nerve conduction and demyelination. Ischemic damage by chronic hyperglycemia in blood vessels that supply the peripheral nerves is implicated in the development of diabetes-related neuropathy. Neuropathy can precede, accompany, or follow the diagnosis of diabetes.

Classification

The 2 major categories of diabetes-related neuropathy are *sensory neuropathy,* which affects the peripheral nervous system, and *autonomic neuropathy.* Each type has several forms.

Sensory Neuropathy

The most common form of sensory neuropathy is distal symmetric polyneuropathy, which affects the hands and/or feet bilaterally. This is sometimes called *stocking-glove neuropathy.* Characteristics include loss of sensation, abnormal sensations, pain, and paresthesias. The pain, which patients describe as burning, cramping, crushing, or tearing, is usually worse at night and may occur only at that time. The paresthesias may be associated with tingling, burning, and itching sensations. The patient may report a feeling of walking on pillows or numb feet. The skin can become so sensitive (hyperesthesia) that the patient cannot tolerate even light pressure from bed sheets. Complete or partial loss of sensitivity to touch and temperature is common. Foot injury and ulcerations can occur without the patient ever having pain (Fig. 48.15). Neuropathy can cause atrophy of the small muscles of the hands and feet, causing deformity and limiting fine movement.

Managing blood glucose is the only treatment for diabetes-related neuropathy. It is effective in many, but not all, cases. Drug therapy may be used to treat neuropathic symptoms, especially pain. At the start of therapy, symptoms usually increase, followed by relief of pain in 2 to 3 weeks.

Drugs commonly used include topical creams (e.g., capsaicin [Zostrix]), tricyclic antidepressants (e.g., amitriptyline), selective serotonin and norepinephrine reuptake inhibitors (e.g., duloxetine [Cymbalta]), and antiseizure drugs (e.g., gabapentin [Neurontin], pregabalin [Lyrica]). Capsaicin is a moderately effective topical cream made from chili peppers. It depletes the accumulation of pain-mediating chemicals in the peripheral sensory neurons. The cream is applied 3 or 4 times a day.

Tricyclic antidepressants are moderately effective in treating diabetes-related neuropathy. They work by inhibiting the reuptake of norepinephrine and serotonin, which are neurotransmitters thought to play a role in the transmission of pain through the spinal cord. We think duloxetine relieves pain by increasing the levels of serotonin and norepinephrine, which improves the body's ability to regulate pain. Antiseizure drugs decrease the release of neurotransmitters that transmit pain.[24]

Autonomic Neuropathy

Autonomic neuropathy can affect nearly all body systems and lead to hypoglycemia unawareness, bowel incontinence and diarrhea, and urinary retention. *Gastroparesis* (delayed gastric emptying) is a complication of autonomic neuropathy that can cause anorexia, nausea, vomiting, gastroesophageal reflux, and persistent feelings of fullness. Gastroparesis can trigger hypoglycemia by delaying food absorption. Cardiovascular abnormalities associated with autonomic neuropathy are postural hypotension, resting tachycardia, and painless MI. Assess patients with diabetes for postural hypotension to determine if they are at risk for falls. Teach the patient with postural hypotension to change from a lying or sitting position slowly.

Diabetes can affect sexual function in men and women. Erectile dysfunction (ED) in men with diabetes is well recognized and common, often being the first manifestation of autonomic neuropathy. ED is associated with other factors, including vascular disease, elevated blood glucose levels, endocrine disorders, psychogenic factors, and medications. Decreased libido is a problem for some women with diabetes. Candida and nonspecific vaginitis are common. ED or sexual dysfunction requires sensitive therapeutic counseling for both the patient and the patient's partner. See Chapter 55 for more about ED.

FIG. 48.15 Neuropathy: Neurotrophic ulceration.

A neurogenic bladder may develop as the sensation in the inner bladder wall decreases, causing urinary retention. A patient with retention has infrequent voiding, difficulty voiding, and a weak stream of urine. Emptying the bladder every 3 hours in a sitting position helps prevent stasis and infection. Tightening the abdominal muscles during voiding and using the Credé maneuver (mild massage downward over the lower abdomen and bladder) may help with complete bladder emptying. Cholinergic agonist drugs, such as bethanechol (Urecholine), may be used. The patient may need to learn self-catheterization (see Chapter 45).

Complications of Feet and Lower Extremities

People with diabetes are at high risk for foot ulcerations and lower extremity amputations. The development of diabetes-related foot complications can be the result of a combination of microvascular and macrovascular diseases that place the patient at risk for injury and serious infection (Fig. 48.16). Sensory neuropathy and peripheral artery disease (PAD) are risk factors for foot complications. In addition, clotting abnormalities, impaired immune function, and autonomic neuropathy have a role. Smoking has a negative effect on the health of lower extremity blood vessels and increases the risk for amputation.

Sensory neuropathy is a major risk factor for lower extremity amputation in the person with diabetes. *Loss of protective sensation* (LOPS) often prevents the patient from being aware that a foot injury has occurred. Improper footwear and injury from stepping on foreign objects while barefoot are common causes of undetected foot injury in the person with LOPS. Because the primary risk factor for lower extremity amputation is LOPS, annual screening using a *monofilament* is important.[25] This is done by applying a thin, flexible filament to several spots on the plantar surface of the foot and asking the patient to report if it is felt. Insensitivity to a monofilament greatly increases the risk for foot ulcers that can lead to amputation.

FIG. 48.16 The necrotic toe developed as a complication of diabetes. **A,** Before amputation. **B,** After amputation.
From Chew SL, Leslie D: *Clinical endocrinology and diabetes: An illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.

PAD increases the risk for amputation by causing a reduction in blood flow to the lower extremities. With decreased blood flow, oxygen, white blood cells (WBCs), and vital nutrients are not available to the tissues. Wounds take longer to heal, and the risk for infection increases. Signs of PAD include intermittent claudication, pain at rest, cold feet, loss of hair, delayed capillary filling, and dependent rubor (redness of the skin that occurs when the extremity is in a dependent position). PAD is diagnosed by history, ankle-brachial index (ABI), and angiography. Management includes reduction of risk factors, especially smoking, cholesterol intake, and hypertension. Bypass or graft surgery is indicated in some patients. PAD is discussed in Chapter 37.

If the patient has LOPS or PAD, aggressive measures must be taken

to teach the patient how to prevent foot ulcers. These measures include choosing proper footwear, including protective shoes. Teach the patient to carefully avoid injury to the foot, practice diligent skin and nail care, inspect the foot thoroughly each day, and treat small problems promptly. Guidelines for patient teaching are listed in Table 48.21.

Proper care of a foot ulcer is critical for wound healing. Several forms of treatment can be used. Casting can redistribute the weight on the plantar surface of the foot. Wound care for the ulcer can include debridement, dressings, advanced wound healing products (becaplermin [Regranex]), vacuum-assisted closure, ultrasound, hyperbaric O_2, and skin grafting.

Table 48.21 Patient & Caregiver Teaching*Foot Care

Include the following instructions when teaching the patient and caregiver about foot care:

1. Wash feet daily with a mild soap and warm water. First test water temperature with elbow.
2. Pat feet dry gently, especially between toes.
3. Examine feet daily for cuts, blisters, swelling, and red, tender areas. Do not depend on feeling sores. If eyesight is poor, have others inspect feet.
4. Use lanolin on feet to prevent skin from drying and cracking. Do not apply between toes.
5. Use mild foot powder on sweaty feet.
6. Do not use commercial remedies to remove calluses or corns.
7. Cleanse cuts with warm water and mild soap, covering with clean dressing. Do not use iodine, rubbing alcohol, or strong adhesives.
8. Report skin infections or nonhealing sores to HCP at once.
9. Cut toenails evenly with rounded contour of toes. Do not cut

down corners. The best time to trim nails is after a shower or bath.

10. Separate overlapping toes with cotton or lamb's wool.
11. Avoid open-toe, open-heel, and high-heel shoes. Leather shoes are preferred to plastic ones. Wear slippers with soles. Do not go barefoot. Inspect feet, socks and shoes for foreign objects before putting on.
12. Wear clean, absorbent (cotton or wool) socks or stockings that have not been mended. Colored socks must be colorfast.
13. Do not wear clothing that leaves impressions, hindering circulation.
14. Do not use hot water bottles or heating pads to warm feet. Wear socks for warmth.
15. Guard against frostbite.
16. Exercise feet daily either by walking or by flexing and extending feet in suspended position. Avoid prolonged sitting, standing, and crossing of legs.

---

* This teaching guide is also appropriate for patients with peripheral vascular problems.

Neuropathic arthropathy, or *Charcot's foot*, results in ankle and foot changes that lead to joint dysfunction and footdrop. These changes occur gradually and promote an abnormal distribution of weight over the foot. This increases the chances of developing a foot ulcer as new pressure points appear. Foot deformity should be recognized early, and proper footwear fitted before ulceration occurs.

Skin Complications

Up to two thirds of persons with diabetes develop skin problems. Diabetes-related dermopathy, the most common skin lesion, is characterized by reddish brown, round or oval patches. They initially are scaly, then they flatten out and become indented. The lesions appear most often on the shins but can occur on the front of the thighs, forearm, side of the foot, scalp, and trunk.

Acanthosis nigricans is a manifestation of insulin resistance. It can appear as a velvety light brown to black skin thickening, mainly on flexures, axillae, and the neck. *Necrobiosis lipoidica diabeticorum* usually appears as red-yellow lesions, with atrophic skin that becomes shiny and transparent, revealing tiny blood vessels under the surface (Fig. 48.17). This condition is uncommon. It occurs more often in young women. It may appear before other signs and symptoms of diabetes. Because the thin skin is prone to injury, special care must be taken to protect affected areas from injury and ulceration.

Infection

A person with diabetes is more susceptible to infections because of a defect in the mobilization of WBCs and an impaired phagocytosis by neutrophils and monocytes. Recurring or persistent infections, such as *Candida albicans,* boils, and furuncles in the undiagnosed patient often lead the HCP to suspect diabetes. Loss of sensation (neuropathy) may delay the detection of an infection.

Persistent glycosuria may predispose patients to bladder infections, especially patients with a neurogenic bladder. Decreased circulation resulting from angiopathy can prevent or delay the immune response. Antibiotic therapy has prevented infection from being a major cause of death in patients with diabetes. The treatment of infections must be prompt and vigorous. Teach patients to prevent infection by practicing good hand hygiene, avoiding exposure to persons who have a communicable illness, and getting an annual influenza vaccine and pneumococcal vaccine. (Guidelines for pneumococcal vaccine are shown in Table 27.5.)

FIG. 48.17 Necrobiosis lipoidica diabeticorum.
From Chew SL, Leslie D: *Clinical endocrinology and diabetes: An illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.

Psychologic Considerations

Patients with diabetes have high rates of depression, anxiety, and eating disorders. Depression contributes to diminished diabetes self-care, feelings of helplessness related to chronic illness, and poor outcomes.[9] Diabetes distress is different from depression and encompasses the stress, fear, and burden of living with and managing a demanding chronic disease. Assess patients for manifestations of depression and/or diabetes distress.

Disordered eating behaviors (DEBs) can occur in people with both type 1 and type 2 diabetes. DEBs include anorexia, bulimia, binge eating, excessive restriction of calories, and intense exercise. The greatest incidence of eating disorders is seen in females. Adolescent girls with diabetes are more than twice as likely to develop DEB than those who do not have diabetes.[26] Patients may intentionally decrease their dose of insulin or omit the dose. This is called "diabulimia." It leads to weight loss, hyperglycemia, and glycosuria because the food ingested cannot be used for energy without adequate insulin. Insulin omission and DEBs can have serious consequences, including retinopathy, neuropathy, lipid abnormalities, DKA, and death.[26]

Open communication is critical to identify these behaviors early. Refer patients with eating disorders to a mental health professional with expertise in eating disorders and an understanding of diabetes management.

Gerontologic Considerations: Diabetes

Diabetes is present in more than 25% of persons over 65 years of age. This age-group is the fastest-growing segment of the population developing diabetes.[2] Older people with diabetes have higher rates of premature death, functional disability, and coexisting illnesses, such as hypertension and stroke, than those without diabetes. The prevalence of diabetes increases with age. A major reason for this is that the process of aging is associated with a reduction in β-cell

function, decreased insulin sensitivity, and altered carbohydrate metabolism. Aging is also associated with conditions that are more likely to be treated with drugs that impair insulin action (e.g., corticosteroids, antihypertensives, phenothiazines). Undiagnosed and untreated diabetes is more common in older adults, partly because many of the normal physiologic changes of aging resemble those of diabetes, such as low energy levels, falls, dizziness, confusion, and chronic UTIs.

Several factors affect setting glycemic goals for an older adult. One is that hypoglycemia unawareness is more common in older adults, making them more likely to have adverse consequences from blood glucose–lowering therapy. They may have delayed psychomotor function that could interfere with the ability to treat hypoglycemia. Other factors include the patient's desire for treatment and coexisting medical problems, such as cognitive impairment. Compounding the challenge, diabetes increases the rate of decline of cognitive function. Although it is generally agreed that treatment is indicated to prevent complications, intensive diabetes management may be hard and dangerous to achieve, especially in older adults.

Ethical/Legal Dilemmas

Durable Power of Attorney for Health Care

Situation

G.V., a 64-yr-old woman, is admitted to the intensive care unit with HF. She has many complications from a long-term history of type 1 diabetes and hypertension, including a right leg above-the-knee amputation and blindness related to retinopathy. She severed ties with her family 30 years ago. She has a life partner of 35 years whom she chose as her proxy in her signed Durable Power of Attorney. She has said many times that she would rather die than have renal dialysis. She has been sedated and intubated for 3 days. The HCP plans to extubate her and resuscitate her so that she can start dialysis.

Her brother shows up at the hospital and supports the HCP's decision. Her partner disagrees with the decision. The HCP refuses to recognize her partner as proxy because she is not a blood relative.

Ethical/Legal Points for Consideration

The Patient Self-Determination Act (1990) requires all health care facilities receiving Medicare and Medicaid funding to make available advance directives allowing persons to state their preferences or refusals of health care in the event that they are incapable of consenting for themselves.

Durable Power of Attorney for health care is one type of advance directive in which people, when they are competent, identify someone else to make decisions for them, should they lose their decision-making ability in the future (see Table 9.6).

The Living Will, another type of advance directive, permits people to state their own preferences and refusals.

Many HCPs mistakenly think that proxies must be family members or blood relatives. Lesbian, gay, bisexual, and transgender (LGBT) persons often have difficulty having their partnership recognized as valid, especially if the patient's family disputes their rights.

Some families are deeply divided on decisions for their loved ones. Sometimes difficulties occur when money and property are also disputed. The passage of time may be an issue where the original documents were executed and then changes occurred (e.g., divorce, death or disability of the proxy, inability to contact the proxy, inability to find a valid original of the advance directive).

Within your scope of nursing practice, you need to know the decision-making laws and regulations in your own state and make advance directive documents available to patients. In addition, you need to (1) teach patients and their families about advance directives, (2) make sure that HCPs are aware of and follow advance directives, (3) assist the patient and family in communicating with the HCPs when a "No Code" order is requested, and (4) assist a conflicted family in obtaining appropriate counseling whenever needed.

Counsel LGBT patients on the importance of having a health care proxy and a will to legally protect their end-of-life choices.

Discussion Questions

1. How would you handle a situation in which the family and surrogate decision maker disagree?
2. How can you assess the patient and family's understanding of durable power of attorney and assist them in understanding their role in decision making?
3. What should you do when an HCP orders dialysis to be started when you know that this goes against the patient's advance directive?

Meal planning and exercise are recommended therapy for older adults with diabetes. Consider functional limitations that may interfere with physical activity and the ability to prepare meals. Because of the physiologic changes that occur with aging, the therapeutic outcome for the older adult who receives OAs may be altered. Assess renal function and creatinine clearance in those over 80 years of age taking metformin. Monitor those taking sulfonylurea drugs (e.g., glipizide) for hypoglycemia and renal and liver dysfunction. Insulin therapy may be started if OAs are not effective. However, older adults are more likely to have limitations in the manual dexterity and visual acuity necessary for accurate insulin administration. Insulin pens may be a safer alternative.

Patient education issues include those related to altered vision, mobility, cognitive status, and functional ability. Plan patient teaching based on individual needs, using a slower pace with simple printed or audio materials in patients with cognitive and functional limitations. Include the family or caregivers in the teaching. Consider the patient's financial and social situation and the effect of multiple drugs, eating habits, and quality-of-life issues.

Case Study

Diabetes-Related Ketoacidosis

© katrinaelena/iStock/Thinkstock.

Patient Profile

N.B., a 48-yr-old farmer, was admitted to the emergency department after he was found unconscious by his wife in their barn. They live 40 miles from the nearest health care facility. He has a medical history of type 1 diabetes, hypertension, and diabetic neuropathy.

Subjective Data (Provided by Wife)

- Diagnosed with type 1 diabetes 15 years ago
- Takes 40 U/day of insulin via insulin pump: 5 U of lispro insulin bolus with breakfast, 5 U bolus with lunch, and 10 U bolus with dinner plus 20 U of basal insulin
- Has history of gastroenteritis for 1 wk with vomiting and anorexia
- Stopped taking meal time boluses 2 days ago when he was unable to eat
- Has not changed his infusion set in 5 days

Objective Data
Physical Examination

- Respirations deep with rate 36 breaths/min
- Fruity acetone smell on breath
- Skin flushed and dry
- Heart rate 118 beats/min; BP 98/60 mm Hg

Diagnostic Studies

- Blood glucose level 730 mg/dL (40.5 mmol/L)
- Blood pH 7.26

Discussion Questions

1. Briefly explain the pathophysiology behind N.B.'s diabetes-related ketoacidosis (DKA).
2. What factors precipitated his developing DKA?
3. What clinical manifestations of DKA does this patient exhibit?
4. What distinguishes this case history from one of hyperosmolar hyperglycemia syndrome (HHS) or hypoglycemia?

5. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Priority Decision:*** What is the priority nursing intervention for N.B.?
7. ***Priority Decision:*** What is the priority teaching for this patient and his family?
8. ***Evidence-Based Practice:*** N.B.'s wife asks you if she should have given her husband insulin when he got sick. How would you respond?
9. ***Collaboration:*** How can the interprofessional team be most effective in caring for N.B?
10. ***Quality Improvement:*** What outcomes would indicate that the interprofessional team was effective in caring for N.B.?
11. Develop a conceptual care map for N.B.

Answers and a corresponding concept map are available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Polydipsia and polyuria related to diabetes are primarily due to
   a. the release of ketones from cells during fat metabolism.
   b. fluid shifts resulting from the osmotic effect of hyperglycemia.
   c. damage to the kidneys from exposure to high levels of glucose.
   d. changes in RBCs resulting from attachment of excess glucose to hemoglobin.
2. Which statement would be correct for a patient with type 2 diabetes who was admitted to the hospital with pneumonia?
   a. The patient must receive insulin therapy to prevent ketoacidosis.
   b. The patient has islet cell antibodies that have destroyed the pancreas's ability to make insulin.
   c. The patient has minimal or absent endogenous insulin secretion and requires daily insulin injections.
   d. The patient may have enough endogenous insulin to prevent ketosis but is at risk for hyperosmolar hyperglycemia syndrome.
3. Analyze the following diagnostic findings for your patient with type 2 diabetes. Which result will need further

assessment?

a. A1C 9%

b. BP 126/80 mmHg

c. FBG 130 mg/dL (7.2 mmol/L)

d. LDL cholesterol 100 mg/dL (2.6 mmol/L)

4. Which statement by the patient with type 2 diabetes is accurate?

a. "I will limit my alcohol intake to 1 drink each day."

b. "I am not allowed to eat any sweets because of my diabetes."

c. "I cannot exercise because I take a blood glucose-lowering medication."

d. "The amount of fat in my diet is not important. Only carbohydrates raise my blood sugar."

5. You are caring for a patient with newly diagnosed type 1 diabetes. What information is *essential* to include in your patient teaching before discharge from the hospital? *(select all that apply)*

a. Insulin administration

b. Elimination of sugar from diet

c. Need to reduce physical activity

d. Use of a portable blood glucose monitor

e. Hypoglycemia prevention, symptoms, and treatment

6. What is the *priority* action for the nurse to take if the patient with type 2 diabetes reports blurred vision and irritability?

a. Call the provider.

b. Give insulin as ordered.

c. Assess for other neurologic symptoms.

d. Check the patient's blood glucose level.

7. A patient with diabetes has a serum glucose level of 824 mg/dL (45.7 mmol/L) and is unresponsive. After assessing the patient, the nurse suspects diabetes-related ketoacidosis rather than hyperosmolar hyperglycemia syndrome based on the finding of

a. polyuria.

b. severe dehydration.

c. rapid, deep respirations.

d. decreased serum potassium.

8. Which are appropriate therapies for patients with diabetes? *(select all that apply)*

a. Use of statins to reduce CVD risk

b. Use of diuretics to treat nephropathy

c. Use of ACE inhibitors to treat nephropathy

d. Use of serotonin agonists to decrease appetite

e. Use of laser photocoagulation to treat retinopathy

1. b, 2. d, 3. a, 4. a, 5. a, d, e, 6. d, 7. c, 8. a, c, e

LEARNING OUTCOMES

1. Explain the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an imbalance of hormones made by the anterior pituitary gland.
2. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an imbalance of hormones made by the posterior pituitary gland.
3. Explain the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with thyroid dysfunction.
4. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with

parathyroid dysfunction.

5. Identify the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an imbalance of hormones made by the adrenal cortex.
6. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an excess of hormones made by the adrenal medulla.
7. List the side effects of corticosteroid therapy.

The endocrine system is made up of several organs and glands that are involved in the synthesis and secretion of hormones that affect every body system. Because hormones have a wide range of action, problems with their regulation are associated with homeostatic changes that can affect many aspects of a person's life. The severity varies widely. There may be adverse effects on perfusion, metabolism, and nutrition. Regulating fluid and electrolyte balance, skin integrity, and temperature may be difficult. The patient may have problems with growth and fertility and reproductive processes since these are hormone dependent. There may be a wide range of psychologic responses, including anxiety and depression.

Disorders of Anterior Pituitary Gland

The pituitary gland is considered the master gland of the endocrine system. The anterior pituitary gland secretes growth hormone (GH), prolactin, and tropic hormones, adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). These hormones affect growth, sexual maturation, reproduction, metabolism, stress response, and fluid balance. As a result, pituitary gland disorders manifest in a variety of ways.

Tumors of the pituitary gland account for 5% to 20% of primary intracranial tumors.[1] The most common, a pituitary adenoma, is a slow-growing, benign tumor. It often occurs in adults between 40 and 60 years of age. Hypersecretory pituitary adenomas secrete an excess of a specific hormone causing manifestations related to the action of

that hormone. The most common are prolactinomas and GH- and ACTH-secreting adenomas.[1]

Acromegaly

Acromegaly is a rare condition characterized by an overproduction of GH. Around 4 of every 1 million adults in the United States are diagnosed annually.[2] It affects both genders equally. The mean age at the time of diagnosis is 40 to 45 years old.

Etiology and Pathophysiology

Acromegaly most often occurs because of a benign GH-secreting pituitary adenoma. The excess GH results in an overgrowth of soft tissues and bones in the hands, feet, and face. Because the problem develops after epiphyseal closure, the bones of the arms and legs do not grow longer.

Clinical Manifestations

The changes resulting from excess GH in adults can occur slowly, over many years, and may go unnoticed by the person, family, and friends. Thickening and enlargement of the bony and soft tissues on the face, feet, and head occur (Fig. 49.1). Patients may have proximal muscle weakness and joint pain that can range from mild to crippling. Carpal tunnel syndrome and peripheral neuropathy may be present.

Tongue enlargement results in dental and speech problems. The voice deepens because of hypertrophy of the vocal cords. Sleep apnea may occur because of upper airway narrowing and obstruction from increased amounts of pharyngeal soft tissues. The skin becomes thick, leathery, and oily with acne outbreaks.

Vision changes may occur from pressure on the optic nerve from a pituitary adenoma. Headaches are common. Since GH antagonizes the action of insulin, glucose intolerance and manifestations of diabetes may occur, including *polydipsia* (increased thirst) and *polyuria*

(increased urination).

The life expectancy of those with acromegaly is reduced by 5 to 10 years. They are prone to cardiovascular disease (CVD), diabetes, and colorectal cancer.[3] Even if patients are cured or the disease is well controlled, manifestations such as joint pain and deformities often remain.

Diagnostic Studies

In addition to the history and physical examination, a diagnosis requires evaluating plasma insulin-like growth factor-1 (IGF-1) levels and GH response to an oral glucose tolerance test (OGTT). IGF-1 mediates the peripheral actions of GH. As GH levels rise, so do IGF-1 levels. Since GH is released in a pulsatile fashion, several samples are needed to obtain an accurate assessment. Serum IGF-1 levels are more constant, giving a more reliable diagnostic measure of acromegaly. During an OGTT, GH concentration normally falls because glucose inhibits GH secretion. In acromegaly, GH levels do not fall and in some cases GH levels rise.

FIG. 49.1 Progressive development of facial changes associated with

acromegaly.
Courtesy Linda Haas, Seattle, WA.

MRI or high-resolution CT scan with contrast media can detect pituitary adenomas. A complete eye examination, including visual fields, is done because a tumor may cause pressure on the optic chiasm or optic nerves.

Interprofessional and Nursing Care

The patient's prognosis depends on the age at onset, age when treatment started, and tumor size. The overall goal is to return the patient's GH levels to normal. Treatment consists of surgery, radiation therapy, drug therapy, or a combination of these therapies. Treatment can stop bone growth and reverse tissue hypertrophy. However, sleep apnea, diabetes, and cardiac problems may persist.

Surgery (hypophysectomy) is the treatment of choice. It offers the best chance for a cure and optimal symptom management, especially for smaller pituitary tumors.[4] Surgery results in an immediate reduction in GH levels. IGF-1 levels fall within a few weeks. Patients with larger tumors or those with GH levels greater than 45 ng/mL may need adjuvant radiation or drug therapy. Surgery and radiation therapy for pituitary tumors are discussed later in this chapter on p. 1145.

Drug therapy is an option for patients whose surgery did not result in a cure and/or in combination with radiation therapy. The main drug used is octreotide (Sandostatin), a somatostatin analog. It reduces GH levels to normal in many patients. Octreotide is given by subcutaneous injection 3 times a week. Long-acting somatostatin analogs, octreotide (Sandostatin LAR), pasireotide (Signifor), and lanreotide SR (Somatuline Depot), are available as IM injections given every 4 weeks. GH levels are measured every 2 weeks to guide drug dosing and then every 6 months until the desired response is achieved.

Dopamine agonists (e.g., bromocriptine, cabergoline) may be given alone or with somatostatin analogs if complete remission has not been

achieved after surgery. These drugs reduce the secretion of GH from the tumor.

GH antagonists (e.g., pegvisomant [Somavert]) reduce the effect of GH in the body by blocking liver production of IGF-1. Most patients taking this drug achieve normal IGF-1 levels with symptom improvement.[3]

Serial photographs showing improvement in appearance may be helpful to the patient's recovery. Psychosocial effects of acromegaly include body image problems, sexual problems, and depression. Fatigue and sleep problems may persist after surgery. Patients will need strategies for dealing with these symptoms. Referral to a support group may be helpful.

Excesses of Other Tropic Hormones

Excess secretion of prolactin or the tropic hormones (e.g., ACTH, TSH) by the anterior pituitary gland will cause other endocrine glands to overproduce certain hormones. An excess of these hormones (discussed later in the chapter) can cause significant problems in metabolism and general health.

A prolactin-secreting adenoma is known as a *prolactinoma.* They account for about 40% of pituitary tumors.[5] Women with prolactinomas may have galactorrhea, anovulation, infertility, infrequent or absent menses, decreased libido, and hirsutism. In men, impotence, decreased sperm density, and libido may result. Compression of the optic chiasm can cause vision changes and signs of increased intracranial pressure, including headache, nausea, and vomiting.

Because prolactinomas do not typically progress in size, drug therapy is usually the first-line treatment. The dopamine agonists cabergoline and bromocriptine are given to block the release of prolactin. Surgery may be an option, depending on the extent and size of the tumor. Radiation therapy can reduce the risk for tumor recurrence for patients with large tumors.

Hypofunction of Pituitary Gland

Hypopituitarism is a rare disorder that involves a decrease in 1 or more of the pituitary hormones. A deficiency of only 1 pituitary hormone is called *selective hypopituitarism.* Total failure of the pituitary gland results in deficiency of all pituitary hormones—a condition referred to as *panhypopituitarism.* The most common hormone deficiencies associated with hypopituitarism involve GH and gonadotropins (e.g., LH, FSH).

Etiology and Pathophysiology

The usual cause of pituitary hypofunction is a pituitary tumor. Autoimmune disorders, infections, pituitary infarction (Sheehan syndrome), or destruction of the pituitary gland (from trauma, radiation, or surgical procedures) can also cause hypopituitarism. Blacks have a higher incidence of pituitary tumors than other ethnic groups.[6]

Anterior pituitary hormone deficiencies can lead to end-organ failure. TSH and ACTH deficiencies are life threatening. ACTH deficiency can lead to acute adrenal insufficiency and hypovolemic shock from sodium and water depletion. Acute adrenal insufficiency is discussed later in this chapter on pp. 1165–1166.

Clinical Manifestations and Diagnostic Studies

The manifestations vary with the type and degree of dysfunction. Early manifestations associated with a space-occupying lesion include headaches, vision changes (decreased visual acuity or decreased peripheral vision), loss of smell, nausea and vomiting, and seizures. Manifestations associated with hyposecretion of the target glands vary widely (Table 49.1).

In addition to a history and physical examination, diagnostic studies such as MRI and CT can identify a pituitary tumor. Laboratory tests generally involve the direct measurement of pituitary hormones (e.g., TSH) or an indirect determination of the target organ hormones

(e.g., triiodothyronine [T_3], thyroxine [T_4]). (See Chapter 47 for more information about diagnostic studies.)

Interprofessional and Nursing Care

The treatment for hypopituitarism often consists of surgery or radiation therapy followed by lifelong hormone therapy. Surgery and radiation therapy for pituitary tumors are discussed in the next section. Appropriate hormone therapy is used (e.g., GH, corticosteroids, thyroid hormone). Hormone therapies for thyroid hormone and corticosteroids are discussed later in this chapter on p. 1156 and p. 1167.

TABLE 49.1 Manifestations of Hypopituitarism

Hormone Deficiency	Manifestations
Adrenocorticotropic hormone (ACTH)	Involves cortisol deficiency: weakness, fatigue, headache, dry and pale skin, ↓ axillary and pubic hair, ↓ resistance to infection, fasting hypoglycemia
Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)	*Women:* Menstrual irregularities, loss of libido, changes in secondary sex characteristics (e.g., ↓ breast size) *Men:* Testicular atrophy, ↓ spermatogenesis, loss of libido, impotence, ↓ facial hair and muscle mass
Growth hormone (GH)	Subtle, nonspecific findings: truncal obesity, osteoporosis, ↓ muscle mass and strength, weakness, fatigue, depression, or flat affect
Thyroid-stimulating hormone (TSH)	Mild form of primary hypothyroidism: fatigue, cold intolerance, constipation, lethargy, weight gain

Somatropin (Genotropin, Humatrope, Omnitrope), recombinant human GH, is used for long-term hormone therapy in adults with GH deficiency. These patients respond well to GH replacement. They have increased energy, increased lean body mass, a feeling of well-being, and improved body image. Mild to moderate side effects of GH include fluid retention with swelling in the feet and hands, myalgia, joint pain, and headache. GH is given daily as a subcutaneous injection (preferably in the evening). The dosing is variable and adjusted based on symptoms, IGF-1 levels, and the presence of adverse effects.

Although gonadal deficiency is not life threatening, hormone therapy will improve sexual function and general well-being. It is contraindicated in those with certain medical conditions, such as phlebitis, pulmonary embolism, breast cancer in women, and prostate cancer in men. Estrogen and progesterone replacement therapy may be given to hypogonadal women to treat hot flashes, vaginal dryness, and decreased libido. (Hormone therapy for women is discussed in Chapter 53.) Testosterone is used to treat men with gonadotropin deficiency. The benefits achieved with testosterone therapy include a return of male secondary sex characteristics; improved libido; and increased muscle mass, bone mass, and bone density. (Hormone therapy for men is discussed in Chapter 54.)

Pituitary Surgery

A *hypophysectomy* is the surgical removal of the pituitary gland. It is the treatment of choice for tumors in the pituitary area, especially smaller pituitary adenomas. Most surgeries are done by an endoscopic *transsphenoidal* approach (Fig. 49.2). When the entire pituitary gland is removed, there is permanent loss of all pituitary hormones. The patient will need lifelong replacement therapy of thyroid hormone, sex hormones, and glucocorticoids.

Radiation therapy can reduce the size of a tumor before surgery. It is also used when surgery does not produce a cure or when patients are poor candidates for surgery. Its full effects may not be noted for months to years. Radiation therapy may lead to hypopituitarism, which then requires lifelong hormone replacement therapy. Stereotactic radiosurgery (gamma knife surgery, proton beam, linear accelerator) is an option for small, surgically inaccessible pituitary tumors or in place of conventional radiation.

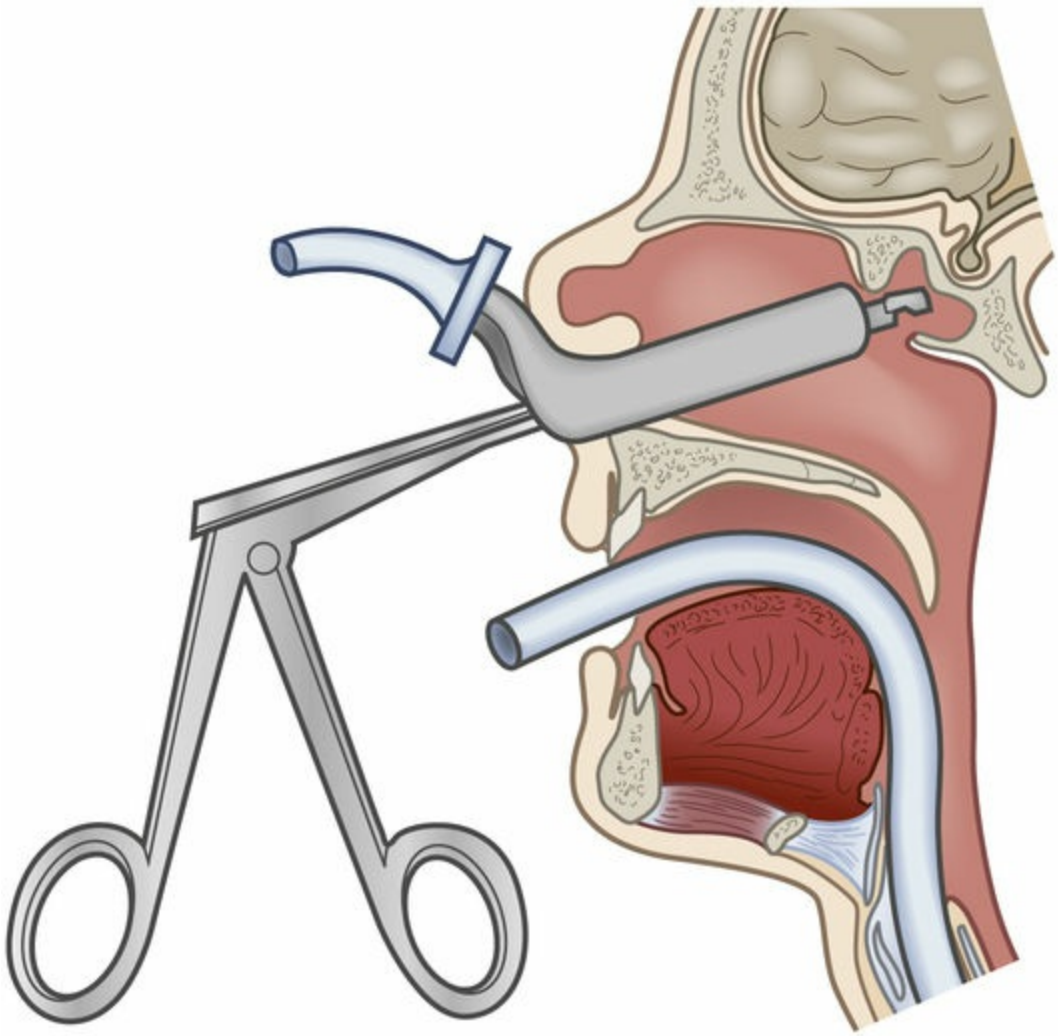

FIG. 49.2 Surgery on the pituitary gland is most often done by a transsphenoidal approach. An incision is made in the inner aspect of the upper lip and gingiva. The sella turcica is entered through the floor of the nose and sphenoid sinuses.

Nursing Management: Pituitary Surgery

After surgery, assess the patient for the formation of a hematoma compressing the optic nerve or optic chiasma. Monitor peripheral vision, visual acuity, extraocular movements, and pupillary response. Report changes at once because prompt intervention may prevent visual deterioration from becoming permanent (Table 49.2).

Cerebrospinal fluid (CSF) leaks and epistaxis are other common complications after surgery.[7] The HCP may place a petroleum jelly–coated ribbon of gauze or a balloon-tipped catheter (like an indwelling urinary catheter) in the sphenoid sinus. It is usually removed after 24 hours. It can be left in for 2 to 3 days if there is concern for bleeding or CSF leak. It is important that the patient does not blow the nose for at least 48 hours after surgery and avoids vigorous coughing, sneezing, and straining at stool.

Monitor the "moustache" dressing regularly for any drainage. Check any clear drainage with a urine dipstick for glucose and protein. If present, notify the HCP of a possible CSF leak. A sample can be sent to the laboratory. A glucose level greater than 30 mg/dL (1.67 mmol/L) indicates CSF leakage from an open connection with the brain. If this happens, the patient is at increased risk for meningitis.

A persistent and severe generalized or supraorbital headache may indicate CSF leakage into the sinuses. A CSF leak usually resolves within 72 hours when treated with head elevation and bed rest. If the leak persists, daily spinal taps may be done to reduce pressure to below-normal levels.

Other measures include elevating the head of the patient's bed at all times to a 30-degree angle. This avoids pressure on the sella turcica and decreases headaches. Monitor the pupillary response, speech patterns, and extremity strength to detect neurologic complications. Gentle mouth care every 4 hours is essential to keep the surgical area clean and free of debris. Have the patient avoid tooth brushing for at least 10 days to protect the suture line.

TABLE 49.2 Nursing ManagementCare of the Patient After Pituitary Surgery

- Monitor vital signs. Assess peripheral pulses and watch for orthostatic hypotension.

- Monitor neurologic/cognitive status (e.g., level of consciousness, orientation, speech) hourly for the first 24 hr and then every 4 hr.
- Assess extremity strength and reflexes.
- Monitor field of vision, visual acuity, extraocular movements, and pupillary response. Notify HCP of any changes.
- Assess dressing for type and amount of drainage. Notify HCP for excessive bleeding or CSF drainage.
- Maintain strict intake and output and monitor fluid balance. Assess for DI or SIADH.
- Keep head of bed elevated at least 30 degrees at all times.
- Encourage deep breathing exercises and incentive spirometer use.
- Monitor for pain and give analgesic medications as prescribed.
- Encourage high-fiber diet to decrease potential for constipation.
- Perform oral care every 4 hr.
- Teach the patient to:
    - Avoid vigorous coughing, sneezing, and blowing the nose
    - Avoid bending over at the waist or straining at stool (Valsalva maneuver) due to potential increased intracranial pressure
    - Avoid use of toothbrushes until incision heals
    - Follow replacement hormone therapy plan

Fluid and electrolyte problems can occur from the development of diabetes insipidus (DI).[8] Transient DI may occur because of the loss of antidiuretic hormone (ADH), which is stored in the posterior lobe of the pituitary gland, or cerebral edema related to manipulation of the pituitary during surgery. DI may be permanent after surgery. To assess for DI, closely monitor urine output and measure specific gravity. Report a urine output of more than 200 mL/hr for more than 3 consecutive hours or a specific gravity level of <1.005. Patients with DI will have a high serum sodium and extreme thirst. DI is treated by giving desmopressin acetate (DDAVP). Fluid replacement may be

needed to avoid hypovolemia related to high urine output. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) can occur after any intracranial surgery. SIADH typically occurs later than DI, usually around the fourth postoperative day. It may occur due to manipulation of the pituitary and other structures causing release of ADH. The fluid retention caused by circulating ADH leads to dilutional hyponatremia. Sodium levels of less than 125 mEq/L will manifest as headache, vomiting, and decreased level of consciousness. The manifestations and treatment of DI and SIADH are discussed in the next section.

ADH, cortisol, and thyroid hormone replacement are needed after a hypophysectomy. Teach the patient about the need for lifelong therapy. Surgery may result in permanent loss or deficiencies in FSH and LH. This can lead to decreased fertility. Assist the patient in working through the grieving process associated with these losses.

Disorders of Posterior Pituitary Gland

The hormones secreted by the posterior pituitary are ADH and oxytocin. ADH, also referred to as *arginine vasopressin* (AVP) or vasopressin, has a key role in the regulation of water balance and serum osmolarity (see Chapter 47). The primary problems associated with ADH secretion are a result of either overproduction or underproduction of ADH.

Syndrome of Inappropriate Antidiuretic Hormone

Etiology and Pathophysiology

Syndrome of inappropriate antidiuretic hormone (SIADH) results from an overproduction of ADH or the release of ADH despite normal or low plasma osmolarity (Fig. 49.3). ADH increases the permeability of the renal distal tubule and collecting duct, which leads

to the reabsorption of water into the circulation. Extracellular fluid volume expands, plasma osmolality declines, glomerular filtration rate increases, and sodium levels decline (dilutional hyponatremia).[8] Thus features of the disorder are fluid retention, serum hypoosmolality, dilutional hyponatremia, hypochloremia, and concentrated urine in the presence of normal or increased intravascular volume.

SIADH occurs more often in older adults. The most common cause is cancer, especially small cell lung cancer (Table 49.3). SIADH tends to be self-limiting when caused by head trauma or drugs. It can be chronic when associated with tumors or metabolic diseases.

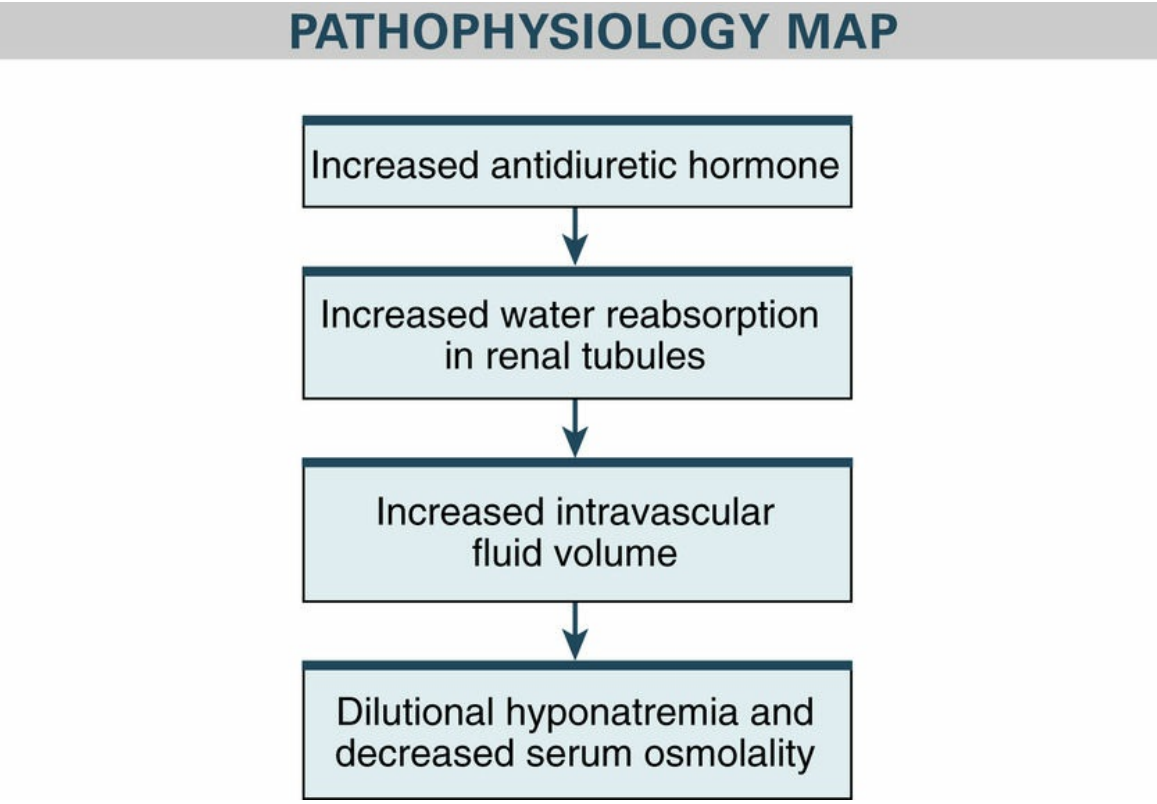

FIG. 49.3 Pathophysiology of SIADH.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

TABLE 49.3 Causes of SIADH

Cancer

- Colorectal cancer
- Lymphoid cancers (Hodgkin's lymphoma, non-Hodgkin's lymphoma, lymphocytic leukemia)
- Pancreatic cancer
- Prostate cancer
- Small cell lung cancer
- Thymus cancer

CNS Disorders

- Brain tumors
- Cerebral atrophy
- Guillain-Barré syndrome
- Head injury (skull fracture, subdural hematoma, subarachnoid hemorrhage)
- Infection (encephalitis, meningitis)
- Stroke
- Systemic lupus erythematosus

Drug Therapy

- carbamazepine (Tegretol)
- Chemotherapy agents (vincristine, vinblastine, cyclophosphamide)
- chlorpropamide
- General anesthesia agents

- Opioids
- oxytocin
- Thiazide diuretics
- Selective serotonin reuptake inhibitor (SSRI) antidepressants
- Tricyclic antidepressants

Miscellaneous Conditions

- Adrenal insufficiency
- Chronic obstructive pulmonary disease
- HIV
- Hypothyroidism
- Lung infection (pneumonia, tuberculosis, lung abscess)
- Positive pressure mechanical ventilation

Clinical Manifestations and Diagnostic Studies

The patient with SIADH has low urine output and increased body weight. At first, the patient has thirst, dyspnea on exertion, and fatigue. Mild hyponatremia causes muscle cramping, irritability, and headache. As the serum sodium level falls (usually below 120 mEq/L [120 mmol/L]), manifestations become more severe and include vomiting, abdominal cramps, and muscle twitching. As plasma osmolality and serum sodium levels continue to decline, cerebral edema may occur, leading to lethargy, confusion, seizures, and coma.

The diagnosis is made by simultaneous measurements of urine and serum osmolality. Dilutional hyponatremia is indicated by a serum sodium less than 135 mEq/L, serum osmolality less than 280 mOsm/kg (280 mmol/kg), and urine specific gravity greater than 1.030. A serum osmolality much lower than the urine osmolality shows the body is inappropriately excreting concentrated urine in the presence of dilute serum.

Interprofessional and Nursing Care

When assessing patients at risk and those who have confirmed SIADH, be alert for low urine output with a high specific gravity, a sudden weight gain without edema, or a decreased serum sodium level. Monitor intake and output, vital signs, and heart and lung sounds. Obtain daily weights. Observe for signs of hyponatremia, including seizures, headache, vomiting, and decreased neurologic function.

Once SIADH is diagnosed, treatment is directed at the underlying cause. Medications that stimulate ADH release should be avoided or discontinued (Table 49.3). If symptoms are mild and serum sodium is greater than 125 mEq/L (125 mmol/L), the only treatment may be a fluid restriction of 800 to 1000 mL/day. This restriction should result in weight reduction and a gradual rise in serum sodium concentration and osmolality. An improvement in symptoms should accompany normalization of serum sodium and osmolality. Provide the patient with frequent oral care and distractions to decrease discomfort related to thirst from the fluid restriction.

A loop diuretic, such as furosemide (Lasix), may be used to promote diuresis. The serum sodium must be at least 125 mEq/L (125 mmol/L) because it may promote further sodium loss. Because furosemide increases potassium, calcium, and magnesium losses, supplements may be needed. Demeclocycline also may be given. This drug blocks the effect of ADH on the renal tubules, resulting in more dilute urine.

Initiate seizure and fall precautions if the patient has an altered sensorium or is having seizures. Position the head of the bed flat or elevated no more than 10 degrees. This enhances venous return to the heart and increases left atrial filling pressure, thus reducing the release of ADH. Frequent turning, positioning, and range-of-motion exercises are important to maintain skin integrity and joint mobility.

In cases of severe hyponatremia (less than 120 mEq/L), especially in the presence of neurologic manifestations, such as seizures, small amounts of IV hypertonic saline solution (3% sodium chloride) may be slowly given. It is important to correct hyponatremia slowly. The

level should not increase by more than 8 to 12 mEq/L in the first 24 hours. Quickly increasing levels can cause osmotic demyelination syndrome with permanent damage to nerve cells in the brain.[8] A fluid restriction of 500 mL/day may be needed for those with severe hyponatremia.

Vasopressor receptor antagonists (drugs that block the activity of ADH) are used to treat euvolemic hyponatremia in hospitalized patients. Two drugs are FDA-approved: conivaptan (Vaprisol) and tolvaptan (Samsca). Conivaptan is given IV; tolvaptan is given orally. Neither should be given to patients with liver disease because they worsen liver function.

Help the patient with chronic SIADH in self-managing the treatment plan. In chronic SIADH, a fluid restriction of 800 to 1000 mL/day is recommended. Ice chips or sugarless chewing gum help decrease thirst. Have the patient obtain a daily weight to monitor changes in fluid balance. Have the patient supplement the diet with sodium and potassium, especially if taking loop diuretics. Teach the patient the symptoms of fluid and electrolyte imbalances, particularly those involving sodium and potassium (see Chapter 16).

Diabetes Insipidus

Etiology and Pathophysiology

Diabetes insipidus (DI) is caused by a deficiency of production or secretion of ADH or a decreased renal response to ADH. The decrease in ADH results in fluid and electrolyte imbalances caused by increased urine output and increased plasma osmolality (Fig. 49.4). Depending on the cause, DI may be transient or a chronic, lifelong condition. There are several types of DI (Table 49.4). Central DI is the most common form.

Clinical Manifestations

Key features of DI are polydipsia and polyuria. The patient excretes

large quantities of urine (2 to 20 L/day) with a very low specific gravity (less than 1.005) and urine osmolality of less than 100 mOsm/kg (100 mmol/kg). Serum osmolality is increased (usually greater than 295 mOsm/kg [295 mmol/kg]) because of hypernatremia (serum sodium greater than 145 mg/dL) caused by pure water loss in the kidneys. Most patients compensate for fluid loss by drinking large amounts of water so that serum osmolality stays normal or is moderately increased. The patient may be tired from nocturia and have generalized weakness. Uncorrected hypernatremia can cause brain shrinkage and intracranial bleeding.[8]

The onset of central DI is usually acute and accompanied by excess fluid loss. After intracranial surgery, central DI has a triphasic pattern: (1) an acute phase with an abrupt onset of polyuria, (2) an interphase in which urine volume normalizes, and (3) a third phase in which central DI may become permanent. The third phase occurs 10 to 14 days after surgery. Central DI from head trauma is often self-limiting and improves with treatment of the underlying problem. Although the manifestations of nephrogenic DI are like those of central DI, the onset and amount of fluid loss are less dramatic.

Severe dehydration can result if oral fluid intake cannot keep up with urinary losses. The patient will have hypotension, tachycardia, and hypovolemic shock. Increasing serum osmolality and hypernatremia can cause central nervous system (CNS) manifestations, ranging from irritability and mental dullness to coma.

Diagnostic Studies

Patients with DI excrete dilute urine at a rate greater than 200 mL/hr with a specific gravity of less than 1.005. Central DI is diagnosed by a water deprivation test. Before the test, body weight, and urine osmolality, volume, and specific gravity are measured. The patient is deprived of water for 8 to 12 hours and then given desmopressin acetate (DDAVP) subcutaneously or nasally. Patients with central DI have a dramatic increase in urine osmolality (from 100 to 600 mOsm/kg) and a significant decrease in urine volume. The patient

with nephrogenic DI will not be able to increase urine osmolality to greater than 300 mOsm/kg.

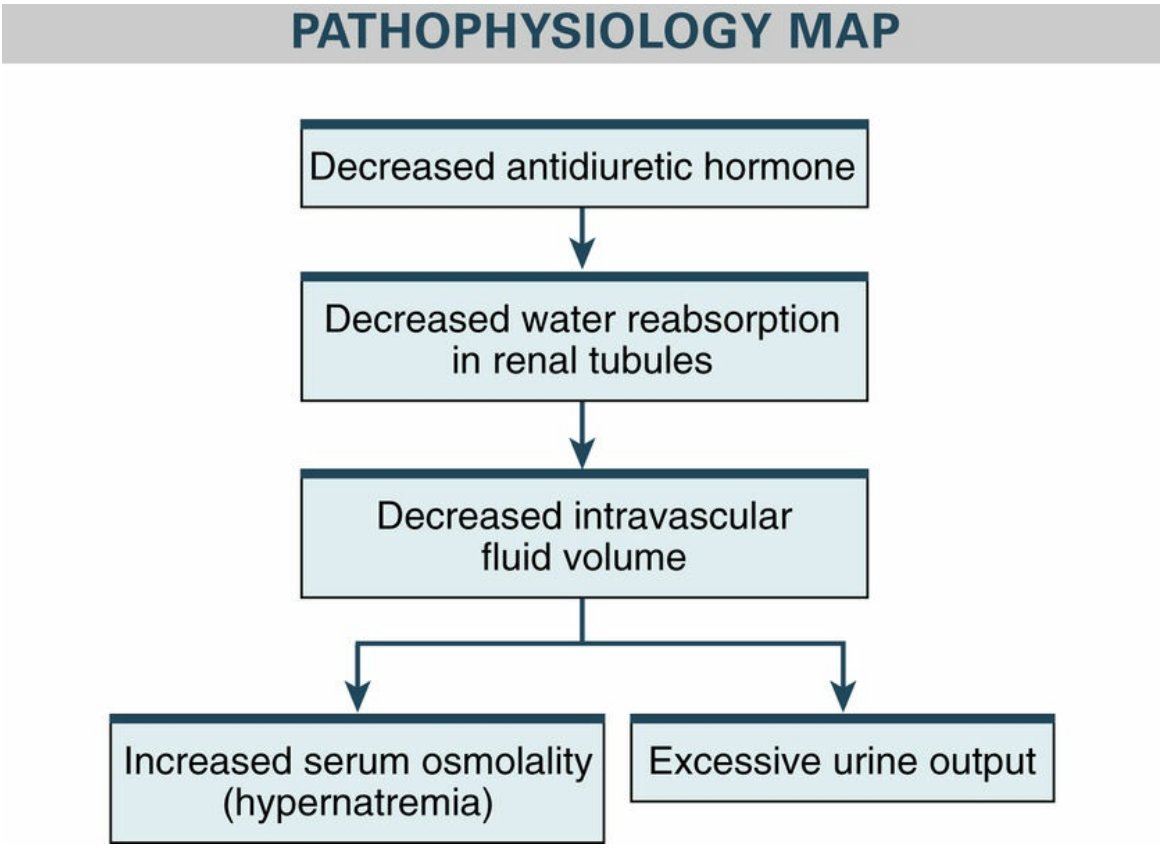

FIG. 49.4 Pathophysiology of diabetes insipidus.

TABLE 49.4 Types of Diabetes Insipidus

Type	Etiology
Central (neurogenic) DI	Interference with ADH synthesis, transport, or release *Examples:* Brain tumor, head injury, brain surgery, CNS infections
Nephrogenic DI	Inadequate renal response to ADH despite presence of adequate ADH *Examples:* Drug therapy (especially lithium), renal damage, hereditary renal disease
Primary DI	Excess water intake *Examples:* Structural lesion in thirst center, psychologic disorder

Another test to distinguish central DI from nephrogenic DI is to measure the level of ADH after an analog of ADH (e.g., desmopressin) is given. If the cause is central DI, the kidneys will respond to the hormone by concentrating urine. If the kidneys do not respond in this way, the cause is nephrogenic.

Interprofessional and Nursing Care

Management of the patient with DI includes early detection, maintaining adequate hydration, and patient teaching for long-term management. A therapeutic goal is maintaining fluid and electrolyte balance.

For central DI, fluid and hormone therapy are the cornerstone of treatment. Fluids are replaced orally or IV, depending on the patient's condition and ability to drink copious amounts of fluids. In acute DI, IV hypotonic saline or dextrose 5% in water (D_5W) is given and titrated to replace urine output. If IV glucose solutions are used, monitor serum glucose levels because hyperglycemia and glycosuria can lead to osmotic diuresis, which increases the fluid volume deficit. Monitoring BP, heart rate, urine output, level of consciousness, and specific gravity is essential and may be done hourly in the acutely ill patient. Assess for signs of acute dehydration. Maintain an accurate record of intake and output and daily weights to determine fluid volume status. Adjustments in fluid replacement should be made accordingly.

DDAVP, an analog of ADH, is the hormone replacement of choice for central DI. Another ADH replacement drug is aqueous vasopressin. DDAVP can be given orally, IV, subcutaneously, or as a nasal spray. Assess the response to DDAVP by monitoring pulse, BP, level of consciousness, intake and output, and specific gravity. Chlorpropamide and carbamazepine (Tegretol) can help decrease thirst associated with central DI.

Because the kidney is unable to respond to ADH in nephrogenic DI, hormone therapy has little effect. Instead, the treatment includes a low-sodium diet and thiazide diuretics (e.g., hydrochlorothiazide,

chlorothiazide [Diuril]), which may reduce flow to the ADH-sensitive distal nephrons. Limiting sodium intake to no more than 3 g/day often helps decrease urine output. If a low-sodium diet and thiazide drugs are not effective, indomethacin (Indocin) may be prescribed. Indomethacin, a nonsteroidal antiinflammatory drug (NSAID), helps increase renal responsiveness to ADH.

Disorders of Thyroid Gland

Problems with thyroid function are among the most common endocrine disorders. The thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), regulate energy metabolism and growth and development. Disorders of the thyroid gland include goiter, benign and malignant nodules, inflammatory conditions leading to hyperthyroidism, and hypothyroidism (Fig. 49.5).

Goiter

A **goiter** is an enlarged thyroid gland. In a person with a goiter, the thyroid cells are stimulated to grow. This may result in an overactive thyroid (hyperthyroidism) or an underactive thyroid (hypothyroidism). The most common cause of goiter worldwide is a lack of iodine in the diet.[9] In the United States, where most people use iodized salt, goiter is more often due to the overproduction or underproduction of thyroid hormones or to nodules that develop in the gland itself. *Goitrogens* (foods or drugs that contain thyroid-inhibiting substances) can cause a goiter (Table 49.5).

A nontoxic goiter is a diffuse enlargement of the thyroid gland that does not result from cancer or an inflammatory process. Normal levels of thyroid hormone are associated with this type of goiter. *Nodular goiters* are thyroid hormone–secreting nodules that function independent of TSH stimulation. There may be multiple nodules (multinodular goiter) or a single nodule (solitary autonomous nodule). The nodules are usually benign follicular adenomas. If these

nodules are associated with hyperthyroidism, they are called *toxic nodular goiters.* This type of goiter is often found in patients with Graves' disease (Fig. 49.6). Toxic nodular goiters occur equally in men and women. Although they can appear at any age, they most often occur in people over 40 years of age.

FIG. 49.5 Continuum of thyroid dysfunction.

TSH and T_4 levels are measured to determine whether a goiter is associated with normal thyroid function, hyperthyroidism, or hypothyroidism. Thyroid antibodies (e.g., thyroid peroxidase [TPO] antibody) show the presence of *thyroiditis* (inflammation of the thyroid). Treatment with thyroid hormone may prevent further thyroid enlargement. Surgery can remove large goiters. Goiter as a manifestation of thyroid disorders is discussed in the next sections.

Thyroiditis

Thyroiditis, an inflammation of the thyroid gland, encompasses several clinical disorders.[10] It is a frequent cause of goiter. *Subacute granulomatous thyroiditis* is thought to be caused by a viral infection. *Acute thyroiditis* is due to bacterial or fungal infection. Subacute and acute forms of thyroiditis have an abrupt onset. The patient reports pain localized in the thyroid or radiating to the throat, ears, or jaw. Systemic manifestations include fever, chills, sweats, and fatigue.

TABLE 49.5 Goitrogens

Thyroid Inhibitors

- iodine in large doses
- methimazole (Tapazole)
- propylthiouracil (PTU)

Other Drugs

- amiodarone
- lithium
- *p*-aminosalicylic acid
- Salicylates
- Sulfonamides

Select Foods

- Broccoli
- Brussels sprouts
- Cabbage
- Cauliflower
- Kale
- Mustard
- Peanuts
- Strawberries
- Turnips

FIG. 49.6 Exophthalmos and goiter of Graves' disease.
From Forbes CD, Jackson WF: *Colour atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.

Hashimoto's thyroiditis (chronic autoimmune thyroiditis) is caused by the destruction of thyroid tissue by antibodies.[11] It is the most common cause of hypothyroid goiters in the United States. Risk

factors include female gender, a positive family history, older age, and white ethnicity. The goiter, which is the hallmark of Hashimoto's thyroiditis, may develop gradually or rapidly. If it enlarges rapidly, it may compress structures in the neck (e.g., trachea, laryngeal nerves), changing the voice and affecting breathing. As thyroid tissue is destroyed by antibodies, there may be a transient phase of hyperthyroidism due to leaking thyroid hormone from the damaged tissues.

Silent, painless thyroiditis, which may be early Hashimoto's thyroiditis, can occur in postpartum women. This condition is usually seen in the first 6 months after delivery. It may be due to an autoimmune reaction to fetal cells in the mother's thyroid gland.

T_4 and T_3 levels are initially increased in subacute, acute, and silent thyroiditis but become decreased with time. Suppressed radioactive iodine uptake (RAIU) is seen in subacute and silent thyroiditis. In Hashimoto's thyroiditis, T_4 and T_3 levels are usually low and the TSH level is high. Antithyroid antibodies are present in Hashimoto's thyroiditis.

Recovery from acute or subacute thyroiditis may be complete in weeks or months without any treatment. If the thyroiditis is bacterial in origin, treatment may include specific antibiotics or surgical drainage. In the subacute and acute forms, NSAIDs (aspirin, naproxen [Aleve]) are used to relieve symptoms. With more severe pain, corticosteroids (e.g., prednisone up to 40 mg/day) can relieve discomfort. Propranolol (Inderal) or atenolol (Tenormin) may relieve cardiovascular symptoms related to a hyperthyroid condition. The patient who is hypothyroid needs thyroid hormone therapy.

Nursing care of the patient with thyroiditis includes patient teaching about the disease process and course of treatment. Teach the patient not to stop medications abruptly. Tell the patient to remain under close health care supervision so that progress can be monitored. Teach the patient to report to the HCP any change in symptoms, such as difficulty breathing or swallowing, swelling to face and extremities, or rapid weight gain or loss. Teach those receiving thyroid hormone about the expected side effects of these drugs and ways to manage

them (see p. 1158).

The patient with Hashimoto's thyroiditis is at risk for other autoimmune diseases, such as Addison's disease, pernicious anemia, or Graves' disease. Teach the patient the signs and symptoms of these disorders, particularly Addison's disease.

Hyperthyroidism

Hyperthyroidism is hyperactivity of the thyroid gland with sustained increase in synthesis and release of thyroid hormones. It occurs in women more than men, with the highest frequency in persons 20 to 40 years old. The most common form is Graves' disease. Other causes include toxic nodular goiter, thyroiditis, excess iodine intake, pituitary tumors, and thyroid cancer. Since hyperthyroidism may be caused by iodinated contrast media used in CT scans and other radiologic studies, monitor those who are at risk closely after iodinated contrast media exposure.[11]

Gender Differences

Endocrine Problems

Men

- Ectopic ACTH production is more common in men.

Women

- Thyroid disorders are more common in women.
- Graves' disease affects 5 times more women.
- Thyroid nodules and thyroid cancer affect up to 4 times as many women.

- Hyperparathyroidism affects twice as many women.
- Cushing disease and primary hyperaldosteronism are more common in women.

The term **thyrotoxicosis** refers to the physiologic effects or clinical syndrome of hypermetabolism resulting from excess circulating levels of T_4, T_3, or both.[12] Hyperthyroidism and thyrotoxicosis usually occur together. Subclinical hyperthyroidism occurs when the patient has a serum TSH level below 0.4 mU/L but normal T_4 and T_3 levels. Overt hyperthyroidism is defined by low or undetectable TSH and increased T_4 and T_3 levels. The patient may or may not have symptoms of hyperthyroidism.

Etiology and Pathophysiology

Graves' Disease

Graves' disease is an autoimmune disease of unknown cause characterized by diffuse thyroid enlargement and excess thyroid hormone secretion. It accounts for 75% of the cases of hyperthyroidism. Causative factors, such as a lack of iodine, smoking, infection, and stressful life events, may interact with genetic factors to cause Graves' disease.

In Graves' disease, the patient develops antibodies to the TSH receptor. These antibodies attach to the receptors and stimulate the thyroid gland to release T_3, T_4, or both. The excess release of thyroid hormones leads to the manifestations associated with thyrotoxicosis. The disease is characterized by remissions and exacerbations, with or without treatment. It may progress to destruction of the thyroid tissue, causing hypothyroidism. Graves' disease is associated with the presence of other autoimmune disorders, including rheumatoid arthritis, pernicious anemia, systemic lupus erythematosus, Addison's disease, celiac disease, and vitiligo.

Clinical Manifestations

The manifestations are related to the effect of excess circulating thyroid hormone. It directly increases metabolism and tissue sensitivity to sympathetic nervous system stimulation.

Palpation of the thyroid gland may reveal a goiter. When the thyroid gland is excessively large, a goiter may be seen on inspection. Auscultating the thyroid gland may reveal bruits, a reflection of increased blood supply. Another common finding is *ophthalmopathy,* a term used to describe abnormal eye appearance or function. A classic finding in Graves' disease is **exophthalmos**, a protrusion of the eyeballs from the orbits that is usually bilateral (Fig. 49.6). Exophthalmos results from increased fat deposits and fluid (edema) in the orbital tissues and ocular muscles. The increased pressure forces the eyeballs outward. The upper lids are usually retracted and elevated, with the sclera visible above the iris. When the eyelids do not close completely, the exposed corneal surfaces become dry and irritated. Corneal ulcers and loss of vision can occur. Changes in the ocular muscles result in muscle weakness, causing diplopia.

Other manifestations are outlined in Table 49.6. Abnormal laboratory findings are listed in Table 49.7. A patient in the early stages of hyperthyroidism may only have weight loss and increased nervousness. *Acropachy* (clubbing of the digits) may occur with advanced disease (Fig. 49.7). Manifestations (e.g., palpitations, tremors, weight loss) in older adults do not differ significantly from those of younger adults (Table 49.8). In older patients who are confused and agitated, dementia may be suspected and delay the diagnosis.

TABLE 49.6 Manifestations of Thyroid Dysfunction

Hyperfunction	Hypofunction
Cardiovascular System	
• **Systolic hypertension** • **↑ Rate and force of cardiac contractions** • **Bounding, rapid pulse** • **↑ Cardiac output** • **Systolic murmurs** • **Dysrhythmias** • **Palpitations** • **Angina**	• ↑ Capillary fragility • ↓ Rate and force of contractions • Varied changes in BP • Cardiac hypertrophy • Distant heart sounds • Anemia • Heart failure • Angina
Gastrointestinal System	
• **↑ Appetite, thirst** • **Weight loss** • **↑ Peristalsis** • **Diarrhea, frequent defecation** • **↑ Bowel sounds** • **Splenomegaly** • **Hepatomegaly**	• ↓ Appetite • Weight gain • Nausea and vomiting • Constipation • Distended abdomen • Enlarged, scaly tongue • Celiac disease
Musculoskeletal System	
• **Fatigue** • **Weakness** • **Proximal muscle wasting** • **Dependent edema** • **Osteoporosis**	• Fatigue • Weakness • Muscular aches and pains • Slow movements • Arthralgia
Nervous System	
• **Hyperactive deep-tendon reflexes** • **Depression** • **Lack of ability to concentrate** • **Rapid speech** • **Insomnia** • **Difficulty focusing eyes** • **Nervousness** • **Fine tremor of fingers and tongue** • **Lability of mood, delirium** • **Restlessness** • **Personality changes of irritability, agitation** • **Stupor, coma**	• Prolonged relaxation of deep tendon reflexes • Anxiety, depression • Slowed mental processes • Slow, slurred speech • Sleepiness • Apathy • Lethargy • Forgetfulness • Hoarseness • Stupor, coma • Paresthesias
Reproductive System	
• **Menstrual irregularities** • **Amenorrhea** • **↓ Libido** • **↓ Fertility** • **Impotence and gynecomastia in men**	• Prolonged menstrual periods or amenorrhea • ↓ Libido • Infertility
Respiratory	
• **Dyspnea on mild exertion** • **↑ Respiratory rate**	• Dyspnea • ↓ Breathing capacity
Skin	
• **Warm, smooth, moist skin** • **Thin, brittle nails detached from nail bed (onycholysis)** • **Hair loss (may be patchy)** • **Clubbing of fingers (thyroid acropachy) (Fig. 49.7)** • **Palmar erythema** • **Fine, silky hair** • **Premature graying (in men)** • **Diaphoresis** • **Vitiligo** • **Pretibial myxedema (infiltrative dermopathy)**	• Dry, thick, inelastic, cold skin • Thick, brittle nails • Dry, sparse, coarse hair • Poor turgor of mucosa • Generalized interstitial edema • Puffy face • ↓ Sweating • Pallor
Other	
• **Goiter (Fig. 49.6)** • **Intolerance to heat** • **Elevated basal temperature** • **Lid lag, stare** • **Eyelid retraction** • **Exophthalmos**	• Goiter • Intolerance to cold • ↑ Risk for infection • ↑ Sensitivity to opioids, barbiturates, anesthesia • ↓ Hearing

TABLE 49.7 Laboratory Results for Hyperthyroid and Hypothyroid Patients

Test	Hyperthyroid	Hypothyroid	
		Primary	Secondary
Thyroid-stimulating hormone (TSH)	↓	↑	↓
T_4 (thyroxine)	↑	↓	↓
Total cholesterol	N	↑	↑

Basal metabolic rate (BMR)	↑	↓	↓
Thyroid peroxidase (TPO) antibody	N	+ (in autoimmune hypothyroidism)	N

N, Normal; +, positive.

Complications

Acute thyrotoxicosis (also called *thyrotoxic crisis* or *thyroid storm*) is an acute, severe, and rare condition that occurs when excess amounts of thyroid hormones are released into the circulation. Although considered a life-threatening emergency, death is rare when treatment is started early. Acute thyroiditis is thought to result from stressors (e.g., infection, trauma, surgery) in a patient with preexisting hyperthyroidism. Patients having a thyroidectomy are at risk because manipulation of the hyperactive thyroid gland results in an increase in hormones released.

FIG. 49.7 Thyroid acropachy. Digital clubbing and swelling of fingers. From Chew SL, Leslie D: *Clinical endocrinology and diabetes: An illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.

TABLE 49.8 Comparison of Hyperthyroidism in Younger and Older Adults

	Younger Adult	Older Adult
Common causes	Graves' disease in >90% of cases	Graves' disease or toxic nodular goiter
Common symptoms	Nervousness, irritability, weight loss, heat intolerance, warm moist skin	Anorexia, weight loss, apathy, lassitude, depression, confusion
Goiter	Present in >90% of cases	Present in about 50% of cases
Ophthalmopathy	Exophthalmos (Fig. 49.6) present in 20%–40% of cases	Exophthalmos less common
Cardiac features	Tachycardia and palpitations common, but without heart failure	Angina, dysrhythmia (especially atrial fibrillation with rapid ventricular response), heart failure may occur

In acute thyrotoxicosis, all the symptoms of hyperthyroidism are prominent and severe. Manifestations include severe tachycardia, heart failure, shock, hyperthermia (up to 106°F [41.1°C]), agitation, delirium, seizures, abdominal pain, vomiting, diarrhea, and coma.

Diagnostic Studies

The primary laboratory findings used to confirm the diagnosis of hyperthyroidism are low or undetectable TSH levels (<0.4 mU/L) and increased free thyroxine (free T_4) levels. Total T_3 and T_4 levels also may be assessed, but they are not as definitive. Total T_3 and T_4 determine both free and bound (to protein) hormone levels. The free hormone is the only biologically active form of these hormones.

The RAIU test can distinguish Graves' disease from other forms of thyroiditis. The patient with Graves' disease shows a diffuse, homogeneous uptake of 35% to 95%, while the patient with thyroiditis shows an uptake of less than 2%. The person with a nodular goiter has an uptake in the high normal range.

Interprofessional Care

The goal of management is to block the adverse effects of excess thyroid hormone, suppress oversecretion of thyroid hormone, and prevent complications. There are several treatment options, including antithyroid medications, radioactive iodine therapy, and surgical intervention (Table 49.9). Supportive therapy is directed at managing respiratory distress, reducing fever, replacing fluid, and eliminating or managing the initiating stressor(s).

TABLE 49.9 Interprofessional CareHyperthyroidism

Diagnostic Assessment

- History and physical examination
- Ophthalmologic examination
- ECG
- Laboratory tests
    - TSH levels, serum free T_4
    - Thyroid antibodies (e.g., thyroid peroxidase [TPO] antibody)
    - Total serum T_3 and T_4
- Radioactive iodine uptake (RAIU)

Management

Drug Therapy

- Antithyroid drugs
    - methimazole (Tapazole)
    - propylthiouracil
- iodine (SSKI)

Radiation Therapy

- Radioactive iodine

Surgical Therapy

- Subtotal thyroidectomy

Nutritional Therapy

- High-calorie, high-protein diet
- Frequent meals

The choice of treatment is influenced by the patient's age and preferences, coexistence of other diseases, and pregnancy status.

Drug Therapy

Drugs used to treat hyperthyroidism include antithyroid drugs, iodine, and β-adrenergic blockers. These drugs are useful in treating thyrotoxic states but are not curative. Radiation therapy or surgery may be needed.

Antithyroid Drugs

The first-line antithyroid drugs are propylthiouracil and methimazole (Tapazole).[12] These drugs inhibit thyroid hormone synthesis. Reasons for use include Graves' disease in the young patient, hyperthyroidism during pregnancy, and the need to achieve a euthyroid state before surgery or radiation therapy. Propylthiouracil is generally used for patients who are in the first trimester of pregnancy, had an adverse reaction to methimazole, or need a rapid reduction in symptoms. It is the first-line therapy in thyrotoxicosis since it blocks the peripheral conversion of T_4 to T_3. An advantage of propylthiouracil is that it achieves the therapeutic goal of being euthyroid more quickly. However, it must be taken 3 times per day. Methimazole is given in a single daily dose.

Improvement usually begins 1 to 2 weeks after the start of drug therapy. Results are usually seen within 4 to 8 weeks. Therapy is usually continued for 6 to 15 months to allow for spontaneous remission, which occurs in 20% to 40% of patients. Emphasize to the patient the importance of adhering to the drug plan. Abruptly stopping drug therapy can result in a return of hyperthyroidism.

Iodine

Iodine is available as saturated solution of potassium iodine (SSKI) and Lugol's solution. Iodine is used with other antithyroid drugs to prepare the patient for thyroidectomy or for treatment of thyrotoxicosis. Rapidly giving large doses of iodine inhibits synthesis

of T_3 and T_4 and blocks the release of these hormones into circulation. It also decreases the vascularity of the thyroid gland, making surgery safer and easier. The maximal effect is usually seen within 1 to 2 weeks. Because of a reduction in the therapeutic effect, long-term iodine therapy is not effective in controlling hyperthyroidism.

Iodine is mixed with water or juice and given after meals. Sipping it through a straw decreases the chance of it staining the teeth. Assess the patient for signs of iodine toxicity, such as swelling of the buccal mucosa and other mucous membranes, excess salivation, nausea and vomiting, and skin reactions. If toxicity occurs, stop administering iodine and notify the HCP.

β-Adrenergic Blockers

β-Adrenergic blockers are used for symptomatic relief of thyrotoxicosis. These drugs block the effects of sympathetic nervous stimulation, thereby decreasing tachycardia, nervousness, irritability, and tremors. Propranolol is usually given with antithyroid agents. Atenolol is the preferred β-adrenergic blocker for use in the hyperthyroid patient with asthma or heart disease.

Radioactive Iodine Therapy

Radioactive iodine (RAI) therapy is the treatment of choice for most nonpregnant adults. RAI damages or destroys thyroid tissue, thus limiting thyroid hormone secretion. RAI has a delayed response. The maximum effect may not be seen for up to 3 months. For this reason, the patient is usually treated with antithyroid drugs and propranolol before and for 3 months after starting RAI until the effects of radiation become apparent. Although RAI is usually effective, 80% of patients have posttreatment hypothyroidism, resulting in the need for lifelong thyroid hormone therapy. Teach the patient the symptoms of hypothyroidism and to seek medical help if these symptoms occur.

RAI therapy is usually given on an outpatient basis. A pregnancy test is done before starting therapy for all women who have menstrual cycles. Tell the patient that radiation thyroiditis and parotitis are possible and may cause dryness and irritation of the mouth and

throat. Relief may be obtained with frequent sips of water, ice chips, or a salt and soda gargle 3 or 4 times per day. This gargle is made by dissolving 1 tsp of salt and 1 tsp of baking soda in 2 cups of warm water. The discomfort should subside in 3 to 4 days. A mixture of antacid (Mylanta or Maalox), diphenhydramine, and viscous lidocaine can be used to swish and spit, increasing patient comfort when eating.

To limit radiation exposure to others, teach the patient receiving RAI home precautions, including (1) using private toilet facilities, if possible, and flushing 2 or 3 times after each use; (2) separately laundering towels, bed linens, and clothes daily at home; (3) not preparing food for others that requires prolonged handling with bare hands; and (4) avoiding being close to pregnant women and children for 7 days after therapy.

Surgical Therapy

A thyroidectomy is done for those who have (1) a large goiter causing tracheal compression, (2) a lack of response to antithyroid therapy, or (3) thyroid cancer (Fig. 49.8). Surgery may be done when a person is not a candidate for RAI. One advantage that thyroidectomy has over RAI is a more rapid reduction in T_3 and T_4 levels. A *subtotal thyroidectomy* is the preferred surgical procedure. It involves removing a significant portion (90%) of the thyroid gland.

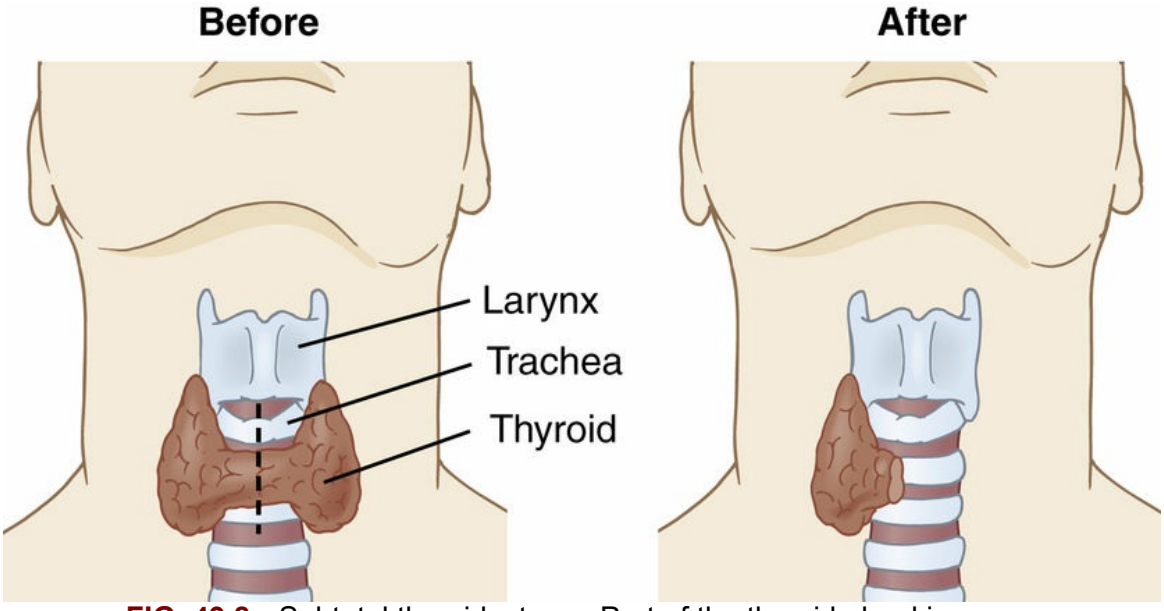

FIG. 49.8 Subtotal thyroidectomy. Part of the thyroid gland is removed.

Some patients may undergo minimally invasive endoscopic or robotic thyroidectomy. Endoscopic thyroidectomy is appropriate for patients with small nodules (less than 3 cm) and no evidence of cancer. Robotic surgery is best for those who are not overweight and have small nodules on only one side of the gland. Advantages of endoscopic and robotic procedures over open thyroidectomy include less scarring, less pain, and a faster return to normal activity.

Nutritional Therapy

With the increased metabolic rate in hyperthyroid patients, there is a high potential for the patient to have nutrition problems. A high-calorie diet (4000 to 5000 cal/day) may be needed to satisfy hunger, prevent tissue breakdown, and decrease weight loss. This can be achieved with 6 full meals a day and snacks high in protein, carbohydrates, minerals, and vitamins. The protein content should be 1 to 2 g/kg of ideal body weight. Increase carbohydrate intake to compensate for increased metabolism. Carbohydrates provide energy and decrease the use of body-stored protein. Teach the patient to avoid highly seasoned and high-fiber foods because they can further stimulate the already hyperactive GI tract. Have the patient avoid

caffeine-containing liquids, such as coffee, tea, and cola, to decrease the restlessness and sleep problems. Refer the patient to a dietitian for help in meeting individual nutritional needs.

Nursing Management: Hyperthyroidism

Nursing Assessment

Subjective and objective data you should obtain from a person with hyperthyroidism are outlined in Table 49.10.

Nursing Diagnoses

Nursing diagnoses for the patient with hyperthyroidism include:

- Activity intolerance
- Impaired nutritional status

Additional information on nursing diagnoses and interventions is presented in eNursing Care Plan 49.1 for the patient with hyperthyroidism (available on the website for this chapter).

Planning

The overall goals are that the patient with hyperthyroidism will (1) have relief of symptoms, (2) have no serious complications related to the disease or treatment, (3) maintain nutritional balance, and (4) cooperate with the therapeutic plan.

Nursing Implementation

Acute Care

Patients with hyperthyroidism are usually treated in an outpatient

setting. However, those who develop acute thyrotoxicosis or undergo thyroidectomy need hospitalization and acute care.

Acute Thyrotoxicosis

Acute thyrotoxicosis requires aggressive treatment, often in an intensive care unit (ICU). Give medications (previously discussed) that block thyroid hormone production and the sympathetic nervous system. Provide supportive therapy, including monitoring for dysrhythmias and decompensation, ensuring adequate oxygenation, and giving IV fluids to replace fluid and electrolyte losses. This is especially important in the patient who has fluid losses from vomiting and diarrhea (Table 49.11).

TABLE 49.10 Nursing AssessmentHyperthyroidism

Subjective Data

Important Health Information

Past health history: Preexisting goiter. Recent infection or trauma, immigration from iodine-deficient area, autoimmune disease
Medications: Thyroid hormones, herbal therapies that may contain thyroid hormone

Functional Health Patterns

Health perception–health management: Positive family history of thyroid or autoimmune disorders
Nutritional-metabolic: Iodine intake, weight loss, ↑ appetite, thirst, nausea, vomiting
Elimination: Diarrhea, polyuria, sweating
Activity-exercise: Dyspnea on exertion, palpitations, muscle

weakness, fatigue
Sleep-rest: Insomnia
Cognitive-perceptual: Chest pain, nervousness, heat intolerance, pruritus
Sexuality-reproductive: ↓ Libido, impotence, gynecomastia (in men), amenorrhea (in women)
Coping–stress tolerance: Emotional lability, irritability, restlessness, personality changes, delirium

Objective Data

General Observation

Agitation, rapid speech and body movements, anxiety, restlessness, hyperthermia, enlarged or nodular thyroid gland

Eyes

Exophthalmos, eyelid retraction, infrequent blinking

Skin

Warm, diaphoretic, velvety skin. Thin, loose nails. Fine, silky hair and hair loss. Palmar erythema, clubbing, white pigmentation of skin (vitiligo), diffuse edema of legs and feet

Respiratory

Tachypnea, dyspnea on exertion

Cardiovascular

Tachycardia, bounding pulse, systolic murmurs, dysrhythmias, hypertension, bruit over the thyroid gland

Gastrointestinal

↑ Bowel sounds. Increased appetite, diarrhea, weight loss, liver and/or spleen enlargement

Neurologic

Hyperreflexia; diplopia. Fine tremors of hands, tongue, eyelids

Musculoskeletal

Muscle wasting

Reproductive

Menstrual irregularities, infertility, impotence, gynecomastia in men

Possible Diagnostic Findings

↑ T_3, ↑ T_4, ↑ T_3 resin uptake, ↓ or undetectable TSH. Chest x-ray showing enlarged heart. ECG findings of tachycardia, atrial fibrillation

Ensuring adequate rest may be a challenge because of the patient's irritability and restlessness. Provide a calm, quiet room because increased metabolism and sensitivity of the sympathetic nervous system causes sleep problems. Other interventions may include (1) placing the patient in a cool room away from very ill patients and noisy, high-traffic areas; (2) using light bed coverings and changing the linen often if the patient is diaphoretic; and (3) encouraging and assisting with exercise involving large muscle groups (tremors can interfere with small-muscle coordination) to allow the release of

nervous tension and restlessness. It is important to establish a supportive, trusting relationship to promote coping by a patient who is irritable, restless, and anxious.

If exophthalmos is present, there is a potential for corneal injury related to irritation and dryness. The patient may have orbital pain. To relieve eye discomfort and prevent corneal ulceration, apply artificial tears to soothe and moisten conjunctival membranes. Restricting salt may help reduce periorbital edema. Elevate the patient's head to promote fluid drainage from the periorbital area. The patient should sit upright as much as possible.

Dark glasses reduce glare and prevent irritation from smoke, air currents, dust, and dirt. If the eyelids cannot be closed, lightly tape them shut for sleep. To maintain flexibility, teach the patient to exercise the intraocular muscles several times a day by turning the eyes in the complete range of motion. Good grooming can help reduce the loss of self-esteem from an altered body image. If the exophthalmos is severe, treatment options include corticosteroids, radiation of retroorbital tissues, orbital decompression, or corrective lid or muscle surgery.

Thyroid Surgery

When a subtotal thyroidectomy is the treatment of choice, the patient must be adequately prepared to avoid complications. Before surgery, antithyroid drugs, iodine, and β-adrenergic blockers may be given to achieve a euthyroid state. Iodine also decreases the vascularization of the thyroid gland, reducing the risk for hemorrhage.

Before surgery, teach the patient about routine postoperative care and comfort and safety measures. Show the patient how to support the head manually while turning in bed, since this minimizes stress on the suture line after surgery. The patient should practice neck range-of-motion exercises. Tell the patient that talking is likely to be difficult for a short time after surgery. Review the importance of performing leg exercises.

Postoperative Care

Postoperative complications include hypothyroidism, damage to or inadvertent removal of parathyroid glands, causing hypoparathyroidism and hypocalcemia, hemorrhage, injury to the recurrent or superior laryngeal nerve, thyrotoxicosis, and infection.[13] Recurrent laryngeal nerve damage leads to vocal cord paralysis. If both cords are paralyzed, spastic airway obstruction will occur, requiring an immediate tracheostomy.

Safety Alert

Airway Obstruction

- Although not common, airway obstruction after thyroid surgery is an emergency.
- Keep O_2, suction equipment, and a tracheostomy tray available in the patient's room.

Respiration may become difficult because of excess swelling of the neck tissues, hemorrhage, and hematoma formation. *Laryngeal stridor* (harsh, vibratory sound) may occur because of edema of the laryngeal nerve. It also may be related to tetany from hypocalcemia, which occurs if the parathyroid glands were removed or damaged during surgery. To treat tetany, IV calcium salts (e.g., calcium gluconate) should be available.

After a thyroidectomy, assess the patient frequently for signs of hemorrhage or tracheal compression (Table 49.12). The patient should expect some hoarseness for 3 or 4 days after surgery because of edema. Keep the patient in a semi-Fowler's position and support the patient's head with pillows. Avoid any tension on the suture lines. Monitor vital signs and assess for any signs of hypocalcemia from hypoparathyroidism. If recovery is uneventful, the patient ambulates within hours after surgery. Fluids are allowed as soon as tolerated. A soft diet starts the day after surgery.

TABLE 49.11 Emergency ManagementAcute Thyrotoxicosis

Etiology	Assessment Findings	Interventions
• **Infection, surgery, trauma in a patient with hyperthyroidism** • **Thyroidectomy**	• Abdominal pain • Agitation • Delirium • Diarrhea • Heart failure • Hyperthermia (up to 106° F [41.1° C]) • Seizures • Severe tachycardia • Shock • Vomiting	• Begin fluid replacement with isotonic saline infusions containing dextrose. • Monitor airway, breathing, and circulation. • Monitor vital signs at least every 30 min. • Apply continuous O_2 saturation and ECG monitoring. • Monitor serial serum electrolytes, serum glucose, ABGs, and serum calcium levels. • Monitor urine output hourly. • Apply ice packs and cooling blankets to reduce fever. Acetaminophen as needed. • Provide pulmonary hygiene. • Assess for manifestations of heart failure or pulmonary edema (e.g., extra heart sounds, adventitious lung sounds). • Decrease O_2 demands by decreasing anxiety and pain. • Restrict visitors, if needed. • Give prescribed drugs and monitor effects: • β-Adrenergic blockers • Antithyroid agents • Iodine compounds • Glucocorticoids

TABLE 49.12 Nursing ManagementCare of the Patient After Thyroid Surgery

- Assess vital signs every 15 min until stable and then every 30 min for the first 24 hr after surgery.
- Monitor airway and respiratory status (patency, rate, rhythm, depth, and effort).
- Assess the patient every 2 hr for 24 hr for signs of hemorrhage or tracheal compression (e.g., irregular breathing, neck swelling, frequent swallowing, choking, blood on the dressings, and sensations of fullness at the incision site).
- Assist the patient with coughing and deep breathing.
- Apply supplemental O_2 with humidification as ordered.
- Have suction equipment and a tracheostomy kit available for immediate use.

- Assess the ability to speak aloud, noting voice quality, tone, and any problems speaking. Notify the HCP of any permanent hoarseness or loss of vocal volume.
- Monitor calcium levels and assess for signs of tetany and hypocalcemia (e.g., tingling in toes, fingers, around the mouth; muscular twitching; apprehension) and any difficulty in speaking and hoarseness. Check Trousseau's sign and Chvostek's sign (see Fig. 16.15).
- Keep calcium salts (calcium gluconate, calcium chloride) available for immediate IV use.
- Assess condition of operative site and dressing. Monitor the area under the patient's neck and shoulders for drainage.
- Place the patient in a semi-Fowler's position. Support the head and neck with pillows. Avoid neck flexion to prevent tension on the suture line.
- Provide comfort measures and give analgesic medications as prescribed.

The appearance of the incision may be distressing to the patient. Reassure the patient that the scar will fade in color and eventually look like a normal neck wrinkle. A scarf, jewelry, a high collar, or other covering can effectively camouflage the scar.

Ambulatory Care

Teach the patient and caregiver that thyroid hormone balance will be monitored periodically. Most patients have a period of relative hypothyroidism soon after surgery because of the substantial reduction in the size of the thyroid. However, the remaining tissue usually hypertrophies over time and recovers the ability to make hormones. Giving thyroid hormone is avoided because the exogenous hormone inhibits pituitary production of TSH and delays or prevents the restoration of normal gland function and tissue regeneration.

To prevent weight gain, caloric intake must be greatly reduced below the amount that was required before surgery. Adequate iodine

is needed to promote thyroid function, but excesses can inhibit the thyroid gland. Seafood once or twice a week or normal use of iodized salt should provide enough iodine intake. Encourage regular exercise to stimulate the thyroid gland. Teach the patient to avoid high environmental temperatures because they inhibit thyroid regeneration.

Regular follow-up care is needed. The patient should see the HCP biweekly for a month and then at least semiannually to assess thyroid function. Tell the patient who had a complete thyroidectomy about the need for lifelong thyroid hormone replacement. Teach the patient the signs and symptoms of thyroid failure and to seek medical care promptly if these develop.

Evaluation

The expected outcomes are that the patient with hyperthyroidism will

- Have relief of symptoms
- Have no serious complications related to the disease or treatment
- Cooperate with the therapeutic plan
- Maintain nutritional balance

Hypothyroidism

Hypothyroidism is a deficiency of thyroid hormone that causes a general slowing of the metabolic rate. About 4% of the U.S. population has mild hypothyroidism, with about 0.3% having more severe disease. Hypothyroidism is more common in women than men. Subclinical hypothyroidism occurs when the TSH is greater than 4.5 mU/L, but the T_4 levels are normal. Up to 10% of women older than 60 years have subclinical hypothyroidism.[14] Patients with overt hypothyroidism have increased TSH and decreased T_4 levels. Critically ill patients may present with nonthyroidal illness syndrome

(NTIS).[15] Those with NTIS have low T_3, T_4, and TSH levels.

Etiology and Pathophysiology

We classify hypothyroidism as primary or secondary. *Primary hypothyroidism* is caused by destruction of thyroid tissue or defective hormone synthesis. *Secondary hypothyroidism* is caused by pituitary disease with decreased TSH secretion or hypothalamic dysfunction with decreased thyrotropin-releasing hormone (TRH) secretion. Hypothyroidism can be brief and related to thyroiditis or stopping thyroid hormone therapy.

Iodine deficiency is the most common cause of hypothyroidism worldwide. In the United States, the most common cause of primary hypothyroidism is atrophy of the thyroid gland. This atrophy is the result of Hashimoto's thyroiditis or Graves' disease. These autoimmune diseases destroy the thyroid gland. Hypothyroidism can develop after treatment for hyperthyroidism, specifically thyroidectomy or RAI therapy. Drugs, such as amiodarone, which contains iodine, and lithium, which blocks hormone production, can cause hypothyroidism.

Hypothyroidism that develops in infancy *(cretinism)* results from thyroid hormone deficiencies during fetal or early neonatal life. All infants in the United States are screened for decreased thyroid function at birth.

Clinical Manifestations

The systemic effects of hypothyroidism are characterized by a slowing of body processes (Table 49.6). Manifestations vary depending on the severity and the duration of thyroid deficiency and the patient's age at the onset of the deficiency. Symptoms may develop over months to years, unless hypothyroidism occurs after a thyroidectomy, after thyroid ablation, or during treatment with antithyroid drugs.

The patient is often tired and lethargic. There may be personality and mental changes, including impaired memory, slowed speech,

decreased initiative, and somnolence. Many appear depressed. Weight gain is a result of a decreased metabolic rate.

Hypothyroidism may cause significant cardiovascular problems, especially in a person with a history of CVD. It is associated with decreased cardiac contractility and decreased cardiac output. The patient may have low exercise tolerance and shortness of breath on exertion. High serum cholesterol and triglyceride levels and the accumulation of mucopolysaccharides in the intima of small blood vessels can result in coronary atherosclerosis. Anemia is common.

Patients with severe, long-standing hypothyroidism may have **myxedema**. Myxedema results from the accumulation of hydrophilic mucopolysaccharides in the dermis and other tissues (Fig. 49.9). It alters the physical appearance of the skin and subcutaneous tissues with puffiness, facial and periorbital edema, and a masklike affect. Patients may have an altered self-image related to their disabilities and altered appearance.

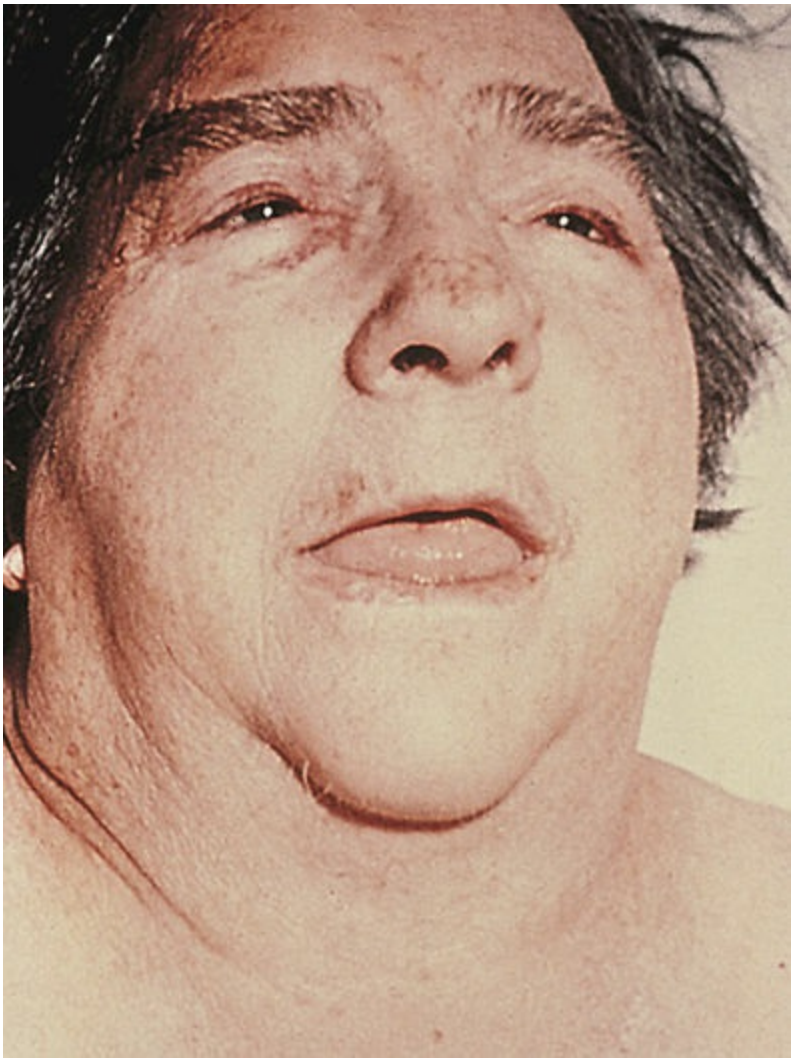

FIG. 49.9 Common features of myxedema. Dull, puffy skin; coarse, sparse hair; periorbital edema; and prominent tongue. Courtesy Paul W. Ladenson, MD, The Johns Hopkins University and Hospital, Baltimore, MD. From Seidel HM, Ball JW, Dains JE, et al, editors: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.

In the older adult, we may attribute the typical manifestations of hypothyroidism (fatigue, cold and dry skin, hoarseness, hair loss, constipation, cold intolerance) to normal aging. For this reason, the patient's symptoms may not raise suspicion of an underlying condition. Older adults who have confusion, lethargy, and depression should be evaluated for thyroid disease.

Complications

The mental sluggishness, drowsiness, and lethargy of hypothyroidism may progress gradually or suddenly to a notable impairment of consciousness or coma. This situation, termed *myxedema coma,* is a medical emergency. Myxedema coma can be precipitated by infection, drugs (especially opioids, tranquilizers, and barbiturates), exposure to cold, and trauma. It is characterized by subnormal temperature, hypotension, and hypoventilation. Cardiovascular collapse can result from hypoventilation, hyponatremia, hypoglycemia, and lactic acidosis. For the patient to survive myxedema coma, vital functions must be supported and IV thyroid hormone replacement given.

Diagnostic Studies

The most reliable laboratory tests for thyroid function are TSH and free T_4. These values, correlated with symptoms obtained from the history and physical examination, confirm the diagnosis of hypothyroidism. Serum TSH levels help determine the cause of hypothyroidism. Serum TSH is high when the defect is in the thyroid and low when it is in the pituitary or the hypothalamus. The presence of thyroid antibodies suggests an autoimmune origin. Other abnormal laboratory findings are high cholesterol and triglycerides, anemia, and increased creatine kinase (Table 49.7).

Interprofessional Care

The treatment goal for a patient with hypothyroidism is to restore a euthyroid state as safely and rapidly as possible with hormone therapy (Table 49.13). A low-calorie diet can promote weight loss or prevent weight gain.

Levothyroxine (Synthroid) is the drug of choice to treat hypothyroidism. In the young and otherwise healthy patient, the maintenance replacement dosage is adjusted according to the patient's response and laboratory findings. When beginning thyroid hormone therapy, the first dosages are low to avoid increases in resting heart rate and BP. In the patient with compromised cardiac status, careful monitoring is needed when starting and adjusting the dosage because

the usual dose may increase myocardial O_2 demand. This may cause angina and dysrhythmias.

TABLE 49.13 Interprofessional CareHypothyroidism

Diagnostic Assessment

- History and physical examination
- Serum TSH and free T_4
- Total serum T_3 and T_4
- Thyroid peroxidase (TPO) antibodies

Management

- Thyroid hormone replacement (e.g., levothyroxine)
- Monitor thyroid hormone levels and adjust dosage (if needed)
- Nutritional therapy to promote weight loss
- Patient and caregiver teaching (Table 49.14)

Drug Alert

Levothyroxine (Synthroid)

- Carefully monitor patients with CVD who take this drug.
- Monitor heart rate and report pulse greater than 100 beats/min or an irregular heartbeat.
- Promptly report chest pain, weight loss, nervousness, tremors, and/or insomnia.

In a patient without side effects, the dose is increased at 4- to 6-week intervals as needed based on the TSH levels. It may take up to 8 weeks before the full effect of hormone therapy is seen. Levothyroxine has a peak of action of 1 to 3 weeks. It is important that the patient regularly take replacement medication. Lifelong thyroid therapy is usually required.

Liotrix is a synthetic mix of levothyroxine (T_4) and liothyronine (T_3) in a 4:1 combination. Liotrix has a faster onset of action with a peak of 2 to 3 days. It can be used in acutely ill patients with hypothyroidism.

Nursing Management: Hypothyroidism

Nursing Assessment

Careful assessment may reveal early and subtle changes in a patient suspected of having hypothyroidism. Note any history of hyperthyroidism and treatment with antithyroid medications, RAI, or surgery. Ask the patient about using iodine-containing medications (Table 49.5). Note any changes in appetite, weight, activity level, speech, memory, and skin (e.g., increased dryness or thickening). Assess for cold intolerance, constipation, and signs of depression. Further assessment should focus on heart rate, tenderness over the thyroid gland, and edema in the extremities and face.

Nursing Diagnoses

Nursing diagnoses for the patient with hypothyroidism may include:

- Activity intolerance
- Constipation
- Impaired nutritional status

Additional information on nursing diagnoses and interventions is presented in the eNursing Care Plan 49.2 for the patient with hypothyroidism (available on the website for this chapter).

Planning

The overall goals are that the patient with hypothyroidism will (1) have relief of symptoms, (2) maintain a euthyroid state, (3) maintain a positive self-image, and (4) adhere with lifelong thyroid therapy.

Nursing Implementation

Health Promotion

Routine screening of thyroid function is not recommended in nonpregnant, asymptomatic adults. Risk factors include being female, white ethnicity, advancing age or having type 1 diabetes, Down syndrome, family history of thyroid disease, goiter, previous hyperthyroidism, and external beam radiation in the head and neck area.[16] High-risk populations should be screened for subclinical thyroid disease.

Acute Care

Most people with hypothyroidism are treated on an outpatient basis. The person who develops myxedema coma needs acute nursing care, often in the ICU. Mechanical respiratory support and cardiac monitoring are often needed.

Give thyroid hormone therapy and all other medications IV because severe gastric hypomotility may prevent the absorption of oral agents. Monitor the core temperature for hypothermia that often occurs in myxedema and myxedema coma. Use gentle soap and moisturize often to prevent skin breakdown. Frequent position changes and a low-pressure mattress help maintain skin integrity.

Monitor the patient's progress by assessing vital signs, body weight, fluid intake and output, and edema. Cardiac assessment is especially important because the cardiovascular response to hormone therapy determines the medication regimen. Note energy level and mental alertness, which should improve within 2 to 14 days and continue a steady progression to normal levels. Neurologic status and TSH levels are used to determine continuing treatment.

Ambulatory Care

Patient teaching about medication management and identification of complications is essential (Table 49.14). At first the hypothyroid patient may have a hard time processing complex instructions. It is important to give written instructions, repeat the information often, and assess the patient's comprehension level.

Stress the need for lifelong drug therapy and avoiding abruptly stopping drugs. Caution patients against doubling up on doses for any reason. Some patients notice weight loss and are tempted to increase dosing to achieve a desired weight. Teach the patient the expected and unexpected side effects, including the signs and symptoms of hypothyroidism and hyperthyroidism (Table 49.6). The manifestations of overdose are the same as hyperthyroidism. Tell the patient to contact the HCP at once if symptoms, such as orthopnea, dyspnea, rapid pulse, palpitations, chest pain, nervousness, or insomnia, are present.

The patient with diabetes should test blood glucose levels at least daily because the return to the euthyroid state often increases insulin requirements. Thyroid drugs increase the effects of anticoagulants and decrease the effect of digitalis compounds. Teach the patient the toxic signs and symptoms of these medications and the need to remain under close medical observation until stable. Medication interactions are an important reason for patients to consult the HCP before switching brands of thyroid replacement medication. Switching brands may change bioavailability of the drug and physiologic response.

TABLE 49.14 Patient & Caregiver TeachingHypothyroidism

Include the following instructions when teaching the patient and caregiver about management of hypothyroidism:

1. Discuss the importance of thyroid hormone therapy:

- Need for lifelong therapy
- Taking thyroid hormone in the morning before food
- Need for regular follow-up care and monitoring of thyroid hormone levels

2. Caution the patient not to switch brands of the hormone since the bioavailability of thyroid hormones may differ.
3. Emphasize the need for a comfortable, warm environment because of cold intolerance.
4. Teach ways to prevent skin breakdown. Use soap sparingly and apply lotion to skin.
5. Caution the patient, especially if an older adult, to avoid sedatives. If they must be used, suggest that the lowest dose be used. Caregiver should closely monitor mental status, level of consciousness, and respirations.
6. Discuss ways to minimize constipation, including:
    - Gradual increase in activity and exercise
    - Increased fiber in diet
    - Use of stool softeners
    - Regular bowel elimination time
    - Tell patient to avoid using enemas. They cause vagal stimulation, which can be hazardous if heart disease is present.

With treatment, striking transformations occur in both appearance and mental function. Most adults return to a normal state. Cardiovascular conditions and psychosis may persist despite corrections of the hormonal imbalance. Relapses occur if treatment is interrupted.

Evaluation

The expected outcomes are that the patient with hypothyroidism will

- Have relief from symptoms
- Maintain a euthyroid state with normal thyroid hormone and

TSH levels
- Avoid complications of therapy
- Adhere to lifelong therapy

Thyroid Nodules and Cancer

A *thyroid nodule* (growth in the thyroid gland) may be benign or malignant (thyroid cancer). More than 95% of all thyroid gland nodules are benign. Prevalence of thyroid nodule development increases with age. Benign nodules are usually not dangerous, but they can cause tracheal compression if they become too large.

Thyroid cancer is the most common type of cancer of the endocrine system. An estimated 62,450 new cases of thyroid cancer are diagnosed annually. The incidence of thyroid cancer has increased significantly in the past 25 years. It is the most rapidly increasing cancer in the United States. Thyroid cancer affects more women, and the incidence is higher in whites and Asian Americans.[17] Adults at risk include those who had head and neck radiation therapy during childhood, were exposed to radioactive fallout, or have a personal or family history of goiter.

Types of Thyroid Cancer

The 4 main types of thyroid cancer are papillary, follicular, medullary, and anaplastic. *Papillary* thyroid cancer is the most common type, accounting for about 70% to 80% of all thyroid cancers. Papillary cancer tends to grow slowly. It initially spreads to lymph nodes in the neck.

Follicular thyroid cancer makes up about 15% of all thyroid cancers. It tends to occur in older patients. Follicular cancer first metastasizes into the cervical lymph nodes and then spreads to the neck, lungs, and bones.

Medullary thyroid cancer, accounts for up to 10% of all thyroid cancers. It is more likely to occur in families and be associated with other endocrine problems. It is diagnosed by genetic testing for a

proto-oncogene called *RET*. Medullary thyroid cancer is a type of multiple endocrine neoplasia. It is often poorly differentiated and associated with early metastasis.

Anaplastic thyroid cancer occurs in less than 2% of patients with thyroid cancer. It is the most advanced and aggressive thyroid cancer. The patient is least likely to respond to treatment and has a poor prognosis.

Clinical Manifestations and Diagnostic Studies

The primary manifestation of thyroid cancer is a painless, palpable nodule or nodules in an enlarged thyroid gland. Most nodules are found during routine palpation of the neck. The presence of firm, palpable, cervical masses suggests lymph node metastasis. Some patients may have difficulty swallowing or breathing because of tumor growth invading the trachea or esophagus. Hemoptysis and airway obstruction may occur if the trachea is involved. Patients with thyroid cancer generally are euthyroid.

Nodular enlargement of the thyroid gland or palpation of a mass requires further evaluation. Ultrasound is often the first test used. Follow-up testing may involve CT, MRI, positron emission tomography (PET), and ultrasound-guided fine-needle aspiration (FNA). An FNA is done when a tissue sample for pathologic examination is needed. A thyroid scan may be done. The scan shows whether nodules on the thyroid are “hot” or “cold.” “Hot” tumors take up radioactive iodine. They are almost always benign. If the nodule does not take up the radioactive iodine, it appears as “cold” and has a higher risk for being cancer.

Increases in serum calcitonin are associated with medullary thyroid cancer. In papillary and follicular cancers, serum thyroglobulin is high. In families with a history of medullary thyroid cancer, family members are encouraged to have genetic testing and thyroid screening on a regular basis.

Interprofessional and Nursing Care

Surgical removal of the tumor is the main treatment for thyroid cancer. Surgical procedures range from unilateral total lobectomy to near-total thyroidectomy with bilateral lobectomy. Lymph nodes in the neck may be removed to determine if the cancer has spread. RAI may be given to some patients to destroy any remaining cancer cells after surgery. RAI therapy improves survival rates in patients with papillary and follicular thyroid cancer. External beam radiation may be given as palliative treatment for patients with metastatic thyroid cancer.

Many thyroid cancers are TSH dependent. Thyroid hormone therapy in high doses is often prescribed to inhibit pituitary secretion of TSH. Chemotherapy, including doxorubicin, may be used for advanced disease. Vandetanib (Caprelsa), lenvatinib (Lenvima), sorafenib tosylate (Nexavar), and cabozantinib (Cometriq) are targeted therapies used for metastatic thyroid cancer. These drugs inhibit tyrosine kinases, enzymes that are involved in the growth of cancer cells.

Nursing care for the patient with thyroid cancer is similar to that of a patient undergoing thyroidectomy (see p. 1154). Because of the surgical site location and the potential for hypocalcemia, the patient needs frequent postoperative assessment. Assess the patient for airway obstruction, bleeding, and tetany since the parathyroid gland may have been disturbed or removed during surgery.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) is an inherited condition characterized by hormone-secreting tumors.[18] It is caused by the mutation of 1 of 2 genes, *MEN1* or *RET,* that normally control cell growth. Tumors may develop in childhood or later in life.

The 2 major types of MEN are type 1 and type 2. Both types are often inherited as autosomal dominant disorders. Persons with type 1 often have parathyroid gland hyperactivity (hyperparathyroidism). Other signs may include hyperactivity of the pituitary gland (prolactinoma) and pancreas (gastrinoma). In most cases, the tumors

are initially benign. Some tumors later become malignant. Persons with type 2 neoplasia often have medullary thyroid carcinoma. They may develop pheochromocytoma (tumor of the adrenal glands). Pheochromocytoma is discussed later in this chapter on p. 1168.

Treatment includes conservative management (watchful waiting), drugs to block the effects of excess hormone, and surgical removal of the gland and/or tumor. It is important for patients to have regular screening visits with the HCP so that new tumors may be detected early and existing tumors carefully monitored.

Disorders of Parathyroid Glands

Hyperparathyroidism

Etiology and Pathophysiology

Hyperparathyroidism is a condition involving an increased secretion of parathyroid hormone (PTH). PTH helps regulate serum calcium and phosphate levels by stimulating bone resorption of calcium, renal tubular reabsorption of calcium, and activation of vitamin D. Thus oversecretion of PTH is associated with increased serum calcium levels.

Hyperparathyroidism is classified as primary, secondary, or tertiary. *Primary hyperparathyroidism* is due to an increased secretion of PTH leading to disorders of calcium, phosphate, and bone metabolism. The most common cause is a benign tumor (adenoma) in the parathyroid gland. Patients who have previously undergone head and neck radiation have an increased risk for developing a parathyroid adenoma. Long-term lithium therapy is also associated with primary hyperparathyroidism. Primary hyperparathyroidism affects 25 of 100,000 persons per year.[19] The peak incidence is in the 40s and 50s. It affects twice as many women as men.[19]

Secondary hyperparathyroidism is a compensatory response to conditions that induce or cause hypocalcemia, the main stimulus of PTH secretion. These include vitamin D deficiencies, malabsorption, chronic kidney disease, and hyperphosphatemia.

Tertiary hyperparathyroidism occurs when there is hyperplasia of the parathyroid glands and a loss of negative feedback (see Chapter 47) from circulating calcium levels. Thus there is autonomous secretion of PTH even with normal calcium levels. This condition is seen in patients who have had a kidney transplant after a long period of dialysis treatment for chronic kidney disease (see Chapter 46).

Excess levels of PTH usually lead to hypercalcemia and hypophosphatemia. Multiple body systems are affected (Table 49.15). Decreased bone density can occur because of the effect of PTH on osteoclastic (bone resorption) and osteoblastic (bone formation) activity. The kidneys cannot reabsorb the excess calcium. This leads to increased urinary calcium levels (hypercalciuria). This urinary calcium, along with a large amount of urinary phosphate, can lead to stone formation.

Clinical Manifestations and Complications

Manifestations range from an asymptomatic person (diagnosed through testing for unrelated problems) to a patient with overt symptoms.[19] The manifestations are associated with hypercalcemia (Table 49.15). Loss of appetite, constipation, fatigue, emotional disorders, shortened attention span, and muscle weakness, particularly in the proximal muscles of the lower extremities, often occur. Complications include osteoporosis, renal failure, kidney stones, pancreatitis, cardiac changes, and long bone, rib, and vertebral fractures.

Diagnostic Studies

PTH levels are increased in patients with hyperparathyroidism. Serum calcium levels usually exceed 10 mg/dL (2.50 mmol/L). Because of its inverse relation with calcium, the serum phosphorus level is usually less than 3 mg/dL (0.1 mmol/L). Hypercalcemia in asymptomatic cases is often identified through a routine chemistry panel.

Increases in other laboratory tests include urine calcium, serum chloride, uric acid, creatinine, amylase (if pancreatitis is present), and

alkaline phosphatase (in the presence of bone disease). Bone density measurements may be used to detect bone loss. Conversely, those with bone loss on a screening dual-energy x-ray absorptiometry (DEXA) scan should be tested for hypercalcemia. MRI, CT, and/or ultrasound can detect an adenoma.

Interprofessional Care

The goal of treatment is to relieve symptoms and prevent complications caused by excess PTH. The choice of therapy depends on the urgency of the situation, degree of hypercalcemia, and underlying cause of the disorder.

Surgical Therapy

The most effective treatment of primary and secondary hyperparathyroidism is surgical intervention. Surgery involves partial or complete removal of the parathyroid glands. The most common procedure involves endoscopy and is done on an outpatient basis. Criteria for surgery include increased serum calcium levels (more than 1 mg/dL above the upper limit of normal), hypercalciuria (greater than 400 mg/day), markedly reduced bone mineral density, overt symptoms (e.g., neuromuscular effects, kidney stones), or age under 50 years. Parathyroidectomy leads to a rapid reduction of high calcium levels.

Patients who have multiple parathyroid glands removed may undergo autotransplantation of normal parathyroid tissue in the forearm or near the sternocleidomastoid muscle. This allows PTH secretion to continue with normalization of calcium levels. If autotransplantation is not possible or if it fails, the patient will need to take calcium supplements for life.

TABLE 49.15 Manifestations of Parathyroid Dysfunction

Hyperfunction	Hypofunction
Cardiovascular System	
• **Hypertension** • **Angina** • **Dysrhythmias** • **Shortened ST segment** • **Shortened QT interval** • **↑ Digitalis effect**	• Hypotension • Edema • Dysrhythmias • Elongation of ST segment • Prolonged QT interval • ↓ Cardiac output
Gastrointestinal System	
• **Vague abdominal pain** • **Anorexia** • **Nausea and vomiting** • **Constipation** • **Pancreatitis** • **Peptic ulcer disease** • **Cholelithiasis** • **Weight loss**	• Abdominal cramps • Fecal incontinence (in older adult) • Malabsorption
Laboratory Findings	
• **↑ Calcium** • **↓ Phosphorus**	• ↓ Calcium • ↑ Phosphorus
Musculoskeletal System	
• **Weakness, fatigue** • **Skeletal pain** • **Backache** • **Pain on weight bearing** • **Osteoporosis** • **Pathologic fractures of long bones** • **Compression fractures of spine; kyphosis** • **↓ muscle tone, muscle atrophy**	• Weakness, fatigue • Painful muscle cramps • Skeletal x-ray changes, osteosclerosis • Soft tissue calcification • Difficulty walking
Neurologic System	
• **Lethargy, weakness, fatigue** • **Psychosis, depression** • **Depressed reflexes** • **Personality changes** • **Irritability** • **Memory impairment** • **Delirium, confusion, coma** • **Headache** • **Poor coordination** • **Gait abnormalities** • **Psychomotor retardation** • **Paresthesias**	• Weakness, fatigue • Depression • Hyperreflexia, muscle cramps • Personality changes • Irritability • Memory impairment • Disorientation, confusion (in older adult) • Headache, ↑ intracranial pressure • Tetany, seizures • Positive Chvostek's and Trousseau's sign • Tremor • Paresthesias of lips, hands, feet
Renal/Urinary System	
• **Hypercalciuria** • **Kidney stones** • **Urinary tract infections** • **Polyuria**	• Urinary frequency • Urinary incontinence
Skin	
• **Skin necrosis** • **Moist skin**	• Dry, scaly skin • Hair loss on scalp and body • Brittle nails, transverse ridging • Lack of tooth enamel
Visual System	
• **Impaired vision** • **Corneal calcification**	• Eye changes, including lenticular opacities, cataracts, papilledema

Nonsurgical Therapy

A conservative approach is often used in patients who are asymptomatic or have mild symptoms of hyperparathyroidism.

Ongoing care includes regular examination with measurements of serum PTH, calcium, phosphorus, alkaline phosphatase, creatinine and blood urea nitrogen (BUN) (to assess renal function), and urinary calcium excretion. Annual x-rays and DEXA scans assess for metabolic bone loss. Continued ambulation and avoiding immobility are important. Dietary measures include high fluid and moderate calcium intake.

Severe hypercalcemia is managed with IV sodium chloride solution and loop diuretics, such as furosemide, to increase the urinary excretion of calcium. Several drugs help to lower calcium levels, but they do not treat the underlying problem. Bisphosphonates (e.g., alendronate [Fosamax]) inhibit osteoclastic bone resorption, normalizing serum calcium levels and improving bone mineral density. IV bisphosphonates (e.g., pamidronate [Aredia]) can rapidly lower serum calcium in patients with dangerously high levels. Phosphates are given if the patient has normal renal function and low serum phosphate levels.

Calcimimetic agents (e.g., cinacalcet [Sensipar]) increase the sensitivity of the calcium receptor on the parathyroid gland, resulting in decreased PTH secretion and calcium blood levels. They are useful in treating secondary hyperparathyroidism in those with chronic kidney disease on dialysis or in patients with parathyroid cancer.

Nursing Management: Hyperparathyroidism

Nursing care for the patient after a parathyroidectomy is similar to that for a patient after thyroidectomy. The major complications are associated with hemorrhage and fluid and electrolyte problems. *Tetany,* a condition of neuromuscular hyperexcitability associated with sudden decrease in calcium levels, is another concern. It is usually apparent early in the postoperative period but may develop over several days. Mild tetany, characterized by unpleasant tingling of the hands and around the mouth, may be present but should decrease

over time. If tetany becomes more severe (e.g., muscular spasms, laryngospasms), IV calcium may be given. IV calcium gluconate should be readily available for patients after parathyroidectomy in case acute tetany occurs.

Monitor intake and output to evaluate the patient's fluid status. Assess calcium, potassium, phosphate, and magnesium levels frequently, as well as Chvostek's and Trousseau's signs (see Fig. 16.15). Encourage mobility to promote bone calcification.

If surgery is not done, treatment to relieve symptoms and prevent complications is started. Help the patient to adapt the meal plan to their lifestyle. A referral to a dietitian may be useful. Because immobility can worsen bone loss, emphasize the importance of an exercise program. Encourage the patient to keep the regular follow-up appointments. Teach the patient the symptoms of hypocalcemia and hypercalcemia and to report them if they occur. Hypocalcemia and hypercalcemia are discussed in Chapter 16.

Hypoparathyroidism

Hypoparathyroidism is an uncommon condition associated with inadequate circulating PTH. It is characterized by hypocalcemia due to a lack of PTH to maintain serum calcium levels. PTH resistance at the cellular level may also occur *(pseudohypoparathyroidism).* This is caused by a genetic defect resulting in hypocalcemia despite normal or high PTH levels. It is often associated with hypothyroidism and hypogonadism.

The most common cause is iatrogenic. This may include accidental removal of the parathyroid glands or damage to the vascular supply of the glands during neck surgery (e.g., thyroidectomy). Idiopathic hypoparathyroidism resulting from the absence, fatty replacement, or atrophy of the glands is a rare disease. It usually occurs early in life and may be associated with other endocrine disorders. Affected patients may have antiparathyroid antibodies. Severe hypomagnesemia (e.g., malnutrition, chronic alcoholism, renal failure) can suppress PTH secretion. Other causes of parathyroid deficiency

include tumors and heavy metal poisoning.

The features of acute hypoparathyroidism are due to hypocalcemia (Table 49.15). Sudden decreases in calcium concentration cause tetany, characterized by tingling of the lips and stiffness in the extremities. Painful tonic spasms of smooth and skeletal muscles can cause dysphagia and laryngospasms, which compromise breathing. Lethargy, anxiety, and personality changes may occur. Abnormal laboratory findings include decreased serum calcium and PTH levels and increased serum phosphate levels.

Interprofessional and Nursing Care

Treatment goals are to treat acute complications, such as tetany, maintain normal serum calcium levels, and prevent long-term complications. Emergency treatment of tetany after surgery requires IV calcium administration.

Give IV calcium slowly. Use ECG monitoring when giving calcium because high serum calcium levels can cause hypotension, serious dysrhythmias, or cardiac arrest. The patient who takes digoxin is particularly vulnerable. It is important to assess IV patency before administration. Calcium chloride can cause venous irritation and inflammation. Extravasation may cause cellulitis, necrosis, and tissue sloughing.

Rebreathing may partially relieve acute neuromuscular symptoms associated with hypocalcemia, including muscle cramps and mild tetany. Have the patient breathe in and out of a paper bag or breathing mask. This reduces CO_2 excretion from the lungs, increases carbonic acid levels in the blood, and lowers the pH. A lower pH (acidic environment) enhances calcium ionization, which causes more total body calcium to be available in the active form.

Check Your Practice

You are caring for a 56-yr-old man admitted 18 hours ago to your

clinical unit. He had a total thyroidectomy for papillary thyroid cancer. As you are preparing to give oral pain medication, he tells you he hopes he "doesn't have any trouble" taking it because his lips feel "a little numb."

- What complication do you suspect could be occurring?
- What assessments do you need to make?
- Describe the actions needed if this complication is occurring.

Teach the patient how to manage long-term drug and nutritional therapy. PTH replacement is not recommended because of the expense and need for parenteral administration. Most patients receive oral calcium supplements, magnesium supplements, and vitamin D.

Vitamin D is used to enhance intestinal calcium absorption. Vitamin D (e.g., 1,25-dihydroxycholecalciferol, calcitriol [Rocaltrol]) increases calcium levels rapidly and is quickly metabolized. Rapid metabolism is desired because vitamin D is a fat-soluble vitamin and toxicity can cause irreversible renal impairment.

A high-calcium meal plan includes foods, such as dark green vegetables, soybeans, and tofu. Tell the patient to avoid foods containing oxalic acid (e.g., spinach, rhubarb) because they inhibit calcium absorption. Teach the patient about the need for follow-up care, including monitoring of calcium levels 3 or 4 times a year.

Disorders of Adrenal Cortex

Adrenal cortex steroid hormones have 3 main classifications: glucocorticoids, mineralocorticoids, and androgens. Glucocorticoids regulate metabolism, increase blood glucose levels, and are critical in the physiologic stress response. The primary glucocorticoid is cortisol. Mineralocorticoids regulate sodium and potassium balance. The primary mineralocorticoid is aldosterone. Androgens contribute to growth and development in both genders and to sexual development in men. The term *corticosteroid* refers to any of these 3 types of

hormones made by the adrenal cortex.

Cushing Syndrome

Etiology and Pathophysiology

Cushing syndrome is a clinical condition that results from chronic exposure to excess corticosteroids, particularly glucocorticoids.[20] Several conditions can cause Cushing syndrome. The most common cause is iatrogenic administration of exogenous corticosteroids (e.g., prednisone). About 85% of the cases of endogenous Cushing syndrome are due to an ACTH-secreting pituitary adenoma (Cushing disease). Less common causes include adrenal tumors and ectopic ACTH production by tumors (usually of the lung or pancreas) outside of the hypothalamic-pituitary-adrenal axis. Cushing disease and primary adrenal tumors are more common in women in the 20- to 40-year-old age-group. Ectopic ACTH production is more common in men.

Clinical Manifestations

Manifestations occur in most body systems and are related to excess levels of corticosteroids (Table 49.16). Although signs of glucocorticoid excess usually predominate, symptoms of mineralocorticoid and androgen excess can occur.

Corticosteroid excess causes pronounced changes in physical appearance (Fig. 49.10). Weight gain is the most common feature. It results from the accumulation of adipose tissue in the trunk (centripetal obesity), face ("moon face"), and cervical areas ("buffalo hump") (Fig. 49.11). Hyperglycemia occurs because of glucose intolerance associated with cortisol-induced insulin resistance and increased gluconeogenesis by the liver. Muscle wasting causes weakness, especially in the extremities. A loss of bone matrix leads to osteoporosis and back pain. The loss of collagen makes the skin weaker, thinner, and more easily bruised. Purplish red striae (usually

depressed below the skin surface) appear on the abdomen, breast, or buttocks (Fig. 49.12). Catabolic processes lead to a delay in wound healing.

TABLE 49.16 Manifestations of Adrenocortical Dysfunction

System	Cushing Syndrome	Addison's Disease
Glucocorticoids		
General appearance	Truncal obesity, thin extremities, rounding of face (moon face), fat deposits on back of neck and shoulders (buffalo hump) (Fig. 49.11)	Weight loss, emaciation
Cardiovascular	Hypervolemia, hypertension, edema of lower extremities	Hypotension, tendency to develop refractory shock, vasodilation
Gastrointestinal	↑ Secretion of pepsin and HCl acid, risk for peptic ulcer disease, anorexia	Anorexia, nausea and vomiting, cramping abdominal pain, diarrhea
Immune	Inhibition of immune response, suppression of allergic response	Tendency for coexisting autoimmune diseases
Metabolic	Hyperglycemia, negative nitrogen balance, dyslipidemia	Hyponatremia, insulin sensitivity, fever
Musculoskeletal	Muscle wasting in extremities, fatigue, osteoporosis, awkward gait, back pain, weakness, compression fractures	Fatigue
Psychologic	Euphoria, irritability, depression, insomnia, anxiety	Depression, exhaustion or irritability, confusion, delusions
Renal/urinary	Glycosuria, hypercalciuria, risk for kidney stones	
Skin	Thin, fragile skin, purplish red striae (Fig. 49.12). Petechial hemorrhages, bruises. Florid cheeks (plethora), acne, poor wound healing	Bronzed or smoky hyperpigmentation of face, neck, hands (especially creases) (Fig. 49.13), buccal membranes, nipples, genitalia, and scars (if pituitary function normal). Vitiligo, alopecia
Mineralocorticoids		
Cardiovascular	Hypertension, hypervolemia	Hypovolemia, tendency toward shock, decreased cardiac output
Fluid and electrolytes	Marked sodium and water retention, edema, marked hypokalemia, alkalosis	Sodium loss, ↓ volume of extracellular fluid, hyperkalemia, salt craving
Androgens		
Musculoskeletal	Muscle wasting and weakness	↓ Muscle size and tone
Reproductive	*Women:* Menstrual irregularities and enlargement of clitoris *Men:* Gynecomastia and testicular atrophy	*Women:* ↓ Libido in women *Men:* No effect in men
Skin	Hirsutism, acne, hyperpigmentation	↓ Axillary and pubic hair (in women)

FIG. 49.10 Cushing syndrome. Facies include a rounded face ("moon face") with thin, reddened skin. Hirsutism may be present.
From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.

Mineralocorticoid excess may cause hypokalemia from potassium excretion and hypertension from fluid retention. Adrenal androgen excess may cause severe acne, the development of male characteristics in women, and feminization in men. Menstrual disorders and hirsutism in women and gynecomastia and impotence in men are seen more often in adrenal cancers.

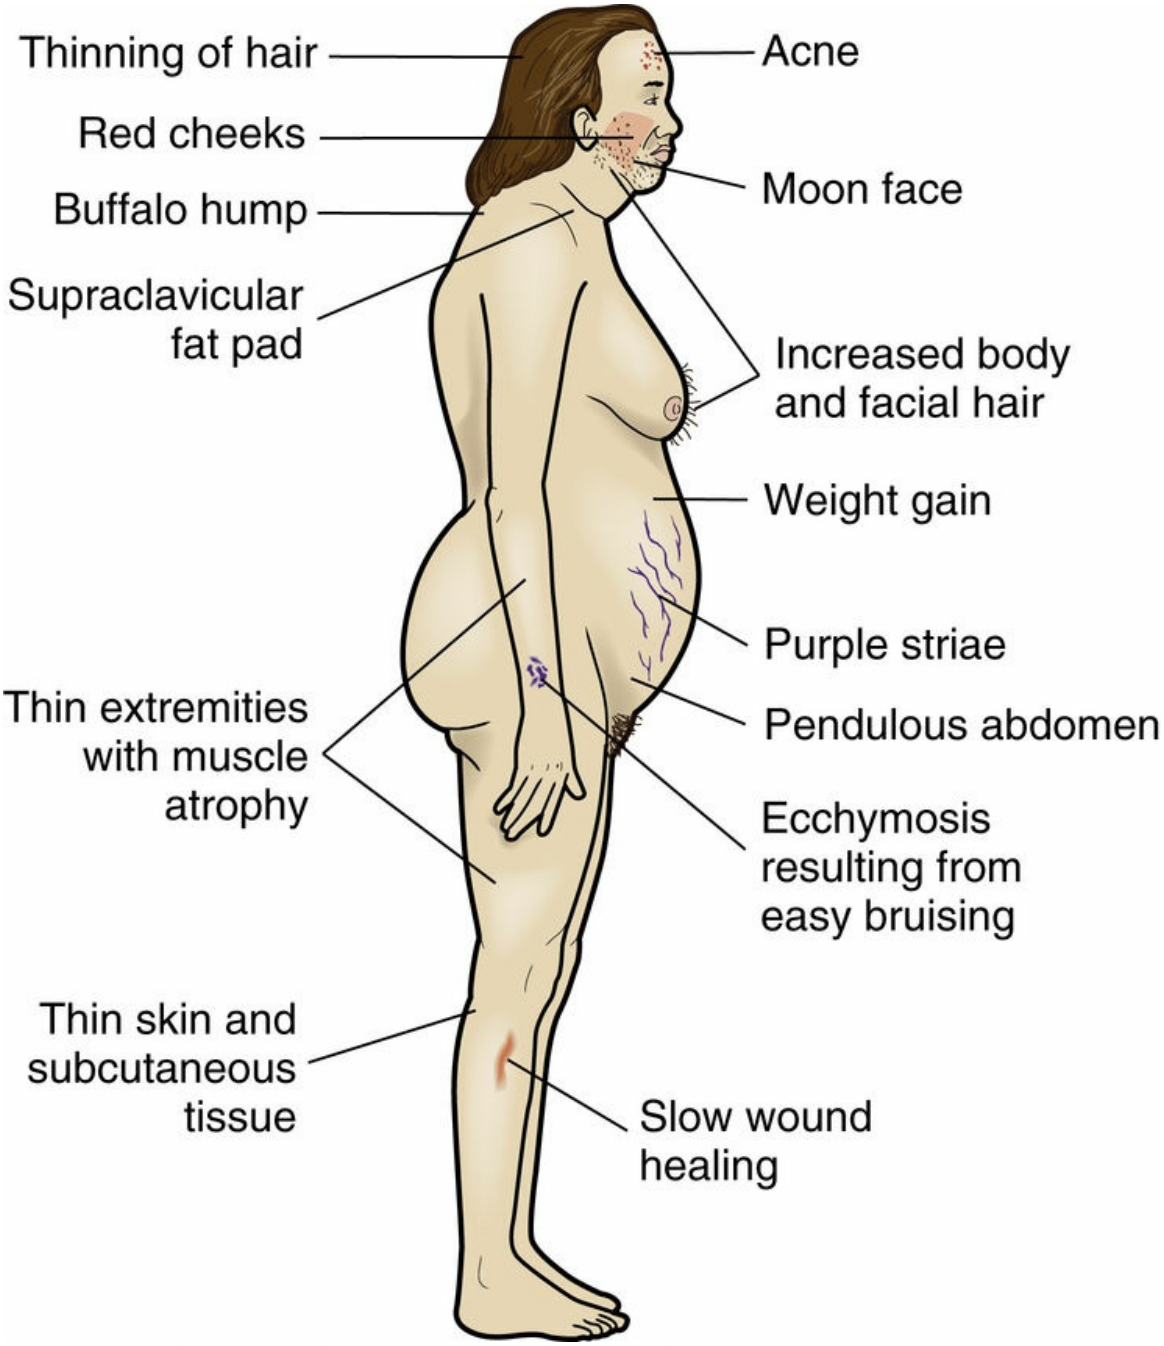

FIG. 49.11 Common characteristics of Cushing syndrome.

Diagnostic Studies

Diagnosing Cushing syndrome begins with confirming increased plasma cortisol levels. We use 3 tests: (1) midnight or late-night salivary cortisol, (2) low-dose dexamethasone suppression test, and (3)

24-hour urine cortisol.[21] Urine cortisol levels higher than 100 mcg/24 hr indicate Cushing syndrome. Urine levels of 17-ketosteroids may be high. A CT scan or MRI of the pituitary and adrenal glands can detect a tumor.

FIG. 49.12 Cushing syndrome. Truncal obesity; broad, purple striae; and easy bruising (left antecubital fossa).
From Chew SL, Leslie D: *Clinical endocrinology and diabetes: An illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.

Plasma ACTH levels may be low, normal, or high, depending on the underlying cause of Cushing syndrome. High or normal ACTH

levels indicate Cushing disease, while low or undetectable levels indicate an adrenal or medication cause. Other findings associated with, but not diagnostic of, Cushing syndrome include leukocytosis, lymphopenia, eosinopenia, hyperglycemia, glycosuria, hypercalciuria, and osteoporosis. Hypokalemia and alkalosis are seen in ectopic ACTH syndrome and adrenal cancer.

Interprofessional Care

The primary goal of treatment is to normalize hormone secretion. The specific treatment depends on the underlying cause (Table 49.17). If the underlying cause is a pituitary adenoma, the standard treatment is surgical removal of the pituitary tumor using the transsphenoidal approach.[21] (This was discussed earlier in this chapter on p. 1145.) Radiation therapy is an option for patients who are not good surgical candidates.

An adrenalectomy is done if Cushing syndrome is caused by adrenal tumors or hyperplasia. Sometimes, bilateral adrenalectomy is needed. A laparoscopic approach is used unless a malignant adrenal tumor is suspected. An open surgical adrenalectomy is usually done for adrenal cancer.

Patients with ectopic ACTH-secreting tumors are best managed by removing the tumor (usually lung or pancreas). This is usually possible when the tumor is benign. If a cancerous tumor has already metastasized, surgical removal may not be possible or successful.

When the patient is a poor candidate for surgery or prior surgery has failed, drug therapy may be tried. The goal of drug therapy is to suppress the synthesis and secretion of cortisol from the adrenal gland *(medical adrenalectomy).* Drugs used include ketoconazole and mitotane. These are used cautiously because they are often toxic at the dosages needed to reduce cortisol secretion. Hydrocortisone or prednisone may be needed to avoid adrenal insufficiency. Mifepristone (Korlym) may be used to control hyperglycemia in patients with endogenous Cushing syndrome who have type 2 diabetes.

TABLE 49.17 Interprofessional CareCushing Syndrome

Diagnostic Assessment

- History and physical examination
- Dexamethasone suppression test
- 24-Hr urine for free cortisol and 17-ketosteroids
- Plasma and salivary cortisol levels
- Plasma ACTH levels
- Complete blood count (CBC) with WBC differential
- Blood chemistries for sodium, potassium, glucose
- CT scan, MRI

Management
Pituitary Adenoma

- Transsphenoidal resection
- Radiation therapy

Adrenocortical Adenoma, Cancer, or Hyperplasia

- Adrenalectomy (open or laparoscopic)
- Drug therapy (e.g., ketoconazole, mitotane, mifepristone [Korlym])

Ectopic ACTH-Secreting Tumor

- Treatment of the tumor (surgical removal or radiation)

Exogenous Corticosteroid Therapy

- Discontinue or change the dose of exogenous corticosteroids

If Cushing syndrome developed because of prolonged use of corticosteroids (e.g., prednisone), the following alternatives may be tried: (1) gradually discontinuing corticosteroid therapy, (2) reducing the corticosteroid dose, and (3) converting to alternate-day dosing. Gradual tapering of the corticosteroids is necessary to avoid potentially life-threatening adrenal insufficiency. In alternate-day dosing, twice the daily dosage of a shorter-acting corticosteroid is given every other morning to minimize hypothalamic-pituitary-adrenal suppression, growth suppression, and altered appearance. This plan is not used when the corticosteroids are given as hormone therapy.

Nursing Management: Cushing Syndrome

Nursing Assessment

Subjective and objective data that should be obtained from a patient with Cushing syndrome are outlined in Table 49.18.

Nursing Diagnoses

Nursing diagnoses for the patient with Cushing syndrome may include:

- Risk for infection
- Impaired nutritional status
- Disturbed body image
- Impaired tissue integrity

Additional information on nursing diagnoses and interventions is presented in eNursing Care Plan 49.3 for the patient with Cushing syndrome (available on the website for this chapter).

Planning

The overall goals are that the patient with Cushing syndrome will (1) have relief of symptoms, (2) avoid serious complications, (3) maintain a positive self-image, and (4) actively take part in the therapeutic plan.

TABLE 49.18 Nursing AssessmentCushing Syndrome

Subjective Data

Important Health Information

Past health history: Pituitary tumor (Cushing disease). Adrenal, pancreatic, or pulmonary cancer. GI bleeding, frequent infections
Medications: Corticosteroids

Functional Health Patterns

Health perception–health management: Malaise
Nutritional-metabolic: Weight gain, anorexia. Prolonged wound healing, easy bruising
Elimination: Polyuria
Activity-exercise: Weakness, fatigue
Sleep: Insomnia, poor sleep quality
Cognitive-perceptual: Headache. Back, joint, bone, and rib pain. Poor concentration and memory
Self-perception–self-concept: Negative feelings about changes in personal appearance

Sexuality-reproductive: Amenorrhea, impotence, ↓ libido
Coping–stress tolerance: Anxiety, mood changes, emotional lability, psychosis

Objective Data

General

Truncal obesity, supraclavicular fat pads, buffalo hump, moon face

Skin

Hirsutism of body and face, thinning of head hair. Thin, friable skin. Acne, petechiae, purpura, hyperpigmentation. Purplish red striae on breasts, buttocks, and abdomen. Edema of lower extremities

Cardiovascular

Hypertension

Musculoskeletal

Muscle wasting, thin extremities, awkward gait

Reproductive

Gynecomastia, testicular atrophy (in men), enlarged clitoris (in women)

Possible Diagnostic Findings

Hypokalemia, hyperglycemia, dyslipidemia, polycythemia, lymphocytopenia, eosinopenia. ↑ Plasma cortisol, ↑ salivary cortisol. High, low, or normal ACTH levels. Abnormal dexamethasone suppression test. ↑ Urine free cortisol, 17-ketosteroids. Glycosuria, hypercalciuria. Osteoporosis on x-ray

Nursing Implementation

Health Promotion

Health promotion focuses on identifying patients at risk for Cushing syndrome. Patients receiving long-term, exogenous corticosteroids are at risk. Teaching related to using medications and monitoring side effects is an important preventive measure.

Acute Care

The patient with Cushing syndrome is seriously ill. Because the therapy has many side effects, assessment focuses on signs and symptoms of hormone and drug toxicity and complicating conditions (e.g., CVD, diabetes, infection). Monitor vital signs, daily weight, and glucose. Assess for infection. Because signs and symptoms of inflammation (e.g., fever, redness) may be minimal or absent, assess for pain, loss of function, and purulent drainage. Monitor for signs and symptoms of thromboembolic events, such as pulmonary emboli (e.g., sudden chest pain, dyspnea, tachypnea).

Another important focus of nursing care is emotional support. Changes in appearance, such as truncal obesity, multiple bruises, hirsutism in women, and gynecomastia in men, can be distressing. The patient may feel unattractive, repulsive, or unwanted. You can help by being sensitive to the patient's feelings and offering respect and unconditional acceptance. Reassure the patient that the physical changes and much of the emotional lability will resolve when hormone levels return to normal.

If treatment involves surgical removal of a pituitary adenoma, an adrenal tumor, or one or both adrenal glands, nursing care will include preoperative and postoperative care.

Preoperative Care

Before surgery, the patient should be brought to optimal physical condition. Hypertension and hyperglycemia must be controlled. Hypokalemia must be corrected with diet and potassium supplements. A high-protein diet helps correct the protein depletion. Preoperative teaching depends on the type of surgical approach planned (hypophysectomy or adrenalectomy). Include information about the expected care after surgery.

Postoperative Care

Surgery on the adrenal glands poses great risks. Because the adrenal glands are vascular, the risk for hemorrhage is increased. After both laparoscopic and open adrenalectomy, the patient may have a nasogastric tube, a urinary catheter, IV therapy, and central venous pressure monitoring. Initiate VTE prophylaxis.

Manipulating glandular tissue during surgery may release large amounts of hormones into the circulation. This can produce marked fluctuations in the metabolic processes affected by these hormones. After surgery, BP, fluid balance, and electrolyte levels may be unstable due to these hormone fluctuations.

High doses of corticosteroids (e.g., hydrocortisone [Solu-Cortef]) are given IV during surgery and for several days afterward to ensure adequate responses to the stress of the procedure. If large amounts of endogenous hormone were released into the systemic circulation during surgery, the patient is likely to develop hypertension, increasing the risk for hemorrhage. High corticosteroid levels cause problems with glycemic control, increase risk for infection, and delay wound healing.

The critical period for circulatory instability is 24 to 48 hours after surgery. During this time, you must constantly be alert for signs of corticosteroid imbalance. Report any rapid or significant changes in BP, respirations, or heart rate. Monitor fluid intake and output carefully and assess for potential imbalances. IV corticosteroids are given, and the dosage and flow rate are adjusted to the patient's manifestations and fluid and electrolyte balance. Oral doses are given

as tolerated. After IV corticosteroids are withdrawn, keep the IV line open for quick administration of corticosteroids or vasopressors. Obtain morning urine samples at the same time each morning for cortisol measurement to evaluate the surgery's effectiveness.

If corticosteroid dosage is tapered too rapidly after surgery, acute adrenal insufficiency may develop. Vomiting, increased weakness, dehydration, and hypotension are signs of hypocortisolism. The patient may have painful joints, pruritus, or peeling skin and may have severe emotional problems. Report these signs and symptoms so that drug doses can be adjusted as needed.

The patient is usually kept on bed rest until the BP stabilizes. Be alert for subtle signs of infection because the usual inflammatory responses are suppressed. To prevent infection, provide meticulous care when changing the dressing and during any other procedures that involve access to body cavities, circulation, or areas under the skin.

Ambulatory Care

Discharge instructions are based on the patient's lack of endogenous corticosteroids and resulting inability to react physiologically to stressors. Consider a home health nurse referral, especially for older adults, because of the need for ongoing evaluation and teaching. Teach the patient to always wear a Medic Alert bracelet and carry medical identification and instructions in a wallet or purse. Teach the patient to avoid exposure to extreme temperatures, infections, and emotional situations. Stress may cause acute adrenal insufficiency because the remaining adrenal tissue cannot meet an increased hormonal demand. Teach patients to adjust their corticosteroid replacement therapy by their stress levels. Consult with the patient's HCP to determine the parameters for dosage changes if this plan is feasible. If the patient cannot adjust their own medication, or if weakness, fainting, fever, or nausea and vomiting occur, the patient should contact the HCP for a possible adjustment in corticosteroid dosage. Many patients require lifetime replacement therapy. However, patients should be prepared for it to take several months to

adjust the hormone dose satisfactorily.

Evaluation

The expected outcomes are that the patient with Cushing syndrome will

- Have no signs or symptoms of infection
- Maintain weight appropriate for height
- State acceptance of appearance and treatment plan
- Show healing of skin and maintaining intact skin

Adrenocortical Insufficiency

Etiology and Pathophysiology

Adrenocortical insufficiency (hypofunction of the adrenal cortex) may be from a primary cause (**Addison's disease**) or a secondary cause (lack of pituitary ACTH secretion). In Addison's disease, all 3 classes of adrenal corticosteroids (glucocorticoids, mineralocorticoids, and androgens) are reduced. In secondary adrenocortical insufficiency, corticosteroids and androgens are deficient but mineralocorticoids rarely are. ACTH deficiency may be caused by pituitary disease or suppression of the hypothalamic-pituitary axis because of the use of exogenous corticosteroids.

Up to 80% of Addison's disease cases in the United States are caused by an autoimmune response.[22] Autoimmune adrenalitis causes the adrenal cortex to be destroyed by antibodies. This results in loss of glucocorticoid, mineralocorticoid, and adrenal androgen hormones. Addison's disease can be present along with other endocrine conditions. This is known as *autoimmune polyglandular syndrome*. It is most common in white females. Those with autoimmune adrenalitis often have other autoimmune disorders, such as type 1 diabetes, autoimmune thyroid disease, pernicious anemia, and celiac disease.[23]

Although tuberculosis causes Addison's disease worldwide, it is

now an uncommon cause in the United States. Other causes include amyloidosis, fungal infections (e.g., histoplasmosis), acquired immunodeficiency syndrome (AIDS), and metastatic cancer. Iatrogenic Addison's disease may be due to adrenal hemorrhage, often related to anticoagulant therapy, chemotherapy, ketoconazole therapy for AIDS, or bilateral adrenalectomy. Adrenal insufficiency most often occurs in adults younger than 60 years of age and affects both genders equally.

Clinical Manifestations

Because manifestations do not tend to become evident until 90% of the adrenal cortex is destroyed, the disease is often advanced before it is diagnosed. The manifestations have a slow (insidious) onset and include anorexia, nausea, progressive weakness, fatigue, and weight loss. Increased ACTH causes the striking feature of a bronze-colored skin hyperpigmentation. It is seen mainly in sun-exposed areas of the body; at pressure points; over joints; and in the creases, especially palmar creases (Fig. 49.13). The changes in the skin are likely due to increased secretion of β-lipotropin (which contains melanocyte-stimulating hormone [MSH]). MSH is increased because of decreased negative feedback and subsequent low corticosteroid levels. Other manifestations include abdominal pain, diarrhea, headache, orthostatic hypotension, salt craving, and joint pain. Irritability and depression may occur in primary adrenal hypofunction.

Patients with secondary adrenocortical hypofunction may have many signs and symptoms similar to those of patients with Addison's disease. However, they usually do not have hyperpigmented skin because ACTH levels are low.

Complications

Patients with adrenocortical insufficiency are at risk for acute adrenal insufficiency *(Addisonian crisis)*. It is a life-threatening emergency caused by insufficient adrenocortical hormones or a sudden sharp decrease in these hormones. Addisonian crisis is triggered by (1) stress

(e.g., from infection, surgery, psychologic distress), (2) the sudden withdrawal of corticosteroid hormone therapy, (3) adrenal surgery, or (4) sudden pituitary gland destruction.

During acute adrenal insufficiency, the patient has severe manifestations of glucocorticoid and mineralocorticoid deficiencies. These include hypotension, tachycardia, dehydration, hyponatremia, hyperkalemia, hypoglycemia, fever, weakness, and confusion. Hypotension may lead to shock. Circulatory collapse associated with adrenal insufficiency is often unresponsive to the usual treatment (vasopressors and fluid replacement). GI manifestations include severe vomiting, diarrhea, and pain in the abdomen. Pain may occur in the lower back and legs.

Diagnostic Studies

The ACTH stimulation test is a common test to diagnose adrenal insufficiency. Baseline cortisol and ACTH levels are measured, and the patient is given an IV injection of synthetic ACTH (cosyntropin). Cortisol and ACTH levels are rechecked after 30 and 60 minutes. The normal response is a rise in blood cortisol levels. People with Addison's disease have little or no increase in cortisol levels. Those with primary adrenal insufficiency have a high ACTH level.[22]

FIG. 49.13 Hyperpigmentation typically seen in Addison's disease. From Chew SL, Leslie D: *Clinical endocrinology and diabetes: An illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.

When the response to the ACTH test is abnormal, a corticotropin-releasing hormone (CRH) stimulation test may be done. The patient is given an IV injection of synthetic CRH, and blood is taken after 30 and 60 minutes. Those with Addison's disease have high ACTH levels but no cortisol. People with secondary adrenal insufficiency from pituitary or hypothalamus problems do not make ACTH or have a delayed response.[23]

Other abnormal laboratory findings may include hyperkalemia, hypochloremia, hyponatremia, hypoglycemia, anemia, and increased BUN levels.[23] An ECG may show low voltage and peaked T waves caused by hyperkalemia. CT scans and MRI can identify other causes, including tumors, fungal infections, tuberculosis, or adrenal calcification.

Interprofessional and Nursing Care

Treatment focuses on managing the underlying cause when possible. The mainstay is often lifelong hormone therapy with glucocorticoids

and mineralocorticoids (Table 49.19). Overall, patients who take their medications consistently can expect a normal life expectancy. Hydrocortisone, the most common form of hormone therapy, has both glucocorticoid and mineralocorticoid properties. Mineralocorticoids are replaced with fludrocortisone. Women need androgen replacement with dehydroepiandrosterone (DHEA) as their only source of androgen production is the adrenal glands.[23] Increased salt is added to the diet.

As a nurse, you have a key role in the long-term management of Addison's disease. The serious nature of the disease and the need for lifelong hormone therapy necessitate a comprehensive teaching plan. Table 49.20 outlines the major areas to include in a teaching plan.

Glucocorticoids are usually given in divided doses, two thirds in the morning and one third in the afternoon. Mineralocorticoids are given once daily, preferably in the morning. This schedule reflects normal circadian rhythm in endogenous hormone secretion and decreases the side effects associated with corticosteroid therapy. Teach patients using mineralocorticoid therapy (fludrocortisone) how to take their BP, increase salt intake, and report any significant changes to the HCP.

TABLE 49.19 Interprofessional CareAddison's Disease

Diagnostic Assessment

- History and physical examination
- ACTH stimulation test
- Serum cortisol and ACTH
- Urine cortisol and aldosterone
- CRH suppression test
- Serum electrolytes
- CT scan, MRI

Management

- Daily glucocorticoid (e.g., prednisone, hydrocortisone) replacement (two thirds on awakening in morning, one third in late afternoon)
- Daily mineralocorticoid (fludrocortisone) in morning
- ↑ Salt in the diet
- Androgen replacement with dehydroepiandrosterone (DHEA) for women
- Salt additives for excess heat or humidity
- ↑ Doses of glucocorticoid for stress situations (e.g., surgery, hospitalization)

The patient with Addison's disease needs an increased dosage of corticosteroids in stressful situations to prevent Addisonian crisis. Examples of situations requiring corticosteroid adjustment are fever, influenza, tooth extraction, and rigorous physical activity, such as playing sports on a hot day or distance running. Provide written and verbal instructions on when to change the dose. Review stress management techniques. If vomiting or diarrhea occurs, as may happen with gastroenteritis, the patient should notify the HCP at once. Electrolyte replacement and parenteral administration of cortisol may be needed.

Teach patients the signs and symptoms of corticosteroid deficiency and excess (Cushing syndrome) and to report these signs to the HCP so that the drug dose can be adjusted. It is critical that the patient wear an identification bracelet (Medic Alert) and carry a wallet card saying the patient has Addison's disease so that appropriate therapy can be started in case of an emergency. The patient should always carry an emergency kit with 100 mg of IM hydrocortisone and syringes. Teach the patient and caregiver how to give an IM injection.

When the patient with Addison's disease is hospitalized, nursing management focuses on monitoring the patient while correcting fluid and electrolyte balance. Assess vital signs and neurologic status.

Monitor for signs of fluid volume deficit and electrolyte imbalance. Obtain a daily weight and keep an accurate intake and output record. Take a complete medication history to determine drugs that can potentially interact with corticosteroids. These drugs include oral hypoglycemics, cardiac glycosides, oral contraceptives, anticoagulants, and NSAIDs.

Note changes in BP, weight gain, weakness, or other manifestations of Cushing syndrome. Guard the patient against exposure to infection and help with daily hygiene. Protect the patient from noise, light, and environmental temperature extremes. The patient cannot cope with these stresses because of the inability to make corticosteroids.

TABLE 49.20 Patient & Caregiver TeachingAddison's Disease

Include the following information in the teaching plan for the patient with Addison's disease and the caregiver:

1. Names, dosages, and actions of drugs
2. Symptoms of overdosage and underdosage
3. Conditions requiring increased dosage (e.g., trauma, infection, surgery, emotional crisis)
4. Course of action to take related to changes in medication
    - Increased dose of corticosteroid
    - Self-administration of large dose of corticosteroid IM
    - Consultation with HCP
5. Preventing infection and need for prompt and vigorous treatment of existing infections
6. Need for lifelong replacement therapy
7. Need for lifelong medical supervision
8. Need to carry medical identification
9. Fall prevention
10. Adverse effects of corticosteroid therapy and prevention techniques

11. Special instruction for patients with diabetes and management of blood glucose when taking corticosteroids

Addisonian crisis is a life-threatening emergency requiring aggressive management. Treatment is directed toward shock management and high-dose hydrocortisone replacement. Large volumes of 0.9% saline solution and 5% dextrose are given to reverse hypotension and electrolyte imbalances until BP returns to normal.

Corticosteroid Therapy

Corticosteroids are effective in treating many diseases and disorders (Table 49.21). However, the long-term administration of corticosteroids at therapeutic doses often leads to serious complications and side effects (Table 49.22). For this reason, corticosteroid therapy is not recommended for minor chronic conditions. Therapy should be reserved for diseases that have a risk for death or permanent loss of function and for conditions in which short-term therapy is likely to produce remission or recovery. The potential benefits of treatment must always be weighed against the risks.

TABLE 49.21 Drug TherapyDiseases/Disorders Treated With Corticosteroids

Hormone Therapy

- Adrenal insufficiency
- Congenital adrenal hyperplasia

Therapeutic Effect

Allergic Reactions

- Anaphylaxis
- Bee stings
- Contact dermatitis
- Drug reactions
- Serum sickness
- Urticaria

Connective Tissue Diseases

- Mixed connective tissue disorders
- Polymyositis
- Polyarteritis nodosa
- Rheumatoid arthritis
- Systemic lupus erythematosus

Endocrine Diseases

- Hypercalcemia
- Hashimoto’s thyroiditis
- Thyrotoxicosis

Gastrointestinal Diseases

- Inflammatory bowel disease
- Celiac disease

Liver Diseases

- Alcoholic hepatitis
- Autoimmune hepatitis

Neurologic Diseases

- Cerebral edema and increased intracranial pressure
- Head trauma

Pulmonary Diseases

- Aspiration pneumonia
- Asthma
- Chronic obstructive pulmonary disease

Other Diseases or Disorders

- Skin diseases
- Cancer, leukemia, lymphoma
- Immunosuppression
- Inflammation
- Nephrotic syndrome

TABLE 49.22 Drug TherapyEffects and Side Effects of Corticosteroids

- Delayed wound healing with ↑ risk for wound dehiscence
- Fat from extremities redistributed to trunk and face
- Glucose intolerance
- Hypertension with ↑ risk for heart failure
- Hypocalcemia related to anti–vitamin D effect
- Hypokalemia
- ↑ Risk for infection

- Infection develops more rapidly and spreads more widely
- Mood and behavior changes
- Pathologic fractures, especially compression fractures of the vertebrae (osteoporosis)
- Peptic ulcer disease
- Pituitary ACTH synthesis suppressed
- Skeletal muscle atrophy and weakness
- Suppressed inflammatory response

Check Your Practice

You are working in the outpatient clinic. Your 39-yr-old female patient has Cushing syndrome from high doses of prednisone use for her severe systemic lupus erythematosus. At her office visit today, she tells you, "I looked in the mirror this morning and did not recognize the fat, ugly woman looking back at me."

- How would you respond to her?

A beneficial effect of corticosteroids in one situation may be a harmful one in another. For example, decreasing inflammation in arthritis is an important therapeutic effect, but increasing the risk for infection is a harmful effect. Suppressing inflammation and the immune response may help save lives in persons with anaphylaxis and in those receiving an organ transplant, but it can reactivate latent tuberculosis and increase the risk for infection and cancer. The vasopressive effect of corticosteroids is critical in allowing a person to function in stressful situations but can cause hypertension when used for drug therapy.

Drug Alert

Corticosteroids

- Teach the patient not to abruptly stop these drugs.
- Monitor the patient for signs of infection.
- Have patients with diabetes closely monitor blood glucose.

Patients receive corticosteroid therapy for many reasons. Detailed instruction is needed to ensure patient adherence. When corticosteroids are used as nonreplacement therapy, they are taken once daily or once every other day. They should be taken early in the morning with food to decrease gastric irritation. Because exogenous corticosteroid use may suppress endogenous ACTH and therefore endogenous cortisol (suppression is time and dose dependent), emphasize the danger of abruptly stopping corticosteroid therapy to patients and caregivers. Corticosteroids taken for longer than 1 week will suppress adrenal production, and oral corticosteroids must be tapered. Ensure that increased doses of corticosteroids are prescribed in acute care or home care settings in situations of physical or emotional stress.

Corticosteroid-induced osteoporosis is an important concern for patients who receive corticosteroid treatment for prolonged periods (longer than 3 months).[24] Therapies to reduce bone resorption include increased calcium intake, vitamin D supplementation, bisphosphonates (e.g., alendronate), and a low-impact exercise program. Further instruction and interventions to minimize the side effects and complications of corticosteroid therapy are outlined in Table 49.23.

Hyperaldosteronism

Hyperaldosteronism (Conn's syndrome) is characterized by excess aldosterone secretion. The main effects of aldosterone are (1) sodium retention and (2) potassium and hydrogen ion excretion. Thus the hallmark of this disease is hypertension with hypokalemic alkalosis.

Primary hyperaldosteronism (PA) is most often caused by a small solitary adrenocortical adenoma. Sometimes, multiple lesions are involved and are associated with bilateral adrenal hyperplasia.

TABLE 49.23 Patient & Caregiver TeachingCorticosteroid Therapy

Include the following instructions when teaching the patient and caregiver to manage corticosteroid therapy:

1. Follow a diet high in protein, calcium (at least 1500 mg/day), and potassium and low in fat and concentrated simple carbohydrates, such as sugar, syrups, and candy.
2. Ensure adequate rest and sleep, such as daily naps and avoiding caffeine late in the day.
3. Take part in an exercise program to help maintain bone integrity.
4. Recognize edema and ways to restrict sodium intake to <2000 mg/day if edema occurs.
5. Monitor glucose levels and recognize symptoms of hyperglycemia (e.g., polydipsia, polyuria, blurred vision). Report hyperglycemic symptoms or capillary glucose levels >120 mg/dL (10 mmol/L).
6. Notify HCP if heartburn after meals or epigastric pain that is not relieved by antacids occurs.
7. See an eye specialist yearly to assess for cataracts.
8. Use safety measures, such as getting up slowly from bed or a chair and good lighting, to avoid accidental injury.
9. Maintain appropriate hygiene practices.
10. Avoid contact with persons with colds or other contagious illnesses to prevent infection.

11. Inform all HCPs about long-term corticosteroid use.
12. Recognize need for ↑ doses of corticosteroids in times of physical and emotional stress.
13. Never abruptly stop the corticosteroids because this could lead to Addisonian crisis and death.

PA affects women more than men and usually occurs between 30 and 50 years of age. A genetic link has been found in some patients.[25] PA causes up to 2% of all cases of hypertension. *Secondary hyperaldosteronism* occurs in response to a nonadrenal cause of increased aldosterone levels, such as renal artery stenosis, renin-secreting tumors, and chronic kidney disease.

Increased aldosterone levels are associated with sodium retention and potassium excretion. Sodium retention leads to hypernatremia, hypertension, and headache. Edema does not usually occur because the rate of sodium excretion increases, preventing more severe sodium retention. Potassium wasting leads to hypokalemia, which causes generalized muscle weakness, fatigue, dysrhythmias, glucose intolerance, and metabolic alkalosis that may lead to tetany.

Hyperaldosteronism should be suspected in hypertensive patients with hypokalemia who are not being treated with diuretics. PA is associated with increased plasma aldosterone levels, increased sodium levels, decreased serum potassium levels, and decreased plasma renin activity. A CT scan or MRI can detect an adenoma.[25] If a tumor is not found, plasma 18-hydroxycorticosterone is measured after overnight bed rest. A level greater than 50 ng/dL indicates an adenoma.

Interprofessional and Nursing Care

The preferred treatment for PA is surgical removal of the adenoma (adrenalectomy). A laparoscopic approach is most often used. Before surgery, patients should be treated with potassium-sparing diuretics (e.g., spironolactone, eplerenone [Inspra]) and antihypertensive agents to normalize serum potassium levels and BP. Spironolactone and

eplerenone block the binding of aldosterone to the mineralocorticoid receptor in the terminal distal tubules and collecting ducts of the kidney, thus increasing sodium and water excretion and potassium retention. Oral potassium supplements and sodium restrictions may be needed. However, potassium supplementation and a potassium-sparing diuretic should not be started simultaneously because of the risk for hyperkalemia. Teach patients taking eplerenone to avoid grapefruit juice as it may increase potential for hyperkalemia.

Patients with bilateral adrenal hyperplasia are treated with a potassium-sparing diuretic. Calcium channel blockers may be used to control BP. Dexamethasone may be used to decrease adrenal hyperplasia.

Nursing care includes careful assessment of fluid and electrolyte balance (especially potassium) and cardiovascular status. Monitor BP frequently before and after surgery because unilateral adrenalectomy is successful in controlling hypertension in only 80% of patients with an adenoma. Tell patients receiving spironolactone about the possible side effects of gynecomastia, impotence, and menstrual disorders, as well as the signs and symptoms of hypokalemia and hyperkalemia. Teach patients how to monitor their own BP and the need for frequent monitoring. Stress the need for continued health supervision.

Disorders of Adrenal Medulla

Pheochromocytoma

Pheochromocytoma is a rare condition caused by a tumor in the adrenal medulla. It affects the chromaffin cells, resulting in an excess production of catecholamines (epinephrine, norepinephrine). The most dangerous immediate effect of the disease is severe hypertension. If left untreated, it may lead to encephalopathy, diabetes, cardiomyopathy, multiple organ failure, and death. It most often occurs in young to middle-aged adults. Pheochromocytoma may be inherited in persons with MEN.[26]

The most striking findings are severe, episodic hypertension

accompanied by severe, pounding headache; tachycardia with palpitations; profuse sweating; and unexplained abdominal or chest pain. Attacks can be induced by direct trauma, mechanical pressure to the tumor, stress (e.g., surgery, exercise, defecation, sexual intercourse, alcohol consumption, smoking), or many drugs, including antihypertensives, opioids, radiologic contrast media, and tricyclic antidepressants. Attacks can last from a few minutes to several hours.

The simplest and most reliable diagnostic test is measurement of urinary fractionated metanephrines (catecholamine metabolites) and fractionated catecholamines and creatinine, usually done as a 24-hour urine collection. Values are increased in at least 95% of persons with pheochromocytoma. Serum catecholamines may be increased during an "attack." CT scans and MRI can detect tumors. Do not palpate the abdomen of a patient with suspected pheochromocytoma. It may cause the sudden release of catecholamines and severe hypertension.

Interprofessional and Nursing Care

The main treatment is surgical removal of the tumor. Treatment with α- and β-adrenergic receptor blockers is required before surgery to control BP and prevent an intraoperative hypertensive crisis. Therapy begins with an α-adrenergic receptor blocker (e.g., doxazosin, prazosin, phenoxybenzamine) 10 to 14 days before surgery to reduce BP.[26] After adequate α-adrenergic blockade, β-adrenergic receptor blockers (e.g., propranolol) are used to decrease tachycardia and dysrhythmias. If β-blockers are started too early, unopposed α-adrenergic stimulation can precipitate a hypertensive crisis. Therapy can cause orthostatic hypotension. Teach the patient to make postural changes cautiously.

Surgery is usually done using a laparoscopic approach. Removing the adrenal tumor often cures the hypertension, but hypertension persists in about 10% to 30% of patients. If surgery is not an option, metyrosine (Demser) can decrease catecholamine production by the tumor.

Case finding is an important nursing role. Although

pheochromocytoma is associated with several symptoms, the diagnosis is often missed. Any patient with hypertension accompanied by symptoms of sympathoadrenal stimulation should be referred to an HCP for definitive diagnosis. Assess the patient for the classic triad of symptoms of pheochromocytoma: severe pounding headache, tachycardia, and profuse sweating. Monitor the BP often if the patient is having an "attack."

Make the patient as comfortable as possible. Monitor blood glucose levels to assess for diabetes. Patients need rest, nourishing food, and emotional support during this period. Surgical care is similar to that for any patient undergoing adrenalectomy. Note that BP fluctuations from catecholamine excesses tend to be severe and must be carefully monitored. Emphasize the importance of follow-up and routine BP monitoring because hypertension may persist even when the tumor is removed.

Case Study

Graves' Disease

© Hemera Technologies/AbleStock.com/Thinkstock.

Patient Profile

R.D., a 52-yr-old white woman, was admitted to the hospital with a high fever. Unable to find a source of infection, the HCP does an endocrine workup. R.D. is diagnosed with Graves' disease.

Subjective Data

- Reports recent job loss because she is no longer able to tolerate work-related stress
- Reports symptoms including fatigue, unintentional weight loss, insomnia, palpitations, vision problems, and heat intolerance

Objective Data
Physical Examination

- Fever of 104° F (40° C)
- BP of 150/80 mm Hg, pulse of 116 beats/min, and respiratory rate of 26 breaths/min
- Hot, moist skin
- Fine tremors of the hands
- 4+ deep tendon reflexes and muscle strength of 1 to 2 out of 5

Interprofessional Care

- Subtotal thyroidectomy planned for 2 months later
- Started on methimazole (Tapazole) and propranolol (Inderal LA)

Discussion Questions

1. Explain the cause of R.D.'s symptoms.
2. What diagnostic studies were probably ordered? What would the results have been to establish the diagnosis of Graves' disease?
3. Why was surgery delayed?
4. ***Collaboration:*** What is the interprofessional team's top priority at this time for R.D.?
5. ***Quality Care:*** What is the expected outcome associated with drug therapy?
6. ***Priority Decision:*** What are her priority teaching needs at this time?
7. ***Patient-Centered Care:*** What teaching will you provide after surgery so that R.D. can successfully self-manage her care?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses pertinent to this patient

while hospitalized? Are there any collaborative problems?

9. ***Evidence-Based Practice:*** Why is R.D. counseled to give up her long-standing cigarette smoking habit?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. After a hypophysectomy for acromegaly, immediate postoperative nursing care should focus on
   a. frequent monitoring of serum and urine osmolarity.
   b. parenteral administration of a GH-receptor antagonist.
   c. keeping the patient in a recumbent position at all times.
   d. patient teaching about the need for lifelong hormone therapy.
2. A patient with a head injury develops SIADH. Manifestations the nurse would expect to find include
   a. hypernatremia and edema.
   b. muscle spasticity and hypertension.
   c. low urine output and hyponatremia.
   d. weight gain and decreased glomerular filtration rate.
3. The health care provider prescribes levothyroxine for a patient with hypothyroidism. After teaching about this drug, the nurse determines that further instruction is needed when the patient says
   a. “I can expect the medication dose may need to be

adjusted."

b. "I only need to take this drug until my symptoms are improved."

c. "I can expect to return to normal function with the use of this drug."

d. "I will report any chest pain or difficulty breathing to the doctor right away."

4. After thyroid surgery, the nurse suspects damage or removal of the parathyroid glands when the patient develops

a. muscle weakness and weight loss.

b. hyperthermia and severe tachycardia.

c. hypertension and difficulty swallowing.

d. laryngospasms and tingling in the hands and feet.

5. Important nursing intervention(s) when caring for a patient with Cushing syndrome include *(select all that apply)*

a. restricting protein intake.

b. monitoring blood glucose levels.

c. observing for signs of hypotension.

d. administering medication in equal doses.

e. protecting patient from exposure to infection.

6. An important preoperative nursing intervention before an adrenalectomy for hyperaldosteronism is to

a. monitor blood glucose levels.

b. restrict fluid and sodium intake.

c. administer potassium-sparing diuretics.

d. advise the patient to make postural changes slowly.

7. To control the side effects of corticosteroid therapy, the nurse teaches the patient who is taking corticosteroids to
   a. increase calcium intake to 1500 mg/day.
   b. perform glucose monitoring for hypoglycemia.
   c. obtain immunizations due to high risk for infections.
   d. avoid abrupt position changes because of orthostatic hypotension.

1. a, 2. c, 3. b, 4. d, 5. b, e, 6. c, 7. a

Assessment

Reproductive System

Kim K. Choma

LEARNING OUTCOMES

1. Describe the structures and functions of the male and female reproductive systems.
2. Outline the functions of the major hormones essential for the functioning of the male and female reproductive systems.
3. Explain the physiologic changes during the stages of sexual response for both a man and a woman.
4. Link the age-related changes of the male and female reproductive systems to the differences in assessment findings.
5. Obtain significant subjective and objective data related to the male and female reproductive systems and information about sexual function from a patient.
6. Perform a physical assessment of the male and female reproductive systems using the appropriate techniques.
7. Distinguish normal from common abnormal findings of a physical assessment of the male and female reproductive systems.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the male and

female reproductive systems.

Conceptual Focus

Hormonal Regulation
Reproduction

Structures and Functions of Male and Female Reproductive Systems

The reproductive systems of males and females consist of primary (or essential) organs and secondary (or accessory) organs. The primary reproductive organs are referred to as **gonads**. The female gonads are the ovaries. The male gonads are the testes. The main purpose of the gonads is secretion of hormones and production of gametes (ova and sperm, sex cells that unite during fertilization to form a new cell called a *zygote*). Secondary (or accessory) organs begin their maturity at puberty under the influence of sex hormones. They are responsible for (1) transporting and nourishing the ova (eggs) and sperm and (2) preserving and protecting the fertilized ova.

Male Reproductive System

The 3 main roles of the male reproductive system are (1) sperm production and transportation, (2) deposition of sperm in the female reproductive tract, and (3) hormone secretion. The primary male reproductive organs are the testes. Secondary reproductive organs include ducts (epididymis, ductus deferens, ejaculatory duct, urethra), sex glands (prostate gland, Cowper's glands, seminal vesicles), and the external genitalia (scrotum, penis) (Fig. 50.1).

Testes

The paired testes are ovoid, smooth, firm organs. They measure 1.4 to 2.2 in (3.5 to 5.6 cm) long and 0.8 to 1.2 in (2 to 3 cm) wide. They lie within the scrotum. It is a loose protective sac composed of a thin outer layer of skin over a tough connective tissue layer. Within the testes, coiled structures called the seminiferous tubules form *spermatozoa* (immature sperm). The process of sperm production is called **spermatogenesis**. Interstitial cells lie between the seminiferous

tubules. These cells make the male sex hormone testosterone.

Ducts

Sperm formed in the seminiferous tubules move through a series of ducts. These ducts transport sperm from the testes to the outside of the body. As sperm exit the testes, they enter and pass through the epididymis, ductus deferens, ejaculatory duct, and urethra.

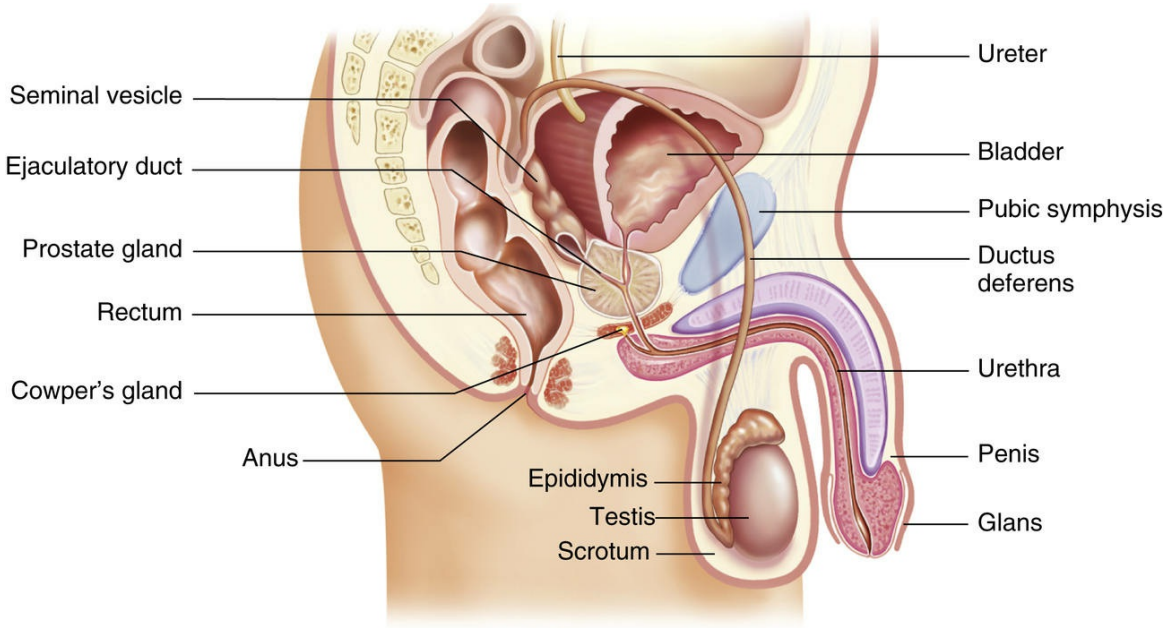

FIG 50.1 Male reproductive tract.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St Louis, 2013, Mosby.

The **epididymis** is a comma-shaped structure found on the posterosuperior aspect of each testis within the scrotum (Figs. 50.1 and 50.2). It is a long, tightly coiled structure that measures, uncoiled, about 20 ft in length.[1] The epididymis transports sperm as they mature. Sperm exit the epididymis through a long, thick tube called the **ductus deferens**.

The ductus deferens (also called the *vas deferens*) is continuous with the epididymis within the scrotal sac. It travels upward through the scrotum and continues through the inguinal ring into the abdominal

cavity. The spermatic cord is composed of a connective tissue sheath that encloses the ductus deferens, arteries, veins, nerves, and lymph vessels as it ascends through the inguinal canal (Fig. 50.2). In the abdominal cavity, the ductus deferens travels up, over, and behind the bladder. Behind the bladder the ductus deferens joins the seminal vesicle to form the ejaculatory duct (Fig. 50.1).

The ejaculatory duct passes downward through the prostate gland, connecting with the urethra. The urethra extends from the bladder, through the prostate, and ends in a slit-like opening (the meatus) on the ventral side of the *glans,* the tip of the penis. During the process of ejaculation, sperm travel through the urethra and out of the penis.

Glands

The seminal vesicles, prostate gland, and Cowper's (bulbourethral) glands are the accessory glands. These glands make and secrete seminal fluid *(semen),* which surrounds the sperm and forms the *ejaculate.* The ejaculate fluid serves as a medium for the transport of sperm and creates an alkaline, nutritious environment that promotes sperm motility and survival.

The seminal vesicles lie behind the bladder, between the bladder and rectum. The ducts of the seminal vesicles fuse with the ductus deferens to form the ejaculatory ducts that enter the prostate gland. The prostate gland lies beneath the bladder. Its posterior surface is in contact with the rectal wall. The prostate normally measures 0.8 in (2 cm) wide and 1.2 in (3 cm) long. It is divided into right and left lateral lobes and an anteroposterior median lobe. Cowper's glands lie on each side of the urethra and slightly posterior to it, just below the prostate. The ducts of these glands enter directly into the urethra.

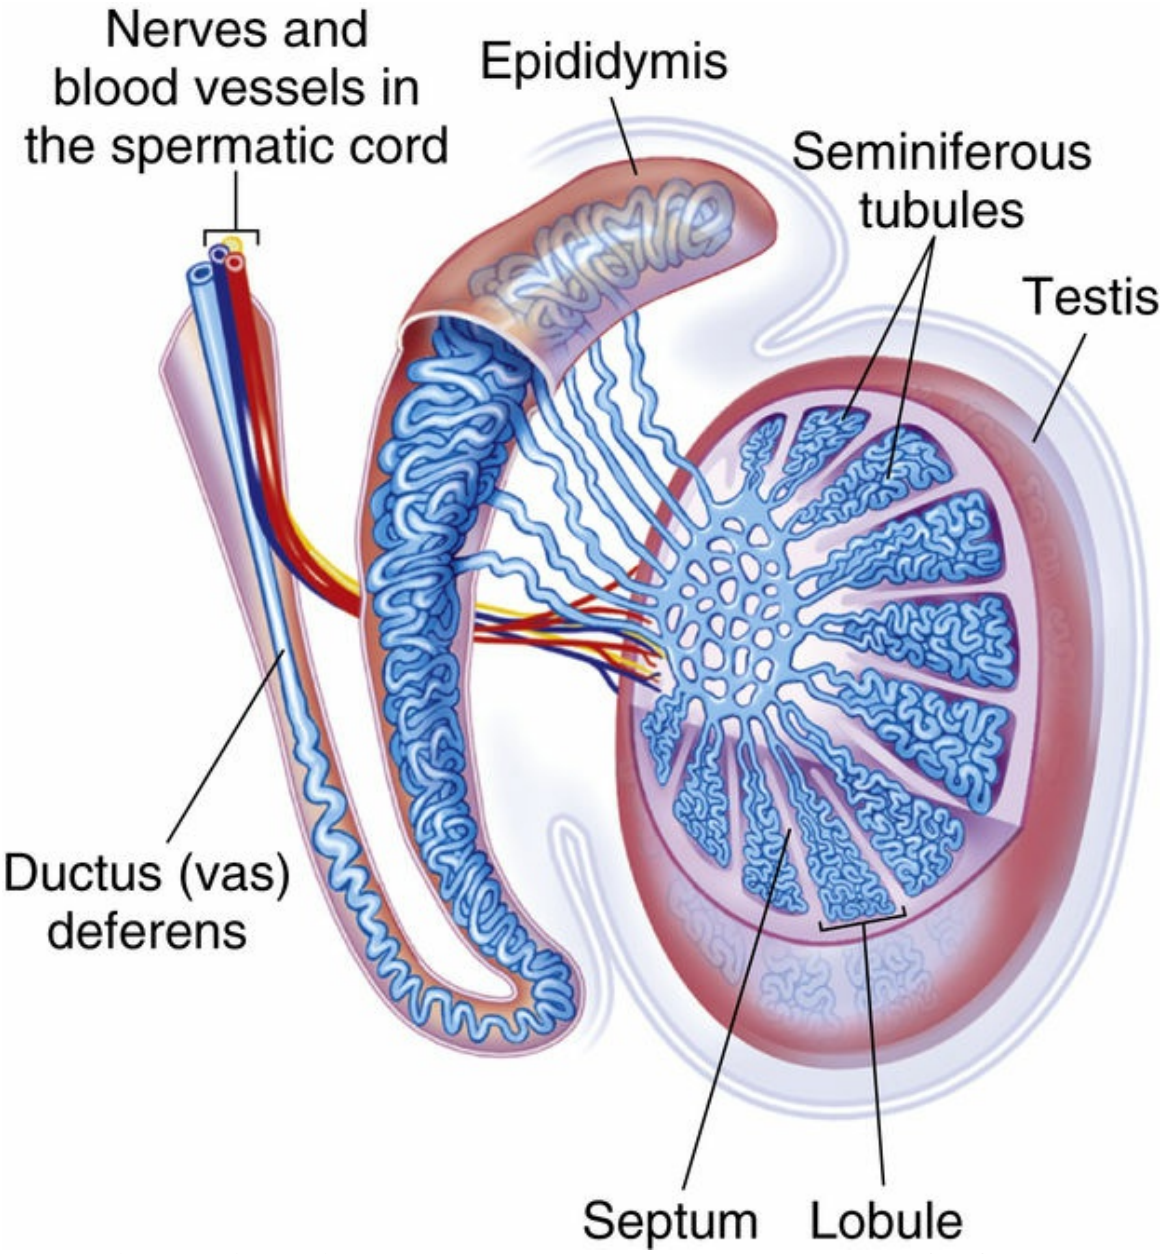

FIG 50.2 Seminiferous tubules, testis, epididymis, and ductus (vas) deferens in the male.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

External Genitalia

The male external genitalia consist of the penis and scrotum. The penis consists of a shaft and tip, which is called the *glans*. The glans is covered by a fold of skin, the prepuce (or foreskin), that forms at the

junction of the glans and shaft of the penis. In circumcised males the prepuce has been removed. The shaft consists of erectile tissue composed of the corpus cavernosum, corpus spongiosum (fibrous sheath that encases the erectile tissue), and urethra. The skin covering the penis is thin, loose, and hairless.

Female Reproductive System

The 3 main roles of the female reproductive system are (1) ova production, (2) hormone secretion, and (3) protect and facilitate the development of the fetus in a pregnant female. Like the male, the female has primary and secondary reproductive organs. The primary reproductive organs in the female are the paired ovaries. Secondary reproductive organs include the ducts (fallopian tubes), uterus, vagina, sex glands (Bartholin's glands, breasts), and external genitalia (vulva).

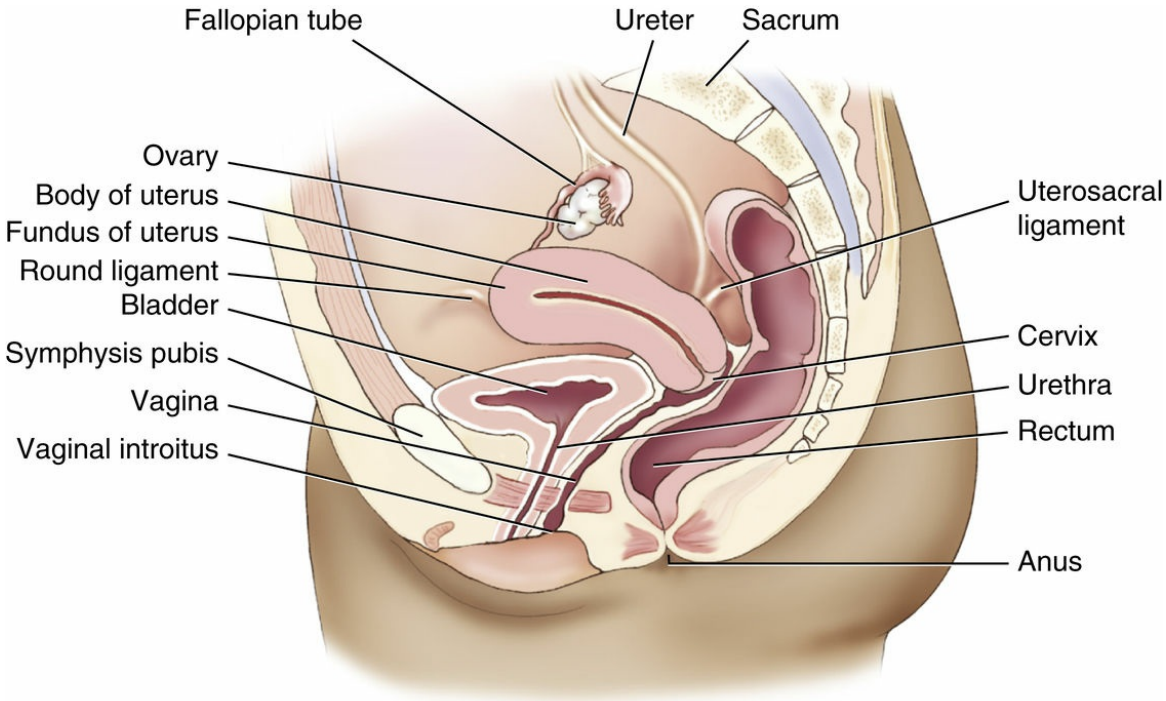

FIG 50.3 Female reproductive tract.
Modified from McKenry L, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* St Louis, 2006, Mosby.

Pelvic Organs

Ovaries

The ovaries are found on either side of the uterus, just behind and below the fallopian tubes (Fig. 50.3). The almond-shaped ovaries are firm and solid, around 0.6 in (1.5 cm) wide and 1.2 in (3 cm) long. Their functions include ovulation and secretion of the 2 major reproductive hormones: estrogen and progesterone.

The outer zone of the ovary has follicles with germ cells, or *oocytes.* Each follicle contains a primordial (immature) oocyte surrounded by granulosa and theca cells. These 2 layers protect and nourish the oocyte until the follicle reaches maturity and ovulation occurs. However, not all follicles reach maturity. In a process termed *atresia,* most of the immature follicles become smaller and are reabsorbed by the body. Thus the number of follicles declines from 1 million at birth to about 400,000 at *menarche* (first menstruation). This is the female's lifetime supply of sex cells. In contrast, males make spermatocytes throughout their reproductive life cycle. As a woman ages, both the number and quality of the oocytes decline. Fewer than 500 oocytes are actually released by ovulation during the reproductive years of the normal healthy woman.[2]

Fallopian Tubes

The fallopian tubes transport the ovum toward the uterus, facilitating fertilization or implantation. The tubes are uterine appendages that end by curling around the ovary. The distal ends of the fallopian tubes consist of fingerlike projections called *fimbriae*. They sweep the ovum from the ruptured ovarian follicle (ovulation) into the fallopian tube. The tubes, which average 4.8 in (12 cm) in length, extend from the fimbriae to the superior lateral borders of the uterus.

Normally, each month during a woman's reproductive years, 1 ovarian follicle reaches maturity. That ovum is ovulated, or expelled, from the ovary through the stimulus of the gonadotropic hormones:

follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The ovum then travels through a fallopian tube, where fertilization by sperm may occur (if sperm are present). Fertilization usually takes place within the outer one third of the fallopian tubes. An ovum can be fertilized up to 72 hours after its release.

Uterus

The **uterus** is a pear-shaped, hollow, muscular organ found between the bladder and rectum (Fig. 50.3). In the mature *nulliparous* (never pregnant) woman, the uterus is about 2.4 to 3.2 in (6 to 8 cm) long and 1.6 in (4 cm) wide. The uterine walls consist of an outer serosal layer, the *perimetrium;* a middle muscular layer, the *myometrium;* and an inner mucosal layer, the *endometrium*.

The uterus consists of the fundus, body (or corpus), and cervix (Fig. 50.3). The body makes up about 80% of the uterus. It connects with the cervix at the isthmus, or neck. The cervix is the lower part of the uterus. It projects into the anterior wall of the vaginal canal. It makes up about 15% to 20% of the uterus in the nulliparous female. The cervix consists of the *ectocervix,* the outer part that protrudes into the vagina, and the *endocervix,* the canal in the opening of the cervix. The opening of the cervix is the *cervical os* (Fig. 50.4).

The ectocervix is covered with squamous epithelial cells. This gives it a smooth, pinkish appearance. The endocervix is lined with columnar epithelial cells, which give it a rough, reddened appearance. The junction at which the 2 types of epithelial cells (squamous and columnar) meet is the *squamocolumnar junction* (Fig. 50.4). Cells sampled from the squamocolumnar junction are examined as part of a Papanicolaou (Pap) test, which is a critical part of cervical cancer screening.

The cervical canal is 0.8 to 1.6 in (2 to 4 cm) long. It is relatively tightly closed. However, menses can be expelled and sperm can enter the uterus through the cervical os. The entrance of sperm into the uterus is facilitated by mucus made by the cervix under the influence of estrogen. Under normal conditions, the cervical mucus becomes watery, stretchy, and more abundant at ovulation. The postovulatory

cervical mucus, under the influence of progesterone, is thick and inhibits sperm passage. The cervix can stretch to allow passage of a fetus during the birth process. The columnar epithelium, under hormonal influence, provides elasticity during labor.

Vagina

The vagina is a tubular structure 3 to 4 in (7.6 to 10 cm) long. The anterior vaginal wall lies along the urethra and bladder. The posterior vaginal wall is next to the rectum. It is lined with squamous epithelium. In reproductive-age women, the vagina has multiple transverse folds called *rugae.* Vaginal secretions consist of cervical mucus, desquamated epithelium, and, during sexual stimulation, a watery secretion. These fluids help protect against vaginal infection. The muscular and erectile tissue of the vaginal walls allows enough dilation and contraction to accommodate the passage of the fetus during labor and penetration of the penis during intercourse.

Pelvis

The female pelvis consists of 4 bones (2 pelvic bones, sacrum, coccyx) held together by several strong ligaments. The pelvis in females has a larger diameter and is circular. A male pelvis is more heart shaped. The wider female pelvis plays a key role in childbirth. The fetal head adapts its position to the pelvic dimensions during labor and delivery through rotation and flexion to pass through the pelvic inlet.[1]

External Genitalia

The external part of the female reproductive system (Fig. 50.5) is often called the **vulva**. It consists of the mons pubis, labia majora, labia minora, vestibule, clitoris, urethral meatus, Skene's glands, vaginal introitus (opening), and Bartholin's glands.

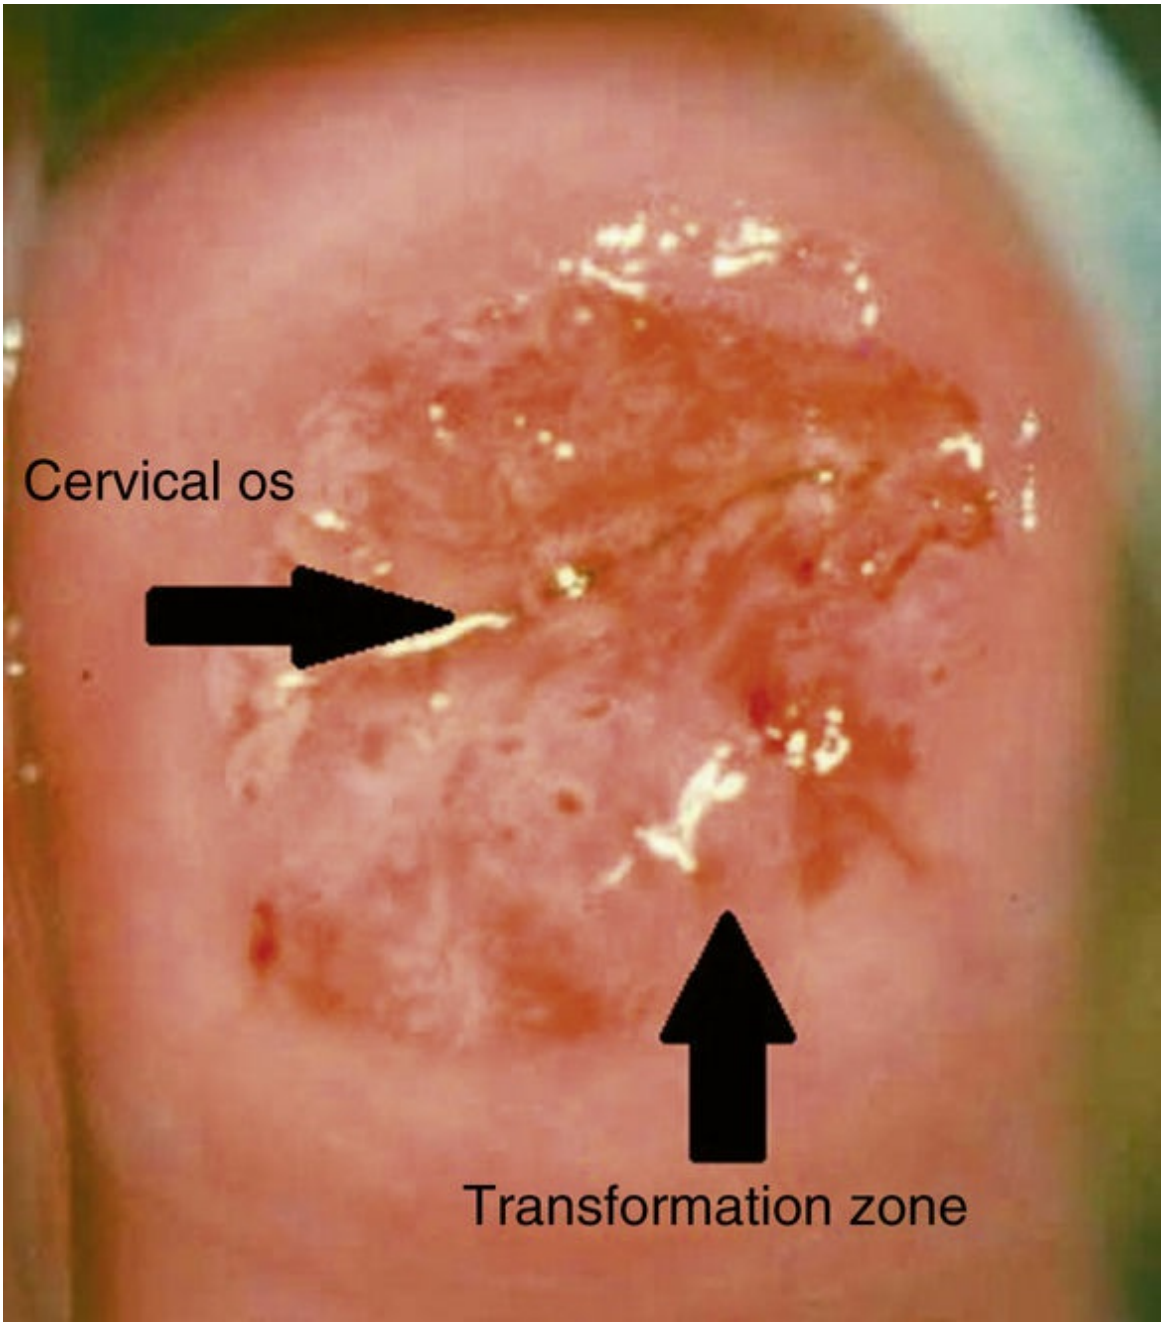

FIG 50.4 Cervical os and squamocolumnar junction (transformation zone).
Courtesy Candy Tedschi, NP, Great Neck, NY.

The *mons pubis* is a fatty layer lying over the pubic bone. It is covered with coarse hair that lies in a triangular pattern. The labia majora are folds of adipose tissue that form the outer borders of the vulva. The hairless labia minora form the borders of the vaginal orifice and extend anteriorly to enclose the clitoris.

The *vestibule* is the space between the labia minora that is seen when they are held apart. It extends from the clitoris to the *posterior fourchette* (a mucous membrane band that forms the posterior ends of the labia minora). The perineum is the area between the vagina and anus. The vaginal introitus (vaginal opening) is surrounded by thin membranous tissue called the *hymen*. It is usually perforated and has many variations in shape. In the adult woman the hymen usually appears as folds or hymenal tags *(carunculae myrtiformes)*. It separates the external genitalia from the vagina.

The *clitoris* is erectile tissue that becomes engorged during sexual excitation. It lies anterior to the urethral meatus and the vaginal orifice and is usually covered by the prepuce. Clitoral stimulation is an important part of sexual activity for many women.

Ducts of the Skene's glands lie alongside the urinary meatus and correspond to the prostate gland in males. We think they help lubricate the urinary meatus. The Bartholin's glands are found at the posterior and lateral aspects of the vaginal orifice. They secrete a thin, mucoid material we think contributes slightly to lubrication during sexual intercourse. These glands are not usually palpable unless sebaceous-like cysts form or they are swollen from an infection, such as a sexually transmitted infection (STI). Bartholin's glands correspond to Cowper's glands in males.

Breasts

The breasts are a secondary sex characteristic that develops during puberty in response to estrogen and progesterone. Cyclic hormonal changes lead to regular changes in breast tissue to prepare it for lactation when fertilization and pregnancy occur.

The breasts extend from the second to the sixth ribs. The extension of breast tissue into the upper-outer quadrant into the axilla is an area referred to as the *tail of Spence* (Fig. 50.6). The fully mature breast is dome shaped and has a pigmented center called the *areola.* The areolar region contains Montgomery's tubercles, which are similar to sebaceous glands. They help lubricate the nipple. During lactation, the alveoli secrete milk. The milk then flows into a ductal system and is

transported to the lactiferous sinuses. The nipple has 15 to 20 tiny openings through which the milk flows during breastfeeding. The fibrous and fatty tissue that supports and separates the channels of the mammary duct system is primarily responsible for the varying sizes and shapes of the breasts.

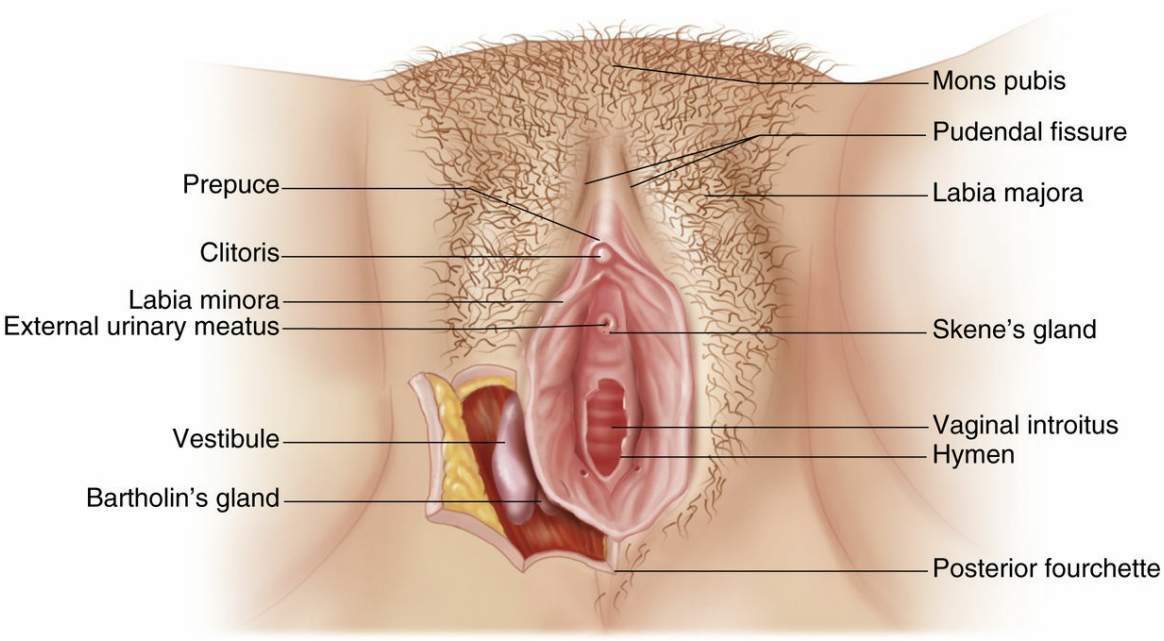

FIG 50.5 External female genitalia.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

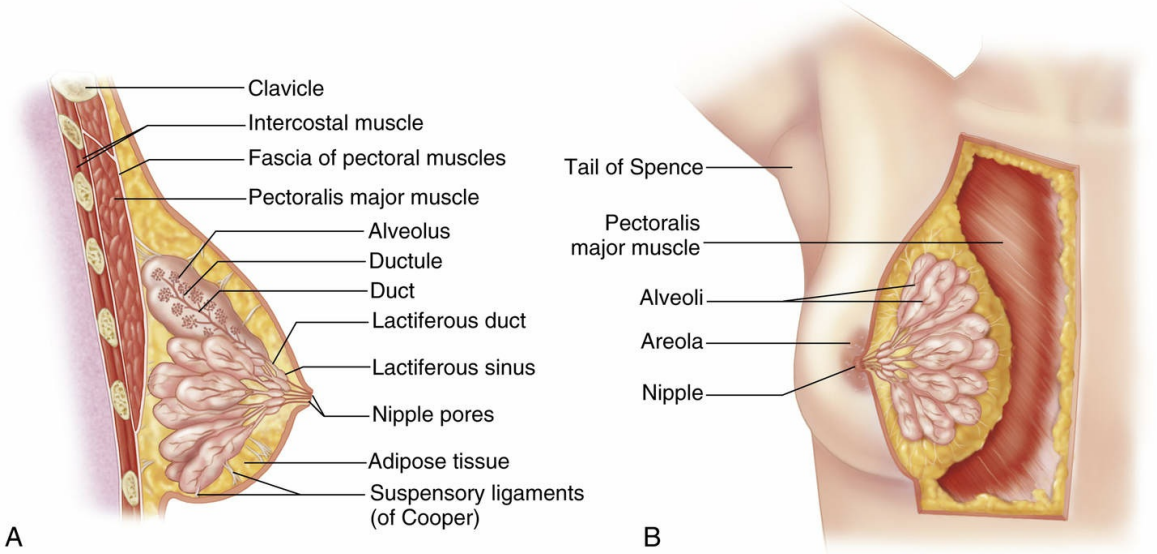

FIG 50.6 The lactating female breast. **A,** Glandular structures are anchored to the overlying skin and the pectoralis muscle by suspensory ligaments of Cooper. Each lobule of glandular tissue is drained by a lactiferous duct that eventually opens through the nipple. **B,** Anterior view of a lactating breast. In nonlactating breasts, glandular tissue is less evident, with adipose tissue making up most of the breast. Modified from Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St Louis, 2013, Mosby.

Neuroendocrine Regulation of Reproductive System

The hypothalamus, pituitary gland, and gonads secrete several hormones (Fig. 50.7). (Endocrine hormones are discussed in Chapter 47.) These hormones regulate the processes of ovulation, sperm formation, and fertilization and the formation and function of the secondary sex characteristics. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary gland to secrete its hormones, including FSH and LH. LH in males is sometimes called *interstitial cell–stimulating hormone (ICSH).* The gonadal hormones are estrogen, progesterone, and testosterone.

In women, FSH production stimulates the growth and maturity of the ovarian follicles necessary for ovulation. The mature follicle makes estrogen, which in turn suppresses the release of FSH. Another

hormone, inhibin, is also secreted by the ovarian follicle. It inhibits both GnRH and FSH secretion. In men, FSH stimulates the seminiferous tubules to make sperm.

LH contributes to the ovulatory process. It causes follicles to complete maturation and undergo ovulation. It affects the development of a ruptured follicle (area where ovum exited during ovulation), which turns into a corpus luteum, which secretes progesterone. **Progesterone** plays a major role in the menstrual cycle, specifically in the secretory phase. It maintains the rich vascular state of the uterus (secretory phase) in preparation for fertilization and implantation. Adequate progesterone is necessary to maintain an implanted ovum. Like estrogen, progesterone is involved in the bodily changes associated with pregnancy. In men, LH triggers testosterone production by the interstitial cells of the testes and thus is essential for the full maturation of sperm.

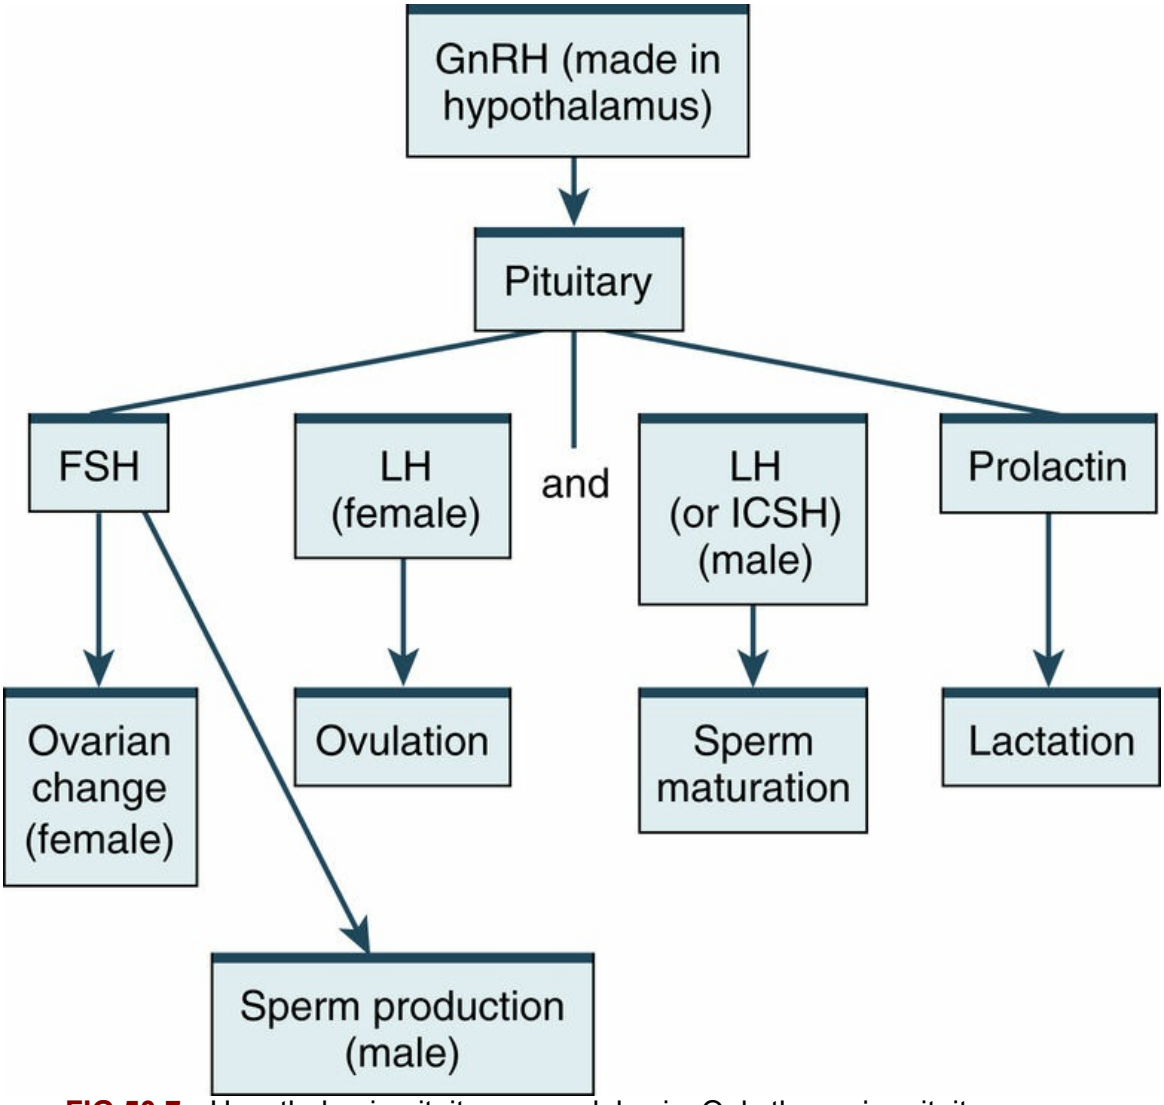

FIG 50.7 Hypothalamic-pituitary-gonadal axis. Only the major pituitary hormone actions are depicted. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

In women, prolactin stimulates the development and growth of the mammary glands. During lactation, it initiates and maintains milk production. In men, prolactin has no known function.

In women the gonadal hormones, estrogen and progesterone, are made by the ovaries. Small amounts of an estrogen precursor are also made in the adrenal cortices. **Estrogen** is essential to the development and maintenance of the secondary sex characteristics, proliferative phase of the menstrual cycle immediately after menstruation, and uterine changes essential to pregnancy. In men, most estrogen is made

in the adrenal cortices. We do not understand the role and importance of estrogen in men.

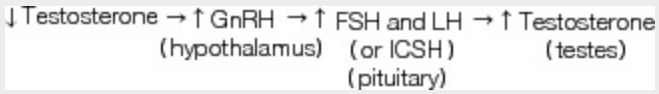

TABLE 50.1 Gonadal Feedback Mechanisms

Negative Feedback

Female

Male

Positive Feedback

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

In men, the major gonadal hormone is testosterone, which is made by the testes. **Testosterone** is responsible for the development and maintenance of secondary sex characteristics and adequate spermatogenesis. In women, the adrenal glands and ovaries make small amounts of androgens.

The circulating levels of gonadal hormones are controlled primarily by a *negative feedback process*. Receptors within the hypothalamus and pituitary are sensitive to the circulating blood levels of the hormones (Table 50.1). Increased hormone levels stimulate a hypothalamic response to decrease the high circulating levels. Likewise, low circulating levels provoke a hypothalamic response that increases the low circulating levels. For example, low circulating testosterone levels stimulate the hypothalamus to secrete GnRH. This triggers the anterior pituitary to secrete greater amounts of FSH and LH, which in turn cause an increase in the testosterone production. The high level of testosterone signals a decrease in GnRH production, and thus FSH and LH.

In women, however, there is a slight variation in the control of gonadal hormones. The circulating levels are controlled through a combination of both a negative and positive feedback system. A *negative feedback control* mechanism exists similar to that described for men. Low circulating estrogen levels stimulate the hypothalamus to increase its production of GnRH. GnRH stimulates the pituitary to secrete greater amounts of FSH and LH, resulting in increased estrogen production by the ovaries. Higher levels of circulating estrogen result in a decreasing secretion of GnRH and thus a decrease in the secretion of FSH by the pituitary.

Women also have a *positive feedback control* mechanism. Here, with increased levels of circulating estrogen, more GnRH is made, resulting in an increased level of LH from the pituitary. Likewise, low estrogen

levels result in a lower level of LH.

Menarche

Menarche is the first episode of menstrual bleeding, indicating that a girl has reached puberty. Menarche usually occurs at around 12 to 13 years of age but can occur as early as 10 years of age in some girls. Menstrual cycles are often irregular for the first 1 to 2 years after menarche because of *anovulatory cycles* (cycles without ovulation).

Menstrual Cycle

The major functions of the ovaries are ovulation and the secretion of hormones. These functions are accomplished during the normal **menstrual cycle**, a monthly process mediated by the hormonal activity of the hypothalamus, pituitary gland, and ovaries. Menstruation occurs during each month in which an ovum is not fertilized (Fig. 50.8). The length of the menstrual cycle ranges from 21 to 35 days, with an average of 28 days. Most women have regular cycles. Irregular cycles may occur and can be due to a variety of factors, including hormonal fluctuations, medications, or conditions, such as uterine fibroids. Table 50.2 describes characteristics of the menstrual cycle and related teaching.

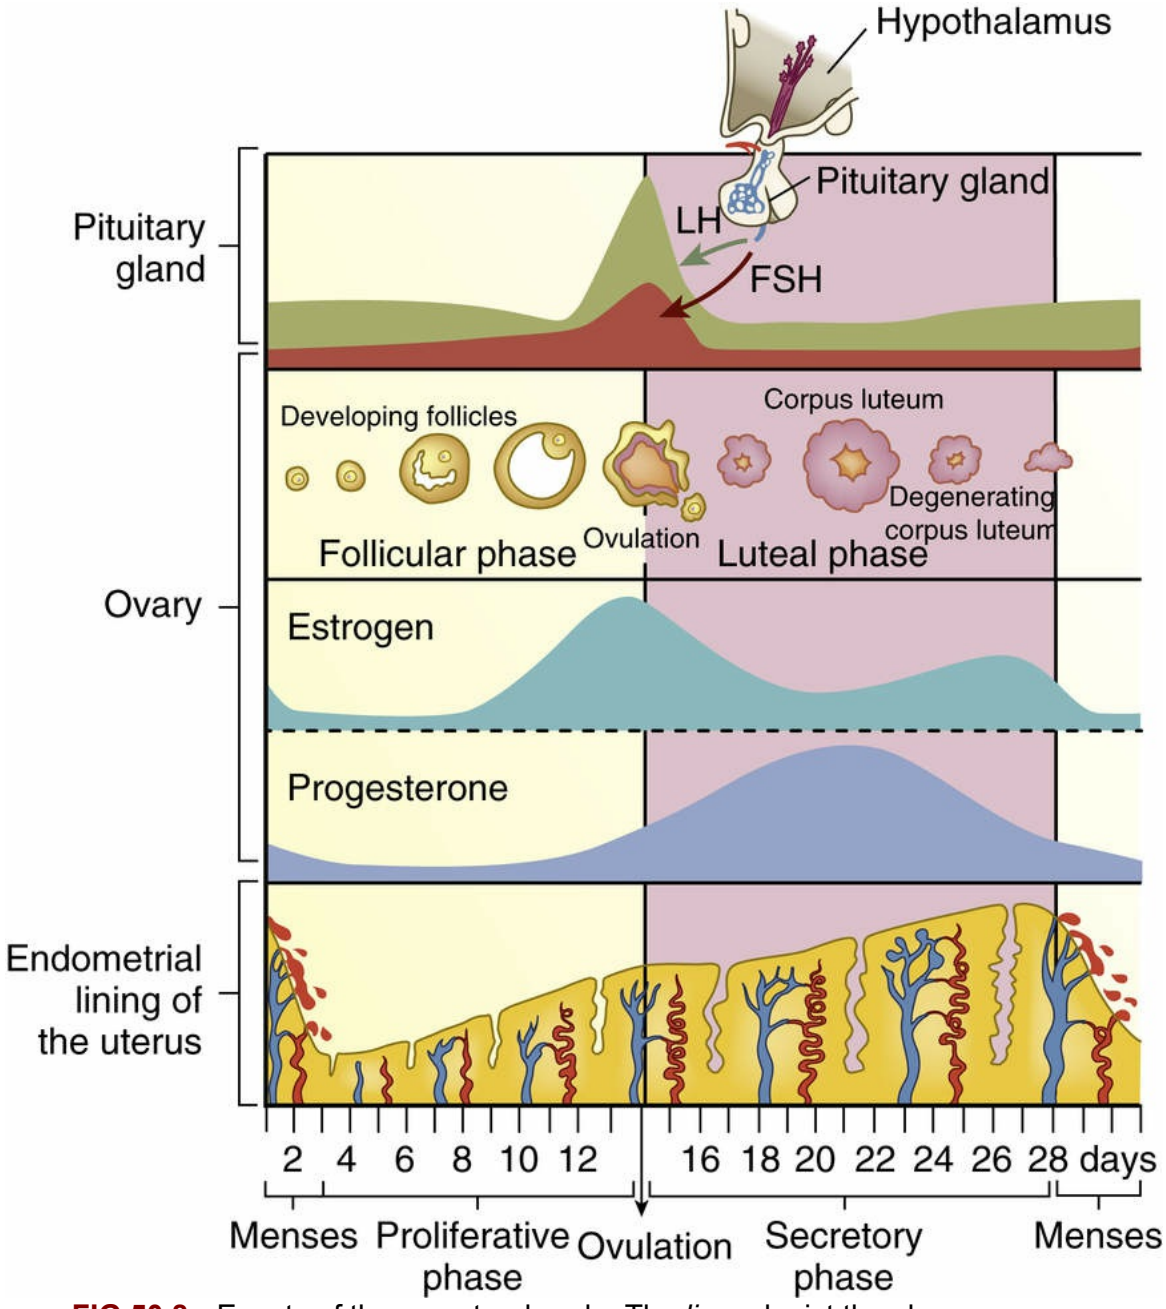

FIG 50.8 Events of the menstrual cycle. The *lines* depict the changes in blood hormone levels, the development of the follicles, and the changes in the endometrium during the cycle.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

The menstrual cycle is divided into 3 phases. They are labeled in relation to uterine and ovarian changes: (1) the *proliferative,* or *follicular, phase;* (2) the *secretory,* or *luteal, phase;* and (3) the *menstrual,* or *ischemic, phase*. The menstrual cycle begins on the first day of

menstruation, which usually lasts 4 to 6 days. The first day of the menstrual cycle is charted as the last menstrual period (LMP). During menstruation, estrogen and progesterone levels are low, but FSH levels begin to increase. During the follicular phase, a single follicle matures fully under FSH stimulation. The mechanism that ensures that usually only 1 follicle reaches maturity is not known. The mature follicle stimulates estrogen production, causing a negative feedback with resulting decreased FSH secretion.

Although the first stage of follicular maturation is stimulated by FSH, complete maturation and ovulation occur only in the presence of LH. When estrogen levels peak on about the 12th day of the cycle, there is a surge of LH, which triggers ovulation 1 or 2 days later. After ovulation, LH promotes the development of the corpus luteum, a temporary functional cyst that forms with the ruptured follicle.

The fully developed corpus luteum continues to secrete estrogen and initiates progesterone secretion. If fertilization occurs, estrogen and progesterone continue to be secreted because of the continued activity of the corpus luteum from stimulation by human chorionic gonadotropin (hCG). If fertilization does not take place, menstruation occurs because of a decrease in estrogen production and progesterone withdrawal.

TABLE 50.2 Patient TeachingCharacteristics of Menstruation

Include the following information when teaching the patient about menstruation:

Characteristic	Teaching
Menarche	
• **Occurs between ages 10 and 16 yr** • **Average age at onset is 12–13 yr**	• See HCP about possible endocrine or developmental abnormality when delayed.
Interval	
• **Usually is 21–35 days** • **Regular cycles as short as 17 days or as long as 45 days are considered normal if pattern is consistent for the person**	• Keep track of periods via an app or calendar to identify menstrual cycle pattern • Expect some irregularity in perimenopausal period • Be aware that drugs (e.g., opioids, contraceptives) and stressful life events can result in missed periods
Duration	
• **Menstrual flow generally lasts 2–8 days**	• Realize that pattern is fairly constant but that wide variations do exist
Amount	
• **Menstrual flow varies from 20–80 mL per menses. Average is 30 mL** • **Amount varies among women and in same woman at different times** • **It is usually heaviest first 2 days**	• Count pads or tampons used per day • The average tampon or pad (when completely saturated) absorbs 20–30 mL • Very heavy flow is indicated by complete soaking of 2 pads in 1–2 hr • Flow increases and then gradually decreases in perimenopausal period • IUD or drugs, such as anticoagulants and thiazides, can cause heavy menses • Women with uterine fibroids may have increased or heavy menses
Composition	
• **Menstrual discharge is mixture of endometrium, blood, mucus, and vaginal cells** • **Dark red, less viscous than blood, and usually does not clot**	• Clots indicate heavy flow or vaginal pooling

During the *follicular phase,* the endometrial lining of the uterus undergoes change. As more estrogen is made, the endometrial lining goes through proliferative changes, including an increase in the length of blood vessels and glandular tissue.

With ovulation and the resulting increased levels of progesterone, the *luteal* (or *secretory*) *phase* begins. If the corpus luteum regresses (when fertilization does not occur) and estrogen and progesterone levels fall, the endometrial lining can no longer be supported. As a result, the blood vessels contract, and tissue begins to slough (fall away). This sloughing results in the menses and the start of the menstrual phase.

Menopause

Menopause is the physiologic cessation of menses associated with declining ovarian function. It is usually considered complete after 1 year of **amenorrhea** (absence of menstruation). Menopause is discussed in Chapter 53.

Phases of Sexual Response

The sexual response is a complex interplay of psychologic and physiologic phenomena. It is influenced by several variables (e.g., stress, illness). The changes that occur during sexual excitement are similar for men and women. Masters and Johnson described the sexual response in terms of the excitement, plateau, orgasmic, and resolution phases.[3]

Male Sexual Response

The penis and urethra are essential to the transport of sperm into the vagina and cervix during intercourse. This transport is facilitated by penile erection in response to sexual stimulation during the *excitement phase*. Erection results from the filling of the large venous sinuses within the erectile tissue of the penis. In the flaccid state the sinuses hold only a small amount of blood. During an erection, they are congested with blood. Because the penis is richly endowed with sympathetic, parasympathetic, and pudendal nerve endings, it is readily stimulated to erection. The loose skin of the penis becomes taut from venous congestion. This tautness allows for easy insertion into the vagina.

As the man reaches the *plateau phase,* the erection is maintained. The penis increases in diameter from a slight increase in vasocongestion. Testicle size also increases. Sometimes the glans penis becomes reddish purple.

The contractions of the penile and urethral musculature during the *orgasmic phase* propel the sperm outward through the meatus. In this process, termed *ejaculation,* sperm are released into the ductus deferens. Sperm advance through the urethra, where fluids from the prostate and seminal vesicles are added to the ejaculate. The sperm continue their path through the urethra, receiving a small amount of fluid from the Cowper's glands. They are finally ejaculated through the urinary meatus. *Orgasm* is characterized by the rapid release of vasocongestion and muscular tension through rhythmic contractions. This occurs primarily in the penis, prostate gland, and seminal

vesicles. After ejaculation, a man enters the *resolution phase*. The penis undergoes involution, gradually returning to its unstimulated, flaccid state.

Female Sexual Response

The changes that occur in a woman during sexual excitation are similar to those in a man. In response to stimulation, the clitoris becomes congested and vaginal lubrication increases from secretions from the cervix, Bartholin's glands, and vaginal walls. This initial response is the excitation phase.

As excitation is maintained in the plateau phase, the vagina expands, and the uterus is elevated. In the orgasmic phase, contractions occur in the uterus from the fundus to the lower uterine segment. There is a slight relaxation of the cervical os, which helps the entrance of the sperm, and rhythmic contractions of the vagina. Muscular tension is rapidly released through rhythmic contractions in the clitoris, vagina, and uterus. A resolution phase follows, in which these organs return to their preexcitation state. However, women do not have to go through the resolution (refractory) recovery state before they can be orgasmic again. They can be multiorgasmic without resolution between orgasms.

Structure	Changes	Assessment Findings Abnormalities
Male		
Breasts	Enlargement	Gynecomastia (abnormal enlargement)
Penis	↓ Subcutaneous fat	Easily retractable foreskin (if uncircumcised) ↓ Size Fewer sustained erections
Prostate	Benign hyperplasia	Enlargement, urinary obstruction, incontinence
Testes	↓ Testosterone production	↓ Size, firmness
Female		
Breasts	↓ Subcutaneous fat, increased fibrous tissue, ↓ skin turgor	Less resilient, looser, more pendulous tissue ↓ Size Duct around nipple may feel like stringy strand
Ovaries	↓ Ovarian function	Nonpalpable ovaries are normal postmenopause
Urethra	↓ Muscle tone, mucosal thinning	Possible urinary tract infections, painful urination (dysuria), urgency, frequency, incontinence
Uterus	↓ Thickness of myometrium	Uterine prolapse
Vagina	Tissue atrophy, ↓ muscle tone, alkaline pH	Mucosa becomes pale, dry, smooth and thins Vagina narrows and shortens
Vulva	↓ Skin turgor	Atrophy ↓ Amount of pubic hair ↓ Size of clitoris and labia

Gerontologic Considerations: Effects of Aging on Reproductive Systems

With advancing age, changes occur in the male and female reproductive systems (Table 50.3). In women, many of these changes are related to decreased estrogen production associated with menopause.[4] Decreased estrogen and other sex steroids in postmenopausal women is associated with breast and genital atrophy, reduced bone mass, and increased rate of atherosclerosis. Vaginal dryness may occur, which can lead to urogenital atrophy and changes in the composition of the vaginal *microbiome* (the aggregate of microorganisms and their genetic material in a particular environment).[5]

Testosterone levels decline in men as they age. Manifestations of this decline are more gradual in men and can be physical, psychologic, or sexual. Changes include an increase in prostate size and a decrease in testosterone level, sperm production, muscle tone of the scrotum, and size and firmness of the testicles. Erectile dysfunction (ED) and sexual dysfunction occur in some men because of these changes.

Gender Differences

Effects of Aging on Sexual Function

Men	Women
• ↑ Stimulation necessary for erection	• ↓ Vaginal lubrication
• ↓ Force of ejaculation	• ↓ Sensitivity with labia shrinking and more clitoris exposed
• ↓ Ability to attain or sustain erection	• Difficulty in maintaining arousal
• ↓ Size and rigidity of the penis at full erection	• Difficulty in achieving orgasm after stimulation
• ↓ Libido and interest in sex	• ↓ Libido and interest in sex

Many factors affect sexuality in later life. Gradual changes occur in the sexual responses of men and women. The cumulative effects of these changes, as well as the negative social attitude toward sexuality in older adults, can affect the sexual practices of older adults. Illness, disability, medicines, and surgeries can affect a person's ability to take part in sexual activities.

Nurses play a vital role in providing accurate and unbiased information about sexuality and age. Emphasize the normalcy of sexual activity in older adults and refer them to resources that address such issues.

Assessment of Male and Female Reproductive Systems

Subjective Data

Important Health Information

In addition to general health information, elicit information specifically related to the reproductive system. Reproduction and sexual issues are often considered extremely personal and private. The extent and depth of the interview about a patient's sexuality and reproductive health depend primarily on your expertise and on the patient's needs and willingness to discuss the topic. Assess your

comfort with your own sexuality because any discomfort in questioning becomes obvious to the patient.

Case Study

Patient Introduction

© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.

A.K. is a 21-yr-old black woman who is being evaluated for pelvic pain and irregular menstrual bleeding for the past several months. She takes oral contraceptive pills orally once daily and naproxen (Aleve) as needed for pain.

Discussion Questions

1. What are the possible causes for A.K.'s irregular menstrual bleeding?
2. What assessment questions would you ask A.K.?
3. How would you individualize the assessment based on her age, ethnic/cultural background, and condition?

You will learn more about A.K. and her condition as you read through this assessment chapter.

(See p. 1182 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

A professional demeanor is important when taking a reproductive or sexual history. Develop trust with the patient to elicit such information. Conduct interviews in an environment that provides reassurance, confidentiality, and a nonjudgmental attitude. Be sensitive, use gender-neutral terms when asking about partners, and maintain an awareness of a patient's culture and beliefs. Begin with the least sensitive information (e.g., menstrual history) before asking questions about more sensitive issues, such as sexual practices or STIs.

Past Health History

The health history should include information about major illnesses, hospitalizations, immunizations, and surgeries. Ask about any infections involving the reproductive system, including STIs. Take a complete obstetric and gynecologic history from the female patient.

Mumps and rubella affect reproductive function. The occurrence of

mumps in young men is associated with an increased risk for sterility. Bilateral testicular atrophy may occur from mumps-related orchitis. Ask male patients if they have had mumps, have been immunized with the mumps vaccine, or have any signs of sterility.

Rubella is of primary concern to women of childbearing age. Having rubella during the first 3 months of pregnancy increases the risk for congenital anomalies. So, encourage immunization for all women of childbearing age who have not been immunized for rubella or have not already had the disease. Antibody titers can determine rubella immunity. Women should not be immunized if they are already pregnant.[6] Advise women to avoid becoming pregnant for 1 month after vaccination, or ideally, when their immunity has been confirmed by antibody titers.

Ask the patient about current health status and any acute or chronic health problems. Chronic illnesses, such as cardiovascular disease, respiratory problems, anemia, cancer, and kidney and urinary tract problems, may affect the reproductive system and sexual functioning.

Ask questions relating to possible endocrine disorders, particularly diabetes, hypothyroidism, and hyperthyroidism. These disorders directly interfere with women's menstrual cycles and with sexual performance. Men with diabetes may have ED and retrograde ejaculation. In women with uncontrolled diabetes, pregnancy may pose significant health risks to both the woman and unborn fetus.

Determine if the patient has a history of a stroke. In men, strokes may cause physiologic or psychologic ED. Men who have had a myocardial infarction (MI) may have ED because of fear that sexual activity could precipitate another MI. Post MI medication, such as β-blockers, may affect a man's ability to achieve an erection.[7] Although most patients have concerns about sexual activity after an MI, many are not comfortable expressing these fears to the nurse. Be sensitive to this concern.

Document the patient's allergies, especially if the patient is allergic to latex or drugs, including sulfonamides, macrolides, cephalosporins, tetracyclines, or penicillin. These drugs are often used to treat reproductive and genitourinary (GU) problems, such as STIs and

urinary tract infections (UTIs). Silicone and latex are often used in diaphragms and condoms. An allergy to these substances precludes their use as contraceptive methods.

Medications

Document all prescription and over-the-counter drugs that the patient is taking, including the reason for use, dosage, and length of time that the drug has been taken. Ask the patient about the use of herbal products and dietary and nutritional supplements.

Particularly relevant is the use of diuretics (sometimes prescribed for premenstrual edema) and psychotropic agents (which may interfere with sexual performance). Antihypertensives, such as amlodipine (Norvasc), lisinopril (Prinivil), propranolol (Inderal), and clonidine (Catapres), may cause ED. Use of drugs such as alcohol, marijuana, barbiturates, amphetamines, or cocaine can affect the reproductive system.

In women, document the use of hormonal contraceptives and hormone therapy (HT). The long-term use of combined HT (specifically a combination of oral conjugated equine estrogen and a progestin, *medroxyprogesterone acetate*) is associated with an increased risk for stroke, breast cancer, deep vein thrombosis, and gallbladder disease. These risks are higher in women who also use tobacco products.[8] For postmenopausal women who may have symptoms, such as hot flashes, newer data that suggest that HT does not increase the risk for mortality. Women will need counseling based on their degree of symptoms and associated morbidities to help balance their quality of life with menopausal symptoms.[9]

A history of cholecystitis and hepatitis is important because these conditions may be contraindications for the use of oral contraceptives. Oral contraceptives often aggravate cholecystitis. Chronic liver inflammation generally precludes the use of estrogen products because they are metabolized by the liver. Chronic obstructive pulmonary disease may be a contraindication to oral contraceptive use because progesterone thickens respiratory secretions.

Surgery or Other Treatments

Note any surgical procedures. Common surgical procedures involving the female reproductive system are listed in Table 53.14. Record any therapeutic or spontaneous abortions and type of intervention (e.g., medical versus surgical abortion).

Functional Health Patterns

The key questions to ask a patient with a reproductive problem are outlined in Table 50.4.

Health Perception–Health Management Pattern

The primary focus of this pattern is the patient's perception of his or her own health and measures that the patient takes to maintain health. Ask about self-examination practices and screenings. Mammography and periodic cervical Pap tests are integral to a woman's health. Men are at risk for testicular and prostate cancer. However, controversy exists about the benefits of routine screening for these cancers.[10] All patients should discuss the benefits and risks of screening with their HCP.

Genetic Risk Alert

- Breast, ovarian, uterine, and prostate cancer have known genetic risk factors.
- Having a first-degree relative with any of these cancers significantly increases the risk for cancer for the patient.
- The risk increases if several family members have had these cancers over succeeding generations.
- Persons with a known hereditary predisposition to breast or ovarian cancer can use this information to make informed decisions about how to minimize their risks.

An accurate family history is avital. Ask about a history of cancer, especially cancer of the reproductive organs. Determine if the patient has a familial tendency for diabetes, hypothyroidism, hyperthyroidism, hypertension, stroke, angina, MI, endocrine disorders, or anemia.

Assessment of the reproductive system is incomplete without knowledge of the patient's lifestyle choices. Determine whether a patient has smoked or is currently smoking, the amount (if any) of alcohol consumption, or if the patient uses illicit drugs. Risks associated with smoking include ectopic pregnancy, miscarriage, an increased risk for perinatal mortality and morbidity, placental abnormalities, preterm delivery, and congenital facial defects of the fetus.[11] Smoking increases the risk for morbidity and mortality in women who use oral contraceptives. Smoking in women is also associated with early menopause.[5] Decreased sperm counts and ED are seen in male smokers. Smoking is a known cofactor for persistence of *human papillomavirus* (HPV) infection for oral and anogenital cancers among men and women.[12]

TABLE 50.4 Health HistoryReproductive System

Health Perception–Health Management

- How would you describe your overall health?
- Describe the health of your family members. Any history of breast, uterine, ovarian, or prostate cancer?*

Women

- Do you perform breast self-examination? Any concerns?
- What was the date of your last Pap test and the results?*
- Any prior abnormalities with your Pap tests?

- What was the date of your last mammogram and the results?*
- Any prior abnormalities with your mammograms?

Men

- Do you perform testicular self-examination? Any concerns?

Nutritional-Metabolic

- Describe what you usually eat and drink.
- Have you had any changes in weight?*
- How do you feel about your current weight?
- Do you take any nutritional supplements, such as calcium or vitamins?*
- Do you have any dietary restrictions?*

Elimination

- Do you have problems with urination (e.g., pain, burning, dribbling, incontinence, frequency)?*
- Have you had bladder infections? If so, when? How often?
- Do you have problems with bowel movements?*
- Do you have any constipation, loose stools, or blood with stools?*
- Do you use laxatives?*

Activity-Exercise

- What activities do you typically do each day?
- Do you have enough energy for your desired activities?

Sleep-Rest

- How many hours do you typically sleep each night?
- Do you feel rested after sleep?
- Do you have any problems associated with sleeping?*

Cognitive-Perceptual

- Do you have pain? If yes, where?
- Do you have pain during sexual activity or intercourse?*

Self-Perception–Self-Concept

- How would you describe yourself?
- Have there been any recent changes that have made you feel differently about yourself?*
- Are you having any problems that are affecting your sexuality?*

Role-Relationship

- Describe your living arrangements. With whom do you live?
- Do you have a significant other? If yes, is this relationship satisfying?
- Are you having any role-related problems in your family?* At work?*
- What are the relationships among your family members?

Sexuality-Reproductive

- Are you sexually active? If so, how many partners do you have?

- What kind of sex do you engage in (e.g., oral, vaginal, anal)?
- How do you protect yourself against sexually transmitted infections and unwanted pregnancy?
- Are you satisfied with your present means of sexual expression? If not, explain.
- Have you had any recent changes in your sexual practices?*

Women

- How old were you when you had your first menstrual period? (Menarche)
- What was the first day of your last menstrual period?
- Describe your period. How many days does it last? How often does it come (e.g., every 28 days)?
- Do you have pain with your period? Do you pass clots?
- Do you feel your flow is heavy or excessive?
- How old were you when you went through menopause?
- Have you had any postmenopausal bleeding or spotting?*
- Pregnancy history: How many times have you been pregnant? How many living children do you have? Have you ever had any miscarriages or abortions? Did they need medical intervention?

Men

- Do you have any problem obtaining or sustaining an erection?
- Do you have any problems with ejaculation?

Coping–Stress Tolerance

- Have there been any major changes in your life within the past couple of years?*

- What is stressful in your life right now?
- How do you handle health problems when they occur?
- Do you feel safe in your home? Work? Has anyone ever tried to hurt or harm you?

Value-Belief

- What beliefs do you have about your health and illnesses?
- Do you use home remedies?*
- Is religion an important part of your life?*
- Do you think that any of your personal beliefs or values may be compromised because of your treatment?*

* If yes, describe.

Nutritional-Metabolic Pattern

Anemia is a common problem in women in their reproductive years, particularly during pregnancy and the postpartum period. Evaluate the adequacy of the diet with this condition in mind. Iron-deficiency anemia is the most common cause of anemia in menstruating females.

Take a thorough nutritional and psychologic history to assess for the presence of an eating disorder. Anorexia nervosa can cause amenorrhea and other problems, such as osteoporosis, that are related to menopause. Obesity can be related to polycystic ovarian syndrome and may be a precursor to type 2 diabetes.

From early adolescence, teach women about adequate calcium and vitamin D intake to prevent osteoporosis. Estimate the patient's daily calcium intake to determine whether supplementation is needed. Evaluate folic acid intake for women in their reproductive years because a deficiency can result in spina bifida and other fetal neural tube defects.[13]

Elimination Pattern

Many gynecologic problems can result in GU problems. Urinary incontinence is common in older women. Factors associated with female incontinence include relaxation of the pelvic musculature caused by multiple births, advancing age, fibroid tumors, diabetes, obesity, and weight gain. Condom, diaphragm, and spermicide use is associated with an increased risk for UTIs. Vaginal infections, such as bacterial vaginosis (BV), facilitate the growth of *Escherichia coli,* which causes most UTIs.[14] Men may have urethritis, an inflammation of the urethra, which may be caused by an STI. Urethritis can cause painful urination. Benign prostatic hyperplasia (BPH) is common in older men. It can cause urinary retention or difficulty in starting the urinary stream.

Activity-Exercise Pattern

Record the amount, type, and intensity of activity and exercise. Lack of weight-bearing exercise is an important factor in the development of osteoporosis, especially in postmenopausal women. Adolescent females who engage in excessive leanness sports may have *female athlete triad.* It is characterized by secondary amenorrhea, low energy availability, and osteoporosis.[15] Anemia can result in fatigue and activity intolerance and interfere with satisfactory performance of activities of daily living.

Sleep-Rest Pattern

Sleep patterns for women may be affected during the postpartum period and while raising young children. Hot flashes and sweating during perimenopause can cause serious sleep interruption when the woman awakens in a drenching sweat. The need to change her nightgown and bedding further disrupts her sleep. Insomnia is common among perimenopausal women. Daytime fatigue can result from sleep problems. In men, frequent urination at night associated with prostate enlargement or hormone therapy for prostate cancer can disturb sleep.

Cognitive-Perceptual Pattern

Pelvic pain is associated with various gynecologic disorders, such as pelvic inflammatory disease, ovarian cysts, and *endometriosis*. **Dyspareunia** (painful intercourse) can be problematic for women in the postmenopausal period. The pain associated with intercourse can create a reluctance to take part in sexual activity and strain relationships with sexual partners. Refer women with dyspareunia to their HCP.

Self-Perception–Self-Concept Pattern

Changes that occur with aging, such as pendulous breasts and vaginal dryness in women and decreased penis size in men, may lead to emotional distress. The subtle changes associated with sexuality and advancing age may affect self-concept.

Role-Relationship Pattern

Obtain information about the family structure and occupation. Ask about recent changes in work-related relationships or family conflict. Assess the patient's role in the family as a starting point to determine family dynamics. Roles and relationships are affected by changes within the family. The addition of a new baby may change family dynamics.

Sexuality-Reproductive Pattern

For women, obtain a menstrual and a chronologic obstetric history. The menstrual history includes the first day of the LMP, description of menstrual flow, age of menarche, and, if applicable, age at menopause. Menstrual history data are used in the detection of pregnancy, infertility, and many gynecologic problems. Have the patient describe any changes in her usual menstrual pattern to determine whether the change is transient and unimportant or connected with a more serious gynecologic problem. Terminology that describes abnormal uterine bleeding patterns is discussed in Chapter 53.

TABLE 50.5 Sexual History FormatThe Five Ps of Taking a Sexual History*

The 5 *Ps*	Questions
1. Partners	Are you currently sexually active? (yes or no) • Do you have sex with men, women, or both? • In the past 2 months, with how many partners have you had sex? • In the past 12 months, with how many partners have you had sex?
2. Practices	To understand your risk for STIs, I need to understand the kind of sex you have had recently. • Genital (penis in the vagina) • Anal (penis in the anus) • Oral (mouth on penis, vagina, or anus)
3. Protection from STIs	Do you and your partner(s) use any protection against STIs? • What kind? • How often?
4. Past history of STIs	Have you ever been diagnosed with an STI? • What type? • When? • How were you treated?
5. Prevention of pregnancy	Are you or your partner trying to get pregnant? • If not, what are you doing to prevent pregnancy?

Adapted from *www.cdc.gov/std/treatment/sexualhistory.pdf*.

* Modify this guide as needed to be culturally appropriate based on culture or gender dynamics.

Identify changes in menstrual patterns associated with the use of oral contraceptives, intrauterine devices (IUDs), birth control patches, vaginal rings, progestin-only implants, or medroxyprogesterone injections. Oral contraceptives usually decrease the amount and duration of flow. Some IUDs can increase menstrual flow. Some IUDs are used for both contraception and as a nonsurgical treatment for heavy menstrual bleeding.

The obstetric history includes the number of pregnancies, full-term births, preterm births, stillbirths, living children, and abortions (including spontaneous [miscarriage], ectopic, or induced). Document the course of each pregnancy, including the duration of each pregnancy, date of delivery, problems that may have occurred with

each pregnancy, and any medical or surgical interventions that were needed.

Table 50.5 outlines *The 5 Ps of Sexual Health* approach for taking a sexual history. Never make an assumption about a patient's sexual orientation. Ask both men and women about their general satisfaction with their sexuality. Ask the patient about sexual beliefs and practices and whether they achieve orgasm. Explore any unexplained change in sexual practices or performance. Reproductive problems can cause physiologic or psychologic problems that can lead to painful intercourse, ED, sexual dysfunction, or infertility.

Coping–Stress Tolerance Pattern

The stress related to situations such as pregnancy or menopause increases dependence on support systems. Determine whom the support people are in the patient's life. The diagnosis of an STI can cause stress for the patient and partner. Explore ways to manage this stress with patients by encouraging them to share their fears and concerns.

Value-Belief Pattern

Sexual and reproductive functioning is closely related to cultural, religious, moral, and ethical values. Be aware of your own beliefs in these areas. Recognize and sensitively react to the patient's personal beliefs associated with reproductive and sexuality issues.

Case Study—cont'd

Subjective Data

© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.

A focused assessment of A.K. revealed the following information:

Health Perception–Health Management: In good health. Pap smear 2 months ago was normal. Has not had any surgeries
Nutritional-Metabolic: 5 ft 4 in, 140 lb (BMI 24 kg/m^2)
Elimination: Denies any changes with urination or bowel movements

Activity-Exercise: Exercises at gym 3 times a week
Cognitive-Perceptual: Denies dyspareunia
Self-Perception–Self Concept: Attends college and hopes to graduate this semester
Role-Relationship: Single, lives with 3 other young women in off-campus housing
Sexuality-Reproductive: Menarche at age 14. Last menstrual period 2 weeks ago. Menses is usually every 28 days, lasting 2 days, but has noted irregular bleeding with increased pelvic pain over past few months. Sexually active with men—3 lifetime partners. In a mutually monogamous relationship of 2 years duration. Practices vaginal and oral sex
Coping–Stress Tolerance: Denies stressors
Value-Belief: Raised Baptist, but does not attend services at school

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. What should be included in the physical assessment?

You will learn more about physical examination of the reproductive system in the next section.
(See p. 1183 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Physical Examination: Male

The examination of the male external genitalia by the nurse includes inspection and palpation of the pubis, penis, and scrotum. The patient may be lying or standing. The standing position is preferred. Sit in front of the standing patient. Use gloves during examination of the

male genitalia.

If breast cancer is suspected or there is a strong family history of breast cancer in a male patient, a clinical breast examination is conducted in the same pattern for a male patient as a female breast examination (see Fig. 51.1).

Pubis

Assess for hair distribution and presence of body lice. Normally, the hair is in a diamond-shaped pattern and coarser than scalp hair. The absence of hair is not a normal finding unless the man is shaving or waxing the pubic hair. Carefully assess the skin for irritation and inflammation.

Penis and Scrotum

Inspect the penis for any lesions, bleeding, or swelling. Note the location of the urethral meatus and the presence of a foreskin. If present, retract the foreskin and note any redness, discharge, irritation, lesions, or swelling from the meatus. Replace the foreskin over the glans after observation. Inspect the scrotum by lifting each testis to inspect all sides of the scrotal sac. Palpate the testes for tenderness or masses. The left testis usually hangs lower than the right. An undescended testis *(cryptorchidism)* is a major risk factor for testicular cancer and a potential cause of male infertility.

Anus

Note if the buttocks have any lesions, swelling, or inflammation. Spread the buttocks apart with both hands to expose the anus. Inspect the anal sphincter and perineal regions for fissures, lesions, masses, and hemorrhoids. The anus should be free from inflammation or skin changes.

Physical Examination: Female

With a chaperone present, physical examination of women often begins with inspection and palpation of the breasts and axillae then

proceeds to the abdomen and genitalia. Examining the abdomen provides an opportunity to detect pain or any masses that may involve the GU system. Abdominal examination is discussed in Chapter 38.

Breasts

To perform a breast examination, first examine the breasts by visual inspection. With the patient seated, inspect the breasts for symmetry, size, shape, skin color, vascular patterns, dimpling, and unusual lesions. Ask the patient to put the arms at the sides, arms overhead, lean forward, and press hands on hips. Observe for any abnormalities during these maneuvers. Palpate the axillae and clavicular areas for enlarged lymph nodes.

After the patient assumes the supine position, place a pillow under the back on the side to be examined. Ask the patient to put the arm above and behind the head. This flattens breast tissue and make palpation easier. Then palpate the breast in a systematic fashion, preferably using a vertical line (see Fig. 51.1). Use the distal finger pads of the index, middle, and ring fingers for palpation. Include the axillary tail of Spence in the examination. This area of the breast lies adjacent to the upper outer quadrant. It is where most breast cancer develops. Palpate the area around the areolae for masses. Document the color, consistency, and odor of any discharge. For patients at average risk who have no breast symptoms, the benefit of routine clinical breast examinations to detect early breast cancer is unclear. Teach patients to be familiar with how their breasts feel and report any significant changes or concerns to an HCP.[16]

External Genitalia

The examination of a woman's genitalia by the nurse includes inspection and palpation of the mons pubis, vulva, and anus. Use gloves for the examination. Assess for hair distribution, presence of body lice, lesions, redness, edema, or discharge. Many women remove hair from the genital region via shaving, waxing, or laser hair removal and may develop folliculitis (infection of the hair follicle). Separate the

labia to fully inspect the clitoris, urethral meatus, and vaginal orifice. Spread the buttocks apart to inspect the anus for fissures, lesions, and hemorrhoids.

Internal Pelvic Examination

HCPs with advanced or specialized training usually do this part of the examination. During the speculum examination, the HCP inspects the walls of the vagina and cervix for inflammation, discharge, polyps, and suspicious growths. A Pap test and specimens for nucleic acid amplification tests (NAATs) for STI sampling and microscopic examination may be obtained. After the speculum examination, a bimanual examination may be done to assess the size, shape, and consistency of the uterus and ovaries. The ovaries and tubes are not normally palpable.

Table 50.6 gives an example of a recording format for the physical assessment findings for the male and female reproductive systems. Tables 50.7 through 50.9 summarize assessment abnormalities of the breasts, female reproductive system, and male reproductive system, respectively.

TABLE 50.6 Normal Physical Assessment of Reproductive System

Male	Female
Breasts	
Nipples soft. No lumps, nodules, swelling, or enlarged tissue noted.	Symmetric without dimpling. Nipples soft. No drainage, retraction, or lesions noted. No masses or tenderness. No lymphadenopathy.
External Genitalia	
Diamond-shaped hair distribution. No penile lesions or discharge noted. Scrotum symmetric, no masses, descended testes. No inguinal hernia.	Triangular hair distribution. Genitalia dark pink, no lesions, redness, swelling, or inflammation in perineal region. No vaginal discharge noted. No tenderness with palpation of Skene's ducts and Bartholin's glands.
Anus	
No hemorrhoids, fissures, or lesions noted.	No hemorrhoids, fissures, or lesions noted.

Case Study—cont'd

Objective Data: Physical Examination

Focused assessment of A.K. reveals the following:

© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.

BP is 118/76 mm Hg; her pulse is 70 beats/min and regular. Skin

warm and dry without lesions. No cyanosis of lips, mucous membranes, or nail beds. Thyroid is not enlarged. Heart examination is normal. Abdomen soft and nontender. External genitalia examination is normal. Bimanual examination by the HCP is negative for cervical motion tenderness, uterine anomalies. She has pain on left side with palpation of a soft mass consistent with an ovarian cyst.

Discussion Questions

1. Based on the subjective and objective assessment findings, what diagnostic tests would you anticipate being ordered for A.K.?

You will learn more about diagnostic studies related to the reproductive system in the next section.

(See p. 1183 for more information on A.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

A *focused assessment* is used to evaluate the status of previously identified reproductive problems and to monitor for signs of new problems. A focused assessment of the reproductive system is presented in the box on this page.

Focused Assessment

Reproductive System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Vaginal or vulvar: discharge, lesions, itching, unusual bleeding, odor	Y	N
Penile pain, lesions, discharge	Y	N
Medications: oral contraceptives, antihypertensives, psychotropics, hormones	Y	N

Clinical examinations of reproductive systems (breast, pelvis, testicular, prostate) and results	Y	N
Pain: abdomen, pelvis, or genitalia	Y	N

Objective: Diagnostic

Check the following for results and critical values.

Serum/urine hCG	✓
Serum PSA	✓
CBC	✓
Hormone studies (testosterone, progesterone, estrogen, FSH, LH, TSH)	✓
NAAT STI results (e.g., *Chlamydia*, gonorrhea, *Trichomonas*)	✓
In office testing (e.g., wet mounts, pH assessment)	✓
Mammography and/or ultrasound of breasts	✓
Ultrasound: abdominal, pelvic, transvaginal, prostate	✓

Objective: Physical Examination

Inspect

External genitalia for redness, swelling, discharge, lesions	✓
Breasts for swelling, dimpling, retraction, drainage, redness, skin changes, masses,	✓

Palpate

Breast tissue for masses or tenderness	✓
External genitalia: tenderness, pain	✓

hCG, Human chorionic gonadotropin; *PSA,* prostate-specific antigen.

Diagnostic Studies of Reproductive Systems

The most common diagnostic studies used to assess the reproductive systems are described in Tables 50.10 through 50.14. Diagnostic studies of the endocrine system may also be done in a person with a reproductive system problem (see Tables 47.6 and 47.7).

Case Study—cont'd

Objective Data: Diagnostic Studies

The following laboratory and diagnostic tests are ordered for A.K.:

© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.

Urine pregnancy test, urinalysis, pelvic and transvaginal ultrasound, complete blood count (CBC), thyroid stimulating hormone (TSH), gonorrhea and chlamydia NAAT testing. Her results are:

Urine pregnancy test: Negative
Urinalysis: Normal

CBC: hemoglobin, 13.2 g/dL, hematocrit, 36%
TSH: 2.3 IU/L
Gonorrhea and chlamydia tests: Negative

The pelvic and transvaginal ultrasound revealed a 4-cm ovarian cyst.

Discussion Questions

1. Which diagnostic and laboratory test results are of concern to you?
2. What patient teaching can you provide A.K. based on her diagnostic test results?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

TABLE 50.7 Assessment AbnormalitiesBreast

Finding	Description	Possible Etiology and Significance
Dimpling	Unilateral, recent onset, no pain	Cancer
Nipple inversion or retraction	Recent onset, redness, pain, unilateral	Abscess, inflammation, cancer
	Recent onset (usually within past year), unilateral presentation, lack of tenderness	Cancer
Nipple scaling or irritation	Unilateral or bilateral presentation, crusting, possible ulceration	Paget's disease, eczema, infection
Nipple secretions		
• **Galactorrhea (female)**	Milky, no relationship to lactation, unilateral or bilateral, intermittent or consistent presentation	Drug therapy, especially phenothiazines, tricyclic antidepressants, methyldopa. Hypofunction or hyperfunction of thyroid or adrenal glands. Hypothalamus or pituitary tumor. Excess estrogen. Prolonged suckling or breast foreplay
• **Galactorrhea (male)**	Milky, bilateral presentation	Chorioepithelioma of testes, pituitary tumor
• **Multicolored or dark green discharge**	Thick, sticky, and often bilateral	Ductal ectasia (dilation of mammary ducts)
• **Purulent**	Gray-green or yellow color. Frequent unilateral presentation. Association with pain, redness, induration, nipple inversion	Puerperal (after birth) mastitis (inflammatory condition of breast) or abscess
	Same as above but usually without nipple inversion	Infected sebaceous cyst
• **Serosanguineous or bloody drainage**	Unilateral presentation	Papillomatosis (widespread development of nipple-like growths), intraductal papilloma, cancer (male and female)
• **Serous discharge**	Clear appearance, unilateral or bilateral, intermittent or consistent presentation	Intraductal papilloma
Nodules, lumps, or masses	Multiple, bilateral, well-delineated, soft or firm, mobile cysts. Pain. Premenstrual occurrence	Fibrocystic changes
	Rubbery consistency, fluid-filled interior, pain	Ductal ectasia
	Soft, mobile, well-delineated cyst, absence of pain	Lipoma, fibroadenoma
	Redness, tenderness, induration	Infected sebaceous cysts, abscesses
	Usually singular, hard, irregularly shaped, poorly delineated, nonmobile	Cancer

TABLE 50.8 Assessment AbnormalitiesFemale Reproductive System

Finding and Description	Possible Etiology and Significance
Vulvar Discharge	
Thin gray or white, copious flow, malodorous or fishy, vulvar irritation	Bacterial vaginosis infection
White, thick, curdy, frequent itching and inflammation, lack of odor or yeast-like smell	Candidiasis (*Candida* or yeast infection), vaginitis
Mucopurulent discharge; bloody discharge	*Chlamydia trachomatis* or *Neisseria gonorrhoeae* infection, menstruation, trauma, cancer
Frothy green or yellow color; malodorous	*Trichomonas vaginalis*
Vulvar Redness	
Bright or beefy red color, itching	*Candida albicans*, allergy, chemical vaginitis
Reddened base, painful vesicles or ulcerations	Genital herpes
Macules or papules, itching	Chancroid, contact dermatitis, scabies, pediculosis
Vulvar Growths	
Soft, fleshy growth, nontender	Condyloma acuminatum (genital warts)
Flat and warty appearance, nontender	Condyloma latum
Same as either of above, possible pain	Cancer
Reddened base, vesicles, and small erosions; pain	Lymphogranuloma venereum, genital herpes, chancroid
Indurated, firm ulcers, no pain	Chancre (syphilis), granuloma inguinale
Abdominal Pain, Tenderness, or Pelvic Masses	
Intermittent or consistent tenderness in right or left lower quadrant	Salpingitis (infection of fallopian tube), ectopic pregnancy, ruptured ovarian cyst, PID, tubal or ovarian abscess
Periumbilical location, consistent occurrence	Cystitis, endometritis (inflammation of endometrium), ectopic pregnancy
Abdominal or pelvic pain, especially with menses, which radiates to back, rectum or vagina.	Endometriosis (a disorder in which the endometrial lining grows on pelvic organs or outside the pelvis in rare cases)
Pelvic masses	Fibroids, ovarian cysts (typically benign); Cancer or metastases (requires additional testing and treatment)

PID, Pelvic inflammatory disease.

TABLE 50.9 Assessment AbnormalitiesMale Reproductive System

Finding and Description	Possible Etiology and Significance
Penile Growths or Masses	
Indurated, smooth, disk-like appearance. Absence of pain. Singular presentation	Chancre (syphilis)
Papular to irregularly shaped ulceration with pus, lack of induration	Chancroid
Ulceration with induration and nodularity	Cancer
Flat, wartlike nodule	Condyloma latum
Raised, fleshy, moist, elongated projections with single or multiple projections	Condyloma acuminatum (genital warts)
Localized swelling with retracted, tight foreskin	Paraphimosis (inability to replace foreskin to its normal position after retraction), trauma
Vesicles, Erosions, or Ulcers	
Painful, reddened base. Vesicular or small erosions	Genital herpes, balanitis (inflammation of glans penis), chancroid
Painless, singular, small erosion with eventual lymphadenopathy	Lymphogranuloma venereum, cancer
Scrotal Masses	
Localized swelling with tenderness, unilateral or bilateral presentation	Epididymitis (inflammation of epididymis), testicular torsion, orchitis (mumps)
Swelling, tenderness	Incarcerated hernia
Swelling without pain. Unilateral or bilateral presentation. Translucent, cordlike or wormlike appearance	Hydrocele (accumulation of fluid in outer covering of testes), spermatocele (firm, sperm-containing cyst of epididymis), varicocele (dilation of veins that drain testes), hematocele (accumulation of blood within scrotum)
Firm, nodular testes or epididymis. Frequent unilateral presentation	Tuberculosis, cancer
Penile Discharge	
Clear to purulent color, minimal to copious flow	Urethritis or gonorrhea, *Chlamydia trachomatis* infection, trauma
Penile or Scrotal Redness	
Macules and papules	Scabies, pediculosis
Inguinal Masses	
Bulging unilateral presentation during straining	Inguinal hernia
1- to 3-cm nodules	Lymphadenopathy

TABLE 50.10 Serology StudiesMale and Female Reproductive Systems

Study	Reference Interval	Description and Purpose
Anti-müllerian hormone (AMH)	*Female:* 13–45 yr: 0.9–9.5 ng/mL >45 yr: <1.0 ng/mL	Measures ovarian function. Level reflects size of the remaining egg supply ("ovarian reserve"). May be done when a woman has manifestations of polycystic ovarian syndrome (PCOS). Used to monitor AMH-producing ovarian tumor. Females with high AMH levels have a better response to ovarian stimulation during fertility treatments.
Estradiol	*Female:* Follicular phase: 20–350 pg/mL (73–1285 pmol/L) Luteal phase: 30–450 pg/mL (110–1652 pmol/L) Postmenopause: ≤20 pg/mL (≤73 pmol/L) *Male:* 10–50 pg/mL (37–184 pmol/L)	Measures ovarian function. Useful in assessing estrogen-secreting tumors and states of precocious female puberty. May be used to confirm perimenopausal status. Increased levels in men may indicate testicular tumor.
Follicle-stimulating hormone (FSH)	In 24-hr urine samples: *Female:* Follicular phase: 2–15 U/24 hr Midcycle: 8–60 U/24 hr Luteal phase: 2–10 U/24 hr Postmenopause: 35–100 U/24 hr *Male:* 3–11 U/24 hr In blood: *Female:* Follicular phase: 1.37–9.9 mU/mL Ovulatory phase: 6.17–17.2 mU/mL Luteal phase: 1.09–9.2 mU/mL Postmenopause: 19.3–100.6 mU/mL *Male:* 1.42–15.4 mU/mL	Assesses gonadal function. Abnormal levels may indicate pituitary tumors or dysfunction. Increased in menopause. May be used to confirm menopausal status.

Table Continued

Study	Reference Interval	Description and Purpose
Human chorionic gonadotropin (hCG)	Qualitative: Negative Quantitative: <5 mIU/mL (<5 IU/L) (males and nonpregnant females)	Detects pregnancy. Detects hydatidiform mole and chorioepithelioma (in men and women). Done with urine or blood.
Luteinizing hormone (LH)	*Female:* Premenopause: 5–25 IU/L, with higher peaks at ovulation Postmenopause: 14–52.3 IU/L *Male:* 1.8–8.6 IU/L	Associated with ovulation in women and testosterone production in men. Used in women in the workup of infertility and menstrual irregularities.
Progesterone	*Female:* Follicular phase: 15–70 ng/dL (0.5–2.2 nmol/L) Luteal phase: 200–2500 ng/dL (6.4–79.5 nmol/L) Postmenopause: <40 ng/dL (1.28 nmol/L) *Male:* 13–97 ng/dL (0.4–3.1 nmol/L)	Used to assess infertility, monitors success of drugs for infertility or the effect of progesterone treatment, determines whether ovulation is occurring. Diagnoses problems with adrenal glands and some types of cancer.
Prolactin	*Female:* 3.8–23.2 ng/mL (3.8–23.2 mg/L) *Male:* 3.0–14.7 ng/mL (3.0–14.7 mg/L)	Detects pituitary dysfunction that can cause amenorrhea, decreased libido, and impotence.
Prostate-specific antigen (PSA)	*Male:* <4 ng/mL (<4 mcg/L)	Detects prostate cancer. Used to monitor response to therapy.
Testosterone	In 24-hr urine samples: *Female:* 2–12 mcg/24 hr (6.9–41.6 nmol/24 hr) *Male:* 40–135 mcg/24 hr (139–469 nmol/24 hr) In blood: *Female:*15–70 ng/dL (0.52–2.43 nmol/L) *Male:* 280–1100 ng/dL (10.4–38.17 nmol/L)	Detects tumors and developmental anomalies of the testicles. Used to assess male infertility.

TABLE 50.11 Radiologic StudiesMale and Female Reproductive System

Study	Description and Purpose
CT scan of pelvis	Detects tumors in the pelvis.
Mammography	X-ray image used to assess breast tissue. Detects benign and malignant masses. Mammography screening guidelines are discussed in Chapter 51.
MRI	Radio waves and magnetic field are used to assess soft tissue. Useful after an abnormal mammogram or in women with dense breast tissue. Breast MRI may be with mammography to detect breast cancer in women at high risk for breast cancer. Used to diagnose abnormalities in female and male reproductive systems.
Ultrasound (US) (breast, pelvic, testicular, transvaginal [TV], rectal [TRUS])	Measures and records high-frequency sound waves as they pass through tissues of variable density. Breast US: Used to detect fluid-filled masses and for follow-up screening after mammography in women with dense breast tissue. Pelvic and TV US: In women, used to detect pelvic masses, such as ectopic pregnancy, ovarian cysts, fibroids, and cancer. Testicular US: Detects testicular masses and testicular torsion. TRUS: Used to diagnose prostate tumors.

TABLE 50.12 Interventional Studies

Study	Description and Purpose	Nursing Responsibility
Colposcopy	Direct visualization of cervix with binocular microscope. Allows magnification of cervix and study of cellular abnormalities. Used as follow-up for abnormal Pap test and for examination of women exposed to DES in utero. Cervical biopsy(ies) may be taken. Assesses for vaginal or vulvar dysplasia.	*Before:* Teach patient about the procedure. Tell patient this test is similar to a speculum examination. *After:* If a biopsy was done, tell patient she may have some vaginal bleeding and to avoid sexual intercourse until healed.
Conization	Cone-shaped sample of squamocolumnar tissue of cervix is removed for direct study.	*Before:* Teach patient about the procedure. Requires use of surgical facilities and anesthesia. *After:* Tell patient to avoid sexual intercourse and tampons for 3–4 wk. May have some discharge or spotting for 1 wk. 3-wk follow-up necessary.
Dilation and curettage (D&C)	Operative procedure that dilates cervix and allows curetting of endometrial lining. Used in assessment of abnormal bleeding and cytologic evaluation of lining.	*Before:* Teach patient about procedure and sedation. *After:* Assess degree of bleeding with frequent pad check during first 24 hr.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Hysterosalpingogram (HSG)	Involves instillation of contrast media through cervix into uterine cavity and through fallopian tubes. X-ray images taken to detect abnormalities of uterus and its adnexa (ovaries and tubes) as contrast progresses through them. Most useful in diagnostic assessment of fertility (e.g., to detect adhesions near ovary, abnormal uterine shape, blockage of tubal pathways).	*Before:* Teach patient about procedure and that it may be uncomfortable. Contrast medium is used. *After:* Tell patient she may have slight vaginal bleeding and cramping. Monitor for foul-smelling vaginal discharge, severe pain, fever, or chills.
Hysteroscopy	Allows visualization of uterine lining through insertion of scope through cervix. Used to diagnose and treat abnormal bleeding, such as polyps and fibroids. Biopsy may be done during procedure. May be part of infertility assessment.	*Before:* Should be NPO for at least 6 hr prior. May be done in the HCP's office or an outpatient setting. *After:* Tell patient that mild cramping and slight bloody discharge is normal.
Laparoscopy	Allows visualization of pelvic structures via fiberoptic scopes inserted through small abdominal incisions. Instillation of CO_2 into the abdominal cavity improves visualization. Used in diagnostic assessment of uterus, tubes, and ovaries (Fig. 50.9). Often used for tubal sterilization or part of infertility assessment.	*Before:* Prepare patient for vaginal operation with preoperative teaching and sedation. *After:* Tell patient referred shoulder pain is likely from residual gas in the abdomen. A heating pad may help. A slight discharge or spotting for 2–5 days is normal.
Loop electrosurgical excision procedure (LEEP)	Excision of cervical tissue via an electrosurgical instrument. Diagnoses and treats cervical dysplasia. Minimal amount of tissue removed and preserves childbearing ability.	*Before:* Teach about procedure. May be done in the HCP's office. Patient may feel slight tingling or abdominal cramping during procedure. *After:* Tell patient that discharge, bleeding, and cramping may occur for 1–3 days.
Ultrasound-guided biopsy	Use of ultrasound guidance while performing a biopsy. Ultrasound used to direct the biopsy needle into the region of interest and obtain a sample of tissue. Can diagnose infection, inflammation, or mass.	*Before:* Teach about procedure. Usually done as an outpatient. *After:* Tell patient to monitor for signs and symptoms of infection at biopsy site.

DES, Diethylstilbestrol.

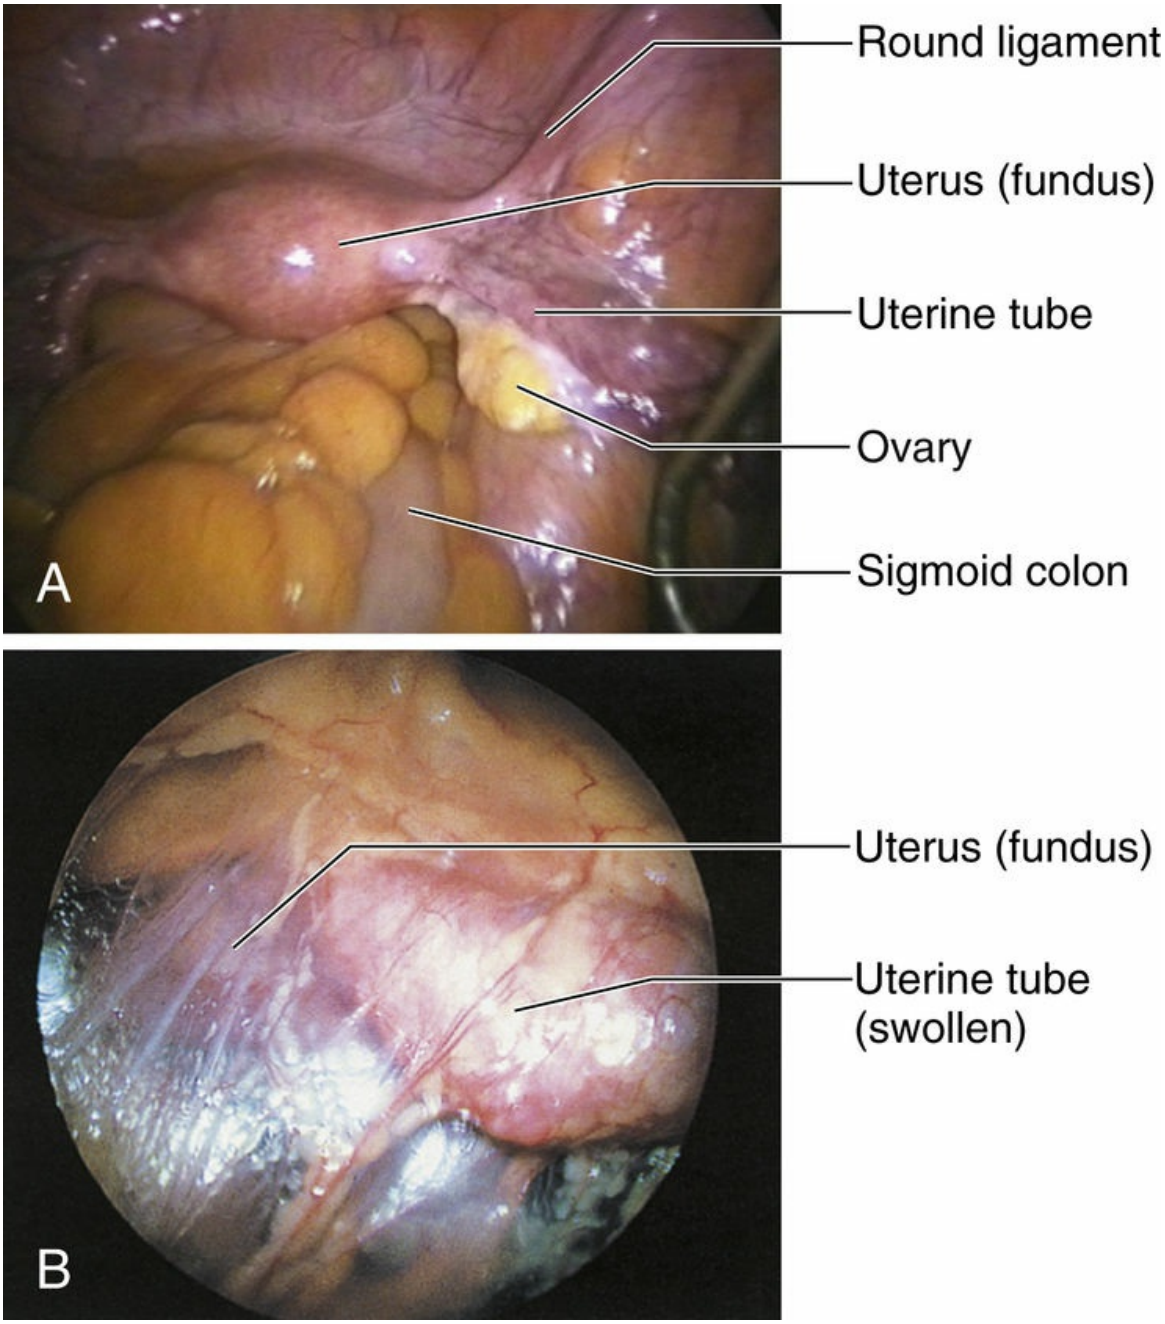

FIG 50.9 Laparoscopic views of the female pelvis. **A,** Normal image. **B,** Pelvic inflammatory disease. (Note reddish inflammatory membrane covering and fixing the ovary and uterus to the surrounding structures.) *A,* From Abrahams P, Marks S, Hutching R: *McMinn's color atlas of human anatomy,* ed 5, Philadelphia, 2003, Saunders. *B,* From Symonds EM, MacPherson MB: *Color atlas of obstetrics and gynecology,* London, 1994, Mosby Wolfe.

TABLE 50.13 Cytology and Microbiologic Studies

Study	Description and Purpose
Cultures	Specimens from urine to assess for gonorrhea, chlamydia or UTIs. Rectal and throat cultures may be taken depending on data from sexual history.
Gram stain	Used for rapid detection of gonorrhea. Presence of gram-negative intracellular diplococci generally needs treatment. Not highly accurate for women. A valid alternative for chlamydia testing.
Nucleic acid amplification test (NAAT)	Nonculture test used to identify small amounts of DNA or RNA in test samples. Sensitivity similar to culture tests. Uses ligase or polymerase chain reaction that amplifies the signal of the nucleic acids in the test sample so that they are easier to identify. CDC preferred method to test for gonorrhea, chlamydia, and trichomoniasis. Can be done on a wide variety of samples, including vaginal, endocervical, urethral, urine, rectal, and pharyngeal.
Papanicolaou (Pap) test	Microscopic study of exfoliated cervical cells to detect abnormal cells. *Conventional cytology* entails fixing cells directly to a slide at the time of collection and sending the slide to the laboratory for interpretation. In *liquid-based cytology* the specimen is sent to the laboratory in a liquid solution that preserves it and is processed for microscopic evaluation at the laboratory. Testing for HPV may be done on specimen obtained for liquid-based Pap test (see Chapter 53).
Wet mounts	Direct microscopic examination of vaginal discharge specimen is done immediately after collection. Determines presence or absence and number of *Trichomonas* organisms, bacteria, white and red blood cells, and candidal buds or hyphae.

TABLE 50.14 Fertility Studies

Study	Description and Purpose
Basal body temperature assessment	Indirectly indicates whether ovulation has occurred. Temperature rises at ovulation and stays high during secretory phase of normal menstrual cycle.
Semen analysis	Assesses semen for volume (2–5 mL), viscosity, sperm count (>20 million/mL), sperm motility (60% motile), and percent of abnormal sperm (60% with normal structure).
Serum anti-müllerian hormone, estradiol, FSH, progesterone	Same as serology studies. See Table 50.10.
Urinary LH	Over-the-counter "ovulation predictor kits." Identifies midcycle LH surge that precedes ovulation by 1 to 2 days.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A normal male reproductive function that may be altered in a patient who undergoes an orchiectomy (removal of testes) is the production of
   a. PSA.

b. GnRH.

c. testosterone.

d. seminal fluid.

2. Luteinizing hormone (LH) secretion by the anterior pituitary (*select all that apply)*

a. results in ovulation.

b. causes follicles to complete maturation.

c. affects development of ruptured follicles.

d. directly inhibits both GnRH and FSH secretion.

e. stimulates testosterone production by interstitial cells of testes.

3. Female orgasm is characterized by

a. resolution.

b. increased breast size.

c. relaxation of cervical os.

d. vasoconstriction and dystonia.

4. An age-related finding during the assessment of the older woman's reproductive system is

a. vaginal atrophy.

b. increased libido.

c. nipple enlargement.

d. increased vulvar skin turgor.

5. Significant information about a person's health history related to the reproductive system should include *(select all that apply)*

a. tobacco use.

b. intellectual status.

c. number of sexual partners.

d. previous history of shingles.

e. previous sexually transmitted infections.

6. Nucleic acid amplification tests (NAATs) used in the diagnosis of STIs can be obtained from *(select all that apply)*

a. urine.

b. vagina.

c. urethra.

d. rectum.

e. endocervix.

7. An abnormal finding noted during physical assessment of the male reproductive system is

a. descended testes.

b. symmetric scrotum.

c. slight clear urethral discharge.

d. the glans covered with prepuce.

8. The nurse is caring for a patient scheduled for hysteroscopy. The nurse explains to the woman that

a. the procedure treats cervical dysplasia.

b. bleeding and discharge are rare after the procedure.

c. the procedure involves curettage of the endometrial lining.

d. the procedure allows visualization of the lining of the uterus.

1. c, 2. a, b, c, e, 3. c, 4. a, 5. a, c, e, 6. a, b, c, d, e, 7. c, 8. d

Breast Disorders

Deena Dell

LEARNING OUTCOMES

1. State screening guidelines for the early detection of breast cancer.
2. Explain the types, causes, clinical manifestations, and interprofessional and nursing management of common benign breast disorders.
3. State the risk factors for breast cancer.
4. Describe the pathophysiology and clinical manifestations of breast cancer.
5. Describe the interprofessional and nursing management of breast cancer.
6. Specify the physical and psychologic aspects of nursing management for the patient undergoing breast cancer surgery.
7. Explain the indications for, types and complications of, and nursing management after reconstructive breast surgery.

Coping
Cellular Regulation
Infection
Pain
Sexuality

Breast disorders are a significant health concern for women. Whether the actual diagnosis is a benign condition or a cancer, the initial discovery of a lump or change in the breast often triggers intense feelings of anxiety and fear. The potential loss of a breast, or part of a breast, may be devastating for many women because of the significant psychologic, social, sexual, and body image implications

associated with it.

The most common breast disorders in women are fibrocystic changes, fibroadenoma, intraductal papilloma, ductal ectasia, and breast cancer. In a woman's lifetime, there is a 1 in 8 (12%) chance that she will be diagnosed with breast cancer.[1] Although rare, breast cancer does occur in men. Being aware of personal risk, including genetic factors, and taking part in recommended screening are important health promotion activities.

Assessment of Breast Disorders

Breast Cancer Screening Guidelines

Screening guidelines for the early detection of breast cancer vary depending on a woman's age and risk. For women at average risk for breast cancer, these are the American Cancer Society (ACS) recommended guidelines[2]:

- Women should undergo regular screening mammography starting at age 45 years.
- Women should be offered the chance to begin screening between the ages of 40 and 44.
- Women aged 45 to 54 years should be screened annually.
- Women 55 years and older should transition to biennial screening or be able to continue screening annually.
- Women should continue screening if their overall health is good, and they have a life expectancy of 10 years or longer.
- The ACS does not recommend depending on clinical breast examination (CBE) for breast cancer screening among average-risk women at any age.

Women at increased risk for breast cancer (family history, genetic link, prior breast cancer, history of thoracic radiation therapy, or certain atypical findings on a prior breast biopsy) should talk with their HCP about the benefits and limitations of starting screening

earlier with 3D mammography and breast magnetic resonance imaging (MRI) and having more frequent clinical breast encounters. A clinical encounter includes an assessment of risk factors, instruction in ways to reduce the risk factors, and a CBE.[3]

Consistent breast self-examination (BSE) may be a useful way to increase self-awareness of how one's breast normally look and feel. However, research has shown that BSE has no effect on reducing deaths from breast cancer. However, you still need to teach women the importance of knowing how their breasts look and feel and to report breast changes (e.g., nipple discharge, a lump) to their HCP.[3]

If a woman wants to learn about BSE, include information related to potential benefits, limitations, and harm (chance of a false-positive test result). Allow time for questions about the procedure and a return demonstration. For women who choose to perform BSE, teach the method described at *www.breastcancer.org/symptoms/testing/types/self_exam/bse_steps*.

Diagnostic Studies

Radiologic Studies

We use several techniques to screen for breast disorders or to help diagnose a suspicious physical finding. *Mammography* is a method used to visualize the breast's internal structure using x-rays (Fig. 51.1). This generally well-tolerated procedure can detect suspicious lumps that cannot be felt. Mammography has significantly improved the early and accurate detection of breast cancer. Improved imaging technology has reduced the radiation dose from mammography.

A comparison of current and prior mammograms may show early tissue changes. Because some tumors metastasize late, early detection by mammography allows for earlier treatment and the prevention of metastasis. In younger women, mammography is less sensitive because of the greater density of breast tissue, resulting in more false-negative results.

With digital mammography x-ray images are digitally coded and stored in a computer (Fig. 51.1). Digital mammograms are more

accurate than traditional film mammography in younger women with dense breasts. The availability and associated costs of digital mammography are issues related to this technology.

3D mammography, or tomosynthesis mammography, produces a 3D image of the breast. It gives a clearer view of overlapping breast tissue structures. It can increase the numbers of cancers detected and decrease the number of false-positive results (a result stating a cancer is present when it is not).[3]

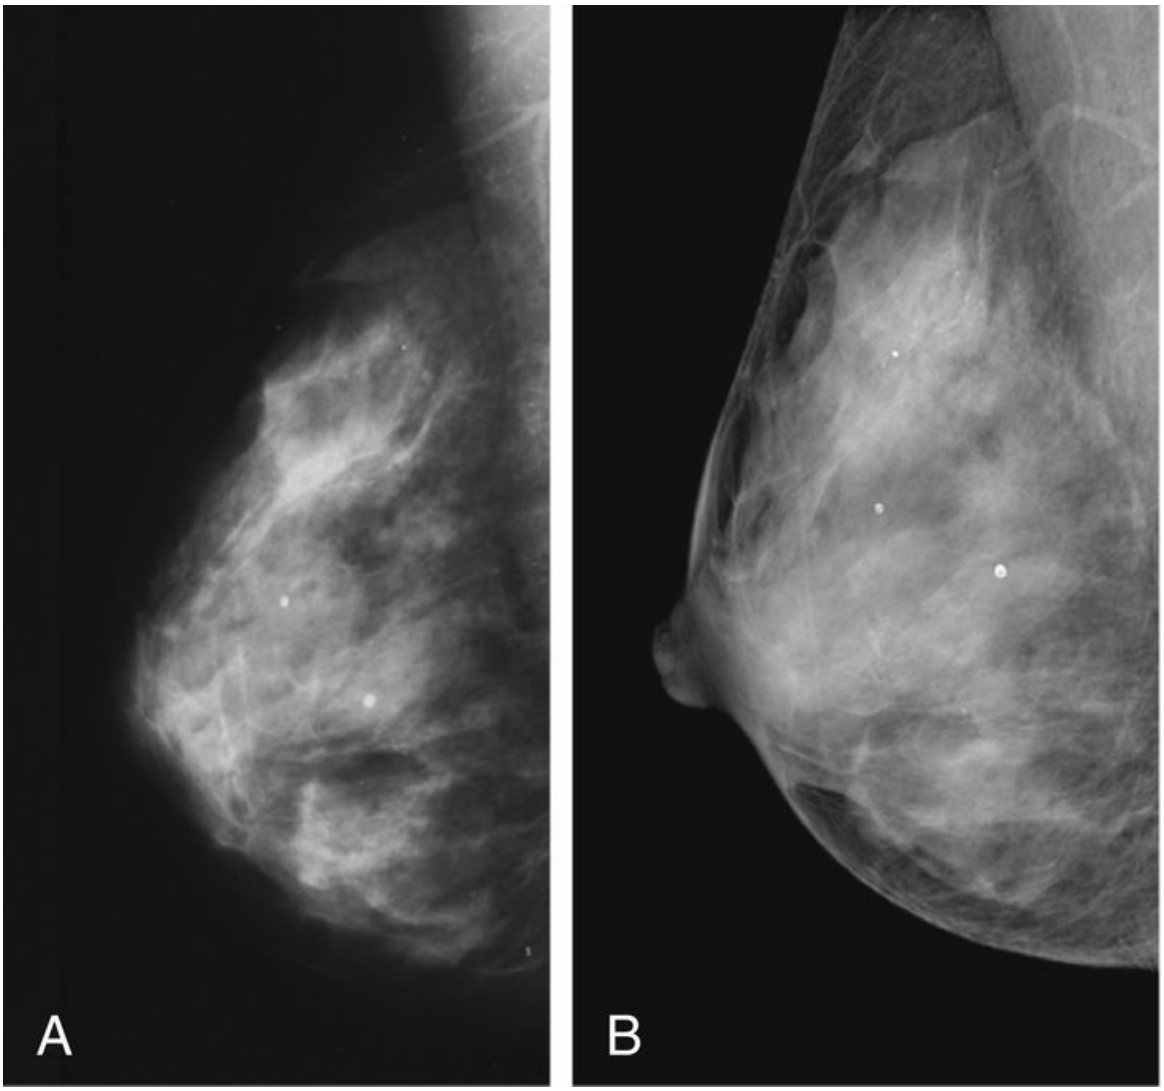

FIG. 51.1 Screening mammogram showing dense breast tissue and benign, scattered microcalcifications of a 57-year-old. **A,** Using conventional x-rays. **B,** Using digital x-rays.

From Adam A, Dixon AK, Grainger RG, et al: *Grainger and Allison's diagnostic radiology*, ed 5, St Louis, 2008, Churchill Livingstone.

Calcifications are the most easily recognized mammogram abnormality (Fig. 51.1). These deposits of calcium crystals form in the breast for many reasons, such as inflammation, trauma, and/or aging. Although most calcifications are benign, they may be associated with breast cancer.

About 10% to 15% of all breast cancers cannot be seen on mammography. They may be detected by palpation or other breast imaging studies, such as ultrasound and MRI. If the clinical findings are suspicious and the mammogram is normal, an ultrasound or MRI may be done. Based on these findings, a biopsy may be done.

Ultrasound is used in conjunction with mammography to discern a solid mass from a cystic mass, to evaluate a mass in a pregnant or lactating woman, and to locate and biopsy a suspicious lesion. MRI is recommended as a screening tool in addition to mammography for women who are at high risk for breast cancer (e.g., first-degree relative with a *BRCA* mutation).[3]

Biopsies

A definitive diagnosis of a suspicious area is made by analyzing biopsied tissue. Biopsy techniques include *fine-needle aspiration* (FNA), core (core needle), vacuum-assisted, and excisional biopsies.

FNA biopsy is done by inserting a needle into a lesion to sample fluid from a breast cyst, remove cells from intercellular spaces, or sample cells from a solid mass. Before the procedure, the breast area is first locally anesthetized. Then the needle is placed into the breast, and fluid and cells are aspirated into a syringe. Usually 3 or 4 passes are made. If the results are negative with a suspicious lesion, another biopsy may be necessary.

A *core (core needle) biopsy* involves removing small samples of breast tissue using a hollow "core" needle. For palpable lesions, this is done by fixing the lesion with one hand and performing a needle biopsy with the other. In the case of nonpalpable lesions, *stereotactic mammography*, ultrasound, or MRI image guidance is used.

Stereotactic mammography uses computers to pinpoint the exact location of a breast mass based on mammograms. With ultrasound, the HCP watches the needle on the ultrasound monitor to help guide it to the area of concern. Because a core biopsy removes more tissue than an FNA, it is more accurate.

Vacuum-assisted biopsy is a version of core biopsy that uses a vacuum technique to help collect the tissue sample. In core biopsy, several separate needle insertions are used to obtain multiple samples. During vacuum-assisted biopsy, the needle is inserted only once into the breast, and the needle can be rotated, which allows for multiple samples through a single needle insertion.

Minimally invasive breast biopsies have become the standard of care for diagnosing abnormalities found either on imaging studies or through CBE. However, in some cases an *excisional biopsy* is recommended. An excisional biopsy is done in an operating room.

Benign Breast Disorders

Mastalgia

Mastalgia, or breast pain, is the most common breast-related symptom reported in women. The most common form is *cyclic mastalgia*, which coincides with the menstrual cycle.[4] Women describe it as diffuse bilateral breast tenderness or heaviness. Breast pain may last 2 or 3 days or most of the month and is related to hormonal sensitivity. The symptoms often decrease with menopause.

Noncyclic mastalgia has no relationship to the menstrual cycle and can continue into menopause. It may be constant or intermittent throughout the month and last for several years. Symptoms include a burning, aching, or soreness in the breast. It usually affects only 1 breast. The pain may be from trauma, fat necrosis, ductal ectasia, costochondritis, or arthritic pain in the chest or neck radiating to the breast.

For patients with breast pain, mammography and targeted ultrasound are often done to exclude cancer and provide information

on the cause of the pain. Evidence supporting treatments for benign breast pain have yielded conflicting results. Some relief for cyclic pain may occur by reducing intake of caffeine and dietary fat; taking vitamin E or gamma-linolenic acid (evening primrose oil); and continually wearing a supportive bra. Compresses, ice, analgesics, and antiinflammatory drugs may help. Tamoxifen may provide relief with few side effects. Danazol is an FDA approved treatment. The androgenic side effects (acne, edema, hirsutism) make this therapy unacceptable for many women. Finally, you need to reassure women that mastalgia is not a usual sign of breast cancer.[4]

Breast Infections

Mastitis

Mastitis is an inflammatory condition of the breast that occurs most often in lactating women (Table 51.1). *Lactational mastitis* presents as a localized area that is erythematous, painful, and tender to palpation. Fever is often present. The infection develops when organisms (usually staphylococci) gain access to the breast through a cracked nipple. In its early stages, mastitis can be cured with antibiotics. Breastfeeding should continue unless an abscess is forming, or there is purulent drainage. The mother may wish to use a nipple shield or to hand-express milk from the involved breast until the pain subsides. The woman should see her HCP promptly to begin a course of antibiotic therapy. Any breast that stays red, tender, and not responsive to antibiotics requires follow-up care and evaluation for inflammatory breast cancer.[4,5]

Mastitis sometimes develops in women who are not lactating. This is called *periductal mastitis.* It is seen most often in regular smokers aged late 20s to early 30s. Treatment is the same as for lactating mastitis.

Lactational Breast Abscess

If lactational mastitis persists after several days of antibiotic therapy, a lactational breast abscess may be present. In this condition, the skin may become red and edematous over the involved breast, often with a corresponding palpable mass, and the patient may have a fever. Antibiotics alone are insufficient treatment for a breast abscess. Ultrasound-guided drainage of the abscess or surgical incision and drainage are needed. The drainage is cultured, sensitivities are obtained, and therapy with the appropriate antibiotic is begun. Breastfeeding can continue in most cases with ongoing treatment of the abscess.

Fibrocystic Changes

Fibrocystic changes in the breast are benign conditions characterized by changes in breast tissue (Fig. 51.2).[6,7] Fibrocystic changes are the most common breast disorder, occurring in more than 50% of women in North America. They occur most often in women between 30 and 50 years of age but may begin under 21 years of age in as many as 10% of women. Fibrocystic changes most often occur in women with premenstrual abnormalities, nulliparous women, women with a history of spontaneous abortion, nonusers of oral contraceptives, and women with early menarche and late menopause.

The use of the term *fibrocystic disease* is incorrect because the cluster of problems represent benign disorders. Fibrocystic changes include the development of excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cyst formation. We think these changes are due to a heightened responsiveness of breast tissue to circulating estrogen and progesterone. They may cause pain from chronic inflammation, edema, nerve irritation, and fibrosis. Pain and nodularity often increase over time. They tend to subside after menopause unless the woman is taking high doses of estrogen replacement. Symptoms related to fibrocystic changes often worsen in the premenstrual phase and subside after menstruation.

TABLE 51.1 Common Benign Breast Disorders

Disorder	Risk Factors	Clinical Manifestations
Lactational mastitis	Occurs in up to 10% of postpartum lactating mothers (both primipara and multipara), usually within first 3 mo after birth	• Warm to touch, indurated, painful, often unilateral • Most often caused by *Staphylococcus aureus*
Fibrocystic changes	Most common between ages 30 and 50	• Not usually discrete masses—nodularity instead • Usually accompanied by cyclic pain and tenderness • Mass(es) often cyclic in occurrence (movable, soft)
Cysts	Most common over age 35. Incidence decreases after menopause. Develop in over half of women in North America	• Palpable fluid-filled mass (movable, soft) • Multiple cysts can occur and recur • Rarely associated with breast cancer
Fibroadenoma	Often occurs in teens and those in their 20s	• Palpable mass (firm, movable), usually 1–3 cm in size • Rarely associated with breast cancer
Fat necrosis	Many women report a history of trauma to breast	• Usually a hard, tender, mobile, indurated mass with irregular borders
Ductal ectasia	Most common in women over 60 yr old. Considered a normal part of aging. May be due to duct obstruction or mastitis	• Nipple fixation, usually accompanied by nipple discharge of thick gray material • Often associated with breast pain

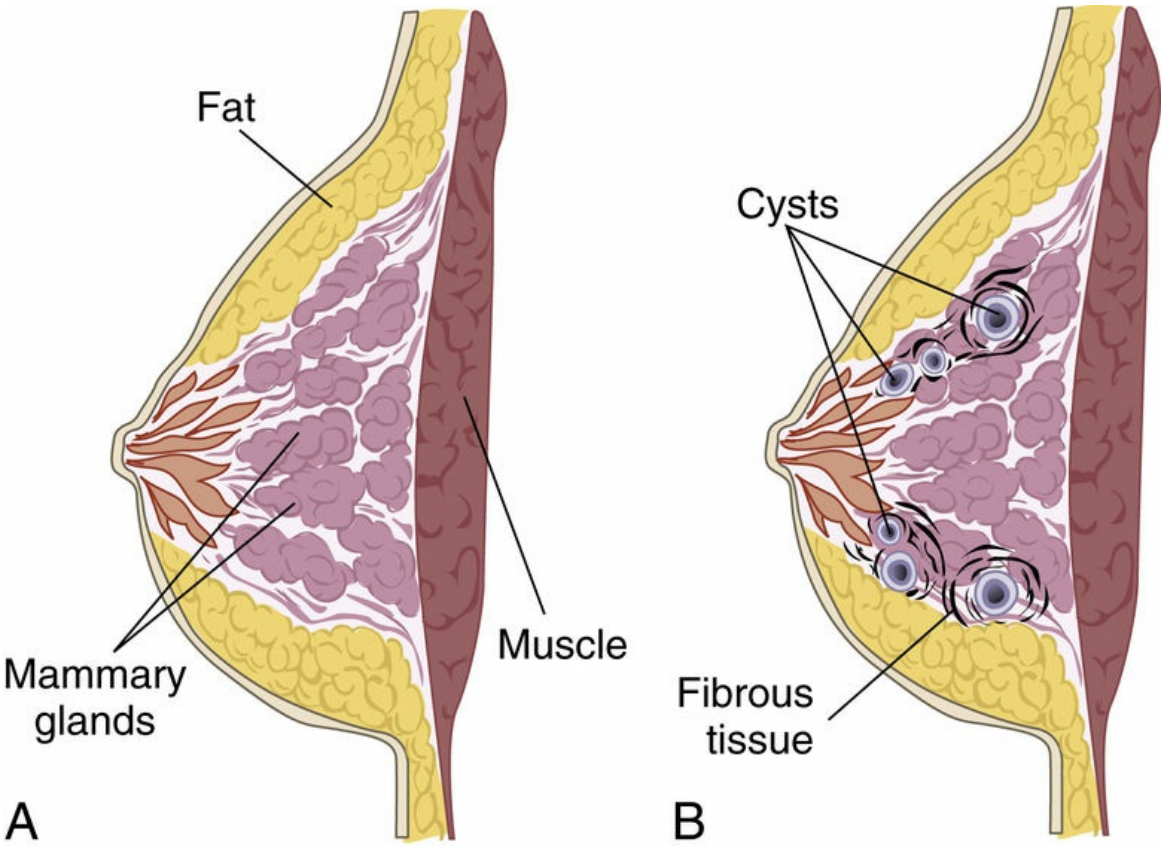

FIG. 51.2 **A,** Normal breast tissue. **B,** Fibrocystic breast tissue.

Manifestations of fibrocystic breast changes include 1 or more palpable lumps that are often round, well delineated, and freely movable within the breast (Table 51.1). Discomfort ranging from tenderness to pain may occur. The lump usually increases in size and sometimes tenderness before menstruation. Cysts may enlarge or shrink rapidly. Nipple discharge associated with fibrocystic breasts is often green or dark brown, not bloody.

Alone, fibrocystic changes are not associated with increased breast cancer risk. Masses or nodules can appear in both breasts. They often occur in the upper, outer quadrants and usually occur bilaterally.

Mammography may be helpful in distinguishing fibrocystic changes from breast cancer. However, in some women, the breast tissue is so dense that it is hard to obtain a mammogram. In these situations, ultrasound may be more useful in differentiating a fluid-filled cyst from a solid mass.

Interprofessional and Nursing Care

With the discovery of a discrete mass in the breast by a woman or her HCP, aspiration or biopsy may be indicated. If the nodularity is recurrent, a wait of 7 to 10 days may be planned in order to note any changes that may be related to the menstrual cycle. With large or frequent cysts, an excisional biopsy may be preferred over repeated aspiration. An excisional biopsy may be done if (1) no fluid is found on aspiration, (2) the fluid is hemorrhagic, or (3) a residual mass remains after fluid aspiration. The biopsy is usually done in an outpatient surgery unit.

Severe fibrocystic changes may make palpation of the breast more difficult. Teach the woman with cystic changes to maintain regular follow-up care with her HCP and encourage breast self-awareness and to report any changes found so they can be evaluated.

Treatment for a fibrocystic condition is similar to that described earlier for mastalgia. Teach the woman with fibrocystic breasts that she may expect a recurrence of the cysts in 1 or both breasts until menopause, and that the cysts may enlarge or become painful just

before menstruation. Reassure her that the cysts do not "turn into" cancer. Tell her that any new lump that does not respond in a cyclic manner over 1 to 2 weeks should be examined by her HCP.

Fibroadenoma

Fibroadenoma is the most common cause of discrete benign breast lumps in young women. It generally occurs in women in their teens and twenties and is found more often in blacks than whites.

The possible cause of fibroadenoma may be increased estrogen sensitivity in a localized area of the breast. Fibroadenomas are usually small (but can be large [2 to 3 cm]), painless, round, well delineated, and very mobile. They are usually solid, firm, and rubbery in consistency. There is no accompanying retraction or nipple discharge. The fibroadenoma may appear as a single unilateral mass, although multiple bilateral fibroadenomas may occur. Growth is slow and often ceases when the size reaches 2 to 3 cm. Menstruation does not affect size. However, pregnancy can stimulate dramatic growth.

Fibroadenomas are easily detected by physical examination and may be visible on mammography and ultrasound. However, definitive diagnosis requires FNA, core, or excisional biopsy and tissue examination to exclude a cancer. Treatment can include observation with regular monitoring if cancer is not present, there are no symptoms, and the mass stays less than 3 cm. A fibroadenoma that increases in size and/or is symptomatic should be removed by surgical resection or, in some cases, cryotherapy. All new lesions should be evaluated by breast ultrasound and possible biopsy.[3]

Nipple Discharge

Nipple discharge may occur spontaneously or because of nipple manipulation. A milky secretion is due to inappropriate lactation, or **galactorrhea**. It may be a result of certain medicines or endocrine or neurologic disorders. Nipple discharge may be idiopathic (no known cause).

Secretions can be serous, bloody, or brown to green. A cytology slide may be made of the secretion to determine the specific cause and recommended treatment. Disorders associated with nipple discharge include benign breast conditions, such as fibrocystic changes, intraductal papilloma, or ductal ectasia. In most cases, nipple discharge is not related to cancer.

Atypical Hyperplasia

Atypical hyperplasia is usually found after a biopsy is done to evaluate a suspicious area found on a mammogram or during a CBE. It can be in either the ducts (atypical ductal hyperplasia) or in the lobules (atypical lobular hyperplasia). Both are associated with an increased risk for developing breast cancer. To follow up on a diagnosis of atypical hyperplasia, an excisional biopsy or lumpectomy may be done to remove all the affected tissue.[6]

Intraductal Papilloma

An **intraductal papilloma** is a benign, soft or hard growth found in the mammary ducts. It is usually unilateral. Typically, the nipple has a bloody discharge that can be intermittent or spontaneous. Most intraductal papillomas are beneath the areola and may be difficult to palpate. They usually occur in women 30 to 50 years of age. A single duct or several ducts may be involved. Papillomas are associated with a slightly increased risk for developing breast cancer. So, a core biopsy should be done. If any abnormal cells are found, surgical excision of the papilloma and the involved duct or duct system is done.[8]

Ductal Ectasia

Ductal ectasia (duct dilation) is a benign breast disease of perimenopausal and postmenopausal women involving the ducts in the subareolar area. It usually involves several bilateral ducts. Nipple

discharge is the primary symptom. Ductal ectasia is initially painless but may progress to burning, itching, pain around the nipple, and swelling in the areolar area. Inflammatory signs are often present, and the nipple may retract. The discharge may become bloody in more advanced disease. It is not associated with cancer. If an abscess develops, warm compresses and antibiotics are usually effective treatments. Therapy consists of close follow-up examinations or surgical excision of the involved ducts.

Male Gynecomastia

Gynecomastia is a transient, noninflammatory enlargement of 1 or both breasts. It is the most common breast problem in men. The condition is usually temporary and benign. Gynecomastia itself is not a risk factor for breast cancer. The most common cause of gynecomastia is a change in the normal ratio of active androgen to estrogen in plasma or within the breast itself.[6]

Gynecomastia can occur in puberty. During puberty, there is often a transient relative imbalance between estrogen and testosterone, leading to gynecomastia. This condition usually resolves by age 20 years when adult androgen-to-estrogen ratios are reached. The treatment of pubertal gynecomastia is reassurance of the parent and teenager about the benign nature of the condition.

Gynecomastia can be a manifestation of other problems. It may accompany diseases such as testicular tumors, adrenal cancer, pituitary adenomas, hyperthyroidism, and liver disease. It can be a side effect of drug therapy, particularly with estrogen and androgen, digitalis, isoniazid, ranitidine, and spironolactone. Marijuana use can also cause gynecomastia.

Senescent Gynecomastia

Senescent gynecomastia occurs in many older men. The likely cause is high plasma estrogen levels with the increased conversion of androgens to estrogens in peripheral circulation. Although initially

unilateral, the tender, firm, centrally located enlargement may become bilateral. A discrete, circumscribed mass with gynecomastia must be biopsied to determine if it is the rare breast cancer in males. Senescent hyperplasia needs no treatment. It usually regresses within 6 to 12 months.

Gerontologic Considerations: Age-Related Breast Changes

The loss of subcutaneous fat and structural support and the atrophy of mammary glands often result in pendulous breasts in the postmenopausal woman. Encourage older women to wear a well-fitting bra. Adequate support can improve physical appearance and reduce pain in the back, shoulders, and neck. It can also prevent *intertrigo,* dermatitis caused by friction between opposing surfaces of skin. Sagging breasts can be surgically lifted (mastopexy).

The decrease in glandular tissue makes a breast mass easier to palpate. This decreased density likely results from age-related decreases in estrogen. Rib margins may be palpable in a thin woman and can be confused with a mass. That is why it is so important that women become familiar with their own breasts and what is normal for them. Because the incidence of breast cancer increases with age, encourage breast awareness in older women. Encourage them to have an annual mammogram and CBE and have any breast-related concern evaluated by their HCP.

Breast Cancer

Breast cancer is the most common cancer in American women except for skin cancer. It is second only to lung cancer as the leading cause of death from cancer in women. In the United States, more than 255,180 new cases of invasive breast cancer and more than 60,000 cases of in situ breast cancer are diagnosed annually. Another 2470 cases of breast cancer happen in men. About 41,070 deaths occur each year related to breast cancer.[1]

The incidence of breast cancer is slowly decreasing, with a slight drop in the number of deaths related to breast cancer. This decline may be the result of the decreased use of hormone therapy after menopause as well as earlier detection and advances in treatment. Breast cancer survivors are the largest group of any cancer survivors.[1]

Etiology and Risk Factors

Although we do not completely understand the cause, several risk factors are related to breast cancer (Table 51.2). Risk factors appear to be cumulative and interacting. So, the presence of multiple risk factors may greatly increase the overall risk, especially for people with a positive family history.

TABLE 51.2 Risk Factors for Breast Cancer

Risk Factor	Comments
Age ≥50 yr	Majority found in postmenopausal women After age 60, ↑ in incidence
Alcohol use	Drinking ≥1 alcoholic beverage per day may have an ↑ risk
Benign breast disease with atypical epithelial hyperplasia, lobular carcinoma in situ	Atypical changes in breast biopsy ↑ risk
Early menarche (before age 12), late menopause (after age 55)	A long menstrual history ↑ risk
Exposure to ionizing radiation	Radiation damages DNA (e.g., prior treatment for Hodgkin's lymphoma)
Family history	Breast cancer in a first-degree relative, particularly when premenopausal or bilateral
Female	Women account for 99% of breast cancer cases
First full-term pregnancy after age 30, nulliparity, no breastfeeding	Prolonged exposure to unopposed estrogen ↑ risk
Genetic factors (*BRCA1, BRCA2, P53, PTEN, PALB2, ATM, CHEK2, NBM*)	Gene mutations play a role in up to 10% of breast cancer cases
Hormone use	Use of estrogen and/or progesterone as hormone therapy, especially in postmenopausal women
Long-term heavy smoking	May ↑ risk, especially in women who begin smoking before first pregnancy
Personal history of breast, colon, endometrial, or ovarian cancer	Personal history significantly ↑ risk for breast cancer, risk for cancer in other breast, and recurrence
Physical inactivity	Risk ↑s most after menopause
Weight gain and obesity after menopause	Fat cells store estrogen, which ↑ the risk for developing breast cancer

Risk Factors for Women

The risk factors most associated with breast cancer include female

gender and advancing age. Women are at far greater risk than men, with 99% of breast cancers occurring in women. Increasing age also increases the risk for developing breast cancer. The incidence of breast cancer in women under 25 years of age is very low. Risk increases gradually until age 60. After age 60, the incidence increases dramatically.

Hormonal regulation of the breast is related to breast cancer development, but the mechanisms are poorly understood. The hormones estrogen and progesterone may act as tumor promoters to stimulate breast cancer growth if cancer changes in the cells have already occurred. The Women's Health Initiative study showed that combined hormone therapy (estrogen plus progesterone) (1) increases the risk for breast cancer after as little as 2 years use and (2) increased the risk for having a larger, more advanced breast cancer at diagnosis. Using estrogen therapy alone for longer than 15 years (for women with a prior hysterectomy) increases a woman's long-term risk for breast cancer in some studies.[9] A link also exists between oral contraceptive use and increased risk for breast cancer. This risk decreases when use stops and is gone after 10 years.

Modifiable risk factors include excess weight gain during adulthood, sedentary lifestyle, smoking, dietary fat intake, obesity, and alcohol use. Environmental factors, such as radiation exposure, may play a role.

Genetic Link

Family history of breast cancer is an important risk factor, especially if the involved family member also had ovarian cancer, was premenopausal, had bilateral breast cancer, or is a first-degree relative (i.e., mother, father, sister, brother, daughter). Having any first-degree relative with breast cancer doubles a woman's risk for breast cancer, especially if the relative was diagnosed at a young age.[10,11] A breast cancer risk assessment tool for HCPs is available (*www.cancer.gov/bcrisktool*). Genetic counseling must be considered for a person at high risk for breast cancer.

Up to 10% of all breast cancers are hereditary. This means that specific genetic abnormalities that contribute to breast cancer development have been inherited. Most inherited cases of breast cancer are associated with mutations in 2 genes: *BRCA1* and *BRCA2*. *BRCA* stands for *BR*east *CA*ncer. Everyone has *BRCA* genes. The *BRCA1* gene, found on chromosome 17, is a tumor suppressor gene that inhibits tumor development when functioning normally. Women who have *BRCA1* mutations have a 41% to 90% lifetime chance of developing breast cancer along with an increased risk for developing cancer in the other breast. The *BRCA2* gene, found on chromosome 11, is another tumor suppressor gene. Women with a mutation of this gene have a similar risk for breast cancer.[10,11]

Genetics in Clinical Practice

Breast Cancer

Genetic Basis

- Mutations occur in *BRCA1* and/or *BRCA2* genes.
- Normally, these genes are tumor suppressor genes involved in DNA repair.
- Transmission is autosomal dominant.
- Other genes (e.g., *ATM, CHEK-2, p53, PTEN, PALB2, NBM, NF1, STR11, CHD1*) may increase the risk for breast cancer.

Incidence

- Up to 10% of breast cancers are related to *BRCA1* and *BRCA2* gene mutations.
- As many as 1 in 300 to 800 women in the United States have *BRCA1* and *BRCA2* gene mutations.[11]

- Women with *BRCA1* and *BRCA2* gene mutations have a 41% to 90% lifetime risk for developing breast cancer.
- Mutations in *BRCA* genes may cause as many as 90% of all inherited breast cancers.
- *BRCA1* and *BRCA2* gene mutations are associated with early-onset breast cancer that is more likely to involve both breasts.
- Men with mutations in *BRCA1* and *BRCA2* have an increased risk for breast cancer and prostate cancer.
- Family history of both breast and ovarian cancer increases the risk for having a *BRCA* mutation.

Genetic Testing

- DNA testing is available for *BRCA1* and *BRCA2* gene mutations.
- Genetic tests can analyze an entire panel of genes in specific breast cancer patient populations.

Clinical Implications

- Most breast cancers (about 90%) are not inherited. They are associated with genetic changes that occur after a person is born (somatic mutations). There is no risk for passing on the mutated gene to children.
- Bilateral oophorectomy and/or bilateral mastectomy reduces the risk for breast cancer and ovarian cancer in women with *BRCA1* and *BRCA2* mutations.
- Women with *BRCA* mutations have a higher risk for developing ovarian, colon, pancreatic, and uterine cancers.[11]
- Genetic counseling and testing for *BRCA* mutations should be offered to patients whose personal or family history puts them at high risk for a genetic predisposition to breast cancer.

In addition to *BRCA* gene mutations, we have identified many other abnormal genes that increase a person's risk for developing breast cancer. These include the tumor suppressor genes *p53* and *PTEN* (which inhibit tumor development when functioning normally), *ATM and NBM* (which help to repair damaged deoxyribonucleic acid [DNA]), *CHEK2* (which stops tumor growth), *PALB2* (which partners with *BRCA* to suppress tumor growth), and *CDH1* (which makes a protein to bind cells together).[12]

Most people who develop breast cancer do not have an abnormal breast cancer gene or a family history of breast cancer. Ongoing research continues to look at the role of genes in the development of breast cancer.

Risk Factors for Men

Predisposing risk factors for breast cancer in men include hyperestrogenism, a family history of breast cancer, and radiation exposure. A thorough examination of the male breast should be a routine part of a physical examination. Men in *BRCA*-positive families should consider genetic testing. Teach men who test positive for a *BRCA* gene mutation to be aware of how their breasts look and feel and to report any changes to their HCP. They should have a CBE every year starting at age of 35. Screening mammography is not recommended as there is no evidence showing this to be of benefit. These men should begin prostate screening at age 35 as they have an increased risk for developing prostate cancer.[11]

Prophylactic Oophorectomy and Mastectomy

In women with *BRCA1* or *BRCA2* mutations, prophylactic bilateral oophorectomy can decrease the risk for breast and ovarian cancers. Removing the ovaries lowers the risk for breast cancer because the ovaries are the main source of estrogen in a premenopausal woman. Removing the ovaries does not reduce the risk for

Check Your Practice

Your best female friend calls you on the phone, and you can tell she has been crying. Her mother has just been diagnosed with stage 3A breast cancer. Between sobs, she tells you that her grandmother died of breast cancer and her aunt (her mother's sister) is receiving chemotherapy for breast cancer. She asks you, "Don't you think that I should just get mine whacked off? Then I would not have to worry anymore."

- How would you respond to her?

breast cancer in postmenopausal women because the ovaries are not the main producers of estrogen in these women. Women with *BRCA* mutations also have a higher risk for developing breast cancer in the unaffected (contralateral) breast. So, they may, as might any woman who has a high risk for developing breast cancer choose, in consultation with her HCP and genetic counselor, to undergo prophylactic bilateral mastectomy.

Pathophysiology

The main components of the breast are lobules (milk-producing glands) and ducts (milk passages that connect the lobules and the nipple). In general, breast cancer arises from the epithelial lining of the ducts *(ductal carcinoma)* or from the epithelium of the lobules *(lobular carcinoma).* Breast cancers may be in situ (within the duct) or invasive (invading through the wall of the duct).

Metastatic breast cancer is breast cancer that has spread to other organs. The most common sites are the bone, liver, lung, and brain. Cancer growth rates can range from slow to rapid. Factors that affect cancer prognosis are tumor size, axillary node involvement (the more nodes involved, the worse the prognosis), tumor differentiation, estrogen and progesterone receptor status, and *human epidermal growth factor receptor 2* (HER-2) status. HER-2 is a protein that helps regulate cell growth.[13]

Types of Breast Cancer

Breast cancer is not just one disease, but a group of diseases characterized by different pathologic findings and clinical behaviors. Breast cancer can be classified as (1) ductal or lobular or other or (2) noninvasive or invasive (Table 51.3). We can also classify it based on hormonal status and genetic subtypes.

Noninvasive Breast Cancer

An estimated 20% of breast cancers are noninvasive. These intraductal cancers include *ductal carcinoma in situ* (DCIS) and pure Paget's disease.[13]

DCIS tends to be unilateral and may progress to invasive breast cancer if left untreated. Treatment options include breast-conserving treatment (lumpectomy) with or without radiation therapy, total mastectomy with or without sentinel lymph node biopsy, and/or hormone therapy (e.g., tamoxifen) to prevent recurrences.[14]

In the past, *lobular carcinoma in situ* (LCIS) was considered a noninvasive breast cancer. However, it has now been reclassified as a benign condition that is a risk factor for developing breast cancer.[13] No surgical or radiation treatment is indicated for LCIS. Hormone therapy may be used as a preventive measure to reduce breast cancer risk for some patients.

Invasive Ductal Carcinoma

Invasive (infiltrating) ductal carcinoma is the most common type of breast cancer. It accounts for about 80% of all invasive breast cancers. It starts in the milk ducts, then breaks through the walls of the duct, invading the surrounding tissue. From there it may metastasize to other parts of the body. Subtypes of invasive ductal carcinoma include medullary carcinoma, tubular carcinoma, colloid (mucinous) carcinoma, papillary carcinoma, and metaplastic carcinoma.

TABLE 51.3 Classification of Breast Cancer

Based on Tissue Type

- Ductal carcinoma (affects milk ducts)
    - Medullary
    - Tubular
    - Colloid (mucinous)
- Lobular carcinoma (affects milk-producing glands)
- Other
    - Inflammatory
    - Paget's disease
    - Phyllodes tumor

Based on Invasiveness
Noninvasive (In situ)

- Ductal carcinoma in situ (DCIS)
- Pure Paget's disease

Invasive (Spreading to Other Locations)

- Invasive ductal carcinoma
- Invasive lobular carcinoma

Based on Hormone Receptor and Genetic Status
Estrogen and Progesterone Receptor Status

- Estrogen receptor positive
- Estrogen receptor negative
- Progesterone receptor positive

- Progesterone receptor negative

HER-2 Genetic Status

- HER-2 positive
- HER-2 negative

Invasive Lobular Carcinoma

Invasive (infiltrating) lobular carcinoma begins in the lobules (milk-producing glands) of the breast. It accounts for about 10% to 15% of invasive breast cancers. The cancer cells can break out of the lobule and metastasize to other areas of the body. Invasive lobular carcinoma usually presents as a subtle thickening in the upper outer quadrant of the breast. It is often not detected by mammography.

Other Types of Breast Cancer

Inflammatory Breast Cancer

Inflammatory breast cancer is an aggressive and fast-growing breast cancer with a high risk for metastasis. It accounts for about 1% to 3% of all breast cancers. In the early stages, it is often mistaken for mastitis. However, the inflammatory changes do not improve with antibiotics, because cancer cells block the lymph channels in the skin of the breast. Because of skin involvement, the breast looks red, feels warm, and has a thickened appearance that is often described as looking like an orange peel *(peau d'orange)*. Sometimes, the breast develops ridges and small bumps that look like hives. A breast mass may not be present. Changes may not show up on mammograms, making diagnosis difficult. Inflammatory breast cancer is associated with a worse prognosis as compared to invasive ductal and lobular breast cancers.[14]

Paget's Disease

Paget's disease is a rare breast cancer that starts in the breast ducts and spreads to the nipple and areola. It causes about 1% of all breast cancers. It is different from Paget's disease of the bone, which is discussed in Chapter 63. Most women with Paget's disease have underlying ductal carcinoma. Only in rare cases is the cancer confined to the nipple and not associated with some invasive cancer (in situ).

Itching, burning, bloody nipple discharge with superficial skin erosion and ulceration may be present. A pathologic examination of the lesion confirms the diagnosis. Nipple changes are often diagnosed as an infection or dermatitis, which can lead to treatment delays.

The treatment of Paget's disease is surgical removal of the involved tissue by either central lumpectomy or mastectomy with or without sentinel node biopsy. Radiation therapy may be used after surgery. The prognosis is good when the cancer is confined to the nipple.[14]

Phyllodes Tumor

A phyllodes tumor is a very rare tumor that develops in the connective tissue (stroma) of the breast. The tumors tend to grow quickly, within a period of weeks or months, to a size of 2 to 3 cm or sometimes larger. Although most are benign, some are cancerous. Treatment is usually excision with a wide margin. Axillary surgery is not necessary.[14]

Triple-Negative Breast Cancer

A patient whose breast cancer tests negative for all 3 receptors (estrogen, progesterone, HER-2) has *triple-negative breast cancer*. Receptor testing is discussed on p. 1198. The incidence of triple-negative breast cancer is higher in blacks, Hispanics, premenopausal women, and those with a *BRCA1* mutation. These patients tend to have more aggressive tumors with a poorer prognosis. These cancers do not respond to hormone therapy or therapy for HER-2. Chemotherapy appears to be the more successful for treating triple-negative breast cancer.

Clinical Manifestations

Breast cancer is usually detected as a lump or thickening in the breast or mammography abnormality. It occurs most often in the upper, outer quadrant of the breast, which is the location of most of the glandular tissue (Fig. 51.3). Breast cancers vary in their growth rate. If palpable, breast cancer is characteristically hard and may be irregularly shaped, poorly delineated, nonmobile, and nontender.

A small number of breast cancers cause nipple discharge. The discharge is usually unilateral and may be clear or bloody. Nipple retraction may occur. Peau d'orange may occur due to plugging of the dermal lymphatics. In large cancers, infiltration, induration, and dimpling pulling in) of the overlying skin may occur.

Complications

The main complication of breast cancer is recurrence (Table 51.4). Recurrence may be *local* or *regional* (skin or soft tissue near the mastectomy site, axillary or internal mammary lymph nodes) or distant. Widely disseminated or metastatic disease involves the growth of cancerous breast cells in parts of the body distant from the breast (most often involving the bone, lung, brain, liver). Metastases primarily occur through the lymphatics, usually those of the axilla (Fig. 51.4). However, metastatic disease can occur anywhere.

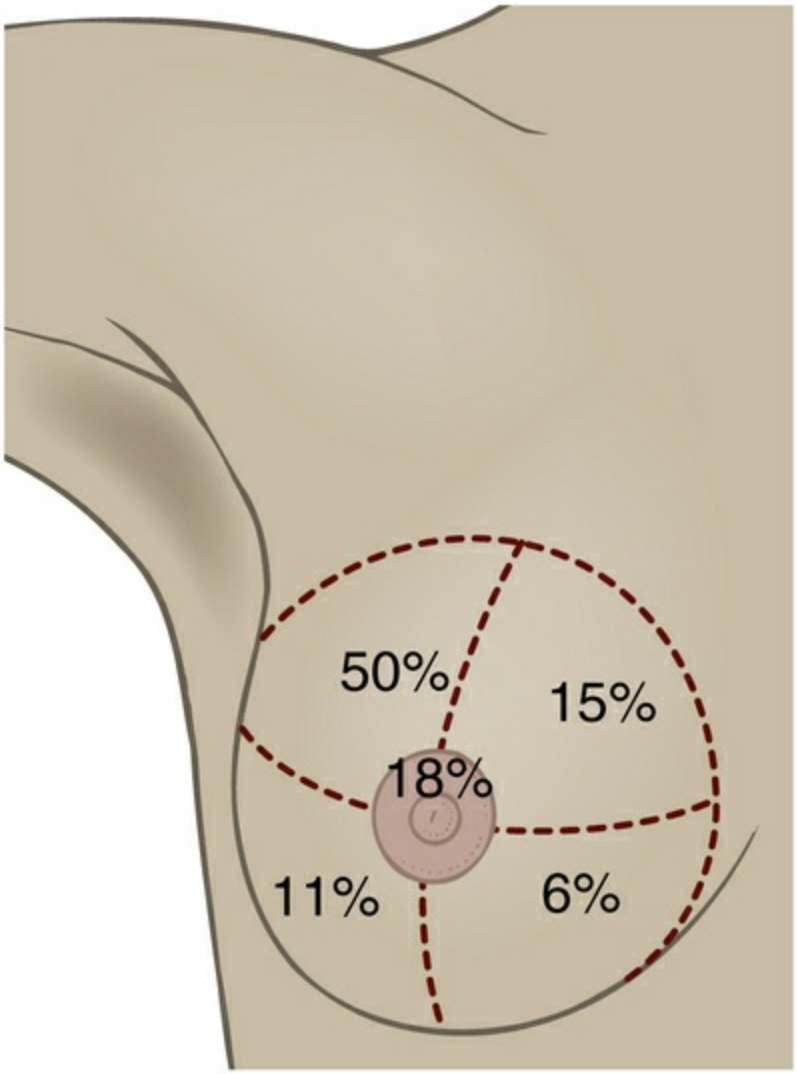

FIG. 51.3 Distribution of where breast cancer occurs.

Diagnostic Studies

In addition to radiologic and biopsy studies used to diagnose breast cancer (see earlier discussion in this chapter on p. 1191), other tests are used to predict the risk for local or systemic recurrence. These tests include axillary lymph node analysis, tumor size, estrogen and progesterone receptor status, cell-proliferative indices (number of cells that are dividing), and genomic assays.

Axillary Lymph Node Analysis

Axillary lymph node involvement is an important prognostic factor in breast cancer. *Axillary lymph nodes* are often examined to see if cancer has spread to the axilla on the same side of the breast as the cancer (Fig. 51.4). The more nodes involved, the greater the risk for recurrence.

A *sentinel lymph node biopsy* (SLNB) helps to identify the lymph node(s) that drain first from the tumor site. Those nodes are called *sentinel node(s)* (SLN). In SLNB, a radioisotope and/or blue dye, which will travel the same route as the cancer, is injected into the affected breast. Then, in surgery, the HCP determines if the radioisotope (using radioactive detector) or dye (visually see blue nodes) is found in any SLNs. A local incision is made in the axilla, and the HCP dissects the blue-stained and/or radioactive SLNs. Generally, with SLNB, 1 to 4 axillary lymph nodes are removed. The nodes are sent for pathologic analysis. If the SLNs are negative, no further axillary surgery is needed.

TABLE 51.4 Sites of Breast Cancer Recurrence and Metastasis

Site	Manifestations
Local Recurrence	
Skin, chest wall	Firm, discrete nodules. Sometimes pruritic, usually painless, often in or near a scar
Regional Recurrence	
Lymph nodes	Enlarged nodes in axilla or supraclavicular area, usually nontender
Distant Metastasis	
Bone marrow	Anemia, infection, ↑ bleeding, bruising, petechiae. Weakness, fatigue, mild confusion, light-headedness, dyspnea
Brain	Headache described as "different," unilateral sensory loss, focal muscular weakness, hemiparesis, incoordination (ataxia), nausea and vomiting unrelated to medication, cognitive changes
Liver	Abdominal distention. Right lower quadrant abdominal pain sometimes radiating to scapular area. Nausea and vomiting, anorexia, weight loss. Weakness and fatigue. Hepatomegaly, ascites, jaundice. Peripheral edema. High liver enzymes
Lung (including lung nodules and pleural effusions)	Shortness of breath, tachypnea, nonproductive cough
Skeletal	Localized pain of gradually increasing intensity, percussion tenderness at involved sites, pathologic fracture caused by involvement of bone cortex
Spinal cord	Progressive back pain, localized and radiating. Change in bladder or bowel function. Loss of sensation in lower extremities

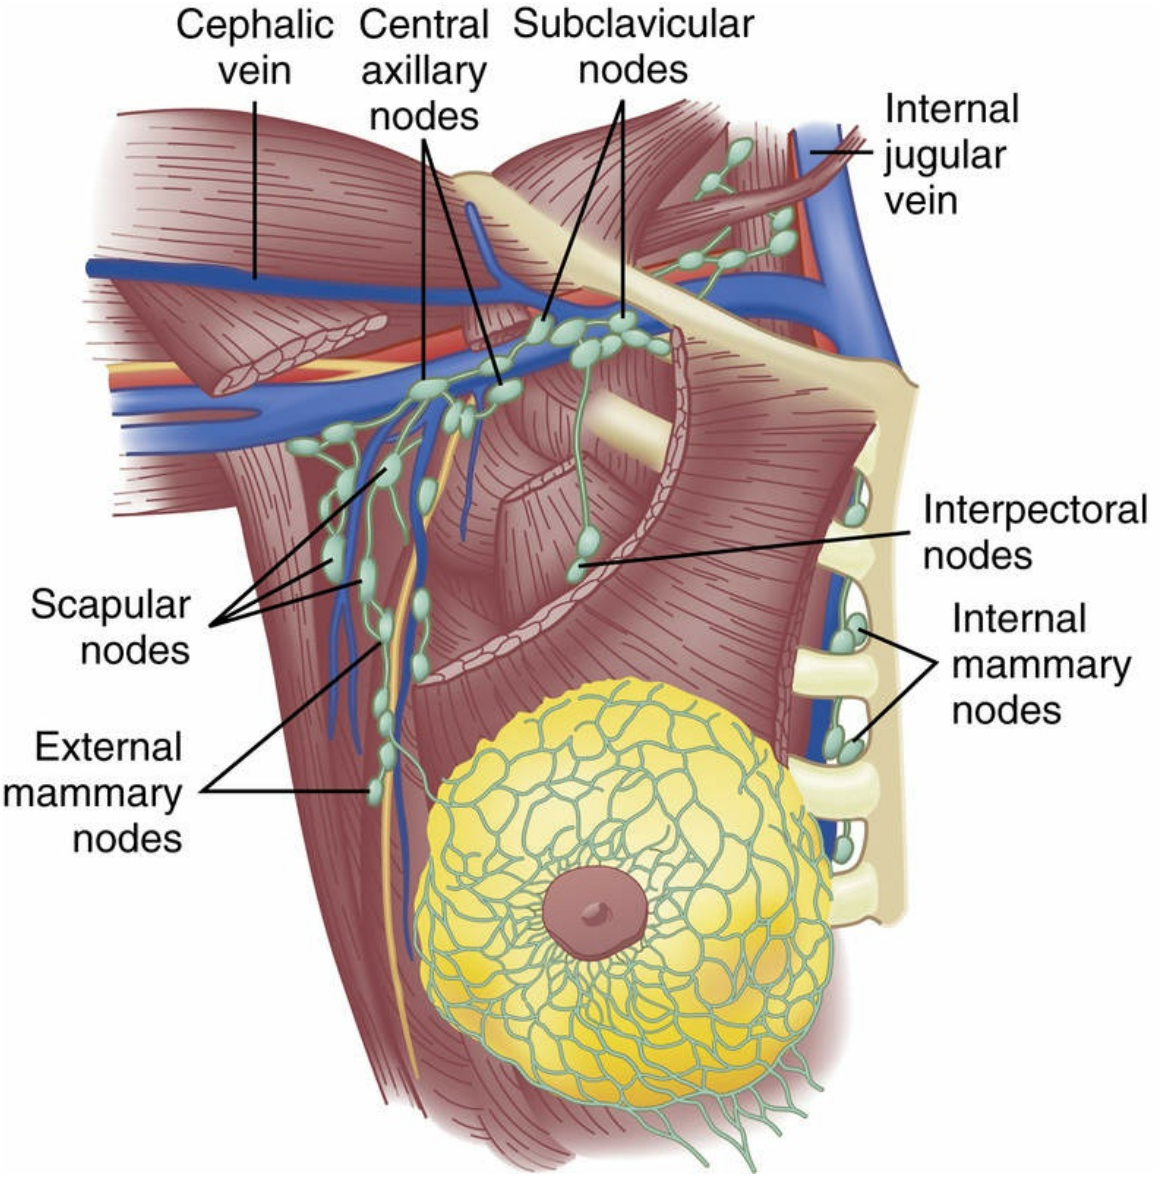

FIG. 51.4 Lymph nodes and drainage in the axilla. The sentinel lymph node is usually found in the external mammary nodes. A complete axillary dissection would remove all nodes.
From Donegan WL, Spratt JS: *Cancer of the breast,* ed 3, Philadelphia, 1988, Saunders.

If the SLNs are positive, a complete *axillary lymph node dissection* (ALND) may be done. In an ALND, the HCP will typically remove 12 to 20 lymph nodes. SLNB is less invasive than ALND and is associated with lower morbidity rates compared with ALND.

Tumor Size

Tumor size is a prognostic variable. In general, the larger the tumor, the poorer the prognosis. The wide variety of biologic types of breast cancer explains the variability of disease behavior. In general, the more well differentiated (like the original cell type) the tumor, the less aggressive it is. The cells of poorly differentiated (unlike the original cell type) tumors appear morphologically disorganized, and they are more aggressive.

Estrogen and Progesterone Receptor Status

Estrogen receptor (ER) and progesterone receptor (PR) status is another diagnostic test useful for decisions about both treatment and prognosis. Receptor-positive tumors (1) often show histologic evidence of being well differentiated, (2) have a lower chance for recurrence, (3) often have a *diploid* (more normal) DNA content and low proliferative indices, and (4) are often hormone dependent and responsive to hormone therapy. Receptor-negative tumors (1) are often poorly differentiated histologically, (2) often recur, (3) have a high incidence of *aneuploidy* (abnormally high or low DNA content) and higher proliferative indices, and (4) are usually unresponsive to hormone therapy. Ploidy status (number of chromosomes in a cell) correlates with tumor aggressiveness. Diploid tumors have a much lower risk for recurrence than aneuploid tumors.

Cell-Proliferative Indices

Cell-proliferative indices indirectly measure the rate of tumor cell proliferation. The number of tumor cells in the synthesis (S) phase of the cell cycle (see Chapter 15, Fig. 15.1) is another important prognostic indicator. Although cell-proliferative indices are not routinely done as part of the breast cancer pathology evaluation, patients with cells that have high S-phase fractions have a higher risk for recurrence and earlier cancer death.

Genomic Assay

An important *genomic assay* is to determine HER-2, which is a

prognostic indicator. Overexpression of HER-2 is associated with unusually aggressive tumor growth, a greater risk for recurrence, and a poorer prognosis. HER-2 is overexpressed in 10% to 20% of patients with breast cancer. The presence of HER-2 helps in the selection and sequence of drug therapy and predicts the patient's response to treatment.

A *genomic* test uses a sample of the breast cancer tissue to analyze the activity of a group of genes that can affect how a cancer is likely to behave and respond to treatment. Knowing whether certain genes are present or absent, or overly active or not active enough, can provide information about the risk for recurrence and the expected benefit of chemotherapy or hormone therapy. The 21-gene recurrence (OncotypeDX) test is the most often used genomic test.[15] Other genomic tests are MammaPrint, PAM50 (Prosigna), EndoPredict, and the Breast Cancer Index.

Interprofessional Care

A wide range of treatment options is available to the patient and HCPs making critical decisions about how to treat breast cancer (Table 51.5). The treatment plan is often determined by prognostic factors, the clinical stage, and biology of the cancer.

Staging of Breast Cancer

The most widely accepted staging method for breast cancer is the TNM system. This system uses traditional anatomic factors of tumor size (T), nodal involvement (N), and presence of metastasis (M) to determine the stage of disease (Table 51.6). The stages range from 0 to IV, with stage 0 being in situ cancer with no lymph node involvement and no metastasis. Stage IV indicates metastatic spread, regardless of tumor size or lymph node involvement. This system is used worldwide to communicate the size of a breast cancer and the extent to which it has spread. It provides an accurate prediction of the outcome of a group of patients.

The latest cancer staging guidelines add biologic factors in making

the final determination of stage. These enable more accurate determination of prognosis and appropriate systemic therapy. These factors include tumor grade, hormone receptor expression, HER-2 overexpression and/or amplification, and genomic panels.[13]

For example, some larger tumors will now be considered stage I instead of stage II based on their biology. For patients with hormone receptor–positive, HER2-negative, lymph node–negative tumors, and a low-risk gene recurrence score, regardless of T size, place into the same prognostic category as T1a-T1b N0 M0. Patients with triple-negative tumors have survival equal to that of patients with disease 1 TNM stage higher who have ER, PR, or HER2-positive expressing tumors.

Surgical Therapy

Surgery is the primary treatment for breast cancer. Table 51.7 describes the most common surgical procedures used to treat breast cancer. The most common surgical options for operable breast cancer are (1) breast conservation surgery (lumpectomy [segmental mastectomy]) and (2) mastectomy with or without reconstruction. Most women diagnosed with early-stage breast cancer (tumors smaller than 5 cm) are candidates for either treatment choice. The overall survival rate with lumpectomy and radiation is the same as that with mastectomy.[14]

TABLE 51.5 Interprofessional CareBreast Cancer

Diagnostic Assessment
Prediagnosis

- Health history, including risk factors
- Physical examination, including breast and lymph nodes
- Mammography

- Ultrasound (if indicated)
- Breast MRI (if indicated)
- Biopsy

Postdiagnosis

- Lymph node analysis
- Estrogen and progesterone receptor status
- Cell-proliferative indices
- HER-2 marker
- Genetic assays (e.g., MammaPrint, Oncotype DX)

Staging

- Complete blood count
- Liver function tests
- Chest x-ray (if indicated)
- CT scan of chest, abdomen, pelvis (if indicated)
- PET/CT, MRI, bone scans (if indicated)

Management
Surgical Therapy

- Breast-conserving surgery (lumpectomy) with SLNB and/or axillary lymph node dissection
- Simple (total) mastectomy with SLNB and/or axillary lymph node dissection
- Modified radical mastectomy
- Reconstructive surgery

Radiation Therapy

- External radiation
- Brachytherapy
- Palliative radiation therapy

Drug Therapy (Table 51.8)

- Chemotherapy
- Hormone therapy
- Immunotherapy
- Targeted therapy

It is important to note that breast reconstruction is an option for any woman undergoing surgical treatment for breast cancer. For women undergoing mastectomy, breast reconstruction can be done at the time of the mastectomy or delayed for months or even years. Women may opt to not have reconstruction and choose to use a breast prosthesis instead.

Breast-Conserving Surgery

Breast-conserving surgery, also called **lumpectomy**, involves removing the entire tumor along with a margin of normal surrounding tissue (Fig. 51.5, *A*). In some cases, it may take 2 or 3 more surgeries to remove all the cancer from the margins. After surgery, radiation therapy is usually delivered to the entire breast, ending with a boost to the tumor bed. If the risk for recurrence is high, chemotherapy may be given before radiation therapy.

Not everyone is a candidate for breast conservation surgery. Contraindications include breast size too small in relation to the tumor size to yield an acceptable cosmetic result, multifocal masses and calcifications, multicentric masses (in more than 1 quadrant), diffuse calcifications in more than 1 quadrant, or prior radiation therapy. Because of the time commitment (i.e., 3 to 7 weeks of daily radiation therapy treatments) and travel distances to access radiation

therapy treatment centers, some patients may choose mastectomy over breast conservation surgery.

TABLE 51.6 Staging of Breast Cancer

Stage	Tumor Size	Lymph Node Involvement	Metastasis
0	TIS (tumor in situ)	No	No
I			
A	<2 cm	No	No
B	<2 cm	<2 mm	No
II			
A	No evidence of tumor ranging to 5 cm	No, or 1–3 axillary nodes and/or internal mammary nodes	No
B	Ranging from ≤2 to >5 cm	No, or 1–3 axillary nodes and/or internal mammary nodes	No
III			
A	Ranging ≤2 to >5 cm	Yes, 1–9 axillary nodes and/or internal mammary nodes	No
B	Any size with extension to chest wall or skin	No, or 1–9 axillary nodes and/or internal mammary nodes	No
C	Any size	Yes, ≥10 axillary nodes, internal mammary nodes, or infraclavicular nodes	No
IV	Any size	Any type of nodal involvement	Yes

Adapted from Guiliano AE, Connolly JL, Edge SB, et al: Breast cancer: Major changes in the American Joint Committee on Cancer 8th edition cancer staging manual, *Cancer J Clin* 67:290, 2017.

Axillary Lymph Node Analysis

SLNB is the preferred standard for axillary lymph node analysis and staging. It was described on p. 1197. However, if the SLN cannot be identified, or if the node is positive for cancer, ALND may have to be done.

Lymphedema

Lymphedema, an accumulation of lymph in soft tissue, can occur because of the lymph node sampling procedure or radiation therapy (Fig. 51.6). When the axillary nodes cannot return lymph fluid to the central circulation, the fluid accumulates in the arm, hand, or breast, causing obstructive pressure on the veins and venous return. The patient may have heaviness, impaired motor function in the arm, and

numbness and paresthesia of the fingers. Cellulitis and progressive fibrosis of the skin can result from untreated lymphedema. (See further discussion on lymphedema later in this chapter on p. 1206.)

Mastectomy

A *total* or *simple mastectomy* removes the entire breast. A *modified radical mastectomy* includes removal of the breast and axillary lymph nodes. It preserves the pectoralis major muscle (Fig. 51.5, *B*). For women desiring breast reconstruction, a skin-sparing mastectomy provides the best cosmetic result and does not increase the chance of the cancer recurring. In a *nipple-sparing mastectomy,* the nipple and/or areola are left in place and the breast tissue under them is removed. Women who have a small, low-grade cancer near the outer part of the breast, with no signs of cancer in the skin or near the nipple, may be able to have nipple-sparing surgery.[14]

Table 51.7 Surgical Procedures for Breast Cancer

Procedure	Side Effects	Complications	Patient Issues
Breast-Conserving Surgery (Lumpectomy) With Radiation Therapy			
Excision of tumor with no tumor at margins, sentinel lymph node biopsy (SLNB) and/or axillary lymph node dissection (ALND) **Radiation therapy**	• Breast soreness • Breast edema • Skin reactions • Arm swelling • Sensory changes in breast and arm	*Short-term:* moist desquamation,* hematoma, seroma, infection *Long-term:* fibrosis,* lymphedema,† myositis, pneumonitis,* rib fractures*	• Prolonged treatment* • Impaired arm mobility† • Change in texture and sensitivity of breast
Mastectomy			
Simple Mastectomy **Removal of breast, preservation of pectoralis muscle, SLNB may be done at same time** **Modified Radical Mastectomy** Removal of breast with ALND, pectoralis muscle is spared	• Chest wall tightness, scar • Phantom breast sensations • Lymphedema • Sensory changes • Impaired range of motion	*Short-term:* skin flap necrosis, seroma, hematoma, infection *Long-term:* sensory loss, muscle weakness, lymphedema	• Loss of breast • Incision • Body image • Need for prosthesis • Impaired arm mobility
Breast Implants and Tissue Expansion			
Expander used to slowly stretch tissue. Saline gradually injected into reservoir over weeks to months **Insertion of implant under musculofascial layer of chest wall**	• Discomfort • Chest wall tightness	*Short-term:* skin flap necrosis, wound separation, seroma, hematoma, infection *Long-term:* capsular contractions, displacement of implant	• Body image • Prolonged HCP visits to expand implants • Potential added surgeries for nipple construction, symmetry
Breast Reconstruction Tissue Flap Procedures‡			
Transverse Rectus Abdominis Musculocutaneous (TRAM) Flap			
Musculocutaneous flap (muscle, skin, fat, blood supply) is transposed from abdomen to the mastectomy site **May be done concurrently with mastectomy**	• Pain related to 2 surgical sites and extensive surgery	*Short-term:* delayed wound healing, infection, skin flap necrosis, abdominal hernia, hematoma	• Longer postoperative recovery
Deep Inferior Epigastric Artery Perforator (DIEP) Flap			
Free flap that transfers skin and fat from the abdomen to the chest. Differs from TRAM flap because no muscle is moved	• Requires more time in surgery than pedicle TRAM flap • Pain related to 2 surgical sites	Needs to be closely monitored first 24–48 hours after surgery. If flap fails, patient needs surgery	• Patients may have less pain and restriction of movement than with a pedicle TRAM flap.

* Specific to radiation therapy.

† If ALND (less likely with SLNB).

‡ This list is not inclusive as other breast reconstruction options are available to patients.

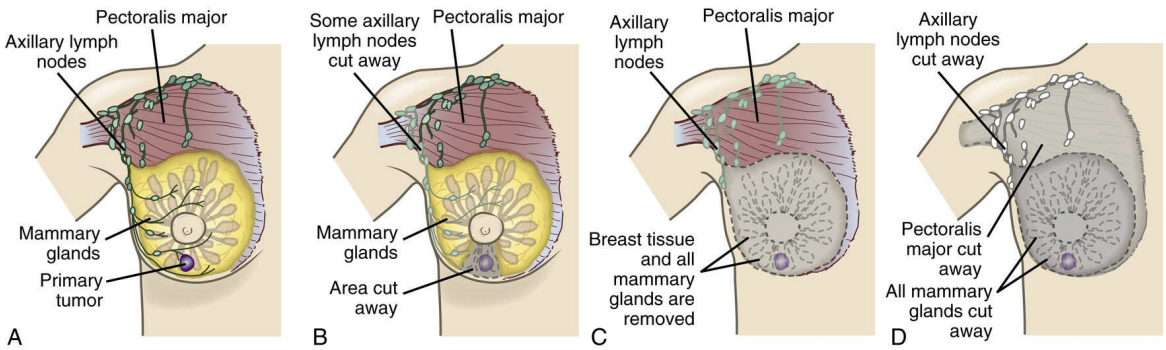

FIG. 51.5 Breast cancer surgery. **A,** Preoperative. **B,** Lumpectomy. **C,** Simple mastectomy. **D,** Modified radical mastectomy.

FIG. 51.6 Lymphedema. Accumulation of fluid in the tissue after excision of lymph nodes.
From Swartz MH: *Textbook of physical diagnosis: History and examination,* ed 6, Philadelphia, 2010, Saunders.

For women who have a mastectomy, breast reconstruction can be done with the mastectomy or it can be delayed. Some women choose not to have reconstruction. There are 2 main types of breast reconstruction procedures: implant reconstruction or tissue flap

procedures (Table 51.7). Breast reconstructive surgery is discussed on pp. 1207–1209.

Post–Breast Therapy Pain Syndrome

Post–breast therapy pain syndrome (PBTPS) occurs in some people who have had procedures for breast cancer. Most often it is caused by injury to nerves during surgery. However, it also can be due to chemotherapy and radiation therapy. The most common theory is that PBTPS results from injury to intercostobrachial nerves. These are sensory nerves that exit the chest wall muscles and provide sensation to the shoulder and upper arm.

Because of its multiple causes, PBTPS symptoms can range from mild to debilitating.[16] Common symptoms include chest and upper arm pain, tingling down the arm, continuous aching and burning, numbness, shooting or pricking pain, and unbearable itching that persists beyond the normal 3-month healing time. Edema may be present.

Treatment includes nonsteroidal antiinflammatory drugs (NSAIDs), low-dose antidepressants, topical anesthetics (e.g., EMLA [lidocaine and prilocaine]), and antiseizure drugs (e.g., gabapentin). Other treatments include biofeedback, physical therapy to prevent "frozen shoulder" syndrome from inadequate movement, guided imagery, and psychologic counseling with a therapist trained in the management of chronic pain syndromes.

Phantom Breast Pain

Phantom breast pain is feeling pain in the breast after the breast was removed via mastectomy. It occurs for the same reasons phantom limb sensation occurs after limb amputations. The brain continues to send signals to nerves in the breast area that were cut during surgery, even though the breast is no longer physically there.

Check Your Practice

You are working in the breast clinic and doing a postoperative assessment on a 56-yr-old woman who had a right radical mastectomy 6 weeks ago. She is reporting sharp, prickly feelings in her right arm. She tells you, "I also feel pain in the breast that was removed. Am I going crazy? That breast is not even attached to my body anymore!"

- How would you respond and what follow-up would you provide?

Radiation Therapy

Radiation therapy is one *adjuvant (additional)* therapy that can be used after surgery. It is used for breast cancer to (1) prevent local breast cancer recurrences after breast-conserving surgery; (2) prevent local and lymph node recurrences after mastectomy; or (3) relieve pain caused by local, regional, or distant spread of cancer.

External Radiation Therapy

When radiation therapy is a primary treatment, it is usually done after surgery for the breast cancer. The decision to use radiation therapy after mastectomy is based on the chance that local, residual cancer cells are present. Radiation of the axilla and/or supraclavicular nodes may be done when lymph nodes are involved to decrease the risk for axillary recurrence. Radiating a localized area does not prevent distant metastasis.

In traditional whole breast, and in some cases regional lymph node, radiation treatment, the area is radiated 5 days per week over the course of about 5 to 7 weeks. An external beam of radiation delivers daily fractions to a total dose of 46 to 50 Gy (4500 to 5000 cGy). Patients who have had breast-conserving surgery may receive a "boost" dose of radiation to the area where the original tumor was located. It is given by external beam and adds 4 to 8 more treatments to the total number given.[14]

Newer and preferred regimens use a type of accelerated external

beam radiation called hypofractionation. This type of radiation has a shortened schedule, daily for 3 to 4 weeks, with a total dose of 40 to 42.5 Gy.[14]

Fatigue, skin changes, and breast edema may be temporary side effects of external radiation therapy. Nursing management of the patient receiving radiation therapy is discussed in Chapter 15.

Brachytherapy

Brachytherapy (internal radiation) is used for partial-breast radiation. It is an alternative to traditional external radiation treatment for some patients with early-stage breast cancer.[14] This method has the same chance for local recurrence as whole breast radiation. However, some studies show the cosmetic results are not as good.

Brachytherapy is minimally invasive. The radiation is delivered directly into the cavity left after a tumor is surgically removed by a lumpectomy. Because the radiation is concentrated and focused on the area with the highest risk for tumor recurrence, it only requires 5 treatments. Therapy is delivered using a multicatheter method or balloon-catheter system.

In the *multicatheter method* (e.g., SAVI) many very small catheters are placed in the breast at the site of the tumor. The SAVI is inserted through a small incision, and the catheter bundle expands uniformly. The ends of the catheters stick out through little holes in the skin. Small radioactive seeds are placed in the catheters. The seeds are left in place just long enough to deliver the radiation dose (e.g., 5 to 10 minutes) then removed. The radiation does not remain in the body between treatments or after the last treatment is over.

In the *balloon-catheter system,* a balloon is placed where the tumor was located. The balloon is filled with fluid, to keep it in place, then radioactive seeds are inserted (Fig. 51.7). Radiation is emitted by a tiny radioactive seed attached by a wire to an afterloader, a computer-controlled machine. The seed travels through the MammoSite applicator into the inflated balloon. As with the multicatheter system, the radiation does not remain in the body between treatments or after the last treatment is over. Once the last session is done, the balloon is

deflated, and the system is removed.

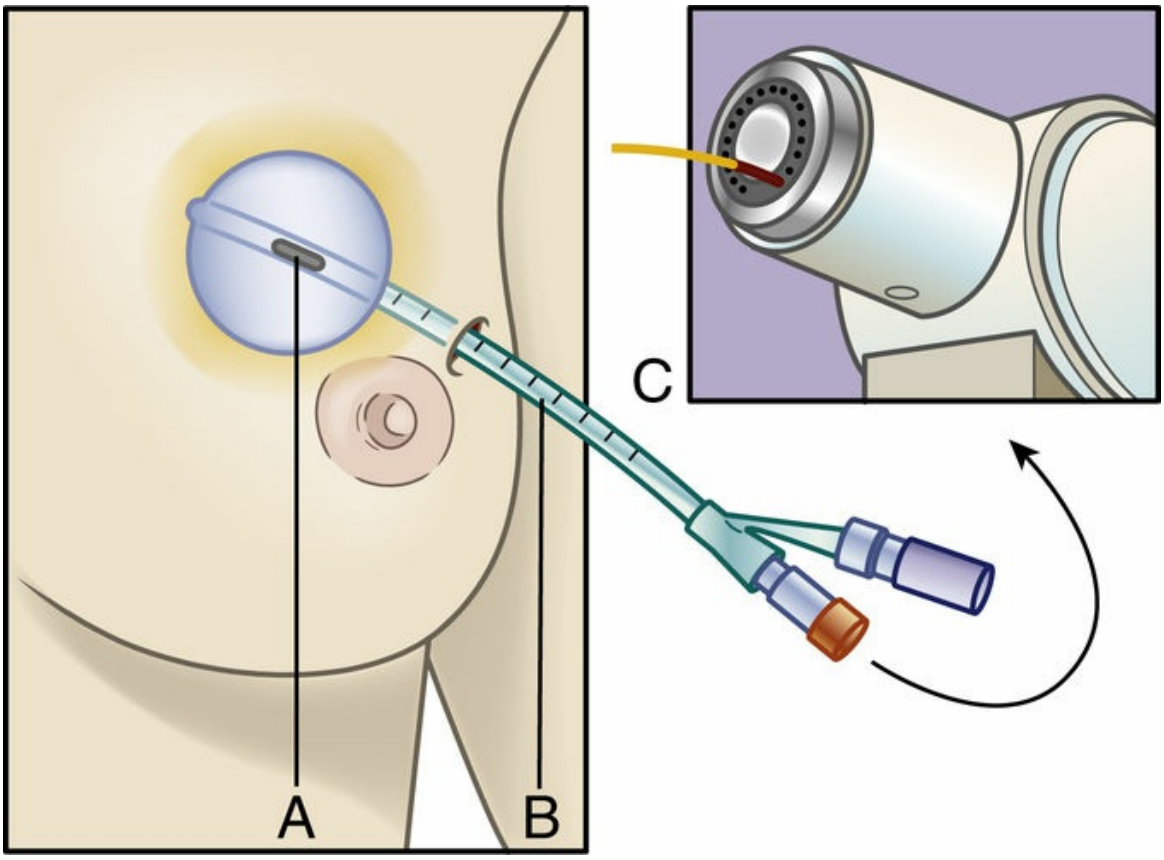

FIG. 51.7 High-dose brachytherapy for breast cancer. The MammoSite system involves the insertion of a single small balloon catheter *(B)* at the time of the lumpectomy or shortly thereafter into the tumor resection cavity (the space that is left after the HCP removes the tumor). A tiny radioactive seed *(A)* is inserted into the balloon, connected to a machine called an *afterloader (C)*, and delivers the radiation therapy.

Palliative Radiation Therapy

In addition to reducing the primary tumor mass with a resultant decrease in pain, radiation therapy can be used to treat symptomatic metastatic lesions in such sites as bone, soft tissue organs, brain, and chest. Radiation therapy often relieves pain and is successful in controlling recurrent or metastatic disease.

Drug Therapy

Drug therapy includes chemotherapy, hormone therapy, immunotherapy, and targeted therapy. When drug therapy is given before surgery, we call it *neoadjuvant therapy.* Neoadjuvant therapy is often used to shrink the size of the tumor enough to make surgical removal possible or to allow for breast-conserving surgery in women who would have been recommended to have a mastectomy. It also allows time for genetic testing to occur (if appropriate) so a patient can make a more informed decision about what type of surgery to have. Drug therapy after surgery is called *adjuvant therapy*. Drug therapy can decrease the rate of recurrence and increase the length of survival. Because of the risk for recurrent disease, nearly all patients with evidence of node involvement, particularly those who are hormone receptor negative, will have some type of drug therapy. Some patients, particularly those with a more aggressive tumor, are known to be at higher risk for recurrent or metastatic disease. Drug therapy may be used for these patients even when there is no evidence of node involvement. Weighing the risks and benefits of drug therapy is a complex process.[14]

Chemotherapy

Chemotherapy is the use of cytotoxic drugs to destroy cancer cells. A combination of drugs is usually superior to the use of a single drug. Combination treatment is best because the drugs have different mechanisms of action and work at different parts of the cell cycle. When used in the neoadjuvant and adjuvant setting, chemotherapy is usually given for 3 to 6 months. However, when a patient has metastasis, chemotherapy may be given for the rest of the patient's life.

Common combination-therapy protocols in the adjuvant and neoadjuvant setting are (1) CMF: cyclophosphamide, methotrexate, and fluorouracil; (2) AC: doxorubicin and cyclophosphamide, with or without the addition of a taxane, such as paclitaxel (Taxol) or docetaxel (Taxotere); or (3) CEF or CAF: cyclophosphamide, epirubicin (Ellence) or doxorubicin, and fluorouracil.

Drug Alert

Doxorubicin

- Monitor for signs of cardiotoxicity and heart failure (e.g., shortness of breath, pedal edema, decreased activity tolerance, dysrhythmias, ECG changes).
- Tell the patient not to have immunizations without the HCP's approval.

Teach patients to avoid contact with those who recently received live virus vaccine and those with infections. Because chemotherapy affects healthy cells, many side effects accompany chemotherapy. The incidence and severity of common side effects are related to specific drug combination, drug schedule, and dosage. The most common side effects involve rapidly dividing cells in the gastrointestinal tract (nausea, anorexia, weight loss), bone marrow (anemia), and hair follicles (hair loss).

Cognitive changes during and after treatment can occur. This phenomenon is called *"chemobrain."* These changes include difficulties in concentration, memory, focus, and attention. Cognitive changes in cancer are discussed in Chapter 15 on p. 251.

Evidence-Based Practice

Treatment for Breast Cancer

C.P. is a 56-yr-old woman who was diagnosed with stage IIIA breast cancer. Her treatment plan is to receive neoadjuvant chemotherapy and then have surgery and radiation. C.P. tells you that she is anxious and will have surgery and radiation but does not want chemotherapy because she is afraid of the side effects.

Making Clinical Decisions

Best Available Evidence. The use of chemotherapy before surgery reduces the size and extent of the tumor, thus making the surgery more likely to succeed. It reduces the chance a more extensive treatment will be needed.

Clinician Expertise. Neoadjuvant chemotherapy is usually recommended for stage IIIA breast cancer. The common side effects (e.g., nausea, vomiting, fatigue) can be managed with appropriate treatment.

Patient Preferences and Values. C.P. does not want chemotherapy and prefers to take her chances. If the cancer comes back, she will have chemotherapy.

Implications for Nursing Practice

1. Why is it important to discuss with C.P. the reason chemotherapy is recommended?
2. What information would you share with her about treatment side effects and how they can be managed?
3. You note her spouse appears attentive and supportive. How will you involve him in C.P.'s care?

National Comprehensive Cancer Network. NCCN guidelines for patients: Invasive breast cancer.. 2018 Retrieved from. www.nccn.org/patients/guidelines/breast-invasive/index.html.

Hormone Therapy

Estrogen can promote the growth of breast cancer cells if the cells are ER positive. Hormone therapy can block the effect and source of

estrogen, promoting tumor regression.

ER and PR status assays can identify women whose breast cancers are likely to respond to hormone therapy. These assays predict whether hormone therapy is a treatment option. Chances of tumor regression are significantly greater in women whose tumors have estrogen and progesterone receptors. The 21-gene recurrence score (OncotypeDX) is an excellent prognostic assay to identify which women with hormone-positive breast cancer can be treated with hormone therapy alone and do not need chemotherapy.

TABLE 51.8 Drug TherapyBreast Cancer

Drug Class	Mechanism of Action	Indications
Hormone Therapy		
Aromatase Inhibitors		
anastrozole (Arimidex) **exemestane (Aromasin)** **letrozole (Femara)**	Prevents production of estrogen by inhibiting aromatase	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor Blockers		
fulvestrant (Faslodex)	Blocks estrogen receptors (ERs)	ER-positive breast cancer in postmenopausal women only
tamoxifen	Blocks ERs	ER-positive breast cancer in premenopausal and postmenopausal women Used as a preventive measure in high-risk premenopausal and postmenopausal women
toremifene (Fareston)	Blocks ERs	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor Modulator		
raloxifene (Evista)	In breast, blocks the effect of estrogen. In bone, promotes effect of estrogen and prevents bone loss	Postmenopausal women
Immunotherapy and Targeted Therapy		
ado-trastuzumab emtansine (Kadcyla)	Trastuzumab connected to a chemotherapy drug called DM1	HER-2-positive breast cancer
everolimus (Afinitor)	Binds to mechanistic target of rapamycin (mTOR), thereby suppressing T cell activation and proliferation	ER-positive, HER-2-negative breast cancer in postmenopausal women
lapatinib (Tykerb)	Inhibits HER-2 tyrosine kinase and EGFR tyrosine kinase	HER-2-positive breast cancer
abemaciclib (Verzenio) **palbociclib (Ibrance)** **ribociclib (Kisqali)**	Kinase inhibitors	ER-positive, HER-2-negative breast cancer in postmenopausal women
neratinib (Nerlynx) **pertuzumab (Perjeta)** **trastuzumab (Herceptin)** **trastuzumab-pkrb (Herzuma)** **trastuzumab-qyyp (Trazimera)**	Blocks HER-2 receptor	HER-2-positive breast cancer

Hormone therapy can (1) block ERs or (2) suppress estrogen synthesis by inhibiting aromatase, an enzyme needed for estrogen synthesis (Table 51.8). Premenopausal women with ER-positive breast cancers may benefit from the removal or suppression of their ovaries. Ovarian ablation can be done surgically or by using luteinizing hormone–releasing hormone (LHRH) analogs, such as goserelin (Zoladex) or leuprolide (Lupron).

Estrogen Receptor Blockers

ER blockers include tamoxifen, toremifene (Fareston), and fulvestrant (Faslodex). Tamoxifen has been the hormone therapy of choice in ER-positive women with all stages of breast cancer over the past 30 years. It also may be used in high-risk women to prevent breast cancer. Common side effects include hot flashes, mood swings, vaginal discharge and dryness, and other effects associated with decreased estrogen. It also increases the risk for blood clots, cataracts, stroke, and endometrial cancer in postmenopausal women.

Drug Alert

Tamoxifen

- Irregular vaginal bleeding or spotting may occur.
- Decreased visual acuity, corneal opacity, and retinopathy can occur in women receiving high doses (240–320 mg/day for >17 mo). These problems may be irreversible.
- Teach the patient to immediately report decreased visual acuity.
- Monitor for signs of deep vein thrombosis, pulmonary embolism, and stroke, including shortness of breath, leg cramps, and weakness.

Aromatase inhibitors

Aromatase inhibitor drugs interfere with the anastrozole enzyme

aromatase, which is needed for the synthesis of estrogen. These drugs include anastrozole, letrozole (Femara), and exemestane (Aromasin). They are used in the treatment of breast cancer in postmenopausal women. Aromatase inhibitors do not block the production of estrogen by the ovaries. Thus they are of little benefit and may be harmful in premenopausal women.

Aromatase inhibitors have different side effects than tamoxifen. They rarely cause blood clots and do not cause endometrial cancer. Because they block the production of estrogen in postmenopausal women, osteoporosis and bone fractures may occur. These drugs have been associated with night sweats, nausea, arthralgias, and myalgias.

Estrogen receptor modulator and others

Raloxifene (Evista) is a selective ER modulator that has both estrogen-agonistic effects on bone and estrogen-antagonistic effects on breast tissue. (Raloxifene is discussed in the section on osteoporosis in Chapter 63.) Less common drugs that may be used to suppress hormone-dependent breast tumors include megestrol acetate, diethylstilbestrol, and fluoxymesterone.

Immunotherapy and Targeted Therapy

As more is known about the genetic changes in breast cancer, we have developed drugs that specifically target cells that have altered gene expression. One of these genetic changes is the overexpression of HER-2. Tumors that overexpress the HER-2 protein tend to be more aggressive and are more likely to recur.

Trastuzumab (Herceptin) is a monoclonal antibody to HER-2. After the antibody attaches to the antigen, blocks signals that tell the cancer cells to proliferate. It can be used alone or in combination with chemotherapy agents. The most common side effects are flu-like symptoms (fever, chills, myalgia), nausea and vomiting, diarrhea, and infusion reactions. Another possible, but more serious side effect, is heart damage. Trastuzumab-qyyp (Trazimera) and trastuzumab-pkrb (Herzuma) are newly approved biosimiliars of trastuzamab.

Drug Alert

Trastuzumab (Herceptin)

- Use with caution in women with preexisting heart disease.
- Monitor for signs of ventricular dysfunction and heart failure.

Other drugs that target HER-2 include pertuzumab (Perjeta) and ado-trastuzumab emtansine (Kadcyla). Kadcyla is trastuzumab connected to a chemotherapy drug called DM1. Lapatinib (Tykerb) works inside the cell by blocking the function of the HER-2 protein. Nerotinib (Nerlynx) is an option for extended adjuvant therapy for some high-risk women. Using 2 of these agents together for neoadjuvant therapy can increase the number of tumors that become undetectable and can improve survival when used for adjuvant therapy. Other drugs that target HER-2 include pertuzumab (Perjeta), trastuzumab-qyyp (Trazimera), trastuzumab-pkrb (Herzuma), and ado-trastuzumab emtansine (Kadcyla). Kadcyla is trastuzumab connected to a chemotherapy drug called DM1. Lapatinib (Tykerb) works inside the cell by blocking the function of the HER-2 protein. Using 2 of these agents together for neoadjuvant therapy can increase the number of tumors that become undetectable.

Drugs in other classes that are used to treat breast cancer include everolimus (Afinitor) and the CDK 4 and 6 inhibitors palbociclib (Ibrance), ribociclib (Kisquali), and abemaciclib (Verzenio). Everolimus works by blocking mTOR, a protein that normally promotes cell growth and division. CDK 4 and 6 inhibitors prevent cells from dividing, thus slowing cancer growth. (The use of immunotherapy and targeted therapy is discussed in Chapter 15.)

Culturally Competent Care: Breast Cancer

Differences exist in the incidence, mortality rates, and care issues among diverse racial and ethnic groups related to breast cancer (see

Promoting Health Equity box on this page). In addition, cultural differences may involve gender roles, health beliefs, religion, family structure, socioeconomic factors (e.g., poverty) and lack of health insurance. Lack of education may influence disparities related to access to health care and having recommended surveillance examinations.[17,18]

Promoting Health Equity

Breast Cancer

- White and black women have the highest incidence of breast cancer.
- Black women have lower survival rates from breast cancer than white women, even when diagnosed at an early stage.
- Hispanic and black women are more likely to be diagnosed at a later stage of breast cancer than white women.
- Triple-negative breast cancer has a higher incidence in black and Hispanic women.
- Mortality rates are lower among Hispanic and Asian/Pacific Islander women than among white and black women.
- Breast cancer is the most common diagnosed cancer among Hispanic women.
- Indian/Alaskan native women have the lowest rate of breast cancer screening of any ethnic group.

Cultural values strongly influence how a person responds to and copes with breast cancer and treatment. Diverse cultural norms influence health beliefs and behaviors. Breast cancer screening, diagnosis, and treatment are affected by the cultural values and meanings (body image, sexuality, modesty, motherhood) associated with the breasts. Women may delay screening or treatment for

varying reasons, including an acceptance of disease as inevitable fate or "God's will," a mistrust of Western medicine, lack of health care benefits, fear, or the stigma of a cancer diagnosis.

Nursing Management: Breast Cancer

Nursing Assessment

You must consider many factors when assessing a patient with a breast problem. The history of the breast disorder helps establish a diagnosis. Investigate the presence of nipple discharge, pain, rate of growth of the lump, breast asymmetry, and correlation with the menstrual cycle.

Carefully record the size and location of the lump or lumps. Assess the physical characteristics of the lesion, including consistency, mobility, and shape. If nipple discharge is present, note the color and consistency and whether it occurs from 1 or both breasts.

Subjective and objective data to obtain from a person suspected of having or diagnosed with breast cancer are outlined in Table 51.9.

Nursing Diagnoses

Nursing diagnoses related to the care of a patient diagnosed with breast cancer vary. After diagnosis and before a treatment plan has been selected, the following nursing diagnoses would apply:

- Difficulty coping
- Lack of knowledge
- Disturbed body image

If surgery is planned, the nursing diagnoses and interventions may include those in eNursing Care Plan 51.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with breast cancer will (1) actively take part in the decision-making process related to treatment, (2) adhere to the therapeutic plan, (3) communicate about and manage the side effects of adjuvant therapy, (4) access and benefit from the support provided by significant others and HCPs, and (5) adhere to recommended follow-up and surveillance after treatment.

Nursing Implementation

Health Promotion

Review the risk factors in Table 51.2. People can reduce their risk factors by maintaining a healthy weight, exercising regularly, limiting alcohol, eating nutritious food, and never smoking (or quitting if currently smoking).

Encourage people to adhere to the breast cancer screening guidelines shown on pp. 1190–1191. A person at high risk needs to develop a personalized plan with the HCP. Early detection can decrease the morbidity and mortality associated with breast cancer.

TABLE 51.9 Nursing AssessmentBreast Cancer

Subjective Data
Important Health Information

Past health history: Benign breast disease with atypical changes. Previous unilateral breast cancer. Menstrual history (early menarche with late menopause), pregnancy history (nulliparity or first full-term pregnancy after age 30). Endometrial, ovarian, or colon cancer. Hyperestrogenism and testicular atrophy (in men)

Medicines: Hormones, especially as postmenopausal hormone therapy and in oral contraceptives. Infertility treatments

Surgery or other treatments: Exposure to therapeutic radiation (e.g.,

Hodgkin's lymphoma or thyroid radiation)

Functional Health Patterns

Health perception–health management: Family history of breast cancer (young age at diagnosis). History of abnormal mammogram or atypical prior biopsy. Palpable change found on BSE. Known *BRCA* mutation carrier, first-degree relative of *BRCA* carrier (but untested)
Nutritional-metabolic: Obesity; unexplained severe weight loss (may indicate metastasis)
Activity-exercise: Level of usual activity
Cognitive-perceptual: Changes in cognition, headache, bone pain (may indicate metastasis)
Sexuality-reproductive: Unilateral nipple discharge (clear, milky, bloody). Change in breast contour, size, or symmetry
Coping–stress tolerance: Psychologic stress
Self-perception–self-concept: Anxiety about threat to self-esteem

Objective Data
General

Axillary and supraclavicular lymphadenopathy

Integumentary

Hard, irregular, nonmobile breast lump most often in upper, outer sector, possibly fixated to fascia or chest wall. Thickening of breast. Nipple inversion or retraction, erosion. Edema ("peau d'orange"), erythema, induration, infiltration, or dimpling (in later stages). Firm, discrete nodules at mastectomy site (may indicate local recurrence). Peripheral edema (may indicate metastasis)

Respiratory

Pleural effusions (may indicate metastasis)

Gastrointestinal

Hepatomegaly, jaundice, ascites (may indicate liver metastasis)

Possible Diagnostic Findings

Finding of mass or change in tissue on breast examination. Abnormal mammogram, ultrasound, or breast MRI. Positive results of FNA or surgical biopsy; similar results with a needle biopsy

Along with these lifestyle choices, there are other risk-reduction options for people at high risk. Genetic testing for *BRCA* and other gene mutations is available. People with a strong family history of breast cancer should talk with their HCP about the possibility of genetic testing. There is no reason for routine screening for genetic abnormalities in women without evidence of a strong family history of breast cancer.

In women with an abnormal *BRCA1* or *BRCA2* gene, prophylactic oophorectomy may reduce their risk for developing breast cancer and ovarian cancer. In deciding whether and when to undergo this surgical procedure, women should receive counseling about the risks and benefits of prophylactic oophorectomy, including fertility issues.

Prophylactic surgery decisions require a great deal of thought, patience, and discussion with the HCP, genetic counselor, and family. Patients need to consider these options and make decisions with which they feel comfortable. Removing both breasts and ovaries at a young age does not eliminate the risk for breast cancer. A small risk exists that cancer can develop in the areas where the breasts used to

be. Close follow-up is necessary even after prophylactic surgery.

Acute Care

The times of waiting for the initial biopsy results and waiting for the HCP to make treatment recommendations are difficult for patients and their families. Even after the HCP has discussed treatment options, the patient often relies on you to clarify and expand on these options. During this stressful time, the patient may not be coping effectively. Appropriate nursing interventions are to explore the patient's usual decision-making processes, help to evaluate the advantages and disadvantages of the options, provide information relevant to the decision, clarify unresolved issues with the HCP, and support the patient and family once the decision is made.

Provide the patient with enough information to ensure informed consent. Some patients seek extensive, detailed information to maintain a sense of control. Others avoid information to decrease anxiety and fear. Be sensitive to the person's need for and preferred type of information. These include (1) instructions on pain control and what to expect after surgery (e.g., dressing and drain care, turning, coughing, deep breathing), (2) a review of mobility restrictions and postoperative exercises, and (3) an explanation of the recovery period.

The woman who has breast-conserving surgery usually has an uncomplicated postoperative course with variable pain intensity. Pain depends primarily on the extent of the lymph node sampling procedure. If an ALND has been done or if the patient had a mastectomy, drains are generally left in place and patients are discharged home with them. Teach the patient and family, with a return demonstration, how to manage the drains at home.

Most patients are discharged from the hospital 24 to 48 hours after a mastectomy, depending on if reconstructive surgery was done. Restoring arm function on the affected side after breast cancer surgery is a key nursing goal. Arm and shoulder exercises, which are started gradually, may begin prior to discharge (Fig. 51.8). These exercises are designed to prevent contractures and muscle shortening, maintain muscle tone, and improve lymph and blood circulation. The difficulty

and pain encountered in performing what used to be simple tasks may cause frustration and depression. The goal of all exercise is a gradual return to full range of motion.

Discomfort can be minimized by giving analgesics regularly when the patient is in pain and about 30 minutes before starting exercises. When the patient can shower, the warm water on the involved shoulder often relaxes the muscle and reduces joint stiffness.

Explain the specific follow-up plan to the patient and emphasize the importance of ongoing monitoring and self-care. After surgery, teach the patient to report symptoms, such as fever, inflammation at the surgical site, erythema, and unusual swelling. Other changes to report are new back pain, weakness, shortness of breath, and change in mental status, including confusion.

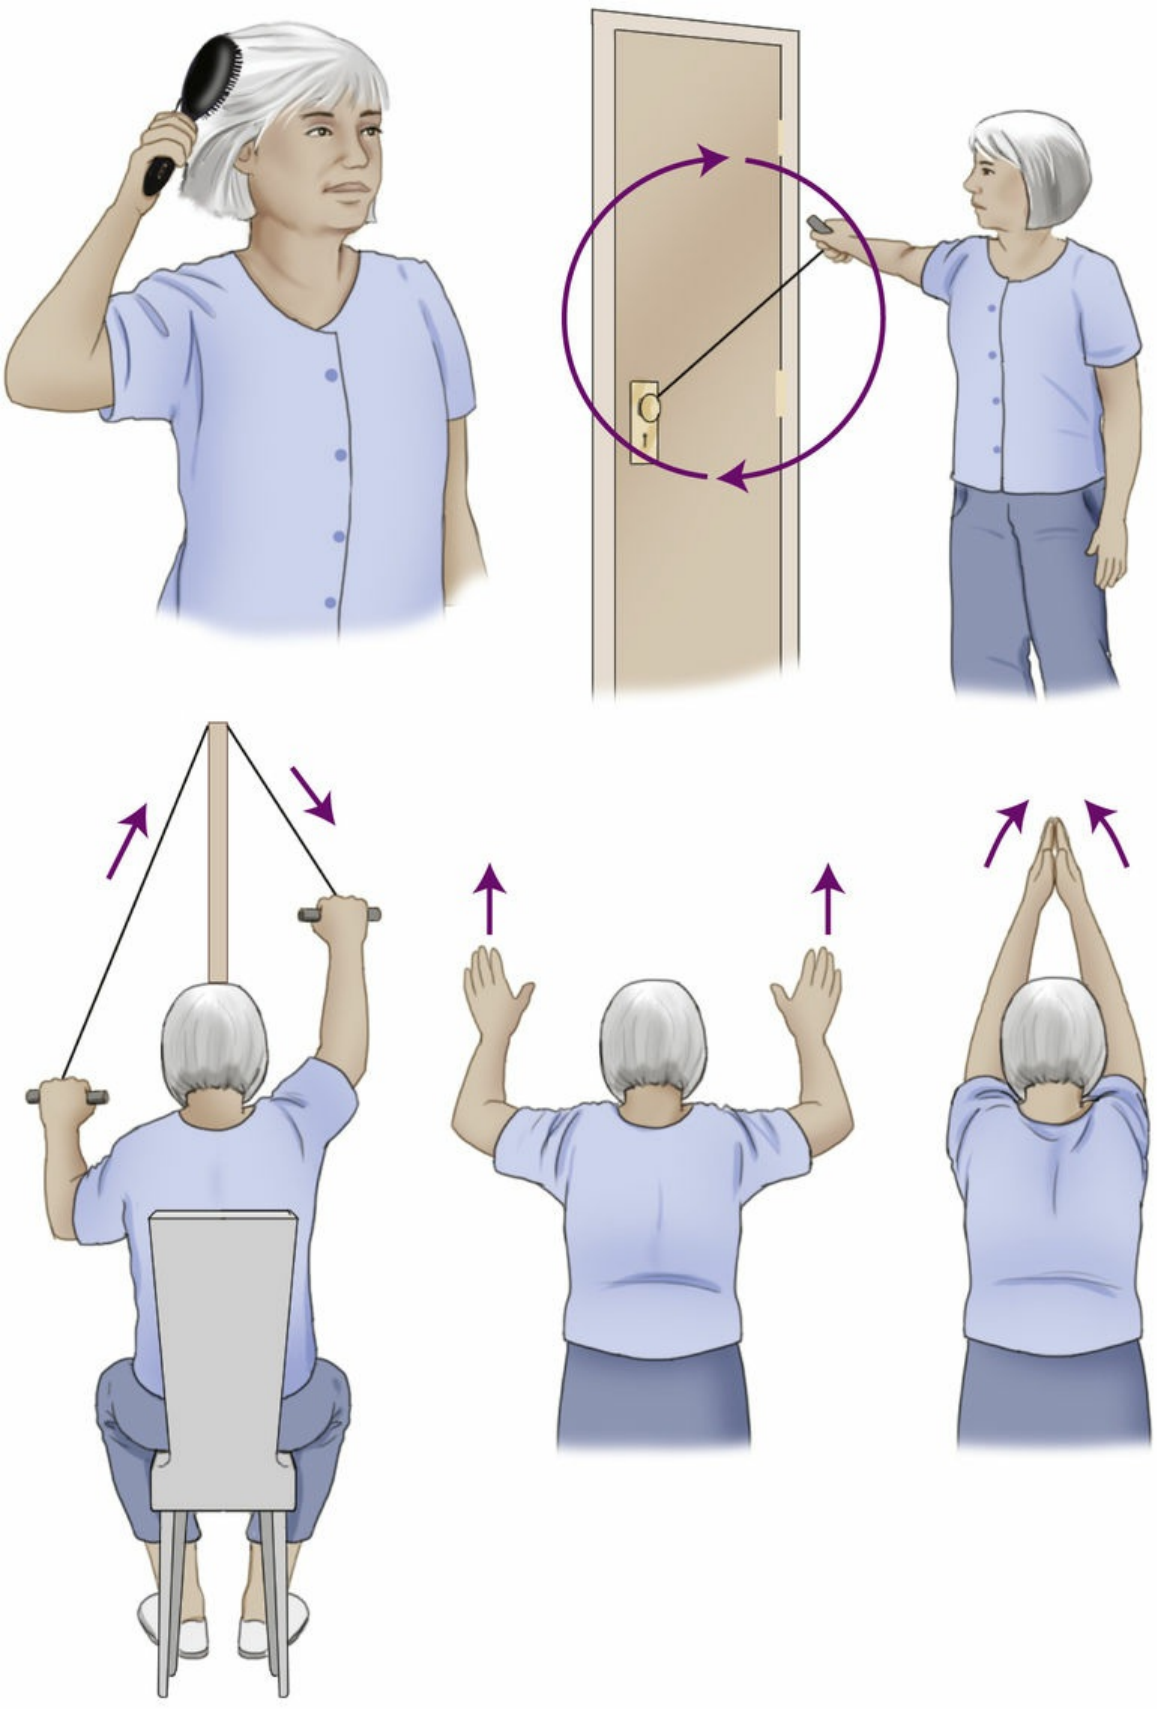

FIG. 51.8 Postoperative exercises for the patient with a mastectomy or lumpectomy with axillary lymph node sampling and/or dissection.

For women who have had a mastectomy without breast reconstruction, a variety of products are available. Your role is to present the choices and resources. Options include garments such as camisoles with soft breast prosthetic inserts or a fitted prosthesis with bra. Should the woman choose a breast prosthesis, a certified fitter can help her choose a comfortable, more permanent weighted prosthesis and bra. This is generally done 4 to 8 weeks after surgery.

Lymphedema

Upper extremity lymphedema can occur at any point after treatment for breast cancer. Teach the patient ways to prevent and reduce lymphedema. These include no BP readings, venipunctures, or injections on the affected arm, if possible. The affected arm should not be dependent for long periods. Caution should be used to prevent infection, burns, or compromised circulation on the affected side. Encourage exercise and maintaining a normal weight.

If trauma to the arm occurs, the area should be washed thoroughly with soap and water and observed. A topical antibiotic ointment and a bandage or other sterile dressing may be applied.

When lymphedema is acute (Fig. 51.6), complete decongestive therapy will be recommended. This therapy is performed by specially trained professionals. It consists of a massage-like technique to mobilize the subcutaneous accumulation of fluid. This may be followed by use of compression bandaging and an intermittent pneumatic compression sleeve. The sleeve applies mechanical massage to the arm and helps move lymph drainage up toward the heart. Elevating the arm so that it is level with the heart and performing isometric exercises reduce the fluid in the arm. To maintain maximum volume reduction, the patient may need to wear a fitted compression sleeve during waking hours and preventively during air travel.

Psychosocial Support

Throughout history, the female breast has been a symbol of beauty, femininity, sexuality, and motherhood. The potential loss of a breast, or part of a breast, may be devastating for many women because of the significant psychologic, social, sexual, and body image implications associated with it. For men diagnosed with breast cancer, isolation and embarrassment related to the diagnosis can occur. You must be aware of resources for men *(www.malebreastcancer.org)*.

As hard as it is to predict which patients will develop physical effects of treatment, it can be even more difficult to foresee the psychosocial effects of treatment. In some cases, psychosocial concerns may increase the physical effects of cancer, such as pain, fatigue, sleep problems, fear of recurrence, and cognitive changes.

Screening all cancer patients for psychosocial distress is a Commission on Cancer accreditation requirement.[19] From the time of diagnosis through treatment, survivorship, or metastatic disease, the patient may have signs of distress or tension (e.g., tachycardia, increased muscle tension, sleep problems, restlessness, changes in appetite or mood). Assess the patient's body language and affect during periods of high stress and indecision so that you can begin appropriate interventions, including referral to a mental health provider.

Remain sensitive to the complex psychologic impact that a diagnosis of cancer and breast surgery can have on patients and their families. With an accepting attitude and the offer of resources, you can help the patient cope with feelings of fear, anger, anxiety, and depression. You can help to:

- Provide a safe environment for the expression of feelings.
- Identify sources of support and strength, such as the partner, family, and spiritual or religious practices.
- Encourage the patient to identify and learn personal coping strengths.
- Promote communication among the patient, family, and friends.
- Answer questions about the disease, treatment options, and

reproductive, fertility, or lactation issues (if appropriate).
- Make resources available for mental health counseling.
- Offer information about local and national community resources.

Referring patients to support resources, such as *www.Breastcancer.org*, the Cancer Support Community, or local breast cancer organizations, is valuable. The ACS and National Cancer Institute can provide excellent materials to help you in meeting the special needs of patients with breast cancer. In addition to in-person and online support programs, multiple free smart phone applications are available through national cancer organizations that provide reliable and current information for the patient and his or her family.

How the loss of part or all of the breast and cancer affect the patient's sexual identity, body image, and relationships can vary. Many HCPs do not adequately address sexual concerns. If you are comfortable, begin a discussion of sexuality by inviting questions about relationships or intimacy concerns. Often the patient's partner and/or family members need help dealing with their emotional reactions to the diagnosis and surgery before they can provide effective support for the patient. There are no physical reasons why a mastectomy would prevent sexual satisfaction. A woman taking hormone therapy may have a decreased sexual

Complementary & Alternative Therapies

Supportive Care

Many women use complementary and integrative therapies as supportive care during cancer treatment to improve quality of life and manage treatment-related side effects.

Scientific Evidence

- There is strong evidence that practicing meditation and relaxation

decreases anxiety and depression and improves quality of life.
- Stress management, yoga, massage, music therapy, and meditation decrease stress, fatigue, anxiety, and depression and improve quality of life.

Nursing Implications

- Women use a variety of integrative therapies during breast cancer treatment.
- Meditation, yoga, relaxation, stress management, massage, music therapy, and energy conservation may be especially helpful in managing symptoms and improving quality of life during treatment.

Reference for Evidence

Greenlee H, DuPont-Reyes M.J, Balneaves L, et al. Clinical practice guidelines on the evidence-based use of integrative therapies during and after breast cancer treatment. *CA Cancer J Clin*. 2017;67:1954.

drive or vaginal dryness. She may need to use lubrication to prevent discomfort during intercourse. If difficulty in adjustment or other problems develop, single or couples counseling may be useful to deal with the emotional side of a diagnosis of cancer.

Depression and anxiety may occur with the continued stress and uncertainty of a cancer diagnosis. A patient's self-esteem and identity may be threatened. The support of family and friends and taking part in a cancer support group and/or counseling are important aspects of care that may improve the patient's quality of life.

Survivorship

Almost 3 million breast cancer survivors are alive in the United States,

making this population the largest group of cancer survivors. We expect this number to grow due to an aging population and improved methods for early detection and treatment. After treatment for breast cancer, the patient will have ongoing survivorship care.[19,20]

A history and physical examination is recommended 1 to 4 times per year as clinically appropriate for 5 years, then annually thereafter. In addition, teach breast cancer survivors to perform monthly BSE and chest wall self-examination and report any changes to their HCP. Local recurrence of breast cancer is usually at the surgical site. Breast cancer survivors should have an annual mammogram. Other breast imaging studies, such as a breast ultrasound or breast MRI, should be done only as an adjunct to mammography and not for annual routine surveillance. Cancer survivorship is discussed in Chapter 15 on p. 264.

Evaluation

Expected outcomes are that the patient after breast cancer surgery will

- Identify activities that can reduce postoperative edema and improve mobility
- Show effective use of coping strategies
- Discuss feelings about and the meaning of changes in physical appearance
- Identify community and online resources, personal counseling resources, and support groups

Gerontologic Considerations: Breast Cancer

A major risk for breast cancer is increasing age. More than half of all breast cancers occur in women who are age 65 or older.[1] Older women are less likely to have mammograms. Screening and treatment decisions for breast cancer should be based on a woman's general health status rather than biologic age, since health status has a greater influence on tolerance to treatment and long-term prognosis. In addition to medical co-morbidities and life expectancy, treatment

decisions for the older woman with breast cancer should be based on an assessment of nutritional and functional status; vision, gait, and balance; and the presence of delirium, dementia, or depression.

Breast cancer treatment is similar for older and younger patients, including the use of surgery, radiation therapy, and drug therapy. For healthy older women, breast cancer survival rates are similar to those of younger women when matched by cancer stage.

Mammoplasty

Mammoplasty is the surgical change in the size or shape of the breast. It may be done electively for cosmetic purposes to either enlarge or reduce the size of the breasts. It also may be done to reconstruct the breast after a mastectomy.

A professional, nonjudgmental attitude and clear information about surgical breast options are most useful for women engaged in decision making about mammoplasty. The desire to change the appearance of the breasts has special significance for each woman as she attempts to change or recreate her body image. Be aware of the cultural value that the woman places on the breast. Help the patient set realistic expectations about what mammoplasty can achieve and possible complications (e.g., hematoma formation, hemorrhage, infection). If an implant is involved, capsular contracture and loss of the implant are possible.

Breast Reconstruction

Breast reconstructive surgery is a type of surgery for women who have had all or part of a breast removed. It is done to achieve symmetry and to restore or preserve body image. It may be done simultaneously with a mastectomy or some time afterward. The timing of reconstructive surgery is personalized based on the patient's physical and psychologic needs.[21]

Indications

The main indication for breast reconstruction is to improve a woman's self-image, regain a sense of normalcy, and assist in coping with the loss of the breast. It restores the contour of the breast without the use of an external prosthesis. Reconstruction techniques cannot restore lactation, nipple sensation, or erectility. Although the breast will not fully resemble its premastectomy appearance, the reconstructed appearance usually is an improvement over the mastectomy scar (Fig. 51.9).

Types of Reconstruction

Breast Implants and Tissue Expansion

Implants have a silicone shell filled with either silicone gel or saline.[22] Some newer types use a cohesive gel, which is a thicker silicone gel. Implant surgery can be done in 1 or 2 stages.

In the 1-stage procedure, the implant is placed at the same time as the mastectomy. The implant is usually placed under the pectoralis muscle.

In the 2-stage procedure, a tissue expander is inserted after the mastectomy. The expander stretches the skin and muscle at the mastectomy site before inserting permanent implants (Fig. 51.10). It is placed in a pocket under the pectoralis muscle, which protects the implant and provides soft tissue coverage. The expander is minimally inflated, then gradually filled by weekly injections of sterile saline solution. This procedure stretches the skin and muscle and can be painful. A small magnet embedded in most expanders helps locate the port where the fluid is injected. A woman should not have an MRI with a magnet in place.

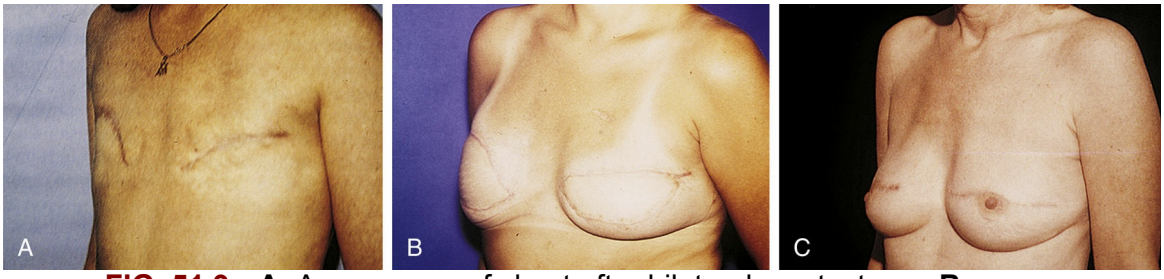

FIG. 51.9 **A,** Appearance of chest after bilateral mastectomy. **B,** Breast reconstruction before nipple-areolar reconstruction. **C,** Breast reconstruction after nipple-areolar reconstruction.
Courtesy Brian Davies, MD. From Fortunato N, McCullough S, eds: *Plastic and reconstructive surgery,* St Louis, 1998, Mosby.

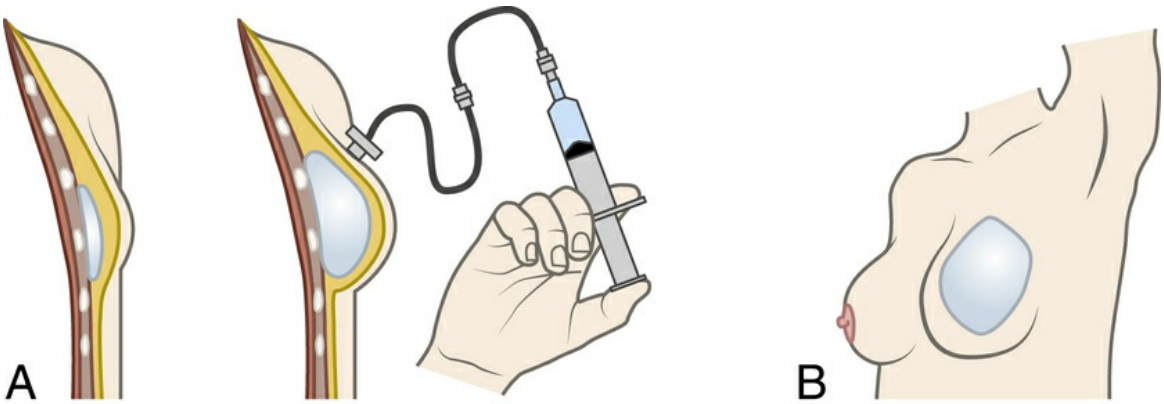

FIG. 51.10 **A,** Tissue expander with gradual expansion. **B,** Tissue expander in place after mastectomy.

The expander can be (1) surgically removed and a permanent implant is inserted or (2) remain in place to become the implant, thus eliminating the need for a second surgical procedure. Tissue expansion does not work well in those with extensive scar tissue from surgery or radiation therapy.

The body's natural response to the presence of a foreign substance is the formation of a fibrous capsule around the implant. If excessive capsular formation occurs because of infection, hematoma, trauma, or reaction to a foreign body, a contracture can develop, resulting in deformity. Although HCPs differ in their approaches to the prevention of contracture formation, gentle manual massage around the implant is routine. Other adverse outcomes include wrinkling,

scarring, asymmetry, pain, and infection at the incision site. There is a small chance of anaplastic large cell lymphoma occurring. This has mostly been associated with textured implants.[19]

Tissue Flap Procedures

Another type of breast reconstruction uses autologous (person's own) tissue to recreate a breast mound. In autologous reconstruction, tissue from the abdomen, back, thighs, or buttocks is used to create a reconstructed breast. The most common types of tissue flap procedures are *transverse rectus abdominis musculocutaneous (TRAM) flap, deep inferior epigastric artery perforator (DIEP) flap,* and *latissimus dorsi flap.*

The TRAM flap is a common flap surgery. The rectus abdominis muscles are paired flat muscles running from the rib cage down to the pubic bone. Arteries running inside the muscles provide branches at many levels, and these branches supply the fat and skin across a large expanse of the abdomen.

There are 2 different types of TRAM flaps: pedicle and free. In a pedicle flap, the tissue stays attached to the rectus muscle and is tunneled under the skin to the patient's chest (Fig. 51.11). In a free flap, the tissue is completely separated from the muscle and its blood supply and moved to the new place on the patient's chest. The tissue is molded and fashioned to form a breast. The abdominal incision is closed, giving the patient a result that is similar to having an abdominoplasty ("tummy tuck"). The procedure can last 6 to 8 hours with recovery taking 6 to 8 weeks. Some patients have report pain and fatigue for up to 3 months. Complications include bleeding, seroma, hernia, infection, and low back pain.

Perforator flaps are a type of free flap (a perforator artery connects a superficial artery with a deep one) that do not use muscle tissue. A *DIEP flap* is the type done most often. With the DIEP flap, only the skin and fat are taken from the same lower abdominal area as the TRAM flap. Patients may have less pain and restriction of movement with this procedure. The *superficial inferior epigastric artery perforator (SIEAP)* is another option using the abdominal area.

The *latissimus dorsi flap* is a pedicle flap. In this type of flap, a block of skin and muscle from the patient's back replaces tissue removed during mastectomy. A small implant may be needed under the flap to gain reasonable breast shape and size. A disadvantage of this technique is a scar on the back.

Less often, flaps are taken from the buttocks, hips, or thighs. The transverse upper gracilis flap, or inner thigh flap, is one type of free flap. Tissue, including the gracilis muscle, is taken from the bottom fold of the buttock extending into the inner thigh. The inferior or superior gluteal artery perforators are used for flaps taken from the buttocks.

Nipple-Areolar Reconstruction

Many patients undergoing breast reconstruction also have nipple-areolar reconstruction. Nipple reconstruction gives the reconstructed breast a much more natural appearance (Fig. 51.9, *C*). Nipple-areolar reconstruction is usually done a few months after breast reconstruction. Tissue to construct a nipple may be taken from the opposite breast or from a small flap of tissue on the reconstructed breast mound. Most often, the areola is tattooed with a permanent pigmented dye. Improved techniques now allow skilled tattoo artists to create a complete 3D nipple-areola complex. Polyurethane removable nipples are also available.

Breast Augmentation

In *augmentation mammoplasty* (procedure to enlarge the breasts), an implant is placed in a surgically created pocket between the capsule of the breast and pectoral fascia, or ideally under the pectoralis muscle. (Implants are discussed on p. 1207.)

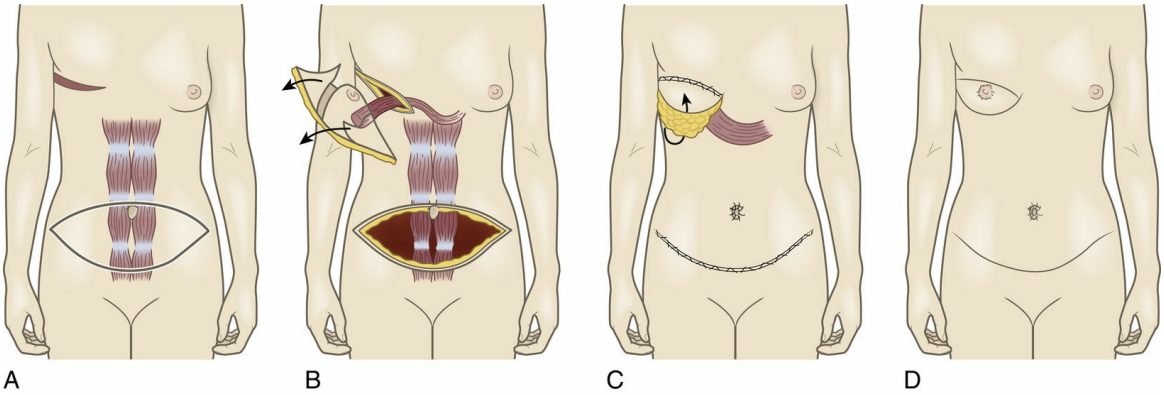

FIG. 51.11 Transverse rectus abdominis musculocutaneous (TRAM) flap. **A,** TRAM flap is planned. **B,** The abdominal tissue, while attached to the rectus muscle, nerve, and blood supply, is tunneled through the abdomen to the chest. **C,** The flap is trimmed to shape the breast. The lower abdominal incision is closed. **D,** Nipple and areola are reconstructed after the breast is healed.

Breast Reduction

For some women, large breasts can be a source of physical and psychologic discomfort. They can interfere with normal daily activities, such as walking, using a computer, and driving a car. The weight of large breasts can lead to back, shoulder, and neck problems, including degenerative nerve changes. Overly large breasts can interfere with self-esteem, self-image, and comfort in wearing some clothing. Reducing breast size can have positive effects on the patient's psychologic and physical health.

Reduction mammoplasty is done by resecting wedges of tissue from the upper and lower quadrants of the breast. The excess skin is removed, and the areola and nipple are relocated on the breast. Lactation usually can be accomplished if massive amounts of tissue are not removed and the nipples are left connected during surgery.

Nursing Management: Breast Augmentation and Reduction

Breast augmentation and breast reduction may be done in the

outpatient surgical area or involve overnight hospitalization. General anesthesia is used. Drains are generally placed in the surgical site to prevent hematoma formation and then removed when drainage is under 20 to 30 mL/day. Examine drainage for color and odor to detect infection or hemorrhage. Monitor the temperature. Change dressings as needed using sterile technique.

After surgery, assure the woman that the breast's appearance will improve when healing is complete. Depending on HCP preference, the patient may be told to wear a bra that provides good support continuously for 2 or 3 days after breast reduction or augmentation. Depending on the extent of the surgery, most women resume normal activities within 2 to 3 weeks. Strenuous exercise must often be avoided for several weeks.

Case Study

Breast Cancer

© XiXinXing/iStock/Thinkstock.

Patient Profile

A.K., a 68-yr-old married Asian American woman, has been diagnosed with a 1.3-cm estrogen- and progesterone-positive, HER-2–negative breast cancer. She is scheduled in the morning for a lumpectomy and sentinel lymph node biopsy (SLNB) with possible axillary node dissection.

Interprofessional Care

Preoperative

- When she is seen in the clinic 1 week before surgery, she is crying uncontrollably and says, “My husband does not want to look at me anymore. He is afraid of what I am going to look like with a flat chest.”
- She says, “I cannot sleep, and I just pace the floor at night.”
- “My mother died of breast cancer when she was 60, and my sister got it when she was 40.”
- Expresses concern that her 2 daughters (34 and 32) and their daughters are going to get “this horrible disease.”

Operative Procedure

- Lumpectomy and SLNB are done
- Tumor was removed with clear margins
- No cancer cells in her sentinel lymph nodes
- 4 lymph nodes are removed
- Tissue specimen sent for a 21-gene recurrence score genomic test

Postoperative

- Does not want to leave hospital and refuses to get out of bed
- Swelling and restricted range of motion in right arm
- Pain not controlled well with pain medication

Follow-Up Findings and Treatment

- 21-Gene recurrence score is 11, low risk
- Scheduled for external radiation and a consult with medical oncologist to discuss hormone therapy

Discussion Questions

1. What in A.K.'s breast cancer experience with her family members may influence her coping response?
2. ***Patient-Centered Care:*** How will you include cultural preferences in A.K.'s plan of care?
3. What complication did she develop after her surgery?
4. Which common exercises will A.K. need to practice after her surgery?
5. What information is important for you to provide to A.K. about her radiation treatment and hormonal therapy?
6. ***Safety:*** Describe specific nursing interventions aimed at minimizing risk for harm for A.K.
7. ***Patient-Centered Care:*** What information would you provide to A.K. about her surgery and why the 21-gene recurrence test was done?
8. What information is important for you to provide to A.K. and her daughters? What early detection measures are important for them to know?
9. ***Evidence-Based Practice:*** A.K. wants to know what the psychologic benefit may be for her daughters if they decide on a breast cancer genetic risk assessment.
10. ***Collaboration***: What types of referrals may be indicated for A.K.?
11. ***Collaboration***: What community resources are available to help A.K. and her family adjust to the change in her body and cope with the diagnosis of cancer?
12. ***Quality Improvement:*** What outcomes would indicate nursing interventions were successful for A.K.?
13. Develop a conceptual care map for A.K.

Answers and a corresponding conceptual care map available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. You are a community health nurse planning a program on breast cancer screening guidelines for women in the neighborhood. Which recommendations you would include? *(select all that apply)*
   a. Women over age 55 may have biennial screening.
   b. Screening should end when the women reaches age 65.
   c. Women aged 45 to 54 years should be screened annually.
   d. Regular screening mammography should start at age 45 years.
   e. Clinical breast examinations can be used if the woman has average risk.
2. You are caring for a young woman who has painful fibrocystic breast changes. Management of this patient would include
   a. scheduling a biopsy to rule out the presence of breast cancer.
   b. teaching that symptoms will subside if she stops using oral contraceptives.
   c. preparing her for surgical removal of the lumps, since they will become larger and more painful.
   d. explaining that restricting coffee and chocolate and supplementing with vitamin E may relieve some discomfort.
3. When discussing risk factors for breast cancer with a group

of women, you emphasize that the greatest known risk factor for breast cancer is

a. being a woman over age 60.

b. experiencing menstruation for 30 years or more.

c. using hormone therapy for 5 years for menopausal symptoms.

d. having a paternal grandmother with postmenopausal breast cancer.

4. A patient with breast cancer has a lumpectomy with sentinel lymph node biopsy that is positive for cancer. You explain that, of the other tests done to determine the risk for cancer recurrence or spread, the results that support the more favorable prognosis are *(select all that apply)*

a. well-differentiated tumor.

b. estrogen receptor–positive tumor.

c. overexpression of HER-2 cell marker.

d. involvement of two to four axillary nodes.

e. aneuploidy status from cell proliferation studies.

5. You are caring for a patient with breast cancer following a simple mastectomy. Postoperatively, to restore arm function on the affected side, you would

a. apply heating pads or blankets to increase circulation.

b. place daily ice packs to minimize the risk for lymphedema.

c. teach passive exercises with the affected arm in a dependent position.

d. emphasize regular exercises for the affected shoulder to increase range of motion.

6. Preoperatively, to meet the psychologic needs of a woman scheduled for a simple mastectomy, you would
   a. discuss the limitations of breast reconstruction.
   b. include her significant other in all conversations.
   c. promote an environment for expression of feelings.
   d. explain the importance of regular follow-up screening.
7. To prevent capsular formation after breast reconstruction with implants, teach the patient to
   a. gently massage the area around the implant.
   b. bind the breasts tightly with elastic bandages.
   c. avoid strenuous exercise until the implant has healed.
   d. exercise the arm on the affected side to promote drainage.

1. a, c, d, 2. d, 3. a, 4. a, b, 5. d, 6. c, 7. a

Sexually Transmitted Infections

Daniel P. Worrall

LEARNING OUTCOMES

1. Identify factors contributing to sexually transmitted infections (STIs) in the United States.
2. Describe the etiology, clinical manifestations, complications, and diagnostic studies for chlamydia, gonorrhea, trichomoniasis, genital herpes, genital warts, and syphilis.
3. Compare and contrast primary genital herpes with recurrent genital herpes.
4. Explain the interprofessional care and treatment of chlamydia, gonorrhea, trichomoniasis, genital herpes, genital warts, and syphilis.
5. Discuss the nursing assessment for patients who have an STI.
6. Describe the nursing management of patients with STIs.
7. Summarize the nursing role in the prevention and control of STIs.

Conceptual Focus

Infection
Pain
Reproduction
Sexuality

Sexually transmitted infections (STIs) are infectious diseases that are spread through sexual contact with the penis, vagina, anus, mouth, or sexual fluids of an infected person. Many do not view STIs as a serious health threat because they are easily treated. However, the complications are serious and can include infertility and cancer. Having an STI can affect persons' well-being, their relationships, and their sexual lives. Patient education, counseling, and referral are essential nursing roles for promoting health and optimal sexual well-being.

Mucosal tissues in the genitals (urethra in men, vagina in women), rectum, and mouth are especially susceptible to the bacteria and viruses that cause STIs. A list of common STIs is shown in Table 52.1. Some STIs, such as genital human papillomavirus (HPV), can spread

from direct skin-to-skin contact with an infected person. Other STIs, such as human immunodeficiency virus (HIV), may be contracted via blood or blood products or be transmitted from mother to baby during pregnancy or labor and delivery. Some STIs can spread through *autoinoculation* (spread of infection by touching or scratching an infected area and transferring it to another part of the body). STIs cannot typically be transmitted from casual contact or inanimate objects.

Factors Affecting Incidence of Stis

STIs are quite common. There are nearly 20 million new STIs diagnosed in the United States each year, resulting in an estimated 16 billion in health care costs.[1] More than 110 million Americans are infected with an STI at any given time. Having 1 STI increases the risk for getting another. A person can have more than 1 STI at the same time.

All STIs have an *incubation period*. It is the time from initial infection to the time when symptoms first appear or screening tests for the infection are positive. This can lead to the transmission of disease from an asymptomatic (but infected) person to another person, even before any symptoms or signs begin.

In the United States, all cases of gonorrhea, chlamydia, and syphilis must be reported to public health authorities for surveillance purposes for federally funded control programs and partner notification. Surveillance and partner notification are a major part of the effort to prevent and control the spread of STIs. Nurses and other HCPs play a vital role, as they are mandated to report these STIs to public health authorities. Despite this requirement, only a small number of infections are reported. This is especially important when considering that the more than 2 million cases of gonorrhea, chlamydia, and syphilis reported in the United States annually do not represent the actual number of infections.

TABLE 52.1 Causes of Sexually Transmitted Infections (STIs)

STI	Cause
Bacterial Infections	
Chlamydial	*Chlamydia trachomatis*
Gonorrhea	*Neisseria gonorrhoeae*
Syphilis	*Treponema pallidum*
Viral Infections	
Genital herpes	Herpes simplex virus (HSV 1 or 2)
Genital warts *(condylomata acuminata)*	Human papillomavirus (HPV)
Human immunodeficiency virus infection (HIV)	Human immunodeficiency virus (HIV) (see Chapter 14)
Hepatitis B and C	Hepatitis B and C viruses (see Chapter 43)
Molluscum	Molluscum contagiosum
Parasitic/Protozoan Infection	
Trichomoniasis	*Trichomonas vaginalis*

TABLE 52.2 Risk Factors for STIs

High-Risk Behaviors

- Alcohol or drug use (inhibits judgment)
- Having new or multiple sexual partners
- Having more than 1 sexual partner
- Having sexual partners who have/have had multiple partners
- Inconsistent or incorrect use of condoms or other barrier methods
- Sharing needles used to inject drugs

High-Risk Medical History

- Having 1 STI is a risk factor for getting another
- Not being vaccinated for STIs or other infections that may be transmitted through some forms sexual activity (HPV, hepatitis A

and B)
- Receiving multiple courses of nonoccupational postexposure prophylaxis for HIV infection

High-Risk Populations

- Adolescents and young adults (age <25)
- Ethnicity (e.g., black, American Indian/Alaskan Native, Native Hawaiian/Other Pacific Islander, Hispanic)[1]
- Men who have sex with men
- Persons in correctional facilities
- Transgender persons
- Victims of sexual assault
- Women

Many factors contribute to the high rate of STIs.[2,3] Earlier reproductive maturity and increased longevity make for a longer sexual life span. Other factors include (1) greater sexual freedom, (2) inconsistent or incorrect use of barrier methods (e.g., condoms) during sexual activity, and (3) the media's increasing emphasis on sexuality without mentioning safer sex. Substance use can further contribute to unsafe sexual practices by impairing judgment. Risk factors for STIs are outlined in Table 52.2.

STIs affect certain groups of people disproportionately. This includes youth under age 25 and those who are socially and economically disadvantaged.

Promoting Health Equity

Sexually Transmitted Infections

Incidence of STIs

- In the United States, depending on their age-group and gender, blacks have[3]:
    - The highest number of chlamydial infections, occurring at a rate 3.7–8.8 times that of whites.
    - More than 50% of cases of gonorrhea, infected at a rate 7.4–10.3 times that of whites.
    - More than 33% of cases of syphilis, infected at a rate 4.6–7.0 times that of whites.
- Non-Hispanic and black persons have a higher seroprevalence of herpes simplex type 2.[3]

Factors Influencing Disparities

- Social and economic disadvantages can make it hard for people to care for their overall health, including their sexual health.
- People who cannot afford basic necessities may have trouble accessing and affording quality sexual health services.
- Fear and distrust of HCPs and institutions can negatively affect racial and ethnic minorities from seeking health care.
- In communities in which there is a higher prevalence of STIs, it may be hard to reduce the risk for infection because with any sexual encounter a person faces a higher chance of having an infected partner than in those communities with a lower prevalence.

Trends in methods of contraceptive use also affect the rate of STIs. The male condom is the best form of protection (other than abstinence) against STIs. Although condom use has increased in the United States, condoms are not often used in the general population. Most women use hormonal (e.g., oral contraceptive pills, patch, injectables) or long-acting reversible contraceptives (e.g., intrauterine devices, implantable devices).[4] These do not provide barrier protection against STIs.[5]

This chapter covers the most common forms of STIs. HIV infection is covered in Chapter 14. Anyone who contracts an STI may also be at risk for HIV infection. HIV preexposure prophylaxis (PrEP) or nonoccupational postexposure prophylaxis (nPEP) may be appropriate for these persons.[6] See Chapter 14 for more about PrEP and nPEP.

STIs Characterized by Discharge, Cervicitis, or Urethritis

Chlamydial Infections

Chlamydia is the most common reportable STI in the United States. Nearly 1.6 million cases are reported annually, and incidence is on the rise. As many infections are asymptomatic, the actual number of infections is significantly higher.[1]

Etiology and Pathophysiology

Chlamydial infections are caused by *Chlamydia trachomatis,* a gram-negative bacterium and intracellular pathogen. *Chlamydia* is transmitted through exposure to sexual fluids during vaginal, anal, or oral sex. Ejaculation does not have to occur for it to be transmitted. The incubation period for chlamydia is 1 to 3 weeks. Infection with *Chlamydia* does not provide protection from reinfection. This means that people who were treated for chlamydial infection can always be reinfected.

The most common site for infection in men is the urethra. Infections in the male urethra are called *urethritis*. The most common site for infection for women is the cervix. Infections in the female cervix are called *cervicitis*. Both men and women can get chlamydia of the rectum from receptive anal sex or the oropharynx from giving oral sex. Because the vagina acts as a natural reservoir for infectious secretions, STI transmission is often more efficient from men to women than it is from women to men.

FIG. 52.1 Chlamydial epididymitis. Red, swollen scrotum.
From Morse S, Moreland A, Holmes K: *Atlas of sexually transmitted diseases and AIDS,* London, 1996, Mosby-Wolfe.

There are many serotypes of the *C. trachomatis* bacteria. A subset of these strains can cause another STI, lymphogranuloma venereum (LGV). More common serotypes are often the cause of nongonococcal urethritis (NGU).

Clinical Manifestations

Patients with chlamydia often have no symptoms. However, if symptoms develop in men, they may have pain with urination or a urethral discharge. Rarely, men can have pain or swelling of the

testicles caused by infection of the epididymis (Fig. 52.1). Symptoms of cervicitis include mucopurulent discharge (mucus with pus), bleeding, dysuria, and pain with intercourse. Symptoms of rectal chlamydia include anorectal pain, discharge, bleeding, pruritus, tenesmus, mucus-coated stools, or painful bowel movements.

Complications

Complications often develop from poorly managed, inaccurately diagnosed, or undiagnosed chlamydia. Chlamydia is often not diagnosed until complications occur. While men rarely have long-term complications from infection, epididymitis can result in male infertility. More often, chlamydia can affect a woman's reproductive tract, resulting in *pelvic inflammatory disease* (PID).[7] PID can damage fallopian tubes and increases a woman's risk for an ectopic pregnancy (pregnancy outside of uterus), infertility, and chronic pelvic pain. The risk for developing PID increases with repeated infection The more episodes of PID, the more likely a woman will experience infertility. Both men and women can develop a rare reactive arthritis, an autoimmune response to infection with *C. trachomatis*.

Diagnostic Studies

Diagnosis of any STI requires an accurate sexual history, a physical examination, and laboratory tests specific to each infection. The preferred method for diagnosing chlamydia is through a nucleic acid amplification test (NAAT) (Table 52.3). NAAT is used to identify small amounts of DNA or RNA in test samples. NAAT can be done on endocervical or vaginal swabs from women, urethral swabs from men, and urine from both men and women. NAATs are the recommended test for rectal and oropharyngeal screening and diagnosis.[8]

TABLE 52.3 Interprofessional CareChlamydial

Infections

Diagnostic Assessment

- History and physical examination
- Nucleic acid amplification test (NAAT)
- Testing for other STIs (gonorrhea, HIV, syphilis)

Management

- Azithromycin (Zithromax) or doxycycline (Vibramycin)
- Alternative regimen: erythromycin, ofloxacin, or levofloxacin (Levaquin)
- Teach to abstain from sexual contact for 7 days after completing treatment
- Treat all sexual partners, who must also wait 7 days before resuming sexual contact

Interprofessional Care

Because of the high prevalence of asymptomatic infections, regular screening for chlamydia in high-risk populations is recommended (Table 52.2). Anyone diagnosed and treated for chlamydia needs to return for testing 3 months after treatment to be sure that they have not been reinfected or to detect treatment failure.

Drug Therapy

The preferred treatment is a single dose of azithromycin (Zithromax) or doxycycline (Vibramycin) twice a day for 7 days (Table 52.3). All sexual contacts within 60 days should be evaluated and treated to prevent reinfection and further transmission. Teach patients to abstain from sexual contact for 7 days after treatment or until all partners have been treated and have also abstained from sexual contact for 7 days. Review the ways to reduce risk for acquiring a repeat or new

STI in the future. Tell patients to return if symptoms persist or recur.

Drug Alert

Doxycycline (Vibramycin)

- Patients should avoid prolonged or excessive exposure to sunlight.
- Take doses on an empty stomach either 1 hour before eating or 2 hours after eating.
- Avoid taking with antacids, iron products, or dairy products.
- Pregnant women should not take doxycycline.

Unfortunately, there is a high rate of recurrence for chlamydia. This often occurs when the sexual partners of infected people are not treated. This "ping-pong" effect (treatment, reexposure, then reinfection) can end only when both partners are treated appropriately. Because of this issue, the CDC recommends *expedited partner therapy* (EPT).[8,9] EPT means HCPs can give drugs or prescriptions to patients with STIs to give to partners without their examining the partner. The legality of EPT varies from state to state, but few states prohibit EPT. EPT is not routinely recommended for men who have sex with men (MSM) because of a higher risk for coexisting infections in partners of MSM, especially undiagnosed syphilis or HIV. It is not recommended for female partners who are symptomatic because of the risk for PID.

Check Your Practice

You are working in a public health STI clinic. You are seeing a 28-yr-old woman for the second time in 2 months for recurrent vaginal discharge. The patient says she has not been with anyone else except

her regular partner. She says, “I don’t know why I have this again. The doctor gave me the pills and I took them.”

- How would you respond?
- What do you think is causing her symptoms?

Gonococcal Infections

Gonorrhea is the second most common reportable STI in the United States. The incidence is on the rise. There are an estimated 820,000 cases each year, though only 468,000 cases are reported.[1]

Etiology and Pathophysiology

Gonorrhea is caused by *Neisseria gonorrhoeae,* a gram-negative, diplococcus bacterium. Gonorrhea can be transmitted by exposure to sexual fluids during vaginal, anal, or oral sex. Ejaculation does not have to occur for it to be transmitted. The incubation period ranges from 1 to 14 days. As in chlamydia, prior infection does not provide protection from reinfection. The most common site for infection for men is the urethra and for women, the cervix. Both men and women can get gonorrhea of the rectum from anal sex or of the oropharynx from oral sex.

Clinical Manifestations

The initial site of infection in men is usually the urethra. Most men will be symptomatic within a few days. The most common symptoms of gonococcal urethritis are dysuria, purulent urethral discharge (Fig. 52.2), or epididymitis. Most women who contract gonorrhea are asymptomatic or have minor symptoms that they often overlook. For women, common symptoms are increased vaginal discharge, dysuria, frequency of urination, or bleeding after sex. Often, redness and swelling can occur at the cervix or urethra along with a purulent exudate (Fig. 52.3).

Both men and women can contract rectal gonorrhea during anal intercourse or oropharyngeal gonorrhea during oral sex. Symptoms of rectal infection include mucopurulent rectal discharge or bleeding, anorectal pain, pruritus, tenesmus, mucus-coated stools, or painful bowel movements. Most patients with gonorrhea in the throat have few symptoms. Some may have a sore throat within days of performing oral sex.

Complications

Because men are often symptomatic and seek treatment early in the course of gonorrhea, they are less likely to develop serious complications than women. The complication in men is epididymitis, which can result in infertility.

Because many women are asymptomatic and seldom seek treatment, serious complications are more common and usually the reason for seeking medical care. Untreated gonorrhea can cause an infection in the Bartholin's glands or Skene's glands or result in PID. PID increases risk for ectopic pregnancy, infertility, and chronic pelvic pain.

Although rare, both men and women can develop disseminated gonococcal infection (DGI). DGI is associated with skin lesions, fever, arthralgia, arthritis, and/or endocarditis (Fig. 52.4).

Neonates can develop gonococcal conjunctivitis *(ophthalmia neonatorum)* from exposure to an infected mother during delivery that can result in permanent blindness. Almost all states have laws or health department regulations requiring the use of prophylactic eye treatment of all newborns to prevent such infections. Because of both improved prenatal screening for gonorrhea and prophylactic treatment regimens, *ophthalmia neonatorum* caused by gonorrhea is rare.

Gender Differences

Sexually Transmitted Infections

Men

- Syphilis and gonorrhea more common, especially in men who have sex with men
- More likely to have symptoms of genital infection than women

- Genital infection results in fewer complications
- Easier to diagnose because of less complex anatomy
- Less likely to seek medical care unless symptomatic

Women

- Anatomy increases risk for STIs
- Less likely to show early signs of genital infection
- Trichomoniasis and herpes simplex type 2 more common
- Are screened for, and therefore more likely, to be diagnosed with HPV
- Have more frequent and serious complications related to STIs (e.g., PID, infertility)

Diagnostic Studies

For men, a presumptive diagnosis of gonorrhea is made if there is a history of sexual contact with a new or infected partner followed within a few days by urethral discharge. For women, making a diagnosis based on symptoms is difficult. Most women are asymptomatic or have symptoms that may be confused with other conditions, such as chlamydial or urinary tract infection.

A culture may be used to diagnose infection. Gram stains of urethral secretions can be used, but the sensitivity is not as good as other methods.

Interprofessional Care

Drug Therapy

Because of a short incubation period and high rates of infectivity, treatment is often given without waiting for positive test results. The first-line treatment is dual therapy with IM ceftriaxone with oral azithromycin (Zithromax) as a single dose (Table 52.4). Over the years, *N. gonorrhoeae* has developed resistance to many classes of antibiotics,

including fluoroquinolones (e.g., ciprofloxacin [Cipro], levofloxacin) and tetracyclines (e.g., doxycycline [Vibramycin]).[10] Given the increasing rate of drug resistance, all patients with gonorrhea must receive treatment with at least 2 antibiotics. Patients treated with a preferred regimen but who have a positive test 7 days after treatment need antibiotic sensitivity testing.

TABLE 52.4 Interprofessional CareGonococcal Infections

Diagnostic Assessment

- History and physical examination
- Gram-stained smears of urethral or endocervical exudate
- Culture for *Neisseria gonorrhoeae*
- Nucleic acid amplification test (NAAT) to detect *N. gonorrhoeae*
- Testing for other STIs (syphilis, HIV, chlamydial infection)

Management

- Uncomplicated gonorrhea: ceftriaxone IM with azithromycin (Zithromax)
- Treatment of sexual contacts
- Teach to abstain from sexual contact for 7 days after treatment
- Treat all sexual partners, who must also wait 7 days before resuming sexual contact
- Reexamination if symptoms persist or recur after treatment

As with chlamydia, all sexual contacts within 60 days should be evaluated and treated to prevent reinfection and further transmission. Teach patients to abstain from sexual contact for 7 days after

treatment, or until all partners have been treated and have also abstained from sexual contact for 7 days. Review the ways to reduce risk for acquiring a repeat or new STI in the future.

Trichomoniasis

Trichomoniasis ("trich") is an STI caused by the protozoan parasite *Trichomonas vaginalis*. It is another common STI in the United States, affecting an estimated 3.7 million people.[1] This infection is often overlooked compared to other STIs. However, better testing methods have improved detection. It is much more common among women than men, especially among women with HIV.

Etiology and Pathophysiology

Trichomonas can be transmitted by exposure to sexual fluids during vaginal, anal, or oral sex, even if ejaculation does not occur. The incubation period is usually 1 week to 1 month but can be much longer. Prior infection does not provide protection from reinfection.

The most common site for infection in men is the urethra and in women is the cervix. It is uncommon for *Trichomonas* to infect the rectum. It is not known to infect the oropharynx. Routine screening should be considered for women in high-risk populations, including HIV-positive women and women seeking care for vaginal discharge.[8]

Clinical Manifestations

Most people do not have symptoms. Men may report burning with urination, ejaculation, or urethral discharge. Women may report painful urination, vaginal itching, painful intercourse, bleeding after sex, or a yellow-green discharge with a foul odor. The cervix can have a "strawberry" appearance.

Complications

The main complications of untreated infection are related to the inflammation and irritation that it causes in the genital tract. This inflammation makes an infected person more likely to contract or transmit another STI, particularly HIV. While gonorrhea and chlamydia are responsible for most PID, trichomoniasis is associated with PID in women with HIV.

Diagnostic Studies

The preferred method of diagnosing trichomoniasis is by NAAT testing of vaginal or endocervical secretions or urine. Other methods include culture, point-of-care testing, or direct visualization of trichomonads under the microscope. Identification of motile trichomonads in the vaginal secretions confirms infection. Tests can be done on liquid-based cervical Pap samples. In men, NAAT testing is recommended.[8]

Interprofessional Care

Drug Therapy

Patients and their partners should be treated with either metronidazole (Flagyl) or tinidazole (Tindamax). Teach patients to abstain from sexual contact for 7 days after treatment or until all sexual partners have completed a full course of treatment and abstained from sexual contact for 7 days. Tell patients to return if symptoms persist or recur. Any sexual partner within the preceding 60 days should be treated. Teach patients to use condoms or other barrier methods with every sexual contact. Because of a high rate of recurrence, repeat testing 3 months after treatment is recommended.

STIs Characterized by Genital Lesions or Ulcers

Genital Herpes Infections

Genital herpes is a common, lifelong, incurable infection. There are 2 strains of herpes: herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2). Although both forms of HSV may cause anogenital infection, HSV-1 is usually associated with oral lesions. HSV-2 is more common in the genitals or anus.[8] However, an increasing proportion of anogenital herpes infections are caused by HSV-1. It is possible, but rare, to have HSV-2 infection of the mouth. Having 1 type does not protect against getting the other.

Around 50 million people in the United States have HSV-2. Most new infections are transmitted by someone who is unaware they are infected. The prevalence of new genital HSV-2 infections is twice as high among women compared to men. Hispanic and black persons are more likely to be infected.[1]

Etiology and Pathophysiology

The virus enters through the mucous membranes or breaks in the skin during contact with an infected person. The virus reproduces inside the cell and spreads to the surrounding cells. Then the virus enters the peripheral or autonomic nerve endings and ascends to the sensory or autonomic nerve ganglion near the infection site, where it often becomes dormant. Viral reactivation (recurrence or "outbreak") occurs when the virus descends to that initial site of infection, either the mucous membranes or skin.

When a person is infected with HSV-1 or HSV-2, the virus persists within the person for life. Transmission of either strain of HSV to others occurs easiest through direct contact with skin or mucous membranes when an infected person is symptomatic. However, both can be transmitted without any apparent symptoms, called *asymptomatic viral shedding*. It is impossible to predict when asymptomatic shedding will occur or for how long. HSV-2 is more likely to shed than HSV-1.

HSV-1 was primarily associated with orolabial disease, known as "cold sores" or "fever blisters" (Fig. 52.5) and HSV-2 with anogenital disease. However, there has been a shift in understanding that either HSV-1 or HSV-2 can cause genital, anal, or orolabial infections. In

most cases, HSV-1 infections are more common "above the waist," involving the gingivae, dermis, upper respiratory tract, and, rarely the central nervous system (CNS). HSV-2 almost always infects sites "below the waist," the genital tract, perineum, or anus. It is important to understand that there is no absolute, single site for either virus.

Clinical Manifestations

Primary Episode

A *primary (initial) episode* of genital herpes has an incubation of 2 to 12 days. Most people do not have any recognizable symptoms of primary HSV genital infection. If symptoms do occur, they follow a series of stages. During the *prodromal stage*, the period before lesions appear, the patient may have burning, itching, or tingling at the site of inoculation. In the *vesicular stage*, few to multiple small, often painful vesicles (blisters) may appear on the buttock, inner thigh, penis, scrotum, vulva, perineum, perianal region, vagina, or cervix. The vesicles have large quantities of infectious viral particles. Next, in the *ulcerative stage,* the lesions rupture and form shallow, moist ulcerations. In the *final stage,* spontaneous crusting and epithelialization of the erosions occur (Fig. 52.6).

FIG. 52.5 Herpes simplex virus (HSV).

A and *C,* From Centers for Disease Control and Prevention. Courtesy Susan Lindsley. *B,* From Morse S, Moreland A, Holmes K: *Atlas of*

Regional (inguinal node) lymphadenopathy and systemic flu-like symptoms, including fever, headache, malaise, and myalgia may occur with the primary episode. Urination may be painful from the urine touching active lesions. The whole process from prodrome to healing varies and can take up to 3 weeks. Autoinoculation can occur if active lesions are touched or scratched, causing additional and potentially recurrent infection at extragenital sites.

Recurrent Episodes

Recurrent genital herpes occurs in many people during the year after the primary episode. The symptoms of recurrent episodes are less severe, and the lesions usually heal more quickly. HSV-1 genital infections recur less often than HSV-2 genital infections. Over time, both decrease in frequency.

Common triggers of recurrence include stress, fatigue, sunburn, general illness, immunosuppression, and menses. Many patients can predict a recurrence by noticing the prodromal symptoms of tingling, burning, and itching at the site where the lesions will recur. The greatest risk for transmitting infection exists when active lesions are present. However, it is possible to transmit the virus when no visible lesions or symptoms are present. Most HSV transmission occurs during these asymptomatic periods.

Complications

Both HSV-1 and HSV-2 can cause rare but serious complications, including blindness, encephalitis, and aseptic meningitis. Autoinoculation can result in the development of extragenital lesions in the buttocks, groin, thighs, fingers, and eyes. Genital ulcers increase the risk for contracting HIV. HSV lesions can be more severe and more persistent in HIV-infected patients.

Pregnant women with HSV can transmit the virus to the baby, especially if the virus is shed while the infant passes though the birth canal. Women with a primary episode of HSV near the time of

delivery have the highest risk for transmitting genital herpes to the neonate. The virus can infect the neonate's skin, eyes, mouth, or the CNS or become widespread and cause significant morbidity and mortality. An active genital lesion at the time of delivery is an indication for cesarean delivery.[8]

One of the most profound consequences for people with genital herpes is the overall impact it can have on their psychologic well-being, their relationships, and their sexual lives. You can help teach patients to understand how to talk to sexual partners about HSV. Refer patients who need counseling. Teach patients with herpes that it is a common, manageable, non–life-threatening condition and help them to understand their treatment options.

Diagnostic Studies

Diagnosis is often based on the patient's reported symptoms, then confirmed by visual examination. Culture from open skin eruptions can be used to diagnose HSV and distinguish between HSV-1 and HSV-2. Highly accurate blood tests for antibodies are available for HSV-1 and HSV-2, but do not show the location of the infection. These antibodies usually appear by 12 weeks after exposure.

Interprofessional Care

Drug Therapy

Although not a cure, antiviral drugs can shorten the duration of HSV viral shedding, shorten the healing time of eruptions, and reduce the frequency of outbreaks by up to 80%.[8] Treatment of HSV should start before diagnostic results are available because early treatment reduces the duration of the ulcers and risk for transmission (Table 52.5).

TABLE 52.5 Interprofessional CareGenital Herpes

Diagnostic Assessment

- History and physical examination
- Antibody assay for HSV type
- Viral isolation by tissue culture

Management

- Identify triggering factors
- Abstain from sexual contact while lesions are present and until fully healed
- Symptomatic care
- Confidential counseling and testing for HIV

Primary (Initial) Infection

- Acyclovir (Zovirax), valacyclovir (Valtrex) or famciclovir (Famvir)

Recurrent Episodic Infection

- Acyclovir, valacyclovir, or famciclovir for shorter duration

Suppressive Therapy

- Acyclovir, valacyclovir, or famciclovir daily at a lower dose

Severe Infection

- IV acyclovir until clinical improvement, followed by oral antiviral

therapy

Three antiviral agents are available for the treatment of HSV: acyclovir (Zovirax), famciclovir (Famvir), and valaciclovir (Valtrex). These drugs inhibit herpetic viral replication. They are prescribed for both primary and recurrent infections. Taken daily at a lower dose, they can be used as suppressive therapy to decrease frequent anogenital recurrences. Teach patients with active outbreaks to maintain good hygiene, wear loose-fitting cotton undergarments, and avoid sexual contact until the outbreak has completely healed to reduce transmission to others.

The main goal is to keep eruptions clean and dry. Techniques to reduce pain with urination include pouring water onto the perineal area while voiding to dilute the urine or voiding in the shower. Pain may need a local anesthetic, such as lidocaine gel, or analgesics, such as ibuprofen, acetaminophen, acetaminophen with codeine, or aspirin. Ice packs to the affected area can give some relief.

IV acyclovir is reserved for severe or life-threatening infections in which hospitalization is needed for the treatment of ocular or widespread infections, CNS infections (e.g., meningitis), or pneumonitis.

Genital Warts

Genital warts *(condylomata acuminata)* are caused by the HPV. There are around 100 types of papillomavirus, of which at least 40 strains are sexually transmitted.[8] "Low-risk" strains of the virus can cause warts on the skin. "High-risk" strains can lead to cancers of the genital tract, anus, or oropharynx in some patients. HPV types 6 and 11 cause about 90% of genital and anal wart cases. About 355,000 people are diagnosed each year. Most sexually active men and women will be infected with some type of HPV at some point in their lives. In most states, HPV is not a reportable infection. (Cervical HPV infection is discussed in Chapter 53.)

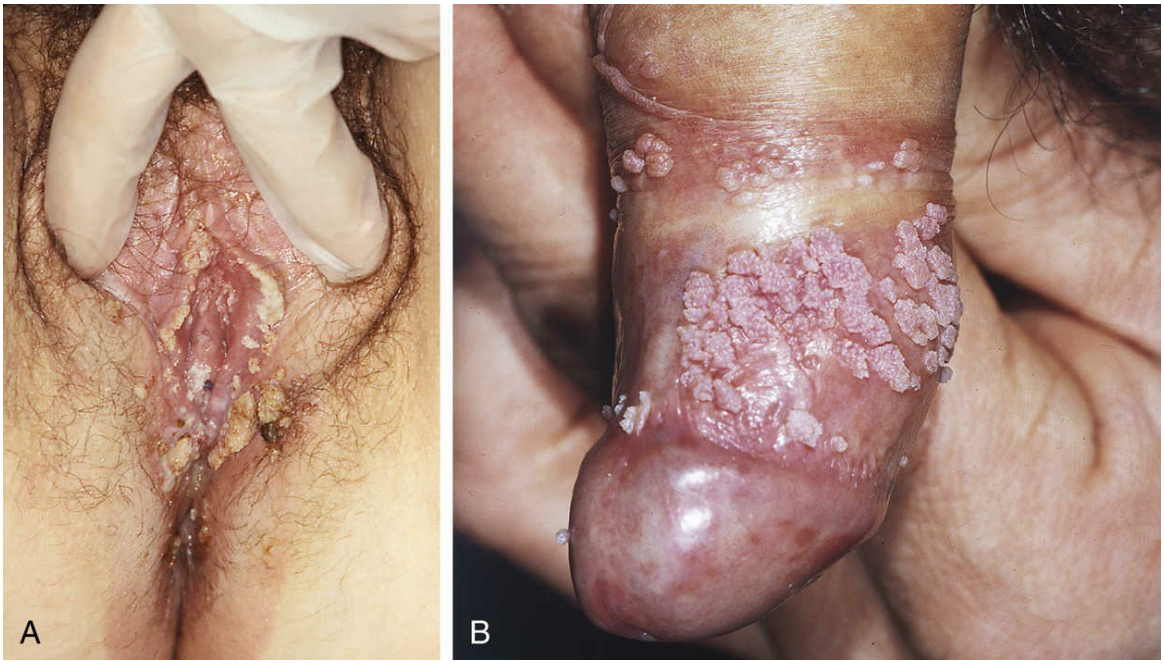

FIG. 52.7 Genital warts. **A,** Vulvar warts. **B,** Multiple warts on the penis.
From Habif TP: *Clinical dermatology*, ed 6, St Louis, 2015, Mosby.

Etiology and Pathophysiology

HPV is transmitted by skin-to-skin contact, most often during vaginal, anal, or oral sex. It can be transmitted during nonpenetrating sexual activity. The basal epithelial cells infected with HPV undergo transformation and proliferation to form a warty growth (Fig. 52.7). The incubation period can range from weeks to months to years. Infection with 1 type of HPV does not prevent infection with another type.

In most people, HPV is considered transient (virus is "cleared" or resolves spontaneously after 1 to 2 years). However, it can persist even when the warts themselves are not visible after treatment. It is unclear whether removing visible warts helps a person to clear the virus, cures the virus, or reduces a person's ability to transmit the virus.[8]

Clinical Manifestations

Most people with HPV do not know that they are infected because they are asymptomatic. Genital or anal warts are discrete single or multiple papillary growths that are white to gray, are pink-flesh colored, or can be hyperpigmented depending on the skin type. They may grow and coalesce to form large, cauliflower-like masses. Most patients have 1 to 10 genital warts.

In men, warts occur on the penis and scrotum, inside or around the anus, or in the urethra. In women, warts occur on the inner thighs, vulva, vagina, or cervix, in the perianal area, including in the internal anal canal (Fig. 52.7). There are usually no other signs or symptoms. Itching may occur with anogenital warts. Bleeding on defecation may occur with anal warts.

Diagnostic Studies

Most early lesions caused by HPV are undetectable by visual examination. A diagnosis of genital warts can be made based on the characteristic appearance of the lesions (Fig. 52.7). Warts may be confused with *condylomata lata* of secondary syphilis, cancer, or benign growths. Testing should be done to rule out other conditions. At present, the only definitive diagnostic procedure is biopsy of any questionable growth. Testing for cervical HPV is discussed in Chapter 53.

Complications

Although genital and anal warts can grow, spread, or be transmitted to others, they have few long-term complications and are not associated with the development of cancer. Infection with "high-risk" strains of HPV (types 16 and 18) can lead to cancers of the cervix, vagina, vulva, penis, anus, and oropharynx. For some people, HPV lesions can cause psychosocial burden due to the cosmetic appearance of lesions or the need for long courses of HPV-related treatment. During pregnancy, warts tend to grow rapidly and increase in size.

Interprofessional Care

HPV Vaccines

It may be possible to eradicate some cancerous HPV types over the next few decades, especially if both girls and boys are vaccinated. Currently 3 vaccines are available to protect against HPV. A quadrivalent vaccine (Gardasil) protects against types 6, 11, 16, and 18. The bivalent vaccine Cervarix offers protection against HPV types 16 and 18. A 9-valent vaccine (Gardasil 9) protects against HPV types 6, 11, 16, 18 and 5 other HPV types. These vaccines are given in 2 or 3 IM doses over a 6-month period and have few side effects. The CDC recommends that all children, male and female, be vaccinated at age 11 to 12, but vaccination can be started as early as age 9.[11] The bivalent and quadrivalent vaccines are approved for persons up to age 26. The 9-valent vaccine is approved for girls 9 to 26 and boys 9 to 15.

These vaccines do not treat active HPV infection. Ideally, persons should receive the vaccine before the start of sexual activity. Those who are infected with HPV can still get protection against HPV types not already contracted. HPV vaccines offer protection against strains causing 90% of genital warts and 70% (Gardasil) to 90% (Gardasil-9) of cervical cancers. They may offer protection from anal and certain types of throat cancer.

Evidence-Based Practice

HPV Vaccine and Young Males

T.N. is a 19-yr-old man who is being seen in the health care center for signs and symptoms of a urinary tract infection. After reviewing his health history, you learn he has not received the HPV vaccine. When asked, he shares with you that he is sexually active and that he does not need to get the vaccine because his girlfriend already has.

Making Clinical Decisions

Best Available Evidence. Males ages 15 to 26 can be vaccinated with 9-valent/9vHPV (Gardasil 9) to reduce the incidence of HPV infections and HPV-related cancers (e.g., anal, oropharyngeal, cervical, penile). HPV infections are caused by HPV types 6, 11, 16, 18, 31, 33, 45, 52, or 58. The HPV vaccine also protects against the 2 HPV types (6 and 11) that cause 90% of anogenital warts. Vaccination rates for HPV lag behind most all other vaccinations for young people.

Clinician Expertise. You know younger men may be unaware of the recommendations for the HPV vaccine. The vaccine was originally approved to prevent cervical, vulvar, and vaginal cancer in females ages 9 through 26. Since there is no routine screening for HPV-related cancers except cervical cancer, a vaccine that prevents most of these cancers is critical. You know that T.N. will need a 3-dose series (0, 1 to 2, 6 months) to complete his immunization.

Patient Preferences and Values. T.N. states he never has unprotected sex and does not like injections.

Implications for Nursing Practice

1. Why is it important to discuss the risks and benefits of the vaccine to T.N.?
2. How would you respond to T.N., who has heard that if you are already sexually active the vaccine will not be effective?
3. How can you address T.N.'s concerns about his dislike of injections?

Drug Therapy

Treatment of genital or anal warts is hampered by the high proportion of asymptomatic and undiagnosed infections and lack of curative treatment. The primary goal of treatment is the removal of symptomatic warts.

In-office treatment consists of chemical or ablative (removal with laser or electrocautery) methods. A common treatment is the use of trichloroacetic acid (TCA) or bichloroacetic acid (BCA) applied directly to the wart surface. Petroleum jelly applied with a cotton swab to the surrounding normal skin can minimize irritation. A sharp, stinging pain is often felt with initial acid contact, but this quickly subsides.

Patient-applied treatments are also available. Podofilox liquid and gel are available by prescription (Condylox, Condylox Gel). The patient applies the solution or gel for 3 successive days. Treatment can be repeated for up to 4 weeks or until resolution of the lesions. Imiquimod cream (Aldara, Zyclara) is an immune response modifier that is applied at bedtime, either 3 times per week (Aldara) or nightly for up to 16 weeks (Zyclara). Sinecatechin ointment (Veregen) is made from the extract of green tea leaves and has antioxidant properties. It is applied 3 times daily for up to 16 weeks.

Treatment of warts may or may not decrease infectivity as the HPV causing these may still be present. Anogenital warts are hard to treat and often need more than 1 treatment or modality. Therapy should be modified if a patient has not improved or cannot tolerate the side effects of certain treatments.

FIG. 52.8 Primary syphilis chancre.
From Morse S, Holmes K, Ballard R: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2010, Saunders.

If the warts do not resolve with topical therapies, treatments such as cryotherapy with liquid nitrogen, electrocautery, laser therapy, local α-interferon injections, or surgical excision may be needed. Teach patients that because treatment does not destroy the virus (merely the infected tissue), recurrence and reinfection are possible. Long-term follow-up is advised.

Syphilis

Syphilis is a sexually transmitted bacterial infection that can cause serious long-term complications if not identified and treated appropriately. Over 88,000 cases of syphilis are reported annually in the United States, with a sharp increase seen in recent years. The population most affected by syphilis is MSM, with the highest rates

among black MSM between 25 and 29 years old.[1]

Etiology and Pathophysiology

Syphilis is caused by *Treponema pallidum,* a bacterial spirochete. It is transmitted by direct contact with a syphilitic ulcer called a *chancre*. A chancre can occur externally on the genitals, anus, or lips or internally in the vagina, rectum, or mouth or tongue (Fig. 52.8) or through the mucosal membranes of an infected person. Transmission can occur during vaginal, anal, or oral sex. The incubation period can range from 10 to 90 days (average 21 days). Having the infection does not provide protection from reinfection, even after successful treatment. An infected pregnant woman can transmit syphilis to her fetus during her pregnancy. There is a high risk for stillbirth or having babies who develop complications after birth, including seizures and death.

Clinical Manifestations

Syphilis is called "*The Great Imitator*" because it can present with a variety of signs and symptoms that mimic other diseases. Compared with other STIs, syphilis is harder to recognize, which can delay treatment. If it is not diagnosed and treated, specific clinical stages occur with the progression of the disease (Table 52.6).

TABLE 52.6 Stages of Syphilis

Primary

- *Infectivity:* Highly infectious
- Duration of stage: 3–6 wk
- Single or multiple chancres (painless indurated lesions) of penis, vulva, lips, mouth, vagina, and rectum) (Fig. 52.8). Occurs 10–90 days after inoculation
- Regional lymphadenopathy (microorganisms drain into the

lymph nodes)
- Exudate and blood from chancre are highly infectious

Secondary

- *Infectivity:* Highly infectious
- *Duration of stage:* Occurs a few weeks after primary chancre heals, lasts 1–2 yr
- Flu-like symptoms: malaise, fever, sore throat, headaches, fatigue, arthralgia, generalized adenopathy
- Mucous patches in mouth (Fig. 52.9), tongue, or cervix
- Symmetric, nonpruritic rash bilaterally that appears on trunk, palms, and/or soles (Fig. 52.10)
- *Condylomata lata* (moist, weeping papules) in the anogenital area
- Weight loss, alopecia

Latent

- *Infectivity:* Early (<1 yr)—infectious; late (≥1 yr)—noninfectious
- *Duration of stage:* Throughout life or progression to late stage
- Absence of signs or symptoms
- Diagnosis based on positive specific treponemal antibody test together with normal CSF and absence of clinical manifestations

Late

- *Infectivity:* Noninfectious
- *Duration of stage:* Chronic (without treatment), occurs 1–20 years after initial infection
- Gummas (chronic, destructive lesions affecting any organ of body, especially skin, bone, liver, mucous membranes) (Fig.

52.11)

- *Cardiovascular:* Aneurysms, heart valve insufficiency, heart failure, aortitis
- *Neurosyphilis*: Can occur at any stage of syphilis
- *General paresis*: Personality changes from minor to psychotic, tremors, physical and mental deterioration
- *Tabes dorsalis* (ataxia, areflexia, paresthesias, lightning pains, damaged joints)

The primary stage is the development of a chancre at the site of transmission. This can appear days to months following infection. In most patients, it occurs by 3 weeks. Chancres can be found on the genitals but often go unnoticed when inside the mouth, vagina, or anus. As the chancre begins to heal or shortly after, patients will progress to the secondary stage of infection if untreated. This stage is usually characterized by a maculopapular rash. It may be coupled with other systemic symptoms. The classic rash appears on the palms of the hands or soles of the feet, but often involves the trunk or extremities. Without treatment, the rash will resolve, but the patient still has syphilis and will remain infectious for some time.

Tertiary, or late syphilis, is the final stage. Patients will not have obvious symptoms. During this stage, the organism is silently causing organ damage over many years. The formation of gummas can lead to serious complications.

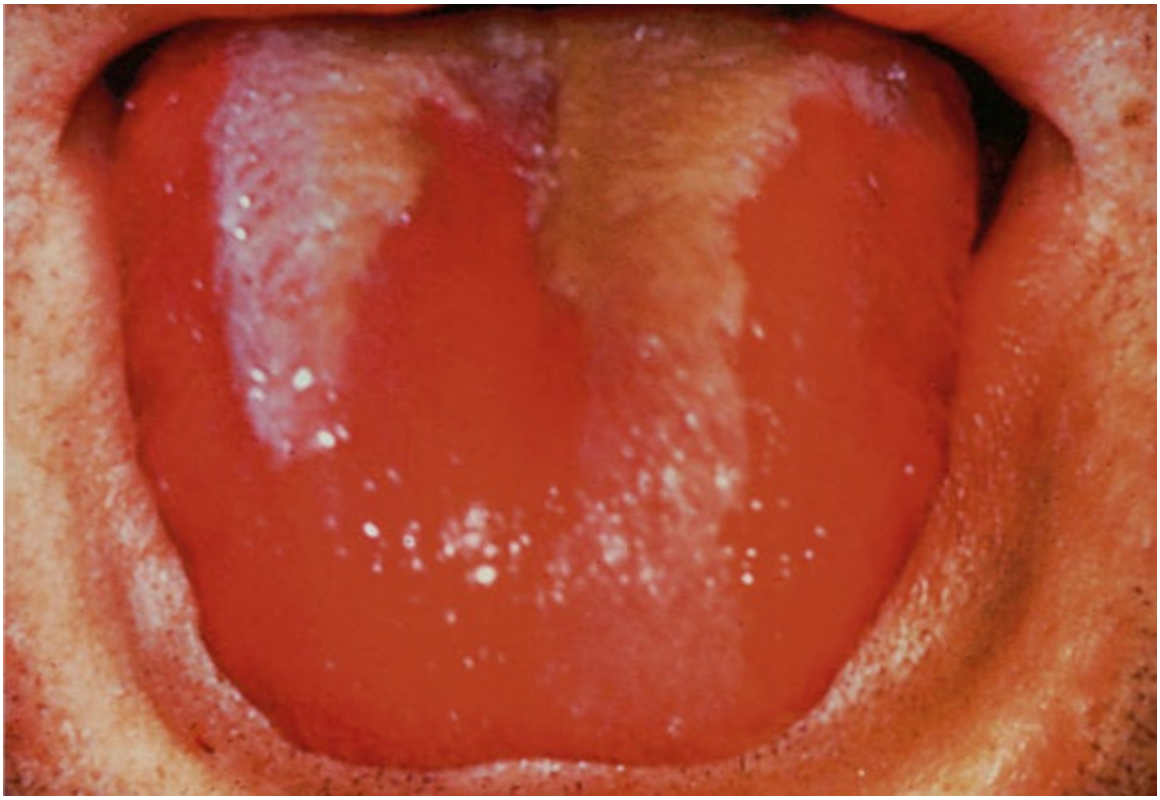

FIG. 52.9 Secondary syphilis. Mucous patch in the mouth.
From Mandell GL, Bennett JE, Dolin R: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.

FIG. 52.10 Secondary syphilis. Palmar rash.
From Centers for Disease Control and Prevention Public Health Image Library. Courtesy Robert Sumpter.

FIG. 52.11 Destructive skin gummas associated with tertiary syphilis. From Gawkrodger D, Ardern-Jones M: *Dermatology,* ed 6, St Louis, 2016, Mosby.

Complications

Gummas may cause irreparable damage to skin, bone, or liver. In cardiovascular syphilis, the resulting aneurysm may press on structures such as the intercostal nerves, causing pain. The risk for rupture exists as the aneurysm increases in size. Scarring of the aortic valve can cause aortic valve insufficiency and heart failure.

Neurosyphilis occurs when *T. pallidum* invades the CNS. It can occur at any stage of syphilis. Visual impairment, *tabes dorsalis* (progressive locomotor ataxia), and dementia are rare, extreme manifestations.

TABLE 52.7 Interprofessional CareSyphilis

Diagnostic Assessment

- History and physical examination
- Dark-field microscopy
- Nontreponemal and/or treponemal serologic testing
- Testing for other STIs (HIV, gonorrhea, chlamydial infection)

Management

- Antibiotic therapy:
- Penicillin G benzathine (Bicillin LA)
- Doxycycline or tetracycline (if penicillin contraindicated)
- Confidential counseling and testing for HIV infection
- Surveillance
- Repeat of nontreponemal tests at 6 and 12 mo
- Examination of cerebrospinal fluid at 1 yr if treatment involves alternative antibiotics or treatment failure has occurred.

Chancres on or inside the genitalia or anus enhance HIV transmission. Patients with HIV and syphilis appear to be at greatest risk for clinically significant CNS involvement and may need more intensive treatment than other patients with syphilis.

Diagnostic Studies

Syphilis is most often diagnosed by a blood test. We classify tests for syphilis as those done for screening and those done to confirm a positive screening test. Nontreponemal tests used for screening detect antibodies that are not specific for syphilis. These tests include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These tests usually become positive 10 to 14 days after the appearance of a chancre. We call the fluorescent treponemal antibody absorption (FTA-Abs) test, *T. pallidum* particle agglutination (TP-PA) test, and syphilis qualitative enzyme-linked immunoassay (EIA) *treponemal tests* because they specifically detect

treponemal antibodies. These tests are used to confirm a diagnosis.[8]

False-negative and false-positive test results can occur with the nontreponemal tests (VDRL, RPR). A false-negative result may occur with primary syphilis if the test is done before the person has had time to make antibodies. A false-positive finding may occur if patients have various other diseases or inflammatory conditions. Positive nontreponemal test results are always confirmed by treponemal tests. In the cerebrospinal fluid (CSF), changes such as an increased WBC count, increased total protein, and a positive treponemal antibody test are diagnostic of neurosyphilis.

If treatment with antibiotics is started early in the course of the disease based on the history and the symptoms, the serologic testing may not show syphilis. If the patient tests positive with screening serology (RPR), it will take time for this to normalize after treatment. This test is often used to ensure cure in patients. Once a person tests positive for syphilis via syphilis-specific testing (TP-PA, EIA), these findings may stay positive for an indefinite period despite successful treatment.

Interprofessional Care

Because of the serious complications associated with untreated syphilis, screening programs for high-risk groups are important for reducing morbidity and mortality. The evaluation of all patients with syphilis should include HIV testing. The CDC recommends annual syphilis testing for HIV patients (Table 52.7).[8]

Drug Therapy

Management is aimed at starting treatment early. Penicillin G benzathine (Bicillin L-A) is the recommended treatment for all stages (Table 52.7). When penicillin is contraindicated, doxycycline or tetracycline may be used. Aqueous procaine penicillin G is the treatment of choice for neurosyphilis. Treatment cannot reverse damage that is already present in the later stages of the disease. All sexual contacts from the preceding 90 days should be treated.

Reexamination and follow-up testing are recommended every 6 months for up to 2 years to ensure cure. Repeat HIV testing should be done on all HIV-negative patients diagnosed with primary or secondary syphilis given the higher risk for HIV transmission during these stages.

Nursing Management: STIs

Nursing Assessment

Subjective and objective data that should be obtained from a person with an STI are outlined in Table 52.8. You must be aware of patients' gender identity and current anatomy. Screen patients based on risk history and sexual behaviors. Assess the patient's risk for contracting an STI. Questions to ask include number of partners (in the last month, year?), types of partners ("Do you have sex with men, women, or both?"), type of birth control used (if applicable), use of condoms or other barrier methods, history of an STI, use of drugs and alcohol, exchange of sex for drugs or money, and risk for violence and personal safety.[12] Plan teaching based on the responses to these questions.

Interpersonal skills necessary for this interview include respect, compassion, and a nonjudgmental attitude. Tailor your counseling to the patient. Start by asking patients how they define themselves, including their gender identity and sexual preferences. Do not assume someone is heterosexual, MSM, or women who have sex with women (WSW) based on appearance. Do not assume MSM engage in the same sexual practices. Finally, do not assume that older people are not at risk. Sex and sexuality are dynamic across the life cycle, and sexually active older adults can be at risk for STIs.[13]

Check Your Practice

You are working on the medicine unit caring for a 68-yr-old man

admitted for IV penicillin for neurosyphilis. The nurse that you are working with says, “I can’t believe a man that old could get syphilis.”

- How would you respond?
- What should you discuss with your colleague?

Nursing Diagnoses

Nursing diagnoses for the patient with an STI include:

- Impaired sexual functioning
- Risk for infection
- Lack of knowledge

Planning

The overall goals are that the patient with an STI will (1) understand the mode of transmission of STIs and the risks associated with STIs, (2) complete treatment and return for appropriate follow-up, (3) notify or assist in notifying sexual contacts about their need for testing and treatment, (4) abstain from sexual contact until infection is resolved, and (5) demonstrate knowledge of safer sex practices.

TABLE 52.8 Nursing AssessmentSTIs

Subjective Data
Important Health Information

Sexual health history: Sexual activity, history of STIs, multiple sexual partners, unsafe sexual practices
Medications: Allergy to antibiotics

Functional Health Patterns

Health perception–health management: Unsafe sexual practices, drug and/or alcohol use
Nutritional-metabolic: Nausea, vomiting, anorexia. Pharyngitis, oral lesions, chills. Alopecia
Elimination: Dysuria, urinary frequency, urethral discharge, pain with bowel movements
Cognitive-perceptual: Arthralgia, headache, painful, burning lesions, itching or irritation at infected site
Sexuality-reproductive: Dyspareunia, vaginal or penile discharge, bleeding with sex, genital or perianal lesions

Objective Data

General

Fever, lymphadenopathy (generalized or inguinal)

Integumentary

Syphilis: Primary: Painless, indurated genital, oral, or perianal lesions
Secondary: Bilateral, symmetric rash on palms, soles, or entire body. Mucous patches on mouth or tongue; alopecia
Genital herpes: Painful genital or anal vesicular lesions
Genital warts: Single or multiple gray or white genital or anal warts

Gastrointestinal

Rectal discharge, rectal lesions

Urinary

Urethral discharge, erythema

Reproductive

Cervical mucopurulent discharge, cervical erythema, cervical bleeding; penile purulent discharge, epididymitis, proctitis, genital lesions

Possible Diagnostic Findings

Chlamydia: Positive culture or NAAT cervical, urethral, anal, oropharyngeal, or urine samples
Gonorrhea: Positive cultures or NAAT from cervical, urethral, anal, oropharyngeal, or urine samples
Genital herpes: Positive HSV-1 or HSV-2 serum antibody test. Positive culture from active lesion indicating HSV-1 or HSV-2
Syphilis: Positive findings on VDRL and RPR, spirochetes on dark-field microscopy
Trichomoniasis: Positive increased pH and positive motile protozoa on wet preparation of discharge. Positive FDA–approved rapid test or liquid-based Pap positive for trichomoniasis

Nursing Implementation

Health Promotion

Many approaches to stopping the spread of STIs have had varying degrees of success. Be prepared to discuss "safer" sex practices and harm reduction with all patients, not only those who are perceived to be at risk. These practices include abstinence, monogamy, avoiding high-risk sexual behaviors, and correctly using condoms and other barriers with every sexual act. Sexual abstinence is the only certain method of avoiding all STIs, but few people consider this option. Limiting sexual contacts to an established, monogamous relationship

in which both partners have been tested for STIs can reduce the risk. Addressing issues related to drug and alcohol use is important for promoting healthy sexual behavior.

TABLE 52.9 Understanding Risk for STIs in Special Populations

When dealing with the following populations at risk for STIs, it is important to consider cultural, behavioral, and other risk factors that may place them at increased risk for STIs or not receiving appropriate screening.

Women Who Have Sex With Women (WSW)

- WSW should not be presumed to be at low or no risk for STIs based on sexual orientation.
- WSW are at risk for acquiring bacterial, viral, and protozoal infections from current and prior partners, both male and female.
- Practices involving digital-vaginal or digital-anal contact, particularly with shared penetrative sex items, present a means for transmission of infected cervicovaginal secretions.
- Female-to-female transmission of chlamydia, trichomoniasis, HIV, HPV, HSV, and syphilis have been reported.
- Report of same-sex behavior in women should not deter HCPs from screening for all STIs.

Men Who Have Sex With Men (MSM)

- MSM are at higher risk for HIV, syphilis, hepatitis C, and other viral and bacterial STIs compared to the general population.
- HIV-uninfected MSM who are diagnosed with an STI should be counseled about the options for HIV prevention, including preexposure prophylaxis (PrEP) and nonoccupational postexposure prophylaxis (nPEP).

- Rates of syphilis, gonorrhea, and chlamydia are increasing in MSM, particularly in HIV-infected MSM.
- Assess risk for STIs among MSM patients and be comfortable asking questions about sexual identity and practices, including insertive and receptive anal sex.

Transgender Persons

- *Transgender man* is a term used to describe a person born anatomically female but who identifies as male. *Transgender woman* is a term used to describe a person born anatomically male but who identifies as female.
- Rates of certain STIs, including HIV, are higher among transgender women, compared to the general population.
- Not all transgender persons have had genital reassignment surgery and may still have the genitals they were assigned at birth. Therefore screen these persons for STIs based on both risk history and current anatomy. For example, a transgender man may still have a vagina and cervix.

Source: Centers for Disease Control: Sexually transmitted disease treatment guidelines. Retrieved from *www.cdc.gov/std/tg2015/specialpops.htm*.

Be prepared to teach special populations, including MSM, WSW, and transgender persons, about their risks (Table 52.9). Encourage routine testing in people who are at higher risk, so STIs can be identified early. This will help decrease the potential for complications and reduce transmission to others. A teaching guide for the patient with an STI is shown in Table 52.10.

Measures to Prevent Infection

Encourage patients to take notice of a sexual partner's genitalia before

sex, paying attention to any discharge, sores, blisters, lesions, or rashes. Help patients to be aware of specific signs and symptoms of infection. This can help them to make good decisions about whether to continue sexual activity with safer-sex modifications or to choose not to have sexual contact at all. Remind patients that most STIs may have no symptoms but can still be transmitted. Emphasize with patients that when they have sex, they are exposed to the infections of everyone with whom their partner has ever had sex.

TABLE 52.10 Patient TeachingSTIs

When teaching the patient with STIs:

1. Explain precautions to take, such as
    - Using condoms and other barrier methods with every sexual encounter
    - Being monogamous, defining what monogamy means with your partner
    - Asking potential partners about their sexual history
    - Asking potential partners if they have been tested for STIs
    - Avoiding sex with partners who have visible oral, inguinal, genital, perineal, or anal lesions or those who use IV drugs
    - Voiding and washing genitalia and surrounding area after sex to flush out/wash away organisms to reduce potential for transmitting infection
2. Explain the importance of taking all antibiotics or antiviral agents as prescribed. Symptoms will improve after 1–2 days of treatment, but organisms may still be present.
3. Teach patients diagnosed with gonorrhea, chlamydia, syphilis, or trichomoniasis that all sexual partners need to be treated to prevent transmission and reinfection.
4. Teach patients to abstain from sexual contact during and for

7 days after treatment and to use condoms or other barrier methods when sexual activity is resumed to prevent spread of infection and reinfection.
5. Explain the importance of follow-up examination and retesting at least once after treatment (if appropriate) to confirm complete cure and prevent relapse.
6. Allow patients and partners to voice their concerns and clarify areas that need explanation.
7. Teach patients about the signs and symptoms of complications and need to report problems to their HCP to ensure proper follow-up and early treatment of reinfection.
8. Tell patients of the infectious nature of these infections to avoid a false sense of security, which may result in careless sexual practices or poor personal hygiene.
9. Tell patients about health department requirements for anonymously reporting certain STIs.

Proper use of a condom is a highly effective mechanical barrier to several infections that may be transmitted by or to a penis. Partners should openly discuss any objections to condom use, such as interference with spontaneity and the presence of a barrier. Information about the mechanics of sexual arousal and incorporating a condom into sex can help in overcoming the resistance to its use. Refusing sexual activity with any partner who will not use a condom is a safe and legitimate option.

The *female condom,* a lubricated polyurethane sheath designed for vaginal use, is another option for some women. Teach patients to avoid the spermicide nonoxynol 9 (N-9), which can be used alone to prevent pregnancy or as a condom lubricant. Nonoxynol 9 is one of the least effective methods of birth control when used alone. It can be irritating to the vagina and rectum, increasing the risk for acquiring an STI.

Promoting Population Health

Preventing Sexually Transmitted Infections

- Follow "safer" sex practices every time you have sexual contact and be responsible for your own protection.
- Have sexual activity only in an established, monogamous relationship.
- Obtain vaccinations to help prevent some types of HPV.
- Know your sex partners. Be comfortable saying "no" to sexual activity.
- Limit alcohol use to moderate levels.
- If you are at risk, obtain testing regularly and encourage partners to do the same.

Screening Programs

Screening programs are an effective means of identifying, treating, preventing, and controlling the spread of STIs. At present, there are CDC-recommended screening programs for certain populations, including young people, MSM, pregnant women, and anyone at increased risk for exposure to an STI (e.g., new partners, nonmonogamous relationships, not using condoms).[8]

Case Finding

Interviewing and case finding are other methods used to control the spread of STIs. These activities are directed toward finding and examining all sexual contacts of patients with reportable STIs so that effective treatment can be started. Public health professionals, often nurses, are aware of the social implications of STIs and the need for discretion in finding partners. Sexual contacts are not told about the origin of the information naming them as a contact or the timing of exposure to ensure patient privacy mandates.

Partner notification and treatment impose a heavy burden on public

health departments. As a result, the notification often becomes the responsibility of the infected partner. The infected partner may choose not to tell sexual partners, and the partners may choose not to seek treatment. Unfortunately, this perpetuates the disease.

Educational and Research Programs

Actively encourage your community to provide better education about STIs for its citizens. High-risk populations (e.g., young people under age 25, MSM) should be a prime target for such educational programs. STI rates are rising in older adults.[13] Older adults are less likely to use condoms and often have a hard time starting discussions of sexual health issues.

Knowledge and understanding can decrease the incidence of STIs. Encourage the HPV vaccine that protects against genital warts and cervical cancer for boys and girls before the start of sexual activity. Accurate and current information may help reduce parental fears related to the vaccine. Consider stressing the prevention of cancer as a reason for the vaccine, which may be more productive and less controversial, thus making the parent and adolescent more receptive.

Acute Care

Psychologic Support

The diagnosis of an STI may be met with a variety of emotions, such as embarrassment, shame, guilt, anger, or even a desire for vengeance. Encourage the patient to voice feelings. Couples in marital or committed relationships have an added problem when an STI is diagnosed if they must face the implication of sexual activity outside the relationship. The STI raises other concerns about their relationship and may serve as an incentive for further problem solving. A referral for professional counseling to explore the impact of the STI on their relationship may be indicated.

A patient who has genital herpes is faced with the fact that future outbreaks will occur and that no cure is available. This can be frustrating and disruptive to the patient's physical, emotional, social,

and sexual life. Help the patient identify and avoid any factors that may precipitate outbreaks, such as stress, local trauma, or sun exposure. Tell the patient that the frequency and severity of recurrences will decrease over time. It is important to stress that herpes is manageable and does not pose a risk to their overall health.

Genital or anal warts involve a prolonged course of treatment. Clearing the virus takes time and is not always possible. Patients can become frustrated and distressed due to frequent office visits, associated costs, potential for unpleasant side effects because of treatment, and effects of the infection on future health and sexual relationships. Support and a willingness to listen to the patient's concerns are needed. Local or online support groups are available for almost all STIs. Help patients to connect with support groups.

Follow-up

If you work in public health facilities, clinics, or other outpatient settings, you are more likely to care for a patient with an STI than if you work in a hospital setting. Whatever the setting, as a nurse, you are in a position to explain and interpret treatment measures, such as the purpose and possible side effects of prescribed drugs and the need for follow-up care (Table 52.10).

Single-dose treatment for gonorrhea, chlamydia, and syphilis helps prevent the problems associated with nonadherence with drug therapy. Give special instructions to the patient receiving multiple-dose therapy to complete the prescribed treatment. Teach the patient about problems resulting from nonadherence. All patients should return to the treatment center for a repeat culture from the infected sites or for serologic testing at designated times to determine the effectiveness of the treatment. Explaining to the patient that cures are not always obtained on the first treatment can reinforce the need for a follow-up visit. Advise the patient to inform sexual partners of the need for testing and treatment as a contact, regardless of whether they are free of symptoms or experiencing symptoms.

Ethical/Legal Dilemmas

Confidentiality and HIPAA

Situation

P.H. is a 22-yr-old woman who recently tested positive for chlamydia. You tell her to tell her sexual partners of the infection. She refuses to tell her boyfriend because he will know that she has had sex with another partner. You later learn that the nursing student who was in the clinic for the day is a friend of her boyfriend and told him that he should have STI testing.

Ethical/Legal Points for Consideration

- Each state has requirements for reporting communicable diseases and other health-related data. Inform the patient of the reporting requirements for communicable diseases.
- Nurses and other HCPs have both a legal and an ethical obligation to maintain confidentiality of patient information. The Health Insurance Portability and Accountability Act (HIPAA) ensures the privacy of personal health information.
- The duty to maintain confidentiality is not absolute and may be limited, as needed, to protect the patient or other parties, or by law or regulation, such as mandated reporting for safety or public health reasons.
- Your main obligation is to the patient seeking care. Patient teaching is one way to establish a partnership with this woman. Share information about the effects of the disease, the consequences of reinfection, and the effect of the disease on others who may not know that they are infected. Then encourage the patient to tell her partners of the diagnosis and discuss the option of expedited partner therapy (EPT) where applicable.

Discussion Questions

- What are your state's requirements for reportable conditions?
- In your opinion, what is the best way to balance the needs of an individual patient with those of the public?
- What are the risks to agencies for the breach of confidentiality and HIPAA?

Reference

Code of Ethics for Nurses. Retrieved from *www.nursingworld.org/practice-policy/nursing-excellence/ethics/code-of-ethics-for-nurses/*.

Hygiene Measures

Emphasize to the patient with an STI the importance of certain hygiene measures, such as frequent hand washing. Tell the patient not to scratch infection sites to avoid autoinoculation of STIs that can be spread to other parts of the body. Washing with soap and water and voiding after sex may have some benefit in decreasing the exposure to STIs but does not give adequate protection against transmission. Teach patients not to douche after sex. It can push bacteria higher into the reproductive tract or undermine local immune responses.

Sexual Activity

Sexual abstinence is needed during the communicable phase of any STI. Long-term precautions must be taken with those STIs that are chronic or recurrent. Emphasize that even single-dose treatments can take up to 1 week to clear the infection. Thus the patient is infectious during this period and should avoid all sexual contact. Emphasize the importance of using condoms or other barrier methods to help prevent the spread of infection and reinfection after treatment. Remind patients that complications can follow if sexual activity occurs before treatment completion. Patients need to discuss re-treatment or continued treatment with an HCP. During treatment, the patient can choose to relate to a partner in an intimate way that avoids

penetrative, oral-genital contact, or skin-to-skin contact.

Ambulatory Care

Because many STIs are cured with a single dose or short course of antibiotic therapy, many patients are casual about the outcome of these infections. The consequences of this attitude can include delays in treatment, nonadherence with instructions, and the development of complications, treatment failure, or reinfection. Complications are serious and costly and can include future infertility.

Surgery and prolonged therapy are needed for many patients with infection-related complications. Major surgical procedures, such as resection of an aneurysm or aortic valve replacement, may be needed to treat cardiovascular problems caused by syphilis. Pelvic surgery and procedures to correct fertility problems from an STI may be needed. If not successful, patients may need assisted reproductive technologies to achieve future pregnancy. Because young people ages 15 to 24 represent about 50% of new STIs annually, it is important to know that almost every state and the District of Columbia have laws that allow minors to consent to STI services without parental involvement (the minimum age varies by state).[8]

Evaluation

Expected outcomes for the patient with an STI are that the patient will

- Understand the course, modes of transmission, and treatment options for the STI
- Relate the potential long-term complications of untreated infection
- Adhere with drug regimens and the follow-up protocol
- Understand the importance of partner notification and treatment
- Have no reinfection and understand STI risk-reducing behaviors and practices going forward

Case Study

Gonococcal and Chlamydial Infection

© Eyecandy Images/Thinkstock.

Patient Profile

C.R. is a 24-yr-old Hispanic woman seen in the outpatient clinic reporting increased yellow vaginal discharge and bleeding after sex for the past 2 weeks. She is sexually active with a new partner. She was treated in the past for chlamydial infection at age 20.

Subjective Data

- She and her partner use condoms "sometimes"
- Last menstrual period was 3 weeks ago
- Noticed her partner had some unusual discharge before they had sex
- Appears anxious and teary

Objective Data

- Cervix: erythematous
- Mucopurulent cervical discharge
- Urine pregnancy test is negative
- NAAT of the cervix is positive for *N. gonorrhoeae* and *C. trachomatis*

Interprofessional Care

- ceftriaxone 250 mg IM × 1 dose
- azithromycin 1 g PO × 1 dose

Discussion Questions

1. What were C.R.'s risk factors for acquiring gonorrhea and chlamydial infection?
2. What complications could occur if C.R.'s infections are not

treated?

3. ***Priority Decision:*** What is the priority of care for C.R.?
4. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
5. ***Patient-Centered Care:*** What instructions should C.R. receive to ensure successful treatment? To prevent reinfection? To prevent further transmission of the infection?
6. ***Patient-Centered Care:*** What impact is her diagnosis likely to have on C.R.'s self-image? On her relationship with her sexual partner?
7. ***Safety:*** C.R. tells you she is worried about how her partner will react when she discloses this information. What safety precautions should be considered?
8. ***Evidence-Based Practice:*** C.R. mentions she is using the spermicide nonoxynol-9 (N-9) to protect herself against STIs. Would you advise her to continue to use it?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which populations have a higher risk for acquiring sexually transmitted infections (STIs)? *(select all that apply)*
   a. Transgender persons
   b. Young adults (age < 25)
   c. Men who have sex with men
   d. Men in long-term care facilities
   e. Women in correctional facilities
2. The nurse is obtaining a subjective data assessment from a

woman reported as a sexual contact of a man with chlamydial infection. The nurse understands that symptoms of chlamydial infection in women

a. are often absent.

b. are similar to those of genital herpes.

c. include a macular palmar rash in the later stages.

d. may involve chancres inside the vagina that are not visible.

3. A primary HSV infection differs from recurrent HSV episodes in that *(select all that apply)*

a. only primary infections are sexually transmitted.

b. symptoms are less severe during recurrent episodes.

c. transmission of the virus to a fetus is less likely during primary infection.

d. systemic manifestations, such as fever and myalgia, are more common in primary infection.

e. lesions from recurrent HSV are more likely to transmit the virus than lesions from primary HSV.

4. Explain to the patient with gonorrhea that treatment will include both ceftriaxone and azithromycin because

a. azithromycin helps prevent recurrent infections.

b. some patients do not respond to oral drugs alone.

c. coverage with more than one antibiotic will prevent reinfection.

d. the increasing rates of drug resistance requires using at least 2 drugs.

5. In assessing patients for STIs, the nurse needs to know that

many STIs can be asymptomatic. Which STIs can be asymptomatic? *(select all that apply)*

a. Syphilis

b. Gonorrhea

c. Genital warts

d. Genital herpes

e. Chlamydial infection

6. To prevent the infection and transmission of STIs, the nurse's teaching plan would include an explanation of

a. the appropriate use of oral contraceptives.

b. the need for annual Pap tests for women with HPV.

c. sexual positions that can be used to avoid infection.

d. sexual practices that are considered high-risk behaviors.

7. Provide emotional support to a patient with an STI by

a. offering information on how safer sexual practices can prevent STIs.

b. showing concern when listening to the patient who expresses negative feelings.

c. reassuring the patient that the disease is highly curable with appropriate treatment.

d. helping the patient who received an STI from their sexual partner in forgiving the partner.

1. a, b, c, e, 2. a, 3. b, d, 4. d, 5. a, b, c, d, e, 6. d, 7. b

Female Reproductive Problems

Kim K. Choma

LEARNING OUTCOMES

1. Summarize the etiologies of infertility and the strategies for diagnosis and treatment of the infertile woman.
2. Describe the etiology, clinical manifestations, and interprofessional and nursing management of menstrual problems and abnormal uterine bleeding.
3. Identify the risk factors, clinical manifestations, and nursing and interprofessional management of ectopic pregnancy.
4. Describe the changes related to menopause and interprofessional and nursing management of the patient with menopausal symptoms.
5. Describe the assessment and interprofessional and nursing management of women with pelvic inflammatory disease and endometriosis.
6. Explain the clinical manifestations, diagnostic studies, interprofessional care, including surgical therapy for cervical, endometrial, ovarian, and vulvar cancers.
7. Discuss the nursing management of the patient requiring surgery of the female reproductive system.
8. Distinguish among the common problems that occur with cystoceles, rectoceles, and fistulas and the related interprofessional and nursing management.

9. Summarize the clinical manifestations of sexual assault and the nursing and interprofessional management of the patient who has been sexually assaulted.

Conceptual Focus

Cellular Regulation
Hormonal Regulation
Infection
Inflammation
Pain
Reproduction
Sexuality

This chapter discusses several disorders, many of which are related to hormonal regulation, infection, inflammation, and cancer. Problems of the female reproductive and genital system can profoundly affect sexuality and reproduction. The consequences of these problems vary widely. Besides the obvious manifestations, a diagnosis of ovarian cancer often triggers intense feelings of anxiety and fear. An infertile couple can struggle with grief and the stress of infertility treatments. Pain and sexual dysfunction from prolapse or endometriosis can cause psychologic, social, and body image problems. We close with discussing sexual assault and the multiple physical and psychologic effects of intimate violence.

Infertility

Infertility is the inability of a couple to conceive after at least 1 year of regular unprotected intercourse. Around 12% to 18% of women are not pregnant after 12 months of trying to conceive.[1] *Fecundability,* the probability of achieving a pregnancy in 1 menstrual cycle, is a more accurate label because it recognizes varying degrees of infertility. Impaired fecundity refers to women who have difficulty getting pregnant or carrying a pregnancy to term.

Etiology and Pathophysiology

Infertility may be caused by male, female, or combined factors. Of couples with infertility, 25% have male factors that affect their chances of conceiving. Conditions that cause male infertility are discussed in Chapter 54. Sometimes the cause of infertility may not be found.

Female infertility may be due to problems with ovulation, the fallopian tubes, or conditions that affect the uterus or cervix. In women the risk for infertility begins around age 30. By the time a woman reaches the age of 40, the chances of conceiving are 10% or less. For both genders, chronic diseases, genital infections, and exposure to environmental toxins can affect fertility.[2]

TABLE 53.1 Interprofessional CareInfertility

Diagnostic Assessment

- History and physical examination of both partners, including psychosocial functioning
- Review of menstrual and gynecologic history
- Assessment of possible sexually transmitted infections
- Hormone levels
    - Serum hormone levels (e.g., FSH, LH, prolactin)
    - Urinary LH
- Pap test with HPV test as indicated by age
- Ovulatory study
- Tubal patency study
    - Hysterosalpingogram
- Semen analysis
- Pelvic ultrasound
- Genetic screening

Management

- Hormone therapy
- Drug therapy (Table 53.2)
- Intrauterine insemination
- Assisted reproductive technologies (ARTs)

Diagnostic Studies

Formal evaluation of the infertile couple is usually done after 1 year of regular unprotected intercourse. Earlier evaluation may occur in women over age 35 or based on medical or physical findings. Couples who are being evaluated usually have a detailed history and physical examination. Based on the findings, diagnostic testing may be ordered (Table 53.1).

A comprehensive evaluation of the female reproductive system includes cervical, uterine, endometrial, tubal, peritoneal, and ovarian factors that could be the source of infertility. A semen sample is done to determine if the cause is related to the male partner.

Interprofessional and Nursing Care

Infertility management depends on the cause. If the cause is due to ovarian function, supplemental hormone therapy may be used. Table 53.2 reviews drugs commonly used for women with infertility. Couples should be involved in fertility treatment decisions. The choices involve 4 major aspects: effectiveness (e.g., live birth rate), burdens of treatments (office visits, frequent injections), safety, (e.g., risk for multiple gestation), and costs.[3]

Assisted reproductive technology (ART) can be used to help women who are having difficulty becoming pregnant. ART includes fertility drugs for ovulation induction, artificial insemination, and surrogacy. Types of ART include (1) in vitro fertilization (IVF), (2) gamete intrafallopian transfer (GIFT), (3) zygote intrafallopian transfer (ZIFT),

(4) donor gametes, (5) freezing of ova, and (6) intracytoplasmic sperm injection (ICSI), a type of IVF that is often used for couples with male factor infertility. Some types of ART, such as IVF, are expensive and can be emotionally stressful. Assisting couples with infertility is critical. You can provide teaching about the physiology of reproduction and an overview of infertility evaluation and treatments.

TABLE 53.2 Drug TherapyInfertility

Drug	Mechanism of Action
Follicle-Stimulating Hormone Agonists	
follitropin (Gonal-f) **urofollitropin (Bravelle)**	Stimulates follicle growth and maturation by mimicking the body's natural FSH.
GnRH Agonists	
leuprolide (Lupron) **nafarelin (Synarel)**	Suppresses release of LH and FSH with continuous use. May be used in the treatment of endometriosis.
GnRH Antagonists	
cetrorelix (Cetrotide) **ganirelix**	Prevents premature LH surges and premature ovulation in women undergoing ovarian stimulation.
Human Chorionic Gonadotropin (hCG)	
Novarel **Pregnyl** **Profasi**	Induces ovulation by stimulating release of eggs from follicles.
Menotropins (Human Menopausal Gonadotropin)	
Humegon **Pergonal** **Repronex**	Product made of FSH and LH to promote the development and maturation of follicles in ovaries.
Selective Estrogen Receptor Modulator	
clomiphene (Clomid)	Stimulates hypothalamus to ↑ production of GnRH, which ↑ release of LH and FSH. End result is stimulation of ovulation.

TABLE 53.3 Types of Spontaneous Abortion

Type	Description
Complete abortion	All products of conception (POC) are expelled
Incomplete abortion	Parts of POC are retained
Inevitable abortion	Cervix is open and pregnancy loss cannot be prevented
Infected (septic)	Endometrium (uterine lining) and POC become infected

abortion	
Missed abortion	Fetus has died but has not been expelled
Threatened abortion	Unexplained bleeding with or without pain. Suggests pregnancy loss may occur

Early Pregnancy Loss

Early pregnancy loss is a term used to describe the loss of a pregnancy before 20 weeks of gestation.[4] **Abortion** is another term we use to describe the loss of pregnancy. Abortions are classified as *spontaneous* (those occurring naturally [e.g., miscarriage]) or *induced* (those occurring from medical intervention). *Miscarriage* is the common term for the unintended loss of a pregnancy.

Spontaneous Abortion

Spontaneous abortion is the natural loss of pregnancy before 20 weeks of gestation (Table 53.3). Nearly 20% of pregnancies result in miscarriage. The loss can be devastating for both the mother and her partner. Fetal chromosomal abnormalities cause many miscarriages before 8 weeks of gestation. Testing for chromosomal anomalies is now available for products of conception (POC) from a miscarriage. Other causes of miscarriage include endocrine abnormalities, maternal infection, uterine abnormalities (e.g., uterine fibroids, endometriosis), immunologic factors, and environmental factors.

TABLE 53.4 Methods for Inducing Abortions

Method	Length of Pregnancy	Description
Dilation and evacuation (D&E)	10–16 wk	Cervix is dilated, and contents of uterus are removed by vacuum cannula and use of other instruments as needed.
Medical vacuum	Usually up to	Catheter is inserted through cervix into uterus, and

aspiration	2 wk after first missed period	suction is applied. Contents of uterus are aspirated.
Mifepristone (Mifeprex) with misoprostol (Cytotec)	Up to 49–63 days*	Mifepristone is given orally, followed by misoprostol orally 48 hr later.
Suction aspiration (curettage)	Up to 12 wk	Cervix is dilated, uterine aspirator is introduced, and suction is applied, removing contents of uterus.

* FDA recommends 49 days. The American Congress of Obstetricians and Gynecologists guidelines state it is safe to use up to 63 days.

Treatment to prevent miscarriage is limited. Although bed rest and avoiding vaginal intercourse are often recommended, there is no evidence that these measures improve the outcome. Women are told to report any bleeding to the HCP.

If the pregnancy is not viable, 2 options are considered: expectant management or medical management. *Expectant management* refers to monitoring the patient to see if the POC are expelled naturally without complications. *Medical management* may be needed if the POC do not pass completely or bleeding becomes excessive. This may involve a *dilation and curettage (D&C)* or the use of medications (e.g., misoprostol [Cytotec]) to expel the remaining contents from the uterus. The D&C involves surgically dilating the cervix and scraping the endometrium of the uterus to empty the contents of the uterus.

Women who have moderate-to-heavy bleeding and the passage of clots during pregnancy may need emergency care at a hospital. Vital signs and blood loss are monitored along with an assessment of psychologic well-being. Any heavy bleeding, severe pain, or fever that occurs after medical management should be reported to the HCP. Ovulation can occur as soon as 2 weeks after early pregnancy loss. Normal menses should return within 4 to 6 weeks.

Provide grief support as the couple deals with the psychologic distress of their loss. Encourage them to share their feelings. Referral to a pregnancy loss support group may be helpful.

Induced Abortion

Induced abortion is an elective termination of a pregnancy.[5] There are several ways to induce an abortion (Table 53.4). Deciding which method to use depends on the length of the pregnancy and the woman's condition.

Once the woman makes the decision to have an abortion, she and her partner need support and acceptance. Prepare the patient for what to expect both emotionally and physically. Grief and sadness are normal emotions after an abortion. Nursing care for a woman who terminates her pregnancy includes assessment of a woman's need for counseling and support, providing for privacy, maintaining her physical comfort, and monitoring her vital signs.

After the abortion, teach the patient the signs and symptoms of complications. These includes abnormal vaginal bleeding, severe abdominal cramping, fever, and foul-smelling drainage. Stress to the patient that as soon as 1 week after having an abortion she can become pregnant again. Normal menstruation returns in 4 to 6 weeks.

Teach patients to refrain from intercourse and putting anything into the vagina for 1 week after the abortion. The exception is for women who use NuvaRing birth control. Oral contraception can be started the day of the abortion or 1 to 2 weeks after the procedure, depending on the patient's needs and desires.

Problems Related to Menstruation

The normal menstrual cycle is discussed in Chapter 50. The menstrual cycle may be irregular the first few years after menarche and in the years preceding menopause. Although most women have a predictable menstrual cycle, considerable normal variation exists among women in cycle length and in duration, amount, and character of the menstrual flow (see Table 50.2). During the perimenopausal period (the years prior to menopause) as ovarian function begins to decrease, women may note a change in their menstrual patterns.

Premenstrual Syndrome

Premenstrual syndrome (PMS) refers to a group of symptoms that occur during a woman's menstrual cycle. Many women have symptoms of PMS. They may be severe enough to affect interpersonal relationships, work responsibilities, academic performance, and social activities.

PMS includes a variety of physical, psychologic, and somatic symptoms. As many as 150 symptoms are associated with PMS. (PMDD) is the term used to describe PMS associated with a severe mood disorder.

Etiology and Pathophysiology

We do not completely understand the cause of PMS. PMS is likely due to a combination of biologic and psychosocial factors. Genetics, hormone and neurotransmitter (e.g., serotonin) imbalances, and nutrition problems are all thought to be causes of PMS.

Clinical Manifestations

PMS is extremely variable in its manifestations, frequency, and severity. Symptoms may also vary from one cycle to another. Common symptoms include breast discomfort, peripheral edema, abdominal bloating, sensation of weight gain, episodes of binge eating, headaches, anxiety, depression, irritability and moodiness, back pain, insomnia, menstrual cramps, fatigue, and generalized muscle pain.

Diagnostic Studies and Interprofessional Care

A focused health history and physical examination are done to identify any underlying conditions which may account for symptoms. These include thyroid problems, uterine fibroids, anemia, nutritional and vitamin deficiencies, autoimmune disorders, endometriosis, and depression.

To accurately diagnose PMS or PMDD, 4 factors are critical: (1) consistency of the syndrome complex, (2) occurrence of the symptoms in the luteal phase and resolution after the beginning of menses, (3) documented ovulatory cycles, and (4) symptoms that disrupt the woman's life.

A holistic approach to managing PMS symptoms for women includes stress management, dietary changes, exercise, teaching, and cognitive behavioral therapy. Mindfulness activities can help women deal with the discomforts of PMS.[6]

Drug Therapy

Selective serotonin reuptake inhibitors (SSRIs) (e.g., sertraline [Zoloft], fluoxetine [Prozac]) have provided relief to women who have anxiety, irritability, and mood changes associated with PMS. Many women choose to take oral contraceptives (OCPs) and/or nonsteroidal antiinflammatory drugs (NSAIDs) to reduce cramping, blood flow, and back pain. Vitamin B_6, calcium, and magnesium have been recommended for mood changes associated with PMS.

Check Your Practice

You are working in the gynecology outpatient clinic. Your patient is a 28-yr-old woman who reporting symptoms of PMS. She tells you, "My PMS has gotten so bad lately that I spend the entire day in bed due to pain. I am very anxious and overwhelmed. I can't function like this anymore."

- How would you respond?
- What are things she can do to relieve symptoms?

Nursing Management: Premenstrual Syndrome

Nursing care for the patient with PMS includes teaching her about the symptoms associated with PMS and how to manage them (Table 53.5). Acknowledging that she has PMS can be therapeutic and empowering. Teaching the woman's partner about the nature of PMS helps the partner better understand PMS and its effects. Provide the patient with support and reassure her that PMS is not an emotional disorder, but one that has a physiologic basis and can be managed.

TABLE 53.5 Interprofessional CarePremenstrual Syndrome (PMS)

Diagnostic Assessment

- History and physical examination
- Symptom diary

Management

- Stress management
- Nutritional therapy
- Aerobic exercise

Drug Therapy

- Diuretics
- Combined OCPs
- Prostaglandin inhibitors (e.g., ibuprofen)
- SSRIs (e.g., sertraline [Zoloft])

Dysmenorrhea

Dysmenorrhea is painful menses with abdominal cramping. The 2 types of dysmenorrhea are *primary* (no pathologic condition exists) and *secondary* (pelvic disease is the underlying cause). Dysmenorrhea is one of the most common gynecologic problems.

Etiology and Pathophysiology

Primary dysmenorrhea begins in the first few years after menarche, typically with the onset of regular menstrual cycles. It is usually related to increased levels of prostaglandin, a hormone that is found in the endometrium. Endometrial stimulation by estrogen and progesterone results in a dramatic increase in prostaglandin production. Prostaglandin stimulates the uterus to contract. Uterine contractions and constriction of small endometrial blood vessels result in tissue ischemia and increased sensitization of the pain receptors. This results in painful menstrual cramps. As menstruation continues, prostaglandin levels decrease each day and menstrual cramping lessens.

Secondary dysmenorrhea usually occurs after adolescence, most commonly at 30 to 40 years of age and worsens as a woman ages. Common pelvic conditions that cause secondary dysmenorrhea include endometriosis, chronic pelvic inflammatory disease (PID), and uterine fibroids. Because secondary dysmenorrhea can be caused by many conditions, the manifestations and severity vary. However, painful menses is the main manifestation.

Clinical Manifestations

Manifestations include menstrual pain that is most severe during the first few days of menses. Painful menstruation rarely lasts more than 2 days. Typical symptoms include lower, colicky abdominal pain that often radiates to the lower back and upper thighs. Nausea, diarrhea, fatigue, and headache may occur.

Secondary dysmenorrhea usually occurs after the woman has little to no pain during the menstrual cycle. The pain, which may be unilateral, is often more constant and continues longer than in

primary dysmenorrhea. Depending on the cause, symptoms such as *dyspareunia* (painful intercourse), painful defecation, or irregular bleeding may occur at times other than menstruation.

Diagnostic Studies

Evaluation begins with a complete health history and pelvic examination. A probable diagnosis of primary dysmenorrhea is given if the history reveals an onset shortly after menarche with symptoms that are associated only with menses. The pelvic examination is otherwise normal. If the HCP finds an underlying cause of dysmenorrhea, the diagnosis is secondary dysmenorrhea.

Interprofessional and Nursing Care

Treatment for primary dysmenorrhea includes pharmacologic and nonpharmacologic therapy. NSAIDs (e.g., naproxen [Naprosyn]) inhibit prostaglandins. OCPs may be used to decrease estrogen and progesterone. This results in lower prostaglandin levels, decreased monthly endometrial lining proliferation, and decreased menstrual flow.

Nonpharmacologic interventions include applying heat to the lower abdomen or back and physical exercise. Regular exercise helps to reduce prostaglandin production. Acupuncture and transcutaneous nerve stimulation may be used for women who have inadequate relief from drugs or who prefer not to take drugs.

Treatment of secondary dysmenorrhea depends on the etiology. Some patients are helped by the approaches used for primary dysmenorrhea. However, if a gynecologic problem is the main cause of secondary dysmenorrhea, then treating that underlying problem is the priority. For example, women with endometriosis who have secondary dysmenorrhea may benefit from OCPs.

Nursing interventions include teaching women with dysmenorrhea about the cause, symptoms, and treatment. This will provide women with a basis for coping with the problem and increase feelings of self-control. Teach women that during acute pain, relief may be obtained

by applying heat to the abdomen or back and taking NSAIDs. Suggest noninvasive pain-relieving practices, such as relaxation breathing and guided imagery, yoga, and meditation. Other measures to reduce discomfort include regular exercise and good nutrition.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) is any change in a woman's menstrual flow, including volume, duration, or cycle pattern. AUB can be classified based on the cause of bleeding (Fig. 53.1). *Heavy menstrual bleeding* (HMB) (instead of the term *menorrhagia*) describes excessive bleeding. *Intermenstrual bleeding* (instead of the term *metrorrhagia*) refers to bleeding between regular menstrual cycles.

Chronic AUB is classified as uterine bleeding that is abnormal in volume, timing, or regularity and has been present for most of the past 6 months. *Acute AUB* is an episode of heavy bleeding that requires immediate treatment.

In reproductive-age women, causes of AUB include uterine fibroids, polyps, ovulatory dysfunction, endometrial problems, or cancer. Other causes include bleeding disorders (e.g., thrombocytopenia), leukemia, medications, eating disorders, or liver failure.[7] For postmenopausal women, endometrial cancer must be considered whenever bleeding or spotting occurs after menstrual bleeding has ceased for 1 year or longer.

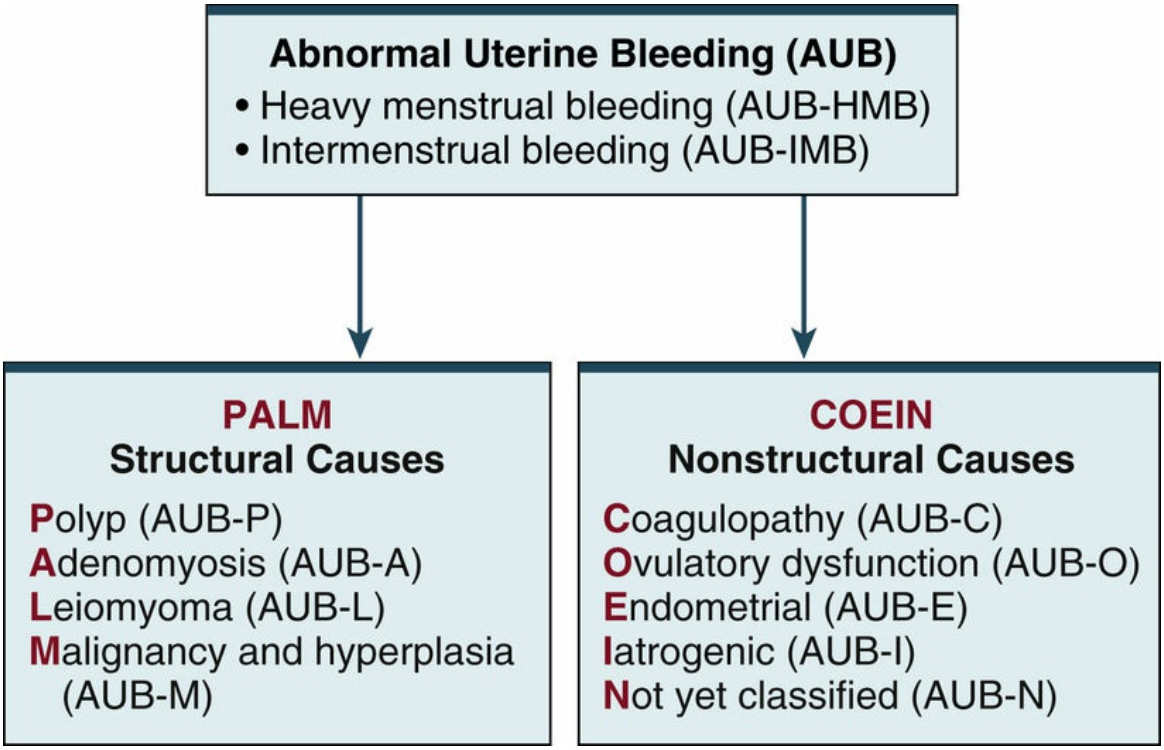

FIG. 53.1 PALM-COIEN classification system for abnormal uterine bleeding.
Used with permission. Munro MG, Critchley HO, Broder MS, et al: FIGO classification system [PALM–OEIN] for causes of AUB in nongravid women of reproductive age, *Int J Gynecol Obstet* 11:3, 2011.

Anovulation is the most common reason for missing menses. Ovulation is often erratic for several years after menarche and before menopause. Bleeding in between periods (spotting) is common for women who start taking OCPs. If spotting continues beyond the first few months on OCPs, a different pill formulation may be prescribed. Spotting with long-acting progestin therapies (e.g., intrauterine devices [IUDs], Nexplanon implant, progestin-only pills [levonorgestrel, norethindrone], progesterone injections [medroxyprogesterone acetate]) is common and not usually associated with any serious complications.

Amenorrhea is the absence or abnormal interruption of menstruation (Table 53.6). *Primary amenorrhea* refers to the failure of menstrual cycles to begin by 16 years of age. *Secondary amenorrhea* occurs when menstrual cycles stop for 3 to 6 months in menstruating women. Primary amenorrhea is often associated with chromosomal or

congenital abnormalities and the female athletic triad. Causes of secondary amenorrhea include primary ovarian insufficiency, polycystic ovary syndrome (PCOS), hypothalamic disorders, and hyperprolactinemia.

Diagnostic Studies and Interprofessional Care

Once it is determined that a patient has AUB, the HCP will determine if the AUB is related to a structural cause or nonstructural cause. A comprehensive history and physical examination are done to find the cause of AUB (Table 53.7). Laboratory evaluation and diagnostic procedures are based on findings from the history and physical examination. Treatment depends on the cause of the problem, degree of threat to the patient's health, her quality of life, and whether children are desired in the future.

Combined OCPs may be prescribed for a woman with amenorrhea to ensure regular shedding of the endometrium. Tranexamic acid (Lysteda) may be used during the menstrual cycle to treat heavy menstrual bleeding. This drug stabilizes a protein that helps blood to clot. The use of tranexamic acid is contraindicated in women who use combined OCPs.

Estradiol valerate/dienogest (Natazia) is the only combined OCP approved for treatment of heavy menstrual bleeding. It may be given to women who want an OCP to prevent pregnancy. Other options for treatment of heavy menstrual bleeding include NSAIDs and the Mirena IUD (progestin IUD).

TABLE 53.6 Causes of Amenorrhea

Genetic

- Congenital absence or doubling of reproductive organ(s)
- Turner's syndrome

Hormonal Imbalance

- Polycystic ovary syndrome (PCOS)
- Pituitary tumors
- Thyroid dysfunction

Lifestyle

- Acute and chronic illness
- Excess exercise
- Low body weight
- Stress

Medications

- Antidepressants
- Antihypertensives
- Antipsychotics
- Chemotherapy
- Hormone therapy (oral or injectable contraceptives, intrauterine devices)

Natural Amenorrhea

- Breastfeeding
- Menopause
- Pregnancy

Structural Problems

- Damage or scarring to reproductive organs from infection, trauma, radiation

TABLE 53.7 Interprofessional CareAbnormal Uterine Bleeding

Diagnostic Assessment

- History, including surgical history and medication history
- Age of menarche/menopause
- Bleeding patterns and perceived severity of bleeding (clots, soaking through clothing)
- Evaluation for obesity/hirsutism (suggestive of polycystic ovary syndrome)
- Pelvic examination
- Pregnancy test
- Complete blood count (CBC)
- Thyroid-stimulating hormone (TSH)
- STI screening
- Screening for bleeding disorders (if indicated)
- Imaging studies and tissue sampling
    - Transvaginal/pelvic ultrasound
    - Saline infusion sonohysterography
    - Endometrial biopsy
    - Hysteroscopy

Management

Based on the cause, may include:

- OCPs
- Hormonal therapy

- NSAIDS
- Mirena IUD

Nursing Management: Abnormal Uterine Bleeding

Teach women about the characteristics of the menstrual cycle to help them identify variations (see Table 50.2). This knowledge can decrease apprehension and dispel misconceptions about the menstrual cycle. Encourage the patient to report excessive bleeding, passing of clots, and unusually long duration of menstrual cycles.

Teach women to avoid the prolonged use of superabsorbent tampons that can increase the risk for toxic shock syndrome (TSS). TSS is an acute life-threatening condition caused by a toxin from *Staphylococcus aureus.* TSS causes high fever, vomiting, diarrhea, weakness, myalgia, and a sunburn-like rash.

Ectopic Pregnancy

An **ectopic pregnancy** is the implantation of the fertilized ovum anywhere outside the uterus. Almost all ectopic pregnancies occur within the fallopian tube. Around 3% of all pregnancies are ectopic (Fig. 53.2). Ectopic pregnancy is a life-threatening condition. Early detection can lead to successful management and reduce morbidity and mortality.

Etiology and Pathophysiology

Ectopic pregnancy can be caused by blockage of the fallopian tube(s) or reduction of tubal peristalsis that impedes or delays the fertilized ovum from passing to the uterus. After the fertilized egg implants itself in the fallopian tube, the growth of the gestational sac expands the tubal wall. Eventually the fallopian tube ruptures, leading to acute peritonitis. This occurs 6 to 8 weeks after the last normal menstrual

period. Often the woman presents due to bleeding and/or pelvic pain or pressure.

Risk factors or causes for ectopic pregnancy include a history of PID, prior ectopic pregnancy, current progestin-releasing IUD, and prior pelvic or tubal surgery. Procedures used in infertility treatment (e.g., IVF, embryo transfer, ovulation induction) increase the risk.

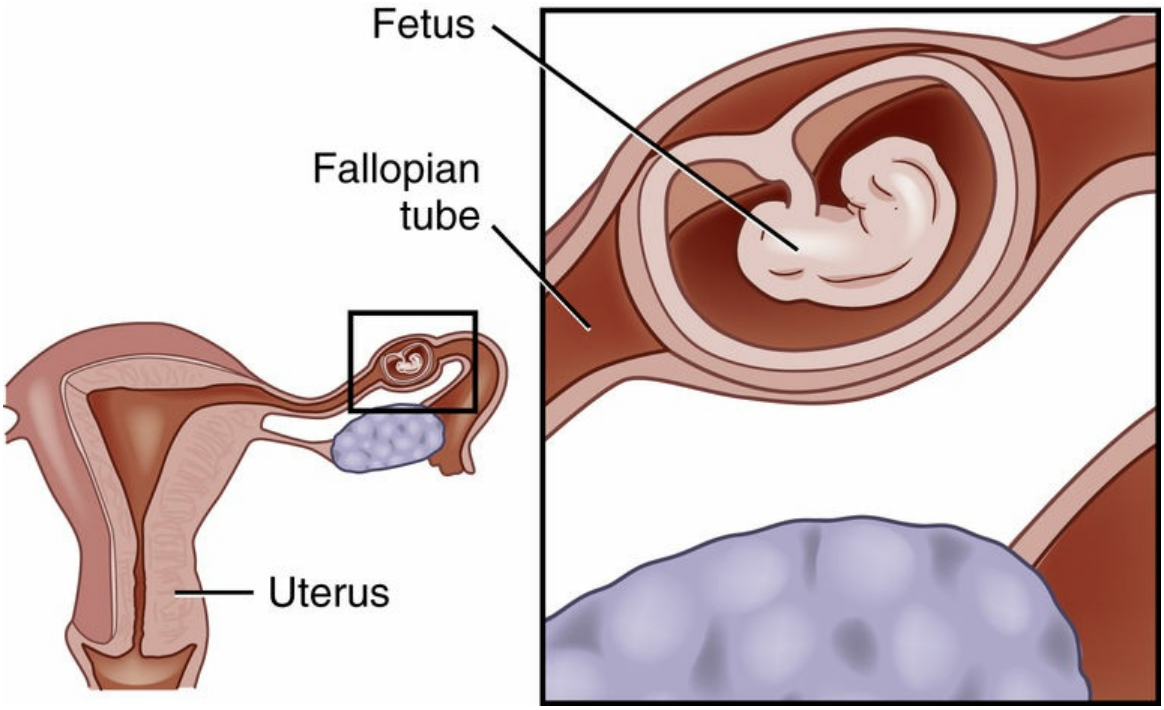

FIG. 53.2 Ectopic pregnancy occurring in the fallopian tube.

Clinical Manifestations

The classic manifestations are abdominal or pelvic pain, missed menses, and/or irregular vaginal bleeding. Others include morning sickness, breast tenderness, gastrointestinal (GI) symptoms, malaise, and syncope. Often, the symptoms of pregnancy (e.g., nausea) decrease as the hormones level off, offering a clue early on that something is not right.

Pelvic and/or abdominal pain is almost always present. It is caused by distention of the fallopian tube. The character of the pain varies

among women. It can be colicky or vague, unilateral or bilateral.

Symptom severity does not necessarily correlate with the extent of vaginal bleeding. Vaginal bleeding that may accompany ectopic pregnancy is usually described as spotting. However, bleeding may be heavier and can be confused with menses. If tubal rupture occurs, there is risk for hemorrhage and hypovolemic shock. This situation is an emergency.

Diagnostic Studies

Diagnosing an ectopic pregnancy can be challenging because of the manifestations. If the HCP suspects an ectopic pregnancy, a pelvic examination, vaginal ultrasound, and serum pregnancy test (quantitative human chorionic gonadotropin [β-hCG]) are done. Serum β-hCG levels can be measured every few days until ultrasound testing can confirm or rule out ectopic pregnancy. This is usually about 5 to 6 weeks after conception.

Check Your Practice

You are working in the ED. Your patient is a 29-yr-old woman who presented with acute abdominal pain. She has had in vitro fertilization. Her pain is 7 (on 0 to 10 pain scale). The HCP suspects an ectopic pregnancy. She is crying, "I am going to lose this baby, and we have been trying so hard to have one."

- As her nurse, what are your priorities?
- How would you respond to her?

Interprofessional and Nursing Care

There are 2 ways to treat ectopic pregnancies: drug therapy or surgery.[8] Drug therapy is used (1) when an ectopic pregnancy is confirmed on ultrasound, (2) the woman is hemodynamically stable,

(3) the woman is compliant with follow-up, and (4) the pregnancy is small and the fallopian tube has not ruptured.

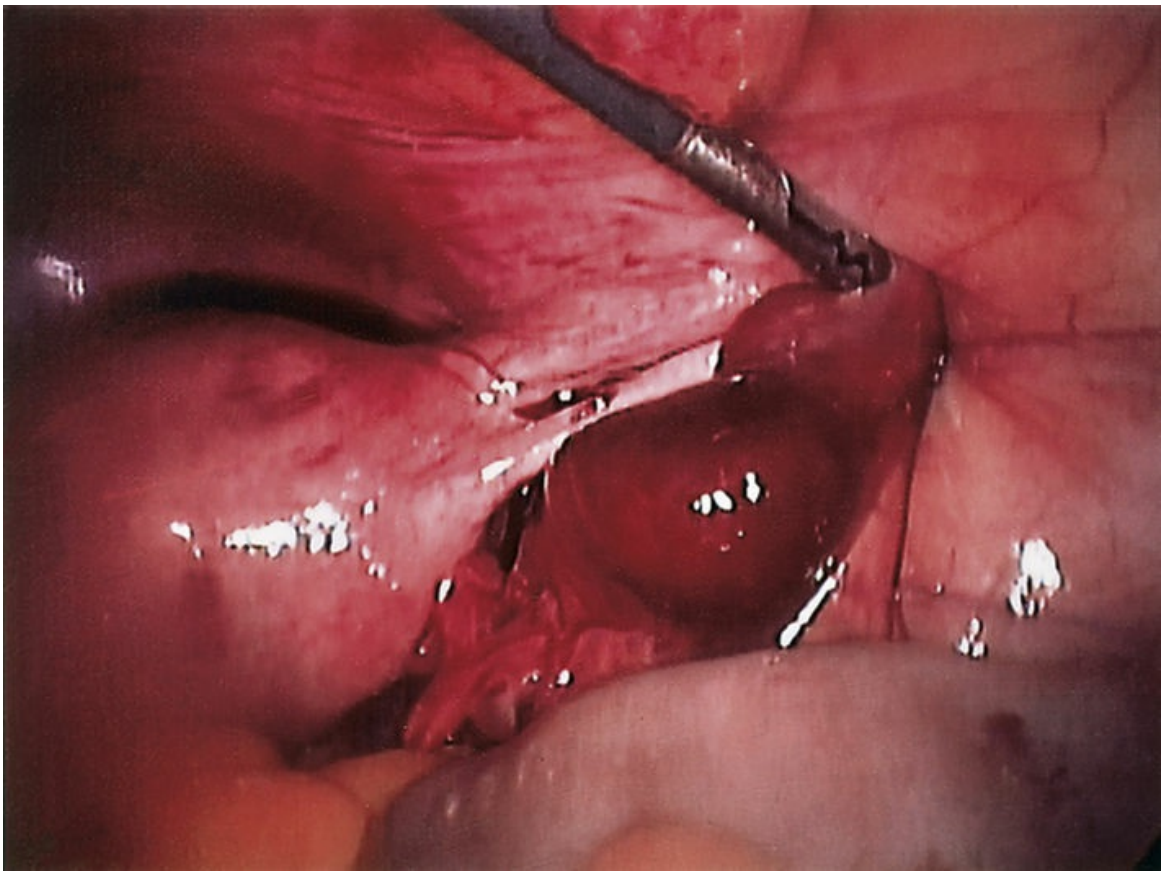

FIG. 53.3 Laparoscopic treatment of ectopic pregnancy in the right fallopian tube.
From Katz V: *Comprehensive gynecology,* ed 5, St Louis, 2007, Mosby.

Methotrexate therapy is the drug therapy of choice. Methotrexate stops the growth of rapidly dividing cells, such as embryonic, fetal, and early placenta cells, by inhibiting DNA synthesis and disrupting cell multiplication. Methotrexate can be given as a single shot or as several injections. The most common side effect is cramping abdominal pain. It usually occurs during the first 2 to 3 days of treatment. Other side effects may include vaginal bleeding, nausea, vomiting, indigestion, or dizziness.

Serum β-hCG levels are measured on posttreatment days 4 and 7. A

15% reduction in β-hCG is expected. Weekly β-hCG tests are done until negative. If at any time serum β-hCG levels plateau or increase, methotrexate may be repeated. If an ectopic pregnancy continues after 2 or 3 doses of methotrexate, surgical treatment is needed to remove the ectopic pregnancy.

If surgery is needed, a conservative approach that limits damage to the reproductive system is the goal. If the pregnancy is small, the pregnancy is removed laparoscopically (Fig. 53.3). If the tube ruptures, emergent surgery is done to stabilize the patient.

Nursing care includes closely monitoring vital signs and observing for signs of shock. Provide patient teaching to prepare her for the diagnostic procedures and drug therapy. Explain the side effects of methotrexate and tell her to avoid NSAIDs. Follow-up with weekly β-hCG tests is required. If the patient needs laparoscopic surgery, provide patient teaching and emotional support.

Perimenopause and Postmenopause

Perimenopause is a normal life transition for women that begins with the first signs of change in menstrual cycles and ends after cessation of menses. Menstrual changes can include shorter or longer cycles, less frequent cycles, lighter cycles, or heavier cycles.

Menopause is a normal physiologic cessation of menses associated with declining ovarian function that ends in cessation of the menstrual cycle and ovulation. *Natural menopause* is diagnosed retrospectively after 12 months of no periods. The average age for a woman is 52 years. The age can vary from 40 to 58 years.

Induced menopause occurs after surgical intervention to remove the ovaries or from side effects of chemotherapy, radiation therapy, or other drugs. *Postmenopause* is a term that refers to the time in a woman's life after menopause.

TABLE 53.8 Manifestations of Perimenopause and

Postmenopause

Perimenopause

- Irregular menstrual cycles
- Mood changes
- Occasional vasomotor symptoms (e.g., hot flashes)
- Sleep problems
- Vaginal dryness

Postmenopause

- Atrophy of genitourinary tissue (e.g., vulvar, vaginal epithelium) with decreased support
- Breast tenderness
- Cessation of menses
- Osteopenia, osteoporosis
- Vasomotor instability (e.g., hot flashes, night sweats)
- Stress and urge incontinence

TABLE 53.9 Manifestations of Estrogen Deficiency

Cardiovascular

- ↓ High-density lipoproteins (HDLs)
- ↑ Increased low-density lipoproteins (LDLs)

Genitourinary

- Atrophic vaginitis

- Dyspareunia from poor lubrication
- Incontinence

Musculoskeletal

- ↑ Fracture rate, especially vertebral bodies but also humerus, distal radius, and upper femur

Psychologic

- Emotional lability
- Change in sleep pattern
- ↓ REM sleep

Vasomotor

- Hot flashes
- Night sweats

Other

- ↓ Collagen content of skin
- Breast tissue changes

Clinical Manifestations

Manifestations of perimenopause and menopause are outlined in Table 53.8. Perimenopause is a time of erratic hormonal fluctuation and irregular menstrual cycles. With the decrease in function of the ovaries, estrogen levels drop, and hot flashes and other symptoms begin. The signs and symptoms of decreased estrogen are listed in Table 53.9.

The loss of estrogen plays a significant role in age-related changes. Changes most critical to a woman's well-being are the increased risks for coronary artery disease (CAD) and osteoporosis (from bone density loss). Other changes include a redistribution of fat, a tendency to gain weight more easily, muscle and joint pain, loss of skin elasticity, changes in hair amount and distribution, and atrophy of external genitalia and breast tissue.

Vasomotor instability (hot flashes) and irregular menses are the main manifestations associated with menopause. A hot flash is a sudden sensation of intense heat along with perspiration and flushing. Atrophy of the vulva and vagina may occur due to decreased estrogen levels. Decreased estrogen also causes thinning of the vaginal mucosa and the disappearance of rugae. This results in a decrease in vaginal secretions and causes the secretions to become more alkaline. Because of these changes, the vagina is easily traumatized. The woman can have dyspareunia and be more susceptible to infection.

Vaginal atrophy can lead to unnecessary and premature cessation of sexual activity. This can be corrected with water-soluble lubricants or, if needed, hormonal creams (vaginal estrogen) or oral hormone replacement therapy. About half of midlife women have vaginal atrophy, but few seek care.

The woman can have atrophic changes in the lower urinary tract and the vulva, which can result in a regression of the labia minora and majora. Bladder capacity decreases. The bladder and urethral tissue lose tone. These changes can cause symptoms that mimic a bladder infection (e.g., dysuria, urgency, frequency) when no infection is present. Decreasing blood serum estrogen levels can cause an array of physical and cognitive changes during menopause that include depression, irritability, insomnia, and memory loss.

Interprofessional Care

The diagnosis of menopause should be made only after careful consideration of other possible causes for a woman's symptoms. Testing of follicle-stimulating hormone (FSH) levels in the perimenopause period is not recommended because hormone levels

change throughout the menstrual cycle. However, once a woman has no periods for at least a year, FSH testing can confirm a diagnosis of menopause. FSH levels are increased in menopause. When a woman's FSH blood level is consistently elevated to 30 mIU/mL or higher, and she has not had a menstrual period for a year, it is generally accepted that she has reached menopause.

Drug Therapy

Hormone replacement therapy (HRT) using estrogen, with or without progesterone, is prescribed for some women. Women may choose to use HRT for short-term symptom management and treatment for several years (4 to 5 years) of menopausal symptoms. The risks (e.g., increased risk for breast and endometrial cancer, risk for blood clots) and benefits (e.g., minimizes bone loss, hot flashes, vaginal atrophic changes) must be carefully considered.[9]

Nonhormonal Therapy

Because of the risks associated with HRT, some women choose to use nonhormonal and nonpharmacologic interventions to manage their symptoms. For significant menopausal symptoms, nonhormonal pharmacologic agents may be used. For example, the SSRI antidepressants paroxetine (Paxil), fluoxetine, and venlafaxine (Effexor XR) are effective alternatives to HRT to reduce hot flashes.

Clonidine (Catapres), an antihypertensive drug, and gabapentin (Neurontin), an antiseizure drug, also have been shown to manage vasomotor symptoms during menopause. Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), are also used to manage menopausal symptoms. SERMs have positive benefits of estrogen, including preventing bone loss, without the negative effects (e.g., endometrial hyperplasia).

Some women seek herbal therapies to ease the symptoms they experience during menopause. While you will see a number of supplements marketed for menopause, there is no research showing that the use of any herb as a treatment for menopause symptoms is effective.

Nutritional Therapy

Good nutrition can decrease the risk for cardiovascular disease (CVD) and osteoporosis and help with vasomotor symptoms. A decrease in metabolic rate and careless eating habits can cause the weight gain and fatigue often attributed to menopause. An adequate intake of calcium and vitamin D helps maintain healthy bones and counteracts loss of bone density.

Complementary & Alternative Therapies

Herbs and Supplements for Menopause

Herb	Scientific Evidence	Nursing Implications
Black cohosh	Mixed evidence for use in the treatment of menopausal symptoms	• Generally well tolerated in recommended doses for up to 6 mo. • Should not be used by women with a liver disorder.
Soy	Mixed evidence for treatment of menopausal symptoms	• Women with a history of breast, ovarian, or uterine cancer or endometriosis should consult with their HCP before using soy or soy products. • Soy may interact with warfarin. Patients taking warfarin should consult with their HCP before using soy or soy products.

Source: *www.nlm.nih.gov/medlineplus/herbalmedicine.html#summary*.

Postmenopausal women not taking supplemental HRT should have a daily calcium intake of at least 1500 mg. Women taking estrogen replacement need at least 1000 mg/day. Calcium supplements are best absorbed when taken with meals, but not taken as a single dose. The woman should divide the calcium she needs into 2 doses per day so that it is absorbed properly. Either dietary calcium or calcium supplements may be used (see Table 63.14).

Nursing Management: Perimenopause and Postmenopause

Menopause is a time of great transition for a woman both physically and psychologically. Many women have symptoms for years during

the perimenopausal period while others transition without any difficulty. Menopause may be occurring simultaneously with role changes in the woman's personal and professional life. The combination of menopause and these changes can cause great emotional distress or a renewed sense of self and well-being.

Women in their perimenopausal and menopausal years need a lot of emotional support. Provide reassurance that symptoms can be treated and managed with either hormonal or nonhormonal therapies. It is important to teach them about strategies to prevent or reduce the risk for CVD and osteoporosis.

Infections of Lower Genital Tract

Etiology and Pathophysiology

The female genital tract is susceptible to different types of infections, especially when the pH of the genital tract is altered. In most women, the vaginal pH is typically below 4.5, which helps prevent certain bacterial infections from occurring. The pH level of the vagina is maintained through a combination of sufficient levels of estrogen and *Lactobacillus,* a naturally occurring bacteria that colonizes the vagina.

Infection and inflammation of the vagina, cervix, and vulva often occur when estrogen levels decrease or medication use (e.g., contraceptives, antibiotics, corticosteroids) affects the microbiome of the vagina, leading to changes in the pH balance of the genital tract. For example, *Candida albicans* may be present in small numbers in the vagina. Women who take an antibiotic for another type of infection may have an overgrowth of *C. albicans*. This leads to a condition called *vulvovaginal candidiasis* (often called a "yeast infection").

TABLE 53.10 Infections of the Lower Genital Tract

Infection and Etiology	Manifestations	Treatment Considerations
Bacterial Vaginosis		
Corynebacterium vaginale ***Gardnerella vaginalis***	Watery discharge with fish-like odor. May or may not have other symptoms	Drug therapy based on cause: • clindamycin (Clindesse)—vaginal • metronidazole (Flagyl)—oral or intravaginal • tinidazole (Tindamax)—oral • *Lactobacillus acidophilus* taken orally by diet (e.g., yogurt, fermented soy products) or supplements can ↓ unwanted vaginal bacteria
Cervicitis		
Chlamydia trachomatis ***Neisseria gonorrhoeae*** **(most often)**	Sexually transmitted. Mucopurulent discharge with postcoital spotting from cervical inflammation	Drug therapy based on cause, common agents include azithromycin (Zithromax) and ceftriaxone. Treat patient and partner. May be reportable according to state laws.
Severe Recurrent Vaginitis (more than 4 episodes per year)		
Candida albicans **(most often) or non-*albicans* strains**	Depend on cause	Drug therapy based on cause. All women who are unresponsive to first-line treatment should be offered HIV testing. Common in women with uncontrolled diabetes or HIV infection.
Trichomonas Vaginitis		
Trichomonas vaginalis **(protozoa)**	Sexually transmitted. Itching, frothy greenish or gray discharge. Hemorrhagic spots on cervix or vaginal walls	Antifungal agents • metronidazole (Flagyl) • tinidazole (Tindamax) Treat patient and partner
Vulvovaginal Candidiasis		
Candida albicans **(fungus)**	Itching, thick white curd-like discharge	Antifungal agents • clotrimazole (Gyne-Lotrimin, Mycelex) • fluconazole (Diflucan) • miconazole (Monistat) • terconazole (Terazol)

Organisms gain entrance to the lower genital tract through contaminated hands, clothing, douching, and intercourse. Women should not douche. Douching changes the natural acidity and microbiome of the vagina, causing an overgrowth of bacteria. Most lower genital tract infections are related to sexual intercourse. Intercourse can transmit organisms, injure tissue, and change the acid-base balance of the vagina.

Table 53.10 presents the causes, manifestations, and interprofessional care of common infections of the female lower genital tract.

Clinical Manifestations

The manifestations of lower genital tract infections depend on the type of infection. Abnormal vaginal discharge and a reddened vulva are common. Women with vulvovaginal candidiasis have a curd-like discharge with intense itching and pain with urination. Women with

bacterial vaginosis often have vaginal discharge that has a fishy odor. With cervicitis, there may be spotting (bleeding) after intercourse.

Common vulvar lesions include herpes infection and genital warts. Initial or primary herpes infections may be extremely painful. Herpes infections begin as a small vesicle followed by a superficial red, painful, ulcer. Genital warts, caused by the human papillomavirus (HPV), vary in appearance. Irregularly shaped "cauliflower" lesions are common. Genital warts are painless unless traumatized. (Herpes infection and genital warts are discussed in Chapter 52.)

Postmenopausal women may develop vulvar changes, such as *lichen sclerosis*. This chronic inflammatory skin condition is associated with intense itching in the genital skin area (e.g., labia minora, clitoris). Although the vulvar changes are white with a "tissue paper" appearance initially, scratching causes changes in the appearance. The cause is unknown.

Interprofessional Care

Evaluation of genital problems includes a history, physical examination, and appropriate laboratory and diagnostic studies. Because many problems relate to sexual activity, a sexual history is essential. The nature of the problem determines the extent of the evaluation. When ulcerative lesions are present, the HCP will usually obtain a culture for herpes and a blood test for syphilis. Genital warts are usually identified by their clinical appearance. Vulvar skin conditions may be examined by colposcopy and biopsy of the skin lesion.

Problems involving vaginal discharge are evaluated by examining the discharge under a microscope or by obtaining specimens for testing. To assess for cervicitis, specimens are obtained for chlamydial, gonorrhea, and trichomonal infections. (Sexually transmitted infections [STIs] are discussed in Chapter 52.)

Drug therapy is based on the diagnosis (Table 53.10). Antibiotics taken as directed will cure bacterial infections. Teach patients how to properly take their medications and get follow-up care. Partners should be treated so that reinfection does not occur.

Women with vaginal conditions or cervical infection should abstain from intercourse for at least 1 week. Sexual partners must be evaluated and treated if the patient is diagnosed with trichomoniasis, chlamydial infection, gonorrhea, syphilis, or HIV.

Treatment of vulvar skin conditions is symptomatic because no cures are available. Treatment involves controlling the "itch-scratch cycle." High-potency topical corticosteroid ointments (e.g., clobetasol), help relieve itching. Stopping the itch-scratch cycle prevents further damage to the skin.

Nursing Management: Infections of Lower Genital Tract

Teach women about common infections of the genital tract and how to reduce their risks for infection. Recognize symptoms that indicate a problem, and help women seek care promptly. Discussing problems that concern the patient's genitalia or sexual intercourse is often hard. Use a nonjudgmental attitude to make women feel more comfortable while empowering them to ask questions.

When a woman is diagnosed with a genital infection, ensure that she fully understands the treatment. If a woman is using a vaginal medication for the first time, show her the applicator and how to fill it. Teach where and how the applicator should be inserted using visual aids or models. Vaginal creams should be inserted before going to bed so the medication will remain in the vagina for a long period.

Pelvic Inflammatory Disease (Pid)

Pelvic inflammatory disease (PID) is an infectious condition of the pelvic cavity. It may involve the fallopian tubes (salpingitis), ovaries (oophoritis), and pelvic peritoneum (peritonitis). A tubo-ovarian abscess may form (Fig. 53.4).

Etiology and Pathophysiology

PID is often the result of an untreated cervical infection. The organism infecting the cervix can spread into the uterus, fallopian tubes, ovaries, and peritoneal cavity. *C. trachomatis* and *N. gonorrhoeae* are the most common causative organisms of PID.[10] Other organisms include anaerobes, mycoplasma, streptococci, and enteric gram-negative rods. It is important to remember that not all cases of PID are the result of an STI. Organisms can gain entrance during sexual intercourse or after pregnancy termination, pelvic surgery, or childbirth.

Women at increased risk for chlamydia infection (e.g., younger than 24 years of age, have multiple sex partners, have a new sex partner) should be routinely tested. The infection can be asymptomatic and unknowingly transmitted during intercourse.

Clinical Manifestations

Lower abdominal pain is a common. The pain typically starts gradually and then becomes constant. The intensity may vary from mild to severe. Movement, such as walking, can increase the pain. The pain is often associated with intercourse. Spotting after intercourse and purulent cervical or vaginal discharge may occur. Fever and chills may be present.

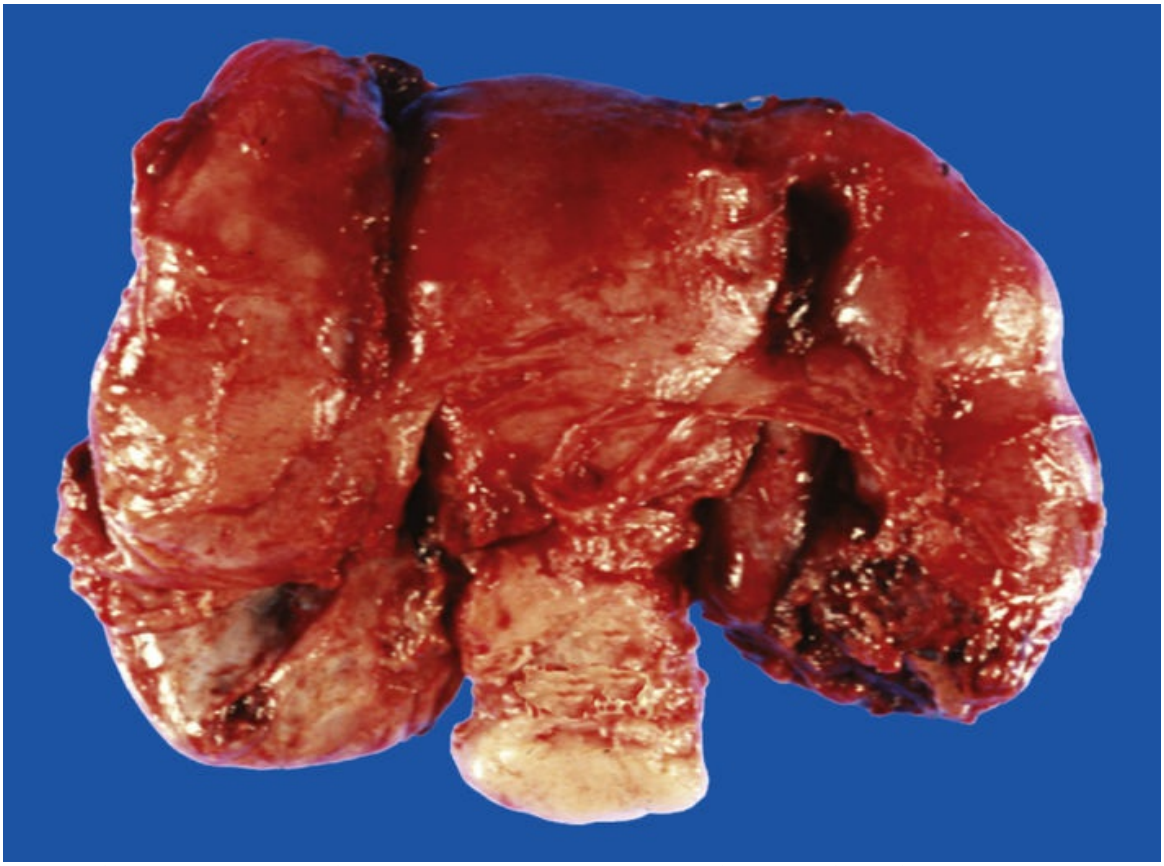

FIG. 53.4 Pelvic inflammatory disease. Acute infection of the fallopian tubes and the ovaries. The tubes and the ovaries have become an inflamed mass attached to the uterus. A tubo-ovarian abscess is present.
From Kumar V, Abbas AK, Aster JC, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Women with less acute symptoms often notice increased cramping pain with menses, irregular bleeding, and some pain with intercourse. Women who have mild symptoms may go untreated either because they did not seek care or the HCP misdiagnoses their symptoms.

Complications

Complications of PID include septic shock, perihepatitis, tubo-ovarian abscess, peritonitis, and embolism. PID can cause adhesions and strictures in the fallopian tubes, which may lead to ectopic pregnancy. After 1 episode of PID, the risk for having an ectopic pregnancy increases nearly 10 times. Further damage can obstruct the fallopian

tubes and cause infertility.

Interprofessional Care

A pelvic examination aids in the diagnosis of PID. Women with PID have lower abdominal tenderness, adnexal tenderness, and positive cervical motion tenderness.

Diagnostic testing includes examination for *N. gonorrhoeae* and *C. trachomatis* and a pregnancy test to rule out an ectopic pregnancy. When the patient's pain or obesity compromises the pelvic examination, a vaginal ultrasound may be done.

PID is usually treated on an outpatient basis. The patient is given a combination of antibiotics to provide broad coverage against the causative organisms. With effective antibiotic therapy, the pain should subside. The patient should abstain from intercourse for 3 weeks. Her partner(s) must be examined and treated. An important part of care is physical rest and oral fluids. Reevaluation in 48 to 72 hours, even if symptoms are improving, is an essential part of outpatient care.

If outpatient treatment is unsuccessful, a tubo-ovarian abscess is present, or the patient is acutely ill or in severe pain, admission to a hospital is needed. IV antibiotics are given in the hospital. Corticosteroids may be added to the antibiotic regimen to reduce inflammation, allowing for faster recovery and optimizing the chances for fertility. Application of heat to the lower abdomen or sitz baths may improve circulation and decrease pain. Bed rest in the semi-Fowler's position promotes drainage of the pelvic cavity by gravity and may prevent the development of abscesses high in the abdomen. Analgesics to relieve pain and IV fluids to prevent dehydration are used.

TABLE 53.11 Nursing AssessmentPelvic Inflammatory Disease (PID)

Subjective Data

Important Health Information

Past health history: Use of IUD. Previous PID, gonorrhea, or chlamydial infection. Multiple sexual partners. Exposure to partner with urethritis. Infertility
Medications: Use of and allergy to any antibiotics
Surgery or other treatments: Recent abortion or pelvic surgery

Functional Health Patterns

Health perception–health management: Malaise
Nutritional-metabolic: Nausea, vomiting; chills, fever
Elimination: Urinary frequency, urgency
Cognitive-perceptual: Lower abdominal and pelvic pain, low back pain, onset of pain just after a menstrual cycle. Dysmenorrhea, dyspareunia, dysuria, vulvar pruritus
Sexuality-reproductive: Abnormal vaginal bleeding and menstrual irregularity. Vaginal discharge

Objective Data
Reproductive

Mucopurulent cervicitis, vulvar maceration, vaginal discharge (heavy and purulent to thin and mucoid), tenderness on motion of cervix and uterus. Presence of inflammatory masses on palpation

Possible Diagnostic Findings

Leukocytosis, ↑ erythrocyte sedimentation rate, positive culture of secretions or endocervical fluid, pelvic inflammation and positive endometrial biopsy on laparoscopic examination,

abscess or inflammation on ultrasonography

Surgery is needed for abscesses that do not resolve with IV antibiotics. The abscess may be drained by laparoscopy or laparotomy. In extreme cases of infection or severe chronic pelvic pain, a hysterectomy may be done. When surgery is done, the capacity for childbearing is preserved whenever possible.

Nursing Management: Pelvic Inflammatory Disease

Subjective and objective data that should be obtained from the woman with PID are outlined in Table 53.11. Prevention, early recognition, and prompt treatment of vaginal and cervical infections can help prevent PID and its serious complications. Give accurate information about factors that place a woman at increased risk for PID. Urge women to seek medical attention for any unusual vaginal discharge or possible infection of their reproductive organs. Tell patients that not all vaginal discharge indicates infection, but early diagnosis and treatment of an infection, if present, can prevent serious complications. Teach patients methods to decrease the risk for getting STIs and to recognize the signs of infection in their partner(s).

The patient may feel guilty about having PID, especially if it is associated with an STI. She may be concerned about the complications associated with PID, such as infertility, and the increased incidence of ectopic pregnancy. Discuss with the patient her feelings and concerns to help her cope with them more effectively.

For hospitalized patients, you have a key role in implementing drug therapy, monitoring the patient's health status, and providing symptom relief and patient teaching. Record vital signs and the character, amount, color, and odor of the vaginal discharge. Assess the degree of abdominal pain to determine the effectiveness of drug therapy.

Chronic Pelvic Pain

Chronic pelvic pain refers to pain in the pelvic region (below the umbilicus and between the hips) that lasts 6 months or longer. The cause of chronic pelvic pain is often hard to find. Many different conditions can cause pelvic pain. Gynecologic etiologies include PID, endometriosis, ovarian cysts, uterine fibroids, pelvic adhesions, and ectopic pregnancies. Abdominal causes include irritable bowel syndrome, interstitial cystitis, and colitis. Psychologic factors (e.g., depression, chronic stress, history of sexual or physical abuse) may increase the risk for developing chronic pelvic pain. Emotional distress makes pain worse. Living with chronic pain contributes to emotional distress.

Chronic pelvic pain has many different manifestations. These include severe and steady pain, intermittent pain, dull and achy pain, pelvic pressure or heaviness, and sharp pain or cramping. Pain may occur during intercourse or while having a bowel movement.

Determining the cause of chronic pelvic pain often involves a process of elimination. In addition to a detailed history and physical examination (including a pelvic examination), the patient may be asked to keep a journal of the onset of symptoms and any precipitating factors.

Diagnostic tests may include specimens from the cervix or vagina (used to detect STIs), ultrasound, CT scan, or MRI to detect abnormal structures or growths. Laparoscopy may be used to see the pelvic organs. This procedure is especially useful in detecting endometriosis and chronic PID.

If the cause of chronic pelvic pain is found, treatment focuses on that cause. If no cause can be found, treatment involves managing the pain. Over-the-counter pain drugs (e.g., aspirin, ibuprofen, acetaminophen) may give some relief. Sometimes stronger pain drugs may be needed. OCPs or other hormonal drugs may help relieve cyclic pelvic pain related to menstrual cycles. If an infection is the source of the problem, antibiotics are used.

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline

[Pamelor]) have pain-relieving and antidepressant effects. These drugs may help improve chronic pelvic pain even in women who do not have depression. Counseling can help the woman live with chronic pain.

Laparoscopic surgery may be used to remove pelvic adhesions or endometrial tissue. As a last resort, a hysterectomy may be done.

Endometriosis

Endometriosis is a condition in which endometrial tissue accumulates outside the endometrium of the uterus. Endometriosis is a common gynecologic problem.

The most frequent sites for endometrial tissue growth are in or near the ovaries, uterosacral ligaments, and uterovesical peritoneum (Fig. 53.5). The tissue responds to the hormones of the ovarian cycle and undergoes a "mini-menstrual cycle" similar to the uterine endometrium. Although it is not a life-threatening condition, endometriosis can cause considerable pain. It can significantly affect a woman's quality of life and ability to conceive. It also increases the risk for ovarian cancer.

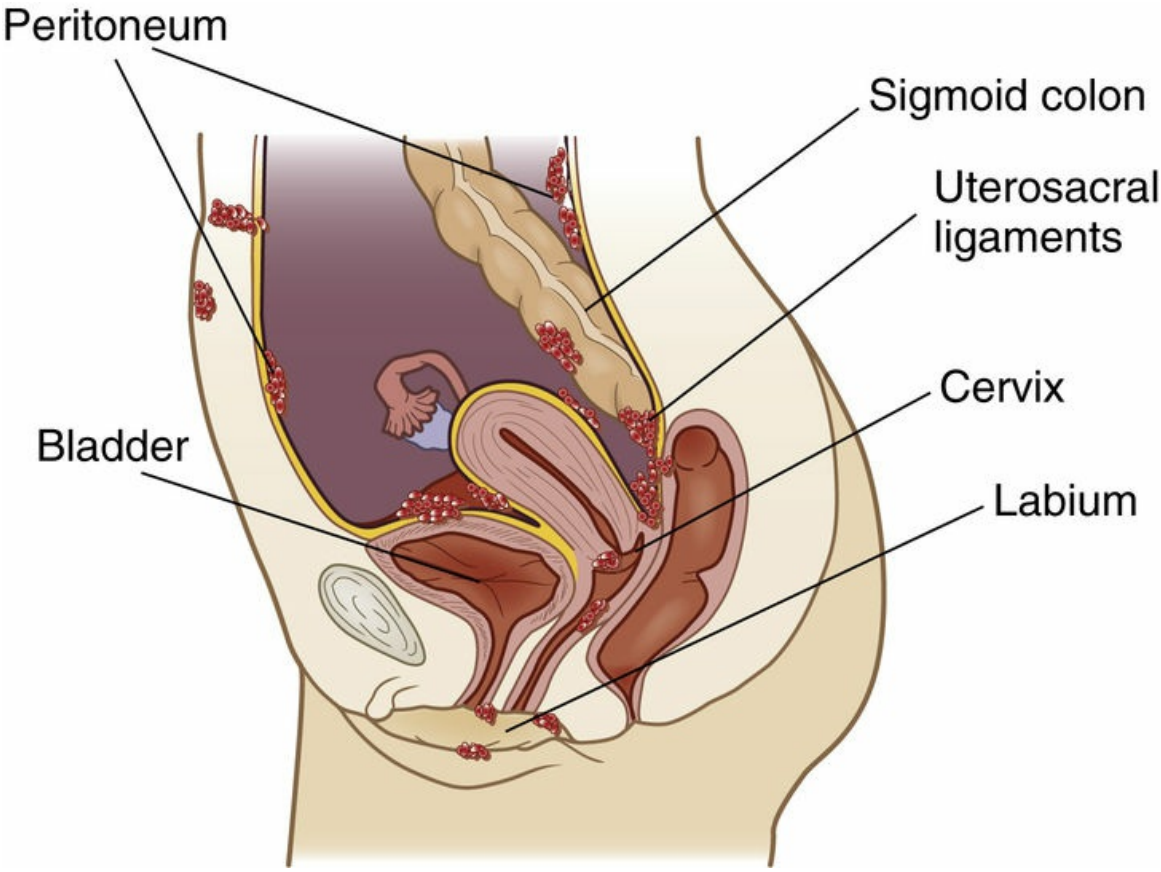

FIG. 53.5 Common sites of endometriosis.

Etiology and Pathophysiology

We have several theories as to the cause of endometriosis. One theory is that the disorder is due to retrograde (backward) flow of endometrial tissue. Instead of flowing out the cervix, the endometrial tissue flows through the fallopian tubes, depositing endometrial tissue into the pelvis.

Other theories suggest that endometrial tissue spreads to the pelvic area through the lymph system or bloodstream. Or, there is an increased sensitivity and production of prostaglandins, which are released prior to onset of menses. Other proposed causes include a genetic predisposition and altered immune function.

Clinical Manifestations

Patients with endometriosis have a wide range of manifestations. The severity of symptoms does not always correlate with the degree of disease found. The most common ones are secondary dysmenorrhea, infertility, pelvic pain, dyspareunia, and AUB. Less common ones include backache, painful bowel movements, and dysuria. With menopause, the ovaries no longer make estrogen and the symptoms may disappear.

Interprofessional and Nursing Care

Endometriosis may be suspected based on a woman's history of the characteristic symptoms and the HCP's palpation of firm nodular lumps in the adnexa on bimanual examination. Laparoscopy with a biopsy is needed for a definitive diagnosis. MRI is now being used more often prior to surgery to determine if gynecologic symptoms the woman is having are from endometriosis.

Treatment is influenced by the patient's age, desire for pregnancy, symptom severity, and extent and location of the disease. When endometriosis is the probable cause of infertility, therapy proceeds more rapidly. When symptoms are not disruptive, a "watch and wait" approach is used (Table 53.12). Teach the patient about comfort measures that may be helpful. Reassure the woman that endometriosis is not life threatening and treatment options exist. Women who have severe disabling pain, sexual difficulties from dyspareunia, and infertility may need psychologic support.

Drug Therapy

Drug therapy does not cure endometriosis but can reduce symptoms. The most common drugs used to control symptoms and cause regression of endometrial tissue are combined OCPs. Their continuous use causes regression of endometrial tissue. NSAIDs, such as ibuprofen, naproxen (Naprosyn), and diclofenac (Voltaren) can relieve pain.

TABLE 53.12 Interprofessional CareEndometriosis

Diagnostic Assessment

- History and physical examination
- Pelvic examination
- Laparoscopy
- Pelvic ultrasound
- MRI

Management

Conservative Therapy

- Watch and wait

Drug Therapy

- Danazol (use is limited by the occurrence of androgenic side effects)
- GnRH agonists (e.g., leuprolide [Lupron])
- NSAIDs
- OCPs

Surgical Therapy

- Laparotomy to remove implanted tissue and adhesions
- TAH-BSO after childbearing

Another class of drugs used is gonadotropin-releasing hormone (GnRH) agonists (e.g., leuprolide [Lupron], nafarelin [Synarel]). These

drugs result in amenorrhea. Side effects are usually the same as those of menopause (hot flashes, vaginal dryness, emotional lability). Loss of bone density can occur in women who stay on the therapy longer than 6 months. "Add-back" therapy with norethindrone acetate (Aygestin) can ease side effects.

Drug Alert

Leuprolide (Lupron)

- Assess patient for pregnancy before starting therapy.
- Monitor patient for dysrhythmias, palpitations.
- Teach patient to use nonhormonal contraceptive measures during therapy.

Surgical Therapy

The only cure for endometriosis is surgical removal of all endometrial tissue.[11] It involves removal or destruction of endometrial tissue and excision of adhesions by laparoscopic laser surgery or laparotomy. Definitive surgery involves removal of the uterus, fallopian tubes, ovaries, and as many endometrial implants as possible. GnRH agonist therapy can be given for 4 to 6 months to reduce the size of the lesions before surgery.

For women wishing to get pregnant, conservative surgical therapy can remove implants blocking the fallopian tube. Adhesions are removed from the tubes, ovaries, and pelvic structures. Efforts are made to conserve all tissues necessary to maintain fertility.

Patients should be actively involved in making the decision about preserving part or all their ovaries, if surgically possible. Explore the patient's feelings about maintaining her ovarian function. The HCP should assess the woman's risk for ovarian cancer and provide this information for her consideration.

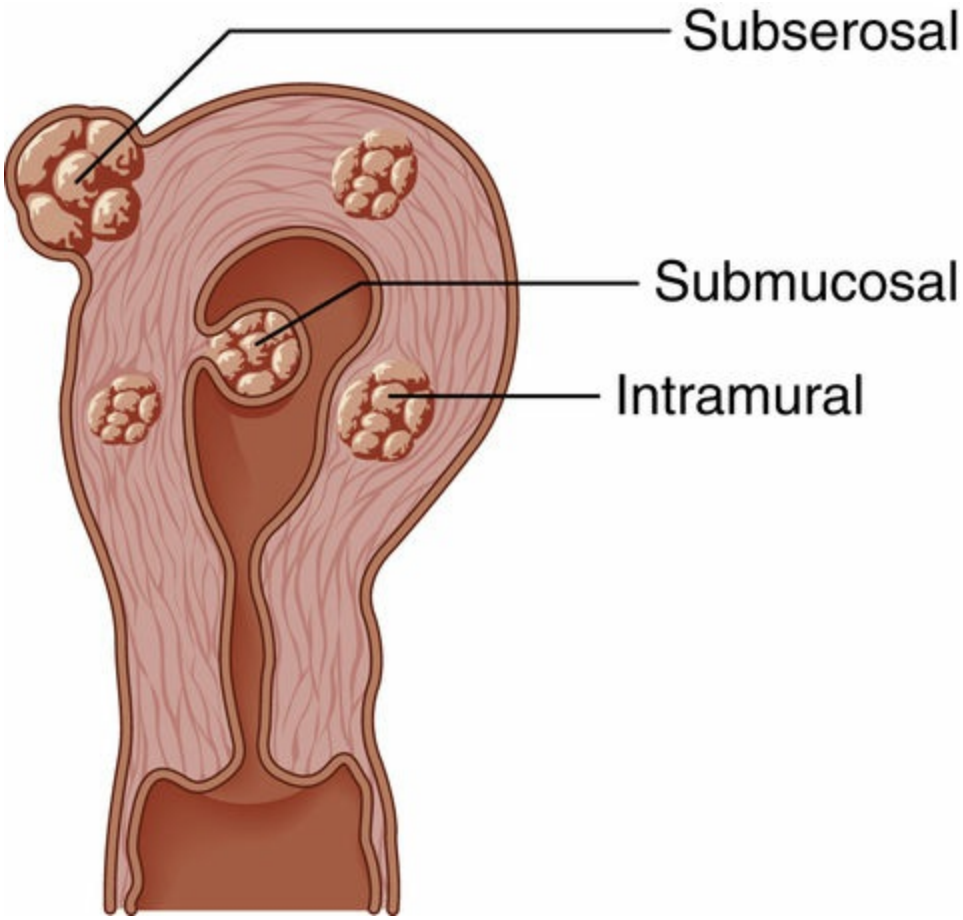

FIG. 53.6 Leiomyomas. Uterine section showing whorl-like appearance and locations of leiomyomas.
From McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.

Benign Tumors of the Female Reproductive System

Leiomyomas

Etiology and Pathophysiology

Leiomyomas (usually called uterine fibroids) are benign smooth-muscle tumors (noncancerous) that occur during the childbearing years. Fibroids do not increase a woman's risk for endometrial cancer. They may be present inside the uterus within the endometrium,

within the muscle of the uterus (myometrium), or outside on the surface of the uterus (subserosal). The size, shape, location, and number of fibroids vary among women. Some fibroids grow in spurts, while others slowly grow during the reproductive years (Fig. 53.6). They can occur at any age but often occur in women ages 30 to 40 years.

The cause of fibroids is unknown. Their growth appears to depend on estrogen and progesterone because they grow during the reproductive years and undergo atrophy after menopause. Fibroids have more estrogen and progesterone receptors than normal uterine tissue. So, they are more sensitive and grow in response to the release of these hormones.

Genetics may play a role. Identical twins and women with mothers and sisters with leiomyomas have an increased risk. Black women have increased incidence. They present with larger uterine fibroids and ones at an early age compared to other women. Other risk factors include early age of menarche, alcohol use, and a diet high in red meat and low in green vegetables.

Clinical Manifestations

Most women who have fibroids do not report any symptoms. Those who do may have abdominal and pelvic pain (i.e., dull, heaving, and/or achy pain and with pelvic pressure), painful sexual intercourse, pressure or dysuria, or frequent urination. If the fibroids are large, women may report constipation and difficulty passing stool. AUB can present as increased duration, more frequent, or increased menstrual bleeding. The pain associated with a fibroid seems to be caused from uterine blood vessel compression as the fibroid grows or from the fibroid pressing on surrounding organs.

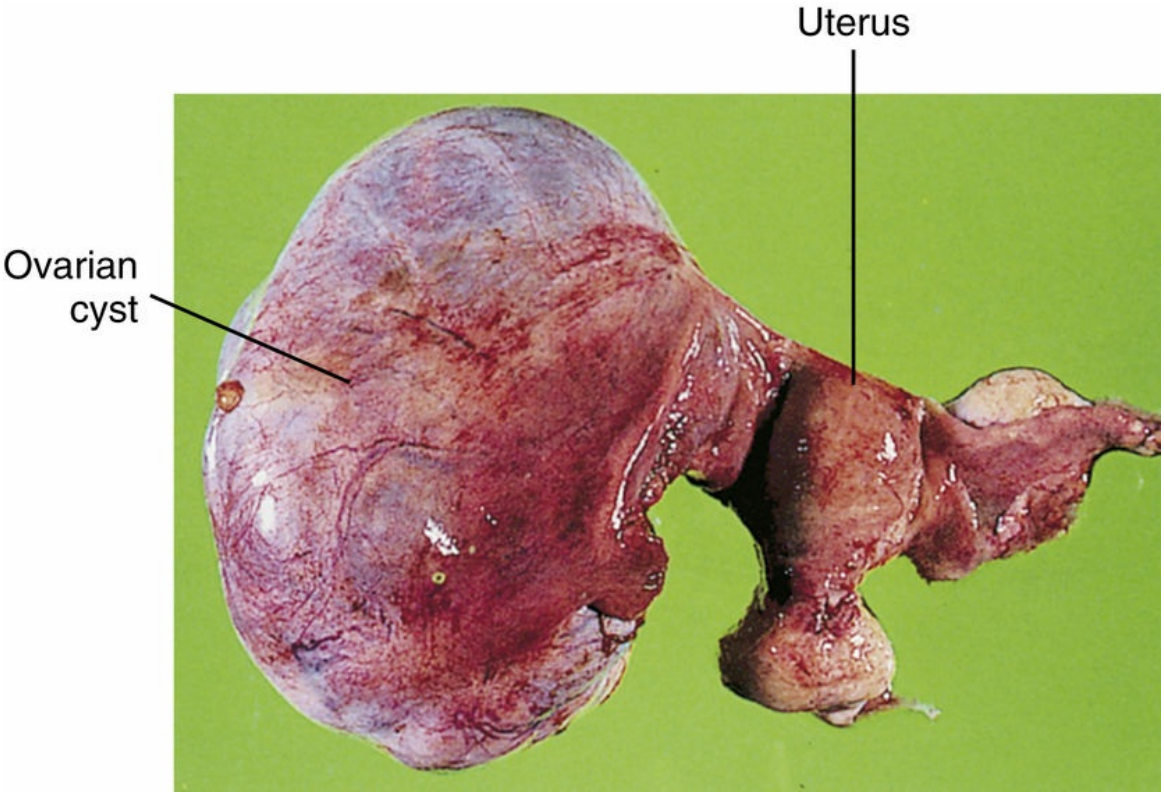

FIG. 53.7 Large ovarian cyst.
From Symonds EM, McPherson MBA: *Colour atlas of obstetrics and gynecology*, London, 1994, Mosby.

Interprofessional and Nursing Care

Diagnosis is based on the characteristic pelvic examination findings of an enlarged uterus distorted by nodular masses. Ultrasound can confirm the diagnosis. In some cases, small fibroids are found during a hysteroscopy, laparoscopy, or hysterosalpingogram when a woman is having a comprehensive workup for other gynecologic conditions, especially infertility.

The treatment depends on the manifestations, patient's age, her desire to conceive, and the location and size of the fibroid. If the symptoms are minimal, the HCP may choose to follow the patient closely for a period of time. Treatment may be needed if a woman is seeking conception, is having AUB, has pelvic pain and pressure, has anemia, or has difficulty with urination and defecation.

The most common and least invasive treatment for fibroids is the

use of OCPs to maintain and slow growth and manage AUB. If surgical intervention is needed, options include a myomectomy (surgical removal of the uterine fibroid only) or a **hysterectomy** (surgical removal of the uterus with or without the ovaries and fallopian tubes). Myomectomies are typically done when the fibroids are small and few in number and the woman would like to preserve her uterus. Hysterectomies are done when there are multiple fibroids s, if they are large, or if their location is affecting bowel and/or bladder function.

Uterine artery embolization (UAE) is increasingly being used as an alternative treatment to treat fibroids. UAE is the process by which embolic material (small plastic or gelatin beads) is injected into the uterine artery. This process blocks blood flow to the uterus and shrinks the fibroid. Because UAE's effects on future fertility are unknown, the procedure is offered to women who no longer want children.

Ovarian Cysts

Ovarian cysts are usually soft and surrounded by a thin capsule. Follicular and corpus luteum cysts are common ovarian cysts (Fig. 53.7). Multiple small ovarian follicles may occur with PCOS. They are not cancerous.

Ovarian cysts are often asymptomatic until they are large enough to cause pressure in the pelvis. Depending on the tumor's size and location, constipation, menstrual irregularities, urinary frequency, a full feeling in the abdomen, anorexia, an increase in abdominal girth, and peripheral edema may occur.

Pelvic pain may be present if the tumor is growing rapidly. Severe pain results when the cyst twists on its pedicle (ovarian torsion). In some cases, an ovarian cyst can rupture. A ruptured ovarian cyst is not only extremely painful, but it can lead to serious complications, such as hemorrhage and infection, especially if large.

Pelvic examination may reveal a mass or an enlarged ovary. A pelvic ultrasound can help determine a diagnosis. In premenopausal

women, ovarian cysts often resolve on their own. If the mass is cystic (does not appear cancerous) and smaller than 5 cm, the patient is asked to return for reexamination in 4 to 6 weeks. This is called "watchful waiting."

In postmenopausal women, watchful waiting may be an option depending on the results of the ultrasound. If the mass is cystic and greater than 5 cm or is solid, laparoscopic surgery or laparotomy is done. Immediate surgery is needed if ovarian torsion occurs, causing the ovary to rotate and cutting off circulation. Surgical techniques are used to save as much of the ovary as possible (if indicated).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a disorder that includes ovulatory dysfunction, polycystic ovaries, and hyperandrogenism.[12] It most often occurs in women under 30 years old and is a cause of infertility.

The cause of PCOS is unknown. We think it is due to the ovaries producing estrogen and excess testosterone but not progesterone. Because of this hormonal imbalance, ovulation fails, and multiple fluid-filled cysts develop from mature ovarian follicles (Fig. 53.8).

Classic manifestations of PCOS include irregular menstrual periods, amenorrhea, hirsutism, and obesity (80% of women). Of these, obesity is associated with severe symptoms, such as excess androgens, amenorrhea, and infertility. Many women start with normal menstrual periods, which become irregular after 1 to 2 years, and then the periods become infrequent. Untreated PCOS can lead to CVD and abnormal insulin resistance with type 2 diabetes.

Successful management includes early diagnosis and treatment to improve quality of life and decrease the risk for complications. Pelvic ultrasound reveals enlarged ovaries with multiple small cysts. Treatment is based on symptoms. OCPs are useful in regulating menstrual cycles. Hirsutism may be treated with spironolactone. Hyperandrogenism can be treated with flutamide and a GnRH agonist, such as leuprolide. Metformin reduces hyperinsulinemia, improves hyperandrogenism, and can restore ovulation. For women

wishing to become pregnant, fertility drugs (e.g., clomiphene [Clomid]) may induce ovulation.

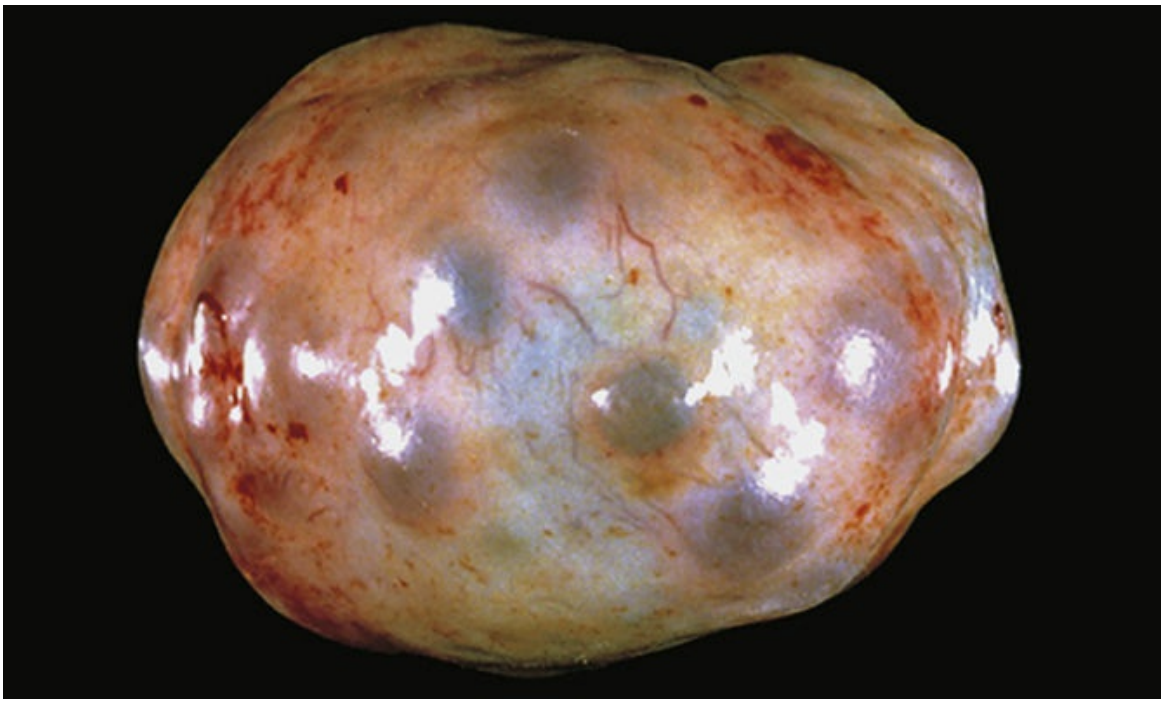

FIG. 53.8 Polycystic ovary syndrome. Multiple fluid-filled cysts in the ovary.
From Kumar V, Abbas A, Fausto N: *Robbins and Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.

Nursing management includes teaching about the importance of weight management and exercise to decrease insulin resistance. Obesity worsens problems related to PCOS. Monitor lipid profile and fasting glucose levels. Hirsutism is cosmetically distressing for many women. Support the patient as she explores measures to remove unwanted hair (e.g., depilating agents, electrolysis). Stress the importance of regular follow-up care to monitor the effectiveness of therapy and to detect any complications.

Cervical Polyps

Cervical polyps are benign pedunculated (stalked) lesions that

generally arise from the endocervical mucosa. Polyps are a characteristic bright cherry red and are soft and fragile. They are usually small, measuring less than 3 cm in length. They may be single or multiple. Their cause is unknown. Symptoms are usually not present, but intermenstrual bleeding after straining for a bowel movement and coitus can occur. Polyps are prone to infection.

Polyps may be seen protruding through the cervical os during a speculum examination. When the polyp is small, it can be excised in an outpatient procedure. If the point of attachment cannot be found and is not accessible to cautery, a polypectomy is done in an operating room. All tissue removed is biopsied as polyps, on rare occasion, are malignant.

Cancers of the Female Reproductive System

Cervical Cancer

Around 13,240 women in the United States are diagnosed with cervical cancer each year and 4100 women will die. While Hispanic women are the most likely to be diagnosed with cervical cancer, black women have the highest mortality rate from cervical cancer.[13]

Cervical cancer was once a common cause of cancer death. However, with early detection (Pap test, HPV testing), the mortality rate from cervical cancer has significantly declined.

Promoting Health Equity

Cancers of the Female Reproductive System

Ovarian Cancer

- The mortality rate for black women is higher than any other

ethnic group.

Endometrial Cancer

- The mortality rate for black women is higher than any other ethnic group.

Cervical Cancer

- The incidence rate is highest among Hispanic women
- Mortality rates are twice as high among black women.

Etiology and Pathophysiology

Risk factors for cervical cancer include (1) infection with high-risk strains of HPV 16 and 18, (2) immunosuppression, (3) using OCPs for a long period of time, (4) being exposed to the drug diethylstilbestrol (DES), (5) giving birth to many children, and (6) smoking.

The cervix is the lower third of the uterus that projects into the vagina. It is made up of glandular cells that line the uterine cavity and endocervical canal. Squamous epithelium lines the vagina and outer part of the cervix. These 2 cell types meet and undergo a normal physiologic process known as *squamous metaplasia*. This is the transformation of columnar epithelium into squamous epithelium, which results in an area called the *transformation zone.* This process begins at puberty and continues throughout a women's reproductive life cycle. The transformation zone moves in and out the endocervical canal, depending upon hormonal status and other factors. While the entire anogenital tract can be infected by HPV, the transformation zone is an area that is particularly susceptible to HPV-associated carcinogenesis.

Clinical Manifestations

Early cervical cancer often has no symptoms. An unusual discharge, AUB, or postcoital bleeding eventually occurs. The discharge is usually thin and watery but becomes dark and foul smelling as the disease advances. Vaginal bleeding first presents as spotting. As the tumor enlarges, bleeding becomes heavier and more frequent (Fig. 53.9). Pain is a late symptom. It is followed by weight loss, anemia, and cachexia.

Diagnostic Studies

The 2 tests used for cervical cancer screening are the Papanicolaou (Pap) test and the HPV test. The Pap test helps find changes in cervical cells that may indicate precancerous changes. Cells are obtained from the cervix during a speculum examination. HPV testing can identify high-risk HPV types 16 and 18, of which 80% are associated with cervical cancer, more than any other high-risk HPV types. The use of the HPV test is age-dependent and Pap result–dependent. To do an HPV test, cervical scrapings are tested for viral DNA or RNA.

All women should begin cervical cancer screening at age 21. Women ages 21 to 29 years should get a Pap test every 3 years. Women between the ages of 30 and 65 should have a Pap test and HPV test every 5 years. This is the preferred approach, but the woman may choose to get a Pap test without an HPV test every 3 years.[14] If both tests are negative, the risk for cervical cancer is very low, and women can wait 5 years before another screening. HPV tests may be used to provide more information when a Pap test has unclear results. Women found to have an abnormal Pap test typically need a *colposcopy* (an examination of the cervical tissue under magnification). Typically, a cervical biopsy(s) is taken and sent for further analysis by a pathologist. Other tests for gonorrhea, chlamydia, and trichomonas can be run off the Pap test.

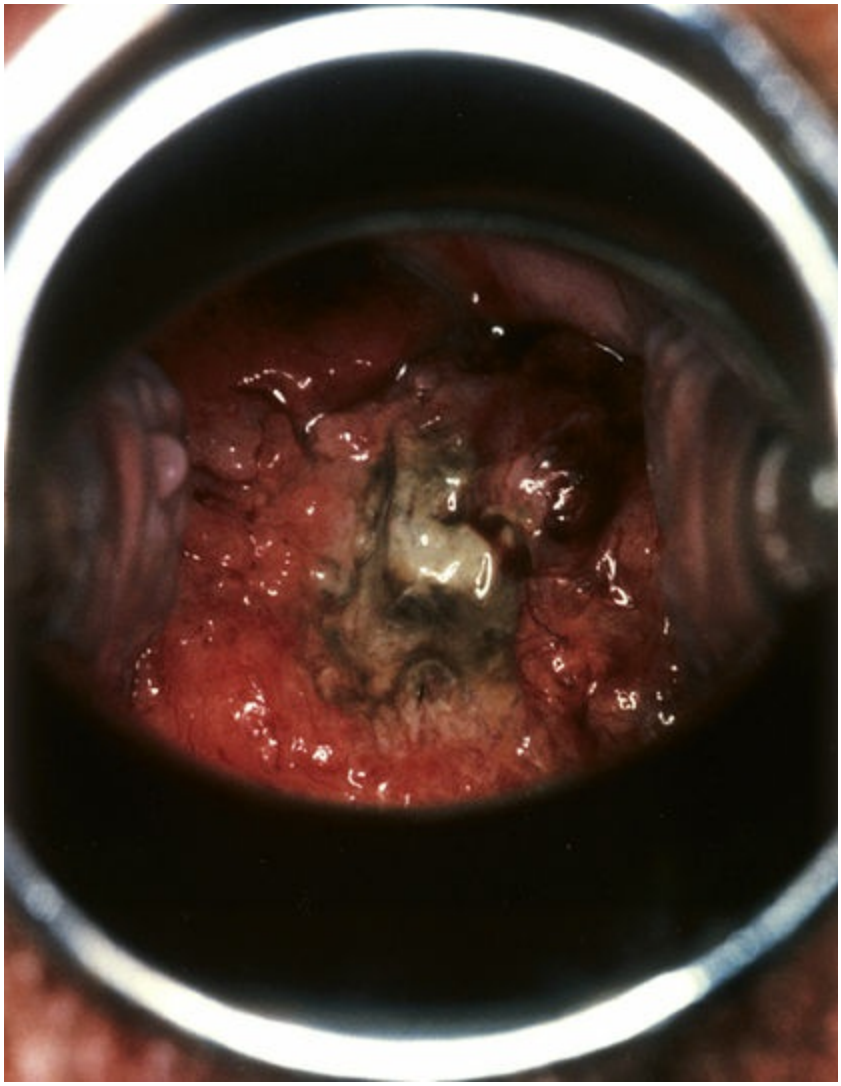

FIG. 53.9 Cervical cancer. View through a speculum inserted into the vagina.

Evidence-Based Practice

Pap Test and Cervical Cancer

E.V. is a 36-yr-old black woman who had a tubal ligation in the outpatient surgery unit. As you prepare her for discharge, you remind her that she needs to have regular Pap tests to screen for

cervical cancer. She expresses concern over the expense of this procedure. She tells you she does not know if her health care insurance pays for screening tests. She does not remember when she last had a Pap test done.

Making Clinical Decisions

Best Available Evidence. For women 21 to 30 years a Pap test alone every 3 years is recommended. For women between the ages of 30 and 65, the screening preference for cervical cancer is a Pap test and HPV test every 5 years. A Pap test alone every 3 years is also within the recommended guidelines.

Clinician Expertise. You know the incidence and death rate of cervical cancer is twice as high for black women compared to all other ethnicities.

Patient Preferences and Values. E.V. is concerned about the costs related to her current procedure and future Pap tests. She adds that no one in her family has ever had cervical cancer.

Implications for Nursing Practice

1. How would you explain to her the current recommendations and her increased risk for cervical cancer?
2. Why is it important to encourage E.V. to learn more about her health care coverage?

Interprofessional Care

Vaccination against HPV provides for primary prevention of cervical cancer. Teach both parents and patients about the need to complete the HPV vaccination series prior to first sexual contact. The CDC recommends that all children, males and females, be vaccinated at age 11 to 12, when the immune system has a better uptake of the vaccine. Vaccines can be given as early as age 9.

Currently 3 vaccines are available to protect against HPV. Gardasil, protects against types 6, 11, 16, and 18. Gardasil 9 protects against HPV types 6, 11, 16, 18, and 5 other HPV types. Cervarix offers protection against HPV types 16 and 18. These vaccines are given in 2 or 3 IM doses (depending upon the patient's age) over a 6-month period. They have few side effects. More specific information about HPV vaccines is discussed in Chapter 52 on p. 1219.

Women diagnosed with cervical cancer are typically referred to a gynecologic oncologist for treatment recommendations.[15] Treatment options can include surgery or a combination of chemotherapy and radiation. For patients with advanced disease, bevacizumab (Avastin), a targeted therapy drug, may be used in addition to cisplatin-based chemotherapy. Bevacizumab is an angiogenesis inhibitor. It works by interfering with the blood vessels that supply nutrients to cancer cells. (Chemotherapy, radiation therapy, and targeted therapy are discussed in Chapter 15.)

Endometrial Cancer

Endometrial cancer is the most common gynecologic cancer. About 63,000 women are diagnosed each year with endometrial cancer, and 11,300 will die.[16] If endometrial cancer is diagnosed in the early stage, it has a low mortality rate, with survival rates over 88%. The average age of a woman diagnosed with endometrial cancer is 60. It is rare in women under the age of 45.

Etiology and Pathophysiology

The major risk factor for endometrial cancer is exposure to estrogen, especially unopposed estrogen. Obesity is a risk factor because adipose cells store estrogen, thus increasing the amount of circulating estrogen. Other risk factors include increasing age, never being pregnant, early menarche, late menopause, smoking, diabetes, and a personal or family history of hereditary nonpolyposis colorectal cancer (HNPCC) (see the Genetics in Clinical Practice box for HNPCC in Chapter 42 on p. 949). Pregnancy, use of OCPs and IUDs, and physical exercise are associated with reduced risk.

Endometrial cancer arises from the lining of the endometrium within the uterus. Most tumors are adenocarcinomas. If endometrial cancer is not diagnosed in early stages, it can invade the myometrium (muscle of the uterus) and the regional lymph nodes. If metastasis occurs, common sites include the lung, liver, bone, and brain. Prognosis depends on tumor size, cell type, degree of invasion into the myometrium, and any metastasis.[17]

Clinical Manifestations

Early manifestations include AUB, especially in postmenopausal women. Later symptoms can include dysuria, dyspareunia, unintentional weight loss, and pelvic pain.

Interprofessional Care

No routine screening test is available for endometrial cancer. Most cases are diagnosed at an early stage because of postmenopausal bleeding. An endometrial biopsy is the main diagnostic test for identifying endometrial cancer. This procedure is typically done in the office.

The National Comprehensive Cancer Network (NCCN) recommends surveillance and risk reduction for women with Lynch syndrome, a hereditary cancer associated with endometrial cancer. Hysterectomy and bilateral salpingo-oophorectomy should be offered to women who have completed childbearing and carry *MLH1, MLH2, or MLH6* mutations. For carriers of *MLH1 or MLH2,* annual

endometrial biopsy is advised.

Treatment of endometrial cancer in the early stage is a total hysterectomy and bilateral salpingo-oophorectomy with lymph node biopsies. These may be done by less invasive types of surgery, including robotics and laparoscopy. (Various types of hysterectomies are shown in Fig. 53.10.) External radiation either to the pelvis or abdomen or internal radiation (brachytherapy) intravaginally follows surgery if there is local or distant metastasis.

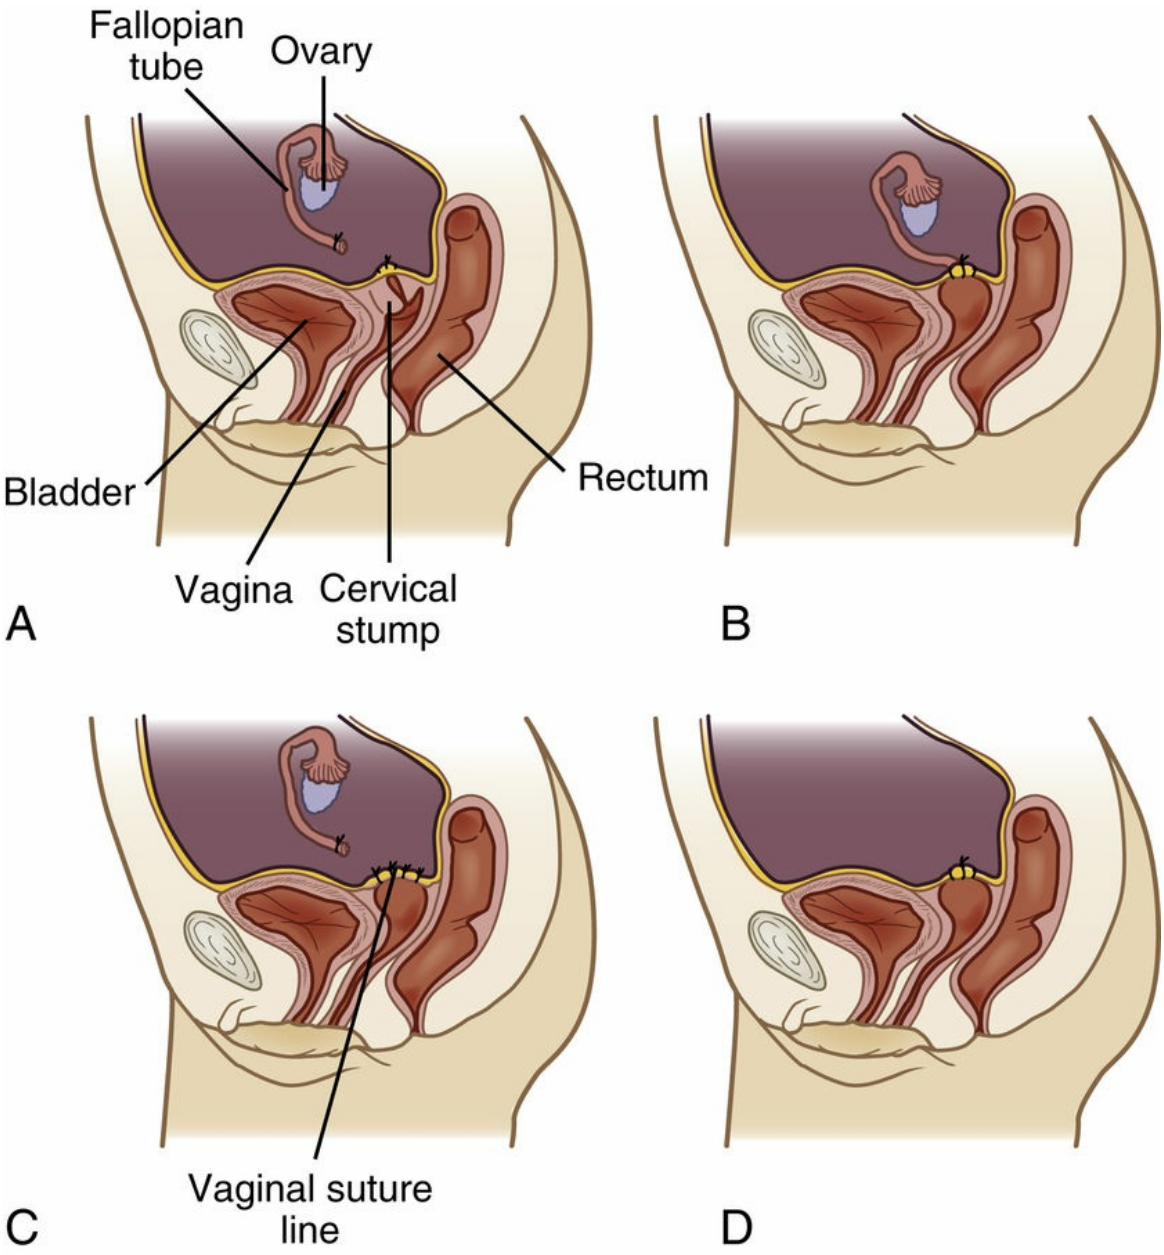

FIG. 53.10 Hysterectomies. **A,** Cross section of subtotal hysterectomy. The cervical stump, fallopian tubes, and ovaries remain. **B,** Cross section of total hysterectomy. The fallopian tubes and ovaries remain. **C,** Cross section of vaginal hysterectomy. The fallopian tubes and ovaries remain. **D,** Total hysterectomy, salpingectomy, and oophorectomy. The uterus, fallopian tubes, and ovaries are completely removed.

The woman with advanced or recurrent disease may receive chemotherapy and hormonal therapy. The 5-year survival rate for stage 1 cancer is 90%, with reductions seen as the grade of the cancer

increases.

Ovarian Cancer

Ovarian cancer is the deadliest gynecologic cancer in the United States. Around 22,240 women will receive an ovarian cancer diagnosis in 2018, and about 14,070 women die. It is the fifth leading cause of cancer deaths in women in the United States. Half of women diagnosed are age 63 and older. Overall the 5- and 10-year survival rates are 45% and 35%, respectively. Most women with ovarian cancer are diagnosed when the disease is advanced, for which the 5-year survival rate is 27%.

Etiology and Pathophysiology

The cause of ovarian cancer is not known. The major risk factor is family history (1 or more first-degree relatives). A family history of breast or colon cancer is also a risk factor. Other risk factors include a personal history of breast or colon cancer and HNPCC (see the Genetics in Clinical Practice box on HNPCC in Chapter 42 on p. 949).

Genetic Link

Women who have mutations of the *BRCA* genes have an increased susceptibility to ovarian cancer. The *BRCA* genes are tumor suppressor genes that inhibit tumor growth when functioning normally. When they mutate, they lose their tumor suppressor ability. This results in an increased risk for women to develop ovarian or breast cancer (see the Genetics in Clinical Practice box).

Genetics in Clinical Practice

Ovarian Cancer

Genetic Basis

- Mutations in *BRCA1* and/or *BRCA2* genes
- Normally these genes are tumor suppressor genes involved in DNA repair
- Transmission is autosomal dominant
- Mutations passed down from either mother or father

Incidence

- 5%–10% of cases of ovarian cancer are related to hereditary factors.
- Women with mutations in *BRCA1* and *BRCA2* are about 10 times more common in those who are Ashkenazi Jewish.
- Women with *BRCA1* mutations have a 35%–70% lifetime risk for developing ovarian cancer.
- Women with *BRCA2* mutations have a 10%–30% lifetime risk for developing ovarian cancer.
- Family history of both breast and ovarian cancer increases the risk for having a BRCA mutation.
- *BRCA* mutations occur in 10%–20% of patients with ovarian cancer who have no family history of breast or ovarian cancer.[18]

Genetic Testing

- DNA testing is available for *BRCA1* and *BRCA2* genetic mutations.

Clinical Implications

- Bilateral salpingectomy-oophorectomy reduces the risk for ovarian cancer in women with *BRCA1* and *BRCA2* mutations.
- Genetic counseling and testing for *BRCA* mutations should be offered to women whose personal or family history puts them at

high risk for ovarian cancer.
- Women with *BRCA* mutations have a higher risk for developing breast, colon, pancreatic, and uterine cancers.

Women who have never been pregnant (nulliparity) are at higher risk. Other risk factors include increasing age, high-fat diet, increased number of ovulatory cycles (usually associated with early menarche and late menopause), HRT, and possibly the use of infertility drugs.

Breastfeeding, multiple pregnancies, OCP use (more than 5 years), and early age at first birth reduce the risk for ovarian cancer. These factors may have a protective effect because they reduce the number of ovulatory cycles and thus reduce the exposure to estrogen.

There are 3 major types of ovarian cancer. About 90% of ovarian cancers are epithelial cancers that arise from malignant transformation of the surface epithelial cells. Germ cell tumors account for another 3%, and sex cord stromal, 2%. Histologic grading is important to determine the prognosis of the disease. Tumor cells are graded according to the level of differentiation, ranging from well differentiated (grade I) to poorly differentiated (grade III) to undifferentiated (grade IV). Grade IV cells have a poorer prognosis than the other grades.

Intraperitoneal dissemination is a common characteristic of ovarian cancer. It metastasizes to the uterus, bladder, bowel, and omentum. In advanced disease, it can spread to the stomach, colon, liver, and other parts of the body.

TABLE 53.13 Interprofessional CareOvarian Cancer

Diagnostic Assessment

- History and physical examination
- Pelvic examination

- Abdominal and transvaginal ultrasound
- CA-125 level
- Laparotomy for diagnostic staging

Management

- Surgery
    - TAH-BSO with pelvic lymph node biopsies
    - Debulking for advanced disease
- Chemotherapy
    - Adjuvant and palliative
- Radiation therapy
    - Adjuvant and palliative

Clinical Manifestations

Early ovarian cancer usually has no obvious symptoms. Most manifestations are vague and nonspecific. These include pelvic or abdominal pain, bloating, urinary urgency or frequency, and difficulty eating or feeling full quickly. Late-stage disease typically presents with abdominal enlargement with ascites (fluid in the abdominal cavity), unexplained weight loss or gain, and menstrual changes.

Diagnostic Studies

No accurate screening test exists for early detection of ovarian cancer. For women at high risk for ovarian cancer, screening using a combination of the tumor marker CA-125, ultrasound, and yearly pelvic examination is recommended. However, this approach is not proven to be effective in reducing ovarian cancer mortality.[18] The CA-125 test is positive in 80% of women with epithelial ovarian cancer. CA-125 is also used to monitor the course of the disease and response to treatment. The problem is that CA-125 levels can be high with other cancers (e.g., pancreatic cancer) or with benign gynecologic

conditions, including fibroids and endometriosis.

Since postmenopausal women should not have palpable ovaries, a mass of any size found during a bimanual pelvic examination is considered suspicious. An abdominal or a transvaginal ultrasound can be done to detect ovarian masses (Table 53.13). An exploratory laparotomy may be used to establish the diagnosis and stage the disease.

Interprofessional Care

Options for women at high risk based on family and health history include prophylactic removal of the ovaries and fallopian tubes and the use of OCPs. While salpingo-oophorectomy significantly reduces the risk for ovarian cancer, it does not completely eliminate the risk for cancer in the peritoneum.

The initial treatment for all stages of ovarian cancer is a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) with removal of the omentum and as much of the tumor as possible (i.e., tumor debulking). Depending on the grade and stage of cancer, treatment options include intraperitoneal and systemic chemotherapy, intraperitoneal instillation of radioisotopes, and external abdominal and pelvic radiation therapy. Combination chemotherapy and radiation therapy should be considered before a single-modality treatment.

The chemotherapy agents most commonly used are taxanes (paclitaxel or docetaxel) and platinum agents (carboplatin or cisplatin). (See for more about these drugs.)

Targeted therapy used to treat advanced ovarian cancer includes bevacizumab (Avastin) (discussed on p. 1243), rucaparib (Rubraca), and olaparib (Lynparza). Rucaparib and olaparib are poly ADP-ribose polymerase (PARP) inhibitors. They block enzymes involved in repairing damaged DNA. They are used for women with ovarian cancer that is associated with defective *BRCA* genes.

Vaginal Cancer

Vaginal cancers are rare, with about 5170 new cases reported annually. They usually occur in women between ages 50 and 70. Vaginal tumors can be secondary sites or metastases of other gynecologic cancers, such as cervical or endometrial cancer. About 70% of vaginal cancers are squamous cell carcinomas, which begin in the squamous epithelium. Intrauterine exposure to diethylstilbestrol (DES) places a woman at risk for clear cell adenocarcinoma of the vagina.

Treatment depends on the type of cells involved, stage of the disease, and the size and location of the tumor.[19] Squamous cell carcinomas can be treated with both surgery and radiation. The process of transitioning from precancer to cancer can take many years. The term for the precancerous condition of squamous cells is *vaginal intraepithelial neoplasia* (VAIN.) There are 3 types of VAIN: VAIN 1, VAIN 2, and VAIN 3. VAIN 3 progresses closest to a true cancer.

Vulvar Cancer

Vulvar cancer is rare. There are about 6020 new cases reported each year, with an estimated 1150 deaths for 2017. Preinvasive lesions are referred to as *vulvar intraepithelial neoplasia (VIN)*, which precedes invasive vulvar cancer. The 3 types of VIN are VIN 1, VIN 2, and VIN 3. The invasive form occurs mainly in women over 60 years of age, with the highest incidence being in women in their 70s.

Patients with vulvar cancer may have symptoms of vulvar itching or burning, pain, bleeding, or discharge. Women who are immunosuppressed and/or have diabetes, hypertension, or chronic vulvar dystrophies have the highest risk for developing vulvar cancer. HPV DNA have been identified in some, but not all, vulvar cancers.

Diagnosis is based on physical examination, colposcopy, and biopsy results of the suspicious lesion. VIN can be treated topically with imiquimod cream (Aldara) or laser surgery. Surgery is the most common treatment for vulvar cancer. The goal is to remove all the cancer without any loss of the woman's sexual function.

If a woman has extensive lesions, a vulvectomy is recommended.

Various types of vulvectomies are described in Table 53.14. As adjuvant measures, the patient may have chemotherapy or radiation therapy after surgery.

Nursing and Interprofessional Management: Cancers of Female Reproductive System

Nursing Assessment

Women with cancer of the reproductive system may have a variety of manifestations. These include leukorrhea, AUB, vaginal discharge, abdominal pain and pressure, bowel and bladder dysfunction, and vulvar itching and burning. Assessment for these signs and symptoms is an important nursing responsibility.

TABLE 53.14 Surgical Procedures Involving the Female Reproductive System

Type of Surgery	Description
daVinci	Minimally invasive surgery using robotics for major gynecologic procedures.
Dilation and Curettage (D&C)	Dilation of cervix and scraping of endometrium.
Endometrial Ablation	An outpatient procedure using hot or cold energy to destroy the endometrial lining of the uterus in cases of AUB.
Hysterectomy	
Abdominal supracervical hysterectomy	Removal of uterus only with cervix remaining intact.
Radical hysterectomy	Panhysterectomy, partial vaginectomy, and dissection of lymph nodes in pelvis.
Total abdominal hysterectomy (TAH)	Uterus and cervix removed using a pfannenstiel incision (bikini cut).
Total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO)	Uterus, cervix, fallopian tubes, and ovaries removed using a pfannenstiel or a vertical incision.
Vaginal hysterectomy	Uterus and cervix removed through a cut in the top of vagina.
Laparoscopic hysterectomy	Laparoscope (video camera and small surgical instruments).
• **Laparoscopic-assisted vaginal hysterectomy (LAVH)**	Incision made at top of vagina. Uterus and cervix removed through the vagina. Laparoscope inserted into abdomen to assist in the procedure.
• **Laparoscopic supracervical hysterectomy**	Uterus removed using only laparoscopic instruments. Cervix is left intact.
Hysteroscopy	Video done with D&C to check for abnormal uterine lining, AUB, polyps.
Myomectomy	Removal of fibroid from the uterus, leaving the uterus in place.
Pelvic Exenteration	Radical hysterectomy, total vaginectomy, removal of bladder with diversion of urinary system and resection of colon and rectum with colostomy.
Vaginectomy	Removal of vagina.
Vulvectomy	Removal of part or all the vulva.
• **Skinning vulvectomy**	Removal of top layer of vulvar skin where the cancer is found. Skin grafts from other parts of the body may be needed to cover the area.
• **Simple vulvectomy**	Entire vulva is removed.
• **Radical vulvectomy**	Entire vulva, including clitoris, labia majora and minora, and nearby tissue, is removed. Nearby lymph nodes may be removed.

Nursing Diagnoses

Nursing diagnoses for the female patient with cancer of the reproductive system include:

- Anxiety
- Acute pain
- Disturbed body image
- Impaired sexual functioning

Planning

The overall goals are that the patient with cancer of the female reproductive system will (1) actively take part in treatment decisions, (2) achieve satisfactory pain and symptom management, (3) recognize and report problems promptly, (4) maintain preferred lifestyle as long as possible, and (5) continue to practice cancer detection strategies.

Nursing Implementation

Health Promotion

Through your contact with women in a variety of settings, teach women the importance of routine screening for cancers of the reproductive system. Cancer can be prevented when screening reveals precancerous conditions. Routine screening increases the chance that a cancer will be found in an early stage.

Teach women about risk factors for cancers of the reproductive system. Limiting sexual activity during adolescence, using condoms, having fewer sexual partners, and not smoking reduce the risk for cervical cancer. When high-risk behaviors are identified, help women in changing their lifestyles to decrease risk.

Acute Intervention Related to Surgery

Types of surgery of the female reproductive tract are described in Table 53.14 and Fig. 53.10. All patients have a degree of anxiety when expecting surgery. The prospect of major gynecologic surgery increases these concerns. Some women may focus on the effect the surgery will have on their appearance and sexual functions. Discuss the woman's feelings and concerns about her surgery. Assess each patient individually. Be willing to listen since this can provide considerable psychologic support.

Preoperatively, prepare the patient physically for surgery with the standard perineal or abdominal preparation. A vaginal douche and enema may be given (based on the HCP's preference). The bladder should be emptied before the patient goes to the operating room. An indwelling catheter is often inserted.

Hysterectomy

After a hysterectomy, abdominal distention may develop from the sudden release of pressure on the intestines when a large tumor is removed or from paralytic ileus due to anesthesia and pressure on the bowel. Food and fluids may be restricted if the patient is nauseated. Ambulation will help relieve flatus.

Initiate venous thromboembolism (VTE) prophylaxis. Apply intermittent pneumatic compression devices and administer anticoagulant therapy. Frequent position changes, avoiding high-Fowler's position, and avoiding pressure under the knees minimize stasis and pooling of blood. Pay special attention to patients with varicosities. Encourage leg exercises to promote circulation.

Check Your Practice

You are working in the preoperative surgery holding unit. Your patient is a 60-yr-old woman who is scheduled for a TAH-BSO for endometrial cancer. When you ask her how she is doing, she tells you that she is worried because "life will never be the same."

- How would you approach this situation? What do you think are her major concerns?

Discharge teaching includes what to expect after surgery (e.g., she will not menstruate). Review specific activity restrictions. Intercourse should be avoided until the wound is healed (about 4 to 6 weeks). However, intercourse is not contraindicated once healing is complete. If a vaginal hysterectomy was done, tell the patient that she may have a temporary loss of vaginal sensation. Reassure her that the sensation will return in several months.

Physical restrictions are needed for a short time. Heavy lifting should be avoided for 2 months. Teach her to avoid activities that may increase pelvic congestion, such as dancing and walking swiftly, for several months. However, activities such as swimming may be both physically and mentally helpful. Assure her that once healing is complete, all previous activity can be resumed.

Salpingectomy and Oophorectomy

Care of the woman who had removal of a fallopian tube (salpingectomy) or an ovary (oophorectomy) is like that for any

patient having abdominal surgery. However, if a large ovarian cyst is removed, she may have abdominal distention caused by the sudden release of pressure in the intestines. An abdominal binder may provide relief until the distention subsides.

When both ovaries are removed (bilateral oophorectomy), surgical menopause results. The symptoms are similar to those of regular menopause but may be more severe because of the sudden withdrawal of hormones.

Vulvectomy

It is important to know the extent of the vulvectomy and the significant effect it is likely to have on the patient's life. Because the surgery causes mutilation of the perineal area and the healing process is slow, the patient is likely to become discouraged. Provide opportunities for the patient to express her feelings and concerns about the operation.

Pay special attention to bowel and bladder care. A low-residue diet and stool softeners prevent straining and wound contamination. An indwelling catheter is used to provide urinary drainage. Be careful not to dislodge the catheter because extensive edema makes its reinsertion difficult. Heavy, taut sutures are often used to close the wounds, resulting in severe discomfort. In other instances, the wound may heal by granulation. Give analgesics to control pain. Carefully position the patient using strategically placed pillows to provide comfort. Initiate VTE prophylaxis.

Discharge teaching includes specific instructions in self-care. Teach her to report any unusual odor, fresh bleeding, breakdown of incision, or perineal pain. Home care nursing can help the patient during her adjustment period.

Sexual function is often retained. Whether clitoral sensation is retained may be critical to some women, particularly if it was the source of orgasmic satisfaction. Discussing alternative methods of achieving sexual satisfaction may be needed.

Pelvic Exenteration

When other forms of therapy do not control the spread of cancer and no metastases have been found outside of the pelvis, pelvic exenteration may be done. This radical surgery usually involves removal of the uterus, ovaries, fallopian tubes, vagina, bladder, urethra, and pelvic lymph nodes (Fig. 53.11). In some situations, the descending colon, rectum, and anal canal also are removed. Women who have this procedure are selected based on their likelihood of surviving the surgery and their ability to adjust to and accept the resulting limitations.

Postoperative care is similar to that of a patient who has had a radical hysterectomy, an abdominal perineal resection, and an ileostomy or a colostomy. The physical, emotional, and social adjustments to life by the woman and her family are great. There are urinary or fecal diversions in the abdominal wall, a reconstructed vagina, possible lymphedema, and the onset of menopausal symptoms.

Assess the patient's physical and emotional adjustment to the changes in body image from the surgery and her ability to carry out any treatment measures. The patient's rehabilitative process should keep pace with her acceptance of the situation. You need to provide understanding and support during a long recovery period. Gently encourage the patient to regain her independence. She needs to share her feelings about her altered body structure. Include her caregiver and family in the plan of care. Careful follow-up monitoring is needed so that early recurrence of the cancer can be identified and treated.

Acute Intervention With Radiation Therapy

Teach the patient who is to receive external radiation to urinate immediately before the treatment to minimize radiation exposure to the bladder. Review the side effects of radiation, including enteritis and cystitis. Discuss measures that can be used to reduce their impact.

Nursing management of the patient receiving internal radiation therapy requires special considerations. Do not stay in the immediate area any longer than is necessary to give proper care and attention. (Radiation therapy is discussed in Chapter 15.)

Evaluation

The expected outcomes are that the patient with cancer of the female reproductive system will

- Actively take part in treatment decisions
- Achieve satisfactory pain and symptom management
- Recognize and report problems promptly
- Maintain preferred lifestyle as long as possible
- Continue to practice cancer detection strategies

Pelvic Organ Prolapse

Pelvic organ prolapse (POP) involves the descent of 1 or more aspects of the uterus and vagina, allowing nearby organs, such as the bladder and rectum, to herniate into the vaginal space.[20] Although vaginal birth increases the risk for POP, it can occur in women who never went through childbirth. Obesity, chronic coughing, and straining during bowel movements can increase the risk for POP. The decreased estrogen that normally accompanies perimenopause decreases connective tissue support and increases the risk.

Uterine Prolapse

Uterine prolapse is the downward displacement of the uterus into the vaginal canal(Fig. 53.12). Prolapse is rated by degrees. In first-degree prolapse, the cervix rests in the lower part of the vagina. Second-degree prolapse means the cervix is at the vaginal opening. Third-degree prolapse means the uterus protrudes through the introitus.

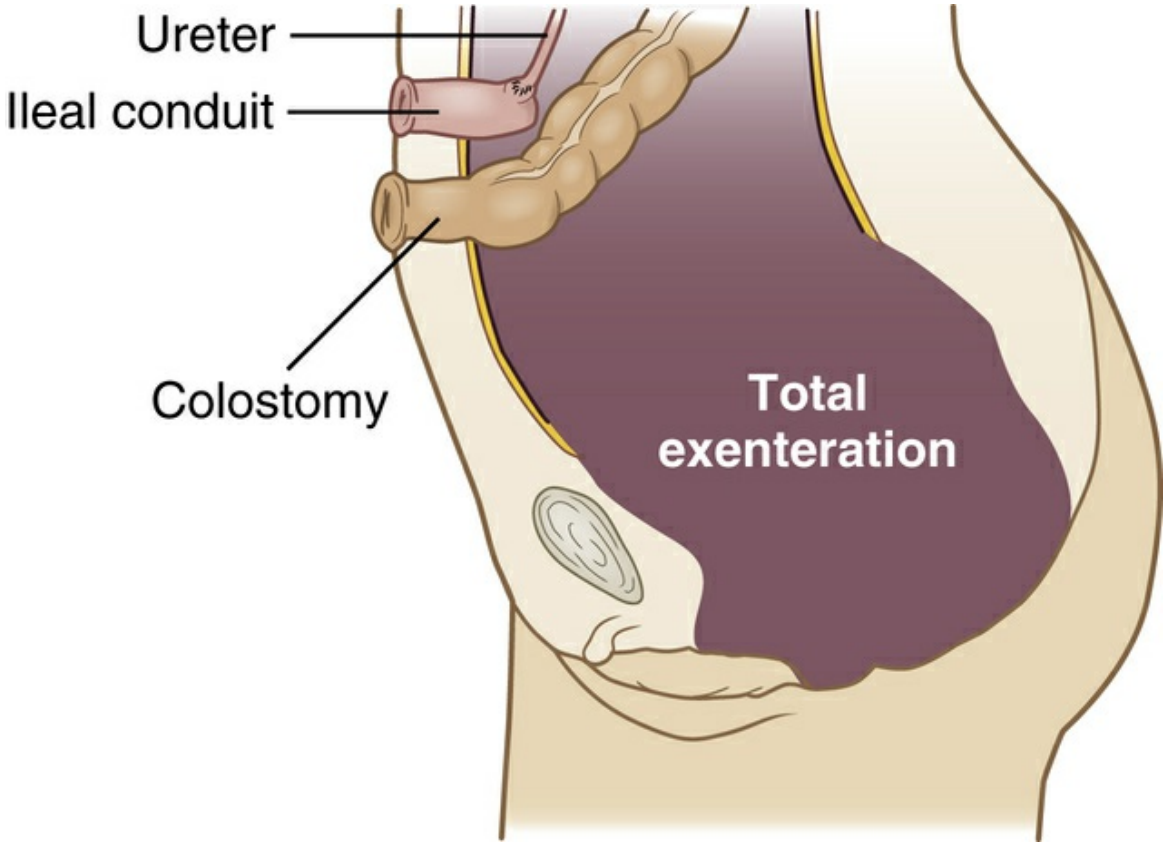

FIG. 53.11 Total exenteration is removal of all pelvic organs with creation of an ileal conduit and a colostomy.

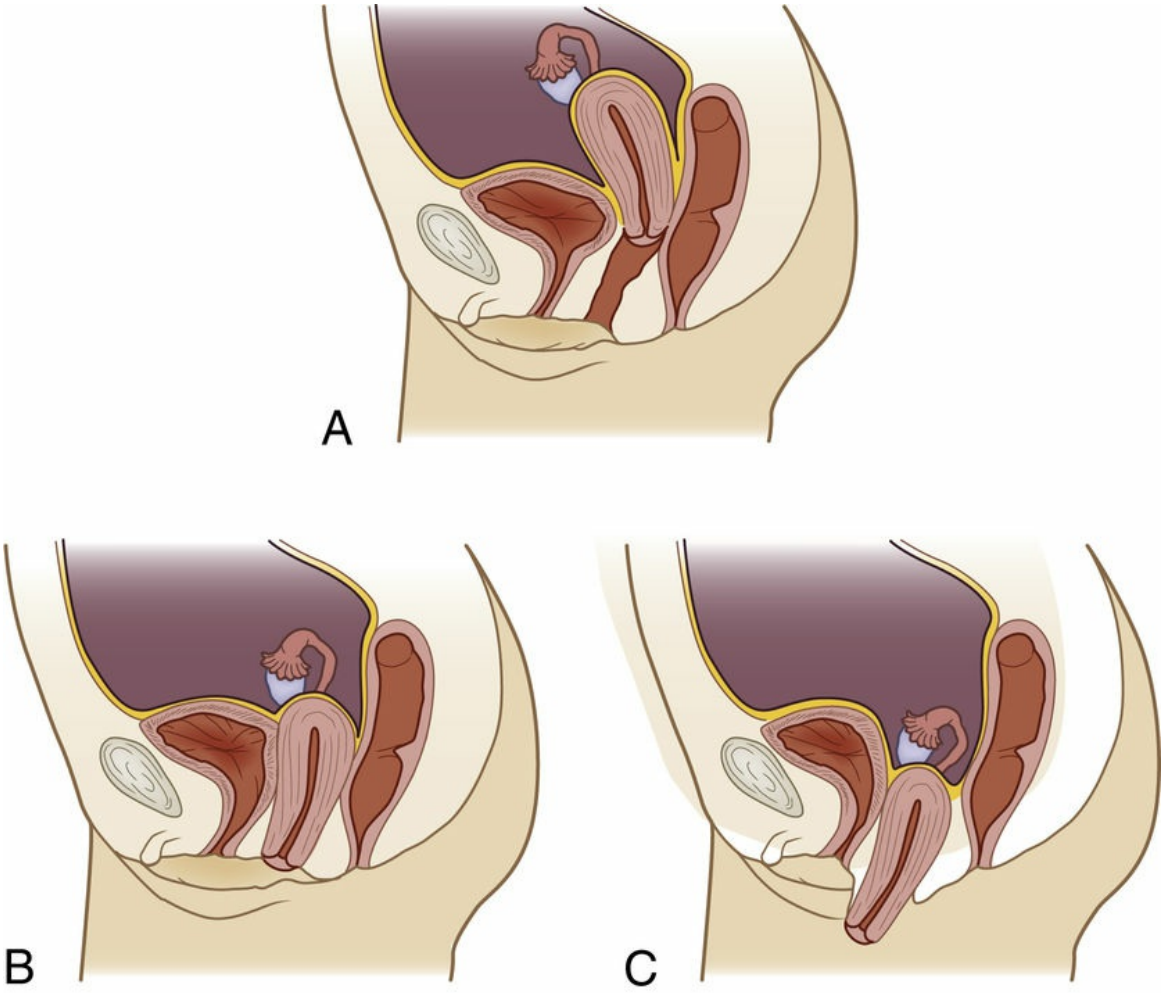

FIG. 53.12 Uterine prolapse. **A,** First-degree prolapse. **B,** Second-degree prolapse. **C,** Third-degree prolapse.

Symptoms vary with the degree of prolapse. The patient may describe a feeling of "something coming down." She may have dyspareunia, a dragging or heavy feeling in the pelvis, and a backache. Stress incontinence is a common and troubling problem. When third-degree uterine prolapse occurs, the protruding cervix and vaginal walls are subjected to constant irritation, and tissue changes may occur.

Therapy depends on the degree of prolapse and how much the woman's daily activities have been affected.[20] Pelvic muscle strengthening exercises (Kegel exercises) may be effective for some women (see Table 45.18). If not, a pessary may be used. A *pessary* is a device that is placed in the vagina to help support the uterus. A wide

variety of shapes exist, including rings, arches, and balls. Most are made of plastic or wire coated with plastic. When a woman first receives a pessary, she needs instructions on how to clean it. Pessaries that are left in place for long periods are associated with erosion, fistulas, and vaginal cancer.

If more conservative measures are not successful, surgery is indicated. Surgery generally involves a vaginal hysterectomy with anterior and posterior repair of the vagina and the underlying fascia.

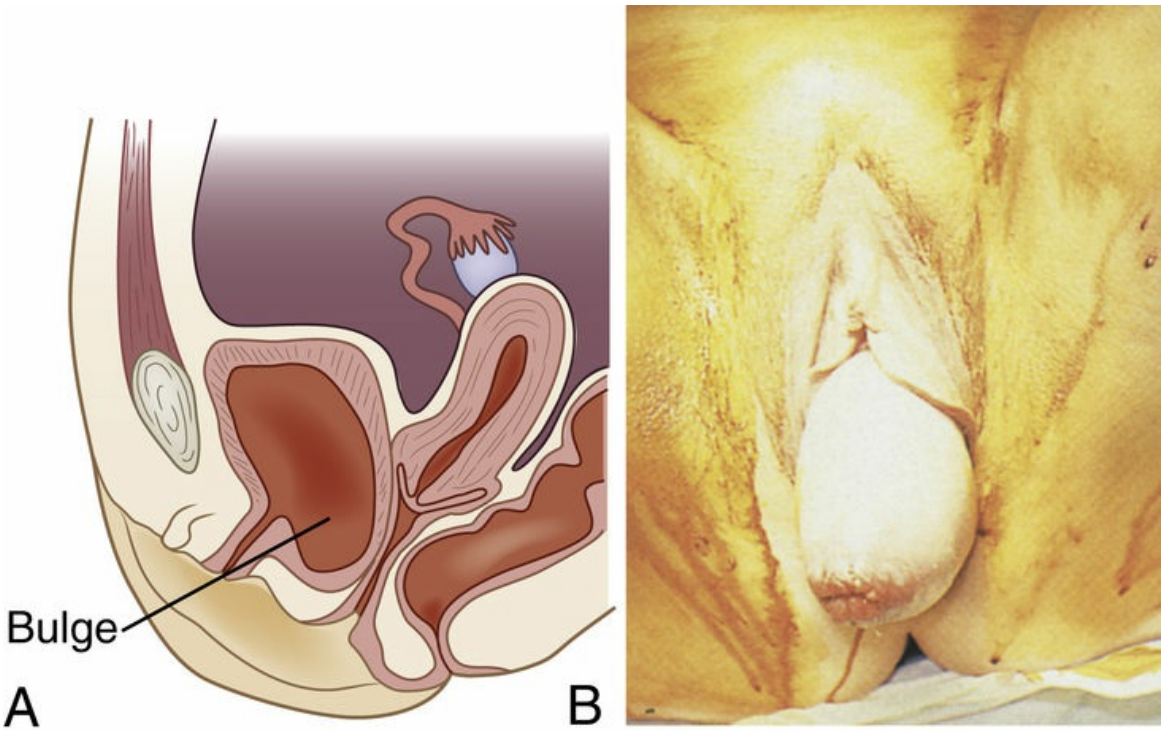

FIG. 53.13 **A,** Cystocele. **B,** Bladder has prolapsed into the vagina, causing a uterine prolapse.

Cystocele and Rectocele

Cystocele occurs when support between the vagina and bladder is weakened (Fig. 53.13). Similarly, a *rectocele* results from weakening between the vagina and rectum (Fig. 53.14). Both are common problems. Many women are asymptomatic. Some have bowel and

bladder problems. With large cystoceles, complete emptying of the bladder can be difficult, predisposing women to bladder infections. A woman with a large rectocele may not be able to completely empty her rectum when defecating unless she helps push the stool out by putting her fingers in her vagina.

As with uterine prolapse, Kegel exercises (see Table 45.18) can strengthen weakened perineal muscles if the cystocele or rectocele is not too problematic. A pessary may be helpful for cystoceles.

Surgery designed to tighten the vaginal wall (colporrhaphy) is the preferred treatment. A cystocele is corrected with a procedure called an anterior colporrhaphy. A posterior colporrhaphy is done for a rectocele. If further surgery is needed to relieve stress incontinence, procedures to support the urethra and restore the proper angle between the urethra and the posterior bladder wall are done.

Nursing and Interprofessional Management: Pelvic Organ Prolapse

Help women avoid or decrease problems with pelvic support by teaching them how to do Kegel exercises.[21] Women of all ages may benefit from these exercises. Teach the patient to pull in or contract her muscles as if she were trying to stop the flow of urine, control the passing of gas, or pinch off a stool (see Table 45.18).

With vaginal surgery, the preoperative preparation usually includes a cleansing douche the morning of surgery. A cleansing enema is usually given before a rectocele repair. A perineal shave may be done.

After surgery, the goals of care are to prevent wound infection and pressure on the vaginal suture line. Perineal care must be done at least twice a day and after each urination or defecation. Apply an ice pack locally to help relieve perineal discomfort and swelling. A disposable glove filled with ice and covered with a cloth works well to create an ice pack. Later, sitz baths may be used.

After an anterior colporrhaphy, an indwelling catheter is usually left in the bladder for 4 days to allow the local edema to subside. The

catheter keeps the bladder empty, preventing strain on the sutures. Twice-daily catheter care with an antiseptic is generally done. To prevent constipation after a posterior colporrhaphy, a high-fiber diet and stool softener may be used.

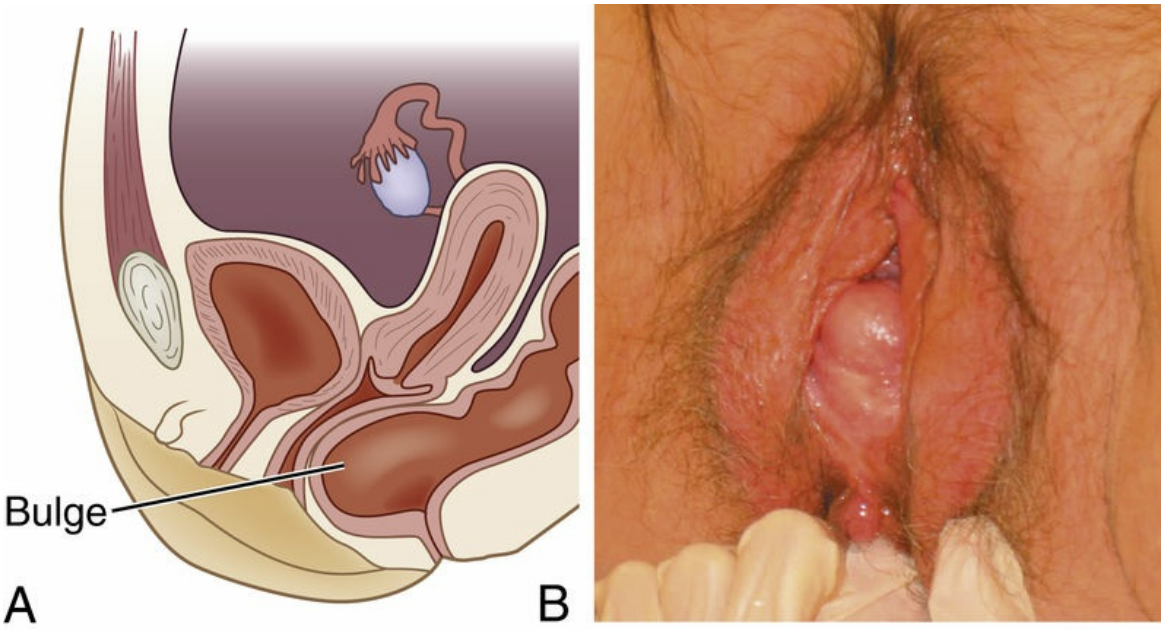

FIG. 53.14 **A,** Rectocele. **B,** Rectum has prolapsed into the vagina. *B,* From Townsend CM: *Sabiston textbook of surgery,* ed 18, St Louis, 2009, Mosby.

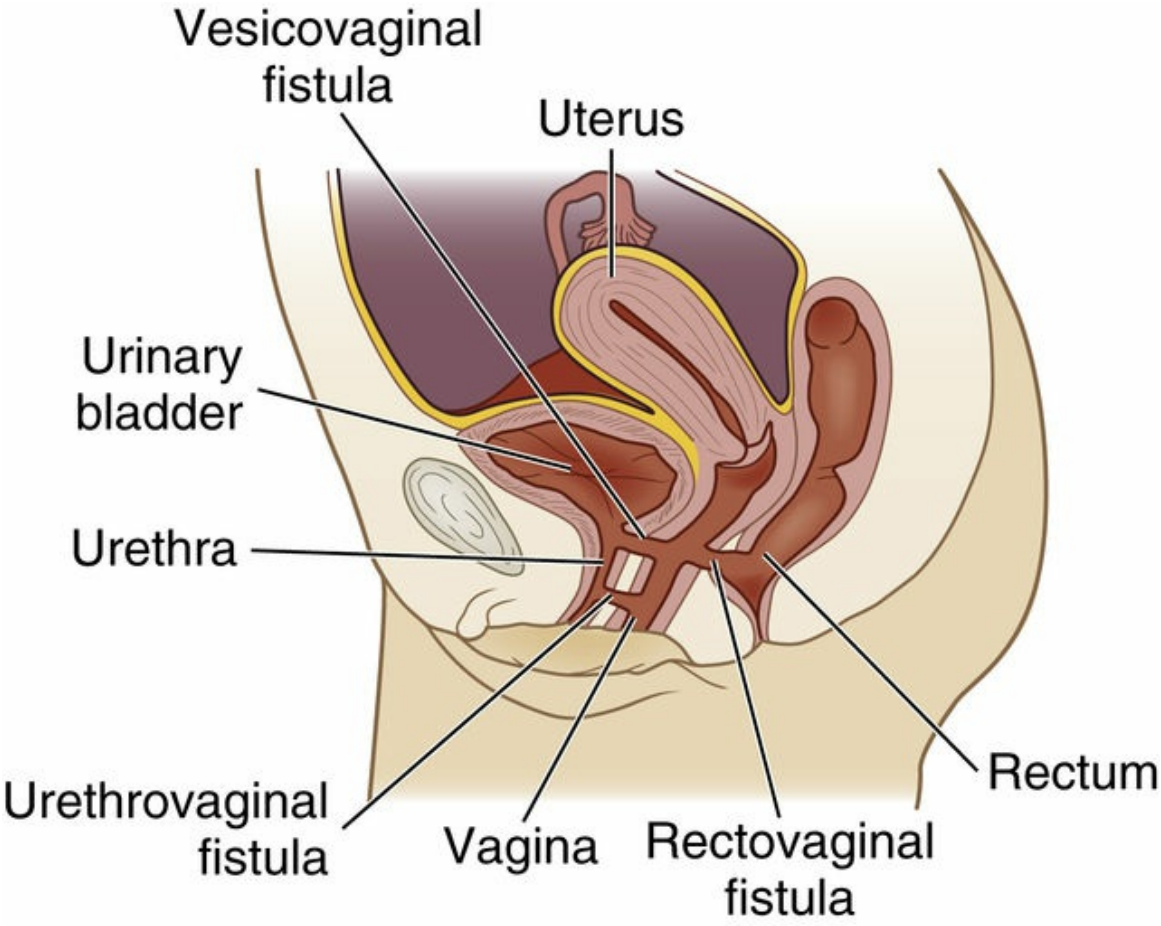

FIG. 53.15 Common fistulas involving the vagina.

Review discharge instructions before the patient leaves the hospital. These include the (1) use of mild laxative as needed; (2) restrictions on heavy lifting and prolonged standing, walking, or sitting; and (3) avoiding intercourse until the HCP gives permission. There may be a temporary loss of vaginal sensation, which can last for several months.

Fistula

A *fistula* is an abnormal opening between internal organs or between an organ and the exterior of the body (Fig. 53.15). Gynecologic procedures cause most urinary tract fistulas. Other causes include injury during childbirth and disease processes such as cancer. Fistulas may develop between the vagina and bladder, urethra, ureter, or

rectum. When *vesicovaginal* fistulas (between the bladder and vagina) develop, some urine leaks into the vagina. With *rectovaginal* fistulas (between the rectum and vagina), flatus and feces escape into the vagina. In both instances, excoriation and irritation of the vaginal and vulvar tissues occur and may lead to severe infections. In addition to wetness, offensive odors may develop, causing embarrassment and severely limiting socialization.

Interprofessional and Nursing Care

Because small fistulas may heal spontaneously within a matter of months, treatment may not be needed. If the fistula does not heal, surgical repair is needed. Inflammation and tissue edema must be eliminated before surgery, which may involve a wait of many months. The fistulectomy may result in the patient having an ileal conduit or temporary colostomy. (See Chapter 45 for care of a patient with an ileal conduit and Chapter 42 for care of a patient with a colostomy.)

Perineal hygiene is of great importance before and after surgery. Cleanse the perineum every 4 hours. Warm sitz baths should be taken 3 times daily if possible. After surgery, emphasize ways to avoid stress on the repaired areas and prevent infection. Make sure the indwelling catheter, usually in place for 7 to 10 days, is draining at all times. Encourage the patient to maintain an adequate fluid intake to provide for internal catheter irrigation. Use minimal pressure and strict asepsis if catheter irrigation is needed. Change perineal pads often. The first stool after bowel surgery may be purposely delayed to prevent wound contamination. Later, give stool softeners or mild laxatives (as ordered).

Surgical repair of fistulas is not always effective, even in the best conditions. Therefore supportive nursing care for the patient and her significant others is especially important. Encouragement and reassurance are needed to help the patient cope with her problems.

Sexual Assault

Sexual assault is the forcible perpetration of a sexual act on a person without their consent. It is a crime of violence and aggression. It can include any of the following actions: sodomy (anal or oral copulation with a person of the same or opposite sex); forced vaginal intercourse; assault with a foreign object; unwanted kissing, touching, or fondling; and serial battery and rape. The Federal Bureau of Investigation's (FBI's) definition of *rape* includes female or male victims who have experienced sexual assault that includes oral or anal penetration.

Sexual assault may be committed by a stranger or by an intimate partner. *Intimate partner violence (IPV)* is a major health problem in the United States.[22] Sexual assault that is perpetrated by a family member is termed *incest*. *Statutory rape* is consensual sexual intercourse with someone younger than a specific age. This age usually varies state to state. Most states use the criteria of a person younger than 16 years of age. Most states consider that an adolescent who is 16 years of age or older can consent to consensual sexual intercourse.

The involvement of children 14 years of age or younger in sexual activity, either consensual or forced, is termed *child sexual abuse*. Child sexual abuse is defined as the employment, persuasion, inducement, enticement, or even coercion of a person younger than 14 years of age in any sexually explicit conduct or simulation of sexual conduct. It includes behaviors that are forced onto the child for the purpose of producing video material, as well as rape, molestation, prostitution, or other forms of exploitation involving any sexual behavior.

Every 98 seconds, an American is sexually assaulted. Annually, 1.3 million rape or rape-related assaults occur to women. 18% of women report that they had been victims of an attempted or completed rape during their lifetime. Most (80%) reported that they were assaulted before the age of 25. Survivors have an array of physical and psychologic health consequences, such as suicidal thoughts and depression, after sexual violence.[23]

Clinical Manifestations

Physical

Some female victims of assault have more injuries than others. Factors that influence the severity of injury include the woman's age, if the perpetrator used a weapon, and if the victim knew the perpetrator. Physical injuries may include fractures, subdural hematomas, cerebral concussions, and intraabdominal injuries. Sexual injuries may include bruising and lacerations of the perineum, hymen, vulva, vagina, cervix, and anus. Sexual assault places women at risk for STIs and pregnancy.

Psychologic

Immediately after the assault, women may show signs of shock, numbness, denial, or withdrawal. Some women may seem unnaturally calm, while others may cry or express anger. Feelings of humiliation, degradation, embarrassment, anger, self-blame, and fear of another assault are often expressed.

These symptoms usually decrease after 2 weeks, and victims may appear to have adjusted. Yet any time from 2 to 3 weeks to months or years after the assault, symptoms may return and become more severe.

Rape trauma syndrome is a classification of posttraumatic stress disorder. Flashbacks, intrusive recall, sleep problems, GI symptoms, and numbing of feelings are common initial symptoms. Women feel embarrassment, self-blame, and powerlessness. Later symptoms include mood swings, irritability, and anger. Feelings of despair, shame, and hopelessness may be internalized and lead to depression, and the risk for suicide may increase.

Interprofessional Care

The highest priority for the victim of assault is her emotional and physical safety. Table 53.15 outlines the emergency management of the patient who has been sexually assaulted. Most emergency departments (EDs) have identified personnel who have received special training to work with women who have been assaulted. The sexual assault nurse examiner (SANE) is a registered nurse who is

certified to provide care to victims of sexual assault, while ensuring evidence is safeguarded. Special procedures are followed in taking the history and conducting the examination to preserve all evidence in case of future prosecution. When the victim of an assault is in the ED or clinic, a specific chain of events occurs to collect legal evidence if the woman chooses to pursue legal action (Tables 53.15 and 53.16).

The SANE takes a comprehensive gynecologic and sexual history and an account of the assault (who, what, when, and where) and does a general physical and pelvic examination. Laboratory tests are done to identify sperm in the vagina and to screen for STIs or pregnancy. The patient receives preventive treatment for pregnancy and STIs and treatment for injuries sustained in the assault.

Follow-up physical and psychologic care is recommended. Women should return weekly for the first month after the assault. This includes the time period when a woman's psychologic reactions may be the most severe.

Nursing Management: Sexual Assault

Nursing care for a sexual assault victim is complex. Provide emotional and nonjudgmental support. Obtain referrals as needed for follow-up care. Part of the role of the SANE is to discuss the risk for pregnancy and STIs and offer the patient an emergency contraception pill and antibiotics (Table 53.17). A social worker or nurse case manager referral should be made by the primary nurse in the ED. They can assist the patient in securing financial compensation to help them pay for emergency services as a result of the assault, counseling services, and any missed work.

TABLE 53.15 Emergency ManagementSexual Assault

Etiology	Assessment Findings	Interventions
• **Assault involving genitalia (male or female) without consent** • **Sexual molestation** • **Sodomy**	• Anger • Crying • ↓ Level of consciousness • Emotional or physical manifestations of shock • Extragenital injuries • Hyperventilation • Hysteria • Pain in genital or extragenital area • Silence • Vaginal, oral, and rectal injuries	Initial • Treat shock and other urgent medical problems (e.g., head injury, hemorrhage, wounds, fractures). • Assess emotional state. • Contact support person (i.e., social worker, rape advocate, sexual assault nurse examiner). • Do *not* clean the patient until all evidence is collected. Make sure the patient does not wash, douche, urinate, brush teeth, or gargle. • Place sheet on floor. Then have patient stand on sheet to remove clothing. Place sheet with clothing in paper bag. • Obtain forensic evidence per local protocol (e.g., body hair, nail scrapings, tissue, dried semen, vaginal washing, blood samples). • Maintain chain of evidence for all legal specimens. Clearly label evidence and keep in locked cabinet until given to law enforcement agency. • Obtain baseline HIV, syphilis, and other STI screening. • Determine method of contraception, date of last menstrual period, and date of last tetanus immunization. • Consider tetanus prophylaxis if lacerations contain soil or dirt. • Vaccinate against hepatitis B if not already done. Ongoing Monitoring • Monitor vital signs and emotional status. • Provide clothing as needed. • Counsel patient about confidential HIV and STI testing.

TABLE 53.16 Evaluation of Alleged Sexual Assault

1. Medicolegal

- Valid written consent for examination, photographs, laboratory tests, release of information, and laboratory samples
- Appropriate “chain of evidence” documentation

2. History

- History of assault (who, what, when, where)
- Penetration, ejaculation, extragenital acts
- Activities since assault (e.g., changed clothes, bathed, douched)
- Inquire about safety
- Menstrual and contraceptive history
- Medical history
- Emotional status

- Current symptoms

3. General Physical Examination

- Vital signs and general appearance
- Extragenital trauma: mouth, breasts, neck
- Cuts, bruises, scratches (photographs taken)

4. Pelvic Examination

- Vulvar trauma, redness. Hymen, anal, and rectal status
- Matted hairs or free hairs
- Vaginal examination with unlubricated speculum for discharge, blood, lacerations
- Uterine size
- Adnexa, especially hematomas

5. Laboratory Samples

- Vaginal vault content sampling
- Vaginal smears: microscope evaluation for trichomonads and semen
- Oral or rectal swabs and smears (if indicated)
- Blood samples: pregnancy test; serologic testing for syphilis, HIV, and hepatitis B infection
- Freeze serum sample for later testing
- Cultures: cervix and other areas (if indicated) for gonorrhea and chlamydia infection
- Fingernail scrapings
- Pubic hair scrapings
- Clipping of matted pubic hairs

6. Treatment

- Care of injuries and emotional trauma
- Prophylaxis for STIs, tetanus, and hepatitis B (see appropriate chapters)
- If appropriate, consider levonorgestrel (Plan-B One-Step) emergency contraceptive pill up to 72 hr after assault; follow-up for pregnancy test in 2–3 wk
- Testing for HIV, syphilis, and hepatitis B may be done at 6–8 wk
- Protection of legal rights
- Recommendation of continued follow-up and services of rape crisis center

TABLE 53.17 Patient TeachingSexual Assault Prevention

Include the following instructions when teaching measures to prevent sexual assault:

1. Be proactive and take a self-defense class.
2. Be aware of date-rape drugs (e.g., GHB, Rohypnol, ketamine). Never leave your beverage unattended when socializing.
3. Place and maintain lights at all entrances to your home.
4. Keep your doors locked and do not open them to a stranger. Ask for identification if a service person comes to the door.
5. Do not advertise that you live alone. List only your initials with your last name in the telephone directory or on the mailbox. Never reveal to a caller that you are home alone.
6. Avoid walking alone in deserted areas. Walk to the parking lot with a friend. Be sure you see each other leave.
7. Have your keys ready as you approach your car or home.
8. Keep all doors locked and the windows up when driving.
9. Never get on an elevator with a suspicious person. Pretend you

have forgotten something and get off.
10. Say what you mean in social situations. Be sure your voice and body language reflect your response.
11. Be cautious with online correspondence.
12. Carry a loud whistle and use it when you think you are in danger.
13. Yell "Fire!" if you are attacked and run toward a lighted area

Case Study

Uterine Fibroids and Endometrial Cancer

© Juanmonino/iStock.com.

Patient Profile

B.C. is a 49-yr-old Latina woman who has lower pelvic discomfort and anemia. She has hypertension and hypothyroidism. B.C. is the mother of 2 teenage children. She has had abnormal uterine bleeding for 5 months. Large multiple uterine fibroids were diagnosed on ultrasound. She comes to the hospital for an abdominal hysterectomy.

Subjective Data

- Was initially reluctant about surgery
- Concerned about her dyspareunia and her husband's reaction to the surgery
- States she has pelvic discomfort and vaginal spotting

Objective Data (Preoperative)

- BP 140/92 mm Hg, pulse 82 beats/min, respirations 14 breaths/min
- Height 5ft, 6 in; weight 145 lb.

Operative

- During surgery, abnormal-looking endometrial tissue was sent for pathologic analysis. The results were positive for endometrial cancer.
- Had total hysterectomy and bilateral salpingo-oophorectomy with lymph node biopsies. 5 large fibroids were found in the uterus.

Postoperative Status

- Returned to room with indwelling urinary catheter in place
- Abdominal incision
- Intermittent pneumatic compression devices on lower extremities

- Patient-controlled analgesia (PCA) pump for pain management

Discussion Questions

1. Can the manifestations of uterine fibroids be distinguished from endometrial cancer?
2. ***Patient-Centered Care:*** Preoperatively, B.C. asks you about the effect of the surgery on her sexuality. How would you respond, and what type of patient teaching would you do?
3. ***Patient-Centered Care:*** When she is told about the diagnosis of endometrial cancer, she is shocked. She cannot believe that it was not discovered before surgery. How would you respond to her?
4. ***Priority Decision:*** What are priorities of care for B.C.?
5. ***Safety:*** When assessing B.C. after you got her out of bed, you note that her abdominal dressing is saturated with blood and she says she feels weak and dizzy. What would you do?
6. What other complications (including reasons for their development) can occur after an abdominal hysterectomy?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. Her 17-yr-old daughter asks you if she is at risk for endometrial cancer. How would you respond?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In telling a patient with infertility what she and her partner can expect, the nurse explains that

a. ovulatory studies can help determine tube patency.
b. a hysterosalpingogram is a common diagnostic study.
c. for most couples, the cause of infertility is usually not found.
d. semen analysis is performed only if testosterone levels are low.

2. An appropriate question to ask the patient with painful menstruation to distinguish primary from secondary dysmenorrhea is
   a. "Does your pain become worse with activity or overexertion?"
   b. "Have you had a recent personal crisis or change in your lifestyle?"
   c. "Is your pain relieved by nonsteroidal antiinflammatory medications?"
   d. "When in your menstrual history did the pain with your period begin?"

3. The nurse should advise the woman recovering from surgical treatment of an ectopic pregnancy that
   a. she has an increased risk for salpingitis.
   b. maintaining bed rest for 12 hours will assist in healing.
   c. having an ectopic pregnancy increases her risk for another.
   d. intrauterine devices and infertility treatments must be avoided.

4. To prevent or decrease age-related changes that occur after menopause in a patient who chooses not to take hormone therapy, the *most* important self-care measure to teach is

a. maintaining usual sexual activity.
b. increasing the intake of dairy products.
c. performing regular aerobic, weight-bearing exercise.
d. taking vitamin E and B-complex vitamin supplements.

5. In caring for a patient with endometriosis, the nurse teaches the patient that interventions used to treat or cure this condition may include *(select all that apply)*
   a. radiation.
   b. antibiotic therapy.
   c. oral contraceptive pills.
   d. surgical removal of tissue.
   e. total abdominal hysterectomy and salpingo-oophorectomy.
6. Nursing care for the patient with endometrial cancer who had a total abdominal hysterectomy and salpingectomy and oophorectomy includes
   a. maintaining absolute bed rest.
   b. keeping the patient in high-Fowler's position.
   c. need for supplemental estrogen after removal of ovaries.
   d. encouraging movement and walking as much as tolerated.
7. Postoperative care for the patient who had an abdominal hysterectomy includes *(select all that apply)*
   a. monitoring urine output.
   b. changing position frequently.
   c. restricting all food for 24 hours.
   d. observing perineal pad for bleeding.

e. encouraging leg exercises to promote circulation.

8. Postoperative nursing care for the woman with a gynecologic fistula includes *(select all that apply)*
   a. bed rest.
   b. bladder training.
   c. warm sitz baths.
   d. perineal hygiene.
   e. use of daily enemas.

9. The *first* nursing intervention for the patient who has been sexually assaulted is to
   a. treat urgent medical problems.
   b. contact support person for the patient.
   c. provide supplies for the patient to cleanse self.
   d. document bruises and lacerations of the perineum and the cervix.

1. b, 2. d, 3. c, 4. c, 5. c, d, e, 6. d, 7. a, b, e, 8. c, d, 9. a

Male Reproductive Problems

Anthony Lutz

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of benign prostatic hyperplasia.
2. Describe the pathophysiology, clinical manifestations, and interprofessional care of prostate cancer.
3. Explain the nursing management of prostate cancer.
4. Specify the pathophysiology, clinical manifestations, and interprofessional and nursing management of prostatitis and problems of the penis and scrotum.
5. Explain the clinical manifestations and interprofessional care of testicular cancer.
6. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of problems related to male sexual function.
7. Discuss the psychologic and emotional implications related to male reproductive problems.

Conceptual Focus

Cellular Regulation
Infection
Pain
Reproduction
Sexuality

This chapter discusses problems of the male reproductive system. These involve a variety of structures, including the prostate, penis,

urethra, ejaculatory duct, scrotum, testes, epididymis, ductus (vas) deferens, and rectum (Fig. 54.1). Many of these problems can profoundly affect sexuality and reproduction. Sexual dysfunction from prostate problems or erectile dysfunction (ED) can cause psychologic and body image problems. The patient may have anxiety because of a perceived loss of his sex role, self-esteem, or quality of sexual interaction with his partner. Patient education and counseling are essential nursing roles for promoting health and optimal sexual well-being.

Problems of the Prostate Gland

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is a condition in which the prostate gland increases in size, disrupting the outflow of urine from the bladder through the urethra. Half of men will have some signs of BPH by the age of 50. That number increases to more than 70% for men 60 to 69 years old.[1] Symptoms of BPH can include bothersome lower urinary tract symptoms (LUTS), such as difficulty starting a urine stream, a decreased/weaker flow of urine, or urinary frequency. BPH with LUTS does not cause or lead to an increased risk for prostate cancer.[2]

Etiology and Pathophysiology

There are several potential factors that may play a role in the development and progression of BPH. We think that hormonal changes associated with aging are a contributing factor. Dihydroxytestosterone (DHT), one of several sex hormones, stimulates prostate cell growth. Excess amounts of DHT can cause overgrowth of prostate tissue. As men age, they have a decrease in testosterone but continue to make and accumulate high levels of DHT, resulting in prostate enlargement.

Another possible cause of BPH is an increased proportion of estrogen (as compared to testosterone). Throughout their lives, men

make both testosterone and small amounts of estrogen. As men age, the amount of active testosterone in the blood decreases, leaving a higher proportion of estrogen. A higher amount of estrogen within the prostate gland increases the activity of substances (including DHT) that promote prostate cell growth.

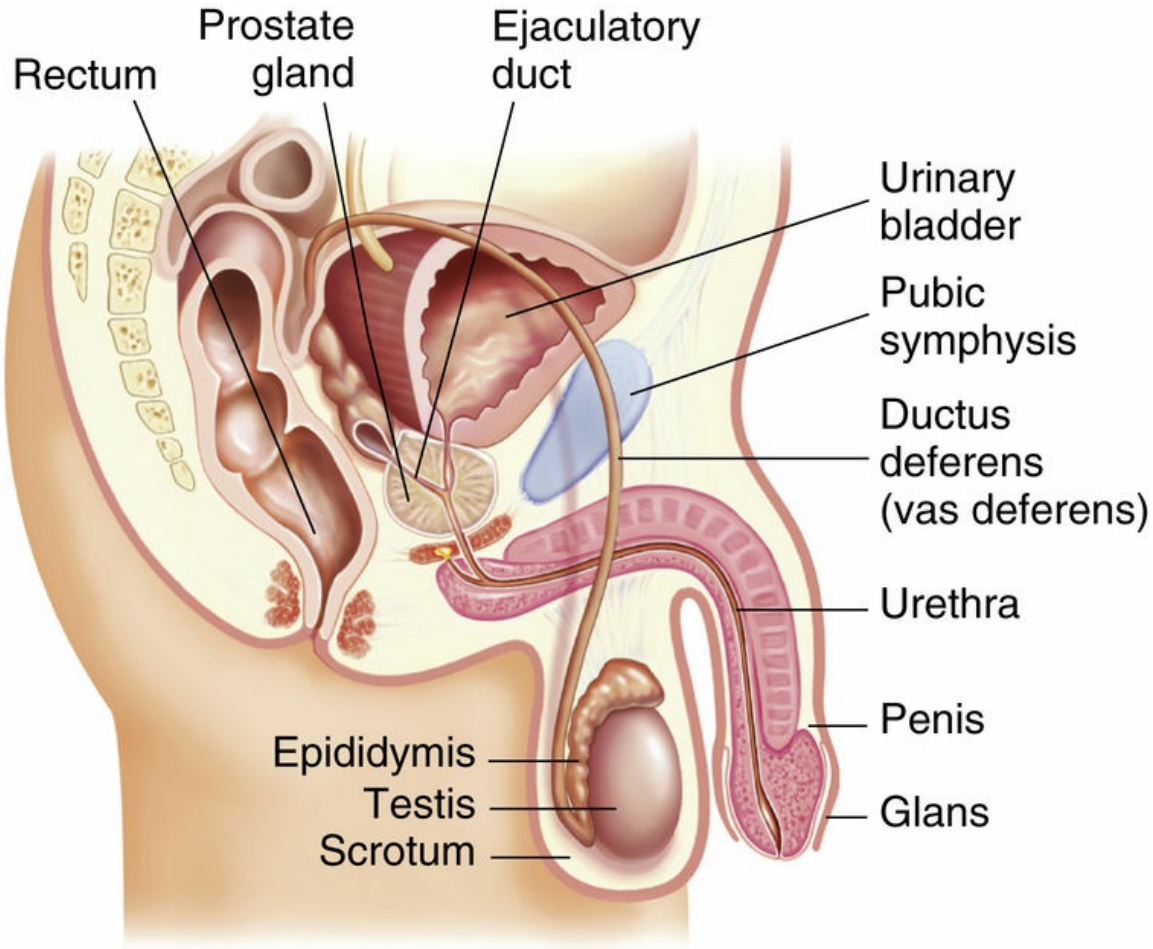

FIG. 54.1 Areas of the male reproductive system in which problems are likely to develop.

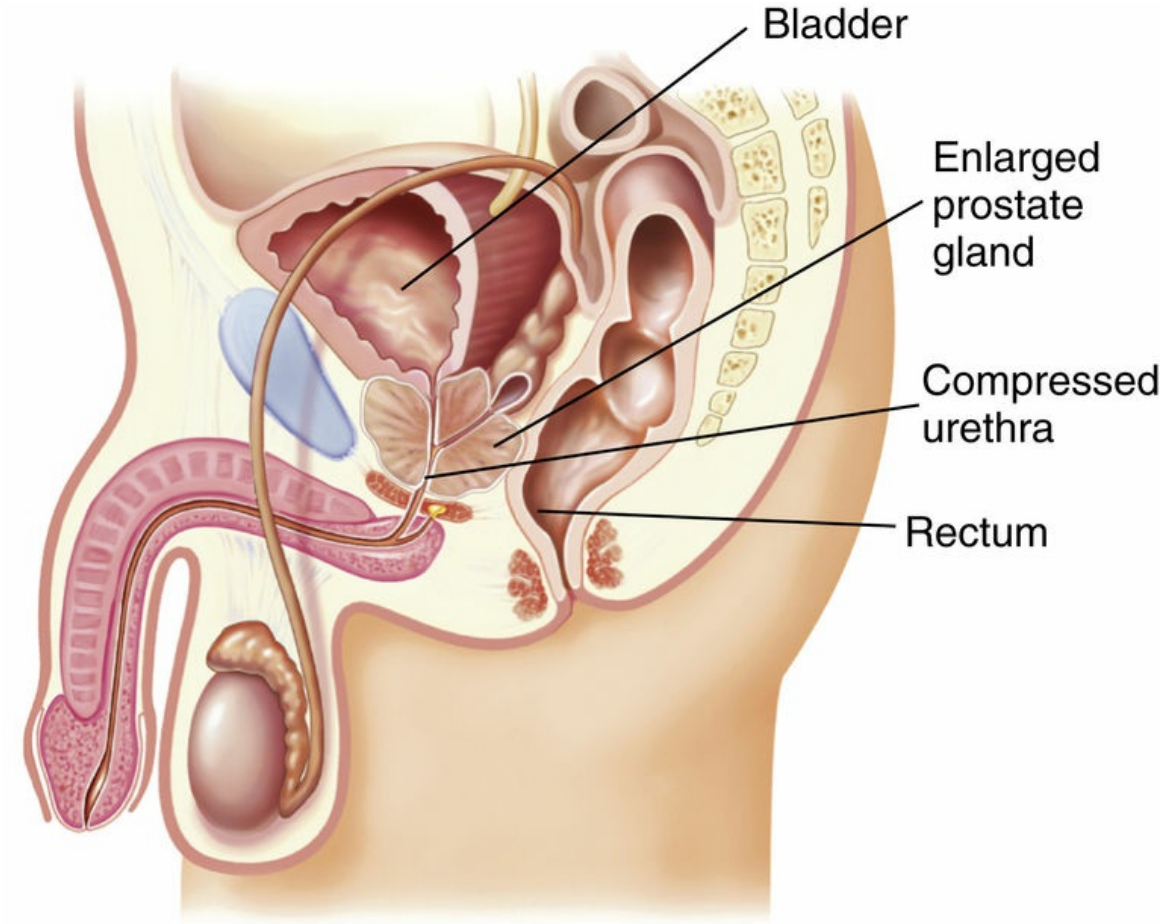

FIG. 54.2 BPH. The enlarged prostate compresses the urethra.

BPH usually develops in the inner part of the prostate, called the transition zone. (Prostate cancer is most likely to develop in the outer part, called the peripheral zone). As the transition zone of the prostate enlarges, it gradually compresses the urethra, leading to partial or complete obstruction (Fig. 54.2). This compression of the urethra leads to the development of clinical manifestations. There is no direct relationship between overall prostate size and the severity of manifestations or degree of obstruction.[3] The location of the enlargement is most significant in the development of obstructive symptoms (Fig. 54.3). For example, it is possible for mild prostate enlargement to cause severe obstructive symptoms or for extreme prostate enlargement to cause few obstructive symptoms.

Risk factors for BPH include aging, obesity (especially increased waist circumference), lack of physical activity, a high amount of

dietary animal protein, alcohol use, ED, smoking, and diabetes. A family history of BPH in a first-degree relative also may be a risk factor.

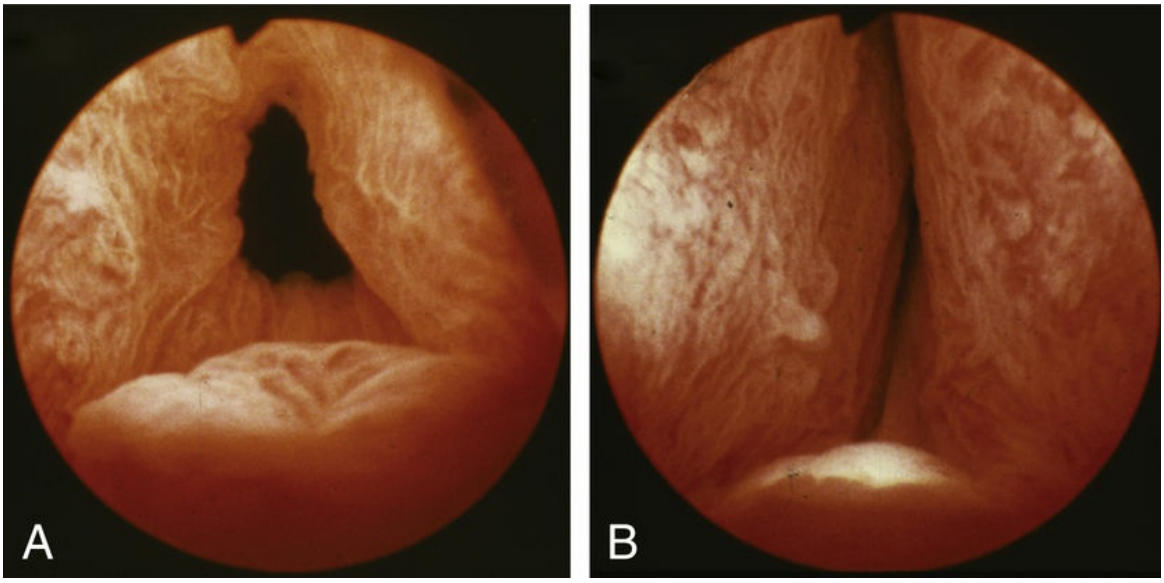

FIG. 54.3 Views of the prostate by cystoscopy. **A,** Normal appearance. **B,** Moderate BPH with urethral obstruction. From Townsend CM, Beauchamp RD, Evers BM, et al: *Sabiston textbook of surgery,* ed 19, Philadelphia, 2012, Saunders.

Clinical Manifestations

Manifestations occur gradually and may not be noticed until prostate enlargement has been present for some time. Early symptoms may not cause many problems because the bladder can compensate for a small amount of resistance to urine flow. As the severity of urethral obstruction increases, symptoms gradually worsen.

Symptoms can be divided into 2 groups: irritative and obstructive. *Irritative symptoms* include nocturia, urinary frequency, urgency, dysuria, bladder pain, and incontinence. These symptoms are related to inflammation or infection. Nocturia is often the first symptom that the patient notices. *Obstructive symptoms,* caused by prostate enlargement, include a decrease in the caliber and force of the urinary stream, difficulty in starting a stream, intermittency (stopping and

starting stream several times while voiding), and dribbling at the end of urination. These symptoms are due to the increased effort of the bladder as it tries to empty through the decreased diameter of the urethra. As a group, both irritative and obstructive symptoms are considered LUTS.

The American Urological Association (AUA) symptom index for BPH (Table 54.1) is a widely used tool to assess voiding symptoms from obstruction.[4] Although this tool is not diagnostic, it helps determine the extent of symptoms and guide treatment. Higher scores on this tool mean greater symptom severity.

Complications

Complications of BPH are relatively rare. Some men may have acute urinary retention. This complication is manifested by the sudden and painful inability to urinate. Treatment involves the insertion of a catheter to drain the bladder. Surgery may be indicated in severe situations.

Urinary tract infection (UTI) can be a complication of BPH. Since the bladder is unable to empty completely, bacteria can grow in the residual urine that remains in the bladder and cause infection. In more severe cases, infection can progress into the kidney and cause pyelonephritis. In severe cases, infection can spread into the bloodstream and sepsis can develop. Bladder calculi (stones) may develop because of the alkalinization of the residual urine. So, the finding of bladder stones often indicates obstruction related to BPH. The risk for kidney stones is not significantly increased in this population.

Other complications include renal failure caused by *hydronephrosis* (distention of the renal pelvis and calyces by urine that cannot flow through the ureter to the bladder) and bladder damage if treatment for acute urinary retention is delayed.

TABLE 54.1 AUA Symptom Index to Determine

Severity of Prostatic Problems

Questions	Aua Symptom Score* (Circle one Number on Each Line)					
	Not At All	Less Than 1 Time in 5	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
Over the Past Month						
1. How often do you have the sensation that your bladder is not completely empty after you finish urinating?	0	1	2	3	4	5
2. How often do you have to urinate again, less than 2 hr after you finish urinating?	0	1	2	3	4	5
3. How often do you stop and start again several times when you urinate?	0	1	2	3	4	5
4. How often do you find it difficult to postpone urination?	0	1	2	3	4	5
5. How often do you have a weak urinary stream?	0	1	2	3	4	5
6. How often do you have to push or strain to begin urination?	0	1	2	3	4	5
7. How many times do you usually get up to urinate from the time you go to bed at night until the time you get up in the morning?	0 (None)	1 (1 time)	2 (2 times)	3 (3 times)	4 (4 times)	5 (5 times or more)
Sum of circled numbers (AUA Symptom Score): ___*						

AUA, American Urological Association.

* Score is interpreted as follows: 0–7, mild; 8–19, moderate; 20–35, severe.

Diagnostic Studies

A detailed history and physical examination are both important in the diagnosis. Diagnostic studies are outlined in Table 54.2. A digital rectal examination (DRE) is done to estimate the prostate size, symmetry, and consistency. In BPH, the prostate is symmetrically enlarged, firm, and smooth.

Other diagnostic testing may include a urinalysis and urine culture and sensitivities to look for bacteria, nitrites, leukocyte esterase, white blood cells (WBCs), or microscopic hematuria (RBCs), which could indicate infection or inflammation.

A prostate-specific antigen (PSA) blood test may be done to screen for prostate cancer. PSA levels may be slightly increased in patients with BPH, as PSA is released into the bloodstream by both benign and malignant prostate cells. Serum creatinine levels can assess for renal

insufficiency. If creatinine levels are high, a renal ultrasound may be done to evaluate for hydronephrosis. Because symptoms of BPH are similar to those of a neurogenic bladder, a neurologic examination may be done.

In patients with an abnormal DRE and high PSA, a transrectal ultrasound (TRUS) is typically ordered. This examination allows for accurate assessment of prostate size and can help to distinguish BPH from prostate cancer. Biopsies can be taken during the ultrasound procedure. A pelvic MRI with attention to the prostate is an alternative imaging test that can be done in the setting of abnormal DRE and high PSA. If abnormal areas are seen on MRI, these areas can be specially targeted on a TRUS prostate biopsy using new software and equipment (called an MRI-fusion targeted biopsy). Currently insurance coverage of pelvic MRI can sometimes be an issue. However, recent studies have shown risk assessment with MRI prior to biopsy and MRI-targeted biopsy is superior to standard TRUS biopsy in men at risk for prostate cancer.[5]

Uroflowmetry, a study that measures the volume of urine expelled from the bladder, is helpful to determine the extent of urethral blockage and the type of treatment needed. Postvoid residual urine volume is can determine the degree of urine flow obstruction. Cystoscopy, a procedure allowing internal visualization of the urethra and bladder, is done if the diagnosis is unclear or to see the degree of prostatic enlargement. If the diagnostic picture is unclear, urodynamic/pressure flow studies can be done to help evaluate bladder function and assess for obstruction.

TABLE 54.2 Interprofessional CareBenign Prostatic Hyperplasia

Diagnostic Assessment

- History and physical examination

- Digital rectal examination (DRE)
- Urinalysis and urine culture and sensitivities
- Prostate-specific antigen (PSA)
- Serum creatinine
- Postvoid residual (by ultrasound)
- Renal ultrasound (if increased serum creatinine/to evaluate for hydronephrosis)
- Transrectal ultrasound (TRUS)
- Uroflowmetry
- Cystoscopy
- Urodynamic/pressure flow studies

Management

Active Surveillance

- Annual PSA and DRE
- Repeat IPSS score and postvoid residual if any symptoms change

Drug Therapy

- 5α-Reductase inhibitors (e.g., dutasteride [Avodart], finasteride [Proscar])
- α-Adrenergic receptor blockers (e.g., alfuzosin, doxazosin, tamsulosin [Flomax])
- Combination 5α-reductase inhibitor and α-adrenergic receptor blocker (e.g., dutasteride plus tamsulosin [Jalyn])
- Erectogenic drugs (e.g., tadalafil [Cialis])

Minimally Invasive Therapy

- Laser enucleation of the prostate (HoLEP or ThuLEP)

- Photoselective vaporization of the prostate (PVP)
- Prostatic urethral lift (PUL)
- Transurethral microwave thermotherapy (TUMT)
- Transurethral needle ablation (TUNA)
- Water vapor thermal therapy

Invasive (Surgery) Therapy

- Transurethral incision of the prostate (TUIP)
- Transurethral resection of the prostate (TURP)
- Simple prostatectomy (open, laparoscopic, or robotic-assisted)

Interprofessional Care

The goals of interprofessional care are to (1) restore bladder drainage, (2) relieve the patient's symptoms, and (3) prevent or treat the complications of BPH. Treatment is generally based on the degree to which the symptoms bother the patient or the presence of complications, rather than the size of the prostate. Alternatives to surgical intervention for some patients include surveillance, drug therapy, and minimally invasive procedures.

The most conservative treatment that is recommended for some patients with BPH is referred to as *active surveillance,* or watchful waiting. When the patient has mild symptoms (AUA symptom scores of 0 to 7), a wait-and-see approach is taken. Teaching patients to make lifestyle changes can help relieve early or mild symptoms. Making dietary changes (decreasing intake of bladder irritants, like caffeine, alcohol, carbonated drinks, artificial sweeteners, and spicy or acidic foods), avoiding certain drugs (e.g., decongestants, anticholinergics), and restricting evening fluid intake may improve symptoms.

In addition, a timed voiding schedule (also referred to as "bladder re-training") may reduce symptoms, eliminating the need for further intervention. If the patient begins to have signs or symptoms that indicate an increase in obstruction, further treatment is needed.

Drug Therapy

The 2 main classes of drugs that are used to treat BPH include 5α-reductase inhibitors and α-adrenergic receptor blockers. Combination therapy using both types of drugs may be more effective in reducing symptoms than using 1 drug alone. A medication in the erectogenic class of drugs also can be used to help treat BPH.

5α-Reductase Inhibitors

5α-Reductase inhibitors work by reducing the size of the prostate gland. They block the 5α-reductase type 1 and 2 isoenzymes, which are necessary for the conversion of testosterone to DHT (main intraprostatic androgen). Prostate size is directly related to the amount of DHT. By blocking DHT, overly enlarged prostates can decrease in size. This class of medication is more effective for men with larger prostates who have bothersome symptoms.

Finasteride (Proscar) inhibits only the type 2 isoenzyme. It is an appropriate treatment option for men who have a moderate to severe symptom score on the AUA symptom index (Table 54.1). Although most men who are treated with the drug have symptom improvement, it can take up to 6 months to be effective. It must be taken on a regular basis to have an effect. Because it blocks the enzyme needed for conversion of testosterone to DHT, a common side effect is decreased libido.

Serum PSA levels may appear decreased by almost 50% when taking finasteride. Therefore, to "correct" for the apparent decrease caused by the finasteride, the HCP should double the PSA value for a patient who has been on a 5α-reductase inhibitor for at least 6 months. This allows for an accurate comparison to premedication levels, in order to track trends more accurately in the PSA.

Dutasteride (Avodart) has the same effect on prostatic tissue as finasteride. It is a dual inhibitor of 5α-reductase types 1 and 2 isoenzymes. The combination of a 5α-reductase inhibitor (dutasteride) and an α-adrenergic receptor blocker (tamsulosin) is available in a single oral medication (Jalyn).

These drugs may lower the risk for some prostate cancers.

However, using them to prevent prostate cancer is not been recommended and research is currently ongoing. Patients who develop a high PSA level while taking these drugs should be referred to their HCP. Encourage the patient to discuss the need for prostate cancer screening with the HCP.

Drug Alert

Finasteride (Proscar)

- Women who may be or are pregnant should not handle tablets due to potential risk to male fetus (anomaly).

α-Adrenergic Receptor Blockers

α-Adrenergic receptor blockers are another drug treatment option for BPH. These drugs selectively block α_1-adrenergic receptors, which are abundant in the prostate, and are increased in hyperplastic prostate tissue. They offer symptom relief by relaxing the smooth muscle of the prostate that surrounds the urethra, thus facilitating urinary flow through the urethra. These medications do not decrease the overall size of the prostate.

α-adrenergic blockers used include alfuzosin (Uroxatral), doxazosin (Cardura), prazosin (Minipress), tamsulosin (Flomax), and silodosin (Rapaflo). Symptom improvement can often be seen within days to weeks of starting α-adrenergic blockers. Because they relax the smooth muscle of the prostatic urethra, one of the most common side effects is retrograde ejaculation.

Erectogenic Drugs

Tadalafil (Cialis) can be used in men who have symptoms of BPH alone or in combination with ED. It is effective in reducing symptoms for both conditions.

Herbal Therapy

Some patients take plant extracts, such as saw palmetto *(Serenoa repens).* However, research shows that saw palmetto has no benefit over a placebo.[6] Advise patients to discuss herbal therapies with their HCP.

Minimally Invasive Therapy

Minimally invasive therapies are becoming more common as an alternative to watchful waiting and invasive treatment (Table 54.3). They generally do not involve hospitalization or catheterization. They are associated with few adverse events. Many minimally invasive therapies have outcomes comparable to invasive techniques.

Photoselective Vaporization of the Prostate

Photoselective vaporization of the prostate (PVP) uses a high-power green laser light to vaporize prostate tissue. The use of laser therapy through visual or ultrasound guidance is an effective alternative to transurethral resection of the prostate (TURP) in treating BPH.[7] The laser beam is delivered transurethrally through a fiber instrument inserted into the meatus and through the urethra. It can cut, coagulate, and vaporize prostatic tissue. Improvements in urine flow and symptoms are almost immediate after the procedure. PVP works well for larger prostate glands, but irritative voiding symptoms may persist for several weeks.

Laser Enucleation of the Prostate

Laser enucleation involves delivering a laser beam transurethrally through a fiber instrument. It is used for rapid coagulation and vaporization of prostatic tissue, with better coagulative properties in the tissue compared with TURP. There are 2 types of lasers in this class: holmium laser enucleation of the prostate (HoLEP) and thulium laser enucleation of the prostate (ThuLEP). Neither penetrate deep tissue, which decreases side effects.

TABLE 54.3 Treatment for Benign Prostatic Hyperplasia

Description	Advantages	Disadvantages
Minimally Invasive		
Laser Enucleation of the Prostate		
Laser beams used to rapidly vaporize and coagulate prostate tissue. Laser does not penetrate deep tissue. 2 types of lasers in this class: holmium laser enucleation of the prostate (HoLEP), thulium laser enucleation of the prostate (ThuLEP).	• Outpatient procedure • Better coagulative properties in tissue compared with TURP • Comparable results to TURP and PVP • Minimal bleeding • Fast recovery time	• Catheter needed after for 24–48 hr • Irritative voiding symptoms, urinary incontinence • Hematuria • Retrograde ejaculation • May be more difficult to perform compared with PVP
Photoselective Vaporization of the Prostate (PVP)		
Procedure uses a laser beam to cut or destroy part of the prostate. May be more effective for small to moderate-sized prostates.	• Short procedure • Comparable results to TURP • Minimal bleeding • Fast recovery time • Rapid symptom improvement • Very effective	• Catheter needed up to 7 days after due to edema and urinary retention • Delayed sloughing of tissue • Takes several weeks to reach optimal effect • Retrograde ejaculation
Prostatic Urethral Lift (PUL)		
Permanent transprostatic implants/tension sutures placed transurethrally via cystoscope. Mechanically open the prostatic urethra by compressing the prostate tissue/parenchyma.	• Outpatient procedure • Erectile dysfunction, urinary incontinence, and retrograde ejaculation are minimal • No change in PSA since no prostate tissue ablated	• Lack of long-term durability/results • Treatment response rates slightly lower when compared with TURP • If unsuccessful, may need repeat PUL or TURP in the future
Transurethral Microwave Thermotherapy (TUMT)		
Use of microwave radiating heat to produce coagulative necrosis of the prostate.	• Outpatient procedure • Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare • Mild effects: bladder spasm, hematuria, dysuria	• Potential for damage to surrounding tissue • Urinary catheter needed after for 2–7 days • Not appropriate for men with rectal problems
Transurethral Needle Ablation (TUNA)		
Low-wave radiofrequency used to heat the prostate, causing necrosis.	• Outpatient procedure • Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare • Precise delivery of heat to desired area • Very little pain • Early return to activities	• Urinary retention common • Irritative voiding symptoms • Hematuria for up to a week • May need a catheter for a short time after
Transurethral Vaporization of Prostate (TUVP)		
Electrosurgical modification of the standard TURP., Vaporization and desiccation are used together to destroy prostatic tissue. Can use a variety of energy delivery mediums (e.g., button, rollerball, or vaportrode).	• Minimal risks • Minimal bleeding and sloughing	• Retrograde ejaculation • Intermittent hematuria
Water Vapor Thermal Therapy		
Heated water vapor/steam used to destroy obstructive prostate tissue. Delivered transurethrally via hand-held device with a retractable needle that releases the water vapor in 9-second doses.	• Outpatient procedure • Can be done in an outpatient office setting • Erectile dysfunction, urinary incontinence, and retrograde ejaculation are rare • Precise delivery of steam to desired area • Very little pain	• Relatively new, so lack of long-term durability/results • Irritative voiding symptoms and UTI • Hematuria
Invasive (Surgery)		
Transurethral Incision of Prostate (TUIP)		

Description	Advantages	Disadvantages
Involves transurethral incisions into prostatic tissue to relieve obstruction. Effective for men with small to moderate prostates.	• Outpatient procedure • Minimal complications • Low occurrence of erectile dysfunction or retrograde ejaculation • Outcomes similar to TURP	• Urinary catheter needed after procedure

Table Continued

Description	Advantages	Disadvantages
Transurethral Resection of Prostate (TURP)		
Use of excision and cauterization to remove prostate tissue via cystoscope. Standard for treatment of BPH.	• Erectile dysfunction unlikely	• Bleeding, clot retention • Retrograde ejaculation • Catheter needed after
Simple Prostatectomy (open, laparoscopic, or robotic-assisted)		
Surgery of choice for men with large prostates (often >100 g), bladder damage, or other complicating factors. If open, involves an external incision with 2 possible approaches (either retropubic or perineal; see Fig. 54.6). If laparoscopic and/or robotic-assisted, involves several small abdominal incisions and 1 slightly larger incision near the umbilicus.	• Complete visualization of the prostate and surrounding tissue	• Erectile dysfunction • Bleeding • Pain • Risk for infection

Prostatic Urethral Lift

Prostatic urethral lift (PUL) involves permanent transprostatic implants or tension sutures delivered transurethrally via cystoscope. They mechanically open the prostatic urethra by compressing the prostate tissue. This alters prostate anatomy without ablation of any tissue. This is a relatively new minimally invasive treatment for BPH. So far, it has been studied only in prostates less than 80 g in size and in prostates without an obstructive median lobe. This means there is a current lack of long-term data on the durability of this treatment over time and the rates of needing either repeat treatment or progression to TURP in the future.

Transurethral Microwave Thermotherapy

Transurethral microwave thermotherapy (TUMT) is an outpatient procedure that involves the delivery of microwaves directly to the prostate through a transurethral probe. The microwaves increase the temperature of the prostate tissue to about 113° F (45° C). The heat causes death of tissue, relieving the obstruction. A rectal temperature probe is used during the procedure to ensure that the temperature in

the rectum is kept below 110° F (43.5° C) to prevent rectal tissue damage. The procedure takes about 90 minutes.

Urinary retention is a common complication. Patients who have a TUMT are generally sent home with an indwelling catheter for 2 to 7 days to maintain urinary flow and facilitate the passing of small clots or necrotic tissue. Antibiotics, pain medication, and bladder antispasmodic medications are used to treat and prevent postprocedure problems. Anticoagulant therapy should be stopped 10 days before treatment.

Transurethral Needle Ablation

Transurethral needle ablation (TUNA) is another procedure that increases the temperature of prostate tissue, thus causing localized necrosis. TUNA differs from TUMT in that low-wave radiofrequency is used to heat the prostate. Only prostate tissue in direct contact with the needle is affected, which allows for more precise removal of the target tissue. Most patients undergoing TUNA have an improvement in symptoms. It is done in an outpatient unit or HCP's office using local anesthesia and IV or oral sedation. The TUNA procedure lasts about 30 minutes.

Check Your Practice

You are caring for a patient who is scheduled for a transurethral needle ablation for BPH. He appears anxious. He tells you, "I'm afraid of the pain after the procedure. They told me I might have to have a tube in my bladder. I don't know how I'll manage at home."

- What type of information and teaching would you provide him?

Transurethral Vaporization of the Prostate

Transurethral vaporization of the prostate (TUVP) is an electrosurgical modification of the standard TURP, where vaporization and desiccation are used together to destroy obstructive prostatic tissue.

There are a variety of energy delivery mediums that can be used to deliver the energy (e.g., button, rollerball, vaportrode). This is why it is referred to as a "button TURP." The results, side effects, and long-term outcomes are equivalent to TURP. Because TUVP uses a bipolar energy delivery surface, an energy current is not passed through the patient's body to a grounding pad. This allows for saline to be used during the procedure for irrigation, which dramatically decreases the risk for TUR syndrome (discussed on p. 1260.).

Water Vapor Thermal Therapy

Water vapor thermal therapy is another relatively new minimally invasive treatment for BPH. It uses heated water vapor/steam to destroy obstructive prostate tissue. The steam is delivered transurethrally directly into the prostate by a hand-held device with a retractable needle. It releases the heated water vapor in 9-second doses. It is potentially a good option for a patient who is looking to minimize the risk for postprocedure ED. This treatment has been studied only on prostates less than 80 g in size thus far. It lacks long-term durability data.

Invasive (Surgery) Therapy

Invasive treatment of symptomatic BPH involves surgery. The choice of the treatment approach depends on the size and location of the prostatic enlargement and patient factors, such as age and surgical risk. Invasive treatments are described in Table 54.3.

Invasive therapy is indicated when a decrease in urine flow causes discomfort, persistent residual urine, acute urinary retention because of obstruction with no reversible precipitating cause, or hydronephrosis. Intermittent catheterization or insertion of an indwelling catheter can temporarily reduce symptoms and bypass the obstruction. However, avoid long-term catheter use because of the increased risk for infection.

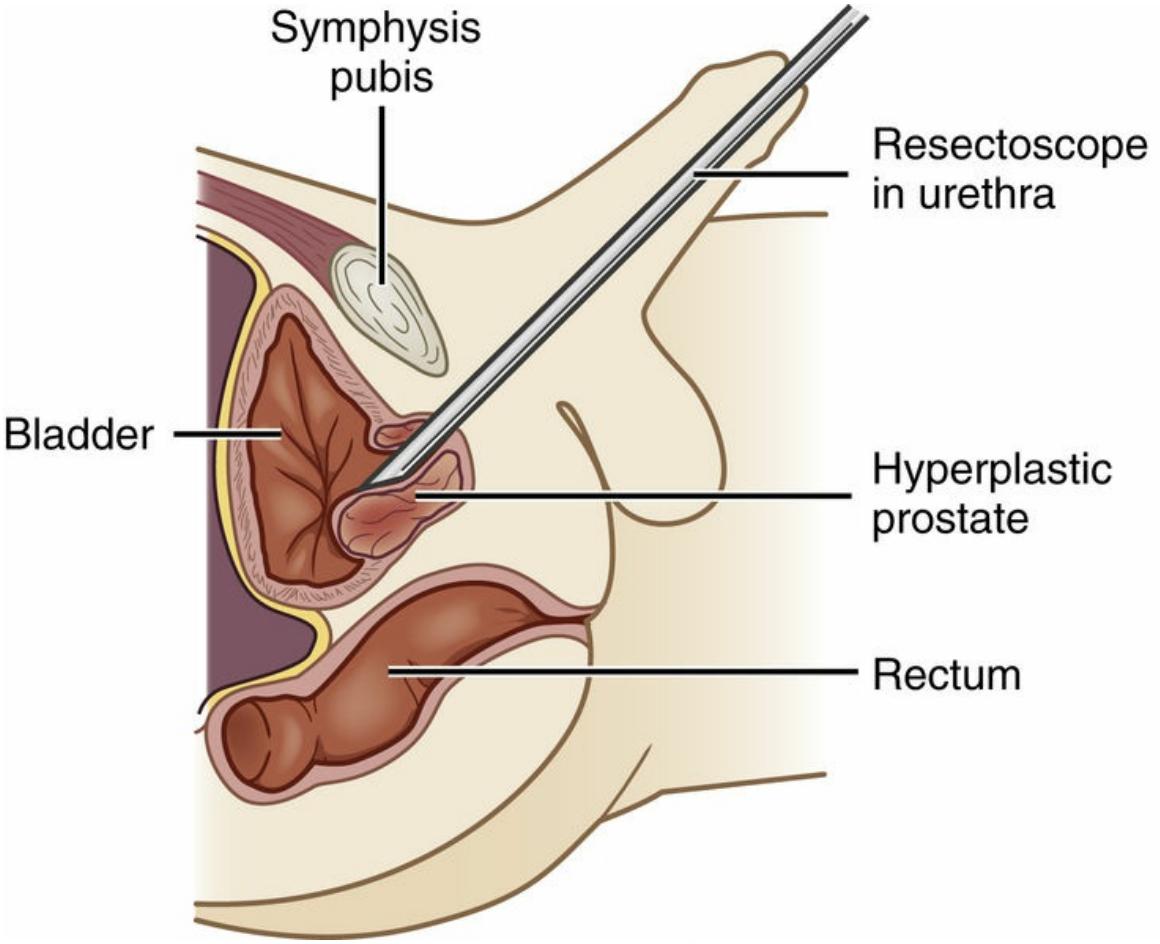

FIG. 54.4 Transurethral resection of the prostate.

Transurethral Incision of the Prostate

Transurethral incision of the prostate (TUIP) is a surgical procedure done under local anesthesia for men with moderate to severe symptoms. Several small incisions are made into the prostate gland to expand the urethra, which relieves pressure on the urethra and improves urine flow. TUIP is an option for patients with a small or moderately enlarged prostate gland.

Transurethral Resection of the Prostate

Transurethral resection of the prostate (TURP) is a surgical procedure involving the removal of prostate tissue using a resectoscope inserted through the urethra. TURP has long been considered the gold standard for surgical treatment of obstructing

BPH. Most patients have marked improvements in symptoms and urinary flow rates. While in the past many TURP procedures required a longer hospital stay, many TURP procedures now are done on an outpatient basis.

In TURP no external surgical incision is made. A resectoscope is inserted through the urethra to excise and cauterize obstructing prostatic tissue (Fig. 54.4). A large 3-way indwelling catheter with a 30-mL balloon is inserted into the bladder after the procedure to provide hemostasis and to facilitate urinary drainage. If there is a large amount of hematuria with clots after surgery, then the bladder can be irrigated, either continuously or intermittently, for the first 24 hours to prevent obstruction from blood clots.

TURP was classically done with a monopolar resectoscope/loop. It sends a current through the patient during the resection to a grounding pad, so iso-osmolar fluid is used for irrigation. TURP has a relatively low risk, but caregivers must be vigilant for signs or symptoms of transurethral resection syndrome (TUR or TURP syndrome). This condition is manifested by nausea, vomiting, confusion, bradycardia, and hypertension. TUR syndrome is the result of hyponatremia due to longer operative times and prolonged intraoperative bladder irrigation with the iso-osmolar fluid. However, it is now common practice for a TURP to be done with a bipolar resectoscope/loop. This allows for saline to be used for irrigation and dramatically decreases the risk for TUR syndrome.

Other complications include bleeding and clot retention. Because bleeding is a common complication, patients taking aspirin, warfarin (Coumadin), or other anticoagulants must stop taking medications several days before surgery. BPH medications are stopped after the procedure.

TABLE 54.4 Nursing AssessmentBenign Prostatic Hyperplasia

Subjective Data

Important Health Information

Medications: Testosterone supplementation
Surgery or other treatments: Previous treatment for BPH

Functional Health Patterns

Health perception–health management: Knowledge of the condition
Nutritional-metabolic: Voluntary fluid restriction
Elimination: Urinary urgency, diminution in caliber and force of urinary stream. Hesitancy in starting voiding. Postvoid dribbling, urinary retention, urinary incontinence
Sleep-rest: Nocturia
Cognitive-perceptual: Dysuria, sensation of incomplete voiding, bladder discomfort
Sexuality-reproductive: Anxiety about sexual dysfunction

Objective Data
General

Older adult male

Urinary

Distended bladder on palpation. Smooth, firm, elastic enlargement of prostate on rectal examination

Possible Diagnostic Findings

Enlarged prostate on ultrasonography, bladder neck obstruction on cystoscopy, residual urine with postvoiding ultrasound or catheterization. WBCs, bacteria, or microscopic hematuria with

bladder infection. ↑ Serum creatinine levels with renal involvement

Nursing Management: Benign Prostatic Hyperplasia

Because you will be most directly involved in care of patients with BPH having invasive therapies, the focus of nursing management in this section is on preoperative and postoperative care.

Nursing Assessment

Subjective and objective data that should be obtained from a patient with BPH are outlined in Table 54.4.

Nursing Diagnoses

Nursing diagnoses for the patient with BPH before surgery may include:

- Acute pain
- Risk for infection
- Impaired urinary system function

Nursing diagnoses and interventions for the patient with BPH who has invasive therapy (surgery) are presented in eNursing Care Plan 54.1 (available on the website for this chapter).

Planning

The overall preoperative goals for the patient having invasive procedures are to have (1) restoration of urinary drainage; (2) resolution of any UTI; and (3) understanding of the upcoming procedure, implications for sexual function, and urinary control. The

overall postoperative goals are to have (1) no complications, (2) restoration of urinary control, (3) complete bladder emptying, and (4) satisfying sexual expression.

Nursing Implementation

Health Promotion

The cause of BPH is largely attributed to the aging process. Health promotion focuses on early detection and treatment. The AUA currently recommends that men age 55 to 69 have the greatest potential benefit from PSA screening. The recommended screening interval is every 2 years.[8] When symptoms of BPH are present, further diagnostic screening may be needed (Table 54.2).

Some men find that consuming alcohol, caffeine, or other bladder irritants tends to increase prostatic voiding symptoms because the diuretic effect increases bladder distention and overactivity. Compounds found in common cough and cold remedies, such as pseudoephedrine (e.g., Sudafed) and phenylephrine (e.g., Allerest PE, Coricidin D), often worsen the symptoms of BPH. These drugs are α-adrenergic agonists that cause smooth muscle contraction. If this occurs, the patient should avoid these drugs.

Teach patients with obstructive symptoms to urinate every 2 to 3 hours and when they first feel the urge. This will minimize urinary stasis and acute urinary retention. Teach patients to maintain a normal level of fluid so that they do not become dehydrated. The patient may think that if he restricts his fluid intake, symptoms will be less severe, but this only increases the chances of an infection while concentrating his urine.

Acute Care

The following discussion focuses on preoperative and postoperative care for the patient undergoing a TURP.

Preoperative Care

Antibiotics are usually given before any invasive genitourinary (GU) procedure. Any infection of the urinary tract must be treated before surgery. Restoring urinary drainage and encouraging a high fluid intake (2 to 3 L/day unless contraindicated) are helpful in managing the infection. Prostatic obstruction may result in acute retention or inability to void. Urinary drainage must be restored before surgery.

A urethral catheter, such as a coudé (curved-tip) catheter, may be needed to restore bladder drainage. In many health care settings, 2% lidocaine gel is inserted into the urethra before catheter placement. The lidocaine gel acts as a lubricant, provides local anesthesia, and helps open the urethral lumen. If a sizable obstruction of the urethra exists, the HCP may insert a filiform catheter with enough rigidity to pass the obstruction. Aseptic technique is important to avoid introducing bacteria into the bladder. (Urinary catheters are discussed in Chapter 45.)

Patients may be concerned about the impact of the impending surgery on sexual function. Provide an opportunity for the patient and his partner to express their concerns. Tell the patient that his ejaculate volume may be decreased or absent after the procedure. Most types of prostatic surgery result in some degree of *retrograde ejaculation*. This is a condition in which some semen travels back into the bladder during orgasm instead of traveling out of the penis. This may decrease orgasmic sensations felt during ejaculation. Retrograde ejaculation is not harmful. The semen is voided during the next urination.

Postoperative Care

The main complications after surgery are hemorrhage, bladder spasms, urinary incontinence, and infection. Adjust the plan of care to the type of surgery, reasons for surgery, and patient's response to surgery.

After surgery, the patient will have a standard catheter or a triple-lumen catheter. Bladder irrigation is typically done to remove clotted blood from the bladder and ensure drainage of urine. The bladder is irrigated either manually on an intermittent basis or more often, as continuous bladder irrigation (CBI) with sterile normal saline solution

or another prescribed solution. If the bladder is manually irrigated, instill 50 mL of irrigating solution and then withdraw with a syringe to remove clots that may be in the bladder and catheter. Painful bladder spasms often occur with manual irrigation.

With CBI, irrigating solution is continuously infused and drained from the bladder. The rate of infusion is based on the color of drainage. Ideally the urine drainage should be light pink without clots. Continuously monitor the inflow and outflow of the irrigant. If outflow is less than inflow, assess the catheter patency for kinks or clots. If the outflow is blocked and patency cannot be reestablished by manual irrigation, stop the CBI, and notify the HCP.

Nursing Management

Patient Receiving Bladder Irrigation

- Assess for bleeding and clots.
- Assess catheter patency by measuring intake and output and presence of bladder spasms.
- Manually irrigate catheter if bladder spasms or decreased outflow occurs.
- Give antispasmodics and analgesics as needed.
- Monitor catheter drainage for increased blood or clots.
- Discontinue CBI and notify HCP if obstruction occurs.
- Teach patient Kegel exercises after catheter removal.
- Provide care instructions for patient discharged with indwelling catheter.

Use careful aseptic technique when irrigating the bladder because bacteria can be easily introduced into the urinary tract. Secure the catheter to the leg with tape or a catheter strap to prevent urethral irritation and minimize the risk for bladder infection. The catheter

should be connected to a closed-drainage system. Do not disconnect unless it is being removed, changed, or irrigated.

Blood clots are expected after prostate surgery for the first 24 to 36 hours. However, large amounts of bright red blood in the urine can indicate hemorrhage. Hemorrhage may occur from displacement of the catheter, dislodgment of a large clot, or increases in abdominal pressure.

Release or displacement of the catheter dislodges the balloon that provides counterpressure on the operative site. Traction on the catheter may be applied to provide counterpressure (tamponade) on the bleeding site in the prostate, thereby decreasing bleeding. Such traction can result in local necrosis if pressure is applied for too long. Pressure should be relieved on a scheduled basis by qualified personnel.

Activities that increase abdominal pressure should be avoided in the recovery period. These include sitting or walking for prolonged periods and straining to have a bowel movement (Valsalva maneuver).

Bladder spasms are a distressing complication for the patient after transurethral procedures. They occur because of irritation of the bladder mucosa from the insertion of the resectoscope, presence of a catheter, or clots leading to obstruction of the catheter. If bladder spasms develop, check the catheter for clots. If present, remove the clots by irrigation so that urine can flow freely. Tell the patient not to urinate around the catheter because this increases the chance of spasm. Belladonna and opium suppositories or other antispasmodics (e.g., oxybutynin [Ditropan XL]), along with relaxation techniques, are used to relieve the pain and decrease spasm.

The catheter is often removed 2 to 4 days after surgery. The patient should have a voiding trial after catheter removal. If he cannot urinate, he will have a catheter reinserted for a day or so or be taught to perform clean intermittent self-catheterization (see Chapter 45).

Sphincter tone may be poor right after catheter removal, resulting in urinary incontinence or dribbling. This is a common but distressing situation for the patient. Sphincter tone can be strengthened by having

the patient practice Kegel exercises (pelvic floor muscle technique) 10 to 20 times per hour while awake. (Kegel exercises are discussed in Table 45.18.) Encourage the patient to practice starting and stopping the stream several times during urination. This helps the patient to target the correct pelvic floor muscles when doing Kegel exercises.

It can take several weeks to achieve urinary continence. In some instances, control of urine may never be fully regained. Continence can improve for up to 12 months. If continence has not been achieved by that time, the patient may be referred to a continence clinic. A variety of methods, including biofeedback, have been used to achieve positive results.

Teach the patient how to use a penile clamp, a condom catheter, or incontinence pads or briefs to avoid embarrassment from dribbling. In severe cases, an occlusive cuff that serves as an artificial sphincter can be surgically implanted to restore continence. Help the patient find ways to manage the problem that allow him to continue socializing and interacting with others. (Urinary incontinence is discussed in Chapter 45.)

Observe the patient for signs of infection. If an external wound is present (e.g., from an open, laparoscopic, or robotic-assisted prostatectomy), assess the area for redness, heat, swelling, and purulent drainage. Special care must be taken if a perineal incision is present because of the proximity of the anus. Avoid rectal procedures, such as rectal temperatures and enemas. The insertion of well-lubricated belladonna and opium suppositories is acceptable.

Dietary intervention and stool softeners are important to prevent the patient from straining while having bowel movements. Straining increases the intraabdominal pressure, which can lead to bleeding at the operative site. A diet high in fiber promotes the passage of stool.

Ambulatory Care

Discharge planning and home care issues are important aspects of care after prostate surgery. Patient teaching includes (1) caring for an indwelling catheter (if one is in place), (2) managing urinary incontinence, (3) maintaining adequate oral fluid intake, (4) observing

for signs and symptoms of urinary tract and wound infection, (5) preventing constipation, (6) avoiding heavy lifting (more than 10 lb [4.5 kg]), and (7) refraining from driving or intercourse after surgery as directed by the HCP.

The patient may have a change in sexual function after surgery. Recovery depends on the type of surgery done and the interval of time between when symptoms first appeared and the date of surgery. For example, it may take up to 1 to 2 years for complete sexual function to return after nerve-sparing prostatectomy. Many men have retrograde ejaculation because of trauma to the internal urethral sphincter. ED may occur if the nerves are cut or damaged during surgery. The patient may have anxiety over the change because of a perceived loss of his sex role, self-esteem, or quality of sexual interaction with his partner. Discuss these changes with the patient and his partner and allow them to ask questions and express their concerns. Sexual counseling and treatment options may be needed if ED becomes a chronic issue. (ED is discussed later in this chapter).

The bladder may take up to 2 months to return to its normal capacity. Teach the patient to drink at least 2 to 3 L of fluid per day and urinate every 2 to 3 hours to flush the urinary tract. Teach the patient to avoid or limit the amounts of bladder irritants, such as caffeine products, citrus juices, and alcohol. Because the patient may have incontinence or dribbling, he may incorrectly believe that decreasing fluid intake will relieve this problem.

Urethral strictures may result from instrumentation or catheterization. Treatment may include teaching the patient intermittent clean self-catheterization or having a urethral dilation.

Tell the patient to discuss the need for a yearly DRE with his HCP if he has had any procedure other than complete removal of the prostate. Hyperplasia or cancer can occur in the remaining prostatic tissue.

Evaluation

The expected outcomes are that the patient with BPH who has surgery will

- Report acceptable pain control
- Report improved urinary function with no pain or incontinence

Prostate Cancer

Prostate cancer is a tumor of the prostate gland. Prostate cancer is the most common cancer among men, excluding skin cancer. It is the second leading cause of cancer death in men, exceeded only by lung cancer. The American Cancer Society estimates that in 2018 there will be 164,690 men diagnosed with prostate cancer, and 29,430 men will die from prostate cancer. A man has a 1 in 9 risk for developing prostate cancer in his lifetime. More than 2.9 million men in the United States are survivors of prostate cancer.[9]

Etiology and Pathophysiology

Prostate cancer is a slow-growing, androgen-dependent cancer. It can spread by 3 routes: by direct extension, through the lymph system, or through the bloodstream. Spread by direct extension involves the seminal vesicles, urethral mucosa, bladder wall, and external sphincter. The cancer later spreads through the lymphatic system to the regional lymph nodes. The bloodstream is the mode of spread to the axial skeleton (e.g., pelvic bones, head of the femur, lower lumbar spine), liver, and lungs.

Age, ethnicity, and family history are known risk factors for prostate cancer. The incidence of prostate cancer rises markedly after age 50. The median age at diagnosis is 66 years old. However, many cases occur in younger men, who sometimes have a more aggressive type of cancer.

Dietary factors and obesity may be related to prostate cancer. A diet high in red and processed meat and high-fat dairy products along with a low intake of vegetables and fruits may increase the risk for prostate cancer. Environment may play a role. There is an increased prevalence of prostate cancer in farmers and commercial pesticide

applicators, possibly due to chemicals found in pesticides. It is not clear if smoking is a risk factor for prostate cancer.

Promoting Health Equity

Cancers of the Male Reproductive System

Prostate Cancer

- Black men have the highest rate of prostate cancer.
- Black men are diagnosed with prostate cancer at an earlier age, have more advanced disease at the time of diagnosis, and have a higher mortality rate than do white men.
- Although the mortality rate for prostate cancer among black men is high, the mortality rate is declining.
- Asian American men have a lower incidence and lower mortality rates from prostate cancer than white men.

Testicular Cancer

- Testicular cancer occurs most often among whites than in other ethnic groups.

Genetic Link

Currently no known single gene causes prostate cancer. Some genes or gene mutations are more common in men with prostate cancer. From a genetics viewpoint, prostate cancer can be classified into 3 categories.

Most prostate cancers (about 75%) are considered *sporadic,* which means that damage to the genes occurs by chance after a person is born. Prostate cancer that runs in a family, called *familial prostate cancer,* is less common (about 20%). It occurs because of a combination

of genes and environment or lifestyle factors. Familial prostate cancer is when 2 or more first-degree relatives (father, brother, son) are diagnosed with prostate cancer.

Hereditary (inherited) prostate cancer is rare (5% to 10%) and occurs when gene mutations are passed down in a family from 1 generation to the next. In hereditary prostate cancer, a family has any of the following characteristics: (1) 3 or more first-degree relatives with prostate cancer, (2) prostate cancer in 3 generations on the same side of the family, and (3) 2 or more close relatives (father, brother, son, grandfather, uncle, nephew) on the same side of the family diagnosed with prostate cancer before age 55.

Having a family history does not mean that a man will develop prostate cancer. It means that he has an increased risk. Men with a family history of prostate cancer should talk with their HCP about their concerns. It is important for the HCP to obtain a detailed family history. Depending on the findings, a referral to a genetic counselor may be appropriate.

Hereditary breast and ovarian cancer (HBOC) syndrome is associated with mutations in the *BRCA1* and/or *BRCA2* genes (BRCA stands for *BR*east *CA*ncer). Women with HBOC have an increased risk for breast and ovarian cancer. Men with HBOC have an increased risk for breast cancer and prostate cancer. Mutations in *BRCA1* and *BRCA2* cause only a small number of familial prostate cancers. Genetic testing may be appropriate for families with prostate cancer that have HBOC.

Clinical Manifestations and Complications

Prostate cancer typically has no symptoms in the early stages. Eventually, the patient may have LUTS similar to those of BPH. Pain in the lumbosacral area that radiates down to the hips or the legs, when combined with urinary symptoms, may indicate metastasis.

The tumor can spread to pelvic lymph nodes, bones, bladder, lungs, and liver. Once the tumor has spread to distant sites, the major problem becomes pain management. As the cancer spreads to the bones (common site of metastasis), pain can become severe, especially in the back and legs because of spinal cord compression and bone

destruction (Fig. 54.5).

Diagnostic Studies

Most men in the United States with prostate cancer are diagnosed by PSA screening. As prostate cancer screening has become more widespread, smaller cancers are being found in older men. In most cases, slow-growing cancers probably do not need to be treated. Many men live and die *with* prostate cancer, but most will not die *from* it.

Men have a chance to make an informed decision with their HCP about whether to be screened for prostate cancer. Men should be told about the potential risks (e.g., subsequent evaluation and treatment that may not be needed) and benefits (early detection of prostate cancer) of PSA screening before being tested. After this discussion, men who want to be screened may have an annual PSA test and DRE. On DRE, an abnormal prostate may feel hard, nodular, and asymmetric.

The AUA thinks that men age 55 to 69 have the greatest potential benefit from PSA screening and recommend screening every 2 years.[8] Men at higher risk (black men, men with a first-degree relative with prostate cancer) will have an individualized screening schedule.

The American Cancer Society recommends that men should have a discussion with their HCP about screening for prostate cancer. Men should not be screened unless they have received this information. The discussion about screening should take place at:

- Age 50 for men who are at average risk for prostate cancer and are expected to live at least 10 more years.
- Age 45 for men at high risk for developing prostate cancer. This includes blacks and men who have a first-degree relative (father, brother, or son) diagnosed with prostate cancer at an early age (younger than age 65).

- Age 40 for men at even higher risk (those with more than 1 first-degree relative who had prostate cancer at an early age).

Table 54.5 Staging of Prostate Cancer

Stage	Tumor Size	Lymph Node Involvement	Metastasis	PSA Level	Gleason Score
I	Not felt on DRE. Not seen by visual imaging.	No	No	<10	≤6
II	Felt on DRE. Seen by imaging. Tumor confined to prostate.	No	No	10–20	6–7
III	Cancer outside prostate. Possible spread to seminal vesicles.	No	No	Any level	Any score
IV	Any size.	Any nodal involvement.	Yes	Any level	Any score

Adapted from American Cancer Society: How is prostate cancer staged? Retrieved from *www.cancer.org/Cancer/ProstateCancer/DetailedGuide/prostate-cancer-staging*.

High PSA levels do not always indicate prostate cancer. Mild elevations in PSA may occur with aging, BPH, recent ejaculation, constipation, acute or chronic prostatitis, or after long bike rides. Cystoscopy, indwelling urethral catheters, and prostate biopsies may cause transient increases in PSA levels.

Neither PSA nor DRE is a definitive diagnostic test for prostate cancer. If PSA levels are continually high or if the DRE is abnormal, a biopsy of the prostate tissue is usually done. Biopsy of prostate tissue is necessary to confirm the diagnosis of prostate cancer. The biopsy is typically done using a transrectal approach. In a transrectal ultrasound (TRUS) procedure, an ultrasound probe allows the HCP to see abnormalities in the prostate. When a suspicious area is found, biopsy needles are inserted through the wall of the rectum into the prostate to obtain tissue samples. A pathologic examination of the specimen is done to assess for malignant changes. For patients at a high risk for infection with a transrectal biopsy, or with a history of prior postbiopsy sepsis, a transperineal approach is another option if it is available at the agency. There can be a lower risk for infection

with the transperineal approach as the biopsy needles do not pierce the rectal wall. It is typically done in the operating room.

Another approach for biopsies is to use an MRI/ultrasound fusion biopsy. In this approach, pelvic MRI 3-dimensional images are fused with real-time, transrectal ultrasound images. This new technique is more accurate than the traditional approach. Typically, men who are candidates for this procedure have a history of a previous negative ultrasound-guided biopsy and increasing PSA. This approach may also be used for men who are on active surveillance. However, as discussed earlier in this chapter, recent studies show risk assessment with MRI prior to biopsy and MRI-targeted biopsy to be superior to standard TRUS biopsy in men at risk for prostate cancer who have never had a prostate biopsy before.[5]

PSA is used to monitor the success of treatment. When treatment has been successful, with either prostatectomy or hormone therapy, PSA levels should fall to undetectable levels. With successful radiation therapy, the PSA level should decrease to a very low number (the nadir) and remain stable near that number. The regular measurement of PSA levels after treatment is important to evaluate the effectiveness of treatment and possible recurrence of prostate cancer.[10]

With advanced prostate cancer, serum alkaline phosphatase can be increased because of bone metastases. Other tests used to determine the location and extent of the spread of the cancer may include a nuclear medicine whole body bone scan, a CT scan of the abdomen and pelvis, and an MRI of the pelvis with special attention to the prostate.

Interprofessional Care

Chemoprevention of prostate cancer is an active area of research. As discussed earlier in this chapter, finasteride and dutasteride, used to treat BPH, may reduce the chance for getting prostate cancer. Men who are concerned about prostate cancer should discuss with their HCP the potential risks and benefits of taking finasteride or dutasteride.

Early recognition and treatment are important to control tumor growth, prevent metastasis, and preserve quality of life. Most patients (93%) with prostate cancer are diagnosed when the cancer is at a local or regional stage.[9,11] The 5-year survival rate with a diagnosis at this stage is almost 100%.

The most common classification system for determining the extent of prostate cancer is the tumor, node, and metastasis (TNM) system (Table 54.5). The tumor is graded based on tumor histology using 2 different grading systems: the Gleason scale and the Grade Group.[12] The Gleason scale grades the tumor from 1 to 5 based on the degree of glandular differentiation. Grade 1 represents the most well-differentiated or lowest grade (most like the original cells), and grade 5 represents the most poorly differentiated (unlike the original cells) or highest grade. The 2 most commonly occurring patterns of cells are graded, and the 2 scores are added together to create a Gleason score. Gleason score ranges from 6 to 10. Currently the lowest risk Gleason score is Gleason 6 (3+3).

The Grade Group system grades the cells based on their differentiation. The Grade Group assigns the tumor a number on a scale from 1 to 5. Grade Group 1 is the lowest risk and Grade Group 5 the highest risk. Currently, the Gleason score and the Grade Group system are used together. A low-risk, well-differentiated prostate cancer specimen may be graded a Grade Group 1, Gleason 6 (3+3) prostate cancer. The trend is moving toward Grade Group scoring only.

The PSA level at diagnosis and the patient's Gleason score and Grade Group are used with the TNM system to determine the stage of the tumor, which is vital to determine treatment options.

The interprofessional care of the patient with prostate cancer depends on the stage of the cancer and the patient's overall health (Table 54.6). None of these diagnostic options can predict the progression of prostate cancer. At all stages, there is more than one treatment option depending on the stage, Gleason score, and PSA. The decision of which treatment course to pursue should be made jointly by patients, their partners, and the interprofessional care team.[10,11]

Active Surveillance

Low-grade prostate cancer is relatively slow growing. Therefore a conservative approach to management of prostate cancer is active surveillance, or "watchful waiting." This strategy is appropriate when the patient has (1) a life expectancy of less than 10 years (low risk for dying of the disease); (2) a low-grade, low-stage tumor; and (3) serious coexisting medical conditions. With active surveillance, patients are typically followed with frequent PSA measurements and DRE to monitor the progress of the disease. Significant changes in the PSA level, the DRE, or the development of symptoms, warrant a reevaluation of treatment options.

TABLE 54.6 Interprofessional CareProstate Cancer

Diagnostic Assessment

- History and physical examination
- Digital rectal examination (DRE)
- Prostate-specific antigen (PSA)
- Transrectal ultrasound (TRUS) or pelvic MRI
- Prostate biopsy
- CT abdomen and pelvis with contrast (to assess for metastatic disease)

Management

Active Surveillance

- Closely monitor PSA and DRE (annually, at minimum)
- Repeat/surveillance prostate biopsies
- Repeat imaging

- Consider genomic testing on biopsy tissue, if appropriate

Surgery

- Radical prostatectomy
- Cryotherapy
- Orchiectomy (for metastatic disease)

Radiation Therapy

- External beam for primary, adjuvant, and recurrent disease
- Brachytherapy

Drug Therapy

- Androgen deprivation therapy (Table 54.7)
- Chemotherapy for metastatic disease

Surgical Therapy

Radical Prostatectomy

With **radical prostatectomy**, the entire prostate gland, seminal vesicles, and part of the bladder neck (ampulla) are removed. The entire prostate is removed because the cancer tends to be in many different places within the gland. A pelvic lymph node dissection is typically done at the same time as prostatectomy to pathologically assess for nodal metastases in the local pelvic area. Typically, a higher number of lymph nodes are removed and dissected if the prostate cancer is higher grade/higher risk on biopsy. Surgery is usually not an option for advanced-stage disease except to relieve symptoms associated with obstruction.

Traditional surgical approaches for an open radical prostatectomy

include retropubic and perineal approaches (Fig. 54.6). With the *retropubic* approach, a low midline abdominal incision is made to access the prostate gland and the pelvic lymph nodes can be dissected. With the *perineal* resection, an incision is made between the scrotum and anus.

A *robotic-assisted* (e.g., da Vinci system) prostatectomy is a type of surgery in which the HCP sits at a computer console while controlling high-resolution cameras and microsurgical instruments. Robotics is being used more often since it allows for increased precision, visualization, and dexterity by the HCP when removing the prostate gland. It results in less bleeding, less pain, and a faster recovery compared with other approaches.[13]

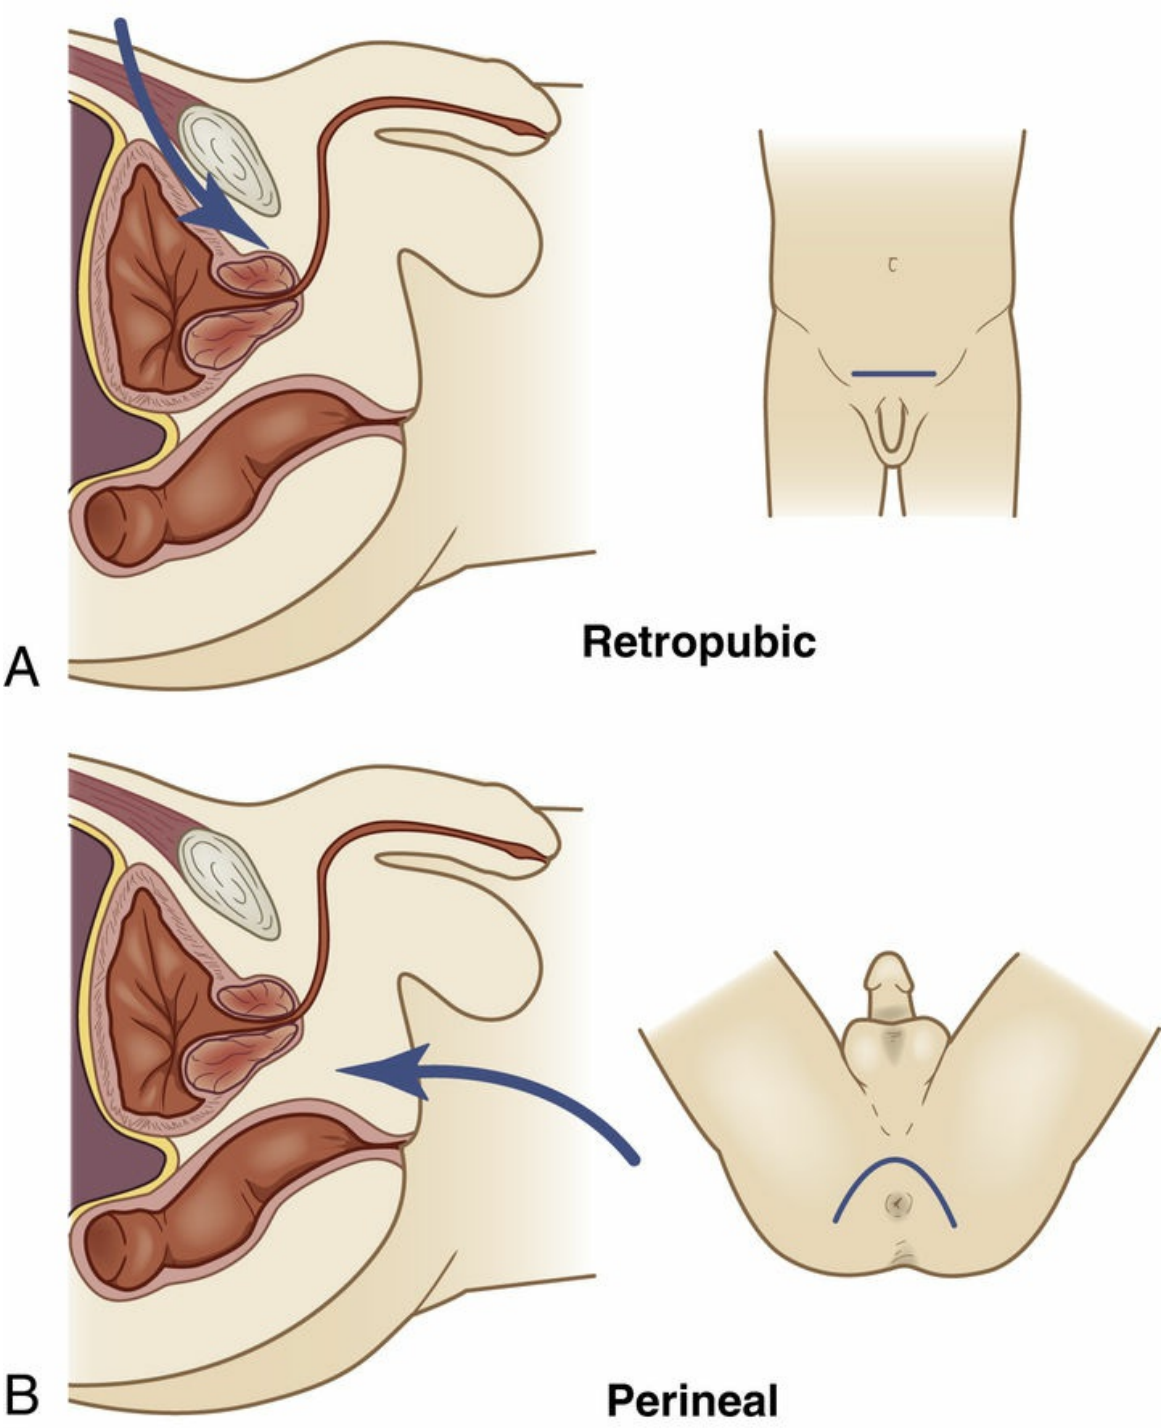

FIG. 54.6 Common approaches used to perform a prostatectomy. **A,** Retropubic approach involves a midline abdominal incision. **B,** Perineal approach involves an incision between the scrotum and the anus.

After surgery, the patient has a large indwelling catheter with a 20-mL or 30-mL balloon placed in the bladder via the urethra. A drain is

left in the surgical site to aid in removing drainage from the area. This drain is typically removed after a few days. Because the perineal approach has a higher risk for infection (because of the location of the incision related to the anus), careful dressing changes and perineal care after each bowel movement are important for comfort and to prevent infection. Depending on the type of surgery, the length of hospital stay ranges from 1 to 3 days.

Two major adverse outcomes after a radical prostatectomy are ED and urinary incontinence. The incidence of ED depends on the patient's age, preoperative sexual function, whether nerve-sparing surgery was done, and the HCP's expertise. Sexual function after surgery tends to return gradually over at least 24 months or more. Phosphodiesterase type 5 (PDE5) inhibitor medications may help improve sexual function.

Problems with urinary control may occur for the first few months after surgery because the bladder must be reattached to the urethra after the prostate is removed. Over time, the bladder adjusts, and most men regain urinary continence. Kegel exercises strengthen the pelvic floor muscles and the urinary sphincter and may help improve continence. (Kegel exercises are discussed in Table 45.18.) Other complications associated with surgery include hemorrhage, seroma, lymphocele, urinary retention, infection, wound dehiscence, and VTE.[14]

Nerve-Sparing Procedure

Near the prostate gland are neurovascular bundles that maintain erectile functioning. The preservation of these bundles during a prostatectomy is possible while still removing all the cancer. Nerve-sparing prostatectomy is not indicated for patients with cancer outside of the prostate gland. Although the risk for ED is reduced with this procedure, there is no guarantee that potency will be maintained.

Cryotherapy

Cryotherapy (cryoablation) is a surgical technique for prostate cancer that destroys cancer cells by freezing the tissue. It has been used both

as an initial treatment and as a second-line treatment after radiation therapy has failed. A TRUS probe is inserted to see the prostate gland. Probes containing liquid nitrogen are then inserted into the prostate. Liquid nitrogen delivers freezing temperatures, thus destroying the tissue. The treatment takes about 2 hours under general or spinal anesthesia and does not involve an abdominal incision.

Complications include damage to the urethra and, in rare cases, an urethrorectal fistula (an opening between the urethra and rectum) or a urethrocutaneous fistula (an opening between the urethra and skin). Tissue sloughing, ED, urinary incontinence, prostatitis, and hemorrhage can occur.

Radiation Therapy

Radiation therapy is another common treatment option for prostate cancer. Radiation therapy may be the only treatment, or it may be used in combination with surgery or with hormone therapy. Salvage radiation therapy given for prostate cancer recurrence after a radical prostatectomy may improve survival in some men.

External Beam Radiation

External beam radiation is the most widely used method of delivering radiation treatments for men with prostate cancer. This therapy can be used to treat cancer confined to the prostate and/or surrounding tissue. Patients are usually treated on an outpatient basis 5 days a week for 4 to 8 weeks. Each treatment lasts less than 1 hour.

Side effects from radiation can be acute (occurring during treatment or within 90 days that follow) or delayed (occurring months or years after treatment). The most common side effects involve changes to the skin (dryness, redness, irritation, pain), gastrointestinal tract (diarrhea, abdominal cramping, bleeding, radiation proctitis), urinary tract (dysuria, hematuria, frequency, hesitancy, urgency, nocturia, radiation cystitis), and sexual function.[15] Fatigue may occur. There is a rare risk for secondary cancers after radiation to the pelvic area (e.g., bladder cancer, rectal cancer). In patients with localized prostate cancer, cure rates with external beam radiation are comparable to

those with radical prostatectomy.

Brachytherapy

Brachytherapy involves placing radioactive seed implants into the prostate gland. This delivers high doses of radiation directly to the tissue while sparing the surrounding tissue (rectum and bladder). The radioactive seeds are placed in the prostate gland with a needle through a grid template guided by TRUS (Fig. 54.7) to ensure accurate placement of the seeds.

Because brachytherapy is a one-time outpatient procedure, many patients find this more convenient than external beam radiation treatment. Brachytherapy is best suited for patients with early-stage disease. The most common side effect is the development of urinary irritative or obstructive problems. Some men may have ED. The AUA Symptom Index (Table 54.1) can be used to measure urinary function for patients undergoing brachytherapy and can be incorporated into nursing management. For those with more advanced tumors, brachytherapy may be offered in combination with external beam radiation treatment.[16] (Brachytherapy is discussed in Chapter 15.)

Drug Therapy

The forms of drug therapy available for the treatment of advanced or metastatic prostate cancer are androgen deprivation (hormone) therapy, chemotherapy, or a combination of both.

Androgen Deprivation Therapy

Prostate cancer growth is largely dependent on the presence of androgens. *Androgen deprivation therapy* (ADT) reduces the levels of circulating androgens to reduce the tumor growth.[17] Androgen deprivation can be produced by inhibiting androgen production or blocking androgen receptors (Table 54.7).

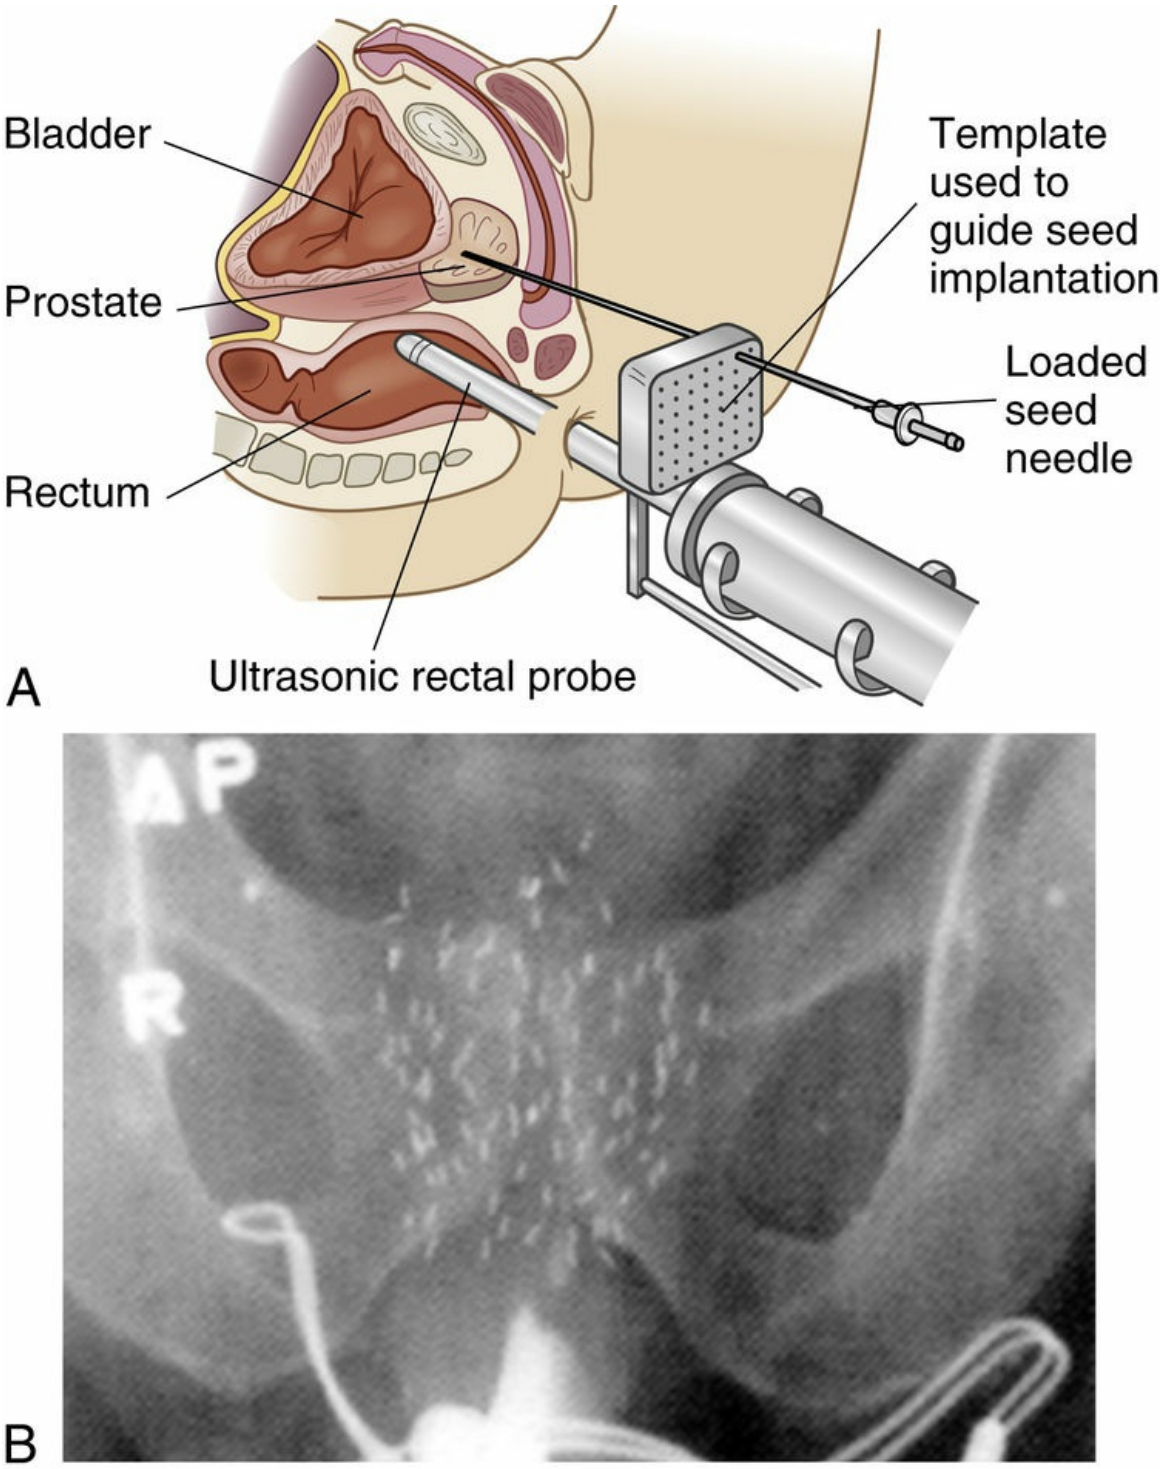

FIG. 54.7 **A,** Prostate brachytherapy. Implantation of radioactive seeds with a needle guided by ultrasound and a template grid. **B,** Radioactive seeds.
B, From Abeloff MD, Armitage JO, Niederhuber JE, et al, eds: *Abeloff's clinical oncology,* ed 4, 2008, Churchill Livingstone.

One of the biggest challenges with ADT is that almost all tumors treated become resistant to this therapy *(hormone refractory)* within a few years. A high PSA level is often the first sign that this therapy is no longer effective. Patients taking ADT have an increased risk for cardiovascular side effects, including high serum cholesterol and triglyceride levels and coronary artery disease.

Osteoporosis and fractures may occur in those receiving ADT. Drugs recommended to reduce bone mineral loss include zoledronic acid (Reclast) and raloxifene (Evista). Zoledronic acid is a bisphosphonate therapy given IV. A rare complication of therapy is osteonecrosis of the jaw. Denosumab (Prolia, Xgeva), a drug that slows the breakdown of bone, may be used to increase bone mass in men with nonmetastatic prostate cancer.

Androgen synthesis inhibitors

The hypothalamus produces luteinizing hormone–releasing hormone (LHRH), which stimulates the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the testicular Leydig cells to make testosterone. *LHRH agonists* super stimulate the pituitary, downregulating the LHRH receptors and leading to a refractory condition in which the anterior pituitary is unresponsive to LHRH. These drugs cause an initial, transient increase in LH and FSH; testosterone abruptly rises resulting in a *flare.* Symptoms may worsen during this time. However, with continued administration, LH and testosterone levels decrease.

LHRH agonists include goserelin (Zoladex), leuprolide (Lupron Depot, Eligard), and triptorelin (Trelstar) (Table 54.7). These drugs essentially produce a chemical castration similar to the effects of an orchiectomy. They are given by subcutaneous or IM injections on a regular basis. Viadur is an implant that is placed subcutaneously and delivers leuprolide continuously for 1 year.

TABLE 54.7 Drug TherapyAndrogen Deprivation

Therapy for Prostate Cancer

Therapy	Mechanism of Action	Side Effects
Androgen Receptor Blockers		
bicalutamide (Casodex) **enzalutamide (Xtandi)** **flutamide** **nilutamide (Nilandron)**	• Block action of testosterone by competing with receptor sites	• Loss of libido, erectile dysfunction, and hot flashes • Breast pain and gynecomastia
Androgen Synthesis Inhibitors		
CYP17 Enzyme Inhibitor		
abiraterone (Zytiga)	• Inhibits CYP17, an enzyme needed to produce testosterone • Inhibits testosterone synthesis from testes, adrenal glands, and prostate cancer cells	• Joint swelling, fluid retention • Muscle discomfort • Hot flashes • Diarrhea
LHRH Agonists		
goserelin (Zoladex) **leuprolide (Eligard , Lupron Depot)** **triptorelin (Trelstar)**	• ↓ Secretion of LH and FSH • ↓ Testosterone production	• Hot flashes, gynecomastia, ↓ libido, erectile dysfunction • Depression and mood changes
LHRH Antagonist		
degarelix (Firmagon)	• Blocks LH receptors • Immediate testosterone suppression	• Pain, redness, and swelling at injection site • High liver enzymes

Degarelix (Firmagon) is an *LHRH antagonist* that lowers testosterone levels to castration levels. Unlike the LHRH agonists, degarelix does not cause a testosterone flare because it acts directly to block LH and FSH receptors. It is given as a subcutaneous injection. Results are seen in 3 days.

Abiraterone (Zytiga) works by inhibiting an enzyme, CYP17, which is needed to produce testosterone. This drug is given orally to men with castration-resistant prostate cancer, usually in combination with prednisone. It improves overall survival by 4 to 5 months.

Androgen receptor blockers

Androgen receptor blockers are another classification of antiandrogen drugs that compete with circulating androgens at the receptor sites. Flutamide, nilutamide (Nilandron), bicalutamide, and enzalutamide (Xtandi) are androgen receptor blockers. They are taken daily as an oral medication and can be used in combination with an LHRH agonist (e.g., goserelin, leuprolide). Combining an androgen receptor blocker with an LHRH agonist results in combined androgen blockade.

Chemotherapy

The use of chemotherapy is limited to treatment for those with hormone-refractory prostate cancer (HRPC) in late-stage disease. In HRPC the cancer is progressing despite treatment. This occurs in patients who have taken an antiandrogen for a certain period. The goal of chemotherapy is mainly palliative.

Some commonly used chemotherapy drugs for prostate cancer include cabazitaxel (Jevtana), cyclophosphamide, docetaxel (Taxotere), estramustine (Emcyt), mitoxantrone, paclitaxel (Abraxane), and vinblastine.

Men with advanced prostate cancer who have HRPC may receive a vaccine (sipuleucel-T [Provenge]). We do not know exactly how, but the vaccine stimulates the patient's system against the cancer. Use prolongs survival by about 4 months but does not reduce tumor burden. It is individually prepared for each man by a process that combines his own WBCs with granulocyte-macrophage colony-stimulating factor (GM-CSF), which then attacks the prostate tumor cells.

Radiotherapy

Radium-223 dichloride (Xofigo) can be used in the treatment of patients with castration-resistant prostate cancer, symptomatic bone metastases, and no known visceral metastatic disease. It is an alpha particle–emitting radiotherapy drug that mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases.

Orchiectomy

A bilateral orchiectomy is the surgical removal of the testes. It may be done alone or after prostatectomy. It is the gold standard for androgen deprivation. There are no side effects to be managed. It is very low cost when compared with other options. For advanced stages of prostate cancer, an orchiectomy is an option for cancer control, with rapid relief of bone pain associated with advanced tumors.

Orchiectomy may shrink the prostate, thus relieving urinary

obstruction in the later stages of disease when surgery is not an option. After an orchiectomy, weight gain and loss of muscle mass can change a man's physical appearance. These physical changes can affect self-esteem, leading to grief and depression. Because this procedure is permanent, many men prefer drug therapy over an orchiectomy.

Culturally Competent Care: Prostate Cancer

Nurses need to be aware of ethnic and cultural considerations when providing information about the risk for prostate cancer and screening recommendations. Consider not only the ethnic differences in the incidence of prostate cancer but also differences in health promotion practices.

Black men have the highest mortality rates from prostate cancer, in part because their prostate cancer often is more advanced at the time of diagnosis. Despite the availability of screening measures (PSA and DRE), black men and those in lower socioeconomic groups may not access these services. This is only partially related to knowledge levels about prostate cancer. In comparison to white men, black men with prostate cancer report more problems with financial access to transportation and health care costs. They describe using more religious coping strategies. White men are perceived as receiving more favorable treatment from their HCPs than black men.[18]

Although exposure to electronic and print media is successful in informing some men about prostate cancer, the effectiveness differs significantly based on demographic variables, such as ethnicity, age, education level, and socioeconomic level. Ideally, all men should be aware of the risks associated with prostate cancer and the screening methods available. Consider the best method to communicate this information to men of all cultures and ethnicities to promote understanding and participation in prostate cancer screening for men in at-risk groups.

Nursing Management: Prostate Cancer

Nursing Assessment

Subjective and objective data that should be obtained from a patient with prostate cancer are outlined in Table 54.8.

Nursing Diagnoses

Nursing diagnoses for the patient with prostate cancer depend on the stage of the cancer. General ones may include:

- Lack of knowledge
- Acute pain
- Urinary retention and impaired urinary system function
- Impaired sexual functioning
- Anxiety

Planning

The overall goals are that the patient with prostate cancer will (1) be an active participant in the treatment plan, (2) have acceptable pain control, (3) follow the therapeutic plan, (4) understand the effect of the therapeutic plan on sexual function, and (5) find an acceptable way to manage the impact on bladder and bowel function.

Nursing Implementation

Health Promotion

One of the most important roles in relation to prostate cancer is to encourage patients, in consultation with their HCPs, to have annual prostate screening (PSA and DRE). The age at which to begin screening was discussed earlier on p. 1263. Because of their increased risk for prostate cancer, black men and other men at high risk, such as

those with a family history of prostate cancer, should discuss the need for annual PSA and DRE beginning at age 45.[9]

Acute Care

Care of the patient having a radical prostatectomy is similar to surgical procedures for BPH. Nursing interventions for the patient who has radiation therapy and chemotherapy are discussed in Chapter 15. Another consideration is the patient's psychologic response to a diagnosis of cancer. Provide sensitive, caring support for the patient and his family to help them cope with the diagnosis. Prostate cancer support groups are available for men and their families to encourage them to be active, informed participants in their own care.

Ambulatory Care

Teach catheter care if the patient is discharged with an indwelling catheter in place. Teach the patient to clean the urethral meatus with soap and water once a day; maintain a high fluid intake; keep the collecting bag lower than the bladder at all times; and keep the catheter securely anchored to the inner thigh or abdomen. Tell them to report any signs of bladder infection, such as bladder spasms, fever, or hematuria.

If urinary incontinence is a problem, encourage the patient to practice pelvic floor muscle exercises (Kegel exercises) at every urination and throughout the day. Continuous practice during the 4- to 6-week healing process improves the success rate. Products used for incontinence specifically designed for men are available through home care product catalogs and retail stores. (Urinary incontinence is discussed in Chapter 45).

TABLE 54.8 Nursing AssessmentProstate Cancer

Subjective Data

Important Health Information

Medications: Testosterone supplements. Use of any medications affecting urinary tract such as morphine, anticholinergics, monoamine oxidase inhibitors, and tricyclic antidepressants

Functional Health Patterns

Health perception–health management: Positive family history. ↑ Fatigue and malaise
Nutritional-metabolic: High-fat diet. Anorexia, weight loss (may indicate metastasis)
Elimination: Hesitancy or straining to start stream, urinary urgency, frequency, retention with dribbling, weak stream, hematuria
Sleep-rest: Nocturia
Cognitive-perceptual: Dysuria. Low back pain radiating to legs or pelvis, bone pain (may indicate metastasis). Pain level
Self-perception–self-concept: Anxiety about self-concept

Objective Data
General

Older adult male. Pelvic lymphadenopathy (late sign)

Urinary

Distended bladder on palpation. Unilaterally hard, enlarged, fixed prostate on rectal examination

Musculoskeletal

Pathologic fractures (metastasis)

Possible Diagnostic Findings

Serum PSA. Serum alkaline phosphatase. Nodular and irregular prostate on ultrasonography, positive biopsy results. Anemia

Palliative and end-of-life care are often appropriate and beneficial to the patient with advanced disease and his family (see Chapter 9). Common problems with advanced prostate cancer include fatigue, bladder outlet obstruction and ureteral obstruction (caused by compression of the urethra and/or ureters from tumor mass or lymph node metastasis), severe bone pain and fractures (from bone metastasis), spinal cord compression (from spinal metastasis), and leg edema (from lymphedema, VTE). Nursing interventions must focus on all these problems.

Pain management is one of the most important aspects of your care for these patients. Pain control involves ongoing pain assessment, giving prescribed medications (both opioid and nonopioid agents), and nonpharmacologic methods of pain relief (e.g., relaxation breathing). (Pain management is further discussed in Chapter 8).

Evaluation

The outcomes are that the patient with prostate cancer will

- Be an active participant in the treatment plan
- Have acceptable pain control
- Follow the therapeutic plan
- Understand the effect of the treatment on sexual function
- Find an acceptable way to manage the impact on bladder or bowel function

Prostatitis

Etiology and Pathophysiology

Prostatitis is a broad term that describes a group of inflammatory and noninflammatory conditions affecting the prostate gland. Prostatitis is one of the most common urologic disorders. It is thought that 10% to 15% of all men in the United States will have prostatitis in their lifetime.[19] Almost 2 million men are treated for prostatitis every year.

The 4 categories of prostatitis syndromes are (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, (3) chronic prostatitis/chronic pelvic pain syndrome, and (4) asymptomatic inflammatory prostatitis. The most common type is nonbacterial.

Both acute and chronic bacterial prostatitis generally result from organisms reaching the prostate gland by ascending from the urethra, descending from the bladder, or invading via the bloodstream or the lymphatic channels. Common causative organisms are *Escherichia coli* (most common), *Klebsiella, Pseudomonas, Enterobacter, Proteus, Chlamydia trachomatis, Neisseria gonorrhoeae,* and group D streptococci.

Chronic bacterial prostatitis differs from acute prostatitis in that it involves recurrent episodes of infection. It is the most common reason for recurrent UTIs in adult men.

Chronic prostatitis/chronic pelvic pain syndrome describes a syndrome of prostate and urinary pain in the absence of an obvious infectious process. The cause of this syndrome is not known. It may occur after a viral illness, or it may be associated with sexually transmitted infections (STIs), especially in younger adults. A culture reveals no causative organisms, but leukocytes may be found in prostatic secretions.

Asymptomatic inflammatory prostatitis is usually diagnosed in those who have no symptoms but are found to have an inflammatory process in the prostate. These patients are usually diagnosed during the evaluation of other GU tract problems. Leukocytes are present in the seminal fluid from the prostate. The cause of this process is unclear.

Clinical Manifestations and Complications

Common manifestations of acute prostatitis include fever, chills, back pain, and perineal pain. In addition, acute urinary symptoms such as dysuria, urinary frequency, urgency, and cloudy urine may occur. The patient may progress to acute urinary retention caused by prostatic swelling if he remains untreated. With DRE, the prostate is extremely swollen, extremely tender, and boggy.

Complications of prostatitis are epididymitis and cystitis. Sexual function may be affected as manifested by postejaculation pain, libido problems, and ED. Prostatic abscess is a potential, but rare, complication.

In chronic bacterial prostatitis and chronic prostatitis/chronic pelvic pain syndrome, manifestations are similar but generally milder than those of acute bacterial prostatitis. These include irritative voiding symptoms (frequency, urgency, dysuria), backache, perineal and pelvic pain, and ejaculatory pain. Obstructive symptoms are rare unless there is coexisting BPH. With DRE, the prostate feels enlarged and soft or boggy and can be slightly tender with palpation. Chronic prostatitis can predispose the patient to recurrent UTIs.

The clinical features of prostatitis can mimic those of a UTI. However, it is important to remember that acute cystitis is not common in men.

Diagnostic Studies

Because patients with prostatitis have urinary symptoms, a urinalysis (UA) and urine culture and sensitivities are needed. Often WBCs and bacteria are present. The patient with a fever needs blood cultures and a complete blood count (CBC) to check the WBC count. The PSA test may be done to rule out prostate cancer. However, PSA levels are often increased with prostatic inflammation or infection. Thus, when inflammation or infection is present, the PSA may not be considered diagnostic.

Microscopic evaluation and culture of expressed prostate secretion can potentially be useful in the diagnosis of prostatitis. Expressed

prostate secretion is obtained using a premassage and postmassage test. The patient is asked to void into a specimen cup just before and just after a vigorous prostate massage. Prostatic massage (for expressed prostate secretion) is becoming less common in clinical practice unless all other diagnostic options are exhausted. It should not be done if acute bacterial prostatitis is suspected, since compression is extremely painful and can increase the risk for bacterial spread. TRUS is not useful in the diagnosis of prostatitis. However, TRUS or MRI may be done to rule out an abscess in the prostate.

Interprofessional and Nursing Care

Antibiotics commonly used for acute and chronic bacterial prostatitis include fluoroquinolones (e.g., ciprofloxacin [Cipro], levofloxacin, ofloxacin), clindamycin, cephalexin (Keflex), trimethoprim/sulfamethoxazole (Bactrim), doxycycline (Vibramycin), or tetracycline. Antibiotics are usually given orally for up to 4 weeks for acute bacterial prostatitis. However, if the patient has high fever or other signs of impending sepsis, he will be hospitalized and given IV antibiotics.

Men with chronic bacterial prostatitis may be given oral antibiotic therapy for 8 to 12 weeks. Antibiotics may be given for a lifetime if the patient is immunocompromised. A short course of oral antibiotics is usually prescribed for those with chronic prostatitis/chronic pelvic pain syndrome in case of bacterial infection. However, antibiotic therapy is often ineffective for patients whose prostatitis is not due to bacteria.

Patients with acute and chronic bacterial prostatitis tend to have a great amount of discomfort. The pain resolves as the infection is treated. However, they may have residual discomfort for several weeks after a course of antibiotics, as it takes time for the prostate to return to normal. Pain management for patients with chronic prostatitis/chronic pelvic pain syndrome is more difficult because the pain persists for weeks to months. No single approach provides relief for everyone. Antiinflammatory agents (e.g., ibuprofen, naproxen)

may be used for pain control in prostatitis, but these drugs provide only moderate pain relief.

Warm sitz baths may help to relieve pain. Relaxation of muscle tissue in the prostate using α-adrenergic blockers (e.g., tamsulosin, alfuzosin) are effective in reducing discomfort for some men.

Acute urinary retention can develop in acute prostatitis, requiring insertion of a urinary catheter. However, passage of a catheter through an inflamed urethra is contraindicated in acute prostatitis. The placement of a suprapubic catheter may then be indicated. Repetitive prostatic massage may be recommended as adjunct therapy for prostatitis for men. This potentially relieves congestion within the prostate by squeezing out excess prostatic secretions, providing pain relief. Like massage, measures to stimulate ejaculation (masturbation and intercourse) may help to drain the prostate and provide some relief.

Because the prostate can serve as a source of bacteria, fluid intake should be kept at a high level. Encourage the patient to drink plenty of fluids. Men with acute bacterial prostatitis have increased fluid needs from fever and infection. Management of fever is an important nursing intervention.

Problems of the Penis

Health problems of the penis are rare if STIs are excluded (see Chapter 52). Problems of the penis may be classified as congenital, problems of the prepuce, problems with the erectile mechanism, and cancer.

Congenital Problems

Hypospadias is a urologic problem in which the urethral meatus is on the ventral surface of the penis. This can be anywhere from the corona to the perineum. Causes include hormonal influences in utero, environmental factors, and genetic factors. Surgical repair of hypospadias, especially those that are close to the scrotum or perineum, is usually done while the boy is young. Surgery may be

done if it is associated with *chordee* (a painful downward curvature of the penis during erection) or if it prevents intercourse or normal urination. Surgery may be considered for cosmetic reasons or emotional well-being in older boys and adult men.

Problems of Prepuce

Problems of the prepuce (foreskin) are not as common in the United States as in most other countries because circumcision (surgical removal of the foreskin of the penis) is a routine procedure for many male infants. However, these conditions do occur and can be very painful and potentially an emergency. It is important to be familiar with these problems so appropriate treatment and pain relief can be promptly provided.

Phimosis is a tightness or constriction of the foreskin around the head of the penis, making retraction difficult (Fig. 54.8, *A*). It is caused by chronic inflammation of the foreskin. It is usually associated with poor hygiene techniques that allow bacterial and yeast organisms to become trapped under the foreskin. Topical corticosteroid cream, with or without an antifungal, applied 2 or 3 times daily to the exterior and interior of the tip of the foreskin may be effective in the initial treatment of inflammation. Definitive treatment is either circumcision or a dorsal slit surgical procedure.

Paraphimosis is tightness of the foreskin resulting in the inability to pull it forward from a retracted position, thus preventing normal return over the glans. It is a urologic emergency. A tightly retracted phimotic ring can compromise arterial flow to the glans. An ulcer can develop if the foreskin stays contracted (Fig. 54.8, *B*). Paraphimosis can occur when the foreskin is pulled back during bathing, use of urinary catheters, or intercourse and is not placed back in the forward position. Replacement of the foreskin after careful cleaning helps prevent this condition. The goal of treatment is to return the foreskin to its natural position over the glans penis through manual reduction. One strategy involves pushing the glans back through the prepuce by applying constant thumb pressure while the index fingers pull the

prepuce over the glans. Ice and/or hand compression on the foreskin, glans, and penis may be applied before to reduce edema. Treatment may include antibiotics or warm soaks. Definitive treatment is either circumcision or a dorsal slit.

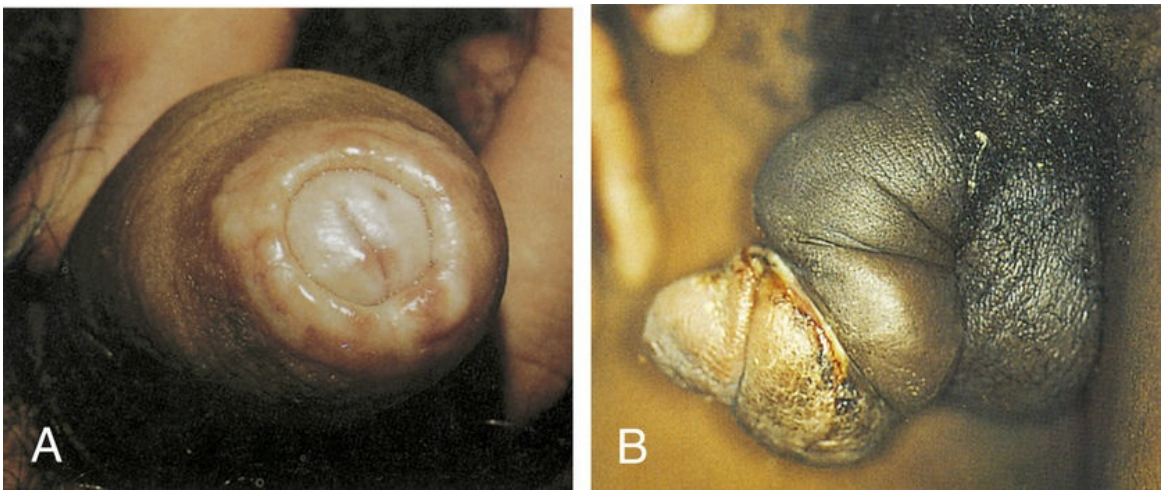

FIG. 54.8 **A,** Phimosis: inability to retract the foreskin due to secondary lesions on the prepuce (foreskin). **B,** Paraphimosis: ulcer with edema from foreskin remaining contracted over the prepuce (foreskin).

Problems of Erectile Mechanism

Priapism is a painful erection lasting longer than 4 hours. It is caused by complex vascular and neurologic factors that result in an obstruction of venous outflow in the penis. Conditions that may be associated with priapism include sickle cell disease, diabetes, trauma to the spinal cord, degenerative lesions of the spine, and drugs (e.g., cocaine, trazodone). Vasoactive drugs (e.g., alprostadil) injected into the corpora cavernosa for ED can cause priapism. Complications include penile tissue necrosis caused by lack of blood flow or hydronephrosis from bladder distention. Without immediate medical treatment, the risk for permanent ED is high.

Treatment varies depending on the cause. Patients with sickle cell

disease may need a blood exchange transfusion. Other patients may be treated with sedatives, an injection of a smooth muscle relaxant directly into the penis, or aspiration and irrigation of the corpora cavernosa with a large-bore needle.

Peyronie's disease is caused by plaque formation in the corpora cavernosa of the penis that results in inelasticity during erection. The palpable, nontender, hard plaque formation may occur spontaneously or result from trauma to the penile shaft. The plaque prevents adequate blood flow into the spongy tissue, which results in a curvature during erection. The condition is not dangerous but can result in painful erections, ED, or embarrassment. Patients may improve slightly over time, stabilize, or need surgery. Collagenase clostridium histolyticum (Xiaflex) and intralesional verapamil (ILV) are medication options. Each is given as a series of injections into the plaque. The goal of therapy is to reduce the curvature and allow men to avoid surgery.

Cancer of Penis

Cancer of the penis is rare in the United States. More than 95% are squamous cell carcinoma. It occurs more often in men who have human papillomavirus (HPV) infection and phimosis or uncircumcised men.[20] The tumor may appear as a superficial ulceration or a pimple-like nodule. Pain is rare. This contributes to a delay in seeking treatment. The nontender warty lesion may be mistaken for a genital wart. Treatment in the early stages is laser removal of the growth. A radical resection of the penis may be done if the cancer has spread. Surgery, radiation, or chemotherapy are options, depending on the extent of the disease, lymph node involvement, or metastasis.

Problems of Scrotum and Testes

It is important for the patient to see his HCP if he feels any scrotal lumps or painful areas in his scrotum or testes. He would not be able

to tell normal variations from cancer when performing self-examination. An incidental finding of a "scrotal lump" results in high anxiety for the patient.

Inflammatory and Infectious Problems

Skin Problems

The skin of the scrotum is susceptible to several common skin diseases. The most common are fungal infections, dermatitis (neurodermatitis, contact dermatitis, seborrheic dermatitis), and parasitic infections (scabies, lice). These conditions involve discomfort for the patient but are associated with few severe complications (see Chapter 23).

Epididymitis

Epididymitis is an acute, painful inflammatory process of the epididymis (Fig. 54.9). It is often due to an infectious process, trauma, or urinary reflux down the ductus (vas) deferens. It is usually unilateral. Swelling may progress to the point that the epididymis and testis are indistinguishable. In men younger than 35 years of age, the most common cause is gonorrhea or chlamydial infection. In men over 35, the most common cause is *E. coli* infection. BPH and prostatitis are common contributors in older men.

The use of antibiotics is important for both partners if the transmission is through sexual contact. Encourage patients to refrain from sexual intercourse until treatment is complete. They should use a condom if they do engage in intercourse. Conservative treatment consists of elevating the scrotum, ice packs, and analgesics. Ambulation places the scrotum in a dependent position and increases pain. Acute tenderness subsides within 1 week, although some discomfort and swelling may last for weeks or months.

Orchitis

Orchitis refers to an acute inflammation of the testis. In orchitis, the testis is painful, tender, and swollen. It generally occurs after an episode of bacterial or viral infection, such as mumps, pneumonia, tuberculosis, or syphilis. It can be a side effect of epididymitis, trauma, infectious mononucleosis, influenza, catheterization, or complicated UTI. Mumps orchitis is a condition contributing to infertility that can be avoided by childhood vaccination against mumps. Treatment is similar to that for epididymitis.

Congenital Problems

Cryptorchidism (undescended testes) is failure of the testes to descend into the scrotal sac before birth. It is the most common congenital testicular condition and is more common on the right. It may occur bilaterally or unilaterally and may be a contributing factor to male infertility if corrective surgery is not done by 2 years of age. The incidence of testicular cancer is higher if the condition is not corrected before puberty. Surgery is done to locate and suture the testis or testes to the scrotum.

Acquired Problems

Hydrocele

A *hydrocele* is a nontender, fluid-filled mass that results from interference with lymphatic drainage of the scrotum and swelling of the tunica vaginalis that surrounds the testis (Fig. 54.10; also Fig. 54.9). Diagnosis is aided by shining a flashlight through the scrotum (transillumination). No treatment is needed unless the swelling becomes large and uncomfortable, then surgical repair of the hydrocele is needed. Hydrocele repair is avoided in men who have not started their family or seek to add to their family as repair can contribute to subfertility or infertility.

Spermatocele

A *spermatocele* is a firm, sperm-containing cyst of the epididymis. It may be visible with transillumination (Fig. 54.9). The cause is unknown. They can become large, tense, and painful. Their size can wax and wane with time. Spermatocele repair is avoided in men who have not started their family or seek to add to their family as repair can contribute to subfertility or infertility.

Varicocele

A *varicocele* is a dilation of the veins that drain the testes (Fig. 54.9). The scrotum can feel wormlike when palpated if the venous dilation is significant. However, this is dependent on the examiner's experience and skill. The cause of the problem is not known.

A varicocele is usually on the left side of the scrotum because of retrograde blood flow from the left renal vein. Surgery is considered if the patient is infertile. Varicoceles are associated with 40% to 50% of cases of infertility. Sperm is thought to be damaged by varicoceles. Repair of

the varicocele may be through injection of a sclerosing agent or by surgical ligation of the spermatic vein. Untreated varicoceles are not associated with any long-term health risk.

Testicular Torsion

Testicular torsion involves a twisting of the spermatic cord that supplies blood to the testes and epididymis (Fig. 54.9). It is considered a surgical emergency. It is most often seen in males younger than age 20. It can occur spontaneously, or because of trauma or an anatomic abnormality.

The patient has severe, sudden onset of scrotal pain, tenderness, swelling, nausea, and vomiting. Urinary symptoms, fever, and WBCs or bacteria in the urine are absent. The pain does not usually subside with rest or elevation of the scrotum. The cremasteric reflex is absent on the side of the swelling. Normal anatomic landmarks are lost due to tissue edema.

A scrotal/testicular Doppler ultrasound is typically done to assess blood flow within the testicle. Decreased or absent blood flow confirms the diagnosis. Torsion is an emergency! If the blood supply to the affected testicle is not restored within 4 to 6 hours, ischemia to the testis will occur, leading to necrosis. Unless the torsion resolves spontaneously, surgery to untwist the cord and restore the blood supply must be done emergently.

Testicular Cancer

Etiology and Pathophysiology

Testicular cancer is overall relatively rare. It accounts for less than 1% of all cancers found in males. However, it is the most common type of cancer in young men between 15 and 44 years of age. In the United States, about 8430 new cases occur annually. The median age at diagnosis is 33 years old.[21]

Testicular tumors are more common in males who have had undescended testes (cryptorchidism) or a family history of testicular cancer or anomalies. Other predisposing factors include orchitis, human immunodeficiency virus (HIV) infection, maternal exposure to exogenous estrogen, and testicular cancer in the other testis.

Most testicular cancers develop from 2 types of embryonic germ cells: seminomas and nonseminomas. Seminoma germ cell cancers are the most common but are the least aggressive. Nonseminoma testicular germ cell tumors are rare but very aggressive. Non–germ cell tumors arise from other testicular tissue. These include Leydig cell and Sertoli cell tumors. They account for less than 10% of testicular cancers.

Clinical Manifestations

Testicular cancer may have a slow or rapid onset depending on the type of tumor (Fig. 54.9). The patient may notice a painless lump in his scrotum, scrotal swelling, and a feeling of heaviness. The scrotal mass usually is nontender and firm. Some patients report a dull ache or heavy sensation in the lower abdomen, perianal area, or scrotum. Acute pain is the first symptom in about 10% of patients. Manifestations associated with advanced disease are varied and include lower back or chest pain, cough, and dyspnea.

Diagnostic Studies

Palpation of the scrotal contents is the first step in diagnosing testicular cancer. A cancerous mass is firm and does not transilluminate. Ultrasound of the testes is done if testicular cancer is

suspected (e.g., palpable mass) or when persistent or painful testicular swelling is present. If testicular cancer is suspected, serum tumor markers should be checked to determine the serum levels of α-fetoprotein (AFP), lactate dehydrogenase (LDH), and human chorionic gonadotropin (hCG). (The tumor markers AFP and hCG are discussed in Chapter 15.)

If ultrasound is suspicious for testicular cancer, a radical inguinal orchiectomy should be done. A chest x-ray, CBC, basic metabolic panel, and liver function tests may be done before. Anemia may be present. Liver function levels may be increased in metastatic disease. If cancer is confirmed by pathology, then a CT scan of the abdomen and pelvis (and possibly the chest) can be done to further stage and assess for metastases.

Interprofessional and Nursing Care

Testicular cancer is one of the most curable types of cancer. Interprofessional care generally involves a radical inguinal orchiectomy (surgical removal of the affected testis, spermatic cord, and regional lymph nodes). Some patients with early-stage disease do not need further treatment after an orchiectomy. Retroperitoneal lymph node dissection and removal also may be done in early-stage disease. These nodes are the primary route for metastasis.

Postorchiectomy treatment may involve radiation therapy, or chemotherapy, depending on the stage of the cancer. Radiation therapy is mainly used for patients with a seminoma, which is very sensitive to radiation. Radiation does not work well for nonseminomas.

Testicular germ cell tumors are more sensitive to systemic chemotherapy than any other adult solid tumor. Chemotherapy protocols use a combination of agents, including bleomycin, cisplatin, etoposide, and ifosfamide (Ifex). Retroperitoneal lymph node dissection may be done after chemotherapy as adjunct therapy in patients with advanced testicular cancer.

Check Your Practice

You are working on the urologic oncology unit caring for a 24-yr-old man who recently had an orchiectomy for testicular cancer. He appears quiet and nonengaged when you assess him. He says, "I'm never going to have a normal sex life."

- How would you respond? What kind of support or information would you provide?

The prognosis for patients with testicular cancer in recent years has greatly improved. 95% obtain complete remission if the disease is detected in the early stages. Because of treatment successes, many men with testicular cancer are long-term survivors.

However, some drugs used to treat testicular cancer can cause serious long-term side effects. These include pulmonary toxicity, kidney damage, nerve damage (which can cause numbness and tingling), and hearing loss (from nerve damage). Secondary cancers can occur due to chemotherapy (see Chapter 15).

All patients with testicular cancer require surveillance and regular physical examinations, chest x-rays, CT scans, and assessment of serum tumor markers (hCG, AFP, LDH). The goal is to detect relapse when the tumor burden is minimal.

Pretreatment subfertility or impaired fertility is identified at diagnosis. In treatment of testicular cancer, chemotherapy with cisplatin and/or pelvic radiation often damages the testicular germ cells. However, spermatogenesis can return in some patients. Because of the high risk for infertility, the cryopreservation of sperm in a sperm bank before treatment begins should be sensitively discussed and recommended for the man with testicular cancer.[22] Ejaculatory dysfunction may result from retroperitoneal lymph node dissection. These issues may be hard to discuss with the newly diagnosed patient. Men may think that the disease is a threat to their masculinity and self-worth.

Sexual Function

Vasectomy

Vasectomy is the bilateral surgical ligation or resection of the ductus deferens performed for the purpose of sterilization (Fig. 54.11). The procedure takes only 15 to 30 minutes. It is usually done with the patient under local anesthesia on an outpatient basis. Although vasectomy is considered a permanent form of sterilization, successful vasectomy reversals *(vasovasotomy, vasoepididymostomy)* are common.

After vasectomy, the patient should not notice any difference in the look or feel of the ejaculate because its major components are seminal and prostatic fluid. The patient must use a different form of contraception until semen examination reveals no sperm. Sperm cells continue to be made by the testes but are stored in the epididymis and reabsorbed by the body rather than being passed through the ductus deferens. Vasectomy does not affect the hormone production, ability to ejaculate, or physiologic mechanisms related to erection or orgasm. Psychologic adjustment may be a problem after surgery. It may be hard for the patient to separate vasectomy from castration at a subconscious level. Some men may develop psychogenic ED or may feel the need to become more sexually active than they were in the past to prove their masculinity.

Erectile Dysfunction

Erectile dysfunction (ED) is the inability to attain or maintain an erection that allows satisfactory sexual activity. Although sexual function is a topic that many persons are uncomfortable discussing, health care professionals must be able and willing to address ED.

ED is a condition that is significant because of its prevalence. More than 10 million men in the United States are thought to have ED. It can occur at any age, although the incidence increases with age. In fact, it is estimated that about 50% of all men between ages 40 and 70 have at least some degree of ED. ED is increasing in all sexually active

males. In younger men, the increase is attributed to substance use (e.g., recreational drugs, alcohol), stress, and anxiety. Middle-aged men are more likely to have ED due to chronic medical conditions (e.g., diabetes, hypertension) or treatment for these conditions (e.g., antihypertensive drugs) that may cause ED.

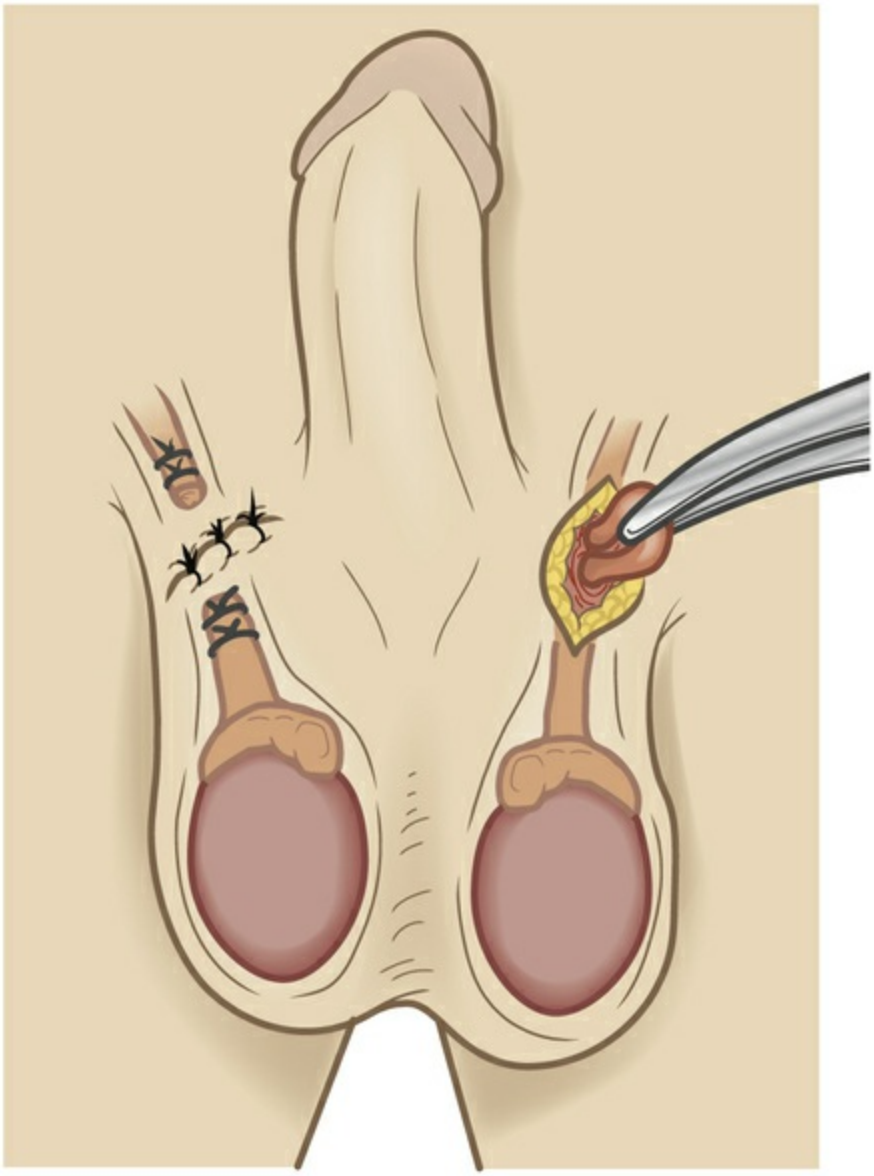

FIG. 54.11 Vasectomy procedure. The ductus deferens is ligated or resected for the purpose of sterilization.

TABLE 54.9 Common Risk Factors for Erectile Dysfunction

Drug Induced

- Alcohol
- Antiandrogens
- Antihypertensives
- Antilipidemic agents
- Major tranquilizers (diazepam [Valium], alprazolam [Xanax])
- Marijuana, cocaine
- Nicotine
- Tricyclic antidepressants (e.g., amitriptyline [Elavil])

Endocrine

- Diabetes
- Hypogonadism
- Obesity

Genitourinary

- Radical prostatectomy
- Renal failure

Neurologic

- Cerebrovascular disease
- Parkinson's disease
- Trauma to the spinal cord

- Tumors or transection of spinal cord

Psychologic

- Anxiety
- Depression
- Stress

Vascular

- Atherosclerosis
- Hypertension
- Peripheral vascular disease

Other

- Aging

Etiology and Pathophysiology

ED can be due to many factors (Table 54.9). Common causes include diabetes, vascular disease, side effects from medications, result of surgery (e.g., prostatectomy), trauma, chronic illness, stress, difficulty in a relationship, or depression. Since ED results from reduced blood flow to the penis, there is a potential association with cardiovascular disease because the risk factors for both disorders are the same.

Normal physiologic age-related changes are associated with changes in erectile function and may be an underlying cause of ED for some men. Table 50.3 lists age-related changes in sexual function. Explain these age-related changes (if necessary) to reassure an anxious older man about normal changes in his sexual abilities. (The male sexual response is discussed in Chapter 50.)

Clinical Manifestations and Complications

The typical symptom of ED is a patient's self-report of problems associated with erectile activity, describing an inability to attain or maintain an erection. The symptoms may occur only occasionally, may be continual with a gradual onset, or may occur with a sudden onset. A gradual onset of symptoms is usually associated with physiologic factors. A sudden or rapid onset of symptoms may be related to psychologic issues. It is common for younger men who seek care for ED to be diagnosed with diabetes, hypertension, depression, or cholesterol abnormalities during their evaluation for ED.[23]

A man's inability to perform sexually can cause great distress in his interpersonal relationships and may interfere with his concept of himself as a man. It can affect the relationship between the man and his partner. Problems with ED can lead to personal issues, including anger, anxiety, and depression.

Diagnostic Studies

The first step in the diagnosis and management of ED begins with a thorough sexual, health, and psychosocial history.[24] Self-administered assessment and treatment-related questionnaires may be useful as primary screening tools. For example, the International Index of Erectile Function (IIEF) identifies a man's response to 5 key areas of male sexual function: erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction.

Second, a physical examination should focus on secondary sexual characteristics. Note if secondary sexual characteristics reflect the person's chronologic age (Tanner stage). A DRE should be done to assess prostate size, consistency, and presence of nodules. Assessment of BP with palpation and auscultation of the femoral arteries and peripheral pulses should be included.

Further examination or diagnostic testing is typically based on findings from the history and physical examination. A serum glucose, hemoglobin A1C (Hb A1C), and lipid profile are recommended to rule out diabetes. Hormonal levels for testosterone, prolactin, LH, and

thyroid hormones may help identify endocrine-related problems. PSA level and a CBC may help to identify other diseases.

Other diagnostic tests may be done to diagnose ED. Nocturnal penile tumescence and rigidity testing is a noninvasive method that involves the continuous measurement of penile circumference and axial rigidity during sleep. These are used to distinguish between physiologic or psychogenic causes of ED. Vascular studies, including penile arteriography, penile blood flow study, and duplex Doppler ultrasound studies, are used to assess penile blood inflow and outflow. These tests help to identify vascular problems interfering with erection.

Interprofessional and Nursing Care

The goal of ED therapy is for the patient and his partner to achieve a satisfactory sexual relationship. The treatment for ED can be based on the underlying cause. Generally, men are moved directly into treatment without a costly workup. A variety of treatment options are available (Table 54.10). Advise patients that no option will restore ejaculation or tactile sensations if they were absent before treatment.

TABLE 54.10 Interprofessional CareErectile Dysfunction

Diagnostic Assessment

- History and physical examination
- Sexual history
- Serum glucose and lipid profile
- Testosterone, prolactin, and thyroid hormone levels
- Nocturnal penile tumescence and rigidity testing
- Vascular studies

Management

- Modify reversible causes
- Sexual counseling

Drug Therapy

- avanafil (Stendra)
- sildenafil (Viagra)
- tadalafil (Cialis)
- vardenafil (Levitra, Staxyn)

Devices and Implants

- Intraurethral medication pellet
- Intracavernosal self-injection
- Penile implants
- Vacuum erection device (VED)

It is important to determine if ED is reversible before treatment is started. For example, if ED appears to be a side effect of prescribed drugs, other treatments can be explored. With an established diagnosis of testicular failure (hypogonadism), androgen replacement therapy may be part of the prescribed treatment.

For men who have ED that is psychologic in nature, counseling for the patient (with or without his partner) is recommended. This counseling should be carried out by a qualified sex therapist.

The man with ED needs a great deal of emotional support for both himself and his partner. Men often do not feel comfortable discussing their problems because of their perceptions of society's expectations of a man's sexual abilities. Reassure the patient that confidentiality will be maintained. Many men delay seeking medical care and may expect

immediate solutions to their problems. The interprofessional care team should provide a support system and accurate information.

Erectogenic Drugs

Avanafil (Stendra), sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra, Staxyn) are erectogenic drugs. These drugs are PDE5 inhibitors. They cause smooth muscle relaxation and increased blood flow into the corpus cavernosum, promoting penile erection. They are taken orally before sexual activity. These drugs have been found to be generally safe and effective for the treatment of most types of ED but are ineffective in the absence of arousal.

Side effects include headaches, leg/back pain, dyspepsia, flushing, and nasal congestion. Rare side effects are blurred or blue-green visual problems, sudden hearing loss, and an erection lasting more than 4 hours (priapism). Teach the patient to seek immediate medical attention if any of these reactions occur. Because these drugs may potentiate the hypotensive effect of nitrates, they are contraindicated for those taking nitrates (e.g., nitroglycerin).

Be aware that increasing numbers of men are seeking other ways to obtain ED medications. This include compounding pharmacies and online pharmacies. This may be due to both the cost of ED medications and the lack of insurance coverage for them.

Drug Alert

Phosphodiesterase Type 5 (PDE5) Inhibitors

- Should not be used with nitrates (nitroglycerin) in any form.
- Can potentiate hypotensive effects of nitrates.

Vacuum Erection Devices

Vacuum erection devices (VEDs) are suction devices that are applied to a flaccid penis then produce an erection by pulling blood up into

the corporeal bodies. A penile ring or constrictive band is placed around the base of the penis to retain venous blood, preventing the erection from subsiding.

Intraurethral Devices and Intracavernosal Injections

Intraurethral devices include the use of vasoactive drugs applied as a topical gel or a medication pellet inserted into the urethra using a medicated urethral system for erection (MUSE) device. Intracavernosal self-injections may be performed, with medication injected directly into the corpus cavernosum.

Alprostadil (Caverject, Edex) is a vasoactive drug that enhances blood flow into the penile arteries. It can be given either by injection or as a transurethral pellet (suppository). When given as a suppository, the drug is placed into the opening at the tip of the penis. When injected, a needle and syringe is used to inject the drug directly into the corpus cavernosum. Trimix (a combination product) includes alprostadil, papaverine, and phentolamine.

Penile Implants

Implantation requires surgery but can sometimes be done in an outpatient setting. The devices are implanted into the corporeal bodies to provide an erection firm enough for penetration. The inflatable implant consists of cylinders in the penis, a small pump in the scrotum, and a reservoir in the lower abdomen. The main complications associated with penile prostheses are infection, erosions, and, rarely, mechanical failure.

Sexual Counseling

Sexual counseling can be recommended at any point during treatment for ED. It may be most valuable in cases with a component of psychogenic ED. Counseling should address psychologic or interpersonal factors that may enhance sexual expression, as well as other factors that are of concern. Counseling can be effective for the patient. It can include his partner, especially if he is involved in a

long-term relationship.

Hypogonadism

Hypogonadism is a gradual decline in androgen secretion that occurs in most men as they age. The primary male androgen that is reduced is testosterone (Fig. 54.12). This has also been called *late onset-hypogonadism* or *hypogonadism of old age*. It can begin as early as age 40. It is unclear what causes a decline in testosterone. Obesity is a contributing factor.

Manifestations associated with low testosterone include decreased libido, fatigue, ED, depression and mood swings, and sleep problems. Since many of these manifestations can be associated with aging, some patients may not mention this to their HCP, or the HCP may not recognize these manifestations as signs of low testosterone. Long-term effects of low testosterone include loss of muscle mass and strength, which may contribute to an increased risk for falls and fractures.

Hypogonadism is diagnosed with a blood test and a physical examination. Normal serum testosterone levels can range from 300 to 1100 ng/dL, but often the normal ranges vary between laboratories. Replacement testosterone therapy is considered once total serum testosterone levels drop below 300 ng/dL on 2 separate early morning measurements/occasions, and the patient has manifestations of low testosterone.[25] Therapy may be started earlier depending on severity of symptoms. Testosterone replacement therapy (TRT) should not be started until the patient, in consultation with his HCP, considers the risks and benefits of therapy. Potential risks of TRT include lowered levels of high-density lipoprotein (HDL) cholesterol, increased hematocrit, and worsening sleep apnea, although these are rare. Since TRT may cause increased growth of prostate tissue, TRT is contraindicated in patients with unmanaged BPH or prostate cancer. Before treatment is started, a DRE and PSA test should be done. Once TRT begins, the HCP should closely monitor the patient.

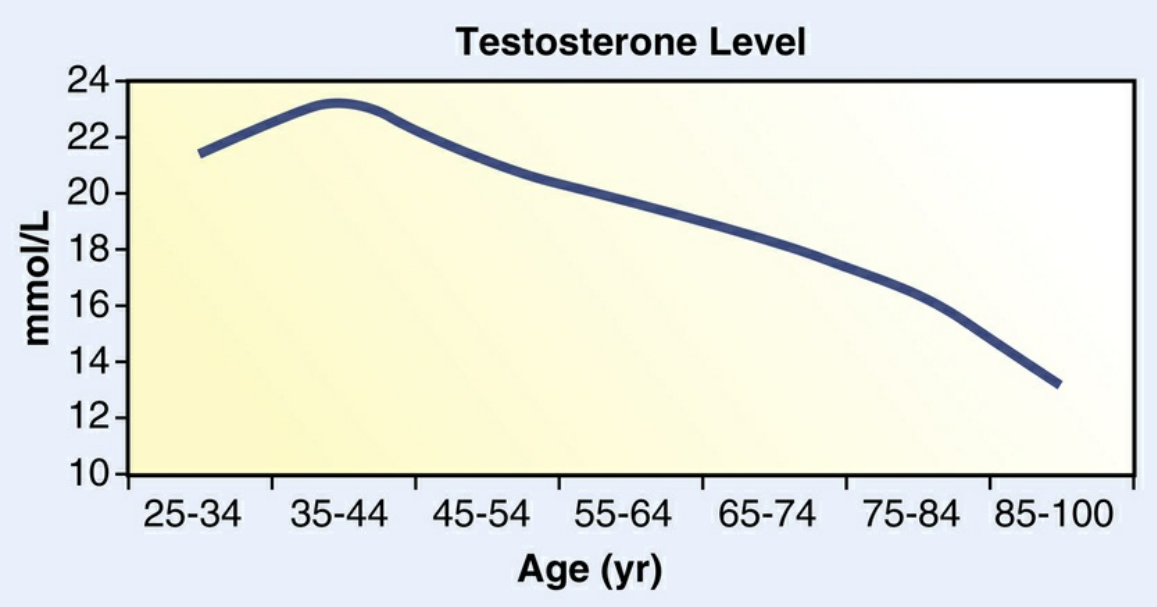

FIG. 54.12 Changes in testosterone plasma level in men as they age.

Replacement therapy is available in different forms, including injection, transdermal, topical, buccal, or intranasal preparations. Oral TRT is not approved for use in the United States. IM injections, such as testosterone cypionate (Depo-Testosterone) and testosterone enanthate (Delatestryl), are available in varying doses. These drugs create a cyclic rise and fall in serum testosterone levels. The highest levels occur 2 to 3 days after the injection. Testosterone levels slowly decrease until the next injection. One side effect of this form of TRT is that men may report mood swings with the hormone fluctuations.

Transdermal preparations, including patches and gels (e.g., Androderm, Testim), are often prescribed. They are applied to the skin at product-specific sites, including the back, arm, and abdomen. Skin irritation is a common side effect. Testosterone may also be given as a buccal tablet (Striant) or intranasally (Natesto).

Emphasize to the patient the importance of hand washing with soap and water after applying testosterone preparations to the skin. Covering the area with clothing until the preparation has dried is recommended.

Women of childbearing age and children should avoid direct contact with testosterone products. Testosterone may cause early signs of puberty in young children and changes (virilization) in the

external genitalia of a female fetus.

Infertility

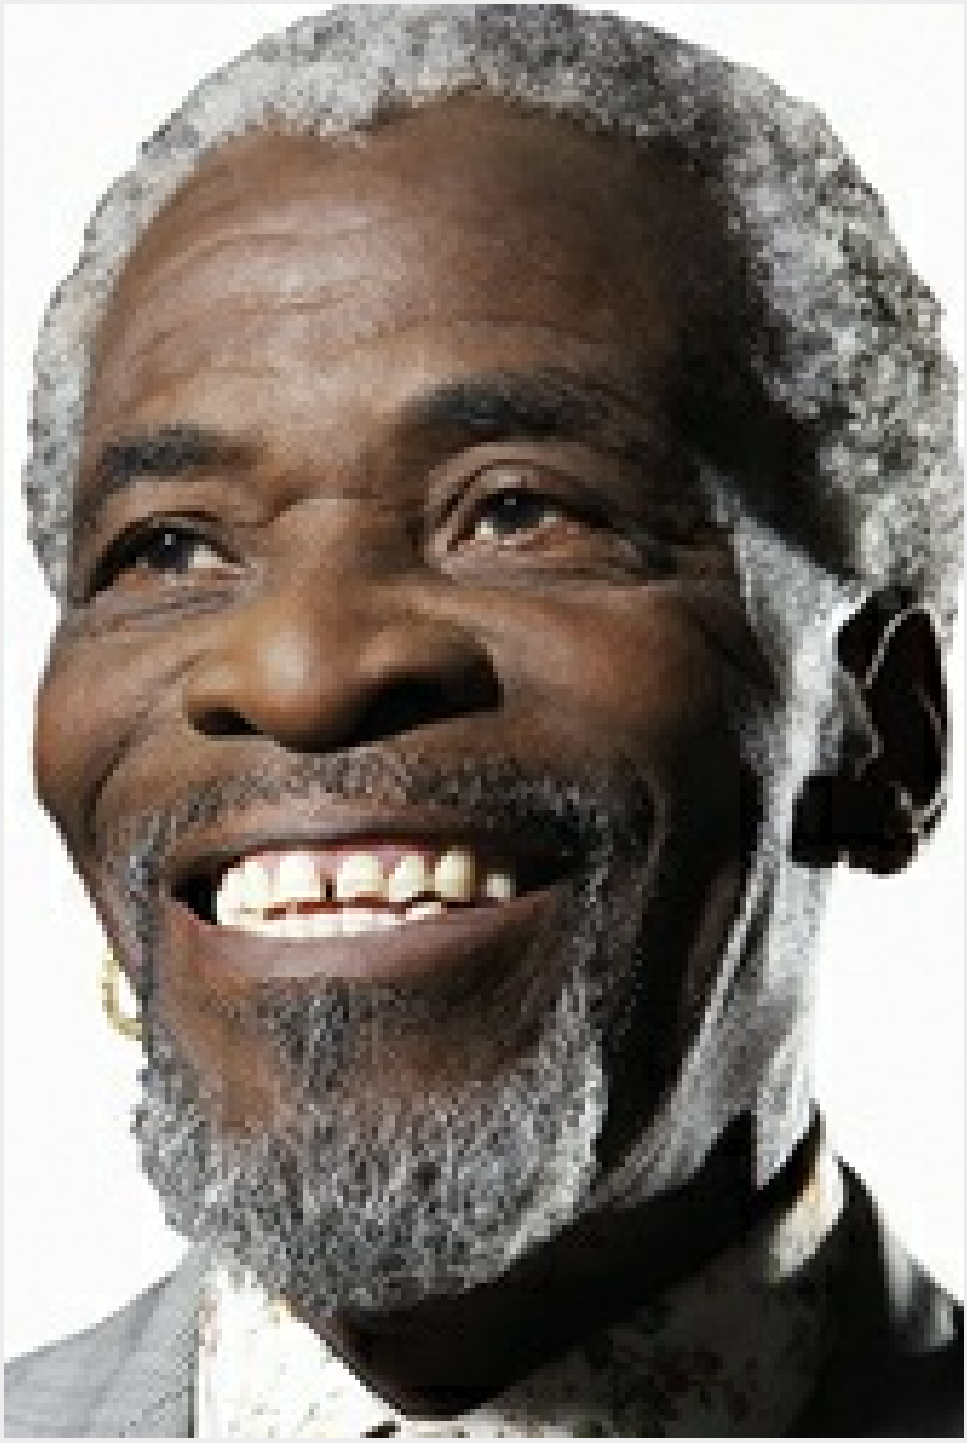
Infertility in a couple is defined as the inability to conceive after 1 year of frequent unprotected intercourse. Infertility is a disorder of a couple, not of one person. For this reason, both partners must be involved in determining the cause of infertility. Infertility is caused by factors involving the man in a significant number of cases. Some estimate 25% of cases are male-related.[26]

Problems of the hypothalamic-pituitary system, testicular disorders, and problems of the ejaculatory system can cause male infertility. The physical causes of infertility can be divided into 3 categories: pretesticular, testicular, and posttesticular. The *pretesticular* or endocrine causes occur in only about 3% of the cases. They can generally be treated with medication or surgery.

Testicular problems make up 50% of the cases. The most common cause of male infertility is a varicocele. Other factors that influence the testes include infection (e.g., mumps virus, STIs, bacterial infections), congenital anomalies, drugs, radiation, substance use (alcohol, nicotine, drugs), and environmental hazards.

Posttesticular causes account for 5% to 7% of the cases. Obstruction, infection, and the result of a surgical procedure are the primary causes. The remaining 40% are classified as *idiopathic,* or of unknown causes.

A careful health history and examination may reveal the cause of a patient's infertility. Thus the history is a starting point for determining cause and treatment. The history should include age; occupation; past injury, surgery, or infections of the genital tract; lifestyle issues (e.g., hot tubs, weight training, wearing tight undergarments); sexual practices; frequency of intercourse; and emotional factors, such as stress levels and the desire for children. Record the use of drugs, such as chemotherapeutic agents, anabolic steroids or testosterone, sulfasalazine (Azulfidine), cimetidine (Tagamet HB), and recreational drugs, since these drugs can reduce the sperm count. A physical



examination may identify a varicocele, Peyronie's disease, or other physical findings.

The first test in the male infertility evaluation is a semen analysis to determine sperm concentration, motility, and morphology. Hormone studies are helpful in determining the cause, including plasma testosterone and serum LH and FSH measurements. Be tactful in dealing with the male patient undergoing infertility studies. Many cultures equate fertility and masculinity. Both male and female partners should undergo evaluation simultaneously to avoid potential treatment delays for the couple.

Treatment options for the man include drugs, conservative lifestyle changes (e.g., avoiding scrotal heat, substance use, high stress), in vitro fertilization techniques, and corrective surgery. Infertility can seriously strain a relationship. The couple may need counseling and discussion of alternatives if conception is not achieved. (Female infertility is discussed in Chapter 53.)

Case Study

Benign Prostatic Hyperplasia With Acute Urinary Retention

© IPGGutenbergUKLtd/iStock/Thinkstock.

Patient Profile

B.G., a 60-yr-old married black man with hypertension, COPD, and coronary artery disease, comes to the ED because of an inability to

void for the past 13 hours and pain in the lower abdomen.

Subjective Data

- Reports the urge to void
- Is restless, anxious, and agitated

Objective Data

- Has prostate enlargement on digital rectal examination
- Has hematuria, bacteria, and WBCs in urine
- Has a tender and palpable bladder above the umbilicus
- PSA test: 8 ng/mL

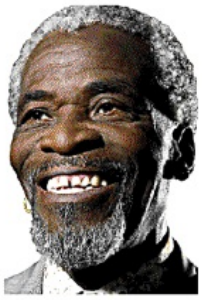
Interprofessional Care

- Indwelling catheter inserted by a urology resident
- Admitted to the hospital for observation

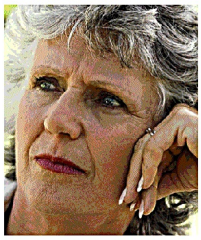
Discussion Questions

1. What risk factors for prostate problems are present in B.G.?
2. Explain the cause of the manifestations that B.G. exhibited.
3. What are possible reasons for B.G.'s high PSA level?
4. Discuss the drug and surgical options available to B.G.
5. ***Patient-Centered Care:*** B.G. asks you about the effect of the various surgical options on his ability to have sex. How would you respond and what type of teaching would you provide?
6. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses?
7. ***Priority Decision:*** What is the priority nursing intervention for B.G.?
8. ***Patient-Centered Care:*** On further assessment, you note that

B.G. is concerned he may have incontinence if he has surgery on his prostate. How would you help him resolve this concern related to treatment options, and how would you teach him about these options?



9. ***Evidence-Based Practice:*** What information would you offer to B.G. when he asks if he should start taking saw palmetto to prevent future UTIs?



Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 6 patients. You have 1 LPN and 1 UAP on your team to help you.

Patients	
 © iStockphoto/Thinkstock.	L.M. is a 35-yr-old Hispanic woman who went to the clinic 3 days ago saying she was just "not feeling well." She was admitted to the hospital for treatment of hypertension caused by newly diagnosed Cushing syndrome. She has been depressed and crying because of her physical appearance. Her last BP was 164/94 mm Hg.
 © iStockphoto/Thinkstock.	N.B. is a 48-yr-old man admitted to the ICU 2 days ago in diabetic ketoacidosis. He was transferred to the clinical unit yesterday evening. His fasting blood glucose level this morning is 296 mg/dL.
 © XiXinXing/iStock/Thinkstock.	A.K. is a 68-yr-old Asian American woman recently diagnosed with adenocarcinoma of her right breast. She had a lumpectomy and axillary node dissection yesterday. She has a Jackson-Pratt drain in her right chest. Her last pain medication was given 1 hour ago, at which time she rated her pain as a 7 on a scale of 0–10.
 © IPGGutenberg/JKLtd/iStock/Thinkstock.	B.G. is a 60-yr-old black man who was admitted to the hospital because of an inability to void for 13 hours and pain in the lower abdomen. He has a urinary tract infection and prostatic enlargement. The urology resident inserted an indwelling catheter. B.G. is scheduled to undergo a TURP this morning.
 © JupiterImages/Photos.com/Thinkstock.	R.D. is a 52-yr-old white woman who was diagnosed with Graves' disease 2 mo ago. She was treated with antithyroid medication for 2 mo and underwent a subtotal thyroidectomy yesterday. In report it was noted that her voice has become slightly "hoarse" in the last hour.

 © Juanmonino/IStock.com.	B.C. is a 49-yr-old Latina woman who had a total abdominal hysterectomy and bilateral salpingo-oophorectomy 1 day ago. She has a urinary catheter in place. Her vital signs are stable. She is not reporting any pain.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Second? Provide a rationale.
2. ***Collaboration:*** Which tasks could you delegate to UAP? *(select all that apply)*
    a. Assist B.C. to ambulate in the hallway.
    b. Teach B.G. what to expect postoperatively.
    c. Take R.D.'s vital signs and report the results to you.
    d. Assess A.K.'s mastectomy incision for manifestations of infection.
    e. Listen to L.M. talk about her feelings while helping her with AM care.
3. ***Priority Decision and Collaboration:*** While you are assessing R.D., the LPN informs you that A.K.'s chest dressing is totally saturated with bloody drainage. Which *initial* action would be most appropriate?
    a. Ask the LPN to call the laboratory for a stat Hgb and Hct on A.K.
    b. Tell the LPN to reinforce the dressing with sterile 4× 4–gauze pads.
    c. Have the LPN stay with R.D. while you assess the patency of A.K.'s Jackson-Pratt drain.
    d. Ask the LPN to stay with A.K. and have the UAP monitor R.D. while you call A.K.'s HCP.

Case Study Progression

A.K.'s Jackson-Pratt drain was not functioning properly. You get it working and change the chest dressing. The incision is well approximated without signs of infection. When you leave the room, the Jackson-Pratt has a small amount of serosanguineous drainage in it. As you enter R.D.'s room, you notice she is having a carpal spasm on the same arm on which the LPN is taking her BP. You recognize this as a manifestation of hypocalcemia and notify the health care provider.

4. Which assessment findings would be *most* important to include in a discussion with the health care provider about R.D.? *(select all that apply)*
    a. Patient is anxious
    b. Hoarseness of voice
    c. Most recent Hgb and Hct
    d. Carpal spasm upon inflation of BP cuff
    e. Blood pressure of 138/76 and heart rate of 78
5. ***Priority Decision:*** Which intervention would be of *highest* priority in caring for L.M.?
    a. Assess her for fall risk.
    b. Assess her for signs and symptoms of hypoglycemia.
    c. Teach her the need for a high-carbohydrate, low-protein diet.
    d. Reassure her that her physical appearance will improve with treatment.
6. B.G. asks you what to expect when he returns from surgery. You explain that he will have a(n)
    a. dressing in his groin as well as a urinary catheter.
    b. 3-way urinary catheter connected to an irrigation system.
    c. patient-controlled analgesia (PCA) pump for pain control.
    d. abdominal and a perineal drain that will be recharged q4hr.
7. ***Priority Decision and Management Decision:*** The LPN is

assigned to give medications to N.B., including his sliding scale Novolog insulin with breakfast. The UAP, who is also a senior nursing student, tells you that the LPN gave N.B.'s insulin at least 30 minutes after the patient ate his breakfast. What is your *best* initial action?

a. Report the incident to the charge nurse for follow-up.
b. Talk to the LPN about the importance of timely medication administration.
c. Ask the LPN what time the insulin was given and when the patient ate breakfast.
d. Ask the UAP to first discuss the concern with the LPN to follow proper channels of communication.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Postoperatively, a patient who has had a laser prostatectomy has continuous bladder irrigation with a 3-way urinary catheter with a 30-mL balloon. When he reports bladder spasms with the catheter in place, the nurse should

a. deflate the balloon to 10 mL to decrease bulk in the bladder.
b. deflate the balloon and then reinflate to ensure that the catheter is patent.
c. explain that this feeling is normal and that he should not try to urinate around the catheter.
d. stop the irrigation, assess the patient's vital signs, and

notify the HCP of possible obstruction.

2. Which factors would place a patient at a higher risk for prostate cancer *(select all that apply)*?
   a. Older than 65 years
   b. Asian or Native American
   c. Long-term use of an indwelling urethral catheter
   d. Father diagnosed and treated for early-stage prostate cancer
   e. Previous history of undescended testicle and testicular cancer

3. A patient scheduled for a radical prostatectomy for prostate cancer expresses the fear that he will have erectile dysfunction. In responding to this patient, the nurse should keep in mind that
   a. PD5 inhibitors are not recommended in prostatectomy patients.
   b. erectile dysfunction can occur even with a nerve-sparing procedure.
   c. the most common complication of this surgery is bowel incontinence.
   d. the provider will place a penile implant during surgery to treat any dysfunction.

4. The nurse explains to the patient with chronic bacterial prostatitis who is undergoing antibiotic therapy that *(select all that apply)*
   a. all patients require hospitalization.
   b. pain will lessen once treatment has ended.
   c. the course of treatment is generally 1 to 2 weeks.

d. long-term therapy may be needed in immunocompromised patient.

e. if the condition is not treated appropriately, he is at risk for prostate cancer.

5. In assessing a patient for testicular cancer, the nurse understands that the manifestations of this disease often include

a. urinary frequency.

b. painless mass in the scrotal area.

c. erectile dysfunction with retrograde ejaculation.

d. rapid onset of dysuria with scrotal swelling and fever.

6. The nurse should explain to the patient who has erectile dysfunction (ED) that *(select all that apply)*

a. the most common cause is benign prostatic hypertrophy.

b. ED may be due to medications or conditions such as diabetes.

c. only men who are 65 years or older benefit from PDE5 inhibitors.

d. there are medications and devices that can be used to help with erections.

e. this condition is primarily due to anxiety and best treated with psychotherapy.

7. To decrease the patient's discomfort related to discussing his reproductive organs, the nurse should

a. relate his sexual concerns to his sexual partner.

b. arrange to have male nurses care for the patient.

c. give him written material and ask if he has questions.

d. maintain a nonjudgmental attitude toward his sexual practices.

1. c, 2. a, d, 3. b, 4. b, d, 5. b, 6. b, d, 7. d

LEARNING OUTCOMES

1. Distinguish between the functions of neurons and glial cells.
2. Explain the anatomic location and functions of the cerebrum, brainstem, cerebellum, spinal cord, peripheral nerves, and cerebrospinal fluid.
3. Identify the major arteries supplying the brain.
4. Describe the functions of the 12 cranial nerves.
5. Compare the functions of the 2 divisions of the autonomic nervous system.
6. Link the age-related changes in the neurologic system to the differences in assessment findings.
7. Obtain significant subjective and objective data related to the nervous system from a patient.
8. Perform a physical assessment of the nervous system using the appropriate techniques.
9. Distinguish normal from abnormal findings of a physical assessment of the nervous system.
10. Describe the purpose, significance of results, and nursing

responsibilities related to diagnostic studies of the nervous system.

Conceptual Focus

Cognition
Functional Ability
Intracranial Regulation
Sensory Perception

The nervous system is one of the most complex systems. It controls all the body's activities. Having a general understanding of the nervous system is critical to your being able to analyze and interpret clinical findings. This chapter reviews the structures and functions, assessment, and diagnostic studies of the nervous system.

Structures and Functions of Nervous System

The nervous system is responsible for the control and integration of the body's many activities. It is divided into the central nervous system and peripheral nervous system. The **central nervous system (CNS)** consists of the brain, spinal cord, and cranial nerves I and II. The **peripheral nervous system (PNS)** consists of cranial nerves III to XII, spinal nerves, and peripheral components of the autonomic nervous system (ANS).

Cells of Nervous System

The nervous system is made up of 2 types of cells: neurons and supportive glial cells.

Neurons

Neurons are the primary functional unit of the nervous system. Although neurons come in many shapes and sizes, they share 3 characteristics: (1) *excitability,* or the ability to generate a nerve impulse; (2) *conductivity,* or the ability to transmit an impulse; and (3) *influence,* or the ability to influence other neurons, muscle cells, or glandular cells.

A typical neuron consists of a cell body, multiple dendrites, and an axon (Fig. 55.1). The *cell body* contains the nucleus and cytoplasm. It is the metabolic center of the neuron. *Dendrites* are short processes extending from the cell body. They receive impulses or signals from other neurons and conduct them toward the cell body. The *axon* projects varying distances from the cell body. The axon carries nerve impulses to other neurons or to end organs, such as smooth and striated muscles and glands.

FIG. 55.1 Structural features of neurons: dendrites, cell body, and axons.
Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Many axons in the CNS and PNS are covered by a *myelin sheath,* a white, lipid protein substance that acts as an insulator for the conduction of impulses. Axons may be myelinated or unmyelinated, as in the case of smaller fibers.

Glial Cells

Glial cells (glia or neuroglia) provide support, nourishment, and protection to neurons. Glial cells make up about half of the brain and spinal cord mass. Glial cells are divided into microglia and macroglia. *Microglia,* specialized macrophages capable of phagocytosis, protect the neurons. These cells are mobile within the brain and multiply when the brain is damaged.

Macroglial cells include astrocytes, oligodendrocytes, and ependymal cells. *Astrocytes* are found mainly in gray matter. They provide structural support to neurons. Their delicate processes form the *blood-brain barrier* with the endothelium of the blood vessels. They also play a role in *synaptic transmission* (conduction of impulses between neurons). When the brain is injured, astrocytes act as phagocytes for cleaning up neuronal debris. They help restore the neurochemical milieu and provide support for repair. Proliferation of astrocytes contributes to the formation of scar tissue *(gliosis)* in the CNS.

Oligodendrocytes are specialized cells that produce the myelin sheath of nerve fibers in the CNS. They are found mainly in the white matter of the CNS. *Ependymal cells* line the brain ventricles and aid in the secretion of cerebrospinal fluid (CSF).

Neuroglia are mitotic and can replicate. In general, when neurons are destroyed, the tissue is replaced by the proliferation of neuroglial cells. Most primary CNS tumors involve glial cells. Primary cancers involving neurons are rare.

Nerve Regeneration

If the axon of the nerve cell is damaged, the cell tries to repair itself. Damaged nerve cells try to grow back to their original destinations by sprouting many branches from the damaged ends of their axons. Axons in the CNS are generally less successful than peripheral axons in regeneration.[1]

Schwann cells myelinate the nerve fibers in the PNS. Injured nerve fibers in the PNS can regenerate by growing within the protective myelin sheath of the Schwann cells if the cell body is intact and the environment is optimal.[2] The final result of nerve regeneration depends on the number of axon sprouts that join with the appropriate Schwann cell columns and reinnervate appropriate end organs.

Neurons have long been thought to be nonmitotic. That is, after being damaged, neurons could not be replaced. Recent research shows a subset of glial cells (astrocytes) proliferate after certain injuries in the CNS, and neurogenesis may occur from stem cells.[3] These findings support the expectation that the patient will have a certain amount of recovery after injury involving the neurons.

Nerve Impulse

The purpose of a neuron is to initiate, receive, and process messages about events both within and outside the body. The initiation of a neuronal message *(nerve impulse)* involves the generation of an action potential. A series of action potentials travel along the axon. When the impulse reaches the end of the nerve fiber, a chemical interaction involving neurotransmitters transmits the impulse across the junction *(synapse)* between nerve cells by. This chemical interaction generates another set of action potentials in the next neuron. These events are repeated until the nerve impulse reaches its destination.

Because of its insulating capacity, myelination of nerve axons speeds the conduction of an action potential. Many peripheral nerve axons have *nodes of Ranvier* (gaps in the myelin sheath) that allow an action potential to travel much faster by jumping from node to node. We call this *saltatory* (hopping) *conduction*. In an unmyelinated fiber,

conduction is slower. The wave of depolarization travels the entire length of the axon, with each part of the membrane becoming depolarized in turn.

Synapse

A **synapse** is the structural and functional junction between 2 neurons. It is where the nerve impulse is transmitted from 1 neuron to another. The nerve impulse also can be transmitted from neurons to glands or muscles. The essential structures of synaptic transmission are a presynaptic terminal, synaptic cleft, and receptor site on the postsynaptic cell (Fig. 55.2).

Neurotransmitters

Neurotransmitters are chemicals that affect the transmission of impulses across the synaptic cleft. *Excitatory neurotransmitters* (e.g., epinephrine, norepinephrine, glutamate) activate postsynaptic receptors that increase the chance that an action potential will be generated. *Inhibitory neurotransmitters* (e.g., serotonin, γ-aminobutyric acid [GABA], dopamine) activate postsynaptic receptors to decrease the chance that an action potential will be generated. For example, endorphins block pain transmission while substance P makes nerves more sensitive to pain.

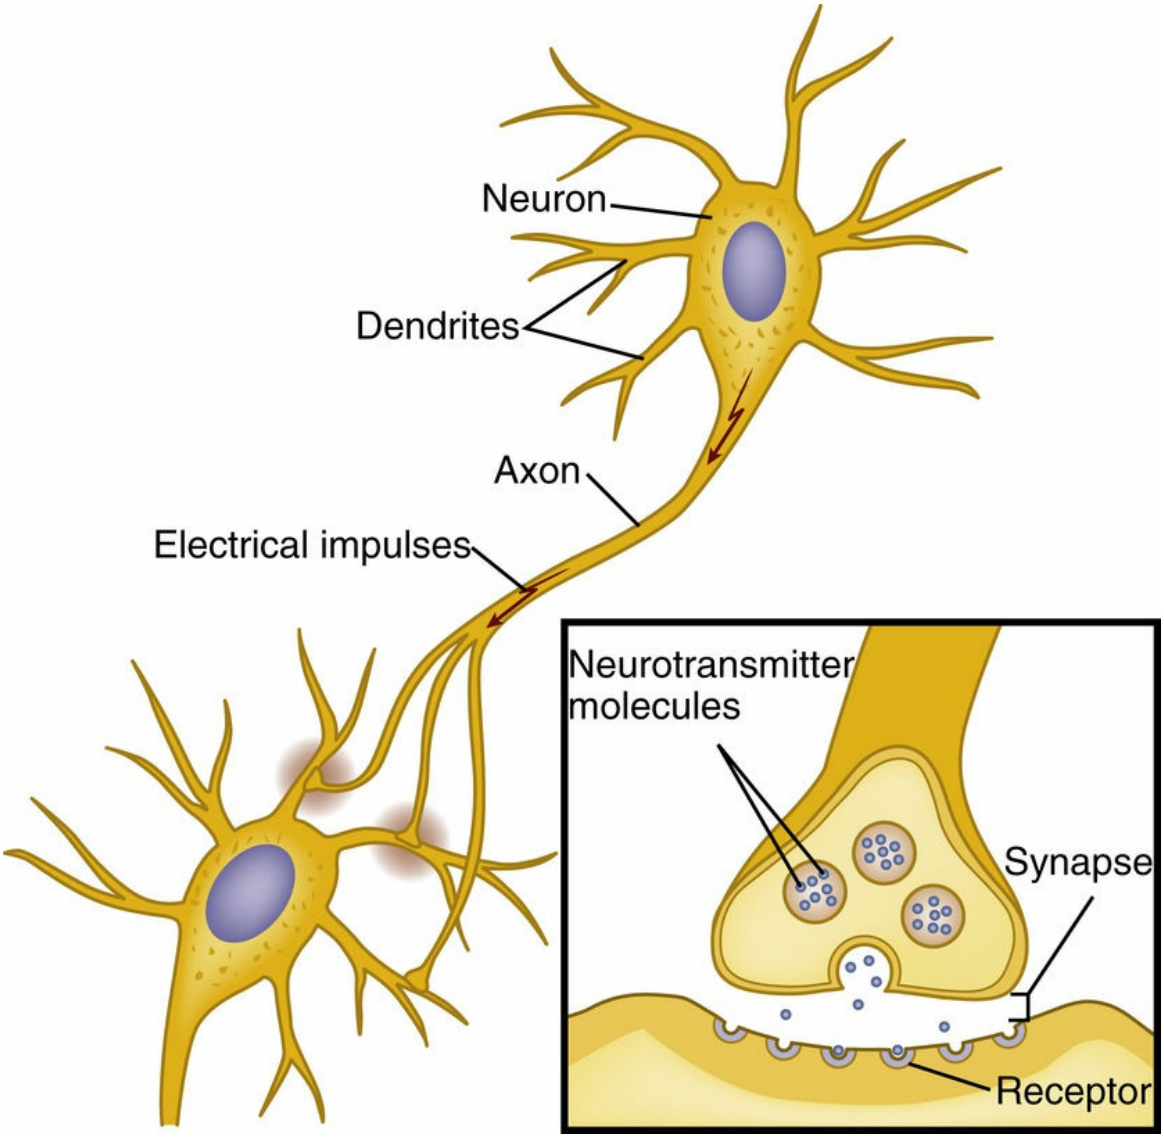

FIG. 55.2 Impulse generation between neurons. Synapse shown with neurotransmitters and receptors.

In general, the net effect (excitatory or inhibitory) depends on the number of presynaptic neurons releasing neurotransmitters on the postsynaptic cell. A presynaptic cell that releases an excitatory neurotransmitter does not always cause the postsynaptic cell to depolarize enough to generate an action potential.

When many presynaptic cells release excitatory neurotransmitters on a single neuron, the sum of their input is enough to generate an action potential. Neurotransmitters continue to combine with the receptor sites at the postsynaptic membrane until they are inactivated

by enzymes, are taken up by the presynaptic endings, or diffuse away from the synaptic region. Drugs and toxins can affect neurotransmitters by changing their function or blocking their attachment to receptor sites on the postsynaptic membrane. We can use cerebral microdialysis to measure neurotransmitter levels in the cerebral cortex (see Chapter 56).

Central Nervous System

The components of the CNS include the cerebrum (cerebral hemispheres), brainstem, cerebellum, and spinal cord.

Spinal Cord

The *spinal cord* is continuous with the brainstem and exits from the cranial cavity through the foramen magnum. A cross section of the spinal cord reveals gray matter that is centrally located in an H shape and surrounded by white matter. The gray matter contains the cell bodies of voluntary motor neurons, preganglionic autonomic motor neurons, and association neurons (interneurons). The white matter contains the axons of the ascending sensory and descending motor fibers. The myelin surrounding these fibers gives them their white appearance. The spinal pathways or tracts are named for the point of origin and the point of destination (e.g., spinocerebellar tract [ascending], corticospinal tract [descending]).

Ascending Tracts

In general, the ascending tracts carry specific sensory information to higher levels of the CNS. This information comes from special sensory receptors in the skin, muscles and joints, viscera, and blood vessels and enters the spinal cord by way of the dorsal roots of the spinal nerves. The ascending tracts are organized by sensory modality and anatomy. The fasciculus gracilis and the fasciculus cuneatus (often called the *dorsal* or *posterior columns*) carry information about touch, deep pressure, vibration, position sense, and kinesthesia (appreciation of movement, weight, and body parts). The *spinocerebellar tracts* carry

information about muscle tension and body position to the cerebellum for coordination of movement. The *spinothalamic tracts* carry pain and temperature sensations.

Other ascending tracts may also carry sensory modalities. The signs and symptoms of various neurologic diseases suggest there are additional pathways for touch, position sense, and vibration.

Descending Tracts

Descending tracts carry impulses that are responsible for muscle movement. Among the most important descending tracts are the corticobulbar and corticospinal tracts, collectively termed the *pyramidal tract*. These tracts carry voluntary impulses from the cerebral cortex to the cranial and peripheral nerves. Another group of descending motor tracts carries impulses from the extrapyramidal system (all motor systems except the pyramidal) concerned with voluntary movement. It includes pathways originating in the brainstem, basal ganglia, and cerebellum. The motor output exits the spinal cord by way of the ventral roots of the spinal nerves.

Reflex Arc

A **reflex** is an involuntary response to stimuli. In the spinal cord, reflex arcs play an important role in maintaining muscle tone, which is essential for body posture. The components of a monosynaptic reflex arc (Fig. 55.3) are a receptor organ, afferent neuron, effector neuron, and effector organ (e.g., skeletal muscle). The afferent neuron synapses with the efferent neurons in the gray matter of the spinal cord. More complex reflex arcs have other neurons (interneurons) in addition to the afferent neuron influencing the effector neuron.

Lower and Upper Motor Neurons

Upper motor neurons (UMNs) originate in the cerebral cortex and project downward. The corticobulbar tract ends in the brainstem, and the corticospinal tract descends into the spinal cord. These neurons influence skeletal muscle movement. UMN lesions generally cause

weakness or paralysis, disuse atrophy, hyperreflexia, and increased muscle tone (spasticity).

Lower motor neurons (LMNs) are the final common pathway through which descending motor tracts influence skeletal muscle. The cell bodies of LMNs, which send axons to innervate the skeletal muscles of the arms, trunk, and legs, are found in the anterior horn of the corresponding segments of the spinal cord (e.g., cervical segments contain LMNs for the arms). LMNs for skeletal muscles of the eyes, face, mouth, and throat are found in the corresponding segments of the brainstem. These cell bodies and their axons make up the somatic motor components of the cranial nerves. LMN lesions generally cause weakness or paralysis, denervation atrophy, hyporeflexia or areflexia, and decreased muscle tone (flaccidity).

Brain

The *brain* has 3 major intracranial components: cerebrum, brainstem, and cerebellum.

Cerebrum

The *cerebrum* is composed of the right and left cerebral hemispheres. It is divided into 4 lobes: frontal, temporal, parietal, and occipital (Fig. 55.4). The functions of the cerebrum are multiple and complex (Table 55.1). The *frontal lobe* controls higher cognitive function, memory retention, voluntary eye movements, voluntary motor movement, and motor functions involved in speech production *(Broca's area).* The *temporal lobe* integrates somatic, visual, and auditory data and contains *Wernicke's receptive speech area*. (Language and potential functional deficits are described with strokes in Chapter 57 [see Table 57.4]).

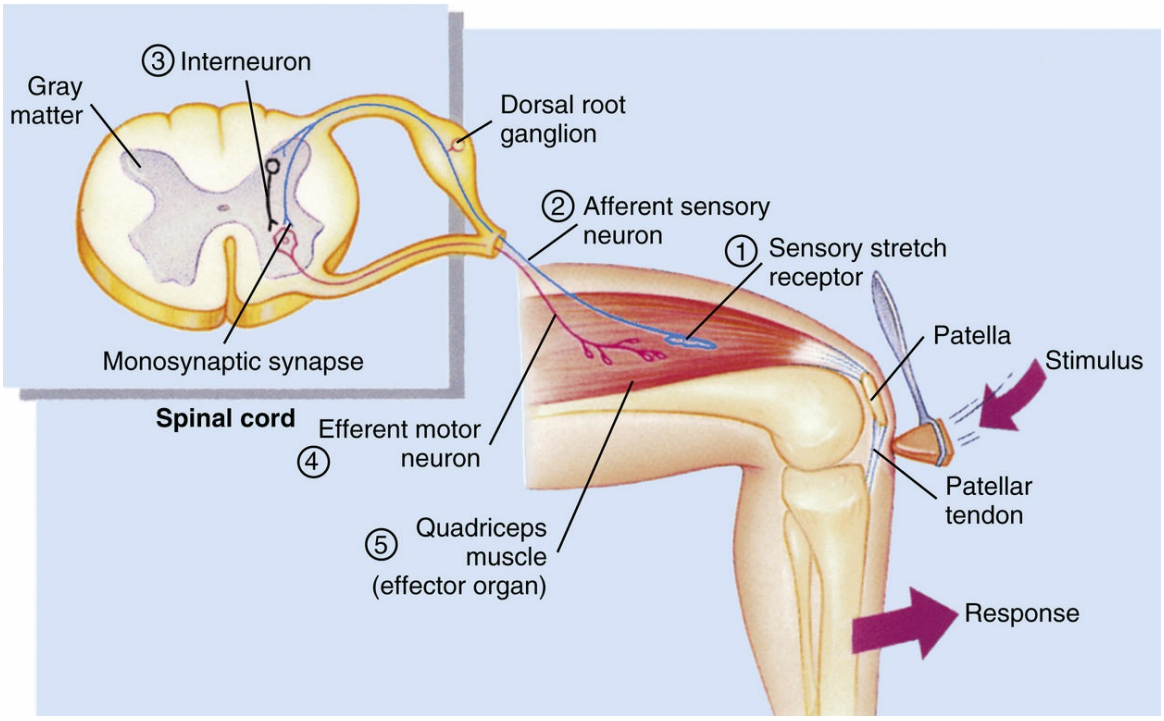

FIG. 55.3 Basic diagram of the patellar "knee jerk" reflex arc, including the *(1)* sensory stretch receptor, *(2)* afferent sensory neuron, *(3)* interneuron, *(4)* efferent motor neuron, and *(5)* quadriceps muscle (effector organ).
Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 6, St Louis, 2007, Mosby.

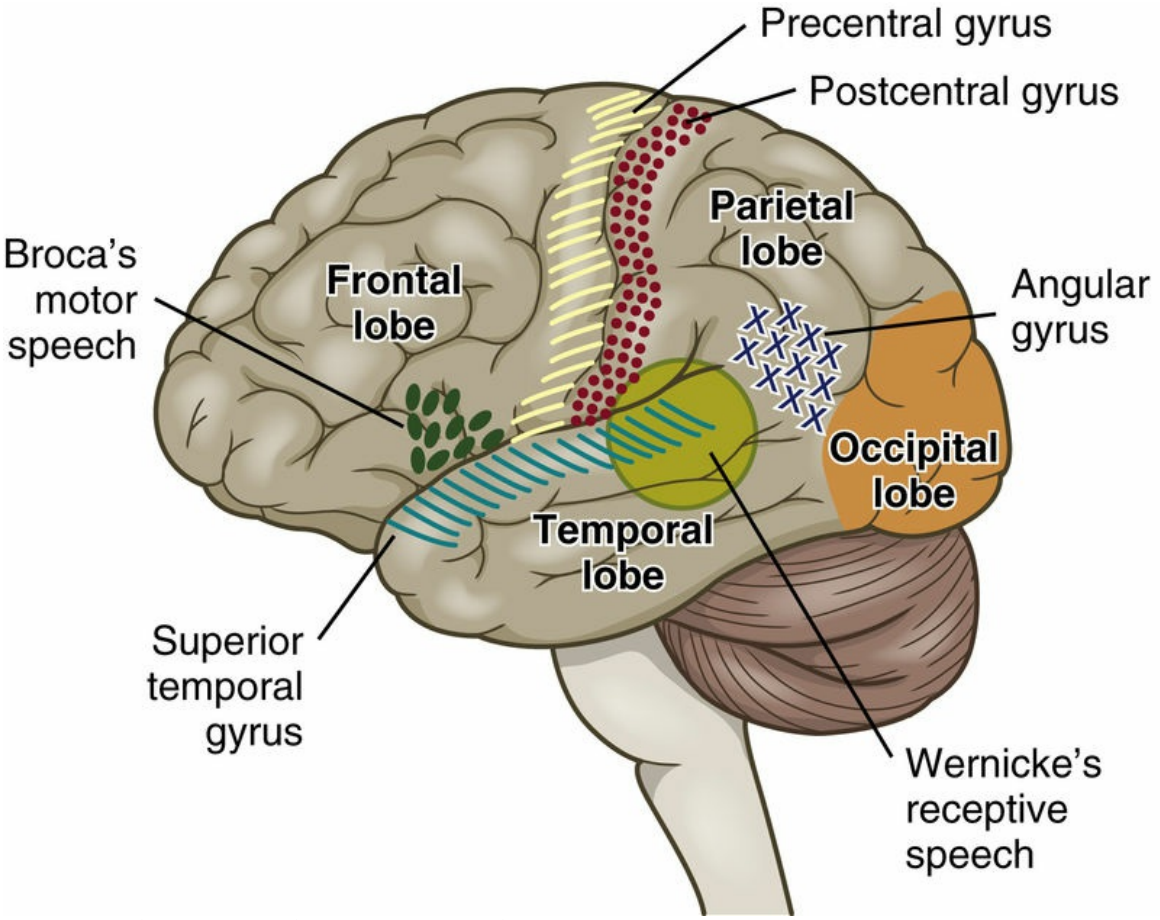

FIG. 55.4 Left hemisphere of cerebrum, lateral surface, showing major lobes and areas of the brain.

The *parietal lobe* interprets spatial information and contains the sensory cortex. Processing of sight takes place in the *occipital lobe*.

The division of the cerebrum into lobes is useful to delineate portions of the neocortex (gray matter), which makes up the outer layer of the cerebral hemispheres. Neurons in specific parts of the neocortex are essential for various highly complex and sophisticated functions, such as language, memory, and appreciation of visual-spatial relationships.

The basal ganglia, thalamus, hypothalamus, and limbic system are also in the cerebrum. The *basal ganglia* are a group of structures found centrally in the cerebrum and midbrain. Most of them are on both sides of the thalamus. The function of the basal ganglia includes the initiation, execution, and completion of voluntary movements, learning, emotional response, and automatic movements associated

with skeletal muscle activity (e.g., swallowing saliva, blinking, swinging the arms while walking).

The *thalamus* lies directly above the brainstem (Fig. 55.5). It is the major relay center for sensory input from the body, face, retina, and cochlear and taste receptors. Motor relay nuclei in the thalamus connect the cerebellum and basal ganglia to the frontal cortex.

The *hypothalamus* is just below the thalamus and slightly in front of the midbrain. It exerts a direct influence on release of hormones from the anterior pituitary gland. It has a rich capillary connection to the pituitary gland to aid in the transport of hormones. These hormones include thyroid-stimulating hormone, growth hormone, luteinizing hormone, and prolactin-releasing hormone, which play a role in regulating reproductive function. In contrast, the supraoptic and paraventricular neurons travel directly through the pituitary stalk to the posterior pituitary, where they release vasopressin and oxytocin. The hypothalamus contains the satiety center that regulates appetite. With input from the limbic system, it also regulates body temperature, water balance (through influence on vasopressin secretion), circadian rhythm, and expression of emotion. The *limbic system* is found near the inner surfaces of the cerebral hemispheres. It is concerned with emotion, aggression, feeding behavior, and sexual response.

Brainstem

The *brainstem* includes the midbrain, pons, and medulla (Fig. 55.5). Ascending and descending fibers to and from the cerebrum and cerebellum pass through the brainstem. The nuclei of cranial nerves III through XII are in the brainstem. The vital centers concerned with respiratory, vasomotor, and heart function are in the medulla.

Also in the brainstem is the *reticular formation,* a diffusely arranged group of neurons and their axons that extends from the medulla to the thalamus and hypothalamus. The functions of the reticular formation include relaying sensory information, influencing excitatory and inhibitory control of spinal motor neurons, and controlling vasomotor and respiratory activity. The *reticular activating system* (RAS) is a complex system that requires communication among the brainstem,

reticular formation, and cerebral cortex. The RAS regulates arousal and sleep-wake transitions. The brainstem also contains the centers for sneezing, coughing, hiccupping, vomiting, sucking, and swallowing.

TABLE 55.1 Function of Cerebrum

Part	Location	Function
Cortical Areas		
Motor		
Primary	Precentral gyrus	Motor control and movement on opposite side of body
Supplemental	Anterior to precentral gyrus	Facilitates proximal muscle activity, including activity for stance and gait, and spontaneous movement and coordination
Sensory		
Association areas	Parietal lobe	Integrates somatic and sensory input
	Posterior temporal lobe	Integrates visual and auditory input for language comprehension
	Anterior temporal lobe	Integrates past experiences
	Anterior frontal lobe	Controls higher order processes (e.g., judgment, reasoning)
Auditory	Superior temporal gyrus	Registers auditory input
Somatic	Postcentral gyrus	Sensory response from opposite side of body
Visual	Occipital lobe	Registers visual images
Language		
Comprehension	Wernicke's area in dominant posterior temporal lobe	Integrates auditory language (understanding of spoken words)
Expression	Broca's area in dominant frontal lobe	Regulates motor speech
Basal Ganglia	Near lateral ventricles of both cerebral hemispheres	Controls and refines learned and automatic movements
Thalamus	Below and slightly posterior to basal ganglia	Relays sensory and motor input to and from cerebrum
Hypothalamus	Below and anterior to thalamus	Regulates endocrine and autonomic functions
Limbic System	Lateral to hypothalamus	Influences emotional behavior and basic drives, such as feeding and sexual behavior

Cerebellum

The *cerebellum* is in the posterior cranial fossa below the occipital lobe. It coordinates voluntary movement and maintains trunk stability and equilibrium. The cerebellum receives information from the cerebral cortex, muscles, joints, and inner ear. It influences motor activity through axonal connections to the thalamus, motor cortex, and brainstem nuclei and their descending pathways.

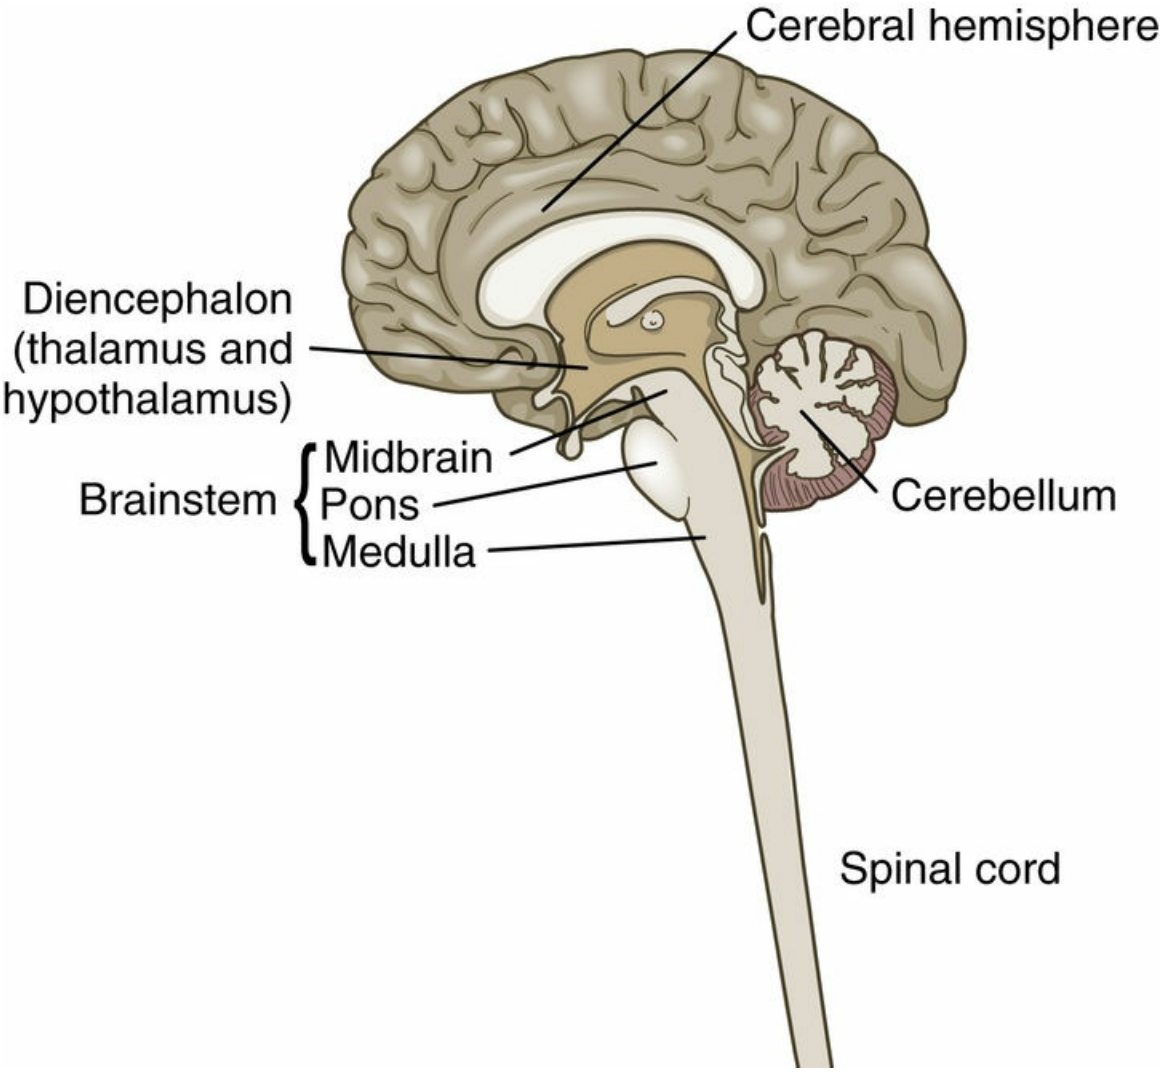

FIG. 55.5 Major divisions of the CNS.

Ventricles and Cerebrospinal Fluid

The ventricles are 4 interconnected fluid-filled cavities. The lower part of the fourth ventricle becomes the central canal in the lower part of the brainstem. The spinal canal extends centrally through the full length of the spinal cord.

Cerebrospinal fluid (CSF) is made largely in the choroid plexuses of the brain within the ventricles. It circulates within the subarachnoid space that surrounds the brain, brainstem, and spinal cord, cushioning the brain and spinal cord. CSF flows from the cranial cavity to the spinal cavity, carrying nutrients through both passive diffusion and

active transport. We make CSF at an average rate of about 500 mL/day. The ventricles and central canal are filled with an average of 150 mL at any given time. Changes in the rate of CSF production or absorption can occur, leading to a change in the volume within the ventricles and central canal. Excessive buildup of CSF results in a condition known as *hydrocephalus*.

CSF circulates throughout the ventricles and seeps into the subarachnoid space surrounding the brain and spinal cord. It is absorbed primarily through the *arachnoid villi* (tiny projections into the subarachnoid space) into the intradural venous sinuses and eventually into the venous system.

The analysis of CSF composition provides useful diagnostic information related to certain nervous system diseases. We often measure CSF pressure in patients with actual or suspected intracranial injury. Increased intracranial pressure, indicated by increased CSF pressure, can force downward (central) herniation of the brain and brainstem. The signs marking this event are part of the herniation syndrome (see Chapter 56).

Peripheral Nervous System

The PNS includes all the neuronal structures that lie outside the CNS. It consists of the spinal and cranial nerves, their associated ganglia (groupings of cell bodies), and portions of the ANS.

Spinal Nerves

The spinal cord can be seen as a series of spinal segments, each on top of another with no visible boundaries. In addition to the cell bodies, each segment has a pair of dorsal (afferent) sensory nerve fibers or roots and ventral (efferent) motor fibers or roots. They innervate a specific region of the body. This combined motor-sensory nerve is called a *spinal nerve* (Fig. 55.6). The cell bodies of the voluntary motor system are in the anterior horn of the spinal cord gray matter. The cell bodies of the autonomic (involuntary) motor system are in the anterolateral part of the spinal cord gray matter. The cell bodies of

sensory fibers are in the dorsal root ganglia just outside the spinal cord. On exiting the spinal column, each spinal nerve divides into ventral and dorsal rami, a collection of motor and sensory fibers that eventually goes to peripheral structures (e.g., skin, muscles, viscera).

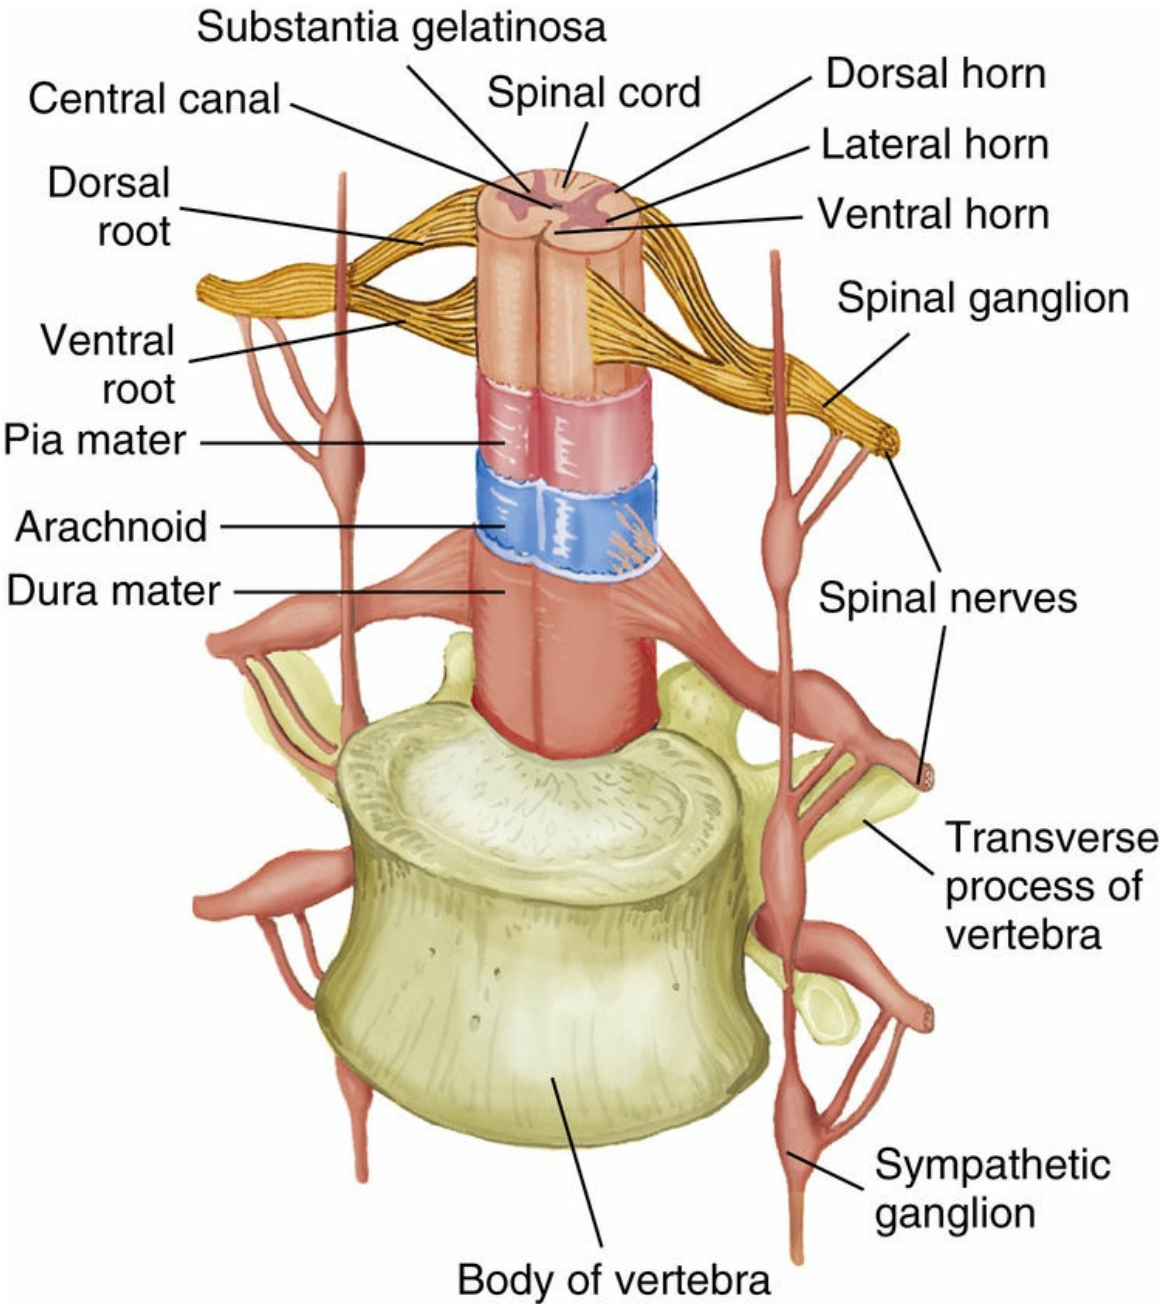

FIG. 55.6 Cross section of spinal cord showing attachments of spinal nerves and coverings of the spinal cord.

A **dermatome** is the area of skin innervated by the sensory fibers of a single dorsal root of a spinal nerve (Fig. 55.7). The dermatomes give a general picture of somatic sensory innervation by spinal segments. A *myotome* is a muscle group innervated by the primary motor neurons of a single ventral root. The dermatomes and myotomes of a given spinal segment overlap with those of adjacent segments because of the development of ascending and descending collateral branches of nerve fibers.

Cranial Nerves

The **cranial nerves (CNs)** are the 12 paired nerves composed of cell bodies with fibers that exit from the cranial cavity. Unlike the spinal nerves, which always have both afferent sensory and efferent motor fibers, some CNs are only sensory, some only motor, and some both.

Table 55.4 (later in this chapter) outlines the motor and sensory components of the CNs. Fig. 55.8 shows the position of the CNs in relation to the brain and spinal cord. Just as the cell bodies of the spinal nerves are found in specific segments of the spinal cord, cell bodies (nuclei) of the CNs found in specific segments of the brainstem. Exceptions are the nuclei of the olfactory and optic nerves. The primary cell bodies of the olfactory nerve are in the nasal epithelium. The cell bodies of the optic nerve are in the retina.

Autonomic Nervous System

The **autonomic nervous system (ANS)** is divided into the sympathetic and parasympathetic systems. The ANS governs involuntary functions of heart muscle, smooth muscle, and glands through both efferent and afferent pathways. The 2 systems function together to maintain a relatively balanced internal environment. The preganglionic cell bodies of the *sympathetic nervous system* (SNS) are found in spinal segments T1 through L2. The major neurotransmitter released by the postganglionic fibers of the SNS is norepinephrine. The neurotransmitter released by the preganglionic fibers is acetylcholine.

FIG. 55.7 Dermatomes of the body.
From Herlihy B: *The human body in health and illness,* ed 4, St Louis, 2011, Saunders.

The preganglionic cell bodies of the *parasympathetic nervous system* (PSNS) are found in the brainstem and sacral spinal segments (S2 through S4). Acetylcholine is the neurotransmitter released at both preganglionic and postganglionic nerve endings.

SNS stimulation activates the mechanisms required for the "fight-or-flight" response that occurs throughout the body (Fig. 55.9). In contrast, the PSNS is geared to act in localized and discrete regions. It conserves and restores the body's energy stores. The ANS provides dual and often reciprocal innervation to many structures. For example, the SNS increases the rate and force of heart contraction and the PSNS decreases the rate and force.

Cerebral Circulation

Knowing the distribution of the brain's major arteries is essential for understanding and evaluating the signs and symptoms of cerebrovascular disease and trauma. The brain's blood supply arises from the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation). They are shown in Fig. 55.10.

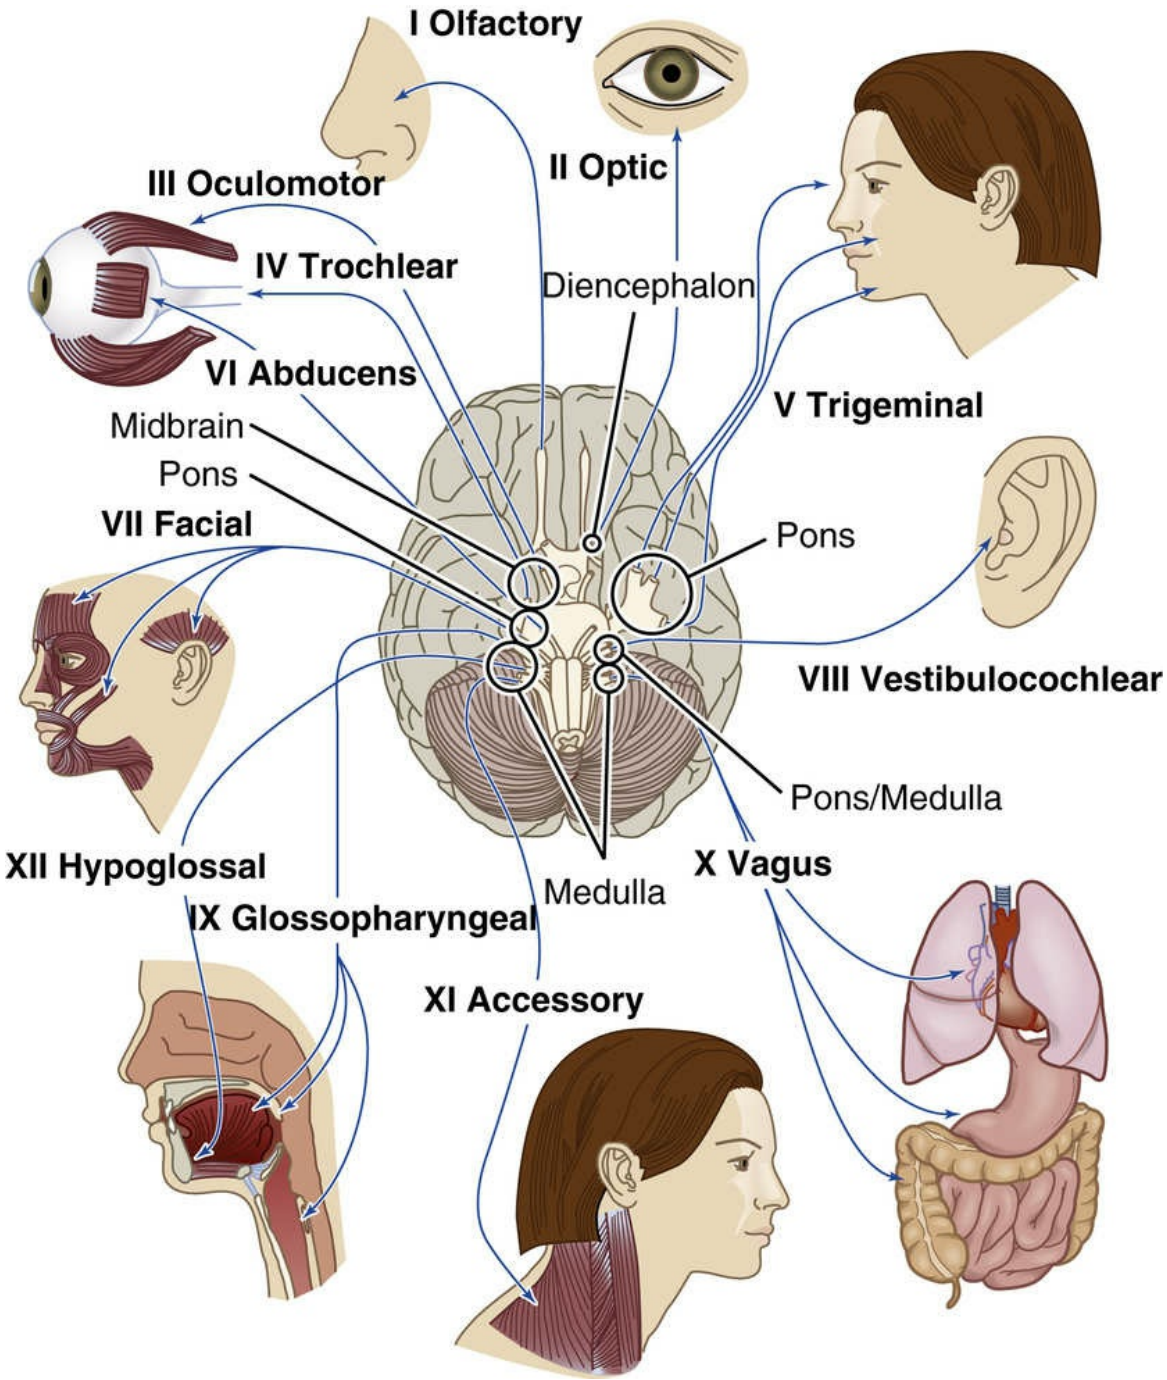

FIG. 55.8 The cranial nerves are numbered by the order in which they leave the brain.
Redrawn from McCance KL, Huether SE: Pathophysiology: *The biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.

The internal carotid arteries provide blood flow to the anterior and middle portions of the cerebrum. The vertebral arteries join to form

the basilar artery, which branches to supply the middle and lower parts of the temporal lobes, occipital lobes, cerebellum, brainstem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The *circle of Willis* is formed by communicating arteries that join the basilar and internal carotid arteries (Fig. 55.11). The circle of Willis plays a key role in cerebral blood flow. Interestingly, only 40% of us have a well-formed, complete circle of Willis. Everyone else has a degree of variation.[4]

Superior to the circle of Willis, 3 pairs of arteries supply blood to the left and right hemispheres. The anterior cerebral artery feeds the medial and anterior portions of the frontal lobes. The middle cerebral artery feeds the outer portions of the frontal, parietal, and superior temporal lobes. The posterior cerebral artery feeds the medial portions of the occipital and inferior temporal lobes. Venous blood drains from the brain through the dural sinuses, which form channels that drain into the 2 jugular veins.

Blood-Brain Barrier

The **blood-brain barrier** is a physiologic barrier between blood capillaries and brain tissue. This barrier protects the brain from harmful agents, while allowing nutrients and gases to enter. The structure of brain capillaries differs from that of other capillaries, so substances that normally pass into most tissues are prevented from entering brain tissue. Lipid-soluble compounds enter the brain easily. Water-soluble and ionized drugs enter the brain and the spinal cord slowly. Thus the blood-brain barrier affects the penetration of drugs. Only certain drugs can enter the CNS from the bloodstream.

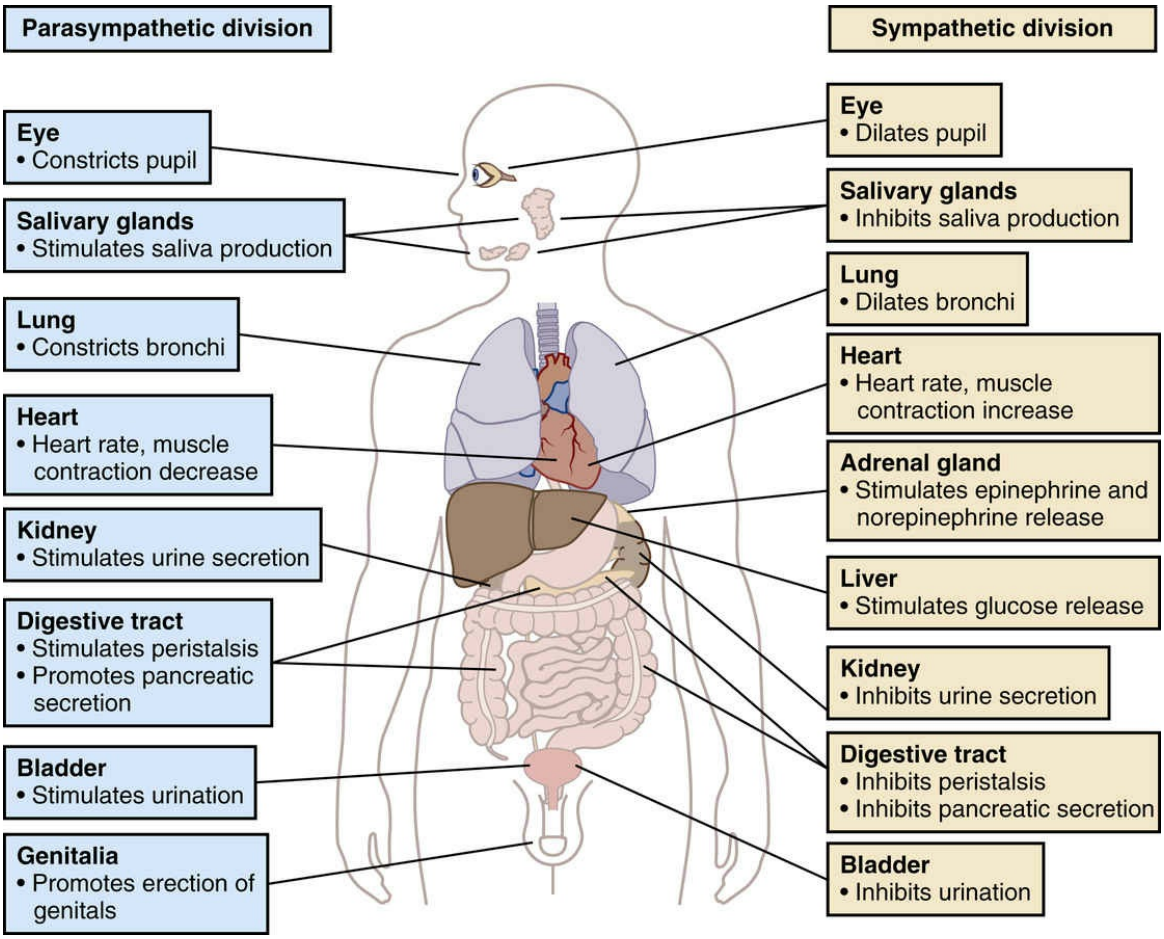

FIG. 55.9 Effects of the sympathetic and parasympathetic systems.

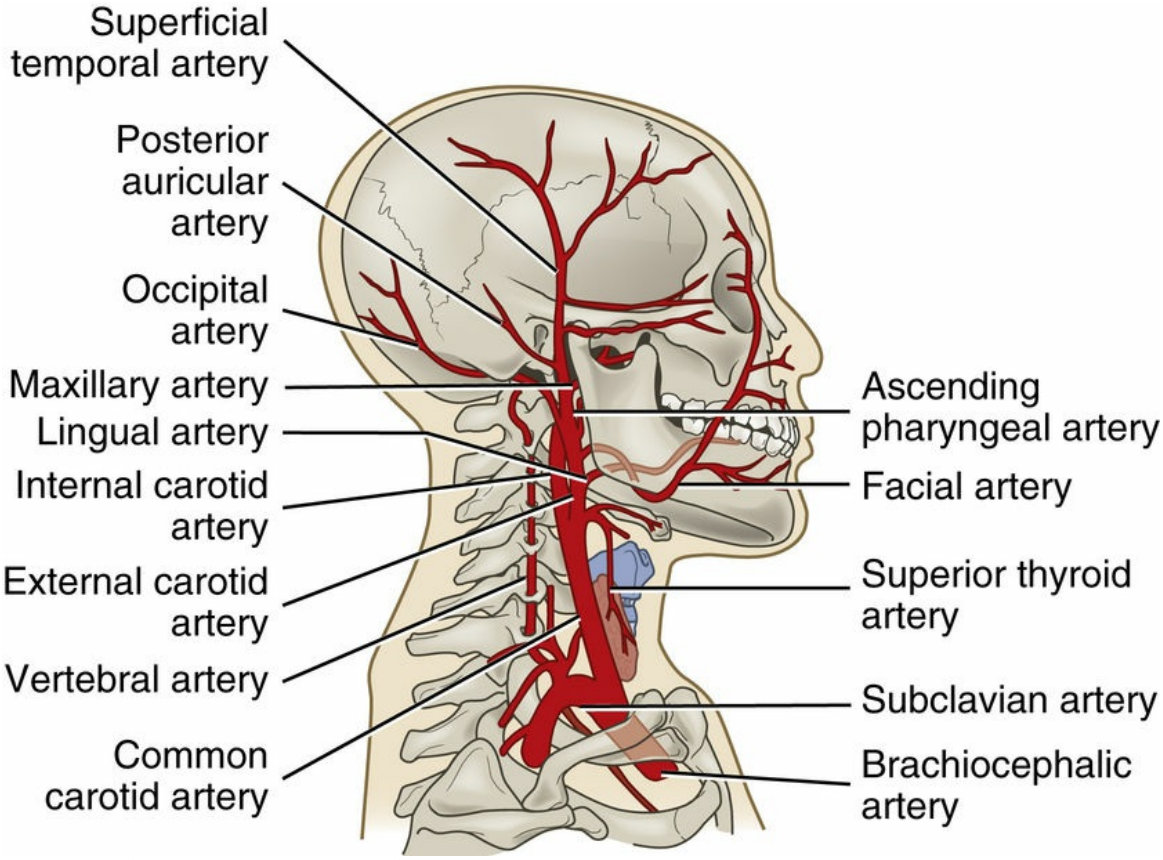

FIG. 55.10 Arteries of the head and neck. Brachiocephalic artery, right common carotid artery, right subclavian artery, and their branches. The major arteries to the head are the common carotid and vertebral arteries.

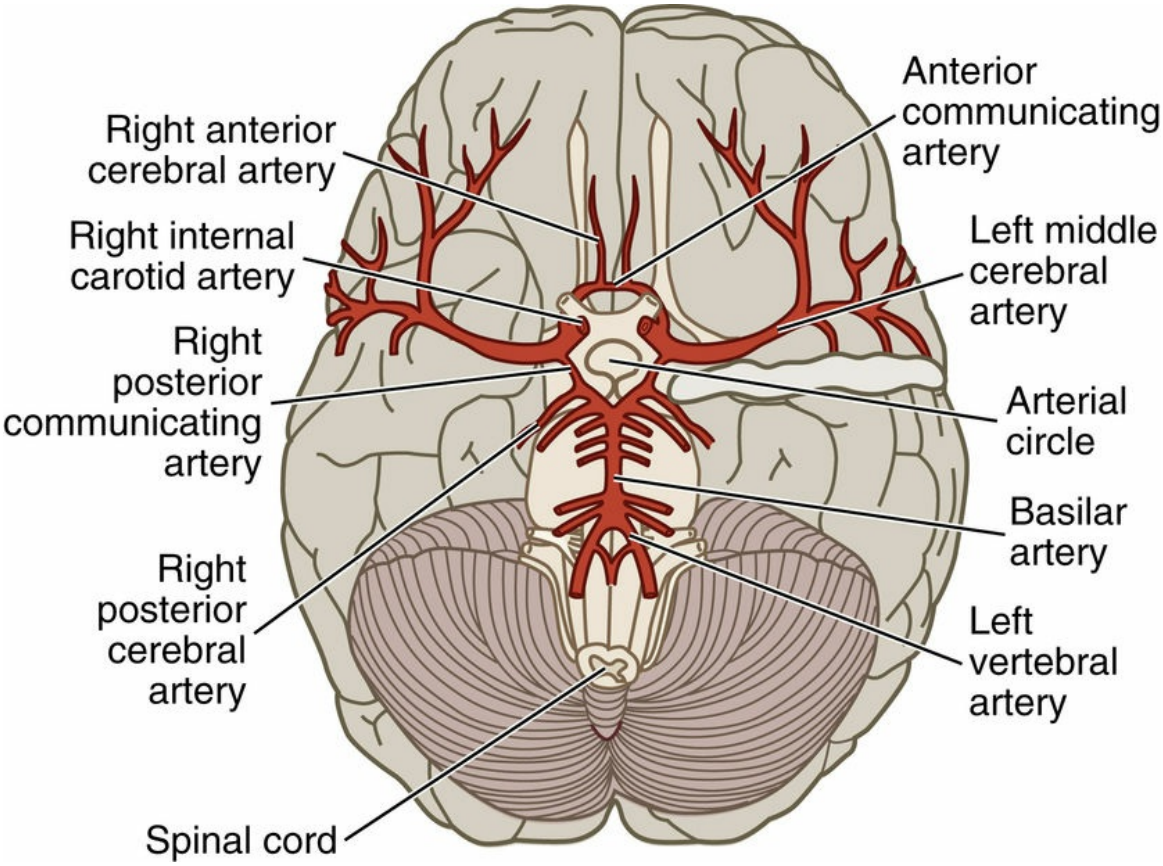

FIG. 55.11 Arteries at the base of the brain. The arteries that compose the circle of Willis are the 2 anterior cerebral arteries joined to each other by the anterior communicating cerebral artery and to the posterior cerebral arteries by the posterior communicating arteries. Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Protective Structures

Meninges

The **meninges** consist of 3 protective membranes that surround the brain and spinal cord: the dura mater, arachnoid, and pia mater (Fig. 55.12). The thick *dura mater* forms the outermost layer. The *falx cerebri* is a fold of the dura that separates the 2 cerebral hemispheres. It slows expansion of brain tissue in conditions such as a rapidly growing tumor or acute hemorrhage. The *tentorium cerebelli* is a fold of dura that separates the cerebral hemispheres from the posterior fossa (which contains the brainstem and cerebellum).

The *arachnoid* layer is a fragile, web-like membrane that lies between the dura mater and *pia mater* (the vascular innermost layer of the meninges). The area between the arachnoid layer and pia mater *(subarachnoid space)* is filled with CSF. Structures such as arteries, veins, and cranial nerves passing to and from the brain and skull must pass through the subarachnoid space. A larger subarachnoid space in the region of the third and fourth lumbar vertebrae is the area used to obtain CSF during a lumbar puncture.

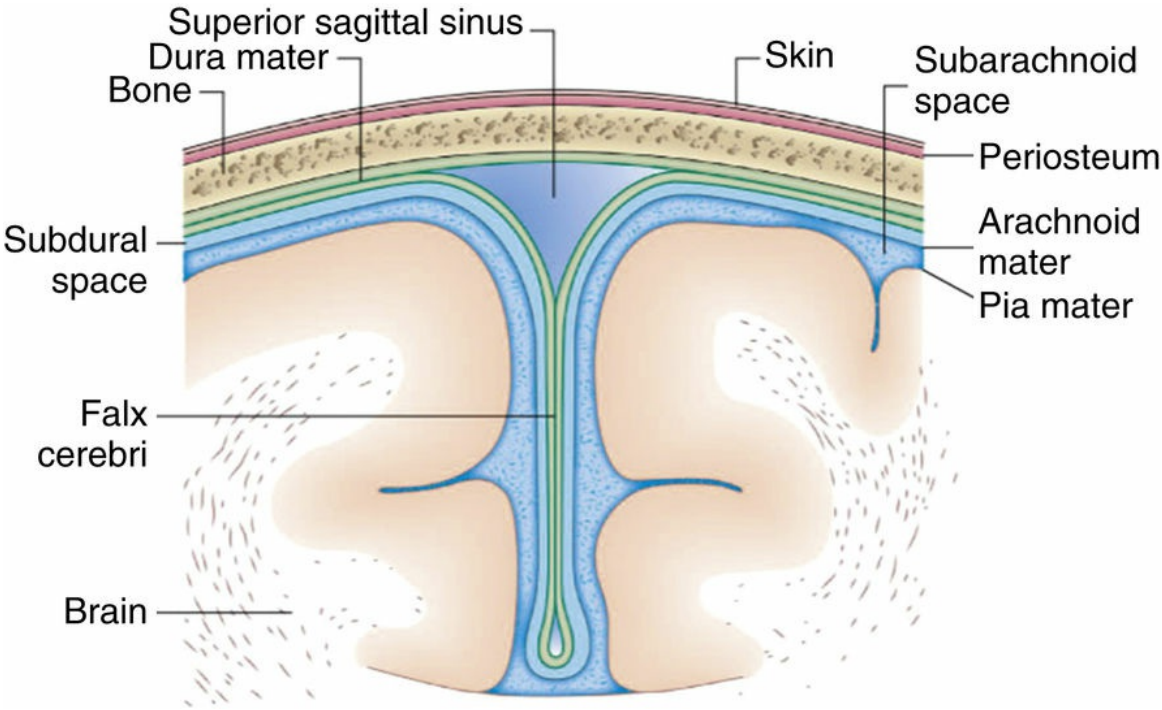

FIG. 55.12 Meninges.

Skull

The *skull* protects the brain from external trauma. It is composed of 8 cranial bones and 14 facial bones. Although the top and sides of the inside of the skull are fairly smooth, the bottom surface is uneven. It has many ridges, prominences, and foramina (holes through which blood vessels and nerves enter the intracranial vault). The largest hole is the *foramen magnum,* through which the brainstem extends to the

spinal cord. The foramen magnum is the only major space for the expansion of brain contents when increased intracranial pressure occurs.

Vertebral Column

The *vertebral column* protects the spinal cord, supports the head, and provides flexibility. The vertebral column is made up of 33 individual vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into 1), and 4 coccygeal (fused into 1). Each vertebra has a central opening through which the spinal cord passes. A series of ligaments holds the vertebrae together. Intervertebral discs occupy the spaces between vertebrae, allowing movement of the column. Fig. 55.13 shows the natural curvature of the spinal column and its relation to the trunk.

Gerontologic Considerations: Effects of Aging on Nervous System

Aging affects several parts of the nervous system. In the CNS, the gradual loss of neurons in certain areas of the brainstem, cerebellum, and cerebral cortex begins in early adulthood. With loss of neurons, the ventricles widen or enlarge, brain weight decreases, cerebral blood flow decreases, and CSF production declines.

In the PNS, degenerative changes in myelin cause a decrease in nerve conduction. Coordinated neuromuscular activity, such as maintaining BP in response to changing from a lying to a standing position, is altered with aging. As a result, older adults are more likely to have orthostatic hypotension. Similarly, coordination of neuromuscular activity to maintain body temperature becomes less efficient with aging. Older adults are less able to adapt to extremes in environmental temperature and are more vulnerable to both hypothermia and hyperthermia.

Other relevant changes associated with aging include decreases in memory, vision, hearing, taste, smell, vibration, position sense, muscle strength, and reaction time. Sensory changes, including decreases in taste and smell perception, may result in decreased dietary intake in

the older adult. Reduced hearing and vision can result in perceptual confusion.[5] Problems with balance and coordination can put the older adult at risk for falls.[6] Changes in assessment findings result from age-related changes in the nervous system (Table 55.2). Changes should not be attributed to aging without considering other underlying causes.

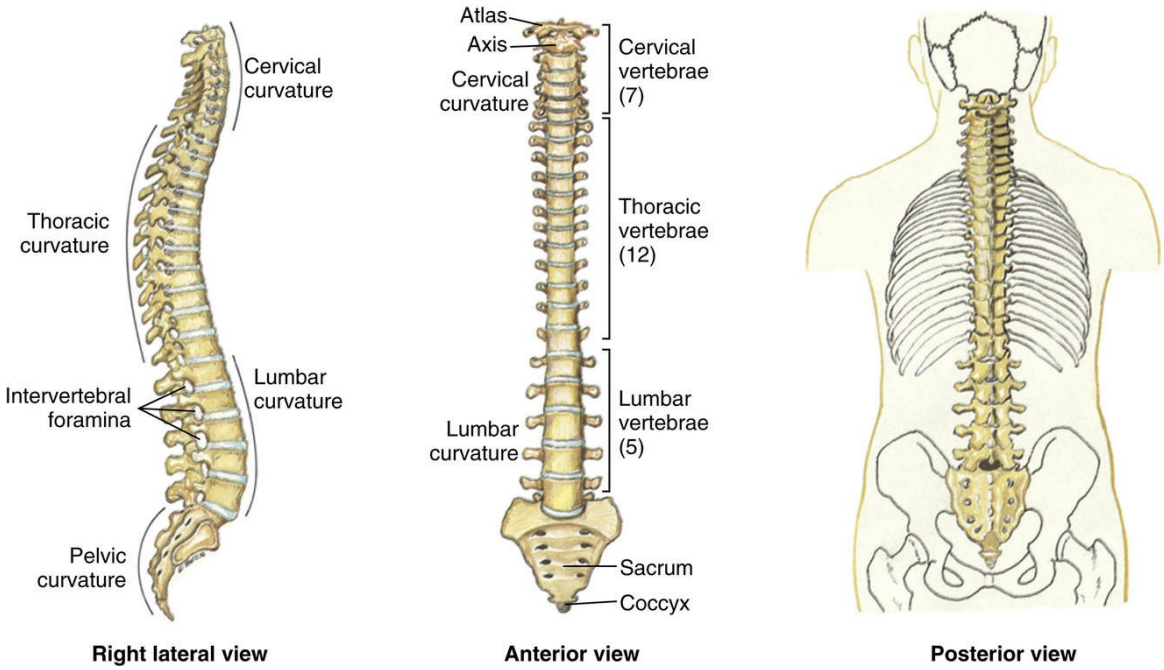

FIG. 55.13 The vertebral column (3 views).

TABLE 55.2 Gerontologic Assessment DifferencesNervous System

Component	Changes	Differences in Assessment Findings
Central Nervous System		
Brain	↓ Cerebral blood flow and metabolism Cerebral tissue atrophy and ↑ size of ventricles ↓ Efficiency of temperature-regulating mechanism ↓ Neurotransmitters, loss of neurons ↓ O_2 supply	• Altered balance, vertigo, syncope, ↑ postural hypotension • Changes in gait and ambulation • Changes in mental functioning • ↓ Kinesthetic sense • Impaired ability to adapt to environmental temperature • ↓ Proprioception, ↓ sensory input • Slowed conduction of nerve impulses, with slowed response time
Peripheral Nervous System		
Cranial and spinal nerves	Cell degeneration, death of neurons Loss of myelin and ↓ conduction time	• ↓ Reaction time in specific nerves • ↓ Speed and intensity of neuronal reflexes
Functional Divisions		
Motor	↓ Muscle bulk	• ↓ Strength and agility
Sensory*	Atrophy of taste buds Degeneration and loss of fibers in olfactory bulb Degenerative changes in nerve cells in inner ear, cerebellum, and proprioceptive pathways ↓ Electrical activity ↓ Sensory receptors	• ↓ Sense of touch, pain, and temperature • Slowing of or change in sensory reception • Signs of malnutrition, weight loss • ↓ Sense of smell • Poor ability to maintain balance, widened gait
Reflexes	↓ Deep tendon reflexes ↓ Sensory conduction velocity	• Below-average reflex score • Sluggish reflexes, slowed reaction time
Reticular Formation		
Reticular activating system	Modification of hypothalamic function ↓ Stage IV sleep	• Changes in sleep patterns
Autonomic Nervous System		
Sympathetic nervous system and parasympathetic nervous system	Morphologic features of ganglia Slowed autonomic nervous system responses	• Orthostatic hypotension, systolic hypertension

* Specific changes related to the eye are listed in Table 20.1. Specific changes related to the ear are listed in Table 21.1.

Case Study

Patient Introduction

© TatyanaGl/iStock/Thinkstock.

J.K. is a 57-yr-old white woman who went to see her HCP for severe, persistent headaches that she has had for a few weeks. She lives alone and has a very stressful job as an office manager in an engineering office. When her HCP did a neurologic examination, he noticed that she had a visual field deficit, especially in the upper left quadrant of her visual field. During the examination, J.K. had a seizure in his office. Staff called 911. She was admitted to the hospital and the on-call neurologist notified.

Discussion Questions

1. What are the possible causes of J.K.'s headaches and seizure?
2. Is her condition stable or an emergency?
3. What type of assessment would be most appropriate for J.K.:

comprehensive, focused, or emergency? What would be your priority?

4. What assessment questions will you ask her?

You will learn more about J.K. and her condition as you read through this assessment chapter.

(See p. 1290 for more information on J.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Assessment of Nervous System

Subjective Data

Important Health Information

Past Health History

When performing a neurologic examination, first determine if an emergency exists. For example, does the patient have decreasing level of consciousness? The neurologic assessment is done when an abnormality is identified during screening or can be expected based on patient history. Is the patient a reliable historian and able to give detailed information? If not, interview someone with first-hand knowledge of the patient's history and current problem. Avoid suggesting symptoms or asking leading questions.

Second, the mode of onset and course of the illness are especially important aspects of the history. Often these facts alone can reveal the nature of a neurologic disease process. Obtain all pertinent data in the history of the present illness, especially data related to the characteristics and progression of the symptoms. In some cases, the history may include birth injury (e.g., cerebral palsy from hypoxia) and/or other neurologic insults, such as a traumatic brain injury, stroke, or degenerative disease.

Growth and developmental history can be important in determining if nervous system dysfunction was present at an early age. Specifically, ask about major developmental tasks, such as

walking and talking.

Medications

Obtain a careful medication history, especially the use of sedatives, opioids, tranquilizers, and mood-elevating drugs. Many other drugs can cause neurologic side effects. Ask the patient to describe the medication regimen to determine adherence to prescribed therapies.

Surgery or Other Treatments

Ask about any surgery involving any part of the nervous system, such as head, spine, or sensory organs. If a patient had surgery, determine the date, cause, procedure, recovery, and current status. Note any history of eye surgery to determine the relevance of abnormal pupil assessment.

Functional Health Patterns

Key questions to ask a patient with a neurologic problem are outlined in Table 55.3.

Health Perception–Health Management Pattern

Ask about the patient's health practices that affect the nervous system, such as substance use, smoking, adequate nutrition, BP management, safe participation in physical and recreational activities, and use of seat belts or helmets. Ask about hospitalizations for neurologic problems.

If the patient has an existing neurologic problem, assess how it affects daily living and the ability to perform self-care. After a careful review of information, ask someone who knows the patient well whether they notice any mental or physical changes in the patient. The patient with a neurologic problem may not be aware of it or may be a poor historian.

Genetic Risk Alert

- Huntington's disease is a genetically transmitted, autosomal dominant disorder.
- Major neurologic disorders that may have a genetic basis include multiple sclerosis (MS), headaches, Parkinson's disease, and Alzheimer's disease. The presence of these problems in a family history increases the chance of similar problems occurring in the patient.
- A careful family history may determine if a neurologic problem has a genetic basis.

Nutritional-Metabolic Pattern

Neurologic problems can result in poor nutrition. Problems related to chewing, swallowing, facial nerve paralysis, and muscle coordination could make it difficult for the patient to ingest adequate nutrients. Certain vitamins, such as thiamine (B_1), niacin, and pyridoxine (B_6), are essential for the health of the CNS. Deficiencies in any of these can result in nonspecific problems, such as depression, apathy, neuritis, weakness, mental confusion, and irritability. Cobalamin (vitamin B_{12}) deficiency can occur in older adults, who may have problems with vitamin absorption from supplements as well as natural food sources, such as meat, fish, and poultry. Untreated, cobalamin deficiency can cause mental function decline. In the patient with brain injury, early nutritional support can markedly improve outcomes.[7]

Elimination Pattern

Bowel and bladder problems often are associated with neurologic problems, such as stroke, head injury, spinal cord injury, MS, and dementia. To plan appropriate interventions, determine if the bowel or bladder problem was present before or after the current neurologic event. Urinary retention and incontinence of urine and feces are the most common elimination problems associated with a neurologic

problem or its treatment. For example, nerve root compression (as occurs in cauda equina conditions) leads to a sudden onset of incontinence. Record key details, such as number of episodes, accompanying sensations or lack of sensations, and measures to control the problem.

Activity-Exercise Pattern

Many neurologic disorders can cause problems in the patient's mobility, strength, and coordination. These problems can affect the patient's usual activity and exercise patterns and can increase the risk for falls.[6] Assess the person's activities of daily living because neurologic diseases can affect the ability to perform motor tasks, which increases the risk for injury.

Sleep-Rest Pattern

Sleep pattern changes can be both a cause and a response to neurologic problems. Pain and reduced ability to change position because of muscle weakness and paralysis could interfere with sleep quality. Hallucinations resulting from dementia or drugs can interrupt sleep. Carefully assess and record the patient's sleep pattern and bedtime routines.

TABLE 55.3 Health HistoryNervous System

Health Perception–Health Management

- What are your usual daily activities?
- Do you use alcohol, tobacco, or recreational drugs?*
- What safety practices do you follow in a car? On a motorcycle? On a bicycle?
- Do you have hypertension? If so, how is it managed?
- Have you ever been hospitalized for a neurologic problem?*

- Do you take any medication to manage neurologic problems? If so, what?

Nutritional-Metabolic

- Are you able to feed yourself?
- Do you have any problems getting adequate nutrition because of chewing or swallowing difficulties, facial nerve paralysis, or poor muscle coordination?*
- Give a 24-hr dietary recall.

Elimination

- Do you have incontinence of your bowels or bladder?*
- Do you ever have problems with urinary hesitancy, urgency, retention?*
- Do you postpone your bowel movements?*

Activity-Exercise

- Describe any problems you have with usual activities and exercise because of a neurologic problem.
- Do you have weakness or lack of coordination?*
- Are you able to perform your personal hygiene needs alone?*

Sleep-Rest

- Describe your sleep pattern.
- When you have trouble sleeping, what do you do?

Cognitive-Perceptual

- Have you noticed any changes in your memory?*
- Do you have dizziness, heat or cold sensitivity, numbness, or tingling?*
- Do you have chronic pain?*
- Do you have any problem with verbal or written communication?*
- Have you noticed any changes in vision or hearing?*

Self-Perception–Self-Concept

- How do you feel about yourself, about who you are?
- Describe your general emotional pattern.

Role-Relationship

- Have you had changes in roles such as spouse, parent, or breadwinner?*

Sexuality-Reproductive

- Are you dissatisfied with your sexual function?*
- Are problems related to your sexual function causing tension in an important relationship?*
- Do you feel the need for professional counseling related to your sexual function?*

Coping–Stress Tolerance

- Describe your usual coping pattern.
- Do you think your present coping pattern is adequate to meet the stressors of your life?*
- What needs are unmet by your current support system?

Value-Belief

- Describe any culturally specific beliefs and attitudes that may influence your care.

---

* If yes, describe.

Cognitive-Perceptual Pattern

Because the nervous system controls cognition and sensory integration, many neurologic problems affect these functions. Consider culture, age, and education when assessing communication because they play a role in our interaction with others. Assess memory, language, calculation ability, problem-solving ability, insight, and judgment. Ask the patient hypothetical questions such as, "What is a reasonable price for a cup of coffee?" or "What would you do if you saw a car crash outside your house?" Consider if the patient's plans and goals match the physical and mental capabilities. Note the presence of factors affecting intellectual capacity, such as cognitive impairment, hallucinations, delusions, and dementia.

Assess a person's ability to use and understand language. Appropriateness of responses is a useful indicator of cognitive and perceptual ability. Determine the patient's understanding and ability to carry out needed treatments. Neurologic-related cognitive changes can interfere with the patient's understanding of the disease and adherence to related treatment.

Pain is common with many neurologic problems and is often the reason a patient seeks care. Carefully assess the patient's pain. (Pain

and pain assessment are discussed in Chapter 8.)

Self-Perception–Self-Concept Pattern

Neurologic diseases can drastically change a patient's control over life and create dependency on others for meeting daily needs. The patient's physical appearance and emotional control can be affected. Sensitively ask about the patient's evaluation of self-worth, perception of abilities, body image, and general emotional pattern.

Role-Relationship Pattern

Physical impairments, such as weakness and paralysis, can alter or limit participation in usual roles and activities. Cognitive changes can permanently alter a person's ability to maintain previous roles. These changes can dramatically affect the patient and caregiver. Ask the patient if a role change has occurred (e.g., spouse or breadwinner) because of neurologic problems and determine how long it has lasted. Caregivers should take part in decision making when neurologic deficits prevent the patient from decisions that will affect the role.

Sexuality-Reproductive Pattern

Assess the person's ability to take part in sexual activity. Many neurologic disorders can affect sexual response. Cerebral lesions may inhibit the desire phase or the reflex responses of the excitement phase. The hypothalamus stimulates the pituitary gland to release hormones that influence sexual desire. Brainstem and spinal cord lesions may partially or completely interrupt the desire or ability to have intercourse. Neuropathies and spinal cord lesions may prevent reflex activities of the sexual response or affect sensation and decrease desire. Despite neurologically related changes in sexual function, many persons can achieve satisfying expression of intimacy and affection.

Coping–Stress Tolerance Pattern

The physical sequelae of a neurologic problem can strain a patient's

coping ability. Often the problem is chronic, and the patient must learn new coping skills. Assess if the patient's coping skills are adequate to deal with the stress of this problem. Also assess the patient's support system.

Value-Belief Pattern

Many neurologic problems have serious, long-term, life-changing effects. Determine what these effects are because they can strain the patient's belief system. Assess if any religious or cultural beliefs could affect the treatment plan.

Case Study—cont'd

Subjective Data

© TatyanaGl/iStock/Thinkstock.

After her admission to the hospital, a subjective assessment of J.K. revealed the following information:

Past Medical History: No history of seizures, migraine, or other headache prior to the current headaches and seizure.
Medications: lisinopril 10 mg PO daily.
Health Perception–Health Management: Never smoked. Occasional social alcohol use. Reports good health other than mild hypertension.
Nutritional-Metabolic: J.K. is 5 ft, 5 in tall; weight 145 lb.
Activity-Exercise: Moderate activity. No formal exercise or participation in sports.
Cognitive-Perceptual: Says her headaches led her to get her eyes

tested. Has had only minor decrease in visual acuity.

***Coping–Stress Tolerance*:** Is depressed and fearful. She is worried that something serious is wrong. Denies dizziness, change in hearing, or memory deficits.

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. Based on these subjective assessment findings, what should be included in the physical assessment?

You will learn more about the physical examination of the neurologic system in the next section.

(See p. 1293 for more information on J.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Physical Examination

The standard neurologic examination helps determine the presence, location, and nature of nervous system disease (Fig. 55.14). The examination assesses 6 categories of function: mental status, cranial nerve function, motor function, sensory function, cerebellar function, and reflexes.[8] Develop a consistent pattern of completing the neurologic examination to remember to include each element for every patient examination.

Mental Status

Assessment of mental status (cerebral function) gives a general impression of how the patient is functioning. It involves determining complex and high-level cerebral functions governed by many areas of the cerebral cortex. Complete most of the mental status examination during your interaction with the patient. For example, assess language

and memory when asking the patient for details of the illness and significant past events. Consider the patient's age, cultural background, and level of education when evaluating mental status.

The components of the mental status examination include:

- *General appearance and behavior:* This includes level of consciousness (awake, asleep, comatose), motor activity, body posture, dress and hygiene, facial expression, and speech pattern. This assessment begins when you first see the patient. A patient who has deficits in self-care as shown by poor grooming is more likely to have other cognitive deficits.

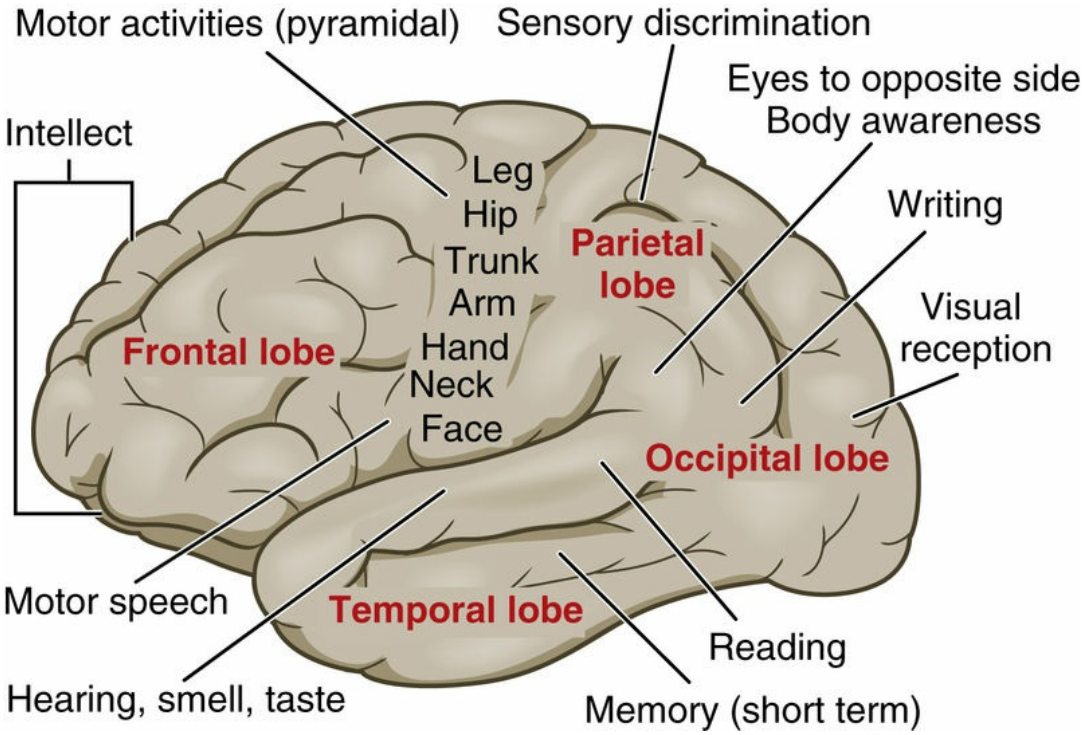

FIG. 55.14 Each area of the brain controls a particular activity.

- *Cognition:* Note orientation to time, place, person, and situation, as well as memory, general knowledge, insight, judgment, problem solving, and calculation. Common questions are "Who were the last 3 presidents?" "What do people use to cut paper?" "Can you count backward from 100

by 7s?"[8] Often a structured mental status questionnaire is used to evaluate these functions and provide baseline data for evaluating changes over time. Common tools include the Mini-Mental State Examination (MMSE) (see Table 59.10) and Montreal Cognitive Assessment (MoCA).[9] Delirium is an acute and transient disorder of cognition that can be seen at any time during a patient's illness. As discussed in Chapter 59, delirium is often an early indicator of various illnesses (see Table 59.16). The Confusion Assessment Method tool is used to assess for delirium (see Table 59.18).

- *Mood and affect:* Note any agitation, anger, depression, or euphoria, and the appropriateness of these states. Use suitable questions to reveal the patient's feelings.

Cranial Nerves

Testing each CN is an essential part of the neurologic examination (Table 55.4).

Olfactory nerve

Chronic rhinitis, sinusitis, and heavy smoking may decrease the sense of smell. Problems with the ability to smell may be associated with a tumor involving the olfactory bulb or the result of a basilar skull fracture that has damaged the olfactory fibers as they pass through the delicate cribriform plate of the skull. *Anosmia* (loss of sense of smell) is an early sign in Parkinson's disease and Alzheimer's disease.[10]

Optic nerve

Visual field defects may arise from lesions of the optic nerve, optic chiasm, or tracts that extend through the temporal, parietal, or occipital lobes. Visual field changes resulting from brain lesions include *hemianopsia* (half of the visual field is affected), *quadrantanopia* (one fourth of the visual field is affected), *bitemporal hemianopsia* (bilateral peripheral vision is affected), or monocular vision. It may be hard to test acuity if the patient does not read English or is aphasic.

Oculomotor, trochlear, and abducens nerves

Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves help move the eye, they are tested together (Table 55.4). With weakness or paralysis of an eye muscle, the eyes do not move together, and the patient has a *disconjugate gaze.* Note the presence and direction of *nystagmus* (fine, rapid jerking movements of the eyes), even though this condition most often indicates vestibulocerebellar problems.

TABLE 55.4 Cranial NervesFunction and Assessment

Nerve	Function	Assessment
IOlfactory	*Sensory:* from olfactory (smell)	Ask patient to close 1 nostril at a time and identify easily recognized odors (e.g., coffee). Any asymmetry in sense of smell is important.
IIOptic	*Sensory:* from retina of eyes (vision)	Examine each eye independently. *Visual fields:* Position yourself opposite the patient. Ask him or her to look directly at the bridge of your nose and indicate when an object (finger, pencil tip) presented from the periphery of each of the visual fields is seen (Fig. 55.15). *Visual acuity:* Ask patient to read a Snellen chart. Record the number on the lowest line the patient can read with 50% accuracy. The patient who wears glasses should wear them during testing unless they are used only for close reading. If a Snellen chart is not available, ask the patient to read newsprint for gross assessment of acuity. Record the distance from patient to newsprint needed for accurate reading.
IIIOculomotor	*Motor:* to 4 eye movement muscles and levator palpebrae muscle *Parasympathetic:* smooth muscle in eyeball	Ask the person to hold the head steady and to follow the movement of your finger, pen, or penlight only with the eyes. Hold the target back about 12 inches so that the person can focus on it comfortably. Move the target to each of the 6 positions (right and up, right, right and down, left and up, left, left and down), hold it momentarily, and then move back to center. Progress clockwise. A normal response is parallel tracking of the object with both eyes. Check for pupillary constriction and *accommodation* (pupils constricting with near vision). To test pupillary constriction, shine a light into the pupil of 1 eye; look for ipsilateral constriction of the same pupil and contralateral (consensual) constriction of the opposite eye. Note the size and shape of the pupils. The optic nerve must be intact for this reflex to occur.
IVTrochlear	*Motor:* to 1 eye movement muscle, the superior oblique muscle	See testing for CN III. Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves help move the eye, they are tested together.
VTrigeminal		
• **Ophthalmic branch**	*Sensory:* from forehead, eye, superior nasal cavity	*Sensory:* Have patient close eyes and identify light touch (cotton wisp) and pinprick in each of the 3 divisions (ophthalmic, maxillary, and mandibular) of nerve on both sides of face. *Motor:* Ask patient to clench teeth and then palpate masseter muscles just above the mandibular angle. Muscles should feel equally strong on both sides. *Corneal (blink) reflex:* Evaluates CN V and CN VII simultaneously. Sensory component (corneal sensation) is innervated by the ophthalmic division of CN V. The motor component (eye blink) is innervated by the facial nerve (CN VII). Have patient look up and away. Then from the other side, lightly touch the cornea with cotton wisp. Look for normal blink reaction of both eyes. Repeat on other side.
• **Maxillary branch**	*Sensory:* from inferior nasal cavity, face, upper teeth, mucosa of superior mouth	
• **Mandibular branch**	*Sensory:* from surfaces of jaw, lower teeth, mucosa of lower mouth, and anterior tongue *Motor:* to muscles of mastication	
VIAbducens	*Motor:* to the lateral rectus muscle of the eye (1 eye movement)	See testing for CN III. Because CN III, CN IV, and CN VI nerves help move the eye, they are tested together.
VIIFacial	*Motor:* to facial muscles of expression and cheek muscle *Sensory:* taste from anterior two thirds of tongue	Ask patient to raise eyebrows, close eyes tightly, purse lips, draw back the corners of mouth in an exaggerated smile, and frown. Note any asymmetry in the facial movements because this can indicate damage to nerve.
VIIIVestibulocochlear		
• **Vestibular branch**	*Sensory:* from equilibrium sensory organ (vestibular apparatus)	Not routinely tested unless the patient has dizziness, vertigo, unsteadiness, or auditory dysfunction.
• **Cochlear branch**	*Sensory:* from auditory sensory organ (cochlea), hearing	Have patient close eyes and indicate when they hear the rustling of your fingertips. For more precise assessment of hearing, perform the Weber and Rinne tests or use an audiometer (see Table 21.6).

Nerve	Function	Assessment
IXGlossopharyngeal	*Sensory:* from pharynx and posterior tongue, including taste *Motor:* to superior pharyngeal muscles	The glossopharyngeal and vagus nerves (CN IX and CN X) are tested together because both innervate the pharynx. To test the gag reflex, touch the sides of the posterior pharynx or soft palate with a tongue blade. If the reflex is weak or absent, the patient is in danger of aspirating food or secretions. Another test for the awake, cooperative patient is to ask the patient to say "ah," and note the bilateral symmetry of elevation of the soft palate. If a patient has an endotracheal tube, the cough reflex (elicited when the suction catheter contacts the *carina* of the respiratory tree) is a method of assessing the vagus nerve.
XVagus	*Sensory:* from much of viscera of thorax and abdomen *Motor:* to larynx and middle and inferior pharyngeal muscles *Parasympathetic:* to heart, lungs, most of digestive system	See testing for CN IX. The glossopharyngeal and vagus nerves (CN IX and CN X) are tested together because both innervate the pharynx.
XIAccessory	*Motor:* to sternocleidomastoid and trapezius muscles	Ask patient to shrug the shoulders and to turn head to either side against resistance. Sternocleidomastoid and trapezius muscles should contract smoothly. Note symmetry, atrophy, or fasciculation of muscle.
XIIHypoglossal	*Motor:* to muscles of tongue	Ask to protrude tongue, which should protrude in midline. Next ask the patient to move the tongue up and down and side to side. Finally, the patient should be able to push the tongue to either side against the resistance of a tongue blade. Note any asymmetry, atrophy, or fasciculation.

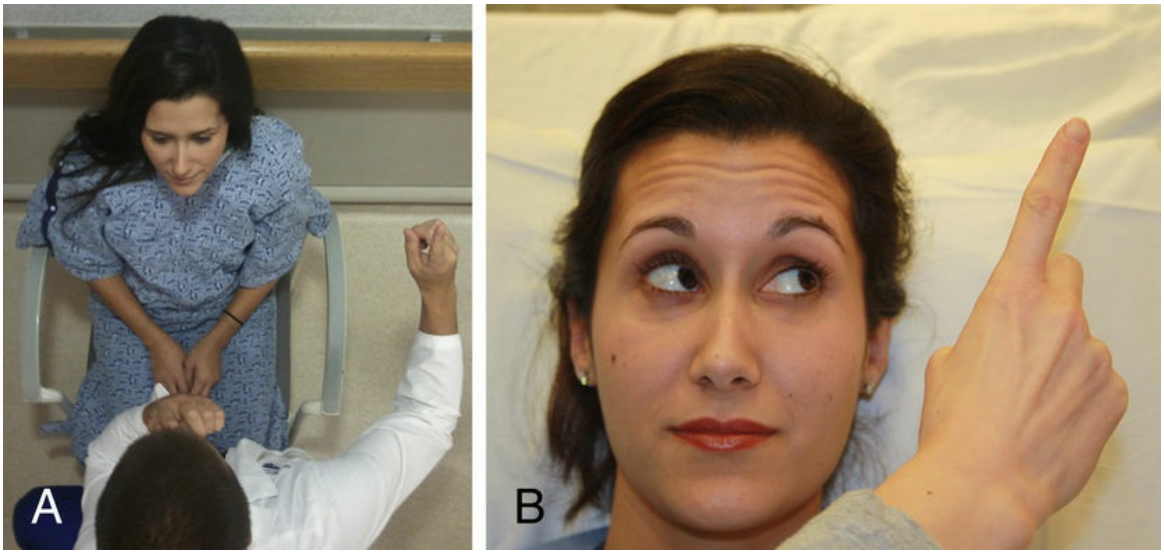

FIG. 55.15 **A,** Nurse checking visual fields. **B,** Nurse checking extraocular movement (EOM).
Courtesy DaiWai Olson, RN, PhD, CCRN, Dallas, TX.

Because the oculomotor nerve exits at the top of the brainstem at the tentorial notch, it can be compressed easily by expanding mass lesions. When this occurs, sympathetic input to the pupil is unopposed; the pupil changes shape and becomes dilated. The lack of

pupillary constriction is an early sign of central herniation (see Chapter 56).

Two abbreviations we often used to record the reaction of the pupils are *PERRL* (*P*upils are *E*qual [in size], *R*ound, and *R*eactive to *L*ight) and *PERRLA* (*P*upils are *E*qual, *R*ound, and *R*eactive to *L*ight and *A*ccommodation). The *PERRL* abbreviation is appropriate when accommodation cannot be assessed, as in an unconscious patient. Convergence and accommodation are tested by having the patient focus on the examiner's finger as it moves toward the patient's nose.

Another function of the oculomotor nerve is to keep the eyelid open. Damage to the nerve can cause *ptosis* (drooping eyelid), pupillary abnormalities, and eye muscle weakness.

Motor System

The motor system examination includes assessment of strength, tone, coordination, and symmetry of the major muscle groups. Test muscle strength by asking the patient to push and pull against the resistance of your arm as it opposes flexion and extension of the patient's muscle. Ask the patient to offer resistance at the shoulders, elbows, wrists, hips, knees, and ankles. Mild weakness of the arm is demonstrated by downward drifting of the arm or pronation of the palm *(pronator drift).* The pronator drift test is especially sensitive when the patient has a potential for vasospasm or increasing edema in 1 hemisphere of the cerebrum. Ask the patient to close the eyes and hold the arms out with palms facing up (like they are holding a large pizza). The patient should hold this position for 30 seconds. Downward drift with palm pronation indicates a problem in the opposite motor cortex. Note any weakness or asymmetry of strength between the same muscle groups of the right and left sides.

Test muscle tone by passively moving the limbs through their range of motion. You should identify a slight resistance to these movements. Abnormal tone is described as *hypotonia* (flaccidity) or *hypertonia* (spasticity). Note any involuntary movements, such as tics, tremor, *myoclonus* (spasm of muscles), *athetosis* (slow, writhing, involuntary movements of extremities), *chorea* (involuntary, purposeless, rapid

motions), and *dystonia* (impairment of muscle tone).

Test cerebellar function by assessing balance and coordination. A good screening test for both balance and muscle strength is to observe the patient's stature (posture while standing) and gait. Note the pace and rhythm of the gait. Observe for normal symmetric and oppositional arm swing. The patient's ability to ambulate helps to determine the level of nursing care needed and the risk for falling.

The finger-to-nose test (having the patient alternately touch the nose, then touch the examiner's finger) and the heel-to-shin test (having the patient stroke the heel of 1 foot up and down the shin of the opposite leg) assess coordination and cerebellar function. Reposition your finger while the patient is touching the nose so that the patient must adjust to a new distance each time your finger is touched. These movements should be performed smoothly and accurately. Other tests include asking the patient to pronate and supinate both hands rapidly and to do a shallow knee bend, first on 1 leg and then on the other. Note dysarthria or slurred speech because it is a sign of incoordination of the speech muscles.

Sensory System

In the somatic sensory examination, several modalities are tested. Each modality is carried by a specific ascending pathway in the spinal cord before it reaches the sensory cortex. As a rule, perform the examination with the patient's eyes closed and avoid providing the patient with clues. Ask "How does this feel?" rather than "Is this sharp?" In the routine neurologic examination, sensory testing of the anterior torso, posterior torso, and all extremities is sufficient. However, if a problem is identified in sensory function, the boundaries of that dysfunction should be carefully delineated along the dermatome.

Touch, pain, and temperature

Light touch is usually tested first using a cotton wisp or light pinprick. Gently touch each extremity and ask the patient to indicate when they feel the stimulus. Test pain by alternately touching the skin with the

sharp and dull end of a pin. Tell the patient to respond "sharp" or "dull." Evaluate each limb separately.

Extinction is assessed by simultaneously touching both sides of the body symmetrically. Normally, the simultaneous stimuli are both perceived (sensed). An abnormal response occurs when the patient perceives the stimulus on only 1 side. The other stimulus is *extinguished*.

Test the sensation of temperature by applying tubes of warm and cold water to the skin and asking the patient to identify the stimuli with the eyes closed. If pain sensation is intact, you do not have to assess temperature sensation because the same ascending pathways carry both sensations.

Vibration sense

Assess vibration sense by applying a vibrating tuning fork to the fingernails and bony prominences of the hands, legs, and feet. Ask the patient if the vibration or "buzz" is felt. Then ask the patient to indicate when the vibration ceases.

Position sense

Assess position sense *(proprioception)* by placing your thumb and forefinger on either side of the patient's forefinger or great toe and gently moving his or her digit up or down. Ask the patient to close the eyes and state the direction in which the digit is moved.

Another test of proprioception is the Romberg test. Ask the patient to stand with feet together and then close his or her eyes. If the patient can maintain balance with the eyes open but sways or falls with the eyes closed (i.e., a positive Romberg test), vestibulocochlear dysfunction or disease in the posterior columns of the spinal cord may be present. Be aware of patient safety during this test.

Cortical sensory functions

Several tests evaluate cortical integration of sensory perceptions (which occurs in the parietal lobes). Explain these tests to the patient before performing them, while his or her eyes are still open. Assess

two-point discrimination by placing the 2 points of a calibrated compass on the tips of the fingers and toes. The minimum recognizable separation is 4 to 5 mm in the fingertips and a greater degree of separation elsewhere. This test is important in diagnosing diseases of the sensory cortex and PNS.

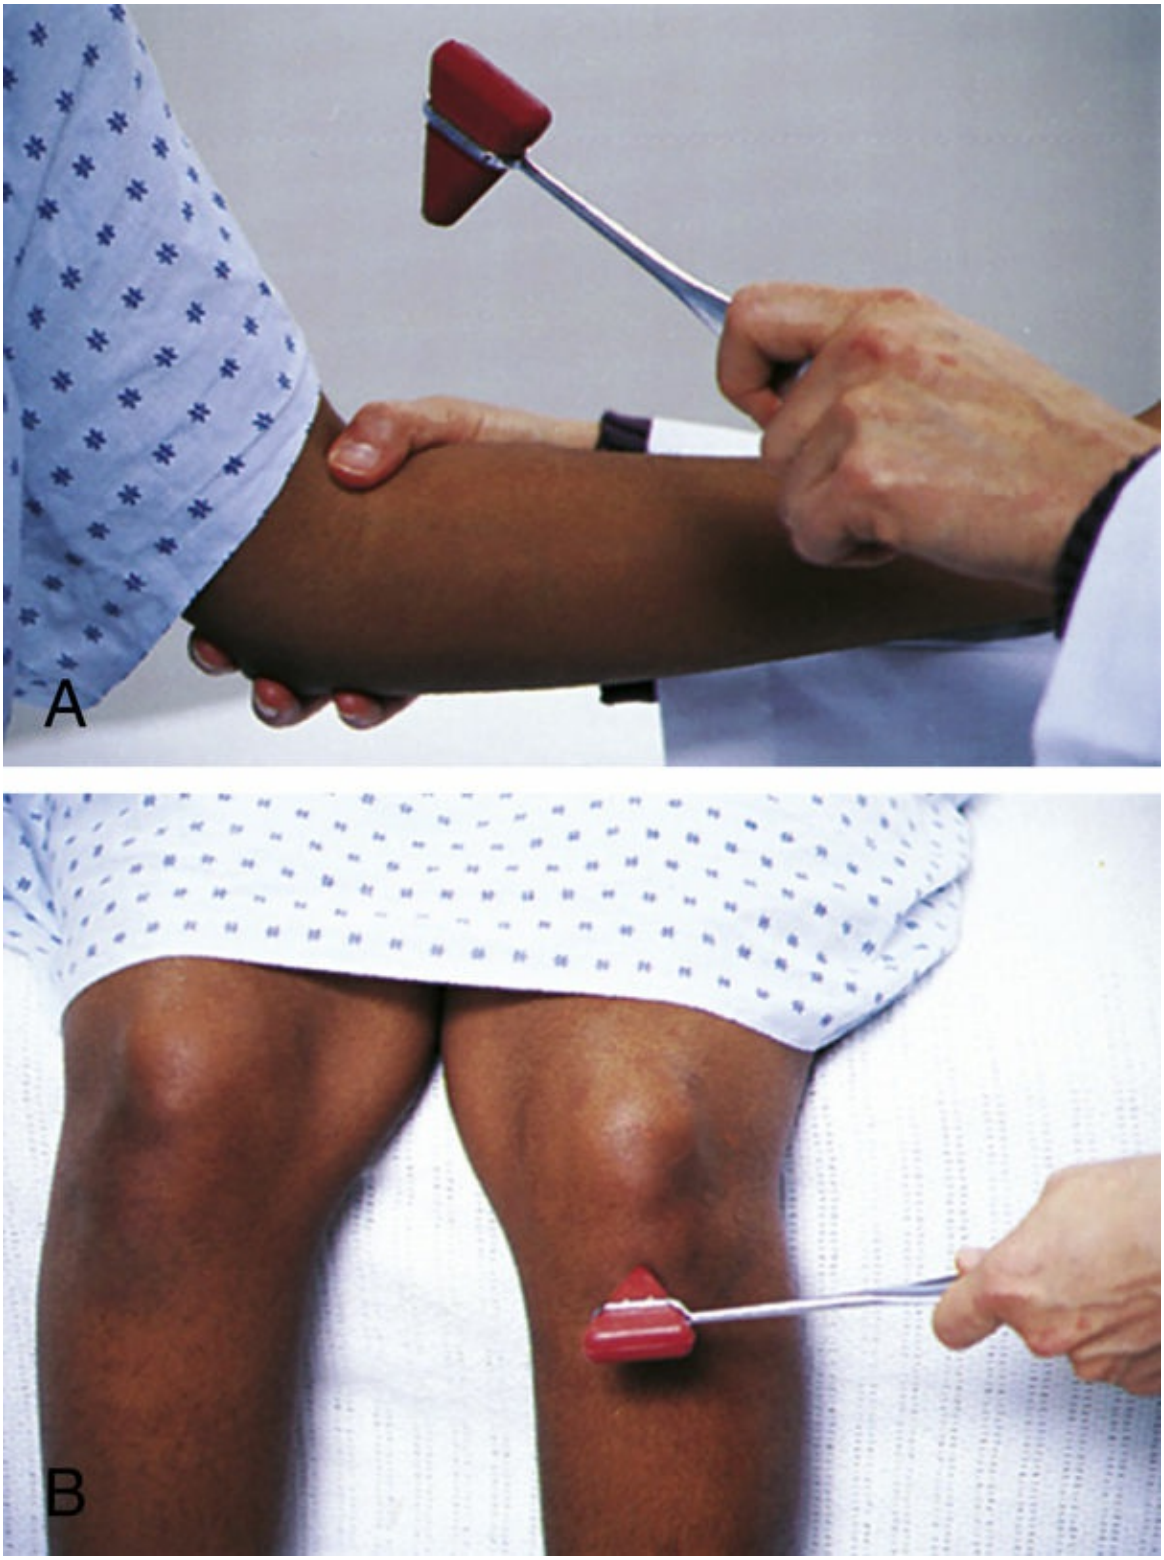

FIG. 55.16 The examiner strikes a swift blow over a stretched tendon to elicit a stretch reflex. **A,** Biceps reflex. **B,** Patellar reflex.

Test *graphesthesia* (ability to feel writing on skin) by having the patient identify numbers traced on the palm of the hands. Test *stereognosis* (ability to perceive the form and nature of objects) by having the patient close the eyes and identify the size and shape of easily recognized objects (e.g., coins, keys, safety pin) placed in the hands.

Reflexes

Tendons have receptors that are sensitive to stretch. A reflex contraction of the skeletal muscle occurs when the tendon is stretched. In general, we test the biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes. Initiate a simple muscle stretch reflex by briskly tapping the tendon of a stretched muscle, usually with a reflex hammer (Fig. 55.16). Measure the response (muscle contraction of the corresponding muscle) on a 0 to 5 scale as follows: 0 = absent reflex; 1 = weak response, seen only with reinforcement; 2 = normal response; 3 = brisk response; 4 = hyperreflexia with nonsustained clonus; and 5 = hyperreflexia with sustained clonus. *Clonus,* an abnormal response, is a continued rhythmic contraction of the muscle with continuous application of the stimulus.

Elicit the *biceps reflex,* with the patient's arm partially flexed and palm up, by placing your thumb over the biceps tendon in the antecubital space and striking the thumb with a hammer. The normal response is flexion of the arm at the elbow or contraction of the biceps muscle that you can feel with your thumb.

Elicit the *triceps reflex* by striking the triceps tendon above the elbow while the patient's arm is flexed. The normal response is extension of the arm or visible contraction of the triceps.

Elicit the *brachioradialis reflex* by striking the radius 3 to 5 cm above the wrist while the patient's arm is relaxed. The normal response is flexion and supination at the elbow or visible contraction of the brachioradialis muscle.

Elicit the *patellar reflex* by striking the patellar tendon just below the patella. The patient can be sitting or lying as long as the leg being tested hangs freely. The normal response is extension of the leg with

contraction of the quadriceps.

Gently dorsiflex the patient's foot at the ankle. Elicit the *Achilles tendon reflex* by striking the Achilles tendon while the patient's leg is flexed at the knee. The normal response is plantar flexion at the ankle.

A *focused assessment* is used to evaluate the status of previously identified neurologic problems and to monitor for signs of new problems. A focused assessment of the neurologic system is shown in the box on p. 1294.

Table 55.5 is an example of a normal neurologic physical assessment. Abnormal assessment findings of the neurologic system are shown in Table 55.6.

Case Study—cont'd

Objective Data: Physical Examination

© TatyanaGl/iStock/Thinkstock.

A physical assessment of J.K. reveals the following:

- BP 145/80, HR 78, RR 20, T 37°C
- Alert, oriented, and appropriate, but anxious
- Strength 5/5 on all extremities
- Visual field deficits in upper left quadrant of visual field

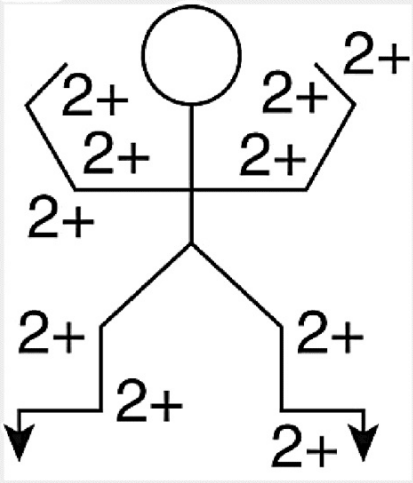
Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based on the results of the subjective and physical assessment, what diagnostic studies do you think may be ordered for J.K.?

You will learn more about diagnostic studies related to the neurologic system in the next section.

(See p. 1298 for more information on J.K.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.



Diagnostic Studies of Nervous System

Many diagnostic studies are available to assess the nervous system (Tables 55.7, 55.8, 55.9, and 55.10). CSF analysis provides information about a variety of CNS diseases. Normal CSF is clear, colorless, odorless, and free of red blood cells. It contains little protein. Normal CSF values are listed in Table 55.7. CSF may be obtained through lumbar puncture (LP) or, on occasion, ventriculostomy.

During LP, the HCP aspirates CSF through a needle inserted into the L3-4 or L4-5 interspace. A manometer attached to the needle is used to obtain CSF pressure. CSF is withdrawn in a series of tubes and sent for analysis. LP is contraindicated in the presence of increased intracranial pressure because of the risk for downward herniation from CSF removal or if there is infection at the intended puncture site. Nursing care of the patient undergoing LP is outlined in Table 55.8.

Biopsies of nerve, muscle, brain, and arterial tissues are useful in diagnosing several disorders (e.g., tumors, infectious disease, degenerative diseases, temporal artery for arteritis). A brain biopsy is usually done using a stereotactic procedure.

TABLE 55.5 Normal Physical Assessment of Nervous System*

Parameter	Findings
Mental status	• Alert and oriented, orderly thought processes. • Appropriate mood and affect.
Cranial nerves†	• Smell intact to soap or coffee. • Visual fields full to confrontation. • Intact extraocular movements. • No nystagmus. Pupils equal, round, reactive to light and accommodation. • Intact facial sensation to light touch and pinprick. • Facial movements full. • Hearing intact bilaterally. • Intact gag and swallow reflexes. Symmetric smile. Midline protrusion of tongue. • Full strength with head turning and shoulder shrugging.
Motor system	• Normal gait and station. Normal tandem walk. Negative Romberg test. • Normal and symmetric muscle bulk, tone, and strength. • Smooth performance of finger-nose, heel-shin movements.
Sensory system	• Intact sensation to light touch, position sense, pinprick, heat, and cold.
Reflexes‡ 	• Biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes 2/5 bilaterally. • Toes pointed down with plantar stimulation.

* If some part of the neurologic examination was not done, this should be indicated (e.g., “Smell not tested”).

† May be recorded as “CN I to XII intact.”

‡ May also be recorded as drawing of stick figure showing reflex strength at appropriate sites.

Focused Assessment

Nervous System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Blackouts/loss of memory	Y	N
Weakness, numbness, tingling in arms or legs	Y	N
Headaches, especially new onset	Y	N
Loss of balance/coordination	Y	N
Orientation to person, place, time, and situation	Y	N

Objective: Diagnostic

Check the following diagnostic results for critical values.

Lumbar puncture	✓
CT or MRI of brain	✓
EEG	✓

Objective: Physical Examination

Inspect/Observe

General level of consciousness/orientation	✓
Oropharynx for gag reflex and soft palate movement	✓
Peripheral sensation of light touch and pinprick (face, hands, feet)	✓
Smell with coffee or soap	✓
Eyes for extraocular movements, PERRLA, peripheral vision, nystagmus	✓
Gait for smoothness and coordination	✓

Palpate

Strength of neck, shoulders, arms, and legs for fullness and symmetry	✓

Percuss

Reflexes	✓

TABLE 55.6 Assessment AbnormalitiesNervous System

Finding	Description	Possible Etiology and Significance
Cranial Nerves		
Dysphagia	Difficulty in swallowing	Lesions involving motor pathways of CN IX and CN X (including lower brainstem)
Ophthalmoplegia	Paralysis of eye muscles	Lesions in brainstem
Eyes		
Anisocoria	Inequality of pupil size	Oculomotor nerve injury Sympathetic pathway injury
Diplopia	Double vision	Lesions affecting nerves of extraocular muscles, cerebellar damage
Homonymous hemianopsia	Loss of vision in one side of visual field	Lesions in the contralateral occipital lobe
Papilledema	"Choked disc," swelling of optic nerve head	Increased intracranial pressure
Mental Status		
Altered consciousness	Stuporous, mute, ↓ response to verbal cues or pain	Intracranial lesions, metabolic disorder, psychiatric disorders
Anosognosia	Inability to recognize bodily defect or disease	Lesions in right parietal cortex
Motor System		
Apraxia	Inability to perform learned movements despite having desire and physical ability to perform them	Cerebral cortex lesion
Ataxia	Lack of coordination of movement	Lesions of sensory or motor pathways, cerebellum Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Dyskinesia	Impairment of voluntary movement, resulting in fragmentary or incomplete movements	Disorders of basal ganglia, idiosyncratic reaction to psychotropic drugs
Hemiplegia	Paralysis on 1 side	Stroke and other lesions involving contralateral motor cortex
Nystagmus	Jerking or bobbing of eyes as they track moving object	Lesions in cerebellum, brainstem, vestibular system Antiseizure drugs, sedatives, hypnotic toxicity (including alcohol)
Reflexes		
Deep tendon reflexes	↓ or absent motor response	Lower motor neuron lesions
Extensor plantar response	Toes pointing up with plantar stimulation	Suprasegmental or upper motor neuron lesion
Sensory System		
Analgesia	Loss of pain sensation	Lesion in spinothalamic tract or thalamus. Analgesic drugs
Anesthesia	Absence of sensation	Lesions in spinal cord, thalamus, sensory cortex, or peripheral sensory nerve. Anesthesia drugs
Astereognosis	Inability to recognize form of object by touch	Lesions in parietal cortex
Paresthesia	Abnormal sensation, such as numbness or tingling	Lesions in the posterior column or sensory cortex
Speech		
Aphasia, dysphasia	Loss of or impaired language faculty (comprehension, expression, or both)	Left cerebral cortex lesion
Dysarthria	Lack of coordination in articulating speech	Cerebellar or cranial nerve lesion Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Spinal Cord		
Bladder dysfunction		
• **Atonic (autonomous)**	Absence of muscle tone and contractility, enlargement of capacity, no sensation of discomfort, overflow with large residual, inability to voluntarily empty	Early stage of spinal cord injury
• **Hypertonic**	↑ Muscle tone, ↓ capacity, reflex emptying, dribbling, incontinence	Lesions in pyramidal tracts (efferent pathways)
• **Hypotonic**	More ability than atonic bladder but less than normal	Interruption of afferent pathways from bladder
Paraplegia	Paralysis of lower extremities	Spinal cord transection or mass lesion (thoracolumbar region)

Finding	Description	Possible Etiology and Significance
Tetraplegia (quadriplegia)	Paralysis of all extremities	Spinal cord transection or mass lesion (cervical region)

TABLE 55.7 Cerebrospinal Fluid Analysis

Parameter	Normal Value
Specific gravity	1.007
pH	7.35
Appearance	Clear, colorless
Red blood cells (RBCs)	None
White blood cells (WBCs)	0–5 cells/μL (0–5 × 10^6 cells/L)
Protein	
• Lumbar	15–45 mg/dL (0.15–0.45 g/L)
• Cisternal	15–25 mg/dL (0.15–0.25 g/L)
• Ventricular	5–15 mg/dL (0.05–0.15 g/L)
Glucose	40–70 mg/dL (2.2–3.9 mmol/L)
Microorganisms	None
Pressure	60–150 mm H_2O

TABLE 55.8 Nursing ManagementCare of the Patient Undergoing Lumbar Puncture

Preprocedure

- Obtain vital signs and a baseline neurologic assessment. Notify HCP of signs of increased intracranial pressure.
- Assess coagulation studies to reduce the risk for epidural hematoma.
- Teach patient and caregiver about procedure. Tell the patient they may feel temporary, sharp pain or tingling radiating down the leg as a sterile needle is passed between 2 lumbar vertebrae.
- Give sedative and analgesia, as ordered.
- Have patient void.

- Place patient in a side-lying position.

Postprocedure

- Monitor neurologic signs and vital signs. Monitor for headache intensity and drainage from the puncture site.
- Apply pressure and a pressure dressing to the puncture site.
- Keep the patient in a reclining position for 1 hour or up to several hours to decrease the risk for spinal headache. The patient may to turn from side to side as long as the head is not raised.
- Ensure proper labeling of CSF specimens and send to laboratory.
- Teach the patient to report numbness, tingling, and movement of the extremities; pain at the injection site; and the inability to void.
- Encourage fluids with a straw to replace the CSF that was removed.
- Give ordered analgesia, as needed.

TABLE 55.9 Radiologic StudiesNervous System

Study	Description and Purpose	Nursing Responsibility
Cerebral angiography	Serial x-ray visualization of intracranial and extracranial blood vessels done to detect vascular lesions (aneurysms, hematomas, arteriovenous malformations) and brain tumors (Fig. 55.17). Catheter is inserted into the femoral (sometimes brachial) artery and passed through the aortic arch into the base of a carotid or a vertebral artery for injection of contrast medium. Timed-sequence radiographic images are obtained as contrast flows through arteries, smaller vessels, and veins.	*Before:* Assess patient for stroke risk because thrombi may be dislodged during procedure. May need to be NPO. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Monitor neurologic signs and VS every 15–30 min for first 2 hr, every hour for next 6 hr, then every 2 hr for 24 hr. Maintain bed rest for 6 hr (1 hr if a closure device is used). Assess for bleeding. Report any neurologic status changes.
CT scan	Provides a rapid means of obtaining radiographic images of the brain (Fig. 55.18, *A*). Computer-assisted x-ray of multiple cross sections of body parts to detect problems such as hemorrhage, tumor, cyst, edema, infarction, brain atrophy, and other abnormalities. Contrast medium may be used to enhance visualization of brain structures.	*Before:* Evaluate renal function before contrast medium used. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 hr prior. If the patient is taking metformin, hold it the day of the test to prevent hypoglycemia or acidosis. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
• **CT angiography (CTA)**	Noninvasive imaging of vascular system (e.g., aneurysms). Evaluates blood volume, flow, and mean transit time as a measure of perfusion. Has fewer complications than cerebral angiography and is less expensive.	Similar to CT (see above).
MRI	Imaging of brain, spinal cord, and spinal canal by means of magnetic energy (Fig. 55.18, *B*). Used to detect strokes, MS, tumors, trauma, herniation, and seizures. Provides greater detail than CT and improved resolution (detail) of intracranial structures. Takes a longer time to complete and may not be appropriate in life-threatening emergencies. Contrast medium may be used to enhance visualization. The contrast agent *gadolinium* has a lower incidence of allergy than iodine used in CT.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still.
• **Magnetic resonance angiography (MRA)**	Uses differential signal characteristics of flowing blood to evaluate extracranial and intracranial blood vessels. Provides both anatomic and hemodynamic information. Can be used in conjunction with contrast medium.	Similar to MRI (see above).
• **Functional MRI (fMRI)**	MRI technique that provides time-related (temporal) images that can evaluate how the brain responds to various stimuli. Makes it possible to detect the brain areas that are involved in a task, process, or an emotion.	Similar to MRI (see above).

Table Continued

Study	Description and Purpose	Nursing Responsibility
• **MR spectroscopy (MRS)**	Noninvasive test for measuring biochemical changes in the brain, especially the presence of tumors. Compares the chemical composition of normal brain tissue with abnormal tumor tissue. Can detect tissue changes in stroke and epilepsy.	Similar to MRI (see above).
Myelogram	X-ray of spinal cord and vertebral column after injection of contrast medium into subarachnoid space. Used to detect spinal lesions (e.g., herniated or ruptured disc, spinal tumor).	*Before:* Give sedative as ordered. Have patient empty bladder. Tell patient that test is done with patient on tilting table that is moved during test. *After:* Patient should lie flat for 1–2 hours to prevent spinal headache. Encourage fluids. Monitor neurologic signs and VS. Headache, nausea, and vomiting may occur.
Positron emission tomography (PET)	Measures metabolic activity of brain to assess cell death or damage. Uses radioactive material that shows up as a bright spot on the image (see). Used for patients with stroke, Alzheimer's disease, seizure disorders, Parkinson's disease, and tumors.	*Before:* Explain procedure to patient. Tell patient not to take sedatives or tranquilizers. Have patient empty bladder. Insert 2 IV lines. *During:* Patient may be asked to perform different activities during test.
Single-photon emission computed tomography (SPECT)	Method of scanning similar to PET but uses more stable substances and different detectors. Radiolabeled compounds are injected, and their photon emissions can be detected. Resulting images are accumulation of labeled compound. Assesses blood flow and O_2 and glucose metabolism in the brain. Used to diagnose strokes, brain tumors, and seizure disorders.	Similar to PET (see above).
Skull and spine x-rays	Simple x-ray of skull and spinal column. Done to detect fractures, bone erosion, calcifications, abnormal vascularity.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient. *During:* Avoid excessive exposure of patient and self.
Ultrasound		
Carotid artery duplex scan	Noninvasive study that evaluates the degree of stenosis of carotid and vertebral arteries. Combines ultrasound and Doppler technology. Probe is placed over the carotid artery and slowly moved along the course of common carotid artery. Frequency of reflected ultrasound signal corresponds to blood velocity. Increased blood flow velocity can indicate stenosis of a vessel.	*Before:* Explain procedure to patient.
Transcranial Doppler	Same technology as carotid duplex but evaluates blood flow velocities of intracranial blood vessels. Probe is placed on skin at various "windows" in the skull (areas in the skull that have only a thin bony covering) to record velocities of the blood vessels.	*Before:* Explain procedure to patient.

TABLE 55.10 Electrographic StudiesNervous System

Electroencephalography (EEG)	Electrical activity of brain is recorded using scalp electrodes. Evaluates seizure disorders, cerebral disease, CNS effects of systemic diseases, brain injury, brain death. Specific tests may be done to evaluate brain's electrical response to lights and loud noises.	*Before:* Tell patient procedure is noninvasive and without danger of electric shock. Determine if any medications (e.g., tranquilizers, antiseizure drugs) should be withheld. *After:* Resume medications and have patient wash electrode paste out of hair.
Electromyography (EMG)	Recording of electrical activity associated with innervation of skeletal muscle. Needle electrodes are inserted into the muscle to record specific motor units. Normal muscle at rest shows no electrical activity. Electrical activity occurs only when the muscle contracts. Activity may be altered in diseases of muscle (e.g., myopathic conditions) or in disorders of muscle innervation (e.g., segmental or LMN lesions, peripheral neuropathic conditions).	*Before:* Explain procedure. Tell patient that pain and discomfort are associated with insertion of needles. HCPs may restrict stimulants (e.g., caffeine) 2–3 hr prior. *After:* Assess needle sites for hematoma or inflammation. Give as-needed analgesics.
Electroneurography (nerve conduction studies)	Measures nerve conduction velocity of peripheral nerves. Involves applying a brief electrical stimulus to a distal portion of a sensory nerve and recording the resulting wave of depolarization at a point proximal to the stimulation. The time between the stimulus onset and the first wave of depolarization at the recording electrode is measured. Damaged nerves have slower conduction velocities.	*Before:* Explain procedure to patient. For example, a stimulus can be applied to the forefinger and a recording electrode placed over the median nerve at the wrist will detect the speed of the conduction.
Evoked potentials	Electrical activity associated with nerve conduction along sensory pathways is recorded by electrodes placed on skin and scalp. A stimulus generates the impulse. Increases in the normal time from stimulus onset to a given peak (latency) indicate slowed nerve conduction or nerve damage. Used to diagnose disease (e.g., MS), locate nerve damage, and monitor function during surgery. Can diagnose disorders of the visual or auditory systems because it shows if a sensory impulse is reaching the right part of brain.	*Before:* Explain procedure to patient. Have patient shampoo hair before test.
Magnetoencephalography (MEG)	Uses a biomagnetometer to detect magnetic fields generated by neural activity. Can accurately pinpoint the part of the brain involved in a stroke, seizure, or other disorder or injury. Measures extracranial magnetic fields and scalp electric field (EEG).	*Before:* Explain procedure to patient. MEG, a passive sensor, does not make physical contact with patient.

CNS, Central nervous system; *LMN,* lower motor neuron.

Case Study—cont'd

Objective Data: Diagnostic Studies

© TatyanaGl/iStock/Thinkstock.

MRI/MRA results show a temporal-parietal glioblastoma that has extended into margins of the occipital lobes.

Discussion Questions

1. Are these the diagnostic studies that you expected to be ordered?
2. Why are these diagnostic study results of concern to you?

This case study is continued in Chapter 57 on p. 1350.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient with a disease that affects the myelin sheath of nerves, such as multiple sclerosis, the glial cells affected are the
   a. microglia.
   b. astrocytes.
   c. ependymal cells.
   d. oligodendrocytes.
2. Drugs or diseases that impair the function of the extrapyramidal system may cause loss of
   a. sensations of pain and temperature.
   b. regulation of the autonomic nervous system.
   c. integration of somatic and special sensory inputs.
   d. automatic movements associated with skeletal muscle activity.
3. During the admitting neurologic examination, the nurse determines the patient has speech difficulties with weakness of the right arm and lower face. The nurse would expect a CT scan to show pathology in the distribution of the
   a. basilar artery.
   b. left middle cerebral artery.
   c. right anterior cerebral artery.
   d. left posterior communicating artery.
4. A patient is seen in the emergency department after diving into the pool and hitting the bottom with a blow to the face

that hyperextended the neck and scraped the skin off the nose. The patient describes "having double vision" when looking down. During the neurologic examination, the nurse finds the patient is unable to abduct either eye. The nurse recognizes this finding is related to

a. a basal skull fracture.

b. an injury to CN VI on both sides.

c. a stiff neck from the hyperextension injury.

d. facial swelling from the scrape on the bottom of the pool.

5. Stimulation of the parasympathetic nervous system results in *(select all that apply)*

a. constriction of the bronchi.

b. dilation of skin blood vessels.

c. increased secretion of insulin.

d. increased blood glucose levels.

e. relaxation of the urinary sphincters.

6. The nurse is assessing the muscle strength of an older adult. The nurse knows the findings cannot be compared with those of a younger adult because

a. nutritional status is better in young adults.

b. muscle tone and strength decrease in older adults.

c. muscle strength should be the same for all adults.

d. most young adults exercise more than older adults.

7. A patient is admitted with a headache, fever, and general malaise. The HCP has asked that the patient be prepared for a lumbar puncture. What is a *priority* nursing action to

avoid complications?

a. Evaluate laboratory results for changes in the white cell count.

b. Give acetaminophen for the headache and fever before the procedure.

c. Notify the provider if signs of increased intracranial pressure are present.

d. Administer antibiotics before the procedure to treat the potential meningitis.

8. During neurologic testing, the patient can perceive pain elicited by pinprick. Based on this finding, the nurse may omit testing for

a. position sense.

b. patellar reflexes.

c. temperature perception.

d. heel-to-shin movements.

9. A patient's eyes jerk while the patient looks to the left. The nurse will record this finding as

a. nystagmus.

b. CN VI palsy.

c. ophthalmic dyskinesia.

d. oculocephalic response.

10. The nurse is caring for a patient with peripheral neuropathy who is scheduled for EMG studies tomorrow morning. The nurse should

a. ensure the patient has an empty bladder.

b. instruct the patient about the risk for electric shock.

c. ensure the patient has no metallic jewelry or metal fragments.

d. teach the patient that pain may be experienced during the study.

1. d, 2. d, 3. b, 4. b, 5. a, b, c, e, 6. b, 7. c, 8. c, 9. a, 10. d

Acute Intracranial Problems

Kristen Keller

LEARNING OUTCOMES

1. Explain the physiologic mechanisms that maintain normal intracranial pressure.
2. Describe the common etiologies, clinical manifestations, and interprofessional care of the patient with increased intracranial pressure.
3. Describe the nursing management of the patient with increased intracranial pressure.
4. Distinguish types of head injury by mechanism of injury and clinical manifestations.
5. Describe the interprofessional and nursing management of the patient with a head injury.
6. Compare the types, clinical manifestations, and interprofessional care of patients with brain tumors.
7. Discuss the nursing management of the patient with a brain tumor.
8. Describe the nursing management of the patient undergoing cranial surgery.
9. Distinguish among the primary causes and interprofessional and nursing management of brain abscess, meningitis, and encephalitis.

Cognition
Functional Ability

Intracranial Regulation
Mobility
Safety
Sensory Perception

The body has various mechanisms by which it regulates the intracranial space to promote optimal brain function. Acute intracranial problems can disrupt these processes, leading to increased intracranial pressure (ICP), reduced blood flow to the brain, and brain tissue damage. This chapter discusses the mechanisms that maintain normal ICP and problems that lead to increased ICP. Head injury, brain tumors, and cerebral infections and inflammatory disorders are common problems that disrupt intracranial regulation.

Intracranial Regulation

Understanding the dynamics associated with ICP is important in caring for patients with different neurologic problems. The skull is an enclosed space with 3 essential volume components: brain tissue, blood, and cerebrospinal fluid (CSF) (Fig. 56.1). The intracellular and extracellular fluids of brain tissue make up about 78% of this volume. Blood in the arterial, venous, and capillary network makes up 12% of the volume. The remaining 10% is the volume of the CSF.

Primary versus secondary injury is an important concept in understanding ICP. *Primary injury* occurs at the initial time of an injury (e.g., impact of car accident, blunt-force trauma). It results in displacement, bruising, or damage to any of the components (brain tissue, blood, CSF).

Secondary injury is the resulting hypoxia, ischemia, hypotension, edema, or increased ICP that follows the primary injury. Secondary injury, which can occur several hours to days after the initial injury, is a concern when managing brain injury. Nursing management of the patient with an acute intracranial problem must include management of secondary injury and increased ICP.

Normal Intracranial Pressure

Intracranial pressure (ICP) is the hydrostatic force measured in the brain CSF compartment. Under normal conditions in which intracranial volume stays relatively constant, the balance among the 3 components (brain tissue, blood, CSF) maintains ICP. Factors that influence ICP under normal circumstances are changes in (1) arterial pressure; (2) venous pressure; (3) intraabdominal and intrathoracic pressure; (4) posture; (5) temperature; and (6) blood gases, particularly CO_2 levels. The degree to which these factors increase or decrease the ICP depends on the brain's ability to adapt to changes.

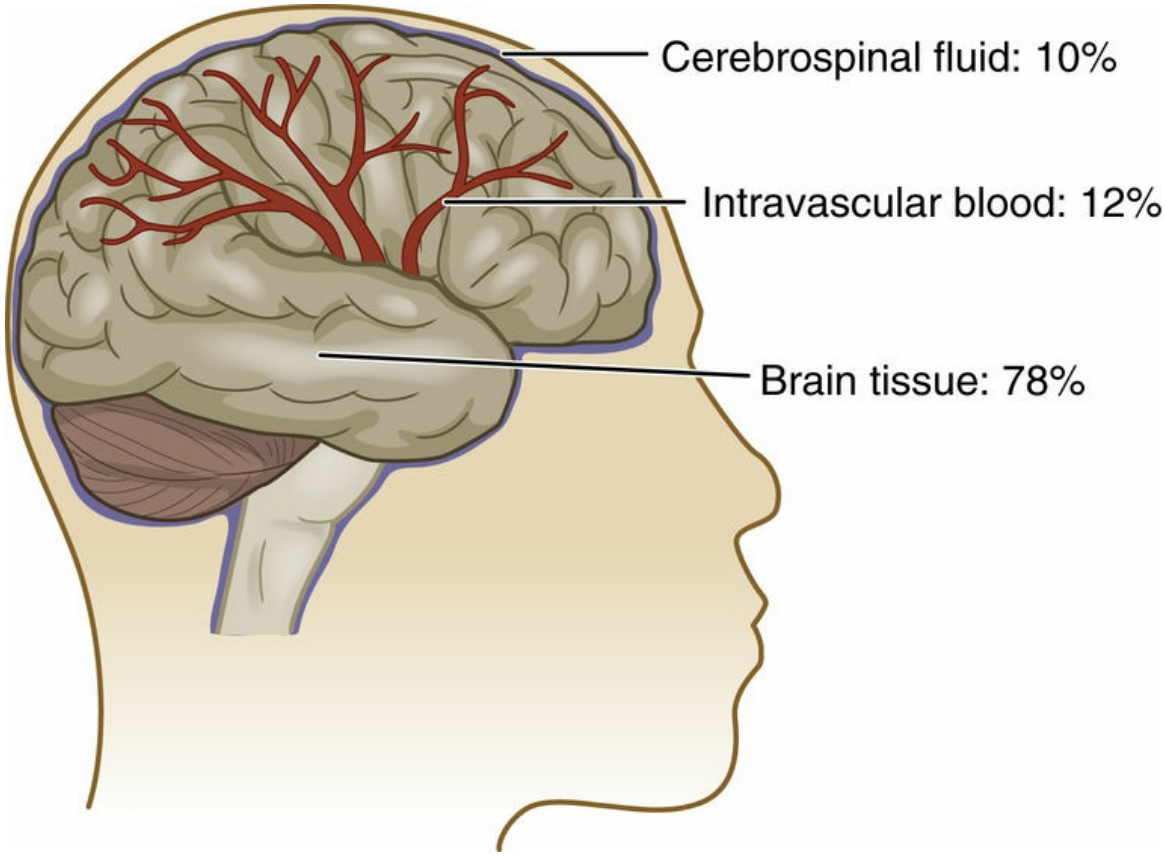

FIG. 56.1 Components of the brain.

The Monro-Kellie doctrine states that the 3 components must stay at a relatively constant volume within the closed skull structure. If the volume of any 1 of the 3 components increases within the cranial vault

and the volume from another component is displaced, the total intracranial volume will not change.[1] This hypothesis is applicable only in situations in which the skull is closed. The hypothesis is not valid in persons with displaced skull fractures or craniectomy (removal of part of the skull).

We can measure ICP in the ventricles, subarachnoid space, subdural space, epidural space, or brain tissue using a pressure transducer.[2] Normal ICP ranges from 5 to 15 mm Hg. A sustained pressure greater than 20 mm Hg is considered abnormal and must be treated.

Normal Compensatory Adaptations

In applying the Monro-Kellie doctrine, the body can adapt to volume changes within the skull in 3 different ways to maintain a normal ICP. The first compensatory mechanisms can include changes in the CSF volume. CSF volume can be changed by altering CSF absorption or production and by displacing CSF into the spinal subarachnoid space. Second, changes in intracranial blood volume can occur through the collapse of cerebral veins and dural sinuses, regional cerebral vasoconstriction or dilation, and changes in venous outflow. Third, brain tissue volume compensates through distention of the dura or compression of brain tissue.

Initially an increase in volume produces no increase in ICP because of these compensatory mechanisms. However, there is limited ability to compensate for changes in volume. As the volume increase continues, ICP rises and decompensation occurs, resulting in compression and ischemia.

Cerebral Blood Flow

Cerebral blood flow (CBF) is the amount of blood in milliliters passing through 100 g of brain tissue in 1 minute. The global CBF is about 50 mL/min/100 g of brain tissue. Maintaining blood flow to the brain is critical because the brain requires a constant supply of O_2 and glucose. The brain uses 20% of the body's O_2 and 25% of its glucose.[3]

TABLE 56.1 Calculation of Cerebral Perfusion Pressure

$$CPP = MAP - ICP$$

$$MAP = DBP + 1/3\ (SBP - DBP)$$

OR

$$MAP = \frac{SBP + 2\ (DBP)}{3}$$

Example: Systemic BP = 122/84 mm Hg
MAP = 97 mm Hg
ICP = 12 mm Hg
CPP = 85 mm Hg

CPP, Cerebral perfusion pressure; *DBP,* diastolic blood pressure;

MAP, mean arterial pressure; *SBP*, systolic blood pressure.

Autoregulation of Cerebral Blood Flow

The brain regulates its own blood flow in response to its metabolic needs despite wide fluctuations in systemic arterial pressure. *Cerebral autoregulation* is the automatic adjustment in the diameter of the cerebral blood vessels by the brain to maintain a constant blood flow during changes in arterial BP. The purpose of autoregulation is to ensure a consistent CBF to provide for the metabolic needs of brain tissue and maintain cerebral perfusion pressure within normal limits.

The lower limit of systemic arterial pressure at which autoregulation is effective in a normotensive person is a mean arterial pressure (MAP) of 70 mm Hg. Below this, CBF decreases, and symptoms of cerebral ischemia, such as syncope and blurred vision, occur. The upper limit of systemic arterial pressure at which autoregulation is effective is a MAP of 150 mm Hg. When this pressure is exceeded, the vessels are maximally constricted, and further vasoconstrictor response is lost.

The *cerebral perfusion pressure* (CPP) is the pressure needed to ensure blood flow to the brain. CPP is equal to the MAP minus the ICP (CPP = MAP − ICP) (see the example in Table 56.1). Normal CPP is 60 to 100 mm Hg. As the CPP decreases, autoregulation fails and CBF decreases. A CPP of less than 50 mm Hg is associated with ischemia and neuronal death. A CPP of less than 30 mm Hg results in ischemia and is incompatible with life.

Though CPP is clinically useful, it does not consider the effect of cerebrovascular resistance. Cerebrovascular resistance, generated by the arterioles within the cranium, links CPP and blood flow as follows:

$$\text{CPP} = \text{Flow} \times \text{Resistance}$$

When cerebrovascular resistance is high, blood flow to brain tissue is impaired. Transcranial Doppler is a noninvasive technique used in intensive care units (ICUs) to monitor changes in cerebrovascular resistance.

Normally, autoregulation maintains an adequate CBF and CPP by adjusting the diameter of cerebral blood vessels and metabolic factors that affect ICP. It is critical to maintain MAP when ICP is increased.

Remember that CPP may not reflect perfusion pressure in all parts of the brain. There may be local areas of swelling and compression limiting regional perfusion pressure. Thus a higher CPP may be needed for these patients to prevent localized tissue damage. For example, a patient with an acute stroke may need a higher BP, increasing MAP and CPP, to increase perfusion to the brain and prevent further tissue damage.

Factors Affecting Cerebral Blood Flow

CO_2, O_2, and hydrogen ion concentration affect cerebral blood vessel tone. An increase in the partial pressure of CO_2 in arterial blood ($PaCO_2$) relaxes smooth muscle, dilates cerebral vessels, decreases cerebrovascular resistance, and increases CBF. A decrease in $PaCO_2$ constricts cerebral vessels, increases cerebrovascular resistance, and decreases CBF.

Cerebral O_2 tension of less than 50 mm Hg results in cerebrovascular dilation. This dilation decreases cerebrovascular resistance, increases CBF, and increases O_2 tension. However, if O_2 tension is not increased, anaerobic metabolism begins, resulting in an accumulation of lactic acid. As lactic acid increases and hydrogen ions accumulate, the environment becomes more acidic. Within this acidic environment, further vasodilation occurs in a continued attempt to increase blood flow. The combination of a severely low partial pressure of O_2 in arterial blood (PaO_2) and increased hydrogen ion concentration (acidosis), which are both potent cerebral vasodilators, may produce a state in which autoregulation is lost and compensatory mechanisms do not meet tissue metabolic demands.

CBF can be affected by cardiac or respiratory arrest, systemic hemorrhage, and other pathophysiologic states (e.g., diabetic coma, encephalopathies, infections, toxicities). Regional CBF can be affected by trauma, tumors, cerebral hemorrhage, or stroke. When regional or global autoregulation is lost, CBF is no longer maintained at a constant level but is directly influenced by changes in systemic BP, hypoxia, or catecholamines.

Increased Intracranial Pressure

Any patient who becomes unconscious acutely, regardless of the cause, should be suspected of having increased ICP.

Mechanisms of Increased Intracranial Pressure

Increased ICP is a potentially life-threatening situation that results from an increase in any or all the 3 components (brain tissue, blood, CSF) within the skull. Increased ICP is clinically significant because it decreases CPP, increases risks for brain ischemia and infarction, and is associated with a poor prognosis.[4] Common causes of increased ICP include a mass (e.g., hematoma, contusion, abscess, tumor) and cerebral edema (from brain tumors, hydrocephalus, head injury, brain inflammation).

These cerebral insults, which may result in hypercapnia, cerebral acidosis, impaired autoregulation, and systemic hypertension, increase the formation and spread of cerebral edema. This edema distorts brain tissue, further increasing the ICP, and leads to even more tissue hypoxia and acidosis. Fig. 56.2 shows the progression of increased ICP.

It is critical to maintain CBF to preserve tissue and thus minimize secondary injury. Sustained increases in ICP result in brainstem compression and herniation of the brain. *Herniation* occurs as the brain tissue is forcibly shifted from the compartment of greater pressure to a compartment of lesser pressure.

Displacement and herniation of brain tissue can cause a potentially reversible process to become irreversible. Ischemia and edema are further increased, compounding the preexisting problem. Compression of the brainstem and cranial nerves may be fatal. Fig. 56.3 shows types of herniation. Herniation forces the cerebellum and brainstem downward through the foramen magnum. If compression of the brainstem is unrelieved, respiratory arrest will occur due to compression of the respiratory control center in the medulla. In this situation, intense pressure is placed on the brainstem. If herniation continues, brainstem death is imminent.

PATHOPHYSIOLOGY MAP

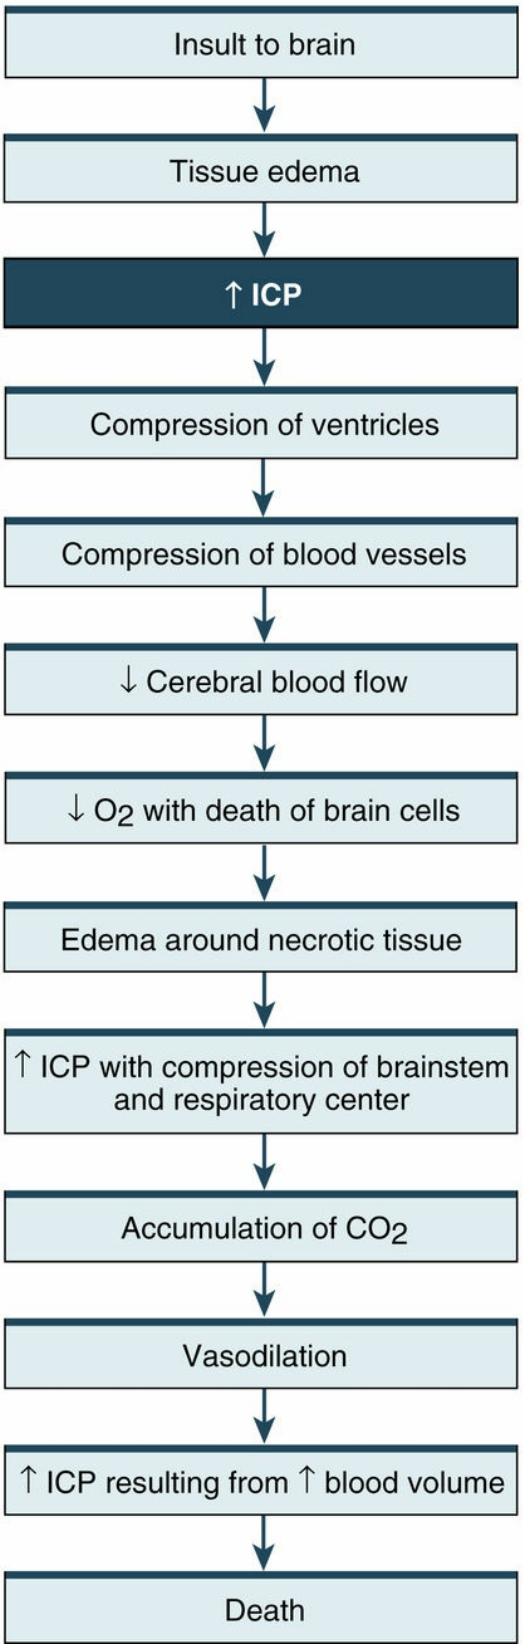

FIG. 56.2 Progression of increased ICP.

Cerebral Edema

There are a variety of causes of **cerebral edema** (increased accumulation of fluid in the extravascular spaces of brain tissue) (Table 56.2). Regardless of the cause, cerebral edema results in an increase in tissue volume that can increase ICP. The extent and severity of the original insult are factors that determine the degree of cerebral edema.

There are 3 types of cerebral edema: vasogenic, cytotoxic, and interstitial. The same patient may have more than 1 type.

- Venous sinus thrombosis

Vasogenic Cerebral Edema

Vasogenic cerebral edema, the most common type of cerebral edema, occurs mainly in the white matter. It is characterized by leakage of large molecules from the capillaries into the surrounding extracellular space. This results in an osmotic gradient that favors the flow of fluid from the intravascular to extravascular space. A variety of problems, such as brain tumors, abscesses, and ingested toxins, may increase in the permeability of the blood-brain barrier and produce an increase in the extracellular fluid volume. The speed and extent of the spread of the edema are influenced by the systemic BP, site of the brain injury, and extent of the blood-brain barrier defect.

This edema may produce a continuum of symptoms, ranging from headache to a decrease in consciousness, including **coma** (profound state of unconsciousness) and focal neurologic deficits.

It is important to recognize that although a headache may seem to be a benign symptom, in cases of cerebral edema it can quickly progress to coma and death. So, you must be vigilant in your assessment.

Cytotoxic Cerebral Edema

Cytotoxic cerebral edema results from disruption of the integrity of the cell membranes. It develops from destructive lesions or trauma to brain tissue, resulting in cerebral hypoxia or anoxia and syndrome of inappropriate antidiuretic hormone (SIADH) secretion. In this type of edema, the blood-brain barrier stays intact. Cerebral edema occurs from fluid and protein shifts from the extracellular space directly into the cells, with subsequent swelling and loss of cellular function.

Interstitial Cerebral Edema

Interstitial cerebral edema is usually a result of hydrocephalus.

Hydrocephalus is a buildup of fluid in the brain. It is manifested by ventricular enlargement. It can be due to excess CSF production, obstruction of flow, or an inability to reabsorb the CSF. Hydrocephalus treatment usually consists of a ventriculostomy or ventriculoperitoneal shunt. Management of hydrocephalus is discussed later in this chapter on p. 1319.

Clinical Manifestations

The manifestations of increased ICP can take many forms, depending on the cause, location, and rate of increases in ICP.

Change in Level of Consciousness

The *level of consciousness* (LOC) is the most sensitive and reliable indicator of the patient's neurologic status. Changes in LOC are a result of impaired CBF, which causes O_2 deprivation to the cells of the cerebral cortex and reticular activating system (RAS). The RAS is found in the brainstem, with neural connections to many parts of the nervous system. An intact RAS can maintain a state of wakefulness even in the absence of a functioning cerebral cortex. Interruptions of impulses from the RAS or changes in functioning of the cerebral hemispheres can cause **unconsciousness**, an abnormal state of complete or partial unawareness of self or environment.

The patient's state of consciousness is defined by the patient's clinical responses and pattern of brain activity (recorded by an electroencephalogram [EEG]). A change in consciousness may be dramatic (as in coma) or subtle (e.g., flattening of affect, change in orientation, decrease in level of attention). In the deepest state of unconsciousness (e.g., coma), the patient does not respond to painful stimuli. Corneal and pupillary reflexes are absent. The patient cannot swallow or cough and is incontinent of urine and feces. The EEG pattern shows suppressed or absent neuronal activity.

Changes in Vital Signs

Increasing pressure on the thalamus, hypothalamus, pons, and

medulla causes changes in vital signs.

Manifestations such as *Cushing's triad* (systolic hypertension with a widening pulse pressure, bradycardia with a full and bounding pulse, irregular respirations) may be present but often do not appear until ICP has been increased for some time or is suddenly and markedly increased (e.g., head trauma). Always recognize Cushing's triad as a medical emergency as it is a sign of brainstem compression and impending death. A change in body temperature may occur because increased ICP affects the hypothalamus.

Check Your Practice

You are monitoring the vital signs of an 82-yr-old woman who was admitted for a head injury after she fell while walking on the sidewalk. She hit her head on a fire hydrant. She was confused on admission, but vital signs were stable at BP 150/86, pulse 84, respirations 14/min. 2 hours after admission, her vital signs are now BP 166/74, pulse 54, respirations 10 to 16/min.

- What is your interpretation of her vital signs?

Ocular Signs

Compression of cranial nerve (CN) III, the oculomotor nerve, results in dilation of the pupil on the same side *(ipsilateral)* as the mass lesion, sluggish or no response to light, inability to move the eye upward and adduct, and ptosis of the eyelid. These signs can be the result of the brain shifting from midline, compressing the trunk of CN III, and paralyzing the muscles controlling pupillary size and shape. In this situation, a fixed, unilateral, dilated pupil is considered a neurologic emergency that indicates brain herniation.

Other cranial nerves may be affected, including the optic (CN II), trochlear (CN IV), and abducens (CN VI) nerves. Signs of problems with these cranial nerves include blurred vision, diplopia, and changes in extraocular eye movements. *Central herniation* may initially

manifest as sluggish but equal pupil response. *Uncal herniation* may cause a dilated unilateral pupil. *Papilledema* (an edematous optic disc seen on retinal examination) is a nonspecific sign associated with persistent increases in ICP.

Decrease in Motor Function

As the ICP continues to rise, the patient has changes in motor ability. A *contralateral* (opposite side of the mass lesion) hemiparesis or hemiplegia may develop, depending on the location of the source of the increased ICP. If painful stimuli are used to elicit a motor response, the patient may localize to the stimuli or withdraw from it.

Noxious stimuli may elicit *decorticate* (flexor) or *decerebrate* (extensor) posturing (Fig. 56.4). Decorticate posture consists of internal rotation and adduction of the arms with flexion of the elbows, wrists, and fingers. It is a result of interruption of voluntary motor tracts in the cerebral cortex. Extension of the legs may be seen. A decerebrate posture may indicate more serious damage. It results from disruption of motor fibers in the midbrain and brainstem. In this position, the arms are stiffly extended, adducted, and hyperpronated. There is hyperextension of the legs with plantar flexion of the feet.

Headache

Although the brain itself is insensitive to pain, compression of other intracranial structures, such as arteries, veins, and cranial nerves, can cause a headache. A nocturnal headache and/or a headache in the morning is cause for concern and may indicate a tumor or other space-occupying lesion that is causing increased ICP. Straining, agitation, or movement may worsen the pain.

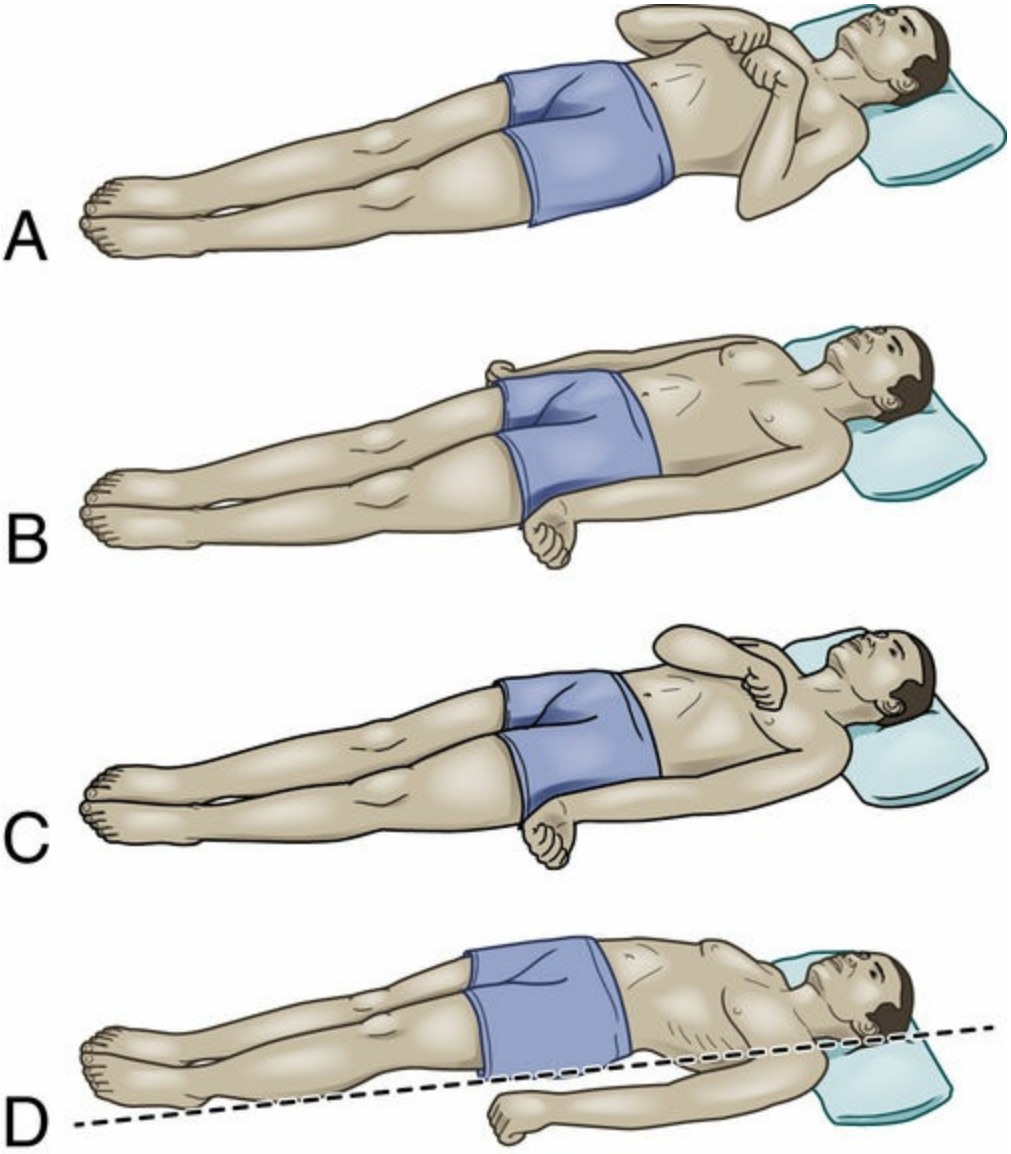

FIG. 56.4 Decorticate and decerebrate posturing. **A,** Decorticate response. Flexion of arms, wrists, and fingers with adduction in upper extremities. Extension, internal rotation, and plantar flexion in lower extremities. **B,** Decerebrate response. All 4 extremities in rigid extension, with hyperpronation of forearms and plantar flexion of feet. **C,** Decorticate response on right side of body and decerebrate response on left side of body. **D,** Opisthotonic posturing.

Vomiting

Vomiting, usually not preceded by nausea, is often a nonspecific sign of increased ICP. This is called *unexpected vomiting* and is related to pressure changes in the cranium. Projectile vomiting may occur and is

related to increased ICP.

Complications

The major complications of uncontrolled increased ICP are inadequate cerebral perfusion and cerebral herniation (Fig. 56.3). To better understand cerebral herniation, 2 important structures in the brain must be described. The *falx cerebri* is a thin wall of dura that folds down between the cortex, separating the 2 cerebral hemispheres. The *tentorium cerebelli* is a rigid fold of dura that separates the cerebral hemispheres from the cerebellum (Fig. 56.3). It is called the *tentorium* (meaning tent) because it forms a tentlike cover over the cerebellum.

Tentorial herniation (central herniation) occurs when a mass lesion in the cerebrum forces the brain to herniate downward through the opening created by the brainstem. *Uncal herniation* occurs when there is lateral and downward herniation. *Cingulate herniation* occurs when there is lateral displacement of brain tissue beneath the falx cerebri.

Diagnostic Studies

Diagnostic studies can be used to identify the cause of increased ICP (Table 56.3). CT and MRI are used to discern the many conditions that can cause increased ICP and assess the effect of treatment.

TABLE 56.3 Interprofessional CareIncreased Intracranial Pressure

Diagnostic Assessment

- History and physical examination
- Vital signs, neurologic assessments, ICP measurements
- Skull, chest, and spinal x-ray studies
- CT scan, MRI, cerebral angiography, EEG, PET

- Transcranial Doppler studies
- Infrascanner
- ECG
- Evoked potential studies
- Lumbar puncture (should not be done if there is a risk for herniation)
- Laboratory studies, including CBC, coagulation profile, electrolytes, serum creatinine, ABGs, ammonia level, drug and toxicology screen, CSF analysis (for protein, WBC, and glucose)

Management

- Elevation of head of bed to 30 degrees with head in a neutral position
- Intubation and mechanical ventilation
- ICP monitoring
- Cerebral oxygenation monitoring ($PbtO_2$, $SjvO_2$)
- Maintain PaO_2 ≥100 mm Hg
- Maintain fluid balance and assess osmolality
- Maintain systolic arterial pressure between 100 and 160 mm Hg
- Maintain CPP >60 mm Hg
- Reduction of cerebral metabolism (e.g., high-dose barbiturates)

Drug Therapy

- Osmotic diuretic (mannitol)
- Hypertonic saline
- Antiseizure drugs (e.g., phenytoin [Dilantin])
- Corticosteroids (dexamethasone) for brain tumors, bacterial meningitis
- Histamine (H_2)-receptor antagonist (e.g., cimetidine) or proton

pump inhibitor (e.g., pantoprazole to prevent GI ulcers and bleeding

Other tests include EEG, cerebral angiography, ICP measurement, brain tissue oxygenation measurement via the LICOX catheter (described later), positron emission tomography (PET), transcranial Doppler studies, and evoked potential studies. In general, a lumbar puncture (LP) is not done when increased ICP is suspected. The reason for this is that cerebral herniation could occur from the sudden release of the pressure in the skull from the area above the LP.

In some agencies, a hand-held near-infrared scanner (Infrascanner) is used to detect life-threatening intracranial bleeding. The scanner directs a wavelength of light that can penetrate tissue and bone. Blood from intracranial hematomas absorbs the light differently from other areas of the brain.

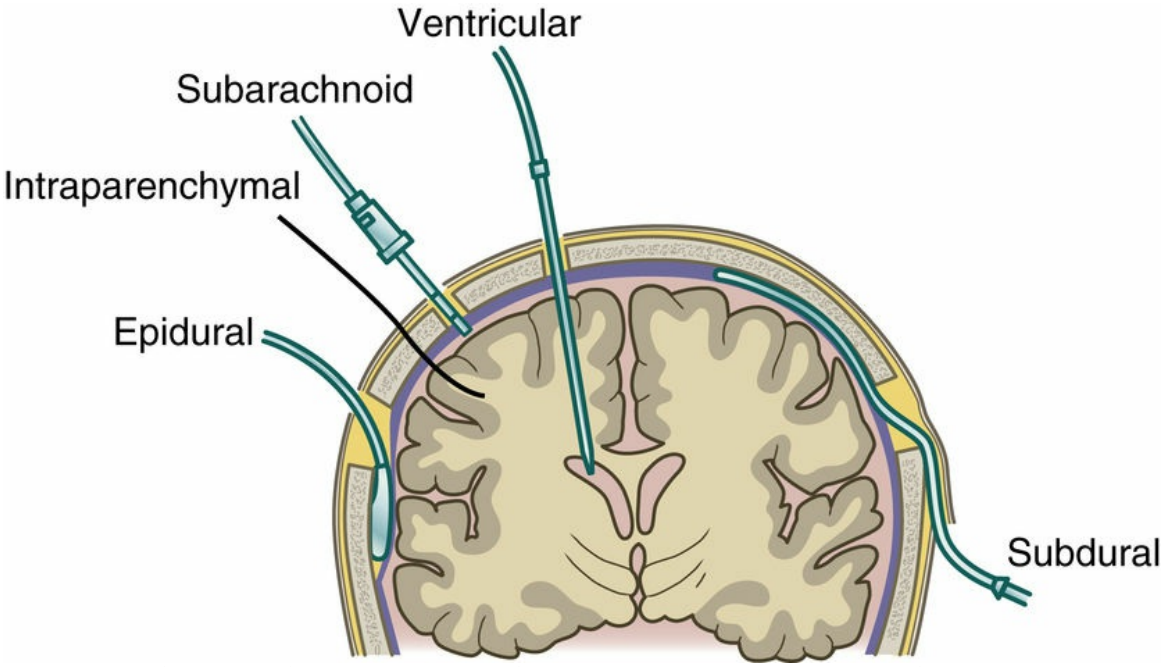

FIG. 56.5 Coronal section of brain showing potential sites for placement of ICP monitoring devices.

Monitoring ICP and Cerebral Oxygenation

Indications for Intracranial Pressure Monitoring

ICP monitoring is used to guide clinical care when the patient is at risk for or has elevations in ICP.[4] It may be used in patients with a variety of neurologic problems, including hemorrhage, stroke, tumor, infection, or traumatic brain injury (TBI). ICP should be monitored in patients admitted with a *Glasgow Coma Scale* (GCS) score of 8 or less and an abnormal CT scan or MRI. These results indicate that the patient may have bleeding, contusion, edema, or other problems. The GCS is discussed later on p. 1308.

Methods of Measuring ICP

Patients with conditions known to elevate ICP, except those with irreversible problems or advanced neurologic disease, usually undergo ICP monitoring in an ICU. Multiple methods and devices are available to monitor ICP in various sites (Fig. 56.5).

The gold standard for monitoring ICP is the *ventriculostomy,* in which a specialized catheter is inserted into the lateral ventricle and coupled to an external transducer (Figs. 56.6 and 56.7). This technique directly measures the pressure within the ventricles, facilitates removal and/or sampling of CSF, and allows for intraventricular drug administration. In this system the transducer is external. It is important to ensure that the transducer is level with the foramen of Monro (interventricular foramen). The system must also be at the ideal height (Fig. 56.8, *A*). A reference point for this foramen is the tragus of the ear. Every time the patient is repositioned, assess the system to ensure it is level.

The *fiberoptic catheter,* an alternative technology, uses a sensor transducer found within the catheter tip. The sensor tip is placed within the ventricle or the brain tissue and gives a direct measurement of brain pressure.

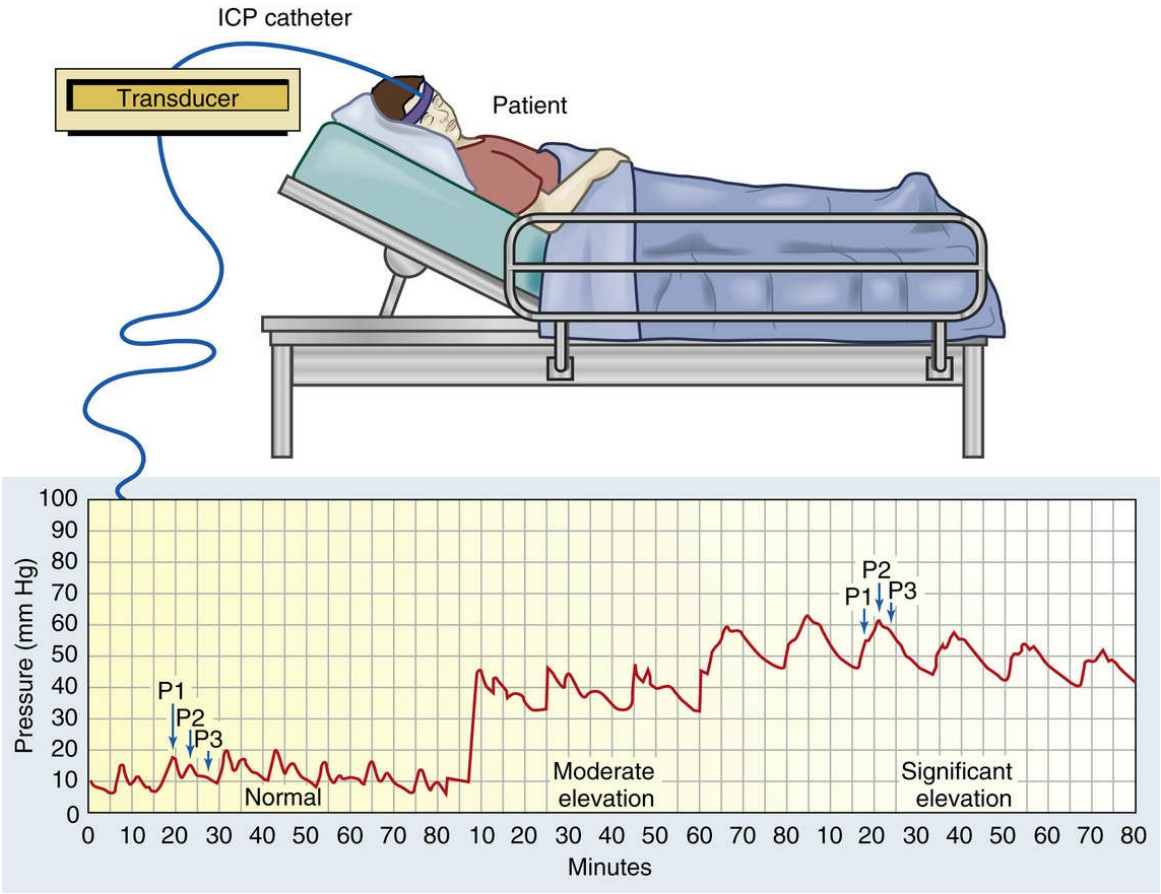

FIG. 56.6 ICP monitoring can be used to continuously measure ICP. The ICP tracing shows normal, elevated, and plateau waves. At high ICP, the P2 peak is higher than the P1 peak, and the peaks become less distinct and plateau.
Modified from Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2013, Mosby.

The *air pouch/pneumatic technology,* another system for monitoring ICP, has an air-filled pouch at the tip of the catheter that maintains a constant volume. The pressure changes within the cranium are transmitted through the changes exerted on this pouch to the monitor.

ICP is represented on the monitor as a mean pressure in millimeters of mercury (mm Hg). If a CSF drainage device is in place, the drain must be closed for at least 6 minutes to ensure an accurate reading. Record the waveform strip along with other pressure monitoring waveforms. The normal ICP waveform has 3 phases (Fig. 56.6 and Table 56.4). It is important to monitor the ICP waveform and the mean CPP. When ICP is normal, P1, P2, and P3 resemble a staircase. As ICP increases, P2 rises above P1. This indicates poor ventricular

compliance (Fig. 56.6). Consider the rate at which changes occur and the patient's clinical condition. Neurologic deterioration may not occur until ICP elevation is pronounced and sustained. Immediately report to the HCP any ICP elevation, either as a mean increase in pressure or as an abnormal waveform configuration.

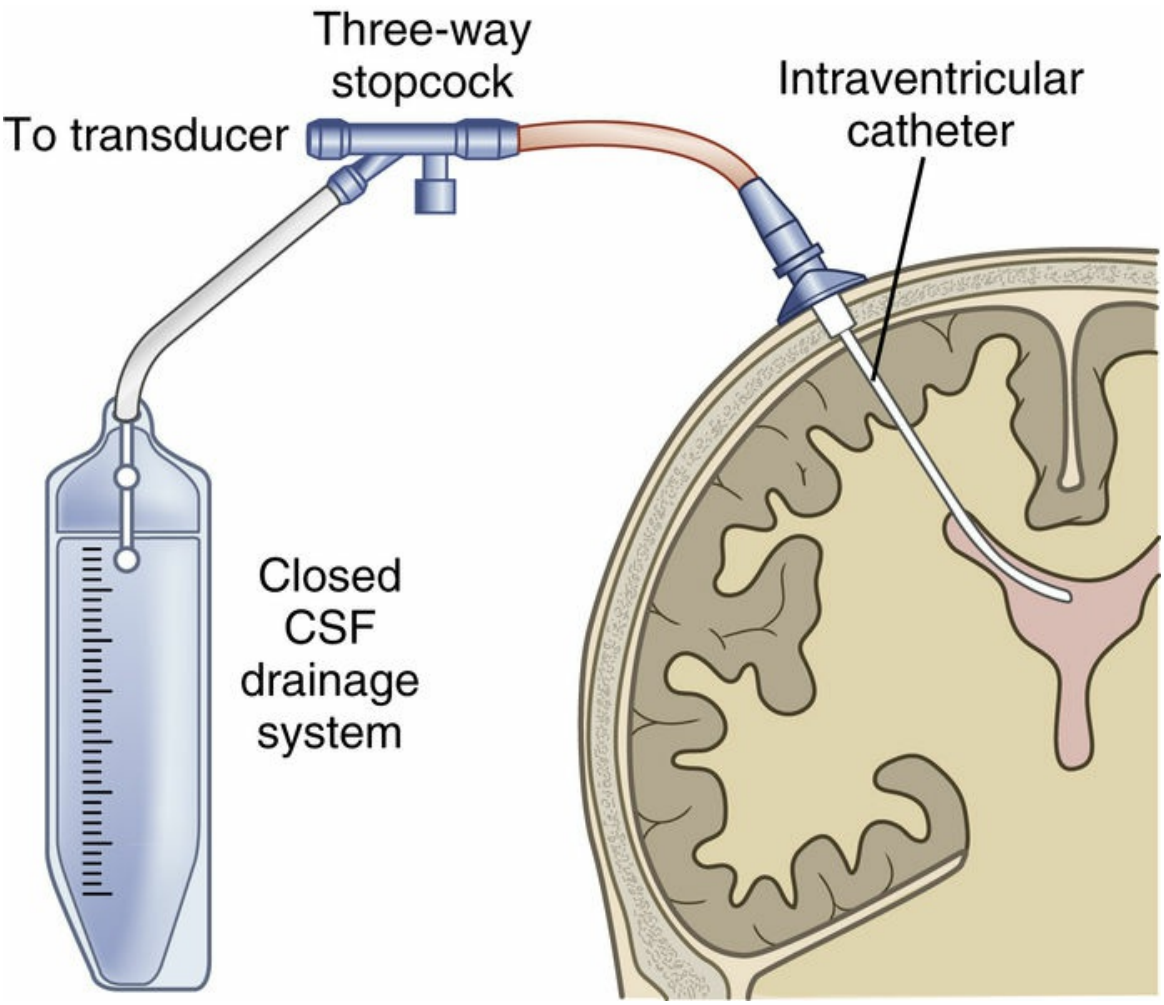

FIG. 56.7 Ventriculostomy in place. Cerebrospinal fluid (CSF) can be drained via a ventriculostomy when ICP exceeds the upper pressure parameter set by the HCP. Intermittent drainage involves opening the 3-way stopcock to allow CSF to flow into the drainage bag for brief periods (30 to 120 seconds) until the pressure is below the upper pressure parameters.

Inaccurate ICP readings can be caused by CSF leaks around the monitoring device, obstruction of the intraventricular catheter (from

tissue or blood clot), a difference between the height of the catheter and the transducer, kinks in the tubing, and incorrect height of the drainage system relative to the patient's reference point. Bubbles or air in the tubing can dampen the waveform.

Infection is a serious complication with ICP monitoring. Factors that contribute to infection include ICP monitoring more than 5 days, use of a ventriculostomy, a CSF leak, and a concurrent systemic infection. Routinely assess the insertion site, use aseptic technique, and monitor the CSF for a change in drainage color or clarity.

Cerebrospinal Fluid Drainage

With the ventricular catheter, it is possible to control ICP by removing CSF (Fig. 56.7). The HCP typically orders a specific level at which to start drainage (e.g., if ICP is greater than 20 mm Hg) and the frequency of drainage (intermittent or continuous). When the ICP is above the indicated level, the system is opened by turning a stopcock and allowing the drainage of CSF, thus relieving pressure inside the cranial vault (Fig. 56.8, *B*). Although CSF removal decreases ICP and improves CPP, there are no universal guidelines for CSF removal. Guidelines are typically based on agency or HCP preference.[5]

The 2 options for CSF drainage are intermittent or continuous. If intermittent drainage is used, open the system at the indicated ICP and allow CSF to drain for 2 to 3 minutes. Then close the stopcock to return the ventriculostomy to a closed system. If continuous ICP drainage is ordered, carefully monitor the volume of CSF drained. Keep in mind that normal CSF production is about 20 to 30 mL/hr. There is a total CSF volume of about 150 mL within the ventricles and subarachnoid space. Post a sign above the patient's bed to notify anyone before turning, moving, or suctioning the patient to prevent the removal of too much CSF, which can result in other complications.

TABLE 56.4 Normal Intracranial Pressure Waveforms*

Waveform	Meaning
P1 Percussion wave	Represents arterial pulsations. Normally the highest of the 3 waveforms.
P2 Rebound wave or tidal wave	Reflects intracranial compliance or relative brain volume. When P2 is higher than P1, intracranial compliance is compromised.
P3 Dicrotic wave	Follows dicrotic notch. Represents venous pulsations. Normally the lowest waveform.

* See Fig. 56.6.

FIG. 56.8 **A,** Leveling a ventriculostomy. **B,** Cerebrospinal fluid is drained into a drainage system.
Courtesy Meg Zomorodi, RN, PhD, CNL, Raleigh, NC.

Complications include ventricular collapse, infection, and herniation or subdural hematoma formation from rapid decompression. Strict aseptic technique during dressing changes or sampling of CSF is crucial to prevent infection. The system must stay intact to ensure that the ICP readings are accurate because treatment is based on the pressures.

Cerebral Oxygenation Monitoring

Technology is available to measure cerebral oxygenation and assess

perfusion. Three intracranial devices used in ICU settings are the LICOX catheter, Neurovent catheter, and jugular venous bulb catheter.

The LICOX and Neurovent catheters are placed in healthy white matter of the brain (Fig. 56.9). These catheters measure brain oxygenation and temperature. These systems provide continuous monitoring of the pressure of O_2 in brain tissue ($PbtO_2$). The normal range for $PbtO_2$ is 20 to 40 mm Hg. A low $PbtO_2$ level indicates ischemia.[2] These catheters can also measure brain temperature. A cooler brain temperature (96.8° F [36° C]) may produce better outcomes.

Jugular venous bulb oximetry, which measures global O_2 extraction, is used in some agencies. The jugular venous bulb catheter is placed in the internal jugular vein and positioned so that the catheter tip is in the jugular bulb. An x-ray verifies placement. This catheter provides a measurement of jugular venous O_2 saturation ($SjvO_2$), which indicates total venous brain tissue extraction of O_2. This is a measure of cerebral O_2 supply and demand. The normal $SjvO_2$ range is 60% to 75%. Values less than 50% indicate impaired cerebral oxygenation.[2]

In addition to measuring ICP and brain oxygenation, many HCPs are now looking at multimodality monitoring in TBI and intracranial hypertension. This technology includes brain microdialysis (measurement of small molecules), continuous EEG, and blood flow monitoring.

Interprofessional Care

The goals of interprofessional care (Table 56.3) are to (1) identify and treat the underlying cause of increased ICP and (2) support brain function. The earlier the condition is recognized and treated, the better the patient outcome. A careful history is important in the search for the underlying cause. The underlying cause of increased ICP is usually an increase in blood (hemorrhage), brain tissue (tumor or edema), or CSF (hydrocephalus) in the brain.

For any patient with increased ICP, it is important to maintain

adequate oxygenation to support brain function and prevent secondary injury. An endotracheal tube or tracheostomy may be needed to maintain adequate ventilation. Arterial blood gas (ABG) analysis guides the O_2 therapy. The goal is to maintain the PaO_2 at 100 mm Hg or greater and to keep $PaCO_2$ in normal range at 35 to 45 mm Hg. The patient may need to be on a mechanical ventilator to ensure adequate oxygenation.

If increased ICP is caused by a mass lesion (e.g., tumor, hematoma), surgical removal of the mass is the best treatment. See the sections on brain tumors and cranial surgery later in this chapter. In aggressive situations, a craniectomy (removal of part of skull) may be done to reduce ICP and prevent herniation.

Drug Therapy

Drug therapy plays an important part in the management of increased ICP. Mannitol (Osmitrol) (25%) is an osmotic diuretic given IV. Mannitol decreases ICP in 2 ways: plasma expansion and osmotic effect. The immediate plasma-expanding effect reduces the hematocrit and blood viscosity. This increases CBF and cerebral O_2 delivery. A vascular osmotic gradient is created by mannitol. Thus fluid moves from the tissues into the blood vessels, reducing the ICP because of the decrease in the total brain fluid content. Monitor fluid and electrolyte status when osmotic diuretics are used. Mannitol may be contraindicated if renal disease is present and serum osmolality increased.

Hypertonic saline solution is another option. It produces massive movement of water out of edematous swollen brain cells and into blood vessels. This movement can reduce swelling and improve cerebral blood flow. Care during an infusion includes frequent monitoring of BP and serum sodium levels because intravascular fluid volume excess can occur. Hypertonic saline infusion is just as effective as mannitol when treating increased ICP. They are often used concurrently when caring for a patient with a severe brain injury.[6]

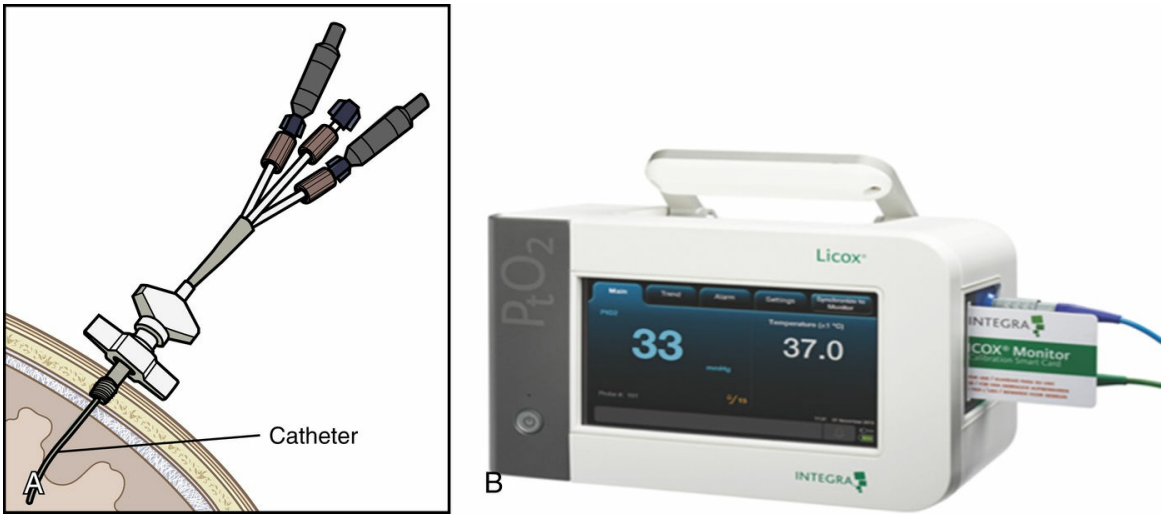

FIG. 56.9 **A,** The LICOX brain tissue O_2 system involves insertion of a catheter. **B,** The system measures O_2 in the brain ($PbtO_2$), brain tissue temperature, and ICP.
B, Courtesy of Integra LifeSciences Corporation, Plainsboro, NJ.

Corticosteroids (e.g., dexamethasone) are used to treat vasogenic edema around tumors and abscesses. These drugs are not recommended for TBI. Corticosteroids stabilize the cell membrane and inhibit the synthesis of prostaglandins (see Fig. 11.2), preventing the formation of proinflammatory mediators. Corticosteroids also improve neuronal function by improving CBF and restoring autoregulation.

Complications associated with the use of corticosteroids include hyperglycemia, increased incidence of infections, and gastrointestinal (GI) bleeding. Regularly monitor fluid intake and sodium levels. Perform blood glucose monitoring at least every 6 hours. Patients receiving corticosteroids should receive antacid, histamine (H_2)-receptor blockers (e.g., cimetidine, ranitidine), or proton pump inhibitors (e.g., pantoprazole) to prevent GI ulcers and bleeding.

IV 0.9% sodium chloride is the preferred solution for giving secondary medications. If 5% dextrose in water or 0.45% sodium chloride is used, serum osmolarity decreases and an increase in cerebral edema may occur.

Metabolic demands, such as fever (greater than 100.4° F [38° C]), agitation or shivering, pain, and seizures, can increase ICP. Implement

measures to reduce these metabolic demands to lower the ICP in the at-risk patient. Monitor patients for seizure activity. They may need prophylactic antiseizure medication. Maintain the temperature at 96.8° to 98.6° F (36° to 37° C) by using antipyretics (e.g., acetaminophen), cool baths, cooling blankets, ice packs, or intravascular cooling devices as needed. Avoid letting the patient shiver or shake, since this increases the metabolic workload on the brain. If this occurs, the patient may need sedatives or a different cooling method.

Drug therapy for reducing cerebral metabolism may be an effective way to control ICP. Reducing the metabolic rate decreases the CBF and therefore the ICP. High doses of barbiturates (e.g., pentobarbital, thiopental) are used in patients with increased ICP refractory to other treatments. Barbiturates decrease cerebral metabolism, causing a decrease in ICP and a reduction in cerebral edema. With this treatment, monitor the patient's ICP, blood flow, and EEG. Barbiturate dosing is typically based on analysis of the bedside EEG tracing and the ICP. The HCP orders the barbiturate infusion at a rate that achieves a desired level of brain wave suppression to control ICP. *Total burst suppression,* recognized by the absence of spikes showing brain activity on the EEG monitor, shows that maximal therapeutic effect has been achieved.

Nutritional Therapy

Because malnutrition promotes continued cerebral edema, maintaining optimal nutrition is important. The patient with increased ICP is in a hypermetabolic and hypercatabolic state that increases the need for glucose as fuel for metabolism of the injured brain. If the patient cannot maintain an adequate oral intake, other means of meeting nutritional requirements, such as enteral feedings or parenteral nutrition, should be started.

Early feeding after brain injury may improve patient outcome.[5] Nutritional replacement should begin within 3 days after injury and reach full nutritional replacement within 7 days after injury. The patient's fluid and electrolyte status and metabolic needs should

guide feedings or supplements. The patient should be kept in a euvolemic fluid state. Continuously evaluate the patient based on clinical factors such as urine output, insensible fluid loss, serum and urine osmolality, and serum electrolytes.

Nursing Management: Increased Intracranial Pressure

Nursing Assessment

Subjective data about the patient with increased ICP can be obtained from the patient, caregiver, or family member who is familiar with the patient. Describe the LOC by noting the specific behaviors seen. Assess the LOC using the GCS. Assess body functions, especially circulation and respiration.

Glasgow Coma Scale

The **Glasgow Coma Scale (GCS)** is a quick, practical, and standard system for assessing the LOC. The 3 areas assessed in the GCS are the patient's ability to (1) open the eyes when a verbal or painful stimulus is applied, (2) speak, and (3) obey commands. Specific assessments evaluate the patient's response to varying degrees of stimulus. Three indicators of response are evaluated: (1) opening of the eyes, (2) best verbal response, and (3) best motor response (Table 56.5).

TABLE 56.5 Glasgow Coma Scale

Appropriate Stimulus	Response	Score
Eyes Open		
• Approach to bedside • Verbal command • Pain	Spontaneous response.	4
	Opening of eyes to name or command.	3
	Lack of opening of eyes to previous stimuli but opening to pain.	2
	Lack of opening of eyes to any stimulus.	1
	Untestable.*	U
Best Verbal Response		
• Verbal questioning with maximum arousal	Appropriate orientation, conversant. Correct identification of self, place, year, and month.	5
	Confusion. Conversant, but disorientation in 1 or more spheres.	4
	Inappropriate or disorganized use of words (e.g., cursing), lack of sustained conversation.	3
	Incomprehensible words, sounds (e.g., moaning).	2
	Lack of sound, even with painful stimuli.	1
	Untestable.*	U
Best Motor Response		
• Verbal command (e.g., "raise your arm, hold up 2 fingers") • Pain (pressure on proximal nail bed)	Obedience of command.	6
	Localization of pain, lack of obedience but presence of attempts to remove offending stimulus.	5
	Flexion withdrawal,* flexion of arm in response to pain without abnormal flexion posture.	4
	Abnormal flexion, flexing of arm at elbow and pronation, making a fist.	3
	Abnormal extension, extension of arm at elbow usually with adduction and internal rotation of arm at shoulder.	2
	Lack of response.	1
	Untestable.*	U

* Added to the original scale by some centers.

Specific behaviors observed as responses to the testing stimulus are given a numeric value. Your responsibility is to elicit the best response on each of the scales: the higher the scores, the higher the level of brain functioning. The subscale scores are particularly important if a patient is untestable in an area. For example, severe periorbital edema may make eye opening impossible.

The total GCS score is the sum of the numeric values assigned to each of the 3 areas. The highest GCS score is 15 for a fully alert person, and the lowest possible score is 3. A GCS score of 8 or less generally indicates coma, and mechanical ventilation should be considered. Plot the results of the GCS scores on a graph, which can be used to determine whether the patient is stable, improving, or deteriorating.

The GCS offers several advantages in the assessment of the unconscious patient. It allows different health care professionals to arrive at the same conclusion about the patient's status. It can be used to determine between different or changing states.

Although the GCS is the gold standard assessment tool for LOC,

other scales, such as the *Full Outline of Unresponsiveness (FOUR) scale,* are also used.[7] In cases of stroke or hemorrhage associated with increased ICP, use the NIH Stroke Scale (see Table 57.10). Other key neurologic assessments include cranial nerve assessment and motor and sensory testing. Cranial nerve assessment is outlined in Table 55.4.

Neurologic Assessment

Compare the pupils with one another for size, shape, movement, and reactivity (Fig. 56.10). If the oculomotor nerve (CN III) is compressed, the pupil on the affected side *(ipsilateral)* becomes larger until it fully dilates. If ICP continues to increase, both pupils dilate.

Test pupillary reaction with a penlight. The normal reaction is brisk constriction when the light is shone directly into the eye. Note a consensual response (slight constriction in the opposite pupil) at the same time. A sluggish reaction can indicate early pressure on CN III. A fixed pupil unresponsive to light stimulus usually indicates increased ICP. However, note that there are other causes of a fixed pupil, including direct injury to CN III, previous eye surgery, atropine administration, and use of mydriatic eye drops.

In some agencies, HCPs are using a hand-held device *(pupillometer)* to measure the pupil reactivity and size. The device removes any subjectivity from the pupil evaluation.

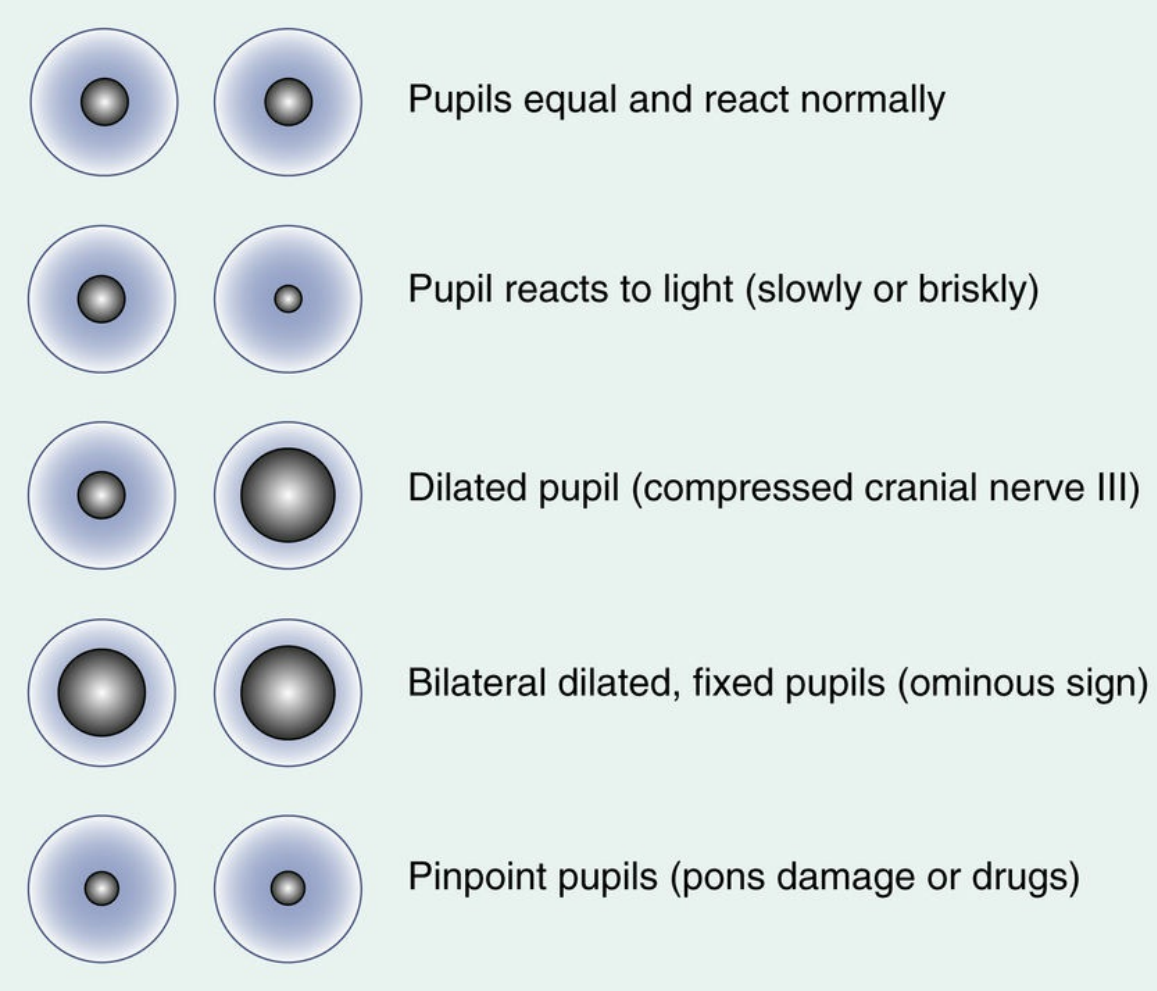

FIG. 56.10 Pupillary check for size and response.

Assess eye movements controlled by CN III, CN IV, and CN VI in the patient who is awake and able to follow commands. They can be used to assess brainstem function. Testing the corneal reflex gives information about the functioning of CN V and CN VII. If this reflex is absent, start routine eye care to prevent corneal abrasion (see Chapter 20).

Eye movements of the uncooperative or unconscious patient can be elicited by reflex with the use of head movements (oculocephalic) and caloric stimulation (oculovestibular). To test the oculocephalic reflex (doll's eye reflex), turn the patient's head briskly to the left or right while holding the eyelids open. A normal response is movement of the eyes across the midline in the direction opposite that of the turning. Next, quickly flex and then extend the neck. Eye movement

should be opposite to the direction of head movement—up when the neck is flexed and down when it is extended. Abnormal responses can help locate an intracranial lesion. This test should not be done if a cervical spine problem is suspected.

To test the oculovestibular reflex (cold caloric), the patient is positioned with the head of bed elevated. A syringe of ice-cold water is instilled into the external auditory ear canal. The patient's eyes are assessed for a total of 1 minute. The absence of eye movement or response indicates severe neurologic demise. This test requires patent external auditory ear canals and tympanic membranes.

Test motor strength by asking the awake and cooperative patient to squeeze your hands to compare strength in the hands. The pronator drift test is an excellent measure of strength in the upper extremities. The patient raises the arms in front of the body with the palms facing upward and eyes closed. If there is any weakness in the upper extremity, the palmar surface turns downward and the arm drifts down. This would indicate a problem in the opposite motor cortex. Asking the patient to raise the foot from the bed or to bend the knees up in bed is a good assessment of lower extremity strength. Test all 4 extremities for strength and for any asymmetry in strength or movement.

Assess the motor response of the unconscious or uncooperative patient by observation of spontaneous movement. If no spontaneous movement is possible, apply a pain stimulus to the patient and note the response. Resistance to movement during passive range-of-motion exercises is another measure of strength. Do not include hand squeezing as part of the assessment of motor movement in the unconscious or uncooperative patient, since this is a reflex action and can misrepresent the patient's status.

Record vital signs, including BP, pulse, respiratory rate, and temperature. Be aware of Cushing's triad, which indicates severely increased ICP. Besides recording respiratory rate, note the respiratory pattern. Specific respiratory patterns are associated with severely increased ICP (Fig. 56.11).

Nursing Diagnoses

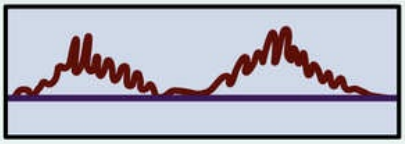
Nursing diagnoses for the patient with increased ICP include:

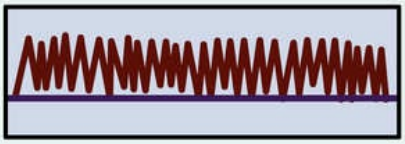
- Decreased intracranial adaptive capacity
- Ineffective tissue perfusion
- Risk for injury

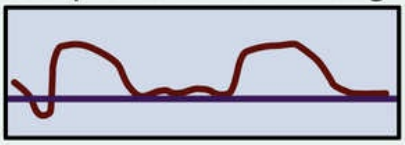
Additional information on nursing diagnoses and interventions for patients with increased ICP is presented in eNursing Care Plan 56.1 (available on the website for this chapter).

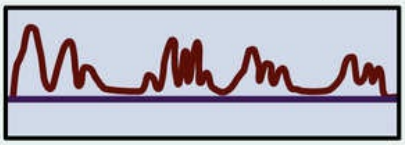
Planning

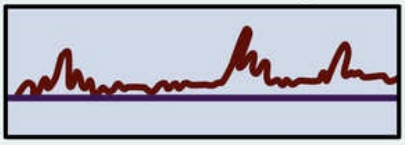
The overall goals for the patient with increased ICP are to (1) maintain a patent airway; (2) have ICP within normal limits; (3) have normal fluid, electrolyte, and nutritional balance; and (4) prevent complications from immobility and decreased LOC.











Pattern	Location of Lesion	Description
1. Cheyne-Stokes 	Bilateral hemispheric disease or metabolic brain dysfunction	Cycles of hyperventilation and apnea
2. Central neurogenic hyperventilation 	Brainstem between lower midbrain and upper pons	Sustained, regular rapid and deep breathing
3. Apneustic breathing 	Mid or lower pons	Prolonged inspiratory phase or pauses alternating with expiratory pauses
4. Cluster breathing 	Medulla or lower pons	Clusters of breaths follow each other with irregular pauses between
5. Ataxic breathing 	Reticular formation of the medulla	Completely irregular with some breaths deep and some shallow. Random, irregular pauses, slow rate

FIG. 56.11 Common abnormal respiratory patterns associated with coma.

Nursing Implementation

Acute Care

Respiratory Function

Maintaining a patent airway is critical in the patient with increased

ICP and is a major nursing responsibility. As the LOC decreases, the patient is at an increased risk for airway obstruction from the tongue dropping back and occluding the airway or from accumulation of secretions.

Safety Alert

Altered Breathing

- Be alert to altered breathing patterns in a patient with increased ICP.
- Snoring sounds indicate obstruction and require immediate intervention.

Remove accumulated secretions by suctioning as needed. An oral airway facilitates breathing and provides an easier suctioning route in the comatose patient. In general, any patient with a GCS of 8 or less or an altered LOC who is unable to maintain a patent airway or effective ventilation needs intubation and mechanical ventilation.

Frequently monitor and evaluate the ABG values. Take measures to maintain the levels within prescribed or acceptable parameters. The appropriate ventilatory support can be ordered based on the PaO_2 and $PaCO_2$ values.

Prevent hypoxia and hypercapnia to minimize secondary injury. Suctioning and coughing cause transient decreases in the PaO_2 and increases in the ICP. Keep suctioning to a minimum and less than 10 seconds in duration. Give 100% O_2 before and after to prevent decreases in the PaO_2. To avoid cumulative increases in the ICP with suctioning, limit suctioning to 2 passes per suction procedure, if possible. Patients with increased ICP are at risk for lower CPP during suctioning.

Try to prevent abdominal distention, since it can interfere with respiratory function. Inserting a nasogastric (NG) tube to aspirate the

stomach contents can prevent distention, vomiting, and aspiration. However, in patients with facial and skull fractures, an NG tube is contraindicated due to risk for inadvertent intracranial placement. Oral insertion of a gastric tube is preferred.

Sedation

Pain, anxiety, and fear related to the primary injury, therapeutic procedures, or noxious stimuli can increase ICP and BP, thus complicating the patient's management and recovery. The appropriate choice or combination of sedatives, paralytics, and analgesics for symptom management is a challenge. Giving these agents may alter the neurologic state, thus masking true neurologic changes. It may be necessary to temporarily stop drug therapy to appropriately assess neurologic status. The choice, dose, and combination of agents may vary depending on the patient's history, neurologic state, and overall clinical presentation.

Opioids, such as morphine sulfate and fentanyl, are rapid-onset analgesics with minimal effect on CBF or O_2 metabolism. The IV sedative propofol (Diprivan) is used to manage anxiety and agitation in the ICU because of its rapid onset and short half-life. An accurate neurologic assessment can be done soon after stopping an infusion of propofol.

Dexmedetomidine (Precedex), an α_2-adrenergic agonist, is used for continuous IV sedation of intubated and mechanically ventilated patients in the ICU setting for up to 24 hours. When using continuous IV sedatives, be aware of the side effects of these drugs, especially hypotension, since this can lower CPP.

Nondepolarizing neuromuscular blocking agents (e.g., vecuronium, cisatracurium besylate [Nimbex]) are useful for achieving complete ventilatory control in the treatment of refractory intracranial hypertension. Because these agents paralyze muscles without blocking pain or noxious stimuli, they are used in combination with sedatives, analgesics, or benzodiazepines.

Benzodiazepines, although useful for sedation, are usually avoided in the managing the patient with increased ICP because of the

hypotensive effect and long half-life. They are usually given as an adjunct to neuromuscular blocking agents.

The patient should be in a quiet, calm environment with minimal noise and interruptions. Observe the patient for signs of agitation, irritation, or frustration. Teach the caregiver and family about decreasing stimulation. Coordinate with team members to minimize procedures that may cause agitation.

Fluid and Electrolyte Balance

Fluid and electrolyte problems can have an adverse effect on ICP. Closely monitor IV fluids with the use of an accurate IV infusion control device or pump. Intake and output, accounting for insensible losses, and daily weights are important parameters in the assessment of fluid balance.

Monitor serum electrolytes, especially glucose, sodium, potassium, magnesium, and osmolality. Discuss abnormal values with the HCP.

Monitor urine output to detect problems related to diabetes insipidus and inappropriate secretion of antidiuretic hormone (SIADH). Diabetes insipidus is caused by a decrease in antidiuretic hormone (ADH). It results in increased urine output and hypernatremia. The usual treatment of diabetes insipidus is fluid replacement, vasopressin, or desmopressin acetate (DDAVP) (see Chapter 49). If it is not treated, severe dehydration will occur.

SIADH is caused by excess secretion of ADH. SIADH results in decreased urine output and dilutional hyponatremia. It may result in cerebral edema, changes in LOC, seizures, and coma. (Treatment of SIADH is described in Chapter 49.)

Monitoring ICP

ICP monitoring is used in combination with other physiologic parameters to guide the care of the patient and assess the patient's response to treatment. Suctioning, hypoxemia, and arousal from sleep are factors that can increase ICP. Be alert to these factors and try to minimize them. Increased intrathoracic pressure can increase ICP by impeding the venous return. So, coughing, straining, sneezing, and

the Valsalva maneuver should be avoided.

Body Position

Proper head positioning is important. Maintain the patient with increased ICP in the head-up position. Keep the head in a midline position, avoiding extreme neck flexion. Flexion can cause venous obstruction and contribute to increased ICP. Adjust the body position to decrease the ICP and improve the CPP. Elevating the head of the bed promotes drainage from the head and decreases the vascular congestion that can produce cerebral edema. However, raising the head of the bed above 30 degrees may decrease the CPP by lowering systemic BP. Carefully evaluate the effects of elevating the head of the bed on both ICP and CPP. Position the bed so that it lowers the ICP while optimizing the CPP and other indices of cerebral oxygenation.

Take care to turn the patient with slow, gentle movements. Rapid changes in position may increase ICP. Prevent discomfort when turning and positioning the patient because pain or agitation increases pressure. Avoid extreme hip flexion to decrease the risk for raising the intraabdominal pressure, which increases ICP. Decorticate or decerebrate posturing is a reflex response in some patients with increased ICP. Turning, skin care, and even passive range of motion can elicit these posturing reflexes.

Provide the physical care to minimize complications of immobility, such as atelectasis and contractures. Turn the patient at least every 2 hours.

Protection From Injury

The patient with increased ICP and decreased LOC needs protection from self-injury. Confusion, agitation, and the possibility of seizures increase the risk for injury. Use restraints judiciously in the agitated patient. If restraints are necessary to keep the patient from removing tubes or falling out of bed, they should be secure enough to be effective. Observe the skin area under the restraints regularly for irritation. Agitation may increase with the use of restraints, which indicates the need for other measures to protect the patient from

injury. Light sedation with sedative agents may be needed. Having a family member stay with the patient may have a calming effect.

For the patient with seizures or the patient at risk for such activity, institute seizure precautions. These include padded side rails, an Ambu bag at the bedside, readily available suction, accurate and timely administration of antiseizure drugs, and close observation. Antiseizure prophylaxis against early seizures (within the first 7 to 10 days) is recommended in severe brain injury. This practice is controversial for mild to moderate brain injury.[8]

The patient can benefit from a quiet, nonstimulating environment. Always use a calm, reassuring approach. Touch and talk to the patient, even one who is in a coma.

Psychologic Considerations

In addition to carefully planned physical care, be aware of the psychologic well-being of patients and their families. Anxiety over the diagnosis and the prognosis can be distressing to the patient, caregiver and family, and nursing staff. Your competent and assured manner in performing care is reassuring to everyone involved. Short, simple explanations are appropriate and allow the patient and caregiver to acquire the amount of information they desire. There is a need for support, information, and teaching of both patients and families. Assess the family members' desires to help with providing care for the patient and allow for their participation as appropriate. Encourage interprofessional management (e.g., social work, chaplain) involving the patient and family in decision-making as much as possible.

Evaluation

The expected outcomes are that the patient with increased ICP will

- Maintain ICP and cerebral perfusion within normal parameters
- Have no serious increases in ICP during or after care activities

- Have no complications of immobility

Head Injury

Head injury includes any injury or trauma to the scalp, skull, or brain. A serious form of head injury is *traumatic brain injury* (TBI). Statistics about the occurrence of head injury are incomplete because many victims die at the injury scene or the condition is considered minor and health care services are not sought. An estimated 2.8 million persons are treated each year in U. S. emergency departments (EDs) for TBI. Of those, 57,000 die and 282,000 are hospitalized. Of those hospitalized, 20% will die.[9] At least 5.3 million Americans (2% of the U.S. population) currently live with disabilities resulting from TBI.

The most common causes of head injury are falls and motor vehicle accidents. Other causes of head injury include firearms, assaults, sports-related trauma, recreational injuries, and war-related injuries.[9] Men are twice as likely to sustain a TBI as women.

Head trauma has a high potential for a poor outcome. Deaths from head trauma occur at 3 points after injury: immediately after the injury, within 2 hours after injury, and about 3 weeks after injury.[10] Most deaths occur immediately after the injury, either from the direct head trauma or from massive hemorrhage and shock. Deaths occurring within a few hours of the trauma are caused by progressive worsening of the brain injury or internal bleeding.[11]

Deaths occurring 3 weeks or more after the injury result from multisystem failure. Expert nursing care in the weeks after the injury is crucial in decreasing the mortality risk and in optimizing patient outcomes.[12]

Types of Head Injuries

Scalp Lacerations

Scalp lacerations are an easily recognized type of external head trauma. Because the scalp contains many blood vessels with poor constrictive

abilities, most scalp lacerations are associated with profuse bleeding. Even relatively small wounds can bleed significantly. The major complications associated with scalp laceration are blood loss and infection.

Skull Fractures

Skull fractures often occur with head trauma. Skull fractures are described in several ways: (1) linear or depressed; (2) simple, comminuted, or compound; and (3) closed or open (Table 56.6). Fractures may be closed or open, depending on the presence of a scalp laceration or extension of the fracture into the air sinuses or dura. The type and severity of a skull fracture depend on the velocity, momentum, direction, and shape (blunt or sharp) of the injuring agent and site of impact.

TABLE 56.6 Types of Skull Fractures

Type	Description	Cause
Comminuted	Multiple linear fractures with fragmentation of bone into many pieces	Direct, high-momentum impact
Compound	Depressed skull fracture and scalp laceration with communicating pathway to intracranial cavity	Severe head injury
Depressed	Inward indentation of skull	Powerful blow
Linear	Break in continuity of bone without change of relationship of parts	Low-velocity injuries
Simple	Linear or depressed skull fracture without fragmentation or communicating lacerations	Low to moderate impact

TABLE 56.7 Manifestations of Skull Fractures

Fracture Location	Manifestations

Basilar	CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, Battle's sign, tinnitus or hearing difficulty, rhinorrhea, facial paralysis, conjugate deviation of gaze, vertigo
Frontal	Exposure of brain to contaminants through frontal air sinus, possible association with air in forehead tissue, CSF rhinorrhea, pneumocranium (air between cranium and dura mater)
Orbital	Periorbital bruising (raccoon eyes), optic nerve injury
Parietal	Deafness, CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, facial paralysis, loss of taste, Battle's sign
Posterior fossa	Occipital bruising resulting in cortical blindness, visual field defects, rare appearance of ataxia or other cerebellar signs
Temporal	Boggy temporal muscle because of extravasation of blood, oval-shaped bruise behind ear in mastoid region (Battle's sign), CSF otorrhea, middle meningeal artery disruption, epidural hematoma

The location of the fracture determines the manifestations (Table 56.7). For example, a basilar skull fracture is a specialized type of linear fracture involving the base of the skull. Manifestations can evolve over the course of several hours and vary with the location and severity of fracture. These may include cranial nerve deficits, Battle's sign (postauricular bruising), and periorbital bruising (raccoon eyes) (Fig. 56.12). This fracture is often associated with a tear in the dura and subsequent leakage of CSF.

Rhinorrhea (CSF leakage from the nose) or *otorrhea* (CSF leakage from the ear) generally confirms that a fracture has traversed the dura (Fig. 56.12). Rhinorrhea may also manifest as postnasal sinus drainage. Rhinorrhea may be overlooked unless the patient is specifically assessed for this finding. The risk for meningitis is high with a CSF leak. Antibiotics should be given as a preventive measure.

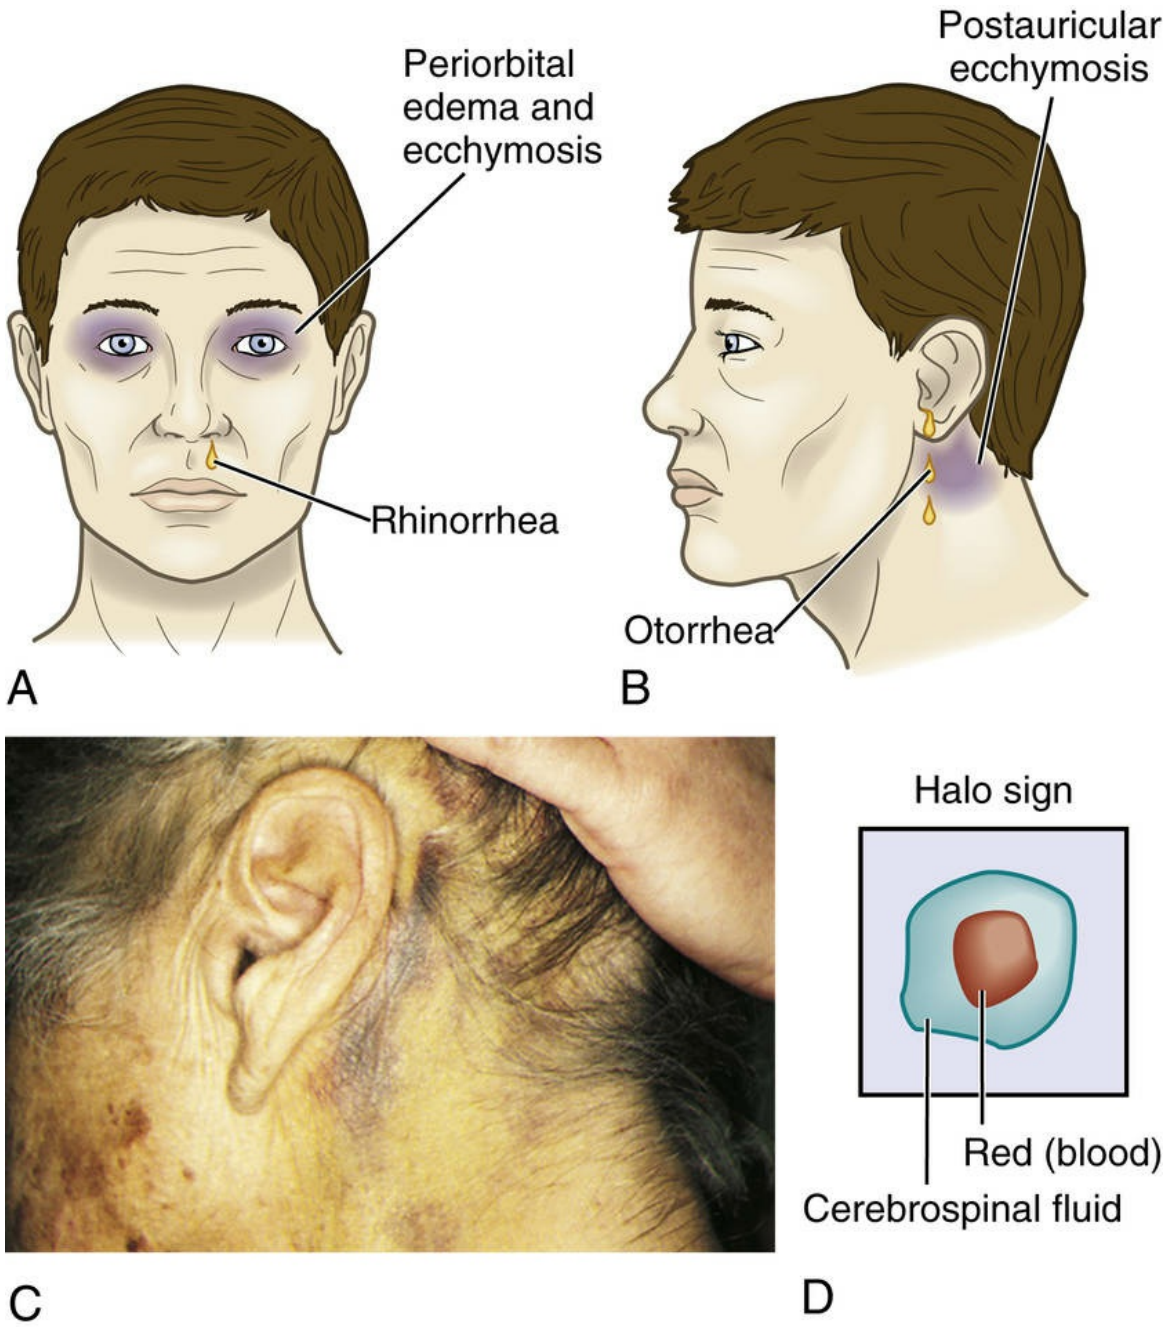


FIG. 56.12 **A,** Raccoon eyes and rhinorrhea. **B,** Battle's sign (postauricular bruising) with otorrhea. **C,** Battle's sign. **D,** Halo or ring sign (see text).
C, From Bingham BJG, Hawke M, Kwok P: *Clinical atlas of otolaryngology,* St Louis, 1992, Mosby.

Two methods of testing can be used to determine whether the fluid leaking from the nose or ear is CSF. The first method is to test the leaking fluid with a Dextrostix or Tes-Tape strip to determine whether

glucose is present. CSF gives a positive reading for glucose. If blood is present in the fluid, testing for glucose is unreliable because blood also contains glucose. In this event, look for the *halo* or *ring* sign (Fig. 56.12, *D*). Allow the leaking fluid to drip onto a white gauze pad (4 × 4) or towel, and then observe the drainage. Within a few minutes, the blood coalesces into the center, and a yellowish ring encircles the blood if CSF is present. Note the color, appearance, and amount of leaking fluid because both tests can give false-positive results.

The major complications of skull fractures are intracranial infections, hematoma, and meningeal and brain tissue damage. When a basilar skull fracture is suspected, an orogastric tube should be inserted rather than a NG tube.

Head Trauma

Brain injuries are categorized as diffuse (generalized) or focal (localized). In a *diffuse* injury (e.g., concussion, diffuse axonal injury), damage to the brain is not localized to one area. In a *focal injury* (e.g., contusion, hematoma), damage is localized to a specific area of the brain. Brain injury can be classified as *minor* (GCS 13 to 15), *moderate* (GCS 9 to 12), or *severe* (GCS 3 to 8).

Diffuse Injury

Concussion, a sudden transient mechanical head injury with disruption of neural activity and a change in the LOC, is considered a minor diffuse head injury. The patient may or may not lose total consciousness with this injury.

Typical signs include a brief disruption in LOC, amnesia about the event (retrograde amnesia), and headache. The manifestations are generally of short duration. If the patient has not lost consciousness, or if the loss of consciousness lasts less than 5 minutes, the patient is usually discharged with instructions to notify the HCP if symptoms persist or if behavioral changes are noted.

Postconcussion syndrome may develop in some patients, usually from 2 weeks to 2 months after the injury. Manifestations include persistent headache, lethargy, personality and behavioral changes, shortened

attention span, decreased short-term memory, and changes in intellectual ability. This syndrome can significantly affect the patient's abilities to perform activities of daily living.

Concussion is generally considered benign and usually resolves spontaneously. For some, the signs and symptoms may be the beginning of a more serious, progressive problem, especially in a patient with a history of prior concussion or head injury. At the time of discharge, it is important to give the patient and caregiver instructions for observation and accurate reporting of symptoms or changes in neurologic status.

Diffuse axonal injury

Diffuse axonal injury (DAI) is widespread axonal damage occurring after a mild, moderate, or severe TBI. The damage occurs primarily around axons in the subcortical white matter of the cerebral hemispheres, basal ganglia, thalamus, and brainstem.[13] Initially, we thought DAI occurred because the tensile forces of trauma sheared axons, resulting in axonal disconnection. There is increasing evidence that axonal damage is not preceded by an immediate tearing of the axon from the traumatic impact. Instead, the trauma changes the function of the axon, resulting in axon swelling and disconnection. This process takes 12 to 24 hours to develop and may persist longer.

The clinical signs of DAI vary. They may include a decreased LOC, increased ICP, decortication or decerebration, and global cerebral edema. About 90% of patients with DAI stay in a persistent vegetative state.[13] Patients with DAI who survive the initial event are rapidly triaged to an ICU. There, they will be vigilantly watched for signs of increased ICP and treated accordingly.

Focal Injury

Focal injury can be minor to severe and localized to an area of injury. Focal injury consists of lacerations, contusions, hematomas, and cranial nerve injuries.

Lacerations involve actual tearing of the brain tissue. They often occur in association with depressed and open fractures and

penetrating injuries. Tissue damage is severe, and surgical repair of the laceration is impossible because of the nature of brain tissue. Medical management consists of antibiotics (until meningitis is ruled out) and preventing secondary injury related to increased ICP. If bleeding is deep into the brain tissue, focal and generalized signs develop.

With major head trauma, many delayed responses can occur. These include hemorrhage, hematoma formation, seizures, and cerebral edema. Intracerebral hemorrhage is generally associated with cerebral laceration. This hemorrhage manifests as a space-occupying lesion accompanied by unconsciousness, hemiplegia on the contralateral side, and a dilated pupil on the ipsilateral side. As the hematoma expands, signs of increased ICP become more severe. Subarachnoid hemorrhage and intraventricular hemorrhage can occur from head trauma.

A **contusion** is bruising of the brain tissue within a focal area. It is usually associated with a closed head injury and often occurs at a fracture site. A contusion may have areas of hemorrhage, infarction, necrosis, and edema.

With contusion, the phenomenon of *coup-contrecoup injury* is often noted (Fig. 56.13). Injuries can range from minor to severe. Damage from coup-contrecoup injury occurs when the brain moves inside the skull due to high-energy or high-impact injury mechanisms. Contusions or lacerations occur both at the site of the direct impact of the brain on the skull *(coup)* and at a second area of damage on the opposite side away from injury *(contrecoup),* leading to multiple contused areas. *Contrecoup* injuries tend to be more severe. The overall prognosis depends on the amount of bleeding around the contusion site.

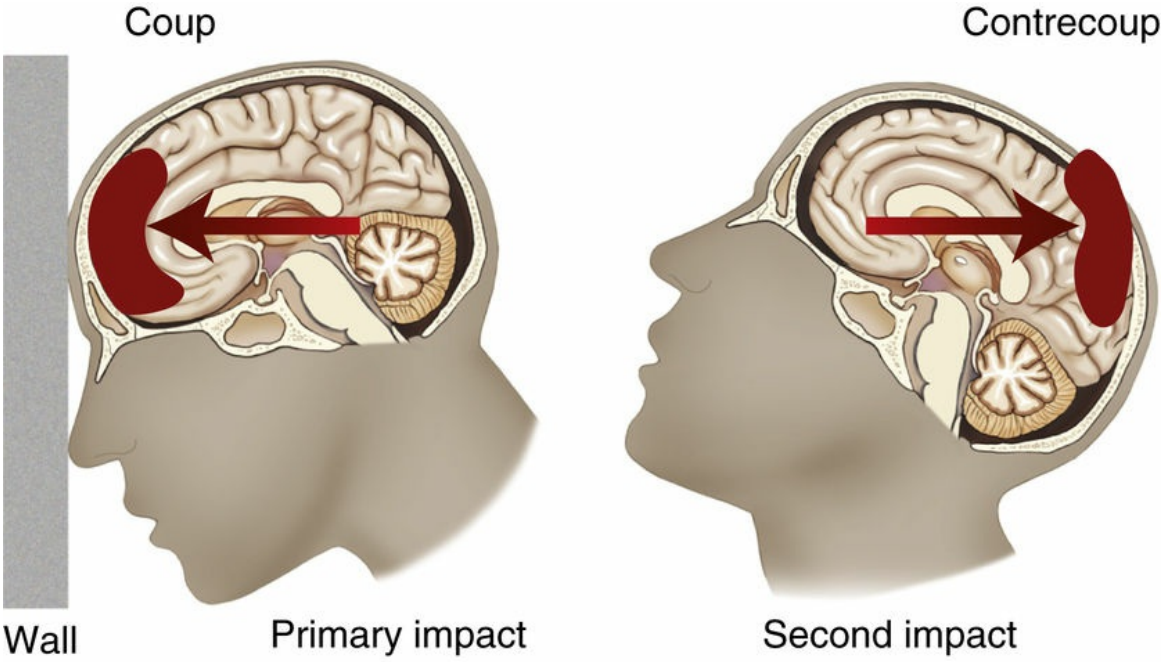

FIG. 56.13 Coup-contrecoup injury. After the head strikes the wall, a coup injury occurs as the brain strikes the skull (primary impact). The contrecoup injury (the second impact) occurs when the brain strikes the skull surface opposite the site of the original impact.

Contusions may continue to bleed or rebleed and appear to "blossom" on subsequent CT scans of the brain. Bleeding worsens the neurologic outcome. Neurologic assessment may show focal and generalized manifestation, depending on the contusion's size and location. Seizures can occur because of a brain contusion, particularly when the injury involves the frontal or temporal lobes. Anticoagulant use and coagulopathy are associated with increased hemorrhage, more severe head injury, and an increased mortality rate.[14] This is especially important with older adults who are taking anticoagulants. If they fall, their contusion is likely to be more severe due to anticoagulant use. Assess for risk for falls in all patients taking anticoagulants.

Complications

Epidural Hematoma

An **epidural hematoma** results from bleeding between the dura and

inner surface of the skull (Figs. 56.14 and 56.15). An epidural hematoma is a neurologic emergency. It is usually associated with a linear fracture crossing a major artery in the dura, causing a tear. It can have a venous or an arterial origin. Venous epidural hematomas are associated with a tear of the dural venous sinus and develop slowly. With arterial hematomas, the middle meningeal artery lying under the temporal bone is often torn. Hemorrhage occurs into the epidural space, which lies between the dura and inner surface of the skull (Fig. 56.14). Because this is an arterial hemorrhage, the hematoma develops rapidly.

Classic signs of an epidural hematoma include an initial period of unconsciousness at the scene, with a brief lucid interval followed by a decrease in LOC. Other manifestations may be a headache, nausea and vomiting, or focal findings. Rapid surgical intervention to evacuate the hematoma and prevent cerebral herniation, along with medical management for increasing ICP, dramatically improves outcomes.

Subdural Hematoma

A **subdural hematoma** occurs from bleeding between the dura mater and arachnoid layer of the meninges (Fig. 56.14). A subdural hematoma usually results from injury to the brain tissue and its blood vessels. The veins that drain from the surface of the brain into the sagittal sinus are the source of most subdural hematomas. Because it is usually venous in origin, a subdural hematoma may be slower to develop. However, an arterial hemorrhage can cause a subdural hematoma, in which case it develops more rapidly.

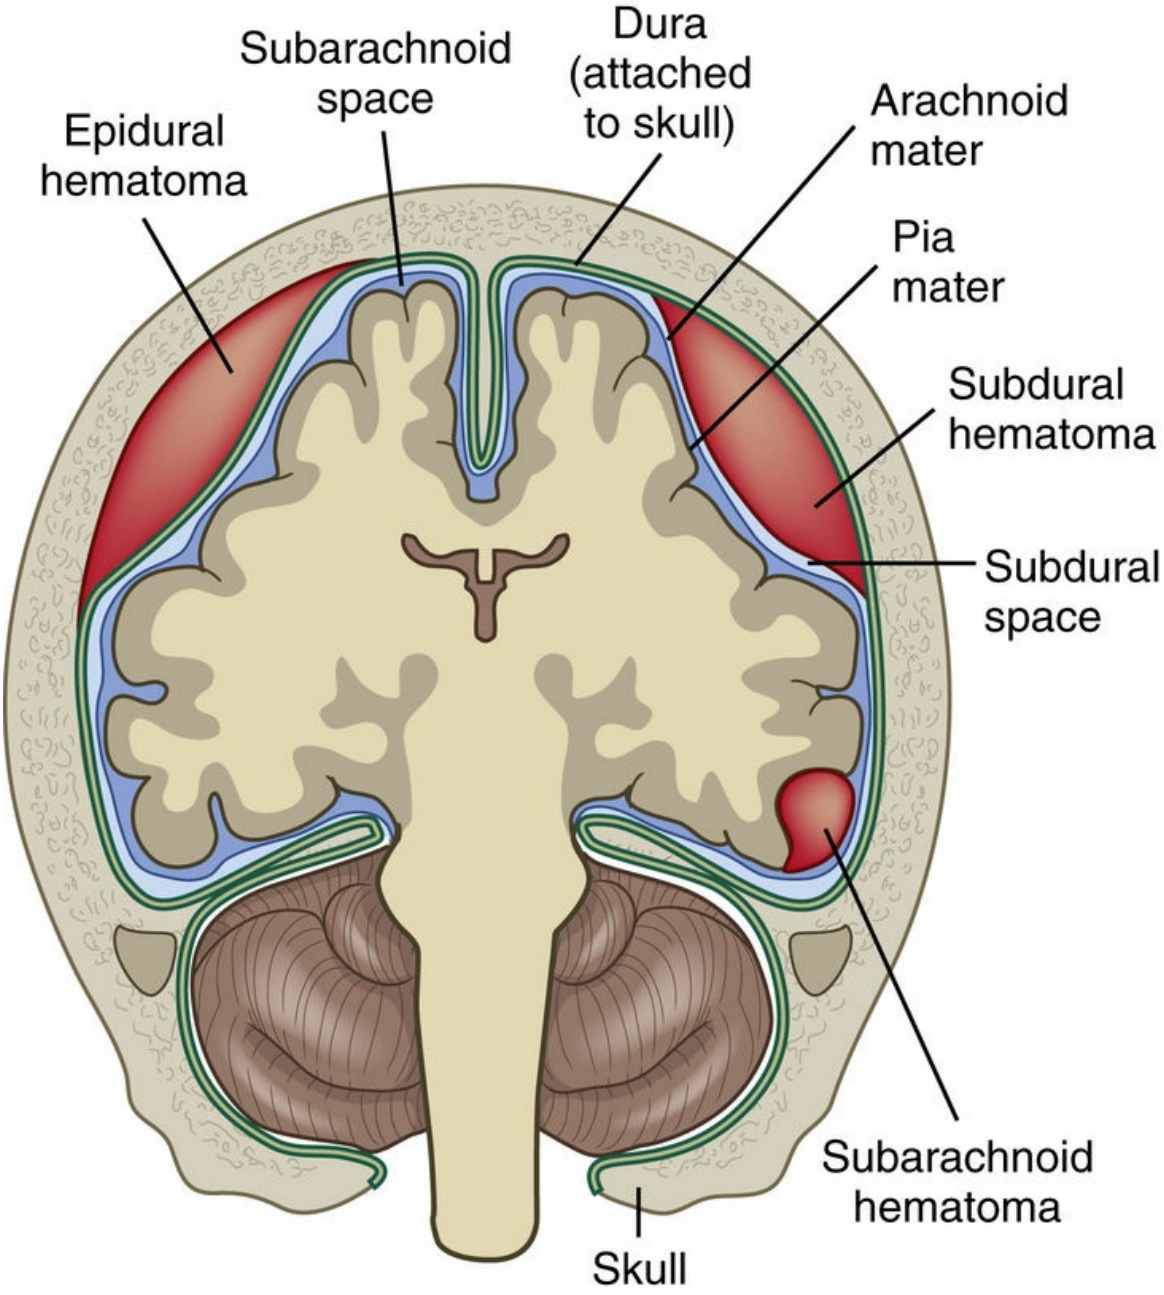

FIG. 56.14 Locations of epidural, subdural, and subarachnoid hematomas.
From Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Mosby.

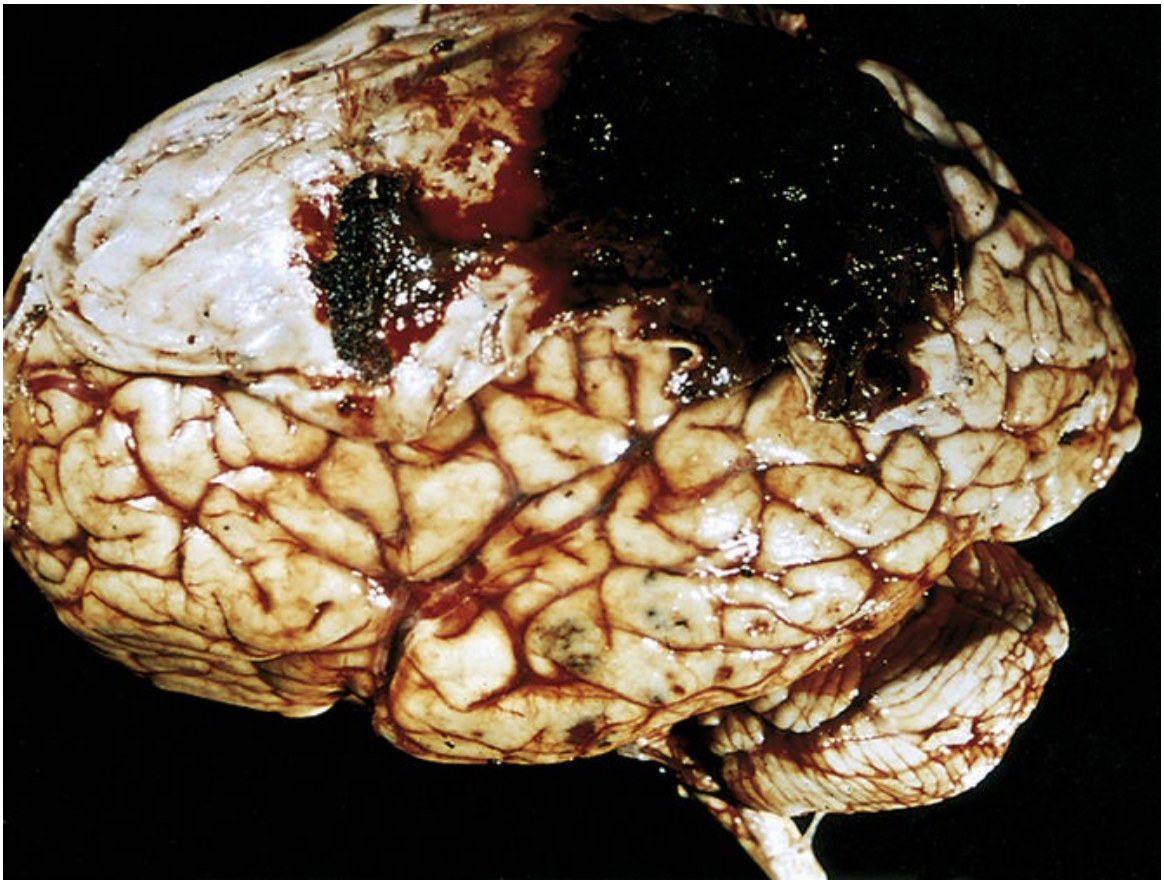

FIG. 56.15 Epidural hematoma covering a portion of the dura. Multiple small contusions are seen in the temporal lobe.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Subdural hematomas may be acute, subacute, or chronic (Table 56.8). An *acute subdural hematoma* manifests within 24 to 48 hours of the injury.[15] The signs and symptoms are similar to those associated with brain tissue compression in increased ICP. They include decreasing LOC and headache. The size of the hematoma determines the patient's presentation and prognosis. The patient's appearance may range from drowsy and confused to unconscious. The ipsilateral pupil dilates and becomes fixed if ICP is significantly increased. Blunt-force injuries that produce acute subdural hematomas may cause significant underlying brain injury, resulting in cerebral edema. The resulting increase in ICP from the cerebral edema can increased morbidity and mortality despite surgery to evacuate the hematoma.

TABLE 56.8 Types of Subdural Hematomas

Occurrence After Injury	Progression of Symptoms	Treatment
Acute		
24–48 hr after severe trauma	Immediate deterioration	Craniotomy, evacuation, and decompression
Subacute		
48 hr–2 wk after severe trauma	Decline in mental status as hematoma develops. Progression dependent on size and location of hematoma	Evacuation and decompression
Chronic		
Weeks or months, usually >20 days after injury. Often injury seemed trivial or was forgotten by patient	Nonspecific, nonlocalizing progression. Progressive change in level of consciousness	Evacuation and decompression, membranectomy

A *subacute subdural hematoma* usually occurs within 2 to 14 days of the injury. After the initial bleeding, this hematoma may appear to enlarge over time as the breakdown products of the blood draw fluid into the subdural space.

A *chronic subdural hematoma* develops over weeks or months after a seemingly minor head injury.[15] They are more common in older adults because of a potentially larger subdural space from brain atrophy. With atrophy, the brain stays attached to the supportive structures and tension is increased. This makes it subject to tearing. Because the subdural space is larger, the presenting problem is focal symptoms (specific to a certain area of the brain) rather than signs of increased ICP.[15] Patients with a history of alcohol use are prone to subdural hematomas because of an increased incidence of falls.

Diagnosis of a subdural hematoma in the older adult may be delayed because symptoms mimic other health problems in this age-group, such as somnolence, confusion, lethargy, and memory loss. The manifestations of a subdural hematoma are often attributed to vascular disease (stroke, transient ischemic attack [TIA]) or dementia.

Check Your Practice

You are doing BP screenings in the senior center when you meet a 76-yr-old man and his wife. As you perform their BP screening, the wife tells you that her husband has been getting severe headaches, is dizzy, and sometimes has difficulty talking. Based on your advice, they go to an urgent care center, where a CT scan is done. The results show he has a chronic subdural hematoma. When you find out the diagnosis, you are puzzled because you thought he was having a stroke and cannot understand how he got a subdural hematoma.

- If you had been the nurse, what would you have done differently when screening this man?

Intracerebral Hematoma

Intracerebral hematoma occurs from bleeding within the brain tissue. It occurs in about 16% of head injuries. It usually happens in the frontal and temporal lobes, possibly from rupture of intracerebral vessels at the time of injury. The size and location of the hematoma are key in determining the patient's outcome.

TABLE 56.9 Emergency ManagementHead Injury

Etiology	Assessment Findings	Interventions
Blunt • **Assault** • **Fall** • **Motor vehicle collision** • **Sports injury** **Penetrating** • **Arrow** • **Gunshot** • **Knife**	**Surface Findings** • Bruises or contusions on face, Battle's sign (bruising behind ears) • Fracture or depressions in skull • Raccoon eyes (dependent bruising around eyes) • Scalp lacerations **Central Nervous System** • Asymmetric facial movements • Combativeness • Confusion • CSF leaking from ears or nose • Decerebrate or decorticate posturing • Decreased level of consciousness • Depressed or hyperactive reflexes • Dilated or unequal pupils, photophobia • Flaccidity • Garbled speech, abusive speech • GCS score <12 • Incontinence • Involuntary movements • Seizures **Respiratory** • Central neurogenic hyperventilation • Cheyne-Stokes respirations • Decreased O_2 saturation • Pulmonary edema	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Assume neck injury with head injury. • Stabilize cervical spine. • Apply O_2 via nonrebreather mask. • Establish IV access with 2 large-bore catheters to infuse normal saline or lactated Ringer's solution. • Intubate if GCS score <8. • Control external bleeding with sterile pressure dressing. • Remove patient's clothing. **Ongoing Monitoring** • Maintain normothermia using blankets, warm IV fluids, as needed. • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, GCS score, pupil size and reactivity. • Expect intubation if gag reflex is impaired or absent. • Assess for rhinorrhea, otorrhea, scalp wounds. • Give fluids cautiously to prevent fluid overload and increasing ICP.

Diagnostic Studies and Interprofessional Care

In general, the diagnostic studies are similar to those used for a patient with increased ICP (Table 56.3). CT scan is the best diagnostic test to evaluate for head trauma. It allows for rapid diagnosis and intervention in the acute care setting. MRI, PET, and evoked potential studies may be used to diagnose head injuries. An MRI scan is more sensitive than the CT scan in detecting small lesions. Transcranial Doppler studies allow for the measurement of cerebral blood flow (CBF) velocity. A cervical spine x-ray series, CT scan, or MRI of the spine may be done since cervical spine trauma often occurs at the same time as a head injury.

Emergency management of the patient with a head injury is outlined in Table 56.9. The principal treatment of head injuries is prompt diagnosis and surgery (if needed), In addition, we institute measures to prevent secondary injury by treating cerebral edema and managing increased ICP. For the patient with concussion and contusion, observation and management of increased ICP are the main management strategies.

The treatment of skull fractures is usually conservative. For

depressed fractures and fractures with loose fragments, a craniotomy is done to elevate the depressed bone and remove the free fragments. If large amounts of bone are destroyed, the bone may be removed (craniectomy) and a cranioplasty will be needed later (see pp. 1321–1322).

In cases of large acute subdural and epidural hematomas or those associated with significant neurologic impairment, the blood must be removed through surgical evacuation. A craniotomy is generally done to see and allow control of the bleeding vessels. Burr-hole openings may be used in an extreme emergency for a more rapid decompression, followed by a craniotomy. A drain may be placed after surgery for several days to prevent blood from reaccumulating. In cases in which extreme swelling is expected (e.g., DAI, hemorrhage), a craniectomy may be done. This involves removing a piece of skull to reduce the pressure inside the cranial vault. It reduces the risk for herniation.

Nursing Management: Head Injury

Nursing Assessment

A patient with a head injury always has the potential to develop increased ICP, which is associated with higher mortality rates and poorer functional outcomes. Objective data are obtained by applying the GCS (Table 56.5), assessing and monitoring the neurologic status, and determining whether a CSF leak has occurred. Nursing assessment related to increased ICP is discussed on pp. 1308–1309. Nursing assessment of the patient with a head injury is outlined in Table 56.10.

Nursing Diagnoses

Nursing diagnoses for the patient who has sustained a head injury may include:

- Decreased intracranial adaptive capacity
- Ineffective tissue perfusion
- Hyperthermia
- Risk for injury
- Anxiety

Planning

The overall goals are that the patient with an acute head injury will (1) maintain adequate cerebral oxygenation and perfusion; (2) stay afebrile; (3) be free of discomfort; (4) be free from infection; (5) have adequate nutrition; and (6) attain maximal cognitive, motor, and sensory function.

TABLE 56.10 Nursing AssessmentHead Injury

Subjective Data

Important Health Information

Past health history: Mechanism of injury: motor vehicle collision, sports injury, industrial incident, assault, falls
Medications: Anticoagulant drugs

Functional Health Patterns

Health perception–health management: Alcohol or recreational drugs. Risk-taking behaviors
Cognitive-perceptual: Headache, mood or behavioral change, mentation changes, aphasia, dysphasia, impaired judgment
Coping–stress tolerance: Fear, denial, anger, aggression, depression

Objective Data

General

Altered mental status

Integumentary

Lacerations, contusions, abrasions, hematoma, Battle's sign, periorbital edema and bruising, otorrhea, exposed brain matter

Respiratory

Rhinorrhea, impaired gag reflex, inability to maintain a patent airway. Impending herniation: altered/irregular respiratory rate and pattern

Cardiovascular

Impending herniation: Cushing's triad (systolic hypertension with widening pulse pressure, bradycardia with full and bounding pulse, irregular respirations)

Gastrointestinal

Vomiting, projectile vomiting, bowel incontinence

Urinary

Bladder incontinence

Reproductive

Uninhibited sexual expression

Neurologic

Altered level of consciousness, seizure activity, pupil dysfunction, cranial nerve deficit(s)

Musculoskeletal

Motor deficit/impairment, weakness, palmar drift, paralysis, spasticity, decorticate or decerebrate posturing, muscular rigidity or increased tone, flaccidity, ataxia

Possible Diagnostic Findings

Location and type of hematoma, edema, skull fracture, and/or foreign body on CT scan and/or MRI; abnormal EEG; positive toxicology screen or alcohol level, ↓ or ↑ blood glucose level; ↑ ICP

Nursing Implementation

Health Promotion

One of the best ways to prevent head injuries is to prevent car and motorcycle accidents. Be active in campaigns that promote driving safety. Speak to driver education classes about the dangers of distracted driving and driving after drinking alcohol or using drugs. Helmets for motorcycle riders is the most effective measure for increasing survival after crashes.

Ethical/Legal Dilemmas

Brain Death

Situation

The emergency nurse receives a call from emergency response system (ERS) personnel, who are in route with R.G., a young man involved in a motorcycle crash. He was not wearing a helmet and has a large open skull fracture. Transport from the accident scene was delayed by 45 min because of a severe thunderstorm and traffic congestion. R.G. has fixed, dilated pupils and is in cardiac arrest. Estimated arrival at the hospital is still another 45 min because of the severe weather. EMS personnel request permission to stop resuscitation efforts.

Ethical/Legal Points for Consideration

- Criteria for brain death include coma or unresponsiveness, absence of brainstem reflexes, and apnea (see Chapter 9).
- The definition of death has changed with the advent of new technology, monitoring devices, and interventions.
- In a situation in which the professional responsible for determining a state of death is in remote contact with the patient, but the monitoring devices available provide virtual contact with the patient, a remote diagnosis of death may be legally acceptable.
- Brain death criteria do not address patients in a permanent vegetative state since the brainstem activity in these patients is adequate to maintain heart and lung function.
- CPR is not appropriate when survival is not expected or the patient is expected to survive without the ability to communicate. Quantitative futility implies that survival is not expected after CPR under given circumstances. In the absence of mitigating factors, prolonged resuscitative efforts are unlikely to be successful and can be stopped if there is no return of spontaneous circulation at any time during 30 minutes of cumulative advanced life support.

- It is ethical for ED personnel to stop treatment started by ERS personnel in the prehospital setting if there is valid, after-the-fact evidence that these interventions are now inappropriate.

Discussion Questions

- What are your feelings about cessation of brain function vs. cessation of heart and lung function as the criteria for death of a patient?
- What are your state's laws or practices about stopping CPR efforts by ERS personnel in the field?

Promoting Population Health

Reducing the Risk for Head Injuries

- Always wear car seat belts in motor vehicles.
- Do not drive after using drugs or alcohol.
- Do not text and drive or drive distracted.
- Wear helmets while bicycling, skating, skateboarding, skiing, and playing contact sports.
- Athletes should follow safe playing techniques and the rules of the game.
- Assess home safety and implement any corrective measures needed.
- Older adults should continue to exercise regularly to improve strength and balance.
- Follow workplace safety precautions, including wearing helmets and protective gear.

Acute Care

Management at the injury scene can have a significant impact on the outcome of a head injury. Emergency management of head injury is outlined in Table 56.9. The general goal of nursing management of the patient with head injury is to maintain cerebral oxygenation and perfusion and prevent secondary cerebral ischemia.

TABLE 56.11 Patient & Caregiver TeachingHead Injury

Include the following instructions when teaching the patient and caregiver about care during the first 2 or 3 days after a head injury:

1. Notify your HCP immediately if you have signs and symptoms that may indicate complications. These include:
    - Increased drowsiness (e.g., difficulty arousing, confusion)
    - Nausea or vomiting
    - Worsening headache or stiff neck
    - Seizures
    - Vision difficulties (e.g., blurring) or sensitivity to light (photophobia)
    - Behavioral changes (e.g., irritability, anger)
    - Motor problems (e.g., clumsiness, difficulty walking, slurred speech, weakness in arms or legs)
    - Sensory problems (e.g., numbness)
    - A heart rate <60 beats/min
2. Have someone stay with you.
3. Abstain from alcohol.
4. Check with your HCP before taking drugs that may increase drowsiness, including muscle relaxants, tranquilizers, and opioid analgesia.
5. Avoid driving, using heavy machinery, playing contact sports, and taking hot baths.

Surveillance or monitoring for changes in neurologic status is critically important because the patient's condition may deteriorate rapidly, requiring emergency surgery. Appropriate nursing interventions are started if surgery is anticipated. Because of the close association between hemodynamic status and cerebral perfusion, be aware of any coexisting injuries or conditions.

Explain the need for frequent neurologic assessments to both the patient and caregiver. Behavioral manifestations associated with head injury can result in a frightened, disoriented patient who is combative and resists help. Your approach should be calm and gentle. A family member may be available to stay with the patient and thus decrease anxiety and fear. An important need of the caregiver and family members in the acute injury phase is information about the patient's diagnosis, treatment plan, and reason for the interventions. Other teaching points are described in Table 56.11.

Perform neurologic assessments at intervals based on the patient's condition. The GCS is useful in assessing the LOC (Table 56.5). Report any signs of a deteriorating neurologic state, no matter how subtle, such as a decreasing LOC or decreasing motor strength, to the HCP. Monitor the patient's condition closely.

The major focus of nursing care for the patient with a brain injury relates to increased ICP (see eNursing Care Plan 56.1). However, some problems need specific nursing intervention.

Eye problems may include loss of the corneal reflex, periorbital bruising and edema, and diplopia. Loss of the corneal reflex may require lubricating eye drops or taping the eyes shut to prevent abrasion. Periorbital bruising and edema decrease with time. Cold and, later, warm compresses provide comfort and hasten the process. Wearing an eye patch can relieve diplopia. Consider a consult with an ophthalmologist.

Fever may occur from injury to or inflammation of the hypothalamus. Fever can cause increased CBF, cerebral blood volume, and ICP. Increased metabolism from fever increases metabolic waste, which in turn causes further cerebral vasodilation. Avoid fever with a goal of a temperature of 96.8° to 98.6° F (36° to 37° C) as the standard

of care. Use interventions to reduce temperature as previously discussed (see p. 1308) in conjunction with sedation to prevent shivering.

If CSF rhinorrhea or otorrhea occurs, inform the HCP at once. The head of the bed may be raised to decrease the CSF pressure so that a tear can seal. A loose collection pad may be placed under the nose or over the ear. Do not place a dressing in the nasal or ear cavities. Document the amount of drainage each shift. Teach the patient not to sneeze or blow the nose. Do not use NG tubes. Do not perform nasotracheal suctioning on these patients because of the high risk for meningitis.

Nursing measures specific to the care of the immobilized patient, such as those related to bladder and bowel function, skin care, and infection, are needed. Nausea and vomiting may be a problem and can be alleviated by antiemetic drugs. Headache can usually be controlled with acetaminophen or small doses of codeine.

If the patient's condition deteriorates, intracranial surgery may be needed (see the section on cranial surgery on pp. 1321–1323). A burr-hole opening or craniotomy may be done, depending on the underlying injury that is causing the problems. The emergency nature of the surgery may hasten the usual preoperative preparation. Consult with the HCP to determine specific preoperative nursing measures.

The patient is often unconscious before surgery, making it necessary for a family member to sign the consent form for surgery. This is a difficult and frightening time for the patient's caregiver and family and requires sensitive nursing management. The suddenness of the situation makes it especially hard for the family to cope. Use a team approach, including social workers, to help the patient and family throughout the hospitalization and recovery time.

Ambulatory Care

Once the condition has stabilized, the patient is usually transferred for acute rehabilitation management. There may be chronic problems related to motor and sensory deficits, communication, memory, and intellectual functioning. Conditions that may need nursing and

interprofessional management include nutrition problems, bowel and bladder problems, spasticity, dysphagia, and hydrocephalus. Many of the principles for managing the patient with a stroke are appropriate for these patients (see Chapter 57).

Seizure disorders may occur in patients with nonpenetrating head injury. Seizures may develop during the first week after the head injury or not until years later. Antiseizure drugs may be used prophylactically to manage posttraumatic seizure activity, but this practice is controversial.

The mental and emotional sequelae are often the most incapacitating problems. One of the consequences of TBI is that the person may not realize that a brain injury has occurred. Many patients with head injuries who were comatose for more than 6 hours undergo some personality change. They may have loss of concentration and memory and defective memory processing. Personal drive may decrease. Apathy may increase. Euphoria and mood swings, along with a seeming lack of awareness of the seriousness of the injury, may occur. The patient's behavior may indicate a loss of social restraint, judgment, tact, and emotional control.

Progressive recovery may continue for years. Specific nursing management in the posttraumatic phase depends on specific residual deficits. Being able to return to work and maintaining employment is one of the challenges during the recovery period.[16] The patient's outward physical appearance does not necessarily reflect what has happened in the brain. It is not a good indicator of how well the patient will ultimately function in the home or work environment.

TABLE 56.12 Types of Brain Tumors

Type	Tissue of Origin	Characteristics
Acoustic neuroma (schwannoma)	Cells that form myelin sheath around nerves. Often affects cranial nerve VIII	Many grow on both sides of the brain. Usually benign or low-grade.
Gliomas		
• **Astrocytoma**	Supportive tissue, glial cells, and astrocytes	Can range from low-grade to moderate-grade.
• **Ependymoma**	Ependymal epithelium	Range from benign to highly malignant. Most are benign and encapsulated.
• **Glioblastoma**	Primitive stem cell (glioblast)	Highly malignant and invasive. Among the most devastating of primary brain tumors.
• **Medulloblastoma**	Primitive neuroectodermal cell	Highly malignant and invasive. Metastatic to spinal cord and remote areas of brain.
• **Oligodendroglioma**	Oligodendrocytes	Benign (encapsulation and calcification).
Hemangioblastoma	Blood vessels of brain	Rare and benign. Surgery is curative.
Meningioma	Meninges	Can be benign or malignant. Most are benign.
Metastatic tumors	Lungs and breast (most common)	Malignant.
Pituitary adenoma	Pituitary gland	Usually benign.
Primary central nervous system lymphoma	Lymphocytes	Increased incidence in transplant recipients and acquired immunodeficiency syndrome (AIDS) patients.

Give the family special consideration. They need to understand what is happening. Provide guidance and referrals for financial aid, child care, and other personal needs. Help the family in involving the patient in family activities whenever possible. Help the patient and family remain hopeful. The family often has unrealistic expectations of the patient as the coma begins to recede. The family expects full return to pretrauma status. In reality, the patient usually has a reduced awareness and ability to interpret environmental stimuli. Prepare the family for the patient's emergence from coma and explain that the process of awakening often takes several weeks. In addition, arrange for social work and chaplain consultations for the family.

When it is the time for discharge planning, the patient, caregiver, and family may benefit from specific instructions to avoid family-patient friction. Special "no" policies that may be suggested by the HCP, neuropsychologist, and nurse include no drinking of alcoholic beverages, no driving, no use of firearms, no working with hazardous implements and machinery, and no unsupervised smoking. Family members, particularly spouses, go through role transition as the role changes from that of spouse to that of caregiver.

Evaluation

The expected outcomes are that the patient with a head injury will

- Maintain normal CPP
- Achieve maximal cognitive, motor, and sensory function
- Have no infection or fever

Brain Tumors

There are an estimated 23,400 people diagnosed each year with brain tumors in the United States. The brain is also a frequent site for metastasis from other sites.[17] Males have a slightly higher incidence of brain tumors than females. Brain tumors most often occur in middle-aged persons, but they may be seen at any age.

Promoting Health Equity

Brain Tumors

- Whites have a higher incidence of malignant brain tumors than blacks.
- White males have the highest incidence of malignant brain tumors.
- Blacks have the highest incidence of benign brain tumors (e.g., meningiomas).

Types

Brain tumors can occur in any part of the brain or spinal cord. Tumors of the brain may be *primary,* arising from tissues within the brain, or *secondary,* resulting from a metastasis of cancer from elsewhere in the body.[18]

Metastatic brain tumors are the most common brain tumor. The cancers that most often metastasize to the brain are lung and breast.

Primary brain tumors are generally classified according to the tissue from which they arise (Table 56.12). Meningiomas are the most

common primary brain tumor. Other common brain tumors are gliomas (e.g., astrocytoma, glioblastoma [most common form of glioma]).

More than half of brain tumors are malignant. They infiltrate the brain tissue and are not amenable to complete surgical removal. Other tumors may be histologically benign but are located such that complete removal is not possible.

Brain tumors rarely metastasize outside the central nervous system (CNS) because they are contained by structural (meninges) and physiologic (blood-brain) barriers. Table 56.12 compares the most common brain tumors. A glioblastoma and meningioma are shown in Fig. 56.16.

Clinical Manifestations and Complications

The manifestations of brain tumors depend mainly on their location and size (Table 56.13). A wide range of manifestations are possible. Headache is common. Tumor-related headaches tend to be worse at night and may awaken the patient. The headaches are usually dull and constant but sometimes throbbing. Seizures are common in gliomas and brain metastases. Brain tumors can cause nausea and vomiting from increased ICP. Cognitive dysfunction, including memory problems and mood or personality changes, is common, especially in patients with brain metastases. Muscle weakness, sensory losses, aphasia, and visual-spatial dysfunction may occur.

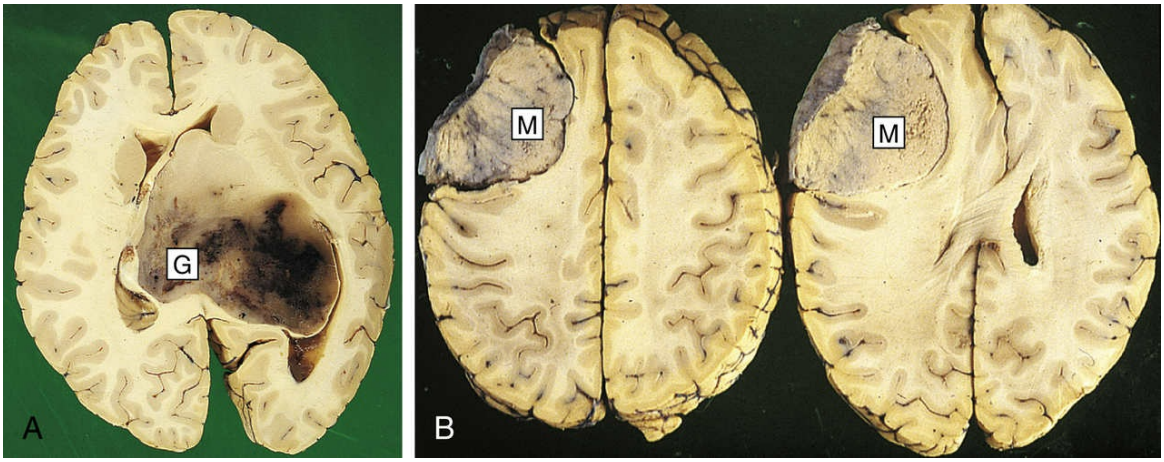

FIG. 56.16 **A,** A large glioblastoma *(G)* arises from one cerebral hemisphere and has grown to fill the ventricular system. **B,** Meningioma. These 2 different sections from different levels in the same brain show a meningioma *(M)* compressing the frontal lobe and distorting underlying brain.
From Stevens A, Lowe J: *Pathology: Illustrated review in colour,* ed 2, London, 2000, Mosby.

TABLE 56.13 Manifestations of Brain Tumors

Tumor Location	Manifestations
Brainstem tumors	Headache on awakening, drowsiness, vomiting, ataxic gait, facial muscle weakness, hearing loss, dysphagia, dysarthria, "crossed eyes" or other visual changes, hemiparesis
Cerebellopontine tumors	Tinnitus and vertigo, deafness
Cerebral hemisphere	
• **Frontal lobe (unilateral)**	Unilateral hemiplegia, seizures, memory deficit, personality and judgment changes, visual changes
• **Frontal lobe (bilateral)**	Symptoms associated with unilateral frontal lobe tumors. Ataxic gait
• **Parietal lobe**	Speech problems (if tumor is in the dominant hemisphere), inability to write, spatial disorders, unilateral neglect
• **Occipital lobe**	Vision changes and seizures
• **Temporal lobe**	Few symptoms. Seizures, dysphagia, hallucinations, auras
Fourth ventricle and cerebellar tumors	Headache, nausea, and papilledema (occur from ↑ ICP). Ataxic gait and changes in coordination
Meningeal tumors	Symptoms associated with compression of the brain and depend on tumor location
Metastatic tumors	Headache, nausea, or vomiting (occur from ↑ ICP). Other symptoms depend on tumor location
Subcortical	Hemiplegia; other symptoms may depend on area of infiltration
Thalamus and sellar tumors	Headache, nausea, vision changes, papilledema, and nystagmus (occur from ↑ ICP). Diabetes insipidus may occur

If the tumor mass obstructs the ventricles or occludes the outlet, ventricular enlargement (hydrocephalus) can occur. As the brain

tumor expands, it may produce manifestations of increased ICP, cerebral edema, or obstruction of the CSF pathways. Unless treated, all brain tumors eventually cause death from increasing tumor volume leading to increased ICP.

Diagnostic Studies

An extensive history and a comprehensive neurologic examination is done in the workup of a patient with a suspected brain tumor. The history and physical examination may provide data with respect to location. New onset of seizures or adult-onset migraines may indicate a brain tumor and should be investigated. Diagnostic studies are similar to those used for a patient with increased ICP (Table 56.3).

The sensitivity of techniques such as MRI and PET scans allows for detection of small tumors and may provide more reliable diagnostic information than a CT scan. CT with contrast and MRI are used to identify the lesion's location. Other tests include magnetic resonance spectroscopy, functional MRI (fMRI), and single-photon emission computed tomography (SPECT). An EEG can rule out seizures but is of less importance. An LP is seldom diagnostic and carries with it the risk for cerebral herniation. Cerebral angiography can determine blood flow to the tumor and further localize the tumor. Other studies are done to rule out a primary lesion elsewhere in the body. Endocrine studies are helpful when a pituitary adenoma is suspected (see Chapter 49).

The correct diagnosis of a brain tumor can be made by obtaining tissue for histologic study. In most patients, tissue is obtained at the time of surgery. Computer-guided stereotactic biopsy is also an option. A smear or frozen section can be done in the operating room for a preliminary interpretation of the histologic type. With this information, the HCP can make a better decision about the extent of surgery.

Interprofessional Care

Treatment goals are aimed at (1) identifying the tumor type and

location, (2) removing or decreasing tumor mass, and (3) preventing or managing increased ICP.

Surgical Therapy

Surgical removal is the preferred treatment for brain tumors. Stereotactic surgical techniques are used with greater frequency to perform a biopsy and remove small brain tumors. The outcome of surgery depends on the tumor's type, size, and location. Meningiomas and oligodendrogliomas can usually be completely removed. The more invasive gliomas and medulloblastomas may only be partially removed. Computer-guided stereotactic biopsy, ultrasound, fMRI, and cortical mapping can localize brain tumors during surgery.

Complete surgical removal of brain tumors is not always possible because the tumor is not always accessible or may involve vital parts of the brain. Surgery can reduce tumor mass, which decreases ICP, provides relief of symptoms, and extends survival time.

Ventricular Shunts

Hydrocephalus due to a tumor obstructing the CSF flow can be treated with the placement of a ventricular shunt. A catheter with 1-way valves is placed in the lateral ventricle and then tunneled under the skin to drain CSF into the peritoneal cavity. Rapid decompression of ICP can cause total body collapse and weakness. Headache may be prevented by gradually introducing the patient to the upright position.

Manifestations of shunt malfunction, which are related to increased ICP, include decreasing LOC, restlessness, headache, blurred vision, or vomiting. This may require shunt revision or replacement. Infection may occur, as exhibited by high fever, persistent headache, and stiff neck. Antibiotics are used to treat the infection. In some situations, the shunt must be replaced. CSF drainage is managed with an extraventricular drainage system while the infection is treated.

Radiation Therapy and Stereotactic Radiosurgery

Radiation therapy may be used as a follow-up measure after surgery. Radiation seeds can be implanted into the brain. Cerebral edema and rapidly increasing ICP may be a complication of radiation therapy. These problems can usually be managed with high doses of corticosteroids (e.g., dexamethasone, methylprednisolone). Radiation therapy is discussed in Chapter 15.

Stereotactic radiosurgery is a method of delivering a highly concentrated dose of radiation to a precise location within the brain. Stereotactic radiosurgery may be used when conventional surgery has failed or is not an option because of the tumor location. (Radiosurgery is discussed on p. 1322.)

Chemotherapy and Targeted Therapy

The effectiveness of chemotherapy has been limited by the difficulty with getting drugs across the blood-brain barrier, tumor cell heterogeneity, and tumor cell drug resistance. Chemotherapy drugs called *nitrosoureas* (e.g., carmustine, lomustine) are used to treat brain tumors. Normally the blood-brain barrier prohibits the entry of most drugs into the brain. Cancer tumors can cause a breakdown of the blood-brain barrier in the area of the tumor, thus allowing chemotherapy agents to be used to treat the cancer. Chemotherapy-laden biodegradable wafers (e.g., Gliadel wafer [polifeprosan with carmustine implant]) implanted at the time of surgery can deliver chemotherapy directly to the tumor site. Other drugs being used include methotrexate and procarbazine (Matulane). One way used to deliver chemotherapy drugs directly to the CNS is intrathecal administration via an Ommaya reservoir.

Temozolomide (Temodar) is an oral chemotherapy agent that can cross the blood-brain barrier. In contrast with many chemotherapy drugs, which require metabolic activation to exert their effects, temozolomide can convert spontaneously to a reactive agent that directly interferes with tumor growth. It does not interact with other common drugs taken by patients with brain tumors, such as antiseizure drugs, corticosteroids, and antiemetics.

Drug Alert

Temozolomide (Temodar)

- Causes myelosuppression. Before using, the absolute neutrophil count should be ≥1500/μL and platelet count should be ≥100,000/μL.
- To reduce nausea and vomiting, take on empty stomach or at bedtime.

Bevacizumab (Avastin) is used to treat patients with glioblastoma that continues to progress after standard therapy. Bevacizumab is a targeted therapy that inhibits the action of vascular endothelial growth factor, which helps form new blood vessels. These vessels can feed a tumor, helping it to grow, and provide a pathway for cancer cells to circulate in the body. Targeted therapy is discussed in Chapter 15 and Table 15.13.

Other Therapies

A medical device system, the Optune System, is used to treat glioblastoma that recurs or progresses after receiving chemotherapy and radiation therapy. With this system, electrodes are placed on the surface of the patient's scalp to deliver low-intensity, changing electrical fields called *tumor treatment fields* (TTFs) to the tumor site.

Nursing Management: Brain Tumors

Nursing Assessment

Interview data are as important as the actual physical assessment. Ask about the medical history, intellectual abilities and educational level, and history of nervous system infections and trauma. Structure the initial assessment to provide baseline data of the patient's neurologic

status. Use this information to design a realistic, patient specific care plan.

Assess the patient's LOC, motor abilities, sensory perception, integrated function (including bowel and bladder function), and balance and proprioception. Determine the presence of seizures, syncope, nausea and vomiting, and headaches or other pain. Assess the coping abilities of the patient, caregiver, and family. Watching a patient perform activities of daily living and listening to the patient's conversation can be part of the neurologic assessment. Having the patient or caregiver explain the problem can be helpful to determine the patient's limitations and obtain information about the patient's insight into the problems. Record all initial data to provide a baseline for comparison to determine whether the patient's condition is improving or deteriorating.

Nursing Diagnoses

Nursing diagnoses for the patient with a brain tumor may include:

- Ineffective tissue perfusion
- Acute pain
- Anxiety
- Risk for injury

Planning

The overall goals are that the patient with a brain tumor will (1) maintain normal ICP, (2) maximize neurologic functioning, (3) achieve control of pain and discomfort, and (4) be aware of the long-term implications with respect to prognosis and cognitive and physical functioning.

Nursing Implementation

A tumor of the frontal lobe can cause behavioral and personality changes. Loss of emotional control, confusion, disorientation, memory

loss, impulsivity, and depression may be signs of a frontal lobe lesion. The patient often does not perceive these changes. They can be disturbing and frightening to the caregiver and family. These changes can also cause a distancing to occur between the family and patient. Help the caregiver and family understand what is happening to the patient and support the family.

The confused patient with behavioral instability can be a challenge. Protecting the patient from self-harm is an important part of nursing care. Essential interventions include close supervision of activity, use of side rails, judicious use of restraints, appropriate sedatives, padding of the rails and the area around the bed, and a calm, reassuring approach.

Perceptual problems associated with frontal and parietal lobe tumors contribute to a patient's disorientation and confusion. Minimize environmental stimuli, create a routine, and use reality orientation for the confused patient. Tumors in the temporal lobe can cause hallucinations, which may be confused with dementia or delirium.

Seizures, which often occur with brain tumors, are managed with antiseizure drugs. Use seizure precautions for the patient's protection. Some behavioral changes seen in the patient are a result of seizure disorders and can improve with adequate seizure control. Patients at risk for seizures may be unable to drive, so be aware of the extra resources needed and collaborate with the social worker and family. Seizure disorders are discussed in Chapter 58.

Motor and sensory dysfunctions interfere with activities of daily living. Encourage the patient to provide as much self-care as physically possible. Self-image often depends on the patient's ability to take part in care within the limitations of the physical deficits.

Language deficits may be present. Motor (expressive) or sensory (receptive) dysphasia may occur. The problem with communication can be frustrating for the patient and may interfere with your ability to meet the patient's needs. Try to establish a communication system that both the patient and staff can use.

Nutritional intake may be decreased because of the patient's

inability to eat, loss of appetite, or loss of desire to eat. Assess nutritional status and ensure adequate nutritional intake. Encourage the patient to eat. Some patients may need enteral or parenteral nutrition (see Chapter 39).

Provide help and support during the adjustment phase and in long-range planning. Social work and home health nurses may be needed to aid the caregiver with discharge planning and to help the family adjust to role changes and psychosocial and socioeconomic factors. Issues related to palliative and end-of-life care must be discussed with both the patient and family (see Chapter 9).

Evaluation

The expected outcomes are that the patient with a brain tumor will

- Achieve control of pain, vomiting, and other discomforts
- Maintain ICP within normal limits
- Have maximal neurologic function given the location and extent of the tumor
- Maintain optimal nutritional status
- Accept the long-term consequences of the tumor and its treatment

Cranial Surgery

Indications for cranial surgery are related to brain tumors, CNS infection (e.g., abscess), vascular abnormalities, craniocerebral trauma, seizure disorder, or intractable pain (Table 56.14).

Types

Various types of cranial surgical procedures are outlined in Table 56.15.

TABLE 56.14 Indications for Cranial Surgery

Indication	Cause	Surgical Procedure
Aneurysm repair	Dilation of weak area in arterial wall (usually near anterior portion of circle of Willis)	Dissection and clipping or coiling of aneurysm
Arteriovenous (AV) malformation	Congenital tangle of arteries and veins (often in middle cerebral artery)	Excision of malformation
Brain abscess	Bacteria that caused intracranial infection	Excision or drainage of abscess
Brain tumors	Benign or malignant cell growth	Excision or partial resection of tumor
Hydrocephalus	Overproduction of cerebrospinal fluid, obstruction to flow, defective reabsorption	Placement of ventriculoperitoneal or (rarely) ventriculoatrial shunt
Intracranial bleeding	Rupture of cerebral vessels because of trauma or stroke	Surgical evacuation through burr holes or craniotomy
Skull fractures	Trauma to skull	Debridement of fragments and necrotic tissue, elevation and realignment of bone fragments

TABLE 56.15 Types of Cranial Surgery

Type	Description
Burr hole	Opening into the cranium with a drill. Used to remove localized fluid and blood beneath the dura.
Craniectomy	Excision into the cranium to cut away bone flap.
Cranioplasty	Repair of cranial defect resulting from trauma, malformation, or previous surgical procedure. Artificial material used to replace damaged or lost bone.
Craniotomy	Opening into cranium with removal of bone flap and opening the dura to remove a lesion, repair a damaged area, drain blood, or relieve ↑ ICP.
Shunt procedures	Alternative pathway to redirect cerebrospinal fluid from one area to another using a tube or implanted device. Examples include ventricular shunt and Ommaya reservoir.
Stereotactic procedure	Precise localization of a specific area of the brain using a frame or frameless system based on 3-dimensional coordinates. Used for biopsy, radiosurgery, or dissection.

Craniotomy

Depending on the location of the pathologic condition, a *craniotomy* may be frontal, parietal, occipital, temporal, suboccipital, or a combination of any of these. The HCP drills a set of burr holes and uses a saw to connect the holes to remove the bone flap (Fig. 56.17). Sometimes operating microscopes are used to magnify the site. After surgery, the bone flap is secured with small plates or wired shut. Sometimes drains are placed to remove fluid and blood. Patients are usually cared for in an ICU until stable.

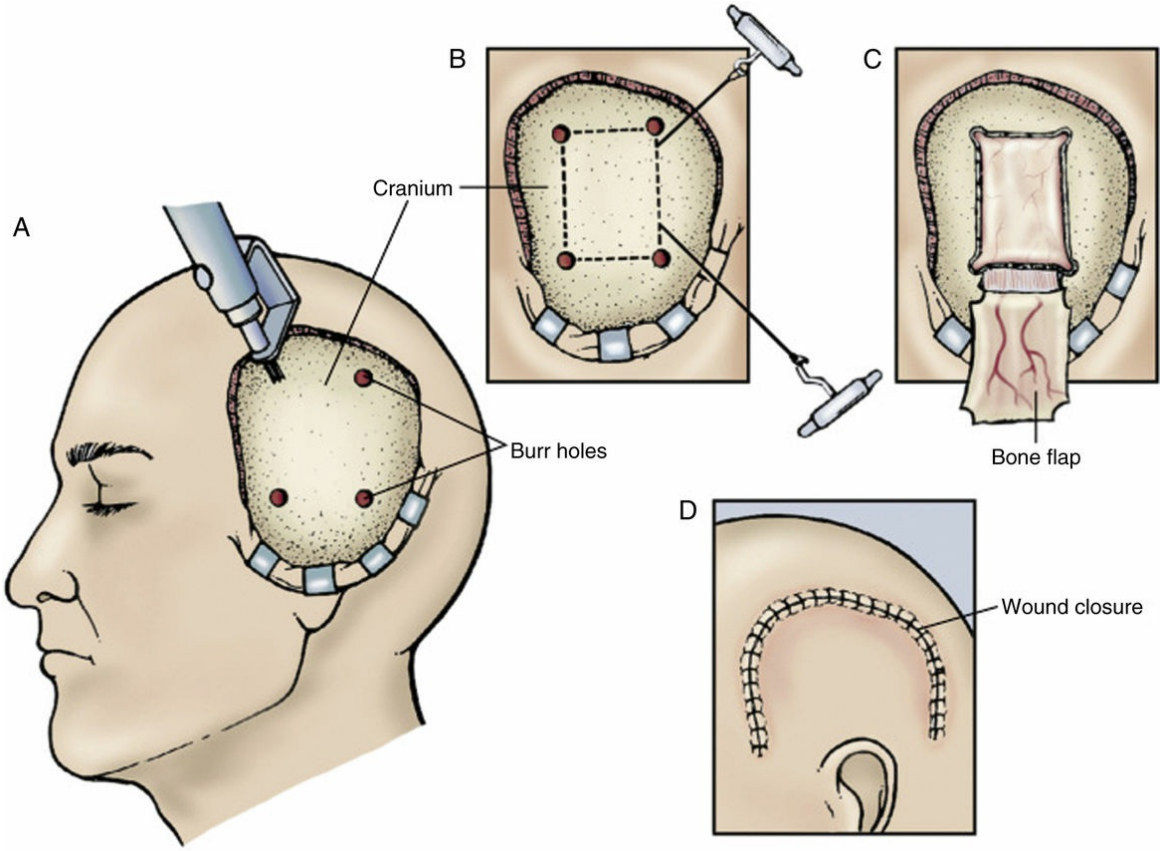

FIG. 56.17 Craniotomy. **A,** Burr holes are drill into skull. **B,** Skull is cut between burr holes with a surgical saw. **C,** Bone flap is turned back to expose cranial contents. **D,** Bone flap is replaced and wound closed. From Monahan F, Sands J, Neighbors M, et al: *Phipps' medical-surgical nursing: Health and illness perspectives,* ed 9, St Louis, 2007, Mosby.

Stereotactic Radiosurgery

Stereotactic procedures use a precision apparatus (often computer guided) to help the HCP precisely target an area of the brain. Stereotactic biopsy can be done to obtain tissue samples for histologic examination. CT scanning and MRI are used to image the targeted tissue. With the patient under general or local anesthesia, the HCP drills a burr hole or creates a bone flap for an entry site and then introduces a probe and biopsy needle. Stereotactic procedures are used for removal of small brain tumors and abscesses, drainage of hematomas, ablative procedures for extrapyramidal diseases (e.g., Parkinson's disease), and repair of arteriovenous malformations. A major advantage of the stereotactic approach is a reduction in damage to surrounding tissue.

Stereotactic radiosurgery is not a form of surgery in the traditional sense. Instead, radiosurgery uses precisely focused radiation to destroy tumor cells and other abnormal growths in the brain. Computers create 3-dimensional images of the brain. These images are used to guide the focused radiation while the patient's head is held still in a stereotactic frame (Fig. 56.18). Radiosurgical techniques can use ionizing radiation generated by a linear accelerator, gamma knife, or CyberKnife. In these procedures, a high dose of cobalt radiation is delivered to precisely targeted tumor tissue. The dose of radiation is delivered in a single treatment lasting a few hours or in multiple sessions. Side effects include fatigue, headache, and nausea.

In combination with stereotactic procedures to identify and localize tumor sites, surgical lasers can be used to destroy tumors. Lasers work by creating thermal energy, which destroys the tissue on which it is focused. Laser therapy provides the benefit of reducing damage to surrounding tissue.

Nursing Management: Cranial Surgery

Nursing Implementation

Acute Care

The general preoperative and postoperative nursing care for the patient undergoing cranial surgery is similar regardless of the cause. It is similar to that for the patient with increased ICP. The patient (if conscious and coherent), caregiver, and family will be concerned about the potential physical and emotional problems that can result from surgery. The uncertainty about the prognosis and outcome requires compassionate nursing care in the preoperative period.

Preoperative teaching is important in allaying the fears of the patient, caregiver, and family and in preparing them for the postoperative period. Provide general information about the type of operation that will be done and what can be expected right after the operation. Explain that some hair may be shaved to allow for better exposure and to prevent contamination. The hair is usually removed in the operating room after induction of anesthesia. Tell them that the patient will be in an ICU or special care unit after surgery.

The main goal of care after cranial surgery is preventing increased ICP. Nursing management of the patient with increased ICP was outlined on pp. 1308–1311. Frequent assessment of the patient's neurologic status is essential during the first 48 hours. Closely monitor fluid and electrolyte levels and serum osmolality to detect changes in sodium regulation, the onset of diabetes insipidus, or severe hypovolemia.

Monitor the patient for pain and nausea. Nausea and vomiting are common after surgery and are usually treated with antiemetics. The use of promethazine is discouraged because it can increase

somnolence and alter the accuracy of a neurologic assessment.

Although the brain itself does not have pain receptors, patients often report headache caused by edema or pain at the incision site. Control pain with short-acting opioids and monitor neurologic status.

The surgical dressing is usually in place for a few days. With an incision over the skull in the anterior or middle fossa, the patient will return from the operating room with the head elevated at an angle of 30 to 45 degrees. The head of the bed should stay elevated at least 30 degrees unless the surgical approach is in the posterior fossa or a burr hole has been made. In these cases, the patient is generally kept flat or at a slight elevation (10 to 15 degrees) during the postoperative phase.

Turning and positioning the patient will depend on the site of the operation. If a bone flap has been removed (craniectomy), do not position the patient on the operative side. Place a sign at the head of the bed, alerting everyone of the craniectomy site and position of the surgical site. Observe the dressing for color, odor, and amount of drainage. Notify the HCP immediately of any excess bleeding or clear drainage. Checking drains for placement and assessing the area around the dressing are important. Scalp care should include meticulous care of the incision to prevent wound infection. Cleanse the area and treat it following agency protocol or the HCP's orders. Once the dressing is removed, use an antiseptic soap for washing the scalp. The psychologic impact of hair removal can be lessened by using a wig, turban, scarves, or cap. For the patient who is receiving radiation, teach the patient to use a sunblock and head covering if any sun exposure is expected.

Ambulatory Care

The rehabilitative potential for a patient after cranial surgery depends on the reason for the surgery, postoperative course, and patient's general state of health. Base your nursing interventions on a realistic appraisal of these factors. Specific rehabilitation potential cannot be determined until cerebral edema and increased ICP subside postoperatively. An overall goal is to foster independence for as long as possible and to the highest degree possible.

Take care to maintain as much function as possible through measures such as careful positioning, meticulous skin and mouth care, regular range-of-motion exercises, bowel and bladder care, and adequate nutrition. Address the needs and problems of each patient individually because many variables affect the plan.

Collaborate with other specialists. The physical therapist may provide an exercise plan to regain functional deficits. A speech therapist will help the patient regain communication skills. The patient's mental and physical deterioration, including seizures, personality disorganization, apathy, and wasting, is difficult for both family and health care professionals. Cognitive and emotional residual deficits are often harder to accept than are motor and sensory losses. Social workers can help the patient and family adapt to changes in their home life, work, and financial circumstances.

Ethical/Legal Dilemmas

Withholding Treatment

Situation

C.J., a 26-yr-old patient in a permanent vegetative state, is diagnosed with her 15th bladder infection. As her home care nurse, you must determine whether to seek antibiotics for this infection. The family members have expressed a concern that no heroic measures be used to extend the life of their daughter and sister. However, they have been unwilling to stop providing enteral nutrition through a gastrostomy tube. Should antibiotics be withheld?

Ethical/Legal Points for Consideration

- Patients in a persistent vegetative state do not recover.
- The main legal issue here is who has the legal right to refuse or consent to treatment for this incapacitated patient. You need to know if a guardian has been appointed by the court or if her

parents retain a form of guardianship to make health care decisions for her.

- You need to know when the vegetative state began; that is, did the patient ever have the right to consent having reached the age of majority as a competent adult or did the vegetative state begin while she was a minor? If the patient did become a competent adult before the vegetative state, did she ever express any preference for quality-of-life and end-of-life decision making?
- The courts have widespread legal precedents for accepting the decision of the patient's guardian or parents or the patient's clearly expressed preferences for quality-of-life decision making.
- Life-sustaining treatment is any treatment that serves to prolong life without reversing the underlying medical condition. Life-sustaining treatment may include, but is not limited to, mechanical ventilation, renal dialysis, chemotherapy, antibiotics, and artificial nutrition and hydration.
- There is no ethical distinction between withdrawing and withholding life-sustaining treatment. If there is not adequate evidence of the incompetent patient's preferences and values, the decision should be based on the best interests of the patient (i.e., what outcome will most likely promote the patient's well-being).

Discussion Questions

1. How would you approach C.J.'s family?
2. What are your feelings about providing nutrition, hydration, and treatments that will prolong life in a patient for whom there is no hope of recovery?
3. What options are available to the family for the care of their daughter once a decision is made about withholding antibiotics?

Inflammatory Conditions of the Brain

Brain abscesses, meningitis, and encephalitis are the most common inflammatory conditions of the brain and spinal cord (Table 56.16). Inflammation can be caused by bacteria, viruses, fungi, and chemicals (e.g., contrast media used in diagnostic tests, blood in the subarachnoid space). CNS infections may occur via the bloodstream, by extension from a primary site, or along cranial and spinal nerves.

The mortality rate for inflammatory conditions of the brain is about 10% to 15% in the general population, with higher rates in older and immunosuppressed patients. Some who recover have long-term neurologic deficits, including hearing loss.[19]

Bacterial Meningitis

Meningitis is an acute inflammation of the meningeal tissues surrounding the brain and spinal cord. Meningitis usually occurs in fall, winter, or early spring. It is often related to a viral respiratory disease. Older adults and persons who are debilitated are affected more often than the general population. College students living in dormitories and people living in institutions (e.g., prisoners) have a high risk for contracting meningitis. Untreated bacterial meningitis has a mortality rate of 50% to 100%.[20]

Etiology and Pathophysiology

Streptococcus pneumoniae and *Neisseria meningitidis* are the leading causes of bacterial meningitis. *N. meningitides* has at least 13 different subtypes (serogroups) with 5 of them (A, B, C, Y, W) causing most cases. *Haemophilus influenzae* was once the most common cause of bacterial meningitis. However, the use of *H. influenzae* vaccine has resulted in a significant decrease in meningitis from this organism.

The organisms usually gain entry to the CNS through the upper respiratory tract or bloodstream. However, they may enter by direct extension from penetrating wounds of the skull or through fractured sinuses in basilar skull fractures.

The inflammatory response to the infection tends to increase CSF

production with a moderate increase in ICP. In bacterial meningitis the purulent secretions quickly spread to other areas of the brain through the CSF and cover the cranial nerves and other intracranial structures. If this process extends into the brain parenchyma or if concurrent encephalitis is present, cerebral edema and increased ICP become more of a problem. Closely observe all patients for manifestations of increased ICP. ICP can increase from swelling around the dura and increased CSF volume.

Clinical Manifestations

Fever, severe headache, nausea, vomiting, and **nuchal rigidity** (neck stiffness) are key signs of meningitis. Photophobia, a decreased LOC, and signs of increased ICP may be present. Coma is associated with a poor prognosis. It occurs in 5% to 10% of patients with bacterial meningitis. Seizures occur in one third of all cases. The headache becomes progressively worse and may be accompanied by vomiting and irritability.

If the infecting organism is a meningococcus, a skin rash is common. Petechiae may be seen on the trunk, lower extremities, and mucous membranes. A *tumbler test* can be done by pressing the base of a drinking glass against the rash. The rash does not blanch or fade under pressure.

Complications

The most common acute complication of bacterial meningitis is increased ICP. Most patients have increased ICP. It is the major cause of an altered mental status.

Another complication is residual neurologic dysfunction. It often involves many cranial nerves. Cranial nerve irritation can have serious sequelae. The optic nerve (CN II) is compressed by increased ICP. Papilledema is often present, and blindness may occur. When CN III, CN IV, and CN VI are irritated, ocular movements are affected. Ptosis, unequal pupils, and diplopia are common. Irritation of CN V results in sensory losses and loss of the corneal reflex. Irritation of CN

VII results in facial paresis. Irritation of CN VIII causes tinnitus, vertigo, and deafness. The dysfunction usually disappears within a few weeks. However, hearing loss may be permanent.

TABLE 56.16 Comparison of Cerebral Inflammatory Conditions

	Meningitis	Encephalitis	Brain Abscess
Cause	Bacteria (*Streptococcus pneumoniae, Neisseria meningitidis*, group B streptococci, viruses, fungi)	Bacteria, fungi, parasites, herpes simplex virus (HSV), other viruses (e.g., West Nile virus)	Streptococci, staphylococci through bloodstream
Cerebrospinal Fluid (Reference Interval)			
• **Pressure (<20 mm H_2O)**	Increased *Bacterial:* 200–500 *Viral:* ≤250	Normal to slight increase	Increased
• **WBC count (0–5 cells/μL)**	*Bacterial:* >1000/μL (mainly neutrophils) *Viral:* 25–500/μL (mainly lymphocytes)	500/μL, neutrophils (early), lymphocytes (later)	25–300/μL (neutrophils)
• **Protein (15–45 mg/dL [0.15–0.45 g/L])**	*Bacterial:* >500 mg/dL *Viral:* 50–500 mg/dL	Slight increase	Normal
• **Glucose (50–77 mg/dL [2.2–3.9 mmol/L])**	*Bacterial:* Decreased 5–40 *Viral:* Normal or low >40	Normal	Low or absent
• **Appearance**	*Bacterial:* Turbid, cloudy *Viral:* Clear or cloudy	Clear	Clear
Diagnostic Studies	CT scan, Gram stain, smear, culture, PCR	CT scan, EEG, MRI, PET, PCR, IgM antibodies to virus in serum or CSF	CT scan
Treatment	Antibiotics, dexamethasone, supportive care, prevention of ↑ ICP	Supportive care, prevention of ↑ ICP, acyclovir (Zovirax) for HSV	Antibiotics, incision and drainage Supportive care

*PCR is used to detect viral RNA or DNA.
IgM, immunoglobulin M; *PCR,* polymerase chain reaction.

Hemiparesis, dysphasia, and hemianopsia may occur. These signs usually resolve over time. If they do not, suspect a cerebral abscess, subdural empyema, subdural effusion, or persistent meningitis. Acute cerebral edema may cause seizures, CN III palsy, bradycardia, hypertensive coma, and death.

Headaches may occur for months after the diagnosis of meningitis until the irritation and inflammation have completely resolved. It is important to implement pain management for chronic headaches.

A noncommunicating hydrocephalus may occur if the exudate

causes adhesions that prevent the normal flow of CSF from the ventricles. CSF reabsorption by the arachnoid villi may be obstructed by the exudate. In this situation, surgical implantation of a shunt is the only treatment.

Waterhouse-Friderichsen syndrome is a complication of meningococcal meningitis. The syndrome is manifested by petechiae, disseminated intravascular coagulation (DIC), adrenal hemorrhage, and circulatory collapse. DIC and shock, which are some of the most serious complications of meningitis, are associated with meningococcemia. DIC is discussed in detail in Chapter 30.

Diagnostic Studies

When a patient has manifestations suggestive of bacterial meningitis, a blood culture and CT scan should be done. Diagnosis is usually verified by doing an LP with analysis of the CSF (Table 56.16). An LP should be done only after the CT scan has ruled out an obstruction in the foramen magnum to prevent a fluid shift resulting in herniation.

Specimens of the CSF, sputum, and nasopharyngeal secretions are taken for culture before the start of antibiotic therapy to identify the causative organism. A Gram stain is done to detect bacteria. The predominant white blood cell type in the CSF with bacterial meningitis is neutrophils.

X-rays of the skull may show infected sinuses. CT scans and MRI may be normal in uncomplicated meningitis. In other cases, CT scans may reveal evidence of increased ICP or hydrocephalus.

Interprofessional Care

Bacterial meningitis is a medical emergency. Rapid diagnosis based on history and physical examination is crucial because the patient is usually in a critical state when health care is sought. When meningitis is suspected, antibiotic therapy is begun after the collection of specimens for cultures, even before the diagnosis is confirmed (Table 56.17).

Ampicillin, penicillin, vancomycin, cefuroxime (Ceftin), cefotaxime,

ceftriaxone, ceftizoxime, and ceftazidime are the main drugs given to treat bacterial meningitis. Dexamethasone may be given before or with the first dose of antibiotics. Collaborate with the HCP to manage the headache, fever, and nuchal rigidity often associated with meningitis.

Nursing Management: Bacterial Meningitis

Nursing Assessment

Initial assessment should include vital signs, neurologic assessment, fluid intake and output, and evaluation of the lungs and skin.

Nursing Diagnoses

Nursing diagnoses for the patient with bacterial meningitis may include:

- Decreased intracranial adaptive capacity
- Ineffective tissue perfusion
- Hyperthermia
- Acute pain

Additional information on nursing diagnoses and interventions for the patient with bacterial meningitis is presented in eNursing Care Plan 56.2 (available on the website for this chapter).

Planning

The overall goals for the patient with bacterial meningitis are to (1) return to maximal neurologic functioning, (2) resolve the infection, and (3) control pain and discomfort.

Nursing Implementation

Health Promotion

Prevention of respiratory tract infections through vaccination programs for pneumococcal pneumonia and influenza is important. Meningococcal vaccines are available that protect against the serogroups of meningococcal disease that are most often seen in the United States. They will not prevent all cases. Two types of meningococcal vaccines are available in the United States:

- Meningococcal conjugate vaccines (MCV4) (Menactra, Menveo)
- Serogroup B meningococcal vaccines (Bexsero, Trumenba)

Early and vigorous treatment of respiratory tract and ear infections is important. Persons who have close contact with anyone who has bacterial meningitis should receive prophylactic antibiotics.

Acute Care

The patient with bacterial meningitis is usually acutely ill. The fever is high, and head pain is severe. Irritation of the cerebral cortex may result in seizures. The changes in mental status and LOC depend on the degree of increased ICP. Assess and record vital signs, neurologic status, fluid intake and output, skin, and lung fields at regular intervals based on the patient's condition.

TABLE 56.17 Interprofessional CareBacterial Meningitis

Diagnostic Assessment

- History and physical examination
- Analysis of CSF (for protein, WBC, and glucose), Gram stain, and

culture
- CBC, coagulation profile, electrolyte levels, glucose, platelet count
- Blood culture
- CT scan, MRI, PET scan
- Skull x-ray studies

Management

- Rest
- IV fluid
- Hypothermia

Drug Therapy

- IV antibiotics
    - ampicillin, penicillin
    - cephalosporin (e.g., cefotaxime, ceftriaxone)
- codeine for headache
- dexamethasone
- acetaminophen or aspirin for temperature >100.4° F (38° C)
- phenytoin IV
- mannitol (Osmitrol) IV for diuresis

Head and neck pain with movement requires attention. Codeine provides some pain relief without undue sedation for most patients. Assist the patient to a position of comfort, often curled up with the head slightly extended. The head of the bed should be slightly elevated. A darkened room and a cool cloth over the eyes relieve the discomfort of photophobia.

For the patient with delirium, low lighting may decrease hallucinations. All patients have some degree of mental distortion and

hypersensitivity. They may be frightened and misinterpret the environment. Make every attempt to minimize environmental stimuli and prevent injury. A familiar person at the bedside may have a calming effect. Be efficient with care while conveying an attitude of caring and unhurried gentleness. The use of touch and a soothing voice to give simple explanations of activities is helpful. If seizures occur, make appropriate observations and take protective measures. Give antiseizure drugs, such as phenytoin (Dilantin) or levetiracetam (Keppra), as ordered. Manage problems associated with increased ICP (see the section on increased ICP on pp. 1308–1311).

Fever is vigorously treated because it increases cerebral edema and the risk for seizures. In addition, neurologic damage may result from an extremely fever over a prolonged time. Acetaminophen or aspirin may be used to reduce fever. If the fever is resistant to aspirin or acetaminophen, more vigorous means are needed (e.g., cooling blanket). Take care not to reduce the temperature too rapidly because shivering may result, causing a rebound effect and increasing the temperature and ICP. Wrap the extremities in soft towels or a blanket covered with a sheet to reduce shivering. If a cooling blanket is not available or desirable, tepid sponge baths with water may be effective in lowering the temperature. Protect the skin from excessive drying and injury and prevent breaks in the skin.

Because high fever increases the metabolic rate and thus insensible fluid loss, assess the patient for dehydration and adequacy of fluid intake. Diaphoresis further increases fluid losses and should be noted on the output record. Calculate replacement fluids as 800 mL/day for respiratory losses and 100 mL for each degree of temperature above 100.4° F (38° C). Supplemental feeding (e.g., enteral nutrition) to maintain adequate nutritional intake may be needed. Follow the designated antibiotic schedule to maintain therapeutic blood levels.

Meningitis generally requires respiratory isolation until the cultures are negative. Meningococcal meningitis is highly contagious, while other causes of meningitis may pose minimal to no infection risk with patient contact. However, standard precautions are essential to protect the patient and nurse.

Ambulatory Care

After the acute period has passed, the patient needs several weeks of recovery before resuming normal activities. In this period, stress the importance of adequate nutrition, with an emphasis on a high-protein, high-calorie diet in small, frequent feedings.

Muscle rigidity may persist in the neck and backs of the legs. Progressive range-of-motion exercises and warm baths are useful. Have the patient gradually increase activity as tolerated but encourage adequate rest and sleep.

Residual effects can result in sequelae such as dementia, seizures, deafness, hemiplegia, and hydrocephalus. Assess vision, hearing, cognitive skills, and motor and sensory abilities after recovery, with appropriate referrals as indicated. Throughout the acute and recovery periods, be aware of the anxiety and stress felt by the caregiver and other family members.

Evaluation

The expected outcomes are that the patient with bacterial meningitis will

- Have appropriate cognitive function
- Be oriented to person, place, and time
- Maintain body temperature within normal range
- Report satisfaction with pain control

Viral Meningitis

The most common causes of viral meningitis are enteroviruses, arboviruses, human immunodeficiency virus, and herpes simplex virus (HSV). Enteroviruses most often spread through direct contact with respiratory secretions. Viral meningitis usually presents as a headache, fever, photophobia, and stiff neck.[19] The fever may be moderate or high.

The Xpert EV test can rapidly diagnose viral meningitis. A sample

of CSF is used to determine if enterovirus is present, and results are available within hours of symptom onset.[20]

The CSF can be clear or cloudy, and the typical finding is lymphocytosis. Organisms are not seen on Gram stain or acid-fast smears. Polymerase chain reaction (PCR) used to detect viral-specific deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) is a sensitive method for diagnosing CNS viral infections.

Antibiotics should be given after the LP while awaiting the results of the CSF analysis. Antibiotics are the best defense for bacterial meningitis. We can easily discontinue them if the meningitis is found to be viral.

Viral meningitis is managed symptomatically because the disease is self-limiting. Full recovery is expected. Rare sequelae include persistent headaches, mild mental impairment, and incoordination.

Brain Abscess

Brain abscess is an accumulation of pus within the brain tissue from a local or systemic infection. Direct extension from an ear, tooth, mastoid, or sinus infection is the main cause. Other causes for brain abscess formation include spread from a distant site (e.g., pulmonary infection, bacterial endocarditis), skull fracture, and prior brain trauma or surgery. Streptococci and *Staphylococcus aureus* are the most common infective organisms.

Manifestations are similar to those of meningitis and encephalitis and include headache, fever, and nausea and vomiting. Signs of increased ICP may include drowsiness, confusion, and seizures. Focal symptoms may reflect the local area of the abscess. For example, visual field defects or psychomotor seizures are common with a temporal lobe abscess. Visual impairment and hallucinations may accompany an occipital abscess. CT and MRI are used to diagnose a brain abscess.

Antimicrobial therapy is the primary treatment for brain abscess. Other manifestations are treated symptomatically. If drug therapy is not effective, the abscess may have to be drained or removed if it is

encapsulated.

Nursing measures are similar to those for management of meningitis or increased ICP. If surgical drainage or removal is the treatment of choice, nursing care is similar to that of a patient having cranial surgery.

Encephalitis

Encephalitis, an acute inflammation of the brain, is a serious and sometimes fatal disease. Several thousand cases occur in the United States each year. It is usually caused by a virus. Many different viruses can cause encephalitis. Some are associated with certain seasons of the year or endemic to certain geographic areas.

Ticks and mosquitoes transmit epidemic encephalitis. Examples of encephalitis include eastern equine, La Crosse, St. Louis, West Nile, and western equine.[21] Nonepidemic encephalitis may occur as a complication of measles, chickenpox, or mumps. HSV encephalitis is the most common cause of acute nonepidemic viral encephalitis. Cytomegalovirus encephalitis occurs in patients with acquired immunodeficiency syndrome (AIDS).

Clinical Manifestations and Diagnostic Studies

Encephalitis can be acute or subacute. The onset is typically nonspecific, with fever, headache, nausea, and vomiting. Signs of encephalitis appear on day 2 or 3 and may vary from minimal changes in mental status to coma. Virtually any CNS abnormality can occur, including hemiparesis, tremors, seizures, cranial nerve palsies, personality changes, memory impairment, amnesia, and dysphasia.

Early diagnosis and treatment of viral encephalitis are essential for favorable outcomes. Diagnostic findings are shown in Table 56.16. Brain imaging techniques include CT, MRI, and PET. PCR tests allow for early detection of HSV and West Nile encephalitis. West Nile virus should be strongly considered in adults over 50 years old who develop encephalitis or meningitis in summer or early fall. The best

diagnostic test for West Nile virus is a blood test that detects viral RNA. This test is also used to screen donated blood, organs, cells, and tissues.

Interprofessional and Nursing Care

Prevention of encephalitis focuses on mosquito control. Measures include cleaning rain gutters, removing old tires, draining bird baths, and removing water where mosquitoes can breed. Insect repellent should be used during mosquito season.

Interprofessional and nursing management of encephalitis, including West Nile virus infection, is symptomatic and supportive. In the initial stages of encephalitis, many patients need intensive care.

Acyclovir (Zovirax) is used to treat encephalitis caused by HSV infection. Its use reduces mortality rates, although neurologic complications may still occur. For maximal benefit, treatment should start before the onset of coma. Treat seizure disorders with antiseizure drugs. Prophylactic treatment with antiseizure drugs may be used in severe cases of encephalitis. Treatment of cytomegalovirus encephalitis in AIDS patients is discussed in Chapter 14.

Case Study

Traumatic Brain Injury

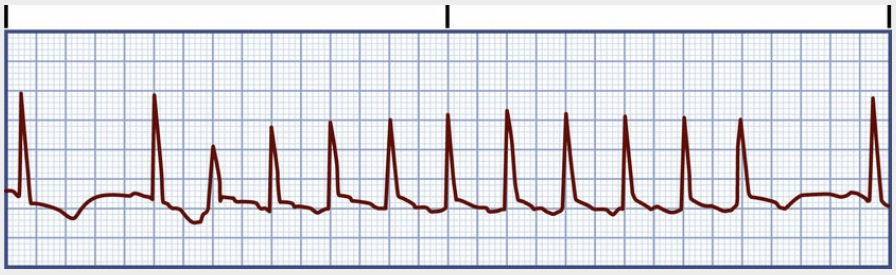
Patient Profile

C.G. is a 24-yr-old black man who has just returned from a 15-month army deployment to Afghanistan. He comes to the outpatient clinic with a report of chronic headaches (pain rating of 8 [0- to 10-point



scale]) and trouble sleeping. His wife has noticed some personality changes since his return from deployment and is concerned that he has posttraumatic stress disorder (PTSD).

Subjective Data

- Reports that he has been depressed lately but attributes it to headache and difficulty returning home
- Headache is worse in the morning or when he lies down
- Uses tobacco and drinks coffee throughout the day
- Has trouble sleeping
- Reports "incidents" of heavy combat and blasts with a loss of consciousness. Cannot remember how many times
- Unable to obtain a more through history as he becomes quite agitated

Objective Data

- During your assessment, you note that C.G. is looking around the room and jumps when the phone rings next door
- Loss of short-term memory (remembers 1 of 3 items)
- Heart rate ranges from 100 to 130 beats/min
- ECG strip is shown below:

- Systolic BP ranges from 120 to 160 mm Hg
- Right pupil, 3 mm sluggishly reactive; left pupil, 3 mm briskly

reactive

Diagnostic Studies

- CT of the head: negative for skull fracture, hematoma, or hemorrhage. Cerebral edema present, with cingulate herniation on the right side
- MRI of the head: Mild diffuse axonal injury

Discussion Questions

1. What could be the cause of C.G.'s hypertension, tachycardia, and ECG rhythm?
2. In addition to PTSD, what do his manifestations suggest?
3. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
4. ***Priority Decision:*** What are the priority nursing interventions that should be implemented?
5. ***Collaboration:*** How can the interprofessional team work together to meet his needs?
6. ***Safety:*** Are there any safety concerns for this patient or his wife?
7. ***Evidence-Based Practice:*** What interventions and support can help his wife?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Vasogenic cerebral edema increases intracranial pressure

by

a. shifting fluid in the gray matter.

b. altering the endothelial lining of cerebral capillaries.

c. leaking molecules from the intracellular fluid to the capillaries.

d. altering the osmotic gradient flow into the intravascular component.

2. A patient with intracranial pressure monitoring has a pressure of 12 mm Hg. The nurse understands that this pressure reflects

a. a severe decrease in cerebral perfusion pressure.

b. an alteration in the production of cerebrospinal fluid.

c. the loss of autoregulatory control of intracranial pressure.

d. a normal balance among brain tissue, blood, and cerebrospinal fluid.

3. A nurse plans care for the patient with increased intracranial pressure with the knowledge that the *best* way to position the patient is to

a. keep the head of the bed flat.

b. elevate the head of the bed to 30 degrees.

c. maintain patient on the left side with the head supported on a pillow.

d. use a continuous-rotation bed to continuously change patient position.

4. The nurse is alerted to a possible acute subdural hematoma in the patient who

a. has a linear skull fracture crossing a major artery.

b. has focal symptoms of brain damage with no recollection of a head injury.

c. develops decreased level of consciousness and a headache within 48 hours of a head injury.

d. has an immediate loss of consciousness with a brief lucid interval followed by decreasing level of consciousness.

5. During admission of a patient with a severe head injury to the emergency department, the nurse places the *highest* priority on assessment for

a. patency of airway.

b. presence of a neck injury.

c. neurologic status with the Glasgow Coma Scale.

d. cerebrospinal fluid leakage from the ears or nose.

6. A patient is suspected of having a brain tumor. The signs and symptoms include memory deficits, visual changes, weakness of right upper and lower extremities, and personality changes. The nurse determines that the tumor is *most* likely located in the

a. frontal lobe.

b. parietal lobe.

c. occipital lobe.

d. temporal lobe.

7. Nursing management of a patient with a brain tumor includes *(select all that apply)*

a. discussing with the patient methods to control inappropriate behavior.

b. using diversion techniques to keep the patient stimulated and motivated.

c. assisting and supporting the family in understanding any changes in behavior.

d. limiting self-care activities until the patient has regained maximum physical functioning.

e. planning for seizure precautions and teaching the patient and the caregiver about antiseizure drugs.

8. The nurse on the clinical unit is assigned to four patients. Which patient should she assess *first*?

a. Patient with a skull fracture whose nose is bleeding

b. An older patient with a stroke who is confused and whose daughter is present

c. Patient with meningitis who is suddenly agitated and reporting a headache of 10 on a 0- to 10 scale

d. Patient 2 days postoperative after a craniotomy for a brain tumor who has had continued vomiting

9. A nursing measure that can reduce the potential for seizures and increased intracranial pressure in the patient with bacterial meningitis is

a. administering codeine for relief of head and neck pain.

b. controlling fever with prescribed drugs and cooling techniques.

c. maintaining strict bed rest with the head of the bed slightly elevated.

d. keeping the room dark and quiet to minimize environmental stimulation.

1. b, 2. d, 3. b, 4. c, 5. a, 6. a, 7. c, e, 8. c, 9. b

Stroke

Michelle Bussard

LEARNING OUTCOMES

1. Describe the incidence of and risk factors for stroke.
2. Explain mechanisms that affect cerebral blood flow.
3. Compare and contrast the etiology and pathophysiology of ischemic and hemorrhagic strokes.
4. Correlate the clinical manifestations of stroke with the underlying pathophysiology.
5. Identify diagnostic studies done for patients with strokes.
6. Distinguish among the interprofessional care, drug therapy, and surgical therapy for patients with ischemic strokes and hemorrhagic strokes.
7. Describe the acute nursing management of a patient with a stroke.
8. Describe the rehabilitative nursing management of a patient with a stroke.
9. Explain the psychosocial impact of a stroke on the patient, caregiver, and family.

Conceptual Focus

Family Dynamics
Functional Ability
Intracranial Regulation
Mobility
Safety
Sensory Perception

Stroke occurs when there is (1) *ischemia* (inadequate blood flow) to a part of the brain or (2) *hemorrhage* (bleeding) into the brain that results

in death of brain cells. In a stroke, functions such as movement, sensation, thinking, talking, or emotions that were controlled by the affected area of the brain are lost or impaired. The severity of the loss of function varies according to the location and extent of the brain damage.

The terms *brain attack* and **cerebrovascular accident (CVA)** are also used to describe stroke. The term *brain attack* communicates the urgency of recognizing the warning signs of a stroke and treating it as a medical emergency, as we would do with a heart attack (Table 57.1). After the onset of a stroke, immediate medical attention is crucial to decrease disability and the risk for death.

Stroke is a major public health concern. An estimated 7 million people over the age of 20 in the United States have had a stroke.[1] With an aging population, we can expect a further increase in the incidence of strokes. However, stroke can occur at any age. About 34% of strokes occur in people younger than 65 years old.[2]

Stroke is currently the fifth most common cause of death in the United States. More than 137,000 deaths occur each year from stroke.[3] While deaths due to stroke have declined, stroke is the leading cause of serious long-term disability. About 800,000 people have a stroke each year, and 15% to 30% have a permanent disability.[4]

Common long-term disabilities include *hemiparesis* (partial paralysis on one side), inability to walk, complete or partial dependence for activities of daily living (ADLs), *aphasia* (dysfunction in communication), and depression. In addition to the physical, cognitive, and emotional impact of the stroke on the survivor, the stroke affects the lives of the stroke victim's caregiver and family. A stroke is a lifelong change for both the stroke survivor and family. Be mindful of this impact when caring for patients who survive stroke.

Pathophysiology of Stroke

Anatomy of Cerebral Circulation

Blood is supplied to the brain by 2 major pairs of arteries: internal

carotid arteries (anterior circulation) and vertebral arteries (posterior circulation). The carotid arteries branch to supply most of the (1) frontal, parietal, and temporal lobes; (2) basal ganglia; and (3) part of the diencephalon (thalamus and hypothalamus). The major branches of the carotid arteries are the middle cerebral and anterior cerebral arteries. The vertebral arteries join to form the basilar artery, which branches to supply the middle and lower parts of the temporal lobes, occipital lobes, cerebellum, brainstem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The anterior and posterior cerebral circulation is connected at the *circle of Willis* by the anterior and posterior communicating arteries (Fig. 57.1). Fig. 55.11 shows the arteries at the base of the brain. Genetic variations in this area are common, and all connecting vessels may not be present.

TABLE 57.1 Patient & Caregiver TeachingFAST for Warning Signs of Stroke

FAST is an easy way to remember the signs of stroke. Include the following information in the teaching plan for a patient at risk for stroke and the patient's caregiver:

F	Face drooping	Does one side of the face droop or is it numb? Ask the person to smile. Is the smile uneven?
A	Arm weakness	Is one arm weak or numb? Ask the person to raise both arms. Does one arm drift downward?
S	Speech difficulties	Is speech slurred? Is the person unable to speak or hard to understand? Ask the person to repeat a simple sentence like "The sky is blue." Is the sentence repeated correctly?
T	Time	Time is CRITICAL! If someone shows any of these signs (even if they go away), call 911 and get the person to the hospital. Note the time when the signs first appeared.

In addition, report the sudden onset of the following:

- Confusion
- Numbness or weakness, especially in 1 side of the body

- Severe headache with no known cause
- Trouble seeing in one or both eyes
- Trouble walking, dizziness, loss of balance or coordination

Regulation of Cerebral Blood Flow

The brain needs a continuous supply of blood to provide the O_2 and glucose that neurons need to function. Blood flow must be maintained at 750 to 1000 mL/min (55 mL/100 g of brain tissue), or 20% of the cardiac output, for optimal brain functioning. If blood flow to the brain is totally interrupted (e.g., cardiac arrest), neurologic metabolism is altered in 30 seconds, metabolism stops in 2 minutes, and cell death occurs in 5 minutes.

The brain is normally protected from changes in mean systemic arterial BP over a range from 50 to 150 mm Hg by a mechanism known as *cerebral autoregulation.* This involves changes in the diameter of cerebral blood vessels in response to changes in pressure so that the blood flow to the brain stays constant. When cerebral ischemia occurs, autoregulation may be impaired, making the brain dependent on systemic BP. CO_2 is a potent cerebral vasodilator. Changes in arterial CO_2 levels have a dramatic effect on cerebral blood flow (CBF). Increased CO_2 levels increase CBF. Decreased CO_2 levels decrease CBF. Very low arterial oxygen (O_2) levels (partial pressure of arterial O_2 less than 50 mm Hg) or increases in hydrogen ion concentration also increase CBF.

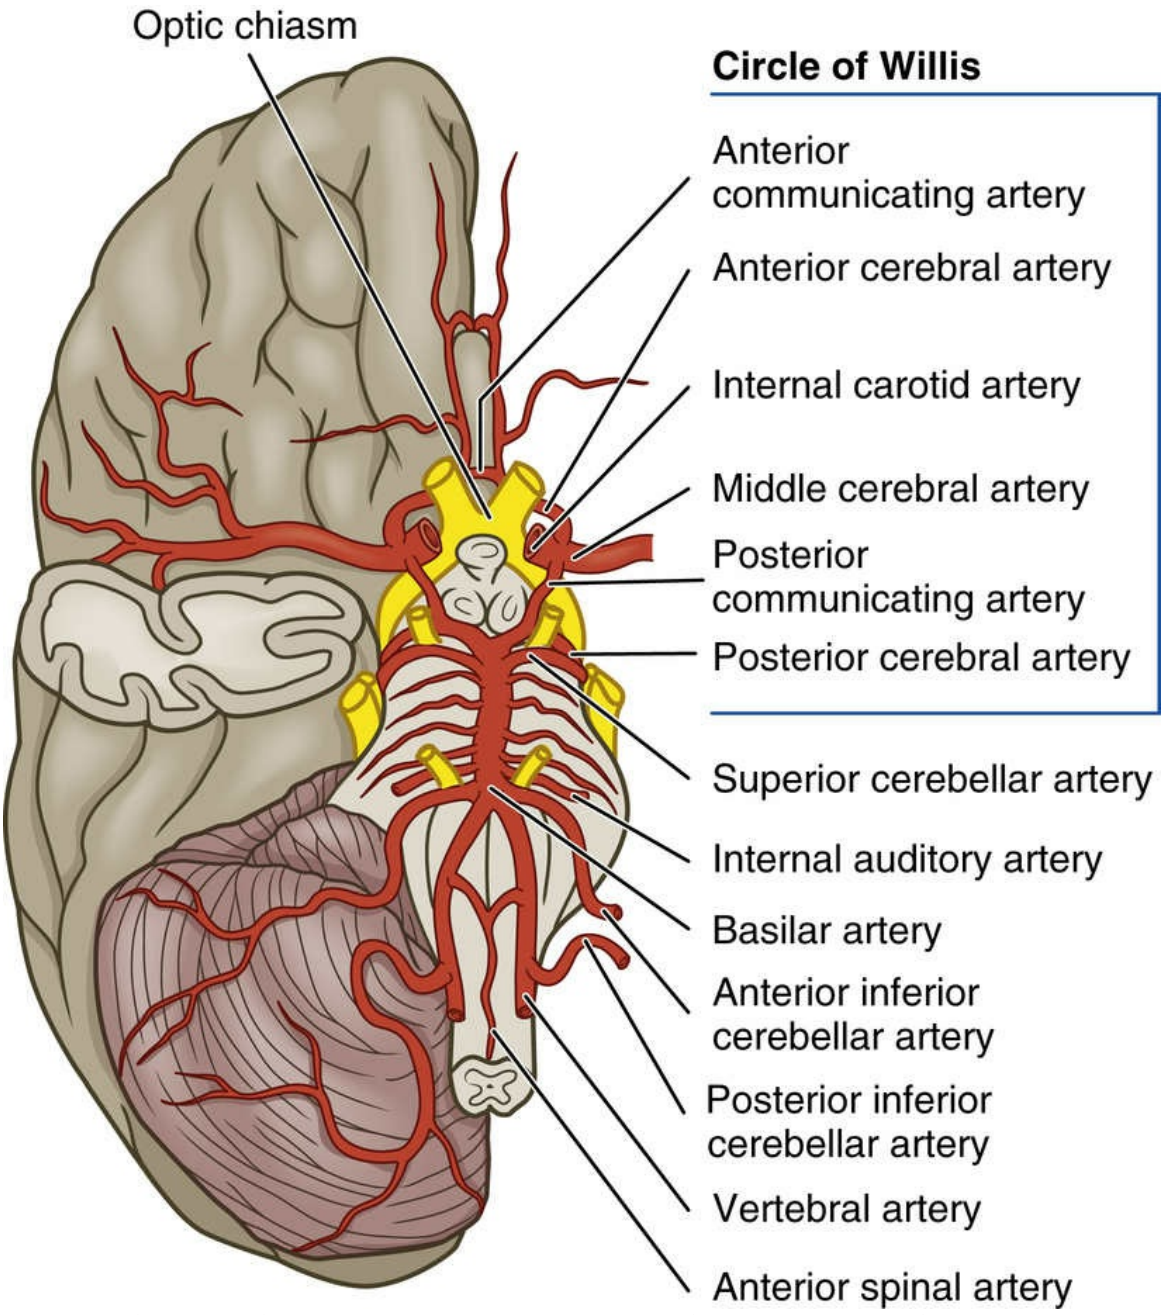

FIG. 57.1 Cerebral arteries and the circle of Willis. The top of the temporal lobe has been removed to show the course of the middle cerebral artery.

Factors that affect blood flow to the brain include systemic BP, cardiac output, and blood viscosity. During normal activity, O_2 requirements vary considerably. Changes in cardiac output, vasomotor tone, and distribution of blood flow normally maintain adequate blood flow to the brain. Cardiac output must be reduced by

one third before CBF is reduced. Changes in blood viscosity affect CBF, with decreased viscosity increasing blood flow.

Collateral circulation may develop over time to compensate for a decrease in CBF. An area of the brain can potentially receive blood supply from another blood vessel even if blood supply from the original vessel has been cut off (e.g., because of thrombosis). In other words, the vessels in the brain make an "alternative route" for blood flow to reach damaged areas, thus preventing a stroke.

Intracranial pressure (ICP) influences CBF. Increased ICP causes brain compression and reduced CBF. One of your major goals when caring for a stroke patient is to reduce secondary injury related to increased ICP (see Chapter 56).

Risk Factors for Stroke

The most effective way to decrease the burden of stroke is prevention and teaching, especially about risk factors. We divide risk factors into nonmodifiable and modifiable. Stroke risk increases with multiple risk factors. Thus, the primary prevention of stroke focuses on reducing modifiable risk factors, which can dramatically reduce the morbidity and mortality of stroke.[5]

Nonmodifiable Risk Factors

Nonmodifiable risk factors include age, gender, ethnicity or race, and family history or heredity. Stroke risk increases with age, doubling each decade after 55 years of age. Two thirds of all strokes occur in persons older than 65 years. Strokes are more common in men, but more women die from stroke than men. Because women tend to live longer than men, they have more opportunity to have a stroke.[2]

Blacks have twice the incidence of stroke and a higher death rate from stroke compared to any other ethnic group. This may be related in part to a higher incidence of hypertension, obesity, and diabetes.[2]

Promoting Health Equity

Stroke

Blacks

- Have a higher incidence of strokes than whites
- Have a rate of first strokes that is twice that of any other ethnic group
- Are 3 times more likely than whites to have an ischemic stroke and 4 times more likely to have a hemorrhagic stroke
- Have increased rates of hypertension, diabetes, and sickle cell anemia, which may be related to the high incidence of strokes
- Have a higher incidence of smoking and obesity than whites, which are 2 risk factors for stroke
- Are twice as likely to die from a stroke as whites

Other Ethnicities

- Hispanics, Native Americans, and Asian Americans have a higher incidence of strokes than whites.
- Hispanics have a high incidence of diabetes, an important risk factor for strokes.
- Native Americans are more likely than whites to have at least 2 risk factors for stroke.

Genetic risk factors are important in the development of all vascular diseases, including stroke. A person with a family history of stroke has an increased risk for having a stroke. We think that genes encoding products involved in lipid metabolism, thrombosis, and inflammation are genetic factors for stroke. People who have at least 2 first-degree relatives with a history of subarachnoid hemorrhage

(SAH) or aneurysm should be screened to rule out anomalies in their cerebral vasculature.[6]

Modifiable Risk Factors

Modifiable risk factors are those that can potentially be altered through lifestyle changes and medical treatment, thus reducing the risk for stroke. They include hypertension, heart disease, diabetes, smoking, obesity, sleep apnea, metabolic syndrome, lack of physical exercise, poor diet, and drug and alcohol use. We think modifiable risk factors cause 90% of strokes.[6]

Hypertension is the single most important modifiable risk factor. It is often undetected and inadequately treated. Increases in systolic BP (SBP) and diastolic BP (DBP) independently increase stroke risk. The proper treatment of hypertension reduces stroke risk up to 50%. New recommendations by the American Heart Association (AHA) include home BP monitoring with a goal of SBP less than 140 mm Hg.[4]

Heart disease, including atrial fibrillation, myocardial infarction (MI), cardiomyopathy, cardiac valve abnormalities, and congenital heart defects, such as patent foramen ovale, is a risk factor for stroke. Atrial fibrillation is responsible for about 25% of all strokes.[7] People with atrial fibrillation are 5 times more likely to have a stroke than people with a regular heart rhythm.[8] The incidence of atrial fibrillation increases with age. Oral anticoagulants (e.g., warfarin, dabigatran) and adherence to their therapy play a vital role in stroke prevention.[4,9]

Diabetes is a significant risk factor for stroke. Stroke risk in people with diabetes is 5 times higher than in the general population.[7]

Smoking nearly doubles the risk for ischemic stroke. Smokers are 4 times as likely to have a hemorrhagic stroke than nonsmokers.[5] The risk associated with smoking decreases substantially over time after the smoker quits. After 5 to 10 years of no tobacco use, former smokers have the same risk for stroke as nonsmokers.

The effect of alcohol on stroke risk appears to depend on the amount consumed. Women who drink more than 1 alcoholic drink

per day and men who drink more than 2 alcoholic drinks per day are at higher risk for hypertension, which increases their chance of stroke. Illicit drug use, especially cocaine use, increases stroke risk.[6]

A waist circumference to hip circumference ratio equal to or above the mid-value for the population increases the risk for ischemic stroke 3-fold. In addition, obesity is associated with hypertension, high blood glucose, and increased blood lipid levels, all of which increase stroke risk.[6] An association of physical inactivity and increased stroke risk is present in both men and women. Benefits of physical activity can occur with even light to moderate regular activity. The American Stroke Association recommends 40 minutes of exercise 3 to 4 days per week to reduce risk for stroke.[9] Nutrition teaching is important, since a diet high in fat and low in fruits and vegetables may increase stroke risk.

The early forms of birth control pills that had high levels of progestin and estrogen increased a woman's chance of having a stroke, especially if the woman smoked heavily. Newer, low-dose oral contraceptives have lower risks for stroke except in those who have hypertension and smoke. The AHA recommends smoking cessation and alternatives to estrogen oral contraceptives for those women to reduce the incidence of stroke.[4]

Women who have migraines with aura have an increased risk for stroke. Other conditions that may increase the stroke risk include inflammatory conditions (e.g., rheumatoid arthritis), sickle cell disease, and blood clotting disorders, such as factor V Leiden mutation.[5]

Transient Ischemic Attack

Another risk factor associated with stroke is a history of a **transient ischemic attack (TIA)**. A TIA is a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, but without acute infarction of the brain. Symptoms typically last less than 1 hour.

It is important to teach the patient to seek treatment for any stroke

symptoms, since there is no way to predict if a TIA will resolve or if it will progress to a stroke. In general, one third of those who had a TIA do not have another, one third have more TIAs, and one third progress to stroke.[10]

TIAs may be due to microemboli that temporarily block the blood flow. TIAs are a warning sign of progressive cerebrovascular disease. The signs and symptoms of a TIA depend on the blood vessel that is involved and the area of the brain that is ischemic. If the carotid system is involved, patients may have a temporary loss of vision in 1 eye *(amaurosis fugax),* transient hemiparesis, numbness or loss of sensation, or a sudden inability to speak. Signs of a TIA involving the vertebrobasilar system may include tinnitus, vertigo, darkened or blurred vision, diplopia, ptosis, dysarthria, dysphagia, ataxia, and unilateral or bilateral numbness or weakness.

Check Your Practice

You are talking with your uncle at your family reunion. He knows that you are a nurse and seems very eager to talk with you. He tells you that earlier this morning he was having problems talking, got dizzy, and then "blanked" out for a while. He found himself just lying on the floor in his room.

- He says, "I think it is just all the excitement of the reunion, but what do you think?"

A TIA is treated as a medical emergency since it can lead to an ischemic stroke. Teach people at risk for TIAs to seek medical attention at once with any stroke-like symptom and to identify the time of onset of symptoms. The $ABCD^2$ score is a tool used to predict stroke risk for a person after a TIA (Table 57.2).[11]

Types of Stroke

Unlike a TIA, in which ischemia occurs without infarction, a stroke results in infarction (cell death). Strokes are classified as ischemic or hemorrhagic based on the cause and underlying pathophysiologic findings (Fig. 57.2 and Table 57.3).

Ischemic Stroke

An **ischemic stroke** results from inadequate blood flow to the brain from partial or complete occlusion of an artery.[12] Ischemic strokes are classified as thrombotic or embolic strokes.

Thrombotic Stroke

A **thrombotic stroke** occurs from injury to a blood vessel wall and formation of a blood clot (Fig. 57.2, *A*). The lumen of the blood vessel becomes narrowed, and, if it becomes occluded, infarction occurs. Thrombosis develops readily where atherosclerotic plaques have already narrowed blood vessels. Thrombotic stroke is the most common cause of stroke. It accounts for about 60% of strokes.[2] They are more common in older adults, especially those with high cholesterol, atherosclerosis, or diabetes. Most thrombotic strokes are associated with hypertension or diabetes, both of which accelerate atherosclerosis. Many times, a TIA precedes thrombotic strokes.[7]

The extent of the stroke depends on rapidity of onset, size of the damaged area, and presence of collateral circulation. Most patients with ischemic stroke do not have a decreased level of consciousness (LOC) in the first 24 hours, unless it is due to a brainstem stroke or other condition, such as seizure, increased ICP, or hemorrhage. Manifestations of ischemic stroke may progress in the first 72 hours as infarction and cerebral edema increase.

Embolic Stroke

Embolic stroke occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area supplied by the involved vessel (Fig. 57.2, *B*). Embolism is the second most

common cause of stroke.[2] Most emboli originate in the endocardial (inside) layer of the heart, when a plaque breaks off from the endocardium and enters the circulation. The embolus travels upward to the cerebral circulation and lodges where a vessel narrows or bifurcates (splits). Heart conditions, including atrial fibrillation, MI, infective endocarditis, rheumatic heart disease, valvular heart prostheses, patent foramen ovale, and atrial septal defects, account for most embolic ischemic strokes.[2] Less common causes of emboli include air and fat from long bone (e.g., femur) fractures.

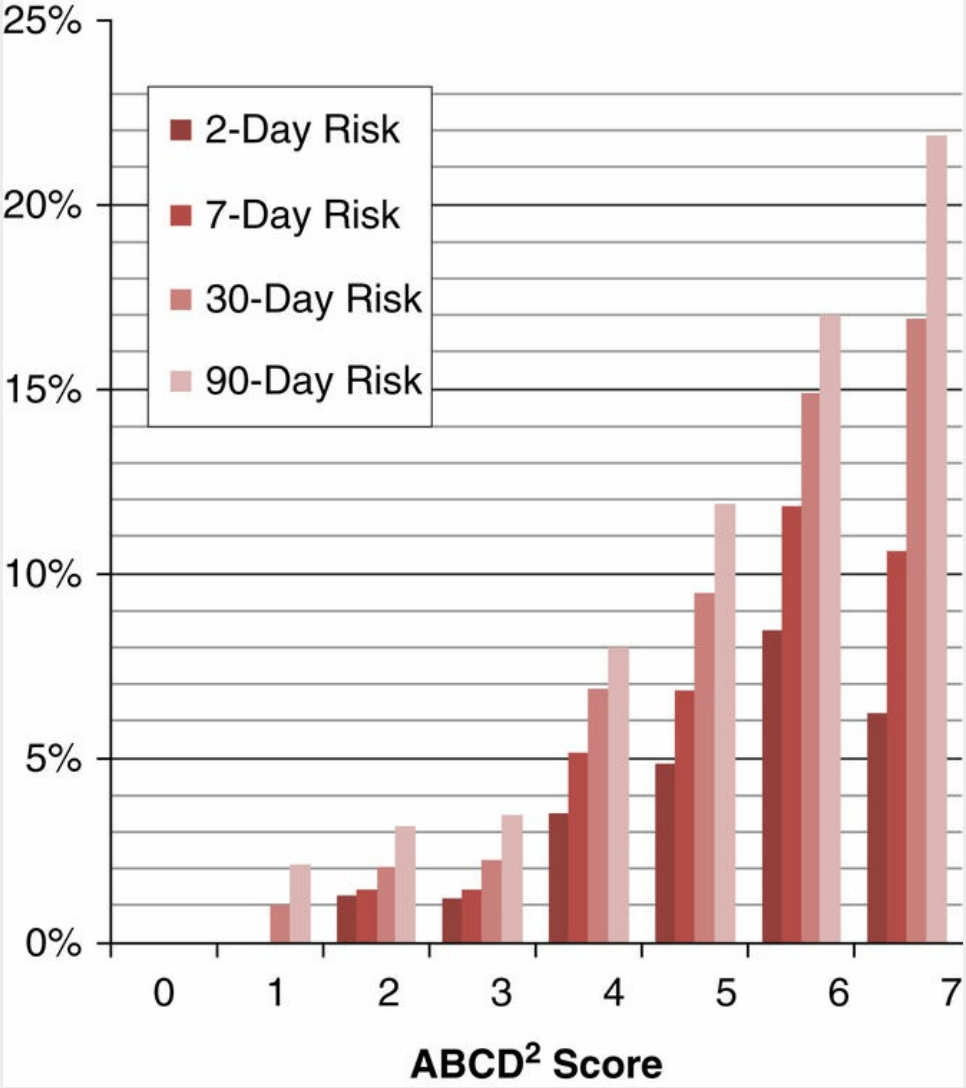

TABLE 57.2 ABCD² Score

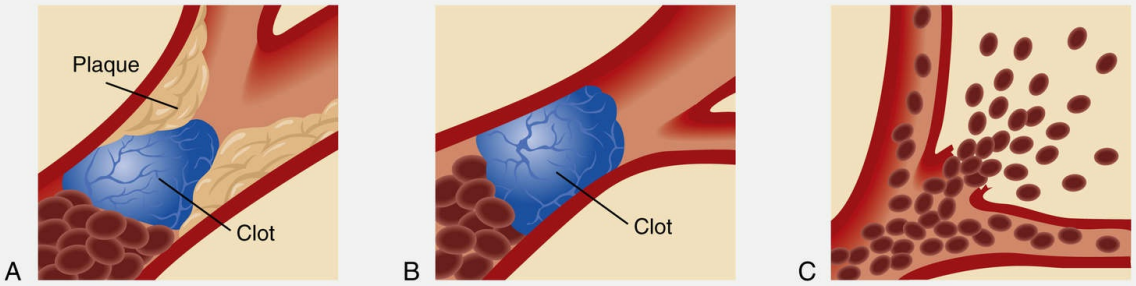
The ABCD² score is a risk assessment tool. It is designed to predict the risk for stroke 2 days after a transient ischemic attack (TIA). Calculate the score by adding up points for 5 factors.

Risk Factor	Points
Age ≥60 yr	1
Systolic BP ≥140 mm Hg *OR* diastolic BP ≥90 mm Hg	1
Clinical features of TIA (choose 1) **Unilateral weakness with or without speech impairment *OR***	2
Speech impairment without unilateral weakness	1
Duration **TIA duration ≥60 min *OR***	2
TIA duration 10–59 min	1
Diabetes	1
Total ABCD² Score	0–7

ABCD² score	2-Day Stroke Risk (%)	Care Needed
0–3	1.0	Hospitalization not needed unless there is another indication (e.g., new atrial fibrillation)

4–5	4.1	Hospitalization in most situations
6–7	8.1	Hospitalization



Permission obtained from National Stroke Association. Retrieved from *www.stroke.org*.

The patient with an embolic stroke often has severe manifestations that occur suddenly. Embolic strokes can affect any age-group. Rheumatic heart disease is a cause of embolic stroke in young to

middle-aged adults. An embolus arising from an atherosclerotic plaque is more common in older adults.

Warning signs are less common with embolic than with thrombotic stroke. The embolic stroke often occurs rapidly, giving little time to accommodate to an obstructed blood vessel with the development of collateral circulation. The patient is usually conscious, although they may have a headache. The effects of the emboli are initially characterized by severe neurologic deficits, which can be temporary if the clot breaks up and allows blood to flow. Smaller emboli then continue to obstruct smaller vessels, which in turn involve smaller portions of the brain with fewer deficits noted.

Thrombotic stroke. The process of clot formation (thrombosis) results in a narrowing of the lumen, which blocks the passage of the blood through the artery.

Embolic stroke. An embolus is a blood clot or other debris circulating in the blood. When it reaches an artery in the brain that is too narrow to pass through, it lodges there and blocks the flow of blood.

Hemorrhagic stroke. A burst blood vessel may allow blood to seep into and damage brain tissues until clotting shuts off the leak.

FIG. 57.2 Major types of stroke.

TABLE 57.3 Types of Stroke

Gender and Age	Warning and Onset	Prognosis
Ischemic		
Incidence: Accounts for 87% of strokes		
Embolic		
Men more than women	*Warning:* TIA (uncommon) *Onset:* Sudden onset, most likely to occur during activity	Single event, signs and symptoms develop quickly, usually some improvement, recurrence common without aggressive treatment of underlying disease.
Thrombotic		
Men more than women **Oldest median age**	*Warning:* TIA (30%–50% of cases) *Onset:* Often during or after sleep	Stepwise progression, signs and symptoms develop slowly, usually some improvement, recurrence in 20%–25% of survivors.
Hemorrhagic		
Incidence: Accounts for 13% of strokes		
Intracerebral		
Slightly higher in women	*Warning:* Headache (25% of cases) *Onset:* Activity (often)	Progression over 24 hr. Poor prognosis, fatality more likely with presence of coma.
Subarachnoid		
Slightly higher in women **Youngest median age**	*Warning:* Headache (common) *Onset:* Activity (often), sudden onset, most often related to head trauma	Usually single sudden event, fatality more likely with presence of coma.

The prognosis is related to the amount of brain tissue deprived of its blood supply. Recurrence of embolic stroke is common unless the underlying cause is aggressively treated.

FIG. 57.3 Massive hypertensive hemorrhage rupturing into a lateral ventricle of the brain.
From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Hemorrhagic Stroke

Hemorrhagic strokes result from bleeding into the brain tissue itself

(intracerebral or intraparenchymal hemorrhage) or into the subarachnoid space or ventricles (SAH or intraventricular hemorrhage).

Intracerebral Hemorrhage

Intracerebral hemorrhage is bleeding within the brain caused by a rupture of a vessel (usually in the basal ganglia) (Fig. 57.2, *C*). The prognosis of patients with intracerebral hemorrhage is poor. The 30-day mortality rate is 40% to 80%. Half of the deaths occur within the first 48 hours.[2]

Hypertension is the most common cause of intracerebral hemorrhage (Fig. 57.3). Other causes include vascular malformations, coagulation disorders, anticoagulant and thrombolytic drugs, trauma, brain tumors, and ruptured aneurysms. Hemorrhage often occurs during periods of activity. Most often there is a sudden onset of symptoms, with progression over minutes to hours because of ongoing bleeding.

Manifestations include neurologic deficits, headache, nausea, vomiting, decreased LOC, and hypertension. The extent of the symptoms varies depending on the amount, location, and duration of the bleeding. A blood clot within the closed skull can result in a mass that causes pressure on brain tissue, displaces brain tissue, and decreases CBF, leading to ischemia and infarction.

Most intracerebral hemorrhages occur in the cerebral lobes, cerebellum, pons, thalamus, subcortical white matter, internal capsule, or a part of the basal ganglia called the putamen. At first, patients have a severe headache with nausea and vomiting. Manifestations of putaminal and internal capsule bleeding include weakness of one side (including the face, arm, and leg), slurred speech, and deviation of the eyes. Progression of symptoms related to a severe hemorrhage includes hemiplegia, fixed and dilated pupils, abnormal body posturing, and coma. Thalamic hemorrhage results in hemiplegia with more sensory than motor loss. Bleeding into the subthalamic areas of the brain leads to problems with vision and eye movement. Cerebellar hemorrhages are characterized by severe headache, vomiting, loss of

ability to walk, dysphagia, dysarthria, and eye movement changes.

Hemorrhage in the pons is the most serious because basic life functions (e.g., respiration) are rapidly affected. Hemorrhage in the pons can be characterized by hemiplegia leading to complete paralysis, coma, abnormal body posturing, fixed pupils, hyperthermia, and death.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) occurs when there is intracranial bleeding into the cerebrospinal fluid (CSF)–filled space between the arachnoid and pia mater membranes on the surface of the brain. SAH is often caused by rupture of a cerebral **aneurysm** (congenital or acquired weakness and ballooning of vessels). Aneurysms may be saccular or berry aneurysms, ranging from a few millimeters to 20 to 30 mm in size, or fusiform atherosclerotic aneurysms. Most aneurysms are in the circle of Willis. Other causes of SAH include trauma and illicit drug (cocaine) use. The incidence of SAH increases with age and is higher in women than men.

The patient may have warning signs and symptoms if the ballooning artery applies pressure to brain tissue. Minor warning symptoms may result from leaking of an aneurysm before major rupture. In general, cerebral aneurysms are viewed as a "silent killer," since people do not have warning signs or symptoms of an aneurysm until rupture has occurred.

Check Your Practice

You are watching your husband's "for fun" soccer game. He leaves the game and is kneeling on the ground. When you try to assess what is going on he says, "I've got a terrible headache. It just started." Knowing that he sometimes gets headaches when he is stressed, you ask him if he is feeling stressed. He almost screams back at you, "NO! This is the worst headache of my life!"

- What should you do?

Loss of consciousness may or may not occur. The patient's LOC may range from alert to comatose, depending on the severity of the bleed. Other manifestations include focal neurologic deficits (including cranial nerve deficits), nausea, vomiting, seizures, and stiff neck.

Complications of aneurysmal SAH include rebleeding before surgery or other therapy is started and cerebral vasospasm (narrowing of the blood vessels), which can result in cerebral infarction. Cerebral vasospasm is likely due to an interaction between the metabolites of blood and the vascular smooth muscle. This occurs when the subarachnoid blood clots break down or dissolve, releasing metabolites that can cause endothelial damage and vasoconstriction. The release of endothelin (a potent vasoconstrictor) may play a key role in the induction of cerebral vasospasm after SAH. Patients with SAH who are at risk for vasospasm are often kept in the intensive care unit (up to 14 days) until the threat of vasospasm is reduced. Peak time for vasospasm is 6 to 10 days after the initial bleed.

TABLE 57.4 Stroke Manifestations Related to Artery Involvement

Artery	Manifestations
Anterior cerebral	Motor and/or sensory deficit (contralateral), sucking or rooting reflex, rigidity, gait problems, loss of proprioception and fine touch
Middle cerebral	*Dominant side:* Aphasia, motor and sensory deficit, hemianopsia *Nondominant side:* Neglect, motor and sensory deficit, hemianopsia
Posterior cerebral	Hemianopsia, visual hallucination, spontaneous pain, motor deficit
Vertebral	Cranial nerve deficits, diplopia, dizziness, nausea, vomiting, dysarthria, dysphagia, and/or coma

Despite improvements in surgical techniques and management, many patients with SAH die. Some die almost immediately when a rupture occurs. Others die from subsequent bleeding. Survivors may

be left with significant morbidity, including cognitive problems.

Clinical Manifestations of Stroke

Neurologic manifestations do not significantly differ between ischemic and hemorrhagic stroke. The reason for this is that destruction of neural tissue is the basis for neurologic dysfunction caused by both types of stroke. The manifestations are related to the location of the stroke. Specific manifestations related to the type of stroke were discussed in the previous section. The general manifestations of ischemic and hemorrhagic stroke are discussed together here.

A stroke can affect many body functions, including motor activity, bladder and bowel elimination, intellectual function, spatial-perceptual changes, personality, affect, sensation, swallowing, and communication. The functions affected are directly related to the artery involved and area of the brain that it supplies (Table 57.4). Manifestations related to right- and left-brain damage differ somewhat. These are shown in Fig. 57.4.

Motor Function

Motor deficits are the most obvious effect of stroke. Motor deficits include impairment of (1) mobility, (2) respiratory function, (3) swallowing and speech, (4) gag reflex, and (5) self-care abilities. Symptoms are caused by the destruction of motor neurons in the pyramidal pathway (nerve fibers from the brain that pass through the spinal cord to the motor cells). The characteristic motor deficits include loss of skilled voluntary movement *(akinesia),* impaired integration of movements, changes in muscle tone, and altered reflexes. The initial *hyporeflexia* (depressed reflexes) progresses to *hyperreflexia* (hyperactive reflexes) for most patients.

Motor deficits after a stroke follow certain specific patterns. Because the pyramidal pathway crosses at the level of the medulla, a lesion on one side of the brain affects motor function on the opposite side of the

body (contralateral). The arms and legs of the affected side may be weakened or paralyzed to different degrees depending on which part of and to what extent the cerebral circulation was compromised. A stroke affecting the middle cerebral artery leads to a greater weakness in the upper extremity than the lower extremity. The affected shoulder tends to rotate internally, and the hip rotates externally. The affected foot is plantar flexed and inverted. An initial period of flaccidity may last from days to several weeks and is related to nerve damage. Spasticity of the muscles, which follows the flaccid stage, is related to interruption of upper motor neuron influence.

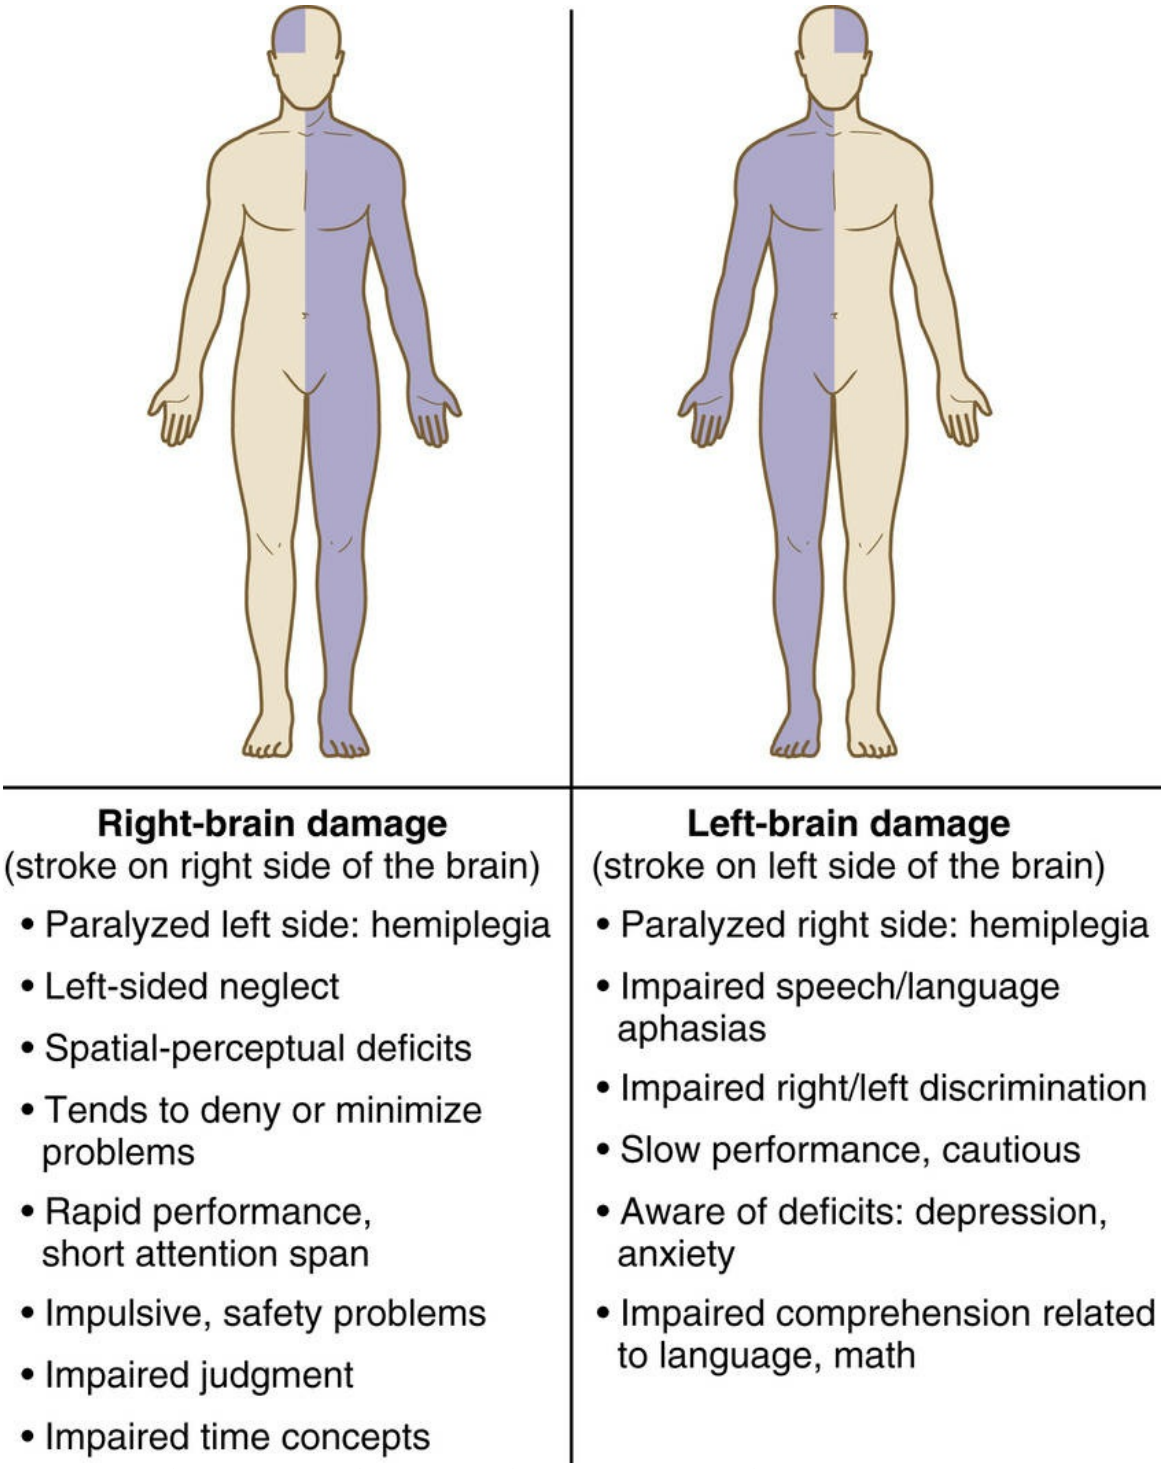


FIG. 57.4 Manifestations of right-brain and left-brain stroke.

Communication

The left hemisphere is dominant for language skills in right-handed

persons and in most left-handed persons.[12] Language disorders involve expression and comprehension of written and spoken words. The patient may have **aphasia**. Types of aphasia include *receptive aphasia* (loss of comprehension), *expressive aphasia* (inability to produce language), or *global aphasia* (total inability to communicate). Aphasia occurs when a stroke damages the dominant hemisphere of the brain.

Dysphasia refers to impaired ability to communicate. However, in most settings the terms *aphasia* and *dysphasia* are used interchangeably. Aphasia is the more common term used. Patterns of aphasia may differ since the stroke affects different portions of the brain. Aphasia may be classified as *nonfluent* (minimal speech activity with slow speech that requires obvious effort) or *fluent* (speech is present but has little meaningful communication) (Table 57.5). Most types of aphasia are mixed, with impairment in both expression and understanding. A massive stroke may result in global aphasia.

TABLE 57.5 Types of Aphasia

Type	Characteristics
Broca's	• Type of nonfluent aphasia • Damage to frontal lobe of brain • Often speak in short phrases that make sense but take great effort • Often omit small words (e.g., is, and, the) • May say, "Walk dog," meaning, "I will take the dog for a walk," or "Book 2 table," for "There are 2 books on the table" • Typically understands others' speech • Often aware of their difficulties and can become easily frustrated
Global	• Type of nonfluent aphasia • Results from damage to extensive portions of language areas of brain • Have severe communication difficulties • May be extremely limited in ability to speak or understand language
Wernicke's	• Type of fluent aphasia • Damage occurs in left temporal lobe, although it can result from damage to right lobe • May speak in long sentences that have no meaning, add unnecessary words, and even create made-up words • May say, "You know that smoodle pinkered and that I want to get him round and take care of him like you want before" • Usually have great difficulty understanding speech • Often unaware of their mistakes • Often difficult to follow what person is trying to say
Other	• Results from damage to different language areas in brain • Some may have difficulty repeating words and sentences, even though they can speak and understand the meaning of the word or sentence • May have difficulty naming objects, even though they know what the object is and what its use is

Many stroke patients have **dysarthria**, a problem with the muscular

control of speech. Impairment may involve pronunciation, articulation, and phonation. Dysarthria does not affect the meaning of communication or the comprehension of language, but it does affect the mechanics of speech. Some patients have a combination of aphasia and dysarthria.

Affect

Patients who had a stroke may have a hard time controlling their emotions. Emotional responses may be exaggerated or unpredictable. Depression and feelings associated with changes in body image and loss of function can make this worse.[13] Mobility and communication problems increase frustration.

Check Your Practice

You are working in the outpatient stroke clinic, counseling the family of one of your favorite patients. He is a well-respected 65-yr-old business man who has returned home after a stroke. His family tells you that during meals he becomes frustrated and begins to cry because of the difficulty getting food into his mouth and chewing. His family cannot understand why a previously very competent man is so emotional.

- How should you counsel the family? What teaching is needed?

Intellectual Function

A stroke may impair both memory and judgment. These impairments can occur with strokes affecting either side of the brain. A left-brain stroke is more likely to result in memory problems related to language. Patients with a left-brain stroke often are cautious in making judgments.

The patient with a right-brain stroke tends to be impulsive and to

move quickly. An example is that they try to rise quickly from a wheelchair without locking the wheels or raising the footrests. On the other hand, people with a left-brain stroke would move slowly and cautiously from the wheelchair. Patients with either type of stroke may find it hard to make generalizations, interfering with their ability to learn.

Spatial-Perceptual Problems

Those who had a stroke on the right side of the brain are more likely to have problems with spatial-perceptual orientation. However, this can also occur in people with left-brain stroke.

Spatial-perceptual problems may be divided into 4 categories.

- The first results from damage of the parietal lobe. It causes the patient to have an incorrect perception of self and illness. In this situation, patients may deny their illnesses or not recognize their own body parts.
- The second category occurs when the patient neglects all input from the affected side (erroneous perception of self in space). This may be worsened by *homonymous hemianopsia,* in which blindness occurs in the same half of the visual fields of both eyes. The patient also has difficulty with spatial orientation, such as judging distances.
- The third spatial-perceptual deficit is *agnosia,* the inability to recognize an object by sight, touch, or hearing.
- The fourth deficit is *apraxia,* the inability to carry out learned sequential movements on command. Patients may or may not be aware of their spatial-perceptual problems. You need to assess for this potential problem as it will affect rehabilitation and recovery.

Elimination

Most problems with urinary and bowel elimination are temporary.

When a stroke affects one hemisphere of the brain, the prognosis for normal bladder function is excellent. At least partial sensation for bladder filling remains, and voluntary urination is present. At first the patient may have frequency, urgency, and incontinence. Although motor control of the bowel is usually not a problem, patients are often constipated. Constipation is associated with immobility, weak abdominal muscles, dehydration, and decreased response to the defecation reflex. Elimination problems may also be related to inability to state the need to eliminate and difficulty managing clothing (resulting in incontinence). Scheduled toileting and clothes that are easily removed encourage independence.

Diagnostic Studies for Stroke

When manifestations of a stroke occur, diagnostic studies (Table 57.6 and 57.7) are done to (1) confirm that it is a stroke and not another type of brain lesion and (2) identify the likely cause of the stroke. Diagnostic study results also guide decisions about therapy. A key assessment is to determine the time of the onset of symptoms. This is important for all types of stroke, especially ischemic strokes since the time can affect treatment decisions.

TABLE 57.6 Diagnostic StudiesStroke

Diagnosis of Stroke (Including Extent of Involvement)

- CT scan
- CT angiography (CTA)
- CT/MRI perfusion and diffusion imaging
- MRI
- Magnetic resonance angiography (MRA)

Cerebral Blood Flow

- Carotid angiography
- Carotid duplex scanning
- Cerebral angiography
- Digital subtraction angiography
- Transcranial Doppler ultrasonography

Cardiac Assessment

- Cardiac markers (troponin, creatine kinase-MB)
- Chest x-ray
- Echocardiography (transthoracic, transesophageal)
- ECG

Additional Studies

- Coagulation studies: prothrombin time, activated partial thromboplastin time
- CBC (including platelets)
- Electrolyte panel with blood glucose
- Lipid profile
- Renal and hepatic studies

Once the person suspected of TIA or stroke arrives in the emergency department, it is important for the patient to rapidly undergo either a noncontrast head CT or MRI. These important diagnostic tests can rapidly distinguish between ischemic and hemorrhagic stroke. They help determine the size and location of the stroke and treatment options. MRI is more effective in identifying ischemic stroke than CT scans. However, a CT scan is a rapid

diagnostic tool to rule out hemorrhage. Serial scans may be used to assess the effectiveness of treatment and to evaluate recovery.

CT angiography (CTA) provides visualization of cerebral blood vessels. It can be done after or at the same time as the noncontrast CT scan. CTA can give an estimate of perfusion and detect filling defects in the cerebral arteries. Magnetic resonance angiography (MRA) can detect vascular lesions and blockages, similar to CTA. CT/MRI perfusion and diffusion imaging may be done.

If the suspected cause of the stroke includes emboli from the heart, diagnostic cardiac tests should be done. Cardiac imaging is recommended because many strokes are caused by blood clots from the heart. Blood tests can help identify conditions contributing to stroke and to guide treatment (Table 57.6).

Angiography can identify cervical and cerebrovascular occlusion, atherosclerotic plaques, and malformation of vessels. Cerebral angiography can definitively identify the source of SAH. Risks of angiography include dislodging an embolus, causing vasospasm, inducing further hemorrhage, and provoking an allergic reaction to contrast media.

Intraarterial digital subtraction angiography (DSA) involves the injection of a contrast agent to visualize blood vessels in the neck and the large vessels of the circle of Willis. It reduces the dose of contrast material, uses smaller catheters, and shortens the length of the procedure compared with conventional angiography. It is considered safer than cerebral angiography because there is less vascular manipulation.

TABLE 57.7 Interprofessional CareAcute Stroke

Diagnostic Assessment

- History and physical examination
- Diagnostic studies (Table 57.6)

Management

Drug Therapy

- Platelet inhibitors (e.g., aspirin)
- Anticoagulation therapy for patients with atrial fibrillation

Surgical Therapy

- Carotid endarterectomy
- Stenting of carotid artery
- Transluminal angioplasty
- Surgical interventions for aneurysms at risk for bleeding

Acute Care

- Maintenance of airway
- Fluid therapy
- Treatment of cerebral edema
- Prevention of secondary injury

Ischemic Stroke

- Tissue plasminogen activator (tPA) IV or intraarterial
- Endovascular therapy

Hemorrhagic Stroke

- Surgical decompression if indicated
- Clipping or coiling of aneurysm

Role of Interprofessional Team Members Speech Therapy

- Assess swallowing reflex
- Evaluate patient for communication defects (e.g., aphasia)

Occupational Therapy

- Evaluate ability to perform self-care
- Teach to perform activities of daily living and adapting tasks

Physical Therapy

- Recommend functional position
- Assess function and together with patient, plan a rehabilitation program

Transcranial doppler (TCD) ultrasonography is a noninvasive study that measures the velocity of blood flow in the major cerebral arteries. TCD is effective in detecting microemboli and vasospasm. It is ideal for the patient suspected of having an SAH. Carotid duplex scanning is used to detect the cause of the stroke and stratify patients for either medical management or carotid intervention if they have carotid stenosis.

An LP can determine if red blood cells are present in the CSF if we suspect a SAH but the CT does not show hemorrhage. An LP is avoided if the patient is suspected of having an obstruction in the foramen magnum or other signs of increased ICP because of the danger of herniation of the brain downward. This could lead to pressure on cardiac and respiratory centers in the brainstem and potentially death.

The LICOX system may be used as a diagnostic tool to evaluate the

progression of stroke. LICOX measures brain oxygenation and temperature (see discussion in Chapter 56 on p. 1307 and). Secondary brain injury adds significantly to mortality risk and poor functional outcome after a stroke.

Interprofessional Care for Stroke

Preventive Therapy

Primary prevention is a priority for decreasing morbidity and mortality risk from stroke. The goals of stroke prevention include health promotion for a healthy lifestyle and management of modifiable risk factors to prevent a stroke. Health promotion focuses on (1) healthy diet, (2) weight control, (3) regular exercise, (4) no smoking, (5) limiting alcohol consumption, (6) BP management, and (7) routine health assessments. Patients with known risk factors (e.g., diabetes, hypertension, obesity, high serum lipids, cardiac dysfunction) need close management.

Promoting Population Health

Stroke Prevention

- Reduce salt and sodium intake.
- Maintain a normal body weight.
- Follow a diet low in saturated fat and high in fruits and vegetables.
- Limit alcohol use to moderate levels.
- Maintain an SBP less than 140 mm Hg.
- Exercise 40 minutes 3 to 4 days per week.
- Avoid cigarette smoking and tobacco products.
- Maintain a normal blood glucose level and control diabetes.

- Follow the prescribed treatment plan for diagnosed cardiac problems.

Preventive Drug Therapy

Measures to prevent the development of a thrombus or an embolus are used in patients with TIAs, since they are at high risk for stroke. Antiplatelet drugs are usually the chosen treatment to prevent stroke in patients who had a TIA. Aspirin, at a dose of 81 mg/day, is the most often used antiplatelet agent. Other agents include ticlopidine, clopidogrel (Plavix), dipyridamole (Persantine), and combined dipyridamole and aspirin (Aggrenox).

Drug Alert

Ticlopidine and Clopidogrel (Plavix)

- Inform all HCPs and dentists that the medication is being taken before scheduling surgery or major dental procedures.
- They may have to be discontinued 10 to 14 days before surgery if antiplatelet effect is not desired.

For patients with atrial fibrillation, oral anticoagulation can include warfarin (Coumadin) and the direct factor Xa inhibitors: rivaroxaban (Xarelto), dabigatran (Pradaxa), and apixaban (Eliquis). The primary advantage of direct factor Xa inhibitors compared to warfarin is that they do not need close monitoring or dosage adjustments. Statins (e.g., simvastatin, lovastatin) are effective in stroke prevention for those with high cholesterol levels who had a TIA.[10]

Left Atrial Appendage Occlusion

The left atrial appendage (LAA) is a pouch that extends off the left atrium. We think the LAA is the source of many stroke-causing

emboli in patients with atrial fibrillation. Removing or occluding the LAA decreases the incidence of strokes. LAA occlusion is a treatment strategy to prevent blood clot formation in patients with atrial fibrillation. It is an alternative for patients who cannot use oral anticoagulants, such as warfarin. After LAA occlusion, patients may be able to stop taking anticoagulants.[9]

A special stapler can be used to remove the LAA. Or, the HCP can place sutures that manually occlude the LAA. There are also special LAA occlusion devices (e.g., AtriClip, Watchman).[9] These devices are positioned around the LAA and then closed, like a clamp that is used to shut off the blood supply. This prevents blood from flowing into and out of the LAA.

Patent Foramen Ovale

Patients with a patent foramen ovale are at increased risk for an ischemic stroke. In this condition, there is a hole between the left and right atriums. Blood clots can pass through this opening and go to the brain, leading to ischemia. An occlusion device implanted in this opening can prevent clot dislodgment (e.g. Amplatzer PFO).[14]

Surgical/Endovascular Therapy for TIA and Stroke Prevention

Surgical interventions for the patient with TIAs due to carotid disease include carotid endarterectomy, transluminal angioplasty, and stenting. In a *carotid endarterectomy* (CEA), the atheromatous lesion is removed from the carotid artery to improve blood flow.

Transluminal angioplasty is the insertion of a balloon to open a stenosed artery in the brain and improve blood flow. The balloon is threaded up to the carotid artery through a catheter inserted in the femoral artery.

Stenting involves intravascular placement of a stent to try to maintain patency of the artery (Fig. 57.5). The stent can be inserted during an angioplasty. Once in place, the system can be used with a tiny filter that opens like an umbrella. The filter catches and removes

the debris that is stirred up during the stenting procedure before it floats to the brain, where it can trigger a stroke. Stenting is a less invasive strategy for revascularization in patients unable to withstand the CEA because of coexisting medical conditions.

Postoperative nursing care includes neurovascular assessment and BP management. Assess for complications, including stent occlusion and retroperitoneal hemorrhage. Minimize the risk for bleeding at the insertion site by keeping the patient's leg straight for the prescribed time.

Acute Care for Ischemic Stroke

During initial evaluation, the single most important point in the patient's history is the time of onset of symptoms. Interprofessional goals during the acute phase are preserving life, preventing further brain damage, and reducing disability (Table 57.7).

Table 57.8 outlines the emergency management of the patient with a stroke. In the unresponsive person, acute care begins with assessing circulation, airway, and breathing. Patients may have difficulty keeping an open and clear airway because of a decreased level of consciousness or decreased or absent gag and swallowing reflexes. Maintaining adequate oxygenation is important. O_2 administration, artificial airway insertion, intubation, and mechanical ventilation may be needed. Baseline neurologic assessment is carried out, and patients are monitored closely for signs of increasing neurologic deficit. Many patients may worsen in the first 24 to 48 hours.

For emergency care, patients should be transported to the closest certified stroke center. If one is not available, they should be sent to the closest facility offering emergency stroke care.[15] The AHA recommends that acute care facilities have stroke teams in place. The stroke team generally consists of a registered nurse, neurologist, radiologist, and radiologic technician.

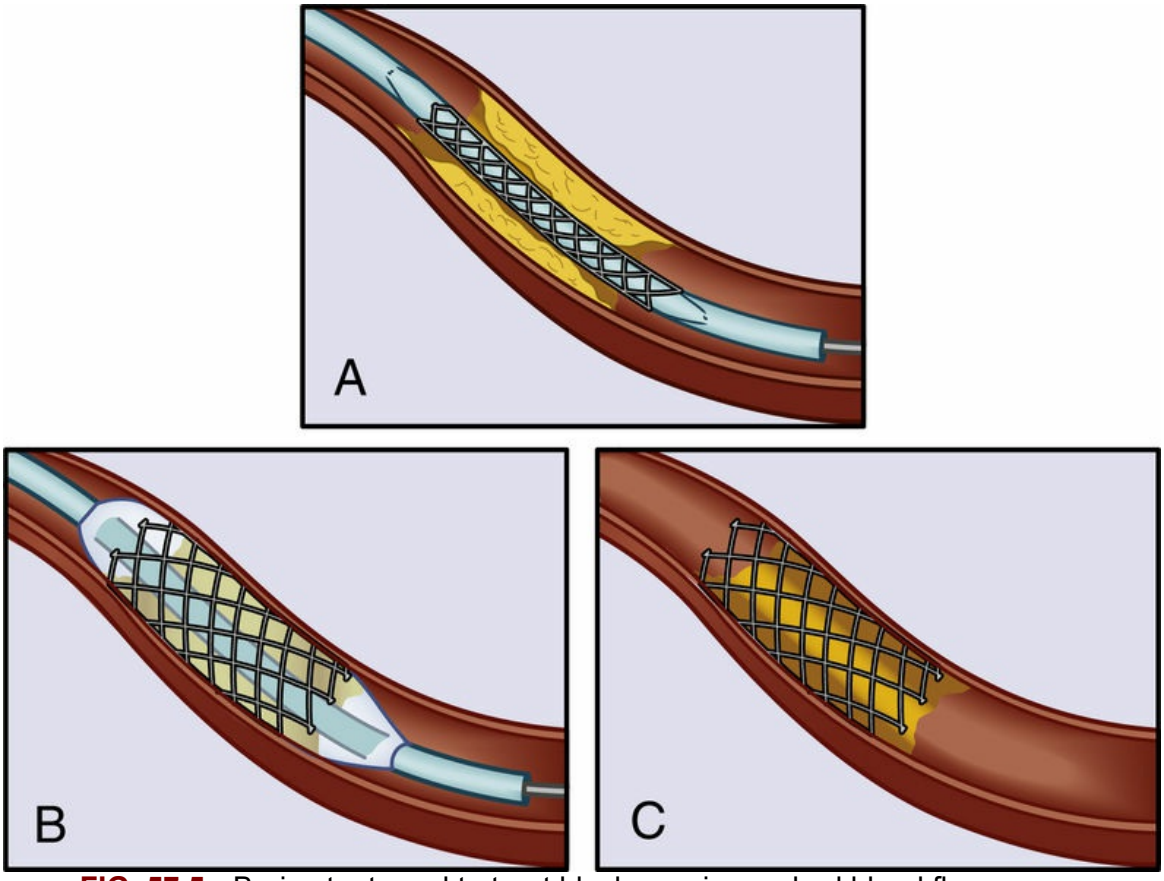

FIG. 57.5 Brain stent used to treat blockages in cerebral blood flow. **A,** A balloon catheter is used to implant the stent into an artery of the brain. **B,** The balloon catheter is moved to the blocked area of the artery and then inflated. The stent expands due to inflation of the balloon. **C,** The balloon is deflated and withdrawn, leaving the stent permanently in place holding the artery open and improving the flow of blood.

Elevated BP is common immediately after a stroke. It may be a protective response to maintain cerebral perfusion. However, it can be detrimental. In patients with an ischemic stroke who do not receive fibrinolytic therapy (discussed later), the use of drugs to lower BP is recommended only if BP is markedly increased (SBP greater than 220 mm Hg or DBP greater than 120 mm Hg). In a patient who is going to have fibrinolytic therapy, the BP must be less than 185/110 mm Hg and then maintained at or below 180/105 mm Hg for at least 24 hours after fibrinolytic therapy. In an acute stroke, IV antihypertensives, such as labetalol and nicardipine (Cardene), are preferred. Although low BP right after a stroke is uncommon, we correct hypotension and

hypovolemia if present.

Fluid and electrolyte balance must be controlled carefully. The goal is to keep the patient adequately hydrated to promote perfusion and decrease further brain injury. Overhydration may compromise perfusion by increasing ICP and cerebral edema. Adequate fluid intake during acute care via oral, IV, or tube feedings is a priority. Monitor urine output to make sure the patient does not become dehydrated.

If secretion of antidiuretic hormone (ADH) increases in response to the stroke, urine output decreases and fluid is retained. Low serum sodium (hyponatremia) may occur. IV solutions with glucose and water are avoided because they are hypotonic and may further increase cerebral edema and ICP. Glycemic control should be maintained to avoid extreme hypoglycemia or hyperglycemia. In general, decisions about fluid and electrolyte replacement therapy are based on the extent of intracranial edema, manifestations of increased ICP, central venous pressure levels, electrolyte levels, and intake and output.

Increased ICP is more likely to occur with hemorrhagic strokes but can occur with ischemic strokes. Increased ICP from cerebral edema usually peaks in 72 hours and may cause brain herniation. Management of increased ICP includes practices that improve venous drainage. These include elevating the head of the bed, keeping head and neck in alignment, and avoiding hip flexion. Other measures for reducing ICP include managing fever (goal temperature of 96.8° to 98.6°F [36° to 37°C]), drug therapy to prevent seizures, pain management, and preventing constipation. CSF drainage may be used in some patients to reduce ICP. The specific management of increased ICP is discussed in Chapter 56.

TABLE 57.8 Emergency ManagementStroke

Etiology	Assessment Findings	Interventions
• **Aneurysm** • **Arteriovenous malformation** • **Embolism** • **Hemorrhage** • **Sudden vascular compromise causing disruption of blood flow to brain** • **Thrombosis** • **Trauma**	• Altered level of consciousness • Bladder or bowel incontinence • Difficulty swallowing • Facial drooping on affected side • Heart rate ↑ or ↓ • Hypertension • Numbness, weakness, or paralysis of part of body • Respiratory distress • Seizures • Severe headache • Speech or visual changes • Unequal pupils • Vertigo	Initial • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Call stroke code or stroke team. • Remove dentures. • Perform pulse oximetry. • Maintain adequate oxygenation (SaO_2 >95%) with supplemental O_2, if needed. • Establish IV access with normal saline. • Maintain BP according to guidelines. • Remove clothing. • Obtain CT scan or MRI. • Perform baseline laboratory tests (including blood glucose) immediately and treat if hypoglycemic. • Position head in midline. • Elevate head of bed 30 degrees if no symptoms of shock or injury. • Institute seizure precautions. • Anticipate thrombolytic therapy for ischemic stroke. • Keep patient NPO until swallow reflex evaluated. **Ongoing Monitoring** • Monitor vital signs and neurologic status, including level of consciousness (NIH Stroke Scale), motor and sensory function, pupil size and reactivity, SaO_2, and cardiac rhythm. • Reassure patient and family.

NIH, National Institutes of Health; *SaO_2,* arterial O_2 saturation.

Drug Therapy for Ischemic Stroke

Fibrinolytic therapy should not be delayed. Recombinant tissue plasminogen activator (tPA) is used to produce localized fibrinolysis by binding to the fibrin in the thrombi. The fibrinolytic action of tPA occurs as the plasminogen is converted to plasmin, whose enzymatic action then digests fibrin and fibrinogen, thus breaking down the clot. Other fibrinolytic agents cannot be substituted for tPA. (Fibrinolytic [thrombolytic] therapy is discussed in Chapter 33.)

tPA is given IV to reestablish blood flow through a blocked artery to prevent cell death in patients with the acute onset of ischemic stroke. tPA must be given within 3 to 4½ hours of the onset of signs of ischemic stroke.[16] Patients are screened carefully before tPA can be given. Screening includes a noncontrast CT scan or MRI to rule out hemorrhagic stroke; blood tests for coagulation disorders; screening for recent history of gastrointestinal (GI) bleeding, stroke, or head trauma within the past 3 months; major surgery within 14 days; or recent active internal bleeding within 22 days.[16]

During tPA infusion, closely monitor the patient's vital signs and neurologic status to assess for improvement or for potential deterioration related to intracerebral hemorrhage. Control of BP (SBP

less than 185 mm Hg) is critical during treatment and for 24 hours following.

Intraarterial infusion of tPA may be used for patients with an ischemic stroke when mechanical thrombectomy is not an option. To be effective, intraarterial tPA must be given within 6 hours of the onset of stroke symptoms. In the intraarterial tPA procedure, the neurovascular specialist inserts a thin, flexible catheter into an artery (usually the femoral artery) and guides the catheter (using angiogram) to the area of the clot. The tPA is given through the catheter and immediately targets the clot. Less tPA is needed when it is delivered directly to the clot, which can reduce the chance for intracranial hemorrhage.

The use of anticoagulants (e.g., heparin) in the emergency phase after an ischemic stroke is not recommended because of the risk for intracranial hemorrhage. Aspirin at a dose of 325 mg may be started within 24 to 48 hours after the onset of an ischemic stroke. Complications of higher dose aspirin include GI bleeding. Aspirin should be given cautiously if the patient has a history of peptic ulcer disease.

After the patient has stabilized and to prevent further clot formation, patients with strokes caused by thrombi and emboli may be treated with anticoagulants and platelet inhibitors (see discussion on stroke prevention on p. 1338.). For patients with atrial fibrillation, oral anticoagulants include warfarin and the direct factor Xa inhibitors: rivaroxaban (Xarelto), dabigatran (Pradaxa), and apixaban (Eliquis). Platelet inhibitors include aspirin, ticlopidine, clopidogrel, and dipyridamole. The use of statins is effective for the patient after an ischemic stroke.[9]

Endovascular Therapy for Ischemic Stroke

Stent retrievers are a way of opening blocked arteries in the brain by using a removable stent system.[17] During the procedure, a catheter is used to guide the small stent from the femoral artery in the groin area to the affected artery in the brain. The stent is guided (using neuroimaging) into the part of the artery where a blood clot has

formed. The stent expands the interior walls of the artery and allows blood to get to the patient's brain immediately to prevent as much brain damage as possible. The clot seeps into the mesh of the stent. Then, after a few minutes the stent and clot are removed together. Stent retrievers are becoming the most effective way of managing ischemic stroke.[17]

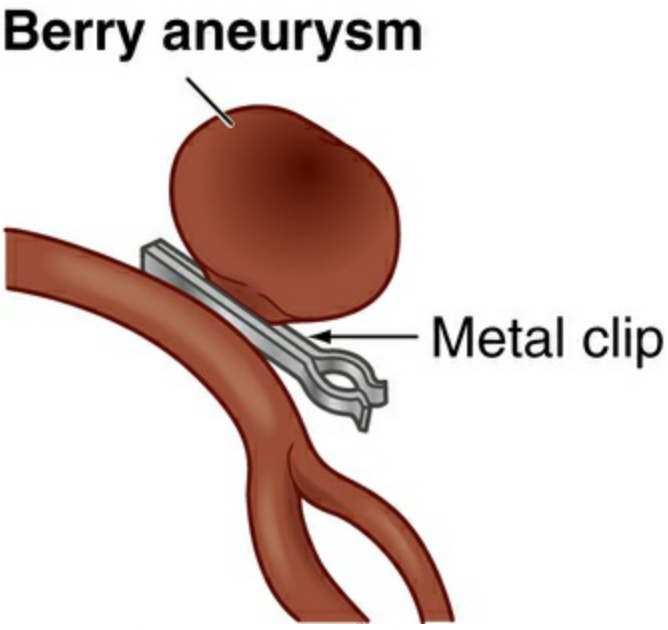

FIG. 57.6 Clipping of aneurysms.

The ENROUTE device accesses the carotid arteries through the neck, rather than the groin. It allows the surgeon to maintain blood flow to the brain while performing carotid angioplasty and stenting.[18]

Acute Care for Hemorrhagic Stroke

Drug Therapy for Hemorrhagic Stroke

Anticoagulants and platelet inhibitors are contraindicated in patients with hemorrhagic strokes. The main drug therapy for patients with hemorrhagic stroke is the management of hypertension. Oral and IV agents may be used to maintain BP within a normal to high-normal range (SBP less than 160 mm Hg). Seizure prophylaxis in the acute

period after intracerebral and subarachnoid hemorrhages is situation specific and decided among the interprofessional care team.[19]

Surgical Therapy for Hemorrhagic Stroke

Surgical interventions for hemorrhagic stroke include immediate evacuation of aneurysm-induced hematomas or cerebellar hematomas larger than 3 cm. Those who have an arteriovenous malformation (AVM) may have a hemorrhagic stroke if the AVM ruptures. The treatment of AVM is surgical resection and/or radiosurgery (i.e., gamma knife). Interventional neuroradiology to embolize the blood vessels that supply the AVM may be done prior.

With SAH, bleeding from a damaged vessel causes blood to accumulate between the brain and skull. The leaked blood can irritate, damage, or destroy the surrounding brain cells. When blood enters the subarachnoid space, it mixes with the CSF. This can block CSF circulation, thus causing increased pressure on the brain. The open spaces in the brain (ventricles) may enlarge, resulting in hydrocephalus. This further increases ICP (due to the large accumulation of blood) and can result in further brain injury. Inserting a ventriculostomy for CSF drainage can dramatically improve these situations by reducing the ICP.[20] Goals for managing ICP are the same for patients with SAH as they are for patients dealing with acute stroke. The management of ICP is discussed in Chapter 56.

SAH is usually caused by a ruptured aneurysm. Patients may have multiple aneurysms. Treatment of an aneurysm involves clipping or coiling the aneurysm to prevent rebleeding (Figs. 57.6 and 57.7). In *clipping* the aneurysm, the neurosurgeon places a metallic clip on the neck of the aneurysm to block blood flow and prevent rupture. The clip stays in place for life.

In the procedure known as *coiling,* a hydrogel-coated platinum coil is inserted into the lumen of the aneurysm via interventional neuroradiology (Fig. 57.7). Guglielmi detachable coils (GDCs) give immediate protection against hemorrhage by reducing the blood pulsations within the aneurysm. Eventually, a thrombus forms within the aneurysm. Then the aneurysm becomes sealed off from the parent

vessel by the formation of an endothelialized layer of connective tissue.

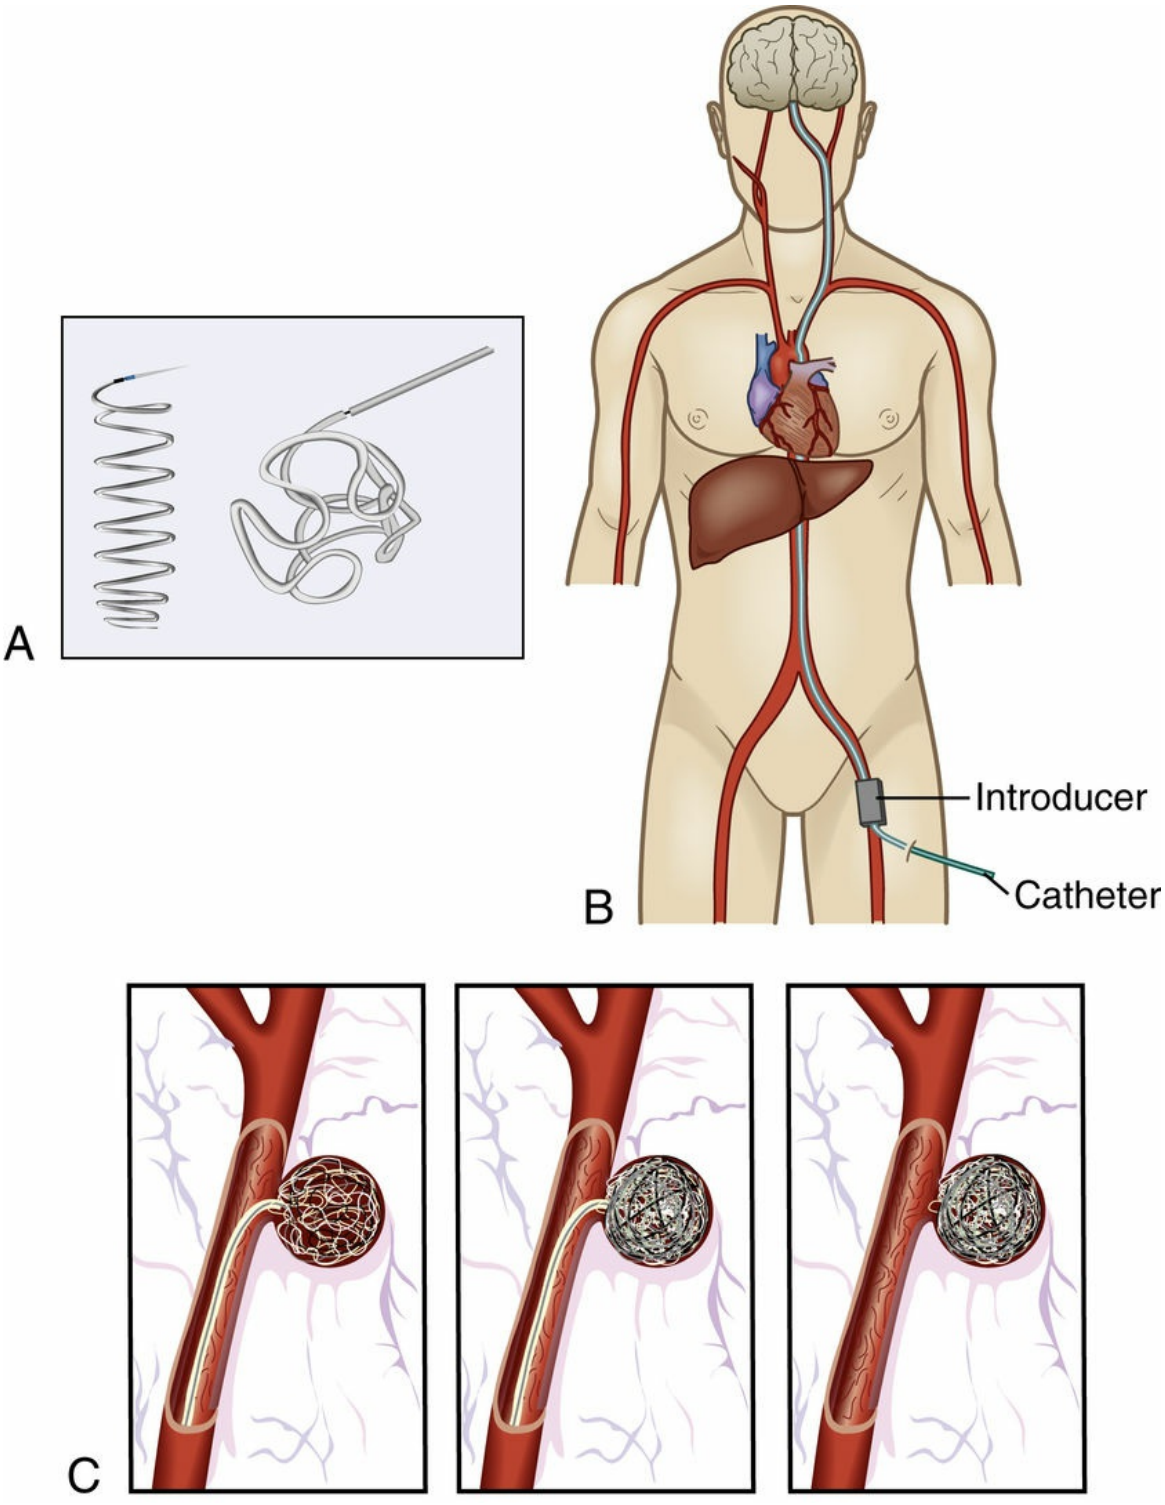

FIG. 57.7 Guglielmi detachable coil (GDC). **A,** A coil is used to occlude an aneurysm. Coils are made of soft, springlike platinum. The softness of the platinum allows the coil to assume the shape of irregularly shaped aneurysms while posing little threat of rupture of the aneurysm. **B,** A catheter is inserted through an introducer (small tube) in an artery in the leg. The catheter is threaded up to the cerebral blood

vessels. **C,** Platinum coils attached to a thin wire are inserted into the catheter and then placed in the aneurysm until the aneurysm is filled with coils. Packing the aneurysm with coils prevents the blood from circulating through the aneurysm, reducing the risk for rupture.

After aneurysmal occlusion via clipping or coiling, hyperdynamic therapy (hemodilution-induced hypertension using vasoconstricting agents, such as phenylephrine or dopamine, and hypervolemia) may be started to increase the mean arterial pressure and cerebral perfusion. Volume expansion is achieved with crystalloid or colloid solutions.

Patients with SAH may receive the calcium channel blocker nimodipine to treat cerebral vasospasms and minimize cerebral damage. It may be given either before or after aneurysm clipping or coiling. Nimodipine restricts the influx of calcium ions into cells by reducing the number of open calcium channels. Although nimodipine is a calcium channel blocker, we do not know its exact mechanism of action in reducing vasospasm.

Drug Alert

Nimodipine

- Assess BP and apical pulses before administration.
- If pulse is ≤60 beats/min or SBP is <90 mm Hg, hold the medication and contact the provider.

Rehabilitation Care

After the stroke patient has stabilized for 12 to 24 hours, interprofessional care shifts from preserving life to lessening disability and reaching optimal function. Many of the interventions discussed in the acute phase are continued during this phase. The patient may be evaluated by a physiatrist (a physician who specializes in physical medicine and rehabilitation). Remember that some aspects of

rehabilitation begin in the acute care phase as soon as the patient is stable. Specific measures related to rehabilitation are discussed in the section on Ambulatory Care on pp. 1347–1349.

TABLE 57.9 Stroke (STK) Core Measure Set

Measure	Topic
STK-1	Venous thromboembolism (VTE) prophylaxis
STK-2	Discharged on antithrombotic therapy
STK-3	Anticoagulation therapy for atrial fibrillation/flutter
STK-4	Thrombolytic therapy
STK-5	Antithrombotic therapy by end of hospital day 2
STK-6	Discharged on statin medication
STK-8	Stroke education
STK-10	Assessed for rehabilitation

Source: The Joint Commission. Stroke core measures. Retrieved from *www.jointcommission.org/stroke*.

Core Measures for Stroke

The stroke (STK) core measures (Table 57.9) were developed in partnership with the American Stroke Association (ASA) for use by primary stroke centers. These measures are used by hospitals for accreditation and certification. The measures align with guidelines supported by the AHA Get With The Guidelines (GWTG) stroke patient management tool and the CDC's Paul Coverdell National Acute Stroke Registry (PCNASR).

Nursing Management: Stroke

Nursing Assessment

Subjective and objective data that you should obtain from a person who has had a stroke are detailed in Table 57.10. Primary assessment focuses on cardiac and respiratory status and neurologic assessment. If the patient is stable, the nursing history is obtained as follows: (1) description of the current illness with attention to initial symptoms, especially symptom onset and duration, nature (intermittent or continuous), and changes; (2) history of having had similar symptoms previously; (3) current medications; (4) history of risk factors and other illnesses, such as hypertension; and (5) family history of stroke, aneurysm, or cardiovascular diseases. Obtain this information through interviewing the patient and caregivers.

Secondary assessment includes a comprehensive neurologic examination. The primary assessment tool to evaluate and document neurologic status in acute stroke patients is the NIHSS, which measures stroke severity (Table 57.11).[21] The NIHSS is a predictor of both short- and long-term outcomes of stroke patients. It also serves as a data collection tool for planning patient care and exchanging information among HCPs. Other assessment data includes (1) LOC; (2) cognition; (3) motor abilities; (4) cranial nerve function; (5) sensation; (6) proprioception; (7) cerebellar function; and (8) deep tendon reflexes. Clear documentation of initial and ongoing neurologic examinations is essential to note changes in the patient's status.

TABLE 57.10 Nursing AssessmentStroke

Subjective Data
Important Health Information

Past health history: Hypertension, previous stroke, TIA, aneurysm, cardiac disease (including recent MI, dysrhythmias, heart failure, valvular heart disease, infective endocarditis. Hyperlipidemia, polycythemia, blood clotting disorders,

diabetes, gout

Family history: Neurologic disorders, aneurysms, stroke, TIA, diabetes, hypertension, coronary artery disease

Medications: Oral contraceptives; use of and adherence with antihypertensive and anticoagulant therapy; illicit substance use

Functional Health Patterns

Health perception–health management: Alcohol use, smoking, drug use

Nutritional-metabolic: Anorexia, nausea, vomiting. Dysphagia, altered sense of taste and smell

Elimination: Change in bowel and bladder patterns

Activity-exercise: Loss of movement and sensation. Syncope, weakness on one side, generalized weakness, easy fatigability

Cognitive-perceptual: Numbness, tingling of one side of the body, loss of memory. Change in speech, language, problem-solving ability. Pain, headache (possibly sudden and severe) (hemorrhage). Visual changes. Denial of illness

Objective Data

General

Emotional lability, lethargy, apathy or combativeness, fever

Respiratory

Loss of cough reflex, labored or irregular respirations, tachypnea, wheezes (aspiration), airway occlusion (tongue), apnea, coughing when eating or delayed coughing

Cardiovascular

Hypertension, tachycardia, carotid bruit

Gastrointestinal

Loss of gag reflex, bowel incontinence, decreased or absent bowel sounds, constipation

Urinary

Frequency, urgency, incontinence

Neurologic

Contralateral motor and sensory deficits, including weakness, paresis, paralysis, anesthesia. Unequal pupils, hand grasps. Akinesia, aphasia (expressive, receptive, global), dysarthria (slurred speech), agnosia, apraxia, visual deficits, perceptual or spatial problems, altered level of consciousness (drowsiness to deep coma) and Babinski's sign, ↓ followed by ↑ deep tendon reflexes, flaccidity followed by spasticity, amnesia, ataxia, personality change, nuchal rigidity, seizures

Possible Diagnostic Findings

Positive CT, CTA, MRI, MRA, or other neuroimaging scans showing size, location, and type of lesion. Positive Doppler ultrasonography and angiography showing stenosis

Nursing Diagnoses

Nursing diagnoses for the person with a stroke may include:

- Decreased intracranial adaptive capacity
- Impaired communication
- Difficulty coping
- Risk for aspiration
- Impaired physical mobility
- Risk for injury

TABLE 57.11 National Institutes of Health Stroke Scale (NIHSS)

Description

The NIH Stroke Scale (NIHSS) is a 15-item neurologic examination used to evaluate the effect of an acute stroke. Total scores on the NIHSS range from 0 to 42, with higher values reflecting more severity.

Procedure for Use

A trained observer rates the patient's ability to answer questions and perform activities. Ratings for each item are scored, and there is an allowance for untestable (UN) items. If an item is left untested, a detailed explanation must be clearly written on the form. Training can be completed free at *www.nihstrokescale.org*.

Item	Scale Definition
Level of consciousness	0 = Alert 1 = Not alert, but arousable by minor stimulation 2 = Not alert, requires repeated stimulation to get attention 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, areflexic
Level of consciousness questions	0 = Answers both questions correctly 1 = Answers 1 question correctly 2 = Answers neither question correctly
Level of consciousness commands	0 = Performs both tasks correctly 1 = Performs 1 task correctly 2 = Performs neither task correctly
Best gaze	0 = Normal 1 = Partial gaze palsy 2 = Forced deviation, or total gaze paresis
Visual	0 = No visual loss 1 = Partial hemianopsia 2 = Complete hemianopsia 3 = Bilateral hemianopsia or blind
Facial palsy	0 = Normal symmetric movement 1 = Minor paralysis 2 = Partial paralysis 3 = Complete paralysis of 1 or both sides
Motor and drift (for each extremity)	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity, limb falls 4 = No movement UN = Amputation
Limb ataxia	0 = Absent 1 = Present in 1 limb 2 = Present in 2 limbs
Sensory	0 = Normal 1 = Mild to moderate sensory loss 2 = Severe to total sensory loss
Best language	0 = No aphasia, normal 1 = Mild to moderate aphasia 2 = Severe aphasia 3 = Mute, no usable speech or auditory comprehension
Dysarthria	0 = Normal 1 = Mild to moderate 2 = Severe UN = Intubated or other physical barrier
Extinction or inattention	0 = No abnormality 1 = Inattention or extinction to bilateral stimulation 2 = Does not recognize own hand
Distal motor function	0 = Normal (no flexion after 5 sec) 1 = At least some extension but not fully extended 2 = No voluntary extension after 5 sec

Source: National Institutes of Health: NIH stroke scale. Retrieved from *www.stroke.nih.gov/resources/scale.htm*.

Additional information on nursing diagnoses and interventions are presented in eNursing Care Plan 57.1 (available on the website for this chapter).

Planning

Establish the goals of nursing care together with the patient, caregiver, and family. Typical goals are that the patient will (1) maintain a stable or improved level of consciousness, (2) attain maximum physical functioning, (3) attain maximum self-care abilities and skills, (4) maintain stable body functions (e.g., bladder control), (5) maximize communication abilities, (6) maintain adequate nutrition, (7) avoid complications of stroke, and (8) maintain effective personal and family coping.

Nursing Implementation

Health Promotion

You have a key role in promoting a healthy lifestyle. Teaching should focus on stroke prevention, especially for persons with known risk factors. Most strokes are caused by modifiable risk factors. Nursing measures to reduce risk factors for stroke are similar to those for coronary artery disease (see Chapter 33) and were discussed earlier in this chapter on p. 1338.

Uncontrolled or undiagnosed hypertension is the primary cause of stroke. Therefore you need to be involved in BP screening and ensuring that patients adhere to using their antihypertensive drugs and home BP monitoring. If a person has diabetes, it is important that it is well controlled. If a person has atrial fibrillation, an anticoagulant (see p. 1338) or aspirin may reduce the risk for stroke. Because smoking is a major risk factor for stroke, you need to be actively involved in helping patients to stop smoking (see Chapter 10,).

Another important aspect of health promotion is teaching patients and families about early symptoms associated with stroke or TIA. Table 57.1 presents information on when to seek health care for these symptoms.

Acute Care

Respiratory System

During the acute phase after a stroke, management of the respiratory system is a nursing priority. Stroke patients are vulnerable to respiratory problems. Advancing age and immobility increase the risk for atelectasis and pneumonia.

Nursing interventions to support adequate respiratory function are tailored to meet the patient's specific needs (Table 57.12). Some stroke patients, especially those with brainstem or hemorrhagic stroke, may need endotracheal intubation and mechanical ventilation. An oropharyngeal airway in a comatose patient may prevent the tongue from falling back and obstructing the airway and provide access for suctioning. Alternatively, a nasopharyngeal airway may be used to provide airway protection and access. When an artificial airway is needed for a prolonged time, a tracheostomy may be done.

Nursing interventions include frequently assessing airway patency and function, providing oxygenation, suctioning, promoting patient mobility, positioning the patient to prevent aspiration, and encouraging deep breathing. In patients who are on mechanical ventilation, oral care at least every 2 hours reduces the occurrence of ventilator-assisted pneumonia.

Risk for aspiration pneumonia is high because of impaired consciousness or dysphagia. Dysphagia after stroke is common. Airway obstruction can occur because of problems with chewing and swallowing, food pocketing (food remaining in the buccal cavity of the mouth), and the tongue falling back. Enteral nutrition (EN) places the patient at risk for aspiration pneumonia. Screen all patients for their ability to swallow. Keep them NPO until dysphagia is ruled out.

Table 57.12 Nursing ManagementCaring for the Patient With an Acute Stroke

- Assess manifestations of stroke and determine when the they started.

- Screen patient for contraindications for tissue plasminogen activator (tPA) therapy.
- Infuse tPA for patients with ischemic stroke who meet the criteria for tPA administration.
- Assess respiratory status and start needed actions, such as O_2, oropharyngeal or nasopharyngeal airways, suctioning.
- Position patient to prevent aspiration and atelectasis.
- Assess neurologic status, including intracranial pressure (ICP), if needed.
- Monitor cardiovascular status, including hemodynamic monitoring, if needed.
- Calculate intake and output, noting imbalances.
- Regulate IV infusions and adjust fluid intake to patient needs.
- Assess patient's ability to swallow in conjunction with the speech therapist.
- Give scheduled anticoagulant and antiplatelet drugs.
- Implement measures to prevent VTE and skin breakdown.
- Delegate to UAP:
    - Obtain vital signs and report these to RN.
    - Measure and record urine output.
    - Help with proper positioning and turning patient at least every 2 hr.
    - Perform passive and active ROM exercises.

Patients who have an unclipped or uncoiled aneurysm may have rebleeding and further increased ICP with coughing or suctioning, so nursing management is aimed at reducing these interventions while maintaining a proper airway.

Neurologic System

Perform ongoing neurologic assessments, including the NIHSS, mental status, pupillary response, and extremity movement and strength. Closely monitor vital signs. A decreasing level of

consciousness may indicate increasing ICP. Monitor ICP and cerebral perfusion pressure if the patient is in a critical care environment. Record your nursing assessment promptly to communicate the patient's neurologic status to the stroke team.

Cardiovascular System

Nursing goals for the cardiovascular system are aimed at maintaining homeostasis. Many patients with stroke have decreased cardiac reserves from cardiac disease. Fluid retention, overhydration, dehydration, or BP changes may further compromise cardiac efficiency. Central venous pressure, pulmonary artery pressure, or hemodynamic monitoring may be used to monitor fluid balance and cardiac function in the critical care unit.

Nursing interventions include (1) monitoring vital signs frequently; (2) monitoring cardiac rhythms; (3) calculating intake and output, noting imbalances; (4) regulating IV infusions; (5) adjusting fluid intake to individual patient needs; (6) monitoring lung sounds for crackles and wheezes, indicating pulmonary congestion; and (7) monitoring heart sounds for murmurs. Bedside monitors or telemetry may record cardiac rhythms.

Hypertension sometimes occurs after a stroke as the body tries to increase CBF. It is important to monitor for orthostatic hypotension before ambulating the patient for the first time. Neurologic changes can occur with a sudden decrease in BP.

The patient is at risk for venous thromboembolism (VTE), especially in the weak or paralyzed lower extremity. VTE is related to immobility, loss of venous tone, and decreased muscle pumping activity in the leg. The most effective prevention is to keep the patient moving. Teach the patient active range-of-motion (ROM) exercises if the patient has voluntary movement in the affected extremity. For the patient with hemiplegia, perform passive ROM exercises several times a day. Other measures to prevent VTE include positioning to minimize the effects of dependent edema and using intermittent pneumatic compression devices. VTE prophylaxis may include low-molecular-weight heparin (e.g., enoxaparin [Lovenox]).[22] The nursing

assessment includes measuring the calf and thigh daily, observing for swelling of the lower extremities, noting unusual warmth of the leg, and asking the patient about pain in the calf.

Musculoskeletal System

The nursing goal for the musculoskeletal system is to maintain optimal function by preventing joint contractures and muscular atrophy. In the acute phase, ROM exercises and positioning are important nursing interventions. Passive ROM exercise is begun on the first day of hospitalization. Muscle atrophy from lack of innervation and activity can develop after stroke, so exercise is an important intervention for rehabilitation and recovery.

The paralyzed or weak side needs special attention when the patient is positioned. Position each joint higher than the joint proximal to it to prevent dependent edema. Specific deformities on the weak or paralyzed side that may be present in patients with stroke include internal rotation of the shoulder; flexion contractures of the hand, wrist, and elbow; external rotation of the hip; and plantar flexion of the foot. Subluxation of the shoulder on the affected side is common. Careful positioning and moving of the affected arm may prevent development of a painful shoulder condition. Immobilization of the affected upper extremity may precipitate a painful shoulder-hand syndrome.

Nursing interventions to optimize musculoskeletal function include (1) trochanter roll at the hip to prevent external rotation; (2) hand cones (not rolled washcloths) to prevent hand contractures; (3) arm supports with slings and lap boards to prevent shoulder displacement; (4) avoidance of pulling the patient by the arm to avoid shoulder displacement; (5) posterior leg splints, footboards, or high-top tennis shoes to prevent footdrop; and (6) hand splints to reduce spasticity.

Using a footboard for the patient with spasticity is controversial. Rather than preventing plantar flexion (footdrop), the sensory stimulation of a footboard against the bottom of the foot increases plantar flexion. Likewise, experts disagree on whether hand splints

decrease spasticity. The decision about using footboards or hand splints is made on an individual patient basis.

Integumentary System

The skin of the patient with stroke is susceptible to breakdown related to loss of sensation, decreased circulation, and immobility. Advanced age, poor nutrition, dehydration, edema, and incontinence compound the risk.

Measures to prevent skin breakdown includes (1) pressure relief by position changes, special mattresses, or wheelchair cushions; (2) good skin hygiene; (3) emollients applied to dry skin; and (4) early mobility. An example of a position change schedule is side-back-side, with a maximum duration of 2 hours for any position. Position the patient on the weak or paralyzed side for only 30 minutes. Controlling pressure is the main factor in both preventing and treating skin breakdown. Use pillows under lower extremities to reduce pressure on the heels. See more information on preventing pressure injuries in Chapter 11.

Gastrointestinal System

The most common bowel problem for the stroke patient is constipation. Fluid and fiber intake goals are determined with the stroke team based on the patient's nutritional and fluid status. Patients may be prophylactically placed on stool softeners and/or fiber (psyllium [Metamucil]). Laxatives, suppositories, or additional stool softeners may be ordered if the patient does not respond to increased fluid and fiber. Enemas are used only if suppositories and digital stimulation are ineffective because they cause vagal stimulation and increase ICP. Physical activity promotes bowel function. If a patient has liquid stools, check for stool impaction.

Bowel retraining may be needed and continued into the rehabilitation phase. A bowel management program consists of placing the patient on the bedpan or bedside commode or taking the patient to the bathroom at a regular time daily to reestablish bowel regularity. A good time for a bowel movement is 30 minutes after breakfast because eating stimulates the gastrocolic reflex and

peristalsis. The timing may have to be adjusted as individual bowel habits may vary.

Urinary System

In the acute stage of stroke, the primary urinary problem is poor bladder control, resulting in incontinence. Take steps to promote normal bladder function and avoid the use of indwelling catheters. If an indwelling catheter is used initially, remove it as soon as the patient is medically and neurologically stable. Long-term use of an indwelling catheter is associated with urinary tract infections and delayed bladder retraining.

Avoid bladder overdistention. An intermittent catheterization program may be used for patients with urinary retention to lower the incidence of urinary infections. An alternative to intermittent catheterizations for a male patient is an external catheter. External catheters do not address problems with urine retention.

Often the patient has functional incontinence, which is associated with communication, mobility, and dressing problems. A bladder retraining program consists of (1) adequate fluid intake, with most of it given between 7:00 AM and 7:00 PM; (2) scheduled toileting every 2 hours using bedpan, commode, or bathroom while encouraging the usual position for urinating (standing for men and sitting for women); (3) observing for signs of restlessness, which may indicate the need for urination; and (4) assessing for bladder distention by palpation. Encourage patients to wear pants without drawstrings, buttons, or zippers. These can be hard to manage if motor or sensory deficits exist.

Assessing postvoid residual volume is often done using bladder ultrasound. The ultrasound measures how much urine is in the bladder after voiding. If urine stays in the bladder, incomplete emptying is a problem and may cause urinary tract infections. A coordinated program by the entire nursing staff is needed to achieve urinary continence.

Nutrition

The patient's nutritional needs require quick assessment and treatment. The patient may initially receive IV infusions to maintain fluid and electrolyte balance and to give drugs. Patients with severe impairment may need EN or parenteral nutrition. Patients should have their nutritional needs addressed in the first 24 hours of admission to the hospital because nutrition is important for recovery and healing.[23]

Many patients have dysphagia after a stroke. Keep patients NPO until a speech therapist performs a swallowing evaluation. This should be done in the first 24 hours after the stroke.[23] You or another member of the interprofessional team may perform the screen if a speech therapist cannot perform the formal evaluation.

Safety Alert

Oral Feeding After Stroke

- Dysphagia is common after stroke.
- Keep the patient on NPO status until a speech therapist does a swallowing evaluation.

Before starting feeding, assess the gag reflex by gently stimulating the back of the throat with a tongue blade. If the gag reflex is present, the patient will gag spontaneously. If it is absent, defer the feeding and begin exercises to stimulate swallowing. The speech therapist or occupational therapist is usually responsible for designing this program. However, you may be involved in helping to develop the program in some clinical settings.

To assess swallowing ability, elevate the head of the bed to an upright position (unless contraindicated). Give the patient a small amount of crushed ice or ice water to swallow. If the gag reflex is present and the patient can swallow safely, you may proceed with feeding.

The speech therapist may recommend various dietary items. Foods should be easy to swallow and provide enough texture, temperature (warm or cold), and flavor to stimulate a swallow reflex. Crushed ice can be used as a stimulant. Pureed foods are not usually the best choice because they are often bland or too smooth. Thin liquids are often hard to swallow and may promote coughing. We can thicken thin liquids with a commercially available thickening agent (e.g., Thick-It). Avoid milk products because they tend to increase the viscosity of mucus and increase salivation.

Mouth care before feeding helps stimulate sensory awareness and salivation and can help swallowing. Keep the patient in the high-Fowler's position, preferably in a chair, for the feeding and 30 minutes afterward. While feeding, keep the head flexed forward. Place food in the unaffected side of the mouth. Teach the patient to swallow and then swallow again. Follow feedings with good oral hygiene because food may collect in the affected side of the mouth.

During the acute and rehabilitation phase of the stroke, a dietitian can help determine the appropriate daily caloric intake based on the patient's size, weight, and activity level. If the patient is unable to take in an adequate oral diet and dysphagia persists, a percutaneous endoscopic gastrostomy (PEG) tube may be used for nutritional support. EN is described in Chapter 39.

The inability to feed one's self can be frustrating and may result in malnutrition and dehydration. Interventions to promote self-feeding include using the unaffected upper extremity to eat; employing assistive devices, such as rocker knives, plate guards, and nonslip pads for dishes (Fig. 57.8); and removing unnecessary items from the tray or table, which can reduce spills. Provide a calm environment (e.g., turn off the television) to decrease sensory overload and distraction. The effectiveness of the dietary program is evaluated in terms of maintenance of weight, adequate hydration, and patient satisfaction. Introduce these interventions in the acute care setting so that maximum rehabilitation can occur once the patient is discharged.

Communication

During the acute stage of stroke, your role in meeting the patient's psychologic needs is primarily supportive. Speech, comprehension, and language deficits are the most difficult problems for the patient and caregiver. Assess the patient for both the ability to speak and the ability to understand. The patient's response to simple questions can guide you in structuring explanations and instructions. If the patient cannot understand words, use gestures to support verbal cues. Collaborate with the speech therapist to assess and formulate a plan of care to enhance communication.

Nursing interventions that support communication include (1) communicating often and meaningfully; (2) allowing time for the patient to comprehend and answer; (3) using simple, short sentences; (4) using visual cues; (5) structuring conversation so that it permits simple answers by the patient; and (6) praising the patient honestly for improvements with speech.

FIG. 57.8 Assistive devices for eating. **A,** The rounded plate helps keep food on the plate. Special grips and weighted handles are helpful for some persons. The cup shape allows drinking without having to tilt the head. **B,** Knives with rounded blades are rocked back and forth to cut food. The person does not need a fork in one hand and a knife in the other. **C,** Plate guards help keep food on the plate. **D,** Cup with special handles promotes independence.
Products *A, B,* and *C* courtesy of Performance Health, Warrenville, IL. *D,* Courtesy of Granny Jo Products, Lakeland, FL.

An alert patient is usually anxious because of lack of understanding about what has happened and because of problems with communication or the inability to communicate. Verbal stimuli can easily overwhelm the patient with aphasia. Give the patient extra time

to understand and respond to communication. Guidelines for communicating with a patient who has aphasia are outlined in Table 57.13. A picture board may be helpful for communicating with the stroke patient. The speech therapist often does further evaluation and treatment of language and communication deficits once the patient has stabilized. It is important to teach the caregiver and family these communication strategies.

Sensory-Perceptual Problems

Patients who had a stroke often have perceptual deficits. Patients with a stroke on the right side of the brain usually have difficulty judging position, distance, and rate of movement. These patients are often impulsive and impatient and tend to deny problems related to strokes. They may fail to correlate spatial-perceptual problems with the inability to perform activities, such as guiding a wheelchair through the doorway. They best understand directions given verbally. Break down the task into simple steps for ease of understanding. The patient with a right-brain stroke and left hemiplegia is at higher risk for injury because of mobility problems. Environmental control (e.g., removing clutter, using good lighting) aids in concentration and safer mobility. Provide nonslip socks at all times. One-sided neglect is common for people with right-brain stroke. You may need to help or remind the patient to dress the weak or paralyzed side or shave the forgotten side of the face.

Patients with a left-brain stroke (right hemiplegia) often are slower in organizing and performing tasks. They tend to have impaired spatial discrimination. These patients usually admit to deficits and have a fearful, anxious response to a stroke. Their behaviors are slow and cautious. Nonverbal cues and instructions are helpful for patients who had a left-brain stroke.

Homonymous hemianopsia (blindness in the same half of each visual field) is common after a stroke. Persistent disregard of objects in part of the visual field should alert you to this possibility. At first, help the patient to compensate by arranging the environment within the patient's perceptual field, such as arranging the food tray so that all

foods are on the right side or the left side to accommodate for field of vision (Fig. 57.9). Later, the patient learns to compensate for the visual defect by consciously attending to or by scanning the neglected side. Weak or paralyzed extremities are carefully checked for adequacy of dressing, hygiene, and trauma.

Table 57.13 Communicating With a Patient With Aphasia

The following are guidelines for communicating with a patient with aphasia:

1. Decrease environmental stimuli that may be distracting and disrupting to communication efforts.
2. Treat the patient as an adult.
3. Speak with normal volume and tone.
4. Present a single thought or idea at a time.
5. Keep questions simple or ask questions that can be answered with "yes" or "no."
6. Let the person speak. Do not interrupt. Allow time for the person to complete thoughts.
7. Make use of gestures as an alternative form of communication. Encourage this by saying, "Show me . . . ." or "Point to what you want."
8. Do not pretend to understand the person if you do not. Calmly say you do not understand. Encourage the use of nonverbal communication or ask the person to write out what they want.
9. Give the patient time to process information and generate a response before repeating a question or statement.
10. Allow body contact (e.g., clasp of a hand, touching) as much as possible. Realize that touching may be the only way the patient can express feelings.
11. Organize the patient's day by preparing and following a schedule (the more familiar the routine, the easier it will be).
12. Do not push communication if the person is tired or upset.

Aphasia worsens with fatigue and anxiety.

13. Teach communication techniques to caregiver and family members.

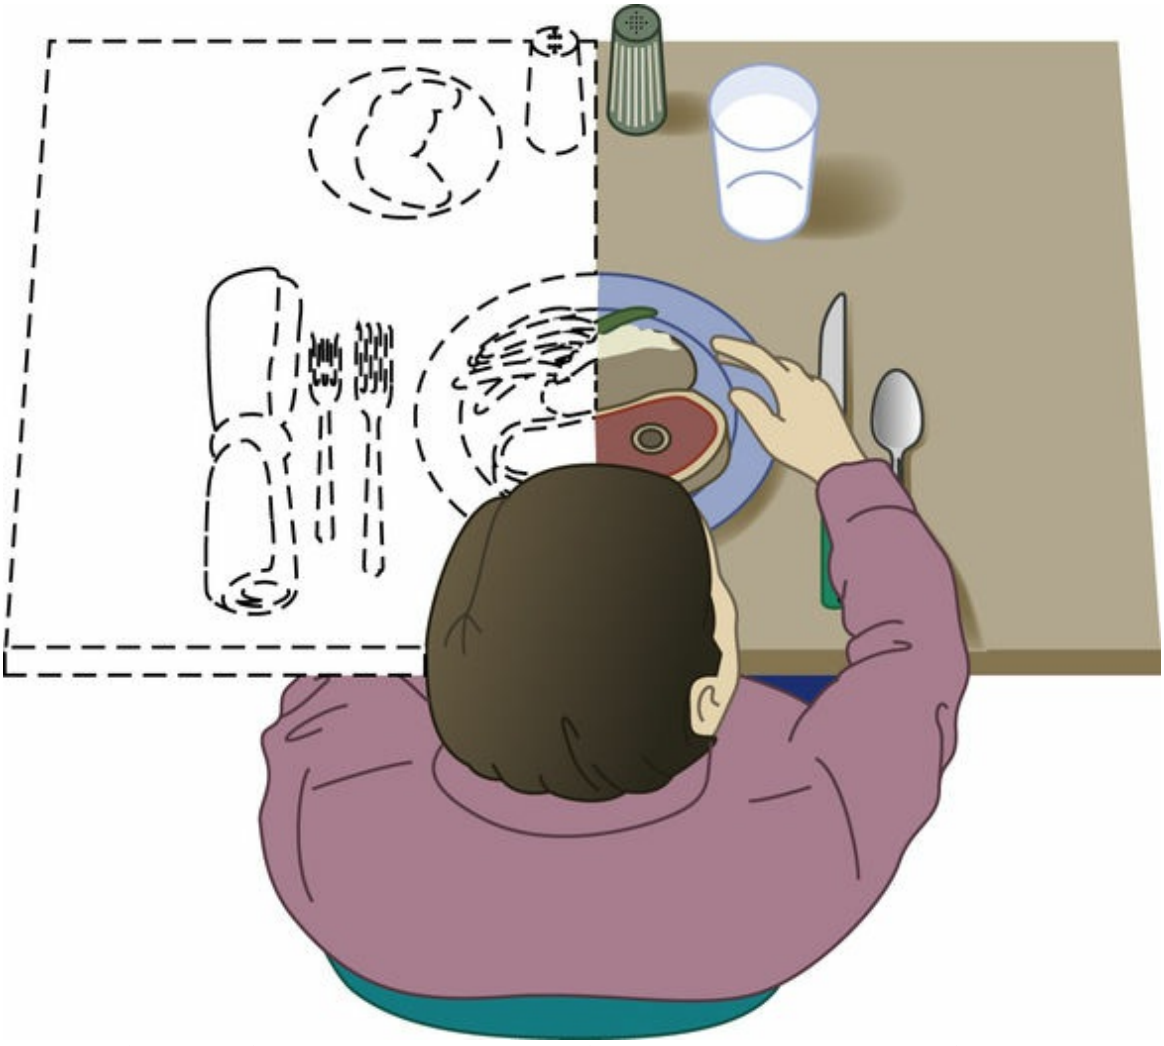

FIG. 57.9 Spatial and perceptual deficits in stroke. Perception of a patient with homonymous hemianopsia shows that food on the left side is not seen and thus is ignored.
Modified from Hoeman SP: *Rehabilitation nursing,* ed 2, St Louis, 1995, Mosby.

In the clinical situation, it is often hard to distinguish between a visual field cut and a neglect syndrome. Both problems may occur with strokes affecting either the right or the left side of the brain. A person may be unfortunate enough to have both homonymous

hemianopsia and a neglect syndrome, which increases the inattention to the weak or paralyzed side. A neglect syndrome results in decreased safety awareness and places the patient at high risk for injury. Immediately after the stroke, anticipate safety hazards and provide protection from injury. Safety measures include closely observing the patient, elevating side rails, lowering the height of the bed, and using video monitors. Avoid using restraints and soft vests because this may agitate the patient.

Other visual problems may include *diplopia* (double vision), loss of the corneal reflex, and *ptosis* (drooping eyelid), especially if the stroke is in the vertebrobasilar distribution. Diplopia is often treated with an eye patch. If the corneal reflex is absent, the patient is at risk for corneal abrasion and should be observed closely and protected against eye injuries. Prevent corneal abrasions with artificial tears or gel to keep the eyes moist and an eye shield (especially at night). We usually do not treat ptosis unless it inhibits vision.

Coping

A stroke is usually a sudden, extremely stressful event for the patient, caregiver, family, and significant others. Stroke is often a family disease, affecting the family emotionally, socially, and financially and changing roles and responsibilities within the family. The stroke patient and family may perceive the stroke as a threat to life and their accustomed lifestyle. Reactions to this threat vary considerably but may involve fear, apprehension, denial of the severity of stroke, depression, anger, and sorrow. During the acute phase of caring for the stroke patient and caregiver, nursing interventions designed to promote coping involve providing information and emotional support.

Explanations to the patient about what has happened and diagnostic and therapeutic procedures should be clear and understandable. Reinforce as needed. Decision making and upholding the patient's wishes during this challenging time are of upmost importance. Advance directives should be honored. Update the family daily and hold family meetings about feeding tube placement or

tracheostomy.

Give the caregiver and family a careful, detailed explanation of what has happened to the patient. However, if the family is extremely anxious and upset during the acute phase, explanations may have to be repeated later. Because family members usually have not had time to prepare for the illness, they may need help in arranging care for family members or pets and for transportation and finances. A social services referral is often helpful.

It is challenging to keep the patient with aphasia adequately informed. Use demeanor and touch to convey support. When communicating with a patient who has a communication deficit, speak in a normal volume and tone, keep questions simple, and present one thought or idea at a time. To decrease frustration, always let the patient speak without interruption and make use of gestures. Use writing and communication boards.

Ambulatory Care

Care Transitions

The patient is usually discharged from the acute care setting to home, an intermediate- or long-term care facility, or a rehabilitation facility. Ideally, discharge planning with the patient and caregiver starts early in the hospitalization and promotes a smooth transition between care settings. The stroke team provides guidance for the appropriate care needed after discharge. Factors that are considered include the patient's medical needs and independence in performing ADLs, caregiver's capacity to provide care, and community setting.[24] If the patient needs a short- or long-term health care facility, the team can make appropriate referrals that allow time to select and arrange for care.

If the patient is returning home, the team can make referrals for needed equipment and services in preparation for discharge. You can prepare the patient and caregiver for discharge through teaching and evaluating the transition plan for any barriers. Follow-up care is carefully planned to allow continuing nursing care; physical,

occupational, and speech therapy; and medical care. Identify community resources to provide recreational activities, group support, spiritual assistance, respite care, adult day care, and home assistance based on the patient's needs.

Rehabilitation

Rehabilitation is the process of maximizing the patient's capabilities and resources to promote optimal functioning related to physical, mental, and social well-being. The goals of rehabilitation are to prevent deformity and maintain and improve function. Ongoing rehabilitation is essential to maximize the patient's abilities. Most patients recover in the first 6 months after a stroke, with maximum benefit 1 year after a stroke.[1]

Rehabilitation requires a team approach so that the patient and caregiver can benefit from the combined, expert care of an interprofessional team. The team must communicate and coordinate care to achieve the patient's goals. As a nurse, you can facilitate this process and are often the key to successful rehabilitation efforts. The rehabilitation team is composed of many members. These include nurses, physicians, psychiatrist, physical therapist, occupational therapist, speech therapist, registered dietitian, respiratory therapist, vocational therapist, recreational therapist, social worker, psychologist, pharmacist, and chaplain.

Physical therapy focuses on mobility, progressive ambulation, transfer techniques, and equipment needed for mobility. Occupational therapy emphasizes retraining for skills of daily living, including eating, dressing, hygiene, and cooking. Occupational therapists are skilled in cognitive and perceptual evaluation and training. Speech therapy focuses on speech, communication, cognition, and eating abilities.

Informatics in Practice

Video Games for Stroke Recovery

- Patients dealing with the effects of a stroke often find it hard to perform activities of daily living.
- Playing active video games, such as Nintendo Wii or Xbox Kinect, brings some fun into stroke recovery and may get patients to spend more time in therapy.
- Gaming helps patients regain lost strength, improve motor skills, and improve problem solving and short- and long-term memory.
- Patients can play with their families, including children, making gaming a way to involve others in rehabilitation.

The rehabilitation nurse assesses the patient, caregiver, and family with attention to the (1) patient's rehabilitation potential, (2) physical status of all body systems, (3) complications caused by the stroke or other chronic conditions, (4) patient's cognitive status, (5) family resources and support, and (6) expectations of the patient and caregiver related to the rehabilitation program. Many interventions started in the acute phase of care continue throughout rehabilitation.

Musculoskeletal Function

The initial assessment consists of determining the stage of recovery of muscle function. If the muscles are still flaccid several weeks after the stroke, the prognosis for regaining function is poor, and care focuses on preventing further loss.

Most patients begin to show signs of spasticity with exaggerated reflexes within 48 hours after the stroke. Spasticity at this phase denotes progress toward recovery. As improvement continues, small voluntary movements of the hip or shoulder may be accompanied by involuntary movements in the rest of the extremity *(synergy).* The last stage of recovery occurs when the patient has voluntary control of isolated muscle groups.

FIG. 57.10 A patient who had a stroke works with a physical therapist to improve arm strength.
© Thinkstock 78783452.

Interventions for the musculoskeletal system advance in a manner of progressive activity. Balance training is the first step. It begins with the patient sitting up in bed or dangling the legs over the edge of the bed. Assess tolerance by noting dizziness or syncope caused by vasomotor instability. Loss of postural stability is common after stroke. When the nondominant hemisphere is involved, walking apraxia and loss of postural control are usually apparent. The patient may be unable to sit upright and tends to fall sideways. Provide proper support with pillows or cushions.

Assess whether patients autocorrect their posture when sitting on the edge of the bed. If the patient can straighten their posture instead of leaning to the weaker side, the patient may be ready for the next step of transferring from bed to chair. Place the chair beside the bed so that the patient can lead with the stronger arm and leg. The patient sits on the side of the bed, stands, places the strong hand on the far wheelchair arm, and sits down. You may either supervise the transfer

or provide minimal aid by guiding the patient's strong hand to the wheelchair arm, standing in front of the patient while blocking the patient's knees with your knees to prevent knee buckling, and guiding the patient into a sitting position.

In some rehabilitation units, the Bobath method is used as an approach to mobility. The goal of this method is to help the patient gain control over patterns of spasticity by inhibiting abnormal reflex patterns. Therapists and nurses use the Bobath approach to encourage normal muscle tone, normal movement, and bilateral function of the body. An example is to have the patient transfer into the wheelchair using the weak or paralyzed side and the stronger side to facilitate more bilateral functioning.

Another approach to stroke rehabilitation is *constraint-induced movement therapy* (CIMT). CIMT encourages the patient to use the weakened extremity by restricting movement of the normal extremity. This approach can be challenging for patients. It is used only under the supervision of physical or occupational therapy. Movement training, skill acquisition, stretching, and exercise are other therapies offered for rehabilitation of the stroke patient.[25]

Supportive or assistive equipment, such as canes, walkers, and leg braces, may be needed on a short- or long-term basis for mobility. The physical therapist usually selects the proper supportive device(s) to meet individual needs and instructs the patient about use. Incorporate physical therapy activities into the patient's daily routine for added practice and repetition of rehabilitation efforts (Fig. 57.10).

Evidence-Based Practice

Virtual Reality Training and Stroke

You are a nurse working in an outpatient rehabilitation setting with C.W., a 62-yr-old woman who had a stroke 2 months ago. She has left-sided weakness especially in her lower extremity that affects her balance and mobility. She tells you she misses not being able to fully

engage with friends with whom she regularly walked with each morning until her stroke.

Making Clinical Decisions

Best Available Evidence. Impaired gait is highly linked with balance disorders in patients with stroke. Reduced balance is a major obstacle to achieving independence in activities of daily living after stroke. A loss of balance often results in falls and even serious injuries. Virtual reality (VR) training on gait and balance ability showed significant benefits on gait speed, Berg Balance Scale scores, and Timed "Up & Go" scores when compared to traditional physical therapy. VR training can improve mobility and daily functioning in patients undergoing rehabilitation for stroke.

Clinician Expertise. You know that a walking program can be an important part of stroke rehabilitation. Improvements in mobility reach their maximum potential in the first year after a stroke. You note the benefit of VR training for practicing daily activities that may currently be unsafe, such as walking, showering, and dressing.

Patient Preferences and Values. C.W. states that she is willing to "try something new" as part of her treatment.

Implications for Nursing Practice

1. What parameters will you use to assess C.W.'s progress with the VR training?
2. Why is it important for you to determine with C.W. if VR training translates into the actual performance of her previous activities?
3. As you coordinate her rehabilitation care, how will you promote communication among interprofessional team members?

Stroke Survivorship and Coping

Patients who had a stroke often have emotional responses that are not appropriate or typical for the situation. They may appear apathetic, depressed, fearful, anxious, weepy, frustrated, and angry. Some patients, especially those with a stroke on the left side of the brain (right hemiplegia), have exaggerated mood swings. The patient may be unable to control emotions and may suddenly burst into tears or laughter. This behavior is out of context and often is unrelated to the patient's underlying emotional state. Nursing interventions for atypical emotional response are to (1) distract the patient who suddenly becomes emotional, (2) explain to the patient and family that emotional outbursts may occur after a stroke, (3) maintain a calm environment, and (4) avoid shaming or scolding the patient during emotional outbursts.

The patient with a stroke may have many losses, including sensory, intellectual, communicative, functional, role behavior, emotional, social, and vocational losses. The patient, caregiver, and family often go through the process of grief and mourning associated with the losses. Some patients develop long-term depression with symptoms, including anxiety, weight loss, fatigue, poor appetite, and sleep problems. The time and energy needed to perform previously simple tasks can result in anger and frustration.

The patient, caregiver, and family need help coping with the losses associated with stroke. Provide assistance by (1) supporting communication between the patient and family; (2) discussing lifestyle changes resulting from stroke deficits; (3) discussing

changing roles and responsibilities within the family; (4) being an active listener to allow the expression of fear, frustration, and anxiety; (5) including the family and patient in short- and long-term goal planning and patient care; (6) supporting family conferences, and (7) identifying support groups and referrals as needed.

Maladjusted dependence with inadequate coping occurs when the patient does not maintain optimal functioning for self-care, family responsibilities, decision making, or socialization. This situation can cause resentment from both the patient and family with a negative cycle of interpersonal dependency and control. Caregivers and family members must cope with 3 aspects of the patient's behavior: (1) recognition of behavioral changes resulting from neurologic deficits that are not changeable, (2) responses to multiple losses by both the patient and family, and (3) behaviors that may have been reinforced during the early stages of stroke as continued dependency.

The patient, caregiver, and family may express guilt over not living healthy lifestyles or not seeking professional help sooner. Family therapy is a helpful adjunct to rehabilitation. Open communication, information about the total effects of stroke, teaching about stroke treatment, and therapy are helpful. Stroke support groups in rehabilitation facilities and the community are helpful in terms of mutual sharing, education, coping skills, and understanding.

Sexual Function

A patient who had a stroke may be concerned about the loss of sexual function. Many patients are comfortable talking about their anxieties and fears about sexual function if you are comfortable and open to the topic. You can start a discussion about the topic with the patient and spouse or significant other. Common concerns include impotence and the chance of another stroke occurring during sex. Nursing interventions include teaching about (1) optional positioning of partners, (2) timing for peak energy periods, and (3) patient and partner counseling.

Community Integration

Traditionally, successful community integration after stroke is hard for the patient because of persistent problems with cognition, coping, physical deficits, and emotional changes that interfere with functioning. Older adults who had a stroke often have more severe deficits and multiple health problems. Failure to continue the rehabilitation regimen at home may result in deterioration and further complications.

Community resources can be an asset to patients and their families. The National Stroke Association provides information, resources, referral services, and quarterly newsletters on stroke. The American Stroke Association, a division of the AHA, has information about stroke, hypertension, diet, exercise, and assistive devices. This association sponsors self-help groups in many areas. Easter Seals supplies wheelchairs and other assistive devices for stroke patients. Local groups can offer more daily help with meals and transportation.

Gerontologic Considerations: Stroke

Stroke is a significant cause of death and disability. The majority (66%) of strokes that require hospitalization occur in adults over age 65.[4] Stroke can result in a profound disruption in the life of an older adult. The magnitude of disability and changes in total function can leave patients wondering if they can ever return to their "old self." Loss of independence may be a major concern. The ability to perform ADLs may require many adaptive changes because of physical, emotional, perceptual, and cognitive deficits. Home management may be challenging if the patient's caregiver is also older or has health problems. There may be limited family members, including adult children, living nearby to provide help.

The rehabilitative phase and helping the older patient deal with the residual deficits of stroke, as well as aging, can be a challenging nursing experience. Patients may become fearful and depressed because they think they may have another stroke or die. The fear can become immobilizing and interfere with effective rehabilitation.

Changes may occur in the patient-spouse relationship. The

dependency resulting from a stroke may threaten the relationship. The spouse may have chronic medical problems that can affect their ability to care for the stroke survivor. The patient may not want anyone other than the spouse to provide care, thus putting a significant burden on the spouse.

You can help the patient and caregiver in the transition through acute hospitalization, rehabilitation, long-term care, and home care. The needs of the patient, caregiver, and family require ongoing nursing assessment and adaptation of interventions in response to changing needs to optimize quality of life for them all.

Case Study

Stroke

© iStockphoto/Thinkstock.

Patient Profile

J.K. is a 57-yr-old white woman who was referred to the neurosurgery service for management of a temporal-parietal glioblastoma (see the Case Study in Chapter 55 on p. 1298). She was diagnosed after presenting with persistent headaches, a seizure in her HCP's office, and left-side upper visual field loss and neglect. Her MRI/MRA showed a temporal-parietal glioblastoma that extends into the occipital lobes. She was scheduled for surgery to debulk the tumor. J.K. lives alone and holds a management position. She was concerned about her ability to return to work after her surgery.

J.K. returned from surgery to the neurosurgery unit drowsy but following commands. Her pupils were equal and responded to light. During the night J.K. developed left-sided weakness of both arm and

leg. She is now having difficulty with answering questions.

Subjective Data

- Left arm and leg are weak and feel numb
- She is trying to answer questions but looks confused and cannot follow commands

Objective Data

- BP 150/90 mm Hg
- Right gaze preference
- Left homonymous hemianopsia
- Left arm weakness (3/5) greater than leg weakness (4/5)
- Decreased sensation on both left arm and leg
- Has speech but not clear. Difficulty with word finding and following commands
- CT scan shows a hemorrhagic stroke into the site of the tumor bed, and temporal-parietal and anterior occipital areas extending into the thalamus

Discussion Questions

1. How did J.K.'s diagnosis (glioblastoma) put her at risk for a stroke?
2. ***Priority Decision:*** What potential complications is J.K. at highest risk for developing?
3. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
4. ***Priority Decision:*** What are the priority nursing interventions for J.K.?
5. **Collaboration:** What nursing interventions for J.K. can the RN

delegate to UAP?

6. What strategies can you implement to improve communication for J.K.?
7. ***Collaboration:*** How would you involve other interprofessional team members in J.K.'s care?
8. ***Safety:*** How can you ensure safety for J.K. in light of her homonymous hemianopsia and left-sided neglect?
9. ***Patient-Centered Care:*** How can you address J.K.'s concerns about her finances and self-care?
10. Develop a conceptual care map for J. K.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which patient has the highest risk for a having a stroke?
   a. An obese 45-yr-old Native American.
   b. A 65-yr-old black man with hypertension
   c. A 35-yr-old Asian American woman who smokes.
   d. A 32-yr-old white woman taking oral contraceptives.
2. The factor related to cerebral blood flow that *most* often determines the extent of cerebral damage from a stroke is the
   a. O_2 content of the blood.
   b. amount of cardiac output.
   c. level of CO_2 in the blood.
   d. degree of collateral circulation.

3. Information provided by the patient that would help distinguish a hemorrhagic stroke from a thrombotic stroke includes
   a. sensory changes.
   b. a history of hypertension.
   c. presence of motor weakness.
   d. sudden onset of severe headache.
4. A patient is having word finding difficulty and weakness in his right arm. What area of the brain is *most* likely involved?
   a. brainstem.
   b. vertebral artery.
   c. left middle cerebral artery.
   d. right middle cerebral artery.
5. The nurse explains to the patient with a stroke who is scheduled for angiography that this test is used to determine the
   a. presence of increased ICP.
   b. site and size of the infarction.
   c. patency of the cerebral blood vessels.
   d. presence of blood in the cerebrospinal fluid.
6. A patient having TIAs is scheduled for a carotid endarterectomy. The nurse explains that this procedure is done to
   a. decrease cerebral edema.
   b. reduce the brain damage that occurs during a stroke in evolution.

c. prevent a stroke by removing atherosclerotic plaques blocking cerebral blood flow.

d. provide a circulatory bypass around thrombotic plaques obstructing cranial circulation.

7. For a patient who is suspected of having a stroke, the *most* important piece of information that the nurse can obtain is

a. time of the patient's last meal.

b. time at which stroke symptoms first appeared.

c. patient's hypertension history and management.

d. family history of stroke and other cardiovascular diseases.

8. Bladder training in a male patient who has urinary incontinence after a stroke includes

a. limiting fluid intake.

b. helping the patient to stand to void.

c. keeping a urinal in place at all times.

d. catheterizing the patient every 4 hours.

9. Common psychosocial problems a patient may have post stroke include *(select all that apply)*

a. depression.

b. disassociation.

c. sleep problems.

d. intellectualization

e. denial of severity of stroke.

1. b, 2. d, 3. d, 4. c, 5. c, 6. c, 7. b, 8. b, 9. a, c, e

Chronic Neurologic Problems

Madona D. Plueger, and Dottie Roberts

LEARNING OUTCOMES

1. Compare and contrast the etiology, clinical manifestations, and interprofessional and nursing management of tension-type, migraine, and cluster headaches.
2. Distinguish the etiology, clinical manifestations, diagnostic studies, and interprofessional and nursing management of seizure disorder, multiple sclerosis, Parkinson's disease, and myasthenia gravis.
3. Describe the clinical manifestations and nursing and interprofessional management of restless legs syndrome, amyotrophic lateral sclerosis, and Huntington's disease.
4. Explain the potential impact of chronic neurologic disease on physical and psychologic well-being.
5. Outline the major goals of treatment for the patient with a chronic, progressive neurologic disease.

Coping
Functional Ability
Inflammation

Intracranial Regulation
Mobility
Safety

This chapter discusses headaches, chronic neurologic disorders, and degenerative neurologic disorders. Chronic neurologic disorders include seizure disorder and restless legs syndrome (RLS). *Degenerative nerve diseases* lead to nerve damage that worsens as the diseases progress. Most of these neurologic problems have no cure. Treatment aims to reduce symptoms and help the patient maintain optimal function. Many have a genetic basis.

Degenerative nerve diseases include multiple sclerosis, Parkinson's disease, myasthenia gravis, amyotrophic lateral sclerosis, and Huntington's disease. They affect many activities, including balance, movement, speech, and respiratory and heart function. Patients with these diseases have similar concerns and problems. They must deal not only with their disease but also with the impact of the disease on their quality of life. Many patients have concerns about safety, mobility, self-care, and coping. Patients and their caregivers often need psychosocial support, especially as the disease progresses and disability gets worse.

Headaches

Headache is the most common type of pain that people have. Most people have functional headaches, such as migraine or tension-type headaches. Others have organic headaches caused by intracranial or extracranial disease. Headaches tend to occur more often in women than in men.

Pain-sensitive structures in the head include venous sinuses, dura, and cranial blood vessels. In addition, there are 3 divisions of the trigeminal nerve (cranial nerve [CN] V), facial nerve (CN VII), glossopharyngeal nerve (CN IX), vagus nerve (CN X), and the first 3 cervical nerves. Because these nerves have both motor and sensory functions, increased pain intensity and symptoms can occur when a

person moves.

Headaches are classified as primary or secondary headache. *Primary headache* includes tension-type, migraine, and cluster headaches. Primary headaches are not caused by a disease or another medical condition. The type of primary headache is determined using the International Headache Society (IHS) guidelines based on characteristics of the headache (Table 58.1).[1] *Secondary headaches* are caused by another condition or disorder, such as sinus infection, neck injury, and brain tumor.

A patient may have more than 1 type of headache. The history and neurologic examination are diagnostic keys to determine the type of headache. The examination of a person with a headache is often normal. Unexplained abnormal findings require further diagnostic studies to identify the underlying cause.

Tension-Type Headache

Tension-type headache (TTH), also called *stress headache,* is the most common type of headache. This type of headache is characterized by its bilateral location and pressing or tightening quality. TTH is usually of mild or moderate intensity. It can last from minutes to days. TTHs are divided by frequency into episodic or chronic.[1] Chronic TTH can become a serious problem that leads to decreased quality of life and severe disability.

Etiology and Pathophysiology

We do not know the cause TTH. It may have a neurobiologic basis similar to migraine headaches. For some, episodic headaches evolve into chronic headaches. Increased frequency, though, does not necessarily increase headache intensity. Headaches may occur intermittently for weeks, months, or even years.

Clinical Manifestations

Patients often have a bilateral frontal-occipital headache described as a constant, dull pressure or a bandlike headache associated with neck pain. There may be increased tone in the cervical and neck muscles. The headache may involve sensitivity to light *(photophobia)* or sound *(phonophobia)* but not nausea or vomiting. There are no *premonitory symptoms* (warning symptoms of impending headache). Physical activity does not worsen symptoms.

Many patients have a combination of migraine headache and TTH, with features of both occurring together. Patients with migraine headaches may have TTH between migraine attacks. Fig. 58.1 shows the location of pain for common headache syndromes.

Diagnostic Studies

Careful history taking may be the most useful tool for diagnosing TTH (Table 58.2). If TTH is present during physical examination, increased resistance to passive movement of the head and tenderness of the head and neck may be seen. Electromyography (EMG) may show sustained contraction of neck, scalp, or facial muscles. However, the patient may not have increased muscle tension with an EMG, even when it is done during a headache. Imaging is ordered when symptoms raise concern about a possible pathologic cause.

Migraine Headache

Migraine headache is a recurring headache characterized by unilateral throbbing pain. Migraines are most common between the ages of 25 and 55. 12% of the population has migraines.[2] Many people who have migraines have a family history of migraines. Other risk factors include age, female gender, obesity, low level of education, depression, and stressful life events. Overuse of medications for acute migraine or ineffective acute treatment can contribute to chronic migraine headache.[3]

The IHS subdivides migraines into categories. *Migraine without aura* (formerly called *common migraine*) is the most common type. *Migraine*

with aura (formerly called *classic migraine*) occurs in 25% to 30% of migraine headache episodes.[4]

Gender Differences

Headaches

Men

- Cluster headaches are 3 times more common than in women.
- Have more exercise-induced headaches than women.

Women

- Migraine headaches are 3 times more common than in men.
- Have more tension headaches than men.

Etiology and Pathophysiology

Although there are many theories about the cause of migraine headaches, we do not know the exact cause. Current theory suggests a complex series of neurovascular events starts the headache. People who have migraines have a state of neuron hyperexcitability in the cerebral cortex, especially in the occipital cortex. Genetics appear to play a role. Risk for migraine headache increases 50% to 75% if even 1 parent has a history of migraine.[5]

Migraine is associated with seizure disorder, ischemic stroke, asthma, depression, anxiety, myocardial infarction, Raynaud's syndrome, and irritable bowel syndrome. In many cases, migraine headaches have no known precipitating events. For some patients, specific factors may trigger a headache. *Triggers* for migraine headaches include bright lights, sound, hormone fluctuations, certain smells, poor sleep, or high stress.[6] Common food triggers include

chocolate, cheese, oranges, tomatoes, onions, monosodium glutamate, aspartame, and alcohol (especially red wine).

Clinical Manifestations

Premonitory symptoms and an aura may precede the headache phase by several hours or days. Premonitory symptoms occur before the onset of aura or headache. They may include sensory experiences (e.g., photophobia, phonophobia); mood, sleep, or cognitive changes (e.g., poor concentration, irritability, fatigue); and homeostatic changes (e.g., thirst and cravings, change in bowel habits).[7] An **aura** is a complex of neurologic symptoms that occur before a headache for some patients. Visual symptoms, such as bright lights, scotomas (patchy blindness), visual distortions, or zigzag lines, are the most common type of aura.[1] They occur in over 90% of patients in at least some attacks. Sensory (voices or sounds that do not exist, strange smells) and/or motor phenomena (e.g., weakness, paralysis, feeling that limbs are moving) may be part of an aura.

A migraine headache may last 4 to 72 hours. Patients often describe the headache as a steady, throbbing pain that is synchronous with the pulse. Although the headache is usually unilateral, it may switch to the opposite side in another episode. During the headache, patients may try to avoid noise, light, odors, people, and problems.

TABLE 58.1 Interprofessional CareHeadaches

Tension-Type Headaches	Migraine Headache	Cluster Headache
Location		
Bilateral, bandlike pressure at base of skull	Unilateral in 60%, may switch sides; often anterior location	Unilateral, radiating up or down from 1 eye
Quality		
Constant, squeezing tightness	Throbbing, synchronous with pulse	Severe, bone crushing
Frequency		
Cycles for many years	Periodic, cycles of several months and years	May have months or years between attacks Attacks occur in clusters over a period of 2–12 wk
Duration		
30 min–7 days	4–72 hr	5 min–3 hr
Time and Mode of Onset		
Not related to time	May be preceded by premonitory symptoms or aura Onset after awakening Improves with sleep	Nocturnal, often awakens person from sleep
Associated Symptoms		
Palpable neck and shoulder muscle tension **Stiff neck** **Tenderness**	Irritability, sweating Nausea, vomiting Photophobia Phonophobia Premonitory symptoms: sensory, motor, or psychic phenomena	Facial flushing or pallor Unilateral lacrimation, ptosis, rhinitis
Treatment: Abortive and Symptomatic Drugs		
Nonopioid analgesics: aspirin, acetaminophen, NSAIDS **Analgesic combinations** **• butalbital/acetaminophen/caffeine** **• butalbital/aspirin/caffeine (Fiorinal)** **• dichloralphenazone/acetaminophen/isometheptene** **Muscle relaxants**	Nonopioid analgesics: aspirin, NSAIDs Serotonin receptor agonists • almotriptan (Axert) • eletriptan (Relpax) • frovatriptan (Frova) • naratriptan (Amerge) • rizatriptan (Maxalt) • sumatriptan (Imitrex) • zolmitriptan (Zomig) Combination • sumatriptan/naproxen (Treximet) α-Adrenergic blockers • ergotamine tartrate (Ergomar) • dihydroergotamine nasal spray (Migranal) Analgesic combinations • acetaminophen/caffeine/aspirin Corticosteroids • dexamethasone	α-Adrenergic blockers • ergotamine tartrate Serotonin receptor agonists • almotriptan • eletriptan • frovatriptan • naratriptan • rizatriptan • sumatriptan • zolmitriptan O_2 100% inhalation via mask
Treatment: Preventive		
Tricyclic antidepressants **• amitriptyline** **• nortriptyline (Pamelor)** **• doxepin** **Selective serotonin reuptake inhibitors** **• fluoxetine (Prozac)** **• paroxetine (Paxil)** **β-Adrenergic blocker:** **• propranolol (Inderal)** **Antiseizure drugs** **• topiramate (Topamax)** **• divalproex (Depakote)** **Other drugs** **• mirtazapine (Remeron)** **Biofeedback** **Psychotherapy** **Muscle relaxation training**	β-Adrenergic blocker • propranolol (Inderal) Antidepressants • amitriptyline (Elavil) • imipramine (Tofranil) Antiseizure drugs • divalproex • gabapentin • topiramate • valproic acid (Depakene) Botulinum toxin A Calcium channel blocker • nifedipine (Procardia) • verapamil Biofeedback Relaxation therapy Cognitive-behavioral therapy	α-Adrenergic blockers • ergotamine tartrate Corticosteroid • prednisone Calcium channel blocker • verapamil Lithium Biofeedback

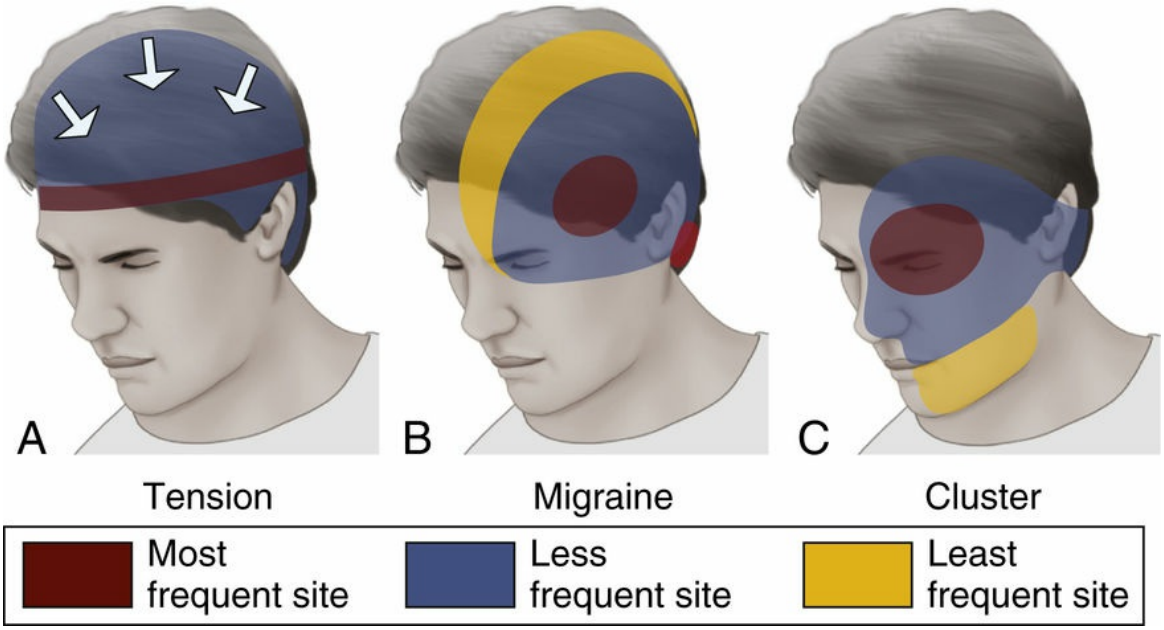

FIG. 58.1 Location of pain for common headache syndromes. **A,** Tension headache is often described as feeling of a weight in or on the head or a band squeezing the head. **B,** Migraine headache is usually unilateral, in the temple on 1 side of the head. The pain can be bilateral. **C,** Cluster headache pain is focused in and around 1 eye.

TABLE 58.2 Diagnostic StudiesHeadaches

History and Physical Examination

- Neurologic examination (often negative)
- Inspection for local infection
- Palpation of head for tenderness, bony swellings
- Auscultation for bruits over major arteries, especially neck

Routine Laboratory Studies

- CBC (may show anemia, infection)
- Electrolytes (may show dehydration, other illnesses)
- Urinalysis (may show infection, other medical diagnoses [e.g.,

diabetes])

- Other diagnostic studies to assess evidence of disease, deformity, or infection: angiography, EMG, EEG, MRA, MRI, LP

Diagnostic Studies

The diagnosis of migraine headache is usually based on the patient history. Neurologic and other diagnostic examinations are often normal (Table 58.2).

No specific laboratory or radiologic test can diagnose migraine headache. Neuroimaging techniques (e.g., head CT scan with or without contrast, MRI) are not part of the routine evaluation of headache unless the neurologic examination is abnormal. If atypical features are present, further testing is done to rule out a secondary headache.

Cluster Headache

Cluster headache is the most severe form of primary headache. It is classified as a trigeminal autonomic cephalalgia (TAC). This reflects its effect on the trigeminal nerve (CN V) and associated autonomic symptoms (e.g., runny or stuffy nose).[8] Repeated headaches occur in clusters, generally at the same time of day or night. Age at onset is typically 20 to 50 years, but they can start at any age. They affect men more than women. They occur more often in persons who smoke.[9] Less than 1% of people in the United States have cluster headache.

Etiology and Pathophysiology

Neither the cause nor how cluster headache occurs is fully known. The patterns of cluster headache suggest dysfunction of the hypothalamus. Many attacks occur at night, waking the person 1 to 2 hours after falling asleep. This may mean there is a circadian rhythm problem. Alcohol is a dietary trigger. Pain often starts within an hour of a drink. Strong odors (e.g., gasoline, paint fumes) can trigger cluster

headache.[10]

Clinical Manifestations

Patients with cluster headache have severe, intense pain lasting from a few minutes to 3 hours. In contrast to the pulsing pain of migraine headache, the pain of cluster headache is sharp and stabbing. The pain is usually around the eye, radiating to the temple, forehead, cheek, nose, or gums. Other manifestations may include swelling around the eye, lacrimation (tearing), facial flushing or pallor, nasal congestion, and miosis (pupil constriction). Most patients have at least 3 of these symptoms. During the headache, the patient may be agitated and restless, unable to sit still or relax.

Cluster headaches can occur every other day and as often as 8 times a day. A cluster typically lasts 2 weeks to 3 months, and then the patient goes into remission for months to years. Typically, 2 cluster periods a year may be separated by months without symptoms. Because cluster periods often occur seasonally, headaches may be mistaken for symptoms of allergies. A small number of patients (10% to 15%) have chronic headaches without remission.[1]

Diagnostic Studies

The diagnosis of cluster headache is based on the patient history according to IHS criteria.[1] Asking patients to keep a headache diary can be useful. CT scan, MRI, or magnetic resonance angiography (MRA) may rule out an aneurysm, tumor, or infection. A lumbar puncture (LP) may rule out other disorders that may cause similar symptoms.

Other Types of Headaches

Other types of headaches can occur. A headache may be the first symptom of a more serious illness. Headache can accompany subarachnoid hemorrhage; brain tumors; intracranial masses; vascular

abnormalities; trigeminal neuralgia (tic douloureux); diseases of the eyes, nose, and teeth; and systemic illness (e.g., infection, carbon monoxide poisoning, altitude sickness, polycythemia vera). Because of the varied causes of headache, thorough clinical evaluation is important. It should include assessment of personality, life adjustment, environment, and living situation, as well as a comprehensive evaluation of neurologic and physical condition.

Informatics in Practice

Social Media Use for Patients With Migraine Headaches

- Many people with migraine headaches think others do not understand their pain and its impact on their quality of life.
- Encourage patients to take part in a social media outlet where people who have migraines share their experiences.
- Patients can describe their physical and emotional pain on social media. It can help them cope better and improve their quality of life.

Interprofessional Care for Headaches

If no systemic disease is the cause, the type of headache guides therapy. Table 58.2 outlines the general assessment of a patient with headaches to rule out any intracranial or extracranial disease. Table 58.1 shows therapies for preventing and managing different types of headaches.

Cognitive-behavioral therapy and relaxation therapy used alone or in conjunction with drug therapy may help some patients (see Chapter 6). Biofeedback involves the use of physiologic monitoring equipment that gives the patient information about muscle tension and peripheral blood flow (e.g., skin temperature of the fingers). The patient is trained to relax the muscles and raise the finger

temperature. Reinforcement occurs when the patient makes these changes. Acupuncture, acupressure, and hypnosis are options for some patients.

Drug Therapy

Tension-Type Headache

Drug therapy for TTH usually involves aspirin, acetaminophen (Tylenol), or nonsteroidal antiinflammatory drugs (NSAIDs) used alone or in combination with caffeine, a sedative, or a muscle relaxant. Treatment is often disappointing. These analgesics may be only partly effective, even with use of the maximum dose. Stronger analgesics provide no additional benefit. For some, analgesics can make the headache worse.[11]

Many of these drugs have serious side effects. Caution the patient about the long-term use of aspirin or aspirin-containing drugs because they can cause gastrointestinal (GI) bleeding and coagulation abnormalities in some patients. Drugs containing acetaminophen can cause kidney damage with chronic use and liver damage when taken in large doses or when combined with alcohol. To decrease the recurrence of TTH, many patients take an antidepressant. Common drugs include tricyclic agents (e.g., amitriptyline, nortriptyline); mirtazapine (Remeron), a nonadrenergic serotonergic antidepressant; and venlafaxine (Effexor XR). Antiseizure drugs, such as topiramate (Topamax) or divalproex (Depakote), also may be used.

Migraine Headache

The aim of drug treatment of an acute migraine is stopping or decreasing the symptoms. Many people with mild or moderate migraine headache can get relief with NSAIDs, aspirin, or caffeine-containing analgesics. For moderate to severe headaches, triptans are the first line of therapy.

Triptans (e.g., sumatriptan [Imitrex]) affect selected serotonin receptors. They reduce neurogenic inflammation of cerebral blood vessels and cause vasoconstriction (Table 58.1). Some patients respond

better to a certain triptan than to others. Triptans are most effective when taken at the start of a migraine headache or during the aura. Sumatriptan is available in several dosage forms and delivery systems (oral, subcutaneous, nasal spray, transdermal). It is also the only ultrafast-acting triptan. A combination of oral sumatriptan and naproxen sodium (Treximet) is more effective for symptom relief than either medication alone. Because triptans cause vasoconstriction, they may not be appropriate for people with heart disease (e.g., hypertension, high cholesterol) or history of stroke. When triptans are contraindicated or ineffective, other drugs can be used (Table 58.1).

Drug Alert

Sumatriptan (Imitrex)

- Should not be given to patients with a history of:
    - Ischemic cardiac, cerebrovascular, or peripheral vascular problems.
    - Uncontrolled hypertension (may increase BP).
- Excess dosage may cause tremor and decrease respirations.

Preventive treatment is important in managing migraine headache. The decision to start preventive treatment is made based on frequency, severity, and disability related to headaches. Several different classes of medications are used.

Topiramate, an antiseizure drug, may be taken daily for migraine prevention. Common side effects include hypoglycemia, paresthesia, weight loss, and cognitive changes. Usually these side effects are mild to moderate and transient. Topiramate must be taken for 2 to 3 months to determine its effectiveness. Not all patients become pain free. HCPs must offer thorough teaching to promote patient adherence. Extended-release forms promote adherence, with fewer cognitive effects and a higher rate of effectiveness.[12]

Drug Alert

Topiramate (Topamax)

Teach patient to:

- Not abruptly stop therapy because this may cause seizures.
- Avoid tasks that require alertness (e.g., driving, operating heavy machinery) until response to the drug is known.
- Take adequate fluids to decrease risk for developing renal stones.
- Tell the HCP if you are pregnant or want to become pregnant.

β-Blockers have been effective in migraine prevention. Commonly prescribed agents include metoprolol (Lopressor) and propranolol (Inderal). Propranolol is similar to amitriptyline in its efficacy. Atenolol (Tenormin) and nadolol (Corgard) are other options for migraine prevention.

Botulinum toxin A (Botox) may be an effective prophylactic treatment for adults who have chronic migraines at least 15 days each month or migraines that do not respond to other medications. Botox is given by multiple injections around the head and neck into the pain fibers involved in headaches. Maximum benefit may not be seen for up to 6 months. During this time, the patient should continue their regular medications. Injections are usually given every 3 months. The most common reactions are neck pain and headache. A slight risk exists for the toxin to migrate from the injection site to other areas of the face and neck, causing swallowing and breathing difficulties. Teach the patient to seek immediate medical attention if this occurs.

Cluster Headache

Triptans are the standard of treatment for occasional cluster headache. Nasal administration or subcutaneous injection is appropriate. However, as discussed earlier, they are contraindicated for patients with vascular risk factors due to their vasoconstrictive effects.

High-flow 100% O_2 by non-rebreather mask is well-tolerated, safe, and effective as an alternative treatment. O_2 delivered at a rate of 6 to 8 L/min for 10 minutes may relieve headache by causing vasoconstriction and increasing synthesis of serotonin in the central nervous system (CNS). Treatment can be repeated after a 5-minute rest. A drawback to this treatment is that the patient must have continuous access to the O_2 supply.

Those with chronic cluster headache often need preventive treatment. High-dose verapamil is the first-choice drug. It is typically given at double or more the dose used for other disorders.[8] Because of its effects on cardiac conduction, verapamil should be started only after careful consideration of the risks. Careful monitoring is needed during treatment. An electrocardiogram (ECG) should be done with every dose increase and every 6 months during treatment for patient safety. Other drug options may include lithium, ergotamine, antiseizure drugs (e.g., topiramate), and melatonin. Options for patients with refractory cluster headaches include invasive nerve blocks, deep brain stimulation, and ablative neurosurgical procedures (e.g., percutaneous radiofrequency).

Other Headaches

Patients with frequent headaches may overuse analgesics or other medications used for headache treatment. *Medication overuse headache* (MOH) is the term used to describe a new type of headache or marked worsening of a preexisting headache condition. Drugs known to cause this problem are acetaminophen, aspirin, NSAIDs (e.g., ibuprofen), triptans, ergotamine, and opioids.[1] Headache often occurs daily and is present on wakening. Patients may have nausea, restlessness, weakness, lack of energy, decreased memory, difficulty concentrating, depression, and irritability. Treatment involves abrupt withdrawal of the offending drug (except for opioids, which must be tapered) and using alternative drugs, such as amitriptyline.

Some people have chronic headaches that are difficult to treat. IV medication administration with novel therapies, such as ketamine and

lidocaine, and neurostimulation are emerging as options.

Nursing Management: Headaches

Nursing Assessment

Table 58.3 outlines subjective and objective data to obtain from a patient with headaches. The history is key and focused on specific details of the headaches. These include location and type of pain, onset, frequency, duration, relation to events (emotional, psychologic, physical), and time of day of the occurrence. Ask about illnesses, surgery, trauma, allergies, family history, and response to medication. A thorough history may suggest headache is due to other drug therapies or a condition other than headache. For example, estrogen withdrawal headache is possible during the drug-free interval of an oral contraceptive.

Ask the patient to keep a diary of headaches with specific details. This record can help identify the type of headache and precipitating events. If there is a history of migraine, TTH, or cluster headache, ask the patient if the character, intensity, or location of the headache has changed. The answer may be an important clue about the cause of the headache.

Nursing Diagnoses

Nursing diagnoses for the patient with headaches may include:

- Acute pain
- Lack of knowledge

Additional information on nursing diagnoses and interventions is presented in eNursing Care Plan 58.1 for the patient with headaches (available on the website for this chapter).

Planning

The overall goals are that the patient with headaches will (1) have reduced or no pain, (2) understand triggering events and treatments, (3) use positive coping strategies to deal with pain, and (4) have increased quality of life and decreased disability.

Nursing Implementation

An inability to cope with daily stresses can cause headaches. Thus effective treatment may involve helping the patient examine the daily routine, recognize stressful situations, and develop effective coping strategies. Help the patient identify precipitating factors and develop ways to avoid or minimize them. Encourage daily exercise, relaxation periods, and socialization as ways to decrease headaches. Suggest relaxation, medication, yoga, and other ways to address headache pain.

TABLE 58.3 Nursing AssessmentHeadaches

Subjective Data
Important Health Information

Past health history: Seizures, cancer, recent fall or other trauma, cranial infection, stroke. Asthma or allergies. Relationship of headache to overwork, stress, menstruation, exercise, food, sexual activity, travel, bright lights, or noxious environmental stimuli

Medications: Hydralazine, bromides, nitroglycerin, ergotamine (withdrawal), NSAIDs (in high daily doses), estrogen preparations, oral contraceptives, OTC medications

Surgical interventions or other treatments: Craniotomy, sinus surgery, facial surgery

Functional Health Pattern

Health perception–health management: Positive family history. Malaise

Nutritional-metabolic: Ingestion of alcohol, caffeine, cheese, chocolate, monosodium glutamate, aspartame, lunch meats (nitrites in cured meats), sausage, hot dogs, onions, avocados. History of anorexia, nausea, vomiting (migraine premonitory symptom); unilateral lacrimation (cluster)

Activity-exercise: Vertigo, fatigue, weakness, paralysis, fainting

Sleep-rest: Insomnia

Cognitive-perceptual

- *Tension type:* Bilateral, bandlike, dull and persistent, base-of-skull headache, neck tenderness
- *Migraine:* Aura. Unilateral, severe, throbbing headache (possible switching of side). Visual changes, photophobia, phonophobia, dizziness, tingling or burning sensations
- *Cluster:* Unilateral and severe, nocturnal headache. Nasal stuffiness

Self-perception–self-concept: Depression

Coping–stress tolerance: Stress, anxiety, irritability, withdrawal

Objective Data

General

Anxiety, apprehension

Integumentary

Migraine: Generalized edema (premonitory symptom) pallor, diaphoresis

Cluster: Forehead diaphoresis, pallor, unilateral facial flushing with cheek edema, conjunctivitis

Neurologic

Horner's syndrome, restlessness (cluster), hemiparesis (migraine)

Musculoskeletal

Resistance of head and neck movement, nuchal rigidity (meningeal, tension type), palpable neck and shoulder muscle tension (tension type)

Possible Diagnostic Findings

Evidence of disease, deformity, or infection on brain imaging (CT, MRI, MRA), cerebral angiogram, LP, EEG, EMG

Teach the patient about drugs prescribed for preventive and symptomatic treatment of headache. The patient should be able to describe the purpose, action, dosage, and side effects of the drugs. To prevent accidental overdose, urge the patient to make a written note of each dose of drug or headache remedy. In addition to using analgesics and analgesic combinations to relieve headache, encourage the patient with migraines to seek a quiet, dimly lit environment. Massage and moist hot packs to the neck and head can help a patient with TTH.

Provide dietary counseling for the patient with headaches triggered by food. Encourage the patient to eliminate foods that may provoke headaches. Active challenge and provocative testing (designed specifically to provoke symptoms) with suspect foods may help determine specific causative agents. However, teach the patient that food triggers may change over time.

TABLE 58.4 Patient & Caregiver TeachingHeadaches

Include the following instructions when teaching the patient with a headache and the patient's caregiver:

1. Keep a diary or calendar of headaches and possible precipitating events.
2. Avoid possible triggers for a headache:
    - Foods containing amines (cheese, chocolate), nitrites (meats, such as hot dogs), vinegar, onions, monosodium glutamate
    - Fermented or marinated foods
    - Caffeine
    - Oranges
    - Tomatoes
    - Aspartame
    - Nicotine
    - Ice cream
    - Alcohol (especially red wine)
    - Emotional stress
    - Fatigue
    - Drugs, such as ergot-containing preparations (ergotamine tartrate) and monoamine oxidase inhibitors (e.g., rasagiline [Azilect])
3. Learn the purpose, action, dosage, and side effects of drugs taken.
4. Self-administer sumatriptan subcutaneously, if prescribed.
5. Use stress management techniques (see Chapter 6).
6. Take part in regular exercise.
7. Contact HCP if any of the following occur:
    - Symptoms become more severe, last longer than usual, or are resistant to medication
    - Nausea and vomiting (if severe or not typical), change in vision, or fever occurs with the headache
    - Problems occur with any drugs

Teach patients to avoid smoking and exposure to triggers, such as strong perfumes and gasoline fumes. Cluster headaches may occur at high altitudes with low O_2 levels during air travel. Ergotamine, taken before the plane takes off, may decrease this risk. See Table 58.4 for a teaching guide for the patient with a headache.

Evaluation

Expected outcomes are that the patient with headaches will

- Report satisfaction with pain management
- Use drug and nondrug measures appropriately to manage pain

Chronic Neurologic Disorders

Seizure Disorder

Seizure disorder, also known as *epilepsy*, is a group of neurologic diseases marked by recurring seizures. It is the fourth most common neurologic disorder. Only migraine, stroke, and Alzheimer's disease occur more often. About 3.4 million Americans have seizure disorder. 1 in 26 people will develop seizure disorder during their lifetime.[13]

Seizure is a transient, uncontrolled electrical discharge of neurons in the brain that interrupts normal function. Seizures may accompany a variety of disorders, or they may occur without any apparent cause. Seizures from systemic and metabolic problems are not considered seizure disorder if they stop when the underlying problem is corrected. Metabolic problems that may cause seizures include acidosis, electrolyte imbalances, hypoglycemia, hypoxia, alcohol and barbiturate withdrawal, dehydration, and water intoxication. Extracranial disorders that may cause seizures include systemic lupus erythematosus; diabetes; hypertension; sepsis; and heart, lung, liver, or kidney diseases.

Etiology and Pathophysiology

Seizure disorder has many possible causes. The most common ones vary by age. Common causes during the first 6 months of life are severe birth injury, congenital defects involving the CNS, infection, and inborn errors of metabolism. In those 2 to 20 years of age, the main causes are birth injury, infection, head trauma, and genetic factors. In young adults 20 to 30 years of age, seizure disorder usually occurs from structural lesions, such as trauma, brain tumors, or vascular disease. After 50 years of age, the main causes are stroke and metastatic brain tumors. However, one third of all cases are idiopathic. This means they cannot be attributed to a specific cause. These cases are known as *idiopathic generalized epilepsy (IGE).*

Seizure disorder is characterized by a group of abnormal neurons that seem to fire without a clear cause. Any stimulus that causes the neuron's cell membrane to depolarize can cause this firing. It spreads by physiologic pathways to involve near or distant areas of the brain. Localization of the *seizure focus* (the place where the seizure originates) is critical to the success of any possible surgical treatment.

Besides neuron alterations, changes in the function of astrocytes may play several key roles in recurring seizures. Activation of astrocytes by hyperactive neurons is one of the crucial factors that causes nearby neurons to generate an epileptic discharge. We continue to learn about abnormal neural antibodies that can cause seizures. *N*-methyl-D-aspartate (NMDA) receptor antibodies are present in the cerebrospinal fluid (CSF) in 80% of patients. The emerging concept of autoimmune seizure disorder may lead to better outcomes for those resistant to drug therapy.[14]

Genetic Link

Genetic abnormalities may be an important factor contributing to IGE. The role of genetics in seizure disorder is complex because it is hard to separate genetic from environmental or acquired influences. In some types, families carry a predisposition to seizure disorder through a naturally low threshold to stimuli, such as trauma, disease, and high fever. Other types of IGE are related to changes in specific genes that

control the flow of ions in and out of cells, regulate neuron signaling, or are involved with protein and carbohydrate metabolism.

Sometimes seizure disorder is related to a specific genetic disorder that affects various parts of the body and causes seizures. Many cause brain abnormalities or metabolic disorders (e.g., phenylketonuria [PKU]) and have seizures as a major feature. Other seizures are known to have a genetic basis, but we have not found the gene that causes them.[15]

Clinical Manifestations

Specific manifestations of seizure are determined by the site of the electrical disturbance. The preferred way of classifying seizures is based on the clinical and electroencephalographic (EEG) manifestations. This system divides seizures into 3 major classes: *generalized onset*, *focal onset*, and *unknown onset* (Table 58.5).[16] They are further described under each classification as *motor* or *nonmotor*. Descriptors address what occurs during the seizure.

TABLE 58.5 Classification of Seizures

Generalized Onset Seizure

(Involves both hemispheres of brain)

- Motor seizure
    - Tonic
    - Clonic
    - Tonic-clonic
    - Myoclonic
    - Myoclonic-tonic-clonic
    - Myoclonic-atonic
    - Atonic
    - Epileptic spasms
- Nonmotor (Absence) seizure

        - Typical
        - Atypical
        - Myoclonic
        - Eyelid myoclonia

Focal-Onset Seizure

(Limited to 1 hemisphere of brain)

- Aware (no impairment of awareness/consciousness)
- Impaired awareness (impairment of awareness/consciousness)
- Motor onset
        - Automatisms
        - Atonic
        - Clonic
        - Epileptic spasms
        - Hyperkinetic
        - Myoclonic
        - Tonic
- Nonmotor onset
        - Autonomic
        - Behavior arrest
        - Cognitive
        - Emotional
        - Sensory

Unknown Onset Seizure

(Due to inadequate information or inability to assign to other categories above)

Adapted from Fisher RS, Cross JH, D'Souza C, et al: Instruction manual for the ILAE 2017 operational classification of seizure types, *Epilepsia* 58:4, 2017.

Depending on the type, a seizure may occur in four phases: (1)

prodromal phase, with sensations or behavior changes that precede a seizure by hours or days; (2) *aural phase,* with a sensory warning that is similar each time a seizure occurs and is considered part of the seizure; (3) *ictal phase,* from first symptoms to the end of seizure activity; and (4) *postictal phase,* the recovery period after the seizure.

Generalized-Onset Seizures

Generalized-onset seizures start over wide areas of both sides of the brain. They are characterized by bilateral, synchronous epileptic discharges from the onset of the seizure. In most cases, the patient has impaired awareness for a few seconds to several minutes.

Tonic-Clonic Seizure

Tonic-clonic seizure (formerly called grand mal) is the most common generalized-onset motor seizure. During a tonic-clonic seizure, the patient loses consciousness and falls to the ground, if upright. The body stiffens (tonic phase) for 10 to 20 seconds and the extremities jerk (clonic phase) for another 30 to 40 seconds. Cyanosis, excessive salivation, tongue or cheek biting, and incontinence may occur during the seizure.

In the postictal phase, the patient usually has muscle soreness, feels tired, and may sleep for several hours. Some patients may not feel normal for several hours or days after a seizure. The patient has no memory of the seizure.

Other Generalized-Onset Motor Seizures

Other types of generalized-onset motor seizures include tonic and clonic. A tonic seizure involves a sudden onset of increased tone in the extensor muscles, contributing to sudden stiff movements. Tonic seizures most often occur in sleep and affect both sides of the body. Patients will fall if they are standing when the seizure occurs. Tonic seizures usually last less than 20 seconds. The patient usually stays aware. Clonic seizures begin with loss of awareness and sudden loss of muscle tone, followed by rhythmic limb jerking that may or may not be symmetric. Clonic seizures are rare.

A generalized *atonic seizure* (or *drop attack*) involves either a tonic episode or a paroxysmal loss of muscle tone. It begins suddenly with the person falling to the ground. Seizures typically last less than 15 seconds. The person usually stays conscious and can resume normal activity immediately. Patients with atonic seizure are at great risk for head injury. They often have to wear protective helmets.

Generalized-Onset Nonmotor (Absence) Seizures

Absence seizure usually occurs only in children and rarely beyond adolescence. This type of seizure may stop altogether as the child matures, or it may evolve into another type of seizure. A *typical absence seizure* is marked by a brief staring spell that resembles daydreaming. It often goes unnoticed because it lasts less than 10 seconds. Usually the patient is unresponsive when spoken to during the seizure.[16] The EEG has a classic spike-wave pattern with 3 per second.

In *atypical absence seizure,* the staring spell is accompanied by other signs and symptoms, such as eye blinking or jerking movements of the lips. This type of seizure often lasts more than 10 seconds (as much as 30 seconds), with a gradual beginning and end. If the patient has existing cognitive impairment, it may be hard to tell seizure activity from usual behavior. Atypical absence seizures usually continue into adulthood. An EEG shows atypical spike-and-wave patterns, with fewer than 3 per second.

Other generalized-onset nonmotor seizures include myoclonic and eyelid myoclonia. The *myoclonic absence seizure* is characterized by rhythmic arm abduction (3 movements per second) leading to progressive arm elevation. It usually lasts 10 to 60 seconds. *Eyelid myoclonia* refers to jerking of the eyelids (at least 3 per second), often with upward eye deviation. It usually lasts less than 10 seconds.[16]

Focal-Onset Seizures

Focal-onset seizures (formerly called *partial* or *partial focal seizures*) are the other major class of seizures (Table 58.5). Focal seizures begin in 1 hemisphere of the brain in a specific region of the cortex, as shown by

the EEG. They cause sensory, motor, cognitive, or emotional manifestations based on the function of the involved area of the brain. For example, if the discharging focus is in the medial aspect of the postcentral gyrus, the patient may have paresthesia in the leg on the side opposite the focus. This can help distinguish the type of seizure event.

Focal-onset seizures may be described by level of awareness (*aware* or *impaired awareness*). However, this is optional and applied only when awareness is known. *Focal awareness seizures* were called simple partial seizures. Patients are conscious and alert but have unusual feelings or sensations that can take many forms. They may have sudden and unexplainable feelings of joy, anger, sadness, or nausea. They may hear, smell, taste, see, or feel things that are not real.

In a *focal impaired awareness seizure* (previously called complex partial seizures), patients have a loss of consciousness or a change in their awareness, producing a dreamlike state. Their eyes are open. They make movements that may seem purposeful, but they cannot interact with observers. During a seizure, some people may do things that can be dangerous or embarrassing, such as walking into traffic or removing their clothes. They may continue an activity started before the seizure, such as counting coins or choosing items from a grocery shelf. After the seizure they do not remember the activity performed during the seizure. Seizures usually last 1 to 2 minutes. Patients may be tired or confused after the seizure and may not return to normal activity for hours.

The degree of awareness can be unspecified, and a seizure classified as *motor* or *nonmotor*. Motor activities include atonic (loss of tone), tonic (sustained stiffening), clonic (rhythmic jerking), myoclonic (irregular, brief jerking), or epileptic spasms (flexion or extension of arms with flexion of trunk). Some people show strange behavior, such as lip smacking or other repetitive, purposeless actions *(automatisms)*. With a focal nonmotor seizure, the patient can have emotional manifestations, such as fear or joy, strange feelings, or symptoms such as a racing heart, goose bumps, or waves of heat or cold.

Psychogenic Nonepileptic Seizures (PNES)

Because of the close resemblance, psychogenic seizures may be misdiagnosed as seizure disorder. Proper diagnosis usually requires video-EEG monitoring to identify associated events. If the diagnosis of seizure disorder is excluded, history of emotional or physical abuse or a specific traumatic event often emerges. Some patients may have both psychogenic seizures and seizure disorder. Care provided by a specialist is essential. Once the diagnosis is made, the treatment of choice is psychological intervention.[17]

Complications

Physical

Status epilepticus (SE) is a state of continuous seizure activity or a condition in which seizures recur in rapid succession without return to consciousness between seizures. SE is defined as any seizure lasting longer than 5 minutes. The longer a seizure lasts, the less likely it is to stop without drug therapy.

SE is a neurologic emergency that can occur with any type of seizure. The highest incidence occurs in children and older adults. During repeated seizures, the brain uses more energy than can be supplied. As neurons become exhausted and cease to function, permanent brain damage may result. *Convulsive status epilepticus* (CSE) is the most common form. It occurs with prolonged or repeated tonic-clonic seizures. The goal of therapy is to rapidly end clinical and electrical seizure activity. Without effective, timely treatment, CSE can lead to fatal respiratory insufficiency, hypoxemia, dysrhythmias, hyperthermia, and systemic acidosis. The prognosis for CSE is related to its duration and the patient's age.[18]

The term *nonconvulsive status epilepticus* is used to described long or repeated focal impaired awareness seizures. Symptoms may be subtle, making it hard to tell recovery from seizure symptoms. No consistent time frame dictates when this state is considered an emergency. It depends on the length and frequency of seizure activity.

Refractory status epilepticus (RSE) is continuous seizure activity despite administration of first- and second-line therapy. RSE carries a high risk for mortality and neurologic damage. This highlights the need for careful, rapid escalation of treatment for CSE to avoid progression. *Super refractory SE* is a refractory condition that continues or recurs 24 hours or more after starting anesthetic treatment. It also includes cases in which seizure activity returns after withdrawal of anesthetic drugs or persists after 7 days of continuous general anesthesia. About 15% of patients who enter the hospital with SE become super-refractory.[19]

Subclinical seizures are a form of SE in which a sedated patient seizes but there are no external signs because of sedative use. For example, a patient under sedation for ventilatory support in the intensive care unit (ICU) could have a seizure without physical movements and we miss the seizure occurrence.

People with seizure disorder have a higher mortality rate than the general population. Severe injury, and even death, can result from trauma suffered during a seizure. Patients who lose consciousness during a seizure are at greatest risk. Other deaths are due to accidents during seizures, suicide, treatment-related death, death from an underlying disease, or sudden unexpected death in epilepsy (SUDEP).

SUDEP affects about 1 in 150 persons with uncontrolled seizures each year.[20] It is almost always associated with tonic-clonic seizures. Occurrence is higher in males, in persons taking multiple antiseizure drugs, and patients with poorly managed seizure activity. The exact cause is not known. It could be related to respiratory dysfunction, dysrhythmias, or cerebral depression. Specific teaching about medication adherence and disease awareness is critical for at-risk people.

Psychosocial

Perhaps the most common complication of seizure disorder is the effect on a patient's lifestyle. Patients may have ineffective coping methods because of psychosocial problems related to having seizure disorder. An increased incidence of depression occurs in people who

have seizures that are difficult to control. Many antiseizure drugs have side effects that overlap with depressive symptoms.

Although attitudes have improved in recent years, a diagnosis of seizure disorder still carries a social stigma. Patients may be victims of discrimination in employment and educational opportunities. Transportation may be difficult if state law does not allow the person to drive. Screen patients often for depression. Encourage them to pursue available treatment options.

Diagnostic Studies

A diagnosis of seizure disorder may have many socioeconomic, physical, and psychologic consequences for the patient. Accurate diagnosis is crucial. The most useful diagnostic tool is an accurate, comprehensive description of seizures and the patient's health history (Table 58.6). Information from caregivers can be helpful.

The EEG is useful, but only if it shows abnormalities. Abnormal findings help determine the type of seizure and pinpoint the seizure focus. Ideally, an EEG should be done within 24 hours of a suspected seizure. However, only a small number of patients with seizure disorder have abnormal EEG findings the first time the test is done. Repeated EEGs or continuous EEG monitoring may be needed to detect abnormalities. An EEG is not a definitive test because some patients without seizure disorder have abnormal patterns on their EEGs. Many patients with seizure disorder have normal EEG results between seizures. If abnormal discharges do not occur during the 30 to 40 minutes of sampling during EEG, the test may not show an abnormality. Magnetoencephalography (MEG) may be done with the EEG. This test has greater sensitivity in detecting small magnetic fields of neuron activity.

TABLE 58.6 Interprofessional CareSeizure Disorder

Diagnostic Assessment

History and Physical Examination

- Birth and developmental history
- Significant illnesses and injuries
- Family history
- Febrile seizures
- Comprehensive neurologic assessment

Seizure History

- Precipitating factors
- Antecedent events
- Seizure description (including onset, duration, frequency, postictal state)

Diagnostic Studies

- CBC, urinalysis, electrolytes, creatinine, fasting blood glucose
- LP for CSF analysis
- CT, MRI, MRA, MRS, PET scan
- EEG

Management

- Antiseizure drugs (Table 58.8)
- Surgery
- Vagal nerve stimulation
- Psychosocial counseling
- Physical therapy

A complete blood count (CBC), serum chemistries, studies of liver and kidney function, and urinalysis should be done to rule out metabolic disorders. A CT scan or MRI should be done in any new-onset seizure to rule out a structural lesion. Cerebral angiography, single-photon emission computed tomography (SPECT), magnetic resonance spectroscopy (MRS), MRA, and positron emission tomography (PET) may be done in certain situations. If an MRI shows a spot or lesion but EEG results differ, MEG can determine if the brain waves are coming from the lesion. MEG can be helpful in a patient with prior brain surgery as EEG results may be affected by changes in the scalp and brain.

The International League Against Epilepsy has developed specific diagnostic criteria for each type of seizure, including conditions that resolve over time *(www.ilae.org)*. If a patient is diagnosed with seizure disorder, the seizure type must be correctly identified to determine the appropriate treatment.

Interprofessional Care

Most seizures do not require emergency medical care because they are self-limiting and rarely cause bodily injury. However, if SE or significant bodily harm occurs, or if the event is a first-time seizure, medical care should be sought immediately. Table 58.6 outlines the diagnostic studies and interprofessional care of seizure disorder. Table 58.7 summarizes emergency care of the patient with a tonic-clonic seizure, the seizure most likely to need emergency medical care.

Drug Therapy

The main treatment for seizure disorder is antiseizure drugs (Table 58.8). Because a cure is not possible, the goal of therapy is to prevent seizures with minimal drug side effects. Drugs generally stabilize nerve cell membranes and prevent spread of the epileptic discharge. Therapy should begin with a single drug based on the patient's age and weight and type, frequency, and cause of seizure. Dosage should be increased until seizures are under control or toxic side effects occur. Antiseizure drugs successfully control seizures for about 70% of

patients.

TABLE 58.7 Emergency ManagementTonic-Clonic Seizures

Etiology	Assessment Findings	Interventions
Drug-Related Processes • **Ingestion, inhalation** • **Overdose** • **Withdrawal of alcohol, opioids, antiseizure drugs** **Head Trauma** • **Cerebral contusion** • **Epidural hematoma** • **Intracranial hematoma** • **Subdural hematoma** • **Traumatic birth injury** • **Idiopathic** **Infectious Processes** • **Encephalitis** • **Meningitis** • **Sepsis** **Intracranial Events** • **Brain tumor** • **Hypertensive crisis** • **Increased ICP due to clogged shunt** • **Stroke** • **Subarachnoid hemorrhage** **Medical Disorders** • **Heart, liver, lung, or kidney disease** • **Systemic lupus erythematosus** **Metabolic Imbalances** • **Fluid and electrolyte imbalance** • **Hypoglycemia** **Other** • **Cardiac arrest** • **High fever** • **Psychiatric disorders**	**Aural Phase** • Bowel and bladder incontinence • Diaphoresis • Loss of consciousness • Pallor, flushing, or cyanosis • Peculiar sensations that precede seizure • Tachycardia • Warm skin **Tonic Phase** • Continuous muscle contractions **Hypertonic Phase** • Extreme muscular rigidity lasting 5–15 sec **Clonic Phase** • Rigidity and relaxation alternating in rapid succession **Postictal Phase** • Altered level of consciousness, lethargy • Confusion and headache • Repeated tonic-clonic seizures for several min	**Initial** • Ensure patent airway. • Protect patient from injury during seizure. *Do not restrain.* Pad side rails. • Remove or loosen tight clothing. • Establish IV access. • Stay with patient until seizure has passed. • Anticipate giving phenobarbital, phenytoin (Dilantin), benzodiazepines (e.g., diazepam [Valium], midazolam [Versed], lorazepam [Ativan]) to try to stop seizures. • Suction as needed. • Assist ventilations if patient does not breathe spontaneously after seizure. • Anticipate need for intubation if gag reflex absent. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, Glasgow Coma Scale results, pupil size and reactivity. • Reassure and orient patient after seizure. • Never force an airway between patient's clenched teeth. • Give IV dextrose for hypoglycemia.

If seizure control is not achieved with a single drug, dosage or timing of administration may be changed or a second drug may be added. About one third of patients need a combination regimen for enough control. Patients should discuss new treatments with their HCPs to provide the best control with the least amount of medication.

The therapeutic range for each drug is the serum level above which

most patients have toxic side effects and below which most continue to have seizures. Therapeutic drug ranges are only guides for therapy. If the patient's seizures are well controlled with a subtherapeutic level, the drug dosage does not have to be increased. Likewise, if a drug level is above the therapeutic range and the patient has good seizure control without toxic side effects, the drug dosage does not have to be decreased. Serum drug levels are monitored if seizures continue to occur, frequency increases, or drug adherence is questioned. Because they have a large therapeutic range, many newer drugs do not require drug-level monitoring.

The main drugs to treat tonic-clonic and focal-onset seizures are phenytoin (Dilantin), carbamazepine (Tegretol), phenobarbital, and divalproex. The drugs used most often to treat generalized-onset nonmotor and myoclonic seizures include ethosuximide (Zarontin), divalproex, and clonazepam (Klonopin). Table 58.8 lists other drugs used for seizure treatment. Some drugs are effective for multiple seizure types. Pregabalin (Lyrica) is used as an additional treatment for focal aware or impaired awareness seizures not successfully controlled with 1 medication.

Drug Alert

Carbamazepine (Tegretol)

- Do not take with grapefruit juice.
- Teach patient to report visual changes (e.g., blurry or double vision).
- Abrupt withdrawal after long-term use may cause seizures.

Treatment of SE requires a rapid-acting IV antiseizure drug. The drugs most often used are lorazepam (Ativan) and diazepam (Valium). Because these are short-acting drugs, their administration is followed with long-acting drugs, such as phenytoin or phenobarbital.

Because many antiseizure drugs (e.g., phenytoin, phenobarbital, ethosuximide, lamotrigine, topiramate) have a long half-life, they can be given once or twice a day. This simplifies the drug plan and increases the patient's adherence because the drug does not have to be taken at work or school. Unnecessary combination therapy is avoided whenever possible. Medications should be reviewed routinely and the least effective medication discontinued by tapering.

TABLE 58.8 Drug TherapySeizure Disorder

- brivaracetam (Briviact)
- carbamazepine (Tegretol)
- clonazepam (Klonopin)
- daclizumab (Zinbryta)
- diazepam (Diastat)
- divalproex (Depakote)
- eslicarbazepine (Aptiom)
- ethosuximide (Zarontin)
- ezogabine (Potiga)
- felbamate (Felbatol)
- gabapentin (Neurontin)
- lacosamide (Vimpat)
- lamotrigine (Lamictal)
- levetiracetam (Keppra)
- lorazepam (Ativan)
- oxcarbazepine (Trileptal)
- perampanel (Fycompa)
- phenytoin (Dilantin)
- pregabalin (Lyrica)
- primidone (Mysoline)

- tiagabine (Gabitril)
- topiramate (Topamax)
- valproic acid (Depakene)
- vigabatrin (Sabril)
- zonisamide (Zonegran)

Drug Alert

Antiseizure Drugs

- Abrupt withdrawal after long-term use may cause seizures.
- If weaning is to occur, the patient must be seizure free for a prolonged period (e.g., 2 to 5 yr) and have a normal neurologic examination and EEG.

Side effects of antiseizure drugs involve the CNS. They include diplopia, drowsiness, ataxia, and mental slowness. Neurologic assessment for dose-related toxicity involves testing the eyes for nystagmus and evaluating hand and gait coordination, cognitive functioning, and general alertness.

As a nurse, you need to be knowledgeable about drug side effects, so you can teach patients and start proper treatment. For example, common side effects of phenytoin are gingival hyperplasia (excess growth of gingival tissue) and hirsutism, especially in young adults. Good dental hygiene, including regular tooth brushing and flossing, can decrease gingival hyperplasia. If gingival hyperplasia is extensive, the hyperplastic tissue may be surgically removed (gingivectomy) and phenytoin replaced with another antiseizure drug.

Medication nonadherence can be a problem in people with seizure disorder, often due to undesirable side effects. Take measures to increase adherence to the prescribed drug plan. If HCPs are aware of nonadherence, they can work with the patient to find an acceptable drug plan. For example, using pregabalin as an adjunct medication in

some cases may allow a decreased dose of the primary antiseizure drug and thus decrease side effects.

Gerontologic Considerations: Drug Therapy for Seizure Disorder

Many older adults have a first single seizure, then do not have another seizure. To be considered for antiseizure drug therapy, older adults should have recurrent seizures, an obvious structural predisposition for seizures, or onset of seizure disorder presenting as SE. Older adults are more responsive to antiseizure drugs than younger adults, but they also are more likely to have side effects at lower serum drug concentrations.

Age-related changes in liver enzymes decrease the liver's ability to metabolize drugs. Because the liver metabolizes phenytoin, it should not be used in older patients with liver problems. The potential effects on cognitive function make phenobarbital, carbamazepine, and primidone less desirable for older adults. Carbamazepine, phenytoin, phenobarbital, or primidone can increase the risk for osteomalacia, osteopenia, and osteoporosis. Several newer antiseizure drugs offer greater treatment benefit to older adults. Compared with older drugs, gabapentin, lamotrigine, oxcarbazepine (Trileptal), and levetiracetam may be safer, have fewer effects on cognitive function, and have fewer interactions with other drugs.

Surgical Therapy

Despite availability of newer drugs with fewer side effects, no solution has been found for *medically refractory epilepsy* (not responsive to drug therapy). About 30% of patients do not respond to antiseizure drugs. For people with a defined site of seizure origin (epileptogenic zone), research shows the benefit of surgical resection of that focal area over continued use of different antiseizure drugs. About 80% are seizure free 5 years after surgery, with 72% still seizure free at 10 years.

Not all patients benefit from surgery. An extensive preoperative evaluation is important, including continuous EEG monitoring and

other tests to ensure precise localization of the focal point. Surgical candidates must meet 3 requirements: (1) a confirmed diagnosis of seizure disorder, (2) an adequate trial with drug therapy without satisfactory results, and (3) a defined electroclinical syndrome (type of seizure disorder).

Other Therapies

Vagal nerve stimulation (VNS), a form of neuromodulation, is used as an adjunct to drugs when an accessible focal point cannot be identified for surgical removal. The exact mechanism of action is unknown. It may increase blood flow to specific brain areas. It could raise levels of neurotransmitters important to seizure control and change EEG patterns during a seizure. In VNS, a surgically implanted electrode in the neck is programmed to deliver electrical impulses to the vagus nerve, usually on the left side. The patient activates the electrode with a magnet when they sense a seizure is imminent. Newer devices respond to an increasing heart rate, which is often associated with seizures. Adverse effects include coughing, hoarseness, dyspnea, and tingling in the neck. Battery life is 5 to 10 years, and surgical replacement is needed. Benefits of VNS can be seen within 24 months after implantation. Contraindications include a history of dysrhythmias or sleep apnea.

Responsive neurostimulation (Neuropace RNS System) is similar to a cardiac pacemaker. It continually monitors the EEG to detect abnormalities, then responds to seizure activity by delivering electrical stimulation to a precise location. The device is placed under the skin, outside the skull, with connections to electrodes over the area of seizure focus. The HCP uses a programmable wand to download information about seizure activity. This is used to assess treatment efficacy and guide care. This modality is an option for persons who are not surgical candidates or have multiple areas of seizure focus.

A *ketogenic diet* is a special high-fat, low-carbohydrate diet that helps control seizures in some people. A person on this diet produces ketones that pass into the brain, where they replace glucose as an energy source. Meals are carefully planned to restrict the amount of

protein and carbohydrate in the diet. Patients on this diet who use anticoagulants need close monitoring for bleeding. Although HCPs are more likely to recommend the diet for children than adults, the diet can work equally well in both age-groups. Most people must continue their use of antiseizure medication but may take smaller doses or fewer medications. Seizures may worsen if the diet is stopped abruptly. Long-term effects of the diet are not clear.

Biofeedback to control seizures is aimed at teaching the patient to maintain a certain brain wave frequency that is refractory to seizure activity. Further trials are needed to assess the effectiveness of biofeedback for seizure control.

Nursing Management: Seizure Disorder

Nursing Assessment

Subjective and objective data to obtain from a patient with seizure disorder are outlined in Table 58.9. Obtain data related to a specific seizure episode from a witness.

TABLE 58.9 Nursing AssessmentSeizure Disorder

Subjective Data
Important Health Information

Past health history: Seizures, birth defects or injuries, anoxic episodes. CNS trauma, tumors, or infections. Stroke, metabolic disorders, alcohol use, exposure to metals and carbon monoxide, hepatic or renal failure, fever, pregnancy, systemic lupus erythematosus

Medications: Adherence to antiseizure medication plan. Barbiturate or alcohol withdrawal. Use and overdose of

cocaine, amphetamines, lidocaine, theophylline, penicillin, lithium, phenothiazines, tricyclic antidepressants, benzodiazepines

Functional Health Patterns

Health perception–health management: Positive family history
Cognitive-perceptual: Headaches, aura, mood or behavioral changes before seizure. Mentation changes. Abdominal pain, muscle pain (postictal)
Self-perception–self-concept: Anxiety, depression. Loss of self-esteem, social isolation
Sexuality-reproductive: Decreased sexual drive, erectile dysfunction. Increased sexual drive (postictal)

Objective Data
General

Precipitating factors, including severe metabolic acidosis or alkalosis, hyperkalemia, hypoglycemia, dehydration, or water intoxication

Integumentary

Bitten tongue, soft tissue damage, cyanosis, diaphoresis (postictal)

Respiratory

Abnormal respiratory rate, rhythm, or depth. Apnea (ictal). Absent or abnormal breath sounds, possible airway occlusion

Cardiovascular

Hypertension, tachycardia or bradycardia (ictal)

Gastrointestinal

Bowel incontinence, excessive salivation

Urinary

Incontinence

Neurologic
Generalized Onset

Tonic-clonic: Loss of consciousness, muscle tightening, then jerking. Dilated pupils. Hyperventilation, then apnea. Postictal somnolence
Absence: Altered consciousness (5–30 sec), minor facial motor activity

Focal Onset

Aware: Aura. Focal sensory, motor, cognitive, or emotional phenomena (focal motor)
Impaired awareness: Altered consciousness with inappropriate behaviors, automatisms, amnesia of event

Musculoskeletal

Weakness, paralysis, ataxia (postictal)

Possible Diagnostic Findings

Positive toxicology screen or blood alcohol level. Altered serum electrolytes, acidosis or alkalosis, very low blood glucose, ↑ blood urea nitrogen or serum creatinine, abnormal liver function tests, ammonia; abnormal CT scan or MRI of head, abnormal findings from LP. Abnormal discharges on EEG

Nursing Diagnoses

Nursing diagnoses for the patient with seizure disorder may include:

- Impaired breathing
- Difficulty coping
- Risk for fall-related injury

Additional information on nursing diagnoses and interventions for the patient with seizure disorder is presented in eNursing Care Plan 58.2 (available on the website for this chapter).

Planning

The overall goals are that the patient with seizure disorder will (1) be free from injury during a seizure, (2) have optimal mental and physical functioning while taking antiseizure drugs, and (3) have satisfactory psychosocial functioning.

Nursing Implementation

Health Promotion

Following general safety measures (e.g., wearing helmets in situations involving risk for head injury) can prevent some seizure disorders. Improved perinatal care has reduced fetal trauma and hypoxia and thus brain damage leading to seizure disorder.

The patient with seizure disorder should practice good general

health habits (e.g., maintain proper diet, get adequate rest, exercise). Help the patient identify events or situations that cause seizures and provide suggestions for avoiding them or handling them better. Teach the patient to avoid excess alcohol use, fatigue, and loss of sleep. Help the patient handle stress constructively.

Acute Care

Nursing care for a hospitalized patient with seizure disorder or a patient who has had seizures due to other factors involves observation and treatment of the seizure, patient and caregiver teaching, and psychosocial intervention.

Check Your Practice

You are making your morning rounds and go to check your 22-yr-old female patient, who was admitted the night before with increased seizure activity. When you go to her room, her roommate is yelling, "Help, help!" You find the patient is on the floor jerking and stiffening and not responding to you.

- What should you do?

When a seizure occurs, carefully observe and record details of the event because the diagnosis and subsequent treatment often rest on the seizure description. What events preceded the seizure? When did the seizure occur? How long did each phase (aural [if any], ictal, postictal) last? What occurred during each phase?

All subjective data (usually the only type of data in the aural phase) and objective data are important. Note the exact onset of the seizure (which body part was affected first and how); the course and nature of the seizure activity (loss of consciousness, tongue biting, automatisms, stiffening, jerking, total lack of muscle tone); body parts involved and their sequence of involvement; and autonomic signs, such as dilated pupils, excessive salivation, altered breathing, cyanosis, flushing,

diaphoresis, or incontinence. Assessment of the postictal period should include a detailed description of the level of consciousness, vital signs, pupil size and position of the eyes, memory loss, muscle soreness, speech disorders (aphasia, dysarthria), weakness or paralysis, sleep period, and the duration of each sign or symptom.

Safety Alert

Seizure

During a seizure, you should:

- Maintain a patent airway for the patient.
- Protect the patient's head, turn the patient to the side, loosen constrictive clothing, ease patient to the floor (if seated).
- Do not restrain the patient.
- Do not place any objects in the patient's mouth

After the seizure, the patient may need repositioning (to open and maintain the airway), suctioning, and O_2. A seizure can be frightening for the patient and others who witnessed it. Assess their level of understanding and provide information about how and why the event occurred. This is an excellent chance for you to dismiss many common misconceptions about seizures.

Nursing Management

Caring for the Patient With Seizure Disorder

Role of the RN

- Teach patient about factors that increase risk for seizures.

- Teach patient about prescribed antiseizure medications, including drug plan, side effects, and monitoring of drug levels.
- Assess and record details of seizure events, including events preceding the seizure; length of each phase of the seizure; course and nature of seizure activity; and level of consciousness, vital signs, and activity during the postictal period.
- Assess airway patency, and position patient to maintain airway during and after seizures.
- Give IV antiseizure medications to the patient with SE.
- Give oral antiseizure medications as scheduled.
- Make appropriate referrals to community agencies to help the patient with the financial impact of seizure disorder, work training, employment, and living arrangements.
- Teach caregivers about management of seizures and SE.
- In the ambulatory and home care setting, evaluate patient self-management of medications and lifestyle.
- Oversee UAP:
    - Place suction equipment, bag-valve-mask, and O_2 at the patient's bedside.
    - Remove potentially harmful objects from the bedside and pad side rails.
    - Immediately report any seizure activity to the RN.
    - Obtain vital signs during the postictal period.

Collaborate With Other Team Members

Respiratory Therapist

- Assess airway patency and suction as needed.
- Assist ventilations if patient does not breathe spontaneously after seizure.
- Assist with intubation if gag reflex absent.

Occupational Therapist

- Help patient with increasing self-care measures, including eating and dressing.

  Social Worker
- Help patient identify and obtain needed resources.
- Offer counseling to develop positive coping skills.

Ambulatory Care

Prevention of recurring seizures is the major goal of treatment. Help the patient understand that for treatment to be effective, drugs must be taken regularly and consistently. Review details of the drug plan and what to do if a dose is missed. Usually the dose is made up if the omission is remembered within 24 hours. Caution the patient not to adjust drug dosages without HCP guidance because this can increase seizure frequency and cause SE. Encourage the patient to report any medication side effects and keep regular appointments with the HCP.

TABLE 58.10 Patient & Caregiver TeachingSeizure Disorder

Include the following information in the teaching plan for the patient with seizure disorder:

1. Take antiseizure medications as prescribed. Report all drug side effects to the HCP.
2. When needed, blood is drawn to ensure therapeutic drug levels. Schedule regular visits with the HCP to discuss treatment options.
3. Use nondrug techniques, such as relaxation therapy, to try to reduce the number of seizures.
4. Be aware of community and online resources for education and help with tracking and explaining seizure activity.
5. Wear a medical alert bracelet or necklace and carry an identification card.

6. Avoid excess alcohol use, fatigue, and loss of sleep.
7. Eat regular meals and snacks in between if feeling shaky, faint, or hungry.
8. Be knowledgeable as a woman of childbearing age about antiseizure medications and contraceptive use.

Caregivers should receive the following information:

Focal-Onset Seizures

1. Stay calm. Guide patient to safety to prevent injury but do not restrain.
2. Observe for asymmetry of activity and focus on specific actions, such as lip smacking and abnormal movements.
3. Assess patient's level of consciousness and ability to converse and respond appropriately.
4. Note the time the seizure started and stopped. Take note of the time of return to baseline.
5. Provide respect and explanation of occurrence.

Generalized-Onset Tonic-Clonic Seizures

1. When seizure occurs outside the hospital setting, activate ERS if (1) the duration is greater than 5 minutes; (2) events recur without the patient recovering to baseline; (3) the patient is unable to establish a normal breathing pattern, is injured or pregnant; or (4) you do not know if this is a first-time seizure event.
2. Maintain patient safety. Lower the patient to the floor or bed, remove glasses if worn, and loosen restrictive clothing.
3. Do not place anything in the patient's mouth. Patient's teeth/dentures may be damaged, and caregiver may be bitten.
4. Position patient on side (if possible) to improve the patient's ability to release oral secretions.
5. Note the time the seizure started and stopped. Take note of the

time of return to baseline.
6. Assess for any injury and lingering motor weakness.

You have a vital role in teaching the patient and caregiver. Review the guidelines for teaching shown in Table 58.10. Teach caregivers the emergency management of tonic-clonic seizures (Table 58.7). Remind them it is not necessary to call an ambulance or send a person to the hospital after a single seizure unless the seizure is prolonged, another seizure immediately follows, extensive injury has occurred, or it is unknown if this was a first-time seizure.

Patients with seizure disorder may have concerns or fears related to recurrent seizures, incontinence, or loss of self-control. Support patients through teaching and by helping them use effective coping mechanisms.

Perhaps the greatest challenge for a patient with seizure disorder is adjusting to the limitations imposed by the illness. Discrimination in employment is a serious problem facing the person with seizure disorder. For issues relating to job discrimination, refer patients to the state department of vocational rehabilitation or the U.S. Equal Employment Opportunity Commission (EEOC).

Help the patient find appropriate resources. If you think associating with others who have seizure disorder would be beneficial, refer the patient to the local chapter of the Epilepsy Foundation (EF). This volunteer agency offers varied services to patients with a seizure disorder *(www.epilepsy.com)*. Refer the patient who is an eligible veteran to a Department of Veterans Affairs medical center that provides comprehensive care. If intensive psychologic counseling is needed, refer the patient to a community mental health center.

Social workers and welfare agencies can help with financial implications and living arrangements. State agencies specializing in vocational rehabilitation services can provide vocational assessment, counseling, and funding for training. They can help with job placement for patients whose seizures are not well controlled. They offer financial assistance for transportation and medical costs related to vocational rehabilitation or job maintenance.

Driving laws for patients who have had a seizure vary from state to state. For example, some states require a 3-month seizure-free period before issuing or reissuing a driver's license. Others require up to 1 year. The EF provides current information on driving laws for each state.

Tell the patient that medical alert bracelets, necklaces, and identification cards are available through the EF, local pharmacies, or companies specializing in identification devices (e.g., Medic Alert). Using medical identification is optional. Some patients have found them beneficial, but others do not want to be identified as having seizure disorder.

Encourage the patient to learn more about seizures through self-education. The EF provides informational pamphlets, has an extensive website, and may offer support groups. Many agencies that offer services to patients with seizure disorder offer teaching aids and support.

Evaluation

Expected outcomes are that the patient with seizure disorder will

- Have a breathing pattern adequate to meet O_2 needs
- Have no seizure-related injury
- Express acceptance of seizure disorder by adhering to treatment plan

Restless Legs Syndrome

Etiology and Pathophysiology

Restless legs syndrome (RLS) *(Willis-Ekbom disease)* is a relatively common sleep and movement disorder with unpleasant sensory (paresthesia) and motor abnormalities of 1 or both legs. About 8% of the U.S. population has RLS.[21] A small number have severe symptoms that affect their quality of life and require medication for treatment.

RLS is more common in older adults and in women.

There are 2 distinct types of RLS: primary (idiopathic) and secondary. Most people have primary RLS. Secondary RLS can occur with metabolic problems associated with iron deficiency, renal disease and hemodialysis, and neuropathy. Sleep deprivation, sleep apnea, pregnancy (especially third trimester), and use of certain medications (e.g., antiemetics, antidepressants that increase serotonin), can cause or worsen symptoms.

We do not know the exact pathophysiology of primary RLS. We think it is related to a dysfunction in the brain's basal ganglia circuits that use the neurotransmitter dopamine (DA), which controls movements. In RLS, this dysfunction causes the urge to move the legs. RLS has a genetic link. Those with primary RLS often report a positive family history, with symptoms that start before age 40.[21]

Clinical Manifestations

The severity of RLS sensory symptoms ranges from infrequent minor discomfort (numbness, tingling, "pins and needles" sensation) to severe pain. Sensory symptoms often appear first. Some patients compare the sensations to bugs creeping or crawling on the legs. The leg pain is localized within the calf muscles. Patients can have pain in the upper extremities and trunk. The discomfort occurs when the patient is inactive. It is most common in the evening or at night.

Pain at night can disrupt sleep. Physical activity, such as walking, stretching, rocking, or kicking, often relieves the pain. In the most severe cases, patients sleep only a few hours at night. This causes daytime fatigue and disrupts the daily routine. Motor problems associated with RLS include voluntary restlessness and stereotyped, periodic, involuntary movements. The involuntary movements usually occur during sleep. Fatigue further worsens symptoms. RLS worsens over time. Symptoms become more frequent and last longer.

Diagnostic Studies

RLS is diagnosed largely based on the patient's history or the report of

the bed partner about nighttime activities. Diagnosis of RLS can be made when the patient meets all 5 specific criteria: (1) overwhelming urge to move the legs, often accompanied by uncomfortable or unpleasant sensations in the legs; (2) urge to move the legs worsens during rest or inactivity; (3) urge to move the legs is partially or totally relieved by movement, as long as the activity continues; (4) urge to move the legs becomes worse in the evening or night; and (5) these features are not due to another medical or behavioral condition.[21]

The patient may have polysomnography studies during sleep to distinguish RLS from other clinical conditions that can disturb sleep (e.g., sleep apnea). While periodic leg movements in sleep can support the diagnosis of RLS, they are not exclusive to RLS. Blood tests, such as a CBC, serum ferritin, and renal function tests (e.g., serum creatinine), may help exclude secondary causes of RLS. A patient with diabetes may have paresthesia caused by peripheral neuropathy related to diabetes or RLS.

Interprofessional and Nursing Care

The goal of interprofessional management is to reduce patient discomfort and distress and improve sleep quality. When RLS is due to renal failure or iron deficiency, treating these conditions may decrease symptoms. Lifestyle changes may help persons with mild to moderate RLS. For example, decreasing the use of alcohol or tobacco, maintaining regular sleep habits, exercising, and massaging and stretching the legs may be helpful. The patient should avoid antihistamine-containing medications (e.g., diphenhydramine).

If nondrug measures fail, drug therapy is an option. No single medication effectively manages RLS for all patients. The main drugs used to treat RLS aim to increase the amount of DA in the brain. They include DA precursors (e.g., carbidopa/levodopa) and DA agonists (e.g., ropinirole [Requip], pramipexole [Mirapex], rotigotine [Neupro]). The antiseizure drug gabapentin enacarbil (Horizant) may decrease the sensory sensations and nerve pain. The patient with iron-deficiency anemia may need to start iron supplementation.

Other drugs may relieve some symptoms of RLS. Very low doses of opioids (e.g., oxycodone) may help patients with severe symptoms who do not respond to other drug therapies. The main side effect of opioids is constipation, so patients may need to take a stool softener or laxative. Clonidine (Catapres) and propranolol (Inderal) are effective in some patients. Benzodiazepines (e.g., lorazepam [Ativan]) may help patients obtain more restful sleep. However, they are last-line treatments due to their side effects.[21]

Using a Relaxis device may help some patients. It produces vibration, providing counter stimulation that competes with and decreases RLS sensations. The patient places the legs on the Relaxis pad. It provides 30 minutes of uninterrupted vibration after being activated, then it slowly winds down over another 5 minutes to complete a 35-minute therapy cycle. If needed, it may be restarted one more time. The patient chooses the vibration intensity based on symptoms.

Degenerative Neurologic Disorders

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic, progressive, degenerative disorder of the CNS characterized by disseminated demyelination of nerve fibers of the brain and spinal cord. MS can affect people of any age. The onset of MS is usually between 20 and 50 years of age, with symptoms first appearing at an average of 30 to 35 years of age. People diagnosed at 50 years of age or older generally have more progressive disease. MS affects women 2 to 3 times more often than men. Around 400,000 people in the United States have MS, with 10,000 new cases diagnosed annually.[22]

MS is more prevalent in temperate climates (between 45 and 65 degrees of latitude), such as those found in the northern United States, Canada, and Europe. People who are born in a high-risk area and move to a low-risk area before age 15 assume the risk of their new home. We suspect exposure to some environmental agent before

puberty may cause a person to develop MS later in life. MS is less common in Hispanics, Asians, and people of African descent. It rarely occurs in some ethnic groups, including Alaskan Natives and Aborigines.

Etiology and Pathophysiology

While we do not know the cause of MS, it is unlikely due to a single cause. We think MS develops in a genetically susceptible person after an environmental exposure, such as an infection. The inherited susceptibility to MS likely involves multiple genes. Having a first-degree relative with MS increases a person's risk for developing the disease. We have found common genetic factors in families with more than 1 affected member.[23]

Possible precipitating factors include infection, smoking, physical injury, emotional stress, excessive fatigue, pregnancy, and a poor state of health. The role of factors such as exposure to pathogens is controversial. We have investigated more than a dozen viruses and bacteria but have not proven any cause MS.

MS is marked by 3 processes: chronic inflammation, demyelination, and gliosis in the CNS. The primary condition is an autoimmune process driven by activated T cells. An unknown trigger in a genetically susceptible person may start this process. The activated T cells in the systemic circulation go to the CNS and disrupt the blood-brain barrier. This may be the first event in the development of MS. Subsequent antigen-antibody reaction within the CNS activates the inflammatory response and leads to axon demyelination.

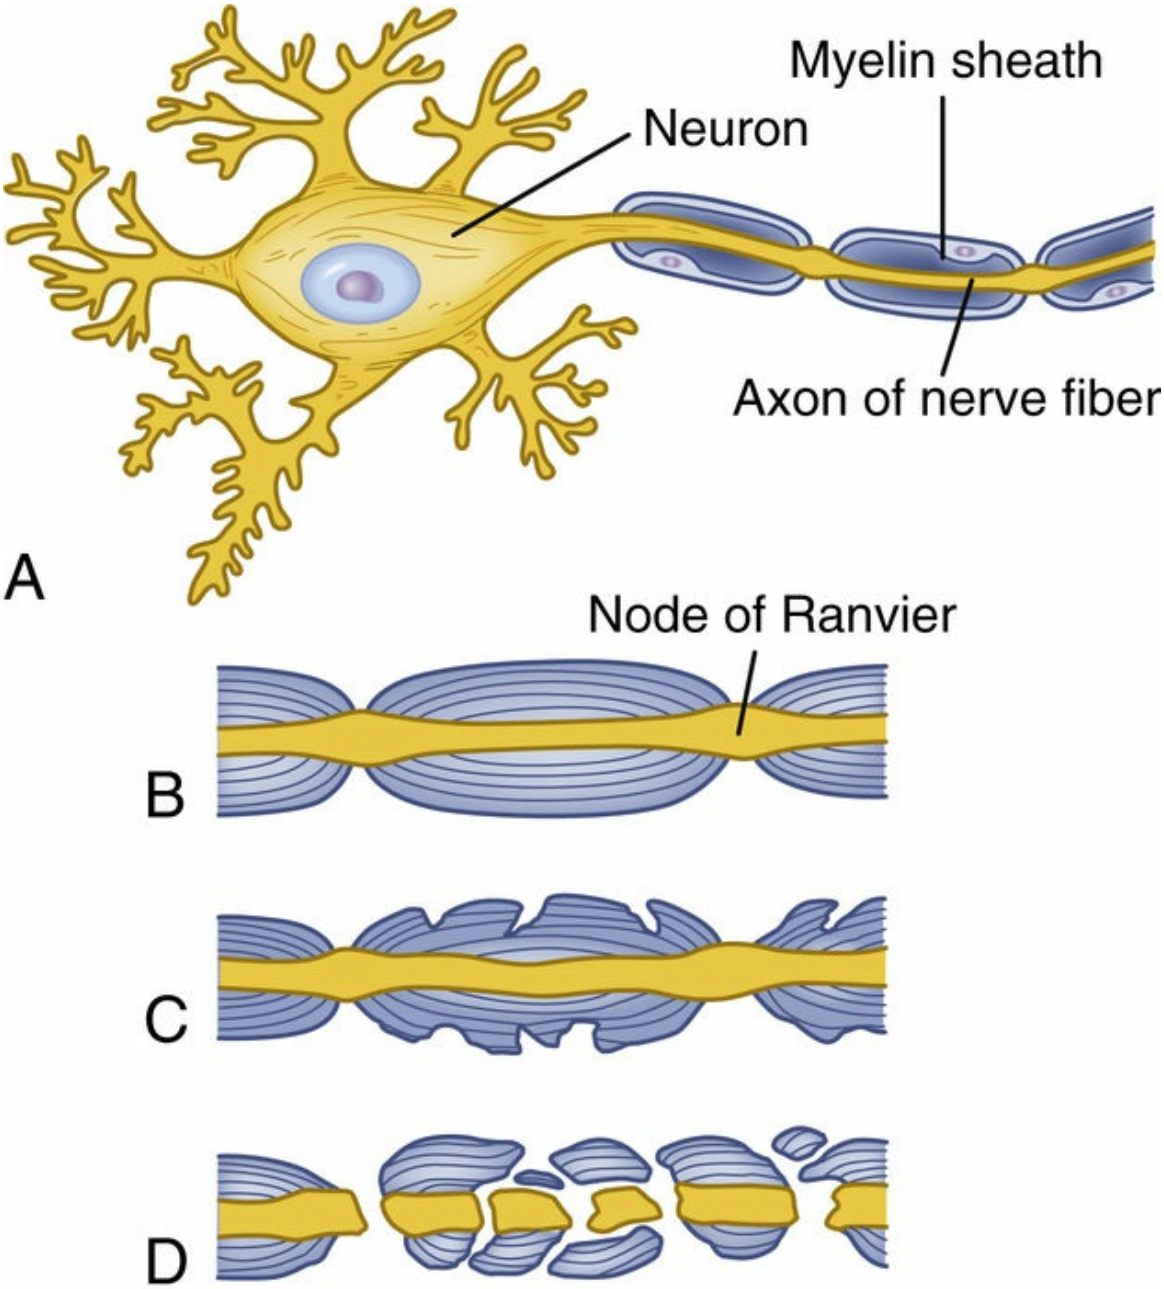

FIG. 58.2 Pathogenesis of multiple sclerosis. **A,** Normal nerve cell with myelin sheath. **B,** Normal axon. **C,** Myelin breakdown. **D,** Myelin totally disrupted; axon not functioning.

Attacks on the myelin sheaths of the neurons in the brain and spinal cord first cause damage to the myelin sheath (Fig. 58.2, *A* to *C*). The nerve fiber is not affected. Transmission of nerve impulses still occurs, but it is slowed. The patient may have a noticeable impairment of function (e.g., weakness). However, myelin can still regenerate. When

it does, symptoms disappear. At that point, the patient has a remission.

As inflammation continues, nearby oligodendrocytes are affected. Myelin loses the ability to regenerate. Eventually damage occurs to the underlying axon. Nerve impulse transmission is disrupted, and nerve function is lost permanently (Fig. 58.2, *D*). As inflammation subsides, glial scar tissue replaces damaged tissue. This leads to the formation of hard, rigid plaques (Fig. 58.3). These plaques are found throughout the white matter of the CNS.

The average life expectancy after the onset of symptoms is more than 25 years. Death usually occurs due to infectious complications of immobility (e.g., pneumonia) or because of an unrelated disease.

Clinical Manifestations

The onset of MS is often slow and gradual. Vague symptoms occur periodically over months or years. Because they do not prompt the patient to seek medical attention, MS may not be diagnosed until long after the first symptom. For some patients, MS is marked by rapid, progressive deterioration. Others have remissions and exacerbations. With repeated exacerbations, the overall trend is progressive deterioration in neurologic function.

Because changes from MS have a spotty distribution in the CNS, symptoms vary with each patient based on the areas of the CNS involved. Some patients have severe, long-lasting symptoms early in the course of the disease. Others have only occasional, mild symptoms for several years after onset. A classification scheme of MS, with 4 primary patterns, has been developed based on the clinical course (Table 58.11).

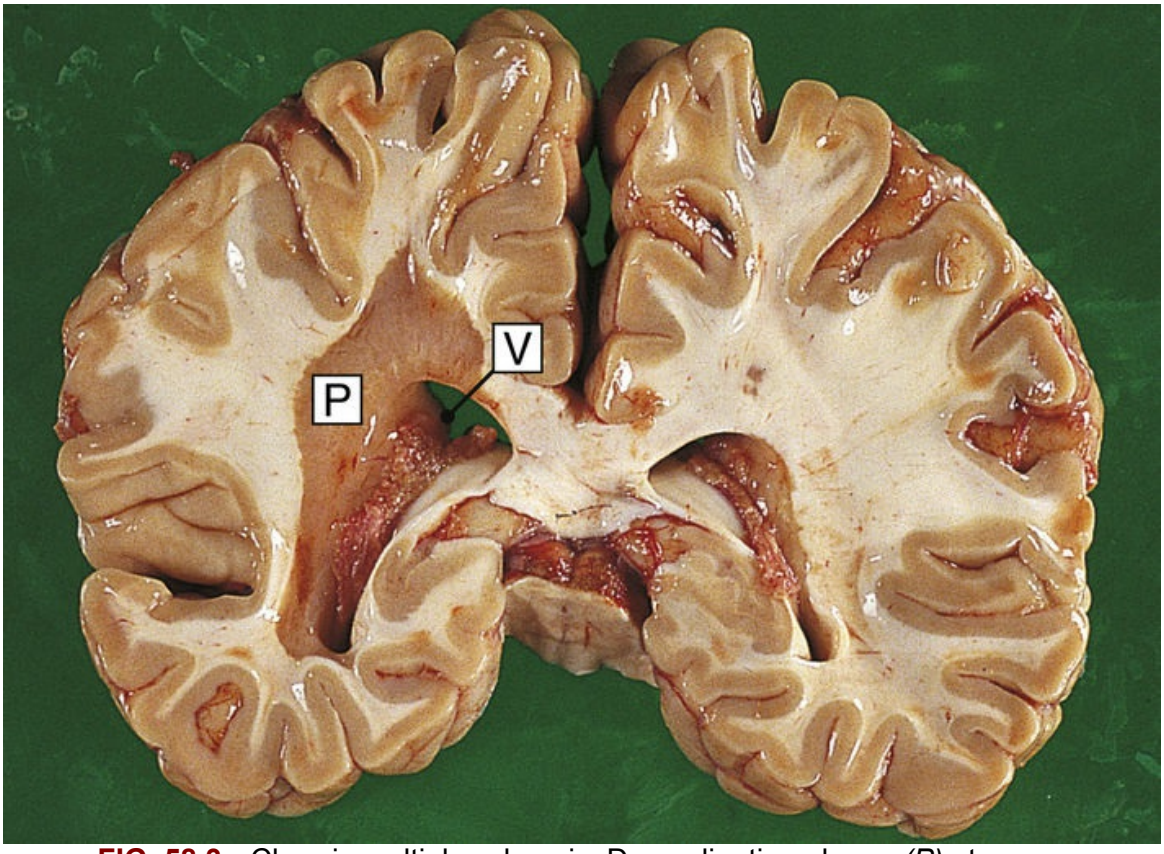

FIG. 58.3 Chronic multiple sclerosis. Demyelination plaque *(P)* at gray-white junction and adjacent partially remyelinated shadow plaque *(V).*
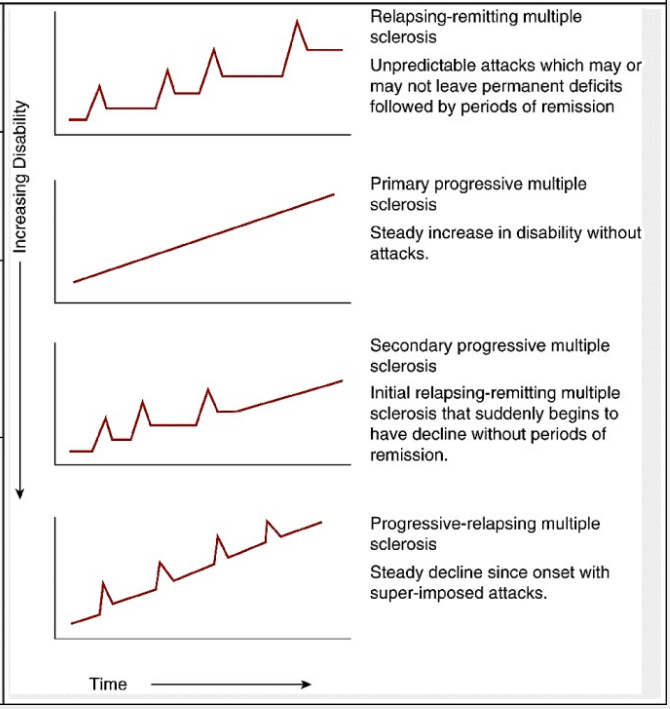
From Stevens A, Lowe J: *Pathology: Illustrated review in colour,* ed 2, London, 2000, Mosby.

The first symptom of MS may be blurred or double vision, red-green color distortion, or even blindness in 1 eye (Fig. 58.4). Many patients describe extremity muscle weakness and problems with coordination and balance. Those symptoms may affect walking or standing. MS can cause partial or complete paralysis in the worst cases. Most have numbness and tingling. *Lhermitte's sign* is a temporary sensory symptom described as an electric shock going down the spine or into the limbs with neck flexion. Some patients report pain, especially in the low thoracic and abdominal regions. Other frequent problems include speech impairments, hearing loss, tremors, and dizziness. Possible cerebellar signs include nystagmus, ataxia, dysarthria, and dysphagia. Many patients have severe, even disabling fatigue. This is worsened by heat, humidity, deconditioning,

and medication side effects.

A rigid plaque is in areas of the CNS that control elimination can bowel and bladder function. Bowel problems usually involve constipation. Urinary problems vary. A common problem in patients with MS is a *spastic* (uninhibited) bladder. The bladder has a small capacity for urine, and its contractions are unchecked. The result is urinary urgency and frequency, often with dribbling or incontinence.



A *flaccid* (hypotonic) bladder occurs with a lesion in the reflex arc controlling bladder function. The patient generally has urinary retention because there is no sensation or desire to void, no pressure, and no pain. Urgency and frequency may be present. A combination of spastic and flaccid bladder can occur. Urinary problems can be diagnosed with urodynamic studies.

Sexual problems occur in many people with MS. Physiologic erectile dysfunction may result from spinal cord involvement in men. Women may have decreased desire for sexual activity (libido), difficulty with orgasm, painful intercourse, and decreased vaginal lubrication. Decreased sensation can prevent a normal sexual response in men and women. The emotional effects of chronic illness and the loss of self-esteem contribute to loss of sexual response. Some women with MS have remission or an improvement in their symptoms during pregnancy. Hormonal changes associated with pregnancy appear to affect the immune system.

About half of people with MS have problems with cognitive function. Most involve problems with short-term memory, attention, information processing, planning, visual perception, and word finding. General intellect stays unchanged and intact. This includes long-term memory, conversational skills, and reading comprehension. Symptoms can be mild and thus easily overlooked. However, about 5% to 10% of patients with MS have such severe cognitive changes that they significantly impair the person's ability to perform activities of daily living (ADLs). Most of the time, cognitive difficulties occur later in the course of the disease. However, they can occur early and sometimes are present at the onset of MS.

TABLE 58.11 Patterns of Multiple Sclerosis

Category	Characteristics
Relapsing-remitting	• Clearly defined attacks of worsening neurologic function *(relapses)* with partial or complete recovery *(remission)*. • 85% of people first diagnosed with this type of MS.
Primary-Progressive	• Steadily worsening neurologic function from the beginning with minor improvements but no distinct relapses or remissions. • 10% of people first diagnosed with this type of MS.
Secondary-progressive	• A relapsing-remitting initial course, followed by progression with or without occasional relapses, minor remissions, and plateaus. • New treatments may slow progression. • Most people initially diagnosed with relapsing-remitting MS eventually transition to this type.
Progressive-relapsing	• Progressive disease from onset, with clear acute relapses, with or without full recovery. Periods between relapses are characterized by continuing progression. • 5% of people with MS.

People with MS may have emotional changes, such as anger, depression, or euphoria. Physical and emotional trauma, fatigue, and infection may worsen or trigger signs and symptoms.

Diagnostic Studies

Because there is no definitive diagnostic test for MS, the history, manifestations, and results of certain diagnostic tests are important (Table 58.12). Imaging in MS is vital. An MRI of the brain and spinal cord may show plaques, inflammation, atrophy, and tissue breakdown and destruction. CSF analysis may show an increase in immunoglobulin G and the presence of oligoclonal banding.[24] Evoked potential responses are often delayed because of decreased nerve conduction from the eye and ear to the brain.

To be diagnosed with MS, the patient must have (1) evidence of at least 2 inflammatory demyelinating lesions in at least 2 different locations within the CNS, (2) damage or an attack occurring at different times (usually 1 month or more apart), and (3) all other possible diagnoses ruled out. If evidence exists for only 1 lesion, or only 1 clinical attack has occurred, the HCP will monitor the patient for another attack or for an attack at a different site in the CNS.

Interprofessional Care

Drug Therapy

Because no cure currently exists for MS, interprofessional care is aimed at treating the disease process and providing symptomatic relief (Table 58.12). No cases of MS are alike, so we tailor therapy to the disease pattern and symptoms of each patient (Table 58.13). Disease-modifying therapy has been found to be more effective when started early in the course of MS. Delays in treatment are linked to poor outcomes.

Treatment of MS begins with use of immunomodulator drugs to modify disease progression and prevent relapses. These drugs include (1) interferon β-1a (Rebif, Plegridy, Avonex), (2) interferon β-1b (Betaseron, Extavia), and (3) glatiramer acetate (Copaxone, Glatopa).

Drug Alert

β-Interferon

- Rotate injection sites with each dose.
- Assess for depression and suicidal ideation.
- Teach patient to wear sunscreen and protective clothing when exposed to sun.
- Tell the patient that flu-like symptoms are common after starting therapy.

Teriflunomide (Aubagio) is an immunomodulatory agent with antiinflammatory properties. The exact mechanism of action is unknown. It may reduce the number of activated lymphocytes in the CNS. Fingolimod (Gilenya) and siponimod (Mayzent)reduce MS disease activity by preventing lymphocytes from reaching the CNS and causing damage. These drugs are used to treat relapsing forms of MS.

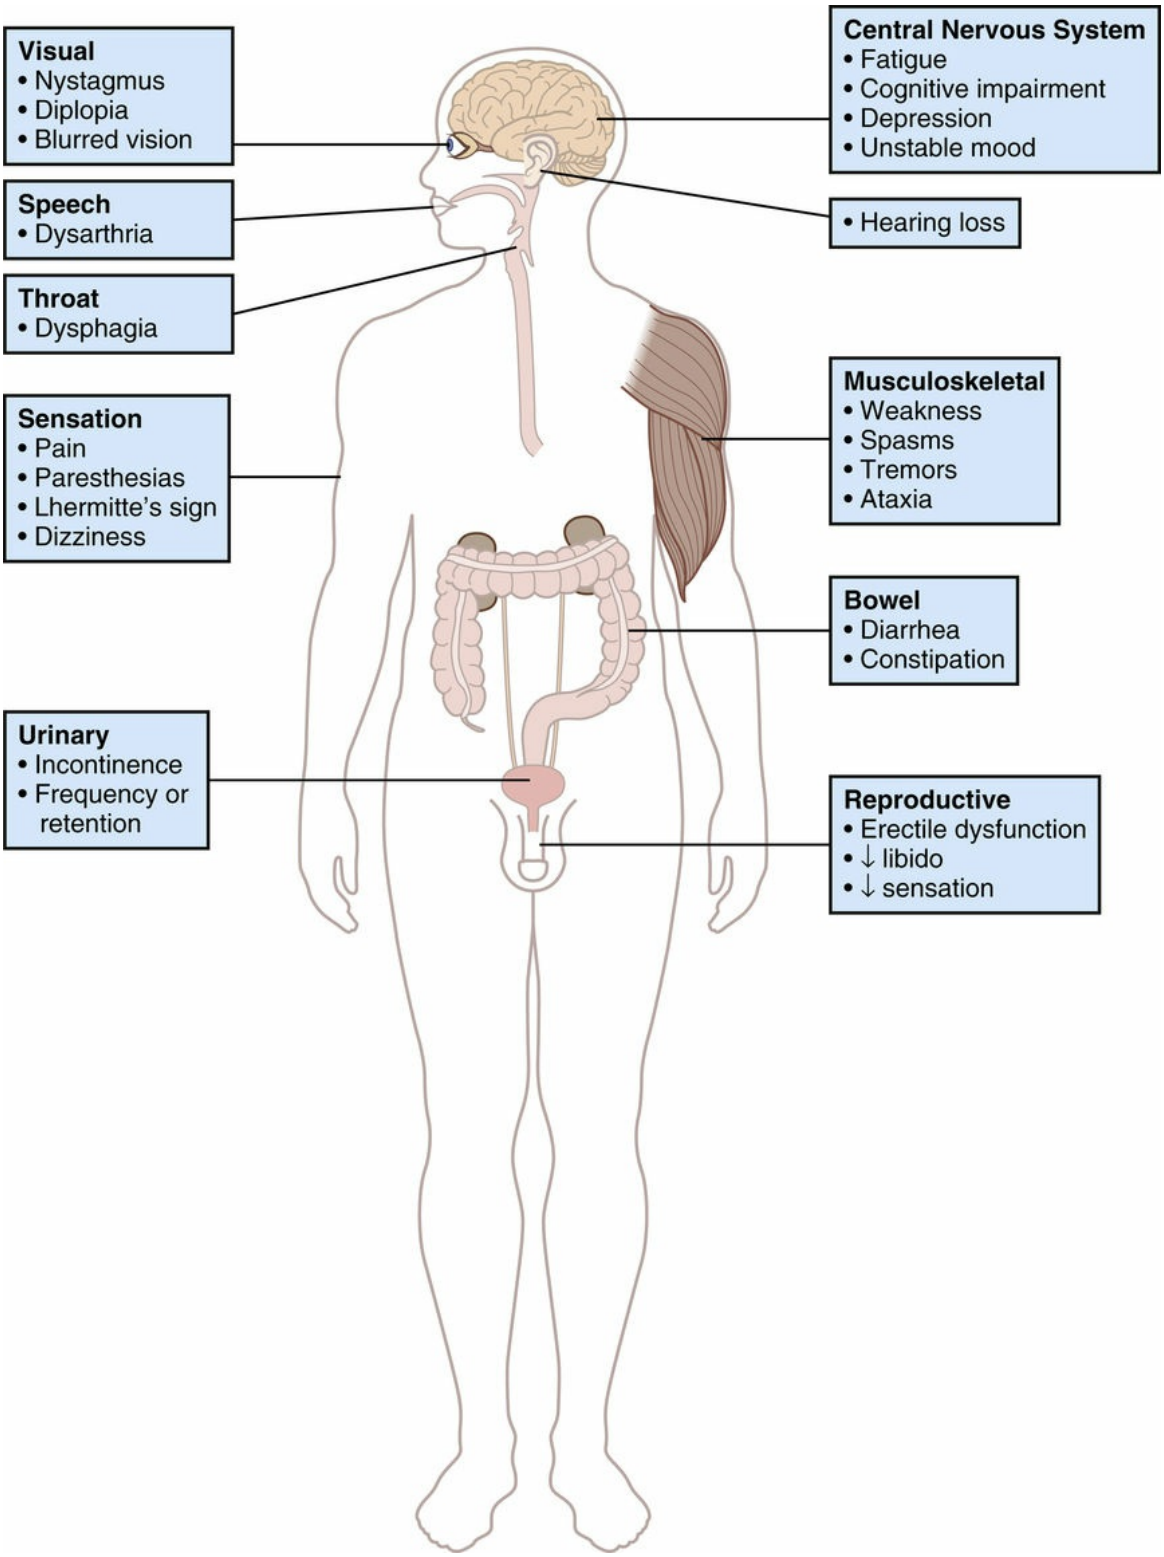


FIG. 58.4 Manifestations of multiple sclerosis.

TABLE 58.12 Interprofessional CareMultiple Sclerosis

Diagnostic Assessment

- History and physical examination
- CSF analysis
- CT scan
- MRI, MRS (magnetic resonance spectroscopy)
- Evoked potential testing
- Somatosensory evoked potential (SSEP)
- Auditory evoked potential (AEP)
- Visual evoked potential (VEP)

Management

- Drug therapy (Table 58.13)
- Surgical therapy
- Thalamotomy (unmanageable tremor)
- Neurectomy, rhizotomy, cordotomy (unmanageable spasticity)
- Physical therapy
- Occupational therapy

For more active and aggressive forms of MS, natalizumab (Tysabri), alemtuzumab (Lemtrada), mitoxantrone, ocrelizumab (Ocrevus), and dimethyl fumarate (Tecfidera) may be used. Natalizumab is given when patients have had an inadequate response to other drugs. An adverse effect of natalizumab is the increased risk for a potentially fatal viral infection of the brain (progressive multifocal leukoencephalopathy). Because of its safety profile, alemtuzumab is reserved for patients who have an inadequate response to 2 or more

drugs used for the treatment of MS.

TABLE 58.13 Drug TherapyMultiple Sclerosis

Drug	Patient Teaching
Disease-Modifying Drugs	
Immunomodulators	
β-1a interferon (Rebif, Plegridy, Avonex) **β-1b interferon (Betaseron, Extavia)** **glatiramer acetate (Copaxone)**	• Perform self-injection techniques. • Report side effects. • Treat flu-like symptoms with an NSAID or acetaminophen.
mavenclad (Cladribine) **teriflunomide (Aubagio)**	• Avoid pregnancy. • No contact with large crowds and people who have an infection. • Follow cancer screening guidelines. • Because it may cause serious liver disease, monitor liver tests. • Avoid pregnancy.
Immunosuppressants	
dimethyl fumarate (Tecfidera) **mitoxantrone**	• Report side effects. • Avoid pregnancy. • No contact with large crowds and people who have an infection.
Monoclonal Antibody	
alemtuzumab (Lemtrada) **daclizumab (Zinbryta)** **natalizumab (Tysabri)**	• Report side effects. • Avoid pregnancy.
Sphingosine 1-Phosphate Receptor Modulators	
fingolimod (Gilenya) **siponimod (Mayzent)**	• Report side effects. • Monitor blood pressure and heart rate regularly. • Avoid pregnancy.
Drugs for Managing Exacerbations	
Corticosteroids	
ACTH **methylprednisolone** **prednisone**	• Restrict salt intake. • Do not abruptly stop therapy. • Know drug interactions.
Drugs for Symptom Management	
Anticholinergics	
oxybutynin (Ditropan XL) **propantheline**	• Consult HCP before using other drugs, especially sleeping aids, antihistamines (possibly leading to potentiated effect).
Cholinergics	
bethanechol (Urecholine) **neostigmine**	• Consult with HCP before using other drugs, including OTC drugs.
Muscle Relaxants	
baclofen (Lioresal) **dantrolene (Dantrium)** **diazepam (Valium)** **tizanidine (Zanaflex)**	• Avoid driving and similar activities because of sedative effects. • Do not abruptly stop therapy. • Do not use with tranquilizers and alcohol.
Nerve Conduction Enhancer	
dalfampridine (Ampyra)	• Be aware that it may cause seizures, especially at higher doses. • Take the tablet whole. Do not take more than 2 in 24 hr.

Mitoxantrone is an antineoplastic medication with serious effects.

These include cardiotoxicity, leukemia, and infertility. Use of ocrelizumab increases the risk for breast cancer. Dimethyl fumarate treats MS by activating the Nrf2 pathway. This pathway provides a way for cells in the body to defend themselves against the inflammation and oxidative stress caused by MS.

Corticosteroids (e.g., methylprednisolone, prednisone) are most helpful to treat acute exacerbations of MS. They reduce edema and acute inflammation at the site of demyelination. However, they do not affect the ultimate outcome or the degree of residual neurologic impairment from disease exacerbation. Therapeutic plasma exchange *(plasmapheresis)* and IV immunoglobulin G may be considered for a short time when treatment with corticosteroids alone does not achieve symptom improvement.

Many other drugs are used to treat the various symptoms of MS. These may include drugs for spasticity, fatigue, tremor, vertigo or dizziness, depression, pain, bowel and bladder problems, sexual problems, and cognitive changes. For example, amantadine, modafinil (Provigil), and fluoxetine (Prozac) are used to treat fatigue. Anticholinergics can treat bladder symptoms. Tricyclic antidepressants and antiseizure drugs are used for chronic pain syndromes.

Dalfampridine (Ampyra) may improve walking speed in MS patients. It is a selective potassium channel blocker that improves nerve conduction in damaged nerve segments. It should not be used in patients with a history of seizure disorder or with moderate to severe kidney disease.

Other Therapies

Spasticity is treated mainly with muscle relaxants. Other options include surgery (e.g., neurectomy, rhizotomy, cordotomy), dorsal-column electrical stimulation, or intrathecal baclofen (Lioresal). Tremors that become unmanageable with drugs are sometimes treated by thalamotomy or deep brain stimulation.

Neurologic dysfunction sometimes improves with physical and speech therapy. Exercise improves daily functioning for patients not

having an exacerbation. Exercise decreases spasticity, increases coordination, and retrains unaffected muscles to act for impaired ones. An especially beneficial type of physical therapy is water exercise (Fig. 58.5). Water, which gives buoyancy to the body, allows the patient to have more control over the body and perform activities that would otherwise be impossible.

FIG. 58.5 Water therapy provides exercise and recreation for the patient with a chronic neurologic disease.

Nursing Management: Multiple Sclerosis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with MS are outlined in Table 58.14.

Nursing Diagnoses

Nursing diagnoses for the patient with MS may include:

- Impaired physical mobility
- Difficulty coping
- Urinary retention

Additional information on nursing diagnoses and interventions for the patient with MS is presented in the eNursing Care Plan 58.3 (available on the website for this chapter).

Planning

The overall goals are that the patient with MS will (1) maximize neuromuscular function, (2) maintain independence in ADLs for as long as possible, (3) manage fatigue, (4) optimize psychosocial well-being, (5) adjust to the illness, and (6) reduce factors that precipitate exacerbations.

TABLE 58.14 Nursing AssessmentMultiple Sclerosis

Subjective Data

Important Health Information

Past health history: Recent or past viral infections or vaccinations, other recent infections, residence in cold or temperate climates, recent physical or emotional stress, pregnancy, exposure to extremes of heat and cold

Medications: Adherence to regimen of corticosteroids, immunomodulators, immunosuppressants, cholinergics, anticholinergics, antispasmodics

Functional Health Patterns

Health perception–health management: Positive family history; malaise
Nutritional-metabolic: Weight loss; difficulty in chewing, dysphagia
Elimination: Urinary frequency, urgency, dribbling or incontinence, retention; constipation
Activity-exercise: Generalized muscle weakness, muscle fatigue; tingling and numbness; ataxia (clumsiness)
Cognitive-perceptual: Eye, back, leg, joint pain; painful muscle spasms; vertigo; blurred or lost vision; diplopia; tinnitus
Sexuality-reproductive: Impotence, decreased libido
Coping–stress tolerance: Anger, depression, euphoria, social isolation

Objective Data
General

Apathy, inattentiveness

Integumentary

Pressure ulcers

Neurologic

Nystagmus, ataxia, tremor, spasticity, hyperreflexia, decreased hearing

Musculoskeletal

Muscle weakness, paresis, paralysis, spasms, foot dragging, dysarthria

Possible Diagnostic Findings

↓ T suppressor cells, demyelinating lesions on MRI or MRS scans, ↑ IgG or oligoclonal banding in CSF, delayed evoked potential responses

IgG, Immunoglobulin G; *MRS,* magnetic resonance spectroscopy.

Nursing Implementation

The patient with MS should be aware of triggers that may cause worsening of the disease. These include infection (especially upper respiratory and urinary tract infections [UTIs]), trauma, immunization, childbirth, stress, and change in climate. Each person responds differently to triggers. Help the patient identify triggers and develop ways to avoid them or decrease their effects.

During the diagnostic phase, reassure the patient that certain diagnostic studies must be done to rule out other neurologic disorders, even if a tentative diagnosis of MS has been made. Help the patient to deal with anxiety caused by a diagnosis of a disabling illness. The patient with recently diagnosed MS may need help with the grieving process.

During an acute exacerbation, the patient may be immobile and confined to bed. The focus of nursing interventions at this phase is to prevent complications of immobility. These include respiratory and UTIs and pressure injuries.

Focus patient teaching on general resistance to illness. This includes avoiding fatigue, extremes of heat and cold, and exposure to infection. Encourage early treatment of infection when it occurs. Teach the patient to seek a good balance of exercise and rest; minimize caffeine intake; and eat nutritious, well-balanced meals. The patient should know the treatment plan, drug side effects, how to identify and

manage side effects, and drug interactions with over-the-counter (OTC) drugs. The patient should consult the HCP before taking any OTC drugs.

Bladder control is a major problem for many patients with MS. Anticholinergics may help some patients to decrease spasticity. You may need to teach others self-catheterization. Constipation is common. A diet high in fiber may help relieve constipation.

The patient with MS and caregivers need to make many emotional adjustments because of disease unpredictability, the need for lifestyle changes, and the challenge of avoiding or decreasing precipitating factors. The uncertainty of disease progression, along with fatigue and decreased mobility, can cause anxiety and depression. The National Multiple Sclerosis Society and its local chapters offer a variety of services to meet the needs of patients with MS.

Evaluation

The expected outcomes are that the patient with MS will

- Maintain or improve muscle strength and mobility
- Use assistive devices appropriately for ambulation and mobility
- Maintain urinary continence
- Make decisions about health and lifestyle modifications to manage MS

Parkinson's Disease

Parkinson's disease (PD) is a chronic, progressive neurodegenerative disorder characterized by slowness in the initiation and execution of movement *(bradykinesia),* increased muscle tone *(rigidity),* tremor at rest, and gait changes. It is the most common form of *parkinsonism* (a syndrome characterized by similar symptoms).

Up to 1 million Americans will be living with PD by 2020. 60,000 persons are diagnosed each year. Incidence of PD increases with age,

though 4% of people with PD are diagnosed before age 50 years. Men are 1.5 times more likely to have PD than women.[25]

Etiology and Pathophysiology

The exact cause of PD is unknown. Although we do not consider PD a hereditary condition, genetic risk factors should be evaluated for their interplay with environmental factors. Exposure to well water, pesticides, herbicides, industrial chemicals, and wood pulp mills may increase risk for PD. Rural residence is considered a risk factor.[25]

Many forms of secondary *(atypical)* parkinsonism exist other than PD. Symptoms of parkinsonism have occurred after exposure to a variety of chemicals, including carbon monoxide and manganese (among copper miners). Drug-induced parkinsonism can follow therapy with metoclopramide (Reglan), reserpine, methyldopa, lithium, haloperidol (Haldol), and chlorpromazine. It can be seen after the use of illicit drugs, including amphetamine and methamphetamine. After stopping these drugs, symptoms of parkinsonism generally disappear. One notable exception is irreversible parkinsonism that follows exposure to the product of meperidine analog synthesis (MTPT). Other causes include hydrocephalus, other neurodegenerative disorders, hypoparathyroidism, infections, stroke, tumor, and trauma.

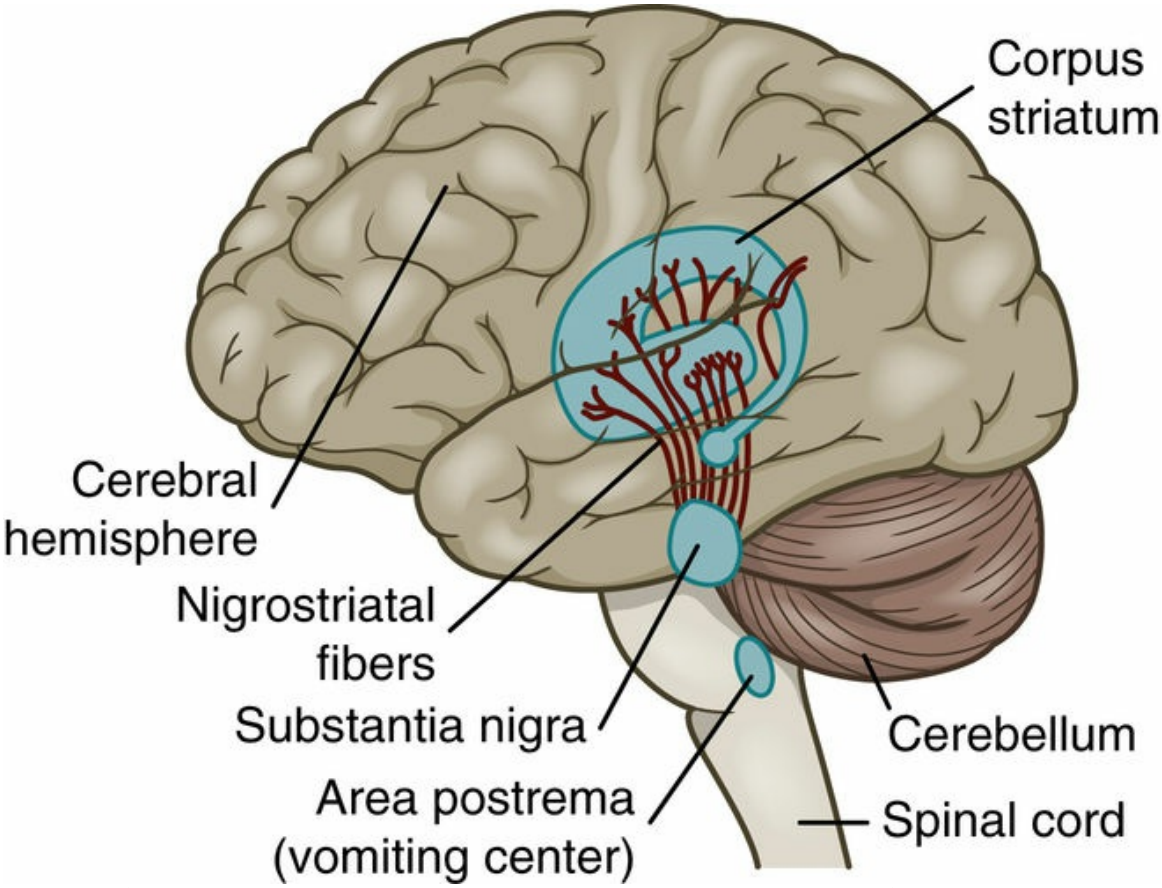

FIG. 58.6 Nigrostriatal disorders produce parkinsonism. Left-sided view of the human brain showing the substantia nigra and the corpus striatum *(shaded area)* lying deep within the cerebral hemisphere. Nerve fibers extend upward from the substantia nigra, divide into many branches, and carry dopamine to all regions of the corpus striatum.

Many changes found in the brains of people with PD may play a part in development of the disease, including a lack of DA. The pathologic process of PD involves degeneration of the DA-producing neurons in the substantia nigra of the midbrain (Figs. 58.6 to 58.8). This in turn disrupts the normal balance between DA and acetylcholine (ACh) in the basal ganglia. The neurotransmitter DA is essential for normal functioning of the extrapyramidal motor system, including control of posture, support, and voluntary motion. Manifestations of PD do not occur until 80% of neurons in the substantia nigra are lost.

Unusual clumps of protein called *Lewy bodies* are found in the brains of patients with PD. It is not known what causes Lewy bodies to form.

Their presence indicates abnormal brain functioning. Lewy body dementia is discussed in Chapter 59.

Genetic Link

We do not fully understand how genetic changes cause PD or influence the risk for developing PD. Around 15% of patients with PD have a family history of PD. Many autosomal dominant and recessive genes are linked to familial PD. Autosomal dominant PD is rare, affecting only 1% to 2% of people with PD. Examples include the *SNCA* and *LRRK2* genes.[25] Mutations in the *LRRK2* gene also appear to have a role in noninherited (sporadic) cases of PD. Recessive genes include parkin *(PARK2, PARK7)*, and *PINK1*. Mutations in these genes are often associated with a younger age of disease onset. They also have more manifestations compared to those typically seen with age-related PD. *PINK1* mutations are related to a rare, early-onset form of PD.

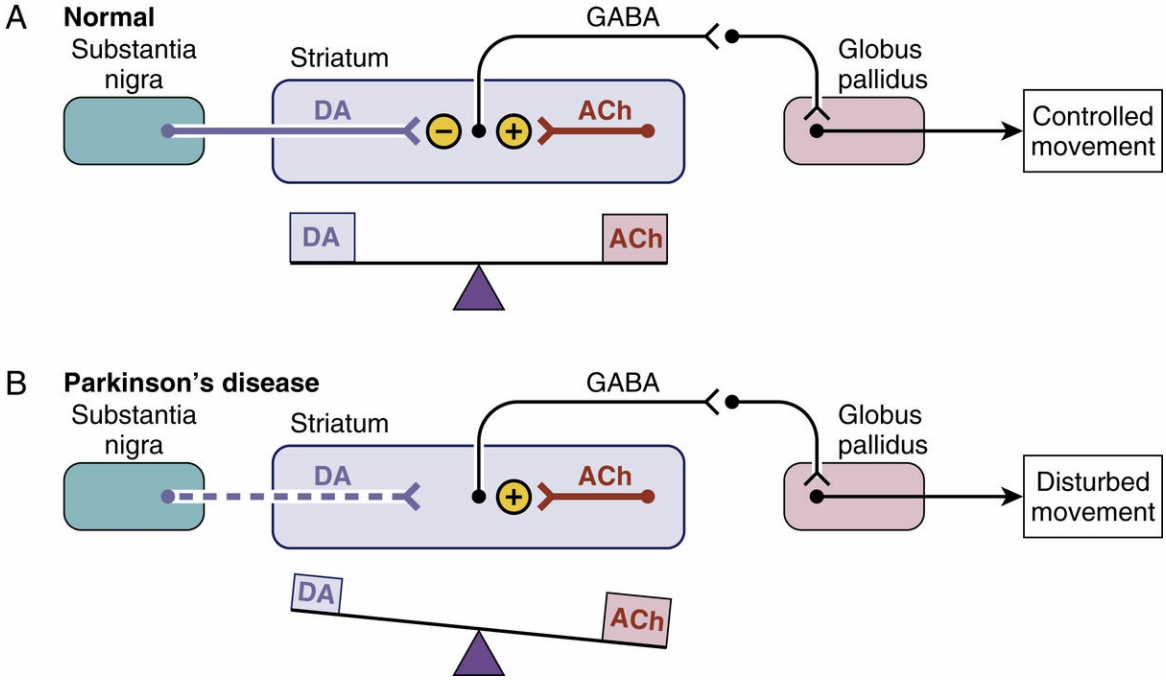

FIG. 58.7 A deficit in dopamine *(DA)* exists in Parkinson's disease. This deficit creates an imbalance between DA and the excitatory neurotransmitter acetylcholine. **A,** In a healthy person, DA released

from neurons in the substantia nigra inhibits the firing of neurons in the striatum that release γ-aminobutyric acid *(GABA).* Conversely, neurons in the striatum, which release acetylcholine *(ACh),* excite the GABAergic neurons. Under normal conditions, inhibitory actions of DA are balanced by excitatory actions of ACh, and controlled movement results. **B,** In Parkinson's disease, neurons in the substantia nigra that supply DA to the striatum degenerate. When a deficit of DA occurs, excitatory effects of ACh go unopposed and disturbed movements (tremor, rigidity) result.
From Lehne RA: *Pharmacology for nursing care,* ed 8, St Louis, 2013, Saunders.

Clinical Manifestations

The onset of PD is gradual, with an ongoing progression. Only 1 side of the body may be involved at first. Classic manifestations can be remembered by the mnemonic *TRAP* (**t**remor, **r**igidity, **a**kinesia, **p**ostural instability). Early in the disease, only a mild tremor, a slight limp, or a decreased arm swing may be seen. Later, the patient may have a shuffling gait and appear unable to stop. The patient's arms are flexed, and postural reflexes seem to be lost. The patient may have speech problems *(hypokinetic dysarthria)* that can affect communication and quality of life.

Tremor

Tremor is often the first sign. It may be minimal at first, so the patient is the only one who notices it. This tremor can affect handwriting, causing it to trail off, especially toward the ends of words. Parkinsonian tremor is more prominent at rest. It is worsened by emotional stress or increased concentration. The hand tremor is described as "pill rolling" because the thumb and forefinger appear to move in a rotary fashion as if rolling a pill, coin, or other small object. Tremor can involve the diaphragm, tongue, lips, and jaw. It rarely causes shaking of the head.

Unfortunately, in many people a benign *essential tremor* is mistakenly diagnosed as PD. Essential tremor occurs during voluntary movement, has a more rapid frequency than parkinsonian tremor, and is often familial.

Rigidity

Rigidity is the increased resistance to passive motion when the limbs are moved through their range of motion (ROM). Parkinsonian rigidity is typified by a jerky quality *(cogwheel rigidity),* as if there were occasional catches in the passive movement of a joint. Sustained muscle contraction causes the rigidity and results in muscle soreness; feeling tired and achy; or pain in the head, upper body, spine, or legs. Slow movement is another result of rigidity because the alternating contraction and relaxation in opposing muscle groups (e.g., biceps and triceps) is inhibited.

Akinesia

Akinesia is the absence or loss of control of voluntary muscle movements. In PD, *bradykinesia* (slowness of movement) is especially evident in the loss of automatic movements. This occurs because of the physical and chemical change of the basal ganglia and other structures in the extrapyramidal portion of the CNS. In the unaffected patient, automatic movements are involuntary and occur subconsciously. They include blinking of the eyelids, swinging of the arms while walking, swallowing saliva, using facial and hand movements for self-expression, and making minor movements to adjust posture.

The patient with PD does not perform these movements and lacks natural activity. This accounts for the stooped posture, masked face (deadpan expression), drooling of saliva, and shuffling gait *(festination)* that are typical of a person with PD. The posture is that of a slowed "old man" image, with the head and trunk bent forward and the legs constantly flexed (Fig. 58.9).

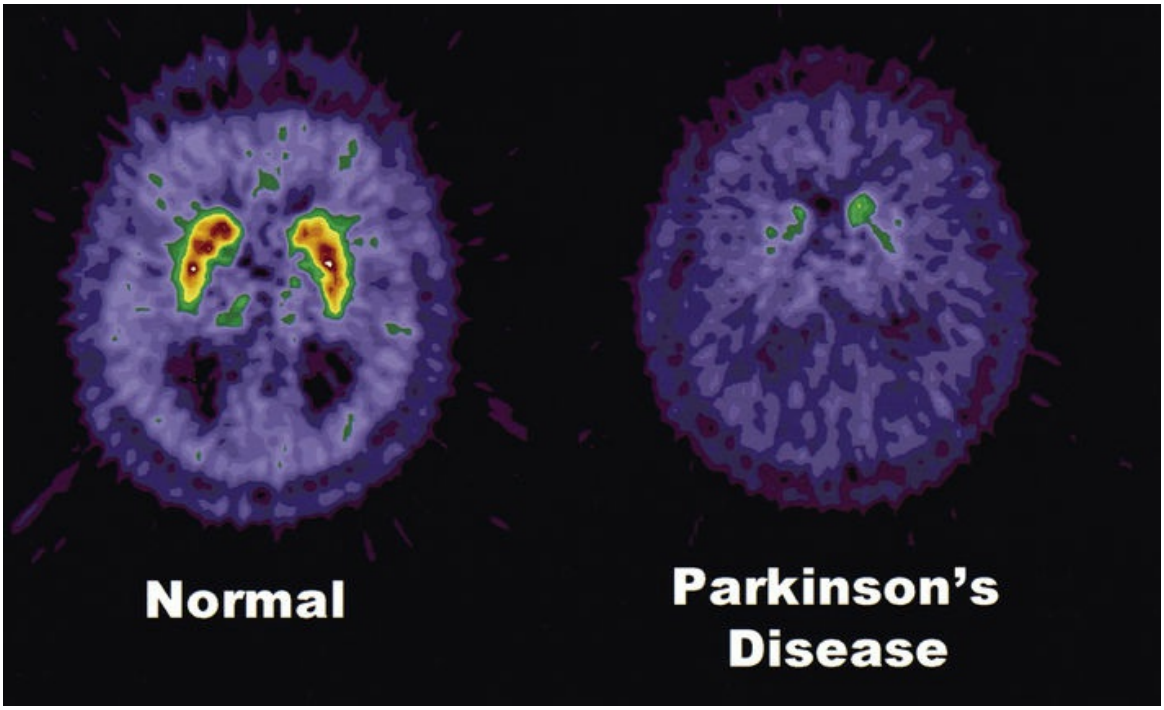

FIG. 58.8 In Parkinson's disease, PET scan showing reduced fluorodopa uptake in the basal ganglia *(right)* compared with a normal control *(left).*
From Aminoff MJ, Daroff RB: *Encyclopedia of the neurological sciences,* Waltham, MA, 2003, Academic Press.

Postural Instability

Postural instability is common. Patients may describe being unable to stop themselves from going forward *(propulsion)* or backward *(retropulsion).* Assessment of postural instability includes the "pull test." The examiner stands behind the patient and gives a tug backward on the shoulder, causing the patient to lose their balance and fall backward.

Many nonmotor symptoms are common. They include depression, anxiety, apathy, fatigue, pain, urinary retention, constipation, erectile dysfunction, and memory changes. Sleep problems are common. They include difficulty staying asleep at night, restless sleep, nightmares, and drowsiness or sudden sleep onset during the day. Rapid eye movement (REM) sleep behavior disorder is a preparkinsonian state that occurs in about one third of patients with PD. It is characterized by violent dreams and potentially dangerous motor activity during

REM sleep. It may cause harm to the patient or bed partner.[26]

Complications

As PD progresses, complications increase. These include motor symptoms (e.g., dyskinesias [spontaneous, involuntary movements], weakness, neurologic problems (e.g., dementia), and neuropsychiatric problems (e.g., depression, hallucinations, psychosis). As PD progresses, dementia often results and is associated with increased mortality.

As swallowing becomes more difficult (dysphagia), malnutrition or aspiration may result. Increasing weakness may lead to pneumonia, UTIs, and skin breakdown. Orthostatic hypotension is common. Along with loss of postural reflexes, it can cause falls or other injury. The patient's increased fall risk means caregivers must be aware of environmental conditions that may contribute to falls.

Diagnostic Studies

Because no specific diagnostic test exists for PD, diagnosis is based on the patient's history and clinical features. Clinical diagnosis requires the presence of TRAP and asymmetric onset. Confirmation of PD is a positive response to antiparkinsonian drugs (levodopa or DA agonist). MRI and CT have a limited role in diagnosis of PD because they do not show a specific pathologic finding. However, they can rule out a stroke or brain tumor.

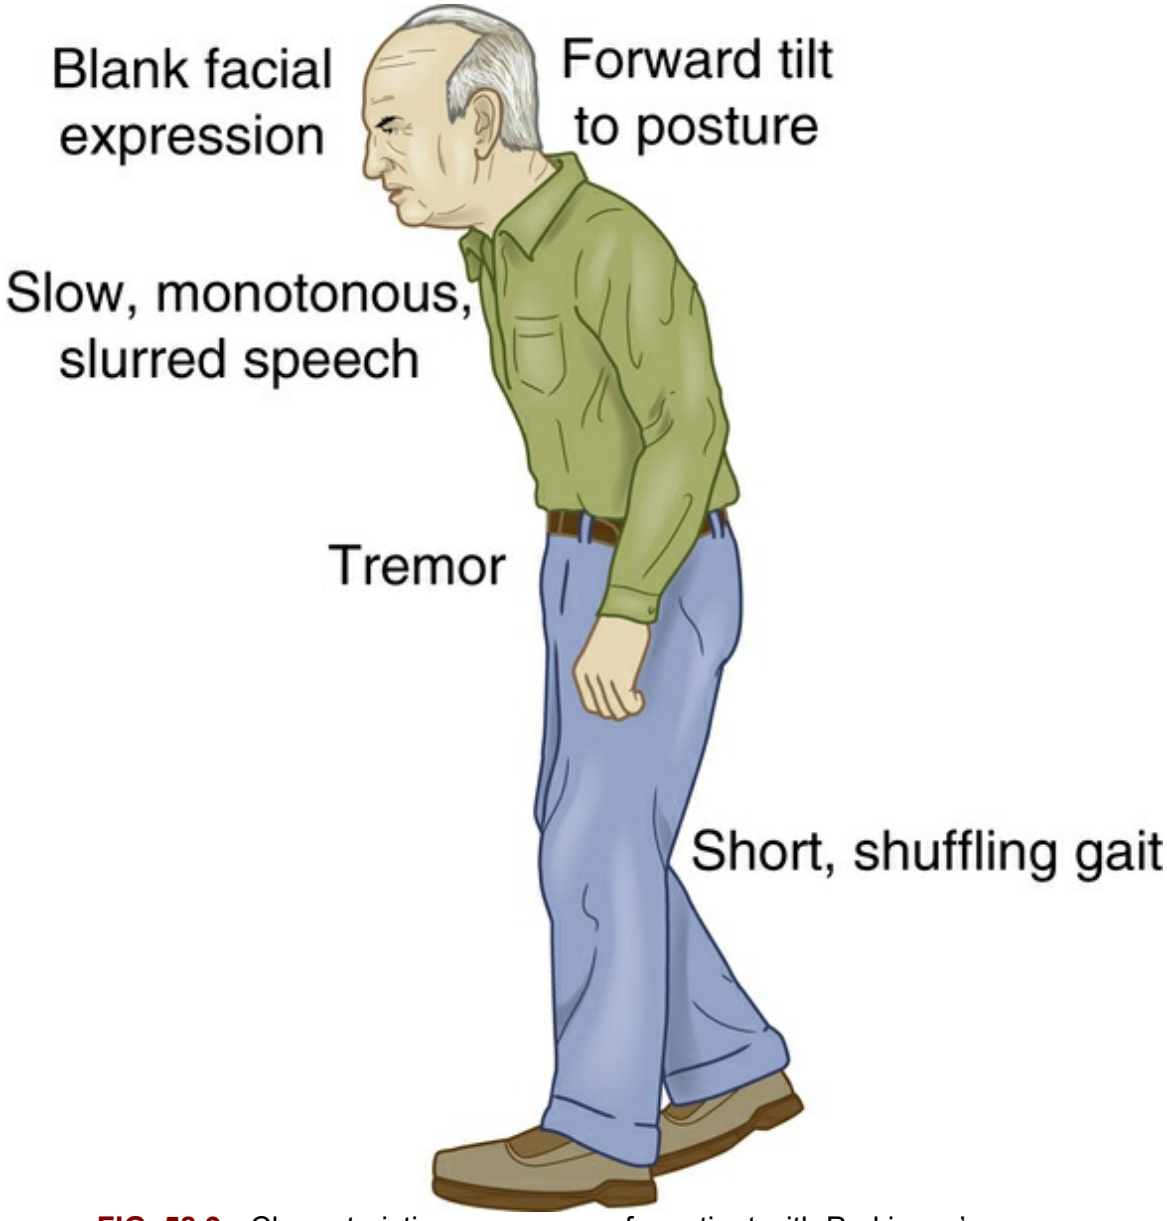

FIG. 58.9 Characteristic appearance of a patient with Parkinson's disease.

Evidence-Based Practice

Exercise and Parkinson's Disease

You are a nurse working with T.K, a 77-yr-old man who has had Parkinson's disease (PD) for 5 years. You note he has a moderate

tremor, shuffling gait, and decreased arm flexion. He asks you what types of physical activity he can do to improve his mobility and balance.

Making Clinical Decisions

Best Available Evidence. Patients with mild to moderately severe PD have improvements in gait performance and health-related quality of life after taking part in exercise programs. Facility-based programs produce greater effects on improving balance and mobility over the short and long term. Exercise training to improve balance and gait ability may prevent falls in people with PD.

Clinician Expertise. You know it is important to promote and encourage patients with PD to take part in physical exercise to help improve or maintain functional mobility and prevent falls. You are aware that we should design exercise programs around physical activities the person enjoys.

Patient Preferences and Values. T.K. says that in years past, he enjoyed dancing with his wife and currently likes to walk in his neighborhood.

Implications for Nursing Practice

1. What information will you provide to T.K. about muscle atrophy and joint contractures and the importance of physical activity?
2. How will you help T.K. and his wife in exploring community resources and programs related to physical activities that support his interests?

Interprofessional Care

Because PD has no cure, interprofessional care focuses on symptom management (Table 58.15).

Drug Therapy

Drug therapy for PD is aimed at correcting the imbalance of neurotransmitters within the CNS. Antiparkinsonian drugs either enhance the release or supply of DA (dopaminergic) or block the effects of the overactive cholinergic neurons in the striatum (anticholinergic) (Fig. 58.7). Levodopa with carbidopa (Sinemet) is the primary treatment for symptomatic patients. Levodopa is a chemical precursor of DA and can cross the blood-brain barrier. It is converted to DA in the basal ganglia. Sinemet is the preferred drug because it also contains carbidopa, an agent that inhibits the enzyme dopa-decarboxylase in the peripheral tissues. Dopa-decarboxylase breaks down levodopa before it reaches the brain. The net result of using this combination is that more levodopa reaches the brain. Thus less drug is needed. Levodopa has many side effects and drug interactions. Prolonged use often results in dyskinesias and "off/on" periods when the medication will unpredictably stop or start working.

Drug Alert

Carbidopa/Levodopa (Sinemet)

- Monitor for signs of dyskinesia.
- Monitor for short-term adverse effects of nausea, vomiting, and

light-headedness.

- Stress that effects may be delayed for several weeks to months.
- Teach patient or caregiver to report any uncontrolled movement of face, eyelids, mouth, tongue, arms, hands, or legs; mental changes; palpitations; and difficulty urinating.
- Do not give levodopa with food because protein reduces absorption.

Many patients receive Sinemet early in the disease course for the management of motor symptoms. However, some HCPs think that, after a few years of therapy, the effectiveness of Sinemet wears off. Therefore they prefer to start therapy with a DA receptor agonist, a drug that directly stimulates DA receptors. Ropinirole (Requip) and pramipexole (Mirapex) may be used alone or in combination with Sinemet. Many of these medications are available in extended-release forms that improve patients' ability to adhere to treatment plans. Rotigotine (Neupro), another DA receptor agonist, is available as a transdermal patch applied once daily. It is an adjunctive therapy for patients taking Sinemet.

Drug Alert

Pramipexole (Mirapex)

- Take the drug with food to decrease nausea.
- Notify the HCP immediately if uncontrollable urges, confusion, muscle rigidity, excess urination, shortness of breath, or vision changes occur.

The antiviral agent amantadine is a weak antagonist of NMDA-type glutamate receptors. It increases DA release and blocks DA reuptake. It may be useful as a single therapy for early PD. It can be used later with levodopa. As a single treatment, amantadine often becomes less

effective after a few months.[27] Withdrawal of amantadine even after extended therapy can worsen dyskinesia.

Anticholinergic drugs, such as trihexyphenidyl and benztropine (Cogentin), decrease the activity of ACh, providing balance between cholinergic and dopaminergic actions.[27] Antihistamines (e.g., diphenhydramine) with anticholinergic properties may be used to manage tremors.

Selegiline (Eldepryl), rasagiline (Azilect), and safinamide (Xadago) are monoamine oxidase type B (MAO-B) inhibitors that may be used in combination with Sinemet.[27] By inhibiting MAO-B, the enzyme that degrades DA, these agents increase the levels of DA and prolong the half-life of levodopa. Rasagiline can be used alone as therapy in early PD. However, MAO-B inhibitors are less effective at treating motor symptoms than DA receptor agonists.

Entacapone (Comtan) and tolcapone (Tasmar) block the enzyme catechol *O*-methyltransferase (COMT), which breaks down levodopa in the peripheral circulation. Thus, they prolong the effect of Sinemet and are used only as adjuncts. They are often used when the patient's response to levodopa is wearing off at the end of the dosing interval. Tolcapone is rarely prescribed because it is associated with fatal hepatotoxicity.[27]

Rivastigmine (Exelon) or donepezil (Aricept) is used to treat dementia. Amitriptyline may be used to treat depression.

TABLE 58.15 Interprofessional CareParkinson's Disease

Diagnostic Assessment

- History and physical examination
- TRAP (tremor, rigidity, akinesia, postural instability)
- Positive response to antiparkinsonian drugs
- MRI

- Rule out side effects of phenothiazines, reserpine, benzodiazepines, haloperidol

Management

- Antiparkinsonian drugs (Table 58.16)
- Surgical therapy
- Deep brain stimulation
- Ablation surgery
- Physical therapy
- Occupational therapy
- Dietitian consult for nutritional therapy

Table 58.16 outlines the drugs commonly used in PD. The use of only 1 drug is preferred because fewer side effects occur and the drug dosage is easier to adjust than when several drugs are used. However, as PD progresses, combination therapy is often needed. Excessive amounts of dopaminergic drugs can worsen rather than relieve symptoms *(paradoxical intoxication)*.

Within 3 to 5 years of standard PD treatments, many patients have episodes of hypomobility (e.g., inability to rise from chair, speak, or walk; also called *off episodes*). Off episodes can occur toward the end of a dosing interval with standard medications (so-called *end-of-dose wearing off*) or at unpredictable times (spontaneous "on/off"). A combination of carbidopa, levodopa, and entacapone (Stalevo) is available for patients with end-of-dose wearing off. It can be prescribed to make dosing easier, with 1 pill substituting for 3. Stalevo is typically prescribed for patients with advanced PD with intense motor fluctuations. The injectable DA receptor agonist apomorphine (Apokyn) can improve movement in hypomobility episodes. Apomorphine must be taken with an antiemetic drug because it causes severe nausea and vomiting when taken alone. It cannot be taken with antiemetics in the serotonin (5-HT3) receptor antagonist

class (e.g., ondansetron [Zofran]). This combination can lead to very low BP and loss of consciousness.

TABLE 58.16 Drug TherapyParkinson's Disease

Drug	Mechanism of Action
Dopaminergics	
Dopamine Precursors	
levodopa (L-dopa) **levodopa/carbidopa (Sinemet)**	Converted to dopamine in basal ganglia
Dopamine Receptor Agonists	
pramipexole (Mirapex) **ropinirole (Requip, Requip XL)** **rotigotine (Neupro [transdermal patch])**	Stimulate dopamine receptors
Dopamine Agonists	
amantadine	Blocks NMDA-type glutamate receptors, increases dopamine release, and blocks dopamine reuptake
apomorphine (Apokyn)	Stimulates postsynaptic dopamine receptors
Anticholinergics	
benztropine (Cogentin) **trihexyphenidyl**	Block cholinergic receptors, thus helping to balance cholinergic and dopaminergic activity
Antihistamine	
diphenhydramine	Has anticholinergic effect
Monoamine Oxidase Inhibitors	
rasagiline (Azilect) **safinamide (Xadago)** **selegiline (Eldepryl)**	Block breakdown of dopamine
Catechol *O*-Methyltransferase (COMT) Inhibitors	
entacapone (Comtan) **tolcapone (Tasmar)**	Block COMT and slow the breakdown of levodopa, thus prolonging the action of levodopa

Surgical Therapy

Surgical procedures to relieve symptoms of PD are usually used in patients who are not responsive to drug therapy or who have developed severe motor complications. Surgical procedures fall into 3 categories: deep brain stimulation (DBS), ablation (destruction), and transplantation. The most common surgical treatment is DBS. This involves placing an electrode in the thalamus, globus pallidus, or subthalamic nucleus and connecting it to a generator placed in the upper chest (similar to a pacemaker) (Fig. 58.10). The device is programmed to deliver a specific current to the targeted brain

location. DBS is preferred to ablation procedures because it is reversible and programmable. It can be safely done bilaterally. DBS reduces the increased neuronal activity produced by DA depletion. It can improve motor function and reduce dyskinesia and medication use. DBS is most effective when patients are carefully selected and screened.[27]

Ablation surgery involves finding, targeting, and destroying an area of the brain affected by PD. The goal is to destroy tissue that produces abnormal chemical or electrical impulses leading to tremors or other symptoms. Typical targets of ablation are the thalamus *(thalamotomy)* and globus pallidus *(pallidotomy)*.[27] Newer treatments, such as the gamma knife and focused ultrasound, are noninvasive options.

Transplantation of fetal neural tissue into the basal ganglia was designed to provide DA-producing cells in the brains of patients with PD. Research of this therapy was largely abandoned after mixed results over several decades. In the last few years, better transplant techniques have renewed interest in this as a potential option.

Nutritional Therapy

Diet is of major importance to patients with PD because malnutrition and constipation can result from poor nutrition. Patients who have dysphagia and bradykinesia need appetizing foods that are easy to chew and swallow. The diet should contain adequate fiber and fruit to reduce constipation.

Eating 6 small meals a day may be less tiring than eating 3 large meals a day. Plan ample time for eating to avoid frustration. Cut food into bite-sized pieces. Protein ingestion and vitamin B_6 can impair the absorption of levodopa. Limiting protein intake to the evening meal can decrease this problem. They may need to consult with the HCP about including vitamin B_6 in a multivitamin and fortified cereals.

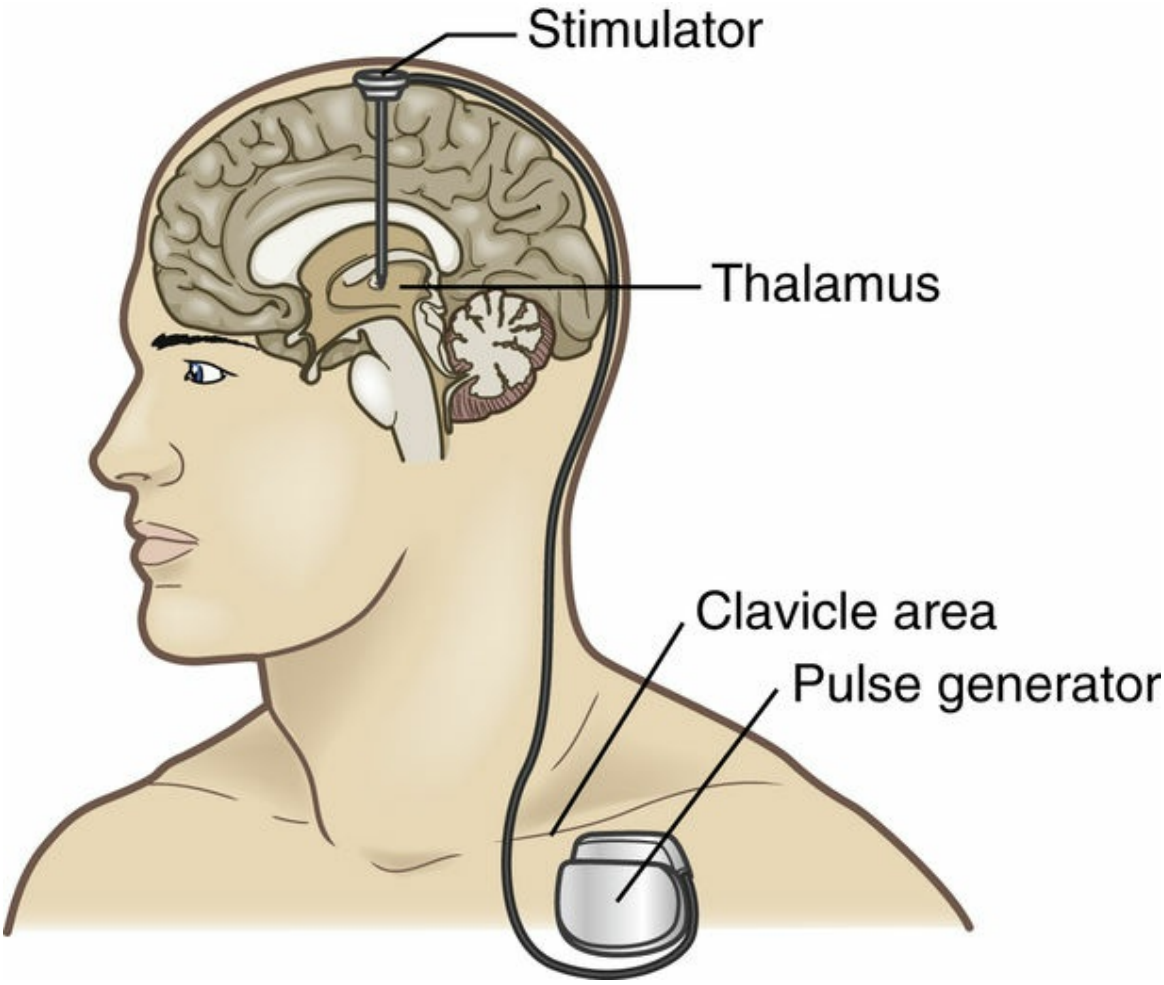

FIG. 58.10 Deep brain stimulation (DBS) can be used to treat tremors and uncontrolled movements of Parkinson's disease. Electrodes are surgically placed in the brain and connected to a neurostimulator (pacemaker device) in the chest.

Nursing Management: Parkinson's Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with PD are outlined in Table 58.17.

Nursing Diagnoses

Nursing diagnoses for the patient with PD may include:

- Impaired physical mobility
- Impaired nutritional status
- Risk for fall-related injury
- Impaired sleep pattern

Additional information on nursing diagnoses and interventions for the patient with PD is presented in eNursing Care Plan 58.4 (available on the website for this chapter).

TABLE 58.17 Nursing AssessmentParkinson's Disease

Subjective Data

Important Health Information

Past health history: CNS trauma, cerebrovascular disorders, exposure to metals and carbon monoxide, encephalitis or other infections

Medications: Major tranquilizers, especially haloperidol (Haldol), and phenothiazines, reserpine, methyldopa, amphetamines

Functional Health Patterns

Health perception–health management: Fatigue

Nutritional-metabolic: Excessive salivation, dysphagia, weight loss

Elimination: Constipation, incontinence, excessive sweating

Activity-exercise: Difficulty in initiating movements, frequent falls, loss of dexterity, micrographia (handwriting deterioration)

Sleep-rest: Insomnia, nightmares, daytime sleepiness

Cognitive-perceptual: Diffuse pain in head, shoulders, neck, back,

legs, and hips. Muscle soreness and cramping

Self-perception–self-concept: Depression, mood swings, hallucinations

Objective Data

General

Blank (masked) facial expression, slow and monotonous speech, infrequent blinking

Integumentary

Seborrhea, dandruff; ankle edema

Cardiovascular

Postural hypotension

Gastrointestinal

Drooling

Neurologic

Tremor at rest, first in hands (pill rolling), later in legs, arms, face, and tongue. Aggravation of tremor with anxiety, absence in sleep. Poor coordination, cognitive impairment and dementia, impaired postural reflexes

Musculoskeletal

Cogwheel rigidity, dysarthria, bradykinesia, contractures, stooped posture, shuffling gait

Possible Diagnostic Findings

No specific tests. Diagnosis based on history and physical findings and ruling out of other diseases

Planning

The overall goals are that the patient with PD will (1) maximize neurologic function, (2) maintain independence in ADLs for as long as possible, and (3) optimize psychosocial well-being.

Nursing Implementation

Because PD is a chronic degenerative disorder with no acute exacerbations, teaching and nursing care are directed toward maintaining good health, encouraging independence, and avoiding complications, such as contractures and falls. Problems due to bradykinesia can be addressed by relatively simple measures.

Check Your Practice

You are working in a rehabilitation facility with a new patient, a 78-yr-old man with Parkinson's disease. He was at your facility briefly 6 months ago with a fractured hip after falling in his yard. The family has asked to talk with you about their fear of taking him for a walk in the hallways because he is so unstable.

- What advice would you give to the family?

Promoting physical exercise and a well-balanced diet are major nursing concerns. Exercise can limit the effects of decreased mobility,

such as muscle atrophy, contractures, and constipation. The American Parkinson Disease Association *(www.apdaparkinson.org)* publishes booklets and fact sheets with helpful exercises that can be used by caregivers and health care professionals.

A physical therapist can design a personal exercise program to strengthen and stretch specific muscles. Overall muscle tone and specific exercises to strengthen the muscles involved with speaking and swallowing should be included. Although exercise will not stop disease progress, it will enhance the patient's functional ability. An occupational therapist can help the patient with ways to increase self-care measures, including eating and dressing.

Safety Alert

Preventing Falls

For patients who are at risk for falling and tend to "freeze" while walking, have them do the following:

- Consciously think about stepping over an imaginary object on the floor.
- Rock from side to side before stepping forward.
- Walk to a beat, such as with music.
- Try to swing both arms from front to back.
- Take 1 step backward and 2 steps forward.

Work closely with the patient's caregivers to find creative ways to promote independence and self-care. The patient can get out of a chair better by using an upright chair with arms and placing the back legs of the chair on small (2-inch) blocks. Encourage environmental changes to improve safety. These include removing rugs and excess furniture to avoid stumbling, using an elevated toilet seat to help the patient get on and off the toilet, and elevating the legs of an ottoman to decrease dependent ankle edema. Clothing can be simplified by

using slip-on shoes and Velcro hook-and-loop fasteners or zippers on clothing, instead of buttons.

Effective management of sleep problems can greatly improve the quality of life for patients with PD. Some patients find the use of satin nightwear or satin sheets helpful. Information on teaching about sleep hygiene practices is discussed in Chapter 7.

In the early stages of PD, many patients have depression and anxiety. Patients need to adjust their lifestyle, including work and home responsibilities. As PD progresses, the impact on the patient's psychologic well-being increases. Assist the patient by listening, providing teaching, gently correcting distorted thoughts, and encouraging social interactions. Psychologic therapy and counseling can be helpful. Ensure that patients with PD receive prescribed medications on time to avoid on-off effects.

In the early stage of PD, the patient may have subtle changes in cognitive function that can progress to dementia. This causes increased caregiver burden and may lead to long-term care placement. Information on care of the patient with dementia is provided in Chapter 59.

Family members (e.g., spouse, children) care for most patients with PD. Their burden increases as the disease progresses. This often occurs while the caregiver's physical and mental health also decline. Help them find appropriate resources.

Evaluation

The expected outcomes are that the patient with PD will

- Maintain optimal muscle function
- Use assistive devices appropriately for ambulation and mobility
- Maintain nutritional intake adequate for metabolic needs
- Have unimpaired swallowing of fluids and/or solids
- Use methods of communication that allow interaction with others

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disease of the neuromuscular junction marked by fluctuating weakness of certain skeletal muscle groups. This weakness increases with muscle use. MG can occur in anyone. An estimated 60,000 people have MG in the United States. In women, the MG starts before age 40 years. Men usually develop MG after age 60.[28]

Etiology and Pathophysiology

MG is caused by an autoimmune process in which antibodies attack ACh receptors. This results in fewer ACh receptor (AChR) sites at the neuromuscular junction. This prevents ACh molecules from attaching to receptors and stimulating muscle contraction. Anti-AChR antibodies are found in the serum of 90% of patients with generalized MG. In the 10% of patients who lack autoantibodies to AChR, muscular weakness may be related to autoantibodies to muscle-specific tyrosine kinase or to other unknown antigens.[29] Thymic hyperplasia and tumors are common in patients with MG, suggesting autoantibody production occurs in the thymus.[28]

Clinical Manifestations and Complications

The key feature is fluctuating weakness of skeletal muscles. MG usually affects multiple muscle groups. This includes muscles used to move the eyes and eyelids, chew, swallow, speak, and breathe. Muscles are generally strongest in the morning and become exhausted with continued activity. Muscle weakness is prominent by the end of the day. A period of rest usually restores strength.

In more than half of patients, the first muscles involved are the ocular muscles, causing ptosis (drooping of the eyelids) in 1 or both eyes and double vision (Fig. 58.11).[29] MG does not progress beyond the ocular muscles in about 20% of patients. When facial muscles are affected, facial mobility and expression can be impaired. Patients may

have difficulty chewing and swallowing food. Speech is affected, and the voice often fades after a long conversation. The muscles of the trunk and limbs are sometimes affected. Of these, the proximal muscles of the neck, shoulder, and hip are more often affected than the distal muscles. No other neural problems accompany MG. No sensory loss occurs, reflexes are normal, and muscle atrophy is rare.

The course of MG is highly variable. Some patients may have short-term remissions, and others may stabilize. Others may have severe, progressive involvement. Fatigue, pregnancy, illness, trauma, temperature extremes, stress, and hypokalemia can exacerbate MG. Certain drugs, including β-adrenergic blockers, quinidine, phenytoin (Dilantin), certain anesthetics, and aminoglycoside antibiotics, can worsen MG.[29]

Myasthenic crisis is an acute worsening of muscle weakness triggered by respiratory infection, surgery, emotional distress, pregnancy, exposure to certain drugs, or beginning treatment with corticosteroids. The major complications of MG result from muscle weakness in areas that affect swallowing and breathing. This results in aspiration, respiratory insufficiency, and respiratory tract infection.

Diagnostic Studies

The diagnosis of MG can be made based on history and physical examination. Other tests may be used for confirmation. EMG may show a decreased response to repeated stimulation of the hand muscles that shows muscle fatigue. Single-fiber EMG is sensitive in confirming MG. Use of drugs and serologic testing for specific antibodies is useful.

The response to a Tensilon test can indicate MG. A patient with MG has rapid improvement in muscle strength after IV injection of edrophonium chloride (Tensilon). Edrophonium is an anticholinesterase agent. It blocks the enzyme acetylcholinesterase, the enzyme that breaks down ACh. This test also helps diagnose a cholinergic crisis (from an overdose of anticholinesterase drug), which occurs due to excessive cholinesterase inhibition. In a cholinergic

crisis, edrophonium may increase muscle weakness. Atropine, a cholinergic antagonist, should be readily available to counteract the effects of edrophonium when it is used diagnostically. In patients with a confirmed diagnosis of MG, a chest CT scan may be done to evaluate the thymus.

Interprofessional Care

Drug Therapy

Drug therapy for MG includes anticholinesterase drugs, alternate-day corticosteroids, and immunosuppressants (Table 58.18). Anticholinesterase drugs enhance transmission at the neuromuscular junction. Inhibiting acetylcholinesterase with an anticholinesterase inhibitor prolongs the action of ACh and improves impulse transmission at the neuromuscular junction. Pyridostigmine (Mestinon) is the most successful drug of this group in the long-term treatment of MG.

FIG. 58.11 "Peek" sign in myasthenia gravis. During sustained forced eyelid closure, he is unable to bury his eyelashes *(left)* and, after 30 sec, he is unable to keep the lids fully closed *(right).*
From Sanders DB, Massey JM: Clinical features of myasthenia gravis. In AG Engel, ed: *Neuromuscular junction disorders: Handbook of*

TABLE 58.18 Interprofessional CareMyasthenia Gravis

Diagnostic Assessment

- History and physical examination
- Fatigability with prolonged upward gaze (2–3 min)
- Muscle weakness
- EMG
- Tensilon test
- Acetylcholine receptor antibodies
- Chest x-ray

Management

- Drug therapy
    - Anticholinesterase agents
    - Corticosteroids
    - Immunosuppressive agents
- Surgery (thymectomy)
- Plasmapheresis
- IV immunoglobulin G

Tailoring the dose to avoid a myasthenic or cholinergic crisis often presents a clinical challenge. Corticosteroids (specifically prednisone) are used to suppress the immune response. Other drugs used for immunosuppression include azathioprine (Imuran), mycophenolate (CellCept), and cyclosporine (Sandimmune). Up to 80% of patients

who receive corticosteroids have complete cessation of symptoms or marked improvement. Some patients become weaker for a brief time before regaining strength. These benefits must be weighed with concerns about chronic use of these medications.

Surgical Therapy

Because the thymus gland in the patient with MG appears to enhance the production of AChR antibodies, removing the thymus gland causes improvement in most patients. Thymectomy is indicated for almost all patients with thymoma, patients with generalized MG between puberty and about age 65 years, and patients with purely ocular MG.

Other Therapies

Plasmapheresis and IV immunoglobulin G can yield short-term improvement in symptoms. They are indicated for patients in myasthenic crisis or in preparation for surgery when corticosteroids must be avoided. Plasmapheresis directly removes circulating AChR antibodies, leading to a decrease in symptoms. (Plasmapheresis is discussed in Chapter 13.) It is not certain how IV immunoglobulin works. It is probably related to a decrease in antibody production.

Nursing Management: Myasthenia Gravis

Nursing Assessment

Assess the severity of MG by asking the patient about fatigue, what body parts are affected, and how severely they are affected. Some patients become so fatigued they are no longer able to work or even walk. Assess the patient's coping abilities and understanding of MG.

Obtain a thorough medication history. Many drugs are contraindicated or must be used with caution in patients with MG. Classes of drugs that should be carefully evaluated before use include

β-adrenergic blockers, quinidine, phenytoin (Dilantin), certain anesthetics, and aminoglycoside antibiotics.[29]

Objective data should include respiratory rate and depth, O_2 saturation, arterial blood gas analyses, and pulmonary function tests. Assess for any evidence of respiratory distress in patients with acute myasthenic crisis. Assess muscle strength of all face and limb muscles, swallowing, speech (volume and clarity), and cough and gag reflexes.

TABLE 58.19 Comparison of Myasthenic and Cholinergic Crises

Myasthenic Crisis	Cholinergic Crisis
Causes	
Exacerbation of myasthenia after precipitating factors, failure to take drug as prescribed, or drug dose too low	Overdose of anticholinesterase drugs resulting in ↑ acetylcholine at the receptor sites, remission (spontaneous or after thymectomy)
Differential Diagnosis	
Improved strength after IV administration of anticholinesterase drugs	Weakness within 1 hr after ingestion of anticholinesterase drugs
↑ Weakness of skeletal muscles manifesting as ptosis, bulbar signs (e.g., difficulty swallowing, difficulty articulating words), or dyspnea	↑ Weakness of skeletal muscles manifesting as ptosis, bulbar signs, dyspnea Effects on smooth muscle include pupillary miosis, salivation, diarrhea, nausea or vomiting, abdominal cramps, ↑ bronchial secretions, sweating, or lacrimation

Nursing Diagnoses

Nursing diagnoses for the patient with MG may include:

- Impaired airway clearance
- Activity intolerance
- Risk for aspiration
- Disturbed body image

Planning

The overall goals are that the patient with MG will (1) have a return of normal muscle strength, (2) manage fatigue, (3) avoid complications, and (4) maintain a quality of life appropriate to the disease course.

Nursing Implementation

The patient with MG who is admitted to the hospital usually has a respiratory tract infection or is in acute myasthenic crisis. Nursing care is aimed at maintaining adequate ventilation, continuing drug therapy, and watching for side effects of therapy. Be able to distinguish cholinergic from myasthenic crisis (Table 58.19) because the causes and treatment of these conditions differ greatly. Features of a cholinergic crisis include involuntary muscle contraction, sweating, excessive salivation, and constricted pupils.

As with other chronic illnesses, focus care on the neurologic deficits and their impact on daily living. Teach the patient about a balanced diet that can easily be chewed and swallowed. Semisolid foods may be easier to eat than solids or liquids. Scheduling doses of drugs to reach peak action at mealtime may make eating easier. Arrange diversional activities that need little physical effort and match the patient's interests. Help the patient plan ADLs to avoid fatigue. Focus teaching on adherence to the treatment plan, complications, potential adverse reactions to specific drugs, complications of therapy (crisis conditions), and what to do about them. Explore community resources, such as the Myasthenia Gravis Foundation of America and MG support groups.

Evaluation

The expected outcomes are that the patient with MG will

- Maintain optimal muscle function
- Be free from side effects of drugs
- Have no complications (myasthenic or cholinergic crises) from MG
- Maintain a quality of life appropriate to the disease course

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a rare progressive neuromuscular disorder marked by loss of motor neurons. ALS usually leads to death 2 to 5 years after diagnosis, but a few patients may survive for more than 10 years. This disease became known as *Lou Gehrig's disease* after the famous baseball player was stricken with it in 1939. Perhaps the best-known patient with ALS is British theoretical physicist Stephen Hawking. He was diagnosed at age 21 years and lived with ALS for over 50 years, dying at age 76. The typical onset is between age 55 and 75 years. ALS is most common in whites, men, and veterans of the Gulf War. About 20,000 Americans have ALS.[30]

In ALS, motor neurons in the brainstem and spinal cord gradually degenerate for unknown reasons. Dead motor neurons cannot produce or transport signals to muscles. Consequently, electrical and chemical messages originating in the brain do not reach the muscles to activate them.

Genetic Link

About 5% to 10% of ALS cases are genetic. Mutations in more than a dozen genes have been found to cause familial ALS (FALS). One gene is "chromosome 9 open reading frame 72," or *C9ORF72*. People with FALS from a *C9ORF72* mutation often develop ALS earlier. This same gene also causes frontotemporal dementia (FTD). A few people have both ALS and dementia (ALS-FTD). Other times FALS results from mutations in the gene that gives instructions to make the enzyme copper-zinc superoxide dismutase 1 (*SOD1*).[31]

Progressive muscle weakness and atrophy are the classic sign of ALS. Early symptoms of weakness vary. For some, symptoms initially affect the arms or legs ("limb-onset" ALS). The person may have trouble with tasks requiring fine motor skills (e.g., writing, typing) or notice they are tripping, dropping things, or stumbling more often. Those who first have problems with slurred speech or swallowing have "bulbar onset" ALS.

Muscle wasting and involuntary contractions result from the

denervation of the muscles and lack of stimulation and use. Other symptoms include pain, sleep disorders, spasticity and hyperreflexia, drooling, emotional lability, constipation, and esophageal reflux. ALS does not affect a patient's intelligence but affected people may have depression and problems with decision making and memory. Death often results from compromised respiratory function due to muscle weakness and paralysis.

Informatics in Practice

Voice Banking Applications for ALS

- For patients with ALS, the loss of voice and the ability to communicate can be isolating.
- Patients can take part in voice banking programs and record key words and phrases in their own voices.
- Voice banking is meant to be an alternative communication tool when patients may not be able to speak.

No cure exists for ALS. Treatment options are limited. Riluzole (Rilutek) slows the progression of ALS. This drug reduces damage to motor neurons by decreasing the release of glutamate (an excitatory neurotransmitter) in the brain. Edaravone (Radicava), approved by FDA in May 2017, is the first new drug treatment for ALS in 20 years. This drug is given IV daily for 14 days, followed by a 14-day drug-free period. Subsequent dosing is over 10 to 14 days, again followed by a 14-day drug-free period. Edaravone is a free radical scavenger that we think relieves effects of oxidative stress, a likely factor in progression of ALS.[32]

The illness trajectory for ALS is devastating because the patient is cognitively intact while wasting away. Guide the patient in the use of moderate-intensity, endurance-type exercises for the trunk and limbs because this may help to reduce ALS spasticity. Nursing interventions

include (1) facilitating communication, (2) reducing aspiration risk, (3) early identification of respiratory insufficiency, (4) decreasing pain from muscle weakness, (5) decreasing risk for fall-related injury, and (6) providing diversional activities, such as reading and companionship.

Support the patient and caregivers emotionally. This includes grieving related to the loss of motor function and impending death. Discuss advance directives and artificial methods of ventilation with the patient and caregiver.

Huntington's Disease

Huntington's disease (HD) is a progressive, degenerative brain disorder. It is a genetically transmitted, autosomal dominant disorder. The offspring of a person with HD have a 50% risk for inheriting it. The onset of HD is usually between ages 30 and 50 years. Diagnosis is often made after the affected person has had children. About 25,000 to 30,000 Americans are symptomatic and 150,000 or more are at risk for HD.[33] It affects men and women equally across races.

The diagnostic process begins with a review of the family history and clinical symptoms. Genetic testing confirms the disease in a person with symptoms. People who are asymptomatic but who have a positive family history of HD must decide if they want genetic testing. If the test is positive, the person will develop HD. However, when the disease will develop cannot be determined.

Like PD, the pathologic process of HD involves the basal ganglia and extrapyramidal motor system. However, instead of a deficiency of DA, HD involves a deficiency of the neurotransmitters ACh and γ-aminobutyric acid (GABA). The net effect is an excess of DA, which leads to symptoms that are the opposite of those of parkinsonism.

Manifestations include movement disorder and cognitive and psychiatric problems. The movement disorder is marked by abnormal and excessive involuntary movements *(chorea).* These are writhing, twisting movements of the face, limbs, and body. The movements get worse as the disease progresses. Because facial movements involving

speech, chewing, and swallowing are affected, aspiration and malnutrition are likely. The gait deteriorates, and ambulation eventually becomes impossible. Eventually all psychomotor processes, including the ability to eat and talk, are impaired.

Psychiatric symptoms are often present in the early stage of HD, even before the onset of motor symptoms. Depression is common. Other psychiatric symptoms include anxiety,

Genetics in Clinical Practice

Huntington's Disease (HD)

Genetic Basis

- Autosomal dominant disorder.
- Caused by mutation in *HTT* gene found on chromosome 4.
- A single copy of altered gene (heterozygous) is enough to cause HD.
- Offspring of a person with HD have a 50% chance of inheriting the disease-causing allele.

Incidence

- Occurs in 3 to 7 in 100,000 people of European ancestry.
- Less common in other populations, including people of Japanese, Chinese, and African descent.

Genetic Testing

- DNA testing is available.
- DNA testing can be done on fetal cells obtained by amniocentesis or chorionic villus sampling.

- Preimplantation genetic diagnosis can be done on embryos before implantation and pregnancy.
- No test is available to predict when symptoms will develop.

Clinical Implications

- Consider genetic counseling if there is a family history of HD.
- Because HD is an autosomal dominant disorder, those at risk have a strong motivation to seek genetic testing.
- A positive result is not considered a diagnosis because it may be obtained decades before symptoms begin.
- A negative test means the person does not carry the mutated gene and will not develop HD.

agitation, impulsivity, apathy, social withdrawal, and obsessiveness. Cognitive deterioration is more variable. It involves perception, memory, attention, and learning.

Death usually occurs 10 to 30 years after the onset of symptoms.[33] The most common cause of death is pneumonia, followed by suicide. Other causes of death include injuries related to falls and other complications.

Because HD has no cure, treatment is palliative. Drugs are available to control movements and behavioral problems. Tetrabenazine (Xenazine) is used to treat chorea. It decreases the amount of DA available at synapses in the brain and thus reducing the involuntary movements of chorea. If chorea is accompanied by other symptoms, tetrabenazine may not be the treatment of choice. For example, tetrabenazine can worsen depression. Deutetrabenazine (Austedo) is related to tetrabenazine. It is also approved for the treatment of chorea. Research suggests this drug is better tolerated than tetrabenzine.[34] Other medications for the movement disorder include neuroleptics (e.g., haloperidol, risperidone), benzodiazepines, and DA-depleting agents, such as reserpine.

Cognitive disorders are treated as needed with nondrug therapies

(e.g., counseling, memory books). Psychiatric disorders can be treated with selective serotonin reuptake inhibitors, such as sertraline (Zoloft) and paroxetine (Paxil). Antipsychotic medication, such as haloperidol or risperidone, may be needed.

HD presents a great challenge to health care professionals. The goal of nursing management is to provide the most comfortable environment possible for the patient and caregiver by maintaining physical safety, treating physical symptoms, and providing emotional and psychologic support.

Because of the chorea, caloric requirements are high. The patient may need as many as 4000 to 5000 cal/day to maintain body weight. As HD progresses, meeting caloric needs becomes a greater challenge when the patient has difficulty swallowing and holding the head still. Depression and mental deterioration can compromise nutritional intake. Enteral or parenteral nutrition may be needed as the disease progresses.

End-of-life issues need to be discussed with the patient and caregiver. These include care in the home or long-term care facility, artificial methods of feeding, advance directives and cardiopulmonary resuscitation (CPR), use of antibiotics to treat infections, and guardianship. Address these topics throughout the course of the disease as the patient and caregiver adapt to increasing disability.

Case Study

Seizure Disorder With Headache

© Purestock/Thinkstock.

Patient Profile

C.S. is a 24-yr-old woman who was diagnosed with seizure disorder at age 15. At that time, she had a generalized-onset tonic-clonic seizure and was given a prescription for valproate (Depakote). She had a second witnessed seizure 4 months later but has since been seizure free. C.S. now reports headaches and says she is afraid her seizures are going to return. She is single, lives alone, and describes

her job as stressful.

Subjective Data

- Describes headache pain on the left side of her forehead as throbbing
- Has vomited with headache
- Describes changes in vision, including flashing lights
- Headache occurs nearly every month on a regular cycle

Objective Data

- Alert and oriented to person
- Neurologic examination negative
- Serum valproate levels within normal limits
- EEG normal
- CT of head normal

Discussion Questions

1. What is seizure disorder?
2. What is the pathophysiology of seizure disorder?
3. What is the significance of the laboratory and diagnostic findings?
4. Is the headache related to seizure activity?
5. ***Safety:*** To ensure C.S.'s safety, what nursing interventions are needed?
6. ***Patient-Centered Care:*** What teaching will you include in the plan of care for C.S. about the course of the disease?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses?
8. ***Evidence-Based Practice:*** Based on current treatment guidelines, what medication may be effective in managing both C.S.'s

seizure disorder and her migraine headaches?

9. Develop a conceptual care map for C.S.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A 50-yr-old man reports recurring headaches. He describes them as sharp, stabbing, and around his left eye. He says his left eye seems to swell and get teary when these headaches occur. Based on this history, you suspect he has
   a. cluster headaches.
   b. tension headaches.
   c. migraine headaches.
   d. medication overuse headaches.
2. A 65-yr-old woman was just diagnosed with Parkinson's disease. The priority nursing intervention is
   a. searching the Internet for educational videos.
   b. helping the caregiver explore respite care options.
   c. promoting physical exercise and a well-balanced diet.
   d. teaching about the benefits and risks of ablation surgery.
3. The nurse finds an 87-yr-old patient is continually rubbing, flexing, and kicking her legs throughout the day. The night shift reports this same behavior escalates at night, preventing her from obtaining sleep. The next step the nurse should take is to

a. ask the provider for a daytime sedative for the patient.

b. request soft restraints to prevent her from falling out of her bed.

c. ask the provider for a nighttime sleep medication for the patient.

d. perform an assessment, suspecting a disorder such as restless legs syndrome.

4. Possible social effects of a chronic neurologic disease include *(select all that apply)*

a. divorce.

b. job loss.

c. depression.

d. role changes.

e. loss of self-esteem.

5. The nurse is reinforcing teaching with a patient newly diagnosed with amyotrophic lateral sclerosis (ALS). Which statement would be appropriate to include in the teaching?

a. "Even though the symptoms you have are severe, most people recover with treatment."

b. "ALS results from excess chemicals in the brain, so symptoms can be controlled with medication."

c. "You need to consider advance directives now, because you will lose cognitive function as the disease progresses."

d. "This is a progressing disease that eventually results in permanent paralysis, though you will not lose any cognitive function."

1. a, 2. c, 3. d, 4. a, b, c, d, e, 5. d

Conceptual Focus

Cognition
Family Dynamics
Functional Ability
Safety
Stress

This chapter discusses the cognitive disorders of dementia and delirium, with a focus on the nursing management of patients with Alzheimer's disease (AD). Cognitive impairment refers to any deficit in intellectual functioning, including problems with memory, orientation, attention, and concentration. The consequences of cognitive impairment can be devastating for the person and caregivers. Ultimately, dementia adversely affects functional ability and the person's ability to work, fulfill responsibilities, and perform activities of daily living (ADLs). There is a high risk for many problems, including injury, impaired nutrition, and social isolation.

Persons with dementia and delirium may have symptoms of depression. Depression and dementia are often mistaken for each another, especially among older adults. Manifestations of depression, especially among older adults, may include sadness, difficulty concentrating, fatigue, apathy, feelings of despair, and inactivity. When depression is severe, poor concentration and attention may result, causing memory and functional impairment. When dementia and depression occur together there can be marked intellectual deterioration. Table 59.1 compares key features of dementia, delirium, and depression. Your ability to interview the patient and family members about presenting symptoms and signs can aide in early diagnosis and treatment.

Dementia

Dementia is a disorder characterized by a decline from previous level of function in 1 or more cognitive domains: complex attention, executive function, language, learning and memory, perceptual-motor, and social cognition.[1] The cognitive decline interferes with ability to function and perform daily activities. This decline does not occur with onset of an acute state of confusion, such as delirium, or the onset of another major mental disorder, such as depression.

As the average life span increases, the number of patients diagnosed with dementia is increasing. AD is the most common form of dementia. It accounts for 60% to 80% of all cases of dementia (Fig. 59.1). In 2018, 5.7 million Americans over age 65 were living with AD. We expect this number to reach 14 million by 2050.[2]

TABLE 59.1 Comparison of Dementia, Delirium, and Depression

Feature	Dementia	Delirium	Depression
Onset	Usually insidious	Abrupt, although initially can be subtle	Often coincides with life changes. Often abrupt
Progression	Slow	Abrupt. Can fluctuate from day to day	Variable, rapid to slow but may be uneven
Duration	Years (average of 8 yr but can be much longer)	Hours to days to weeks. Can be prolonged in some	Can be several months to years, especially if not treated
Thinking	Difficulty with abstract thinking, impaired judgment, words difficult to find	Disorganized, distorted. Slow or accelerated incoherent speech	Intact but with apathy, fatigue. May be indecisive. Feels sense of hopelessness. May not want to live
Perception	Misperceptions often present. Delusions and hallucinations	Distorted. Delusions and hallucinations	May deny or be unaware of depression. May have feelings of guilt
Psychomotor behavior	May pace or be hyperactive. As disease progresses, may not be able to perform tasks or movements when asked	Variable. Can be hyperactive or hypoactive, or mixed	Often withdrawn and hypoactive
Sleep-wake cycle	Sleeps during day. Frequent awakenings at night. Fragmented sleep	Disturbed sleep. Reversed sleep-wake cycle	Disturbed, often with early morning awakening

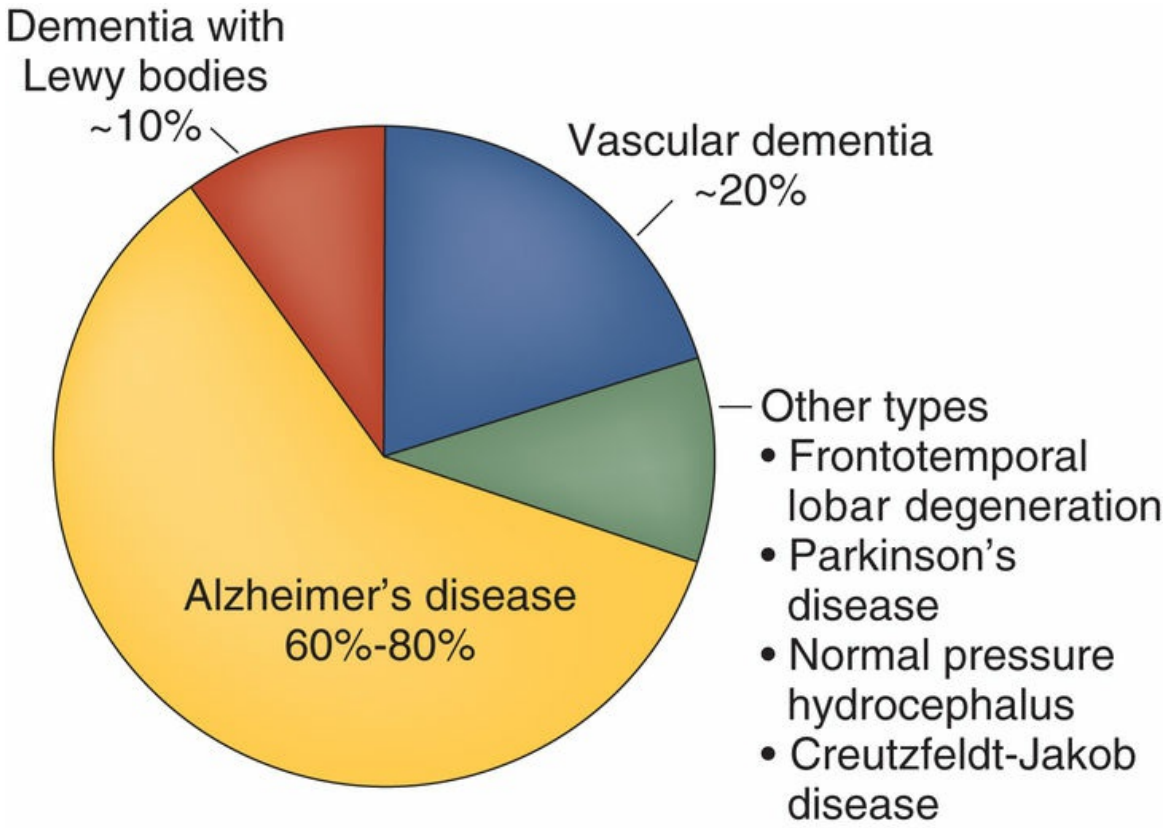

FIG. 59.1 Causes of dementia.

Etiology and Pathophysiology

Dementia is caused by treatable and untreatable conditions. Table 59.2

describes the types of dementia and their underlying causes. Treatable causes may initially be reversible. However, with prolonged exposure or disease, irreversible changes may occur.

The most common causes of dementia are neurodegenerative conditions that cannot be reversed (Table 59.3). Most of these are due to AD. Other causes include dementia with Lewy bodies (DLB), frontotemporal dementia (FTD), and Parkinson's disease with dementia (PDD). Vascular, or multiinfarct dementia (VaD), is a loss of cognitive function caused by cardiovascular disease (CVD). The prevalence of VaD is higher among blacks and those with hypertension and diabetes. VaD may be caused by a single infarct (stroke) or multiple strokes.

Mixed dementia occurs when 2 or more types of dementia are present at the same time. It is characterized by the hallmark abnormalities of AD and another type of dementia. Usually the other type of dementia is VaD, but it can be other types.

Normal pressure hydrocephalus is a rare disorder characterized by an obstruction in the flow of cerebrospinal fluid (CSF). This causes a buildup of CSF in the brain. Manifestations include dementia, urinary incontinence, and difficulty walking. Meningitis, encephalitis, or head injury may cause the condition. If diagnosed early, it is treatable by surgery in which a shunt is inserted to divert the fluid away from the brain.

TABLE 59.2 Causes of Dementia

Type of Dementia	Cause
Neurodegenerative disorders	• AD • Amyotrophic lateral sclerosis (ALS) • Dementia with Lewy bodies (DLB) • Down syndrome • Frontotemporal lobar degeneration (FTLD) • Huntington's disease • Parkinson's disease
Vascular diseases	• Chronic subdural hematoma* • Subarachnoid hemorrhage* • Vascular (multiinfarct) dementia
Immunologic diseases or infections	• Multiple sclerosis • Systemic exertion intolerance disease • Infections (e.g., Creutzfeldt-Jakob disease) • Acquired immunodeficiency syndrome (AIDS) • Meningitis* • Encephalitis* • Neurosyphilis* • Systemic lupus erythematosus*
Medications†	• Anticholinergics • Antiparkinsonian drugs • Cardiac drugs: digoxin, methyldopa • Cocaine • Heroin • Hypnotics • Opioids • phenytoin (Dilantin) • Tranquilizers
Metabolic or nutritional diseases	• Alcohol use disorder • Cobalamin (vitamin B_{12}) deficiency* • Folate deficiency* • Hyperthyroidism* • Hypothyroidism* • Thiamine (vitamin B_1) deficiency*
Systemic diseases	• Dialysis dementia* • Hepatic encephalopathy* • Uremic encephalopathy* • Wilson's disease
Trauma	• Head injury*
Tumors	• Brain tumors (primary)* • Metastatic tumors*
Ventricular disorders	• Hydrocephalus*

* Potentially reversible.

† These are examples of drugs that may cause cognitive impairment that is potentially reversible.

TABLE 59.3 Neurodegenerative Causes of Dementia

Neurodegenerative Disorder	Characteristics	Management
Dementia With Lewy Bodies (DLB)		
• **Characterized by presence of Lewy bodies (abnormal deposits of protein α-synuclein) in brainstem and cortex** • **Has features of both AD and Parkinson's disease.** • **Imperative that a correct diagnosis is made**	• Diagnosis is based on manifestations • Typically have manifestations of parkinsonism (extrapyramidal signs [bradykinesia, rigidity, postural instability, but not always a tremor]), hallucinations, short-term memory loss, unpredictable cognitive shifts, and sleep problems • Pneumonia is a common complication	• Drugs may include levodopa/carbidopa and acetylcholinesterase inhibitors • Manage dementia and problems related to dysphagia and immobility • Swallowing problems can lead to impaired nutrition • At risk for falls from impaired mobility and balance
Down Syndrome		
• **Genetic disorder caused by presence of all or part of a third copy of chromosome 21**	• Typically associated with physical growth delays, characteristic facial features, and mild to moderate intellectual disability	• Much higher risk for developing dementia • Estimated 80% will develop dementia
Frontotemporal Lobar Degeneration (FTLD)		
• **Associated with atrophy of frontal and temporal lobes of brain** • **In Pick's disease, a type of FTLD, brain may have abnormal microscopic deposits called *Pick bodies*** • **Often misdiagnosed as a psychiatric problem because of strange behaviors**	• Changes in behavior, sleep, and eventually memory • Progresses relentlessly and may lead to language impairment, erratic behavior, and dementia • Tends to occur at a younger age than does AD, typically about age 60	• No specific treatment • Antidepressants and antipsychotics to treat behavioral manifestations
Parkinson's Disease, Huntington's Disease, and Amyotrophic Lateral Sclerosis		
• **Chronic, progressive, and incurable diseases**	• Associated with development of dementia in the later stages of disease	• See Chapter 58

Clinical Manifestations

The onset of manifestations varies depending on the cause. Manifestations associated with neurologic degeneration usually occur gradually and progress over time. Symptoms of VaD may appear abruptly or progress in a stepwise pattern. While the cause of dementia cannot be determined based only on the history of symptom progression, patterns can guide your thinking about the different causes. An acute change that occurs over days to weeks or subacute change that occurs over weeks to months may indicate an infectious or metabolic cause of dementia, such as encephalitis, meningitis, hypothyroidism, or drug-related dementia. Other manifestations of dementia are discussed in the section on clinical manifestations of AD on p. 1387.

Diagnostic Studies

The diagnosis of dementia is focused on determining the cause (e.g., reversible versus irreversible factors). An important first step is a thorough medical, neurologic, and psychologic history. During the history, special attention is given to reviewing the cognitive and behavioral changes that have occurred. Family members and significant others can give important information. Elicit information about (1) problems with judgment; (2) reduced interest in hobbies/activities; (3) repeating questions, stories, or statements; (4) trouble learning how to use a tool or appliance; (5) forgetting the correct month or year; (6) problems handling financial affairs; (7) difficulty remembering appointments; and (8) consistent problems with thinking and/or memory.

Obtain a complete medication history, including the use of prescribed and over-the-counter medications, herbal supplements, and recreational substances. Ask about drugs that can impair cognition, such as analgesics, anticholinergics, psychotropics, and sedative-hypnotics.

A thorough physical assessment is done to rule out other potential medical conditions. For example, slow movement, rigidity, asymmetric tremor of an extremity, and shuffling gait are suggestive of Parkinsonism. Dementia, urinary incontinence, and ataxic gait suggest normal pressure hydrocephalus. The neurologic assessment includes a mental status examination or screening test. Agreement among findings from the assessment, screening tests, and history can help confirm the presence of dementia.

Based on history and physical assessment findings, diagnostic studies are ordered to confirm the most likely cause and exclude other possible conditions. The American Academy of Neurology (AAN) recommends routine screening tests, including an electrolyte panel, liver function tests, serum vitamin B_{12} level, complete blood count, and thyroid function tests.[3] Specialized laboratory tests, such as red blood cell folate in a patient with alcoholism or ionized serum calcium in a patient with multiple myeloma, are ordered based on history. Neuroimaging with a head CT or MRI scan is important for patients with acute onset of cognitive impairment, rapid neurologic

deterioration, or findings that suggest a subdural hematoma, thrombotic stroke, or cerebral hemorrhage.

Interprofessional and Nursing Care

Management of patients with dementia is similar to the management of patients with AD, which is described later in this chapter. Preventive measures for VaD include treatment of risk factors, such as hypertension, diabetes, smoking, hypercholesterolemia, and dysrhythmias. Stroke is discussed in Chapter 57. Drugs that are used for patients with AD are also useful for patients with VaD. Drug therapy is discussed on p. 1392 later in this chapter.

Alzheimer's Disease

Alzheimer's disease (AD) is a chronic, progressive, neurodegenerative brain disease. It is thought that 11% of people age 65 and older, and nearly one third of those over age 85, have AD. Only a small number of people younger than 60 years of age develop AD. When AD develops in someone younger than 60 years, it is referred to as *early-onset AD.* AD that occurs in people over 60 years old is called *late-onset AD*.

Ultimately the disease is fatal. Death typically occurs 4 to 8 years after diagnosis, although some patients have lived for 20 years. AD is the sixth leading cause of death in the United States.[2] It is the only cause of death among the top 10 in the United States that cannot be prevented or cured, nor its progression slowed.

The burden of caring for a patient with AD is well documented. 25% of AD caregivers are caring for both someone with the disease and a child or grandchild. 60% of family caregivers describe high or very high emotional stress.[2] More than 1 in 6 family caregivers report they had to stop working due to caregiving responsibilities. 74% of caregivers described becoming "somewhat concerned" to "very concerned" about maintaining their own health since becoming caregivers.

Gender Differences

Alzheimer's Disease and Dementia

Men

- Men have a higher incidence of VaD than women.

Women

- Nearly two thirds of people with AD are women.
- Women are more likely to develop AD than men, mainly because they live longer.
- About twice as many women as men die each year from AD.

Promoting Health Equity

Alzheimer's Disease

- Older blacks are about twice as likely to have AD as older whites.
- Older Hispanics are about 1½ times as likely to have AD as older whites.
- Variations in health, lifestyle, and socioeconomic risk factors across ethnic groups account for most of the differences in risk.
- Increased rates of CVD and diabetes may be related to the increased prevalence of AD in blacks and Hispanics.
- Lower levels of education and other socioeconomic characteristics may increase risk.[2]

Source: Alzheimer's Association: 2018 Alzheimer's disease facts and

figures, *Alzheimers Dement* 14:367, 2018.

Etiology

The exact cause of AD is unknown. It is likely a combination of multiple factors.

Aging

The greatest risk factor for AD is age. Most people with AD are diagnosed at age 65 or older. While age is the greatest risk factor, AD is not a normal part of aging and age alone does not cause the disease.[2]

Family History

Family history of AD is an important risk factor.[1] Persons with a first-degree relative (parent or sibling) with dementia are more likely to develop the disease. Those who have more than 1 first-degree relative with dementia are at even higher risk for developing AD.

Genetic Link

Persons with a clear pattern of inheritance within a family have familial AD (FAD). FAD is associated with onset before age 60 and a more rapid disease course. Cases are referred to as sporadic when there is no familial connection. The pathogenesis of FAD and sporadic AD is similar.

The first gene associated with late-onset and sporadic forms of AD was the epsilon (E)-4 allele of the apolipoprotein E *(ApoE)* gene on chromosome 19. *ApoE* contains the instructions to make a protein that helps to carry cholesterol and other types of fat in the bloodstream. *ApoE* may have a role in clearing amyloid plaques. Mutations in this gene result in more amyloid deposits.

ApoE comes in several different alleles or forms. Three alleles occur most often. People inherit 1 allele (e.g., *ApoE-2, ApoE-3, ApoE-4*), from each parent. The presence of *ApoE-4*, which is a risk-factor gene,

increases the risk for developing late-onset AD. *ApoE* testing is controversial. Not all people with *ApoE-4* develop AD. Among patients with dementia who meet the clinical criteria for AD, finding *ApoE-4* increases the reliability of diagnosis.

In patients with early-onset AD, 3 genes have been identified as important: presenilin-1 *(PSEN1),* presenilin-2 *(PSEN2),* and amyloid precursor protein *(APP)* (see the Genetics in Clinical Practice box). When these genes mutate, they cause brain cells to overproduce β-amyloid.[2] *PSEN1* mutations cause AD before age 60 and often before age 50. *PSEN2* causes early-onset FAD.

Cardiovascular Factors

Brain health is closely linked to the health of the heart and blood vessels. Brain functioning depends on a good blood supply and nutrients delivered to it by that blood supply.

Many factors increase the risk for CVD. These include diabetes, hypertension, obesity, hypercholesterolemia, and smoking. Diabetes dramatically increases the risk for developing AD and other types of dementia. Diabetes can contribute to dementia in several ways. Chronic high levels of insulin and glucose may be directly toxic to brain cells. Insulin resistance, which causes high blood glucose and can lead to type 2 diabetes, may interfere with the body's ability to break down amyloid, a protein that forms brain plaques in AD. High blood glucose and high cholesterol have a role in atherosclerosis, which contributes to VaD.[4]

Diabetes may contribute to poor memory and decreased mental function in other ways. The disease causes microangiopathy, which damages small blood vessels throughout the body. Ongoing damage to blood vessels in the brain may be one reason why people with diabetes are at a higher risk for cognitive problems as they age.[5] People with diabetes may lose brain volume, especially gray matter, as the disease progresses.

Head Trauma

Head trauma is a risk factor for dementia. Professional football players and military veterans who had traumatic brain injury or posttraumatic stress disorder have an increased risk for AD and other types of dementia.[6]

Pathophysiology

Characteristic findings of AD related to changes in the brain's structure and function include (1) amyloid plaques, (2) neurofibrillary tangles, (3) loss of connections between neurons, and (4) neuron death.[7] Fig. 59.2 shows the pathologic changes in AD.

As part of aging, people develop some plaques in their brain tissue. In AD, more plaques appear in certain parts of

Genetics in Clinical Practice

Alzheimer's Disease

Genetic Basis

Early Onset (Familial) (<60 Yr Old at Onset)

- Autosomal dominant disorder
- Various mutations in the following genes:
    - Amyloid precursor protein *(APP)* gene on chromosome 21
    - Presenilin-1 *(PSEN1)* gene on chromosome 14
    - Presenilin-2 *(PSEN2)* gene on chromosome 1

Late Onset (Sporadic) (>60 Yr Old at Onset)

- Genetically more complex than early-onset AD.
- Apolipoprotein E-4 *(ApoE-4)* allele on chromosome 19 increases

the chance for developing AD.
- Presence of *ApoE-2* allele is associated with a lower risk for AD.

Incidence
Early Onset

- Rare form of AD, accounting for <5% of cases.
- 50% risk for disease for children of affected parents.
- May occur in people as young as 30 yr.

Late Onset

- *ApoE-4* is present in 40% to 65% of people with late-onset AD.
- Many *ApoE-4*–positive people do not develop AD, and many *ApoE-4*–negative people do.

Genetic Testing
Early Onset

- Genetic screening is available for mutations on chromosomes 1, 14, and 21.

Late Onset

- Blood test can identify which *ApoE* allele a patient has but cannot predict who will develop disease.
- In a patient who meets the clinical criteria for AD, finding *ApoE-4* increases the reliability of the diagnosis.

Clinical Implications

- Genetic testing for family members of patients with early-onset AD may be appropriate.
- Testing should be done only with formal genetic counseling, especially when asymptomatic family members are involved.
- If a patient tests positive for *ApoE-4*, it does not mean that the patient will develop AD.

the brain. These plaques consist of clusters of insoluble deposits of a protein called β-amyloid, other proteins, remnants of neurons, non-nerve cells such as microglia (cells that surround and digest damaged cells or foreign substances), and other cells, such as astrocytes.

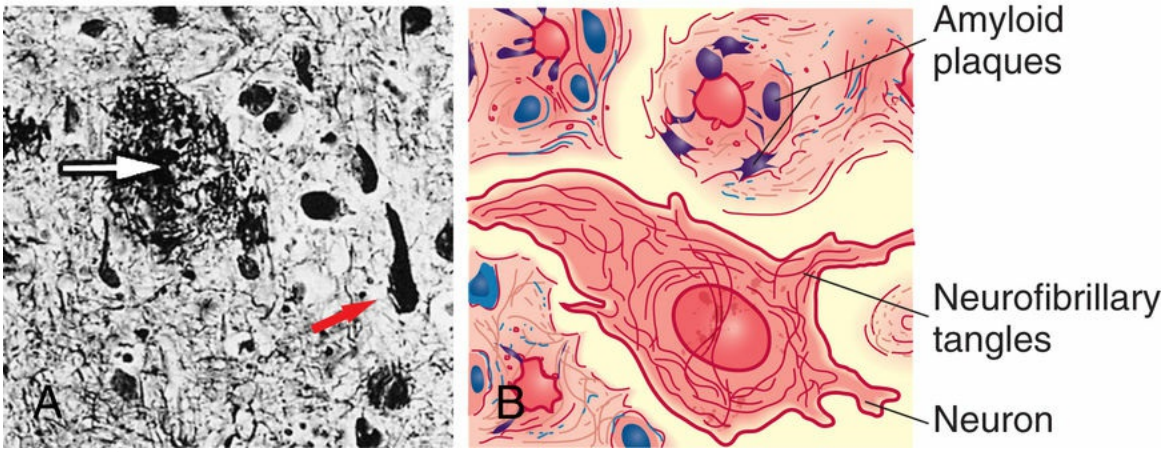

FIG. 59.2 Pathologic changes in AD. **A,** Plaque with central amyloid core *(white arrow)* next to a neurofibrillary tangle *(red arrow)* on the histologic specimen from a brain autopsy. **B,** Schematic representation of amyloid plaque and neurofibrillary tangle.

β-Amyloid is cleaved from amyloid precursor protein (APP), which is associated with the cell membrane (Fig. 59.3). The normal function of APP is unknown. Genetic factors may play a critical role in how the brain processes the β-amyloid protein. Overproduction of β-amyloid is an important risk factor for AD. Abnormally high levels of β-amyloid cause cell damage either directly or by eliciting an inflammatory response and ultimately neuron death.

In AD, plaques develop first in areas of the brain used for memory

and cognitive function, including the hippocampus (a structure that is important in forming and storing short-term memories). Eventually AD attacks the cerebral cortex, especially the areas responsible for language and reasoning.

Neurofibrillary tangles are abnormal collections of twisted protein threads inside nerve cells. The main component of these structures is a protein called tau. Tau proteins in the central nervous system (CNS) are involved in providing support for intracellular structure through their support of microtubules. Tau proteins hold the microtubules together like railroad ties. In AD tau protein is altered. As a result, the microtubules twist together in a helical fashion (Fig. 59.3). This ultimately forms the neurofibrillary tangles found in the neurons of people with AD.

Plaques and neurofibrillary tangles are not unique to patients with AD or dementia. They are also found in the brains of people without cognitive impairment. However, they are more abundant in the brains of those with AD.

The other feature of AD is the loss of connections between neurons and neuron death. These processes result in structural damage. Affected parts of the brain begin to shrink in a process called brain atrophy. By the final stage of AD, brain tissue has shrunk significantly (Fig. 59.4).

Clinical Manifestations

Research suggests AD causes pathologic changes in the brain at least 15 years before the manifestations of AD appear.[8] The Alzheimer's Association has developed a list of 10 warning signs that are common manifestations of AD (Table 59.4).

Symptoms do not always directly relate to abnormal changes in the brain caused by AD. The stages of AD can be categorized as mild, moderate, and severe (Table 59.5). The rate of progression from mild to severe is highly variable and ranges from 3 to 20 years.

The initial manifestations are usually related to changes in cognitive functioning. The person may have memory loss, mild disorientation,

or trouble with words and numbers. Often a family member reports the patient's declining memory to the HCP.

Normal age-related memory decline is characterized by mild changes that do not interfere with ADLs (Table 59.6). In AD the memory loss initially relates to recent events, with remote memories still intact. With time and progression of AD, memory loss includes both recent and remote memory and affects the ability to perform self-care.

As AD progresses, personal hygiene deteriorates, as does the ability to concentrate and maintain attention. Ongoing loss of neurons in AD can cause the person to act in unpredictable ways. Behavioral manifestations, such as agitation or aggression, result from changes that take place within the brain. These behaviors are neither intentional nor controllable by the person with the disease. Some people develop delusions and hallucinations.

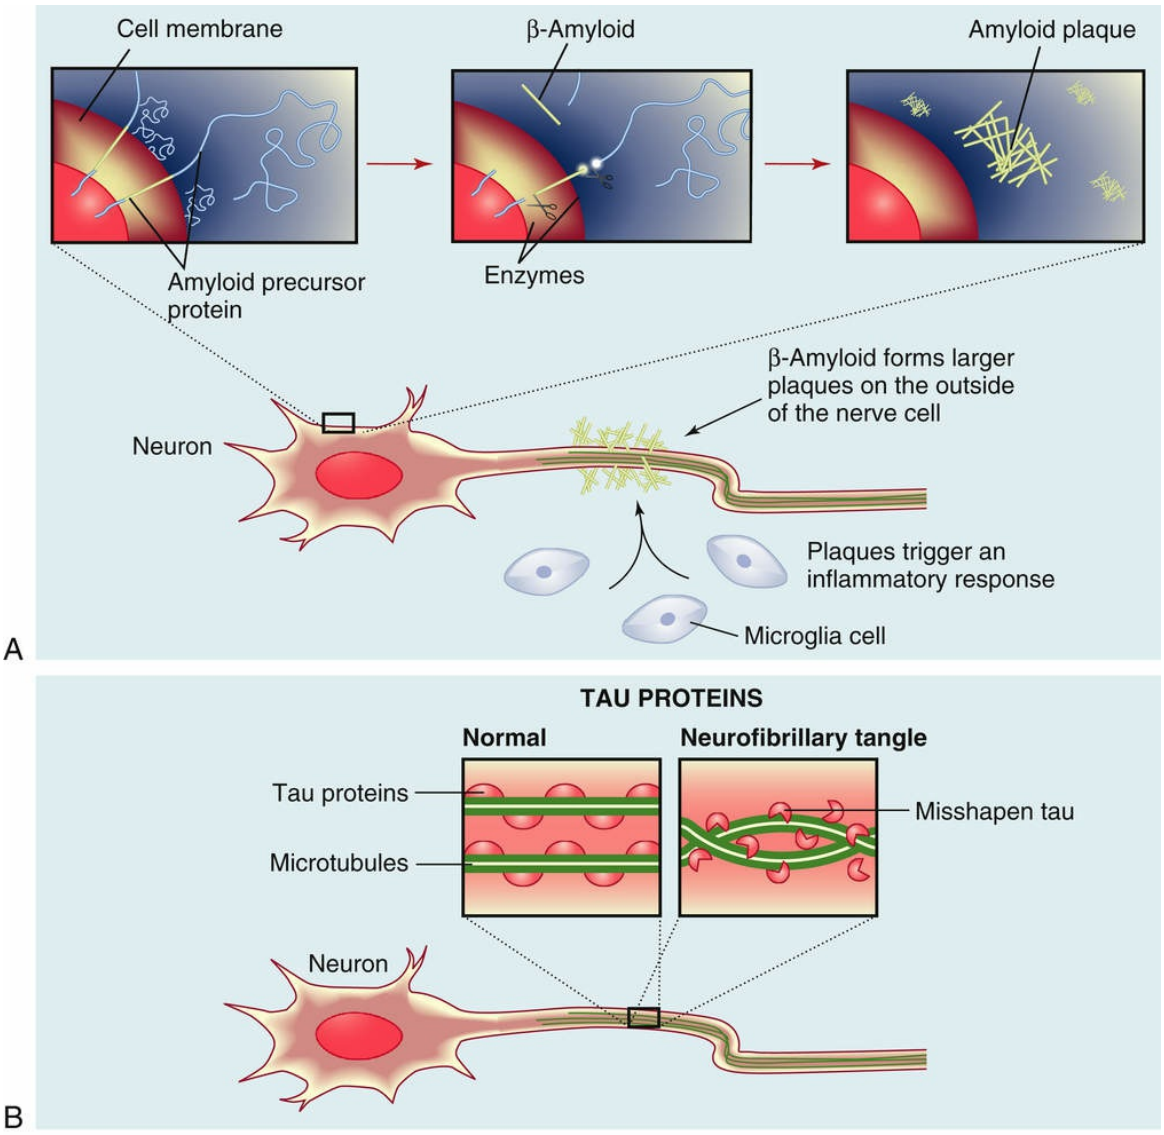

FIG. 59.3 Current theories about the development of AD. **A,** Abnormal amounts of β-amyloid are cleaved from the amyloid precursor protein *(APP)* and released into the circulation. The β-amyloid fragments come together in clumps to form plaques that attach to the neuron. Microglia react to the plaque, and an inflammatory response results. **B,** Tau proteins provide structural support for the neuron microtubules. Chemical changes in the neuron cause structural changes in tau proteins. This results in twisting and tangling (neurofibrillary tangles).

FIG. 59.4 Effects of AD on the brain. This figure compares a normal brain *(left)* with a brain affected by AD *(right)*.

With progression of AD, more cognitive impairments occur. These include dysphasia (difficulty comprehending language and oral communication), apraxia (inability to manipulate objects or perform purposeful acts), visual agnosia (inability to recognize objects by sight), and dysgraphia (difficulty communicating by writing). Eventually long-term memories cannot be recalled, and the person may not recognize family members and friends. Later in the disease, the ability to communicate and perform ADLs is lost. Some tend to wander. In the late stages of AD, the person is unresponsive, incontinent, and needs total care.

Retrogenesis

Retrogenesis is the process in which the decline in AD mirrors, in reverse order, brain development that occurs from birth.[9] Thus it compares the developmental stages of childhood with the deterioration of patients with AD. As seen in Fig. 59.5, a relationship exists between the developmental stage and deterioration of function. For example, it is appropriate for a patient with AD in the moderate stage to feel good about putting together puzzles that belong to his 3-yr-old grandson. In fact, they may play well together on the same task or project.

Diagnostic Criteria for Alzheimer's Disease

The National Institute on Aging and the Alzheimer's Association have criteria and guidelines for diagnosing AD.[10] Guidelines address the use of imaging and biomarkers that may help determine whether changes are due to AD.

TABLE 59.4 Patient & Caregiver TeachingEarly Warning Signs of Alzheimer's Disease

Include the following information in the teaching plan for the patient with Alzheimer's disease:

1. Memory loss that affects job skills
    - Frequent forgetfulness or unexplainable confusion at home or in the workplace may signal that something is wrong.
    - This type of memory loss goes beyond forgetting an assignment, colleague's name, deadline, or phone number.
2. Problems with abstract thinking
    - For the patient with AD, this goes beyond challenges, such as balancing a checkbook.

- The patient with AD may not be able to recognize numbers or do basic calculations.

3. Difficulty doing familiar tasks
    - It is normal for most people to become distracted and to forget something (e.g., leave something on the stove too long).
    - People with AD may cook a meal, then forget not only to serve it but also that they made it.
4. Poor or decreased judgment
    - Many people from time to time may choose not to dress appropriately for the weather (e.g., not bringing a coat or sweater on a cold evening).
    - The patient with AD may dress inappropriately in more noticeable ways, such as wearing a bathrobe to the store or a sweater on a hot day.
5. Problems with language
    - Most people have trouble finding the "right" word from time to time.
    - People with AD may forget simple words or substitute inappropriate words, making their speech difficult to understand.
6. Misplacing things
    - For many people, temporarily misplacing keys, purses, or wallets is a normal, albeit frustrating, event.
    - The patient with AD may put items in inappropriate places (e.g., eating utensils in clothing drawers) but have no memory of how they got there.
7. Changes in mood
    - Most people have mood changes.
    - The patient with AD tends to have more rapid mood swings for no apparent reason.
8. Changes in personality
    - As most people age, they may have some change in personality (e.g., become less tolerant).
    - The patient with AD can change dramatically, either

suddenly or over time. For example, someone who is easygoing may become angry, suspicious, or fearful.

9. Loss of initiative
    - The patient with AD may become and remain uninterested and uninvolved in many or all of his or her usual pursuits.

Adapted from Alzheimer's Association: *Early warning signs,* Chicago, The Association. Retrieved from *www.alz.org/alzheimers_disease_know_the_10_signs.asp*.

AD is considered on a spectrum (Table 59.7). The stages are preclinical AD, mild cognitive impairment, and dementia due to AD.[10] Dementia marks the terminal stage of the disease.

Preclinical Stage

A long lag exists between pathologic changes in the brain and manifestations of AD. The future goal would be to modify the disease process of AD before it becomes symptomatic. Once plaques and tangles have formed in sufficient quantity, it may be too late to intervene to prevent the disease or its progression. Although current attempts at modifying the disease process have not been successful, research is ongoing.

Mild Cognitive Impairment

Mild cognitive impairment (MCI) is the second stage in the AD spectrum. It is a state of cognitive function in which persons have problems with memory, language, or other essential cognitive functions. The problems are severe enough to be noticed by the person having them and by others and can be found on screening tests. Family members may see changes in the person's abilities (Table 59.6). To the casual observer, the person with MCI may seem normal. Because the problems do not interfere with daily activities, the patient does not meet the criteria for being diagnosed with dementia.

We classify MCI based on the cognitive skills affected. MCI that primarily affects memory is called amnestic MCI. With amnestic MCI, a person may forget important information that they would have recalled easily, such as appointments. The person is often aware of the change in memory.

MCI that affects other cognitive skills is nonamnestic MCI. Skills that may be affected include the ability to make sound decisions or complete a complex task.[11]

Between 15% and 20% of people 65 years and older have MCI. They are at high risk for developing AD. Some people with MCI show no progression and do not go on to develop AD. An estimated 15% of people with MCI will eventually develop AD.[2]

No drugs have been approved for the treatment of MCI. There is little evidence that drugs used in AD, such as cholinesterase inhibitors, affect progression to dementia or improve cognitive test scores in people with MCI.[11]

The primary treatment of MCI consists of ongoing monitoring. Monitoring the patient with MCI for changes in memory and thinking skills that indicate a worsening of symptoms or a progression to AD or other dementia is critical (Table 59.4).

Diagnostic Studies

No definitive diagnostic test exists for AD. The diagnosis is primarily a diagnosis of exclusion. In patients with cognitive impairment, there is increased emphasis on early and careful evaluation. As discussed earlier, many conditions can cause manifestations of dementia, some of which are treatable or reversible (Table 59.2).

TABLE 59.5 Stages of Alzheimer's Disease

Mild	Moderate	Severe
• Forgetfulness beyond what is seen in a normal patient • Short-term memory impairment, especially for new learning • Loss of initiative and interests • May forget recent events or the names of people or things • Impatient • May no longer be able to solve simple math problems • Slowly loses the ability to plan and organize	• Memory loss and confusion become more obvious • Has more trouble organizing, planning, and following directions • May need help getting dressed • May start having episodes of incontinence • Trouble recognizing family members and friends • Agitation, restlessness • May lack judgment and begin to wander, gets lost • May have trouble sleeping • Delusions, hallucinations, paranoia • Behavioral problems	• Severe impairment of all cognitive functions • Little memory, unable to process new information • Unable to perform self-care activities • Often needs help with daily needs • May not be able to talk • Cannot understand words • May have problems eating, swallowing • May not be able to walk or sit up without help • Immobility • Incontinence

TABLE 59.6 Comparison of Normal Forgetfulness and Memory Loss

Normal Forgetfulness	Memory Loss in Mild Cognitive Impairment	Memory Loss in Alzheimer's Disease
• Sometimes misplaces keys, eyeglasses, or other items	• Often misplaces items	• Forgets what an item is used for or puts it in an inappropriate place
• Momentarily forgets an acquaintance's name	• Often forgets people's names and is slow to recall them	• May not remember knowing a person
• Sometimes has to search for a word	• Has increasing difficulty finding desired words	• Begins to lose language skills and may withdraw from social interaction
• Sometimes forgets to run an errand	• Begins to forget important events and appointments	• Loses sense of time, does not know what day it is
• May forget an event from the distant past	• May forget recent events or newly learned information	• Seriously impaired recent memory and problems learning and remembering new information
• When driving, may momentarily forget where to turn, but quickly orients self	• Becomes temporarily lost more often, may have trouble understanding and following a map	• Becomes easily disoriented or lost in familiar places, sometimes for hours
• Jokes about memory loss	• Worries about memory loss, family and friends notice lapses	• May have little or no awareness of cognitive problems

Adapted from Rabins P: Memory. In *The Johns Hopkins white papers,* Baltimore, 2007, Johns Hopkins University.

Stage	Alzheimer's Disease	Reisberg Stage*	Developmental Age	Diversion/Distraction Activities
Mild	No difficulty at all	1		
	Some memory trouble begins to affect job/home. Forgets familiar names.	2		
	Much difficulty maintaining job performance. Withdrawal from difficult situations.	3	12+ yr	Can function with understanding. Enjoy things previously enjoyed—watch TV, play and listen to music, play games.
	Can no longer hold a job, plan and prepare meals, handle personal finances, etc. Driving becomes difficult, although can drive to familiar places.	4	8–12 yr	Can still enjoy simple games, watch TV and videos. Enjoys family photos and memories.
Moderate	Can no longer select proper clothing for occasion or season. Needs help to remain safe in home. Forgets to bathe.	5	5–7 yr	Needs age-appropriate toys and games.
	Requires assistance with dressing.	6a	4–5 yr	Enjoy many of the same activities as preschoolers.
	Requires assistance with bathing.	6b	4–5 yr	
	Can no longer use toilet without assistance.	6c	4 yr	
	Urinary incontinence	6d	3–4.5 yr	
	Fecal incontinence	6e	2–3 yr	
Severe	Speech now limited to about words per day.	7a	15 mo	Enjoys infant toys, mobiles, dangling ribbons.
	Speech now limited to 1 word per day.	7b	1 yr	
	Can no longer walk without assistance.	7c	1 yr	
	Can no longer sit up without assistance.	7d	6–10 mo	
	Can no longer smile.	7e	2–4 mo	
	Can no longer hold up head.	7f	1–3 mo	

FIG. 59.5 Retrogenesis (back to birth) in AD.

*Based on Functional Assessment Staging. From Reisberg B: Functional assessment staging [FAST], *Psychopharmacol Bull* 24:653, 1988.

TABLE 59.7 Diagnostic Criteria for Alzheimer's Disease

Stage and Description		Recommendations for Biomarkers
Preclinical Alzheimer's disease (AD)	• Brain changes, including amyloid buildup and other early neuron changes, may already be in process • At this point, significant symptoms are not yet evident • In some people, amyloid buildup can be detected with PET scans and cerebrospinal fluid (CSF) analysis	• Use of imaging and biomarker tests at this stage are recommended only for research • Biomarkers are still being developed and standardized, and are not used by clinicians in general practice
Mild cognitive impairment (MCI) due to AD	• MCI stage is marked by symptoms of memory problems, enough to be noticed and measured, but not compromising a patient's independence • May or may not progress to AD	• Used primarily by researchers • May be used in specialized clinical settings to supplement standard tests to help determine possible causes of MCI • May help confirm that the patient's impairment is related to AD
Dementia due to Alzheimer's disease	• Characterized by memory, thinking, and behavioral symptoms that impair a patient's ability to function in daily life • Dementia marks the terminal stage of AD • Encompasses all stages shown in Table 59.5	• Can increase the level of certainty about a diagnosis of AD • May be used to distinguish AD from other dementias

Source: National Institute on Aging: Diagnostic criteria for Alzheimer's disease. Retrieved from *www.nia.nih.gov/health/alzheimers-disease-diagnostic-guidelines*.

When all other possible conditions that can cause cognitive impairment have been excluded, a clinical diagnosis of AD can be made. A comprehensive evaluation includes a complete health history, physical examination, neurologic and mental status assessments, and laboratory tests (Table 59.8). A definitive diagnosis of AD requires an examination of brain tissue at autopsy and findings of neurofibrillary tangles and plaques.

Neuroimaging techniques allow for detection of changes early in the disease and monitoring of treatment response. In AD, multiple brain structures atrophy and the volume of the brain correlates with neurodegeneration. Brain imaging tests, such as CT or MRI, may show brain atrophy in the later stages of the disease. This finding occurs in other diseases and can be seen in people without cognitive impairment. PET scanning can help distinguish AD from other forms of dementia (Fig. 59.6). PET determines brain metabolism using glucose tracers. PET can also detect amyloid.

Guidelines identify 2 biomarker categories: (1) biomarkers showing the level of β-amyloid accumulation in the brain and (2) biomarkers showing that nerve cells in the brain are injured or actually degenerating. Biomarkers include (1) CSF neurochemical markers: β-amyloid and tau proteins, and (2) imaging biomarkers: volumetric MRI and PET. The level of tau in the CSF is an indication of

neurodegeneration. Plasma levels of tau or β-amyloid are not of any value in diagnosing AD.

Some imaging biomarkers are used in specialized clinical settings. CSF biomarkers are mainly used for research. Biomarkers may be used in some cases to increase the level of certainty about a diagnosis of AD and to distinguish AD from other dementias. However, we need to do more research with biomarkers before they can be routinely used in practice.

Neuropsychologic testing is important for diagnostic purposes and to establish a baseline for evaluating changes over time. They are repeated at regular intervals during the course of care to assess changes in the patient's cognitive status. Common tools include the Mini-Cog (Table 59.9), Mini-Mental State Examination (MMSE) (Table 59.10), and Montreal Cognitive Assessment (MoCA). Brief screenings, such as the Mini-Cog, are useful for ongoing screening, especially when time is limited. The clock drawing test can be used as part of the Mini-Cog or by itself to assess cognitive function (Fig. 59.7). The MMSE takes about 7 minutes to complete. It gives information about orientation, recall, attention, calculation, language manipulation, and constructional praxis. The MoCA takes about 10 minutes to do. It assesses memory, language, attention, visuospatial, and executive functions.

TABLE 59.8 Interprofessional CareAlzheimer's Disease

Diagnostic Assessment

- History and physical assessment, including psychologic evaluation
- Neuropsychologic testing, including Mini-Cog (Table 59.9), Mini-Mental State Examination (Table 59.10)
- Brain imaging tests: CT, MRI, MRS, PET

- CBC
- ECG
- Serum glucose, creatinine, blood urea nitrogen
- Serum levels of vitamins B_1, B_6, B_{12}
- Thyroid function tests
- Liver function tests
- Screening for depression

Management

- Drug therapy for cognitive problems (Table 59.11)
- Behavioral modification
- Moderate exercise
- Assistance with functional independence
- Assistance and support for caregiver

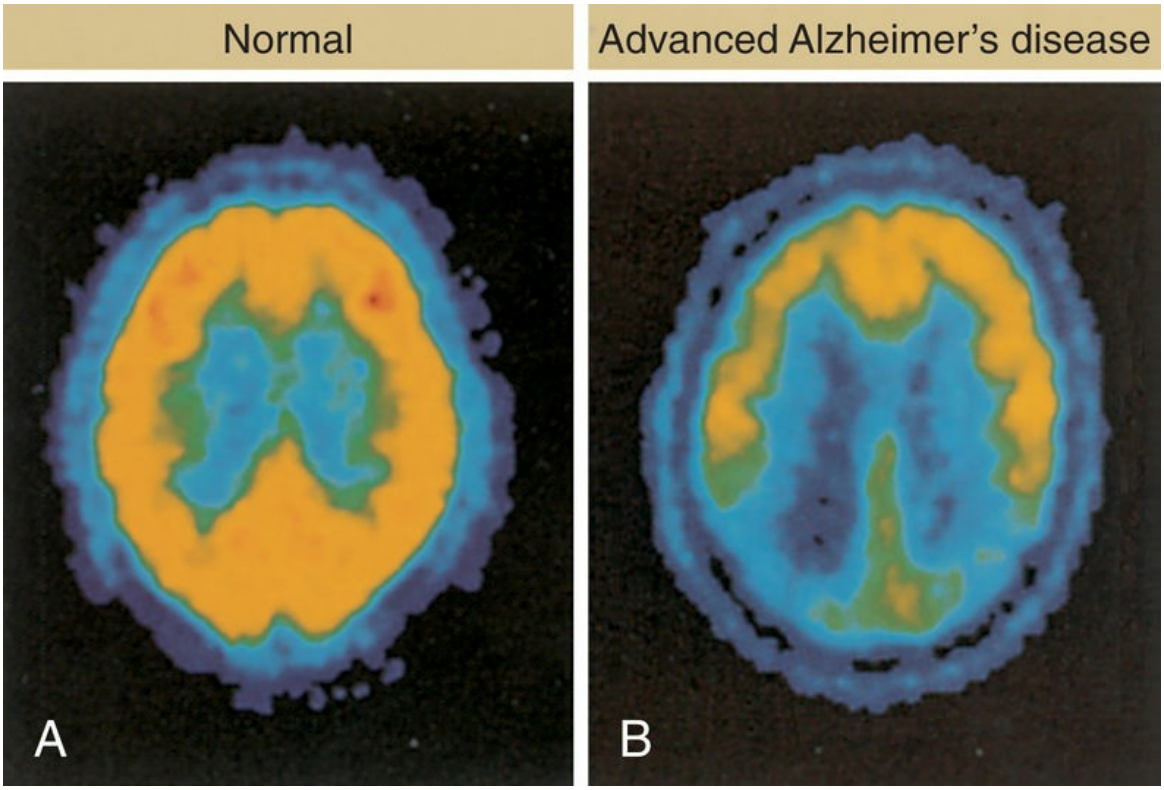

FIG. 59.6 PET scan assist in diagnosing AD. Radioactive fluorine is applied to glucose (fluorodeoxyglucose), and the yellow areas show metabolically active cells. **A,** A normal brain. **B,** Advanced AD is recognized by hypometabolism in many areas of the brain.
From Roberts GS: *Neuropsychiatric disorders,* London, 1993, Mosby-Wolfe.

TABLE 59.9 The Mini-Cog

The Mini-Cog is used as a brief assessment tool for cognitive impairment. It can be quickly administered and can guide the need for further evaluation.

Administration

- Tell the patient to listen carefully to and remember 3 unrelated words and then to repeat the words. *Example:* apple, table, penny. (This initial step is not scored.) The same 3 words may be repeated to the patient up to 3 tries to register all 3 words.

- Tell the patient to draw the face of a clock, either on a blank sheet of paper or on a sheet with the clock circle already drawn on the page. After the patient puts the numbers on the clock face, ask them to draw the hands of the clock to read a specific time (11:10). The test is considered normal if all numbers are present in the correct sequence and position and the hands readably display the requested time.
- Ask the patient to repeat the 3 previously stated words.

Scoring (out of total of 5 points)

Give 1 point for each recalled word after the clock drawing test.

- Patients recalling none of the 3 words are classified as cognitively impaired (score = 0).
- Patients recalling all 3 words are classified as not cognitively impaired (score = 3).
- Patients with intermediate word recall of 1 or 2 words are classified on the clock drawing test:

The clock drawing test is scored 2 if normal and 0 if abnormal.

Interpretation of results

0–2: Positive screen for dementia

3–5: Negative screen for dementia

TABLE 59.11 Drug TherapyAlzheimer's Disease

Problem	Drugs
Decreased memory and cognition	Cholinesterase inhibitors • donepezil (Aricept) • galantamine (Razadyne) • rivastigmine (Exelon) *N*-methyl-D-aspartate (NMDA) receptor antagonist • memantine (Namenda)
Depression	Selective serotonin reuptake inhibitors (SSRIs) • citalopram (Celexa) • fluoxetine (Prozac) • sertraline (Zoloft) • fluvoxamine (Luvox) Atypical antidepressants • mirtazapine (Remeron) • trazodone
Behavioral problems (e.g., agitation, physical aggression, disinhibition)	Antipsychotics* • aripiprazole (Abilify) • haloperidol (Haldol) • olanzapine (Zyprexa) • quetiapine (Seroquel) • risperidone (Risperdal) Benzodiazepines • clonazepam (Klonopin) • lorazepam (Ativan)
Sleep problems	• zolpidem (Ambien)

* The use of these drugs in older patients with dementia is associated with an increased risk for death.

Interprofessional Care

At this time there is no cure for AD. Treatment does not stop the deterioration of brain cells. Interprofessional care of patients with AD is aimed at controlling undesirable behavioral manifestations and providing support for family caregivers.

Drug Therapy

Although medication for AD is available (Table 59.11), these drugs do not cure or reverse the progression of the disease. They help many

people for a period of time by leading to a modest decrease in the rate of decline of cognitive function. There is no effect on overall disease progression.[2]

Cholinesterase inhibitors block cholinesterase, the enzyme responsible for the breakdown of acetylcholine in the synaptic cleft (Fig. 59.8). Cholinesterase inhibitors include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). Rivastigmine is available as a patch.

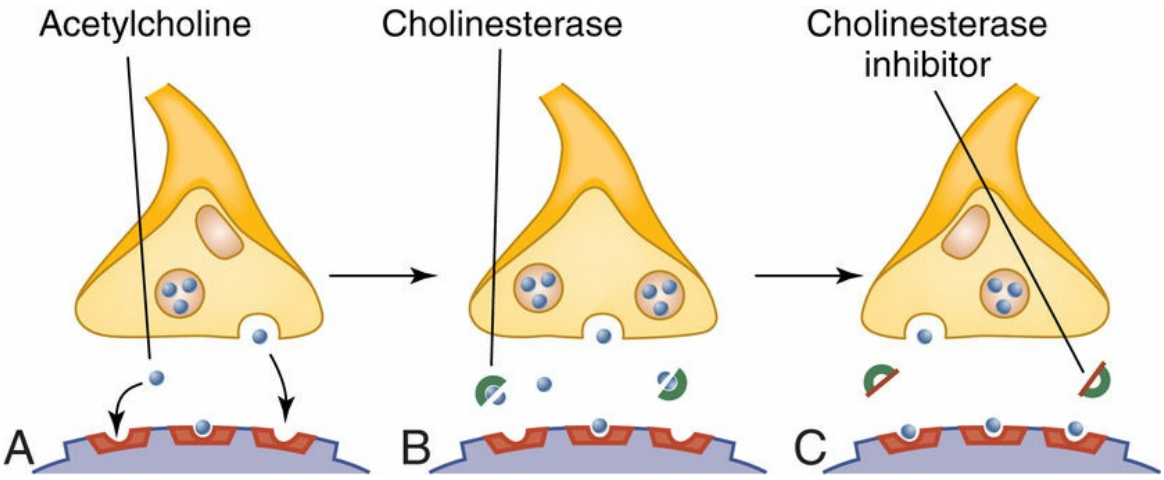

FIG. 59.8 Mechanism of action of cholinesterase inhibitors. **A,** Acetylcholine is released from the nerve synapses and carries a message across the synapse. **B,** Cholinesterase breaks down acetylcholine. **C,** Cholinesterase inhibitors block cholinesterase, thus giving acetylcholine more time to transmit the message.

Memantine (Namenda) protects the brain's nerve cells against excess amounts of glutamate, which is released in large amounts by cells damaged by AD. The attachment of glutamate to *N*-methyl-D-aspartate (NMDA) receptors permits calcium to flow freely into the cell, which in turn may lead to cell degeneration. Memantine may prevent this destructive sequence by blocking the action of glutamate.

Treating the depression that is often associated with AD may improve cognitive ability. Depression is often treated with selective serotonin reuptake inhibitors, including fluoxetine (Prozac), sertraline (Zoloft), fluvoxamine (Luvox), and citalopram (Celexa). The

antidepressant trazodone may help with problems related to sleep.

Antipsychotic drugs approved for treating psychotic conditions have been used for the management of agitation and aggressive behavior, which occurs in some patients with AD. These drugs have been shown to increase the risk for death and cognitive decline in patients with AD. They should be used only in patients with AD when agitation and psychosis symptoms are severe, are dangerous, and/or cause significant distress to the patient.[12]

Nursing Management: Alzheimer's Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with AD are outlined in Table 59.12. Useful questions for the patient and caregiver are, "When did you first notice the memory loss?" and "How has the memory loss progressed since then?"

Nursing Diagnoses

Nursing diagnoses for AD may include:

- Confusion
- Risk for injury
- Altered perception

Additional information on nursing diagnoses and interventions for the patient with AD is presented in eNursing Care Plan 59.1 (available on the website for this chapter).

Planning

The overall goals are for the patient with AD to (1) maintain functional ability for as long as possible, (2) be in a safe environment

with a minimum of injuries, (3) have personal care needs met, and (4) have dignity maintained. The overall goals for the caregiver of a patient with AD are to (1) reduce caregiver stress, (2) maintain personal, emotional, and physical health, and (3) cope with the long-term effects of caregiving.

TABLE 59.12 Nursing AssessmentAlzheimer's Disease

Subjective Data

Important Health Information

Past health history: Repeated head trauma, stroke, CNS infection, family history of dementia
Medications: Use of any drug to decrease symptoms (e.g., tranquilizers, hypnotics, antidepressants, antipsychotics)

Functional Health Patterns

Health perception–health management: Positive family history. Emotional lability
Nutritional-metabolic: Anorexia, malnutrition, weight loss
Elimination: Incontinence
Activity-exercise: Poor personal hygiene, gait instability, weakness, inability to perform activities of daily living
Sleep-rest: Frequent nighttime awakening, daytime napping
Cognitive-perceptual: Forgetfulness, inability to cope with complex situations, difficulty with problem solving (early signs), depression, withdrawal, suicidal ideation (early)

Objective Data

General

Disheveled appearance, agitation

Neurologic

Mild: Loss of recent memory, disorientation to date and time, flat affect, lack of spontaneity. Impaired abstraction, cognition, and judgment
Moderate: Agitation, impaired ability to recognize close family and friends, loss of remote memory, confusion, apraxia, agnosia, alexia (inability to understand written language); aphasia, inability to do simple tasks
Severe: Inability to do self-care, incontinence, immobility, limb rigidity, flexor posturing

Possible Diagnostic Findings

Diagnosis by exclusion, cerebral cortical atrophy on CT scan, poor scores on mental status tests, hippocampal atrophy on MRI scan, abnormal changes on PET

Nursing Implementation

Health Promotion

Can AD be prevented? Although there is no known definitive way to prevent AD, there are several things that we can do to keep our brain healthy and modify the risk for developing dementia (Table 59.13).

Early recognition and treatment of AD are important. You have a responsibility to inform patients and their families about the early signs of AD (Table 59.4). In the early stages of AD, patients are often aware that their memory is faulty and do things to mask the problem.

Acute Care

The diagnosis of AD is traumatic for both the patient and family. It is

not unusual for the patient to have depression, denial, worry, fear, and feelings of loss and dread.[13] You are in an important position to assess for depression. Antidepressant drugs and counseling may be needed. Family caregivers may be in denial and may not seek medical attention early in the disease. You can assess family caregiver's ability to accept and cope with the diagnosis.

Although there is no treatment that reverses AD, ongoing monitoring of both the patient and caregiver is important. Patients with AD move through the stages at variable rates. HCPs collaborate with caregivers and patients to manage manifestations, which change over time.

TABLE 59.13 Patient & Caregiver TeachingDecreasing Risk for Cognitive Decline

The following are tips to reduce the risk for cognitive decline and dementia:

1. Avoid harmful substances
   Excessive drinking and drug use can damage brain cells. Stop smoking because it increases the risk for cognitive decline.
2. Challenge your mind
   Read often, do crossword puzzles. Keep mentally active. Learn new skills. Go back to school. This strengthens the brain connections and promotes new ones.
3. Exercise regularly
   Even low to moderate level activity, such as walking or gardening 3 to 5 times per week, can make you feel better. Daily physical activity, even in older adults, can decrease the risk for cognitive decline.
4. Stay socially active
   Pursue social activities that have meaning to you. Family, friends, church, and a sense of community may all contribute to better brain health.

5. Avoid trauma to the brain
   Because traumatic brain injury may be a risk factor for developing AD, promote safety in physical activities and driving. Use the car seat belt. Wear a helmet when playing contact sports or riding a bike. Fall proof your home.
6. Take care of mental health
   Recognize and treat depression early. Depression may cause or worsen memory loss and other cognitive impairment.
7. Treat diabetes.
   Better blood glucose control can help to prevent the cognitive decline associated with diabetes.
8. Take care of your heart
   Risk factors for cardiovascular disease and stroke (hypertension, obesity) negatively affect your cognitive health. Heart health is linked to brain health.
9. Get enough sleep
   Not getting enough sleep may result in problems with memory and thinking.
10. Get the right fuel
   A healthy and balanced diet low in fats and high in vegetables and fruits helps to reduce the risk for cognitive decline.

Adapted from Alzheimer's Association: 10 Ways to love your brain. Retrieved from *www.alz.org/help-support/brain_health/10_ways_to_love_your_brain;* and Baumgart M, Snyder HM, Carrillo MC, et al: Summary of evidence on modifiable risk factors for cognitive decline and dementia: A population-based perspective, *Alzheimers Dement* 11:718, 2015.

The nursing care needed by the patient with AD changes as the disease progresses, which emphasizes the need for regular assessment

and support. The severity of the problems and amount of nursing care needed increase over time. The specific manifestations of the disease depend on the area of the brain involved. Nursing care focuses on decreasing manifestations, preventing harm, and supporting the patient and caregiver throughout the disease process.

Patients with AD may have other acute and chronic illnesses that require hospitalization or surgical interventions. Hospitalization can be traumatic for the patient with AD and the caregiver. Hospitalization can precipitate a worsening of dementia or development of delirium among patients with AD. Caregivers and health care professionals need to help patients who have difficulty explaining their symptoms or recalling their health and medical histories. In the acute care setting, patients with AD need to be observed more closely because of concerns for their safety. They should be frequently reassured and oriented to place and time. Anxiety or disruptive behavior may be reduced with using consistent nursing staff.

Ambulatory Care

Currently, family members and friends care for many people with AD in their homes. Other patients with AD live in various types of facilities, including long-term care and assisted living facilities. A facility that is good for one patient may not be suitable for another. What is helpful for a patient at one point in the disease process may be completely different from what is best when the disease progresses.

After the initial diagnosis, patients need to be aware that the progression of the disease is variable. Effective management of the disease may slow symptom progression and decrease the burden on the patient, caregiver, and family. Decisions related to care should be made with the patient, family members, and interprofessional care team early in the disease. You have a role in advising the patient and caregiver to initiate health care decisions, including advance directives, while the patient has the capacity to do so. This can ease the burden for the caregiver as the disease progresses.

In the early stages of AD, memory aids, such as calendars, may be

beneficial. Patients often become depressed during this phase. Depression may be related to the diagnosis of an incurable disorder and the impact of the disease on ADLs, including driving, socializing, and taking part in recreational activities. Nurses teach caregivers to perform tasks needed to maximize quality of life and safety of the patient with AD.

Adult day care is one of the options available to the patient with AD. Although programs vary in size, structure, physical environment, and staff experience, the common goals of all day care programs are to provide respite for the family and a protective environment. During the early and moderate stages of AD, the patient can still benefit from stimulating activities that encourage independence and decision making in a protective environment. The patient returns home tired, content, less frustrated, and ready to be with the family. The respite from the demands of care allows the caregiver to be more responsive to the patient's needs.

As the disease progresses, the demands on the caregiver eventually exceed the resources, and the patient with AD may need to be placed in a long-term care facility. Special dementia units are becoming increasingly common. The dementia unit is designed with an emphasis on safety. Many facilities have designated areas that allow the patient to walk freely within the unit, while the unit is secured so that the patient cannot wander outside.

As the disease progresses to the late stage, the patient is severely impaired, having difficulty with basic functions, including walking and talking. Total care is needed for this patient. Specific problems relate to the care of the patient with AD in all phases of the disease. These problems are described next.

Behavioral Problems

Behavioral problems occur in about 90% of patients with AD. These problems include repetitiveness or asking the same question repeatedly, delusions, hallucinations, agitation, aggression, altered sleeping patterns, wandering, hoarding, and resisting care. Many times, these behaviors are unpredictable and may challenge

caregivers. Caregivers must be aware that these behaviors are not intentional and are often difficult to control. Behavioral problems are often the reason that patients are placed in institutional care settings.[14]

These behaviors are often the patient's way of responding to pain, frustration, temperature extremes, or anxiety. When these behaviors become problematic, you must plan interventions carefully. Assess the patient's physical status. Check for changes in vital signs, urinary and bowel patterns, and pain that could account for behavioral problems. Assess the environment to identify factors that may trigger behavior disruptions. Extremes in temperature or excessive noise may lead to behavior changes. When environmental conditions are agitating the patient, either move the patient or remove the stimulus.

When a patient resists or pulls tubes or dressings, cover these items with stretch tube gauze or remove them from the visual field. Reassure the patient that you are present to keep him or her safe. Do not ask challenging "why" questions. The patient with AD cannot think logically. If the patient cannot state distress, validate their mood. Rephrase the patient's statement to validate its meaning. Closely observe the patient's emotional state.

Nursing strategies that address difficult behavior include redirection, distraction, and reassurance. When a patient is restless or agitated, redirecting involves changing the patient's focus by having them perform activities, such as sweeping, raking, or dusting. Providing snacks, taking a car ride, sitting on a porch swing or rocker, listening to favorite music, watching videotapes, looking at family photographs, or walking may distract an agitated patient. Reassure patients by telling them that they will be protected from danger, harm, or embarrassment. Repetitive activities, including songs, poems, music, massage, aromas, or a favorite object can be soothing.

Do not threaten to restrain an agitated patient. Ask a calming family member to stay with the patient. Monitor the patient frequently and record all interventions. As verbal skills decline, you and the caregiver must rely more on the patient's body language to communicate care needs. The use of positive nursing actions can reduce the use of chemical (drug therapy) restraints.

Disruptive behaviors have been treated with antipsychotic drugs (Table 59.11). However, as discussed on p. 1393, these have adverse side effects. All other measures of treating behavioral issues should be exhausted before drug treatment is started.

Check Your Practice

You are working in a secure Alzheimer's unit. While making rounds at 4 PM you see Dan, one of the UAPs, screaming at an 84-yr-old male resident. When you approach Dan and the resident, you ask what is going on. Dan responds, "Every day about this time he gets so agitated and starts yelling at me, so I yell back."

- How would you handle the situation? What teaching does Dan need?

A specific type of agitation, termed **sundowning**, is when the patient becomes more confused and agitated in the late afternoon or evening. Behaviors related to sundowning include agitation, aggressiveness, wandering, resistance to redirection, and increased verbal activity, such as yelling. The cause of sundowning is unclear. It may be due to a disruption of circadian rhythms. Other causes include pain, hunger, unfamiliar environment and noise, medications, reduced lighting, and fragmented sleep.[15]

Managing sundowning can be challenging for you, the patient, and the family. When a patient has sundowning, remain calm and avoid confrontation. Assess the situation for possible causes of the agitation. Nursing interventions that may be helpful include (1) creating a quiet, calm environment; (2) maximizing exposure to daylight by opening blinds and turning on lights during the day; (3) evaluating medications to determine if any could cause sleep problems; (4) limiting naps and caffeine; and (5) consulting with the HCP about drug therapy.

Nursing Management

Caring for the Patient With Alzheimer's Disease

The RN is responsible for ongoing assessment of the patient's level of function and for developing the plan of care. Since most patients with AD are cared for at home or in long-term care settings, many routine nursing activities are performed by licensed practical/vocational nurses (LPN/VNs), unlicensed assistive personnel (UAP), or family caregivers.

- Assess patients' memory and level of function.
- Teach patients and caregivers about using memory enhancement aids, such as calendars or notes.
- Monitor for physiologic problems, such as pain, swallowing difficulties, urinary tract infection, pneumonia, skin breakdown, and constipation.
- Assess nutritional and fluid intake and develop a plan to ensure adequate intake.
- Evaluate safety risk factors.
- Determine possible precipitating factors for behavioral changes and develop strategies to address difficult behavior.
- Assess family caregivers' stress level and coping strategies.
- Make referrals for community services, such as adult day care and respite care.
- Delegate to LPN/VN*:*
    - Monitor for behavioral changes that may indicate physiologic problems.
    - Check the environment for potential safety hazards.
    - Give enteral feedings to patients who are unable to swallow, if ordered.
    - Give ordered medications.
- Oversee UAP**:**

- Help patients to use the toilet, commode, or bedpan at frequent intervals.
- Provide personal hygiene, skin care, and oral care.
- Help patients with eating.
- Aid patients with daily activities.
- Use bed alarms and surveillance to decrease risk for falls.

Collaborate With Other Team Members

Dietitian

- Assess nutrition status and provide prescribed nutritional support.
- Offer practical suggestions to enhance dietary intake.

Occupational Therapist

- Suggest ways to help patients retain self-care ability as long as possible.

Social Worker

- Help caregivers identify and obtain needed resources.
- Provide support and counseling to caregivers.

Safety

The patient with AD is at risk for problems related to personal safety. Potential hazards include falling, ingesting dangerous substances, wandering, injuring others and self with sharp objects, being burned, and being unable to respond to crisis situations. These concerns require careful attention in the home environment to minimize risk. Supervision is needed. As the patient's cognitive function declines over time, they may have problems navigating physical spaces and interpreting environmental cues. Help the caregiver assess the home environment for safety risks.

Safety Alert

Preventing Falls

Teach the caregiver to take the following steps:

- Have stairwells well lit.
- Make sure the patient can grasp the handrails.
- Tack down carpet edges.
- Remove throw rugs and extension cords.
- Use nonskid mats in tub or shower.
- Install handrails in the bath and by the commode.

Wandering is a major concern for caregivers. Wandering may be related to loss of memory or to side effects of medications. It may be an expression of a physical or emotional need, restlessness, curiosity, or stimuli that trigger memories of earlier routines. As with other behaviors, observe for factors or events that may precipitate wandering. For example, the patient may be sensitive to stress and tension in the environment. In such cases, wandering may reflect an attempt to leave.

When someone with AD is discovered missing, every second counts. To assist caregivers with finding them, the Alzheimer's Association and the MedicAlert Foundation have created an alliance called MedicAlert + Alzheimer's Association Safe Return.[16] This program includes identification products (e.g., bracelet, necklace, wallet cards), a national photo and information database, a 24-hour toll-free emergency crisis line, local chapter support, and wandering behavior education and training for caregivers and families.

Tracking devices (e.g., global positioning system [GPS]) can be used to find people who wander. These devices can be placed in shoes, sewn into pockets, worn as a bracelet or pendant, or clipped to a belt.

Pain Management

Because of difficulties with oral and written language, patients with AD may have a hard time expressing physical problems, including pain. You need to rely on other clues, such as the patient's behavior. Pain can result in changes in behavior, including increased vocalization, agitation, withdrawal, and changes in function. Pain should be recognized and treated promptly and the patient's response monitored.

Eating and Swallowing Difficulties

Undernutrition is a problem in the moderate and severe stages of AD. Loss of interest in food and decreased ability to self-feed *(feeding apraxia),* as well as co-morbid conditions, can result in significant nutritional problems. In long-term care facilities, inadequate aid with feeding may add to the problem.

Use pureed foods, thickened liquids, and nutritional supplements when chewing and swallowing become problematic for the patient. The patient may need reminders to chew their food and to swallow. A quiet and unhurried environment without distractions (e.g., television) at mealtimes can be helpful. Low lighting, music, and simulated nature sounds may improve eating behaviors. Easy-grip eating utensils and finger foods may allow the patient to self-feed. Liquids should be offered frequently.

When oral feeding is not possible, explore alternative routes. Nasogastric (NG) feeding may be used for short periods. However, for the long term, the NG tube is uncomfortable and may add to the patient's agitation. A percutaneous endoscopic gastrostomy (PEG) tube is another option (see Fig. 39.7). PEG tubes can be problematic since patients with AD are vulnerable to aspiration of feeding formula and tube dislodgment. The potential positive outcomes to be gained from nutritional therapies are considered in light of overall outcome goals and potential adverse effects of the specific therapy. Nutritional support therapies are described in Chapter 39.

Oral Care

In the late stages of AD, the patient is unable to perform oral self-care. With decreased tooth brushing and flossing, dental problems are likely to occur. Because of swallowing difficulties, patients may retain food in the mouth, adding to the potential for tooth decay. Dental caries and tooth abscess can cause discomfort or pain and increase agitation. Inspect the mouth regularly and provide mouth care to those patients unable to perform self-care.

Infection Prevention

Urinary tract infection and pneumonia are the most common infections in patients with AD. Such infections are the cause of death in many patients with AD. Because of feeding and swallowing problems, the patient is at risk for aspiration pneumonia. Immobility can predispose the patient to pneumonia.

Reduced fluid intake, prostate enlargement in men, poor hygiene, and urinary drainage devices can predispose patients to bladder infection. Any manifestations of infection, such as a change in behavior, fever, cough, or pain on urination, require prompt evaluation and treatment.

Skin Care

It is important to monitor the patient's skin over time. Note and treat rashes, areas of redness, and skin breakdown. In the late stages, incontinence along with immobility and undernutrition can place the patient at risk for skin breakdown. Keep the skin clean and dry. Change the patient's position regularly to avoid areas of pressure over bony prominences.

Elimination Problems

During the moderate and severe stages of AD, urinary and fecal incontinence lead to increased need for nursing care. When possible, behavioral retraining of bladder and bowel function by scheduled toileting may help decrease episodes of incontinence.

Another common elimination problem is constipation. Causes may

relate to immobility, reduced fiber intake, and decreased fluid intake. Increased dietary fiber, fiber supplements, and stool softeners are the first lines of management. The combination of aging, other health problems, and swallowing difficulties may increase the risk for complications associated with the use of mineral oil, stimulants, osmotic agents, and enemas. Management of constipation is discussed in Chapter 42.

Caregiver Support

More than 16 million Americans provide unpaid care for people with AD or other dementias.[2] Most of these are family members providing care in the home (Fig. 59.9). AD disrupts all aspects of patient and family life. Caregivers for people with AD describe it as very stressful. They often have adverse consequences relating to their own emotional and physical health.

The chronic and often severe stress associated with dementia caregiving increases the risk for the development of dementia in spouse caregivers.[17] One mechanism proposed is that the detrimental effects of the chronic stress of caregiving can affect the hippocampus, a region of the brain responsible for memory.

FIG. 59.9 Caregivers of patients with dementia face an incredible challenge that often causes deterioration in their own physical and emotional health.
© iStock/Thinkstock.

As the disease progresses, the relationship between the caregiver and patient with AD changes. Family roles may be altered or reversed. A child may care for a parent. Decisions must be made, including when to tell the patient about the diagnosis, have the patient stop driving or doing activities that may have become dangerous, ask for assistance, and place the patient in adult day care or a long-term care facility. With early-onset AD, the patient is affected during their most productive years in terms of career and family. The consequences can be devastating to the patient and family.

Sexual relations for couples are seriously affected by AD. As the disease progresses, sexual interest may decline for both the patient and partner. Several reasons account for this, including fatigue, memory impairment, and episodes of incontinence. Some patients become sexually driven and uninhibited as the disease progresses.

Work with the caregiver to assess stressors and identify coping strategies to reduce the burden of caregiving. For example, ask which behaviors are most disruptive to family life at a given time. This is likely to change as the disease progresses. Determining what is most disruptive or distressful to the caregiver can help establish priorities.

Patient safety is a high priority. It is important to assess what the caregiver's expectations are about the patient's behavior. Are the expectations reasonable given the progression of the disease? A family and caregiver teaching guide based on the disease stages is provided in Table 59.14. Other tips for caregivers are listed in Table 59.15. A nursing care plan for the family caregiver (eNursing Care Plan 59.2) is available on the website for this chapter.

TABLE 59.14 Patient & Caregiver TeachingAlzheimer's Disease

Include the following instructions when teaching families and caregivers the management of the patient with Alzheimer's disease:

Mild Stage

- Many treatable (and potentially reversible) conditions can mimic dementia (Table 59.2). Try to establish a diagnosis.
- Get the patient to stop driving. Confusion and poor judgment can impair driving skills and potentially put others at risk.
- Encourage activities such as visiting with friends and family, listening to music, enjoying hobbies, and exercising.
- Provide cues in the home, establish a routine, and determine a specific location where essential items (e.g., glasses) must be kept.

- Do not correct misstatements or faulty memory.
- Register with MedicAlert + Alzheimer's Association Safe Return, a program established by the MedicAlert Foundation and the Alzheimer's Association to locate those who wander from their homes.
- Make plans in terms of advance directives, care options, financial concerns, and personal preference for care.

Moderate Stage

- Install door locks for patient safety.
- Provide protective wear for urinary and fecal incontinence.
- Ensure that the home has good lighting, install handrails in stairways and bathroom, and remove area rugs.
- Label drawers and faucets (hot and cold) to ensure safety.
- Develop ways, such as distraction and diversion, to cope with behavioral problems. Identify and reduce potential triggers (e.g., reduce stress, extremes in temperature) for disruptive behavior.
- Provide memory triggers, such as pictures of family and friends.

Severe Stage

- Follow a regular schedule for toileting to reduce incontinence.
- Provide care to meet needs, including oral care and skin care.
- Monitor diet and fluid intake to ensure their adequacy.
- Continue communication through talking and touching.
- Consider placement in a long-term care facility when providing total care becomes too difficult.

Support groups for caregivers and family members (Fig. 59.10) can provide an atmosphere of understanding and give current information about the disease itself and related topics, such as safety,

legal, ethical, and financial issues. The Alzheimer's Association has many educational and support systems available to help family caregivers *(www.alz.org)*.

TABLE 59.15 Nursing Management

Do

- Treat the adult with respect and dignity, even when behavior is childlike.
- Use gentle touch and direct eye contact.
- Remain patient, flexible, calm, and understanding.
- Expect challenging behaviors, since the patient's ability to think logically is affected.
- Give directions using gestures or pictures.
- Simplify tasks. Focus on one thing at a time.
- Avoid questions or topics that require extensive thought, memory, or words.
- Be flexible. If one approach does not work, try another.
- Use distraction, changing the subject, redirecting to another activity.
- Provide reassurance. Praise sincerely for success.

Do Not

- Criticize, correct, or argue.
- Rush or hurry the patient.
- Force participation in activities or events.
- Talk about the patient as if they are not there.
- Blame the patient with AD. Instead, blame the disease.
- Take challenging behaviors patiently. These behaviors are due to

the disease.

- Use condescending terms, such as “honey” or “sweetie.”
- Use threatening gestures.
- Overreact to the patient with AD.
- Try to explain “why” or rationalize.

FIG. 59.10 Support groups are an effective way to help caregivers cope.
© iStockphoto/Thinkstock.

Evaluation

Expected outcomes are that the patient with AD will:

- Function at the highest level of cognitive ability
- Perform basic personal care ADLs, by self or with assistance,

as needed
- Have no injury
- Stay in a restricted area during ambulation and activity

Delirium

Delirium is a state of confusion that develops over days to hours.[1] The patient has decreased ability to direct, focus, sustain, and shift attention and awareness. Deficits in memory, orientation, language, visuospatial ability, or perception may be present. The patient may be hypoactive or hyperactive. Emotional problems include fear, depression, euphoria, or perplexity. Sleep may be disturbed.

These symptoms represent a change from the patient's baseline and tend to fluctuate throughout the day. They do not occur in the context of a severely reduced level of arousal, such as coma, and cannot be explained by another preexisting, evolving, or established neurocognitive disorder.

Etiology and Pathophysiology

We do not know the exact cause of delirium. A main contributing factor is impairment of cerebral oxidative metabolism, in which the brain gets less oxygen and has problems using it. Multiple neurotransmitter abnormalities may be involved. Cholinergic deficiency, excess release of dopamine, and both increased and decreased serotonin activity may contribute to delirium. Proinflammatory cytokines, including interleukin-1 (IL-1), IL-2, IL-6, tumor necrosis factor-α (TNF-α), cytokines, and interferon, appear to play a role.

Delirium is rarely caused by a single factor. It most often occurs among hospitalized older adults. Up to 60% of older adults hospitalized for medical conditions have delirium at some time during their hospitalization.[18] Stress, surgery, and sleep deprivation have been linked to delirium. Delirium is the most common surgical complication among older adults. The incidence is 15% to 25% after

major elective surgery and 50% after high-risk procedures, such as hip fracture repair and heart surgery.[19] Pain and depression contribute to delirium, especially among older adults.[19]

Delirium is often the result of the interaction of the patient's underlying condition with a precipitating event. Delirium can occur after a relatively minor insult in a vulnerable patient. For example, a patient with underlying health problems, such as heart failure (HF), cancer, cognitive impairment, or sensory limitations, may develop delirium in response to a minor change, such as use of a sleeping medication. In other less vulnerable patients, it may take a combination of factors, such as anesthesia, major surgery, mechanical ventilation, infection, and prolonged sleep deprivation, to precipitate delirium. Delirium can be a symptom of a serious medical illness, such as bacterial meningitis.

Dementia is the leading risk factor for delirium. Furthermore, delirium is a risk factor for developing dementia. Delirium may cause permanent neuronal damage and lead to dementia.[20]

Understanding factors that can lead to delirium can help determine effective interventions. Common factors that can precipitate delirium are listed in Tables 59.16 and 59.17. Many of these factors are more common among older adults. Older adults have limited compensatory mechanisms to deal with physiologic insults, such as hypoxia, hypoglycemia, and dehydration. They are more susceptible to drug-induced delirium, in part because of their increased use of multiple drugs. Many drugs, including sedative-hypnotics, opioids (especially meperidine [Demerol]), benzodiazepines, and anticholinergics, can cause or contribute to delirium, especially in older or vulnerable patients.[21]

TABLE 59.16 Factors That Precipitate Delirium

Demographic Characteristics

- Age 65 year or older
- Male gender

Cognitive Status

- Cognitive impairment
- Dementia
- Depression
- History of delirium

Decreased Oral Intake

- Dehydration
- Malnutrition

Drugs

- Alcohol or drug use or withdrawal
- Aminoglycosides
- Anticholinergics
- Opioids
- Sedative-hypnotics
- Treatment with multiple drugs

Environmental

- Admission to ICU
- Emotional stress
- Pain (especially untreated)
- Sleep deprivation

- Use of physical restraints

Functional Status

- Functional dependence
- History of falls
- Immobility

Medical Conditions

- Acute infection, sepsis, fever
- Chronic kidney or liver disease
- Electrolyte imbalances
- Fracture or trauma
- History of stroke
- Neurologic disease
- Severe acute illness
- Terminal illness

Sensory

- Sensory deprivation
- Sensory overload
- Visual or hearing impairment

Surgery

- Cardiac surgery
- Noncardiac surgery
- Orthopedic surgery

- Prolonged cardiopulmonary bypass

TABLE 59.17 Mnemonic for Causes of Delirium

Dementia, dehydration
Electrolyte imbalances, emotional stress
Lung, liver, heart, kidney, brain
Infection, intensive care unit
Rx drugs
Injury, immobility
Untreated pain, unfamiliar environment
Metabolic disorders

Clinical Manifestations

Patients with delirium can have a variety of manifestations, ranging from hypoactivity and lethargy to hyperactivity, agitation, and hallucinations. Patients can have mixed delirium, with both hypoactive and hyperactive symptoms. Delirium can develop over the course of hours to days. It usually develops over a 2- to 3-day period. The early manifestations often include inability to concentrate, disorganized thinking, irritability, insomnia, loss of appetite, restlessness, and confusion. Later manifestations may include agitation, misperception, misinterpretation, and hallucinations.

Delirium can last from 1 to 7 days. However, delirium may persist for months or years. Some patients do not completely recover.

TABLE 59.18 Confusion Assessment Method (CAM)

Delirium is diagnosed with the presence of features 1 and 2, and either 3 or 4.

Feature 1
Acute Onset and Fluctuating Course

Data usually obtained from a family member or nurse.
Shown by positive responses to the following questions:

- Is there evidence of an acute change in mental status from the patient's baseline?
- Did the (abnormal) behavior fluctuate during the day (i.e., tend to come and go, or increase and decrease in severity)?

Feature 2
Inattention

Shown by positive response to the following question:

- Did the patient have problem focusing attention (e.g., being easily distractible, or having problem keeping track of what was being said)?

Feature 3
Disorganized Thinking

Shown by a positive response to the following question:

- Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Feature 4
Altered Level of Consciousness

Shown by any answer other than "alert" to the following question:

- Overall, how would you rate this patient's level of consciousness (alert [normal], vigilant [hyper alert], lethargic [drowsy, easily aroused], stupor [difficult to arouse], or coma [unarousable])?

Adapted from Inouye S, van Dyck C, Alessi C, et al: Clarifying confusion: The Confusion Assessment Method, *Ann Intern Med* 113:941, 1990.

Manifestations of delirium are sometimes confused with those of dementia. A key distinction between them is that the patient who has sudden cognitive impairment, disorientation, or clouded sensorium is more likely to have delirium rather than dementia. A comparison of delirium and dementia is shown in Table 59.1.

Diagnostic Studies

Diagnosing delirium is complicated because many critically ill patients cannot communicate their needs. A careful medical and psychologic history and physical assessment are the first steps in diagnosing delirium and its underlying cause. This includes careful attention to medications, both prescription and OTC. The Confusion Assessment Method (CAM) is a reliable tool for assessing delirium (Table 59.18). The version of the CAM may vary depending on the clinical setting. It is important to distinguish whether the delirium is part of underlying dementia.

Once delirium has been diagnosed, explore potential causes. Carefully review the patient's health history and medication record. Laboratory tests include complete blood count, serum electrolytes, blood urea nitrogen, and creatinine levels; ECG; urinalysis; liver and thyroid function tests; and oxygen saturation level. Drug and alcohol levels may be obtained. If unexplained fever or nuchal rigidity is present and meningitis or encephalitis is suspected, a lumbar puncture may be done. CSF is examined for glucose, protein, and bacteria. If the patient's history includes head injury, appropriate x-

rays or scans may be ordered. In general, brain imaging studies, such as CT and MRI, are used only when head injury is known or suspected.

Ethical/Legal Dilemmas

Board of Nursing Disciplinary Action

Situation

The state board of nursing has received multiple complaints about J.R., an RN who works in a long-term care facility. J.R. has signed off on 3 controlled substances count sheets that have been determined to be inaccurate. During an investigation it was discovered that several members of the nursing staff knew about J.R.'s reported behavior, but they did not report their observations to the unit administrator because the administrator is J.R.'s aunt. After the investigation, the board of nursing subpoenas J.R. to a meeting to discuss charges in preparation for a disciplinary hearing.

Ethical/Legal Points for Consideration

Regulation of professional nursing practice is the right of each of the 50 states. Most have regulatory agencies charged with writing regulations and rules to implement the state nurse practice act. The regulations approved by these agencies carry the weight of law. Failure to behave accordingly places a nurse at risk for disciplinary action.

The RN who is charged with unprofessional behavior has been charged with an offense and is entitled to the same legal rights as any other person, including a fair and timely hearing, opportunity to confront the accusers, right to be represented by an attorney, and right to prepare a defense.

Possible disciplinary actions include temporary suspension of the nursing license, revocation of the nursing license, mandatory rehabilitation for substance use, and mandated supervision and evaluation of practice. Sometimes the disciplinary action includes

fines and requires reeducation. The state board of nursing may report the action to the state attorney general if evidence suggests that a crime has been committed. The RN who is found guilty of unprofessional practice must report this action on all future applications for nursing positions.

All RNs should be familiar with their state's nurse practice act and regulations, and the composition and actions of the state board of nursing. Nurses should pay attention to the regulation that lists examples of actionable behavior and disciplinary actions sanctioned by the state.

RNs have a legal and ethical obligation to report suspected illegal behavior to their administrators and to continue reporting until the situation is resolved. By failing to report, the RN may be charged as an accessory to the act or aiding and abetting the behavior. This RN may be charged with unprofessional behavior and risks losing his or her nursing license. Shifting the obligation to someone else to report or failure to continue reporting each incident does not satisfy this duty.

Discussion Questions

1. How would you handle a situation in which retaliation for reporting unprofessional behavior may occur?
2. What would you do if the nurse suspected of illegal behavior is related to someone in the administrative hierarchy?

Nursing and Interprofessional Management: Delirium

Treatment is important as many cases of delirium are potentially reversible. In caring for the patient with delirium, you are responsible for prevention, early recognition, and treatment. Prevention of delirium involves recognition of patients at high risk, including those with neurologic disorders, such as dementia, stroke, CNS infection, and Parkinson's disease.[22] Other risk factors include sensory

impairment, older age, surgery, hospitalization in an intensive care unit (ICU), and untreated pain. Risk factors are listed in Table 59.16.

Care of the patient with delirium focuses on eliminating precipitating factors. If it is drug induced, medications are discontinued. Keep in mind that delirium can accompany drug and alcohol withdrawal. Depending on the history, drug screening may be done. Fluid and electrolyte imbalances and nutritional deficiencies (e.g., thiamine) are corrected if appropriate. If the problem is related to an overstimulating or understimulating environment, then changes should be made. If delirium is from infection, appropriate antibiotic therapy is started. Similarly, if delirium is due to chronic illness, such as chronic kidney disease or HF, treatment focuses on these conditions.

Check Your Practice

You are working in the medical ICU. Your patient is an 82-yr-old man who had a hip replacement 3 days ago. He was doing well after surgery and then developed bilateral pneumonia. He was transferred to the ICU yesterday. When you walk into his room, you notice his daughter is staring out the window and does not respond to your greeting. When you approach her, you notice she is very upset. When you ask her what is wrong, she bursts out crying, "How can this be? My dad was always such a vibrant and brilliant man. Now look at him. He talks to himself. He screams at me. He thinks I am his wife. Mom died 5 years ago. What happened to him?"

- How would you assess the situation?
- What can you do to help the daughter?

Care of the patient with delirium includes protecting the patient from harm. Give priority to creating a calm and safe environment. This may include encouraging family members to stay at the bedside, providing familiar objects and family photos, transferring the patient

to a private room or one closer to the nurses' station, and planning for consistent nursing staff if possible. Use reorientation and behavioral interventions in patients with delirium. Provide the patient with reassurance and reorienting information as to place, time, and procedures. Clocks, calendars, and lists of scheduled activities are helpful. Reduce environmental stimuli, including noise and light levels.

Personal contact through touch and verbal communication can be an important reorienting strategy. If the patient uses eyeglasses or a hearing aid, they should be readily available because sensory deprivation can precipitate delirium. Avoid the use of restraints. Other interventions, including relaxation techniques, music therapy, and massage, may be appropriate for some patients with delirium.

Comprehensive interventions to prevent delirium should be implemented by the health care team.[23] The team may address issues related to polypharmacy, pain, nutritional status, and potential for incontinence. The patient with delirium is at risk for the adverse consequences of immobility, including skin breakdown. Give attention to increasing physical activity or providing range-of-motion exercises, when appropriate, and maintaining skin integrity.

Focus on supporting the family and caregivers during episodes of delirium. Family members need to understand factors that may have precipitated the delirium, as well as the potential outcomes. Patient education materials are available at *www.ICUdelirium.org*.

Drug Therapy

Drug therapy is reserved for patients with severe agitation, especially when it interferes with needed medical treatments. Agitation can put the patient at risk for falls and injury. Medication therapy is used cautiously because many of the drugs used to manage agitation have psychoactive properties. Drugs should be used only when nonpharmacologic interventions have failed.

Dexmedetomidine (Precedex), an α-adrenergic receptor agonist, has been used in ICU settings for sedation. The use of low-dose

antipsychotics (e.g., haloperidol, risperidone [Risperdal], olanzapine [Zyprexa], quetiapine [Seroquel]), though common practice, is controversial.[24] Research suggests their use does not change the duration of delirium or the length of hospitalization.[24]

Haloperidol can be given IV, IM, or orally and will produce sedation. Other side effects include hypotension; extrapyramidal side effects, including *tardive* dyskinesia (involuntary muscle movements of face, trunk, and arms) and *athetosis* (involuntary writhing movements of the limbs); muscle tone changes; and anticholinergic effects. Carefully monitor older patients receiving antipsychotic agents.

Short-acting benzodiazepines (e.g., lorazepam [Ativan]) can be used to treat delirium associated with sedative and alcohol withdrawal or in conjunction with antipsychotics to reduce extrapyramidal side effects. However, these drugs may worsen delirium caused by other factors and must be used cautiously.

Case Study

Alzheimer's Disease

© iStock/Thinkstock.

Patient Profile

M.Y., a 78-yr-old Asian American man, was diagnosed with Alzheimer's disease (AD) 3 years ago shortly after his wife died. Today his 45-yr-old son brings him to the emergency department because he wandered from his son's home, fell, and injured his left hip.

Subjective Data

- Can say his name, confused as to place and time
- Denies memory of wandering or falling
- Agitated, trying to get up
- Denies pain

Objective Data

Physical Examination

- Left leg shorter than right leg
- Tense and anxious

Diagnostic Studies

- X-ray of left hip indicates a fracture
- Mini-Cog testing indicates cognitive impairment

Discussion Questions

1. What is the pathogenesis of AD?
2. What precipitating factors may have resulted in M.Y.'s fall?
3. ***Safety:*** What safety precautions need to be taken regarding the inpatient care of M.Y.?
4. ***Patient-Centered Care:*** What is the priority nursing intervention for M.Y.?
5. ***Patient-Centered Care:*** What teaching plan should you develop for M.Y. and his son?
6. Surgery is planned to repair his fractured hip. Why is he at risk for delirium?
7. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Collaboration:*** What nursing activities can the RN delegate to unlicensed assistive personnel (UAP)?
9. ***Evidence-Based Practice:*** M.Y.'s son asks you if he should give his father ginkgo to help his memory. How would you respond?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Dementia is defined as a
   a. syndrome that results only in memory loss.
   b. disease associated with abrupt changes in behavior.
   c. disease that is always due to reduced blood flow to the brain.
   d. syndrome characterized by cognitive dysfunction and loss of memory.
2. Vascular dementia is associated with
   a. transient ischemic attacks.
   b. bacterial or viral infection of neuronal tissue.
   c. cognitive changes secondary to cerebral ischemia.
   d. abrupt changes in cognitive function that are irreversible.
3. Dementia with Lewy bodies (DLB) is characterized by
   a. remissions and exacerbations over many years.
   b. memory impairment, muscle jerks, and blindness.
   c. parkinsonian symptoms, including muscle rigidity.
   d. increased intracranial pressure from decreased CSF drainage.
4. Which statement(s) accurately describe(s) mild cognitive impairment? *(select all that apply)*
   a. Cannot be detected by screening tests
   b. The person may appear normal to the casual observer
   c. Family members may see changes in the patient's abilities

d. Problems that the person is experiencing interfere with daily activities

e. The person is usually aware that there is a problem with his or her memory

5. The clinical diagnosis of dementia is based on

a. CT or MRS.

b. brain biopsy.

c. electroencephalogram.

d. patient history and cognitive assessment.

6. A *priority* goal of treatment for the patient with Alzheimer's disease is to

a. maintain patient safety.

b. maintain or increase body weight.

c. return to a higher level of self-care.

d. enhance functional ability over time.

7. Which patient is *most* at risk for developing delirium?

a. A 50-yr-old woman with cholecystitis

b. A 19-yr-old man with a fractured femur

c. A 42-yr-old woman having an elective total hysterectomy

d. A 78-yr-old man admitted to the medical unit with complications of heart failure

1. d, 2. c, 3. c, 4. b, c, e, 5. d, 6. a, 7. d

Spinal Cord and Peripheral Nerve Problems

Cindy Sullivan

LEARNING OUTCOMES

1. Outline the classification of spinal cord injuries and associated clinical manifestations.
2. Describe the clinical manifestations and interprofessional and nursing management of neurogenic and spinal shock.
3. Relate the clinical manifestations of spinal cord injury to the level of disruption and rehabilitation potential.
4. Describe the nursing management of the patient with a spinal cord injury.
5. Explain the types, clinical manifestations, and interprofessional and nursing management of spinal cord tumors.
6. Explain the etiology, clinical manifestations, and interprofessional and nursing management of trigeminal neuralgia and Bell's palsy.
7. Describe the etiology, clinical manifestations, and interprofessional and nursing management of Guillain-Barré syndrome/acute inflammatory demyelinating polyneuropathy.
8. Explain the etiology, clinical manifestations, and interprofessional and nursing management of chronic inflammatory demyelinating polyneuropathy.

Conceptual Focus

Family Dynamics
Functional Ability

Mobility
Pain
Sensory Perception

This chapter discusses spinal cord and peripheral nerve problems, including spinal cord injuries, spinal cord tumors, cranial nerve disorders, and polyneuropathies. A focus of this chapter is the nursing management of the problems encountered by the patient with spinal cord injury (SCI). The potential for disruption of individual growth and development, altered family dynamics, economic loss from unemployment, and the high cost of rehabilitation and long-term health care make SCI a major problem. While many people with SCI can care for themselves independently, those with the highest level of injury need around-the-clock care at home or in a long-term care facility. The nurse's role in providing holistic care can have a significant impact on the patient's general health and well-being.

Spinal Cord Problems

Spinal Cord Injury

Spinal cord injury (SCI) is caused by trauma or damage to the spinal cord. It can result in temporary or permanent alteration in the function of the spinal cord. About 17,000 Americans have SCIs each year. Some 282,000 persons in the United States are living with SCI. The average life expectancy for persons with SCI is less than those without SCI and has not improved since the 1980s. Mortality rates are high in the first year after injury with a 30% rehospitalization rate.[1]

Etiology and Pathophysiology

SCI is usually a result of trauma. The 4 most common causes are motor vehicle collisions (38%), falls (30.5%), violence (13.5%), and sports injuries (9%).[1]

Types of Injury

Neurologic damage caused by SCI occurs in 2 phases: *primary injury* (initial physical disruption of the spinal cord) and *secondary injury* (from processes, such as ischemia, hypoxia, hemorrhage, edema).

Primary Injury

Primary injury results from direct physical trauma to the spinal cord due to blunt or penetrating trauma. Trauma can cause spinal cord compression by bone displacement, interruption of blood supply, or distraction from pulling. Penetrating trauma, such as gunshot and stab wounds, can cause tearing and transection.

Secondary Injury

Secondary injury refers to the ongoing, progressive damage that occurs after the primary injury. Secondary injury causes further permanent damage. It begins a few minutes after injury and lasts for months. Fig. 60.1 shows the cascade of events causing secondary injury. These events result in edema, ischemia, and inflammation. They result in cell death, disruption of the blood-brain barrier, and demyelination. This can extend the level of deficit and worsen long-term outcome.

Seconds after the insult, mechanical disruption leads to small hemorrhages in the white and gray matter, damage to the axons, and cell membrane destruction.[2,3] Over the next minutes to hours, neuron destruction occurs. Blood-spinal barrier disruption allows for an influx of inflammatory cytokines. This further increases spinal cord edema and promotes ongoing inflammation.[4] Edema due to the inflammatory response is especially harmful because of limited space for tissue expansion. Thus compression of the spinal cord occurs. Edema extends above and below the injury, increasing ischemic damage. Within 24 hours, permanent damage may occur from edema.

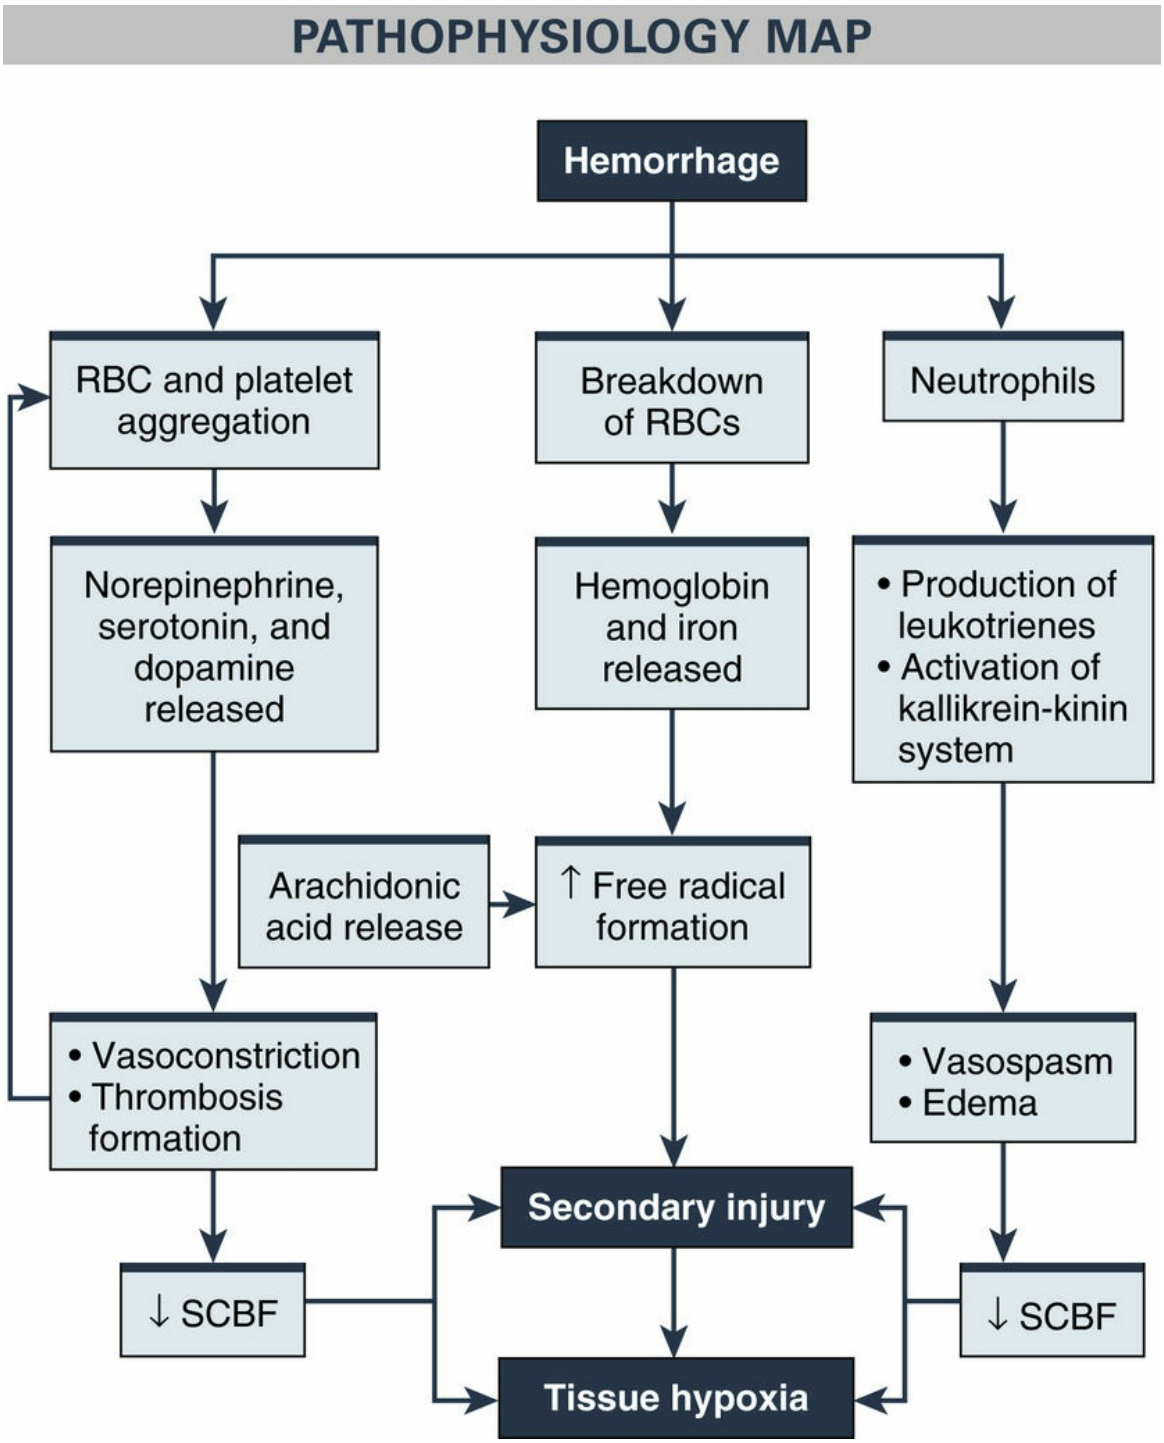

FIG. 60.1 Cascade of metabolic and cellular events that leads to spinal cord ischemia and hypoxia of secondary injury. *RBCs,* Red blood cells; *SCBF,* spinal cord blood flow.
Modified from Marciano FF, Greene KA, Apostolides PJ, et al: Pharmacologic management of spinal cord injury: Review of the literature, *BNI Q* 11:11, 1995. In KL McCance, SE Huether, editors: *Pathophysiology: The biologic basis for disease in adults and children,* ed 5, St Louis, 2006, Mosby.

The resulting hypoxia reduces O_2 levels below the metabolic needs of the spinal cord. Lactate metabolites and an increase in vasoactive substances, including norepinephrine, serotonin, and dopamine, occur. High levels of these substances cause vasospasms and hypoxia with subsequent necrosis. Unfortunately, the spinal cord has minimal ability to adapt to vasospasm.

A*poptosis* (programmed cell death) continues for weeks. It contributes to postinjury demyelination. The inflammatory response at the site of the initial injury focuses on clearing up the initial cellular debris without damaging normal tissue. This results in a central non-neural core of connective tissue that we refer to as a glial scar (Fig. 60.2). The glial scar creates a physical barrier. It restricts the cells in the spinal cord from migration and regeneration. This leads to irreversible nerve damage and permanent neurologic deficit.

Spinal and Neurogenic Shock

Spinal shock may occur shortly after acute SCI. It is characterized by loss of deep tendon and sphincter reflexes, loss of sensation, and flaccid paralysis below the level of injury. This syndrome lasts days to weeks. It often masks postinjury neurologic function.[3]

In contrast to spinal shock, **neurogenic (vasogenic) shock** can occur in cervical or high thoracic injury (T6 or higher). It occurs from unopposed parasympathetic response due to loss of sympathetic nervous system (SNS) innervation. It causes peripheral vasodilation, venous pooling, and decreased cardiac output. Manifestations include significant hypotension (< 90 mmHg), bradycardia, and temperature dysregulation. Neurogenic shock can continue for 1 to 3 weeks.[5] Hypotension can result in poor perfusion and oxygenation to the spinal cord and worsen spinal cord ischemia.[6]

Classification of Spinal Cord Injury

SCI is classified by the (1) mechanism of injury, (2) level of injury, and (3) degree of injury.

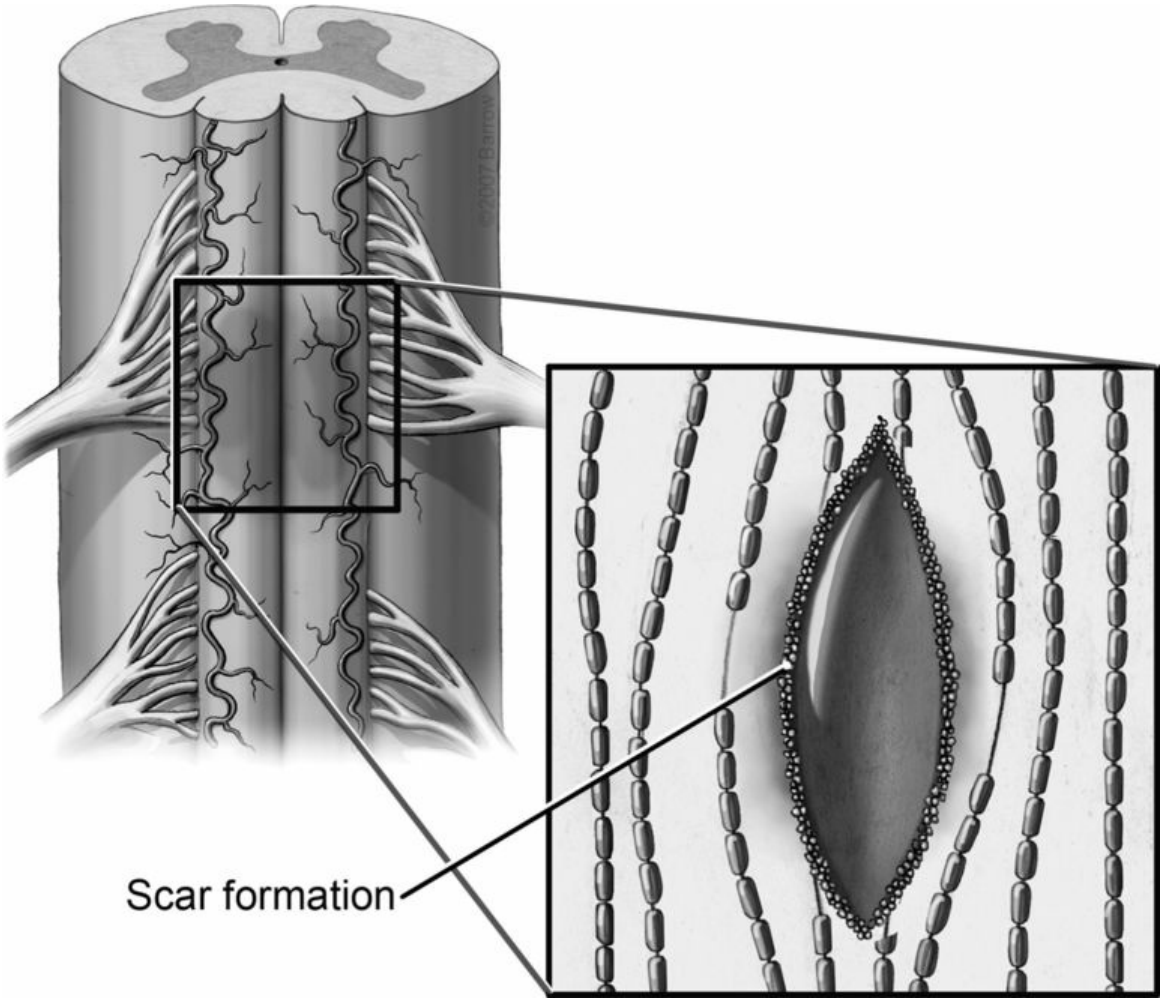

FIG. 60.2 1 to 2 days following the injury, astrocytes proliferate and surround the edges of the fibrotic scar to confine inflammation to the area of injury. This process may take 7 to 10 days. It protects neighboring neural tissue from further damage.
Used with permission from Barrow Neurological Institute, Phoenix, AZ.

Mechanisms of Injury

The major mechanisms of injury include flexion, flexion-rotation, hyperextension, vertical compression, extension-rotation, and lateral flexion (Fig. 60.3). Flexion-rotation injury is the most unstable because ligaments that stabilize the spine are torn. This injury most often contributes to severe neurologic deficits.

Level of Injury

Skeletal level of injury is the vertebral level with the most damage to vertebra and related ligaments. *Neurologic level* is the lowest segment of the spinal cord with normal sensory and motor function on both sides of the body. The level of injury may be cervical, thoracic, lumbar, or sacral. Cervical and lumbar injuries are most common because those areas of the spine are associated with the greatest flexibility and movement.

Injury from C1 to T1 can cause paralysis of all 4 extremities, resulting in **tetraplegia** (formerly called *quadriplegia*). The degree of impairment in the arms after cervical injury depends on the level of injury. The lower the level, the more function is retained in the arms.

Paraplegia (paralysis and loss of sensation in the legs) can occur in SCI below the level of T2.[2] Fig. 60.4 shows affected structures and functions at different levels of cord injury.

Degree of Injury

The degree of spinal cord involvement may be complete or incomplete (partial). *Complete cord involvement* results in total loss of sensory and motor function below the level of injury. *Incomplete cord involvement* results in a mixed loss of voluntary motor activity and sensation and leaves some tracts intact. The degree of sensory and motor loss depends on the level of injury and reflects specific damaged nerve tracts.

Five major syndromes are associated with incomplete injuries: central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, cauda equina syndrome, and conus medullaris syndrome (Table 60.1).

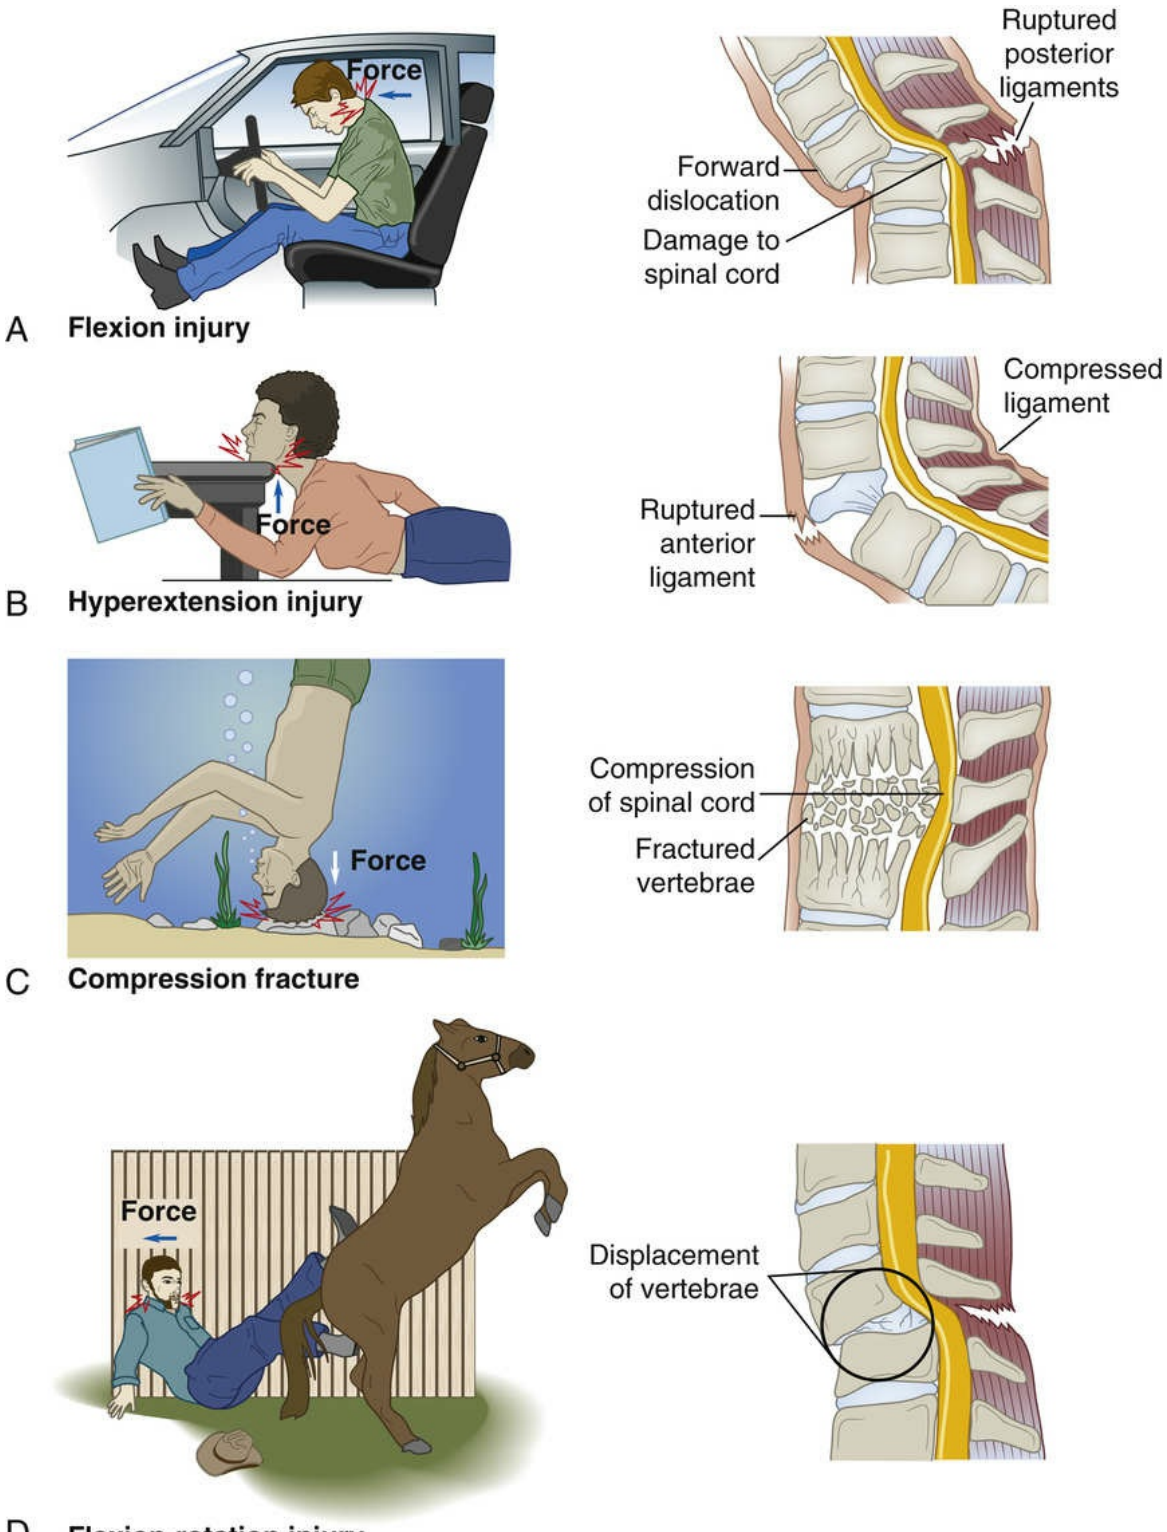

FIG. 60.3 Examples of mechanisms of spinal cord injury. **A,** Flexion injury of the cervical spine ruptures the posterior ligaments. **B,** Hyperextension injury of the cervical spine ruptures the anterior ligaments. **C,** Compression fractures crush the vertebrae and force bony fragments into the spinal canal. **D,** Flexion-rotation injury of the

cervical spine often results in tearing of ligamentous structures that normally stabilize the spine.
A, B, and *C,* From Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2014, Mosby.

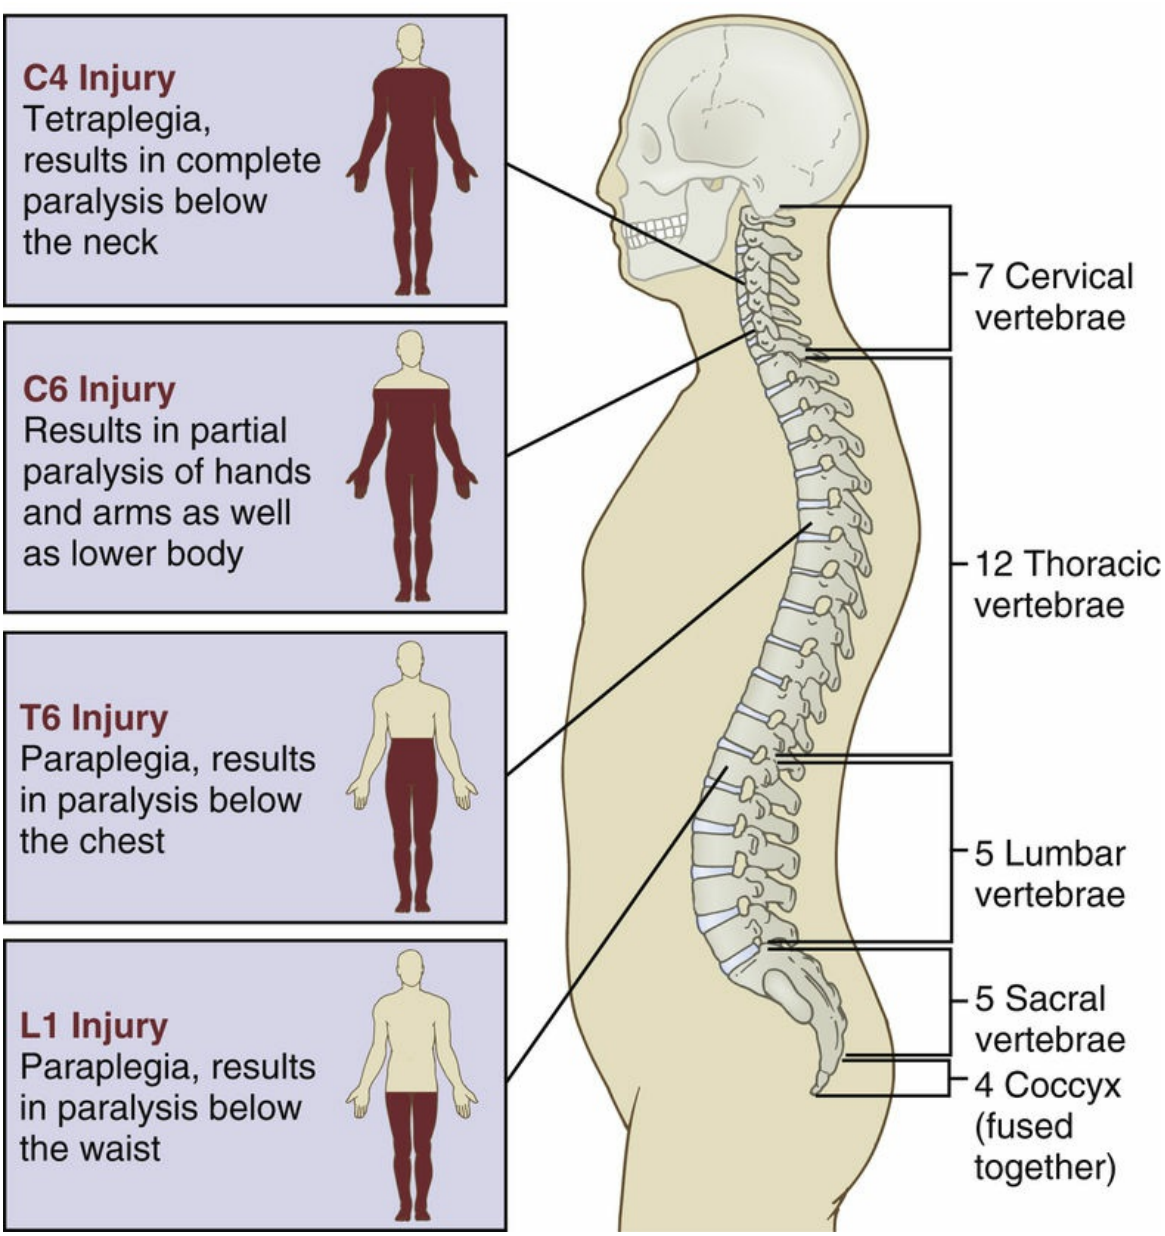

FIG. 60.4 Symptoms, degree of paralysis, and potential for rehabilitation depend on level of spinal injury.

Clinical Manifestations

Manifestations of SCI are generally the direct result of trauma that causes cord compression, ischemia, edema, and possible cord transection. They are related to the level and degree of injury. The patient with an incomplete injury may have a mix of manifestations.

Motor and Sensory Effects

The American Spinal Injury Association (ASIA) Impairment Scale is used to classify the severity of impairment from SCI. It combines assessments of motor and sensory function to determine neurologic level and completeness of injury (Fig. 60.5).[7]

The sensory regions are called *dermatomes*. Each segment of the spinal cord innervates a specific area of skin. A dermatome map is shown in Fig. 55.7 on p. 1284. Each dermatome has a recommended point for testing.

The ASIA Impairment Scale is useful for recording changes in neurologic status. It also helps us identify rehabilitation goals. Movement and rehabilitation potential related to specific locations of SCI are described in Table 60.2. In general, sensory function closely matches motor function at all levels.

Respiratory System

Respiratory complications closely correspond to the level of injury. Cervical injuries above C3 present special problems because of the total loss of respiratory muscle function. These patients have respiratory arrest within minutes of injury if not intubated. Patients with high cervical injury (C3-5) have respiratory insufficiency due to loss of phrenic nerve innervation to the diaphragm and decreases in chest and abdominal wall strength.[8] Patients with complete SCI above C5 should be intubated at once. Patients with incomplete SCI injury will have a high degree of variability in their respiratory function.

Cervical and thoracic injuries cause paralysis of abdominal muscles and often the intercostal muscles. The patient cannot cough effectively enough to remove secretions, increasing the risk for aspiration,

atelectasis, and pneumonia. Hypoventilation and impairment of the intercostal muscles lead to a decrease in vital capacity and tidal volume.

TABLE 60.1 Incomplete Spinal Cord Injury Syndromes

Description	Manifestations
Anterior Cord Syndrome	
• **Damage to anterior spinal artery** • **Results in compromised blood flow to anterior spinal cord** • **Typically results from acute compression of anterior part of the spinal cord** • **Common with flexion injury**	• Motor paralysis and loss of pain and temperature sensation below level of injury • Since posterior cord tracts are not injured, sensations of touch, position, vibration, and motion remain intact
Brown-Séquard Syndrome	
• **Damage to half of the spinal cord** • **Typically results from penetrating injury to spinal cord**	• *Contralateral* (opposite side of injury): Loss of pain and temperature sensation below level of injury • *Ipsilateral* (same side as injury): Loss of motor function, light touch, pressure, position, and vibratory sense
Cauda Equina Syndrome	
• **Damage to cauda equina (lumbar and sacral nerve roots)**	• Asymmetric distal weakness, patchy sensation in lower extremities • May cause flaccid paralysis of lower extremities • Complete loss of sensation between legs and over buttocks, inner thighs, and backs of legs (*saddle area*) • Areflexic (flaccid) bladder and bowel • Severe, radicular, asymmetric pain
Central Cord Syndrome	
• **Damage to central spinal cord** • **Occurs most often in cervical cord region** • **More common in older adults** • **Caused by hyperextension injury in people with degenerative disease**	• Motor weakness and altered sensation present in upper extremities • Lower extremities not usually affected • Burning pain in upper extremities
Conus Medullaris Syndrome	
• **Damage to conus medullaris (lowest part of spinal cord)**	• Motor function in legs may be preserved, weak, or flaccid • Decrease in or loss of sensation in perianal area • Areflexic bowel and bladder • Impotence

Associated traumatic injuries, such as lung contusions, can further compromise pulmonary function. Fluid overload can cause pulmonary edema. Neurogenic pulmonary edema may occur due to a dramatic increase in SNS activity at the time of injury.

Maintaining an arterial saturation above 92% reduces hypoxemia, which can lead to bradycardia and worsen secondary injury. Patients are assessed for manifestations of respiratory distress, including

dyspnea, decreased vital capacity, and pCO_2 > 20mm Hg above baseline, which would indicate the need for intubation.

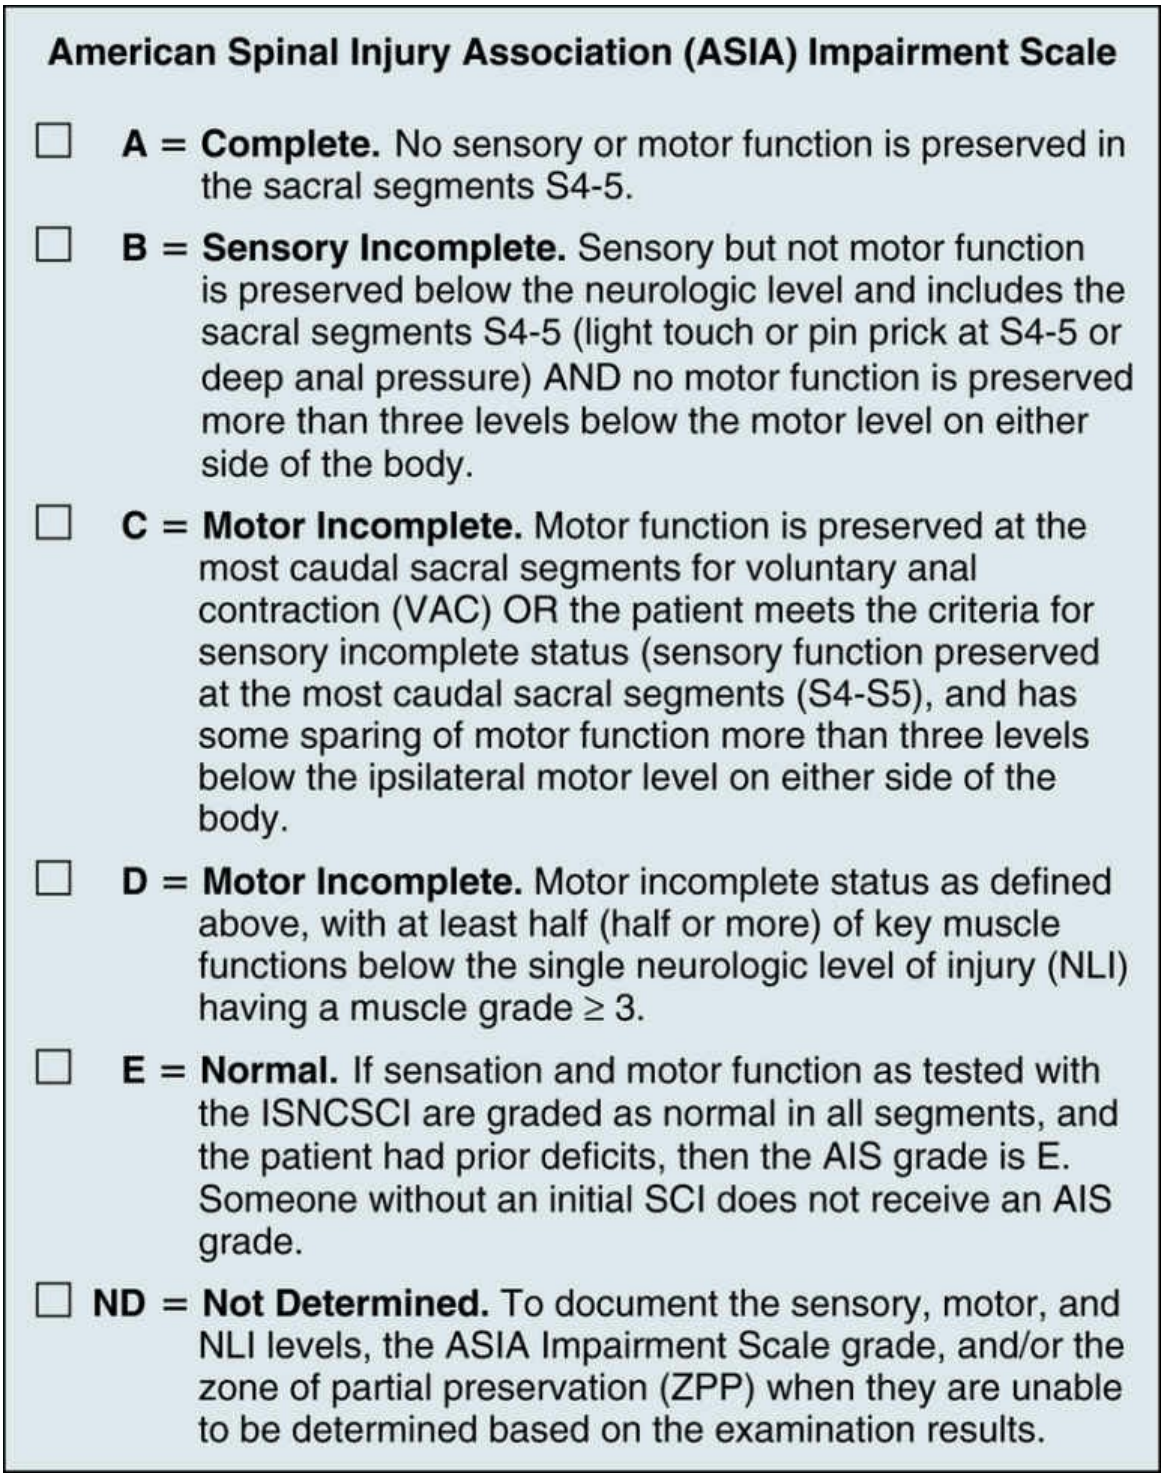

FIG. 60.5 The ASIA Impairment Scale.
From American Spinal Injury Association.

Cardiovascular System

Any cord injury above T6 leads to dysfunction of the SNS. The result may be bradycardia, peripheral vasodilation, and hypotension (neurogenic shock). Peripheral vasodilation causes relative hypovolemia because of the increase in the capacity of the dilated veins. It reduces venous return of blood to the heart. Cardiac output then decreases, leading to hypotension. Other injuries can cause hemorrhagic shock and further reduce BP. It is important to identify all causes of hypotension in the person with SCI. Those on β-blockers, young healthy patients, and older adults may not be tachycardic with hemorrhage.[8]

Urinary System

Urinary dysfunction occurs in most patients after SCI. **Neurogenic bladder** describes any type of bladder dysfunction related to abnormal or absent bladder innervation. After SCI, the ability for the bladder muscles and the micturition center in the brain to transmit information is impaired. Both the detrusor muscle (bladder wall) and sphincter muscle (a valve around the top of the urethra) may be overactive due to the lack of brain control. This may cause high bladder pressures and urinary retention. Incontinence results from reflex emptying and failure to store urine.

Depending on the injury, a neurogenic bladder may (1) have no reflex detrusor contractions *(flaccid, hypotonic),* which can result in bladder stretching from overdistention; (2) have hyperactive reflex detrusor contractions *(spastic),* seen in SCI above T12, leading to incontinence; or (3) lack coordination between detrusor contraction and urethral relaxation *(dyssynergia),* resulting in reflux of urine into the kidneys. Reflux into the kidneys can lead to stone formation, hydronephrosis, pyelonephritis, and renal failure.[9]

Gastrointestinal System

Decreased gastrointestinal (GI) motor activity contributes to gastric distention and the development of paralytic ileus. Gastric emptying may be delayed, especially in patients with higher level SCI. Excessive release of hydrochloric acid (HCl) in the stomach may cause stress

ulcers. Dysphagia may be present in patients who need mechanical ventilation, tracheostomy, and anterior spine surgery.

Intraabdominal bleeding may be hard to diagnose because the person with SCI may not have pain or tenderness. Continued hypotension and decreases in hemoglobin and hematocrit may be the only signs of bleeding. Expanding abdominal girth may be seen.

Loss of voluntary control of the bowel after SCI results in **neurogenic bowel**. SCI above the level of the conus medullaris results in a *hyperreflexic* bowel with increased rectal and sigmoid compliance. Combined with increased anal sphincter tone and the inability to sense a full rectum, this causes stool retention and constipation.[10] SCI at or below the conus medullaris causes the bowel to be *areflexic*. Peristalsis is impaired and stool movement is slow. The defecation reflex may be damaged and anal sphincter tone relaxed. This leads to constipation, increased risk for incontinence, and possible impaction, ileus, or megacolon. Hemorrhoids can occur over time.

Integumentary System

The risk for skin breakdown over bony prominences in areas of decreased or absent sensation is a major consequence of immobility related to SCI. Pressure injuries can occur quickly and lead to infection and sepsis.

Thermoregulation

*Poikilothermi*a is the inability to maintain a constant core temperature, with the patient assuming the temperature of the environment. It occurs in SCI because interruption of the SNS prevents peripheral temperature sensations from reaching the hypothalamus. There is a decreased ability to sweat or shiver below the level of injury, which affects the ability to regulate body temperature. The degree of poikilothermia depends on the level of injury. Cervical injuries are associated with a greater loss of ability to regulate temperature than are thoracic or lumbar injuries.

Metabolic Needs

The person with SCI has increased nutritional needs due to increased metabolism and more protein breakdown. Lean body mass decreases and muscles atrophy, leading to weight loss. In the acute injury phase, stress on the body from hemodynamic instability and medical interventions, such as surgery, can worsen stress. Nutritional support should start early. Enteral nutrition (EN) or parenteral nutrition (PN) can supply the person's caloric, protein, and micronutrient requirements needs.[11] Adequate nutrition helps prevent skin breakdown, reduce infection, and decrease the rate of muscle atrophy.

Peripheral Vascular Problems

Venous thromboembolism (VTE) is a common problem after SCI due to hypercoagulability, venous stasis, and venous endothelial injury.[12] Immobilization promotes venous stasis and thrombi of the lower extremities. Detecting a deep venous thrombosis (DVT) may be hard in a person with SCI because usual signs and symptoms, such as pain and tenderness, are not present.

Pain

Pain after SCI differs in type and severity. The patient's physical functioning and emotions influence pain. The pain can be nociceptive or neuropathic.

Nociceptive pain in SCI can result from musculoskeletal, visceral, and/or other types of injury (e.g., skin ulceration, headache). Patients often describe musculoskeletal pain as dull or aching. It starts or worsens with movement. Visceral pain is in the thorax, abdomen, and/or pelvis. It may be dull, tender, or cramping.

TABLE 60.2 Level of Spinal Cord Injury and Rehabilitation Potential

Movement Remaining	Rehabilitation Potential
Tetraplegia	
C1-3	
• **Often fatal** • **Movement in neck and above, loss of innervation to diaphragm, absence of independent respiratory function**	• Able to drive electric wheelchair equipped with portable ventilator by using chin control or mouth stick, headrest to stabilize head • Computer use with mouth stick, head wand, or noise control • Attendant care 24 hr/day, able to instruct others
C4	
• **Sensation and movement in neck and above** • **May be able to breathe without ventilator**	• Same as C1-3
C5	
• **Full neck, partial shoulder, back, biceps** • **Gross elbow, inability to roll over or use hands** • **↓ Respiratory reserve**	• Able to drive electric wheelchair with mobile hand supports • Indoor mobility in manual wheelchair • Able to feed self with setup and adaptive equipment • Attendant care 10 hr/day
C6	
• **Shoulder and upper back abduction and rotation at shoulder** • **Full biceps to elbow flexion, wrist extension, weak grasp of thumb** • **↓ Respiratory reserve**	• Able to help with transfer and perform some self-care • Feed self with hand devices • Push wheelchair on smooth, flat surface • Drive adapted van from wheelchair • Independent computer use with adaptive equipment • Attendant care 6 hr/day
C7-8	
• **All triceps to elbow extension, finger extensors and flexors** • **Good grasp with some decreased strength** • **↓ Respiratory reserve**	• Able to transfer self to wheelchair • Roll over and sit up in bed • Push self on most surfaces • Perform most self-care • Independent use of wheelchair • Able to drive car with powered hand controls (in some patients) • Attendant care 0–6 hr/day
Paraplegia	
T1-6	
• **Full innervation of upper extremities** • **Back, essential intrinsic muscles of hand** • **Full strength and dexterity of grasp** • **↓ Trunk stability, decreased respiratory reserve**	• Full independence in self-care and in wheelchair • Able to drive car with hand controls (in most patients) • Independent standing in standing frame
T6-12	
• **Full, stable thoracic muscles and upper back** • **Functional intercostal muscles, resulting in ↑ respiratory reserve**	• Full independent use of wheelchair • Able to stand erect with full leg brace, ambulate on crutches with swing (although gait difficult) • Unable to climb stairs
L1-2	
• **Varying control of legs and pelvis** • **Instability of lower back**	• Good sitting balance • Full use of wheelchair • Ambulation with long leg braces
L3-4	
• **Quadriceps and hip flexors** • **Absence of hamstring function, flail ankles**	• Completely independent ambulation with short leg braces and canes • Unable to stand for long periods

Neuropathic pain in SCI occurs from damage to the spinal cord or nerve roots. The pain can be at or below the level of injury. Patients often describe the pain as hot, burning, tingling, pins and needles, cold, and/or shooting. They may be extremely sensitive to stimuli. Even light touch can cause significant pain. (Pain is discussed in Chapter 8.)

Diagnostic Studies

CT scan is the preferred imaging study to diagnose the location and degree of injury and the degree of spinal canal compromise. Cervical x-rays are done when CT scan is not readily available. However, it is hard to see C7 and T1 on a cervical x-ray, decreasing the ability to fully evaluate a cervical spine injury.

MRI is used to assess soft tissue injury, neurologic changes, unexplained neurologic deficits, or worsening neurologic condition. MRI results guide clinical decisions about surgery.[2] Perform a comprehensive neurologic examination with assessment of the head, chest, and abdomen for other injuries or trauma. Patients with cervical injuries who have altered mental status may need a CT angiogram to rule out vertebral artery damage. Table 37.9 presents the diagnostic studies used to determine the site or location and extent of a VTE.

Interprofessional Care

Prehospital

Goals immediately after injury include maintaining a patent *airway,* adequate ventilation/*breathing,* and adequate *circulating* blood volume (ABCs) and preventing extension of spinal cord damage (secondary injury). Table 60.3 outlines emergency management of the patient with SCI. Spinal motion should be restricted with a combination of a rigid cervical collar and a supportive backboard with straps. Patients should be kept supine and may be logrolled for transfers. Uncooperative patients may need chemical sedation or physical restraints to protect them from further injury.[13] Reverse Trendelenburg position may be used if necessary. Spinal immobilization in patients with penetrating trauma should be tried as long as it does not affect resuscitation efforts.[13]

Intubation to secure the airway is done as soon as possible for patients with respiratory distress. Using end-tidal CO_2 monitoring can help determine the need for rapid sequence intubation (RSI). Patients with stable airways in the field may need intubation at the medical

facility. Systemic and neurogenic shock are treated with IV fluids and vasopressors to maintain systolic BP (SBP) greater than 90 mm Hg. After cervical injury, all body systems must be maintained until the full extent of the damage can be evaluated. After stabilization at the injury scene, the person should be transferred to the nearest medical facility. The preferred facility is one that specializes in acute SCI care. A thorough assessment determines the degree of deficit and the level and degree of injury.

TABLE 60.3 Emergency ManagementSpinal Cord Injury

Etiology	Assessment Findings	Interventions
Blunt Trauma • **Compression, flexion, extension, or rotation injuries to spinal column** • **Diving** • **Falls** • **Motor vehicle crash** • **Pedestrian accidents** • **Sports injuries** **Penetrating Trauma** • **Gunshot wounds** • **Stab wounds** • **Stretched, torn, crushed, or lacerated spinal cord**	• Respiratory distress/difficulty breathing • Neurogenic shock: hypotension, bradycardia, cool or warm dry skin • Spinal shock • Muscle weakness, paralysis, or flaccidity • Changes in sensation: temperature, light touch, deep pressure, proprioception • Numbness, paresthesia • Pain, tenderness, deformities, or muscle spasms adjacent to vertebral column • Cuts; bruises; open wounds on head, face, neck, or back • Bowel and bladder incontinence • Urinary retention • Priapism • Decreased rectal sphincter tone	**Initial** • Ensure patent airway and adequate breathing. • Maintain SaO_2 >90%: • Apply O_2 via nasal cannula, nonrebreather mask, or endotracheal tube. • Maintain SBP >90 mm Hg. • Establish IV access with 2 large-bore catheters to infuse normal saline or lactated Ringer's solution. • Immobilize and stabilize cervical spine. • Assess for other injuries. • Control external bleeding. • Obtain appropriate imaging. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, motor and sensory function, O_2 saturation, cardiac rhythm, urine output. • Anticipate need for intubation if in respiratory distress or gag reflex absent. • Maintain normal temperature.

Acute Care

Interprofessional care during the acute phase for a patient with a cervical injury is described in Table 60.4. Compared to cervical injury, patients with SCI of the thoracic and lumbar vertebrae need less intense support. At this level of injury, respiratory compromise is not as severe, and bradycardia is usually not a problem. Other problems are treated symptomatically.

Obtain a history, with emphasis on how the incident occurred.

Assess the extent of injury perceived by the patient or by the emergency response system (ERS) personnel right after the event. Initial assessment occurs in the emergency department (ED). It includes managing the person's ABCs and vital signs to ensure a secure airway and maintain oxygenation saturation (SaO_2) greater than 92% and mean arterial pressure (MAP) greater than 85 mm Hg. Avoid SBP less than 90 mm Hg. Appropriate medical interventions and diagnostics are implemented to ensure the patient is hemodynamically stable.

Perform a complete neurologic assessment using the ASIA tool (Fig. 60.5). Muscle groups are tested with and against gravity, alone and against resistance, on both sides of the body. Record strength, symmetry, and spontaneous movement. Complete a sensory examination, including touch and pain, as tested by pinprick. Start at the toes and work upward toward the head. Assess rectal tone and note the presence of *priapism.* Voluntary anal contractions indicate incomplete SCI. If time and conditions permit, assess position sense and vibration.

Mechanisms of injury that cause spinal cord trauma, especially involving the cervical cord, may result in brain injury and/or vertebral artery injury. Assess for a history of unconsciousness, signs of concussion, and increased intracranial pressure (see Chapter 56). Carefully assess for musculoskeletal injuries and trauma to internal organs. Because the patient may have altered or no muscle, bone, or visceral sensations below the level of injury, the only clue to internal trauma with hemorrhage may be a rapidly decreasing BP and increasing pulse. Check urine for hematuria, which indicates internal injuries.

Move the patient in alignment as a unit *(logroll)* during transfers and when repositioning to prevent further injury. Monitor respiratory, cardiac, urinary, and GI functions. The patient may go directly to surgery after the initial evaluation or to the intensive care unit (ICU) for monitoring and management.

Nonoperative Stabilization

Nonoperative treatments involve stabilization of the injured spinal segment and decompression, either through traction or realignment. Stabilization eliminates damaging motion at the injury site. It is meant to prevent secondary spinal cord damage caused by narrowing of the spinal canal, or continued contusion or compression of the spinal cord at the level of the injury. Early realignment of an unstable fracture-dislocation injury by closed reduction through craniocervical traction is effective and safe.

Surgical Therapy

Surgical treatment after acute SCI is used to manage instability and decompress the spinal cord. It may reduce secondary injury and improve the patient's outcome. Early surgery (within 24 hours after the injury) is recommended for persons with central cord syndrome and for adults with an acute SCI at any level.[2] The type of surgery depends on the severity and level of the injury, mechanism of injury, and location and degree of compression.

Surgery to stabilize the spine can be done from the back of the spine *(posterior approach)* or from the front of the spine *(anterior approach).* In some cases, both approaches may be needed. Fixation involves attaching metal screws, plates, or other devices to the bones of the spine to help keep them aligned. This procedure is usually done when 2 or more vertebrae are injured. Small pieces of bone may be attached to the injured bones to help them fuse into 1 solid piece. The bone used is obtained from the patient's spinal bone harvested during surgery, from another bone in the patient's body, or from donor bone. (Specific surgical and nursing interventions for these techniques are discussed in Chapter 63 on pp. 1488–1489.)

Drug Therapy

Current evidence for the use of methylprednisolone is mixed. Guidelines for managing spinal cord injuries issued by both the American Association of Neurological Surgeons and Congress of Neurological Surgeons do not recommend its use for treating acute SCI.[14] The FDS no longer approves its use either. However,

recommendations in the AOSPine 2017 Guidelines suggest a 24-hour infusion of high-dose methylprednisolone within 8 hours of acute SCI.[2] So, some HCPs may consider this option.

VTE prophylaxis with low-molecular-weight heparin (LMWH) (e.g., enoxaparin [Lovenox]) or fixed, low-dose heparin should start within 72 hours after injury, unless contraindicated. Contraindications include internal or external bleeding and recent surgery. For those with abnormal kidney function, heparin is best as LMWH is mainly excreted via the kidneys.

Vasopressor agents (e.g., phenylephrine, norepinephrine) are used in the acute phase of injury as adjuvants to treatment. They maintain the MAP to improve perfusion to the spinal cord. Use of vasopressors has significant risk for complications. These include ventricular tachycardia, troponin elevation, metabolic acidosis, and atrial fibrillation. Dopamine has more complications than phenylephrine in SCI. Considerations for vasopressor selection include level of injury, patient age, and comorbidities (e.g., heart problems).

TABLE 60.4 Interprofessional CareCervical Cord Injury

Diagnostic Assessment

- History and physical examination, including complete neurologic examination
- ABGs
- Electrolytes, serum glucose, coagulation profile, hemoglobin and hematocrit
- Urinalysis
- CT scan, MRI, EMG (measure evoked potentials)
- Anteroposterior, lateral, and odontoid spinal x-rays
- Serial bedside pulmonary function tests (PFTs)

Management

Acute Care

- Immobilization and stabilization of vertebral column
- ABCs (airway, breathing, circulation)
- O_2 by high-humidity mask (PaO_2 >60 mm Hg)
- Intubation (if indicated by ABGs and PFTs)
- Maintain heart rate (e.g., atropine) and BP (e.g., dopamine) (SBP >90 mm Hg, MAP >85)
- Administer IV fluids
- Insert NG tube and attach to suction.
- Assessment and management of nutrition
- Maintain normal body temperature
- Indwelling urinary catheter
- Pain management
- VTE prophylaxis
- Pressure injury prevention
- Stress ulcer prophylaxis
- Bowel and bladder care and training
- Mobilization once spine stabilized
- Physical, occupational, speech therapy and physiatrist consults

Rehabilitation and Home Care

- Physical therapy (ROM, mobility, strength, equipment)
- Occupational therapy (splints, ADLs training)
- Speech therapy (swallow and cognition)
- Pain management
- Spasticity management
- Bowel and bladder training

- Autonomic dysreflexia prevention
- Pressure injury prevention
- Recreational therapy
- Patient and caregiver teaching

Nursing Management: Spinal Cord Injury

Nursing Assessment

Subjective and objective data you should obtain from a patient with recent SCI are outlined in Table 60.5.

TABLE 60.5 Nursing AssessmentSpinal Cord Injury

Subjective Data

Important Health Information

Past health history: Motor vehicle crash, sports injury, industrial incident, gunshot or stabbing injury, falls

Functional Health Patterns

Health perception–health management: Use of alcohol or recreational drugs. Risk-taking behaviors

Activity-exercise: Loss of strength, movement, and sensation below level of injury. Dyspnea, inability to breathe adequately ("air hunger")

Cognitive-perceptual: Tenderness, pain at or above level of injury. Numbness, tingling, burning, twitching of extremities

Coping–stress tolerance: Fear, denial, anger, depression

Objective Data

General

Poikilothermia (unable to regulate body heat)

Integumentary

Warm, dry skin below level of injury (neurogenic shock)

Respiratory

Injury at C1-3: Apnea, inability to cough
Injury at C4: Poor cough, diaphragmatic breathing, hypoventilation
Injury at C5-T6: ↓ Respiratory reserve

Cardiovascular

Injury above T6: Bradycardia, hypotension, postural hypotension, absence of vasomotor tone

Gastrointestinal

↓ Or absent bowel sounds (paralytic ileus in injuries above T5), abdominal distention, constipation, fecal incontinence, fecal impaction

Urinary

Retention (for injuries at T1-L2), flaccid bladder (acute stages), spasticity with reflex bladder emptying (later stages)

Reproductive

Priapism, altered sexual function

Neurologic

Complete: Areflexic, flaccid paralysis and anesthesia below level of injury resulting in tetraplegia (injuries above C8) or paraplegia (injuries below C8), hyperactive deep tendon reflexes and bilaterally positive Babinski test (after resolution of spinal shock)
Incomplete: Mixed loss of voluntary motor activity and sensation

Musculoskeletal

Muscle atony (in flaccid state), contractures (in spastic state)

Pain

Neuropathic, musculoskeletal, and/or visceral

Possible Diagnostic Findings

Location of level and type of bony involvement on spinal x-ray. Injury, edema, compression on CT scan and MRI; positive finding on myelogram

Nursing Diagnoses

Nursing diagnoses for the patient with SCI depend on the severity of the injury and level of dysfunction. Nursing diagnoses for a patient with SCI may include:

- Impaired breathing
- Impaired nutritional status
- Ineffective tissue perfusion
- Impaired tissue integrity
- Impaired urinary system function
- Constipation
- Difficulty coping

Additional information on nursing diagnoses and interventions for the patient with complete cervical SCI is presented in eNursing Care Plan 60.1 (available on the website for this chapter).

Planning

Overall goals are that the patient with an SCI will (1) maintain an optimal level of neurologic functioning; (2) have minimal or no complications of immobility; (3) learn new skills, gain new knowledge, and acquire new behaviors to be able to care for self or direct others to do so; and (4) return home at an optimal level of functioning.

Nursing Implementation

Health Promotion

Nursing interventions for the prevention of SCI include identifying high-risk persons and providing teaching. Support measures to combat distracted and impaired driving. Teach people to use child safety seats and helmets for motorcyclists and bicyclists. Promote programs for older adults (e.g., STEADI) aimed at preventing accidental death and injury.[15]

Emphasize the importance of health promotion and screening

behaviors after SCI. Health-promoting behaviors after SCI can have significant impact on the general health and well-being of the person with SCI. Nursing interventions include (1) teaching and counseling; (2) referring to programs such as smoking cessation classes, recreation programs, and alcohol treatment programs; and (3) performing routine physical examinations for non-neurologic problems. Promotion and screening programs must be accessible to and accommodate people with SCI. Nurses should advocate for wheelchair-accessible examination rooms, adjustable-height examination tables, and appointment scheduling that allows extra time if needed.

Acute Care

High cervical cord injury caused by flexion-rotation is the most complex SCI. It is the focus of this section. Interventions for this type of injury can be modified for patients with less severe injuries.

Immobilization

To restrict spinal motion, maintain the neck in a neutral position. For cervical injuries, closed reduction with skeletal traction is used for early realignment *(reduction)* of the injury. Crutchfield (Fig. 60.6) or Gardner-Wells tongs or halo (halo ring) can provide this type of traction. A rope extends from the center of the device over a pulley to weights attached at the end. Traction must be maintained at all times. Possible displacement of the skull pins is a disadvantage of tongs. If pin displacement occurs, hold the patient's head in a neutral position and get help. Immobilize the head while the HCP reinserts the tongs.

Safety Alert

Cervical Spine Injuries

- Always keep the patient's body in correct alignment.

- Turn the patient as a unit (e.g., logrolling) to prevent movement of the spine.

No specific guidelines address the maximum weight for traction. The HCP may start with 10 lb and add 5 lb for each level to the injury. The goal is spinal reduction. Awake patients are monitored with x-ray and neurologic and pain assessment. Comatose patients need serial x-rays to evaluate the effects of traction. The need for surgery is determined after the spine is reduced. After cervical fusion or other stabilization surgery, the patient may have a hard cervical collar or sternal-occipital-mandibular immobilizer brace (Fig. 60.7).

Some patients with spinal fractures with or without acute SCI may not be able to have surgery but still need immobilization for their cervical fracture. In these patients, the halo frame can be attached to a special vest (Halo vest) (Fig. 60.8). This allows the patient to move and ambulate while cervical bones fuse. Surgery is used instead of the halo if the patient has ligament instability from the injury; has severe cervical deformity; or is morbidly obese, older, cachectic, or noncompliant.

Infection at the tong or pin insertion sites is a potential problem. Preventive care is based on agency protocol. A common protocol involves cleansing sites twice a day with chlorhexidine. Antibiotic ointment is then applied to act as a mechanical barrier to the entrance of bacteria. Patient and caregiver teaching for a patient with a halo vest is outlined in Table 60.6.

Patients with stable thoracic or lumbar spine injuries may be immobilized with a custom thoracolumbar sacral orthosis (TLSO or body jacket) to limit spinal flexion, extension, and rotation. A Jewett brace may be used instead to restrict forward flexion. Unstable injuries may require surgical decompression and fusion in addition to the TLSO or lumbosacral orthotic (LSO).

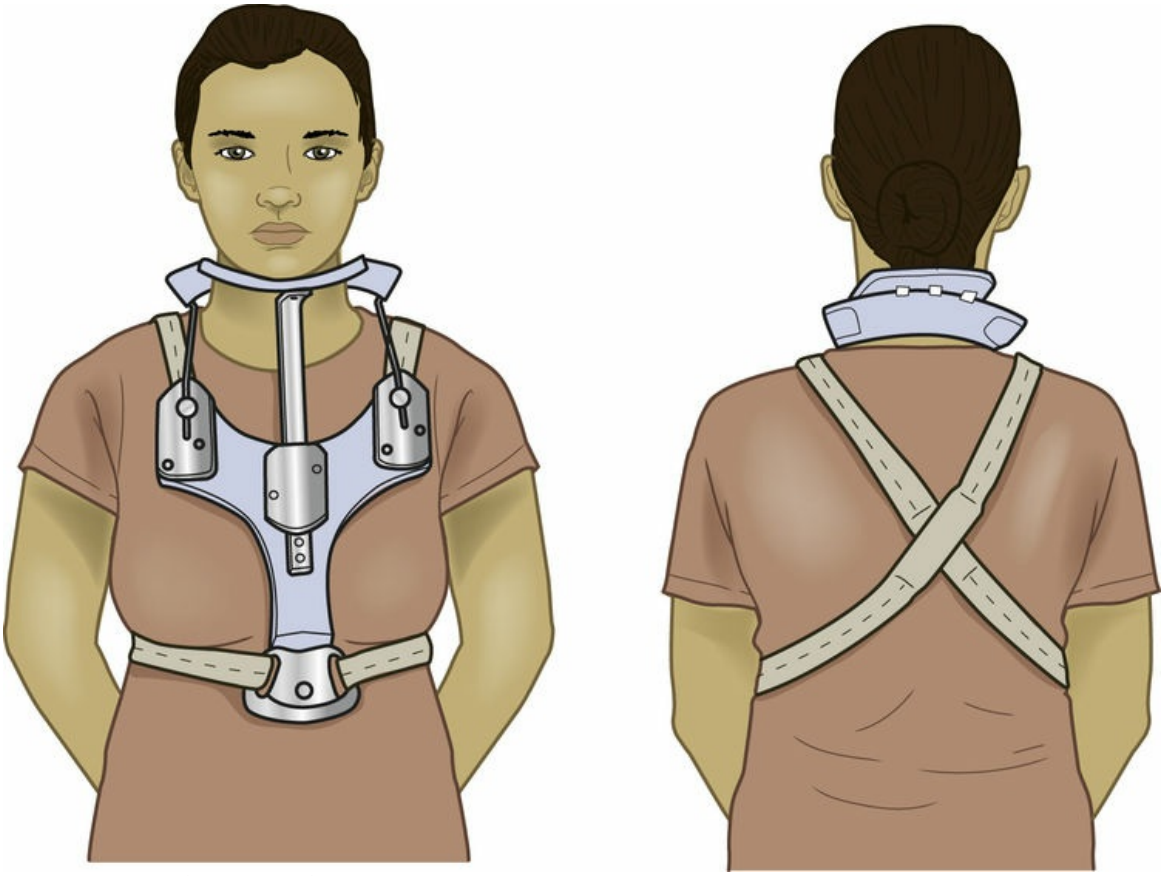

FIG. 60.7 Sternal-occipital-mandibular immobilizer brace.

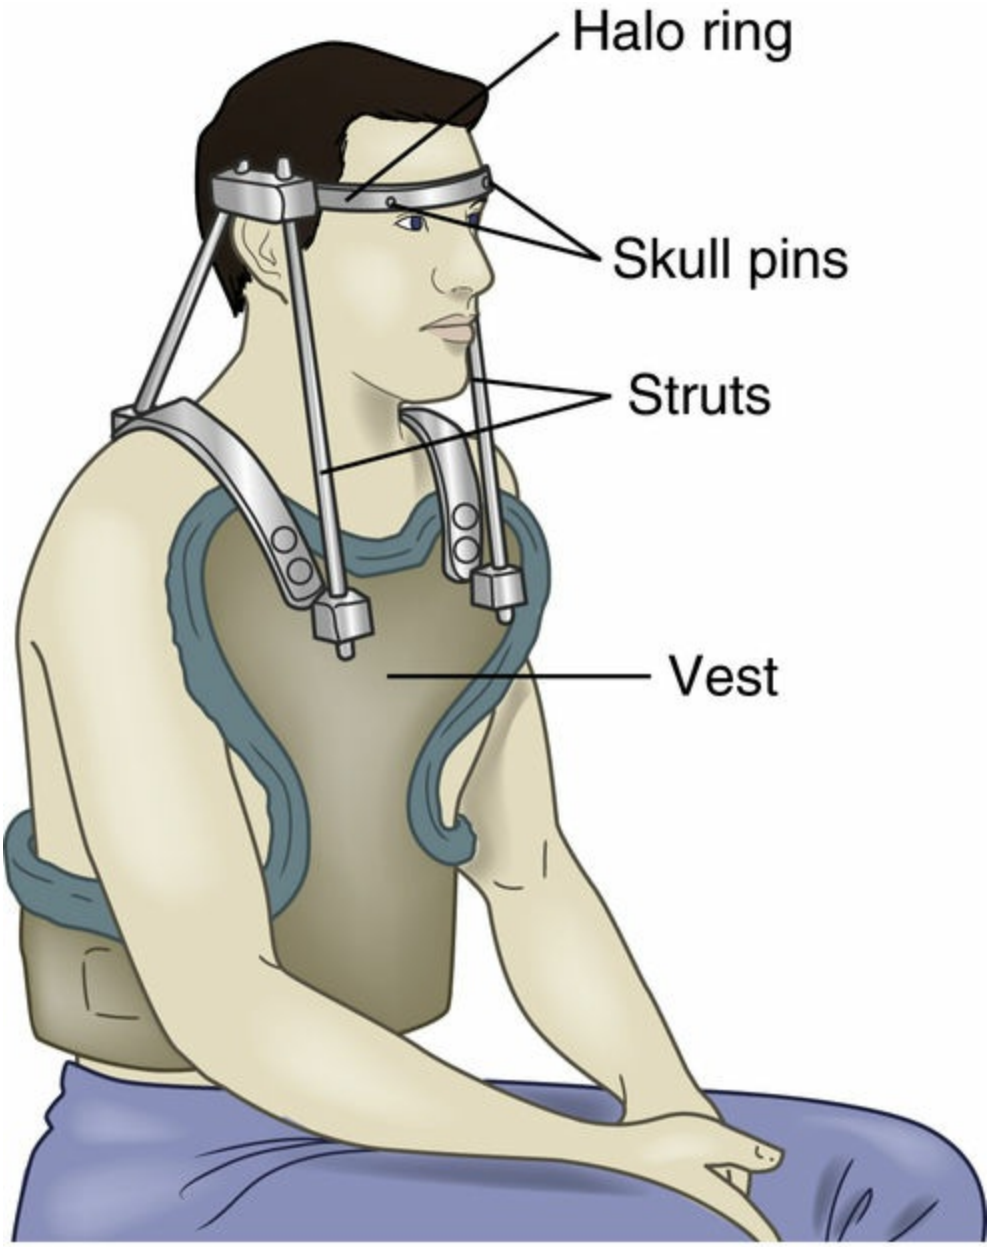

FIG. 60.8 Halo vest. The halo traction brace immobilizes the cervical spine, which allows the patient to ambulate and take part in self-care. Modified from Urden LD, Stacy KM, Lough ME: *Priorities in critical care nursing,* ed 6, St Louis, 2012, Mosby.

TABLE 60.6 Patient & Caregiver TeachingHalo Vest Care

Include the following instructions when teaching the patient and caregiver management of a halo vest:

1. Inspect the pins on the halo traction ring. Report to HCP if pins are loose or signs of infection are present, including redness, tenderness, swelling, or drainage at insertion sites.
2. Clean around pin sites carefully with chlorhexidine, water, or half-strength peroxide on a cotton swab as directed.
3. Apply antibiotic ointment as prescribed.
4. For skin care, have patient lie down with the head resting on a pillow to reduce pressure on the brace. Loosen 1 side of the vest. Gently wash the skin under the vest with soap and water, rinse area, and then dry it thoroughly. At the same time, check the skin for pressure points, redness, swelling, bruising, or chafing. Close the open side and repeat the procedure on the other side.
5. If the vest becomes wet or damp, carefully dry it with a blow dryer.
6. Encourage patient to use assistive device (e.g., cane, walker) to improve balance; encourage use of flat shoes.
7. Teach patient to turn the entire body, not just the head and neck, when trying to look sideways.
8. In case of an emergency, always keep a set of wrenches close to the halo vest.
9. Mark the vest strap to maintain consistent buckling and fit.
10. Avoid grabbing bars or vest to help the patient.
11. Keep sheepskin pad under vest. Change and wash pad at least weekly.
12. If perspiration or itching is a problem, encourage patient to wear a cotton T-shirt under the sheepskin. The T-shirt can be modified with a Velcro seam closure on one side.

The effects of immobility can be great. Thorough skin care is important because decreased sensation and circulation increase the risk for skin breakdown. Remove the patient's backboard as soon as

possible. Replace it with other forms of immobilization to prevent skin breakdown in the coccygeal and occipital areas. Fit cervical collars properly. Carefully assess areas under any device used for immobilization. We often place patients on special beds (Fig. 60.9). Kinetic therapy involves continuous side-to-side rotation of a patient to 40 degrees or more to help prevent lung complications. This lateral rotation also redistributes pressure, helping prevent pressure injuries.

FIG. 60.9 The RotoRest Therapy System helps prevent and treat lung

complications for immobile patients, including those with unstable cervical, thoracic, and lumbar fractures. Kinetic therapy, the continual side-to-side bilateral rotation of the patient, redistributes pulmonary blood flow and mobilizes secretions to improve ventilation and perfusion matching. The therapy system helps to prevent pressure injuries.

Respiratory Dysfunction

Respiratory complications are the leading acute and chronic causes of morbidity and mortality in SCI.[16] Respiratory dysfunction is present in up to 65% of patients with cervical SCI. During the first 48 hours after injury, spinal cord edema may increase the level of dysfunction, and respiratory distress may occur. Injury at or above C4 affects the phrenic nerve, which leads to the diaphragm, and breathing can stop.

Monitor the patient carefully for respiratory compromise and be prepared for quick action if arrest occurs. Regularly assess (1) breath sounds, (2) arterial blood gases (ABGs), (3) tidal volume, (4) vital capacity, (5) skin color, (6) breathing patterns (especially use of accessory muscles), (7) subjective comments about the ability to breathe, and (8) amount and color of sputum. A PaO_2 greater than 60 mm Hg and a $PaCO_2$ less than 45 mm Hg are acceptable values in a patient with uncomplicated tetraplegia. A patient who is unable to count to 20 aloud without taking a breath needs immediate attention.

In addition to ongoing assessment, intervene to maintain ventilation. Apply O_2 and provide appropriate ventilatory support until ABGs stabilize. If the patient is exhausted from labored breathing or ABGs show inadequate oxygenation or ventilation, endotracheal intubation or tracheostomy and mechanical ventilation is needed. Patients who have chest trauma or difficulty weaning from the ventilator may need a tracheostomy for airway management.

Clearing secretions is vital in reducing the risk for lung complications and possible respiratory failure.[16] Perform tracheal suctioning if crackles or coarse breath sounds are present. Chest physiotherapy and assisted (augmented) coughing can help. Perform assisted coughing either manually, by placing the heels of both hands

just below the xiphoid process and exert firm upward pressure to the area timed with the patient's efforts to cough (see Fig. 67.6), or mechanically with an insufflation-exsufflation device. Encourage the use of incentive spirometry.

The older adult has more difficulty responding to hypoxia and hypercapnia. Thus aggressive chest physiotherapy, adequate oxygenation, and proper pain management are essential to maximize respiratory function and gas exchange.

Cardiovascular Instability

Heart rate is slowed, often to less than 60 beats/min, because of unopposed vagal response. Any increase in vagal stimulation, as occurs with turning or suctioning, can cause cardiac arrest. Loss of SNS tone in peripheral vessels results in chronic low BP with potential orthostatic hypotension. The lack of muscle tone to aid venous return can cause sluggish blood flow and predispose the patient to VTE. Dysrhythmias may occur.

Frequently assess vital signs. If bradycardia is symptomatic, give an anticholinergic drug, such as atropine. A temporary or permanent pacemaker may be inserted in some patients. Maintain SBP greater than 90 mm Hg and keep MAP between 85 and 90 mm Hg for the first 7 days after SCI. Manage hypotension with fluid replacement and a vasopressor agent, such as phenylephrine or norepinephrine.

Maintain a normal blood volume. If blood loss has occurred from other injuries, monitor hemoglobin and hematocrit and give blood according to protocol. Assess the patient for signs of hypovolemic shock from hemorrhage.

Orthostatic hypotension is likely to occur in the patient with injury at T6 and above. The patient may have light headedness, dizziness, and nausea. Assess orthostatic BP when mobilizing the patient. Some lose consciousness when moved from the bed to a chair. For symptomatic patients, use an abdominal binder and graduated compression stockings to promote venous return. Drugs used to increase intravascular volume include salt tablets and fludrocortisone. Midodrine may be given to promote blood vessel contraction and

increase venous return.

Consider the effects of aging on the cardiovascular system of the older adult. The older patient is less able to manage the stress of traumatic injury because heart contractions weaken, and cardiac output is reduced. Maximum heart rate is reduced. The older adult may also have cardiovascular disease.

Use LMWH or low-dose heparin in combination with intermittent pneumatic compression devices or graduated compression stockings to promote venous return and reduce the risk for VTE. Remove stockings every 8 hours for skin care. Assess thighs and calves every shift for signs of VTE. Regularly perform range-of-motion (ROM) exercises and stretching. Continue VTE prophylaxis for 3 months after injury.

Fluid and Nutritional Management

During the first 48 to 72 hours after the injury, the GI tract may stop functioning *(paralytic ileus).* A nasogastric (NG) tube must be inserted if ileus occurs. Because the patient cannot have oral intake, monitor fluid and electrolyte status.

Nutrition should be started within the first 72 hours after injury. Specific solutions and additives are determined by individual requirements. Due to severe catabolism, a high-protein, high-calorie diet is needed for energy and tissue repair. If the patient cannot be fed through the GI system, either orally or through EN, PN should be started to reduce nitrogen losses that occur during the hypermetabolic state.

Once bowel sounds are present or flatus is passed, and the patient is not receiving mechanical ventilation, a formal swallow evaluation is done. If no risk for aspiration is identified, gradually introduce oral food and fluids. If the patient fails the swallow evaluation or is unable to eat due to an endotracheal tube or tracheostomy, a more secure feeding tube may be placed in the stomach or jejunum (see Chapter 39).

Check Your Practice

You are working in the spinal cord unit. Your 28-yr-old male patient with SCI at T6 weighs 168 lb. When he was admitted 3 weeks ago he weighed 186 lb. He asks you, "Well, what is my weight? Are you gonna make me eat now? You know you can't do that."

- What assessment data are important for you to obtain?
- What interventions would help him avoid further weight loss and regain lean body mass?

Patients may have anorexia due to depression, boredom with agency food, or discomfort at being fed (often by a hurried person). Some patients have a normally small appetite. Sometimes refusal to eat is a way of asserting control. If the patient is not eating adequately, assess the cause.

Based on assessment findings, make a contract with the patient with mutual goal setting for the diet. This contract gives the patient increased control and often results in improved nutritional intake. General measures also may be effective. For example, provide a pleasant eating environment, allow adequate time to eat (including any self-feeding the patient can achieve), encourage the family to bring in special foods, and plan social rewards for eating.

Consult a dietitian to ensure evaluation of the appropriate laboratory markers and develop the treatment plan. Keep a calorie count and record the patient's daily weight to evaluate progress. If possible, the patient should take part in recording calorie intake. Dietary supplements may be needed to meet nutritional goals. Include increased dietary fiber to promote bowel function.

Bladder and Bowel Management

Immediately after the injury, urine retention occurs because of the loss of autonomic and reflex control of the bladder and sphincter *(neurogenic bladder).* Because there is no sensation of fullness,

overdistention of the bladder can result in reflux into the kidney and cause renal failure. Bladder overdistention may even result in rupture of the bladder. Thus an indwelling catheter may be inserted soon after injury. Ensure patency of the catheter by frequent inspection and irrigation, if needed. In some agencies, an HCP's order is required for this procedure. Strict aseptic technique for catheter care is essential to prevent infection. During the period of indwelling catheterization, encourage a large fluid intake. Check the catheter to prevent kinking and ensure free flow of urine.

Catheter-acquired urinary tract infection (CAUTI) is a common problem. The best way to prevent CAUTI is regular and complete bladder drainage. Once the patient is stabilized, assess the best means of managing long-term urinary function. Clean intermittent catheterization (CIC) is the preferred method for emptying the bladder. CAUTI and CIC are discussed in Chapter 45.

CIC should be done 4 to 6 times daily to prevent bacterial overgrowth from urinary stasis. Keep urine residuals under 500 mL to prevent bladder distention. If the urine is cloudy or has a strong odor or if the patient develops symptoms of a urinary tract infection (UTI) (e.g., chills, fever, malaise), send a specimen for culture.

Consider age-related changes in renal function. The older adult is more likely to develop renal stones. Older men may have benign prostatic hyperplasia, which may interfere with urinary flow and complicate management of urinary problems. It can affect the ability to complete CIC.

Start a bowel program to combat constipation from neurogenic bowel. This involves inserting a rectal stimulant (suppository or small-volume enema) daily at a regular time, followed by gentle digital stimulation or manual evacuation until evacuation is complete. At first, the program may be done in bed with the patient in the side-lying position. However, as soon as the patient has resumed sitting, the patient should be in the upright position on a padded bedside commode chair. These programs typically take 30 to 60 minutes to complete. Measures to reduce constipation include adequate fluid intake, a diet high in fiber and vegetables, and increased activity and

exercise.

Temperature Control

Monitor the environment closely to maintain an appropriate temperature. Regularly assess the patient's body temperature. Do not use excess covers or unduly expose the patient (e.g., during bathing). If an infection with high fever develops, more aggressive methods for temperature control may be needed (e.g., a cooling blanket).

Stress Ulcers

Stress ulcers can occur in the patient with SCI because of the physiologic response to severe trauma and psychologic stress. Peak incidence of stress ulcers is 6 to 14 days after injury. Test stool and gastric contents daily for blood. Monitor the hematocrit for a slow drop. Histamine (H_2)-receptor blockers (e.g., ranitidine) or proton pump inhibitors (e.g., pantoprazole, omeprazole) given prophylactically decreases the secretion of HCl acid and prevents ulcers.

Sensory Deprivation

To prevent sensory deprivation, compensate for the patient's absent sensations by stimulating the patient above the level of injury. Conversation, music, and interesting foods can be a part of the nursing care plan. If the head of the bed must stay flat, provide prism glasses to help the patient read and watch television.

Help the patient avoid withdrawing from the environment. Promote adequate rest and sleep. Assess for changes in mood. Depression is common (discussed later in chapter on p. 1418).

Pain Management

Musculoskeletal nociceptive pain can develop from injuries to bones, muscles, and ligaments. The pain is worse with movement or palpation. Antiinflammatory drugs, such as ibuprofen (Motrin), may help with pain. Opioids may be used to manage nociceptive pain.

Visceral nociceptive pain is a dull, tender, or cramping pain in the thorax, abdomen, or pelvis. It may originate in the bladder or bowel. Assess the patient's bowel and bladder function to avoid bladder distention or constipation. Other causes of nociceptive pain include UTI and renal stones. Notify the HCP if the patient has persistent pain despite treatment. Diagnostic imaging may be needed to determine the cause.

Neuropathic pain in the initial phase is usually at the level of SCI. It may occur on 1 or both sides of the body within the affected dermatome and up to 3 levels below. The patient will describe hot, burning, tingling, shooting, electric pain. Pregabalin (Lyrica) is used to reduce symptoms.

Neuropathic pain can occur months or years after SCI, become chronic, and negatively affect sleep. The patient's mood, sudden noise, constipation, and infection can affect the pain. Teach the patient and caregiver about possible pain triggers and offer relaxation therapy. Other modes of treatment may include tricyclic antidepressants, intrathecal drugs, antiseizure drugs, epidural stimulation, and destructive surgical intervention.

Skin Care

The most common long-term complication in SCI is pressure injury (PI) formation. Healthy skin requires adequate blood circulation. Constant pressure in 1 position can compress blood vessels and limit blood supply, causing cell death and PI. Little evidence addresses interventions for prevention and treatment of PI in SCI.[17] Factors associated with increased risk for PI formation include heart and renal disease, smoking, alcohol or drug use, diabetes, hypoxia, hypotension, and pneumonia, UTI, and other infections.[18]

Prevention of PI requires diligent nursing care. Perform a risk assessment for PI formation with a daily comprehensive visual and tactile examination of the skin. Areas most vulnerable to breakdown include the sacrum, ischia, trochanters, and heels. Assess surgical incisions for healing and skin integrity under collars and braces. Regularly assess nutritional status. Both weight loss and gain can

contribute to skin breakdown. Teach the patient and caregiver about the causes and risk factors for PI development.[19]

A consult with the wound, ostomy, continence nurse (WOCN) can assist with prevention and management strategies (e.g., surface overlays).[19] Monitor incontinence and implement appropriate neurogenic bowel and bladder management interventions. Apply skin barrier creams.

Carefully position and reposition the patient at least every 2 hours. Gradually increase the times between turns if no redness over bony prominences is seen when turning. While the patient is supine in bed, float the heels to reduce pressure. Consider prophylactic dressings to prevent sacral and heel wounds. Move the patient carefully during turns and transfers to avoid stretching and folding of soft tissues *(shear)* or abrasion.

Many patients are placed on specialty mattresses.[17] When the patient is moved to a chair or wheelchair, use pressure-relieving cushions. Pressure relief should be scheduled every 15 to 20 minutes when the patient is in a chair and should last 30 to 60 seconds each time.

Reflexes

Once spinal cord shock is resolved, return of reflexes may complicate rehabilitation. Lacking control from the higher brain centers, reflexes are often hyperactive and have exaggerated responses. Penile erection can occur from a variety of stimuli, causing embarrassment and discomfort. Spasms ranging from mild twitches to convulsive movements below the level of injury may occur. The patient or caregiver may interpret this reflex activity as a return of function. Tactfully explain the reason for the activity. Tell the patient of the positive use of these reflexes in sexual, bowel, and bladder retraining. Antispasmodic drugs, such as baclofen (Lioresal), dantrolene (Dantrium), and tizanidine (Zanaflex), may help control spasms. Botulism toxin injections may be given to treat severe spasticity.

Autonomic Dysreflexia

The return of reflexes after the resolution of spinal shock means patients with injury at T6 or higher may develop autonomic dysreflexia. **Autonomic dysreflexia (AD)** is a massive, uncompensated cardiovascular reaction mediated by the SNS. It involves stimulation of sensory receptors below the level of the SCI. The intact SNS below the level of injury responds to the stimulation with a reflex arteriolar vasoconstriction that increases BP. The parasympathetic nervous system is unable to directly counteract these responses via the injured spinal cord. Baroreceptors in the carotid sinus and aorta sense the hypertension and stimulate the parasympathetic system. This causes a decrease in heart rate. Visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the injured spinal cord. It most often presents in the chronic phase after SCI.[20]

The most common precipitating cause of AD is a distended bladder or rectum. However, any sensory stimulation, including contraction of the bladder or rectum, stimulation of the skin, or stimulation of pain receptors can cause AD. AD is a life-threatening condition that requires immediate resolution. Proper identification and elimination of the inciting stimulus for AD can resolve the event. If uncorrected, it can lead to status epilepticus, stroke, myocardial infarction, and even death.

Manifestations include hypertension, throbbing headache, marked diaphoresis above the level of injury, bradycardia (30 to 40 beats/min), piloerection from pilomotor spasm, flushing of the skin above the level of injury, blurred vision or spots in the visual fields, nasal congestion, anxiety, and nausea. Measure BP when a patient with SCI reports a headache. Suspect AD in adults with SBP elevation of 20 to 40 mm Hg above baseline.[20]

Immediate nursing interventions include elevating the head of the bed 45 degrees or sitting the patient upright (to lower the BP) and determining the cause (bowel impaction, urinary retention, UTI, PI, tight clothing). Notify the HCP. The most common cause is bladder irritation. Immediate catheterization to relieve bladder distention may be needed. Instill lidocaine jelly in the urethra before catheterization.

If a catheter is already in place, check it for kinks or folds. If it is plugged, perform small-volume irrigation slowly and gently to open the catheter or insert a new catheter.

Stool impaction can cause AD. Apply an anesthetic ointment to avoid increasing symptoms, then perform a digital rectal examination (if trained). Remove all skin stimuli, such as constrictive clothing and tight shoes. Monitor BP often during the episode. If symptoms persist after the source has been relieved, give a rapid-onset and short-duration agent, such as nitroglycerin, nitroprusside, or hydralazine. Continue careful monitoring until vital signs stabilize.

Teach the patient and caregiver to recognize causes and symptoms of AD (Table 60.7). They must understand the life-threatening nature of AD, know how to relieve the cause, and activate the ERS, if needed.

Rehabilitation and Home Care

Rehabilitation of the person with SCI is complex. With physical and psychologic care and intensive and specialized rehabilitation, the patient with SCI can learn to function at the highest level of wellness. All patients with a new SCI should receive comprehensive inpatient rehabilitation in a rehabilitation unit or center that specializes in SCI rehabilitation.[2] Rehabilitation is an interprofessional team effort. Team members include rehabilitation nurses, HCPs, physical therapists, occupational therapists, speech therapists, vocational counselors, psychologists, therapeutic recreation specialists, prosthetists, orthotists, case managers, social workers, and dietitians.

TABLE 60.7 Patient & Caregiver TeachingAutonomic Dysreflexia

For a patient at risk for autonomic dysreflexia, include the following information in the teaching plan for the patient and caregiver:

1. Signs and symptoms
    - Sudden onset of acute headache.

- Elevation in BP and/or reduction in pulse rate.
- Flushed face and upper chest (above level of injury) and pale extremities (below level of injury).
- Sweating above level of injury.
- Nasal congestion.
- Feeling of apprehension.
- Immediate interventions.
- Raise the person to a sitting position.
- Remove the noxious stimulus (fecal impaction, kinked urinary catheter, tight clothing).
- Call the HCP if above actions do not relieve the signs and symptoms.

2. Measures to decrease the incidence of autonomic dysreflexia
   - Maintain regular bowel function.
   - If manual rectal stimulation is used to promote bowel function, use a local anesthetic to prevent autonomic dysreflexia.
   - Monitor urine output.
   - Teach the patient to wear a Medic Alert bracelet indicating a history of risk for autonomic dysreflexia.

Many of the problems that begin in the acute period become chronic and continue throughout life. Rehabilitation focuses on retraining physiologic processes as well as extensive patient and caregiver teaching about how to manage the physiologic and life changes resulting from the injury (Fig. 60.10).

Rehabilitation care is organized around the patient's goals and needs. The patient is expected to be involved in therapies and learn self-care for several hours each day. Such intensive work at a time when the patient is dealing with the sudden change in health and function can be stressful. Progress may be slow. The rehabilitation nurse has a key role in providing encouragement, specialized nursing care, and patient and caregiver teaching and in helping to coordinate efforts of the rehabilitation team.

Respiratory Rehabilitation

The patient with mechanical ventilation will need around-the-clock caregivers who are knowledgeable about respiratory hygiene and tracheostomy care. The rehabilitation nurse and respiratory therapist should teach patients and caregivers about home ventilator and tracheostomy care. The patient may need chest percussion or postural drainage to manage secretions to lower the risk for atelectasis and pneumonia. Refer to appropriate community agencies as needed.

Some patients with high cervical SCI have improved respiratory function with phrenic nerve stimulators or electronic diaphragmatic pacemakers.[21] These devices are not appropriate for all ventilator-dependent patients but are safe and effective for those with an intact phrenic nerve. Some ventilators are portable, allowing ventilator-dependent patients with tetraplegia to be mobile and less dependent.

If the patient was weaned from the ventilator during hospitalization, downsizing (gradual decrease in size) and removal of the tracheostomy will be done during rehabilitation. Teach assisted coughing, regular use of incentive spirometry, and breathing exercises to the patient who is not ventilator dependent. They should limit exposure to persons with fever, cold, and cough. Adhering to swallowing precautions (e.g., proper positioning of head and neck) and diet recommendations can prevent aspiration.

FIG. 60.10 A spinal cord injury has a major effect on a person's physical, emotional, and psychologic health.

TABLE 60.8 Types of Neurogenic Bladder

Type	Characteristics	Causes	Manifestations
Uninhibited bladder (spastic, overactive)	• No inhibitions influence time and place of voiding • Bladder empties in response to stretching of bladder wall	• Results from lesions above the pons • Observed in stroke, brain tumor, brain trauma	• Incontinence, frequency, urgency • Voiding is unpredictable and incomplete

Upper motor neuron bladder (flaccid, spastic/overactive)	• *Mixed A type* (most common):
	  • Bladder is flaccid and external sphincter is spastic, leading to urinary retention.
	• *Mixed B type:*
	  • Bladder is spastic with flaccid external sphincter leading to urinary incontinence.
		• Results from lesions between pons and sacral spinal cord
		• Seen in SCI or multiple sclerosis involving the cervicothoracic spinal cord
			• Detrusor-sphincter dyssynergia
			• Can lead to high bladder pressures and kidney damage from urinary reflex
			• Sensory function impaired

Lower motor neuron bladder (flaccid, underactive, areflexic)	• Bladder acts as if all motor functions were paralyzed • Bladder fills without emptying	• Results from lower motor neuron injury caused by trauma involving S2-4 or below • Lesions of cauda equina, pelvic nerves	• If sensory function intact, patient feels bladder distention and hesitancy • No control of micturition, resulting in urinary retention, over distention of bladder, overflow incontinence, and UTI

Neurogenic Bladder

Types of neurogenic bladder are described in Table 60.8. The type of bladder dysfunction determines management options. After the patient's overall condition is stable and assessment shows return of neurologic reflexes, urodynamic testing (see Table 44.11) and a urine culture may be done. Diagnostic and interprofessional care of neurogenic bladder is described in Table 60.9.

The patient with SCI and a neurogenic bladder needs a comprehensive program to manage bladder function. The goal is to improve quality of life and safety through preserving renal function, minimizing UTI and bladder stones, and developing a plan for urinary continence. Many factors are considered when selecting a bladder management strategy. These include patient preference, upper extremity function, and caregiver availability. For the selected strategy, teach the patient and caregiver successful self-management. Teach them about the various management techniques, how to obtain supplies, care of supplies and equipment, and when to seek health care.

Various drugs can be used to treat patients with a neurogenic bladder. Anticholinergic drugs (e.g., oxybutynin, tolterodine [Detrol]) may be used to suppress bladder contraction. α-Adrenergic blockers (e.g., terazosin, doxazosin [Cardura]) can relax the urethral sphincter. Antispasmodic drugs (e.g., baclofen) may decrease spasticity of pelvic

floor muscles. *Botulinum toxin* is an effective alternative in patients with neurogenic detrusor overactivity who cannot tolerate or had an inadequate response to anticholinergic drugs.[22]

Numerous drainage methods are possible. These include bladder reflex retraining (if partial voiding control remains), indwelling catheter, CIC, and external catheter (condom catheter). Evaluate long-term use of an indwelling catheter because of the associated high incidence of CAUTI, fistula formation, and diverticula. However, this is the best option for some patients. Patients with indwelling catheters need to have adequate fluid intake (at least 3 to 4 L/day). Regularly check the patency of the indwelling catheter. Frequency of routine catheter changes ranges widely depending on the type of catheter used and agency policy.

TABLE 60.9 Interprofessional CareNeurogenic Bladder

Diagnostic Assessment

- History and physical examination, including neurologic and pelvic examinations
- Laboratory: Urinalysis, urine culture and sensitivity, blood urea nitrogen, serum creatinine, creatinine clearance
- Urodynamic testing (postvoid residual, cystometric testing, EMG, urethral pressure profile)

Management

- Patient teaching
- Voiding diary
- Bladder retraining: time voiding, manual expression, intermittent catheterization

- Fluid schedule: intake of 1800–2000 mL/day
- Indwelling urinary catheter

Drug Therapy

- Tricyclic antidepressants
- Anticholinergic drugs
- α-Adrenergic blockers
- Antispasmodics
- Botulinum toxin injection into bladder wall

Bladder and/or Urethral Surgical Therapy

- Bladder augmentation
- Sphincter resection or removal *(sphincterotomy)*
- Electrode placement for electrical stimulation
- Urinary diversion
- Urethral stents and balloon dilation
- Artificial urinary sphincter

CIC is recommended as the first-line option for bladder management (see Chapter 45). Nursing assessment is important in selecting the time interval between catheterizations. At first, catheterization is done every 4 hours. Measure bladder volume before catheterization using a bladder ultrasound machine. If less than 200 mL of urine is present, the time interval until catheterization may be extended. If more than 500 mL of urine is present, the time interval is shortened. CIC is usually done 4 to 6 times daily.

TABLE 60.10 Patient & Caregiver TeachingBowel

Management After Spinal Cord Injury

For the patient with a spinal cord injury, include the following information about bowel management in the teaching plan for the patient and caregiver:

1. Optimal nutritional intake includes the following:
    - 3 well-balanced meals each day
    - 2 servings from the milk group
    - 2 or more servings from the meat group, including beef, pork, poultry, eggs, fish
    - 4 or more servings from the vegetable and fruit groups
    - 4 or more servings from the bread and cereal group
2. Fiber intake should be about 20–30 g/day. Increase the amount of fiber eaten gradually over 1–2 wk.
3. Consume at least 2–3 L of fluid per day unless contraindicated. Drink water or fruit juices (fluid softens hard stools). Limit caffeinated beverages, such as coffee, tea, and cola (caffeine stimulates fluid loss through urination).
4. Avoid foods that produce gas (e.g., beans) or upper GI upset (e.g., spicy foods).
5. *Timing:* Follow a regular schedule for bowel elimination. A good time is 30 min after the first meal of the day.
6. *Position:* If possible, an upright position with feet flat on the floor or on a step stool enhances bowel evacuation. Staying on the toilet, commode, or bedpan for longer than 20–30 min may cause skin breakdown. Based on stability, someone may need to stay with the patient.
7. *Activity:* Exercise is important for bowel function. In addition to improving muscle tone, it increases appetite and GI transit time. Exercise muscles, including stretching, ROM, position changing, and functional movement.
8. *Drug treatment:* Suppositories may be needed to stimulate a bowel movement. Manual stimulation of the rectum may be helpful in starting defecation. Use stool softeners as needed to regulate stool consistency. Use oral laxatives only if necessary.

Suprapubic catheters are a safe option in select patients. Because of personal preference or the inability to catheterize due to neurologic dysfunction, 30% of patients with SCI use indwelling urethral or suprapubic catheters. The incidence of bacteriuria after catheter introduction is 5% to 10% per day.

Traditional bladder management options include *urinary diversion surgery* for the recurrent UTI patient with renal involvement or repeated stones. Surgical treatment of neurogenic bladder includes bladder neck revision (sphincterotomy), bladder augmentation (augmentation cystoplasty), perineal ureterostomy, cystotomy, vesicostomy, and anterior urethral transplantation. Placement of a sacral cord stimulator, penile prosthesis, or artificial sphincter is possible. Urinary diversion procedures are discussed in Chapter 45.

Neurogenic Bowel

Careful management of bowel evacuation is necessary in the patient with SCI because voluntary control may be lost. Usual measures for preventing constipation include high-fiber diet and adequate fluid intake (see Table 42.10). Patient and caregiver teaching is needed to promote successful independent bowel management. Guidelines related to bowel management are outlined in Table 60.10.

These measures may not be adequate to stimulate evacuation. Suppositories (e.g., bisacodyl [Dulcolax], glycerin) or small-volume enemas and digital stimulation (done 20 to 30 minutes after suppository insertion) by the nurse or patient may be needed. In the patient with an upper motor neuron injury, digital stimulation can relax the external sphincter to promote defecation. A stool softener, such as docusate sodium (Colace), can help regulate stool consistency. Oral stimulant laxatives should be used only if absolutely necessary and not on a regular basis.

Valsalva maneuver and manual stimulation are useful in patients with lower motor neuron injuries. Because the Valsalva maneuver requires intact abdominal muscles, it is used in patients with injuries below T12. In general, a bowel movement every other day is considered adequate. However, consider preinjury patterns. Fecal

incontinence can result from too much stool softener or a fecal impaction.

Timing of defecation is important. Planning bowel evacuation for 30 to 60 minutes after the first meal of the day may enhance success by taking advantage of the gastrocolic reflex induced by eating. This reflex may also be stimulated by drinking a warm beverage right after the meal. Discuss timing of the bowel program among the interprofessional team so there are no interruptions when the patient is doing therapy (e.g., swimming pool therapy).

Record all bowel movements, including amount, time, and consistency. Consider using the International Spinal Cord Injury Bowel Function Data Set. This is a 16-item, comprehensive, standardized format for assessing bowel function in the patient with SCI.[23]

Spasticity

Spasticity can be both beneficial and undesirable. It aids with mobility, especially for the patient with incomplete SCI. Spasticity improves circulation by promoting venous return, decreasing orthostatic hypotension and the risk for VTE. Unfortunately, the patient with marked spasticity and tone may have difficulty with positioning and mobility from spasms. Spasms can cause significant pain and make activities of daily living (ADLs) difficult for the patient.

The Ashworth and Modified Ashworth Scales are used to evaluate spasticity. Treatment includes ROM exercises to prevent muscle and joint tightness and reduce the risk for contracture. Antispasmodic drugs, such as baclofen or tizanidine, may be given. Botulinum toxin injection is useful for specific muscle involvement.

Skin Care

Prevention of PI is part of the lifelong treatment plan after SCI. Nurses in rehabilitation are responsible for teaching the patient and caregiver about daily skin care. PI may not be noticed until severe damage has occurred. Include information on the importance of adequate

nutrition to skin condition. Anticipatory guidance about potential risks is essential. Patient and caregiver teaching related to skin care is outlined in Table 60.11.

Pain Management

The acute pain of the initial injury may persist during the first few weeks of rehabilitation. Chronic pain can result from overuse of muscles in the shoulders and arms for movement and repositioning. Pain often disrupts sleep. Assess, evaluate, and treat pain routinely. Use analgesics and interventions, such as massage and repositioning, to help the patient during therapy. Patients may benefit from referral to a pain management specialist.

Sexuality

Sexuality is an important issue regardless of the patient's age or sex. Open discussion with the patient about sexual rehabilitation is essential. A nurse or other rehabilitation professional trained in sexual counseling should provide support for the patient and the partner. Alternative methods of obtaining sexual satisfaction, such as oral-genital sex, may be suggested. Explicit films may help, such as a film showing sexual activities of a patient with paraplegia and a nondisabled partner. Use graphics cautiously because they may focus too much on the mechanics of sex rather than on the relationship.

TABLE 60.11 Patient & Caregiver TeachingSkin Care After Spinal Cord Injury

To prevent skin breakdown in a patient with spinal cord injury, include the following instructions when teaching the patient and caregiver:

Change Position Frequently

- If in a wheelchair, lift self and shift weight every 15–30 min.
- If in bed, change position with a regular turning schedule (at least

every 2 hr) that includes sides, back, and abdomen.
- Use pressure-reducing mattresses and wheelchair cushions (not eggcrate).
- Use pillows to protect bony prominences when in bed.

Monitor Skin Condition

- Inspect skin often for areas of redness, swelling, and breakdown.
- If a wound develops, follow standard wound care procedures.

Protect Skin

- Do not sit too close to fires, space heaters, or other sources of heat.
- Use sunscreen liberally when outdoors.
- Keep fingernails trimmed to avoid scratches and abrasions.
- Do not wear clothes that are too tight or too loose.
- Dress warmly in cold weather to prevent frostbite.
- Do not put hot foot in your lap without protection.

Knowledge of the level and completeness of injury is needed to understand the male patient's potential for orgasm, erection, and fertility, and the patient's capacity for sexual satisfaction. Men normally have 2 types of erections: psychogenic and reflex. The process of *psychogenic erection* begins in the brain with sexual thoughts. Signals from the brain are sent through the nerves of the spinal cord to the T10-L2 levels. The signals are then relayed to the penis and trigger an erection. Men with low-level incomplete injuries are more likely to have psychogenic erection than men with higher level incomplete injuries. Men with complete injuries are less likely to have psychogenic erection.[24]

A *reflex erection* occurs with direct physical contact to the penis or

other erotic areas. This short lived, uncontrolled, erection is involuntary and does not require sexually stimulating thoughts. Most men with SCI can have a reflex erection with physical stimulation if the S2-S4 nerve pathways are not damaged.

Treatment for erectile dysfunction includes drugs, vacuum devices, and surgical procedures. Phosphodiesterase inhibitors (e.g., sildenafil [Viagra]) have become the first-line treatment in men with SCI between T6 and L5. Sexual stimulation is needed to get an erection after taking the medication. Penile injection of vasoactive substances (papaverine, alprostadil, or a combination) is another medical treatment. Risks include scarring, bruising, and infection. Use may lead to priapism. Vacuum suction devices use negative pressure to encourage blood flow into the penis. Erection is maintained by a constriction band placed at the base of the penis. The main surgical option is implantation of a penile prosthesis.[24] (Erectile dysfunction is discussed in Chapter 54.)

SCI affects male fertility, causing poor sperm motility and ejaculatory dysfunction. Recent advances in methods of sperm retrieval include penile vibratory stimulation and rectal probe electroejaculation. Surgical removal of sperm is a last resort for sperm retrieval. Once retrieved, sperm can be directly injected into an egg via intracytoplasmic sperm injection (ICSI). These techniques have changed the prognosis for men with SCI to father children from unlikely to a reasonable chance of successful outcomes.[24]

The effect of SCI on female sexual response is less clear. A woman of childbearing age with SCI usually stays fertile. The injury does not affect the ability to become pregnant or deliver normally through the birth canal. Menses may cease for as long as 6 months after injury. If sexual activity is resumed, protection against unplanned pregnancy is needed. Pregnancy is associated with increased risk for diabetes and UTI and higher rates of AD, PI, increased spasticity, and catheter-related issues. Labor and delivery have high rates of complications.[25]

Care should be taken not to dislodge an indwelling catheter during sexual activity. A patient with an external catheter should refrain from fluids and remove the catheter before sexual activity. Teach patients

about the risk for AD. The bowel program should include evacuation the morning of sexual activity. Encourage the patient to tell the partner that incontinence is always possible. The woman may need a water-soluble lubricant to supplement decreased vaginal secretions and ease vaginal penetration. Women with some residual pelvic innervation can achieve normal orgasm. Use of the Eros device may help with orgasmic dysfunction.[25]

Grief and Depression

Depression after SCI is common and disabling. Patients with SCI may feel an overwhelming sense of loss. They may temporarily lose control over everyday activities as they depend on others for ADLs and for life-sustaining measures. Patients may feel they are useless and burdens to their families. At a life stage when independence is of great importance, they may be totally dependent on others.

Working through grief is a hard, lifelong process for which the patient needs support and encouragement. Table 60.12 outlines the grief response to SCI and appropriate nursing interventions. Your role in grief work is to support the patient and family and to allow mourning as part of the rehabilitation process. Maintaining hope is important during the grieving process and should not be interpreted as denial. With recent advances in rehabilitation, the patient is often independent physically and discharged from the rehabilitation center before completing the grief process.

The goal of recovery is related more to adjustment than to acceptance. *Adjustment* implies the ability to go on with living with certain limitations. Problem-based strategies are effective in supporting positive adjustment. When the patient accepts the current new normal, levels of coping and adjustment are improved. Nonacceptance is more predictive of psychologic distress, disengagement, denial, fantasy, and dependence on drugs and alcohol.

When the patient is depressed, be patient. Sympathy is not helpful. Treat the patient as an adult and encourage participation in care planning.[26] A primary nurse relationship is helpful. To adjust, the

patient needs continual support throughout the rehabilitation process in the form of acceptance, affection, and caring. Be attentive when the patient needs to talk and sensitive to needs at various stages of the grief process.

Although depression during the grief process usually lasts days to weeks, some patients become clinically depressed and need treatment for depression. Evaluation by a psychiatric nurse or psychiatrist is recommended. Treatment may include drugs and therapy. Treatment is maximized when the patient's personal preferences are identified, and care is tailored to patient needs.

Ethical/Legal Dilemmas

Right to Refuse Treatment

Situation

R.D., a 25-yr-old man, had a SCI to C7-8 after a motorcycle accident. He was diagnosed with anterior cord syndrome and has motor paralysis, which may prevent him from riding motorcycles again. He has become extremely depressed and no longer wishes to live. Because of his emotional state, R.D. is now refusing to eat. Can he be forced to receive EN?

Ethical/Legal Points for Consideration

- Withholding treatment in a newly injured but otherwise healthy young adult may present an ethical dilemma for some nurses. They may consider it assisted suicide and believe that it violates the ethical principles of beneficence and nonmaleficence.
- A competent adult has the right to consent to or refuse medical treatment under the right to privacy, the Fourteenth Amendment of the Constitution, and case law.*
- Case law has supported the concept that forced treatment is battery (unlawful use of force on somebody). A mentally

competent, physically incapacitated adult can refuse EN. The health agency must follow the patient's wishes.[†]

- To be competent to take part in informed consent or refusal, an adult must be able to understand the information provided about the procedure or treatment, consider choices among available alternatives, and make a choice based on his values and preferences. Depression may not be a factor in determining competency to make informed treatment choices.
- If, after adequate evaluation and treatment for pain, depression, or other medical conditions, the patient persists in his refusal, his wishes must be respected.
- Refusal to eat or drink has never been upheld as illegal, and the alternative—forced eating and drinking—is clearly a violation of patient rights and the criminal act of battery.

Discussion Questions

1. What are your feelings about requests to withhold treatment in a young person with a newly acquired disability?
2. What resources are available to help R.D., his family, and nursing staff deal with this emotionally charged and ethically complex situation?

---

[*] *Cruzan v. Director, Missouri Department of Health*, 497 U.S. 261, 1990. Retrieved from *www.supreme.justia.com/cases/federal/us/497/261*.

[†] *Bouvia v. Superior Court*, 1986. Retrieved from *http://law.justia.com/cases/california/calapp3d/179/1127.html*.

Caregivers need counseling to avoid promoting dependency in the patient through guilt or misplaced sympathy. They have intense grieving. A support group of family members and friends of patients with SCI can help them increase their participation and knowledge of

the grieving process, physical problems, rehabilitation plan, and meaning of the disability.

Evaluation

Expected outcomes are that the patient with SCI will

- Maintain adequate ventilation and have no signs of respiratory distress
- Maintain adequate circulation and BP
- Maintain intact skin over bony prominences
- Maintain adequate nutrition
- Establish a bowel management program based on neurologic function and personal preference
- Establish a bladder management program based on neurologic function, caregiver status, and lifestyle choices
- Have no episodes of AD

TABLE 60.12 Grief Response in Spinal Cord Injury

Patient Behavior	Nursing Intervention
Shock and Denial	
Struggle for survival, complete dependence, excessive sleep, withdrawal, fantasies, unrealistic expectations	• Provide honest information. • Use simple diagrams to explain injury. • Encourage patient to begin road to recovery. • Establish agreement to use and improve all current abilities while not denying the possibility of future improvement.
Anger	
Refusal to discuss paralysis, ↓ self-esteem, manipulation, hostile and abusive language	• Coordinate care with patient and encourage self-care. • Support family members. • Use humor appropriately. • Allow patient outbursts of emotions. • Do not allow fixation on injury.
Depression	
Sadness, pessimism, anorexia, nightmares, insomnia, agitation, "blues," suicidal preoccupation, refusal to take part in any self-care activities	• Encourage family involvement and use of community resources. • Plan graded steps in rehabilitation to give success with minimal opportunity for frustration. • Give cheerful and willing assistance with ADLs. • Avoid sympathy. • Use firm kindness.
Adjustment and Acceptance	
Planning for future, actively taking part in therapy, finding personal meaning in experience and continuation of growth, returning to premorbid personality	• Remember patients have unique personalities. • Balance support systems to encourage independence. • Set goals with patient input. • Emphasize potential.

Gerontologic Considerations: Spinal Cord Injury

Because of increased work and recreational activities among older adults, more of them have SCI (Fig. 60.11). Falls are the leading cause of SCI for people age 65 and older. Older adults with traumatic injuries have more complications than younger patients, are hospitalized longer, and have higher mortality rates.

Chronic illnesses associated with aging can have a serious impact on older adults living with SCI. As patients with SCI age, both individual aging changes and length of time since injury can affect functional ability. For example, bowel and bladder dysfunction can increase with the duration and severity of SCI.

Health promotion and screening are important for the older patient with SCI. Daily skin inspections and UTI prevention measures are critical. Regular breast examinations for women and prostate cancer screening for men are recommended. Heart disease is the most common cause of morbidity and mortality among older adults with SCI. The lack of sensation, including chest pain, in persons with high-

level injuries may mask acute myocardial ischemia. Altered autonomic nervous system function and decreases in physical activity can place patients at risk for heart problems, including hypertension.

Rehabilitation for the older adult with SCI may take longer because of preexisting conditions and poorer health status at the time of initial injury. An interprofessional approach to rehabilitation is essential in preventing secondary complications.

FIG. 60.11 An increasing number of older adults are living with a chronic spinal cord injury.

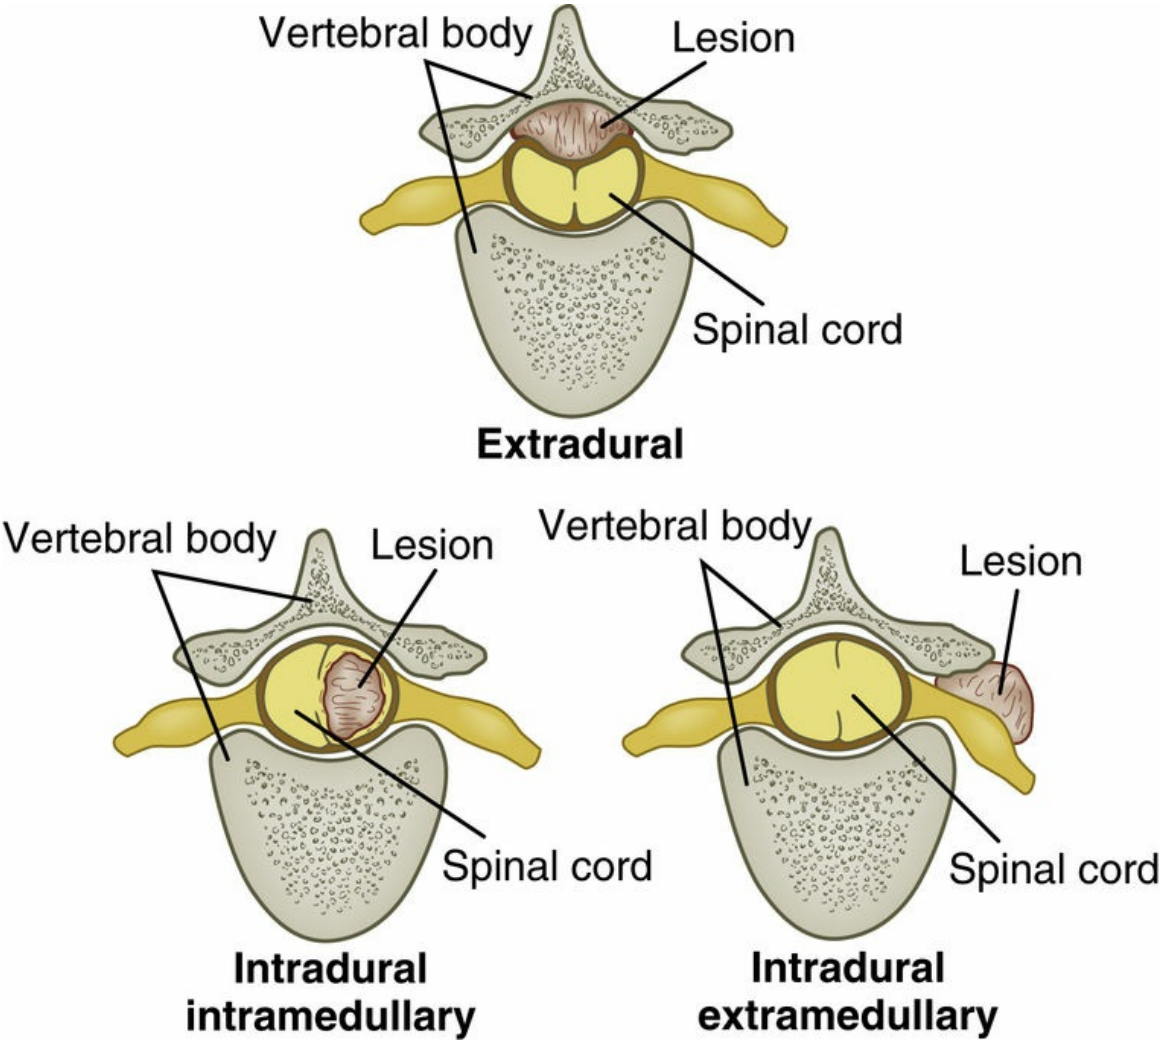

FIG. 60.12 Types of spinal cord tumors.

Spinal Cord Tumors

Spinal cord tumors can have a devastating impact due to spinal compression and neurologic dysfunction. Tumors are classified as *primary* (arising from some part of spinal cord, dura, nerves, or vessels) or *secondary* (from primary growths in other places in the body that have metastasized to the spinal cord).

Etiology and Pathophysiology

Spinal cord tumors are either *extradural* (outside the dura), *intradural-*

extramedullary (between the spinal cord and dura), and *intramedullary* (within the substance of spinal cord itself) (Fig. 60.12 and Table 60.13).

Extradural tumors include metastatic cancer and benign schwannomas. Many patients with cancer will have metastasis to the spine. Metastatic lesions can invade intradurally and compress the spinal cord. Tumors that often metastasize to the spinal epidural space are those that spread to bone, such as prostate, breast, lung, and kidney cancer. Intradural-extramedullary lesions include meningiomas that develop in the arachnoid membrane, schwannomas and neurofibromas that extend from the nerve root, and ependymomas found at the end of the spinal cord. Intramedullary tumors arise from glial or ependymal cells found throughout the entire spinal cord. The most common lesions are astrocytes and ependymomas.[27]

Many spinal cord tumors are slow growing. Their symptoms are due to the mechanical effects of slow compression and irritation of nerve roots, displacement of the spinal cord, or gradual obstruction of the blood supply. The slowness of growth does not cause secondary injury as in traumatic SCI. Thus complete functional restoration may be possible when the tumor is removed.

Clinical Manifestations

Both sensory and motor problems may result, with the location and extent of the tumor determining the severity and extent of the problem. The most common early symptom of a spinal cord tumor is back pain or pain radiating along the compressed nerve route.[28] Location of the pain depends on the level of compression. Pain may worsen with activity, coughing, straining, and/or lying down. There may be slowly increasing clumsiness, weakness, and spasticity. Paralysis can develop. Sensory disruption occurs as coldness, numbness, and tingling in 1 or more extremities. Neurogenic bowel and bladder are marked by incontinence, constipation, and urgency with difficulty in starting the flow, progressing to retention with overflow incontinence.

TABLE 60.13 Classification of Spinal Cord Tumors

Type	Incidence	Treatment	Prognosis
Extradural			
Outside spinal cord in extradural space	Metastatic lesions and benign schwannomas	Relief of cord pressure by surgical laminectomy, radiation, chemotherapy, or combination approach	*Benign:* Excellent with resection *Metastatic:* Poor, treatment usually palliative
Intradural Extramedullary			
Within dura mater but outside spinal cord	Mostly benign. Meningiomas, neurofibromas, schwannomas	Complete surgical removal of tumor (if possible) Partial removal followed by radiation	Usually very good if no damage to cord from compression
Intramedullary			
Within spinal cord	Mostly benign. Astrocytomas, ependymomas	Complete surgical removal of tumor (if possible) Partial removal followed by radiation	Usually very good if no damage to cord from compression Complete surgical resection of astrocytomas difficult

Interprofessional and Nursing Care

Extradural tumors can be seen on routine spinal x-rays. Intradural extramedullary and intramedullary tumors require MRI, CT scan, or CT myelogram for detection. CSF analysis may reveal tumor cells. Patients with tumors suspicious for metastatic disease need an oncology referral and further diagnostic testing to identify the primary cancer.[27]

Spinal cord compression is an emergency. Relief of ischemia related to the compression is the goal of therapy. Corticosteroids (e.g., dexamethasone) are generally given immediately to relieve tumor-related edema.[29]

Indications for surgery depend on the type of tumor and neurologic deficit. Emergency surgery may be needed to decompress the spinal cord, obtain tissue for biopsy, and help to determine appropriate treatment.[27] Primary spinal tumors may be removed with the goal of cure. In patients with metastatic tumors, treatment is mainly palliative. The goal is to restore or preserve neurologic function, stabilize the spine, and alleviate pain. Radiation and/or chemotherapy may be used to treat the tumor.

Relieving pain and maximizing neurologic function are the ultimate goals of treatment. Assess the patient's neurologic status before and after treatment. Giving analgesia as needed is an important nursing responsibility. Depending on the amount of neurologic dysfunction, care of the patient may be similar to that of a patient recovering from SCI.

Cranial Nerve Disorders

Cranial nerve disorders are often classified as peripheral neuropathies. The 12 pairs of cranial nerves are considered the peripheral nerves of the brain. The disorders usually involve the motor and/or sensory branches of a single nerve *(mononeuropathies).* Causes of cranial nerve problems include tumors, trauma, infection, inflammatory processes, and idiopathic (unknown) causes. The 2 cranial nerve disorders discussed here are trigeminal neuralgia and Bell's palsy.

Trigeminal Neuralgia

Trigeminal neuralgia (TN) *(tic douloureux)* is characterized by sudden, usually unilateral, severe, brief, stabbing, recurrent episodes of pain in the distribution of the trigeminal nerve. It occurs in about 12 per 100,000 Americans each year. TN affects more women than men. It occurs most often in people over age 50.

We classify TN as *classic* (TN 1) or *atypical* (TN 2). Patients may have both types. The pain intensity and lifestyle disruption that accompany TN can cause marked physical and psychologic dysfunction.

Etiology and Pathophysiology

The trigeminal nerve, the fifth cranial nerve (CN V), has both motor and sensory branches. TN most often affects the sensory (afferent) branches of the second and third division (maxillary and mandibular branches) of CN V (Fig. 60.13).

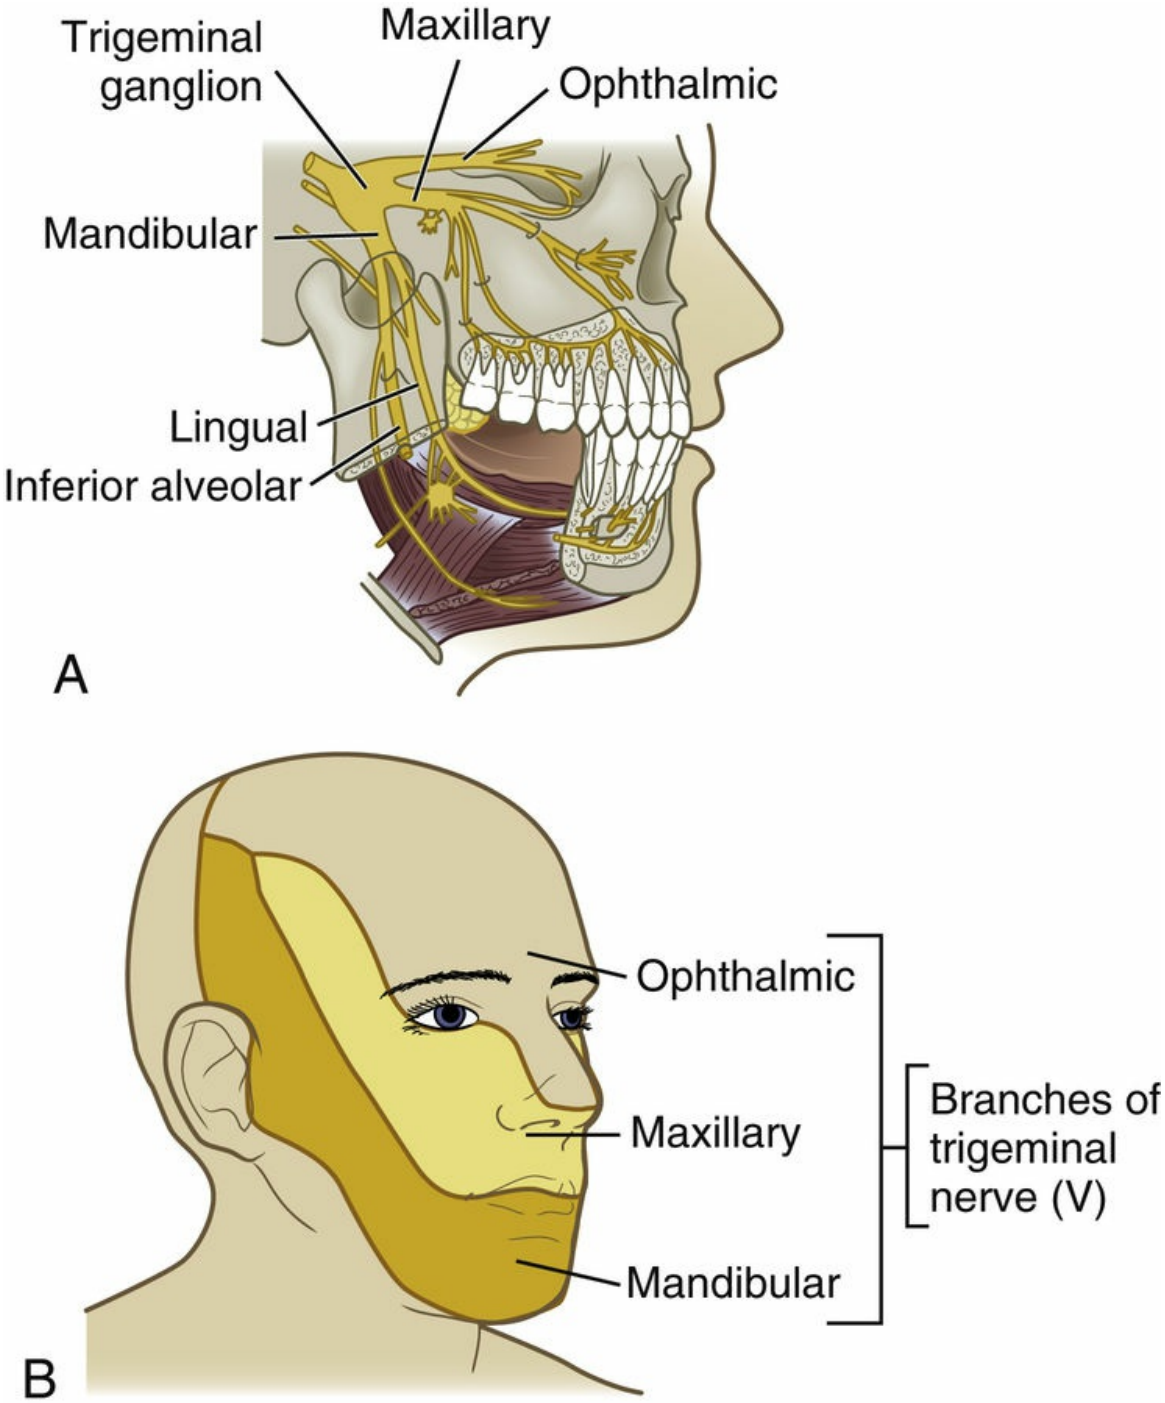

FIG. 60.13 **A,** Trigeminal (fifth cranial) nerve and its 3 main divisions: ophthalmic, maxillary, and mandibular nerves. **B,** Cutaneous innervation of the head.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Most cases result from vascular compression of the trigeminal nerve root by an abnormal loop of the superior cerebellar artery. This artery

compresses the nerve as it exits the brainstem. Constant compression appears to lead to chronic injury, causing flattening and atrophy of the nerve and damage to the myelin sheath.[30] In some cases, TN may be related to underlying pathology, such as multiple sclerosis, shingles, or masses in the cerebellum or brainstem.

Clinical Manifestations

The first episode of TN is sudden with a memorable onset. In TN 1, the patient has an abrupt onset of waves of excruciating pain. It is described as a burning, knifelike, or lightning-like shock in the lips, upper or lower gums, cheek, forehead, or side of the nose.[31] Facial twitching, grimacing, and frequent blinking and tearing of the eye can occur during the acute attack (giving rise to the term *tic douloureux*). Some patients may have facial sensory loss. Attacks are usually brief, lasting only seconds to 2 or 3 minutes. Frequency ranges from 1 to over 50 times a day.[31]

Pain episodes are usually started by a triggering mechanism of light touch at a specific point *(trigger zone)* along the distribution of the nerve branches. Precipitating stimuli include chewing, brushing the teeth, feeling a hot or cold blast of air on the face, washing the face, yawning, or even talking. As a result, the patient may eat improperly, neglect hygienic practices, wear a cloth over the face, and withdraw from interaction with others. The patient may sleep excessively as a means of coping with pain.

TN 2 manifests as constant aching, burning, crushing, or stabbing pain. The pain has a lower intensity and does not subside completely.[32] The distinct attacks associated with TN 1 do not occur in TN 2.

Diagnostic Studies

Diagnosis is based almost entirely on history, along with results from physical and neurologic examinations. Other disorders that cause facial pain should be ruled out before TN is diagnosed. MRI may be

used to assess for sinusitis, cancer, multiple sclerosis, or masses in the cerebellopontine angle. 3D reconstruction and angiography MRI are helpful with seeing the specific brain anatomy, nerve roots, and vasculature involved. A complete neurologic assessment is required along with consulting other subspecialties, such as neurology, neuroradiology, neurosurgery, dentistry, maxillofacial surgery, and pain management.

Interprofessional Care

Once a diagnosis is made, the goal is relief of pain with either medical or surgical treatment (Tables 60.14 and 60.15). Electrical stimulation of the nerves and nerve blocks with local anesthetics or botulinum toxin are options.

Drug Therapy

Antiseizure drug therapy may reduce pain by stabilizing the neuronal membrane and blocking nerve firing. These drugs are usually effective in treating TN 1 but less effective in TN 2. First-line drugs include carbamazepine (Tegretol) and oxcarbazepine (Trileptal). Topiramate (Topamax), clonazepam (Klonopin), phenytoin (Dilantin), lamotrigine (Lamictal), gabapentin, and valproic acid are other options.[30]

Tricyclic antidepressants, such as amitriptyline or nortriptyline, can help treat the constant burning or aching pain. Analgesics or opioids are usually not effective in controlling pain in TN 1 but may help with pain in TN 2.[30]

Surgical Therapy

If a conservative approach is ineffective or the patient is unable to tolerate adverse effects of medications, surgical therapy is available (Table 60.15). In percutaneous procedures, affected nerve fibers are damaged to eliminate pain. Although most patients are pain-free after any of the procedures, pain relief lasts longest with microvascular decompression. About half of treated patients develop recurrent pain

within 12 to 15 years.[30]

Nursing Management: Trigeminal Neuralgia

Patients usually receive outpatient treatment. Assess the attacks in detail, including triggering factors, characteristics, frequency, and pain management techniques. This information helps you to plan patient care. Evaluate the degree of pain and its effects on the patient's lifestyle, drug use, emotional state, and suicidal tendencies. Note behavior (including withdrawal).

TABLE 60.14 Interprofessional CareTrigeminal Neuralgia

Diagnostic Assessment

- History and physical examination (including neurologic examination)
- MRI

Management

- Drug therapy
    - Antiseizure drugs (e.g., carbamazepine, oxcarbazepine [Trileptal], gabapentin [Neurontin])
    - Tricyclic antidepressants (e.g., amitriptyline)
- Local nerve block
- Surgical therapy (Table 60.15)

Monitor the patient's response to drug therapy and note any side

effects. Discuss complementary pain management measures, such as acupuncture, biofeedback, and yoga. Environmental assessment is essential during an acute period to decrease triggering stimuli. The room should be kept at an even, moderate temperature and free of drafts. The patient may prefer to complete all self-care activities, fearing someone else will inadvertently cause injury.

Assess the patient's nutritional status and hygiene (especially oral). Teach the patient about the importance of nutrition, hygiene, and oral care. Convey understanding if oral neglect is apparent. A small, soft-bristled toothbrush or a warm mouthwash helps promote oral care. Hygiene activities are best done when analgesia is at its peak.

TABLE 60.15 Surgical Therapy for Trigeminal Neuralgia

Procedure	Description
Percutaneous Procedures	
Balloon compression	• Cannula is inserted through cheek and guided to a natural opening in the base of skull. • Soft catheter with a balloon tip is threaded through cannula. • Balloon is inflated and mechanical compression damages trigeminal nerve.
Glycerol rhizotomy (injection into 1 or more branches of trigeminal nerve) (Fig. 60.14)	• Thin needle inserted through puncture in cheek and guided through natural opening in base of skull. • Glycerol is injected into trigeminal ganglion. • Procedure can be repeated multiple times.
Radiofrequency thermal lesioning	• Needle is passed through cheek thorough a natural opening in base of skull. • Patient is awakened, then a small electric current is passed through the needle, causing tingling. • When the needle is positioned so the tingling occurs in the same area of pain, patient is sedated again, then radiofrequency current is used to destroy part of the nerve. • Can result in facial numbness (although some degree of sensation may be retained), corneal anesthesia, and trigeminal motor weakness
Surgical Procedures	
Microvascular decompression, with or without neurectomy	• Small craniotomy done behind the ear (suboccipital craniotomy). • Blood vessels that appear to be compressing the nerve at the root entry zone where it exits the pons are then displaced and repositioned. • If there is no compression, cutting of the nerve (neurectomy) may be done.
Stereotactic radiosurgery (gamma knife, cyber knife)	• Uses stereotactic localization to focus high doses of radiation to area where trigeminal nerve exits the brainstem. • Radiation causes slow formation of a lesion on nerve and disrupts transmission of pain signals to brain. • Pain relief from this procedure may take several months. (Radiosurgery is discussed in Chapter 56.)

Encourage food that is high in protein and calories and easy to chew. Food should be served lukewarm and offered frequently. If oral intake is sharply reduced and the patient's nutritional status is

compromised, an NG tube can be inserted on the unaffected side for EN.

Appropriate teaching related to surgical procedures depends on the type of procedure planned (e.g., percutaneous). The patient needs to know they will be awake during local procedures in order to cooperate when corneal and ciliary reflexes and facial sensations are checked. After the procedure, compare the patient's pain with the preoperative intensity. Evaluate the corneal reflex, extraocular muscles, hearing, sensation, and facial nerve function often (see Chapter 55). If the corneal reflex is impaired, take special care to protect the eyes. This includes using artificial tears or eye shields.

After a percutaneous radiofrequency procedure, apply an ice pack to the jaw on the operative side for 3 to 5 hours. To avoid injuring the mouth, the patient should not chew on the operative side until sensation has returned. If intracranial surgery was done, general postoperative nursing care after a craniotomy is appropriate. (Nursing care related to craniotomy is discussed in Chapter 56.)

Plan for regular follow-up care. Teach the patient about any medications. Although pain may be relieved, encourage the patient to keep environmental stimuli to a moderate level and to use stress management techniques. Long-term management after surgical intervention depends on residual effects of the procedure. If anesthesia is present or the corneal reflex is altered, teach the patient to (1) chew on the unaffected side; (2) avoid hot foods or beverages, which can burn the mucous membranes; (3) check the oral cavity after meals to remove food particles; (4) practice meticulous oral hygiene and continue with semiannual dental visits; (5) protect the face against extremes of temperature; (6) use an electric razor; (7) wear a protective eye shield and avoid rubbing eyes; and (8) examine eye regularly for symptoms of infection or irritation.

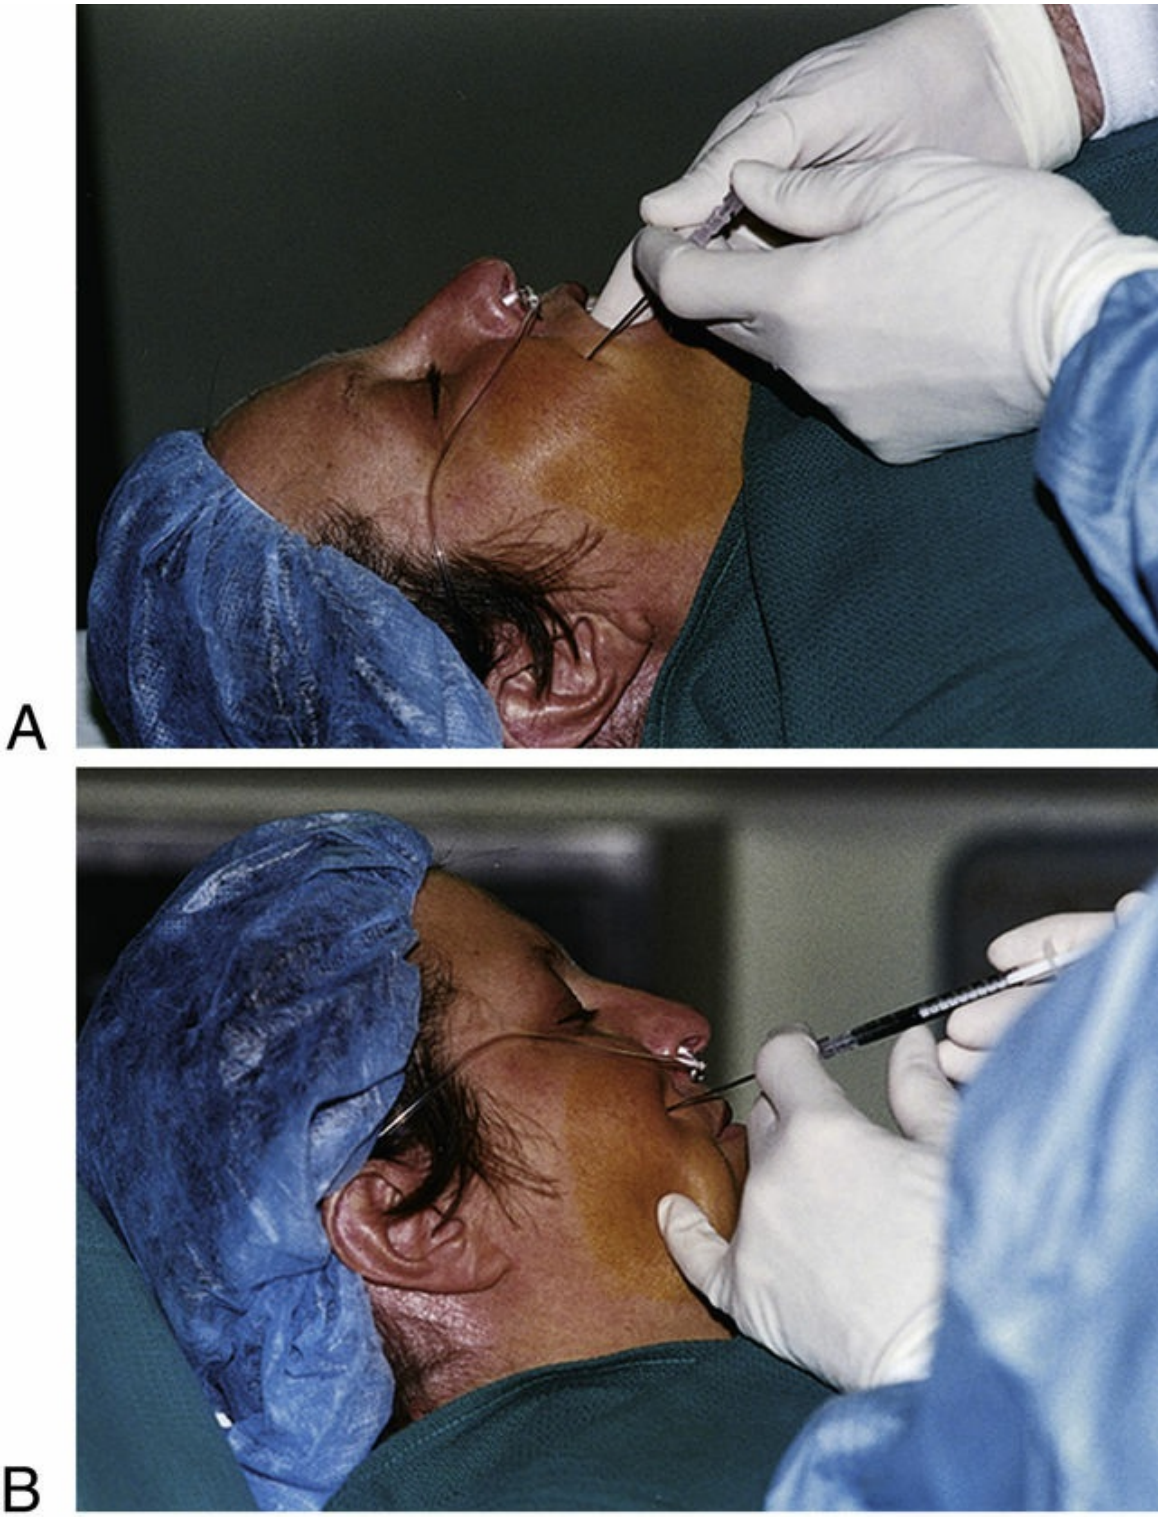

FIG. 60.14 Glycerol rhizotomy for the treatment of trigeminal neuralgia. **A,** Patient with trigeminal neuralgia having needle placed. **B,** HCP injecting glycerol.

Bell's Palsy

Bell's palsy is an acute, usually temporary, facial paresis (or palsy) resulting from damage or trauma of the facial nerve (CN VII). It usually affects only 1 side of the face, but both sides can be affected.

Bell's palsy is the most common facial nerve disorder.[33] Each year about 40,000 Americans are diagnosed with Bell's palsy. It occurs equally between men and women and can affect any age-group. The peak incidence is between ages 15 and 60 years. There is a high incidence during pregnancy and in persons with upper respiratory tract conditions (e.g., flu, colds), obesity, diabetes, and hypertension.[33]

Etiology and Pathophysiology

We do not know the exact cause. Several theories exist. Some think it is a reactivation of herpes simplex virus isoform (HSV-1) and/or herpes zoster virus (HZV). The viral infection causes inflammation, leading to nerve compression and the subsequent clinical features (Fig. 60.15). Another cause may be acute demyelination similar to what happens in Guillain-Barré syndrome.

The prognosis for persons with Bell's palsy is generally very good. The extent of nerve damage determines the extent of recovery. Most begin to get better within 2 weeks after the onset and recover some or all facial function within 6 months. In some cases, there may be residual effects, including facial asymmetry or abnormal facial movements.

Clinical Manifestations

CN VII is a mixed cranial nerve with motor, sensory, and autonomic function, which accounts for the manifestations. The key feature of Bell's palsy is the acute onset of unilateral lower motor facial weakness. 50% to 60% have pain around and behind the ear and neck. Other manifestations include drooping of the eyelid and corner of the mouth, drooling, facial twitching, dryness of the eye or mouth, facial

numbness, altered taste, hearing loss, and excessive tearing in 1 eye.[33] Most often these symptoms begin suddenly and reach their peak within 48 to 72 hours.

Quality of life is often decreased due to problems with eating, swallowing, speech, and taste. Patients may have psychologic withdrawal because of changes in appearance, malnutrition, dehydration, mucous membrane trauma, corneal abrasions, muscle stretching, and facial spasms and contractures.

FIG. 60.15 Facial characteristics of a person with Bell's palsy.

Diagnostic Studies

Bell's palsy is a clinical diagnosis. No definitive diagnostic test exists. The diagnosis and prognosis are indicated by clinical examination and observing the typical pattern of onset. Current guidelines do not

support routine laboratory, imaging, or neurophysiologic testing at first presentation of Bell's palsy. If indicated, MRI and CT can eliminate other causes for facial paralysis. Blood tests can diagnose infections or other diseases. Electromyography (EMG) can confirm the presence of nerve damage. Patients should be referred to a neurologist or otolaryngologist as soon as possible to exclude other neurologic conditions.

Interprofessional Care

The patient with Bell's palsy is treated as an outpatient. Care focuses on relieving symptoms, preventing complications, and protecting the eye on the affected side.

Treatment is often started to try to improve the chance of a complete recovery. Oral corticosteroid therapy to reduce inflammation and swelling should be started within 72 hours of onset.[34] Some patients should receive an antiviral agent, such as acyclovir (Zovirax), in addition to the steroid therapy. Surgical decompression of the facial nerve is controversial but is considered in refractory cases.

Nursing Management: Bell's Palsy

Mild analgesics can relieve pain. Moist heat can reduce discomfort and aid circulation. Electrical stimulation of the nerve, facial massage, and physical therapy help maintain muscle tone and ease pain. A facial sling may be helpful to support affected muscles, improve lip alignment, and facilitate eating. The facial sling is usually made and fitted by a physical or occupational therapist. When function begins to return, active facial muscle exercises are done several times a day. Tell the patient to protect the face from cold and drafts because trigeminal *hyperesthesia* (extreme sensitivity to pain or touch) may occur.

Check Your Practice

You are working in the outpatient neurology clinic. Your patient is a 68-yr-old woman with Bell's palsy. Her main problem today is dry eyes. When you are doing an assessment, she tells you, "I hate the way I look. I cannot go anywhere, and I am afraid to leave the house. I am ugly and scary looking."

- How can you help her cope with her disorder?
- What can you suggest to increase moisture in the affected eye?

Eye protection is important. The patient may wear dark glasses for protective and cosmetic reasons. Artificial tears (methylcellulose) should be instilled often during the day to prevent drying of the cornea. Ointment and an impermeable eye shield can be used at night to retain moisture. In some patients, taping the lids closed at night may be needed. Teach the patient to report ocular pain, drainage, or discharge.

Maintaining good nutrition is important. Teach the patient to chew on the unaffected side of the mouth to avoid trapping food and to enjoy the taste of food. Thorough oral hygiene must be done after each meal to prevent parotitis, caries, and periodontal disease from accumulated residual food.

The change in physical appearance from Bell's palsy can be devastating. Reassure the patient that a stroke did not occur and that chances for a full recovery are good. Enlisting support from family and friends is important. Tell the patient most people recover within 3 to 6 months after onset of symptoms.

Polyneuropathies

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an autoimmune process that occurs a few days or weeks after a viral or bacterial infection. GBS is

rare, affecting about 1 person in every 100,000.[35] It can occur at any age, but those over age 50 are at greatest risk.[36] The most common type of GBS is **acute inflammatory demyelinating polyneuropathy (AIDP)**. Other types include acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN). AMAN is more common in children.

Etiology and Pathophysiology

The cause of GBS is unknown. Both cellular and humoral immune responses likely play a role in AIDP. Humoral responses appear to cause AMAN.[36] Following an infection, immune responses cause injury to either the myelin sheath (AIDP) or the nerve axon itself (AMAN). There is edema and inflammation of affected nerves. The result is segmental loss of the myelin sheath with exposed nerve membranes in nerve terminals and the nodes of Ranvier. Transmission of nerve impulses is stopped or slowed. This leads to flaccid paralysis with muscle denervation and atrophy. In the recovery phase, remyelination occurs slowly. Neurologic function returns in a proximal-to-distal pattern.

Most cases of GBS follow a viral or bacterial infection of the GI or upper respiratory tract. Cytomegalovirus is the most common viral cause. *Campylobacter jejuni* gastroenteritis is the most common bacterial cause, especially for AMAN. Other related infections include Epstein-Barr virus, *Mycoplasma pneumoniae, Haemophilus influenza,* hepatitis (A, B, E), and Zika virus.[35] Surgery and trauma may trigger GBS.

Clinical Manifestations and Complications

The main features of GBS include acute, ascending, rapidly progressive, symmetric weakness of the limbs. The first symptoms are weakness, *paresthesia* (numbness and tingling), and *hypotonia* (reduced muscle tone) of the limbs. Reflexes in the affected limbs are weak or absent. Maximal weakness is reached in 4 weeks.

Autonomic nervous system dysfunction occurs with AIDP and

AMSAN, causing orthostatic hypotension, hypertension, and abnormal vagal responses (bradycardia, heart block, asystole). Other autonomic dysfunction effects include bowel and bladder dysfunction, facial flushing, and diaphoresis. Cranial nerve involvement manifests as facial weakness and paresthesia, extraocular eye movement problems, and dysphagia.

Pain is common. It can include paresthesia, muscular aches and cramps, and hyperesthesia. It is often worse at night. Pain may contribute to decreased appetite and interfere with sleep.

The most serious complication of GBS is respiratory failure. It occurs if the paralysis progresses to nerves that innervate the thoracic area. Frequently assess the respiratory system by checking respiratory rate and depth to determine the need for immediate intervention, including intubation and mechanical ventilation. Respiratory infection or UTI may occur. Immobility from paralysis can cause paralytic ileus, muscle atrophy, VTE, PIs, orthostatic hypotension, and nutritional deficiencies.[37]

Diagnostic Studies

Diagnosis is based mainly on the patient's history and clinical signs. Clinical features required for diagnosis include progressive weakness of more than 1 limb and decreased or absent reflexes. Electrolyte levels, liver function tests, creatinine phosphokinase, and erythrocyte sedimentation rates are evaluated. Cerebrospinal fluid (CSF) analysis helps exclude other causes. In GBS the CSF has more protein than normal.[37] Results of EMG and nerve conduction studies (NCS) are used after 2 weeks to confirm the diagnosis. NCS allow the HCP to diagnose the subtype. NCS in AIDP show demyelination. This information helps with prognosis, as patients with demyelination often need mechanical ventilation and have a poorer outcome.[38]

Interprofessional and Nursing Care

The management of GBS is supportive. Ventilatory support is critical during the acute phase. Patients may be in ICU for hemodynamic

monitoring. Immunomodulating treatments, such as plasma exchange (PE) *(plasmapheresis)* or high-dose IV immunoglobulin (IVIG), are most effective if used within the first 2 weeks of symptom onset. They are equally effective. PE removes antibodies and other immune factors. It is used 5 times either daily or every other day in the first 2 weeks. (PE is discussed in Chapter 13.) IVIG interferes with antigen presentation. It is given over 5 days. It is readily available and is the preferred treatment in many centers.[39] After 4 weeks past disease onset, PE and IVIG therapies have little value. Corticosteroids have little effect on the prognosis or duration of the disease.

Assessment is the most important aspect of nursing care during the acute phase. During the neurologic assessment, evaluate motor and sensory function. Report changes in motor function (e.g., ascending paralysis), reflexes, cranial nerve function (gag, cornea, swallow), and level of consciousness.

Carefully assess respiratory and cardiac function. Monitor ABGs and vital capacity. Closely monitor BP and cardiac rate and rhythm during the acute phase because dysrhythmias, orthostatic hypotension, and increased or decreased BP and heart rate may occur. Vasopressor agents and volume expanders may be needed to treat the low BP. If fever develops, obtain sputum and blood cultures to identify the pathogen. Appropriate antibiotic therapy is then started.

Nutritional needs must be met despite possible problems associated with delayed gastric emptying, paralytic ileus, and potential for aspiration if the gag reflex is lost. In addition to testing for the gag reflex, note drooling and other problems with secretions that may indicate an inadequate gag reflex. EN or PN may be used to ensure adequate caloric intake.

Throughout the course of the illness, provide support and encouragement to the patient and caregivers. Early referrals should be made for physical, occupational, and speech therapy. Counseling may help the patient adjust to the sudden disabling syndrome and dependence on others.

Most patients with GBS will start to recover spontaneously at about 28 days. 80% of patients walk independently at 6 months with 60%

making a full recovery in 1 year. GBS patients who have a GI infection, are older in age, have a rapid clinical onset, have a hospital length of stay longer than 11 days, have poor upper extremity motor strength, or need mechanical ventilation have a poorer prognosis.[39]

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a motor and sensory neuropathy. CIDP is a rare autoimmune disorder, affecting 1 to 2 persons per 100,000.[40] CIDP is more common in those in their 50s and 60s and in men more than women.[41]

Like GBS, there are different types of CIDP. CIDP differs from GBS in that symptoms gradually occur over 8 weeks and there is not an acute onset. CIDP is not self-limiting (with an end to the acute phase). Early recognition and treatment can help the patient avoid significant disability.

Etiology and Pathophysiology

We do not know the exact cause of CIDP. There is evidence to support the theory that like GBS, it has an autoimmune basis.[40] CIDP seems to be associated with infection, HIV, hepatitis C, Sjögren's syndrome, inflammatory bowel disease, melanoma, lymphoma, and diabetes.

Clinical Manifestations and Diagnostic Studies

It is important to recognize the differences between CIPD and GBS to prevent incorrect or delayed treatment. The classic presentation of patients with CIPD includes progressive symptoms lasting over 2 months, more weakness than sensory deficits, symmetric weakness in the arms and legs, impaired sensation (from distal to proximal), paresthesia and dysesthesia, and absent or decreased reflexes in all extremities. Tremors, facial weakness, and papilledema may be

present. Sensory ataxia and impaired vibration and pinprick sensation occur more often in CIDP.

CIDP diagnostic tests are similar to those for GBS. CSF shows high protein levels. MRI may show changes. Key identifying features of CIDP include nerve conduction block and slowed conduction velocity, possibly due to demyelination. Nerve biopsy is done when other studies do not confirm a diagnosis.[41]

Interprofessional and Nursing Care

Early recognition and diagnosis of CIDP are key to reducing permanent disability. The goal of treatment is to halt the immune response and stop nerve inflammation and demyelination. Use of IVIG, high-dose corticosteroids, or plasma exchange are all effective treatments.[41]

Patients continue therapy until maximum clinical improvement is achieved or until they reach a clinical plateau. Patients will need maintenance therapy to prevent relapse or progression. Appropriate referrals to rehabilitation should be made early in the patient's care to promote maximum recovery. Therapy may improve muscle strength, function, and mobility while minimizing muscle atrophy and joint distortion.[40]

Tetanus

Tetanus (lockjaw) is a severe infection of the nervous system affecting spinal and cranial nerves. In the United States, because of widespread immunization and careful wound care, there are only about 30 cases per year.[42] The annual worldwide incidence is between 500,000 and 1 million cases.[43]

Tetanus results from the effects of a potent neurotoxin (tetanospasmin) released by the anaerobic bacillus *Clostridium tetani.* The spores of the bacillus are present in soil, garden mold, and manure. Tetanospasmin binds to motor nerves and enters the axons. From there it can travel to the brain and spinal cord and stop the

release of inhibitory neurotransmitters. The result is sustained muscle contraction. If the toxin reaches the blood or lymph system, many different muscles can be affected.[42]

C. tetani enters the body through a wound that provides an appropriate low-O_2 environment for the organisms to mature and make toxin. Examples of such wounds include IV drug use injection sites, human and animal bites, puncture wounds from stepping on a nail, gardening injuries, burns, frostbite, open fractures, and gunshot wounds. The incubation period is typically 4 to 14 days. The shorter the period, the more severe the symptoms.

The hallmark feature of generalized tetanus is muscle rigidity and spasms. Patients may have muscle soreness, cramping, or difficulty swallowing. Facial muscles are affected first with stiffness in the jaw *(trismus)*. Patients may have a sardonic smile *(risus sardonicus)* due to facial muscle contractions. As the disease progresses, the neck muscles, back, abdomen, and extremities become increasingly rigid. In severe forms, continuous tonic seizures may occur with *opisthotonos* (extreme arching of the back and retraction of the head).[42] Laryngeal and respiratory spasms cause apnea and anoxia. The slightest noise, jarring motion, or bright light can set off a painful seizure.

Tetanus prevention and immunizations, which are the most important factors influencing incidence, are outlined in Table 68.6. Adults should receive a tetanus and diphtheria toxoid booster every 10 years.[43] Teach the patient that immediate, thorough cleansing of all wounds with soap and water is important to prevent tetanus. If an open wound occurs and the patient has not been immunized within 5 years, contact the HCP so that a tetanus booster can be given.

Tetanus is a medical emergency that requires hospitalization. Patients are given immediate treatment with tetanus immune globulin (TIG). It provides temporary immunity by directly providing antitoxin.[43] Drugs to control spasms are essential. Diazepam (Valium) or barbiturates are given to promote sedation and skeletal muscle relaxation. In severe cases, neuromuscular blocking agents (e.g., vecuronium) are given to paralyze skeletal muscles. Opioid analgesics, such as morphine or fentanyl, are used for pain

management. A 10- to 14-day course of penicillin, metronidazole (drug of choice), tetracycline, or doxycycline is recommended to inhibit further growth of *C. tetani.*

Because of laryngospasm and the potential need for neuromuscular blocking drugs, the patient is placed on mechanical ventilation. Sedative agents and opioid analgesics are given to all patients who are pharmacologically paralyzed. IV fluids are needed for proper hydration due to sustained muscle contraction. Any wound should be debrided or abscess drained. Antibiotics may be given to prevent secondary infections.

Botulism

Botulism is a rare, but the most serious type, of food poisoning. It is caused by GI absorption of a neurotoxin made by *Clostridium botulinum.* This organism is found in the soil, and the spores are hard to destroy. It can grow in any food contaminated with the spores. Improper home canning of foods is often the cause.

We think the neurotoxin destroys or inhibits the neurotransmission of acetylcholine at the myoneural junction, resulting in disturbed muscle innervation. Neurologic manifestations can develop rapidly or evolve over several days. They include a descending paralysis with muscle incoordination and weakness, difficulty swallowing, and seizures. Respiratory muscle weakness can quickly lead to respiratory and/or cardiac arrest.

The manifestations, prevention, and treatment are described in Table 41.24. Patient and caregiving teaching related to food poisoning are outlined in Table 41.25. Nursing care during the acute illness is like that for GBS. Supportive nursing interventions include rest, activities to maintain respiratory function, adequate nutrition, and preventing loss of muscle mass.

Case Study

Spinal Cord Injury

© ComstockImages/Stockbyte/Thinkstock.

Patient Profile

Acute Phase

S.W., an 18-yr-old white woman, is admitted to the ED with the diagnosis of a cervical spinal cord injury (SCI). S.W. was swimming at a neighbor's backyard pool. She dove into the shallow end, striking her head on the bottom of the pool. Her friends noticed she did not resurface. They rescued her and brought her to the side of the pool.

They maintained neck immobilization until the rescue crews arrived.

Subjective Data

- Awake and alert
- Reporting neck pain
- Anxious and asking why she cannot move her legs
- Asking to see her family

Objective Data

Physical Examination

- Weak elbow flexion (biceps) movement bilaterally
- No triceps movement bilaterally
- Gross shoulder movement present bilaterally
- No movement in bilateral lower extremities
- Decreased sensation from the shoulders down
- No bladder or bowel control
- BP 85/50 mm Hg; pulse 56 beats/min; respirations 32 breaths/min and labored

Diagnostic Studies

- CT C-spine shows C5 subluxation and compression fracture
- MRI C-spine shows severe spinal cord compression at C5-6

Interprofessional Care

- Intubated in the ED
- Started on mechanical ventilation
- Placed in tongs and traction on arrival to the ICU

Discussion Questions (Acute Phase)

1. ***Priority Decision:*** What nursing activities would be a priority on S.W.'s arrival in the ICU?
2. What physiologic problems are causing S.W. to have hypotension and bradycardia?
3. What would be the initial treatment for S.W.'s hypotension and bradycardia?
4. ***Safety*****:** What signs and symptoms would indicate respiratory distress? What physiologic problem would cause respiratory distress in S.W.'s injury state?
5. ***Collaboration***: What can the interprofessional team do to decrease S.W.'s anxiety?
6. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? What are the collaborative problems?
7. ***Collaboration:*** Identify activities that can be delegated to unlicensed assistive personnel (UAP).

Patient Profile
Rehabilitation Phase

S.W. is now 1-month postinjury and has been admitted to a local inpatient SCI rehabilitation agency. She has been extubated and uses a wheelchair to mobilize. She eats 3 meals a day with help and is on a strict bowel and bladder program.

Subjective Data

- Awake and alert but anxious
- Reporting a severe headache, blurred vision, and nausea

Objective Data
Physical Examination

- Flushed and diaphoretic above the level of injury
- No bowel movement for 2 days
- BP 235/106 mm Hg, pulse 32 beats/min, respirations 30 breaths/min and labored

Discussion Questions (Rehabilitation Phase)

1. ***Priority Decision:*** What initial priority nursing interventions would be appropriate?
2. What physiologic problem is causing S.W.'s hypertension and bradycardia?
3. Once the HCP has been notified, what other interventions would be appropriate?
4. ***Quality Improvement:*** What outcomes would indicate that nursing interventions were successful?
5. ***Patient-Centered Care:*** Patient and caregiver involvement in the rehabilitation process is vital. What teaching will you provide about bowel management?
6. ***Evidence-Based Practice:*** S.W. and her family are concerned about the risk for autonomic dysreflexia. What effective strategies to prevent autonomic dysreflexia would you discuss with them?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. During rehabilitation, a patient with spinal cord injury begins to ambulate with long leg braces. Which level of injury does the nurse associate with this degree of

recovery?

a. L1-2

b. T6-7

c. T1-2

d. C7-8

2. A patient with a T4 spinal cord injury has neurogenic shock due to sympathetic nervous system dysfunction. What would the nurse recognize as characteristic of this condition?

a. Tachycardia

b. Hypotension

c. Increased cardiac output

d. Peripheral vasoconstriction

3. A patient with spinal cord injury has severe neurologic deficits. What is the *most* likely mechanism of injury for this patient?

a. Compression

b. Hyperextension

c. Flexion-rotation

d. Extension-rotation

4. A patient undergoing rehabilitation for a C7 spinal cord injury tells the nurse he must have the flu because he has a bad headache and nausea. The nurse's *first priority* is to

a. call the health care provider.

b. check the patient's temperature.

c. measure the patient's blood pressure.

d. elevate the head of the bed to 90 degrees.

5. The most common early symptom of a spinal cord tumor is
   a. urinary incontinence.
   b. back pain that worsens with activity.
   c. paralysis below the level of involvement.
   d. impaired sensation of pain, temperature, and light touch.

6. During assessment of the patient with trigeminal neuralgia, the nurse should *(select all that apply)*
   a. inspect all aspects of the mouth and teeth.
   b. assess the gag reflex and respiratory rate and depth.
   c. lightly palpate the affected side of the face for edema.
   d. test for temperature and sensation perception on the face.
   e. ask the patient to describe factors that initiate an episode.

7. During routine assessment of a patient with Guillain-Barré syndrome, the nurse finds the patient is short of breath. The patient's respiratory distress is caused by
   a. elevated protein levels in the CSF.
   b. immobility resulting from ascending paralysis.
   c. degeneration of motor neurons in the brainstem and spinal cord.
   d. paralysis ascending to the nerves that stimulate the thoracic area.

8. A nurse is caring for a patient newly diagnosed with chronic inflammatory demyelinating polyneuropathy (CIDP). Which statement can the nurse accurately use to

teach the patient about CIDP?

a. "Corticosteroids have little effect on this disease."

b. "Maintenance therapy will be needed to prevent relapse."

c. "You will go into remission in approximately eight weeks."

d. "You should be able to walk without help within three months."

1. a, 2. b, 3. c, 4. c, 5. b, 6. a, d, e, 7. d, 8. b.

Assessment

Musculoskeletal System

Colleen Walsh

LEARNING OUTCOMES

1. Describe the gross and microscopic anatomy of bone.
2. Explain the classification system for joints and movements at synovial joints.
3. Describe the functions of cartilage, muscles, ligaments, tendons, fascia, and bursae.
4. Link age-related changes in the musculoskeletal system to the differences in assessment findings.
5. Obtain significant subjective and objective assessment data related to the musculoskeletal system from a patient.
6. Perform a physical assessment of the musculoskeletal system using appropriate techniques.
7. Distinguish normal from abnormal findings of a physical assessment of the musculoskeletal system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the musculoskeletal system.

Conceptual Focus

Functional Ability
Mobility
Safety

The musculoskeletal system is composed of voluntary muscle and 6

types of connective tissue: bone, cartilage, ligaments, tendons, fascia, and bursae. The purpose of the musculoskeletal system is to protect body organs, provide support and stability for the body, store minerals, and allow coordinated movement. This chapter reviews the structure and function of the musculoskeletal system to facilitate nursing assessment and evaluation of the assessment findings.

Structures and Functions of Musculoskeletal System

Bone

Function

The main functions of bone are support, protection of internal organs, voluntary movement, blood cell production, and mineral storage. Bones provide the supporting framework that keeps the body from collapsing. It allows the body to bear weight. Bones protect underlying vital organs and tissues. For example, the skull encloses the brain and vertebrae surround the spinal cord. The rib cage protects the lungs and heart.

Bones serve as a point of attachment for muscles and ligaments. Muscles are connected to bones by tendons. Bones act as a lever for muscles. Movement occurs because of muscle contractions applied to these levers. Ligaments provide stability to joints. Bone marrow contains hematopoietic tissue responsible for making red and white blood cells. Bones serve as a storage site for inorganic minerals, including calcium and phosphorus.

Bone is a dynamic tissue that continuously changes form and composition. It contains both organic material (collagen) and inorganic material (calcium, phosphate). The internal and external growth and remodeling of bone are ongoing processes.

Microscopic Structure

Bone is classified according to structure as *cortical* (compact and

dense) or *cancellous* (spongy). In *cortical bone,* cylindrical structural units called *osteons (Haversian systems)* fit closely together to create a dense bone structure (Fig. 61.1, *A*). Within the systems, the Haversian canals run parallel to the bone's long axis. They contain the blood vessels that travel to the bone's interior from the periosteum. Surrounding each osteon are concentric rings known as *lamellae,* which indicate mature bone. Smaller canals *(canaliculi)* extend from the Haversian canals to the *lacunae,* where mature bone cells are embedded.

B

FIG. 61.1 Bone structure. **A,** Cortical bone showing numerous structural units called osteons. **B,** Anatomy of a long bone (tibia) showing cancellous and compact bone.
A, From Herlihy B, Maebius N: *The human body in health and illness,* ed 4, Philadelphia, 2011, Saunders. *B,* From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Cancellous bone has a different structure than cortical bone. The lamellae are not arranged in concentric rings. Instead, they occur along the lines of maximum stress placed on the bone. Cancellous bone is filled with red or yellow marrow. Blood reaches the bone cells by passing through spaces in the marrow.

The 3 types of bone cells are osteoblasts, osteocytes, and osteoclasts.[1] *Osteoblasts* synthesize organic bone matrix (collagen) and are the basic bone-forming cells. *Osteocytes* are mature bone cells. *Osteoclasts* take part in bone remodeling by helping in the breakdown of bone tissue. **Bone remodeling** is the removal of old bone by osteoclasts *(resorption)* and the deposit of new bone by osteoblasts *(ossification).* The inner layer of bone is made mostly of osteoblasts with a few osteoclasts.

Gross Structure

The anatomic structure of bone is best represented by a typical long bone, such as the tibia (Fig. 61.1, *B*). Each long bone consists of the epiphysis, diaphysis, and metaphysis. The *epiphysis,* the widened area at each end of a long bone, is made mostly of cancellous bone. The wide epiphysis allows greater weight distribution and provides stability for the joint. The epiphysis is a primary location of muscle attachment. Articular cartilage covers the ends of the epiphysis. It provides a smooth, low-friction surface for joint movement.

The *diaphysis* is the main shaft of the long bone. It provides structural support and is composed of cortical bone. The tubular structure of the diaphysis allows it to withstand bending and twisting forces more easily.

The *metaphysis* is the flared area between the epiphysis and diaphysis. Like the epiphysis, it is composed of cancellous bone.

The *epiphyseal plate* (physis or growth plate) is the cartilaginous area

between the epiphysis and metaphysis. In skeletally immature children who still have open growth plates, the epiphyseal plate actively makes chondrocytes that become mature bone. Division of the chondrocytes causes longitudinal bone growth in children. Injury to the epiphyseal plate in a growing child can cause the formation of new bone to stop at the growth plate. This leads to a shorter extremity and may contribute to significant functional problems. In the adult, the metaphysis and epiphysis become joined when chondrocyte formation at the growth plate stops and bone formation is complete.

The *periosteum* is composed of fibrous connective tissue that covers the bone. Tiny blood vessels penetrate the periosteum to bring nutrition to underlying bone. Musculotendinous fibers attach to the outer layer of the periosteum. Collagen bundles attach the inner layer of the periosteum to the bone. There is no periosteum on the articular surfaces of long bones. These bone ends are covered by articular cartilage.

The medullary *(marrow)* cavity in the center of the diaphysis contains either red or yellow bone marrow.[2] In adults, red marrow is found mainly in the *flat bones,* such as the pelvis, skull, sternum, cranium, ribs, vertebrae, and scapulae, and *cancellous* ("spongy") bone at the epiphyseal ends of long bones, such as the femur and humerus. Red bone marrow is involved in blood cell production (hematopoiesis). In the adult, the medullary cavity of long bones contains yellow bone marrow (mainly adipose tissue). Yellow marrow is involved in hematopoiesis in times of great blood cell need.

Types

The skeleton consists of 206 bones. They are classified according to shape as long, short, flat, or irregular.

Long bones have a central shaft *(diaphysis)* and 2 widened ends *(epiphyses)* (Fig. 61.1, *B*). Examples include the femur, humerus, and tibia. *Short bones* are composed of cancellous bone covered by a thin layer of compact bone. Examples include the carpals in the hand and tarsals in the foot.

Flat bones have 2 layers of compact bone separated by a layer of

cancellous bone. Examples include the ribs, skull, scapula, and sternum. The spaces in the cancellous bone contain bone marrow. *Irregular bones* appear in a variety of shapes and sizes. Examples include the sacrum, mandible, and ear ossicles.

Joints

A *joint* (articulation) is a place where the ends of 2 bones are close and move in relation to each other. Joints are classified by the degree of movement that they allow (Fig. 61.2).

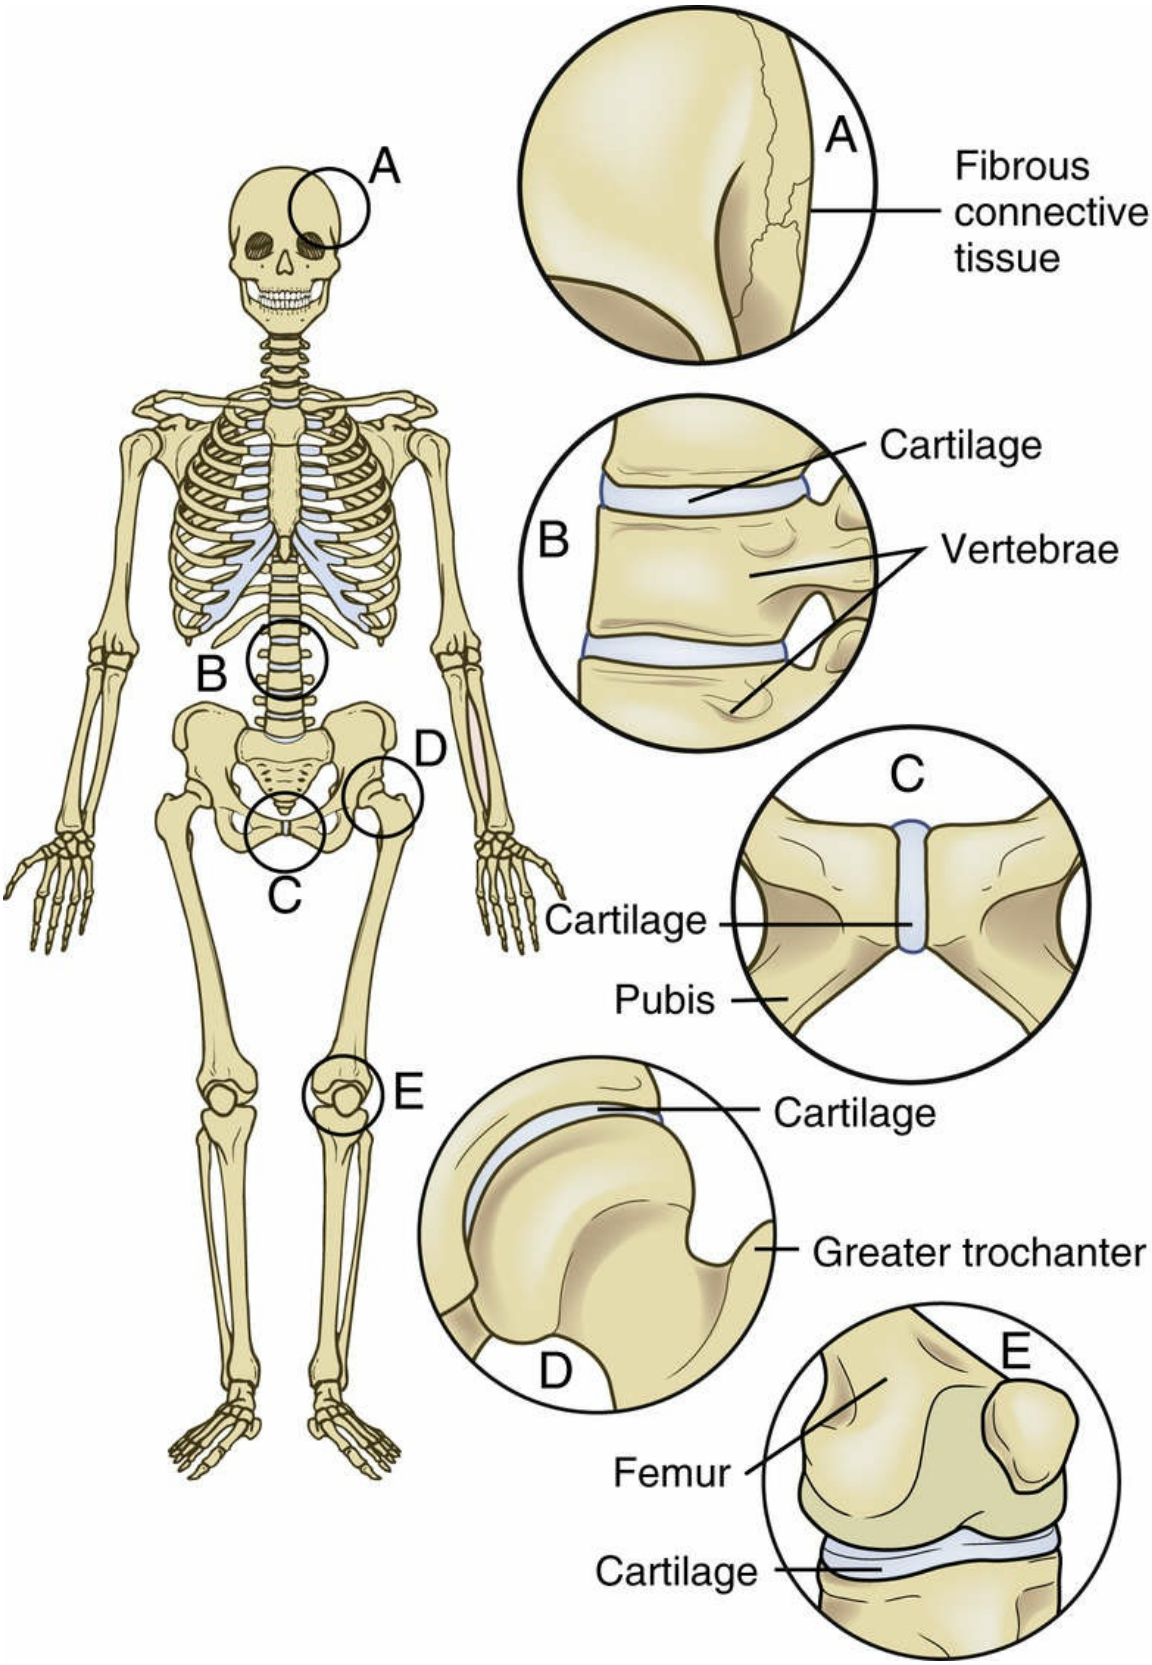

FIG. 61.2 Classification of joints. **A** to **C,** Synarthrotic (immovable) and amphiarthrotic (slightly movable) joints. **D** and **E,** Diarthrodial

(*freely* movable) joints.

The most common joint is the freely movable *diarthrodial* (synovial) type. Each joint is enclosed in a capsule of fibrous connective tissue, which joins the 2 bones together to form a cavity (Fig. 61.3). The capsule is lined by a synovial membrane, which secretes thick synovial fluid. This fluid lubricates the joint, reduces friction, and allows opposing surfaces to slide smoothly over each other. The end of each bone is covered with articular (hyaline) cartilage. Supporting structures (e.g., ligaments, tendons) reinforce the joint capsule. They provide limits and stability to joint movement. Types of diarthrodial joints are shown in Fig. 61.4.

Cartilage

The 3 types of *cartilage* are hyaline, elastic, and fibrous. *Hyaline cartilage* is the most common. It has a moderate amount of collagen fibers. It is found in the trachea, bronchi, nose, epiphyseal plate, and articular surfaces of bones.

Elastic cartilage, which has both collagen and elastic fibers, is more flexible than hyaline cartilage. It is found in the ear, epiglottis, and larynx.

Fibrous cartilage (fibrocartilage) consists mostly of collagen fibers. It is a tough tissue that often functions as a shock absorber. Fibrous cartilage is found between the vertebral discs. It also forms a protective cushion between the bones of the pelvic girdle, knee, and shoulder.

Cartilage in synovial joints serves as a support for soft tissue and provides the articular surface for joint movement. It protects underlying tissues. Because articular cartilage is avascular, it must receive nourishment by the diffusion of material from the synovial fluid. The lack of a direct blood supply contributes to the slow metabolism of cartilage cells and explains why healing and repair of cartilage tissue occur slowly. The cartilage in the epiphyseal plate is also involved in the growth of long bones before physical maturity is reached.

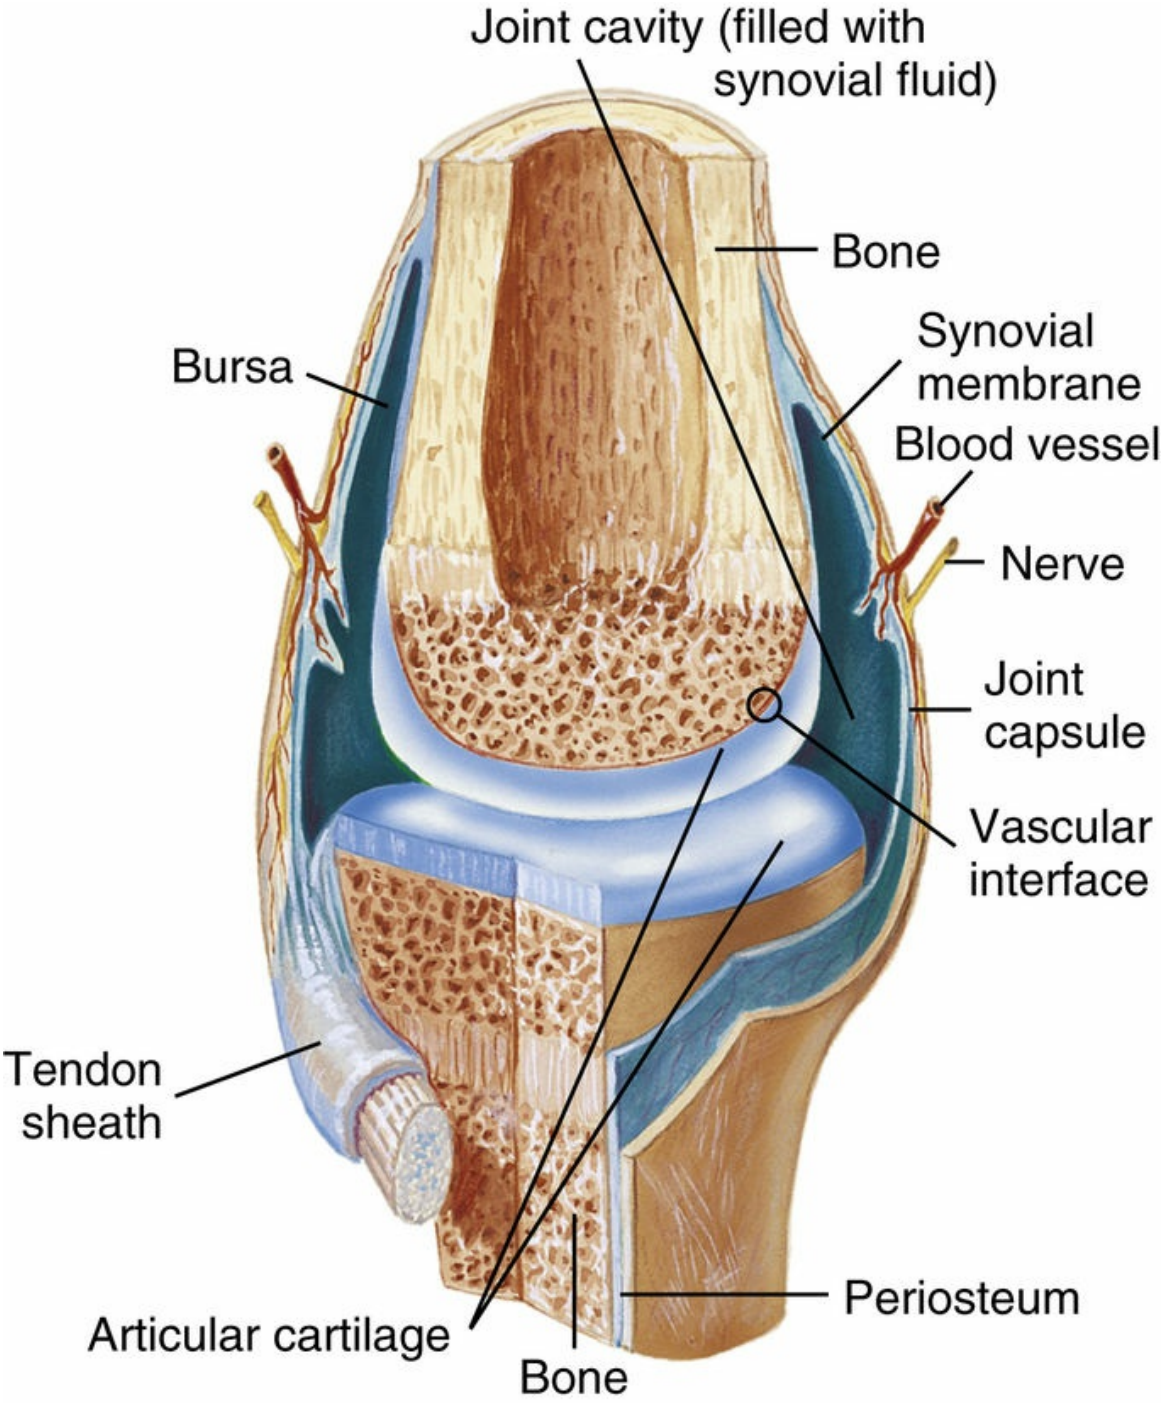

FIG. 61.3 Structure of diarthrodial (synovial) joint.

Muscle

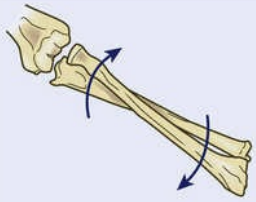
Types

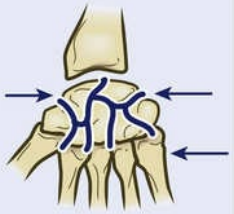
The 3 types of muscle tissue are cardiac (striated, involuntary), smooth (nonstriated, involuntary), and skeletal (striated, voluntary) muscle. *Cardiac muscle* is found only in the heart. Its spontaneous contractions pump blood through the circulatory system. *Smooth muscle* is found in the walls of hollow structures, such as airways, arteries, gastrointestinal (GI) tract, urinary bladder, and uterus. Smooth muscle contraction is controlled by neuronal and hormonal influences. *Skeletal muscle,* which requires neuronal stimulation for contraction, accounts for about half of a human's body weight. It is the focus of the following discussion.

Structure

The skeletal muscle is enclosed by the *epimysium,* a continuous layer of deep fascia. The epimysium helps muscles slide over nearby structures. Connective tissue surrounding and extending into the muscle can be subdivided into fiber bundles *(fasciculi).* These bundles are covered by *perimysium* and an innermost connective tissue layer called the *endomysium* that surrounds each fiber (Fig. 61.5).

The structural unit of skeletal muscle is the muscle cell or muscle fiber. It is highly specialized for contraction. Skeletal muscle fibers are long, multinucleated cylinders that contain many mitochondria to support their high metabolic activity. Muscle fibers are composed of myofibrils, which in turn are made up of protein contractile filaments. The *sarcomere* is the contractile unit of the myofibrils. Each sarcomere consists of *myosin* (thick) filaments and *actin* (thin) filaments. The arrangement of the thin and thick filaments causes the characteristic banding of muscle seen under a microscope. Muscle contraction occurs as thick and thin filaments slide past each other, causing the sarcomeres to shorten.





Joint	Movement	Examples	Illustration
Hinge joint	Flexion, extension	Elbow joint (shown), interphalangeal joints, knee joint	
Ball and socket (spheroidal)	Flexion, extension; adduction, abduction; circumduction	Shoulder (shown), hip	
Pivot (rotary)	Rotation	Atlas-axis, proximal radioulnar joint (shown)	
Condyloid	Flexion, extension; abduction, adduction; circumduction	Wrist joint (between radial and carpals) (shown)	
Saddle	Flexion, extension; abduction, adduction; circumduction, thumb-finger opposition	Carpometacarpal joint of thumb (shown)	
Gliding	One surface moves over another surface	Between tarsal bones, sacroiliac joint, between articular processes of vertebrae, between carpal bones (shown)	

FIG. 61.4 Types of diarthrodial (synovial) joints.

Contractions

Skeletal muscle contractions allow posture maintenance, body

movement, and facial expressions. **Isometric contractions** increase the tension within a muscle but do not produce movement. **Isotonic contractions** shorten a muscle to produce movement. Most contractions are a combination of tension generation *(isometric)* and shortening *(isotonic).* Repeated isometric and/or isotonic contractions provide stress to stimulate muscle growth. Muscular *atrophy* (decrease in size) occurs with the absence of contractions that results from immobility or decreased neuronal stimulation. Increased muscular activity leads to *hypertrophy* (increase in size).

Skeletal muscle fibers are divided into 2 groups based on the type of activity they show. *Slow-twitch muscle fibers* support prolonged muscle activity, such as marathon running. Because they also support the body against gravity, they help in posture maintenance. *Fast-twitch muscle fibers* are used for rapid muscle contraction needed for activities, such as blinking the eye, jumping, or sprinting. Fast-twitch fibers tend to tire more quickly than slow-twitch fibers.

Neuromuscular Junction

Skeletal muscle fibers require a nerve impulse to contract. A nerve fiber and the skeletal muscle fibers it stimulates are called a *motor endplate.* The junction between the axon of the nerve cell and the adjacent muscle cell is called the *myoneural* or *neuromuscular junction* (Fig. 61.6).

Presynaptic neurons release acetylcholine. It diffuses across the neuromuscular junction to bind with receptors on the motor endplate of the muscle. In response to this stimulation, the sarcoplasmic reticulum releases calcium ions into the cytoplasm. The presence of calcium triggers the contraction in the myofibrils. When calcium is low, *tetany* (involuntary contractions of skeletal muscle) can occur.

Energy Source

The direct energy source for muscle fiber contractions is adenosine triphosphate (ATP). ATP is synthesized by cellular oxidative metabolism in the numerous mitochondria found close to the myofibrils. It is rapidly depleted through conversion to adenosine

diphosphate (ADP) and must be rephosphorylated. Phosphocreatine provides a rapid source for the resynthesis of ATP, but it is, in turn, converted to creatine. Glycolysis can serve as a source of ATP when the O_2 supply is inadequate for metabolic needs of the muscle tissue. In this process, 1 glucose molecule is broken down to 2 ATP molecules.

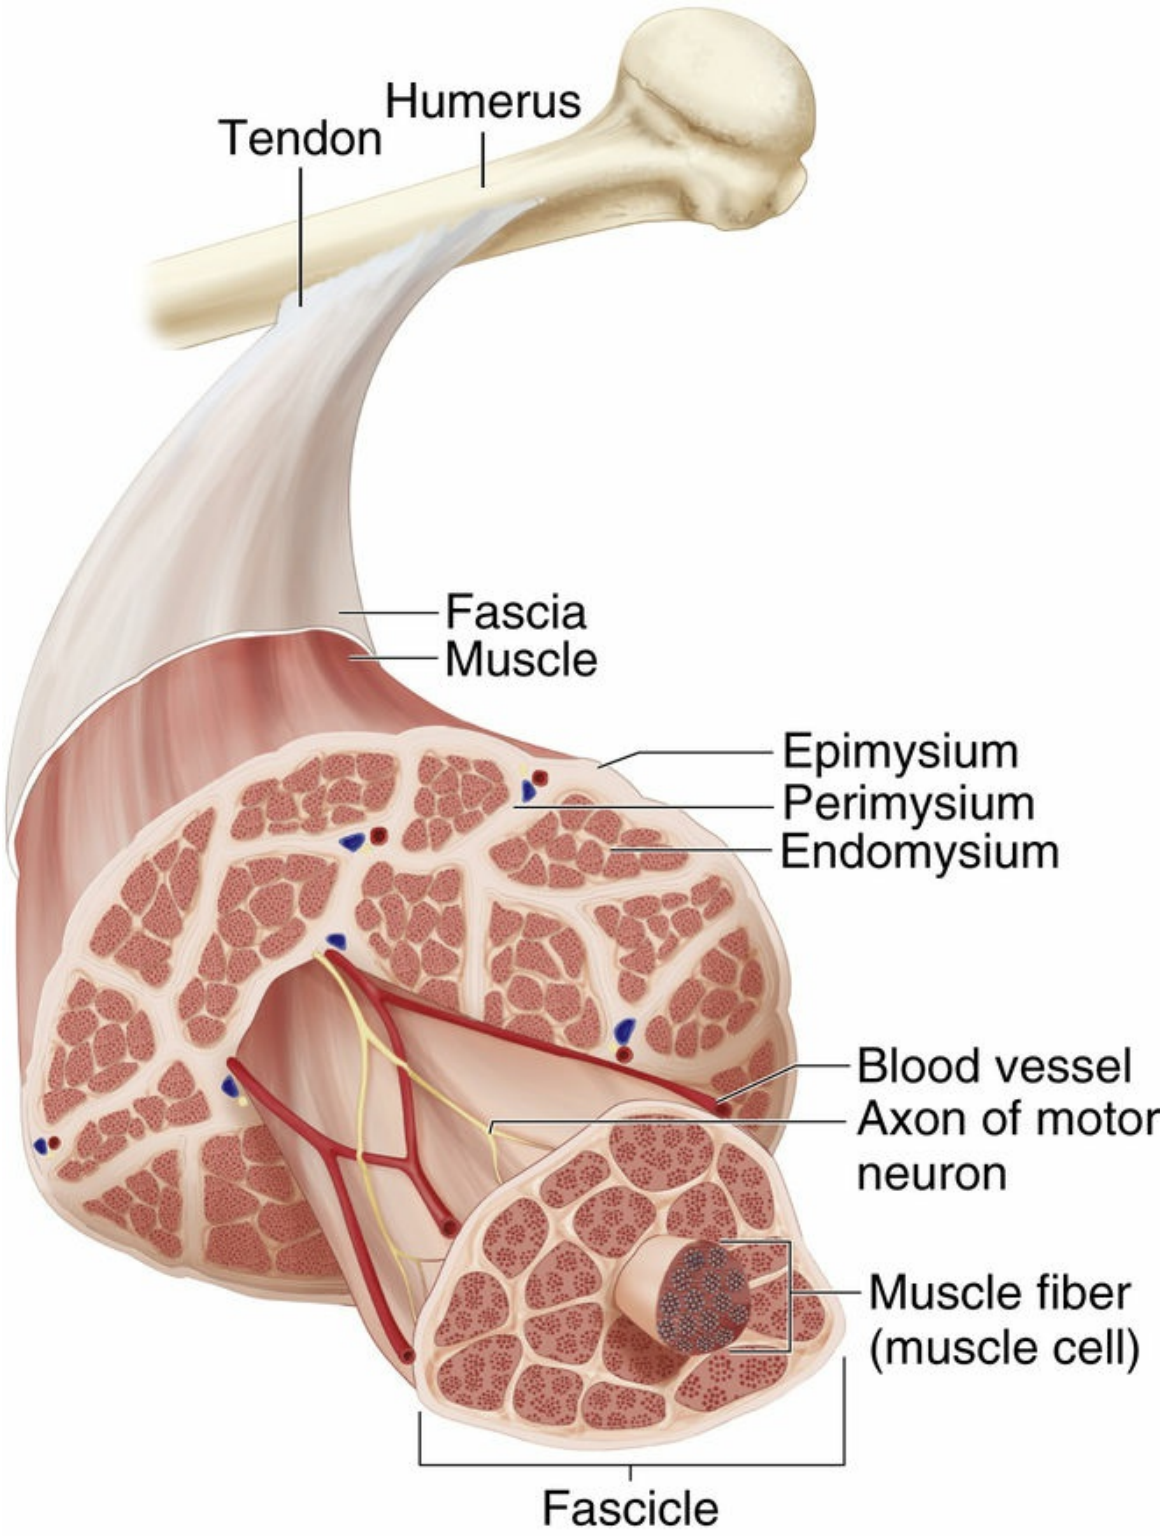


FIG. 61.5 Structure of a muscle.
From Patton KT, Thibodeau GA, Douglas M: *Essentials of anatomy and physiology,* St Louis, 2012, Mosby.

Ligaments and Tendons

Ligaments and tendons are composed of dense, fibrous connective tissue with bundles of closely packed collagen fibers arranged in the same plane for additional strength. *Tendons* attach muscles to bones as an extension of the muscle sheath that adheres to the periosteum. *Ligaments* connect bones to bones (e.g., tibia to femur at knee joint). They have a higher elastic content than tendons.[3] Ligaments provide stability while allowing controlled movement at joints.

Ligaments and tendons have a relatively poor blood supply. This can make tissue repair a slow process after injury. For example, the stretching or tearing of ligaments that occurs with a sprain may require a long time to mend.

Fascia

Fascia refers to layers of connective tissue with intermeshed fibers that can withstand limited stretching. Superficial fascia lies right under the skin. Deep fascia is a dense, fibrous tissue that surrounds muscle bundles, nerves, and blood vessels. It also encloses individual muscles, allowing them to act independently and to glide over each other during contraction. In addition, fascia provides strength to muscle tissues.

Bursae

Bursae are small sacs of connective tissue lined with synovial membrane and containing viscous synovial fluid. They are found at bony prominences or joints to relieve pressure and decrease friction between moving parts.[4] For example, bursae are found between the (1) patella and skin (prepatellar bursae), (2) olecranon process of the elbow and skin (olecranon bursae), (3) head of the humerus and acromion process of the scapula (subacromial bursae), and (4) greater trochanter of the proximal femur and skin (trochanteric bursae). *Bursitis* is an inflammation of a bursa sac. The inflammation may be acute or chronic.

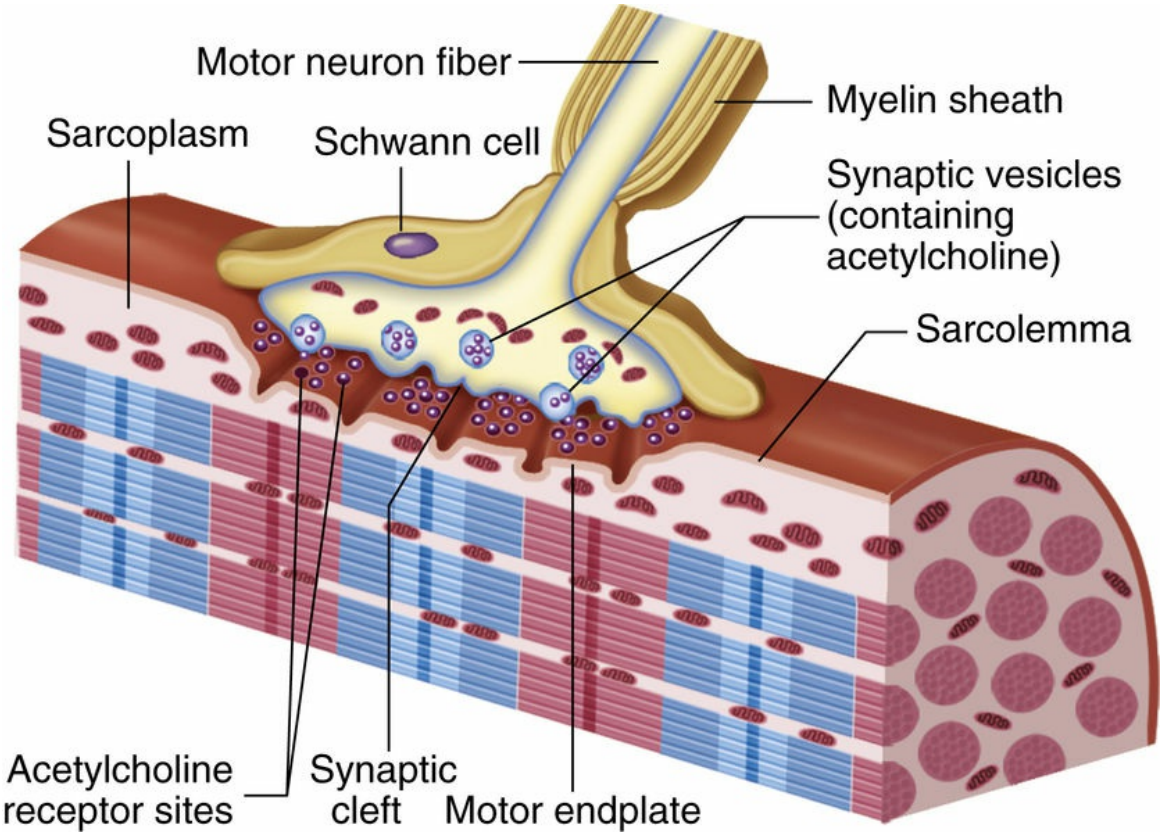

FIG. 61.6 Neuromuscular junction.
From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Gerontologic Considerations: Effects of Aging on Musculoskeletal System

Many functional problems experienced by the older adult are related to changes in the musculoskeletal system. Although some changes begin in early adulthood, obvious signs of musculoskeletal impairment may not appear until later adult years. Changes may affect the older adult's ability to complete self-care tasks and pursue other usual activities. Effects of musculoskeletal changes may range from mild discomfort and decreased ability to perform ADLs to severe, chronic pain and immobility.

The bone remodeling process changes in the aging adult. Increased bone resorption and decreased bone formation cause a loss of bone density. This contributes to the development of osteopenia and

osteoporosis (see Chapter 63). Muscle mass and strength decrease. Almost 30% of muscle mass is lost by age 70. A loss of motor neurons can cause problems with skeletal muscle movement. Tendons and ligaments become less flexible, making movement more rigid.

Perform a musculoskeletal assessment with an emphasis on exercise practices. Obtain information on the type of exercise performed, including frequency and warm-up activities. Determine the impact of age-related changes of the musculoskeletal system on functional status. Specifically ask about changes in self-care habits and ability to be independent in the home environment. Functional limitations that are accepted by the older adult as a normal part of aging can often be addressed with appropriate preventive strategies (see Table 62.1).

The risk for falls increases in the older adult due in part to loss of strength. Aging can also bring changes in the patient's balance, making the person unsteady. *Proprioception* (awareness of self in relation to the environment) may be altered. Identify any musculoskeletal changes that increase the patient's risk for falls. Discuss fall prevention strategies.

Osteoarthritis is more likely to affect joints in the aging adult (see Chapter 64).[5] Metabolic bone diseases involve the deterioration of bone tissue (osteoporosis) and destruction of cartilage (osteoarthritis). Carefully distinguish between expected changes and the effects of disease in the aging adult. Symptoms of disease can be treated in many cases, helping the older adult to return to a higher functional level. Age-related changes in the musculoskeletal system and differences in assessment findings are outlined in Table 61.1.

TABLE 61.1 Gerontologic Assessment DifferencesMusculoskeletal System

Changes	Differences in Assessment Findings
Bone	
• ↓ Bone density and strength • Slowed remodeling process	• Loss of height and deformity, such as dowager's hump (kyphosis), from vertebral compression and degeneration • Back pain, stiffness • Bony prominences more pronounced • ↑ Risk for osteopenia and osteoporosis
Joints	
• ↑ Risk for cartilage erosion that leads to direct contact between bone ends and overgrowth of bone around joint margins • Loss of water from discs between vertebrae, ↓ height of intervertebral spaces	• Joint stiffness, ↓ mobility, limited ROM, possible crepitation on movement • Pain with motion and/or weight bearing • Loss of height and shortening of trunk from disc compression. Posture change
Muscles	
• ↓ Number and diameter of muscle cells. Replacement of muscle cells by fibrous connective tissue • Loss of elasticity and deterioration of cartilage • ↓ Ability to store glycogen. ↓ Ability to release glycogen as quick energy during stress • ↓ Basal metabolic rate	• ↓ Muscle strength and mass • Abdominal protrusion • ↑ Rigidity in neck, shoulders, back, hips, and knees • ↓ Fine motor dexterity, ↓ agility • Slowed reaction times and reflexes from slowed conduction of nerve impulses along motor units • Earlier fatigue with activity

Assessment of Musculoskeletal System

Subjective Data

Important Health Information

Past Health History

The most common manifestations of musculoskeletal impairment include pain, weakness, deformity, limitation of movement, stiffness, and joint crepitation (crackling sound). Ask the patient about changes in sensation or in the size of a muscle.

Questions should focus on symptoms of arthritic and connective tissue diseases (e.g., gout, psoriatic arthritis, systemic lupus erythematosus [SLE]), osteomalacia, osteomyelitis, and fungal infection of bones or joints. Ask the patient about sources of a secondary bacterial infection, such as ears, tonsils, teeth, sinuses, lungs, or genitourinary tract. These infections can enter the bones, resulting in osteomyelitis or joint destruction. Get a detailed account of the course and treatment of any of these problems.

Certain illnesses are known to affect the musculoskeletal system

directly or indirectly. Ask the patient about medical problems, such as tuberculosis, poliomyelitis, diabetes, parathyroid problems, hemophilia, rickets, soft tissue infection, and neuromuscular disability.

Trauma to the musculoskeletal system is a common reason for seeking medical care. The patient who is a good historian can recount minor and major injuries of the musculoskeletal system. Record information chronologically and include:

Case Study

Patient Introduction

(© pixelheadphoto/iStock/Thinkstock.)

G.A. is a 58-yr-old black woman whose husband brought her to the

emergency department (ED) this morning after she awoke with a sudden onset of excruciating pain in her left great toe. She denies any injury to her foot. She says she has never had this type of pain before.

Discussion Questions

1. What are the possible causes for G.A.'s acute pain in her great toe?
2. Is this condition stable or an emergency?
3. What type of assessment would be most appropriate for G.A.: comprehensive, focused, or emergency? What is the basis for your decision?
4. What assessment questions will you ask G.A.?
5. How will you individualize the assessment based on her age, ethnic/cultural background, and condition?

You will learn more about how to assess G.A.'s condition as you read through this chapter.

See p. 1436 for more information on G.A.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

- Mechanism and circumstances of the injury (e.g., twist, crush, stretch)
- Methods and duration of treatment
- Current status related to the injury
- Need for assistive devices
- Interference with ADLs

Medications

Ask the patient about prescription and over-the-counter drugs, herbal products, and nutritional supplements. Get detailed information about each treatment, including its name, dose and frequency, length of time it was taken, reason for use, and any possible side effects. Ask about the use of skeletal muscle relaxants, opioids, nonsteroidal antiinflammatory drugs, corticosteroids, and calcium and vitamin D

supplements.

Review the use of drugs that can have detrimental effects on the musculoskeletal system. Some of these and their potential side effects include antiseizure drugs (osteomalacia), phenothiazines (gait changes), corticosteroids (avascular necrosis, decreased bone and muscle mass), and potassium-depleting diuretics (muscle cramps and weakness). Ask postmenopausal women about the use of hormone therapy.

Surgery or Other Treatments

Ask about any hospitalizations related to a musculoskeletal problem. Document the reason for hospitalization; the date and duration; and the treatment, including ongoing rehabilitation. Record details of emergency treatment for musculoskeletal injuries. Get specific information about any surgical procedure, postoperative course, and complications. Ask the patient about past total knee or total hip replacement. If the patient had a period of prolonged immobilization, consider the possible development of disuse osteoporosis and muscle atrophy.

Functional Health Patterns

Past or developing musculoskeletal problems can affect the patient's overall health. The use of functional health patterns helps organize assessment data. Table 61.2 outlines specific questions to ask in relation to functional health patterns.

TABLE 61.2 Health HistoryMusculoskeletal System

Health Perception–Health Management Pattern

- Describe your usual daily activities.
- Do you have any problems performing these activities?* Describe

what you do if you have trouble dressing, preparing meals and feeding yourself, performing basic hygiene, writing or using the phone, or maintaining your home.
- Do you have to lift heavy objects? Do your work or exercise habits require repetitive motion or joint stress? Describe any special equipment you use or wear when you work or exercise that helps protect you from injury.
- Do you take any drugs or herbal products to manage your musculoskeletal problem? If so, what are their names and what are the expected effects?

Nutritional-Metabolic Pattern

- What is your usual daily intake of food and snacks?
- Do you have problems preparing your food?
- What dietary supplements do you take? Do you take calcium or vitamin D supplements?
- What is your weight? Describe any recent weight loss or gain.

Elimination Pattern

- Does your musculoskeletal problem make it hard for you to reach the toilet in time?*
- Do you need any assistive devices or equipment to manage toileting?*
- Do you have constipation related to decreased mobility or drugs taken for your musculoskeletal problem?*

Activity-Exercise Pattern

- Do you need help in completing your usual daily activities because of a musculoskeletal problem?*

- Describe your usual exercise pattern. Do you have musculoskeletal symptoms before, during, or after exercising?*
- Are you able to move all your joints comfortably through full range of motion?
- Do you use any prosthetic or orthotic devices?*

Sleep-Rest Pattern

- Do you have any problems sleeping because of a musculoskeletal problem?*
- Do you need frequent position changes at night?*
- Do you wake up at night because of musculoskeletal pain?*
- Do you use complementary and alternative therapies to help you sleep at night?*

Cognitive-Perceptual Pattern

- Describe any musculoskeletal pain you have. How do you manage your pain? Ask about adjunctive therapies, such as heat and cold, or complementary and alternative therapies, such as acupuncture.

Self-Perception–Self-Concept Pattern

- Have changes in your musculoskeletal system (posture, walking, muscle strength) and decreased ability to do certain things affected how you feel about yourself?*
- Have these changes affected your lifestyle?*

Role-Relationship Pattern

- Do you live alone?
- Describe how family, friends, or others help you with your musculoskeletal problem.
- Describe the effect of your musculoskeletal problem on your work and your social relationships.

Sexuality-Reproductive Pattern

- Describe any sexual concerns related to your musculoskeletal problem.

Coping–Stress Tolerance Pattern

- Describe how you deal with problems such as pain, weakness, or immobility that have resulted from your musculoskeletal problem.

Value-Belief Pattern

- Describe any cultural practices or religious beliefs that may influence the treatment of your musculoskeletal problem.

---

* If yes, describe.

Health Perception–Health Management Pattern

Ask about the patient's health practices related to the musculoskeletal system. This includes maintaining normal body weight, avoiding excessive stress on muscles and joints, and using proper body mechanics when lifting objects. Ask the patient about tetanus, pertussis, and polio immunizations.

Safety practices can affect the patient's predisposition for certain

injuries and illnesses. Ask the patient about safety practices related to the work environment, home life, recreation, and exercise. For example, if the patient is a computer programmer, ask about ergonomic adaptations in the office that decrease the risk for carpal tunnel syndrome or low back pain. Identifying problems in this area will direct your plan for patient teaching.

Get a family history of rheumatoid arthritis, SLE, ankylosing spondylitis, osteoarthritis, gout, osteoporosis, and scoliosis. A patient may have a genetic predisposition to these or other musculoskeletal disorders.

Nutritional-Metabolic Pattern

The patient's description of a typical day's diet gives clues to areas of nutritional concern that can affect the musculoskeletal system. Adequate intake of vitamins C and D, calcium, and protein is essential for a healthy musculoskeletal system. Abnormal nutritional patterns can contribute to problems such as osteomalacia and osteoporosis. Maintaining normal weight is an important nutritional goal. Obesity places added stress on weight-bearing joints, such as the knees, hips, and spine. This increases the risk for cartilage deterioration and ligament instability.

Genetic Risk Alert

Autoimmune Diseases

- Many autoimmune diseases of the musculoskeletal system have a genetic basis involving human leukocyte antigens (HLAs).
- These diseases include ankylosing spondylitis, rheumatoid arthritis, and SLE.

Osteoporosis

- Genetic factors contribute to osteoporosis by influencing bone mineral density, and bone size, quality, and turnover.

Osteoarthritis, Gout, and Scoliosis

- A genetic predisposition is a contributing risk factor in all these diseases.

Muscular Dystrophy

- The most common types of muscular dystrophy are X-linked recessive disorders.

Elimination Pattern

Questions about the patient's mobility may reveal problems with ambulating to the toilet. Ask the patient if an assistive device, such as an elevated toilet seat or a grab bar, is needed to manage toileting. Decreased mobility from a musculoskeletal problem can lead to constipation. Musculoskeletal problems can contribute to bowel or bladder incontinence when ambulation is a problem.

Activity-Exercise Pattern

Many musculoskeletal problems can affect the patient's activity-exercise pattern. Get a detailed account of the type, duration, and frequency of exercise and recreational activities. Compare daily, weekend, and seasonal patterns because occasional exercise can be more of a problem than regular exercise. Ask the patient about clumsiness or limitations in movement, pain, weakness, crepitus, or any change in bones or joints that interferes with daily activities.

Extremes of activity related to occupation can affect the musculoskeletal system. For example, a desk job can negatively affect muscle flexibility and strength. Jobs that require heavy lifting or pushing can lead to damage of joints and supporting structures.

Specifically ask the patient about work-related musculoskeletal injuries, including treatment and time lost from work.

Sleep-Rest Pattern

The discomfort caused by musculoskeletal problems can interfere with the patient's normal sleep pattern and lead to fatigue.[6] Ask the patient about any changes in sleep patterns. If the patient describes poor sleep related to a musculoskeletal problem, ask about the type of bedding and pillows used, bedtime routine, sleeping partner, and sleeping positions.

Cognitive-Perceptual Pattern

Fully discuss any pain reported by the patient due to a musculoskeletal problem. To give a baseline for later reassessment, ask the patient to describe the intensity of the pain on a numeric scale from 0 to 10 (0 = no pain, 10 = most severe pain imaginable). Reassessments over time help to determine the effectiveness of any treatment plan. Ask the patient about measures used to manage pain. Also ask about related problems, such as joint swelling or muscle weakness, and any adjustments that help with the problem. (Pain is discussed in Chapter 8.)

Self-Perception–Self-Concept Pattern

Many chronic musculoskeletal problems lead to deformities and a reduction in activities. This can have a serious negative impact on the patient's body image and sense of personal worth.[6] Assess the patient's feelings about these changes and any effect on interactions with family and friends.

Role-Relationship Pattern

Impaired mobility and chronic pain from musculoskeletal problems can negatively affect the patient's ability to perform in roles of spouse, parent, and/or employee. The ability to pursue and maintain meaningful social and personal relationships also can be affected by

musculoskeletal problems. Carefully ask the patient about role performance and relationships.

If the patient lives alone, any musculoskeletal problem and rehabilitation may make it hard or impossible to continue to do so. Assess how much help is available from family, friends, and other caregivers. Find out if other resources are needed, such as physical therapy and home health care.

Sexuality-Reproductive Pattern

Ask women about their menstrual history. Episodes of premenopausal amenorrhea can contribute to the development of osteoporosis.[7] The pain of musculoskeletal problems can affect the patient's ability to obtain sexual satisfaction. Explore this area in a sensitive and nonjudgmental way. Help the patient feel comfortable discussing any sexual problems related to pain, movement, and positioning. More information on obtaining patient data in this area is discussed in Chapter 50.

Coping–Stress Tolerance Pattern

Mobility limitations and pain are serious potential stressors that challenge the patient's coping resources. Recognize the potential for difficulty coping in the patient and family or significant other. Additional questions will help to determine if a musculoskeletal problem is causing difficulties in coping and adjusting.

Value-Belief Pattern

Ask the patient about cultural or religious beliefs that may influence acceptance of treatment for the musculoskeletal problem. These may include recommendations for diet, exercise, medication, and lifestyle modifications.

Case Study—cont'd

Subjective Data

(© pixelheadphoto/iStock/Thinkstock.)

A focused subjective assessment of G.A. revealed the following

information:

Past Medical History: Hypertension for 6 years. Type 2 diabetes for 11 yr, 40-pack-yr smoking history.
Medications: Metformin (Glucophage) 500 mg PO bid; glyburide (DiaBeta) 5 mg/day PO; hydrochlorothiazide 50 mg PO bid.
Health Perception–Health Management: Currently smokes 1 pack of cigarettes per day. Is trying to quit but finding it difficult. Drinks alcohol at night.
Nutritional-Metabolic: G.A. is 5 ft, 2 in tall and weighs 160 lb (BMI 29.3 kg/m^2). Does not take any nutritional supplements and avoids milk and other dairy products because they make her "gassy."
Activity-Exercise: Minimally active; does not exercise. Able to perform ADLs without assistance. Denies any history of musculoskeletal problems.
Cognitive-Perceptual: Rates toe pain at 8 on a scale of 0 to 10. Describes sharp, burning pain that increases in intensity with any movement.
Coping–Stress Tolerance: Is asking for pain medicine "as strong as you can give me."

Discussion Questions

1. What subjective assessment findings are of most concern to you?
2. Is this an appropriate time to talk with G.A. about her weight?
3. Based on these subjective findings, what should be included in the physical assessment?

You will learn more about the physical assessment of the musculoskeletal system in the next section.

See p. 1438 for more information on G.A.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Physical Examination

The basic musculoskeletal physical examination involves inspection, palpation, neurovascular assessment, and range of motion, strength, and reflex testing. Other special tests can be used to assess for specific conditions. Conduct a general overview. While obtaining a careful health history, choose areas to concentrate on during the local examination. Take specific measurements as indicated by the local examination.

Inspection

A systematic inspection is done, starting at the head and neck then moving to the upper extremities, lower extremities, and trunk. The regular use of a systematic approach is important to avoid missing important aspects of the examination. Inspect the skin for general color, scars, or other overt signs of previous injury or surgery. Certain skin lesions require further investigation because they can indicate underlying disorders. For example, butterfly rash over the cheeks and nose is characteristic of SLE.

Note the patient's general posture and body build, muscle size and symmetry, and symmetry and contour of joints. Observe for any swelling, deformity, nodules or masses, and discrepancies in limb length or muscle size. Use the patient's opposite body part for comparison when you suspect an abnormality.

If the patient can move independently, assess posture and gait by watching the patient walk, stand, and sit. Musculoskeletal and neurologic problems can result in abnormal gait patterns.

Palpation

As with inspection, palpation usually proceeds head to toe. Examine the neck, shoulders, elbows, wrists, hands, back, hips, knees, ankles, and feet. Warm your hands to prevent muscle spasm, which can interfere with identifying essential landmarks or soft tissue structures. Carefully palpate any specific areas of concern because of a subjective

report or abnormal appearance on inspection.

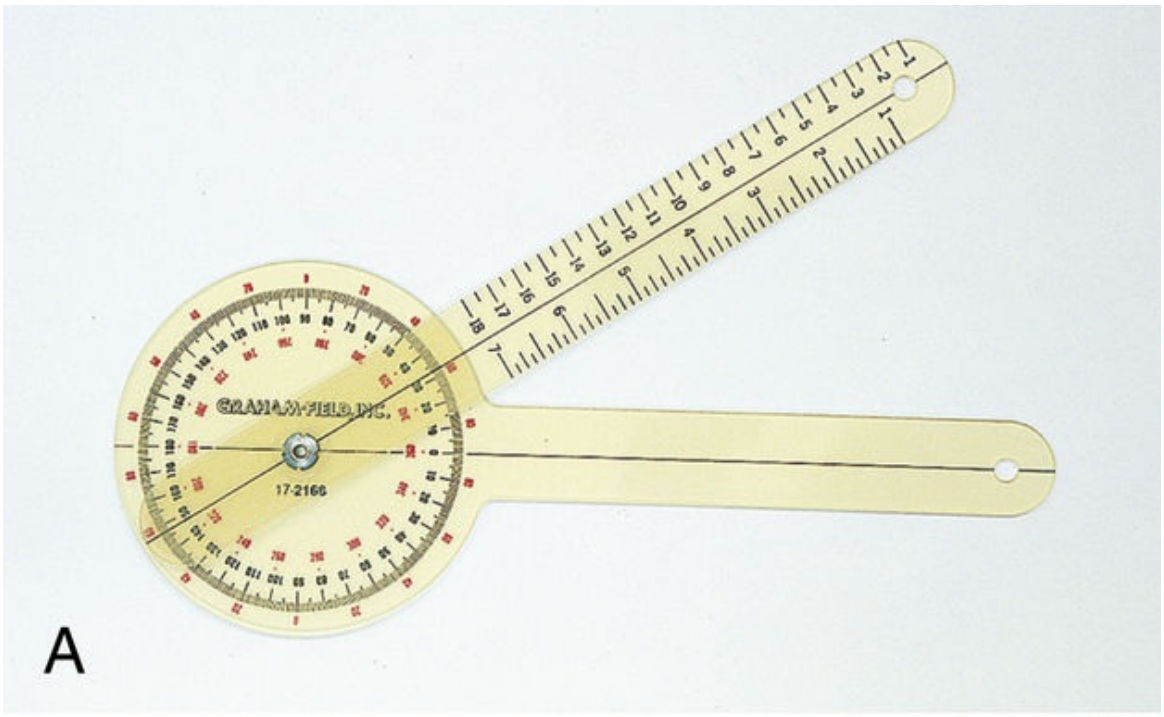
Both superficial and deep palpation are usually done consecutively. Consider the underlying anatomy structures and landmarks you are palpating. Purposefully palpate both muscles and joints to evaluate skin temperature, local tenderness, swelling, and crepitation. Establish the relationship of adjacent structures. Evaluate the general contour, abnormal prominences, and local landmarks. Note the specific anatomic location of any abnormal findings.

Motion

When assessing the patient's joint mobility, carefully evaluate active and passive **range of motion** (ROM). ROM is the full movement potential of a joint. Measurements should be similar for active and passive maneuvers. *Active ROM* means the patient takes their own joints through all movements without assistance. *Passive ROM* occurs when someone else moves the patient's joints without their assistance through the full ROM. Be careful in performing passive ROM because of the risk for injury to underlying structures. If pain or resistance occurs, stop at once.

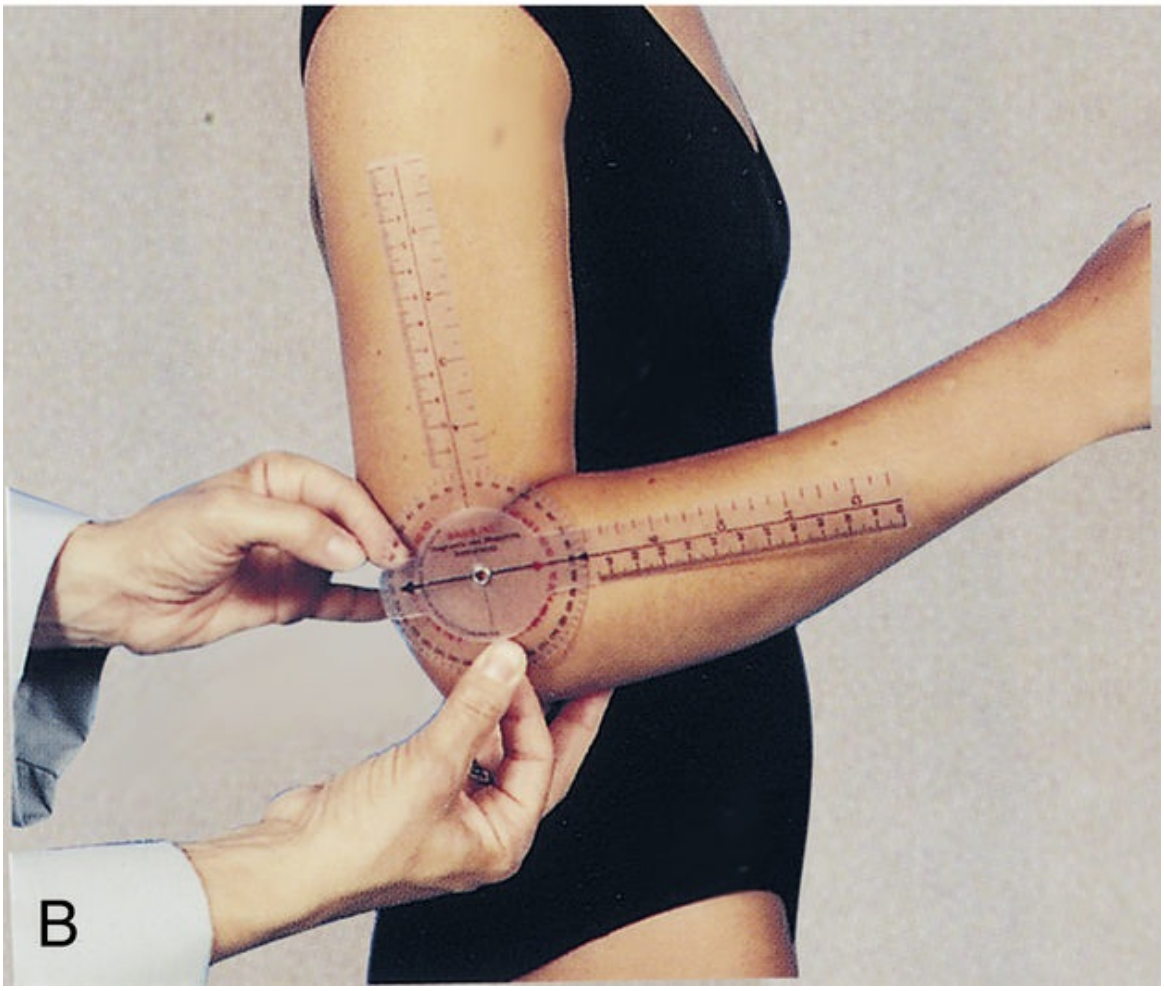
If you note deficits in active or passive ROM, assess functional ROM to determine if joint changes are affecting the ability to perform ADLs. Ask the patient if activities, such as eating, grooming, dressing, and bathing, require help or cannot be done at all.

We use a goniometer to accurately assess ROM. It measures the angle of the joint (Fig. 61.7). We do not usually measure specific degrees of ROM of all joints. If a specific musculoskeletal problem has been identified, measure ROM of the affected joint. A less exact but valuable assessment method is simply to compare the ROM of 1 extremity with that on the opposite side. Common movements that occur at the synovial joints, including *abduction, adduction, flexion,* and *extension,* are described in Table 61.3.



Muscle-Strength Testing

Grade the strength of individual muscles or groups of muscles during contraction on a 5-point scale (Table 61.4). Grade normal muscle



strength with full resistance to opposition as a 5/5 bilaterally. To test resistance to opposition, have the patient apply resistance as you exert a force. For example, have the patient try to extend the elbow while you try to flex it. Compare muscle strength with the strength of the opposite extremity. Note any subtle variations in muscle strength when comparing the patient's dominant and nondominant sides. Variations in strength also exist when comparing people.

Measurement

When limb length discrepancies or subjective problems are noted, measure limb length and circumferential muscle mass. For example, when gait disorders are observed, measure leg length between the anterosuperior iliac crest and the bottom of the medial malleolus. Then compare it with the similar measurement of the opposite extremity. Measure muscle mass circumferentially at the largest area of the muscle. When recording measurements, record the exact location at which the measurements were obtained (e.g., the left quadriceps muscle was measured 15 cm above the patella). This tells the next examiner of the exact area to measure and ensures consistency during reassessment.

FIG. 61.7 **A,** Goniometer. **B,** Measurement of joint ROM using a goniometer.
A, From Wilson SF, Giddens JF: *Health assessment for nursing practice,* ed 5, St Louis, 2013, Mosby. *B*, From Barkauskas V, Baumann L, Stoltenberg-Allen K, et al: *Health and physical assessment,* ed 2, St Louis, 1998, Mosby.

TABLE 61.3 Synovial Joint Movements

Movement	Description
Abduction	Movement of part away from midline of body
Adduction	Movement of part toward midline of body
Circumduction	Circular motion of a body part from a combination of flexion, abduction, extension, and adduction
Dorsiflexion	Flexion of the ankle and toes toward the shin
Eversion	Turning of sole outward away from midline of body
Extension	Straightening of joint that ↑ angle between 2 bones
External rotation	Movement along longitudinal axis away from midline of body
Flexion	Bending of joint from muscle contraction that causes ↓ angle between 2 bones
Hyperextension	Extension in which angle exceeds 180 degrees
Internal rotation	Movement along longitudinal axis toward midline of body
Inversion	Turning of sole inward toward midline of body
Opposition	Moving the first and fifth metacarpals anteriorly from a flattened palm ("cupping position"); makes it possible to hold objects between the thumb and fingers
Plantar flexion	Flexion of the ankle and toes toward the plantar surface of the foot ("toes pointed")
Pronation	Turning of palm downward
Supination	Turning of palm upward

TABLE 61.4 Muscle Strength Scale

0/5	No detection of muscular contraction
1/5	Barely detectable flicker or trace of contraction with observation or palpation
2/5	Active movement of body part with elimination of gravity
3/5	Active movement against gravity only and not against resistance
4/5	Active movement against gravity and some resistance
5/5	Active movement against full resistance without evident fatigue (normal muscle strength)

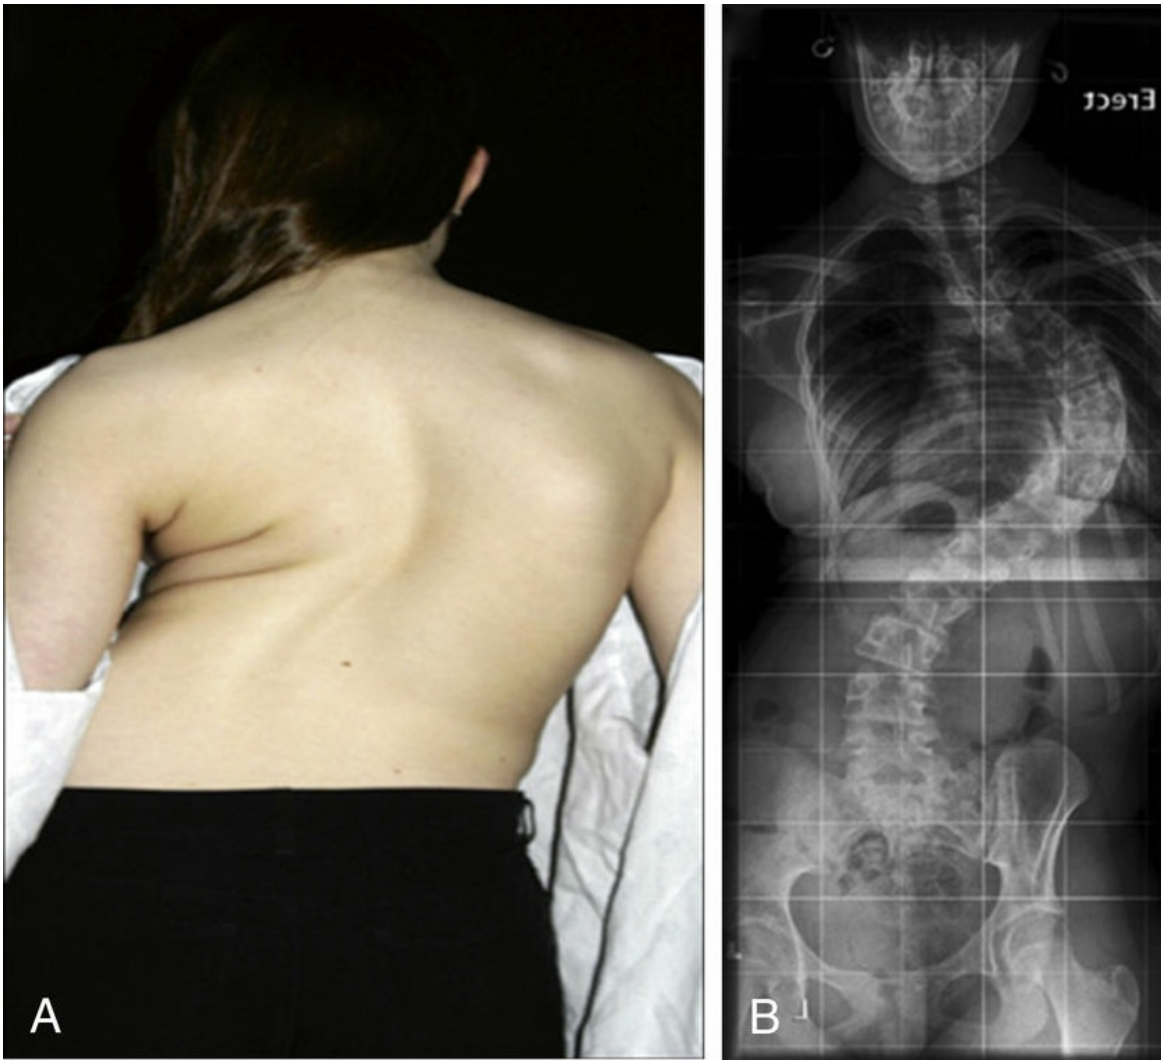

FIG. 61.8 **A,** Thoracic scoliosis. **B,** X-ray of same patient showing scoliosis greater than 90 degrees.
From Hawary R, Chukwunyerenwa C: *Update on evaluation and treatment of scoliosis, Pediatr Clin North Am* 61:1223, 2014.

Other

Note the patient's use of an assistive device, such as a walker or cane. Assess the patient for proper fit while reviewing the safe and correct technique for using these devices. Regularly review with the patient the use of the assistive device to be sure it is still appropriate and safe. Ask the patient if the assistive device is used regularly. If not, determine possible reasons for inconsistent use.[8]

Scoliosis is a lateral S-shaped curvature of the thoracic and lumbar spine. Unequal shoulder and scapula height is usually noted when the patient is observed from the back (Fig. 61.8). Ask the patient to place the hands together above the head as if diving into a swimming pool and slowly bend forward at the waist, allowing assessment of thoracic rib prominence or paravertebral muscle prominence in the lumbar spine. Advanced scoliosis can impair lung and heart function.

The *straight-leg-raising test* is done on the supine patient with sciatica or leg pain. Passively raise the patient's leg 60 degrees or less. The test is positive if the patient reports pain along the distribution of the sciatic nerve. A positive test shows nerve root irritation from intervertebral disc prolapse and herniation, especially at level L4-5 or L5-S1.

Assessment of reflexes is discussed in Chapter 55. Table 61.5 shows an example of how to record a normal physical assessment of the musculoskeletal system. Abnormal assessment findings of the musculoskeletal system are described in Table 61.6.

TABLE 61.5 Normal Physical Assessment of the Musculoskeletal System

- Ordinary spinal curvatures
- No muscle atrophy or asymmetry
- No joint swelling, deformity, or crepitation

- No tenderness on palpation of spine, joints, or muscles
- Full ROM of all joints without pain or laxity
- Muscle strength of 5/5

A *focused assessment* is used to evaluate previously identified musculoskeletal problems and to monitor for signs of new problems. See the Focused Assessment of the Musculoskeletal System box.

Case Study—cont'd

Objective Data: Physical Examination

(© pixelheadphoto/iStock/Thinkstock.)

A focused assessment of G.A. reveals the following:

BP 128/94, heart rate 88, respiratory rate 26, temp 96.8° F, O_2 saturation 98%. Alert and oriented × 3. Lungs are clear bilaterally. Left great toe is red and swollen. No open wounds. Tremendous pain on palpation and with any movement of the left great toe. +1 Pedal pulses bilaterally.

Discussion Questions

1. What physical assessment findings concern you most?
2. Based on results of the subjective and physical assessment, what diagnostic studies might you expect to be ordered for G.A.?

You will learn more about diagnostic studies related to the musculoskeletal system in the next section.

See p. 1442 for more information on G.A.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Focused Assessment

Musculoskeletal System

Use this checklist to be sure key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Joint pain or stiffness	Y	N
Muscle weakness	Y	N
Bone pain	Y	N

Objective: Diagnostic

Check the results of the following diagnostic studies.

X-ray	✓

MRI or CT scan	✓
Bone scan	✓

Objective: Physical Examination Inspect and Palpate

Spine and extremities (compare sides) for alignment, contour, symmetry, size, gross deformities	✓
Joints for ROM, tenderness or pain, heat, crepitus, swelling	✓
Muscles (compare sides) for size, symmetry, tone, tenderness, or pain	✓
Bones for tenderness or pain	✓

TABLE 61.6 Assessment AbnormalitiesMusculoskeletal System

Finding	Description	Possible Etiology and Significance
Achilles tendonitis	Pain in ankle and posterior calf, initially when running or walking. Can progress to pain at rest.	Stress on Achilles tendon over time causing inflammation.
Ankylosis	Stiffness and fixation of a joint.	Chronic joint inflammation and destruction (e.g., rheumatoid arthritis).
Antalgic gait	Shortened stride with minimal weight bearing on the affected side, resulting in a limp.	Pain or discomfort in the lower extremity on weight bearing. Can be due to trauma or other disorders.
Ataxic gait	Staggering, uncoordinated gait often with sway.	Neurogenic disorders (e.g., spinal cord lesion).
Atrophy	↓ Size and strength of muscle leading to ↓ function and tone.	Muscle denervation, contracture, prolonged disuse from immobilization.
Boutonnière deformity	Finger abnormality, flexion of proximal interphalangeal (PIP) joint and hyperextension of the distal interphalangeal (DIP) joint of the fingers (see Fig. 64.4, *B*).	Typical deformity of rheumatoid and psoriatic arthritis caused by disruption of extensor tendons over the fingers.
Contracture	Resistance of movement of muscle or joint	Shortening of muscle or

	due to fibrosis of supporting soft tissues.	ligaments, tightness of soft tissue, incorrect positioning of immobilized extremity.
Crepitation (crepitus)	Frequent, audible crackling sound with palpable grating that accompanies movement.	Fracture, dislocation, temporomandibular joint dysfunction, osteoarthritis.
Dislocation	Separation of 2 bones from their normal position within a joint.	Trauma, disorders of surrounding soft tissues.
Festinating gait	While walking, neck, trunk, and knees flex and the body is rigid. Delayed start with short, quick, shuffling steps. Speed may ↑ as if patient is unable to stop (festination).	Neurogenic disorders (e.g., Parkinson's disease).
Ganglion cyst	Small fluid-filled mass over a tendon sheath or joint, usually on dorsal surface of wrist or foot.	Inflammation of tissues around a joint, which can increase in size or disappear.
Kyphosis (dowager's hump)	Exaggerated thoracic curvature.	Poor posture, tuberculosis, arthritis, osteoporosis, growth disturbance of vertebral epiphyses, vertebral fractures.
Lateral epicondylitis (tennis elbow)	Dull ache along outer aspect of elbow, worsens with twisting and grasping motions.	Injury, inflammation, and/or partial tearing of tendon at its insertion on epicondyle.
Limited range of motion (ROM)	Joint does not achieve expected degrees of motion.	Injury, inflammation, contracture.
Lordosis (swayback)	Exaggerated lumbar curvature.	Other spinal deformities, muscular dystrophy, obesity, flexion contracture of hip, congenital dislocation of hip.
Muscle spasticity	↑ Muscle tone (rigidity) with sustained muscle contractions (spasms); stiffness or tightness may interfere with gait, movement, speech.	Neuromuscular disorders, such as multiple sclerosis (MS) or cerebral palsy.
Myalgia	General muscle tenderness and pain.	Chronic pain syndromes (e.g., fibromyalgia). Overuse, injury, or strain. May result from statin therapy.
Paresthesia	Numbness and tingling, often described as a "pins and needles" sensation.	Compromised sensory nerves, often due to edema in a closed space (e.g., cast, bulky dressing). Spinal stenosis.
Pes planus (flatfoot)	Abnormal flatness of the sole and arch of the foot.	Hereditary, muscle paralysis, mild cerebral palsy, early muscular dystrophy, injury to posterior tibial tendon.
Plantar fasciitis	Burning, sharp pain on heel and sole of foot. Worse in the morning with first step out of bed.	Chronic degenerative/reparative cycle resulting in inflammation.
Scoliosis	Asymmetric elevation of shoulders, scapulae, and iliac crests with lateral spine curvature (Fig. 61.8).	Idiopathic or congenital condition, neuromuscular, fracture or dislocation,

		osteomalacia.
Short-leg gait	A limp, unless corrective footwear used.	Leg length discrepancy ≥1 in, generally of structural origin (arthritis, fracture).
Spastic gait	Short steps with dragging of foot. Jerky, uncoordinated, cross-knee (scissor) movement.	Neurogenic (e.g., cerebral palsy, hemiplegia).
Steppage gait	↑ Hip and knee flexion to clear the foot from the floor. Foot drop is evident, foot slaps down and along walking surface.	Neurogenic disorders (e.g., peroneal nerve injury, paralyzed dorsiflexor muscles).
Subluxation	Partial dislocation of joint.	Instability of joint capsule and supporting ligaments (e.g., trauma, arthritis).
Swan neck deformity	Hyperextension of the PIP joint with flexion of the metacarpophalangeal (MCP) and DIP joints of the fingers (see Fig. 64.4, *D*).	Typical deformity of rheumatoid and psoriatic arthritis caused by contracture of muscles and tendons.
Swelling	Enlargement, often of a joint due to fluid collection. Usually leads to pain, stiffness.	Trauma or inflammation.
Tenosynovitis	Superficial swelling, pain, and tenderness along a tendon sheath.	Inflammation that often occurs with infection, injury, or overuse.
Torticollis (wryneck)	Neck is rotated and laterally bent in unusual position to one side.	Prolonged contraction of neck muscles (congenital or acquired).
Ulnar deviation (ulnar drift)	Fingers drift to ulnar side of forearm (see Fig. 64.4, *A*).	Typical deformity of rheumatoid arthritis due to tendon contracture.
Valgum deformity (knock-knees)	When knees are together and there is <1 in (2.5 cm) between the medial malleoli.	Poliomyelitis, congenital deformity, arthritis.
Varum deformity (bowlegs)	When knees are apart and the medial malleoli are together, a space of >1 in (2.5 cm) exists.	Arthritis, congenital deformity.

Diagnostic Studies of Musculoskeletal System

Many diagnostic studies are used to assess the musculoskeletal system. Tables 61.7, 61.8, and 61.9 present the most common studies. Select studies are described in more detail next.

The use of studies such as x-rays, MRI, and bone scans has greatly improved orthopedic care. The **x-ray** is the most common diagnostic

study used to assess musculoskeletal problems and to monitor treatment effectiveness. Because bones are denser than other tissues and contain calcium, most x-rays are absorbed by the bone tissue and do not penetrate it. Dense areas show as white on the standard x-ray. X-rays provide information about bone deformity, joint congruity, bone density, and calcification in soft tissue. X-rays are useful for diagnosing fractures. They also help evaluate genetic, developmental, infectious, inflammatory, malignant, metabolic, and degenerative disorders.

Aspirated synovial fluid is assessed for volume, color, clarity, viscosity, and mucin clot formation. Normal synovial fluid is transparent and colorless or straw colored. It should be scant in amount and of low viscosity. Fluid from an infected joint may be purulent and thick or gray and thin. In gout, the fluid may be whitish yellow. Blood may be aspirated if there is hemarthrosis due to injury or a bleeding disorder.

The mucin clot test indicates the character of the protein portion of the synovial fluid. Normally a white, ropelike mucin clot is formed. In the presence of inflammation, the clot fragments easily. The fluid is examined grossly for floating fat globules, which indicate bone injury. In septic arthritis, protein content is increased, and glucose is considerably decreased. Presence of uric acid crystals suggests a diagnosis of gout. A Gram stain and culture also may be done to assess for the presence and type of infection.

TABLE 61.7 Serology StudiesMusculoskeletal System

Test	Reference Intervals	Description and Purpose
Aldolase	22–59 mU/L	Useful in monitoring muscular dystrophy, dermatomyositis.
Alkaline phosphatase	30–120 U/L (0.5–2.0	Enzyme made by osteoblasts, needed for mineralization of organic bone matrix. ↑ Levels found with healing fractures, bone cancers, osteoporosis, osteomalacia, Paget's disease.

	μkat/L)	
Anticyclic citrullinated peptide (anti-CCP)	Negative or <20.0 U	Assesses presence of CCP antibodies. More specific for rheumatoid arthritis than rheumatoid factor. Positive result indicates high likelihood of RA.
Anti-DNA antibody	<5 IU/mL	Detects serum antibodies that react with DNA. Most specific test for SLE.
Antinuclear antibody (ANA)	Negative at 1:40 dilution	Assesses presence of antibodies capable of destroying nucleus of tissue cells. Positive in 95% of patients with SLE. May be positive in those with scleroderma, rheumatoid arthritis, small number of normal persons.
Calcium	9.0–10.5 mg/dL (2.25–2.62 mmol/L)	Bone is primary organ for calcium storage. Calcium provides bone with rigid structure. ↓ Level found in osteomalacia, kidney disease, hypoparathyroidism. ↑ Level found in hyperparathyroidism, some bone tumors.
C-reactive protein (CRP)	<1.0 mg/dL	Used to diagnose inflammatory diseases, infections, active widespread cancer. Synthesized by liver. Present in large amounts in serum 18–24 hr after onset of tissue damage.
Creatine kinase (CK)	*Male:* 55–170 U/L *Female:* 30–135 U/L	Highest concentration found in skeletal muscle. ↑ Level in progressive muscular dystrophy, polymyositis, traumatic injuries.
Human leukocyte antigen (HLA)–B27	Negative	Antigen often present in autoimmune disorders, such as ankylosing spondylitis and rheumatoid arthritis.
Potassium	3.5–5.0 mEq/L (3.5–5.0 mmol/L)	Released into serum with cell destruction. ↑ Level with muscle trauma.
Phosphorus	3.0–4.5 mg/dL (0.97–1.45 mmol/L)	Amount present is indirectly related to calcium metabolism. ↓ Level found in osteomalacia. ↑ Level found in chronic kidney disease, healing fractures, osteolytic metastatic tumor.
Rheumatoid factor (RF)	Negative or titer <1:17	Presence of autoantibody (rheumatoid factor) in serum. Not specific for rheumatoid arthritis. Seen in other connective tissue diseases and in a small number of normal persons.

TABLE 61.8 Diagnostic StudiesMusculoskeletal System

Study	Description and Purpose	Nursing Responsibilities
Basic x-ray	Evaluates structural or functional changes of bones and joints. Can give a general impression of bone density. In anteroposterior view, x-ray beam passes from front to back, allowing 1-dimensional view. Lateral position provides 2-dimensional view.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient. *During:* Avoid excessive exposure of patient and self.
Bone scan	Involves injection of radioisotope (usually technetium [Tc]-99m) that is taken up by bone. Uniform uptake of isotope is normal. ↑ Uptake seen in osteomyelitis, primary and metastatic cancer of bone, certain fractures. ↓ Uptake seen in areas of avascular necrosis.	*Before:* Explain that radioisotope is given 2 hr before procedure. Have patient void before scan. Tell patient that no harm will result from isotopes. *During:* Patient must lie completely still during scan. *After:* Increase fluids after scan.
Computed tomography (CT) scan	X-ray beam used with a computer to provide a 3D picture. Used to identify soft tissue abnormalities, bony abnormalities, and various types of musculoskeletal trauma.	*Before:* Evaluate renal function before contrast medium used. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 hr prior to study. If the patient is taking metformin, hold it the day of the test to prevent hypoglycemia or lactic acidosis. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
Discogram	X-ray of cervical or lumbar intervertebral disc is done after injection of contrast media into nucleus pulposus. Permits visualization of intervertebral disc abnormalities.	*Before:* Assess patient for allergy to contrast medium. Explain procedure. *After:* May have mild back pain for 1–2 days. Use as-needed analgesics.
Dual energy x-ray absorptiometry (DEXA)	Measures bone mineral density of spine, femur, forearm, total body. Allows assessment of bone density with minimal radiation exposure. Used to diagnose metabolic bone disease (e.g., osteoporosis), monitor changes in bone density with treatment.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient.
Electromyogram (EMG)	Evaluates electrical potential associated with skeletal muscle contraction. Small-gauge needles are inserted into certain muscles. Needle probes are attached to leads that send information to EMG machine. Recordings of electrical activity of muscle are traced on audio transmitter and on oscilloscope and recording paper. Provides information related to lower motor neuron dysfunction and primary muscle disease.	*Before:* Explain procedure. Tell patient that pain and discomfort are associated with insertion of needles. Some HCPs may restrict stimulants (e.g., caffeine) 2–3 hr prior. *After:* Assess needle sites for hematoma or inflammation. Use as-needed analgesics.
MRI	Radio waves and magnetic field used to view soft tissue. Used to diagnose avascular necrosis, disc disease, tumors, osteomyelitis, ligament tears, cartilage tears. Patient placed inside scanning chamber. Gadolinium may be injected IV to enhance visualization of structures.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during test.
Myelogram with or without CT	Involves injecting a radiographic contrast medium into sac around nerve roots. CT scan may follow to show how bone is affecting the nerve roots. Sensitive test for nerve impingement, can detect subtle lesions and injuries.	*Before:* Give sedative as ordered. Have patient empty bladder. Tell patient that test is done with patient on tilting table that is moved during test. *After:* Keep patient flat for 1–2 hr after procedure to prevent spinal headache. Encourage fluids. Monitor neurologic signs and VS. Headache, nausea, and vomiting may occur after procedure.
Somatosensory evoked potential (SSEP)	Evaluates evoked potential of muscle contractions. Electrodes are placed on skin and provide recordings of electrical activity of muscle. Used to identify subtle dysfunction of lower motor neuron and primary muscle disease. Measures nerve conduction along pathways not accessible by EMG. Transcutaneous or percutaneous electrodes applied to the skin help identify neuropathy and myopathy. Used during spinal surgery for scoliosis to detect neurologic compromise when patient is under anesthesia.	*Before:* Tell patient that procedure is like an EMG but does not involve needles. Electrodes are applied to the skin.
Thermography	Uses infrared detector to measure degree of heat radiating from skin surface. Used to evaluate cause of inflamed joint and determine patient response to antiinflammatory drug therapy.	*Before:* Tell patient that procedure is painless and noninvasive.
Quantitative ultrasound (QUS)	Evaluates bone mineral density, elasticity, and strength of bone using ultrasound rather than radiation. Used to assess heel.	*Before:* Tell patient that procedure is painless and noninvasive.

TABLE 61.9 Interventional StudiesMusculoskeletal System

Study	Description and Purpose	Nursing Responsibilities
Arthrocentesis	Incision or puncture of joint capsule to obtain samples of synovial fluid or to remove excess fluid. Local anesthesia and aseptic preparation are used before needle is inserted into joint and fluid aspirated. Used to diagnose joint inflammation, infection, meniscal tears, and subtle fractures.	*Before:* Explain procedure to patient. HCP may have patient be NPO prior. Usually done at bedside or in examination room. *After:* Send samples of synovial fluid to laboratory for examination (if indicated). Apply compression dressing and ice to decrease pain and swelling. Observe for leakage of blood or fluid on dressing. Assess the joint for any pain, fever, or swelling. Review activity restrictions.
Arthroscopy	Involves insertion of arthroscope into joint to see interior of joint cavity. Can be used for surgery (removal of loose bodies, biopsy); repair of joint structures; and diagnosis of abnormalities of meniscus, articular cartilage, ligaments, or joint capsule. Structures that can be seen through an arthroscope include knee, shoulder, elbow, wrist, jaw, hip, and ankle (Fig. 61.9).	*Before:* Explain the procedure to the patient. Can be done in outpatient setting. Local or general anesthesia may be used. HCP may have patient be NPO prior. *After:* Cover wound with sterile dressing. Apply ice to decrease pain and swelling. Observe for bleeding. Assess the joint for any pain, weakness, or swelling. Review activity restrictions.

FIG. 61.9 Knee arthroscopy in progress. Notice the monitor in the background.
From Miller MD, Howard RF, Plancher KD: *Surgical atlas of sports medicine,* Philadelphia, 2003, Saunders.

Case Study—cont'd

Objective Data: Diagnostic Studies

(© pixelheadphoto/iStock/Thinkstock.)

The HCP in the ED immediately orders the following diagnostic

studies:

- X-ray of left foot
- CBC, electrolytes
- Aspiration of the great toe

The x-ray of the foot shows minor soft tissue swelling but no evidence of fracture. Very mild arthritis is noted at the interphalangeal joint of the great toe. CBC and electrolytes are within normal limits.

Aspiration of the interphalangeal joint shows clear synovial fluid. Protein and glucose are within normal limits. Microscopic analysis of the synovial fluid shows urate crystals.

Discussion Questions

1. Which diagnostic results are abnormal?
2. What diagnostic study results are of most concern to you?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The bone cells that function in the formation of new bone tissue are called

   a. osteoids.

   b. osteocytes.

   c. osteoclasts.

   d. osteoblasts.

2. While performing passive range of motion for a patient, the nurse puts the elbow joint through the movements of *(select all that apply)*
   a. flexion and extension.
   b. inversion and eversion.
   c. pronation and supination.
   d. flexion, extension, abduction, and adduction.
   e. pronation, supination, rotation, and circumduction.
3. A patient with a torn ligament in the knee asks what the ligament does. The nurse's response is based on the knowledge that ligaments
   a. connect bone to bone.
   b. provide strength to muscle.
   c. lubricate joints with synovial fluid.
   d. relieve friction between moving parts.
4. The increased risk for falls in the older adult is likely due to *(select all that apply)*
   a. changes in balance.
   b. decrease in bone mass.
   c. loss of ligament elasticity.
   d. erosion of articular cartilage.
   e. decrease in muscle mass and strength.
5. The nurse is obtaining a health history of a patient with a fracture. Which condition poses the most concern related to the musculoskeletal system?
   a. Diabetes
   b. Hypertension

c. Chronic bronchitis

d. Nephrotic syndrome

6. When grading muscle strength, the nurse records a score of 3/5, which indicates

a. no detection of muscular contraction.

b. a barely detectable flicker of contraction.

c. active movement against full resistance without fatigue.

d. active movement against gravity but not against resistance.

7. An abnormal assessment finding of the musculoskeletal system is

a. equal leg length bilaterally.

b. ulnar deviation and subluxation.

c. full range of motion in all joints.

d. muscle strength of 5/5 in all muscles.

8. A patient is scheduled for a bone scan. The nurse explains that this diagnostic test involves

a. incision or puncture of the joint capsule.

b. insertion of small needles into certain muscles.

c. administration of a radioisotope before the procedure.

d. placement of skin electrodes to record muscle activity.

1. d, 2. a, c, 3. a, 4. a, b, c, e, 5. a, 6. d, 7.b, 8. c

Musculoskeletal Trauma and Orthopedic Surgery

Matthew C. Price

LEARNING OUTCOMES

1. Distinguish the etiology, pathophysiology, manifestations, and interprofessional and nursing management of soft tissue injuries.
2. Relate the sequence of events involved in fracture healing.
3. Compare closed reduction, cast immobilization, open reduction, and traction in terms of purpose, complications, and nursing management.
4. Assess the neurovascular condition of an injured extremity.
5. Explain common complications associated with a fracture and fracture healing.
6. Describe the interprofessional and nursing management of patients with various kinds of fractures.
7. Describe indications for and interprofessional and nursing management of the patient with an amputation.
8. Describe types of joint replacement surgery.
9. Prioritize management of the patient having joint replacement surgery.

Conceptual Focus

Functional Ability
Infection
Mobility
Pain
Perfusion
Safety

The most common cause of musculoskeletal injury is a traumatic event resulting in fracture, dislocation, subluxation, and/or soft tissue injury. Most of these injuries are not fatal. However, the cost in terms of pain, disability, medical expense, and lost wages is enormous. Accidents are 1 of the top 3 causes of death for persons ages 1 to 64 years.[1] Nurses play a key role in teaching the public about basic principles of safety and accident prevention.

This chapter discusses musculoskeletal problems resulting from trauma and common orthopedic surgical procedures. Following trauma or surgery, the injured area is often immobilized while healing occurs. The nurse's role in preventing complications (e.g., pressure injuries, constipation, infection, venous thromboembolism [VTE]) and promoting functional ability in patients with fractures and orthopedic surgery is emphasized.

Health Promotion

Teach people in the community to take proper safety precautions to prevent injuries while at home or work, driving, or taking part in sports. The morbidity associated with accidents can be significantly reduced if people are aware of environmental hazards, use proper safety equipment, and apply safety and traffic rules. In the work setting, teach employees and employers about use of proper safety equipment and avoiding hazardous working situations.

Promoting Population Health

Reducing the Risk for Musculoskeletal Injuries

- Regularly wear seatbelts.
- Drive within posted speed limits.
- Avoid distracted driving (e.g., no texting, eating, talking on a cell phone).
- Do not drive under the influence of alcohol or drugs (prescribed or illicit).
- Warm up muscles before exercise.
- Use protective athletic equipment (helmets and knee, wrist, and elbow pads).
- Use proper safety equipment at work.

Encourage people, especially older adults, to take part in moderate exercise to help maintain muscle strength and balance. Ways to prevent common musculoskeletal problems in the older adult are listed in Table 62.1. To reduce risk for falls, urge them to wear nonskid, hard-soled footwear and assess their living environment for safety risks (e.g., remove throw rugs, ensure adequate lighting, maintain clear paths to the bathroom for nighttime use). Stress the importance of adequate calcium and vitamin D intake for bone health.

Safety Alert

Falls

- Falls cause many musculoskeletal injuries in the home.
- Provide preventive teaching to high-risk persons (e.g., people with gait instability, visual or cognitive impairment).
- Stress the importance of wearing shoes with functional, stable soles and heels.
- Remind patients to avoid wet or slippery surfaces.

- Encourage removal of throw rugs in the home.

TABLE 62.1 Patient & Caregiver TeachingPrevention of Musculoskeletal Problems in Older Adults

To prevent musculoskeletal problems, include the following instructions when teaching older adults and their caregivers:

1. Use ramps in buildings and at street corners instead of steps to prevent falls.
2. Remove throw rugs from the home.
3. Treat pain and discomfort from osteoarthritis.
    - Rest in positions that decrease discomfort.
    - Use medication as prescribed for pain.
4. Use a walker or cane to help prevent falls.
5. Eat the amount and kind of foods needed to prevent weight gain. Obesity adds stress to joints, which may predispose to osteoarthritis.
6. Get regular and frequent exercise.
    - ADLs provide range-of-motion exercises. Tai Chi may be helpful.
    - Hobbies (e.g., jigsaw puzzles, needlework, model building) exercise finger joints and prevent stiffness.
    - Do daily weight-bearing exercise (e.g., walking) to improve bone health.
7. Use shoes with good support for safety and comfort.
8. Avoid sudden change in position. Rise slowly to a standing position to prevent dizziness, falls, and fractures.
9. Do not walk on uneven surfaces and wet floors.

Soft Tissue Injuries

Soft tissue injuries include sprains, strains, dislocations, and

subluxations. They usually result from trauma. As more people have become involved in fitness programs or sports, the incidence of soft tissue injuries has increased. Common sports-related injuries are described in Table 62.2. Sports injuries that often result in a visit to the emergency department (ED) for younger patients include sprains and strains, growth plate injuries, and repetitive motion injuries.[2]

Sprains and Strains

Sprains and strains often result from abnormal stretching or twisting forces during vigorous activities. These injuries tend to occur around joints and in the spinal musculature.

A **sprain** is an injury to the ligaments surrounding a joint. Sprains are usually caused by a wrenching or twisting motion. Most occur in the ankle, wrist, and knee joints.[3] A sprain is classified according to the degree of ligament damage. A *first-degree (mild) sprain* involves tears in only a few fibers, with mild tenderness and minimal swelling. A *second-degree (moderate) sprain* results in partial disruption of the involved tissue with more swelling and tenderness. A *third-degree (severe) sprain* is a complete tear of the ligament with moderate to severe swelling.

A **strain** is an excessive stretching of a muscle and its fascial sheath, often involving the tendon. Most strains occur in the large muscle groups, including the lower back, calf, and hamstrings. Strains are classified as first degree (mild or slightly pulled muscle), second degree (moderate or moderately torn muscle), and third degree (severely torn or ruptured muscle). A defect in the muscle may be apparent or palpated through the skin if the muscle is torn. Because areas around joints are rich in nerve endings, the injury can be very painful.

Manifestations of sprains and strains are similar. They include pain, edema, decreased function, and bruising. Continued use of the joint, tendon, or ligament makes pain worse. Edema develops in the injured area because of the local inflammatory response.

Mild sprains and strains are usually self-limiting. Full function

generally returns within 3 to 6 weeks. X-rays of the affected part may be taken to rule out a fracture. A severe sprain can cause an *avulsion fracture,* in which the ligament pulls loose a fragment of bone. The joint structure may become unstable, causing subluxation or dislocation. At the time of injury, *hemarthrosis* (bleeding into a joint space or cavity) or disruption of the synovial lining may occur. Severe strains may need surgical repair of the muscle, tendon, or surrounding fascia.

TABLE 62.2 Soft Tissue Injuries

Injury	Description	Treatment
Anterior cruciate ligament tear	Tearing of ligament by deceleration forces with pivoting or odd positions of the knee or leg.	PT with rehabilitation, knee brace. If knee instability or further injury, reconstructive surgery may be done.
Impingement syndrome	Entrapment of soft tissues and nerves under coracoacromial arch of shoulder.	NSAIDs. Rest until symptoms ↓, then begin gradual ROM and strengthening exercises.
Ligament injury	Tearing or stretching of ligament. Usually occurs from inversion, eversion, shearing, or torque applied to a joint. Characterized by sudden pain, swelling, and instability.	Rest, ice, elevation of extremity if possible, NSAIDs. Protect affected extremity by use of brace. If symptoms persist, surgical repair may be needed.
Meniscus injury	Injury to fibrocartilage discs in knee. Characterized by popping, clicking, tearing sensation, effusion, and/or swelling.	Rest, ice, elevation of extremity if possible, NSAIDs. Gradual return to regular activities. If symptoms persist, MRI to assess meniscus injury. Possible arthroscopic surgery.
Rotator cuff tear	Tear within muscle, tendons, or ligaments around shoulder.	*If minor tear:* rest, NSAIDs, and gradual mobilization with ROM and strengthening exercises. *If major tear:* surgical repair.
Shin splints	Inflammation of periosteal bone *(periostitis)* along anterior calf. Caused by improper shoes, overuse, or running on hard pavement.	Rest, ice, NSAIDs, proper shoes. Gradual ↑ in activity. If pain persists, x-ray to rule out tibial stress fracture.
Tendonitis	Inflammation of tendon due to overuse or incorrect use.	Rest, ice, NSAIDs. Gradual return to sport activity. Protective brace *(orthosis)* may be needed if symptoms recur.

Nursing Management: Sprains and Strains

Nursing Implementation

Health Promotion

Warming up muscles before exercising and vigorous activity,

followed by stretching, may significantly reduce the risk for sprains and strains. Strength, balance, and endurance exercises are important. Strengthening exercises that involve working against resistance build muscle strength and bone density. Balance exercises, which may overlap with some strengthening exercises, help prevent falls. Endurance exercises should start at a low level of effort and progress gradually to a moderate level.

Promoting Population Health

Health Impact of Regular Physical Activity

- Helps with weight management.
- Increases lean muscle and decreases body fat.
- Helps maintain and improve bone mass.
- Increases muscle strength, flexibility, and endurance.
- Helps prevent high BP.
- Reduces the risk for heart disease, diabetes, and colon cancer.
- Enhances sense of well-being and reduces risk for depression.

Acute Care

If an injury occurs, immediate care focuses on (1) stopping the activity and limiting movement to the injured part, (2) applying ice packs to the injured area, (3) compressing the involved area, (4) elevating the extremity, and (5) providing analgesia as needed (Table 62.3). Most sprains and strains are treated in the outpatient setting.

RICE (*R*est, *I*ce, *C*ompression, *E*levation) may decrease local inflammation and pain for most musculoskeletal injuries. Movement should be restricted, and the extremity rested as soon as pain is felt. Unless the injury is severe, prolonged rest is usually not needed.

There are several forms of cold therapy *(cryotherapy)* we can use. Cold causes vasoconstriction in the soft tissue and reduces the

transmission and perception of nerve pain impulses. These changes also reduce muscle spasms, inflammation, and edema. Cold is most useful when applied immediately after an injury has occurred and used for 24 to 28 hours. Apply ice no more than 20 to 30 minutes at a time. Do not apply ice directly to the skin.

Compression helps decrease edema and pain. We often use an elastic compression bandage. It can be wrapped around the injured part. To prevent edema and encourage fluid return, wrap the bandage starting distally (at the point farthest from the trunk of the body) and progress proximally (toward the trunk of the body). The bandage is too tight if there is numbness or tingling below the area of compression or pain or more swelling occurs beyond the edge of the bandage. Leave the bandage in place for 30 minutes, then remove it for 15 minutes. Use of an elastic wrap may provide extra support during training, athletic, and work activities.

Elevate the injured part above heart level, even during sleep, for 24 to 48 hours to help mobilize excess fluid from the area and prevent further edema. Mild analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) may be used to manage patient discomfort.

After the acute phase (usually 24 to 48 hours), apply warm, moist heat to the affected part to reduce swelling and provide comfort. Heat applications should not exceed 20 to 30 minutes, allowing a "cool-down" time between applications. Encourage the patient to use the limb if the joint is protected by a cast, brace, splint, or taping. Joint movement maintains nutrition to the cartilage. Muscle contraction improves circulation and helps resolve bruising and swelling. Movement also helps to prevent *contracture* (stiffening) of tendons and ligaments.

TABLE 62.3 Emergency ManagementAcute Soft Tissue Injury

Etiology	Assessment Findings	Interventions
• **Crush injury** • **Direct blows** • **Falls** • **Motor vehicle crashes** • **Sports injuries**	• Bruising • ↓ Movement with limited function or inability to bear weight (lower extremity) • ↓ Pulse, coolness, capillary refill >2 sec • ↓ Sensation • Edema • Muscle spasms • Pain, tenderness • Pallor • Shortening or rotation of extremity	Initial • Ensure airway, breathing, and circulation. • Perform neurovascular assessment of involved limb. • Elevate involved limb. • Apply compression bandage unless dislocation present. • Apply ice packs to affected area. • Immobilize affected extremity in the position found. Do *not* try to realign or reinsert protruding bones. • Anticipate x-rays of injured extremity. • Give analgesia as needed. • Give tetanus prophylaxis if there is an open fracture. • Give antibiotic prophylaxis for open fracture, large tissue defects, or mangled extremity injury. **Ongoing Monitoring** • Monitor for changes in neurovascular condition. • Implement weight-bearing restrictions as ordered for lower extremity involvement. • Anticipate compartment pressure monitoring if neurovascular assessment changes and compartment syndrome suspected.

Emphasize the importance of strengthening and conditioning exercises to prevent reinjury.[4] The physical therapist may help with pain relief by using ultrasound or other interventions. The therapist may also teach the patient exercises to improve flexibility and strength.

Dislocation and Subluxation

Dislocation is the complete displacement or separation of the articular surfaces of the joint. **Subluxation** is a partial or incomplete displacement of the joint surface. Symptoms of subluxation are similar to those of a dislocation but are less severe. Multiple structures contribute to the stability of a joint. Injury to, or excessive laxity of, ligaments is a major factor in dislocations or subluxations. Weak or atrophied muscles can cause chronic joint instability. Fibrocartilage structures, such as the labrum around hip and shoulder sockets and the meniscus at the knee, play an important role in joint stability. Even small tears to these structures can result in recurrent, chronic dislocations or subluxations.

Dislocations typically result from forces on the joint that disrupt the surrounding soft tissue support structures. The joints most often dislocated in the upper extremity include the thumb, elbow, and shoulder. The shoulder most often dislocates anteriorly. Posterior

shoulder dislocations are rare. They typically only happen after electrocution or seizure. In the lower extremity, the hip is vulnerable to dislocation from severe trauma, often associated with motor vehicle crashes (Fig. 62.1). The kneecap *(patella)* may dislocate because of a sharp, direct blow or after a sudden twisting inward motion while the planted foot is pointed outward.[5]

The most obvious sign of a dislocation is deformity. For example, if the hip dislocates in a posterior (or backward) direction, the affected limb may be shorter and internally rotated. Other manifestations include local pain, tenderness, loss of function of the injured part, and swelling of soft tissues near the joint. Major complications of a dislocated joint are open joint injuries, *intraarticular* fractures (within the joint), *avascular necrosis* (bone cell death from blood supply), and damage to adjacent nerves and blood vessels.

X-rays can determine the extent of displacement. The joint may be aspirated to assess for hemarthrosis or fat cells. Fat cells in the aspirate indicate a probable intraarticular fracture.

Interprofessional and Nursing Care

A dislocation requires prompt attention. It is often considered an orthopedic emergency because it may be associated with significant vascular injury. The longer the joint is dislocated, the greater the risk for avascular necrosis. The femoral head of the hip joint is especially susceptible to avascular necrosis. Compartment syndrome (discussed on p. 1460) may occur after dislocation due to vascular injury and resulting ischemia. Neurovascular assessment is critical (see pp. 1455–1456).

The first goal of management of a dislocation is to realign the dislocated part of the joint to its original anatomic position. Closed reduction (no incision) may be done under local or general anesthesia or IV moderate to deep sedation. Anesthesia is often needed to relax the muscle so that the bones can be manipulated. Sometimes, open reduction (joint visualized through surgical incision) may be needed. After reduction, the extremity is immobilized by a brace, splint, or

sling or by taping to allow torn ligaments and surrounding tissue to heal.

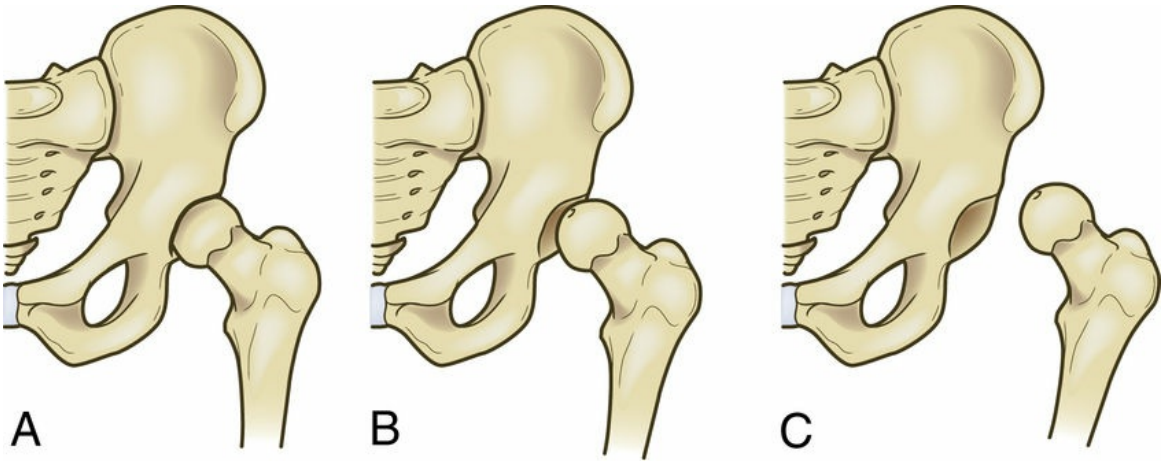

FIG. 62.1 Soft tissue injury of the hip. **A,** Normal. **B,** Subluxation (partial dislocation). **C,** Dislocation.

Nursing management is directed toward pain management and support and protection of the injured joint. After the joint has been reduced and immobilized, motion is usually restricted. A carefully monitored rehabilitation program can prevent further instability and joint dysfunction. Gentle range-of-motion (ROM) exercises may be done if the joint is stable and well supported. An exercise program slowly restores the joint to its original ROM without causing another dislocation. The patient should gradually return to normal activities.

A patient who has dislocated a joint may be at greater risk for repeated dislocations because of damage or laxity to the previously mentioned structures. Activity restrictions may be imposed on the affected joint to decrease the risk for repeated dislocations.

Repetitive Strain Injury

Repetitive strain injury (RSI) and *cumulative trauma disorder* are terms used to describe injuries resulting from prolonged force or repetitive movements and awkward postures. RSI is also called *repetitive trauma disorder, nontraumatic musculoskeletal injury, overuse syndrome* (sports

medicine), *regional musculoskeletal disorder,* and *work-related musculoskeletal disorder.* Repeated movements strain the tendons, ligaments, and muscles, causing tiny tears that become inflamed. The exact cause of these disorders is unknown. No specific diagnostic tests exist, and diagnosis is often difficult.

Persons at risk for RSI include musicians, dancers, butchers, grocery clerks, vibratory tool workers, and those who frequently use a computer mouse and keyboard. Competitive athletes and poorly trained athletes may develop RSI. Swimming, overhead throwing (e.g., baseball), weight lifting, gymnastics, tennis, skiing, and kicking sports (e.g., soccer) require repetitive motion. Overtraining compounds the effects of RSI.

Other factors related to RSI include poor posture and positioning, poor workspace ergonomics, badly designed workplace equipment (e.g., computer keyboard), and repetitive lifting of heavy objects without sufficient muscle rest. Inflammation, swelling, and pain in the muscles, tendons, and nerves of the neck, spine, shoulder, forearm, and hand may result. Symptoms of RSI include pain, weakness, numbness, or impaired motor function.

RSI can be prevented through education and *ergonomics* (the science that promotes efficiency and safety in the interaction of humans and their work environment). For example, ergonomic considerations for those who work at a desk and use a computer include keeping the hips and knees flexed to 90 degrees with the feet flat, keeping the wrist straight to type, having the top of the computer monitor even with the forehead, and taking at least hourly stretch breaks.

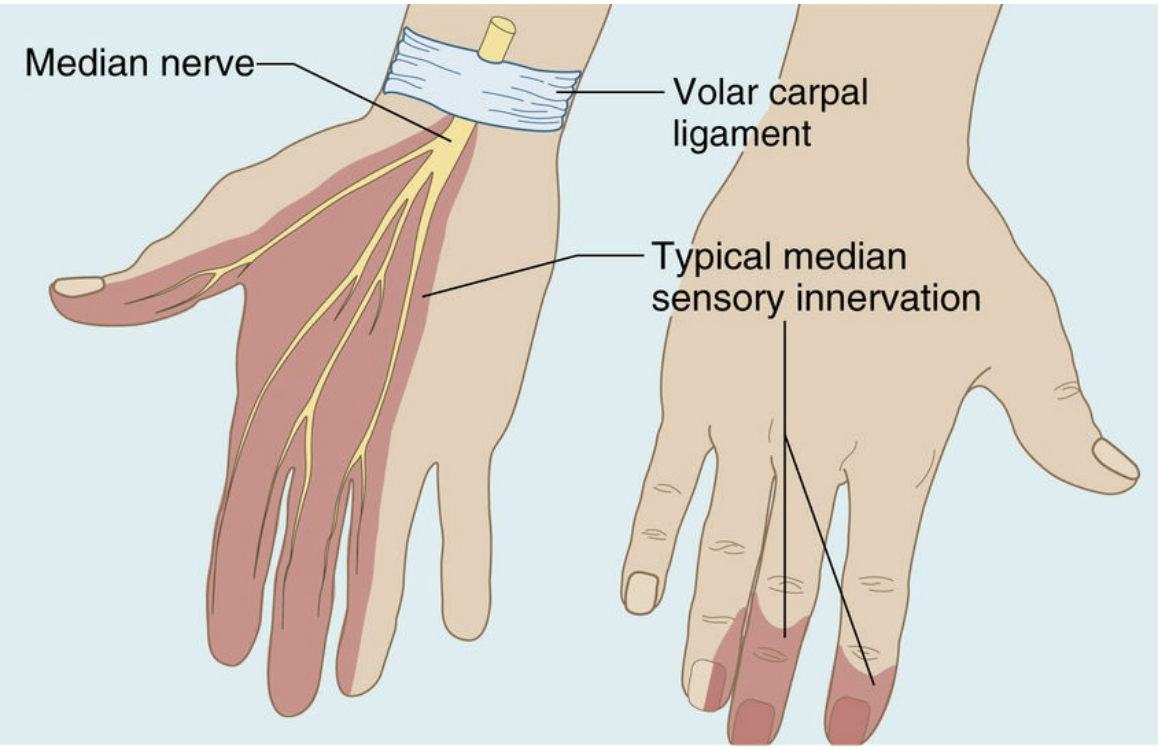

FIG. 62.2 Wrist structures involved in carpal tunnel syndrome. Median nerve distribution. *Shaded areas* show the locations of pain in carpal tunnel syndrome.
From Buttaravoli P: *Minor emergencies,* ed 3, Philadelphia, 2012, Saunders.

Once RSI is diagnosed, treatment consists of (1) identifying the precipitating activity; (2) modifying equipment and/or activity; (3) pain management, including heat or cold therapy and NSAIDs; (4) rest; (5) physical therapy (PT) for strengthening and conditioning exercises; and (6) lifestyle changes.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is caused by compression of the median nerve, which enters the hand at the wrist through the narrow carpal tunnel (Fig. 62.2). The carpal tunnel is formed by ligaments and bones. CTS is the most common compression neuropathy in the upper extremity. It is associated with hobbies or work that require continuous wrist movement (e.g., musicians, carpenters, computer operators).

CTS is often caused by pressure from trauma or edema (due to inflammation of a tendon *[tenosynovitis]*), cancer, rheumatoid arthritis (RA), or soft tissue masses, such as ganglia. Hormones may be involved because CTS often occurs during the premenstrual period, pregnancy, and menopause. Persons with diabetes, peripheral vascular disease (PVD), and RA have a higher incidence of CTS because of swelling that changes blood flow to the nerve and narrows the carpal tunnel.[6] Women are more likely than men to develop CTS, possibly because of a smaller carpal tunnel.

Manifestations of CTS are impaired sensation, pain, numbness, or weakness in the distribution of the median nerve (Fig. 62.2). Numbness and tingling may awaken the patient at night. Shaking the hands often relieves these symptoms. Clumsiness in performing fine hand movements is common.

The patient may have a positive Tinel's sign and Phalen's sign. *Tinel's sign* can be elicited by tapping over the median nerve as it passes through the carpal tunnel in the wrist. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. *Phalen's sign* can be elicited by allowing the wrists to fall freely into maximum flexion and maintain the position for longer than 60 seconds. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. In late stages, atrophy of the muscles around the base of the thumb results in recurrent pain and eventual dysfunction of the hand.

Interprofessional and Nursing Care

To prevent CTS, teach employees and employers to identify risk factors. Adaptive devices, such as wrist splints, may be worn to hold the wrist in a slight extension and relieve pressure on the median nerve. Special keyboard pads and computer mice that help prevent repetitive pressure on the median nerve are available for computer users. Other ergonomic changes include workstation modifications, change in body positions, and frequent breaks from work-related activities.

Care of the patient with CTS is directed toward relieving the underlying cause of the nerve compression. Early symptoms of CTS can usually be relieved by stopping the aggravating movement and by resting the hand and wrist by immobilization in a hand splint. Splints worn at night help keep the wrist in a neutral position and may reduce night pain and numbness. PT with hand and wrist exercises may lessen symptom severity. A corticosteroid injection directly into the carpal tunnel may give short-term relief. The patient may need to consider a change in occupation because of discomfort and sensory changes.

Carpal tunnel release is generally done if symptoms last more than 6 months or if there is significant impairment to conduction on electromyography (EMG). Surgery involves severing the band of tissue around the wrist to reduce pressure on the median nerve (Fig. 62.2). Surgery is done in the outpatient setting using local anesthesia. The types of carpal tunnel release surgery include open release and endoscopic surgery. In *open release surgery*, an incision is made in the wrist and then the carpal ligament is cut to enlarge the carpal tunnel. *Endoscopic carpal tunnel release* is performed through 1 or more small puncture incisions in the wrist and palm. A camera is attached to a tube, and the carpal ligament is cut. The endoscopic approach may allow a faster recovery and cause less discomfort than traditional open release surgery.

Although symptoms may be relieved right after surgery, full recovery may take months. After surgery, assess the hand's neurovascular status. Teach the patient about wound care and assessments to perform at home.

Rotator Cuff Injury

The rotator cuff is made up of 4 muscles in the shoulder: the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. These muscles stabilize the humeral head in the glenoid fossa while assisting with ROM of the shoulder joint and rotation of the humerus.

A tear in the rotator cuff may occur as a gradual, degenerative

process due to aging, repetitive stress (especially overhead arm motions), or injury to the shoulder. In sports, repetitive overhead motions, such as in swimming, weight lifting, and swinging a racquet (tennis, racquetball), often cause injury. The rotator cuff can tear because of sudden adduction forces applied to the cuff while the arm is held in abduction. Other causes include (1) falling onto an outstretched arm and hand, (2) a blow to the upper arm, (3) heavy lifting, or (4) repetitive work motions.

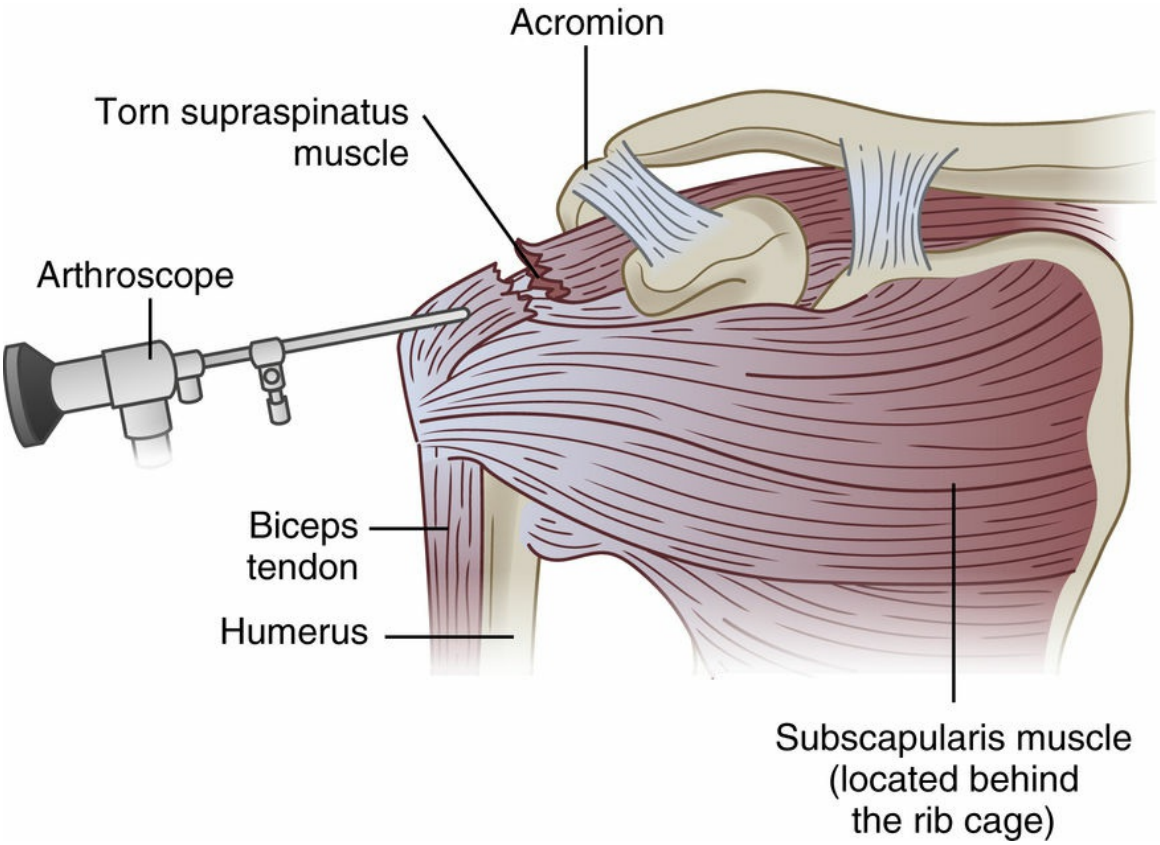

FIG. 62.3 A torn rotator cuff is repaired using arthroscopic surgery.

Manifestations include shoulder weakness, pain, and decreased ROM. The patient usually has severe pain when the arm is abducted between 60 and 120 degrees (the painful arc). A positive *drop arm test* is a sign of rotator cuff injury. In this test, the arm is abducted 90 degrees, and the patient is asked to slowly lower the arm to the side. If the arm falls suddenly, rotator cuff injury is suspected. An x-ray alone

is not helpful in the diagnosis. A tear can usually be confirmed by MRI.

The patient with a partial tear or cuff inflammation may be treated conservatively with rest, ice and heat, NSAIDs, corticosteroid injections into the subacromial space, ultrasound, and PT. If the patient does not respond to conservative treatment or if a complete tear is present, surgical repair may be needed. Most surgical repairs are done as outpatient procedures through an arthroscope (Fig. 62.3). If the tear is extensive, part of the acromion may be surgically removed *(acromioplasty)* to relieve compression of the rotator cuff during movement. A shoulder immobilizer with an abduction pillow is typically used for 6 weeks after surgery to limit shoulder movement. However, the shoulder should not be immobilized for too long because "frozen" shoulder *(arthrofibrosis)* may occur. Pendulum exercises and other passive exercises typically begin the first postoperative day. Active PT starts after 6 weeks of immobilization. Weight restrictions for lifting are usually given. Full recovery may take 6 to 12 months.

Meniscus Injury

The menisci are crescent-shaped pieces of fibrocartilage in the knee. Menisci are also found in other joints, including the acromioclavicular (AC), sternoclavicular, and temporomandibular joints. Meniscus injuries are associated with ligament sprains common among athletes in sports such as basketball, football, soccer, and hockey.[7] These activities produce rotational stress when the knee is in varying degrees of flexion and the foot is planted or fixed. A blow to the knee can cause shearing of the meniscus between the femoral condyles and tibial plateau, causing a torn meniscus. Older adults and people who have jobs that require squatting or kneeling are at risk for degenerative tears.[7]

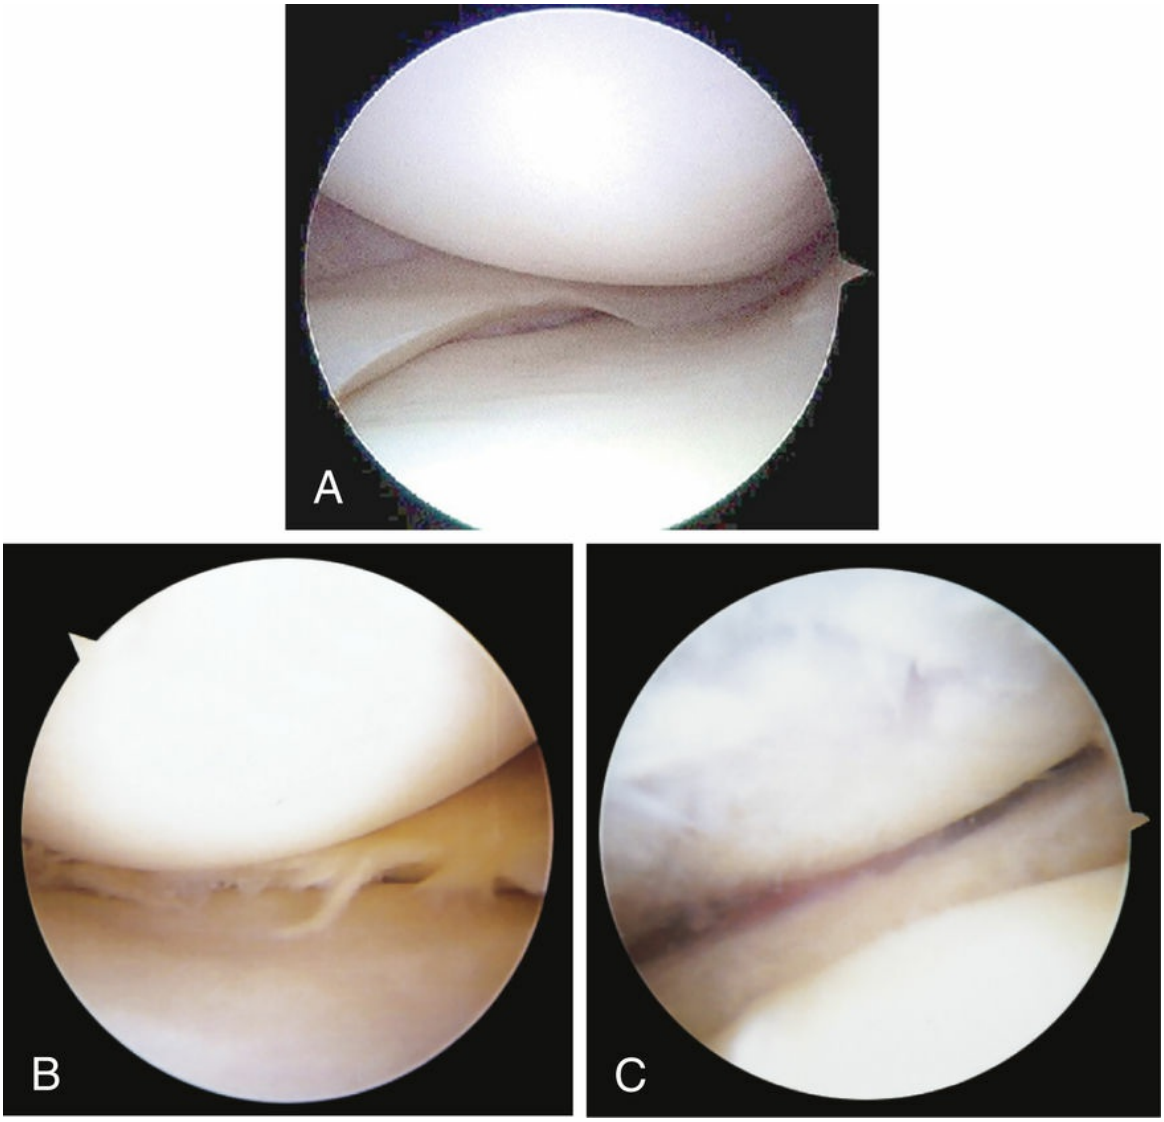

FIG. 62.4 Arthroscopic views of the meniscus. **A,** Normal meniscus. **B,** Torn meniscus. **C,** Surgically repaired meniscus. *A,* From David Lintner, MD, Houston, TX, *www.drlintner.com. B* and *C,* Courtesy Peter Bonner, Placitas, NM.

Meniscus injuries alone do not usually cause significant edema because most cartilage is avascular. However, an acutely torn meniscus may present with localized tenderness, pain, and effusion (Fig. 62.4). Pain occurs with flexion, internal rotation, and then extension of the knee *(McMurray's test).* The patient may feel that the knee is unstable and often reports that the knee "clicks," "pops," "locks," or "gives way." Quadriceps atrophy is usually present if the injury has been present for some time. Traumatic arthritis may occur

from repeated meniscus injury and chronic inflammation.

MRI can confirm the diagnosis before arthroscopy. The patient's age, occupation, sport activities, degree of knee pain, and dysfunction may affect the decision whether to have surgery.

Interprofessional and Nursing Care

Most meniscus injuries are treated in an outpatient setting. The acutely injured knee should be examined within 24 hours of injury. Initial care involves ice application, immobilization, and use of crutches with weight bearing as tolerated. Using a knee brace or immobilizer during the first few days after the injury protects the knee and offers some pain relief.

After acute pain has decreased, PT can help the patient regain knee flexion and muscle strength to aid in returning to full function. Teach athletes to do warm-up exercises to reduce the risk for sports-related injuries. In older adults with degenerative meniscus tears, progressive exercise therapy may improve neuromuscular function and muscle strength.[8]

Surgical repair or excision of part of the meniscus *(meniscectomy)* may be needed (Fig. 62.4). Meniscal surgery is done by arthroscopy. Pain relief may include NSAIDs or other analgesics. Rehabilitation starts soon after surgery, including quadriceps and hamstring strengthening exercises and ROM. When the patient's strength is back to its preinjury level, normal activities may be resumed.

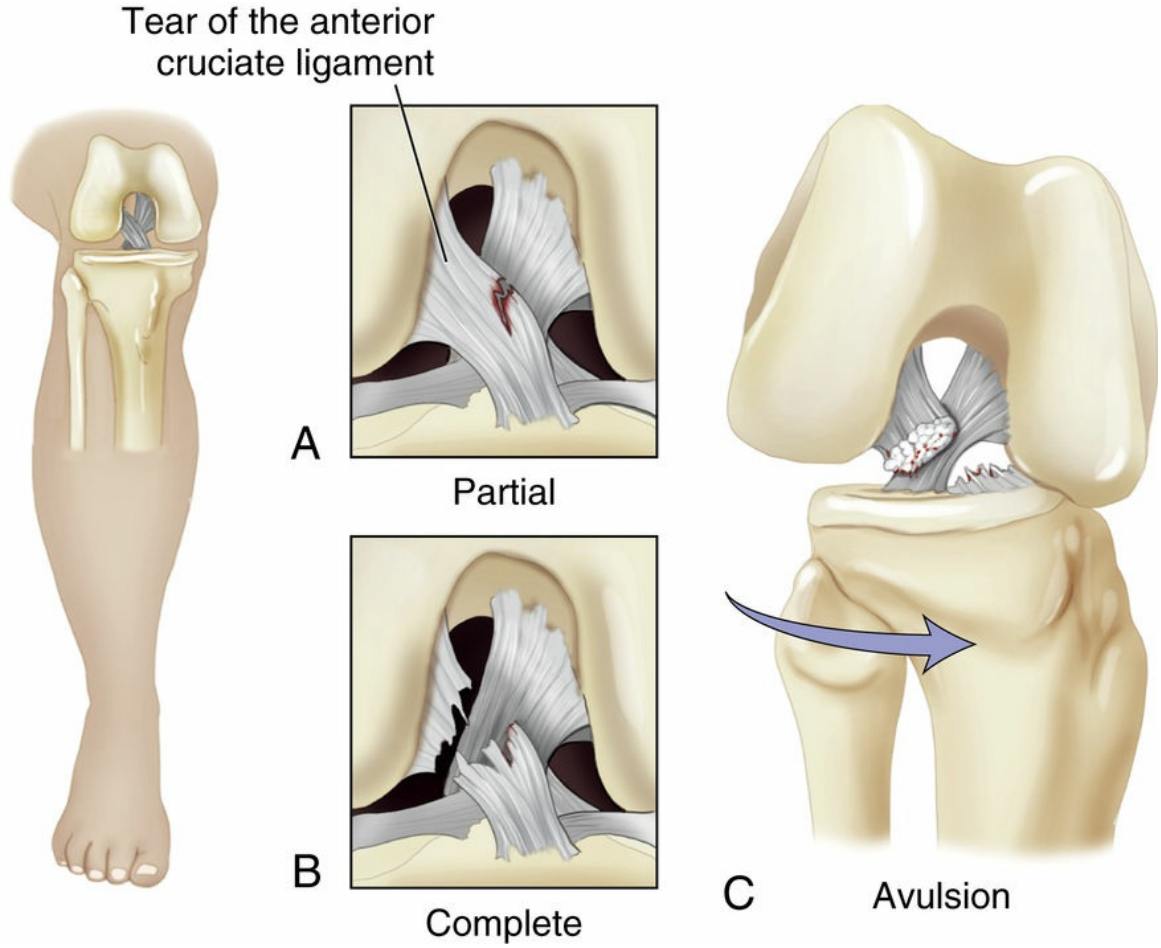

FIG. 62.5 Anterior cruciate ligament (ACL) injury. **A,** Partial tear. **B,** Complete tear. **C,** Avulsion.

Anterior Cruciate Ligament Injury

Knee injuries account for more than 50% of all sports injuries. The most commonly injured knee ligament is the anterior cruciate ligament (ACL). ACL injuries are usually noncontact injuries that occur when the athlete pivots, lands from a jump, or stops abruptly when running. Patients often report coming down on the knee, twisting, and hearing a pop, followed by acute knee pain and swelling. The knee may feel unstable. Athletes usually cannot continue playing. Injury to the ACL can result in a partial tear, a complete tear, or an *avulsion* (tearing away) from the bones that form the knee (Fig. 62.5).

A positive *Lachman's test* suggests an ACL tear. This test is done by flexing the knee 15 to 30 degrees and pulling the tibia forward while the femur is stabilized. The test is considered positive for an ACL tear if forward motion of the tibia occurs with the feeling of a soft or indistinct endpoint. MRI is often used to diagnose an ACL tear and coexisting conditions, including a fracture, meniscus tearing, and collateral ligament injuries.

Interprofessional and Nursing Care

Prevention programs can significantly reduce ACL injuries in athletes. Conservative treatment for an intact ACL injury includes rest, ice, NSAIDs, elevation, and ambulation as tolerated with crutches. If present, a tight, painful effusion may be aspirated. A knee immobilizer or hinged knee brace may provide support. PT often helps the patient maintain knee joint motion and muscle tone.

Reconstructive surgery is usually recommended for physically active patients who have sustained severe injury to the ACL and meniscus. In reconstruction, the torn ACL tissue is removed and replaced with graft tissue. ROM is encouraged soon after surgery. The knee is placed in a brace or immobilizer. Rehabilitation with PT is critical, with progressive weight bearing determined by the degree of surgical repair. A safe return to the patient's prior level of physical functioning may take 6 to 8 months.

Bursitis

Bursae are closed sacs that are lined with synovial membrane and contain a small amount of synovial fluid. They are found at sites of friction, such as between tendons and bones and near the joints. **Bursitis** (inflammation of the bursa) results from repeated or excessive trauma or friction, gout, RA, or infection.

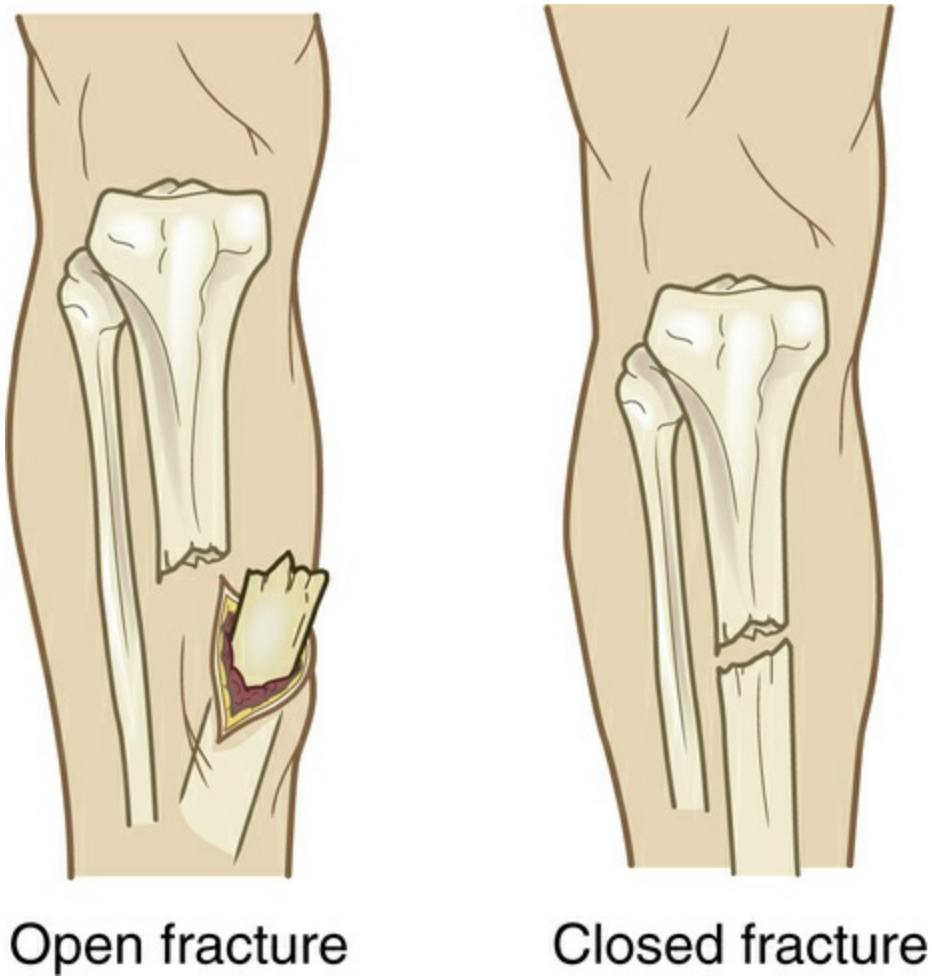

FIG. 62.6 Fracture classification according to communication with the external environment.

Symptoms of bursitis include warmth, pain, swelling, and limited ROM in the affected part. Common sites are the hands, elbows, shoulders, knees, and greater trochanters of the hip. Improper body mechanics, repetitive kneeling (carpet layers, coal miners, and gardeners), jogging in worn-out shoes, and prolonged sitting with crossed legs are common precipitating activities.

Try to determine and correct the cause of the bursitis. Rest is often the only treatment needed. The affected part may be immobilized in a compression dressing or splint. Ice and NSAIDs can reduce pain and inflammation.[9] Aspiration of the bursal fluid and intraarticular corticosteroid injection may be needed. If the bursal wall has become thickened and continues to interfere with normal joint function,

surgical excision *(bursectomy)* may be done. Septic bursae may be treated with oral antibiotics, but usually need surgical incision and drainage.

Fractures

Classification

A **fracture** is a disruption or break in the continuity of bone. Although traumatic injuries cause most fractures, some fractures are due to a disease process, such as cancer or osteoporosis *(pathologic fracture).*

We classify fractures in several ways. Fractures are described as *open* or *closed* based on communication with the external environment (Fig. 62.6). In an *open fracture*, the skin is broken and bone exposed, causing soft tissue injury. In a *closed fracture*, the skin is intact over the site.

We also describe fractures as complete or incomplete. A fracture is *complete* if the break goes completely through the bone. An *incomplete* fracture occurs partly across a bone shaft, but the bone is still intact. An incomplete fracture is often the result of bending or crushing forces applied to a bone.

Fractures are identified according to the direction of the fracture line. Types include linear, oblique, transverse, longitudinal, and spiral fractures (Fig. 62.7).

Finally, fractures can be classified as displaced or nondisplaced. In a *displaced* fracture, the 2 ends of the broken bone are separated from each other and out of their normal positions. Displaced fractures are often *comminuted* (more than 2 fragments) or *oblique* (Fig. 62.7). In a *nondisplaced* fracture, the bone fragments stay in alignment. Nondisplaced fractures are usually transverse, spiral, or greenstick (Fig. 62.7).

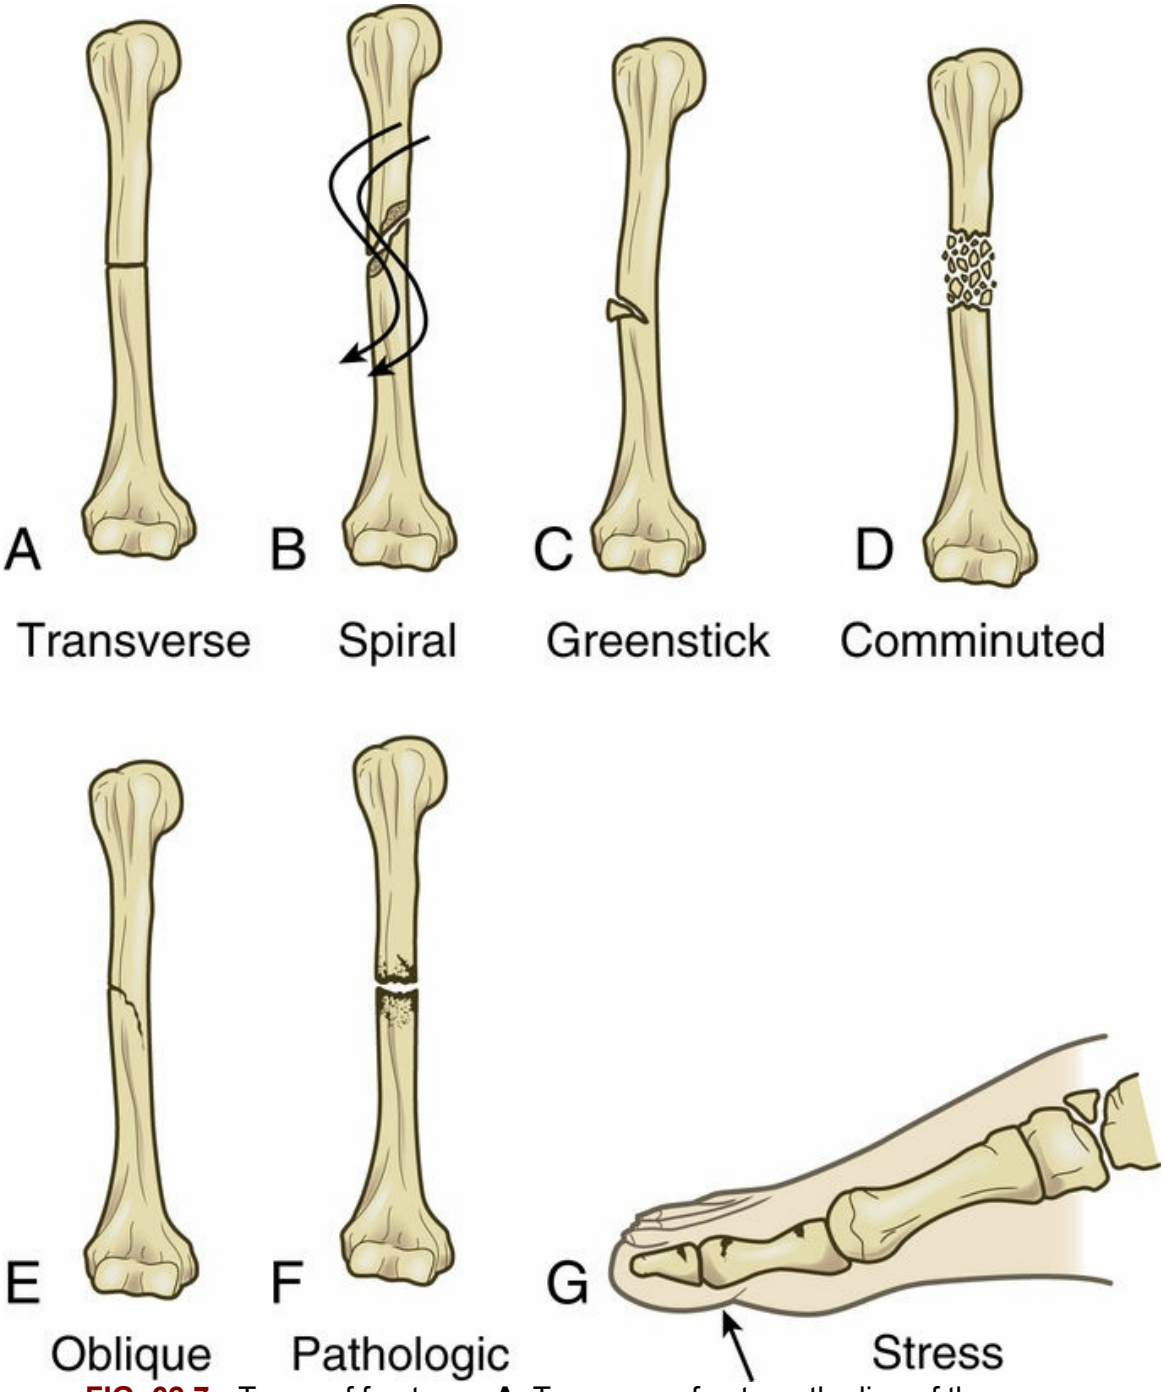

FIG. 62.7 Types of fractures. **A,** Transverse fracture: the line of the fracture extends across the bone shaft at a right angle to the longitudinal axis. **B,** Spiral fracture: the line of the fracture extends in a spiral direction along the bone shaft. **C,** Greenstick fracture: an incomplete fracture with 1 side splintered and the other side bent. **D,** Comminuted fracture: a fracture with more than 2 fragments. The smaller fragments appear to be floating. **E,** Oblique fracture: the line of the fracture extends across and down the bone. **F,** Pathologic fracture: a spontaneous fracture at the site of a diseased bone. **G,** Stress fracture: occurs in normal or abnormal bone that is subject to repeated

stress, such as from jogging or running.

Manifestations

Manifestations include immediate localized pain, decreased function, and inability to bear weight or use the affected part (Table 62.4). The patient guards and protects the extremity against movement. Obvious bone deformity may be present.

Fracture Healing

Knowledge of the stages of fracture healing (Fig. 62.8) is needed to provide appropriate interventions. Bone goes through a complex multistage healing process *(union)* that occurs in 6 stages:

1. *Fracture hematoma:* When a fracture occurs, bleeding creates a hematoma that surrounds the ends of the bone fragments. The hematoma is composed of extravasated blood that changes from a liquid to a semisolid clot in the first 72 hours after injury.[10]
2. *Granulation tissue:* During this stage, active phagocytosis absorbs the products of local necrosis. The hematoma converts to granulation tissue. Granulation tissue (consisting of new blood vessels, fibroblasts, and osteoblasts) forms the basis for new bone substance *(osteoid)* during days 3 to 14 after injury.
3. *Callus formation:* As minerals (calcium, phosphorus, and magnesium) and new bone matrix are deposited in the osteoid, an unorganized network of bone is formed and woven about the fracture parts. *Callus* is primarily composed of cartilage, osteoblasts, calcium, and phosphorus. It usually appears by the end of the second week after injury. An x-ray can show evidence of callus formation.

TABLE 62.4 Manifestations of Fracture

Manifestation	Significance
Bruising	
Discoloration of skin from extravasation of blood in subcutaneous tissues.	May appear immediately after injury and distal to injury. Reassure patient that process is normal, and discoloration will resolve.
Crepitation	
Grating or crunching of bony fragments, producing palpable or audible crunching or popping sensation.	May ↑ chance for nonunion if bone ends are allowed to move excessively. Micromovement of fragments (postfracture) helps in osteogenesis (new bone growth).
Deformity	
Abnormal position of extremity or part from original forces of injury and action of muscles pulling fragment into abnormal position. Seen as a loss of normal bony contours.	Classic sign of fracture. If uncorrected, it may cause problems with bony union and restoration of function of injured part.
Edema and Swelling	
Disruption or penetration of skin or soft tissues by bone fragments, or bleeding into surrounding tissues.	Unchecked bleeding and swelling in closed space can occlude blood vessels and damage nerves (e.g., ↑ risk for compartment syndrome).
Loss of Function	
Disruption of bone or joint, preventing functional use of limb or part.	Fracture must be managed properly to ensure restoration of function to limb or part.
Muscle Spasm	
Irritation of tissues and protective response to injury and fracture.	May displace nondisplaced fracture or prevent it from reducing spontaneously.
Pain and Tenderness	
Muscle spasm due to involuntary reflex action of muscle, direct tissue trauma, ↑ pressure on nerves, movement of fracture fragments.	Prompt the patient to splint muscle around fracture and reduce motion of injured area.

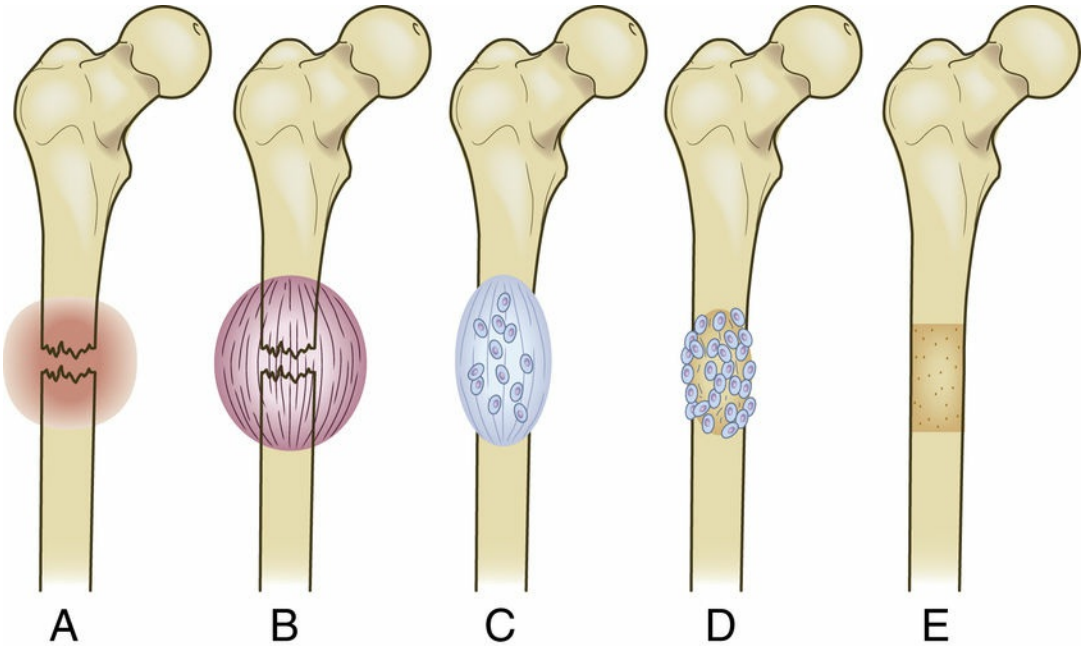

FIG. 62.8 Bone healing (schematic representation). **A,** Bleeding at fractured ends of the bone with hematoma formation. **B,** Organization of hematoma into fibrous network. **C,** Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. **D,** Callus formation: new bone is built up as osteoclasts destroy dead bone. **E,** Remodeling is accomplished as excess callus is resorbed and trabecular bone is laid down.

TABLE 62.5 Complications of Fracture Healing

Complication	Description
Angulation	Fracture heals in abnormal position in relation to midline of structure (type of malunion).
Delayed union	Fracture healing progresses more slowly than expected. Healing eventually occurs.
Malunion	Fracture heals in expected time but in unsatisfactory position. May cause deformity or dysfunction.
Myositis ossificans	Deposition of calcium in muscle tissue at site of significant blunt muscle trauma or repeated muscle injury.
Nonunion	Fracture does not heal despite treatment. No x-ray evidence of callus formation.
Pseudoarthrosis	Type of nonunion occurring at fracture site in which a false joint is formed with abnormal movement at site.
Refracture	New fracture occurs at original fracture site.

4. *Ossification:* Ossification of the callus occurs from 3 weeks to 6 months after the fracture and continues until the fracture has healed. Callus ossification is sufficient to prevent movement at the fracture site when the bones are gently stressed. However, the fracture is still evident on x-ray. During this stage of *clinical union,* the patient may be allowed limited mobility, or the cast may be removed.
5. *Consolidation:* As callus continues to develop, the distance between bone fragments decreases and eventually closes. Ossification continues and can be equated with *radiologic union,* which occurs when an x-ray shows complete bony union. This phase can occur up to 1 year after injury.
6. *Remodeling:* Excess bone tissue is resorbed in the last stage of bone healing, and union is complete. Gradual return of the injured bone to its preinjury structural strength and shape occurs. Bone remodels in response to physical loading stress

(Wolff's law). Initially, stress is provided through exercise. Weight bearing is gradually introduced. New bone is deposited in sites subjected to stress and resorbed at areas of little stress.

Many factors influence the time needed for complete fracture healing. They include displacement and site of the fracture, blood supply, other local tissue injury, immobilization, and use of internal fixation devices (e.g., screws, pins). Ossification may be slowed or even stopped by inadequate immobilization, excessive movement of fracture fragments, infection, poor nutrition, and systemic disease (e.g., diabetes).[11] Healing time for fractures increases with age. For example, an uncomplicated midshaft femur fracture heals in 3 weeks in an infant and in 20 weeks in an adult. Smoking increases fracture healing time. Fracture healing may not occur in the expected time *(delayed union)* or may not occur at all *(nonunion)*. Table 62.5 describes complications of fracture healing.

Interprofessional Care

The overall goals of fracture treatment are (1) anatomic realignment of bone fragments through reduction, (2) immobilization to maintain realignment, and (3) restoration of normal or near-normal function of the injured part. Table 62.6 outlines the interprofessional care of fractures.

TABLE 62.6 Interprofessional CareFractures

Diagnostic Assessment

- History and physical examination
- X-ray
- CT scan, MRI

Management
Fracture Reduction

- Manual traction
- Closed reduction
- Skeletal traction
- Open reduction

Fracture Immobilization

- Casting or splinting
- Skeletal traction
- External fixation
- Internal fixation

Open Fractures

- Surgical debridement and irrigation
- Tetanus and diphtheria immunization
- Prophylactic antibiotic therapy

Fracture Reduction

Closed Reduction

Closed reduction is the nonsurgical, manual realignment of bone fragments to their anatomic position. Traction and countertraction are manually applied to the bone fragments to restore position, length, and alignment. Closed reduction is usually done while the patient is under local or general anesthesia. Traction, casting, splints, or orthoses (braces) may be used after reduction to maintain alignment and immobilize the injured part until healing occurs.

Open Reduction

Open reduction is the correction of bone alignment through a surgical incision. It usually includes internal fixation of the fracture with wires, screws, pins, plates, intramedullary rods, or nails. The type and location of the fracture, patient age, and concurrent disease influence the decision to use open reduction. The main risks of open reduction are infection, complications associated with anesthesia, and effects of preexisting medical conditions (e.g., diabetes). However, open reduction internal fixation (ORIF) facilitates early ambulation, thus decreasing the risk for complications related to prolonged immobility.

Traction

Traction is the application of a pulling force to an injured or diseased body part or extremity. Traction is used to (1) prevent or reduce pain and muscle spasm (e.g., whiplash, unrepaired hip fracture), (2) immobilize a joint or part of the body, (3) reduce a fracture or dislocation, and (4) treat a pathologic joint condition (e.g., tumor, infection). Traction is also used to (1) provide immobilization to prevent soft tissue damage, (2) promote active and passive exercise, (3) expand a joint space during arthroscopic procedures, and (4) expand a joint space before major joint reconstruction.

Traction devices apply a pulling force on a fractured extremity to attain realignment while *countertraction* pulls in the opposite direction. The most common types of traction are skin traction and skeletal traction. *Skin traction* is generally used for short-term treatment (48 to 72 hours) until skeletal traction or surgery is possible. Tape, boots, or splints are applied directly to the skin, mainly to help decrease muscle spasms in the injured extremity. Traction weights are usually 5 to 10 lb (2.3 to 4.5 kg). *Buck's traction* is a type of skin traction sometimes used for the patient with a hip, knee, or femur fracture (Fig. 62.9).[12] Pelvic or cervical skin traction may require heavier weights applied intermittently. In skin traction, regular assessment of the skin is a priority because pressure points and skin breakdown may develop quickly. Assess key pressure points every 2 to 4 hours.

FIG. 62.9 Buck's traction is most often used for fractures of the hip and femur.
Courtesy Mary Wollan, RN, BAN, ONC, Spring Park, MN.

FIG. 62.10 Balanced suspension skeletal traction. Most often used for fractures of the femur, hip, and lower leg.
Courtesy Zimmer, Inc.

Skeletal traction is used to align injured bones and joints or to treat joint contractures and congenital hip dysplasia. It provides a long-term pull that keeps the injured bones and joints aligned. To apply skeletal traction, the HCP inserts a pin or wire into the bone, and weights are attached to align and immobilize the injured body part. Weight for skeletal traction ranges from 5 to 45 lb (2.3 to 20.4 kg). The use of too much weight can result in delayed union or nonunion. The major complications of skeletal traction are infection at the pin insertion site and the effects of prolonged immobility.

A common type of skeletal traction is balanced suspension traction (Fig. 62.10). Fracture alignment depends on the correct positioning and alignment of the patient while the traction forces stay constant.

For extremity traction to be effective, forces also must be pulling in the opposite direction *(countertraction).* Countertraction is supplied by the patient's body weight or by weights pulling in the opposite direction. Elevating the end of the bed can help. Traction must be maintained continuously. Keep the weights off the floor and moving freely through the pulleys.

Fracture Immobilization

Fracture immobilization is achieved with casts, braces, splints, immobilizers, and external and internal fixation devices.

Casts

A *cast* is a temporary immobilization device often applied after closed reduction. It allows the patient to perform many normal ADLs while providing enough immobilization to ensure stability. A cast generally immobilizes the joints above and below a fracture. This restricts tendon and ligament movement, thus assisting with joint stabilization while the fracture heals. The 2 most common cast materials are natural (plaster of Paris) and fiberglass. We use fiberglass casts most often because they are lighter, relatively waterproof, and longer wearing than plaster of Paris.[13] They also allow early weight bearing. Plaster of Paris is now used primarily for contact casting in the treatment of diabetic foot ulcers.[14]

To apply a cast on an extremity, first cover the affected part with stockinette that is cut longer than the extremity. Then place cotton padding over the stockinette, with extra padding for bony prominences. If using plaster of Paris, immerse it in warm water and then wrap and mold it around the affected part. The number of layers of plaster bandage and the technique of application determine the strength of the cast. The plaster sets within 15 minutes, so the patient may move around without difficulty. However, it is not strong enough for weight bearing until about 36 to 72 hours after application.[13] The decision about the patient's weight bearing is made by the HCP. Casts made of fiberglass or other synthetic materials

(thermolabile plastic, thermoplastic resins, polyurethane) are activated by submersion in cool or tepid water. Then they are molded to fit the torso or extremity.

Leave a fresh plaster cast uncovered to allow air circulation. Covering the cast allows heat to build up in the cast. This may cause a burn and delay drying. Avoid direct pressure on the cast during the drying period. Handle the cast gently with an open palm to avoid denting the cast. Once the cast is thoroughly dry, the rough edges may be *petaled* to minimize skin irritation. Petaling also prevents plaster of Paris debris from falling into the cast and causing irritation or pressure necrosis. Place several strips (petals) of tape over the rough areas to ensure a smooth cast edge.

Upper extremity injuries

An acute fracture or soft tissue injury of the upper extremity can be immobilized by using a (1) sugar-tong splint, (2) posterior splint, (3) short arm cast, or (4) long arm cast (Fig. 62.11). The *sugar-tong splint* is applied for acute wrist injuries or injuries that may result in significant swelling. Splints are placed over a well-padded forearm, beginning at the phalangeal joints of the hand, extending up the dorsal aspect of the forearm around the distal humerus, and then down the volar aspect of the forearm to the distal palmar crease. The splinting material is wrapped with either elastic bandage or bias stockinette. The sugar-tong posterior splint accommodates early swelling in the fractured extremity.

The *short arm cast* is often used for the treatment of stable wrist or metacarpal fractures. An aluminum finger splint can be built into the short arm cast for treatment of phalangeal injuries. The short arm cast is a circular cast extending from the distal palmar crease to the proximal forearm. This cast immobilizes the wrist and allows unrestricted elbow motion.

The *long arm cast* is often used for stable forearm or elbow fractures and unstable wrist fractures. It is similar to the short arm cast but extends to the proximal humerus, restricting motion at the wrist and elbow. Support the extremity and reduce edema by elevating the

extremity with a sling. However, when a hanging arm cast is used for a proximal humerus fracture, avoid elevation or use of a supportive sling. The hanging provides traction and maintains fracture alignment.

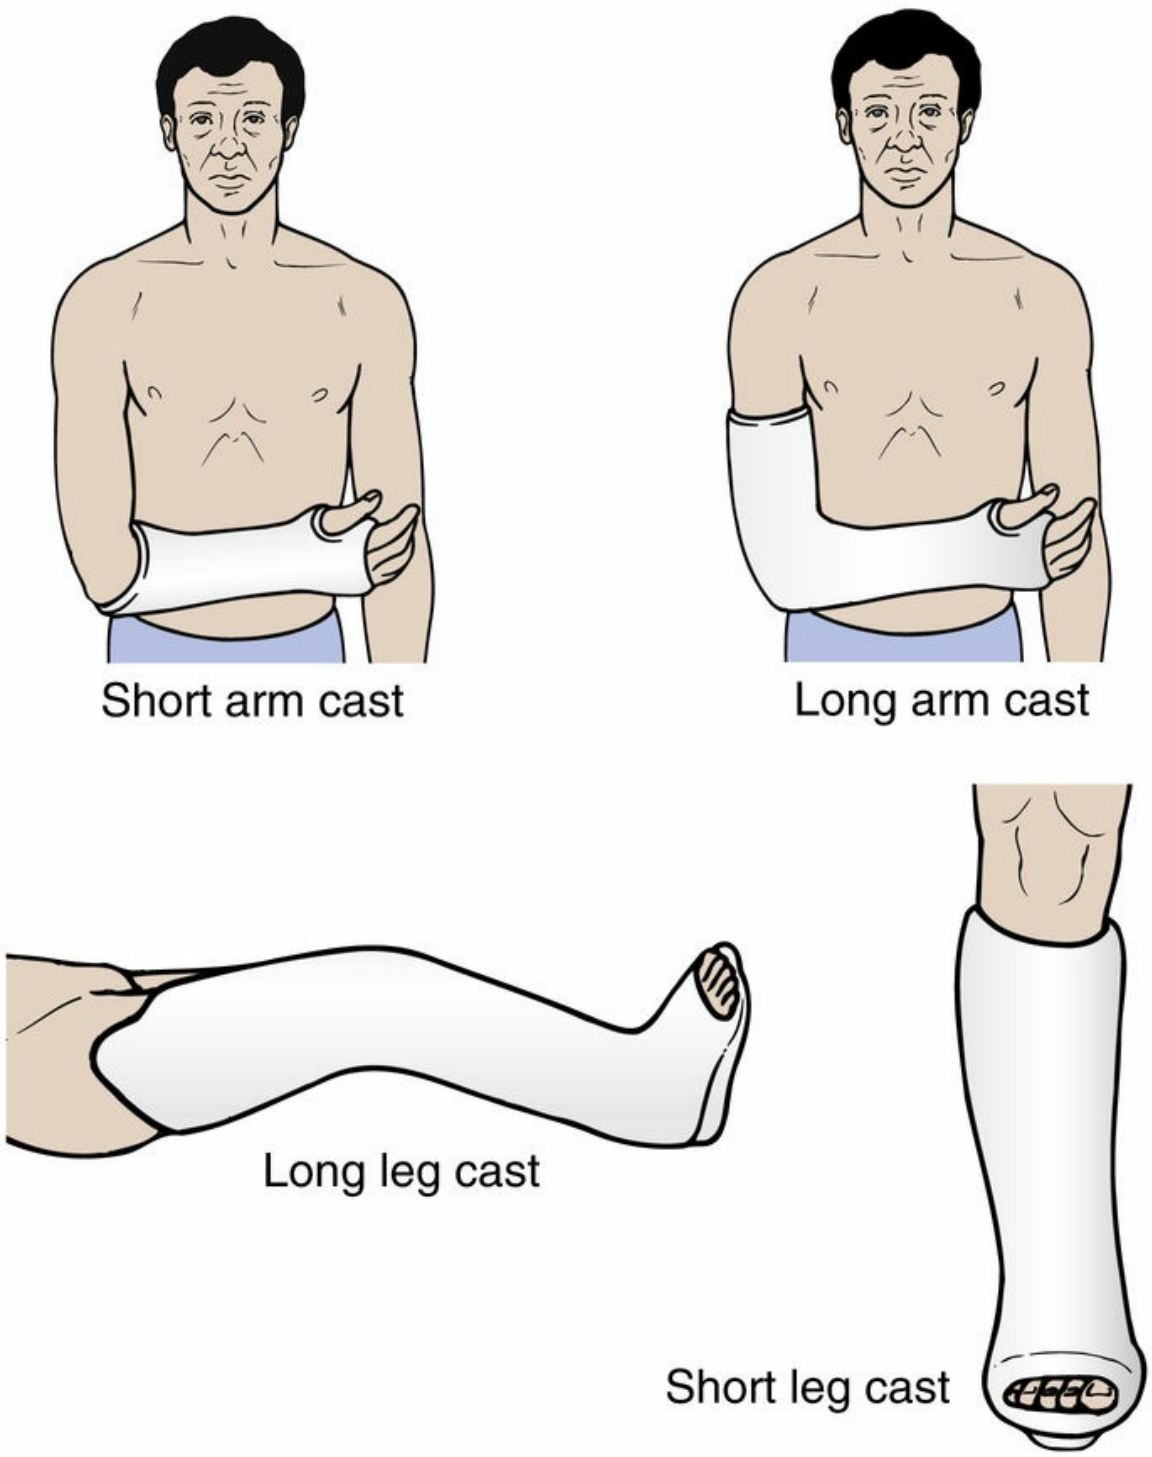

FIG. 62.11 Common types of casts.

When a sling is used, ensure the axillary area is well padded to prevent skin breakdown from direct skin-to-skin contact. Apply the sling carefully to avoid putting undue pressure on the neck.

Encourage movement of the fingers (unless contraindicated) to decrease edema by enhancing the pumping action of blood vessels. Teach the patient to actively move joints of the upper extremity if not immobilized to prevent stiffness and contractures.

Vertebral injuries

The *body jacket brace* is used for immobilization and support for stable spine injuries of the thoracic or lumbar spine. The brace goes around the chest and abdomen, extending from above the nipple line to the pubis. After application of the brace, assess the patient for the development of superior mesenteric artery syndrome *(cast syndrome).* This condition occurs if the brace is too tight, compressing the superior mesenteric artery against the duodenum. The patient generally has abdominal pain, abdominal pressure, nausea, and vomiting. Assess the abdomen for decreased bowel sounds (there may be a window in the brace over the umbilicus). Treatment of cast syndrome includes gastric decompression with a nasogastric (NG) tube and suction. Assess respiratory status, bowel and bladder function, and areas of pressure over the bony prominences, especially the iliac crest. The brace may have to be adjusted or removed if any complications occur.

Lower extremity injuries

Injuries to the lower extremity can be immobilized with a long leg cast, short leg cast, cylinder cast, or prefabricated splint or immobilizer. The usual indications for a long leg cast are an unstable ankle fracture, soft tissue injuries, a fractured tibia, and knee injuries. The cast usually extends from the base of the toes to the groin and gluteal crease. The short leg cast is used for stable ankle and foot injuries. A cylinder cast is used for knee injuries or fractures. It extends from the groin to the malleoli of the ankle. A Robert Jones dressing may be used temporarily to limit mobility of a joint. It is composed of soft padding materials (absorption dressing and cotton sheet wadding), splints, and an elastic wrap or bias-cut stockinette.

FIG. 62.12 Knee immobilizer.
From Maher AB, Salmond SW, Pellino T, editors: *Orthopedic nursing,* ed 3, Philadelphia, 2002, Saunders.

After application of a lower extremity cast or dressing, elevate the extremity above the heart on pillows for the first 24 hours. After that,

a casted extremity should not be placed in a dependent position as this may increase edema. After cast application, observe for signs of compartment syndrome (discussed on p. 1460) and increased pressure, especially in the heel, anterior tibia, head of the fibula, and malleoli. Increased pressure presents as pain or a burning feeling in these areas.

Prefabricated knee and ankle splints and immobilizers are used in many settings. This type of immobilization is easy to apply and remove, which allows close observation of the affected joint for swelling and skin breakdown (Fig. 62.12). Depending on the injury, removal of the splint or immobilizer promotes ROM of the affected joint and faster return to function.

The *hip spica cast* is mainly used for femur fractures in children to immobilize the affected extremity and trunk. It extends from above the nipple line to the base of the foot (single spica) and may include the opposite extremity up to an area above the knee (spica and a half) or both extremities (double spica). Assess the patient with a hip spica cast for the same problems associated with the body jacket brace.

External Fixation

An *external fixator* is composed of metal pins and wires that are inserted into the bone and attached to external rods to stabilize the fracture while it heals (Fig. 62.13). It can be used to apply traction or to compress fracture fragments and immobilize reduced fragments when the use of a cast or traction is not appropriate. The external device holds fracture fragments in place similar to a surgically implanted internal device. External fixation is used mainly for complex fractures with extensive soft tissue damage, correction of congenital bony defects, nonunion or malunion, and limb lengthening.

External fixation is often used to try to salvage extremities that otherwise may require amputation. Because the use of an external device is a long-term process, ongoing assessment for pin loosening and infection is critical. Infection may require removal of the device. Teach the patient and caregiver about meticulous pin care. Although each HCP has a protocol for pin care cleaning, chlorhexidine is often

used.[15]

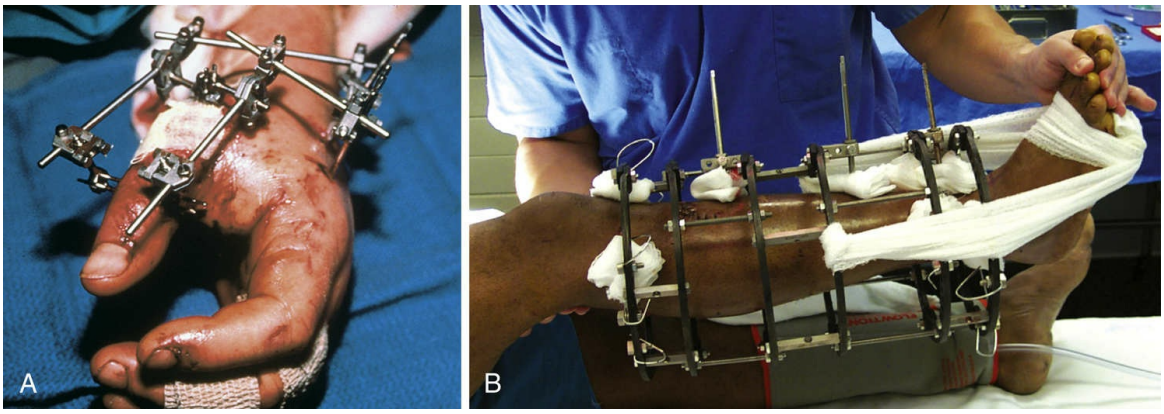

FIG. 62.13 External fixators. **A,** Stabilization of hand injury. **B,** Stabilization of a tibial fracture.

FIG. 62.14 Views of internal fixation devices to stabilize a fractured tibia and fibula.
From Jeremy Lewis, MD, Albuquerque, NM.

Internal Fixation

Internal fixation devices (pins, plates, intramedullary rods, metal and bioabsorbable screws) are surgically inserted to realign and maintain position of bony fragments (Fig. 62.14). These metal devices are biologically inert and made from stainless steel, vitallium, or titanium. Proper alignment and bone healing are evaluated regularly by x-rays.

Electrical Bone Growth Stimulation

Electrical bone growth stimulation can promote healing, especially with fracture nonunion or delayed union. The mechanism of action may include (1) increasing calcium uptake and the production of bone growth factors, (2) increasing collagen synthesis, and (3) promoting

the growth of new blood vessels.[16]

There are noninvasive, semi-invasive, and invasive methods of electrical bone growth stimulation. Noninvasive stimulators use direct current or pulsed electromagnetic fields (PEMFs) to generate a weak electrical current. Electrodes are typically in a band applied over the patient's skin or cast and worn 10 to 12 hours each day, usually while the patient is sleeping. Semi-invasive or percutaneous bone growth stimulators use an external power supply and electrodes that are inserted through the skin and into the bone. Invasive stimulators require surgical implantation of a current generator in an IM or subcutaneous space. An electrode is implanted in the bone fragments.

Drug Therapy

Patients with fractures have varying degrees of pain associated with muscle spasms. Central and peripheral muscle relaxants, such as carisoprodol (Soma), cyclobenzaprine, or methocarbamol (Robaxin), may be given to manage pain associated with muscle spasms.

Give tetanus and diphtheria toxoid or tetanus immunoglobulin to the patient with an open fracture who has not been previously immunized or whose immunization is expired (see Table 68.6). Bone-penetrating antibiotics, such as a cephalosporin (e.g., cefazolin), are used prophylactically before surgery.

Nutritional Therapy

Proper nutrition is essential to ensure optimal soft tissue and bone healing. An adequate energy source is needed to promote muscle strength and tone, build endurance, and provide energy for ambulation and gait-training skills. The patient's dietary requirements must include adequate protein (e.g., 1 g/kg of body weight), vitamins (especially B, C, and D), calcium, phosphorus, and magnesium. Low serum protein and vitamin C deficiencies interfere with tissue healing. Immobility and bone healing increase calcium needs.

A fluid intake of 2000 to 3000 mL/day promotes optimal bladder and bowel function. Adequate fluid and a high-fiber diet with fruits and vegetables prevent constipation. If immobilized in bed with

skeletal traction or in a body jacket brace, the patient should eat 6 small meals. This helps avoid overeating that can cause abdominal pressure and cramping.

Nursing Management: Fractures

Nursing Assessment

A brief history of the traumatic episode, mechanism of injury, and position in which the patient was found can be obtained from the patient or witnesses. As soon as possible, the patient should be transported to an ED, where thorough assessment can be done and treatment started (Table 62.7). Subjective and objective data that should be obtained from a person with a fracture are outlined in Table 62.8.

If a fracture is suspected, the extremity is immobilized in the position in which it is found. Unnecessary movement increases risk for damage to adjacent nerves and blood vessels. It may also convert a closed fracture to an open fracture.

Neurovascular Assessment

A thorough neurovascular assessment of the affected extremity, distal to the fracture site, is a primary concern. Musculoskeletal injuries may cause changes in the neurovascular status of an injured extremity. Poor positioning, physiologic responses to the traumatic injury, and application of a cast or constrictive dressing can cause nerve or vascular damage, usually distal to the injury. Record clinical findings before fracture treatment. This way if a problem occurs later, it will help determine if it was missed during the original examination or a result of treatment.

TABLE 62.7 Emergency ManagementFractured Extremity

Etiology	Assessment Findings	Interventions
Blunt Trauma • **Direct blow** • **Fall** • **Forced flexion or hyperextension** • **Motor vehicle crash** • **Pedestrian event** • **Twisting force** **Penetrating Trauma** • **Blast** • **Gunshot** **Other** • **Pathologic condition** • **Violent muscle contraction (seizures)** • **Crush injury**	• Bruising • ↓ Distal pulses • Deformity or unnatural position of affected limb • Edema • Grating (crepitus) • Loss of function • Muscle spasm • Numbness, tingling • Tenderness, pain • Warmth at site • Wound over injured site, exposure of bone	**Initial** • Treat life-threatening injuries first. • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Control external bleeding with direct pressure or sterile pressure dressing and elevation of the extremity. • Assess neurovascular condition distal to injury before and after splinting. • Elevate injured limb if possible. • Do not try to straighten fractured or dislocated joints. • Do not manipulate protruding bone ends. • Apply ice packs to affected area. • Obtain x-rays of affected limb. • Give tetanus prophylaxis if there is a break in skin integrity. • Mark location of pulses to aid repeat assessment. • Splint fracture site, including joints above and below fracture site. **Ongoing Monitoring** • Assess vital signs, level of consciousness, O_2 saturation, neurovascular condition, pain. • Assess for compartment syndrome (excessive pain, pain with passive stretch of the affected extremity muscles, pallor, paresthesia, with late signs of paralysis and pulselessness). • Assess for FES (dyspnea, chest pain, temperature elevation).

TABLE 62.8 Nursing AssessmentFracture

Subjective Data

Important Health Information

Past health history: Traumatic injury, long-term repetitive forces (stress fracture), bone or systemic diseases, prolonged immobility, osteopenia, osteoporosis
Medications: Corticosteroids (osteoporotic fractures); analgesics
Surgery or other treatments: First aid treatment of fracture, musculoskeletal surgeries

Functional Health Patterns

Health perception–health management: Calcium and vitamin D supplementation
Activity-exercise: Loss of motion or weakness of affected part, muscle spasms
Cognitive-perceptual: Sudden and severe pain in affected area; numbness, tingling, loss of sensation distal to injury; ongoing

pain that increases with activity (stress fracture)

Objective Data

General

Apprehension, guarding of injured site

Integumentary

Skin lacerations, pallor and cool skin or bluish and warm skin distal to injury; bruising, edema at fracture site

Cardiovascular

Reduced or absent pulse distal to injury, ↓ skin temperature, delayed capillary refill

Neurovascular

Paresthesia, absent or ↓ sensation, hypersensation

Musculoskeletal

Restricted or lost function of affected part; local bony deformities, abnormal angulation; shortening, rotation, or crepitation of affected part; muscle weakness

Possible Diagnostic Findings

Identification and extent of fracture on x-ray, bone scan, CT scan, or MRI

The neurovascular assessment consists of *peripheral vascular assessment* (color, temperature, capillary refill, peripheral pulses, edema) and *peripheral neurologic assessment* (sensation, motor function, pain). Throughout the neurovascular assessment, compare both extremities to obtain an accurate assessment.

Assess an extremity's color (pink, pale, cyanotic) and temperature (hot, warm, cool, cold) around the injury. Pallor or a cool-to-cold extremity below the injury could indicate arterial insufficiency. A warm, cyanotic extremity could indicate poor venous return. Next, assess capillary refill. A delay in returning to its original color (greater than 3 seconds) can occur with arterial insufficiency.[17]

Compare pulses on the unaffected and injured extremities to identify differences in rate or quality. This contralateral evaluation is critical. A decreased or absent pulse distal to the injury can indicate vascular dysfunction and insufficiency. Assess peripheral edema. Pitting edema may be present with severe injury.

Assess ulnar, median, and radial nerve function to evaluate sensation and motor innervation in the upper extremity. Assess motor function by asking the patient to (1) abduct the fingers (ulnar nerve), (2) oppose the thumb and small finger (median nerve), and (3) flex and extend the wrist (or the fingers, if in a cast) (radial nerve). In the lower extremity, assess the patient's ability to perform dorsiflexion (peroneal nerve) and plantar flexion (tibial nerve). Evaluate sensory function of the peroneal nerve by touching the web space between the great and second toes. Stroke the plantar surface (sole) of the foot to assess sensory function of the tibial nerve.

The patient may report *paresthesia* (abnormal sensation [e.g., numbness, tingling]) and hypersensation or hyperesthesia. Partial or full loss of sensation (paresis or paralysis) may be a late sign of neurovascular damage. Teach the patient to immediately report any changes in sensation or the ability to move the digits in the affected extremity.

Nursing Diagnoses

Nursing diagnoses for the patient with a fracture may include:

- Impaired physical mobility
- Risk for infection
- Acute pain

Additional information on nursing diagnoses and interventions for the patient with a fracture is presented in eNursing Care Plan 62.1 (on the website for this chapter).

Planning

The overall goals are that the patient with a fracture will (1) have healing with no associated complications, (2) have acceptable pain relief, and (3) achieve maximal rehabilitation potential.

Nursing Implementation

Acute Care

Patients with fractures may be treated in an ED or an HCP's office and released to home care. They also may need hospitalization for varying amounts of time. Specific nursing measures depend on the setting and type of treatment.

Preoperative Care

If surgical intervention is needed to treat a fracture, patients must be prepared. In addition to the usual preoperative nursing care (see Chapter 17), teach the patient about the type of immobilization and assistive devices that will be used. Discuss expected activity limitations after surgery. Assure them that nursing staff will help meet their personal needs until they can resume self-care. Review pain management strategies.

Postoperative Care

In general, nursing care after surgery involves monitoring vital signs and applying general principles of postoperative nursing care (see Chapter 19). Frequent neurovascular assessment of the affected extremity is needed to detect early and subtle changes. Carefully follow any limitations related to turning, positioning, and extremity support. Minimize pain and discomfort through proper alignment and positioning. Frequently observe dressings or casts for any signs of bleeding or drainage. Report a significant increase in size of the drainage area to the HCP. If a wound drainage system is in place, regularly measure the volume of drainage and assess its character (e.g., bloody, purulent). Report increased or purulent drainage at once to the HCP. Maintain the patency of any drainage systems, using aseptic technique to avoid contamination.

Other nursing responsibilities depend on the type of immobilization used. A blood salvage and reinfusion system may be used to allow recovery and reinfusion of the patient's own blood. The blood is retrieved from a joint space or cavity; then the patient receives this blood in the form of an autotransfusion. (Autotransfusion is discussed in Chapter 30.)

Other Measures

Patients often have reduced mobility because of a fracture. Plan care to decrease risk for the many possible complications of immobility. Prevent constipation by increasing patient activity. Maintain high fluid intake (more than 2500 mL/day unless contraindicated by the patient's health status) and a diet high in bulk and roughage (fresh fruits and vegetables). If these measures are not effective in continuing the patient's normal bowel elimination pattern, give stool softeners, laxatives, or suppositories. Maintain a regular time for elimination to promote bowel regularity.

Renal stones can develop from bone demineralization due to reduced mobility. Hypercalcemia from demineralization causes a rise in urine pH and stone formation from calcium precipitation. Unless contraindicated, maintain a fluid intake of 2500 mL/day to decrease the risk for stone formation. (Renal stones are discussed in Chapter

45.)

Rapid deconditioning of the cardiopulmonary system can occur from prolonged bed rest, resulting in orthostatic hypotension and decreased lung capacity. Unless contraindicated, decrease these effects by having the patient sit on the side of the bed, allowing the patient's lower limbs to dangle over the bedside, and having the patient perform standing transfers. When the patient is allowed to increase activity, assess for orthostatic hypotension. Assess patients for signs of VTE. VTE is discussed in Chapter 37.

Nursing Management

Caring for the Patient With a Cast or Traction

- Perform neurovascular assessment on the affected extremity.
- Monitor pain intensity and give prescribed analgesics.
- Determine correct body alignment to enhance traction.
- Monitor skin integrity around cast and at traction pin sites.
- Monitor cast during drying for denting or flattening.
- Teach patient and caregiver about cast care or traction and measures to prevent complications (e.g., ROM exercises).
- Assess for complications associated with immobility (e.g., constipation, VTE, kidney stones, atelectasis) and develop a plan to minimize those complications.
- Oversee unlicensed assistive personnel (UAP):
    - Position casted extremity above heart level as directed by RN.
    - Apply ice to cast as directed by RN.
    - Maintain body position and integrity of traction (if trained in this procedure).
    - Help patient with passive and active ROM exercises.
    - Notify RN about patient reports of pain, tingling, or

decreased sensation in the affected extremity.

Collaborate With Physical Therapist

- Assess patient's current mobility and need for assistance.
- Teach safe ambulation with assistive device based on patient's weight-bearing restrictions.
- Establish exercise plan and teach patient to perform exercises safely.
- Coordinate PT with RN so that patient can receive timely analgesia.
- Discuss home environment with patient and identify modifications to promote safety (e.g., stair training).

Collaborate With Occupational Therapist

- Assess impact of patient's condition on ability to perform ADLs.
- Teach patient use of assistive devices (e.g., long-handled reacher, shoe donner) to promote self-care while maintaining activity restrictions.

Traction

When slings are used with traction, regularly inspect exposed skin areas. Pressure over a bony prominence created by wrinkled sheets or blankets may cause pressure necrosis. Persistent skin pressure may impair blood flow and cause injury to peripheral nerves and blood vessels. Assess skeletal traction or external fixation pin sites for signs of infection. Pin site care may vary. It often includes regularly cleansing with chlorhexidine, rinsing with sterile saline, and drying the area with sterile gauze.

External rotation of the affected extremity is a classic assessment finding for a patient with unrepaired hip fracture. If skin traction is ordered before surgery, apply traction without trying to reposition or

realign the extremity. Movement of fracture fragments can occur during repositioning, causing increased pain and possible nerve impingement. Keep the patient in the center of the bed in a supine position to provide adequate countertraction.

Discuss specific patient activity with the HCP. If exercise is allowed, encourage patient participation in a simple exercise program based on activity restrictions. Have the patient perform frequent position changes, ROM exercises of unaffected joints, deep-breathing exercises, and isometric exercises. These activities should be done several times each day. Teach the patient to use the trapeze bar (if permitted) to raise the body off the bed for linen changes and placement of the bedpan. Encourage and help the hospitalized patient to stay connected with friends and family by telephone or through social media resources.

Ambulatory Care

Cast Care

Most uncomplicated fractures are treated in an outpatient setting. Whatever the type of cast material, a cast can interfere with circulation and nerve function if it is applied too tightly or excess edema occurs after application. Frequent neurovascular assessment of the immobilized extremity is critical. Teach the patient to recognize and promptly report tightness of the cast and areas of pressure or discomfort. Explain the importance of elevating the extremity above heart level to promote venous return and applying ice to control or prevent edema during the initial phase. However, if compartment syndrome is suspected, do not elevate the extremity above the heart.

Patient and caregiver teaching is important to prevent complications. Table 62.9 describes patient and caregiver instructions for cast care. Teach the patient to exercise joints above and below the cast. Tell the patient not to scratch or place anything inside the cast because this may cause skin injury and infection. For itching, direct a hair dryer on a cool setting under the cast. Confirm the patient's and caregiver's understanding of these instructions before discharge. A

follow-up phone call is appropriate. Home care nursing visits may be needed, especially for the patient with a body jacket brace.

The cast is typically removed in the outpatient setting. Patients often fear being cut by the oscillating blade of the cast saw. Reassure the patient that damage to the skin is unlikely. Teach the patient about possible changes in the appearance of the extremity beneath the cast (e.g., dry, wrinkled skin; atrophied muscle; foul odor). The patient may be scared to use the injured extremity after cast removal.

Ambulation

Know the overall goals of PT in relation to the patient's abilities, needs, and tolerance. The physical therapist is responsible for mobility training and teaching about the use of assistive aids (cane, crutches, walker). Reinforce these instructions to the patient. The patient with lower extremity fractures usually starts mobility training when able to sit in bed and dangle the feet over the side. Work with the physical therapist to give analgesia before a PT session.

TABLE 62.9 Patient & Caregiver TeachingCast Care

After a cast is applied, include the following instructions when teaching the patient and the caregiver:

Do

1. Apply ice directly over fracture site for first 24 hr (avoid getting cast wet by keeping ice in plastic bag and protecting cast with cloth).
2. Check with HCP before getting fiberglass cast wet.
3. Dry cast thoroughly if inadvertently exposed to water.
    - Blot dry with towel.
    - Use hair dryer on low setting until cast is thoroughly dry.

4. Elevate extremity above heart level for first 48 hr.
5. Regularly move joints above and below cast.
6. Use hair dryer on cool setting for itching inside the cast.
7. Report signs of possible problems to HCP:
    - Increasing pain despite elevation, ice, analgesia.
    - Swelling associated with pain and discoloration of toes or fingers.
    - Pain during movement.
    - Burning or tingling under cast.
    - Sores or foul odor under cast.
8. Keep appointment to have fracture and cast checked.

Do Not

1. Get cast wet.
2. Remove any padding.
3. Insert any objects inside cast.
4. Bear weight on new cast for 48 hr (not all casts are made for weight bearing; check with HCP when unsure).
5. Cover cast with plastic for prolonged periods.

When the patient begins to ambulate, know the patient's weight-bearing status and the correct technique if the patient is using an assistive device. Ambulation occurs in different degrees of weight-bearing: (1) non–weight bearing (no weight on the involved extremity), (2) touch-down/toe-touch weight bearing (contact with floor for balance but no weight borne), (3) partial–weight-bearing ambulation (25% to 50% of patient's weight borne), (4) weight bearing as tolerated (based on patient's pain and tolerance), and (5) full–weight-bearing ambulation (no limitations).

Assistive Devices

Devices for ambulation range from a cane (can relieve up to 40% of the weight normally borne by a lower limb) to a walker or crutches

(may allow for complete non–weight-bearing ambulation). The HCP decides which device is best, balancing the need for maximum stability and safety with the need for maneuverability in small spaces, such as bathrooms. Discuss with the patient lifestyle requirements and help select a device that allows the patient to feel most secure and independent. The technique for using assistive ambulation devices varies. The involved limb is usually advanced at the same time or immediately after advance of the device. The uninvolved limb is advanced last. Canes are held in the hand opposite the involved extremity.

Place a transfer belt (gait belt) around the patient's waist to provide stability while teaching the patient how to use an assistive device. Discourage the patient from reaching for furniture or relying on another person for support. A patient with inadequate upper limb strength or poorly fitted crutches bears weight at the axilla rather than at the hands. This can damage the neurovascular bundle that passes across the axilla. If verbal coaching does not correct the problem, teach the patient another form of ambulation (e.g., walker) until strength is adequate.

Patients who must ambulate without weight bearing need enough upper limb strength to lift their own weight at each step. Because the muscles of the shoulder girdle and upper arm may not be accustomed to this work, patients require focused training for this task. Push-ups, pull-ups using the overhead trapeze bar, and weight lifting develop the triceps and biceps muscles. Straight-leg raises and quadriceps-setting exercises strengthen the quadriceps muscles.

Psychosocial Concerns

Short-term rehabilitative goals address the transition from dependence to independence in performing simple ADLs. They are directed at preserving or increasing strength and endurance. Long-term rehabilitative goals are aimed at preventing problems associated with musculoskeletal injury (Table 62.10). During the rehabilitative phase, help the patient adjust to any problems caused by the injury (e.g., separation from family, financial impact of medical care, loss of

income from inability to work, potential for disability). Assess patients for posttraumatic stress disorder. This is especially important if significant injury to others or fatalities were associated with the patient's injuries.

The caregiver may have a key role in providing long-term care. Teach the caregiver how to help with strength and endurance exercises, mobility, and promoting activities that enhance the quality of daily living. Offer support and encouragement while actively listening to the patient's and caregiver's concerns.

Evaluation

The expected outcomes are that the patient with a fracture will

- Report satisfactory pain management
- Show proper care of cast or immobilizer
- Have uncomplicated bone healing

Complications of Fractures

Most fractures heal without complications. Complications of fractures may be direct or indirect. *Direct complications* include problems with bone infection, bone union, and avascular necrosis. *Indirect complications* include compartment syndrome, VTE, fat embolism syndrome (FES), breakdown of skeletal muscle *(rhabdomyolysis),* and hypovolemic shock. Most musculoskeletal injuries are not life threatening. Death after a fracture is usually due to damage to underlying organs and vascular structures or complications of the fracture or immobility. Open fractures, fractures with severe blood loss, and fractures that damage vital organs (e.g., lung, heart) are medical emergencies requiring immediate attention.

Infection

Open fractures and soft tissue injuries have a high rate of infection. An

open fracture usually results from severe external forces. Communication of the fracture site with the outside environment can contaminate the fracture site with microorganisms or foreign bodies. Damage to the surrounding soft tissue and blood vessels impairs the ability of defense mechanisms to respond to microorganisms.[18] Dying or contaminated tissue is an ideal medium for many common pathogens, including anaerobic bacilli, such as *Clostridium tetani*. Measures to prevent infection and osteomyelitis are important.

TABLE 62.10 Problems Associated With Musculoskeletal Injuries

Problem	Description	Nursing Considerations
Atrophy	• ↓ Muscle mass occurs from disuse after prolonged immobilization. • Loss of nerve function can cause muscle atrophy.	• Isometric muscle-strengthening exercises as able with immobilization device helps reduce amount of atrophy. • Muscle atrophy interferes with and prolongs rehabilitation process.
Contracture	• Abnormal condition of joint characterized by flexion and fixation. • Caused by atrophy and shortening of muscle fibers and ligaments or by loss of normal elasticity of skin over joint.	• Can be prevented by frequent position change, correct body alignment, active-passive ROM exercises several times a day. • Intervention requires gradual progressive stretching of muscles or ligaments in region of joint.
Footdrop	• Plantar-flexed position of the foot occurs when Achilles tendon in ankle shortens because it has been allowed to assume an unsupported position. • Peroneal nerve palsy (a compression neuropathy) can cause footdrop and spinal nerve compression.	• For patient with long-term injuries, support foot in neutral position to ↓ risk for footdrop. • Once footdrop has developed, can significantly hinder ambulation and gait training. • May need splint to keep feet in neutral position. • High-top athletic shoes may help. Apply at scheduled times to keep feet in neutral position.
Muscle spasms	• Caused by involuntary muscle contraction after fracture, muscle strain, or nerve injury. • May last several weeks. • Pain associated with muscle spasms is often intense and can last from several seconds to several minutes.	• Measures to ↓ intensity of muscle spasms are similar to actions for pain management. • Do not massage muscle spasms. Massage may stimulate muscle tissue contraction that ↑ spasm and pain. • Thermotherapy, especially heat, may reduce muscle spasm.
Pain	• Common with fractures, edema, muscle spasm. • May be mild to severe and described as aching, dull, burning, throbbing, sharp, or deep.	• Causes include incorrect positioning and alignment of extremity, incorrect support of extremity, sudden movement of extremity, immobilization device that is applied too tightly or incorrectly, constrictive dressings, motion at fracture site. • Determine causes of pain so that corrective action can be taken.

Open fractures require aggressive surgical debridement. The wound is initially cleaned by saline lavage in the operating room. Gross contaminants are irrigated and mechanically removed. Contused, contaminated, and devitalized tissue (muscle, subcutaneous fat, skin, and bone fragments) is surgically excised *(debridement).* The amount of soft tissue damage determines if the

wound is closed at the time of surgery or if it needs repeat debridement, closed suction drainage, and/or skin grafting. During surgery, the open wound may be irrigated with antibiotic solution. Antibiotic-impregnated beads also may be placed in the surgical site. Patients usually receive IV antibiotics for at least 3 days.[18] In conjunction with aggressive surgical management, antibiotics have greatly reduced the occurrence of infection.

Compartment Syndrome

Compartment syndrome is a condition in which swelling causes increased pressure within a limited space (muscle compartment). Because the fascia surrounding the muscle has limited ability to stretch, continued swelling can cause pressure that compromises the function of blood vessels and nerves in the compartment. Capillary perfusion is reduced below a level needed for tissue life. Compartment syndrome often involves the leg but can occur in any muscle group.

There are 38 compartments in the upper and lower extremities. Two basic causes of compartment syndrome are (1) decreased compartment size resulting from restrictive dressings, splints, casts, excessive traction, or premature closure of fascia; and (2) increased compartment contents due to bleeding, inflammation, edema, or IV infiltration.

Edema can create enough pressure to obstruct circulation and cause venous occlusion, which further increases edema. Arterial flow is eventually compromised, causing ischemia in the extremity. As ischemia continues, muscle and nerve cells are destroyed. Fibrotic tissue eventually replaces healthy tissue. Contracture, disability, and loss of function can occur. Delays in diagnosis and treatment may lead to irreversible muscle and nerve ischemia. The extremity may become functionally useless or severely impaired.

Compartment syndrome is usually associated with fractures (especially of long bones), extensive soft tissue damage, and crush injury.[19] Fractures of the distal humerus and proximal tibia are the

most common fractures associated with compartment syndrome. Compartment injury can also occur after knee or leg surgery. Prolonged pressure on a muscle compartment may result when someone is trapped under a heavy object or a person's limb is trapped beneath the body because of response to drugs or alcohol.

Clinical Manifestations

Compartment syndrome may occur initially from the body's physiologic response to the injury, or it may be delayed for several days after the original insult or injury. Ischemia can occur within 4 to 8 hours after the onset of compartment syndrome.

One or more of the "6 *P*s" are specific to compartment syndrome: (1) *pain* out of proportion to the injury that is not managed by opioid analgesics, and *pain* on passive stretch of muscle in the compartment; (2) increasing *pressure* in the compartment; (3) *paresthesia* (numbness and tingling); (4) *pallor,* coolness, and loss of normal color of the extremity; (5) *paralysis* or loss of function; and (6) *pulselessness* (decreased or absent peripheral pulses).

Interprofessional Care

Prompt diagnosis of compartment syndrome is critical.[19] Perform and document regular neurovascular assessment on all patients with fractures, especially those with injury of the extremities or soft tissue in these areas. Early recognition and effective treatment of compartment syndrome are essential to avoid permanent damage to muscles and nerves.

Carefully assess the location, quality, and intensity pain (see Chapter 8). Evaluate the patient's pain intensity on a scale of 0 to 10. Pain unrelieved by drugs and out of proportion to the level of injury is one of the *first* signs of compartment syndrome. Paresthesia is also an early sign. Notify the HCP immediately of these changes in the patient's condition. Relieving the source of pressure (e.g., cast is cut [bivalved] or dressing loosened by order of the HCP) typically decreases pain and paresthesia and can avoid compartment syndrome. Reducing traction weight may also decrease external

pressures on the extremity. Pulselessness and paralysis are later signs of compartment syndrome. Do not wait until these late signs occur to contact the HCP. Amputation may be needed due to prolonged ischemia.

With suspected compartment syndrome, do not elevate the extremity above the heart. Similarly, do not apply cold compresses. They may cause vasoconstriction and worsen compartment syndrome.

Surgical decompression (e.g., fasciotomy) of the involved compartment may be needed (Fig. 62.15).[19] The fasciotomy site is left open for several days to allow adequate soft tissue decompression. Infection resulting from delayed wound closure is a potential problem after fasciotomy. In severe cases of compartment syndrome, amputation is done.

Check Your Practice

Your 22-yr-old male patient had a fall while mountain climbing. He returned from surgery 8 hours ago with a long leg cast placed for open fractures of the femur and tibia. He continually reports pain that IV morphine does not seem to help.

- How will you assess his neurovascular condition?
- What signs and symptoms would suggest the development of compartment syndrome?
- What is the most likely intervention if compartment syndrome is developing?

Venous Thromboembolism

Veins of the lower extremities and pelvis are at great risk for clot (thrombus) formation after a fracture, especially a hip fracture. VTE may also occur after total hip or total knee replacement surgery. In patients with limited mobility, inactivity of muscles that normally

help pump venous blood from the extremities to the heart worsens venous stasis.

FIG. 62.15 Fasciotomy associated with compartment syndrome. Stabilization of fracture with external fixator.
From Browner BD, Jupiter JB, Levine AM, Trafton P: *Skeletal trauma: Fractures, dislocations, ligamentous injuries,* ed 4, Philadelphia, 2009, Saunders.

Because of the high risk for VTE in the orthopedic surgical patient, prophylactic anticoagulant drugs should be given for at least 10 to 14 days.[20] The most common agents used include (1) warfarin (Coumadin), (2) low-molecular-weight heparin (LMWH) (e.g., enoxaparin [Lovenox], fondaparinux), (3) aspirin, or (4) a factor Xa inhibitor (e.g., rivaroxaban [Xarelto], apixaban).[20] Besides wearing compression gradient stockings (antiembolism hose) or using intermittent pneumatic compression devices, the patient should dorsiflex and plantar flex the ankle of an affected lower extremity against resistance and perform ROM exercises on the unaffected leg. For upper extremity injuries, have the patient flex and extend the wrist if not immobilized by a cast or splint and perform ROM exercises on the unaffected arm. VTE is discussed in Chapter 37.

Safety Alert

Anticoagulant Therapy

- Monitor for signs of external bleeding (e.g., nosebleeds) or internal bleeding (e.g., tea-colored urine).
- Teach patient signs of bleeding and what to do if bleeding occurs.
- Teach patient safe self-injection if taking an injectable anticoagulant after discharge.
- Encourage patient to keep appointments for laboratory testing to monitor effects of warfarin (if prescribed).

Fat Embolism Syndrome

Fat embolism syndrome (FES) is characterized by fat globules entering the circulatory system from fractures. They collect in areas with abundant blood vessels, especially the lungs and brain.[21] FES contributes to mortality associated with fractures. The fractures most often associated with FES are those of the long bones, ribs, tibia, and pelvis. FES can also occur after total joint replacement, spinal fusion, liposuction, crush injuries, and bone marrow transplantation.

Two theories about FES exist. According to the mechanical theory, fat emboli originate from fat released from the marrow of injured bone. The fat enters systemic circulation, where it travels to other organs. As fat droplets become stuck in small blood vessels, local ischemia and inflammation occur. The biochemical theory suggests hormonal changes caused by trauma or sepsis stimulate systemic release of free fatty acids (e.g., chylomicrons) that form the fat emboli.

Clinical Manifestations

Early recognition of FES is crucial to prevent patient death. Most patients have symptoms within 24 to 48 hours after injury. Severe forms have occurred within hours of injury. Fat emboli in the lungs cause hemorrhagic interstitial pneumonitis with signs and symptoms of acute respiratory distress syndrome (ARDS). These include chest pain, tachypnea, cyanosis, dyspnea, apprehension, tachycardia, and

hypoxemia.[21] These symptoms are caused by poor O_2 exchange. Changes in mental status due to hypoxemia are common. Petechiae on the neck, anterior chest wall, axilla, buccal membrane, and conjunctiva of the eye may help distinguish FES from other problems. They may appear due to intravascular thromboses caused by decreased oxygenation. However, petechiae occur in only 20% to 60% of cases of FES. They may fade before they are noticed.[21]

The clinical course of FES may be rapid and acute. In a short time, skin color can change from pallor to cyanosis. The patient may become comatose. No specific laboratory tests aid in the diagnosis. However, certain abnormalities may be present. These include fat cells in blood, urine, or sputum; a decrease of PaO_2 to less than 60 mm Hg; ST segment and T-wave changes on ECG; decreased platelet count and hematocrit; and high erythrocyte sedimentation rate (ESR). A chest x-ray may show bilateral pulmonary infiltrates.

Interprofessional Care

Management of FES is supportive and related to managing symptoms. Treatment includes fluid administration to prevent hypovolemic shock, correction of acidosis, and blood transfusions. Dobutamine and nitrous oxide may be given for hemodynamic support.[21] Use of corticosteroids to prevent or treat FES is controversial.

The patient needs appropriate respiratory support. Administer O_2 to treat hypoxia. Intubation or intermittent positive pressure ventilation may be an option if satisfactory PaO_2 cannot be obtained with supplemental O_2 alone. Some patients develop pulmonary edema and/or ARDS, leading to increased mortality. Most persons survive FES with few complications.

Preventing the development of FES is important. Careful immobilization and handling of a long bone fracture are the most important factors in preventing FES. Reposition the patient as little as possible before fracture immobilization or stabilization to decrease the risk of dislodging fat droplets into the general circulation.

Check Your Practice

You are caring for a 24-yr-old male patient who had a femur fracture in a motorcycle accident last night. He is scheduled for ORIF later today. While doing your assessment, you notice that he seems very restless. You note some axillary petechiae.

- What complication would you suspect is occurring?
- Why is this patient particularly at risk for this complication?
- What is the most important intervention for a patient with this complication?

Rhabdomyolysis

Rhabdomyolysis is a syndrome caused by the breakdown of damaged skeletal muscle cells. This breakdown causes the release of myoglobin into the bloodstream. Myoglobin precipitates and causes obstruction in renal tubules. This results in acute tubular necrosis and acute kidney injury (AKI). Because of possible muscle damage, assess urine output. Common signs are dark reddish-brown urine and symptoms of AKI (see Chapter 46).

Types of Fractures

Colles' Fracture

A *Colles' fracture* is a fracture of the distal radius. The styloid process of the ulna may be involved as well. The injury usually occurs when the patient falls on an outstretched arm and hand. It is one of the most common types of fractures in adults. It most often occurs in patients over 50 years old whose bones are osteoporotic *(fragility fracture)* (Fig. 62.16). A younger person with a Colles' fracture caused by a low-energy force should be referred for an osteoporosis evaluation.

Symptoms include pain in the immediate area of injury,

pronounced swelling, and dorsal displacement of the distal fragment (silver-fork deformity). This displacement appears as an obvious deformity of the wrist. The major complication is vascular insufficiency from edema. CTS can be a later complication.

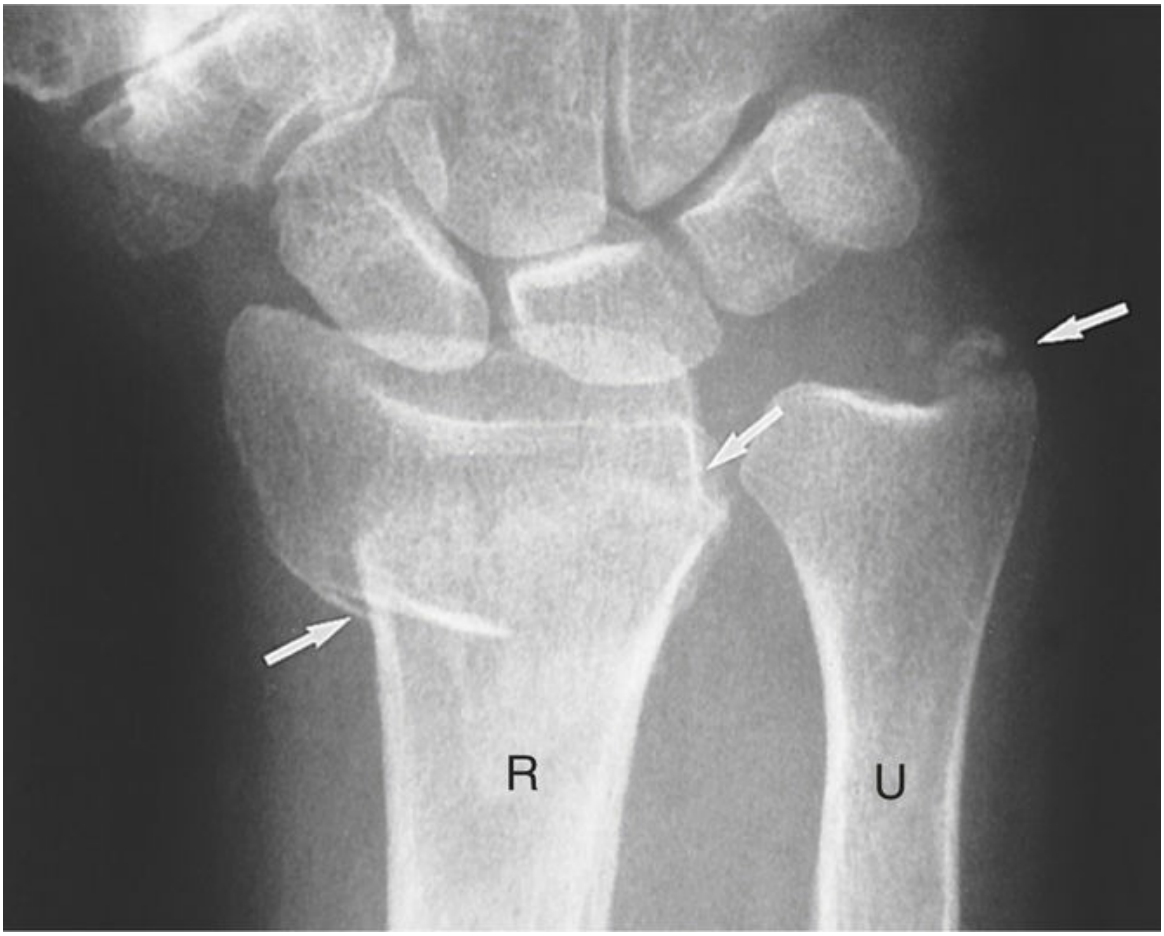

FIG. 62.16 Colles' fracture. Fracture of the distal radius *(R)* and ulnar *(U)* styloid from patient falling on the outstretched hand.
From Mettler FA: *Essentials of radiology,* ed 2, Philadelphia, 2005, Saunders.

A Colles' fracture is usually managed with closed reduction of the fracture and application of a splint or cast. If displaced, the fracture is typically managed with open reduction and internal or external fixation. Nursing management includes frequent neurovascular assessment and measures to reduce edema. Provide support and protect the extremity. Encourage active movement of the thumb and

fingers to reduce edema and increase venous return. Teach the patient to perform active movements of the shoulder to prevent stiffness or contracture.

Humeral Shaft Fracture

Fractures involving the shaft of the humerus are common among young and middle-aged adults. The most common symptoms are obvious displacement of the humeral shaft, shortened extremity, abnormal mobility, and pain. Complications associated include radial nerve injury and injury to the brachial artery due to laceration, transection, or muscle spasm.

Treatment depends on the specific fracture location and displacement. Nonoperative treatment may include a hanging arm cast, shoulder immobilizer, sling and swathe (a type of immobilizer that prevents shoulder movement), or humeral cuff brace (Fig. 62.17).

The humeral cuff brace is typically used to stabilize mid-shaft humerus fractures. Two pieces of molded plastic are fitted together in a clam-shell configuration and held together with Velcro straps. The humeral cuff brace is a good option for nonoperative fracture management if the patient is at increased risk for intraoperative complications.

When these devices are used, elevate the head of the bed to assist gravity in reducing the fracture. Allow the arm to hang freely when the patient is sitting or standing. Provide measures to protect the axilla and prevent skin breakdown. Carefully place absorbable composite dressing pads (e.g., ABD pads) in the axilla. Change them twice daily or as needed. Skin or skeletal traction may be used for reduction and immobilization.

During the rehabilitative phase, an exercise program to improve strength and motion of the injured extremity is extremely important. Exercises should include assisted motion of the hand and fingers. The shoulder can be exercised if the fracture is stable. This helps prevent stiffness from frozen shoulder or fibrosis of the shoulder capsule.

FIG. 62.17 Humeral cuff brace.

Pelvic Fracture

Pelvic fractures range from relatively minor to life threatening, depending on the mechanism of injury and associated vascular damage. Although only a small number of fractures are pelvic fractures, this type of injury is associated with a high mortality rate. Attention to more obvious injuries at the time of a traumatic event may result in oversight of pelvic injuries.

Pelvic fractures may cause serious intraabdominal injury, including laceration and hemorrhage of the urethra, bladder, or colon. They can cause acute pelvic compartment syndrome. Paralytic ileus may occur after pelvic fracture. Patients may survive the pelvic injury, only to die from sepsis, FES, or VTE.

Abdominal assessment may show local swelling, tenderness, deformity, unusual pelvic movement, and bruising. Assess the neurovascular condition of the lower extremities and determine associated injuries. Pelvic fractures are diagnosed by x-ray and CT scan.

Treatment depends on the severity of the injury. Stable, nondisplaced fractures require little intervention. Ambulation with weight bearing as tolerated is typically encouraged.[22] Complex or displaced fractures (e.g., open book fracture) need external fixation alone or combined with ORIF (e.g., screws), often done emergently. Use extreme care in handling or moving the patient, to prevent further injury. Turn the patient only when ordered by the HCP. Because a pelvic fracture can damage other organs, assess bowel and urinary elimination. Regularly perform distal neurovascular assessment. Provide back care with adequate help or while the patient is raised from the bed by independent use of a trapeze.

Ethical/Legal Dilemmas

Entitlement to Treatment

Situation

D.C., a 35-yr-old English tourist, was in a hang-gliding accident while touring the United States. She was taken to the regional trauma center for treatment of internal injuries, blood loss, and severe pelvic fractures. She has become septic, is now in renal failure, and has ARDS. She has no health insurance. Despite a poor chance of survival, her husband and parents want all possible measures to be taken.

Ethical/Legal Points for Consideration

- Federal law requires hospitals receiving federal funds through Medicare and Medicaid to provide emergency evaluation and treatment to stabilize patients (Emergency Medical Treatment and Active Labor Act [EMTALA]). Once the patient is stabilized, they are under no obligation to continue treatment and may transfer the patient to another facility.
- Discussions with the family must occur to clarify treatment goals (e.g., recovery, survival, continued biologic existence, nonabandonment of the patient) and what they mean by wanting "everything done." There is no legal or ethical obligation to continue medical treatment when treatment goals cannot be met.
- Contact with the English consulate may result in collaboration to stabilize the patient and transport her to England.
- Neither HCPs nor hospitals are required to provide medically futile care (care that provides no benefit to the patient).
- Although her home country (England) offers universal health care, D.C. assumed the risk when engaging in a potentially dangerous activity and did not obtain international health insurance coverage for her visit to a foreign country.

Discussion Questions

1. How can the nurse facilitate discussions with the family about

treatment goals for D.C.?
2. Are family members able to state D.C.'s wishes for her own care in such a situation?

Hip Fracture

Hip fractures are common in older adults. 95% of hip fractures result from a fall.[23] More than 320,000 patients are admitted to hospitals each year because of a hip fracture. Up to 37% of those patients die within 1 year of injury. Many older adults develop disabilities that require long-term care. By age 90, about 33% of all women and 17% of all men will have had a hip fracture. In adults over 65 years old, hip fracture occurs more often in women than in men because of osteoporosis.

Hip fracture refers to a fracture of the proximal (upper) third of the femur, which extends 5 cm below the lesser trochanter (Fig. 62.18). Fractures within the hip joint capsule are *intracapsular fractures.* Intracapsular fractures are further identified by their specific locations: (1) *capital* (fracture of the head of the femur), (2) *subcapital* (fracture just below the head of the femur), and (3) *transcervical* (fracture of the femoral neck). These fractures, which are often associated with osteoporosis and minor trauma, are called *fragility fractures*.

Extracapsular fractures occur outside the joint capsule. They are either (1) *intertrochanteric* (in a region between the greater and lesser trochanter) or (2) *subtrochanteric* (below the lesser trochanter). Most are caused by severe direct trauma or a fall.

Clinical Manifestations

Manifestations include external rotation, muscle spasm, shortening of the affected extremity, and severe pain and tenderness around the fracture site. Displaced femoral neck fractures may disrupt blood supply to the femoral head, resulting in avascular necrosis of the femoral head.

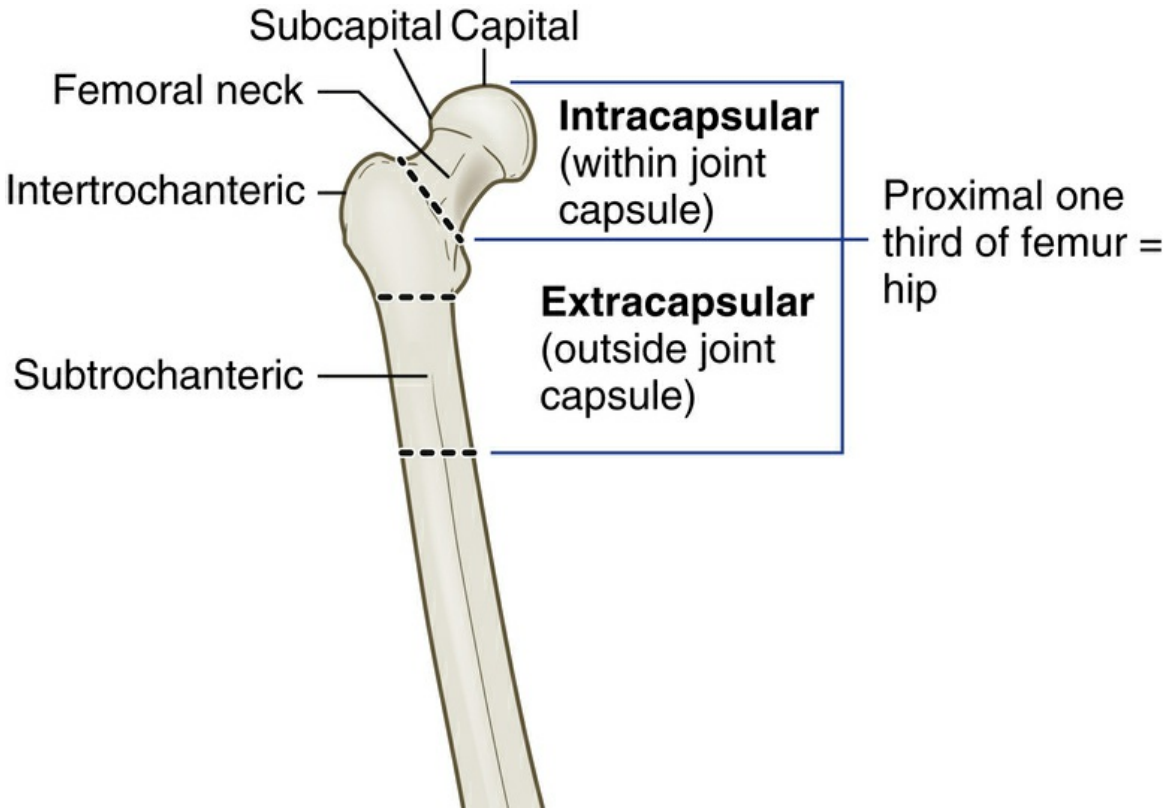

FIG. 62.18 Femur with location of various types of fracture.

Interprofessional Care

Immediate surgery is the standard of care. Initially the affected extremity may be immobilized with Buck's traction (Fig. 62.9) if the patient's physical condition needs stabilized before surgery can be done. Buck's traction can be used for 24 to 48 hours to relieve painful muscle spasms.

Surgical treatment allows early mobilization and decreases the risk for major complications. The type of surgery depends on the location and severity of the fracture and the person's age. Surgical options include (1) closed reduction with percutaneous pinning (CRPP) (minimally invasive surgery to stabilize the femoral neck and head with screws), (2) repair with internal fixation devices (e.g., hip compression screw, intramedullary devices), (3) replacement of the femoral head with a prosthesis (partial hip replacement or *hemiarthroplasty*, often used for fracture of the femoral neck) (Fig.

62.19), and (4) total hip replacement (involves both the femur and acetabulum) (Fig. 62.20).

Nursing Management: Hip Fracture

Nursing Implementation

Preoperative Care

In addition to the usual preoperative nursing care (see Chapter 17), teaching may be done in the ED. Most patients are medically stable and thus do not have an overnight preoperative period in which to receive instructions. Most people who have hip fractures are older adults. When planning treatment of the hip fracture, consider the patient's chronic health problems (e.g., diabetes, heart and pulmonary disease). Surgery may be delayed briefly until the patient's general health is stabilized. Begin to consider discharge plans because the length of stay after surgery will be no more than a few days.

Before surgery, severe muscle spasms can increase pain. Analgesics or muscle relaxants, comfortable positioning (unless contraindicated), and properly applied traction (if used) can help to manage the spasms.

Postoperative Care

Similar principles of patient care apply to any of the surgical procedures for hip fractures. In the initial postoperative period, assess vital signs, intake, and output. Monitor respiratory function and encourage deep breathing and coughing. Assess pain and give pain medication. Observe the dressing and incision for signs of bleeding. See eNursing Care Plan 62.2 for the orthopedic surgical patient (available on the website for this chapter).

FIG. 62.19 Types of surgical repair for a hip fracture: **A,** Closed reduction with percutaneous pinning. **B,** Intramedullary nail. **C,** Sliding hip screw. **D,** Hemiarthroplasty.
Courtesy Matthew C. Price, MS, RN, CNP, ONP-C, RNFA, Columbus, OH.

Neurovascular impairment is possible. Assess the patient's extremity for (1) color, (2) temperature, (3) capillary refill, (4) distal pulses, (5) edema, (6) sensation, (7) motor function, and (8) pain. Decrease edema by elevating the leg when the patient is in bed or in a chair. Pain in the affected extremity can be reduced by maintaining limb alignment with pillows between the patient's knees when turning the patient to the nonoperative side.

Encourage the patient to use the overhead trapeze bar and the opposite side rail to help in position changes. Avoid turning the patient to the affected side unless approved by the HCP. A physical therapist can teach the patient how to transfer out of the bed to a chair. Have the patient exercise the unaffected leg and both arms

If hemiarthroplasty or total joint replacement was done by a *posterior approach* (incision posterior to the midline of the greater trochanter down the femoral shaft), measures to prevent dislocation must be used (Table 62.11). Tell the patient and caregiver about positions and activities that increase the patient's risk for dislocation (more than 90 degrees of flexion, adduction across the midline [crossing of legs and ankles], internal rotation of hip). Many daily activities may reproduce these positions: (1) putting on shoes and socks, (2) crossing the legs or feet while seated, (3) assuming the side-lying position incorrectly, (4) standing up or sitting down while the hip is flexed more than 90 degrees relative to the chair, and (5) sitting on low seats, especially low toilet seats. Teach the patient to avoid these activities until the soft tissue capsule around the hip has healed enough to stabilize the prosthesis (usually at least 6 weeks).

FIG. 62.20 Total hip replacement (arthroplasty) with cementless femoral prosthesis of metal alloy with plastic acetabular socket.

TABLE 62.11 Patient & Caregiver TeachingPosterior Hip Replacement

After a hip replacement by posterior surgical approach, include the following instructions when teaching a patient and caregiver:

Do

- Use an elevated toilet seat.
- Place chair inside shower or tub and remain seated while washing.
- Use pillow between legs for first 6 wk after surgery when lying on nonoperative side or when supine.
- Keep hip in neutral, straight position when sitting, walking, or lying.

- Notify HCP at once if severe pain, deformity, or loss of function occurs.
- Discuss personal risk factors for prosthetic joint infection with HCP and dentist before dental work.

Do Not

- Flex hip greater than 90 degrees (e.g., sitting in low chairs or toilet seats).
- Adduct hip (e.g., bring legs together at knees).
- Internally rotate hip (e.g., turn toward planted foot on affected side).
- Cross legs at knees or ankles.
- Put on own shoes or stockings without adaptive device (e.g., long-handled shoehorn or stocking-helper) for 4–6 wk after surgery.
- Sit on chairs without arms. The arms of chairs will help the patient rise to a standing position.

Elevated toilet seats and chair alterations (e.g., raising the seat with a folded blanket, keeping a straight back) are needed. Avoid placing a soft pillow in the patient's seat because sitting on it can cause internal rotation. If a foam abduction wedge is ordered to prevent joint dislocation, place it between the patient's legs (Fig. 62.21). Apply the top straps above the knee to avoid putting pressure on the peroneal nerve at the lateral tibial tubercle. Some HCPs want the patient to keep the abductor wedge in place except when bathing or walking.

If hemiarthroplasty or total joint replacement was done by an *anterior approach* (incision is made in the front of the hip with patient lying on the back), the hip muscles are left intact. This approach generally provides a more stable hip in the postoperative period with a lower rate of complications. Precautions related to motion and weight bearing are few. They typically include instructions to avoid

hyperextension.

FIG. 62.21 Maintaining abduction after total hip replacement. Courtesy Mary Wollan, RN, BAN, ONC, Spring Park, MN.

Weight bearing on the involved extremity varies. Limited weight bearing is typically the only restriction for the patient who had ORIF of the hip fracture. Weight bearing after ORIF is generally restricted until x-ray examination shows adequate healing, usually 6 to 12 weeks. Tell the patient and caregiver about the weight-bearing status after surgery.

Taking a tub bath and driving a car are not allowed for 4 to 6 weeks. An occupational therapist (OT) may teach the patient to use assistive devices, such as long-handled shoehorns, sock assists, and reachers or grabbers, to avoid bending over to pick up something on the floor. The knees must be kept apart. Teach the patient to never cross the legs or twist to reach behind.

The physical therapist usually supervises exercises for the affected extremity and ambulation when the HCP allows it. The patient is usually out of bed the first postoperative day. In collaboration with the physical therapist, monitor the patient's ambulation for proper use of crutches or a walker. To be discharged home, the patient must

show proper use of crutches or a walker over a functional distance (about 150 ft). The patient must be able to transfer to and from a chair and bed and to go up and down stairs.

Complications associated with femoral neck fracture include nonunion, avascular necrosis, dislocation, and osteoarthritis (OA). The affected leg may be shorter if the patient had an intertrochanteric fracture. A cane or shoe lift may be needed for safe ambulation.

Sudden severe pain, a lump in the buttock, limb shortening, and external rotation indicate prosthesis dislocation. This requires closed reduction with moderate to deep sedation or open reduction under general anesthesia to realign the femoral head in the acetabulum. If any of these signs occur (regardless of the setting), keep the patient NPO in anticipation of surgical intervention.

Help the patient and caregiver to adjust to restrictions and dependence because of the hip fracture. Anxiety and depression can easily occur, but creative nursing care and awareness of potential problems can help to prevent them. Tell the patient and caregiver about community services that can help with rehabilitation after hospital discharge.

Check Your Practice

You are taking care of an 83-yr-old patient who fell down the steps outside her house while getting her mail. She was diagnosed with a femoral neck fracture and Colles' fracture. She is returning to the clinical unit after surgery. She had a hemiarthroplasty for the femoral neck fracture and closed reduction of the Colles' fracture.

- Based on these injuries, what are some possible complications?
- How will you mobilize a patient with these injuries?
- What are your discharge concerns?

Ambulatory Care

Hospitalization averages 3 or 4 days. Older adults or patients who live alone may require care in a subacute rehabilitation unit, at a skilled nursing facility, or in an acute rehabilitation facility for a few weeks before returning home. If the patient has skilled nursing needs or is homebound for PT after discharge from postacute care, the HCP may order follow-up home health care.

Home care considerations include ongoing assessment of pain management, monitoring for infection, and prevention of VTE. If incision is closed with metal staples, they will be removed at the HCP's office. Teach the patient who is receiving an anticoagulant to report signs of bleeding to the HCP (see Chapter 37). Review how to administer an injectable anticoagulant (if needed). Teach the patient receiving warfarin about required laboratory testing.

Exercises to restore strength and tone in the quadriceps and muscles around the hip are essential to improve function and ROM. These include quadriceps setting (e.g., pressing the kneecap down), gluteal muscle setting (e.g., tightening the buttocks), leg raises in supine and prone positions, and abduction exercises from the supine and standing positions (e.g., swinging the leg out but never crossing midline). The patient continues these exercises for many months after discharge. Teach the exercise program to the caregiver who will be encouraging the patient at home.

A physical therapist assesses ROM, ambulation, and adherence to the exercise program. The patient gradually increases the number of exercise repetitions and may add ankle weights. Swimming and stationary cycling may tone quadriceps and improve cardiovascular fitness. Teach the patient to avoid high-impact exercises and sports, such as jogging and tennis, because they may loosen the implant. A physical therapist may perform a home assessment to identify hazards that may cause the patient to fall again.

Evaluation

The expected outcomes are that the patient with a hip fracture will

- Report satisfactory pain management
- Have uncomplicated bone healing
- Take part in exercise therapy

Gerontologic Considerations: Hip Fracture

Factors that increase the risk for a hip fracture in older adults include (1) increased risk for falling due to an altered center of gravity and inability to correct a postural imbalance, (2) decreased fat and muscle to act as local tissue shock absorbers, and (3) reduced skeletal strength. Other factors that increase the older adult's risk for falling include (1) gait and balance problems, (2) altered vision and hearing, (3) slowed reflexes, (4) orthostatic hypotension, and (5) medication use. Homes can be made safer by (1) eliminating tripping hazards (e.g., throw rugs, uneven surfaces), (2) adding grab bars inside and outside the tub or shower, and beside the toilet, (3) adding railings on both sides of the stairs, and (4) installing better lighting.[23]

Many falls occur when getting in or out of a chair or bed. Falls to the side, the most common type seen in frail older adults, are more likely to result in a hip fracture than a forward fall. External hip protectors may help prevent hip fractures in the frail older patient.[24] Older adults may have low bone density *(osteopenia)* or osteoporosis, which increases their risk for fragility fractures.

Calcium and vitamin D supplementation are given to patients with osteopenia or osteoporosis. A bisphosphonate drug (e.g., alendronate [Fosamax]) may be prescribed to decrease bone loss or increase bone density. This reduces the chance of fracture. (Osteoporosis is discussed in Chapter 63.)

Femoral Shaft Fracture

Because the femur can bend slightly to absorb stress, femoral shaft fracture occurs from a severe direct force. The force exerted to cause the fracture (e.g., from a motor vehicle crash or gunshot wound) often also damages the adjacent soft tissue. These injuries may be more

serious than the bone injury. Young adults have a high incidence of this type of fracture.

Displacement of fracture fragments often causes increased soft tissue damage. Considerable blood loss (1 to 1.5 L) can occur. The most common types of femoral shaft fracture include transverse, spiral, comminuted, oblique, and open (Figs. 62.6 and 62.7).

A femoral shaft fracture is marked by pain, notable deformity and angulation, shortening of the extremity, and inability to move the hip or knee. Complications include FES; nerve and vascular injury; and problems associated with bone union, open fracture, and soft tissue damage.

Initial management involves patient stabilization and fracture immobilization. Traction may be used as a temporary measure before surgery or in the patient unable to have surgery. Placement of an *intramedullary rod* is the most common surgical treatment for femoral shaft fracture. The metal rod is placed into the marrow canal of the femur. The rod passes across the fracture to keep fragments in position. Plates and screws also may be used. Internal fixation is preferred because it reduces the hospital stay and complications associated with prolonged bed rest. External fixation may be used for an open fracture.

After surgery, gluteal and quadriceps isometric exercises will promote and maintain strength in the affected extremity. Encourage the patient to perform ROM and strengthening exercises for all uninvolved extremities to prepare for ambulation. The patient may be allowed to begin non–weight-bearing activities with an assistive device (e.g., walker, crutches). Full weight bearing is usually restricted until x-rays show union of fracture fragments. Teach the patient to carefully follow the HCP's instructions for weight bearing.

Tibial Fracture

Although the tibia is vulnerable to injury because it lacks a covering of anterior muscle, strong force is needed to cause a fracture. As a result, soft tissue damage, devascularization, and open fracture are common.

The tibia is also a common site for stress fracture. Complications of tibial fractures include compartment syndrome, FES, delayed union or nonunion, and possible infection with an open fracture.

Recommended management for closed tibial fractures is closed reduction followed by immobilization in a long leg cast. ORIF with intramedullary rods, plate fixation, or external fixation is needed for complex fractures and those with extensive soft tissue damage. An emphasis of care is maintaining quadriceps strength.

Assess the neurovascular condition of the affected extremity at least every 2 hours during the first 48 hours. Have the patient perform active ROM exercises with the uninvolved leg and the upper extremities to build the strength needed for crutch walking. When the HCP has determined the patient is ready for gait training, review principles of crutch walking introduced by the physical therapist. The patient may be non–weight bearing for 6 to 12 weeks, depending on healing. Home nursing visits may be needed to monitor the patient's progress if the patient is homebound.

Stable Vertebral Fracture

In a stable fracture, the fracture fragments are unlikely to move or cause spinal cord damage. This type of injury is often confined to the vertebral body (anterior part of the spinal column) in the lumbar region. Sometimes it involves the cervical and thoracic regions. Vertebral bodies are usually protected from displacement by intact spinal ligaments. Stable fractures of the vertebral column are usually caused by motor vehicle crashes, falls, diving, or sports injuries. Patients with osteoporosis have more than 700,000 vertebral compression fractures annually, many of which are stable.

Most patients with stable fractures have only brief periods of disability. However, if spinal ligaments are significantly disrupted, dislocation of the vertebrae may occur. Instability and injury to the spinal cord may result (unstable fracture). These injuries generally require surgery. The most serious complication of vertebral fractures is fracture displacement, which can cause damage to the spinal cord

(see Chapter 60). Although stable vertebral fractures are not associated with abnormal spinal cord pathology, all spinal injuries should be considered unstable and potentially serious until diagnostic tests determine the fracture to be stable.

The patient usually has pain and tenderness in the affected region of the spine. There may be a kyphotic deformity (flexion angulation of thoracic vertebrae) known as a *dowager's hump.* This deformity is readily identified during the physical examination (see Fig. 63.9). *Lordosis* (extreme inward curve of lumbar spine) and cervical spine involvement are possible. Sudden loss of function below the fracture indicates spinal cord impingement and paraplegia. Bowel and bladder dysfunction may occur if there is interruption of the autonomic nervous system nerves or injury to the spinal cord.

The overall goal in managing stable vertebral fractures is to keep the spine in good alignment until union is achieved. Many nursing interventions are aimed at assessing for spinal cord trauma (see Chapter 60). Regularly evaluate vital signs and bowel and bladder function. Monitor the motor and sensory function of peripheral nerves distal to the injured region. Promptly report any deterioration in the patient's neurovascular condition.

Treatment includes pain medication followed by early mobilization and bracing. The patient's mattress should be firm to support the spinal column, relax muscles, decrease edema, and prevent potential compression on nerve roots. Teach the patient to keep the spine straight when turning by moving the shoulders and pelvis together. The patient will need nursing help to learn the technique of logrolling. Several days after the initial injury, the HCP may apply a specially constructed orthotic device (e.g., thoracolumbar sacral orthosis [TLSO]), a jacket cast, or a removable corset if there is no evidence of neurologic deficit. The device gives extra support during healing and is used for a short period of time.

Lightweight bracing (e.g., Jewett or Bähler-Vogt brace) may be used for patients with stable vertebral compression fractures due to osteoporosis. Patients with osteoporosis also may be treated with 2 outpatient procedures: vertebroplasty or balloon kyphoplasty.

Vertebroplasty uses radioimaging to guide the injection of bone cement into a fractured vertebral body. When hardened, the cement stabilizes the vertebra and prevents further compression. *Balloon kyphoplasty* involves first inserting a balloon into the vertebral body and then inflating it. This creates a cavity that is filled with bone cement under low pressure to restore the height of the vertebral body. Kyphoplasty is now the surgical treatment of choice for compression fractures. This is due to the decreased incidence of bone cement leakage into nearby structures (e.g., colon, lung) compared to vertebroplasty. Patients have decreased pain almost at once with these procedures. However, later compression fractures of adjacent vertebrae are a risk.

If the fracture is in the cervical spine, the patient may wear a hard cervical collar. Some cervical fractures are immobilized by use of a halo vest (see Fig. 60.8). This consists of a plastic jacket or cast fitted about the chest and attached to a halo held in place by skeletal pins inserted into the cranium. These devices immobilize the spine in the fracture area while allowing the patient to ambulate.

The patient with a stable vertebral fracture is discharged after (1) showing safe ambulation, (2) learning care of the cast or orthotic device, and (3) stating ways to address safety and security concerns related to the injury and treatment. Unstable vertebral fractures and spinal cord injuries are the subject of Chapter 60.

Facial Fracture

Any bone of the face can be fractured from trauma, such as a motor vehicle crash, an assault, or a fall. After facial injury it is critically important to establish and maintain a patent airway and provide adequate ventilation. Suctioning may be needed to remove foreign material and blood. A surgically created airway *(tracheostomy)* may be needed if a patent airway cannot be maintained.

Facial fractures and cervical spine injuries often occur together. All patients with facial injuries should be treated as if they have a cervical injury until proven otherwise by examination and CT scan or x-ray. Table 62.12 describes clinical manifestations of common facial

fractures.

Related soft tissue injury often makes assessment of facial injury difficult. Perform oral and facial examinations after any life-threatening situations have been treated. Carefully assess ocular muscles and cranial nerves III, IV, and VI. X-rays help determine the extent of the injury. CT scanning helps distinguish between bone and soft tissue injury.

Suspect injury to the eye when facial injury occurs, especially if the injury is near the orbit. If an eye-globe rupture is suspected, stop and place a protective shield over the eye. Signs of rupture include vitreous humor forced out of the eye. Brown tissue (iris or ciliary body) may be seen on the surface of the globe or penetrating through a laceration, with an off-center or teardrop-shaped pupil.

TABLE 62.12 Manifestations of Facial Fractures

Fracture	Manifestation
Frontal bone	Rapid edema that may mask underlying fractures
Mandible	Tooth fractures, bleeding, limited motion of mandible
Maxilla	Segmental motion (instability) of maxilla and tooth fracture at socket
Nasal bone	Displacement of nasal bones, nosebleed *(epistaxis)*
Periorbital bone	Possible frontal sinus involvement, entrapment of ocular muscles
Zygomatic arch	Depression of cheek bone *(zygomatic arch)* and entrapment of ocular muscles

Specific treatment depends on the site and extent of the facial fracture and associated soft tissue injury. Immobilization or surgical stabilization may be needed. Maintain a patent airway and adequate nutrition throughout the recovery period.

Be sensitive about changes in appearance that may occur after facial fracture. Changes in appearance may be drastic. Edema and discoloration subside with time, but soft tissue injuries can cause permanent scarring.

Mandibular Fracture

Mandibular fracture may result from trauma to the face or jaw. Maxillary fractures may also occur, but they are less common than mandibular fractures. The mandibular fracture may be simple, with no bone displacement, or may involve loss of tissue and bone. The fracture may need immediate treatment to ensure the patient's survival. Long-term treatment is sometimes needed to restore satisfactory appearance and function.

Mandibular fractures may be done therapeutically to correct an underlying alignment problem *(malocclusion)* that cannot be adjusted by orthodontics alone. The mandible is resected during surgery and manipulated forward or backward to correct the occlusion problem.

Surgery for a mandibular fracture includes immobilization, usually by wiring the jaws *(intermaxillary fixation).* Internal fixation may be done with screws and plates. In a simple fracture with no loss of teeth, the lower jaw is wired to the upper jaw. Wires are placed around the teeth, and then cross-wires or rubber bands are used to hold the lower jaw tight against the upper jaw (Fig. 62.22). Arch bars may be placed on the maxillary and mandibular arches of the teeth. Vertical wires placed between the arch bars hold the jaws together. If teeth are missing or bone is displaced, other forms of fixation may be needed (e.g., metal arch bars in the mouth or insertion of a pin in the bone). Bone grafting may be needed. Immobilization is usually needed for only 4 to 6 weeks because the fractures often heal rapidly.

Nursing Management: Mandibular Fracture

Teach the patient before surgery about what is involved in the surgical procedure, how the face will look afterward, and changes caused by the surgery. Reassure the patient about the ability to breathe normally, speak, and swallow liquids. Hospitalization for respiratory monitoring is brief unless there are other injuries or problems.

FIG. 62.22 Intermaxillary fixation.
Courtesy R.A. Weinstein, Denver, CO.

Postoperative care focuses on a patent airway, oral hygiene, communication, pain management, and adequate nutrition. Two potential problems in the immediate postoperative period are airway obstruction and aspiration of vomitus. Because the patient cannot open the jaws, an airway must be maintained. Observe for signs of respiratory distress (e.g., dyspnea; changes in rate, quality, and depth of respirations). After surgery place the patient on the side with the head slightly elevated.

Tape a wire cutter or scissors (for rubber bands) to the head of the bed. Send it with the patient to all appointments and examinations away from the bedside. The wire cutter or scissors may be used to cut the wires or elastic bands in case of an emergency requiring access to the pharynx or lungs (e.g., cardiac arrest or respiratory distress). In the care plan include a picture with the appropriate wires to cut in an emergency. In some cases, cutting the wires may cause the entire facial and upper jaw structure to shift or collapse and worsen the problem. A tracheostomy or endotracheal tray should always be available.

If the patient begins to vomit or choke, try to clear the mouth and airway. Suction via the nasopharyngeal or oral route, depending on the extent of injury and type of repair. An NG tube can remove fluids

and gas from the stomach to help prevent vomiting and aspiration. The NG tube can later be used as a feeding tube. Antiemetics may be given. Teach the patient to clear secretions and vomitus.

Oral hygiene is very important. Teach the patient to remove food debris by rinsing the mouth often, especially after meals and snacks. Warm normal saline solution, water, or alkaline mouthwashes may be used. A syringe and soft irrigation catheter or a Water Pik may be effective for thorough oral cleansing. Inspect the mouth several times a day to see that it is clean. Use a tongue depressor to retract the cheeks. Keep the lips, corners of the mouth, and buccal mucosa moist. Cover any sharp edges of the wires with dental wax to prevent irritation of the buccal mucosa.

Communication may be a problem, especially in the early postoperative period. Establish an effective way of communicating before surgery (e.g., use of dry erase board, pad and pencil). Usually the patient can speak well enough to be understood, especially a few days after surgery.

Intake of adequate nutrients may be a challenge because the diet must be liquid. The patient easily tires of sucking through a straw or laboriously using a spoon. Work with the dietitian and patient to plan a diet with adequate calories, protein, and fluids. Liquid protein supplements may improve the patient's nutrition. The low-bulk, high-carbohydrate diet and intake of air through the straw contribute to constipation and gas. Ambulation, prune juice, and bulk-forming laxatives may help relieve these problems.

The patient is usually discharged with the wires in place. Encourage the patient to share feelings about the changes in appearance. Discharge teaching should include oral care, diet, how to handle secretions, how and when to use wire cutters or scissors, and when to notify the HCP about concerns and problems.

Amputation

An **amputation** is the removal of a body extremity by trauma or surgery. About 2 million Americans are living with limb loss.[25] About

185,000 amputations occur each year in the United States. Most amputations are done due to PVD, especially in older patients with diabetes. These patients often have peripheral neuropathy that progresses to deep ulcers and gangrene. Amputation in young people is usually due to trauma (e.g., motor vehicle crashes, farm-related injury). Battle injuries have affected over 1700 veterans since 2003, with several losing more than 1 limb.[26] Other common reasons for amputation include thermal injuries, tumors, osteomyelitis, and congenital limb disorders.

Diagnostic Studies

Diagnostic studies depend on the underlying reason for the amputation (Table 62.13). An increased white blood cell (WBC) count with abnormal differential may show infection. Vascular tests such as arteriography, Doppler studies, and venography give information about circulation in the extremity.

Interprofessional Care

If amputation is planned or elective, as for the patient with PVD, carefully assess the patient's general health. Chronic illnesses and infection must be managed before an amputation is done. Help the patient and caregiver understand the need for the amputation. Assure them that rehabilitation can help with quality of life. If the amputation is done emergently after trauma, patient management is physically and emotionally more complicated.

The goal of surgery is to preserve the greatest extremity length and function while removing all infected, pathologic, or ischemic tissue. Levels of amputation of upper and lower extremities are shown in Fig. 62.23. The type of amputation depends on the reason for the surgery. A closed amputation creates a weight-bearing *residual limb* (or stump). An anterior skin flap with dissected soft tissue padding covers the bony part of the residual limb. The skin flap is sutured posteriorly so that the suture line will not be in a weight-bearing area. Take special care to prevent accumulation of drainage, which can cause pressure

and harbor bacteria that may cause infection.

Disarticulation is an amputation done through a joint. A *Syme's amputation* is a form of disarticulation at the ankle. After an open amputation *(guillotine amputation),* the surface of the residual limb is left uncovered with skin. This type of surgery is generally done to control actual or potential infection. The wound is usually closed later by a second surgical procedure or closed by skin traction surrounding the residual limb.

TABLE 62.13 Interprofessional CareAmputation

Diagnostic Assessment

- History and physical examination
- Physical appearance of soft tissues
- Skin temperature
- Sensory function
- Quality of peripheral pulses
- Arteriography
- Venography
- Plethysmography (measures blood flow in the arms or legs)
- Transcutaneous ultrasonic Doppler recordings

Management

Medical

- Appropriate management of underlying disease
- Stabilization of trauma victim

Surgical

- Residual limb management
- Immediate or delayed prosthesis fitting

Rehabilitation

- Coordination of prosthesis-fitting and gait-training activities
- Coordination of muscle-strengthening and PT programs

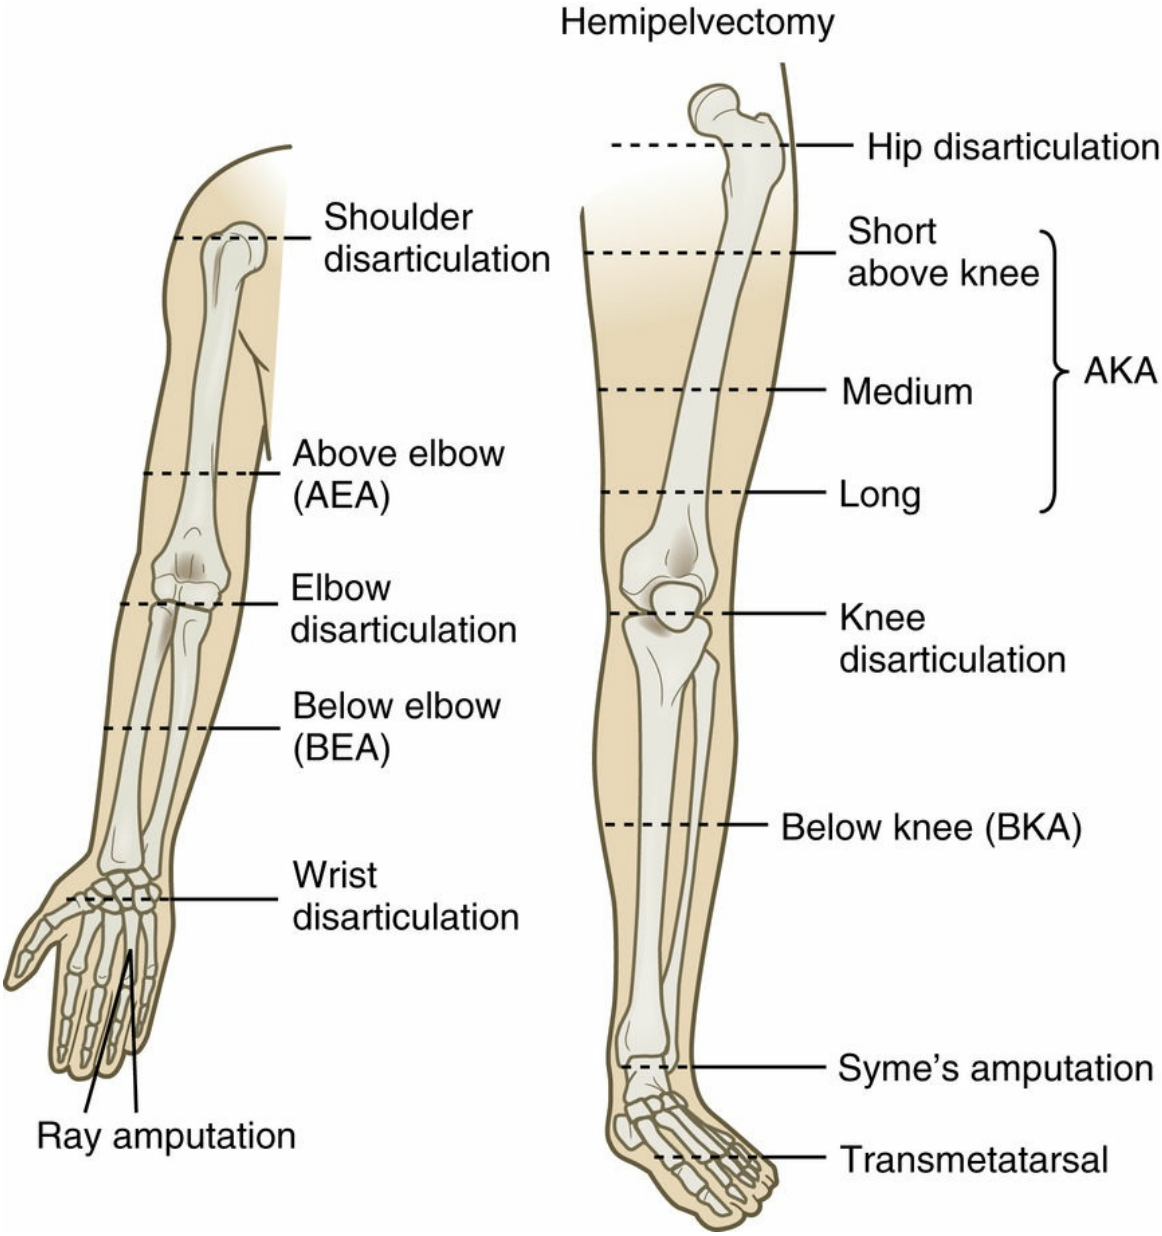

FIG. 62.23 Location and description of amputation sites of the upper and lower extremities. *AKA,* Above-the-knee amputation.

Nursing Management: Amputation

Nursing Assessment

Assess for any preexisting illnesses. Because most amputations are done for vascular problems, assessment of vascular and neurologic

condition is especially important (see Chapters 31 and 55).

Nursing Diagnoses

Nursing diagnoses for the patient with an amputation may include:

- Disturbed body image
- Impaired tissue integrity
- Chronic pain
- Impaired physical mobility

Planning

The overall goals are that the patient with an amputation will (1) have adequate relief from the underlying health problem, (2) have satisfactory pain management, (3) reach maximum rehabilitation potential (with the use of a prosthesis, if indicated), (4) cope with the body image changes, and (5) make satisfying lifestyle adjustments.

Nursing Implementation

Health Promotion

Control of illnesses, such as PVD, diabetes, chronic osteomyelitis, and pressure injuries, can eliminate or delay the need for amputation. Teach patients with these problems to carefully examine their lower extremities daily for signs of infection or skin breakdown. If the patient cannot do this, the caregiver should help. Teach the patient and caregiver to report changes in the feet or toes to the HCP. These include decreased or absent sensation, tingling, burning pain, cuts, or abrasions, and changes in skin color or temperature.

Review safety precautions for people taking part in recreational activities and potentially hazardous work. This responsibility is especially important for the occupational health nurse.

Acute Care

Reasons for amputation and the rehabilitation potential depend on a person's age, diagnosis, occupation, personality, resources, and support system. Be aware of the tremendous psychologic and social implications of amputation. Body image problems related to amputation often cause a patient to go through a grieving process. Use therapeutic communication to help the patient and caregiver through this process and develop a realistic attitude about the future.

Preoperative Care

Before surgery, reinforce information that the patient and caregiver have received about reasons for the amputation, proposed prosthesis, and mobility-training program. To meet the patient's educational needs, know the level of amputation, type of dressings to be applied, and type of prosthesis to be used. Teach the patient to perform upper extremity exercises, such as push-ups in bed or the wheelchair, to promote arm strength for crutch walking and gait training. Discuss general postoperative nursing care, including positioning, support, and residual limb care. If a compression bandage will be used after surgery, teach the patient about its purpose and how it will be applied. If immediate prosthesis use is planned, discuss general ambulation expectations.

Tell the patient that the amputated limb may feel like it is still present after surgery. This phenomenon, termed **phantom limb sensation**, occurs in many amputees. (Nursing management of phantom limb sensation is discussed in the next section.)

Postoperative Care

General care for the patient who had an amputation depends largely on the patient's age and general state of health and the reason for the amputation. Monitor patients who had an amputation due to a traumatic injury for posttraumatic stress disorder because they may have had no time to prepare or even take part in the decision to have a limb amputated.

Prevention and detection of complications are important after surgery. Carefully monitor the patient's vital signs. Assess dressings

for hemorrhage. Use sterile technique during dressing changes to reduce the risk for wound infection.

If an *immediate* postoperative prosthesis has been applied, carefully observe the surgical site. If excess bleeding occurs, notify the HCP at once. Keep a surgical tourniquet available for emergency use.

FIG. 62.24 A double amputee fitted with prostheses. Photo courtesy US Army.

The *delayed* prosthetic fitting may be the best choice for older adults, patients with infection, or patients who have had amputations above the knee or below the elbow (Fig. 62.24). Appropriate timing for the use of a prosthesis depends on satisfactory healing of the residual

limb and the patient's general condition. A temporary prosthesis may be used for partial weight bearing after sutures are removed. If there are no problems, the patient can bear full weight on a permanent prosthesis about 3 months after amputation.

Not all patients are candidates for prostheses. The seriously ill or debilitated patient may not have the upper body strength and energy needed to use a lower extremity prosthesis. Mobility with a wheelchair may be the most realistic goal for this patient.

Patients are often extremely worried about phantom limb sensation because they still perceive pain in the missing part of the limb. As recovery and ambulation progress, phantom limb sensation and pain usually subside. However, the pain may become chronic. The patient may have shooting, burning, or crushing pain as well as feelings of coldness, heaviness, and cramping,

Unfortunately, there is no one therapy for phantom limb sensation. Mirror therapy reduces symptoms in some patients (Fig. 62.25).[27] We do not know why looking in the mirror at the remaining limb would improve symptoms. The mirror is thought to give visual information to the brain, replacing sensory feedback expected from the missing limb. Mirror therapy may also improve patient function after a stroke.

Success of the rehabilitation program depends on the patient's physical and emotional health. Chronic illness and deconditioning can complicate rehabilitation. Physical and occupational therapy must be a central part of the patient's overall plan of care.

Flexion contractures may delay rehabilitation. The most common and debilitating contracture is hip flexion. Hip adduction contracture is rare. To prevent flexion contractures, have patients avoid sitting in a chair for more than 1 hour with hips flexed or having pillows under the surgical extremity. Unless contraindicated, patients should lie on their abdomen for 30 minutes 3 or 4 times each day and position the hip in extension while prone.

FIG. 62.25 Mirror therapy, a type of treatment that may reduce phantom limb sensation and pain.
US Navy photo courtesy Mass Communication Specialist Seaman Joseph A. Boomhower.

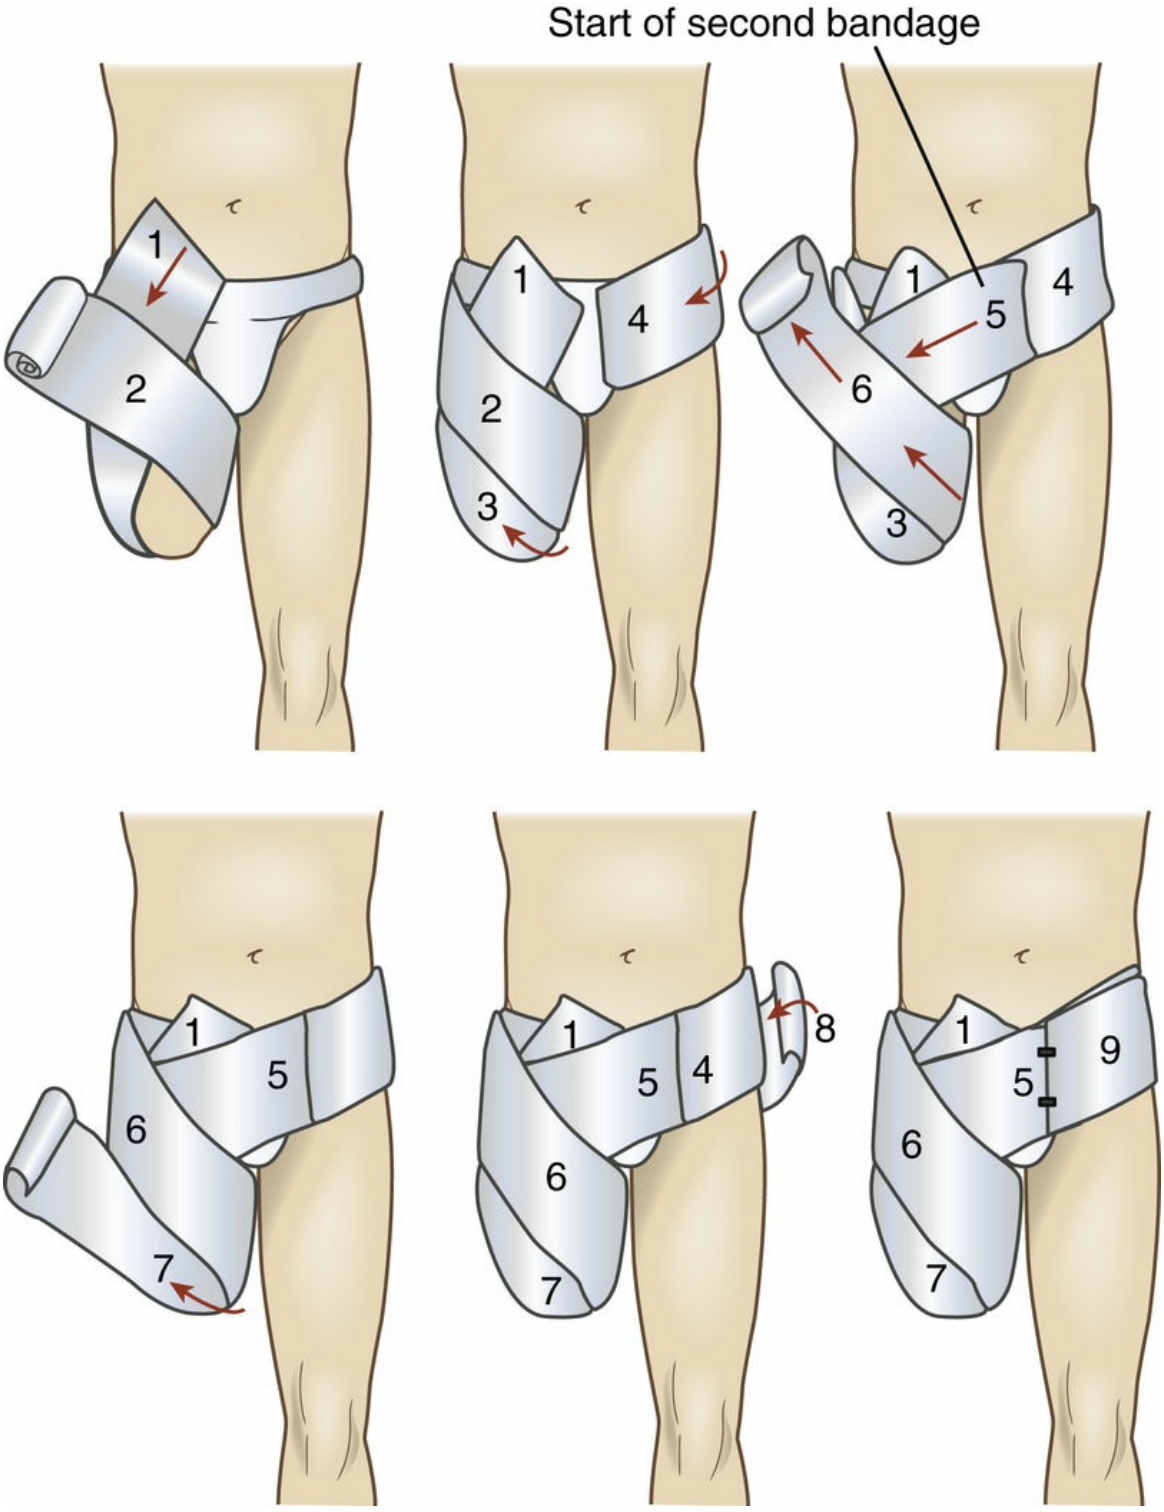

FIG. 62.26 Bandaging for the above-the-knee amputation residual limb. Figure-8 style covers progressive areas of the residual limb; 2 elastic wraps used.

Proper bandaging ensures the residual limb is shaped and molded

for eventual prosthesis fitting (Fig. 62.26). The HCP usually orders a compression bandage to be applied right after surgery to support soft tissues, reduce edema, hasten healing, and minimize pain. Compression also promotes residual limb shrinkage and maturation. This bandage may be an elastic roll applied to the residual limb or a residual limb shrinker, which is an elastic stocking that fits tightly over the residual limb.

TABLE 62.14 Patient & Caregiver TeachingLower Extremity Amputation

After lower extremity amputation, include the following instructions when teaching the patient and caregiver:

1. Inspect the residual limb daily for signs of skin irritation, especially redness, abrasion, and odor. Especially evaluate areas prone to pressure.
2. Stop using the prosthesis if irritation develops. Have the area checked before resuming use of the prosthesis.
3. Wash the residual limb thoroughly each night with warm water and bacteriostatic soap. Rinse thoroughly and dry gently. Expose the residual limb to air for 20 min.
4. Do not use lotions, alcohol, powders, or oil on residual limb unless prescribed by the HCP.
5. Wear only a residual limb sock in good condition and supplied by the prosthetist.
6. Change residual limb sock daily. Launder in mild soap, squeeze, lay flat to dry.
7. Use prescribed pain management techniques.
8. Perform ROM to all joints daily. Perform general strengthening exercises (including for upper extremities) daily.
9. Do not elevate residual limb on a pillow.
10. Lay prone with hip in extension for 30 min 3 or 4 times daily.

At first, the patient always wears the compression bandage except during PT and bathing. Remove and reapply the bandage several times daily. Take care to apply it snugly but not so tight as to interfere with circulation. Wash and change shrinker bandages daily. After the residual limb is healed, bandage it only when the patient is not wearing the prosthesis. Teach the patient to avoid dangling the residual limb over the bedside to decrease edema.

As the patient's overall condition improves, the HCP and physical therapist start and supervise an exercise program. Active ROM exercises for all joints should be started as soon as possible after surgery. To prepare for mobility, the patient should increase triceps and shoulder strength for lower limb support. The patient will need to learn to balance the altered body. The lost weight of an amputated limb requires adaptation of the patient's proprioception and coordination to prevent falls and injury.

Crutch walking starts as soon as the patient is physically able. Follow orders for weight bearing carefully to avoid injury to the skin flap and delay of tissue healing. Before discharge, teach the patient and caregiver about residual limb care, ambulation, contracture prevention, recognition of complications, exercise, and follow-up care (Table 62.14).

Ambulatory Care

When healing has occurred satisfactorily, and the residual limb is well molded, the patient is ready for prosthesis fitting. A prosthetist makes a mold of the residual limb and measures landmarks for creation of the prosthesis. The molded limb socket allows the residual limb to fit snugly into the prosthesis. The residual limb is covered with a stocking to ensure good fit and prevent skin breakdown. If the limb continues to shrink, causing a loose fit, a new socket has to be made. The patient may need to have the prosthesis adjusted to prevent rubbing and friction between the residual limb and socket. Excessive movement of a loose prosthesis can cause severe skin irritation, breakdown, and gait problems.

Artificial limbs become an integral part of the patient's changed

body image. Teach the patient to clean the prosthesis socket daily with mild soap and rinse thoroughly to remove irritants. Leather and metal parts of the prosthesis should not get wet. Encourage the patient to have regular maintenance on the prosthesis. Consider the condition of the patient's shoe. A badly worn shoe alters the gait and can damage the prosthesis.

Special Considerations in Upper Limb Amputation

Emotional implications of an upper limb amputation are often more devastating than for lower limb amputation. Despite technologic advances, we cannot replicate the movements and functional capacity of our hands with upper extremity prostheses.[28] The enforced dependency due to being 1-handed may be depressing and frustrating to the patient. Because most upper extremity amputations result from trauma, the patient likely had little time to adjust psychologically or be a part of the decision-making process.

Both immediate and delayed prosthetic fittings are possible for the below-the-elbow amputee. Prosthetic fitting is delayed for the above-the-elbow amputee. The usual functional prosthesis is the arm and hook. A cosmetic hand is available but has limited functional value. As with the lower limb prosthesis, patient motivation and perseverance are major factors contributing to a satisfactory outcome.

Evaluation

The expected outcomes are that the patient with an amputation will

- Accept changed body image and integrate changes into lifestyle
- Have no evidence of skin breakdown
- Have reduction or absence of pain
- Become mobile within limitations imposed by amputation

Gerontologic Considerations: Amputation

If a lower limb amputation has been done on an older adult, the patient's previous ability to ambulate may affect the extent of recovery. Using a prosthesis requires significant strength and energy for ambulation. For example, walking with a below-the-knee prosthesis requires 40% more energy than walking on 2 legs. An above-the-knee prosthesis requires 60% more. Older adults whose general health is weakened by disorders such as heart or lung disease may not be able to use a prosthesis. The patient's ability to ambulate may be limited. If possible, discuss these issues with the patient and caregiver before surgery so that realistic expectations can be set.

Common Joint Surgical Procedures

Surgery plays a vital role in the treatment and rehabilitation of patients with various joint problems. The goals of surgery are to relieve chronic pain, improve joint motion, correct deformity and misalignment, and remove diseased cartilage. If the joint problem is not corrected, contraction with permanent limitation of motion may occur. Limited joint motion can be noted on physical examination. Joint-space narrowing can be seen on x-rays.

Types of Joint Surgeries

Synovectomy

Synovectomy (removal of synovial membrane) is done to remove inflamed tissue that is causing unacceptable pain or limiting ROM in RA. A synovectomy is best done early in the disease process when there is minimal bone or cartilage destruction. Removing the thickened synovium does not cure RA but may relieve symptoms temporarily. Common sites for this surgery include the elbow, wrist, and fingers. Synovectomy in the knee is done less often because knee joint replacement is usually done.

Osteotomy

An **osteotomy** involves removing a wedge or slice of bone to restore alignment (joint and vertebral) and to shift weight bearing, thus relieving pain. Cervical osteotomy may be used to correct a kyphotic deformity in patients with ankylosing spondylitis. Halo vests and body jacket braces are worn until fusion occurs (3 to 4 months). Osteotomy is not effective in patients with inflammatory joint disease. However, femoral osteotomy may provide some pain relief and improve motion in select patients with hip osteoarthritis (OA). Tibial osteotomy also provides pain relief in some patients with knee instability or OA.[29]

Care of a patient who had an osteotomy is similar to that of a patient with ORIF of a fracture at a comparable site. Internal wires, screws and plates, bone grafts, or an external fixator usually fixes the bone in place.

Debridement

Debridement is the removal of debris, such as pieces of bone or cartilage *(loose bodies)* or osteophytes, from a joint using a fiberoptic arthroscope. This procedure is usually done on an outpatient basis on the knee or shoulder. A compression dressing is applied after surgery. Weight bearing is permitted after knee arthroscopy. Patient teaching includes monitoring for signs of infection, managing pain, and restricting activity for 24 to 48 hours.

Arthroplasty

Arthroplasty is the reconstruction or replacement of a joint to relieve pain, improve or maintain ROM, and correct deformity. Arthroplasty is most often done on patients with OA, RA, avascular necrosis, congenital deformities or dislocations, and other systemic problems. Types of arthroplasty include surgical reshaping of the bones of the joints, replacement of part of a joint (hemiarthroplasty), and total joint replacement. Around 1 million Americans have knee and hip

replacement surgery annually.[30] Arthroplasty is also available for elbows, shoulders, fingers, wrists, ankles, and feet.

Total Hip Arthroplasty

Total hip arthroplasty (THA), or a total hip replacement, provides significant relief of pain and improved function for patients with joint deterioration from OA, RA, and other conditions. THA is also used to treat hip fractures.

In THA, the prosthesis (implant) replaces the ball-and-socket joint formed by the upper shaft of the femur and pelvis (Fig. 62.27). Both the ball-and-socket components can be cemented in place with polymethyl methacrylate, which bonds to the bone. They may also be inserted without cement (cementless). Cementless THA may provide longer stability by enabling ingrowth of new bone tissue into the porous surface coating of the prosthesis. Cementless devices are recommended for younger, more active patients and patients with good bone quality so that bone ingrowth into the components can be readily achieved.

The nursing care for a patient who had a THA is discussed in the section on nursing management of a patient with a hip fracture on pp. 1463–1466.

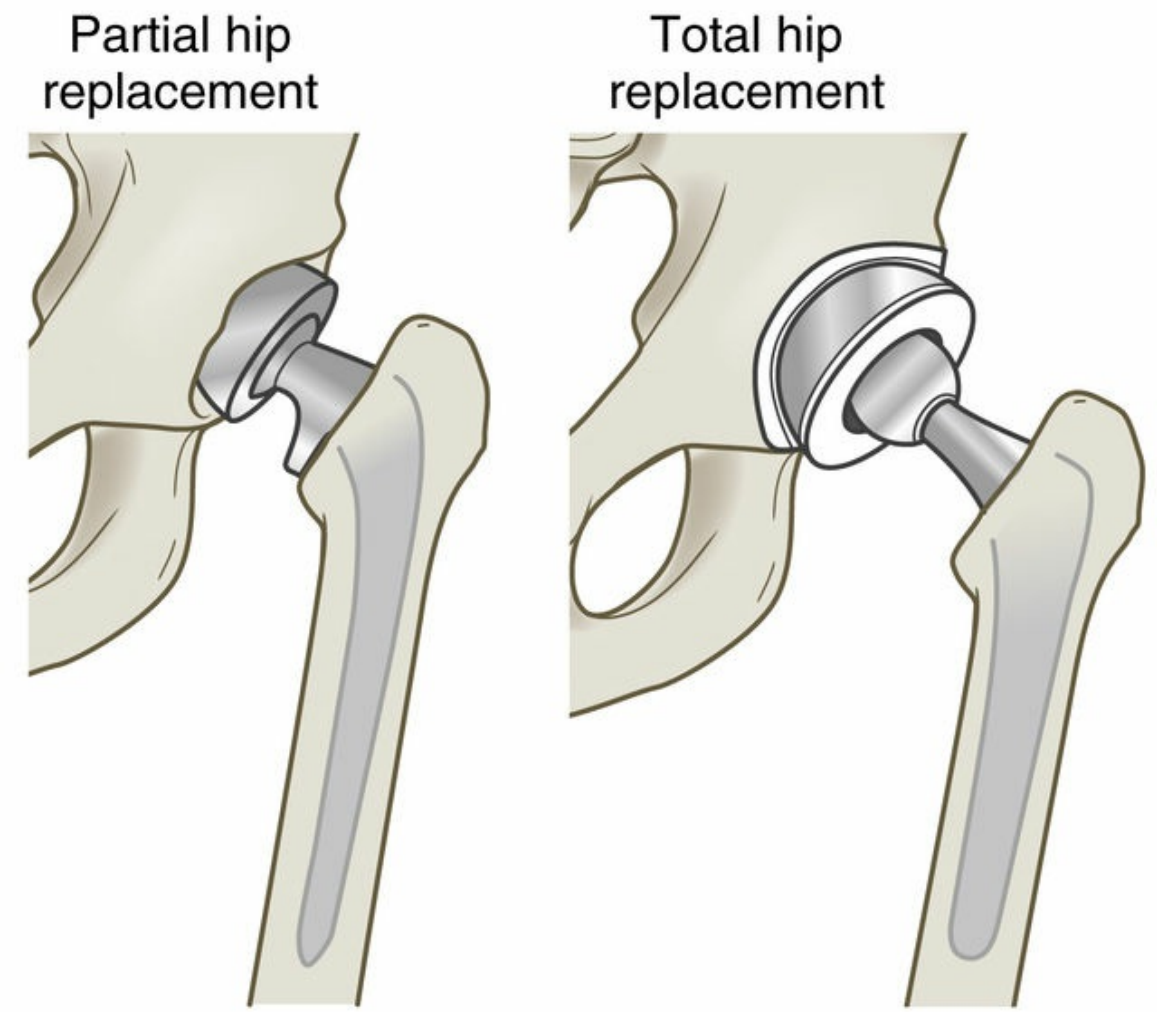

FIG 62.27 Types of hip replacements.

Informatics in Practice

Web-Based Knee and Hip Replacement Community

- Most hospitals offer preoperative classes for patients undergoing joint replacement surgery, but fewer resources are available after discharge.
- Online knee and hip replacement communities offer the patient a place to share experiences and receive social support. The patient is likely to feel relieved knowing that others have similar

experiences.

- Encourage patients to confirm any advice with the HCP before taking action.

Hip Resurfacing Arthroplasty

An alternative to hip replacement is hip resurfacing arthroplasty. It preserves and reshapes the femoral head (ball) rather than replacing it as in THA. The resurfaced femoral head is then capped by a metal prosthesis. Hip resurfacing may be an option for patients younger than age 60 with larger frames. A small number of patients will have a femoral neck fracture after hip resurfacing. This is not possible with THA. In addition, metal ions may be released into the bloodstream from the prosthesis. Patients may develop sensitivity or allergy to these ions.[31] Patients receiving a smaller femoral head (including many women) have a higher failure rate with a resurfaced implant when compared with patients receiving THA.

Knee Arthroplasty

Unrelieved pain and instability due to severe deterioration of the knee joint are the main reasons for total knee arthroplasty (TKA), or a total knee replacement (Fig. 62.28). Partial arthroplasty can be done on a patient with osteoarthritis limited to 1 part (compartment) of the knee.

Immediately after surgery a compression dressing may be used to immobilize the knee in extension. This dressing is removed before discharge. If the patient is unable to perform a straight-leg raise, a knee immobilizer or posterior plastic shell to maintain extension may be used during ambulation and at rest for about 4 weeks.

After surgery, emphasis is on pain management and PT. Managing pain is a primary nursing goal. Doing so decreases the patient's risk for complications and hastens the return to function.[32] Adequate analgesia should be ordered at discharge to allow the patient to continue with the exercise program. Effective pain management is key to achieving positive rehabilitation outcomes.

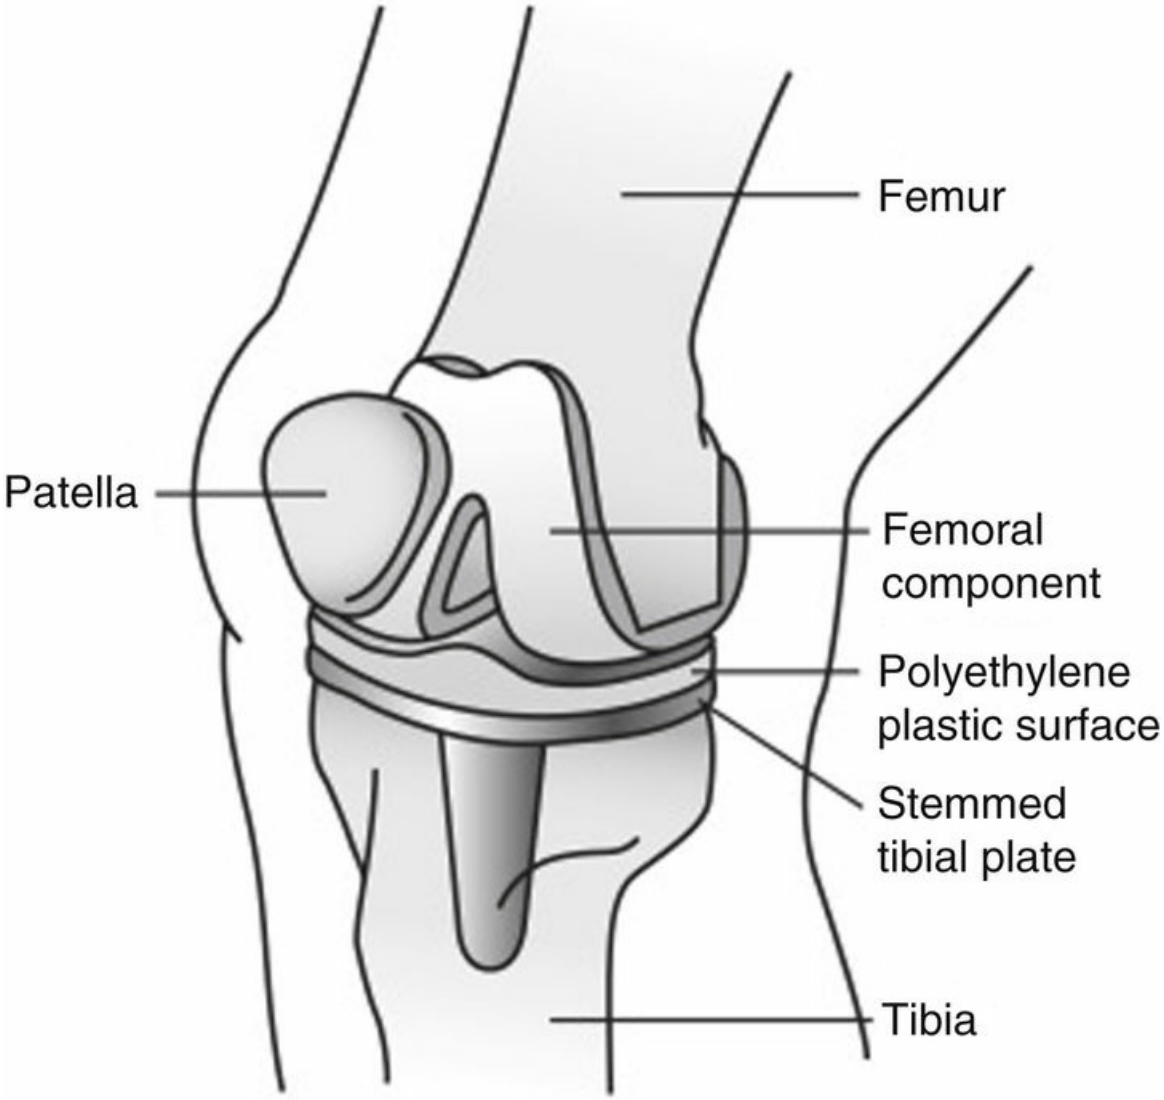

FIG. 62.28 Knee arthroplasty components. Up to 3 bone surfaces can be replaced in a total knee replacement.
Modified from Odom-Forren J: *Drain's perianesthesia nursing,* ed 7, St Louis, 2018, Elsevier.

PT begins early with isometric quadriceps setting. Therapy progresses to straight-leg raises and gentle ROM to increase muscle strength and obtain 90-degree knee flexion. Active flexion exercises or passive flexion exercises with a continuous passive motion (CPM) machine may promote joint mobility. Ambulation starts early and typically progresses to full weight bearing before discharge. An active home exercise program involves progressive ROM with muscle strengthening and flexibility exercises. After TKA, many older

patients with advanced OA show significant improvement in mobility, motor function tests, and ability to complete daily tasks.

Finger Joint Arthroplasty

A silicone rubber arthroplastic device is used to restore function in the fingers of the patient with RA. Ulnar deviation often causes severe functional limitations of the hand. The goal of hand surgery is primarily to restore function related to grasp, pinch, stability, and strength rather than to correct cosmetic deformity. Before surgery, the patient is taught hand exercises, including flexion, extension, abduction, and adduction of the fingers.

After surgery, a bulk dressing is placed and the hand is kept elevated. Perform regular neurovascular assessment and monitor for signs of infection. Success of the surgery depends largely on the postoperative treatment plan, which is usually implemented by an OT. After the dressing is removed, a guided splinting program is started. The patient is discharged with splints to use while sleeping and hand exercises to do at least 3 or 4 times a day for 10 to 12 weeks. Teach the patient to avoid lifting heavy objects.

Elbow and Shoulder Arthroplasty

Total replacement of elbow and shoulder joints is not as common as other forms of arthroplasty. Shoulder replacements are done in patients with severe pain because of RA, OA, avascular necrosis, or trauma. A specialized type of shoulder replacement, called a reverse total shoulder arthroplasty, may be done for pain and dysfunction caused by massive, irreparable, rotator cuff tears. Shoulder replacement is usually considered if the patient has adequate surrounding muscle strength and bone density. If joint replacement is needed for both elbow and shoulder, the elbow is usually done first because a severely painful elbow interferes with the shoulder rehabilitation program.

Most patients have no pain at rest or minimal pain with activity after elbow and shoulder arthroplasty. Functional improvements contribute to better hygiene and increased ability to perform ADLs.

However, rehabilitation is longer and more difficult than with other joint surgeries.

Ankle Arthroplasty

Total ankle arthroplasty (TAA) is indicated for RA, OA, trauma, and avascular necrosis. Although use of TAA is not widespread, it is a good alternative to fusion for treatment of severe ankle arthritis in certain patients. Available devices include several fixed-bearing devices and a mobile-bearing cementless prosthesis. This device more closely imitates natural ankle function.

Ankle fusion is often done over arthroplasty because the result is more durable. However, fusion leaves the patient with a stiff foot and the inability to change heel height. TAA achieves a more normal gait pattern. After surgery, the patient may not bear weight for 6 weeks. Teach the patient to elevate the extremity to reduce edema, take steps to prevent infection, and maintain immobilization as directed by the HCP.

Arthrodesis

Arthrodesis is the surgical fusion of a joint. This procedure is done only if articular surfaces are too severely damaged or infected to allow joint replacement or if reconstructive surgery fails. Arthrodesis relieves pain and provides a stable but immobile joint. The fusion is usually done by removing the articular hyaline cartilage and adding bone grafts across the joint surface. The affected joint must be immobilized until bone healing has occurred. Common areas fused are wrist, ankle, cervical spine, lumbar spine, and metatarsophalangeal (MTP) joint of the great toe.

Complications of Joint Surgery

Infection is a serious complication of joint surgery, especially joint replacement surgery. The most common causative organisms are gram-positive aerobic streptococci and staphylococci. Infection may

lead to pain and loosening of the prosthesis, generally requiring further surgery. Efforts to reduce infection include the use of specially designed self-contained operating suites, operating rooms with laminar airflow, and prophylactic antibiotic administration.

VTE is another potentially serious complication after joint surgeries, especially those involving the lower extremities. Provide prophylactic measures, such as anticoagulant drugs, use of intermittent pneumatic compression devices, and early ambulation. Assess patients for signs of VTE. VTE is discussed in Chapter 37.

Nursing and Interprofessional Management: Joint Surgery

Preoperative Management

The primary goal of preoperative assessment is to identify risk factors for postoperative complications so we can implement measures to promote optimal outcomes. A careful history includes (1) medical diagnoses and complications, such as diabetes and VTE; (2) pain tolerance and management preferences; (3) current functional level and expectations after surgery; (4) current social support; and (5) home care needs after discharge. The patient should be free from infection and acute joint inflammation.

Preoperative teaching about the expected hospital course and postoperative management at home is important for the patient and caregiver. Explain postoperative procedures, such as turning, deep breathing, use of bedpan and bedside commode, and use of an abductor pillow. Assure the patient that analgesia will be available. A preoperative PT visit allows practice of postoperative exercises and measurement for crutches or other assistive devices. Provide opportunities for practice with assistive devices.

If lower extremity surgery is planned, assess upper extremity muscle strength and joint function to determine the type of assistive devices needed for ambulation and ADL performance. Discuss ways to maximize the usefulness and longevity of the prosthesis. Patients

need to realize that recovery does not occur rapidly. Talking with other people who have had joint arthroplasty may help the patient better understand the reality of rehabilitation.

Discharge planning begins immediately. Discuss the duration of the hospital stay and the expected postoperative events so that the patient and caregiver can prepare. Discuss the safety and accessibility of the home environment (e.g., throw rugs, cords). Are the bathroom and bedroom on the first floor? Are door frames wide enough to accommodate a walker? Assess the patient's social support. Is a friend or family member available to help the patient at home? Will the patient need homemaker or meal services? The older patient may need to be discharged to a subacute or extended care facility for a few weeks to regain independent living skills.

Postoperative Management

Regularly perform neurovascular assessment postoperatively. Give ordered anticoagulant medication, analgesia, and parenteral antibiotics. Pain management strategies may include epidural or intrathecal analgesia, femoral nerve block, patient-controlled IV analgesia, and oral opioids or NSAIDs. Assess patient comfort often during the postoperative period. Monitor for postoperative complications. Nursing interventions for the patient having orthopedic surgery are presented in eNursing Care Plan 62.2 (available on the website for this chapter).

Assess ROM at regular intervals to facilitate the goal of improved functional performance. In general, the affected joint is exercised and ambulation is encouraged as early as possible to prevent complications of immobility. Specific protocols vary according to the patient, type of prosthesis, and HCP preference. Depending on the surgical approach, an abduction pillow may be used after THA.

The hospital stay after arthroplasty is about 3 days depending on the patient's course and need for PT. Some patients are discharged in 1 to 2 days. Some knee replacement surgeries are done at ambulatory surgical centers. Teach the patient to report complications, including infection (e.g., fever, increased pain, drainage) and dislocation of the

prosthesis (e.g., pain, loss of function, shortening or malalignment of an extremity).

PT and ambulation enhance mobility, build muscle strength, and reduce the risk for VTE. Prophylactic anticoagulant drugs should be given for at least 10 to 14 days.[20] Some patients need therapy for up to 35 days. If the patient is taking warfarin, therapy starts on the day of surgery and the INR and prothrombin times are measured daily. Therapy with LMWH (e.g., enoxaparin), apixaban, or rivaroxaban usually starts the morning after surgery.[33]

Case Study

Periprosthetic Hip Fracture and Revision Arthroplasty

© aronaze/iStock.com.

Patient Profile

M.C. is a 64-yr-old white man who has had both hips replaced (left 6 years ago, right 2 years ago). He has a history of hypothyroidism. He was admitted to the ED after tripping over a short retaining wall in his backyard while gardening. He landed on his right side.

Subjective Data

- Acute, severe pain in right hip, unable to bear weight on right leg
- Takes cholecalciferol (vitamin D_3) 1000 IU every day without calcium supplement. States calcium upsets his stomach

- Reports loss of about 30 lb in the last year through diet and exercise. Exercises 3 times a week
- Lives in multilevel house with his wife. Bedrooms are on the second level
- Has smoked ½ pack of cigarettes a day for the past 30 years
- Describes himself as “a very light social drinker”

Objective Data

- 5 ft, 9 in tall, 175 lb

Diagnostic Studies

- X-rays show periprosthetic right proximal femur fracture at the greater trochanter with loss of fixation in the femoral part of the THA
- Normal CBC, chest x-ray
- Serum calcium 8.1 mg/dL

Interprofessional Care

- Revision of femoral part of his right total hip replacement with open reduction of the femoral fracture and fixation with 3 wires
- IV hydromorphone (Dilaudid) 1 mg IV every 3 hr as needed

- Cefazolin 1 gram IV every 8 hr for 24 hr
- Enoxaparin (Lovenox) 40 mg subcutaneous daily for 4 wk
- Calcium citrate 600 mg plus 800 IU vitamin D orally daily
- Levothyroxine (Synthroid) 125 mcg orally daily
- PT for transfers, gait, and stair training
- Occupational therapy for ADLs training
- Discharge planning based on mobility limitations and need for continued PT and OT

Discussion Questions

1. ***Patient-Centered Care:*** How do M.C.'s previous total joint

surgeries affect his recovery after this surgery?
2. ***Priority Decision:*** As you plan care for M.C., what are the perioperative priority nursing interventions?
3. What are the most likely postoperative complications M.C. could develop?
4. In considering M.C.'s patient profile, what issues can you identify that may affect his bone healing?
5. ***Priority Decision:*** What are the priority assessments that should be done prior to discharge?
6. ***Collaboration:*** What is the interprofessional team's top priority at this time for M.C.?
7. ***Quality Improvement:*** What outcomes would indicate interprofessional care was effective?
8. ***Safety:*** What safety precautions should be considered for M.C.?
9. ***Evidence-Based Practice:*** Why is satisfactory pain management an important postoperative nursing goal for M.C.?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse suspects an ankle sprain when a patient at the urgent care center describes
   a. being hit by another soccer player during a game.
   b. having ankle pain after sprinting around the track.
   c. dropping a 10-lb weight on his lower leg at the health club.
   d. twisting his ankle while running bases during a baseball game.

2. A patient with a humeral fracture is returning for a 4-week checkup. The nurse explains that initial evidence of healing on x-ray is indicated by
   a. formation of callus.
   b. complete bony union.
   c. hematoma at the fracture site.
   d. presence of granulation tissue.
3. A patient with a comminuted fracture of the tibia is to have an open reduction with internal fixation (ORIF) of the fracture. The nurse explains that ORIF is indicated when
   a. the patient is unable to tolerate prolonged immobilization.
   b. the patient cannot tolerate the surgery for a closed reduction.
   c. other nonsurgical methods cannot achieve adequate alignment.
   d. a temporary cast would be too unstable to provide normal mobility.
4. The nurse suspects a neurovascular problem based on assessment of
   a. exaggerated strength with movement.
   b. increased redness and heat below the injury.
   c. decreased sensation distal to the fracture site.
   d. purulent drainage at the site of an open fracture.
5. A patient with a stable, closed humeral fracture has a temporary splint with bulky padding applied with an elastic bandage. The nurse notifies the provider of possible early compartment syndrome when the patient has

a. increasing edema of the limb.
b. muscle spasms of the lower arm.
c. bounding pulse at the fracture site.
d. pain when passively extending the fingers.

6. A patient with a pelvic fracture should be monitored for
a. changes in urine output.
b. petechiae on the abdomen.
c. a palpable lump in the buttock.
d. sudden increase in blood pressure.

7. The nurse teaches the patient with an above-the-knee amputation that the residual limb should not be routinely elevated because this position promotes
a. hip flexion contracture.
b. clot formation at the incision.
c. skin irritation and breakdown.
d. increased risk for wound dehiscence.

8. A patient with osteoarthritis is scheduled for total hip arthroplasty. The nurse explains the purpose of this procedure is to *(select all that apply)*
a. fuse the joint.
b. replace the joint.
c. prevent further damage.
d. improve or maintain ROM.
e. decrease the amount of destruction in the joint.

9. A patient is scheduled for total ankle replacement. The nurse should tell the patient that after surgery he should

avoid

a. lifting heavy objects.

b. sleeping on the back.

c. abduction exercises of the affected ankle.

d. bearing weight on the affected leg for 6 weeks.

1. d, 2. a, 3. c, 4. c, 5. d, 6. a, 7. a, 8. b, d, 9. d

Musculoskeletal Problems

Diane Ryzner

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of osteomyelitis.
2. Distinguish among the types, pathophysiology, clinical manifestations, and interprofessional management of bone cancer.
3. Distinguish between the causes and characteristics of acute and chronic low back pain.
4. Explain the conservative and surgical treatment of intervertebral disc damage.
5. Describe the postoperative nursing management of a patient who has undergone vertebral disc surgery.
6. Discuss the etiology and nursing management of common foot disorders.
7. Describe the etiology, pathophysiology, clinical manifestations, and nursing and interprofessional management of osteomalacia, osteoporosis, and Paget's disease.

Conceptual Focus

Functional Ability
Mobility
Pain
Safety

We were made to move! This chapter reviews a variety of acute and chronic musculoskeletal problems unrelated to trauma that affect the musculoskeletal system. These include osteomyelitis, bone cancer, foot disorders, back pain, and metabolic bone diseases. These

problems can lead to changes in mobility that affect almost every system in the body. They are a common source of pain and physical limitations that restrict the ability to fully take part in activities of daily living (ADLs), leading to disability. The nurse plays a key role in assessing pain and functional ability and initiating interventions to prevent injury and maintain mobility.

Osteomyelitis

Etiology and Pathophysiology

Osteomyelitis is a severe infection of the bone, bone marrow, and surrounding soft tissue. Although *Staphylococcus aureus* is the most common cause of infection, a variety of pathogens can cause osteomyelitis (Table 63.1).[1]

Infecting microorganisms can invade by indirect or direct entry. *Indirect entry* (hematogenous) is usually associated with infection with 1 microorganism. Indirect injury accounts for only 20% of all cases. It most often affects children younger than 17 years. Risk factors in adults are older age, debilitation, hemodialysis, sickle cell disease, and IV drug use. The vertebrae are the most common site of infection in adults.[2]

Direct entry osteomyelitis most often affects adults. It can occur when an open wound (e.g., penetrating wounds, fractures, surgery) allows microorganisms to enter the body. Osteomyelitis also may be related to a foreign body, such as an implant or an orthopedic prosthetic device (e.g., plate, total joint prosthesis). It may occur in the feet of patients with diabetes or vascular disease–related ulcers or in the hips or sacrum near a pressure injury. More than 1 microorganism is usually involved.[1]

After entering the blood, microorganisms grow and pressure increases because of the nonexpanding nature of most bone. This increasing pressure eventually leads to ischemia and vascular compromise of the periosteum. The infection spreads through the bone cortex and marrow cavity, obstructing blood flow and causing

and necrosis.

Table 63.1 Organisms Causing Osteomyelitis

Organism	Predisposing Problem
Staphylococcus aureus	Pressure injury, penetrating wound, open fracture, orthopedic surgery, disorders with vascular insufficiency (e.g., diabetes, atherosclerosis)
Staphylococcus epidermidis	Indwelling prosthetic devices (e.g., joint replacements, fracture fixation devices)
Streptococcus viridans	Abscessed tooth, gingival disease
Escherichia coli	Urinary tract infection
Mycobacterium tuberculosis	Tuberculosis
Neisseria gonorrhoeae	Gonorrhea
Pseudomonas	Puncture wounds, IV drug use
Salmonella	Sickle cell disease
Fungi, mycobacteria	Immunocompromised host

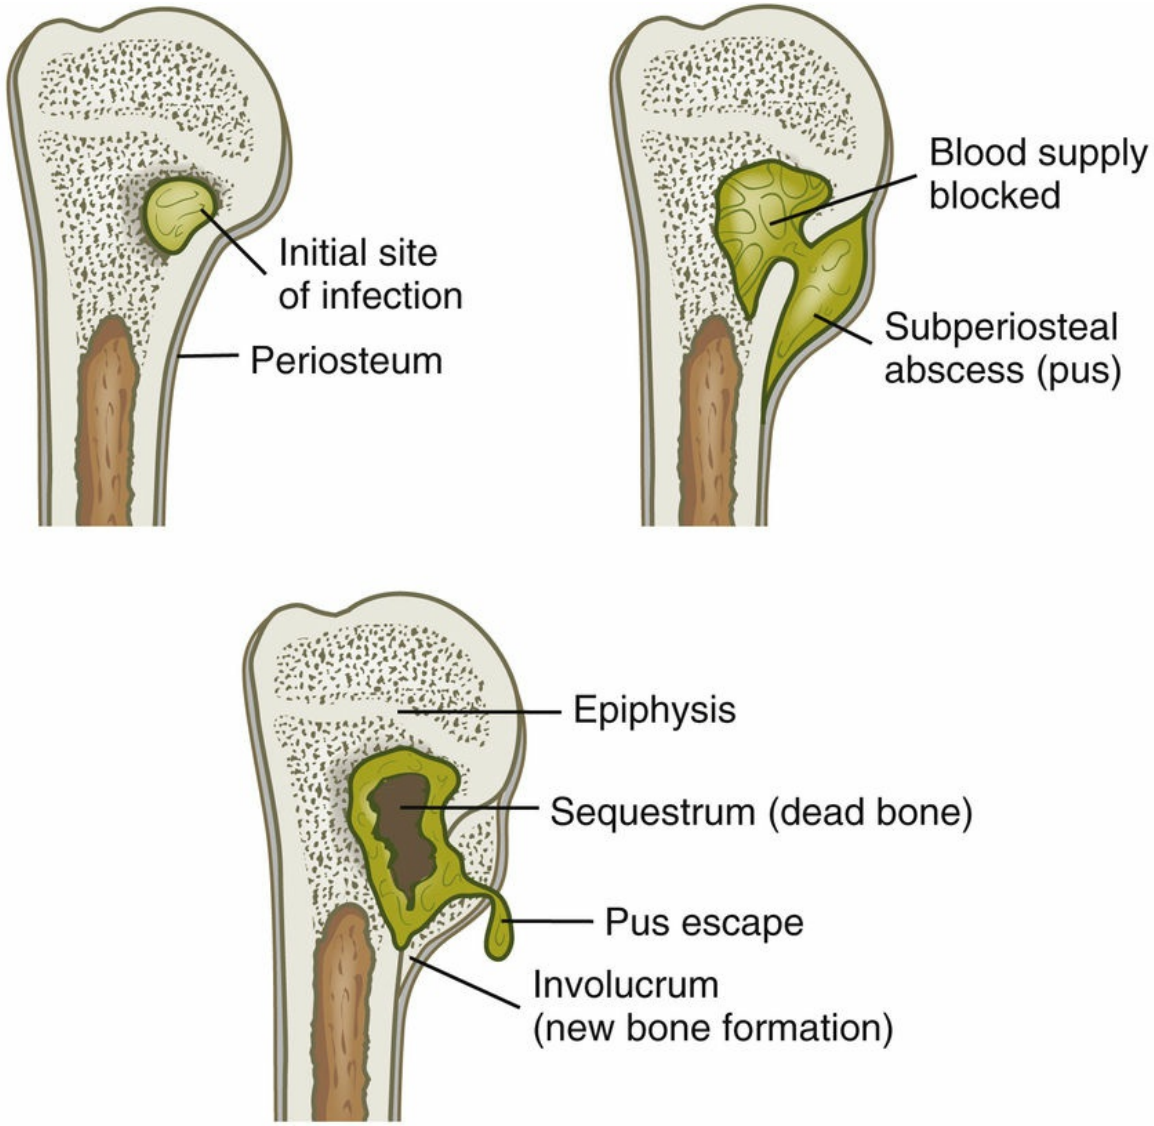

FIG. 63.1 Development of osteomyelitis infection with involucrum and sequestrum.

Bone death occurs due to ischemia. The area of dead bone eventually separates from the surrounding living bone, forming *sequestra.* The part of the periosteum that continues to have a blood supply forms new bone called *involucrum* (Fig. 63.1). Antibiotics or white blood cells (WBCs) have difficulty reaching the sequestrum through the blood. Thus sequestrum may become a reservoir for microorganisms that spread to other sites, including the lungs and brain. If the sequestrum does not resolve or is not debrided surgically, a sinus tract may develop. Chronic, purulent cutaneous drainage from

the tract results.

Clinical Manifestations and Complications

Acute osteomyelitis refers to the initial infection or an infection of less than 1 month in duration. Local manifestations of acute osteomyelitis include constant bone pain that worsens with activity and is unrelieved by rest; swelling, tenderness, and warmth at the infection site; and restricted movement of the affected part. Systemic manifestations include fever, night sweats, chills, restlessness, nausea, and malaise. Later signs include drainage from cutaneous sinus tracts or the fracture site.

FIG. 63.2 Resection of femur due to osteomyelitis.
From Thibodeau GA, Patton KT: *The human body in health and disease,* ed 5, St Louis, 2010, Mosby.

Chronic osteomyelitis refers to a bone infection that lasts longer than 1 month or an infection that did not respond to initial antibiotic treatment. Chronic osteomyelitis may be a continuous, persistent problem (a result of inadequate acute treatment) or a process of exacerbations and remissions (Fig. 63.2). Systemic manifestations are lessened. Local signs of infection become more common, including

constant bone pain and swelling and warmth at the infection site. Over time, granulation tissue turns to scar tissue. The avascular scar tissue is an ideal site for continued microorganism growth because it cannot be penetrated by antibiotics.

Long-term, and mostly rare, complications of osteomyelitis include septicemia, septic arthritis, pathologic fractures, and amyloidosis.

Diagnostic Studies

Bone or soft tissue biopsy is the definitive way to identify the causative agent. The patient's blood and wound cultures are often positive. Increased WBC count and erythrocyte sedimentation rate (ESR) may occur. High C-reactive protein (CRP) may occur with acute infection. Signs of osteomyelitis usually do not appear on x-rays until 2 to 4 weeks after the initial clinical symptoms. By this time, the disease will have progressed. Compared to x-rays, CT scan may be more helpful in assessing the extent of infection. In the acute phase, MRI may be more sensitive than CT in detecting bone marrow edema, which is an early sign of osteomyelitis. Radionuclide bone scans (technetium-99m) also show abnormalities earlier than x-rays. A WBC scan (indium-111–labeled cells) may help pinpoint the area of infection.[2]

Interprofessional Care

Aggressive, prolonged IV antibiotic therapy is the treatment of choice for acute osteomyelitis if bone ischemia has not yet occurred. Cultures or a bone biopsy should be done, if possible, before starting drug therapy. Any related soft tissue abscess or ulceration often needs surgical debridement or drainage.

IV antibiotic therapy starts in the hospital and then continues at home for 4 to 6 weeks. A few persons need therapy for 3 to 6 months. Patients may be discharged to home care or a skilled nursing facility so the antibiotics can be given through a central venous access device (CVAD). (CVADs are discussed in Chapter 16.) A variety of antibiotics are used, depending on the culture results and likelihood of

resistance. These include oxacillin, nafcillin, clindamycin, vancomycin, ceftriaxone, cefazolin, ceftazidime, gentamicin, and linezolid.

Drug Alert

Gentamicin

- Assess patient for dehydration before starting therapy.
- Ensure renal function testing is done before starting therapy, especially in older patients.
- Monitor peak and trough blood levels to achieve therapeutic effect and minimize renal and inner ear toxicity.
- Teach patient to notify HCP if any vision, hearing, or urinary problems develop.

Treatment of chronic osteomyelitis includes (1) surgical removal of the poorly perfused tissue and dead bone and (2) extended use of antibiotics. In adults with chronic osteomyelitis, oral therapy with a fluoroquinolone (e.g., ciprofloxacin [Cipro]) for 6 to 8 weeks may be prescribed instead of IV antibiotics. Oral antibiotics also may be given for 4 to 8 weeks after acute IV therapy is done to ensure the infection is resolved. The patient's response to drug therapy is monitored through bone scans and ESR testing.

Acrylic bead chains containing antibiotics may be implanted to help combat the infection. After debridement of the dead, infected tissue, a suction irrigation system may be inserted, and the wound closed. Intermittent or constant irrigation of the area with antibiotics may be used. Another option for wound management is negative-pressure wound therapy (discussed in Chapter 11). Casts or braces may be applied to protect the limb or the surgical site.

Hyperbaric O_2 may be given as an adjunct therapy in refractory cases of chronic osteomyelitis. It stimulates new blood growth and healing in the infected tissue (see p. 167 in Chapter 11).

If an orthopedic prosthetic device is the source of chronic infection, it must be removed. Muscle flaps or skin grafts provide wound coverage over the dead space (cavity) in the bone. Bone grafts may help to restore blood flow. However, flaps or grafts should never be placed in the presence of active or suspected infection.

Amputation of the extremity may be needed if bone destruction is extensive. Amputation should improve quality of life and may save the patient's life if systemic complications are developing.

Nursing Management: Osteomyelitis

Nursing Assessment

Subjective and objective data that should be obtained from a person with osteomyelitis are outlined in Table 63.2.

Nursing Diagnoses

Nursing diagnoses for the patient with osteomyelitis may include:

- Acute pain
- Impaired physical mobility
- Lack of knowledge

TABLE 63.2 Nursing AssessmentOsteomyelitis

Subjective Data Important Health Information
Past health history: Bone trauma, open fracture, open or puncture wounds, other infections (e.g., streptococcal sore throat, bacterial pneumonia, sinusitis, skin or tooth infection, chronic urinary tract infection)

Medications: Analgesics or antibiotics
Surgery or other treatments: Bone surgery

Functional Health Patterns

Health perception–health management: IV drug and alcohol use. Malaise
Nutritional-metabolic: Anorexia, weight loss. Chills
Activity-exercise: Weakness, paralysis, muscle spasms around affected area
Cognitive-perceptual: Local tenderness over affected area, increased pain with movement of affected area
Coping–stress tolerance: Irritability, withdrawal, dependency, anger

Objective Data
General

Restlessness. High, spiking temperature. Night sweats

Integumentary

Diaphoresis. Erythema, warmth, edema at site of infection

Musculoskeletal

Restricted movement; wound drainage. Spontaneous fracture

Possible Diagnostic Findings

Leukocytosis, positive blood and/or wound cultures, ↑ ESR.

Presence of sequestrum and involucrum on x-rays, radionuclide bone scans, CT, and MRI

Additional information on nursing diagnoses and interventions for the patient with osteomyelitis can be found in eNursing Care Plan 63.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with osteomyelitis will (1) have satisfactory pain and fever management, (2) not have any complications associated with osteomyelitis, (3) adhere to the treatment plan, and (4) maintain a positive outlook on the outcome of the disease.

Nursing Implementation

Health Promotion

Control of other current infections (e.g., urinary or respiratory tract, pressure injuries) is important in preventing osteomyelitis. Persons at risk for osteomyelitis are those who are immunocompromised or have diabetes, orthopedic prosthetic implants, or vascular insufficiency. Teach the at-risk patient about the local and systemic signs of osteomyelitis. Encourage the patient to contact the HCP about bone pain, fever, swelling, and restricted limb movement so that treatment can be started. Teach caregivers about their role in monitoring the patient's health.

Acute Care

Some immobilization of the affected limb (e.g., splint, traction) is usually needed to decrease pain and reduce risk for further injury. Carefully handle the limb and avoid undue manipulation. This may increase pain and cause a pathologic fracture. Assess the patient's pain. Muscle spasms may cause minor to severe pain. Nonsteroidal antiinflammatory

Nursing Management

Caring for the Patient With Osteomyelitis

- Give IV antibiotics as ordered.
- Assess wound for signs of worsening infection.
- Teach patient and caregiver about antibiotic side effects and length of treatment, signs and symptoms of worsening infection, and use of hyperbaric O_2 if ordered.
- Assess for muscle spasms and give muscle relaxant as ordered. Assess patient response.
- Assess pain intensity and give analgesics as ordered. Assess patient response.
- Handle affected limb carefully to decrease pain and additional injury.
- Assess neurovascular condition of affected limb and immediately inform HCP of significant changes.
- Oversee UAP:
    - Handle affected limb carefully based on RN instruction.
    - Help patient with passive ROM of adjacent joints and active ROM exercises of unaffected limb.
    - Notify RN about patient reports of pain, tingling, or decreased sensation in the affected extremity.

Collaborate With Physical Therapist

- Assess patient's current mobility and need for aid.
- Teach safe ambulation with assistive device based on patient's weight-bearing restrictions.
- Establish exercise plan and teach patient to perform exercises safely.

- Coordinate PT so that patient can receive timely analgesia.
- Discuss home environment with patient and identify modifications to promote recovery (e.g., stair training, bed placement on first level).

Collaborate With Occupational Therapist

- Assess impact of patient's condition on ability to perform ADLs.
- Teach patient use of assistive devices (e.g., long-handled reacher, shoe donner) to promote self-care while maintaining activity restrictions.

drugs (NSAIDs), opioid analgesics, and muscle relaxants may be given. Encourage nondrug approaches to pain management (e.g., guided imagery, relaxation breathing) (see Chapter 6).

Dressings are used to absorb drainage from wounds and debride dead tissue from the wound bed. These include dry, sterile dressings; dressings saturated in saline or antibiotic solution; wet-to-dry dressings; and dressings applied with negative-pressure wound therapy. Sterile technique is essential when changing the dressing. Handle soiled dressings carefully to prevent transfer of bacteria to other areas of the wound. Discard dressings appropriately to prevent spread of infection to other patients.

The patient is often placed on bed rest in the early stages of acute infection. Good body alignment and frequent position changes promote comfort and prevent complications related to immobility. Flexion contracture of the affected lower extremity is common as the patient often positions the leg in a flexed position to promote comfort. Footdrop can develop quickly due to Achilles tendon contracture if the foot is not supported in a neutral position by a splint or boot. A tight splint or dressing may compress and injure the peroneal nerve.

Teach the patient the possible adverse and toxic reactions associated with prolonged high-dose antibiotic therapy. These reactions include hearing deficit, impaired renal function, and neurotoxicity (e.g., limb

weakness or numbness, cognitive changes, vision changes, headache, behavioral problems). Reactions associated with cephalosporins (e.g., cefazolin) include hives, severe or watery diarrhea, blood in stools, and throat or mouth sores.

Tendonitis or tendon rupture (especially the Achilles tendon) can occur with use of fluoroquinolones (e.g., ciprofloxacin). Monitor peak and trough blood levels of most antibiotics to avoid adverse effects. Lengthy antibiotic therapy can cause an overgrowth of *Candida albicans* and *Clostridium difficile* in the genitourinary (GU) and gastrointestinal (GI) tracts, especially in immunosuppressed and older adult patients. Teach the patient to report any changes in the oral cavity (e.g., whitish yellow, curdlike lesions) or the GU tract (e.g., perianal itching, discharge).

Check Your Practice

Your patient on the orthopedic unit is a 22-yr-old man who was in a serious all-terrain vehicle accident in a remote area 4 days ago. He is now slowly recovering from his head injury and surgical repair of an open fracture of the femur. Yesterday, he was diagnosed with acute osteomyelitis. He is very angry and at times disoriented. When you try to assess his leg, he yells at you, "It hurts. Leave it alone!"

- What are your priorities of care?
- What signs and symptoms would suggest the patient's condition is worsening?

The patient and caregivers may be anxious and discouraged because of the serious nature of osteomyelitis, the uncertainty of the outcome, and the long, costly treatment. Continued psychologic and emotional support is an integral part of nursing management.

Ambulatory Care

IV antibiotics can be given to the patient in a skilled nursing facility or

home setting. If at home, teach the patient and caregiver how to manage the CVAD. Review how to administer the antibiotic and reinforce the need for follow-up laboratory testing. Stress the importance of continuing to take the full course of antibiotics prescribed, even after symptoms have improved.

Dressing changes are often needed if the patient has an open wound. The patient and caregiver may need supplies and instruction for completing the dressing change. If the osteomyelitis becomes chronic, the patient needs continued physical and psychologic support.

Evaluation

The expected outcomes are that the patient with osteomyelitis will

- Have satisfactory pain management
- Adhere to the recommended treatment plan
- Show a consistent increase in mobility and range of motion

Bone Tumors

Primary bone tumors, both benign and malignant, are rare in adults. They account for only about 3% of all tumors. Metastatic bone cancer, in which cancer has spread from another site, is a more common problem.

Benign Bone Tumors

Benign bone tumors are more common than primary malignant tumors. The main types of benign bone tumors are osteochondroma, osteoclastoma, and enchondroma (Table 63.3). They are often removed surgically.

Osteochondroma

Osteochondroma is the most common primary benign bone tumor. It is characterized by an overgrowth of cartilage and bone near the end of the bone at the growth plate. They most often occur in the pelvis, scapula, or long bones of the leg.

Manifestations include a painless, hard, immobile mass; shorter-than-normal height for age; soreness of muscles close to the tumor; one leg or arm longer than the other; and pressure or irritation with exercise. Some may be asymptomatic. Diagnosis is confirmed using x-ray, CT scan, and MRI.

No treatment is needed for asymptomatic osteochondroma. Patients should have regular screening examinations to detect progression to cancer as soon as possible. If the tumor is causing pain or neurologic manifestations because of compression, surgical removal is usually done.

Malignant Bone Tumors

A **sarcoma** is a malignant tumor that develops in bone, muscle, fat, nerve, or cartilage. The most common types of sarcomas are osteosarcoma, chondrosarcoma, and Ewing's sarcoma (Table 63.3). In 2018, 3450 new cases of bone and joint cancer are expected in the United States, with an estimated 1590 deaths.[3] Primary malignant tumors occur most often during childhood and young adulthood. They cause bone destruction and have rapid metastasis.

Osteosarcoma

Osteosarcoma is an extremely aggressive primary bone cancer that rapidly spreads to distant sites. It usually occurs in the pelvis or metaphyseal region of the long bones of extremities, especially in the distal femur, proximal tibia, and proximal humerus (Fig. 63.3, *A*). Osteosarcoma is the most common bone cancer affecting children and young adults. It can occur in older adults, but not as often. It is most often associated with Paget's disease (discussed on p. 1495) and prior radiation.

The gradual onset of pain and swelling in the affected bone are the most common manifestations. The pain may be worse at night and increase with activity. A minor injury does not cause the cancer but may bring it to medical attention. Metastasis is present in 10% to 20% of people at the time of diagnosis.

Diagnosis is confirmed from tissue biopsy, increased serum alkaline phosphatase and calcium, x-ray, CT or PET scans, and MRI.

Preoperative chemotherapy may be used to decrease tumor size before surgery. Limb salvage procedures are usually considered if a clear (no cancer present) 6- to 7-cm margin surrounds the lesion. Limb salvage is usually not possible if the patient has major nerve or blood vessel involvement, pathologic fracture, infection, or extensive muscle involvement.

The use of adjunct chemotherapy after amputation or limb salvage has increased the 5-year survival rate to 70% in people without metastasis. Chemotherapy includes combinations of methotrexate, doxorubicin, cisplatin, ifosfamide, cyclophosphamide, and etoposide.[4]

Metastatic Bone Cancer

The most common type of malignant bone tumor occurs because of spread *(metastasis)* from a primary tumor at another site. Common primary sites include breast, colon, prostate, lungs, kidney, and thyroid.[5] Metastatic cancer cells travel from the primary tumor to the bone via the lymph and blood supply. Metastatic bone lesions often occur in the spine, ribs, or pelvis.[5] Pathologic fractures at the site of metastasis are common because the bone is weakened. High serum calcium occurs as damaged bones release calcium.

TABLE 63.3 Types of Primary Bone Tumors

Types	Description
Benign	
Enchondroma	• Intramedullary cartilage tumor usually found in cavity of a single hand or foot bone • Rarely transforms to cancer • If tumor becomes painful, surgical resection is done • Peak incidence in people ages 10–20 yr
Osteochondroma	• Most common benign bone tumor • Often found in pelvis, scapula, or metaphyseal part of long bones • Occurs most often in people ages 10–25 yr • May transform to cancer (chondrosarcoma)
Osteoclastoma (giant cell tumor)	• Arises in cancellous ends of arm and leg bones • About 10% are locally aggressive and may spread to lungs • High rate of local recurrence after surgery and chemotherapy
Malignant	
Chondrosarcoma	• Most often occurs in cartilage in arm, leg, and pelvic bones of adults ages 50–70 yr • Can arise from benign bone tumors (osteochondromas) • Wide surgical resection is typically done as tumor rarely responds to radiation and chemotherapy • Survival rate depends on stage, size, and grade of tumor (Fig. 63.3, *B*)
Ewing's sarcoma	• Develops in medullary cavity of pelvis and long bones, especially femur, humerus, and tibia • Usually occurs in children and teenagers • Use of wide surgical resection, radiation, and chemotherapy has improved 5-yr survival rate to 60%
Osteosarcoma	• Most common primary bone cancer • Occurs mostly in males ages 10–25 • Most often in pelvis or bones of arms, legs (Fig. 63.3, *A*)

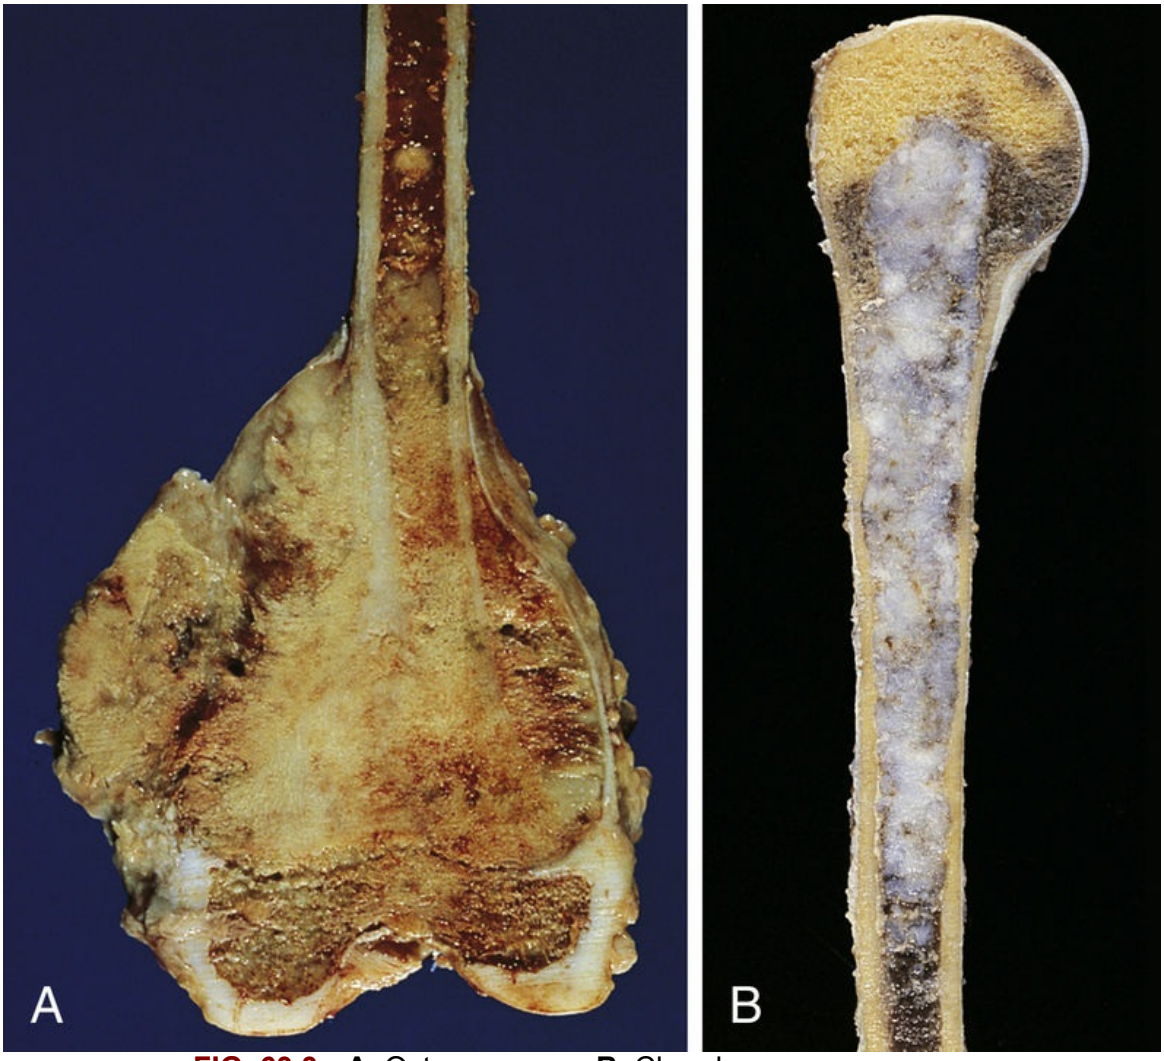

FIG. 63.3 **A,** Osteosarcoma. **B,** Chondrosarcoma.
From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.

Once a primary lesion has been found, radionuclide bone scans are often done to detect metastatic lesions before they are visible on x-ray. Metastatic bone lesions may occur at any time (even years later) after diagnosis and treatment of the primary tumor. Bone metastasis should be suspected in any patient who has local bone pain and a history of cancer. Surgical stabilization of the bone may be indicated for fracture or to prevent fracture in a high-risk patient. Prognosis depends on the primary type of cancer and any other sites of metastasis. Possible palliative treatment consists of radiation and pain management (see Chapter 15).

Nursing Management: Bone Cancer

Nursing care of the patient with bone cancer does not differ significantly from the care provided to the patient with cancer of any other body system (see Chapter 15). Monitor the tumor site for swelling, changes in circulation, and decreased movement, sensation, or joint function.

Use special care to prevent pathologic fractures and reduce the complications associated with them. Prevent fractures by careful handling and support of the affected extremity and logrolling the patient on bed rest. Note weakness caused by anemia and decreased mobility.

Treatment for hypercalcemia may be started if bone decalcification occurs. The patient may be unwilling to exercise or take part in activities because of weakness from the disease and treatment, fear of falling and fracturing a bone, and fear of pain. Provide regular rest periods between activities.

Assess the patient for the location and severity of pain. The pain associated with bone cancer can be severe. It is often caused by the tumor pressing against nerves and other organs near the bone. New onset or changes in pain severity may indicate pathologic fracture. Ensure adequate pain medication is provided. Sometimes radiation therapy is used as a palliative therapy to shrink the tumor and decrease pain.

Assist the patient and caregiver in accepting the prognosis associated with bone cancer. Give special attention to problems of pain and disability, side effects of chemotherapy, and postoperative care (e.g., after spinal cord decompression or amputation). As with all types of cancer, stress the importance of follow-up examinations.

Muscular Dystrophy

Muscular dystrophy (MD) is a group of genetic diseases characterized by progressive symmetric wasting of skeletal muscles without evidence of neurologic involvement. A gradual loss of

strength with increasing disability and deformity occurs with all forms of MD. The types of MD differ in the groups of muscles affected, age of onset, rate of progression, and mode of genetic inheritance (Table 63.4). Duchenne MD is the most common type.

Genetic Link

Duchenne and Becker MD are X-linked recessive disorders usually seen only in males. (X-linked recessive disorders are discussed in Chapter 12.) These disorders are caused by a mutation of the dystrophin *(DMD)* gene. Dystrophin is a protein that helps keep skeletal muscle fibers intact. Abnormal dystrophin can cause defects in the muscle fiber and muscle fiber degeneration. Genetic testing can detect a mutation in the *DMD* gene and confirm a diagnosis.[6]

TABLE 63.4 Select Types of Muscular Dystrophy

Type	Genetic Basis	Manifestations
Becker	• X-linked • Mutation of dystrophin gene	• Very similar but less severe than Duchenne MD • Onset ages 5–15 • Slower course of pelvic and shoulder muscle wasting than Duchenne • Cardiomyopathy • Respiratory failure • May survive into 50s
Duchenne	• X-linked • Mutation of dystrophin gene	• Most common form of MD • Primarily affects boys • Onset before age 5 • Progressive weakness of pelvic and shoulder muscles • Unable to walk by age 12 • Cardiomyopathy • Respiratory failure in 20s • Mental impairment
Facioscapulohumeral	• Autosomal dominant • Deletion of chromosome *4q35*	• Onset before age 20 • Slowly progressive weakness of face, shoulder muscles, and upper arms and lower legs • Can affect vision and hearing
Limb-girdle	• Autosomal recessive or autosomal dominant • Mutation in any of at least 15 genes affecting proteins needed for muscle function	• Group of disorders affecting voluntary muscles, especially those of hips and shoulders • Onset ranges from early childhood to early adulthood or later • Slow progressive weakness of hip and shoulder muscles

Other diagnostic studies for MD include muscle serum enzymes

(especially creatine kinase), electromyogram (EMG) testing, and muscle fiber biopsy. Classic findings on muscle biopsy include fat and connective tissue deposits, muscle fiber degeneration and necrosis, and a deficiency of dystrophin. An ECG may show abnormalities that suggest cardiomyopathy.

No definitive therapy is available to stop progressive muscle wasting of MD. Corticosteroid therapy is part of the standard of care. It may slow disease progression for up to 2 years.[7] In 2017 the FDA approved 2 new medications to treat MD. Deflazacort (Emflaza) is the first corticosteroid approved to treat Duchene MD. Eteplirsen (Exondys 51) is the first disease-modifying drug to treat Duchene MD patients who have a certain dystrophin gene mutation.[8] Other clinical trials underway involve gene therapy and stem cell transplantation.

The main treatment goals are to preserve mobility and independence through exercise, physical therapy, and use of assistive devices. Progressive muscle weakening around the trunk can cause spinal collapse. The patient may be fitted early with an orthotic jacket to give stability and prevent further deformity or injury.[9]

Life expectancy is increasing due to advances in cardiac and respiratory care. Cardiomyopathy often occurs and causes heart failure. Dysrhythmias are a frequent cause of death.[6] Gradual decreases in respiratory function often lead to the use of continuous positive airway pressure (CPAP). Eventually tracheostomy and mechanical ventilation are needed to support respiratory function.

Encourage communication between the patient and family to cope with the emotional and physical demands of MD. Teach the patient and caregiver range-of-motion (ROM) exercises, principles of good nutrition, and signs of disease progression. Genetic testing and counseling may be recommended for persons with a family history of MD.

Genetics in Clinical Practice

Duchenne and Becker Muscular Dystrophy (MD)

Genetic Basis

- Caused by various mutations in the dystrophin *(DMD)* gene
- Gene provides instructions for making dystrophin, a protein that helps keep muscle fibers intact
- Dystrophin is found mainly in skeletal and cardiac muscle
- Inherited in an X-linked recessive pattern
- Females in affected families have a 50% chance of inheriting and passing the defective gene to their children

Incidence

- Between 400 and 600 boys are born with MD each year in the United States.
- Together these disorders affect 1 in 3500 to 5000 newborn males worldwide.

Genetic Testing

- DNA testing for mutations in dystrophin gene is available.
- Genetic testing and counseling should be considered for those with a family history of MD.

Clinical Implications

- Because there are many types of MD with different genetic bases, knowing the type of MD is important to determine treatment and possible genetic counseling recommendations.

Focus care on keeping the patient active as long as possible.

Prolonged bed rest should be avoided because immobility can cause more muscle wasting. As the disease progresses, teach the patient to limit sedentary periods to prevent skin breakdown and respiratory complications. Ongoing medical and nursing care is needed throughout the patient's life.

The Muscular Dystrophy Association (*www.mda.org*) is an important resource with information about support services for the patient and caregivers. The website gives updates about the latest clinical trials and treatment advances.

Safety Alert

Muscular Dystrophy

- Support respiratory function as needed.
- Fit patient with an orthotic jacket or brace to prevent deformity or injury.

Low Back Pain

Low back pain is most often due to a musculoskeletal problem. It may be localized or diffuse. In *localized pain,* patients feel soreness or discomfort when a specific area of the lower back is palpated or pressed. *Diffuse pain* occurs over a larger area and comes from deep tissue.

Low back pain may be radicular or referred. *Radicular pain* is caused by irritation of a nerve root. Radicular pain is not isolated to a single location. Instead, it radiates or moves along a nerve distribution. Sciatica is an example of radicular pain. *Referred pain* is felt in the lower back, but the source of the pain is another location (e.g., kidneys, lower abdomen).

Low back pain affects about 80% of adults in the United States at least once during their lives. Backache is second only to headache as

the most common pain problem. It is the leading cause of job-related disability and a major contributor to missed work days.[10]

Low back pain is common because the lumbar region (1) bears most of the weight of the body, (2) is the most flexible region of the spinal column, (3) has nerve roots that are at risk for injury or disease, and (4) has a naturally poor biomechanical structure. Risk factors include lack of muscle tone, excess body weight, stress, poor posture, smoking, pregnancy, prior compression fracture of the spine, spinal problems since birth, and a family history of back pain. Jobs that require repetitive heavy lifting, vibration (such as a jackhammer operator), and extended periods of sitting are associated with low back pain.

The causes of low back pain of musculoskeletal origin include (1) acute lumbosacral strain, (2) instability of the lumbosacral bony mechanism, (3) osteoarthritis of the lumbosacral vertebrae, (4) degenerative disc disease, and (5) herniation of an intervertebral disc.

Health care personnel who perform direct patient care activities are at high risk for developing low back pain.[11] Lifting and moving patients, excessive bending or leaning forward, and frequent twisting can result in low back pain that causes lost time and productivity and disability. Nurses should follow the agency's safe patient handling standards to avoid injury.[12]

Acute Low Back Pain

Acute low back pain lasts 4 weeks or less. Most acute low back pain is caused by trauma or an activity that produces undue stress (often hyperflexion) on the lower back. Examples of trauma or activities that cause acute back pain are heavy lifting; overuse of back muscles during yard work; a sports injury; or a sudden jolt, as in a motor vehicle crash.

Often symptoms do not appear at the time of injury. They develop later (usually within 24 hours) because of a gradual increase in pressure on the nerve from an intervertebral disc and/or associated edema. Symptoms may range from muscle ache to shooting or

stabbing pain, limited flexibility or ROM, or an inability to stand upright.

Few definitive diagnostic abnormalities are present with nerve irritation and muscle strain. One test is the straight-leg-raising test (see Chapter 61, p. 1438). MRI and CT scans are not done unless trauma or systemic disease (e.g., cancer, spinal infection) is suspected. MRI findings may be limited in the acute phase of an injury due to increased edema near the injury.

Nursing and Interprofessional Management: Acute Low Back Pain

Nursing Assessment

Subjective and objective data that should be obtained from the patient with low back pain are outlined in Table 63.5.

TABLE 63.5 Nursing AssessmentLow Back Pain

Subjective Data

Important Health Information

Past health history: Acute or chronic lumbosacral strain/trauma, osteoarthritis, degenerative disc disease, obesity

Medications: Opioid analgesics and NSAIDs, muscle relaxants, corticosteroids, over-the-counter remedies (e.g., topical ointments, patches)

Surgery or other treatments: Back surgery, epidural corticosteroid injections

Functional Health Patterns

Health perception–health management: Smoking, lack of exercise
Nutritional-metabolic: Obesity
Activity-exercise: Poor posture, muscle spasms, activity intolerance
Elimination: Constipation
Sleep-rest: Interrupted sleep
Cognitive-perceptual: Pain in back, buttocks, or leg associated with walking, turning, straining, coughing, leg raising. Numbness or tingling of legs, feet, toes
Role-relationship: Occupations requiring heavy lifting, vibrations, or extended driving. Change in role within family structure due to inability to work and provide income

Objective Data

General

Guarded movement

Neurologic

Depressed or absent Achilles tendon reflex or patellar tendon reflex. Positive straight-leg-raising test, positive crossover straight-leg-raising test, positive Trendelenburg test

Musculoskeletal

Tense, tight paravertebral muscles on palpation, ↓ range of motion in spine

Possible Diagnostic Findings

Localization of site of lesion or disorder on myelogram, CT scan,

or MRI. Determination of nerve root impingement on EMG

Nursing Implementation

Health Promotion

Serve as a role model by always using proper body mechanics. This includes increasing the patient's bed height, bending at the knees, asking for help in lifting and moving patients, and using lifting devices.

Assess the patient's use of body mechanics and offer advice when the person does activities that could produce back strain. Some HCPs refer patients with back pain to a program called "Back School." This formal program is usually taught by an HCP, nurse, or physical therapist. It is designed to teach the patient how to minimize back pain and avoid repeat episodes of pain. Tips for prevention of back injury are listed in Table 63.6. Referral to a physical therapist or personal trainer to address posture and core and abdomen strength may be appropriate. Recommend flat shoes or shoes with low heels and shock-absorbing shoe inserts for women.

Advise patients to maintain a healthy body weight. Excess body weight places more stress on the lower back. It weakens abdominal muscles that support the lower back. Sleeping position is important in preventing low back pain. Teach patients to avoid sleeping in a prone position because it causes excessive lumbar lordosis, placing stress on the lower back. Sleeping in a supine or side-lying position with knees and hips flexed prevents pressure on support muscles, ligaments, and lumbosacral joints. Recommend use of a firm mattress.

TABLE 63.6 Patient & Caregiver TeachingLow Back Problems

Include the following instructions when teaching the patient and caregiver how to manage low back problems:

Do

- Maintain healthy body weight.
- Maintain a neutral pelvic position if standing. Place 1 foot on a low stool if standing for long periods.
- Choose a seat with good lower back support, armrests, and a swivel base. Place a pillow at the lumbar spine to maintain normal curvature. Keep knees and hips level.
- Sleep in a side-lying position with knees and hips bent, and a pillow between the knees for support.
- Sleep on back with a lift under knees and legs or on back with 10-in–high pillow under knees to flex hips and knees.
- Use proper body mechanics when lifting heavy objects. Bend at the knees, not at the waist, and stand up slowly while holding object close to your body.
- Take part in regular strength and flexibility training and low-impact aerobic exercise.
- Use local heat and cold application to relieve muscle tension.

Do Not

- Lean forward without bending knees.
- Lift anything above level of elbows.
- Stand unmoving for prolonged time.
- Sleep on abdomen or on back or side with legs out straight.
- Exercise without consulting HCP if having severe pain.
- Exceed prescribed amount and type of exercises without consulting HCP.
- Smoke or use tobacco products.

Teach patients the importance of smoking cessation. Tobacco use impairs circulation to the intervertebral discs and contributes to low back pain.

Acute Care

If acute muscle spasms and accompanying pain are not severe and unbearable, the patient is treated as an outpatient with NSAIDs and muscle relaxants (e.g., cyclobenzaprine). Massage and back manipulation, acupuncture, and the application of cold and hot compresses may help some patients. Severe pain may require a brief course of corticosteroids or opioid analgesics.

Some people may need a brief period (1 to 2 days) of rest at home but should avoid prolonged bed rest. Most patients do better if they continue their regular activities. Patients should refrain from activities that increase the pain, including lifting, bending, twisting, and prolonged sitting. Symptoms of acute low back pain usually improve within 2 weeks and often resolve without treatment.

Teach the patient about the cause of the pain and ways to prevent further episodes. Muscle stretching and strengthening exercises may be part of the management plan. Although the physical therapist often teaches the exercises, reinforce the type and frequency of prescribed exercise and the reason for the program.

Other nursing interventions for the patient with low back pain are detailed in eNursing Care Plan 63.2 (available on the website for this chapter).

Ambulatory Care

The goal of management is to make an episode of acute low back pain an isolated incident. If the lumbosacral area is unstable, repeated episodes are likely. Obesity, poor posture, poor muscle support, older age, or trauma may weaken the lumbosacral spine, so it is unable to meet the demands placed on it without strain. Exercise is aimed at strengthening the supporting muscles.

Persistent use of poor body mechanics may result in repeated episodes of low back pain. If the strain is work related, occupational counseling may be needed. Low back pain can cause frustration, pain, and disability. Provide emotional support and understanding care of the patient.

Chronic Low Back Pain

Chronic low back pain lasts more than 3 months or involves a repeated incapacitating episode. It is often progressive, and the cause can be hard to determine. Causes include (1) degenerative conditions, such as arthritis or disc disease; (2) osteoporosis or other metabolic bone diseases; (3) weakness from the scar tissue of prior injury; (4) chronic strain on lower back muscles from obesity, pregnancy, or stressful postures on the job; and (5) congenital spine problems.

Spinal Stenosis

Spinal stenosis is a narrowing of the spinal canal, which holds the spinal cord. Stenosis in the lumbar spine is a common cause of chronic low back pain. Spinal stenosis can be acquired or inherited. A common acquired cause is osteoarthritis. Arthritic changes (bone spurs, calcification of spinal ligaments, disc degeneration) narrow the space around the spinal canal and nerve roots, eventually leading to compression. Inflammation caused by the compression results in pain, weakness, and numbness.

Other acquired conditions that may cause spinal stenosis include rheumatoid arthritis, spinal tumors, Paget's disease, and traumatic damage to the vertebral column. Inherited conditions that lead to spinal stenosis include congenital spinal stenosis and scoliosis.

The pain associated with lumbar spinal stenosis often starts in the lower back and then radiates to the buttock and leg. It is worse with walking or prolonged standing. Numbness, tingling, weakness, and heaviness in the legs and buttocks may be present. History of decreased pain when the patient bends forward or sits is often a sign of spinal stenosis. In most cases, stenosis slowly progresses.

Interprofessional and Nursing Care

The management and treatment of chronic low back pain are similar to those for acute low back pain. Manage the patient's pain and stiffness with mild analgesics, such as NSAIDs, for daily comfort.

Antidepressants (e.g., duloxetine [Cymbalta]) may help with pain management and sleep problems. The antiseizure drug gabapentin (Neurontin) may improve walking and relieve leg symptoms.

Weight reduction, rest periods, local heat or cold application, physical therapy, and exercise and activity throughout the day help keep the muscles and joints mobilized. Cold, damp weather worsens the back pain. Pain can be decreased with rest and local heat application. Complementary and alternative therapies, such as biofeedback, acupuncture, and yoga, may help reduce the pain. "Back School" (discussed on p. 1485) can significantly reduce pain and improve body posture.

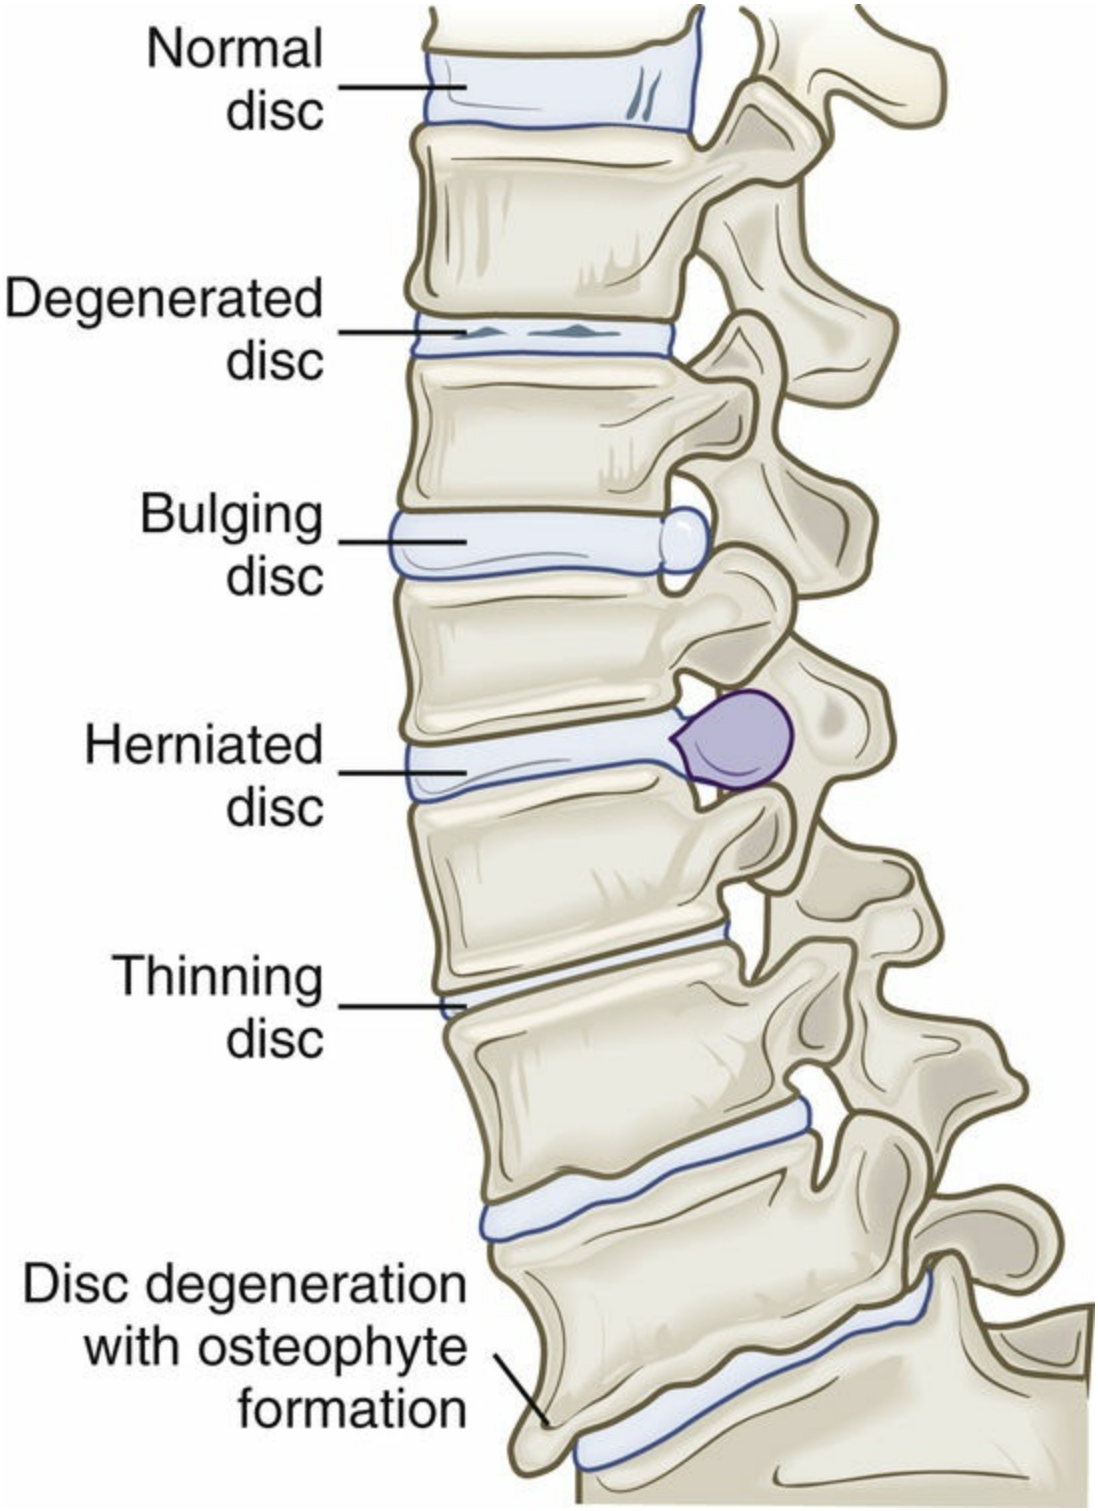

FIG. 63.4 Common causes of degenerative disc damage.

Minimally invasive treatments, such as epidural corticosteroid injections and implanted devices that deliver pain medication, are

options for those with chronic low back pain that does not respond to the usual therapeutic options. Surgical intervention may be indicated in patients with severe chronic low back pain who receive no benefit from conservative care and/or have continued neurologic deficits. (Surgery for low back pain is discussed on p. 1488.)

Intervertebral Disc Disease

Intervertebral discs separate the vertebrae and help absorb shock for the spine. *Intervertebral disc disease* involves the deterioration, herniation, or other dysfunction of the intervertebral discs. Disc disorders can affect the cervical, thoracic, and lumbar spine.

Etiology and Pathophysiology

Degenerative disc disease (DDD) results from loss of fluid in the intervertebral discs with aging. The discs lose their elasticity, flexibility, and shock-absorbing abilities. Unless it is accompanied by pain, DDD is a normal process.[13] The discs become thinner as the *nucleus pulposus* (gelatinous center of the disc) starts to dry out and shrink. This change limits the disc's ability to distribute pressure between vertebrae. The pressure is then transferred to the *annulus fibrosus* (strong outside part of the disc), causing progressive destruction. When the disc is damaged, the nucleus pulposus may seep through a torn or stretched annulus. This is called a **herniated disc** *(slipped disc),* a condition in which a spinal disc bulges outward between the vertebrae (Fig. 63.4).

A herniated disc can result from degeneration with age or repeated stress and trauma to the spine. The most common sites of herniation are the lumbosacral discs, specifically L4-5 and L5-S1. Disc herniation may also occur at C5-6 and C6-7. It may be the result of spinal stenosis, in which narrowing of the spinal canal forces the intervertebral disc to bulge.

The spinal nerves emerge from the spinal column through an opening *(intervertebral foramen)* between adjacent vertebrae. Herniated

discs can press against these nerves ("pinched nerve") causing *radiculopathy* (radiating pain, numbness, tingling, decreased strength and/or range of motion).

TABLE 63.7 Manifestations of Lumbar Disc Herniation*

Intervertebral Level	Pain	Affected Reflex	Motor Function	Sensation
L3-4	Back to buttocks to posterior thigh to inner calf	Patellar	Quadriceps, anterior tibialis	Inner aspect of lower leg, anterior part of thigh
L4-5	Back to buttocks to dorsum of foot and big toe	None	Anterior tibialis, extensor hallucis longus, gluteus medius	Dorsum of foot and big toe
L5-S1	Back to buttocks to sole of foot and heel	Achilles	Gastrocnemius, hamstring, gluteus maximus	Heel and lateral foot

* A disc herniation can involve pressure on more than 1 nerve root.

Osteoarthritis (OA) of the spine is associated with DDD and the stresses placed on the vertebrae. As the poorly lubricated joints rub against each other, the protective cartilage is damaged and painful bone spurs occur as one of the changes found in OA.

Clinical Manifestations

In *lumbar disc disease,* the most common manifestation is low back pain. Radicular pain that radiates down the buttock and below the knee, along the distribution of the sciatic nerve, generally indicates disc herniation. Specific manifestations of lumbar disc herniation are outlined in Table 63.7. A positive straight-leg-raising test may indicate nerve root irritation (see Chapter 61, p. 1438). Back or leg pain may be reproduced by raising the leg.

Low back pain from other causes may not be accompanied by leg pain. Reflexes may be depressed or absent, depending on the spinal nerve root involved. Numbness and tingling *(paresthesia)* or muscle weakness in the legs, feet, or toes may occur.

Multiple lumbar nerve root compressions *(cauda equina syndrome)* from a herniated disc, tumor, or an epidural abscess may be marked by (1) severe low back pain, (2) progressive weakness, (3) increased pain, and (4) bowel and bladder incontinence or retention. Saddle anesthesia (loss of or altered sensation of the perineum, buttocks, inner thighs and back of the legs [saddle area]) may be present. Symptoms of cauda equina syndrome may develop suddenly or evolve slowly over time. They may vary in intensity. Cauda equina is a medical emergency that requires surgical decompression to reduce pressure on the nerves and prevent permanent paralysis.[14]

In *cervical disc disease,* pain radiates into the arms and hands, following the pattern of the involved nerve. Like lumbar disc disease, reflexes may or may not be present. The handgrip is often weak. Because manifestations of cervical disc disease may include shoulder pain and dysfunction, the HCP must rule out shoulder disorders as part of the diagnosis.

Diagnostic Studies

X-rays are done to detect any structural defects. A myelogram, MRI, or CT scan is helpful in localizing the damaged site. An epidural venogram or diskogram may be needed if other diagnostic studies are inconclusive. An EMG of the extremities can be done to determine the severity of nerve irritation or to rule out other conditions, such as peripheral neuropathy.

TABLE 63.8 Interprofessional CareIntervertebral Disc Disease

Diagnostic Assessment

- History and physical examination
- X-ray

- CT scan
- MRI
- Myelogram
- Diskogram
- EMG

Management

Conservative Therapy

- Restricted activity for several days, limited total bed rest
- Local ice or heat
- Physical therapy
- Analgesics (e.g., tramadol [Ultram])
- NSAIDs
- Muscle relaxants (e.g., cyclobenzaprine)
- Antiseizure drugs (e.g., gabapentin)
- Antidepressants (e.g., pregabalin)
- Epidural corticosteroid injections

Surgical Therapy

- Intradiscal electrothermoplasty (IDET)
- Radiofrequency discal nucleoplasty
- Interspinous process decompression system (X-Stop)
- Laminectomy with or without spinal fusion
- Discectomy
- Percutaneous laser discectomy
- Artificial disc replacement (e.g., Charité disc)
- Spinal fusion with instrumentation (e.g., plates, screws) or without instrumentation

Interprofessional Care

The patient with suspected disc damage is usually managed with conservative therapy (Table 63.8). This includes limitation of extremes of spinal movement (e.g., brace, corset, belt), local heat or ice, ultrasound and massage, traction, and transcutaneous electrical nerve stimulation (TENS). Drug therapy to manage pain includes NSAIDs, short-term oral corticosteroids, opioid analgesics, muscle relaxants, antiseizure drugs, and antidepressants.[15] Epidural corticosteroid injections may reduce inflammation and relieve acute pain. However, pain tends to recur if the underlying cause remains.

When symptoms subside, the patient should begin back-strengthening exercises twice a day and continue for life. Teach the patient the principles of good body mechanics. Discourage extremes of flexion and torsion. With a conservative treatment plan, most patients heal after 6 months.

Surgical Therapy

If conservative treatment is unsuccessful, radiculopathy becomes worse, or loss of bowel or bladder control occurs, surgery may be considered. Surgery for a damaged disc is generally done if the patient is in constant pain and/or has a persistent neurologic deficit.

Intradiscal electrothermoplasty (IDET) is a minimally invasive outpatient procedure for treatment of back and sciatic pain. A needle is inserted into the affected disc with x-ray guidance. A wire is then threaded through the needle and into the disc. As the wire is heated, small nerve fibers that have invaded the degenerating disc are destroyed. The heat also partially melts the annulus fibrosus. This causes the body to generate new reinforcing proteins in the fibers of the annulus.

Another outpatient technique is *radiofrequency discal nucleoplasty* (coablation nucleoplasty). A needle is inserted into the disc similar to IDET. Instead of a heated wire, a special radiofrequency probe is used. The probe generates energy that breaks the molecular bonds of the gel in the nucleus pulposus. Up to 20% of the nucleus is removed. This

decompresses the disc and reduces pressure on the disc and surrounding nerve roots. Subsequent pain relief varies.

A third procedure involves use of an *interspinous process decompression system* (X-Stop). This titanium device fits onto a mount that is placed on vertebrae in the lower back. The X-Stop is used in patients with pain due to lumbar spinal stenosis. The device works by lifting vertebrae off the pinched nerve.

Laminectomy is a common, traditional surgical procedure for lumbar disc disease. It involves surgical excision of part of the vertebra (referred to as the *lamina*) to access and remove the protruding disc.[13] Laminectomy is often done as an outpatient procedure. However, a hospital stay of 1 to 3 days is not uncommon.

Discectomy also can be done to decompress the nerve root. Microsurgical discectomy is a version of the standard procedure. The HCP uses a microscope to better see the disc and disc space, which helps in removal of the damaged portion. This helps maintain bony stability of the spine.

Percutaneous discectomy is a safe and effective outpatient surgical procedure. A tube is passed through the retroperitoneal soft tissues to the disc with the aid of fluoroscopy. A laser is then used on the damaged part of the disc. Minimal blood loss occurs because of access through small stab wounds. The procedure decreases rehabilitation time.

The goals of artificial disc replacement surgery are to restore movement and eliminate pain. The *Charité disc* is used in patients with lumbar disc damage associated with DDD. This artificial disc has a high-density core sandwiched between 2 cobalt-chromium endplates (Fig. 63.5). After removing the damaged disc, the device is surgically placed in the spine (usually through a small incision below the umbilicus). The disc restores movement at the level of the implant. The *ProDisc-L* is another type of artificial lumbar disc used to treat DDD.[16]

Options for treatment of DDD of the cervical spine include the Prestige cervical disc, Mobi-C disc, and Secure-C artificial cervical disc.

A *spinal fusion* may be needed if the spine is unstable. The spine is stabilized by creating *ankylosis* (fusion) of adjacent vertebrae with a bone graft from the patient's fibula or iliac crest *(autograft)* or from donated cadaver bone *(allograft).* Metal fixation with rods, plates, or screws may be placed to give more stability and decrease vertebral motion. A posterior lumbar fusion may be done to give extra support for bone grafting or a prosthetic device.

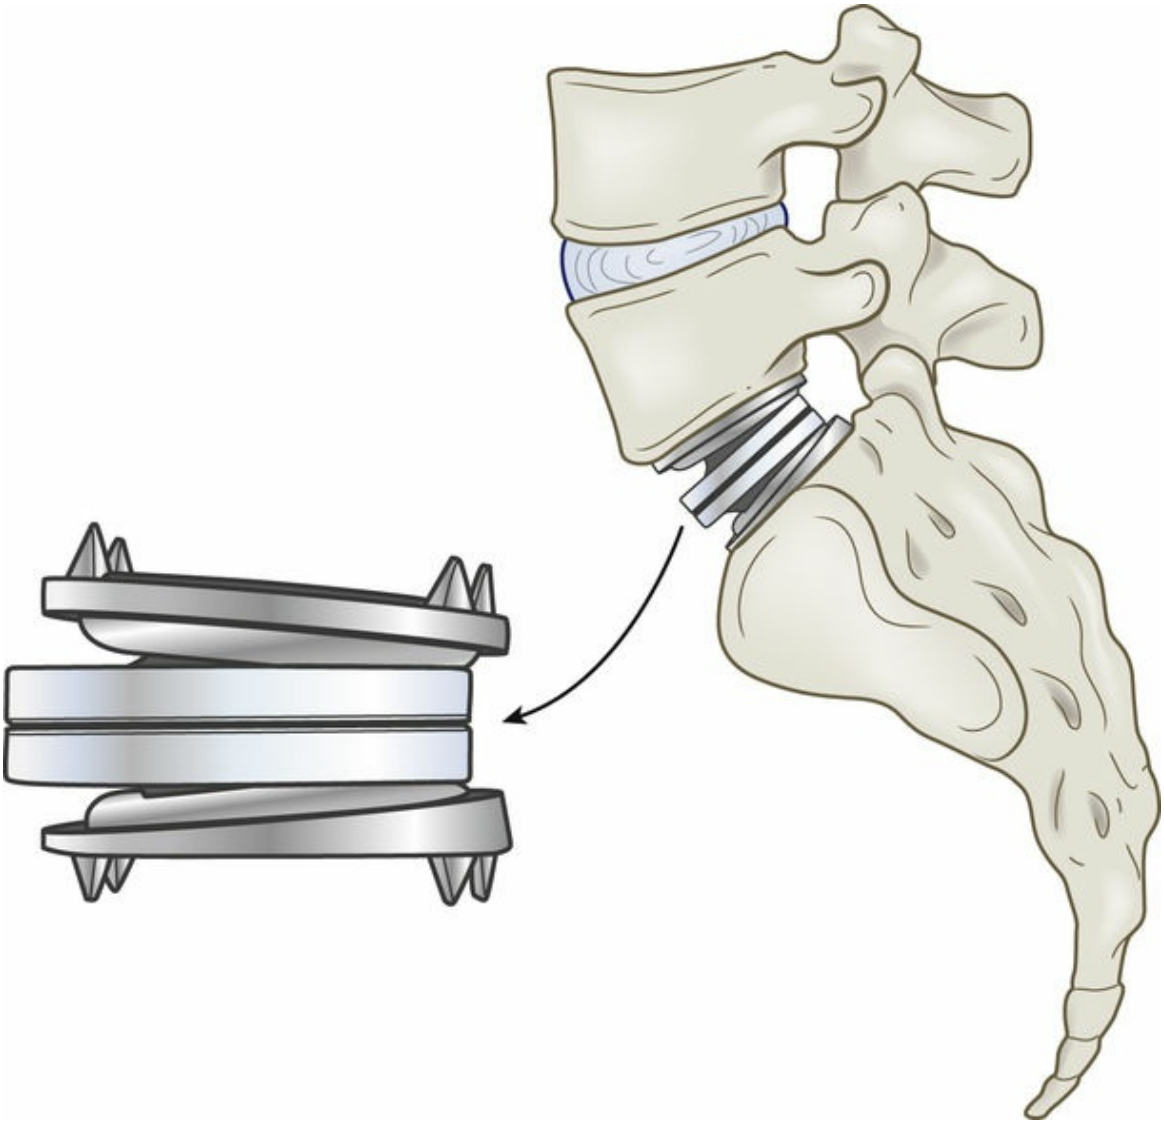

FIG. 63.5 The Charité artificial disc, used to replace a damaged intervertebral disc in degenerative disc disease of the lumbar spine. A movable high-density plastic core is placed between 2 cobalt-chromium alloy endplates. The disc's design helps realign the spine and preserve

movement.

Bone morphogenetic protein (BMP), a genetically engineered protein, may be used to stimulate bone growth of the graft in spinal fusions.[17] A dissolvable sponge soaked with BMP is implanted into the spine. BMP on the sponge stimulates the body's cells to become active and produce bone, promoting fusion. The body absorbs the sponge, leaving living bone behind.

Nursing Management: Vertebral Disc Surgery

After vertebral disc surgery, a key focus of nursing interventions is maintaining proper alignment of the spine until it has healed. Depending on the type and extent of surgery and the HCP's preference, the patient may be able to dangle the legs at the side of the bed, stand, or even ambulate the day of surgery.

After lumbar fusion, place pillows under the patient's thighs when supine and between the legs when in the side-lying position to provide comfort and ensure alignment. The patient often fears turning or any movement that may increase pain by stressing the surgical area. Have the patient logroll when changing position in bed. Reassure the patient that proper technique is being used to maintain body alignment. Remove the bed trapeze, if present, since use is contraindicated for spinal surgery patients. Enough staff should be available to move the patient without undue pain or strain for the patient or staff.

After surgery, most patients need opioids, such as morphine IV, for 24 to 48 hours. Patient-controlled analgesia (PCA) allows maintenance of optimal analgesic levels and is the preferred method of continuous pain management. Once the patient receives oral fluids, oral drugs, such as acetaminophen with codeine, hydrocodone, or oxycodone (Percocet), may be used. Diazepam (Valium) may be prescribed for muscle relaxation. Assess and document pain intensity and pain management effectiveness.

Because the spinal canal may be entered during surgery, cerebrospinal fluid (CSF) leakage is possible. Immediately report leakage of CSF on the dressing or if the patient reports a severe headache. CSF appears as clear or slightly yellow drainage on the dressing. It has a high glucose concentration and is positive for glucose when tested with a dipstick. Note the amount, color, and characteristics of drainage.

Frequently assess the patient's peripheral neurologic condition. Movement of the arms and legs and assessment of sensation should at least equal the preoperative status. Repeat these assessments every 2 to 4 hours during the first 48 hours after surgery and compare with the preoperative assessment. Paresthesia may not be relieved right after surgery. Report any new muscle weakness or paresthesia at once to the HCP and record this finding in the patient's medical record. Assess extremity circulation using skin temperature, capillary refill, and pulses.

Paralytic ileus and interference with bowel function may occur for several days. Opioids can slow bowel elimination. Assess if the patient is passing gas, has bowel sounds in all quadrants, and has a flat, soft abdomen. Stool softeners (e.g., docusate [Colace]) and laxatives may prevent and relieve constipation.

Emptying the bladder may be hard due to activity restrictions, opioids, or anesthesia. Encourage men to dangle the legs over the side of the bed or stand to urinate if allowed by the HCP. Urge patients to use a bedside commode or ambulate to the bathroom when allowed to promote bladder emptying. Intermittent catheterization or an indwelling urinary catheter may be needed by patients who have problems urinating.

Loss of sphincter tone or bladder tone may indicate nerve damage. Monitor for incontinence or problems with bowel or bladder elimination. Immediately report problems to the HCP.

In addition to nursing care appropriate for a patient who had a laminectomy, other nursing activities are needed if the patient has also had a spinal fusion. Because a bone graft is usually involved, the healing time is prolonged compared with a laminectomy. Activity

limitations may be needed for an extended time. A rigid orthosis (thoracolumbar sacral orthosis [TLSO] or chairback brace) is often used during this period. Some HCPs want patients to learn to apply and remove the brace by logrolling in bed. Others allow their patients to apply the brace in a sitting or standing position. Verify the preferred method before starting this activity.

With cervical spine surgery, be alert for signs of spinal cord edema, such as respiratory distress and a worsening neurologic condition of the upper extremities. After surgery, the patient's neck may be immobilized in a soft or hard cervical collar.

In addition to the primary surgical site, regularly assess the bone graft donor site. The posterior iliac crest is the most often used donor site, although the fibula may be used. The donor site usually causes greater pain than the spinal fusion area. The donor site is bandaged with a pressure dressing to prevent excessive bleeding. If the donor site is the fibula, frequent neurovascular assessment of the extremity is a key nursing intervention.

After spinal fusion, the patient may have some immobility of the spine at the fusion site. Teach the patient to use proper body mechanics and avoid sitting or standing for prolonged periods. Encourage activities that include walking, lying down, and shifting weight from one foot to the other when standing. Teach the patient about any lifting restrictions. Encourage the patient to think through an activity before starting any potentially injurious task, such as bending or stooping. Any twisting movement of the spine is contraindicated. Teach the patient to use the thighs and knees, rather than the back, to absorb the shock of activity and movement. A firm mattress or bed board is essential.

Neck Pain

Neck pain occurs almost as often as low back pain, affecting 10% to 20% of adults at any point in time.[18] Neck pain may result from many different conditions, including benign (e.g., poor posture) and serious (e.g., herniated cervical disc) (Table 63.9).

TABLE 63.9 Causes of Neck Pain

- Degenerative disc disease, including herniation
- Meningitis
- Osteomyelitis
- Osteoporosis
- Poor posture
- Rheumatoid arthritis
- Spondylosis
- Strain or sprain
- Trauma (e.g., fractures, subluxation)
- Tumor

TABLE 63.10 Patient & Caregiver TeachingNeck Exercises

When teaching the patient exercises for neck pain, include the following instructions for the patient and caregiver:

- Bend your head backward until you are looking up at the ceiling. Repeat slowly 5 times. Stop if dizziness occurs.
- Bring your head forward so that your chin touches your chest and your face is looking down at the floor. Repeat slowly 5 times.
- With your head facing forward, bend your ear down toward one shoulder. Alternate this movement with your other ear. Repeat slowly 5 times on each side.
- Turn your head slowly around to one side as far as it will go. Repeat toward the other side. Repeat exercise 5 times on each side.

Cervical neck sprains and strains occur from hyperflexion and hyperextension injuries. Patients have stiffness and neck pain with possible radicular pain into the arm and hand. Pain may radiate to the head, anterior chest, thoracic spine region, and shoulders. Weakness or paresthesia of the arm and hand suggests cervical nerve root compression from stenosis, DDD, or herniation.

The cause of neck pain is diagnosed by history, physical examination, x-ray, MRI, CT scan, and myelogram. An EMG of the upper extremities may diagnose cervical radiculopathy.

Conservative treatment for neck pain in patients without an underlying disorder includes head support using a soft cervical collar, gentle traction, heat and ice applications, massage, rest until symptoms subside, ultrasound, and NSAIDs. Therapeutic neck exercises and acupuncture also may be used for pain relief.[19] Most neck pain resolves without surgical intervention.

Preventing neck pain that occurs with everyday activities, such as prolonged sitting at a computer or television, sleeping in nonaligned spinal positions, or making jarring movements during exercise, is important. Encourage patients to practice good posture and maintain neck flexibility (Table 63.10).

Foot Disorders

The foot is the platform that supports the weight of the body and absorbs shock when the person ambulates. It is a complicated structure composed of bony structures, muscles, tendons, and ligaments. The foot can be affected by (1) congenital conditions; (2) structural weakness; (3) traumatic and stress injuries; and (4) systemic conditions, such as diabetes and rheumatoid arthritis. Table 63.11 outlines common foot disorders.

Footwear is used to (1) provide support, foot stability, protection, shock absorption, and a foundation for orthotics; (2) increase friction with the walking surface; and (3) treat foot abnormalities. Poorly fitting shoes cause or worsen a great deal of the pain, deformity, and disability from foot disorders.[20] Shoes may cause crowding and

angulation of the toes and inhibit normal movement of foot muscles.

TABLE 63.11 Common Foot Disorders

Disorder	Description	Treatment
Forefoot		
Hallux rigidus	Painful stiffness of first MTP joint caused by osteoarthritis or local trauma.	• Conservative treatment includes intraarticular corticosteroids and passive manual stretching of first MTP joint. • Shoe with a stiff sole decreases pain in the joint during walking. • Surgical treatment is joint fusion or arthroplasty with silicone rubber implant.
Hallux valgus (bunion)	Painful deformity of great toe with lateral angulation of great toe toward second toe, bony enlargement of medial side of first metatarsal head, swelling of bursa and formation of callus over bony enlargement (Fig. 63.6).	• Conservative treatment includes wearing shoes with wide forefoot or "bunion pocket" and use of bunion pads to relieve pressure on bursal sac. • Surgical treatment involves removal of bursal sac and bony enlargement and correction of lateral angulation of great toe. • May include temporary or permanent internal fixation.
Hammer and claw toes	Hammer toe is a deformity of PIP joint on 2nd to 5th toes causing toe to be permanently bent, resembling a hammer. Mallet toe is a similar condition affecting the DIP joint. Claw toe is a similar deformity with dorsiflexion of the proximal phalanx on the MTP joint combined with flexion of both PIP and DIP joints. Symptoms include burning on bottom of foot and pain and difficulty walking when wearing shoes.	• Conservative treatment includes passive manual stretching of PIP joint and use of metatarsal arch support. • Surgical correction consists of resection of base of middle phalanx and head of proximal phalanx, bringing raw bone ends together. • Kirschner wire maintains straight position.
Morton's neuroma (Morton's toe or plantar neuroma)	Neuroma in web space between third and fourth metatarsal heads, causing sharp, sudden attacks of pain and burning sensations.	• Surgical excision is the usual treatment.
Midfoot		
Pes cavus	Elevation of longitudinal arch of foot resulting from contracture of plantar fascia or bony deformity of arch.	• Surgical correction is needed if condition interferes with ambulation.
Pes planus (flatfoot)	Loss of metatarsal arch causing pain in foot or leg.	• Symptoms are relieved by use of resilient longitudinal arch supports. • Surgical treatment consists of triple arthrodesis or fusion of subtalar joint.
Hindfoot		
Calcaneus stress fracture	Heel pain after moderate walking. Common causes are overtraining, running on hard surfaces, or osteoporosis.	• Rest, ice, shoe heel pad, and NSAIDs. • See HCP to assess for osteoporosis.
Heel pain	Heel pain with weight bearing. Common causes are plantar bursitis, plantar fasciitis, or bone spur.	• Corticosteroids are injected locally into inflamed bursa, and sponge-rubber heel cup is used. • Surgical excision of bursa or spur is done. • Stretching exercises, ice, shoe heel cup, shock-wave therapy, NSAIDs, and corticosteroids are used for plantar fasciitis.
Other Problems		

Disorder	Description	Treatment
Callus	Localized thickening of skin. Covers wide area and usually found on weight-bearing part of foot.	• Softened with warm water or preparations containing salicylic acid and trimmed with razor blade or scalpel. • Pressure on bony prominences caused by shoes is relieved.
Corn	Localized thickening of skin caused by continual pressure over bony prominences, especially metatarsal head, often causing localized pain.	• Same as with callus.
Plantar wart	Painful papillomatous growth caused by virus that may occur on any part of skin on sole of foot. Warts tend to cluster on pressure points.	• Remedies containing salicylic acid (e.g., Compound W), excision with electrocoagulation, or surgical removal. • Laser treatments. • May disappear without treatment.
Soft corn	Painful lesion caused by bony prominence of a toe pressing against adjacent toe. Usual location is web space between toes. Softness caused by secretions keeping web space relatively moist.	• Pain is relieved by placing cotton or spacers between toes to separate them. • Surgical treatment is excision of projecting bone spur (if present).

DIP, Distal interphalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal.

Nursing Management: Foot Disorders

Nursing Implementation

Health Promotion

Well-made and properly fitted shoes are essential for healthy, pain-free feet. Women's footwear is often influenced by current styles instead of comfort and support. Stress the importance of having a shoe that conforms to the foot rather than to fashion trends. The shoe must be long enough and wide enough to avoid crowding the toes and forcing the great toe into a position of **hallux valgus** (Fig. 63.6). At the metatarsal head, the shoe should be wide enough to allow foot muscles to move freely and toes to bend. The shank (narrow part of sole under the instep) of the shoe should be rigid enough to give good support. The height of the heel should be realistic in relation to the shoe's purpose. Ideally, the heel of the shoe should not rise more than 1 inch higher than the forefoot support. Wearing higher heeled shoes with a narrow toe box will cause hammertoes and corns over time.

FIG. 63.6 **A,** Severe hallux valgus with bursa formation. **B,** Postoperative correction.
From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.

Prolonged use of improper footwear can also cause a *Morton's neuroma*. They cause compression of an intermetatarsal plantar nerve, resulting in paresthesia and burning. At first, patients with Morton's neuroma may describe feeling as if a sock is rolled up under their toes. Neuromas usually occur between the third and fourth toes.

Acute Care

Many foot problems require referral to a podiatrist. Depending on the problem, conservative therapies are tried first (Table 63.11). These include NSAIDs, ice, physical therapy, footwear changes, stretching, warm soaks, orthotics, ultrasound, and corticosteroid injections. If these methods do not help, surgery may be needed.

Check Your Practice

A 53-yr-old woman is scheduled for surgical correction of a bunion after a diagnosis of hallux valgus. You are doing her preoperative

assessment. She asks you, “Do you think I caused this problem? I love shoes and have a whole closet full of fancy ones. Now I have to wear this ugly bunion shoe. I am not sure I can handle taking care of myself after surgery.”

- How will you respond to the patient?
- What teaching will you provide about her postoperative care?

Depending on the type of surgery, pins or wires may extend through the toes, or a protective splint may be placed over the end of the foot. After surgery, the foot is usually immobilized by a bulky dressing (Fig. 63.7), short leg cast, slipper (plaster) cast, or a platform shoe that fits over the dressing and has a rigid sole (also known as a *bunion shoe*).

Elevate the foot with the heel off the bed to reduce discomfort and prevent edema. Assess neurovascular condition frequently during the immediate postoperative period. Inserted devices may interfere with assessment for movement. Be aware that evaluating sensation may be hard because the patient may be unable to distinguish surgical pain from pain caused by nerve pressure or circulatory impairment.

The type and extent of surgery determine the orders for ambulation. Crutches, a walker, or a cane may be needed. The patient may have pain or a throbbing sensation when lowering the affected leg. Reinforce instructions from the physical therapist. Teach the patient the importance of walking with an erect posture with proper weight distribution. Report gait problems or continued pain to the HCP. Encourage frequent rest periods with the foot elevated.

FIG. 63.7 Postoperative supportive dressing for treatment of moderate forefoot deformity. Dressing must be conforming and binding enough to hold toe in exact position.
From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.

Ambulatory Care

Teach the patient to perform daily hygienic foot care and wear clean stockings. Stockings should be long enough to avoid wrinkling and causing pressure areas. Trimming toenails straight across helps prevent ingrown toenails and reduces the risk for infection. Provide detailed instruction to patients with impaired circulation or diabetes to prevent serious complications from blisters, pressure areas, and infection. (See Table 48.21 for guidelines on foot care.)

Gerontologic Considerations: Foot Problems

The older adult is prone to foot problems because of poor circulation,

atherosclerosis, and decreased sensation in the lower extremities. This is especially true for those with diabetes. A patient may develop an open wound but not feel it because of altered sensation from peripheral vascular disease or diabetic neuropathy. Teach older adults to inspect their feet daily and report any open wounds or breaks in the skin to their HCP.[21]

Untreated wounds may become infected, lead to osteomyelitis, and need surgical debridement. If the infection becomes widespread, lower limb amputation may be needed. Teach the caregiver of the older adult who needs help with hygiene practices the importance of carefully assessing the feet at regular intervals.

Metabolic Bone Diseases

Normal bone metabolism is affected by hormones, nutrition, and genetics. When dysfunction occurs in any of these factors, generalized reduction in bone mass and strength may result. Metabolic bone diseases include osteomalacia, osteoporosis, and Paget's disease.

Osteomalacia

Osteomalacia is caused by a vitamin D deficiency that causes bone to lose calcium and become soft. The disease is uncommon in the United States. It is the same disorder as rickets in children, except the epiphyseal growth plates are closed in adults. Vitamin D is required for the absorption of calcium from the intestine. Insufficient vitamin D intake can interfere with normal bone mineralization. With little or no calcification, bones become soft.

Causes include limited sun exposure (ultraviolet rays needed for vitamin D synthesis), GI malabsorption (post weight loss surgery, celiac disease), chronic diarrhea, and pregnancy. Residents of long-term care settings may have inadequate sun exposure and thus poor synthesis of vitamin D. Persons with dark skin do not synthesize vitamin D as easily as persons with fair skin. Obese persons are at higher risk because of decreased physical activity. Chronic liver,

kidneys, and small intestine disease may contribute to vitamin D deficiency. Long-term use of antiseizure drugs (e.g., phenytoin) and phosphate-binding antacids (e.g., Maalox) may decrease calcium and vitamin D absorption.[22]

Common manifestations are bone pain and muscle weakness. The pain is often worse at night and affects the lower back, pelvis, hips, legs, and ribs.[23] Muscle weakness and progressive deformity of weight-bearing bones (e.g., spine, extremities) can lead to problems walking and a waddling gait. Fractures are common and indicate delayed bone healing.

Laboratory findings include decreased serum calcium or phosphorus, decreased serum 25-hydroxyvitamin D, and increased serum alkaline phosphatase. X-rays may show effects of generalized bone demineralization, especially loss of calcium in the bones of the pelvis and associated bone deformity. *Looser's transformation zones* (ribbons of decalcification in bone found on x-ray) are diagnostic of osteomalacia. However, significant osteomalacia may exist without x-ray changes.

Interprofessional care is directed toward correcting the vitamin D deficiency. The patient often has a dramatic response when vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) supplements are used. Calcium or phosphorus supplements may be prescribed. Encourage dietary intake of eggs, meat, and oily fish (e.g., salmon, tuna). Milk and breakfast cereals fortified with calcium and vitamin D should be part of the diet. Exposure to sunlight and weight-bearing exercise are valuable as well. Assess patients who had weight loss surgery to treat obesity for osteomalacia. Any vitamin D deficiencies should be corrected.[24]

Osteoporosis

Osteoporosis is a chronic, progressive metabolic bone disease marked by low bone mass and deterioration of bone tissue, leading to increased bone fragility (Fig. 63.8). More than 54 million persons in the

United States have decreased bone density or osteoporosis.[25] Osteoporosis is known as the "silent thief" because it slowly robs the skeleton of its banked resources. Bones eventually become so fragile that they cannot withstand normal mechanical stress.

Osteoporosis is more common in women. This is for several reasons: (1) women tend to have lower calcium intake than men throughout their lives (men between 15 and 50 years of age consume twice as much calcium as women); (2) women have less bone mass because of their generally smaller frames; (3) bone resorption begins at an earlier age in women and becomes more rapid at menopause; (4) pregnancy and breastfeeding deplete a woman's skeletal reserve unless calcium intake is adequate; and (5) longevity increases the risk for osteoporosis.

Current guidelines recommend an initial bone density test in all women over age 65 years. If results are normal and the person is at low risk for osteoporosis, another test is not needed for 15 years. Women who are younger than 65 and at high risk (e.g., low body weight, smoker, prior fractures) should have a bone density test earlier. Testing should also start earlier and be done more often if a person is at high risk for fractures. Currently there is not enough evidence that shows any benefit for screening men.[26]

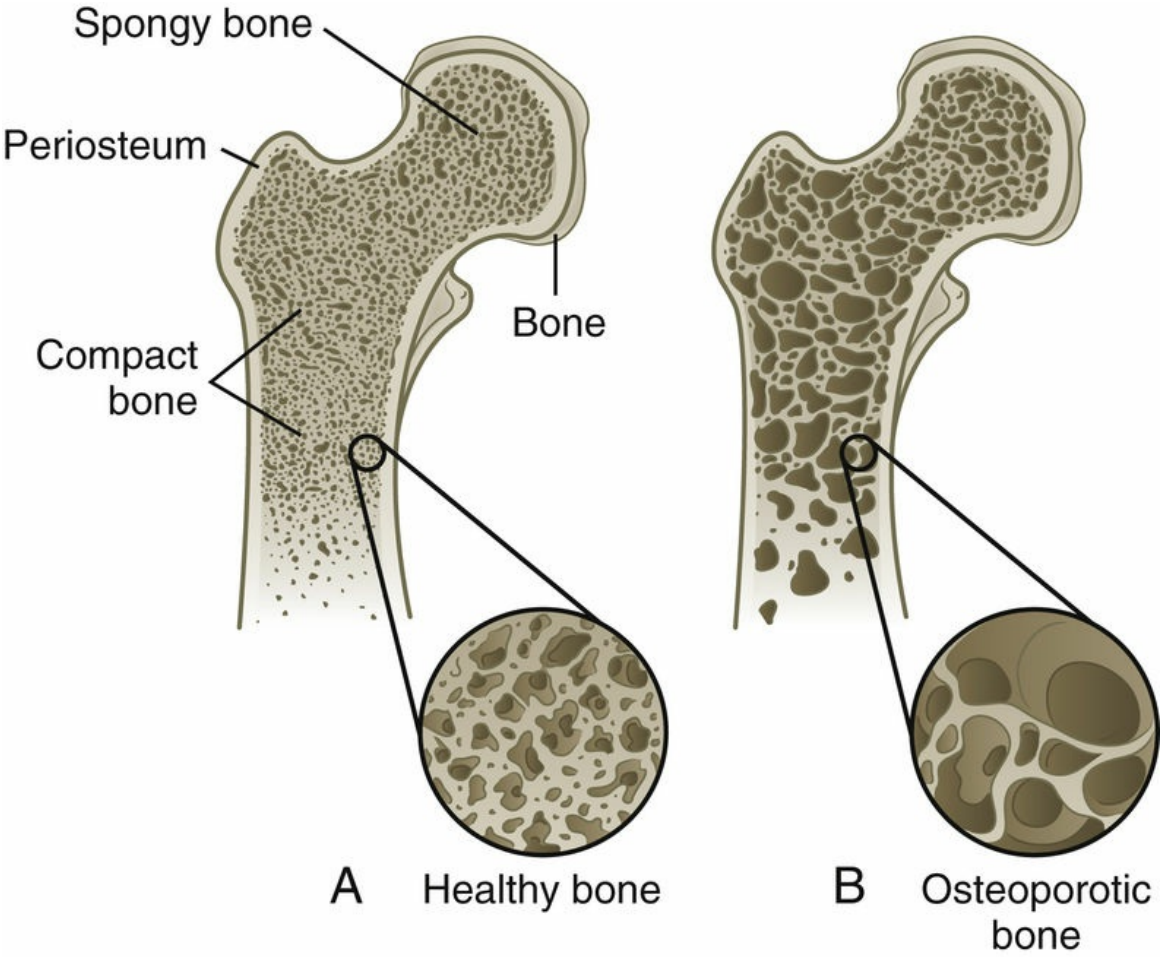

FIG. 63.8 **A,** Normal bone. **B,** Osteoporotic bone.

TABLE 63.12 Risk Factors for Osteoporosis

- Advancing age (>65 yr)
- Female gender
- Low body weight
- White or Asian ethnicity
- Cigarette smoking
- Sedentary lifestyle
- Estrogen deficiency in women (surgical or age-related

menopause)
- Family history of osteoporosis
- Diet low in calcium or vitamin D deficiency
- Excess use of alcohol (>2 drinks/day)
- Low testosterone in men
- Long-term use of corticosteroids, thyroid replacement, heparin, long-acting sedatives, or antiseizure drugs

Promoting Health Equity

Osteoporosis

- White and Asian American women have the highest incidence of osteoporosis.
- Black women begin menopause with more bone mass and have the lowest rate of bone loss after menopause.
- Risk for fracture is highest in white women.

Etiology and Pathophysiology

Risk factors for osteoporosis are listed in Table 63.12. Decreased risk is associated with regular weight-bearing exercise and adequate intake of fluoride, calcium, and vitamin D. Low testosterone is a major risk factor in men.

Peak bone mass (maximum bone tissue) is typically achieved before age 20. It is largely determined by 4 factors: heredity, nutrition, exercise, and hormone function. Heredity may be responsible for up to 70% of a person's peak bone mass. Genetic factors also influence bone size, quality, and turnover. Bone loss from midlife (ages 35 to 40 years) onward is inevitable, but the rate of loss varies. At menopause, women have rapid bone loss when the decline in estrogen production is the greatest. The rate of loss then slows and eventually matches the rate of bone lost by men ages 65 to 70 years.

Bone is continuously being deposited by osteoblasts and resorbed by osteoclasts, a process called *remodeling*. Rates of bone deposition and resorption are normally equal, so total bone mass stays constant.[27] In osteoporosis, bone resorption exceeds bone deposition.

Diseases associated with osteoporosis include inflammatory bowel disease, intestinal malabsorption, kidney disease, rheumatoid arthritis, hyperthyroidism, alcohol use disorder, cirrhosis, hypogonadism, and diabetes. Many drugs can interfere with bone metabolism, including corticosteroids, antiseizure drugs (e.g., divalproex sodium [Depakote], phenytoin), aluminum-containing antacids, heparin, some chemotherapy drugs, and excess thyroid hormones. When one of these drugs is prescribed, teach the patient about this possible side effect. Long-term corticosteroid use is a major contributor to osteoporosis.

Gender Differences

Osteoporosis

Men

- Men are underdiagnosed and undertreated for osteoporosis compared with women.
- 1 in 4 men over age 50 will have an osteoporosis-related fracture in his lifetime.

Women

- Osteoporosis is 8 times more common in women than in men.
- 1 in 2 women over age 50 years will have an osteoporosis-related fracture in her lifetime.

Clinical Manifestations

Osteoporosis occurs most often in bones of the spine, hips, and wrists. Typical early manifestations are back pain and spontaneous fractures. The loss of bone mass causes the bone to become mechanically weaker and prone to spontaneous fractures or fractures from minimal trauma. A person who has a vertebral fracture due to osteoporosis has an increased risk for having a second vertebral fracture within 1 year. Over time, vertebral fractures and wedging cause gradual loss of height and a humped thoracic spine (*kyphosis,* or "dowager's hump") (Fig. 63.9).

Diagnostic Studies

Osteoporosis often goes unnoticed because it cannot be detected by conventional x-ray until 25% to 40% of calcium in the bone is lost. Serum calcium, phosphorus, and alkaline phosphatase levels usually are normal. Alkaline phosphatase may be increased after a fracture.

Bone mineral density (BMD) measurements are typically expressed as grams of mineral per unit volume. BMD is determined by peak bone mass and amount of bone loss. (Procedures for BMD measurement are described in Table 61.8.) BMD may be measured by quantitative ultrasound (QUS) and dual-energy x-ray absorptiometry (DEXA). QUS uses sound waves to measure bone density in the heel, kneecap, or shin. DEXA (considered the gold standard of BMD studies by the World Health Organization) measures bone density in the spine, hips, and forearm.[28] These represent the most common sites of fragility fractures from osteoporosis. DEXA studies are useful to evaluate changes in bone density over time and assess effectiveness of osteoporosis treatment.

The BMD test results are compared to the ideal or peak bone mineral density of a healthy 30-yr-old adult and reported as T-scores. A T-score of 0 means the BMD is equal to the norm for a healthy young adult. Differences between the BMD and that of the healthy young adult norm are measured in units called *standard deviations (SDs).* The more standard deviations below 0 (indicated as negative

numbers), the lower the BMD and the higher the risk for fracture.

A T-score between +1 and –1 is normal. A T-score between –1 and –2.5 indicates **osteopenia** (bone loss that is more than normal, but not yet at the level for a diagnosis of osteoporosis). A T-score of –2.5 or lower indicates osteoporosis. The greater the negative number, the more severe the osteoporosis.[28]

Sometimes the HCP uses a Z-score instead of a T-score. In this case a person is compared with someone their own age, gender, and/or ethnic group instead of a healthy 30-yr-old person. Among older adults, Z-scores can be misleading because decreased bone density is common. If the Z-score is –2 or lower, it may suggest that something other than aging is causing abnormal bone loss.

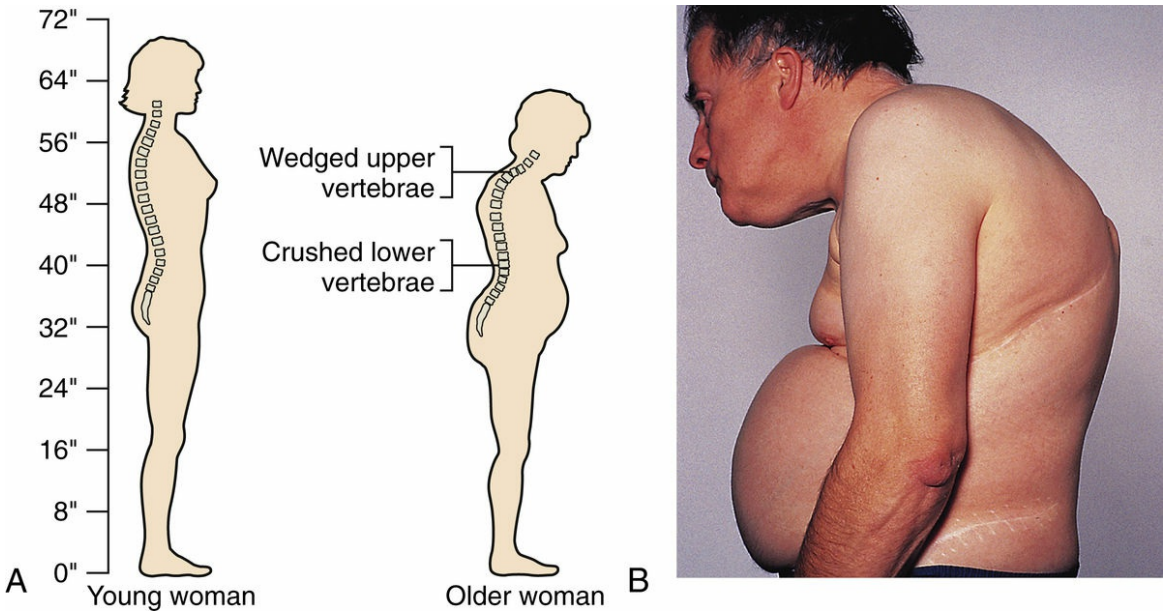

FIG. 63.9 The effects of osteoporosis. **A,** Comparison of young woman with an older woman. **B,** Severe fixed kyphosis producing a question-mark appearance.

Nursing and Interprofessional

Management: Osteoporosis

Interprofessional care focuses on proper nutrition, calcium and vitamin D supplementation, exercise, prevention of falls and fractures, and drugs (Table 63.13). The National Osteoporosis Foundation recommends treatment for osteoporosis for postmenopausal women with (1) a T-score of less than −2.5, (2) a T-score between −1 and −2.5 with additional risk factors (Table 63.12), or (3) prior history of a hip or vertebral fracture.

A patient's risk for fracture from osteoporosis also can be calculated with the Fracture Risk Assessment (FRAX) tool. The FRAX considers BMD and other clinical factors when assessing fracture risk.[29]

The recommended calcium intake is 1000 mg/day for women ages 19 to 50 years and men ages 19 to 70 years and 1200 mg/day in women age 51 years or older and men 71 years or older. Foods high in calcium include milk, yogurt, turnip greens, cottage cheese, ice cream, sardines, and spinach (Table 63.14). If dietary intake of calcium is inadequate, supplemental calcium may be given.

It is difficult for us to absorb calcium in single doses greater than 500 mg. Teach the patient the importance of taking calcium supplements as divided doses to increase absorption. The amount of elemental calcium varies in calcium preparations. Calcium carbonate has 40% elemental calcium. It should be taken with meals because stomach acid is needed to dissolve and absorb this supplement. Calcium citrate has about 20% elemental calcium but is less dependent on stomach acid for absorption. It is better absorbed by patients taking a proton pump inhibitor (e.g., esomeprazole [Nexium]) or histamine receptor blocker (e.g., cimetidine) for acid reflux. Calcium lactate and calcium gluconate are not recommended because they have small amounts of elemental calcium.

TABLE 63.13 Interprofessional CareOsteoporosis

Diagnostic Assessment

- History and physical examination
- Serum calcium, phosphorus, alkaline phosphatase, vitamin D
- Bone mineral densitometry
- Dual-energy x-ray absorptiometry (DEXA)

Management

- Adequate dietary calcium (Table 63.14)
- Calcium supplements
- Sun exposure or vitamin D supplements
- Exercise program

Drug Therapy

- Bisphosphonates (recommended)
    - alendronate (Fosamax, Binosto)
    - risedronate (Actonel)
    - zoledronic acid (Reclast)
- Monoclonal antibodies
    - denosumab (Prolia)
    - romosozumab (Evenity)
- Bisphosphonates (other available agents)
    - etidronate (Didronel)
    - ibandronate (Boniva)
    - pamidronate (Aredia)
- Recombinant parathyroid hormone (e.g., teriparatide [Forteo], abaloparatide [Tymlos])

Minimally Invasive Procedures

- Vertebroplasty
- Kyphoplasty

Vitamin D is important in calcium absorption and function and may have a role in bone formation. Most people get enough vitamin D from their diet or naturally through synthesis in the skin from exposure to sunlight. Being in the sun for 20 minutes a day is generally enough. However, supplemental vitamin D (800 IU) is recommended for postmenopausal women, older men, persons who are homebound or in long-term care settings, and those in northern climates due to decreased sun exposure.

Regular physical activity is important to build and maintain bone mass. Exercise increases muscle strength, coordination, and balance. The best exercises are weight-bearing exercises that force a person to work against gravity. These include walking, hiking, weight training, stair climbing, tennis, and dancing. Walking is preferred to high-impact aerobics or running. Both may put too much stress on the bones and cause stress fractures. Encourage patients to walk 30 minutes 3 times a week. Teach patients to quit smoking and decrease alcohol use to minimize negative effects on bone mass.

Encourage patients with osteoporosis to remain ambulatory to prevent further loss of bone density due to immobility. Treatment may also involve the use of a gait aid to walk safely and protect areas of potential pathologic fractures. For example, a TLSO may be used to maintain the spine in proper alignment after fracture or treatment of a vertebral fracture. (Fractures are discussed in Chapter 62.)

Vertebroplasty and *kyphoplasty* are minimally invasive procedures used to treat osteoporotic vertebral fractures (see Chapter 62).[30] In vertebroplasty, bone cement is injected into the collapsed vertebra to stabilize the spine and improve the patient's pain. This procedure does not restore vertebral height or correct deformity. In kyphoplasty, a small balloon is inserted into the collapsed vertebra and inflated to restore vertebral body height before injection of bone cement. Kyphoplasty is the preferred surgical treatment for vertebral compression fractures.

TABLE 63.14 Nutritional TherapySources of Calcium

Food	Calcium (mg)
Good Sources	
1 cup milk	
• Whole	279
• Skim	299
1 oz cheese	
• Mozzarella	222
• Cheddar	214
• Cottage	138
1 cup almonds	304
1 cup ice cream	168
6 oz calcium-fortified orange juice	261
3 oz seafood	
• Salmon	181
• Sardines	325
8 oz yogurt	313–384
Soft serve frozen yogurt	206
Poor Sources	
Egg	28
3 oz beef, pork, poultry	10
Apple, banana	10
1 med carrot	14
1 med potato	14
¼ head lettuce	27

Drug Therapy

The recommended drug therapies for the prevention and treatment of osteoporosis are the bisphosphonates alendronate, risedronate, and zoledronic acid, or denosumab. Bisphosphonates inhibit osteoclast-mediated bone resorption and slow the cycle of bone remodeling. Although a modest increase in BMD is typical, bone remodeling may be suppressed to the extent that normal bone formation is impaired and fracture risk increases. Treatment should continue for 5 years (Table 63.13).[31]

Common side effects are anorexia, weight loss, and gastritis. Teach the patient to take the medication correctly to improve its absorption

(see Drug Alert). These precautions also decrease GI side effects (especially esophageal irritation). A rare, but serious, side effect of bisphosphonates is *osteonecrosis* (bone death) of the jaw. Its cause is unknown. Those with dental disease, cancer, Paget's disease, or renal disease are most at risk for this complication. Patients should see a dentist before beginning treatment and then annually to ensure good oral health.

Drug Alert

Bisphosphonates

Teach patient to:

- Take with full glass of water.
- Take 30 min before food or other medications.
- Remain upright for at least 30 min after taking.

Alendronate (Fosamax) is available as a daily or weekly oral tablet. The immediate-release form of risedronate (Actonel) is given daily, weekly, or monthly, based on the dose. Zoledronic acid (Reclast) is given as a once-yearly or every-other-year IV infusion. Renal function tests and serum calcium must be assessed before administration. Other bisphosphonates are shown in Table 63.13.

Denosumab (Prolia) may be given to postmenopausal women with osteoporosis who are at high risk for fractures. It is a monoclonal antibody that binds to a protein (RANKL) involved in the formation and function of osteoclasts. Denosumab is given as a subcutaneous injection every 6 months.

Other agents used include the new monoclonal antibody romosozumab (Evenity). It inhibits the action of sclerostin, a regulatory factor in bone metabolism. This increases bone formation and, to a lesser extent, decreases bone resorption. It is given by subcutaneous injection every month for a total of 12 doses.

Raloxifene (Evista)is a selective estrogen receptor modulator (SERM). This drug mimics the effect of estrogen on bone by reducing bone resorption without stimulating the tissues of the breast or uterus. Raloxifene reduces the risk for vertebral, but not hip, fractures. Side effects, including leg cramps, hot flashes, and increased risk for blood clots, limit use.[31]

Teriparatide (Forteo) is a recombinant form of human parathyroid hormone (PTH) that increases the action of osteoblasts. This drug is used to treat osteoporosis in men and postmenopausal women at high risk for fractures, including risk related to long-term corticosteroid use.[31] Side effects include leg cramps and dizziness. Teriparatide is the first drug approved to stimulate new bone formation in osteoporosis. Most drugs only prevent further bone loss. It is self-administered daily by subcutaneous injection from a preloaded pen.

Women no longer routinely use estrogen replacement therapy or estrogen with progesterone after menopause to prevent osteoporosis because of the increased risk for heart disease and breast and uterine cancer. A woman who takes short-term estrogen therapy to treat menopausal symptoms, such as hot flashes, may receive some protection against bone loss and hip and vertebrae fractures.[32] We think estrogen inhibits osteoclast activity, leading to decreased bone resorption.

Medical management of patients receiving corticosteroids includes prescribing the lowest effective dose for the shortest possible time. Ensure an adequate intake of calcium and vitamin D, including supplements, when osteoporosis drugs are prescribed. If osteopenia is present on bone densitometry in people who are taking corticosteroids, treatment with bisphosphonates may be considered.

Paget's Disease

Paget's disease *(osteitis deformans)* is a chronic skeletal bone disorder in which excessive bone resorption is followed by replacement of normal marrow by vascular, fibrous connective tissue. The new bone is larger, disorganized, and weaker. Areas commonly affected include

the pelvis, long bones, spine, ribs, sternum, and skull. Up to 5% of adults in the United States are affected by Paget's disease.[33] Men are affected twice as often as women. Paget's disease is uncommon in people under age 40.

We do not know exactly what causes Paget's disease. The cause may be viral or genetic. Up to 40% of all patients with the disease have at least 1 relative with the disorder.

In milder forms of Paget's disease, patients do not have any symptoms. The disease may be found incidentally through x-ray or serum chemistry findings of high alkaline phosphatase.[34] Bone pain may develop gradually and progress to severe intractable pain. Other early manifestations include fatigue and progressive development of a waddling gait. Patients report becoming shorter or their heads are becoming larger. Headaches, dementia, vision deficits, and loss of hearing can result from an enlarged, thickened skull. Increased bone volume in the spine can cause spinal cord or nerve root compression.

Pathologic fracture is the most common complication and may be the first sign of Paget's disease. Other complications include osteosarcoma, fibrosarcoma, and osteoclastoma (giant cell) tumors.

Serum alkaline phosphatase is markedly increased in advanced disease, showing high bone turnover.[34] X-rays may show curvature of an affected bone. The bone cortex becomes thicker and irregular, especially in weight-bearing bones and the cranium. Bone scans using a radiolabeled bisphosphonate show increased uptake in the affected skeletal areas.

Interprofessional care is usually limited to symptomatic and supportive care, with correction of secondary deformities by surgical intervention or braces. Bisphosphonate drugs (Table 63.13) are used to slow bone resorption. Zoledronic acid may be given specifically to build bone. Calcium and vitamin D can decrease hypocalcemia, a common side effect of drug therapy. Monitor drug effectiveness by regular assessment of serum alkaline phosphatase.

Calcitonin is an option for patients who cannot tolerate bisphosphonates. Human calcitonin inhibits osteoclastic activity, prevents bone resorption, relieves acute symptoms, and lowers serum

alkaline phosphatase. This drug is available as a subcutaneous injection. Salmon calcitonin is 1 form. It has a longer half-life and greater milligram potency than human calcitonin. Response to calcitonin therapy is not permanent and often ends when therapy stops.

Pain is usually managed with NSAIDs. Orthopedic surgery for fractures, hip and knee replacement, and knee realignment may be needed.

A firm mattress can provide back support and relieve pain. The patient may need to wear a corset or light brace to relieve back pain and give support when upright. Teach the patient to correctly apply the device and regularly examine the skin for friction damage. Discourage lifting and twisting. Good body mechanics are essential. Physical therapy may increase muscle strength. A well-balanced diet is important in management of metabolic bone disorders. Vitamin D, calcium, and protein are especially important to ensure available components for bone formation. To decrease risk for falls and related fractures, teach the patient to use an assistive device and make environmental changes (e.g., do not use throw rugs).

Safety Alert

Paget's Disease

To reduce the risk for patient harm from falls:

- Assess environmental fall risk factors (poor lighting, clutter, pets in the home).
- Identify personal risk factors for falls, including drugs and uncorrected vision.
- Take action to address any identified risks.

Gerontologic Considerations: Metabolic

Bone Diseases

Osteoporosis and Paget's disease are common in older adults. Teach patients proper nutrition to decrease risk for further bone loss. Keep the patient as active as possible to slow demineralization of bone from disuse or extended immobilization.

Because metabolic bone disorders increase the risk for pathologic fractures, use extreme caution when turning or moving the patient. Hip fractures, in particular, may decrease quality of life and lead to admission to a long-term care facility. A supervised exercise program is essential to osteoporosis treatment. Encourage ambulation if the patient's condition permits.

Case Study

Metastatic Bone Tumor/Pathologic Fracture

(© ChristopherRobbins/Photodisc/Thinkstock.)

Patient Profile

L.R. is a 60-yr-old white woman with a history of hypertension, hypothyroidism, and osteoporosis. Four years ago, she was diagnosed with stage 3a breast cancer and treated with surgery, radiation therapy, and chemotherapy. Today she was admitted to the emergency department after falling down 2 stairs.

Subjective Data

- Denies hitting her head or loss of consciousness
- States she was able to bear weight on her lower extremities but has significant left thigh pain after the fall
- Describes recent insidious onset of generalized weakness and fatigue
- Denies alcohol or tobacco use
- Takes levothyroxine (Synthroid) and atenolol (Tenormin) every morning. Takes risedronate (Actonel) once a month

Objective Data

- Left lower extremity slightly shorter and externally rotated compared to right lower extremity
- Moderate edema with associated ecchymosis on left thigh
- Thigh soft, compressible to palpation
- Reports pain with internal/external rotation of left lower extremity
- 2+ dorsalis pedis and posterior tibialis pulses bilaterally
- Gross motor/sensation intact in affected extremity

Diagnostic Studies

- X-ray shows oblique mid-shaft left femur fracture with lytic lesion in the femoral neck
- Normal CBC and blood chemistry results, slightly increased liver function tests
- CT scans of the chest, abdomen, and pelvis show multiple bony metastases throughout the pelvis, as well as lesions of the liver and spleen, widespread abdominal cancer, compression fractures with lesions of T11 vertebral body, and bilateral rib fractures with

associated lesions.

- Whole body bone scan consistent with findings from x-ray and CT
- CT-guided biopsy of femur fracture site showed poorly differentiated cells consistent with breast cancer

Interprofessional Care

- Diagnosed with stage IV breast cancer
- Intramedullary nail for femur fracture
- Pain management
- Postoperative chemotherapy and hormone therapy
- High-protein, high-calcium, nutrient-rich diet
- Depression assessment and management
- Ambulation evaluation with gait aids as needed

Discussion Questions

1. Why did a relatively low-energy injury cause L.R.'s fracture?
2. ***Patient-Centered Care:*** What factors could result in inadequate caloric intake after surgery? How could you help L.R. increase her intake of protein and calcium?
3. What factors increase L.R.'s risk for delayed union or nonunion of the fracture?
4. ***Priority Decision:*** What are the priority teaching needs for L.R.?
5. ***Collaboration:*** Which persons on the interprofessional team should be responsible for L.R.'s home care instructions? Who should be responsible for ambulation and home safety teaching and assessments? Who should help L.R. with transfers and ambulation during her hospital stay?
6. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses?
7. ***Quality Improvement:*** What outcomes would indicate that

interprofessional care was effective?

8. ***Safety:*** What safety precautions should be considered for this patient?
9. ***Evidence-Based Practice:*** L.R asks why it is important for her to have daily injections of enoxaparin after surgery. How do you respond?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with osteomyelitis undergoes surgical debridement with implantation of antibiotic beads. When the patient asks why the beads are used, the nurse answers *(select all that apply)*
   a. "Oral or IV antibiotics are not effective in most cases of bone infection."
   b. "The beads are an adjunct to debridement and antibiotics for deep infections."
   c. "The beads are used to deliver antibiotics directly to the site of the infection."
   d. "This is the safest method to deliver long-term antibiotic therapy for bone infection."
   e. "Ischemia and bone death related to osteomyelitis are impenetrable to IV antibiotics."
2. A patient with osteosarcoma of the humerus shows understanding of his treatment options when he states
   a. "I accept that I have to lose my arm with surgery."

b. “The chemotherapy before surgery will shrink the tumor.”

c. “This tumor is related to the melanoma I had 3 years ago.”

d. “I’m glad they can take out the cancer with such a small scar.”

3. Which persons are at high risk for chronic low back pain? *(select all that apply)*

a. A 63-yr-old man who is a long-distance truck driver

b. A 30-yr-old nurse who works on an orthopedic unit and smokes

c. A 55-yr-old construction worker who is 6 ft, 2 in and weighs 250 lb

d. A 44-yr-old female chef with prior compression fracture of the spine

e. A 28-yr-old female yoga instructor who is 5 ft, 6 in and weighs 130 lb

4. A patient with suspected disc herniation has acute pain and muscle spasms. The nurse’s responsibility is to

a. encourage total bed rest for several days.

b. teach principles of back strengthening exercises.

c. stress the importance of straight-leg raises to decrease pain.

d. promote use of cold and hot compresses and pain medication.

5. In caring for a patient after a spinal fusion, the nurse would report which finding to the health care provider?

a. The patient has a single episode of emesis.

b. The patient is unable to move the lower extremities.

c. The patient is nauseated and has not voided in 4 hours.

d. The patient reports of pain at the bone graft donor site.

6. A patient who has had surgical correction of bilateral hallux valgus is being discharged from the same-day surgery unit. The nurse will teach the patient to

a. rest frequently with the feet elevated.

b. wear shoes continually except when bathing.

c. soak the feet in warm water several times a day.

d. expect the feet to be numb for the next few days.

7. What is most important to include in the teaching plan for a patient with osteopenia?

a. Lose weight.

b. Stop smoking.

c. Eat a high-protein diet.

d. Start swimming for exercise.

1. b, c, 2. b, 3. a, b, c, d, 4. d, 5. b, 6. a, 7. b

LEARNING OUTCOMES

1. Outline the sequence of events leading to joint destruction in osteoarthritis and rheumatoid arthritis.
2. Detail the clinical manifestations and interprofessional and nursing management of osteoarthritis and rheumatoid arthritis.
3. Describe the pathophysiology, clinical manifestations, and interprofessional care of gout, Lyme disease, and septic arthritis.
4. Discuss the pathophysiology, clinical manifestations, and interprofessional and nursing management of ankylosing spondylitis, psoriatic arthritis, and reactive arthritis.
5. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of systemic lupus erythematosus, scleroderma, polymyositis, dermatomyositis, and Sjögren's syndrome.
6. Explain the drug therapy and related nursing management associated with arthritis and connective tissue diseases.
7. Relate possible etiologies, clinical manifestations, and interprofessional and nursing management of fibromyalgia and systemic exertion tolerance disease.

Conceptual Focus

Fatigue
Functional Ability
Inflammation
Mobility
Pain
Self-Management
Stress

This chapter discusses *rheumatic diseases*, which primarily affect body joints, tendons, ligaments, muscles, and bones. These diseases are often marked by inflammation, pain, and loss of function in 1 or more of the body's connecting or supporting structures. The patient may be challenged by problems of limited function and fatigue, loss of self-esteem, altered body image, and fear of disability. More than 100 kinds of rheumatic diseases have been identified.[1] Over 54 million people in the United States have rheumatic conditions.[2]

Arthritis

Arthritis involves inflammation of a joint or joints. Most forms of arthritis affect women more often than men in every age-group.[2] Osteoarthritis is the most common chronic condition of the joints.[3] Other forms include rheumatoid arthritis (RA), fibromyalgia, systemic lupus erythematosus (SLE), and gout.

Osteoarthritis

Osteoarthritis (OA) is a slowly progressive noninflammatory disorder of the diarthrodial *(synovial)* joints. Currently OA affects 30 million Americans. This number is expected to greatly increase as the population ages.[2]

Etiology and Pathophysiology

OA involves the gradual loss of articular cartilage with formation of bony outgrowths (spurs or osteophytes) at the joint margins.[3] OA is not a normal part of the aging process, but aging is one risk factor for disease development. Cartilage destruction likely begins between ages 20 and 30. Most adults are affected by age 40. Few patients have symptoms until after age 50 or 60. More than half of those over age 65 have x-ray evidence of OA in at least 1 joint.[2]

TABLE 64.1 Causes of Osteoarthritis

Cause	Effects on Joint Cartilage
Drugs	Drugs, such as indomethacin, colchicine, and corticosteroids, can stimulate collagen-digesting enzymes in joint synovium.
Hematologic or endocrine disorders	Chronic hemarthrosis (e.g., from hemophilia) contributes to cartilage deterioration.
Inflammation	Release of enzymes in response to local inflammation can affect cartilage health.
Joint instability	Damage to supporting structures causes instability, placing uneven stress on joint cartilage.
Mechanical stress	Repetitive physical activities (e.g., sports) cause cartilage deterioration.
Neurologic disorders	Pain and loss of reflexes from neurologic disorders, such as diabetic neuropathy and Charcot joint, cause abnormal movements that contribute to cartilage deterioration.
Skeletal deformities	Congenital or acquired conditions (e.g., dislocated hip) contribute to cartilage deterioration.
Trauma	Dislocations or fractures may lead to avascular necrosis or uneven stress on cartilage.

OA may be caused by a known event or condition that directly damages cartilage or causes joint instability (Table 64.1). However, we cannot identify a single cause for many persons with OA. In these situations, various genetic traits may contribute to the development of cartilage defects. People with hand OA are more likely to develop knee OA.[2]

Decreased estrogen at menopause may contribute to the increased

incidence of OA in aging women. Obesity is a modifiable risk factor that contributes to hip and knee OA. It increases mechanical stress on the joints. Regular moderate exercise, which helps with weight management, decreases the risk for disease development and progression. Anterior cruciate ligament injury from quick stops and pivoting, as in football and soccer, are linked to an increased risk for knee OA.[3] Work that requires frequent kneeling and stooping also increase the risk for knee OA.

Gender Differences

Osteoarthritis (OA)

Men

- Except for traumatic arthritis, men do not have OA as often as women until age 70 or 80 years.
- Hip OA is more common in men.

Women

- OA affects women more often.
- Hand OA (interphalangeal joints and thumb base) is more common in women.
- Knee OA is more common in women, especially after menopause. It is likely to be more severe.

The development of OA is complex. Genetic, metabolic, and local factors interact to cause cartilage deterioration from damage at the level of the chondrocytes (Fig. 64.1). The normally smooth, white, translucent articular cartilage becomes dull, yellow, and granular as the disease progresses. Affected cartilage steadily becomes softer and

less elastic. It is less able to resist wear with heavy use.

The body's attempts at cartilage repair cannot keep up with the destruction of OA. As the collagen structure in the cartilage changes, articular surfaces become cracked and worn. While central cartilage becomes thinner, cartilage at the joint edges becomes thicker and osteophytes form. Joint surfaces become uneven, affecting the distribution of stress across the joint and causing reduced motion.

Although inflammation is not typical of OA, secondary synovitis may occur when phagocytes try to rid the joint of small pieces of cartilage torn from the joint surface. These changes cause the early pain and stiffness of OA. Pain in later disease occurs when articular cartilage is lost, and bony joint surfaces rub each other.
